ABSTRACT

Solution-processed n-ZnO/p-poly(3,3‴-didodecylquaterthiophene) (PQT-12) vertical p–n junction diodes were prepared on ITO-coated glass. A continuous film of ZnO nanoparticles was grown on the ITO glass by dip-coating and subsequent heat treatment of a zinc acetate film. PQT-12 was then spin-coated to form the ZnO/PQT-12 diode. Gold was chosen as the top electrode to complement ITO for this diode. The microstructures of ZnO films are studied by atomic force microscopy (AFM) and show a continuous, dense layer of ZnO nanoparticles. The current–voltage (I–V) measurement shows that the maximum current density for this p–n junction diode is 400 A/cm^2, which is much higher than previously reported polymer diodes. Capacitance–voltage (C–V) data also provide evidence of formation of the p–n junction. The rectification was characterized by observation of full input-half output waves. Data indicate that these devices can operate up to frequencies of 14 MHz under ambient environment conditions. This rectification frequency is higher than other reported polymer Schottky diodes under these conditions. Turnon voltages of this diode are also much lower than for the reported polymer diodes.

1. Introduction

There is great interest in electronic devices based on solution-processed polymer [1–7], organic [8,9] and inorganic oxide [10,11] semiconductors in recent years because of the possibility of producing printable, low-cost, large-area, lightweight and flexible devices. Most of these reports concern field effect transistors and diodes for applications including light-emitting diodes [12,13], solar cells [14,15], non-volatile memory [16,17], and logic circuits [18,19]. Fast device response is very important for a broad spectrum of electronic applications including high frequency identification (RF-ID) tag circuits [21,22]. For diodes, one evaluates response speed by studying the rectification property of the device at different frequencies [20]. From the manufacturing point of view, it is desirable to use solution-processable semiconductors to enable printing and roll-to-roll processing, which facilitates low-cost fabrication using an all-in-line printing process [23].

An RF-ID circuit comprises a high-speed diode which can operate at frequencies of 13.54 MHz with a high rectification ratio [24,25]. A number of groups have tried to develop a solution-processed Schottky diode [1,2,4–7], however, the performance was inadequate for application due to very poor current density [1,2,4–7], high turnon voltage [1,2,4–7], and high reverse bias current [1,5,6]. On the other hand, in the case of inorganic oxide p–n junction diodes, performance is limited due to the non-availability of good quality p-type oxide semiconductors [10,26–29]. For these reasons, none of these diodes have been tested for high frequency rectification. In our present work we introduce one solution-processed inorganic semiconductor with a polymeric material to fabricate a p–n junction diode in which diode parameters are improved. We employ high-mobility, highly stable ZnO (inorganic) as the n-semiconductor and high-mobility poly(3,3‴-didodecylquaterthiophene) (PQT-12) as the p-semiconductor. We also provide additional evidence for the correlation between morphology and current density from a study of poly(3-hexylthiophene)-aluminum (P3HT-Al) Schottky diodes. These are the solution-processable p–n junction

vertical diodes which can operate at MHz frequency, with much higher current density and low turn on voltage than related previously reported diodes [2,20,24,25].

In order to fabricate high current density and high-speed diodes, one needs materials that allow high forward current with considerably low operating voltage and very low reverse current with quite high reverse breakdown voltage. Normally this is achieved using electrodes that match in energy position, or make low potential barriers, to the energy levels of the semiconductors. In the case of a p–n junction diode, electrons and holes move towards the depletion region at forward bias and recombine. In case of thin film vertical diodes where electrons and holes cross one or two nanometer-scale grains from electrodes to the recombination zone, current density and speed can be expected to be higher compared to devices where numerous grain boundaries and defect sites must be crossed. Another important factor is relative band structure of two type semiconductors. The energy barrier at the depletion region depends on the differences between bulk Fermi energy levels of the two semiconductors [30]. For low turnon voltage and high current density this barrier is desirably be low [31]. The polymer/inorganic semiconductor p–n junction

discussed here meets these criteria. Although, we use two different classes of semiconductor, they are compatible for fabrication because they are deposited in separate steps (one dip-coating another spin-coating, from very different solvents) which are very well known and established techniques in solution-processed device fabrication.

2. Device and band structure of semiconductors

The device structure is shown in Fig. 1. In n-ZnO/p-PQT-12 vertical p–n junction diodes, indium tin oxide (ITO) and gold (Au) metals were chosen as bottom and top electrodes, respectively. Fig. 2a shows the schematic energy band diagram of an ITO/ZnO/PQT-12/Au device. Work functions of ITO and Au are 4.7 and 5.1 eV, respectively. The electron injection barrier at the ITO/ZnO interface and the hole injection barrier at the Au/PQT-12 interface are low, resulting in almost ohmic contacts at these interfaces. In Fig. 2b, we show the band diagram for the ZnO and PQT-12 after their heterojunction formation at thermal equilibrium. The band gaps of the two semiconductors are, respectively, 3.30 and 2.27 eV [18,32]. At thermal equilibrium the quasi-Fermi levels of both semiconductors are

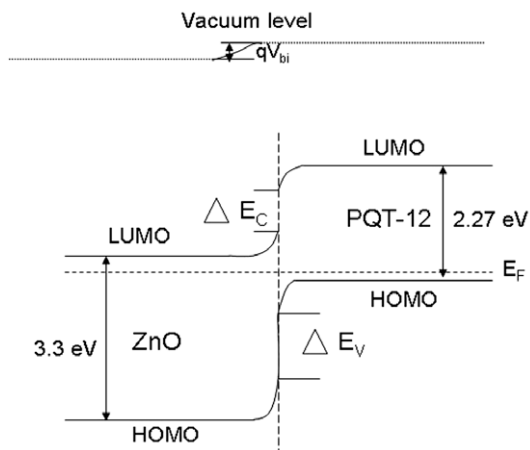

Fig. 2a. Schematic energy band diagram of ITO/ZnO/PQT-12/Au device.

Fig. 2b. Band diagram for ZnO and PQT-12 after heterojunction formation at thermal equilibrium.

equal to the equilibrium Fermi level E_F. On the same figure, ΔE_C and ΔE_V correspond to the band offset for conduction bands and valence bands, respectively. Since ΔE_C is much lower than ΔE_V, the energetic barrier for electrons is lower than for holes. Thus, electrons are the major carriers through these heterojunctions [31]. The qV_{bi} is the energy barrier of the junction which is equal to the difference between the bulk Fermi levels of the two semiconductors, where V_{bi} indicates the barrier potential of the junction. From this figure it is very clear that this barrier height is quite low, which enables high current density, high-speed rectification and low turnon voltage [31,33].

3. Experiment

Fig. 1 provides the schematic illustration of the polymer-inorganic hybrid p–n junction diode, which comprises an ITO–ZnO(n)–PQT-12(p)–Au structure. For this device, a clean ITO-coated glass was taken as substrate (<0.005 Ω cm). For a solution-processed ZnO film, we used zinc acetate [Zn(OAc)$_2$] (40 mM) solution in ethanol solvent. The substrate was then dip-coated with this solution with a speed approximately 2 mm/s with an angle 60° with horizontal and immediately was placed on a 70 °C heater. This process was carried out four times. The zinc acetate-coated substrate was annealed on a 300 °C hot plate for 30 min to form a thin layer of continuous dense polycrystalline ZnO nanoparticle film. Around 30 nm of ZnO film thickness was measured by SEM. The detailed morphology of ZnO film was also studied by AFM. PQT-12 (warmed at 60 °C) of concentration 7 mg/ml was then spin-coated (at 800 rpm) from 1,2-dichlorobenzene to form a polymer film over the ZnO-coated ITO substrate. The thickness of PQT-12 (150 nm) was determined by scratching the PQT-12 film and measuring by AFM. Subsequently 50 nm-thick gold electrodes were deposited using a TEM grid (200 mesh) as shadow mask. After this the whole substrate was annealed at 140 °C for 10 min then cooled down slowly at approximate 2 °C/min. DC electrical characteristics of diodes were measured by using a semiconductor parameter analyzer (Agilent 4155C). All electrical characterization results reported in this paper were obtained under ambient atmospheric conditions.

4. Results and discussion

Fig. 3a shows the current density–voltage (I–V) characteristics of our present device. The current density is 400 A/cm^2, which is few orders of magnitude higher then recent polymer vertical diodes [2–4]. The DC rectification ratio at ±2.5 V is around 4×10^2 (Fig. 3b). The turnon voltage is 1.2 V, which is considerably lower than the previously reported polymer diode [1–4]. The breakdown voltage of our diode is 15 V, 13 times higher than the threshold voltage. The forward bias was analyzed using the thermionic emission model and reverse bias using the reverse soft breakdown model [34,35]. The total current can be written as

$$I = I_s[\exp(qV/\eta kT) - 1] - I_{tun}[\exp(-qV/\eta_{tun}kT) - 1] \qquad (1)$$

where I_s and I_{tun} are the reverse saturation current and tunneling saturation current, respectively, and η and η_{tun} are the ideality factor and tunneling ideality factor. The fitted values of I–V parameters are listed below, and are com-

the input signal voltage and the rectified current density, respectively. There is a phase shift in the rectified signal which increases with frequency and is caused by the connecting wires, a limitation of our setup. The rectified signal for a particular device remained the same under six hours of steady observation. The long term storage stability of the device was also studied. The device was kept two months in dark and low vacuum, and retested. The results indicate that it essentially maintains its original characteristics. With respect to open atmosphere measurement, the response speed of this device is much higher than the previously reported polymer vertical Schottky diode with relatively less operating voltage.

The *C–V* characteristic of the p–n junction diode was measured in the frequency range 50–300 kHz using an LCR meter (Agilent 4284A). The capacitance per unit area of this kind of heterojunction can be described by Anderson's model, which can be expressed as [37,38]

$$C^2 = \frac{qN_D N_A \varepsilon_0 \varepsilon_1 \varepsilon_2}{2(N_A \varepsilon_1 + N_D \varepsilon_2)} \frac{1}{(V_D + V_b)} \qquad (2)$$

where q is the electronic charge, ε_0 is the vacuum permittivity, ε_1 and ε_2 are the dielectric constants of n-ZnO and p-PQT-12, respectively, N_D and N_A are the doping density concentrations in the ZnO and PQT-12, respectively, V_D is the diffusion voltage and V is the applied voltage. Fig. 5

shows the $1/C^2$ vs. V_D behavior of the measured devices, where almost linear behaviors in the 0.0 to −0.8 V range are observed. This behavior is a clear indication that the fabricated diode is an abrupt junction.

Fig. 6 shows the AFM micrograph of the ZnO layer. The image shows a film of dense ZnO nanoparticles with average particle size around 40 nm. Detailed surface examination indicates that there is a lack of pinholes on the film, with low surface roughness (10 nm). This low roughness of the ZnO-coated film is favorable for the overlying polymer (PQT-12) film to avoid pinholes through the top surface. Thus, electrons cross one or two grains of ZnO particles from the ITO electrode whereas holes cross the nanometer-range film of PQT-12 from the top Au electrode to recombine at the interface. We believe this short range recombination mechanism is one of the key reasons for the high current density and high frequency rectification.

We also provide additional evidence for the correlation between morphology and current density from a parallel study of Au (50 nm)/P3HT (50 nm)/pentacene (225 nm)/ Al (70 nm) Schottky diodes. Fig. 7a shows the schematic structure of this diode and Fig. 7b and c show AFM images of pentacene films on Au electrodes with and without P3HT. Larger grain sizes (∼250 nm) were observed when pentacene was deposited on the P3HT-Au-electrode, preferable for charge transport. *I–V* characteristics of the

(For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

pentacene diode with and without P3HT as interface layer are shown in Fig. 7d. The maximum current density at 10 V was 30 A/cm^2 in the presence of the P3HT interface layer; however, without the interface layer, the current density was only 0.8 A/cm^2. Thus, it can be concluded that carrier transport throughout the film was more facile when pentacene grain size increased from 150 to 250 nm (and the electrode junction became more graded) after adding P3HT as the interface layer. Fig. 8 showed the response speed of the pentacene-based Schottky diode with and without P3HT as interface layer. Response speed at frequencies of 2 MHz was achieved with the interface layer. Without the interface layer, the maximum rectification speed was only 30 kHz. Two megahertz is a lower response frequency relative to that of the ITO/ZnO/PQT-12/Au diode. From the AFM image, a large surface roughness of pentacene film compared to that of the ZnO film is apparent; such large surface roughness leads to the generation of pinholes, which increase contact resistance and affect diode characteristics. In addition, if the Au/P3HT/pentacene/Al diode device area is further decreased, and the pentacene film is further purified, much higher response frequency should be attained.

5. Conclusion

In summary, in this paper we report the fabrication and characterization of vertical p–n junction polymer-inorganic hybrid diodes. The maximum current density is 400 A/cm^2 and the AC rectification is fully maintained up to 14 MHz. The current density and rectification speed in the open atmosphere are much higher than previously reported all-polymer vertical diodes with relatively lower operating voltage, and the stability is encouraging. The capacitance–voltage (C–V) study also implies that device structure can be portrayed as a p–n junction diode.

ABSTRACT

The interface formation between the organic semiconductor copper-phthalocyanine and the ferromagnets Co and Fe has been investigated for the case of metal deposition onto the organic film using photoemission as well as X-ray absorption spectroscopy. Such interfaces might allow the injection of spin polarized currents into organic semiconductors. Our data reveal the formation of interfaces which are characterized by chemical reactions in the interfacial region.

The active control and the manipulation of spin degrees of freedom in electronic devices – often called spintronics – is anticipated to enable the fabrication of future electronic systems [1]. Recently, it has been demonstrated that it is possible to inject spin polarized currents in organic semiconductors [2,3] or to built organic based spin valves [4–6] and tunnel magnetoresistance (TMR) units [7,8]. These observations can be regarded as the starting point of an organic spintronics, which combines the flexibility and variability of organic semiconducting materials with a further degree of freedom: to switch or control a device via external magnetic or electric fields.

The metallic electrode contacts in organic spintronic devices are required to have a substantial spin polarization of their conduction electrons, and consequently materials such as the metallic ferromagnets Fe, Ni, Co or corresponding alloys (e.g. permalloy) are obvious candidates for such contact electrodes and have already been used in a number of cases [4–9]. Moreover, recent studies of spin injection into organic semiconductors indicate that spin polarized electrons can be injected from a ferromagnet into an organic semiconductor with high efficiency [9–11].

Often, it is necessary to produce top contacts on an organic semiconducting layer via the deposition of the respective materials in vacuum chambers, but it is unclear to what extent this production procedure results in well defined contact interfaces, which is in contrast to the importance of the contacts for the device performance.

In general, interfaces between metals and organic semiconductors have been extensively studied in the past [12–17], and most of these interfaces are characterized by the presence of a short range interface dipole, whereas the origin of this interface dipole is not yet fully understood [18]. Moreover, it has been demonstrated that the deposition of metals onto organic semiconductors in the majority of cases results in reactions at these interfaces, often accompanied by a diffusion of metal atoms deep into the organic layer [14,19–23]. The knowledge of the interface energy level alignment, interface reactions and charge carrier injection barriers is an indispensable prerequisite for the understanding and modelling of the device performance as well as for potential optimization of the devices.

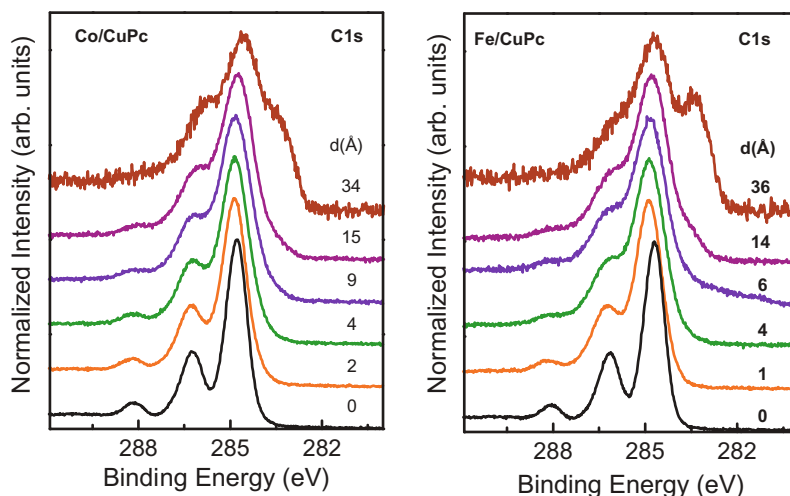
In this contribution we present a detailed analysis of interfaces that are produced by thermal deposition of the ferromagnetic elements Fe and Co onto the model organic semiconductor copper-phthalocyanine (CuPc) using two complementary spectroscopic methods, photoemission spectroscopy and near edge X-ray absorption fine structure (NEXAFS) measurements. If such interfaces will turn out to be sharp, this would demonstrate again the potential for high efficiency of spin polarized electron injection from the deposited Co (and Fe) contact into a CuPc thin film substrate [9,11].

X-ray photoemission spectroscopy (XPS) measurements were carried out using a commercial PHI 5600 system, which was equipped with a monochromatized Al-Kα X-ray source providing photons with 1486.6 eV. The total-energy resolution of the spectrometer was determined by analyzing the width of a Au Fermi edge to be 350 meV. The energy scale was aligned by measuring the Fermi edge (0 eV), as well as the $4f_{7/2}$ emission (84.0 eV) of the gold substrate. The error produced by this alignment procedure is smaller than 0.1 eV. All measurements were carried out at room temperature.

The NEXAFS experiments were performed at the ELETTRA (Trieste, Italy) synchrotron radiation facility using soft-X-ray light emitted by the BEAR high energy resolution dipole beam line [24]. The soft-X-ray absorption spectra were recorded in the total electron yield mode and normalized to the incident photon flux. The resolution for the NEXAFS measurements is determined exclusively by the performance of the beam line and was about 100 meV FWHM for the transition metal absorption edges shown below. The acquired spectra were energy calibrated using the C $1s \rightarrow \pi^*$ and N $1s \rightarrow \pi^*$ photoionization spectra of Ar and N_2 gases [25]. The pressure in the experimental system during data acquisition was always better than 1.5×10^{-10} Torr.

As substrate for CuPc film deposition, we used the $(1\,0\,0)$ surface of a gold single crystal. The surface was prepared by repeated sputtering and annealing cycles after which a 5×20 surface reconstruction was observed using low energy electron diffraction, while no remaining contamination was detected in the core level photoemission spectra. The CuPc film was deposited in sample preparation chambers directly linked to analyzer chambers. The deposition rate, monitored by a quartz microbalance, was 1–2 Å/min. The core level photoemission spectra indicated clean CuPc films without detectable traces of contamination including oxygen. The CuPc films used for our studies were about 70 Å thick, which is large enough to minimize contributions from the gold substrate in the photoemission spectra, and small enough to avoid charging effects.

Fe and Co were evaporated onto the CuPc films from molybdenum crucibles heated by electron bombardment. The deposition rates, measured by a quartz thickness monitor, were 0.5–1 Å/min. In addition, the total amount of metal coverage at each step of deposition was evaluated from a comparison of the relative intensities of the core levels of substrate atoms and deposited metals. The sensitivity factors of the core-levels for the corresponding photon energies were taken from tabulated cross-sections [26]. Other experimental details can be found elsewhere [23,27].



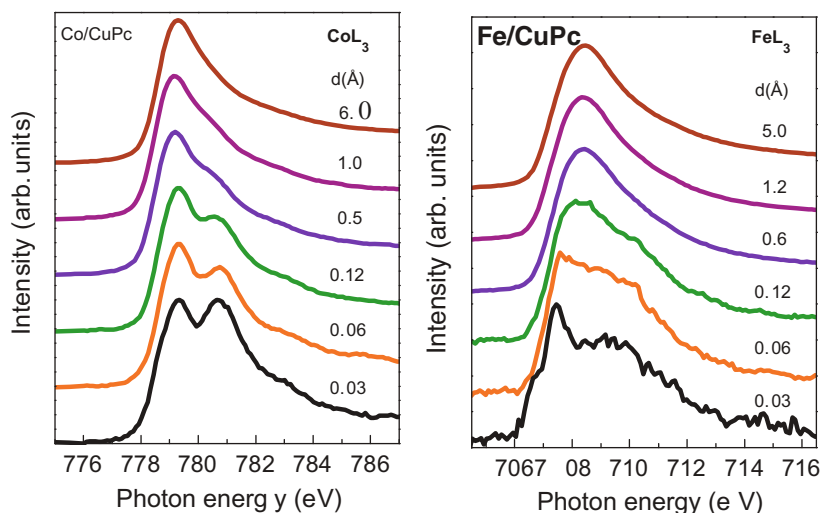


Fig. 1. Normalized C 1s core level photoemission data of CuPc thin films as a function of Co (left panel) and Fe deposition (right panel). The metal overlayer thickness is indicated. The data are normalized to equal intensity to ease comparison. The absolute intensity is strongly reduced upon metal addition (see text).

In Fig. 1 we show the evolution of the C 1s core level photoemission spectra as a function of Co and Fe deposition onto CuPc. Note that the data are normalized to equal intensities for comparison. The absolute C 1s photoemission intensity is strongly reduced upon metal addition. At a metal coverage of about 35 Å it is only about 2–3% of its starting value. This is well consistent with a homogeneous metal coverage on top of CuPc and the corresponding exponential thickness (d) dependence of the photoemission intensity ($\exp(-d/\lambda)$) taking into account an electron mean free path (λ) of about 10 Å for electrons with a kinetic energy of about 1200 eV (i.e. C 1s core level emission).

The C 1s signal (resulting from C atoms of CuPc) is characterized by a distinct fine structure due to chemically inequivalent carbon sites in the CuPc molecule and the appearance of satellite features, as has been described in detail previously [27,28]. Upon initial metal deposition there is a small upshift of the spectra, while the spectral shape remains unchanged. We attribute this initial energy shift to the formation of a short range interface dipole of about 0.1 eV and 0.2 eV for Co and Fe on CuPc, respectively. Further Co or Fe addition at first does not lead to further changes of the spectral shape, for thicker metal overlayers however, the C 1s spectra change substantially. We observe the occurrence of an additional C 1s feature at the low binding energy side. Since with growing overlayer thickness the C 1s signal increasingly arises from the CuPc molecules situated directly at the interface, the data in Fig. 1 are a clear indication that Co and Fe do not diffuse into the organic CuPc film but a sharp interface is formed. At this interface, though, there is chemical interaction resulting in the spectral changes seen in Fig. 1, i.e. carbon atoms with a different chemical environment.

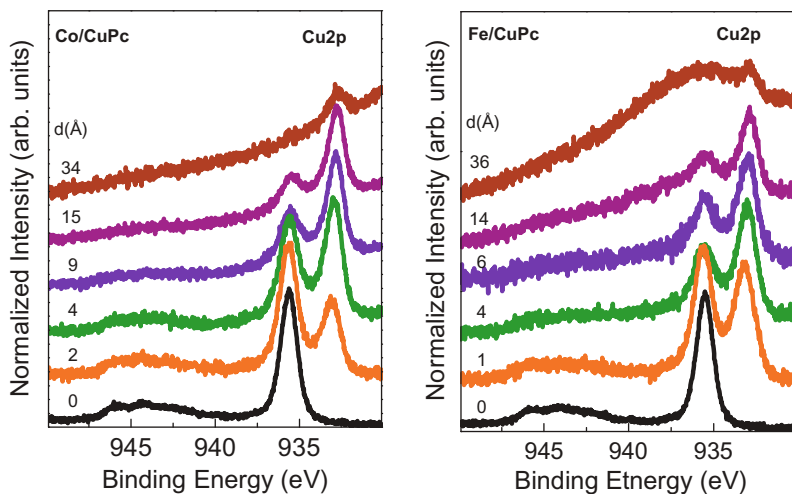
Fig. 2. Co L$_3$ (left panel) and Fe L$_3$ (right panel) absorption edges as a function of Co or Fe overlayer thickness on CuPc as indicated. The data are normalized to equal intensity, the absolute intensity scales with the metal overlayer thickness.


Fig. 3. Normalized Cu 2p core level photoemission data of CuPc thin films as a function of Co (left panel) and Fe deposition (right panel). The metal overlayer thickness is indicated.

This conclusion is corroborated in Fig. 2 where we show the Co and Fe L$_3$ NEXAFS spectra, again as a function of metal overlayer thickness and normalized to equal intensity. For thin metal films on top, the data clearly consist of two components, which reveal Co or Fe atoms with different chemical environments. The feature at lower excitation energy grows upon increasing metal film thickness, while the second excitation feature disappears. These data can be rationalized by the presence of oxidized (i.e. cationic) Co or Fe atoms directly at the the Co/CuPc or Fe/CuPc interface, giving rise to the higher energy core level excitation. With increasing metal film thickness this excitation feature vanishes because its relative weight decreases, and only the typical NEXAFS spectral shape for the respective metal is observed.

The Cu 2p core level photoemission data shown in Fig. 3 complete our picture on the interface reaction at the (Co,Fe)/CuPc interfaces. Already the deposition of small amounts of metal results in the appearance of a spectral feature at the low binding energy side, which is reminiscent of the XPS data of Cu(I) compounds such as Cu$_2$O [29]. This low binding energy feature grows with increasing overlayer thickness, which again demonstrates that the corresponding reaction only occurs directly at the interface. Therefore we infer, that as a consequence of Co or Fe deposition onto CuPc, copper atoms at the interface are reduced from Cu(II) to Cu(I), while Co or Fe are oxidized as indicated in Fig. 2. The metal core level data in Figs. 2 and 3 would be consistent with a scenario where deposited Co or Fe atoms replace Cu in the center of the phthalocyanine, whereas the released Cu remains at the interface. This would parallel the effects of Li deposition onto CuPc, where it has been reported that Cu atoms are liberated from CuPc [30]. The C 1s data as shown in Fig. 1, however, evidence that this picture is too simple and that the phthalocyanine molecule as a whole is affected by the interface reactions. The situation at the Co/CuPc and Fe/CuPc interfaces studied here might be similar to what has been observed for the deposition of Al onto phthalocyanine molecules [20]. In this case, it has been proposed that Al–Pc complexes form, resulting in core level spectra similar to what is observed in Figs. 1 and 3. Moreover, a recent study on the deposition of Co on pentacene layers has revealed that Co only slightly penetrates into the pentacene films and that the interface is characterized by chemical reaction, equivalent to our results [31].

In summary, we have investigated the chemistry and the electronic structure of interfaces that are produced by deposition of the ferromagnets Co and Fe onto the organic semiconductor CuPc using two complementary spectroscopic methods, XPS and NEXAFS. In contrast to the deposition of other metals onto CuPc, our results demonstrate that for both metals there is no evidence of metal diffusion into the organic film, which is favorable for the application of such interfaces in organic spintronic devices. These interfaces however are characterized by chemical interactions in the interfacial region, which might lead to the formation of interface electronic states that can act as charge carrier traps and thus have an unwanted impact on the injection of spin polarized currents.

ARTICLE INFO

ABSTRACT

This paper demonstrates the effects of the imidization ratio of polyimide gate insulators on the performance of organic thin-film transistors (OTFTs). We report the synthetic results of polyimide films imidized at a temperature of 200 °C along with an easily removed organic base catalyst (1,8-diazabicyclo[5.4.0]undec-7-ene, DBU), and their application in gate insulators of organic thin-film transistors. The degree of imidization increased to almost 100% after a thermal treatment at 200 °C for 40 min in the presence of DBU. The performance of the pentacene OTFT dramatically improved by using low temperature cured polyimide film as the gate insulator.

1. Introduction

Research on organic thin-film transistors (OTFTs) has been rapidly growing in recent years. They are potential candidates for use in wide range of applications in low-cost and large area electronics. The performance of OTFTs including organic gate insulators has been significantly improved. Organic gate insulators are required to have a relatively high dielectric constant, heat and chemical resistance, pinhole-free thin-film formability, and comparability with organic semiconductors [1–7]. In addition, since OTFTs are targeting low-cost and large area flexible applications, their processing temperature should be low enough to be integrated on inexpensive plastic substrates, such as polyethyleneterephthalate (PET), polyethyl- enenaphthalate (PEN), and polyethersulfone (PES). Several polymeric gate insulators, such as poly(vinylphenol) (PVP) [8–10], poly(methylmethacrylate) (PMMA) [11], polyvinyl- alcohol (PVA) [12], polyimide (PI) [13,14], and benzocyc- lobutene (BCB) [13] have been investigated. Among these materials, polyimides are currently considered promising gate insulators because of their excellent chemical resis- tance and mechanical properties. However, a major obsta- cle to the use of polyimides is their high processing temperature. Usually, fully aromatic polyimide has been extensively used in the microelectronics industry as inter- dielectric layers and passivation layers due to its excellent chemical, physical, and mechanical properties. We recently reported poly(amic-acid) based polyimide gate insulators for the application of OTFT [15,16]. However, those polyi- mides were not perfect candidates for OTFTs due to their high processing temperature, more than 250 °C, which is much higher than the glass transition temperature of

plastic substrates. We also published soluble polyimide gate insulators which can be processed into thin-film at low temperature. In that case, however, polyimides did not have fully aromatic structure, therefore, mechanical and leakage current properties of them were somewhat poor [17]. Basically if the imidization reaction of polyimide is conducted below 350–400 °C, the conversation of the poly(amic acids) to the PI is incomplete, which can result in high leakage current for the OTFT devices. In this paper, we describe new synthetic results of fully aromatic polyimide films imidized at the low temperature of 200 °C in the presence of an organic base catalyst, which can be easily removed after the imidization reaction, and investigate the performance of organic thin-film transistors fabricated with the polyimides as gate insulators.

2. Experimental

We have prepared new fully aromatic polyimide precursor, the poly(amic acid) from rigid aromatic dianhydride, 3,3′4,4′-biphenyl tetracarboxylic dianhydride (BPDA) and rigid aromatic diamines, p-phenylenediamine (p-PDA) in N-methyl-2-pyrollidone (NMP). The molar ratio of the two monomers (BPDA: p-PDA) for the preparation of the poly(amic acid) was 1:1. The poly(amic acid) was converted into the corresponding polyimide, PI(NC)-200, without the catalyst through only a thermal imidization reaction, which was conducted at 200 °C for 40 min on a hot plate. PI(C)-200 was synthesized from the poly(amic acid) solution containing 5 wt% [weight percent to the poly(amic acid)] of DBU under the same thermal imidization conditions as that of PI(NC)-200.

To determine the capacitance and gate leakage of the polyimide gate insulators, MIM (metal–insulator–metal) capacitor structures were prepared on the patterned ITO coated glass substrates. The fully aromatic polyimide solutions were spin coated on top of the bottom ITO electrode

and then the film was annealed at 90 °C for 10 min and 200 °C for 40 min. MIM devices were then completed by a deposition of the top gold electrodes. The final thicknesses of all films were controlled to 300 nm. The active area of a MIM device was 50.24 mm^2.

The OTFT device geometry for all electrical characterizations was a top-contact. Indium tin oxide (ITO) coated glass was used as the substrate and the ITO was patterned (2 mm wide stripes) to produce the gate electrode with a conventional photolithographic method: coating with a photoresist, ultraviolet light exposure, then developing and etching. The patterned ITO substrate was cleaned using a typical cleaning process for electronic applications: sonication in detergent, deionized water, acetone, and isopropyl alcohol in that order for 20 min at room temperature. The pentacene OTFT devices were fabricated using the polyimides as gate insulators. The final thickness of the polyimide gate insulators were adjusted to about 300 nm. A 60-nm-thick layer of pentacene was deposited on top of the gate insulator through a shadow mask by thermal evaporation at a pressure 1×10^{-6} Torr. The evaporation rate of the pentacene was 1 Å/s and the substrate temperature was 90 °C. The OTFTs were then completed by thermal evaporating 50-nm-thick gold source and drain electrodes on top of the pentacene layer through a shadow mask, creating transistors with channel lengths (L) and widths (W) of 50 and 1000 μm, respectively.

3. Results and discussion

3.1. Polyimide gate insulators and pentacene

The chemical structures of the polyimides are shown in Fig. 1. The structures of the poly(amic acid), PI(NC)-200, and PI(C)-200 were characterized by ^{1}H NMR and FT-IR spectroscopy. We determined the imidization degree of the polyimide films by comparing the characteristic

Fig. 1. Chemical structures of the PI(NC)-200 and PI(C)-200.

absorption bands at 1515 ($v_{C=C}$) cm^{-1} and 1357 cm^{-1} (v_{C-N}) using Eq. (1) where A_{1357} stands for the absorbance of characteristic imide II band (v_{C-N}) and A_{1515} is the absorbance of aromatic ring stretching band ($v_{C=C}$). The poly(amic acid) (PAA$_{init}$) film dried at 100 °C for 1 h in a vacuum oven and the fully imidized polyimide (PI$_{ref}$) film cured at 350 °C for 1 h were used as reference films.
$$D I \, (\%) = \frac{\left(\frac{A_{1357}}{A_{1515}}\right)_{sample} - \left(\frac{A_{1357}}{A_{1515}}\right)_{PAA_{init}}}{\left(\frac{A_{1357}}{A_{1515}}\right)_{PI_{ref}} - \left(\frac{A_{1357}}{A_{1515}}\right)_{PAA_{init}}} \times 100 \tag{1}$$

As shown in Fig. 2, the characteristic absorption bands due to the carbonyl group of the poly(amic acid), normally appearing at 1650 ($v_{C=O}$) cm^{-1}, had disappeared with an increasing imidization temperature. And, the characteristic absorption bands of the imide ring appeared at 1774 ($v_{C=O}$, asym), 1715 ($v_{C=O}$, sym.), 1357 (v_{C-N}), and 725 (deformation) cm^{-1} in the IR spectra. Especially, the imidization degree of the PI(C)-200 film fabricated at 200 °C in the presence of the DBU was close to 100%, which was a remarkable increase compared to that of PI(NC)-200 cured at same temperature without the catalyst (83%). That is, the introduction of an organic base catalyst into the poly(amic acid) solution made it possible to prepare a fully imidized polyimide film at a temperature of 200 °C.

We also investigated the surface properties of the PI(NC)-200 and PI(C)-200 films. Fig. 3 shows the contact angles and surface energies of the PI(NC)-200 and PI(C)-200 were somewhat different. The surface energies of the PI(NC)-200 and PI(C)-200, calculated from the contact angle of water and diiodomethane, were 52.9 and 55.0 dyne/cm, respectively. The contact angle of a water drop on the PI(C)-200 and PI(NC)-200 films were similar, but the contact angle of a diiodomethane drop on the PI(C)-200 and PI(NC)-200 films were 29.4° and 18.1°, respectively, which was decreased by the introduction of

Fig. 3. Optical microscopy images of water and diiodomethane drops on the surface of (a) PI(NC)-200 and (b) PI(C)-200.

the imidization catalyst. This means that the surface of the PI(C)-200 becomes more hydrophobic with an increase in the degree of imidization.

Surface properties are known to influence the mechanism of the initial growth of pentacene and thus the performance of OTFTs. AFM experiments were performed in order to investigate the effect of the surface property on the morphology of the pentacene thin layers deposited on the gate insulator. AFM images of the 60 nm thick pentacene on the gate insulators are shown in Fig. 4. The morphology of the pentacene on both insulators showed similar dendritic structures. On the other hand, the grain size of the pentacene on the PI(C)-200, with its smaller diiodomethane contact angle, was larger than that of the pentacene on the PI(NC)-200. This would be due to the high inter-molecular interaction of the pentacene molecule with the PI(C)-200. That is, the surface of the PI(C)-200 becomes more hydrophobic with an increase in the degree of imidization, resulting in a higher diffusion rate of the pentacene molecules in the in-plane direction and considerable increase the nucleation density. The pentacene on PI(C)-200 film shows the corresponding XRD peaks is composed of a series of sharp (001) peaks indicating that the pentacene is highly ordered. The main XRD peak at 5.7° was observed from the thin-film phase. The measured Bragg refraction angles of 5.7° correspond to tilts of the c-axis of the pentacene molecules with respect to the surface normal of 15.0°.

The leakage current density of the device with the PI(NC)-200 insulator was less than 9.2×10^{-11} A/cm^2, while biased from 0 to 50 V. The breakdown voltage and the capacitance were more than 1.5 MV/cm and 129.5 pF/mm^2, respectively. On the other hand, the device with

the fully imidized polyimide insulator, the PI(C)-200, showed a leakage current density of 5.9×10^{-11} A/cm^2, which was lower than the device with the PI(NC)-200 insulator. The breakdown voltage and capacitance were similar to the device with the PI(NC)-200 insulator, 1.5 MV/cm and 140.0 pF/mm^2, respectively. These results showed that the fully aromatic polyimide prepared from BPDA and p-PDA monomers in this study had a higher chain packing density owing to strong π–π bond interaction between the phenyl rings, which resulted in remarkably improved insulating properties compared to those of the alicyclic polyimide insulators reported by our group (3.5×10^{-8} – 1.5×10^{-9} A/cm^2) [16,17]. For comparison, the energy-minimized structures of the polyimides synthesized from different monomers were calculated by a HyperChem® v 7.5 program. As shown in Fig. 5, the alicyclic polyimide (a) connected with a flexible methylene linkage had a more bent structure than that of the polyimide [PI(C)-200] and (b) prepared from BPDA and p-PDA with rigid, flat monomer structures.

3.2. Device characteristics

The output (I_{ds} vs. V_{ds}) characteristics of the OTFTs having the PI(NC)-200 and PI(C)-200 as insulators were investigated. The OTFTs exhibit typical p-type characteristics with a transition from linear to saturation behavior in both devices. At a given negative gate voltage (V_{gs}), I_{ds} initially increases linearly with a small negative V_{ds} and then saturates due to a pinch off of the accumulation layer. Clear saturation behavior was observed for the OTFT device with the PI(C)-200 gate insulator with a high imidization ratio, which might be due to the complete removal of the carboxylic acids and amide groups of the original poly(amic acid). Fig. 6 exhibits transfer (I_{ds} vs. V_{gs}) characteristic curves of the OTFTs fabricated with the PI(NC)-200 and PI(C)-200. The field-effect mobility (μ) was calculated from the plot of the square root of the drain current ($I_{ds}^{1/2}$) and gate voltage (V_{gs}) in the saturation regime. The threshold voltage (V_T) of the device was determined from the plot of ($I_{ds}^{1/2}$) and V_{gs} by extrapolating the measured data to

Fig. 5. Energy minimized structures of the polyimides (calculated by a HyperChem® v 7.5). (a) Polyimide based on CBDA and MDA16 and (b) polyimide based on BPDA and p-PDA [PI(C)-200].

Fig. 6. Transfer characteristics (for the square root of the drain current vs. gate voltage, $I_{ds}^{1/2}$ vs. V_{gs} and drain current vs. gate voltage, I_{ds} vs. V_{gs},) of OTFTs with PI(NC)-200 and PI(C)-200. The drain voltage (V_{ds}) is set to −30 V. Note that the Y-axis is in (a) log ($−I_{ds}$) and (b) ($−I_{ds}$)$^{1/2}$.

$I_{ds} = 0$. When V_{gs} was swept from +20 to −40 V and V_{ds} was set at −30 V, the mobility, off-current, on/off ratio, and subthreshold swing (SS) of the pentacene OTFT with the PI(NC)-200 gate insulator were 0.18 cm^2/Vs, 6.9×10^{-8} A, 2.5×10^2, and 10.1 V/dec, respectively. On the other hand, the mobility, off-current, on/off ratio, and subthreshold slope (SS) of the pentacene OTFT with the PI(C)-200 gate insulator were 0.36 cm^2/Vs, 2.1×10^{-10} A, 2.0×10^5, and 2.1 V/dec, respectively. That is, when the PI(C)-200 was introduced as a gate insulator, the mobility increased by about two times (0.36 cm^2/Vs). In addition, it is clearly seen that the leakage current of OTFTs with PI(C)-200 was reduced dramatically by two orders of magnitude from 6.9×10^{-8} to 2.1×10^{-10} A, the value of SS also decreased significantly from 10.1 to 2.1 V/s. These results are much similar with the research reported by Yagi et al. They showed that traps at the pentacene/SiO$_2$ interface were suppressed with 1,1,1,3,3,3-hexamethyldisilazane treatment, which improved off-current conduction. In their experiment, they showed that the hydrophobic surface treatment effectively improved of the off-current of the devices and the off-current suppression could be caused by the reduction of the interfacial charge trapping at the pentacene/SiO$_2$ interface [18]. As mentioned in our text, the off-current of the pentacene OTFT device with a PI(C)-200 gate insulator is improved compared to that of the device with the PI(NC)-200, and it might be due to the complete removal of the hydrophilic carboxylic acids and amide groups of the original poly(amic acid). It has been well known that the carboxylic acids and amide groups of the poly(amic acid) easily absorb the water molecule from the atmosphere. As reported by Kumaki et al., it can be considered that the chemical reaction between the carboxylic acids on the gate-insulator surface and the absorbed water molecules is associated with the high off-current of the pentacene OTFT device even at zero and positive gate voltage [19]. We have also investigated the transfer characteristics of the devices with different direction of the gate voltage sweep to get more information about

the effects of the interface between the dielectric-semiconductor on the performance of organic transistors. The hysteresis was observed in the drain current (I_{ds}) vs. gate voltage (V_{gs}) characteristics (recorded under constant S/D bias V_{ds}) when V_{gs} was swept from −10 to +5 V and back to −10 V. That is, when sweeping V_{gs} back from +5 to −10 V, we observed a shift in the recorded I_{ds}–V_{gs} toward the positive V_{gs} side. A significant dependence of the hysteresis on the type of gate insulators was also observed. The device fabricated with less-polar gate insulator, PI(C)-200 showed much smaller hysteresis compared to that of the devices with the polar interface. The width of the hysteresis in V_{gs} exhibited a significant dependence on the surface polarity of the gate insulator. As shown in Fig. 7, The difference in the threshold voltage values due to hysteresis increased from near zero for PI(C)-200 to 2.5 V for PI(NC)-200. The positive shift of the Vth reveals that the hole is accumulated at the channel region of pentacene layer even at zero and positive gate voltage, which can be attributed to the influence of the trap site, which is caused by the adsorption of the water molecules. These results suggest that the hysteresis is caused by the high polarity of the gate insulators.

Furthermore, it can be seen that the performance of OTFTs can be affected by the grain size, orientation, and crystallinity of an organic semiconductor. These properties are usually determined by the surface properties of gate insulators, which can affect the crystal structure of organic semiconductors. The surface of the PI(C)-200 becomes more hydrophobic with an increase in the imidization degree, which leads to the formation of a more stable interface and well-aligned crystalline structure, contributing
Fig. 7. (a) I_{ds}–V_{gs} curves recorded for the OTFT device made of PI(NC)-200 as the gate insulator under the V_{gs} sweep rates of 1.35 V/s. Bias voltage, $V_{ds} = 30$ V. (b) I_{ds}–V_{gs} curves recorded for the OTFT device made of PI(C)-200 as the gate insulator under the same measuring condition of (a).

to an improvement of field-effect mobility of pentacene OTFT with PI(C)-200. As increasing the imidization degree of PI(C)-200 with the catalyst, the leakage current also was decreased effectively by the complete removal of the carboxylic acids and amide groups from polyimide insulator. This performance improvement in the pentacene OTFT with the PI(C)-200 gate insulator indicates that the high imidization degree obtained by the introduction of the base catalyst could be an effective approach to improving OTFT performance.

4. Concluding remarks

In this study, we have reported a new synthetic route to convert the poly(amic acid) to the polyimide at a temperature of 200 °C by the introduction of an organic base catalyst. The effect of the imidization ratio on the performance of pentacene OTFT devices has been investigated. The device fabrication temperature of a pentacene OTFT with fully aromatic polyimide as a gate insulator was lowered to 200 °C, which was a remarkably lower temperature, compared to conventional thermal imidization processes without the catalyst. The leakage current of the pentacene OTFT device with a PI(C)-200 gate insulator was remarkably improved compared to that of the device with the PI(NC)-200, which might be due to the complete removal of the carboxylic acids and amide groups of the original poly(amic acid). In addition, the mobility of the OTFT with the PI(C)-200 was 0.36 cm^2/Vs, which is two times larger than that of the OTFT device fabricated with the PI(NC)-200. Further, the SS of OTFTs with the PI(C)-200 decreased from 10.1 to 2.1 V/dec. The lowered SS indicates that the lower density of the trap exists at the interface between a gate insulator and semiconductor due to the more pentacene growth-friendly gate insulator. Consequently, by employing a base-catalyzed imidization method of fully aromatic polyimide, many aromatic polyimide with difference structures can be utilized not only for gate insulator of OTFT and also for other organic electronic devices which require low processing temperature.

ARTICLE INFO

ABSTRACT

This work presents post-fabrication electric field and heat treatment methods developed for polymer light emitting diodes (PLEDs), which have degraded due to exposure to oxygen and water vapors during low-cost fabrication performed in standard room conditions. Investigated PLEDs have structures composed of indium tin oxide (ITO), poly(3,4-ethylene-dioxythiophene), poly(styrenesulfonate), (PEDOT:PSS), poly[2-methoxy-5-(2′-ethyl-hexyl-oxy)-1,4-phenylene vinylene] (MEH-PPV), and aluminum (Al). Heat treatment restores the light emitting function of dysfunctional PLEDs but also causes a high turn-on voltage of 10 V. Electric field treatment utilizing −1 V reduces this high turn-on voltage to 3 V. This procedure also improves open circuit voltages from 5 mV to 55 mV, and short circuit currents from 0.5 nA to 5 nA when PLEDs are operated as photovoltaic cells under a light intensity of 500 mW/m². Repeated *I–V* sweep measurements additionally show improved stability and uniformity. The reasons for these improvements, the usage of an optimal treatment temperature of 130 °C, and the usage of treatment voltages of 0 and −1 V are discussed.

1. Introduction

Conjugated polymers are semiconductors used in fabricating light emitting diodes [1], polymer transistors [2], electronic circuits [3] and photovoltaic cells [4]. Their varied capabilities make them attractive for monolithic integration of electronic, optoelectronic, microelectromechanical, and sensory devices [5,6] on a single substrate. In addition, polymer based systems are flexible, light, easy to fabricate, low in cost and are amenable to roll production [7]. However, when compared to their inorganic counterparts, current polymer semiconductor devices have lower performance, are less reliable, and have shorter lifetimes [8–10] due to rapid degradation of performance on exposure to oxygen and water vapor under ambient atmosphere.

It has been shown by several groups that increased stability and performance characteristics of polymer light emitting diodes [11–15] and solar cells [16] can be attained by the use of treatment methodologies such as UV ozone, oxygen plasma or chemical treatments applied to ITO or conducting polymers [11–16]. High efficiencies can be achieved if the fabrication is performed under an inert atmosphere, such as nitrogen and argon, to prevent contamination of the semiconductor devices and degradation of the polymers [17–19]. Although fabrication under an inert atmosphere improves performance, it also increases the complexity and cost of fabrication.

This paper presents a two-step post-fabrication heat treatment and electric field treatment method, and its influences on the performance of PLEDs fabricated using ITO/PEDOT:PSS/MEH-PPV/Al layers. Differing from typical

fabrication process in literature; fabrication is performed in standard room conditions without using glove-boxes. Therefore, during each fabrication step, the polymer materials are contaminated by humidity and oxygen in the environment and the resulting devices do not emit light when forward biased. However, the post-fabrication thermal treatment restores the electroluminescent function of PLEDs. The electric field treatment following the heat treatment improves this function by lowering their turn-on voltages. Furthermore, it improves their photovoltaic function by increasing their open circuit voltages and short circuit currents by an order of magnitude. This way fabrication is made easier and the cost is lowered since the equipment consisting of spin-coater, hotplate, stirrer, high vacuum thin film evaporator, wiring tools, and packaging tools used in the production of PLEDs does not have to be connected together inside a big glove-box to secure an inert atmosphere.

Previously, similar post-fabrication treatment have been shown to work on polymer solar cells [20,21], organic light emitting diodes (OLED) based on dendrimers [22], double layer OLEDs [23] and PLEDs [24]. In [20], the solar cell structure is ITO/PEDOT:PSS/poly(3-hexylthiophene) (P3HT) : [6,6]-phenylC$_{61}$-butyric acid methyl ester (PCBM)/lithium fluoride (LiF)/Al. A thermal treatment at 75 °C and a forward biased voltage treatment at 2.7 V increase the short circuit current and the efficiency of the solar cells. In [21], the solar cell structure is ITO/PEDOT:PSS/ MEH-PPV:Fullerene (C$_{60}$)/Al. In this case, thermal anneal under reverse bias of −6 V increases the short circuit current and the efficiency of the solar cells. In [22], the OLED structure is ITO/PEDOT/Dendrimer:2-(4-biphenylyl)-5-(4-tert-butylphenyl)-1,3,4-oxadiazole (PBD)/Calcium(Ca)/Al. Electrical annealing with a forward bias of 12.4 V without any thermal treatment reduces turn-on voltages of the devices and increases their brightness and efficiency. In [23], the OLED structure is ITO/N,N'-diphenyl-N,N'-(3-methyl-phenyl)-1,1'-biphenyl-4,4'-diamine (TPD)/tris(8-hydroxy-quinonate)aluminum (Alq$_3$)/magnesium (Mg):silver (Ag). Short-circuit electrical treatment at atmospheric pressure for 10 min or reverse bias treatment at −5 V for 10 min without a thermal treatment decreases the driving voltage and recovers the drop in luminance that occurs during the device operation. In [24], the PLED structure is ITO/MEH-PPV/Al. The devices are electrically treated at forward bias of 15 V after being thermally treated. As a result, turn-on voltages of the devices are reduced significantly to 3 V and their efficiency are enhanced dramatically.

The usage of forward bias or reverse bias electric field treatment on polymer solar cells, OLEDs and PLEDs for performance improvement changes from device to device in the literature. Improvement due to forward bias treatment is typically attributed to enhanced charge injection facilitated by an ionic dipole moment or space charge field near the electrodes formed by the ionic diffusion induced by the applied electric field [22,24]. Reverse bias treatment, on the other hand, is suggested to improve the performance by enhancing charge mobility through the modification and reorientation of the polymer chains along the direction of the applied electric field [21]. To date, thermal treatment with reverse bias electrical treatment has been shown to work only on solar cells [21]. Furthermore, none

of the related works have studied the effects of the electrical treatments on the electroluminescent and photovoltaic properties of PLEDs at the same time. This work shows, for the first time, that post-fabrication treatments to PLEDs based on MEH-PPV with the PEDOT:PSS layer must start with a thermal treatment and must be followed with an electrical treatment under reverse bias.

In this paper, the fabrication steps used to produce PLEDs are presented in detail. They are followed by an explanation of the details used in the post-fabrication thermal and electric field treatments. The effects of the heat treatment alone, and the effects of the electric field treatment following the heat treatment on the turn-on voltages and photovoltaic properties of PLEDs are presented, analyzed and discussed.

2. Experiment

2.1. Fabrication

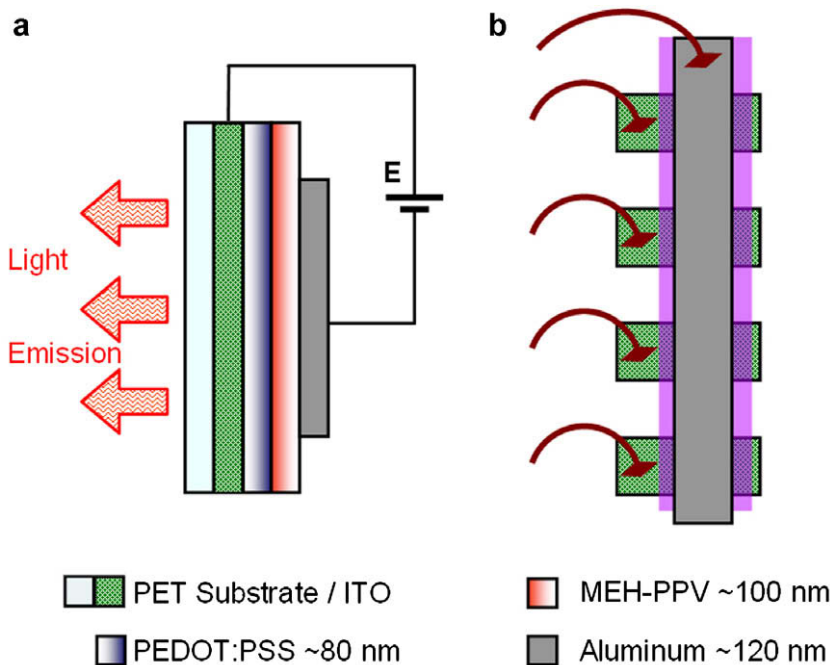
All fabrication steps are performed in standard room conditions, with a relative humidity level of 40–50% and a temperature of 21–26 °C. The substrate material chosen for fabrication is ITO coated PET sheets with a sheet resistivity of 35 ohm/square, purchased from Aldrich. The sheets are cut into circular, wafer-shaped segments with diameters of 4″ and attached to 1 mm thick glass wafers with silicone gel. They are cleaned in acetone, isopropyl alcohol, and deionized water consecutively for 3 min using an ultrasonic cleaner. To eliminate the hydrophobic nature of the PET surface against PEDOT:PSS, which is an aqueous solution, and to cleanse the surface of ITO from organic residuals, an oxygen plasma with a power of 1.3 W is used for 15 min in a 300 mTorr vacuum. In addition, oxygen plasma treatment of ITO improves the performance of the device as it decreases surface roughness [25] and increases the work function of ITO [26]. PEDOT:PSS is purchased from Sigma as an aqueous solution. After the filtration of PEDOT:PSS with a 0.25 μm syringe filter, a film approximately 80 nm in thickness is obtained on the wafer by spin-coating the solution at 1200 rpm for 30 s. To increase the conductivity of the PEDOT:PSS film, the sample is baked at 110 °C under nitrogen atmosphere for one hour and then baked in a vacuum of 150 Torr for 1 h. To minimize thermal stress, temperature is increased and decreased gradually. Next, a 4 mg/ml MEH-PPV/toluene solution is stirred at 50 °C on a hot plate for at least 4 h until the polymer is fully dissolved. After filtering the mixture with a 0.25 μm Teflon syringe filter, the MEH-PPV solution is spin coated onto the wafer at 1000 rpm. Then, the film is baked at 65 °C for 1 h. This obtains a film thickness of approximately 100 nm. For the deposition of the aluminum electrodes, a shadow mask is prepared from a 50 μm thick copper foil. A vacuum chamber with a base pressure of 10^{-6} Torr is then used to evaporate a 120 nm aluminum layer. The shadow mask with 3 mm wide holes is aligned perpendicular to the patterned ITO and forms 3 × 3 mm^2 square test cells. Drawings of the cross-sectional and the top view of the test samples are shown in Fig. 1.


Fig. 1. (a) Cross sectional view of PLED and (b) top view of the wire bonded samples.

2.2. Post processing treatments

The post-fabrication treatments utilized in this work consist of two stages: heat treatment and electric field treatment immediately following it under the same environmental conditions. Heat treatment is performed on a hotplate inside a vacuum chamber with in-situ packaging capability. Open atmospheric fabrication of these devices inevitably lead to absorption of water vapor and oxygen in the thin film layers of these devices, which are detrimental to their performance. This treatment removes most of the oxygen and water vapors absorbed inside the devices.

In the heat treatment process, different temperatures are experimented with to determine an optimum value. Square PLED cells with an area of 3×3 mm^2 are chosen from the wafer with close proximity to one another. This reduces the effect of process variations between batches, allowing the treatment to be tested on similar samples. Temperature annealing is proposed to take place for one hour. At the end of the experimental trials, no significant further improvement was observed by heat treating the PLEDs for more than an hour as also reported in a similar work [27]. Temperature is changed gradually in stages to minimize the thermal stress between the layers. Treatment is performed in a vacuum of 150 Torr in a dark

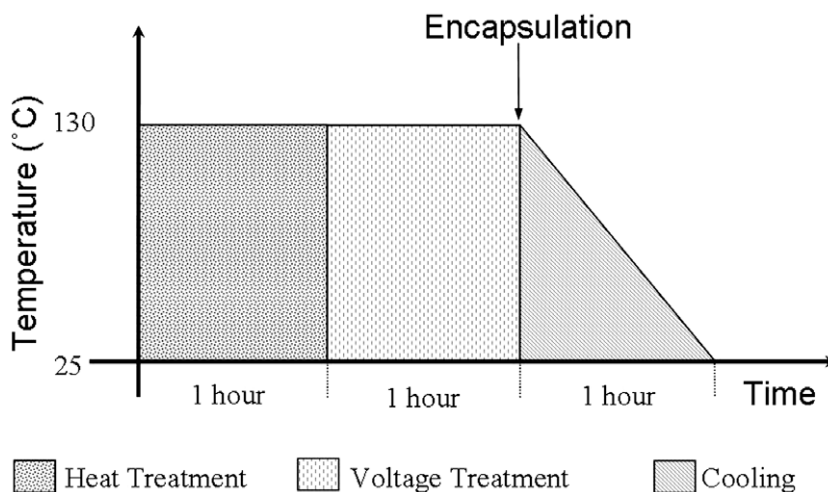

Fig. 2. Temperatures of the treatment stages.

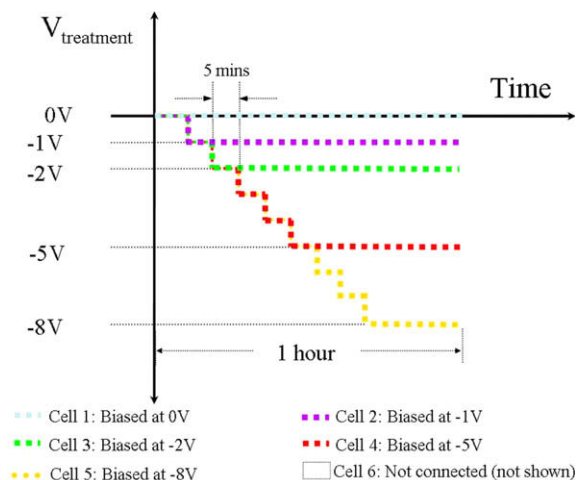
environment. Following the heat treatment, the devices are electrically reversed-biased at voltages varying from 0 to −8 V. Finally, encapsulation and cooling stages are exe-


cuted. The phases of treatments, their durations and temperatures are given in Fig. 2. In the electric field treatment phase, the magnitude of the negative bias voltage of each sample is increased in steps of 1 V/5 min, as shown in Fig. 3. In addition to a reference cell which is not connected to a certain bias supply, 0, −1, −2, −5 and −8 V potential levels are used in this phase. Different magnitudes are used to determine the effects of potential magnitude on device performance. The reference cell in this case is a device that receives only heat treatment.

At the end of treatment processes, samples are packaged immediately without breaking vacuum. The experimental setup used to apply heat, electrical field treatment, and the packaging under vacuum conditions is shown in Fig. 4. A layer of hot melted silicone approximately 2 mm thick purchased from Henkel is used to encapsulate the devices. The silicone is melted above 90 °C by turning on a separate custom-made heater, which holds solid silicone pieces. This heater is located on the surface of the primary hot plate. It is thermally isolated from the hot plate using glass supports. The whole setup is inside the vacuum chamber. The electrical controls for this custom-made heater and the primary heater are outside the chamber. The encapsulating silicone is intention-

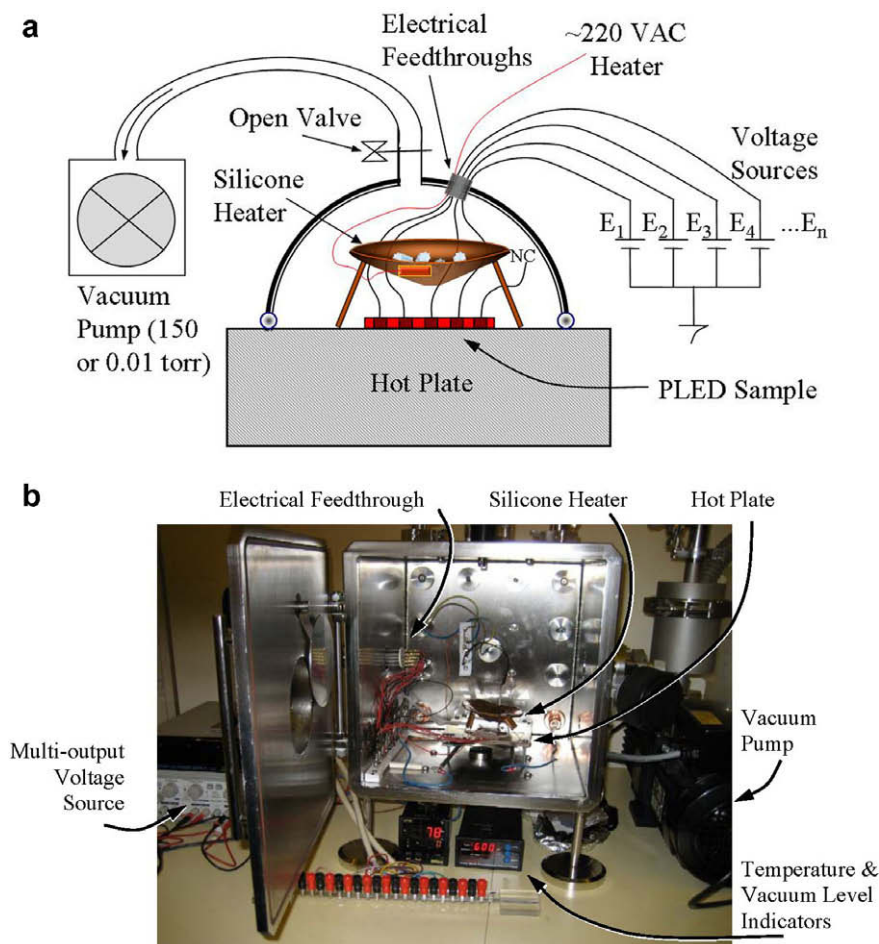


Fig. 4. (a) Depiction of the experiment setup for heat and electric field treatment (b) Photograph of the real setup.

ally deposited in a thick layer to eliminate water and oxygen diffusion to the semiconductor polymers. After encapsulation, the samples are cooled to room temperature without breaking vacuum so that the silicone layer solidifies and acts as a diffusion barrier. This encapsulation additionally makes the devices robust against mechanical disturbances.

The optical characteristics of PLEDs are determined with an optical setup composed of equipment purchased from Ocean Optics. For relative measurements, a bare fiber optic probe with a 200 µm radius is used. The same fiber optic probe is also used to determine the light spectra of the PLEDs. The luminance observed by the fiber optic probe is measured with a fiber optic spectrometer (Ocean Optics USB 4000). For absolute measurements, a fiber optic integrating sphere (FOIS-1) is used to capture the total luminous emitted from the device. One side of the fiber optic probe is attached to integrating sphere (IS) and other side is connected to the fiber optic spectrometer. Calibrations are performed with a calibrated light source (LS-1-CAL-INT). Electrical measurements of the device parameters are performed using a Keithley 4200 Semiconductor Characterization System, an Agilent 34410A Digital Multimeter, and adjustable DC power supplies.

3. Results and discussion

It has been proven that heat treatment, also referred to as thermal annealing of polymer junctions, after fabrication is an effective tool for improving device performance. It decreases contact resistance, improves morphology, and enhances junction characteristics. The temperature of annealing must be higher than the glass transition temperature of the polymers [27].

Heat treatment under partial vacuum followed by packaging under the same conditions restores the light emitting characteristics of PLEDs. However, this result in devices with high turn-on voltages, around 10 V, compared to 2.1 V, which is the turn-on voltage of an ideal PLED based on MEH-PPV [28]. Furthermore, photovoltaic properties of the devices are hardly measurable.

Four different temperature levels, 90, 110, 130 and 150 °C are tested in the heat treatment stage. I–V curves of the devices in Fig. 5 show that the most effective temperature for heat treatment is 150 °C. These results also indicate that temperatures higher than 150 °C may improve the I–V curves even further, similar to the results of [27], which show further improvement in the device performance with a thermal treatment at 170 °C. However, due to increased thermal stress and operation difficulties encountered with PET substrates at temperatures greater than 130 °C, 130 °C is selected as optimal value and used in the remainder of the treatments.

The effect of electric field treatments is tested on both light emitting and photovoltaic properties of PLEDs. Fig. 6 shows the pictures of PLED samples, which are electrically treated with different voltages, taken at the given test voltages. For the devices that have been heat treated but not electric field treated, shown as unbiased cell on the column named NC (not connected), the turn-on voltage is relatively high and the uniformity is very poor. By treating de-

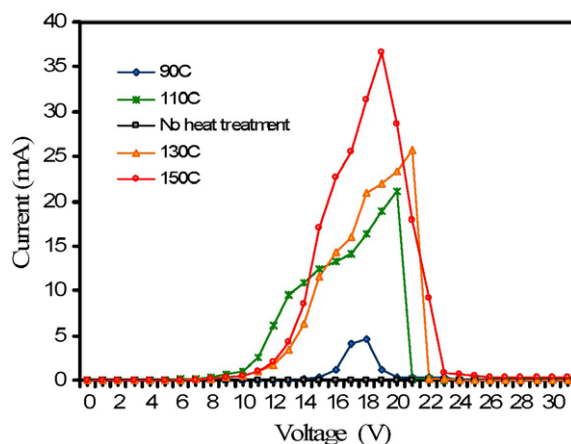

Fig. 5. Voltage–current characteristics of PLEDs heat treated at different temperatures.

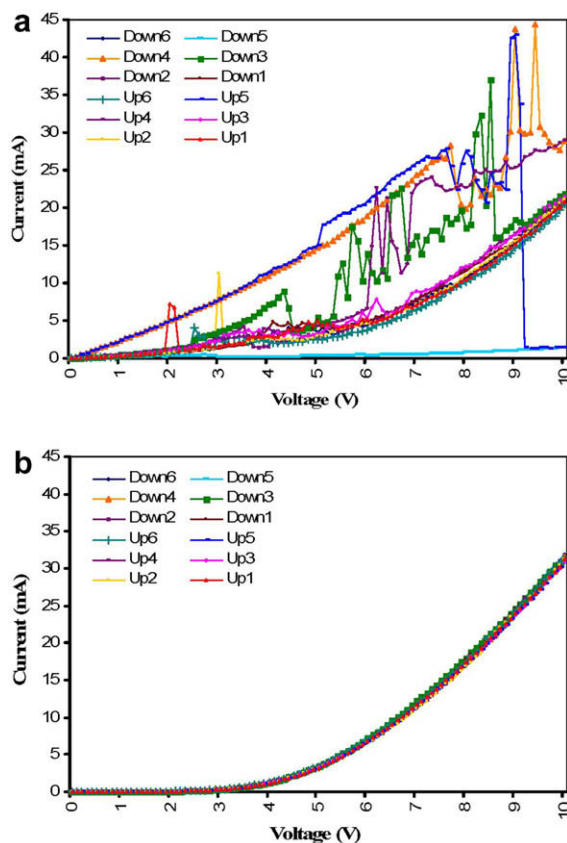
vices with negative electric fields after fabrication, the turn-on voltages of the PLEDs drop to lower voltages. Turn-on voltages increase slowly with the magnitude of the negative voltage treatment. For example, a device that experienced only heat treatment (NC column in Fig. 6) has a turn-on voltage of around 10 V. However, a device that experiences both heat treatment and an electric field treatment with −1 V (−1 column in Fig. 6), has a turn-on voltage of around 3 V. A device that is treated with −5 V (−5 column in Fig. 6), has a turn-on voltage of around 4 V. This is also true for the voltage levels at which PLEDs are most luminous. These results can be better understood in Fig. 7. This figure shows how the relative illuminance of PLEDs that are electrically treated with different negative voltages are altered upon applying test voltages. Electrical field treatments with 0 and −1 V give the lowest turn-on voltages and produce wide operating regions with better uniformity.

Another important advantage of the electric field treatment is that the turn-on and maximum illumination voltage levels of the devices, which in electrically untreated cells are unstable and vary over the lifetime of operation, are stabilized to certain values that are determined by the magnitudes of the treatment voltages. This is clearly shown in Fig. 8b where thermal (130 °C) and electrical (−1 V) treatment in combination produces a stable, uniform and repeatable I–V characteristics measured using a Keithley 4200 Semiconductor Characterization System with sweeping drive voltages in upward and downward directions. However, samples that are thermally treated (130 °C) but not electrically treated have non-uniform and unstable response with large hysteresis in the I–V sweeps. They typically fail after several sweeps, as shown in Fig. 8a. The electric field treatment additionally improves the uniformity of the light emitting surface.

Another point which should be addressed concerning the electric field treatment process is that if the voltage bias applied during the treatment stage is not removed before cooling, the performance of the polymer light emitting devices significantly degrades. Therefore, the wire connection between the voltage supply and the polymer junctions
Fig. 6. Pictures of PLED samples, which are electrically treated with different voltages, taken at the given test voltages.

Fig. 7. Electroluminescence responses of the devices treated with various voltage levels.

Fig. 8. (a) I–V sweep measurement of a heat treated (130 °C) but not electrically treated sample and (b) I–V sweep measurement of a heat treated (130 °C) and electrically treated (−1 V) sample.

must be opened before the cooling stage begins. Although the reason for this behavior is still under investigation, we believe that the molecular arrangement of the polymeric chains may be disturbed by the applied electric field when the temperature is under the T_g (65 °C) of MEH-PPV


(Mn = 400,000, Mw = 626,000) [27] but is above the T_g (40 °C) of PEDOT:PSS [29].

The photovoltaic responses of PLEDs are tested by measuring open circuit voltages and short circuit currents in a dark environment, as well as under the light of a solar simulator with a light intensity of 500 W/m². Figs. 9 and 10 show the transient responses of the devices in the dark environment when exposed to the light under the solar simulator. The measured open circuit voltage of the heat treated but not electrically treated PLED is noisy and its average value when the device is exposed to the light is indistinguishable. However, the output voltage of the polymer device that is treated with both the heat and electric field treatments is stabilized at a certain level and its average value (55 mV for −1 V treatment) is an order of magnitude higher than the electrically untreated (heat treated but not electric field treated) ones (5 mV) as shown in Fig. 9. Similar to the open circuit voltage characteristics, short circuit currents are enhanced significantly after the electric field treatment (Fig. 10). Without electric field treatment, the short circuit response of the devices when exposed to the light can not be distinguished from the dark response. Unstable output fluctuates between 1 and −1 nA with a rough average estimate of 0.5 nA. However, for the devices treated with an electric field, the intensity of the

Fig. 11. Average values and standard deviations of (a) short circuit currents and (b) open circuit voltages of the photovoltaic responses of PLEDs under light intensity of 500 mW/m^2 after different treatments.

light on the devices can be easily detected from their short circuit response (5 nA for −1 V treatment).

The average open circuit voltages and average short circuit currents obtained from electric field treated samples are strongly dependent on the treatment voltages. Moreover, the heat treatment alone is not sufficient to allow PLEDs work as photovoltaic cells. Therefore, the average and standard deviation of the photovoltaic responses of the devices, which were treated at different voltage levels, are measured as shown in Fig. 11. The responses of the devices that were not treated with electric fields when exposed to light are not detectable. Furthermore, the results from devices in different batches vary significantly. On the other hand samples treated with −1 V or −2 V are very stable, and their electrical responses are easily measurable. It is worth mentioning that electric field treatment, which improves the light emitting operation of PLEDs as shown previously in Figs. 6 and 7, improves their photovoltaic operation as well. These results are significant as they show that when the correct electric field treatment is applied to PLEDs after fabrication, they can also be used as photovoltaic cells.

The light emitting property of a PLED can be restored by the use of a heat treatment step alone because the heat treatment removes most of oxygen and water vapors absorbed by the PLED during fabrication. Further improvement of both the light emitting and photovoltaic functions of a PLED by the electric field treatment after heat treatment can be explained by the diode like molecular reorientation caused by the applied electric field as discussed in [30]. Electric field treatment above the glass transition temperatures of the polymers orients the polar molecules, improving molecular order. In this way, the barrier height between the polymers and electrodes is reduced for charge injection or extraction. This treatment also enhances charge mobility. Molecular order improvement, barrier height reduction, and charge mobility improvement after the application of an electric field treatment are shown to occur in [30]. In this case, the field is applied to a single polymer layer sandwiched between two aluminum layers at a temperature above the glass transition temperature. The improvement in the performance of polymer solar cells of ITO/PEDOT:PSS/MEH-PPV:C$_{60}$/Al discussed in [21] due to the thermal treatment under reverse bias electric field treatment is also explained by the modified and ordered orientation of the active polymer chains due to the applied electric field. The work in [21] also claims that the treatment increases

the mobility of charge carriers. Similarly, above the glass transition temperatures, the polymer chains in the polymer layers of our devices become mobile. They are reoriented by the applied electric field resulting in more uniform structures. This new arrangement improves the chemical bonds between interfacial junctions and lowers the contact resistances and voltage barriers. Since the newly oriented polymer devices are cooled and packaged in these conditions, the molecules remain oriented. As evident from the sweep experiments shown in Fig. 8, this orientation remains stable during device operation.

Based on this explanation, it may be assumed that applying a zero bias voltage treatment does not form an electric field inside the polymer devices, and thus it should not improve the performace of the devices, contradicting our results. However, when a zero external bias voltage is applied to these devices, any diode, or any LED, a built-in electric field is formed across the junctions resulting in a built-in or junction potential. This built-in (intrinsic) electric field under zero bias orients polar molecules during electric field treatment, improving junction properties. This also explains why reverse bias treatments improve the device performance whereas the forward bias treatments do not. Applied reverse biases contribute to this built-in electric field, creating higher electric fields in the junction and orienting the molecules more effectively. However, forward biases reduce this built-in electric field. Thus, they do not improve the junction properties.

The results also show that reverse bias treatments up to certain voltages (0 and −1 V) work more effectively than higher bias voltages. Above these voltages, even though the electric field treatment still improves the device performance, the rate of improvement decreases. This can be explained by the diffusion of anodic and cathodic materials into the polymers due to heat and the increase of their penetration thicknesses due to electric fields, which has been previously reported in [31]. Elevated electric fields increase the electrochemical reactions (oxidation–reduction) of the electrodes. Accelerated oxidation of electrodes, resulting from the high electric fields under reverse bias, and the diffusion of this oxide into the polymer layers can create barrier layers inside polymers. As a result, these barrier layers increase turn-on voltages and deteriorate the uniformity of the light emitting surfaces of the devices. Therefore, treatment voltages up to a threshold produce an obvious and long term improvement in both electroluminescent and photovoltaic response of PLEDs.

4. Conclusions

In this work, the effect of post-fabrication heat treatment alone and heat treatment coupled with an electric field treatment on the performance of PLEDs has been investigated. PLEDs have been completely fabricated under ambient atmosphere without taking any preventive measures against exposure to oxygen and water vapors. This way, the fabrication is simplified and the cost is reduced. Heat treatment is performed at 130 °C, which is above the glass transition temperatures (T_g) of MEH-PPV and PEDOT:PSS, for one hour and electric field treatment is per-

formed afterwards with voltage levels from 0 to −8 V. Heat treatment after fabrication, followed by packaging under the same conditions, restores the light emitting properties of otherwise dysfunctional PLEDs. It removes the absorbed oxygen and water vapors inside the devices, restoring their functionality.

Reverse biased electric field treatment after heat treatment is applied to PLEDs based on MEH-PPV and PEDOT:PSS for the first time in this work. Electric field treatment performed after heat treatment lowers the turn-on voltage levels and the voltage levels at which PLEDs reach their maximum luminescence, when used as light emitting devices. The turn-on voltage of a PLED drops to 3 V when treated with a reverse bias voltage of −1 V in comparison to 10 V when treated with heat and no bias voltage. Reverse biased electric field treatment increases the average short circuit current and open circuit voltage of the photovoltaic response of PLEDs by an order of magnitude compared to devices treated with heat only. Using a light intensity of 500 mW/m^2 in the photovoltaic measurements, a 5 mV open circuit voltage and a 0.5 nA short circuit current after heat treatment improve to 55 mV and 5 nA, respectively after an electric field treatment with −1 V. Furthermore, the uniformity and stability of the light emitting surface increases significantly after electric field treatment, as evident from repeated *I–V* sweep measurements.

ABSTRACT

Control of blend morphology at the nanoscale and high charge mobility is essential for polymer photovoltaic devices in terms of their power conversion efficiencies (PCE). In the case of bulk heterojunctions solar cells, both blend morphology and charge mobility are influenced by thermal treatment. In this manuscript, we study the effects of annealing temperature on polymer PV devices with blends of poly[9,9'- dioctyl-fluorene-co-bithiophene] (F8T2) and [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM). The morphological changes of blended films were observed upon thermal annealing temperature near and above glass transition temperature (130 °C). Such microstructural transformations resulted in modified charge transport pathways and therefore greatly influenced the device performance. The highest PCE of 2.14% with an open-circuit voltage (V_{OC}) of 0.99 V and a short-circuit current (J_{SC}) of 4.24 mA/cm^2 was achieved by device annealing at 70 °C for 20 min.

1. Introduction

Polymer photovoltaic (PV) cells offer great technological potential as a renewable, alternative source of electrical energy including the possibility of low-cost fabrication, low specific weight, and mechanical flexibility. Since solution processed bulk heterojunction (BHJ) solar cells were first reported in mid-1990s, they have been the subject of intense research interests due to their processing advantage as well as the superior mechanical properties of the polymers, such as flexibility. Although the BHJ provides quite a large interface for charge seperation, the power conversion efficiency (PCE) is still limited by the space-charge effects inherent in the BHJ structure due to the imbalance between electron (μ_e) and hole mobility (μ_h) and the unfavorable morphology [1,2]. Regioregular poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl C61-butyric acid methyl ester (PCBM) blend is one of the most promising candidates for realizing high power conversion efficiency (PCE) because P3HT possesses some unique properties over other polymers including its high self-organization capability [3,4], high hole mobility, and extended absorption in the red region of the electromagnetic

spectrum. Various independent approaches have been demonstrated to improve the PCE of blends consisted P3HT and PCBM. These approaches include thermal annealing [5], post-fabrication annealing at high temperature [6], and slow film growth by controlling the solvent evaporation rate of the active layer which resulted in the reduced series resistance and improved optical absorption of the devices. Subsequent annealing of the PV cells at a high temperature promotes the aggregation of PCBM which forms bi-continuous pathways in the entire active layer with the ordered P3HT phase and enhances efficient charge separation and transport. The slow solvent evaporation speed facilitates the growth of a highly crystalline film, interchain interactions become stronger and thus improve the electroconductivities, significantly [7]. These efficient enhancements are based on the unique chemical structure of P3HT. It crystallizes along its moderately long alkyl group at the 3-position and forms a more ordered structure leading to higher charge mobilities. Subsequently, an entirely positive effect in terms of solar cell efficiency has been reported due the smaller μ_h compared with μ_e in the blend in generally.

Recently, a group of polymers that works well in solar cells is an alternating copolymer based on fluorene. Polyfluorene copolymers are well known for their high charge carrier mobility, good processability, and high absorption coefficients. The physical properties of polyfluorene derivatives can be easily tuned through the design of various alternating copolymers. Currently, PCE approaching 3.5–5.5% have been reported by several groups for organic PV devices based on blend films of polyfluorene copolymers and PCBM [8–10]. These results indicate that the PV cells based on polyfluorene copolymers are good candidates for conversion solar energy into electricity. However, the annealing and slow growth effects on the polymer based on fluorene copolymer is still not clear. The fluorene-bithiophene copolymer, poly[9,9'-dioctyl-fluorene-co-bithiophene] (F8T2) reveals good hole transporting properties [11] and excellent thermotropic liquid crystallinity [12–15]. It has also well been explored in the area of organic field-effect transistors, with good hole transporting properties [16]. On the basis of the result, it can be expected that the charge transport in F8T2:PCBM is strongly balanced. Therefore, it appears to be one of the most promising candidates among the conjugated polymers for high efficiency polymer solar cell. In this manuscript, we fabricate PV devices based on F8T2 and PCBM. We demonstrate the annealing effect on F8T2:PCBM devices through the nanoscale morphology aspect and clarify how it influences the associated PV performance.

Fig. 1. (a) Chemical structure of F8T2, PCBM (b) absorption and photoluminescence spectra of pristine F8T2 and blend.

2. Experimental

The polymer PV cells in this study consists of a layer of F8T2:PCBM blend thin film sandwiched between transparent anode indium tin oxide (ITO) and metal cathode. Before device fabrication, the ITO glasses (1.5×1.5 cm^2) were ultrasonically cleaned in detergent, de-ionized water, acetone and isopropyl alcohol before the deposition. After routine solvent cleaning, the substrates were treated with UV ozone for 15 min. Then a modified ITO surface was obtained by spin-coating a layer of poly(ethylene dioxythiophene): polystyrenesulfonate (PEDOT:PSS) ($\sim$30 nm). Subsequently, the active layer of F8T2:PCBM (1:1 w/w) was spin coated from 1,2,4-trichlorobenzene (TCB) on the PEDOT:PSS modified ITO surface. Finally, 30 and 100 nm thick calcium and aluminium were thermally evaporated under vacuum at a pressure below 6×10^{-6} Torr through a shadow mask. The active area of the device was 0.12 cm^2.

Heavily doped p-type silicon (p$^+$-Si) wafer and a 300 nm thermally oxidized SiO$_2$ film were used as the gate and dielectric for the F8T2-based field-effect transistors (FETs). The substrates were cut to 1.5 cm $\times$ 1.5 cm in size through mechanical scribing. Prior to the deposition, the substrates were cleaned by acetone and isopropanol in an ultrasonic bath followed by UV–ozone cleaning for 15 min. The semiconductor layer F8T2 was prepared by spin-coating a solution of F8T2 (2 wt%) in TCB at 2500 rpm and with a thickness of around 110–130 nm. The F8T2 film was baked at different annealing temperature 70–250 °C for 30 min to remove the residual solvent. Finally, the 50 nm thick gold film was thermally evaporated onto the F8T2 film through a shadow mask to form the source/drain electrodes.

The solar cell testing was done inside a glove box under simulated AM 1.5 G irradiation (100 W/cm^2) using a Xenon lamp based solar simulator (Thermal Oriel 1000 W). The electrical measurements of the F8T2 based FETs were also performed at room temperature in a nitrogen environment inside a glove box by using HP 4156C. The absorption and photoluminescence (PL) spectra were obtained from Jasco-V-670 UV–visible spectrophotometer and Hitachi F-4500, respectively. Surface morphology and cross sections of thin films images were obtained using atomic force microscopy (AFM, Digital instrument NS 3a controller with D3100 stage) and scanning electron microscopy (SEM, Hitachi S-4700), respectively. X-ray diffraction (XRD) studies were performed by Philips X'Pert/MPD. Fluorescence lifetime signal was measured by the confocal laser scanning microscope (FV300, Olympus Corporation Inc.) with a configuration of PCI-board for time-correlated single photon counting (TimeHarp 200, PicoQuant GmbH) combined a detector of single photon avalanche diode (PDM series, PicoQuant GmbH). Excitation light source was 470 nm of pulse diode laser (LDH-P-C-470, PicoQuant GmbH) and acquisition time for each lifetime signal was 5 s.

3. Results and discussion

Fig. 1a shows the chemical structure of F8T2 and PCBM. The UV-visible absorption and PL emission spectra of pristine F8T2 and their blend films with PCBM are shown in Fig. 1b. The F8T2 film absorption peak is at 460 nm with a shoulder at 490 nm. The onset of the absorption occurred at 520 nm, from which the band gap was estimated to be approximately 2.4 eV. Based on cyclic voltamperometry measurements reported previously, the highest occupied molecular orbital (HOMO) level and lowest unoccupied molecular orbital (LUMO) of the polymer can be estimated at the onset point [17]. Therefore, the HOMO and LUMO levels are estimated to be 5.5 and 3.1 eV, respectively. It can be seen the band gap offset between the LUMOs of donor and acceptor is enough for electrons to be driven forward from the energy level diagram. The solid-state photoluminescence (PL) of the polymer lies near the green region with a maximum of emission at 545 nm with a vibrotic feature at 515 and 585 nm. The PL emission is significantly quenched by the addition of 50 wt% PCBM. This highly efficient photoluminescence quenching is the consequence of ultrafast photoinduced charge transfer from the polymer to PCBM.

Side view cross-sections of the films for annealing at 100 and 250 °C are shown in Fig. 2. The nanodomains are embedded within the F8T2:PCBM films. The nanodomains

Fig. 2. SEM side views of F8T2:PCBM blend films cast from TCB annealed at (a) 100 °C (b) 250 °C.

under different annealing temperatures with diameters increased from 30–40 (100 °C) to 70–80 nm (250 °C) are assigned to the F8T2 with a coil structure formed by several polymer chains. This means the F8T2 polymer chains tend to crystallize after annealing at high temperature. The nanodomains are dispersed within the film annealed at 100 °C. Therefore, the F8T2 nanodomains and PCBM clusters are well-mixed which can achieve bi-continuous pathways in the entire layer for efficient charge separation and transport. However in the case of film annealed at 250 °C, much larger PCBM clusters can be seen. The PCBM clusters are surrounded by the polymer nanoparticles. It is expected that much of the photoexcitations will lead to recombine within the surrounding F8T2 layer. A similar result was also found for the blends based on poly[2-methoxy-5-(3,7-dimethyloctyloxy)]-1,4-phenylenevinylene (MDMO-PPV) and PCBM [18,19]. The reorganization of the F8T2 nanodomains under different annealing temperatures can be further confirmed by the observation of the surface morphology. Fig. 3 presents the AFM images for the as-cast film and the ones with thermal annealing. For the as-cast film, the surface is very smooth with a root mean square (RMS) roughness of 0.55 nm. However after undergoing thermal treatment at 130, 190 and 250 °C for 30 min, the RMS roughness increased to 0.91, 1.98 and 6.73 nm. The film without thermal annealing reveals an uniform and featureless morphology. With increasing the annealing temperature, the chain-like morphology running across the surfaces forms gradually. The features are the domains of pristine F8T2 crystallites originated from the highly

tight stack of several polymer chains. For the case of annealing at 250 °C, the formation of lamella-like crystallites can be observed. The crystallites are similar to those of P3HT with the a-axis orientation (backbone parallel and side-chains perpendicular to the substrate) [20].

Fig. 4 shows the UV–vis and PL emission spectra under various annealing temperatures. The films annealed at the temperatures higher than 130 °C show an increase and red-shift in the UV–vis absorption. Such shifts have been observed for conjugated polymers with a strong interchain interaction [7]. The thermal annealing process enables spatial rearrangement of the polymer chains leading to a tight stacking and a strong interchain interaction. Although a higher extraction of photocurrent can be expected in the case of strong absorption. PL emission spectra also show an increase after thermal annealing. That means the photo-induced charge tends to recombine before transporting to the electrodes. This can be well explained by the SEM cross sectional images as shown in Fig. 2. The F8T2 nanodomains are dispersed in the whole film annealed at 100 °C which forms percolated pathway for electrons and holes to transport. However in the case of blend annealed at higher temperatures, the PCBM clusters are surrounded by the F8T2 nanodomains offering an inappropriate morphology for charge transport. Therefore, most of the photogenerated holes simply recombine with electrons which transport through the polymer-rich matrix phase leading to a higher emission. XRD shows that structural changes occur due to high temperature annealing process. An increase in crystallinity of F8T2 can be seen clearly in

Fig. 3. AFM images of the blending films in various annealing temperature (a) as-cast film (b) 130 °C (C) 190 °C (d) 250 °C.
Fig. 4. (a) Absorption and (b) photoluminescence spectra of the blends annealed at different temperatures.

the results shown in Fig. 5. X-ray data show that prior to heating, the F8T2 is in a disordered state. Increased intensity is observed with increasing annealing temperature in the peak at $2\theta \approx 5.7$ which corresponds to the layering distance, d_{100} = Å, between the sheets of F8T2 chains associated with the plane perpendicular to their longitudinal axes. The features are in good agreement with the results of AFM images. This lamella structure appears due to the

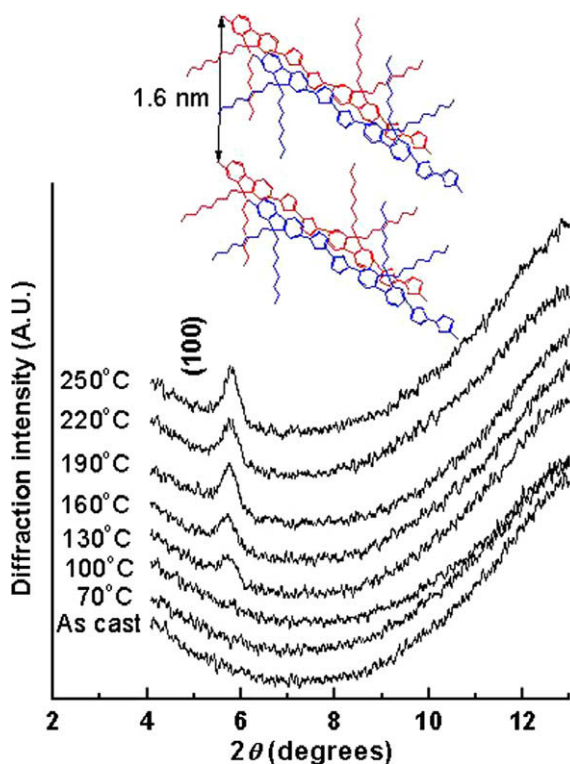

Fig. 5. XRD spectra of F8T2:PCBM films annealed at different temperatures.

segregation of main chain backbones from the aggregated alkyl side chains.

Additional evidence supporting the dependence of the crystallinity of F8T2 on the annealing temperature is provided by the observation of charge transport from field effect transistors (FETs) made with F8T2. Fig. 6 shows transfer characteristic of F8T2-based FETs at different annealing temperatures. The performance of F8T2 FETs is increased with rising up the annealing temperature. The improvement of device performance is attributed to the degree of F8T2 film crystallization which is coincident with above results. When annealing temperature is at 250 °C, the corresponding devices exhibit highest hole field effect mobility, 2.7×10^{-4} cm^2/Vsec, depicting superior performance in p-channel conduction among the various annealing temperature conditions.

In order to get more careful investigation of the photophysics in the F8T2:PCBM systems, we perform the time-resolved PL to see the exciton decay as a function of annealing temperature as shown in Fig. 7. It is found the PL life time (1.87 ns) for the blend without thermal treatment is shorter than that of the pristine F8T2 thin film (3.83 ns), indicating that the charge separation occurs at the interfaces between F8T2 and PCBM by providing a new non-radiative process for photogenerated excitons. However, the exciton life time increases with increasing the annealing temperature. This indicates the thermal process results in an unfavorable morphology. The unfavorable morphology reduces the interface between F8T2 and PCBM whish is in good agreement with the SEM results as shown in Fig. 2 in the text. As the annealing temperatures increased from 70 to 250 °C, the poor morphology leads to a non-efficient charge separation and the exciton life time increases from 1.91 to 2.84 ns.

The current-voltage characteristics under illumination for PV devices that have undergone various thermal annealing are shown in Fig. 8 and the device parameters (PCE, V_{OC}, J_{SC}, FF) are summarized in Table 1. Although the FET characteristics have shown the formation of more
Fig. 6. Transfer characteristic of F8T2 based FETs at different annealing temperatures when drain to source voltage (V_{DS}) is −80 V. The inset is the schematic configuration of F8T2 FETs.

**Fig. 7.** Photoluminescence lifetime decay of the F8T2 and the blends annealed at various temperatures.

Fig. 8. J–V characteristics under illumination for PV devices based on F8T2:PCBM (1:1) with different annealing temperatures.

ordered structures in the blend by thermal treatment, thereby increasing the charge mobility, the unfavorable morphologies are also formed by the annealing process which leads to phase separation and charge recombination as shown in the SEM cross-sectional images. As a result of the influence by the two factors, it can be observed the photocurrent show an increase first and then a dramatic decrease while annealing temperature is higher than 130 °C. It is worthy to mention the temperature at which the values of J_{SC} and V_{OC} drop dramatically is the temperature that crystallization takes place. This means the performance of the PV devices is largely dominated by a

Table 1
Short-circuit current (J_{SC}), open circuit-voltage (V_{OC}), fill factor (FF) and power conversion efficiency (PCE) as a function of annealing temperature for the PV devices based on F8T2:PCBM with PCBM concentration equal to 50 wt%.

Annealing temp (°C)	J_{sc} (mA/cm^2)	V_{oc} (V)	FF (%)	PEC (%)
As-cast	3.91	0.97	51.4	1.95
70	4.24	0.99	50.8	2.13
100	3.94	0.99	46.7	1.82
130	3.51	0.89	45.4	1.42
160	1.71	0.82	40.5	0.57
190	0.85	0.75	37.0	0.23
250	0.08	0.48	22.0	0.01

favorable morphology and not a higher charge mobility in the F8T2:PCBM system. This results quite differ from the case in P3HT:PCBM. Several researches have been shown independently a positive effect on solar cell performance with the thermal treatment [21–23]. The best device performance was obtained at 70 °C, and the values were $J_{SC} = 4.24$ mA/cm^2, $V_{OC} = 0.99$, FF = 0.51, and PCE = 2.14% with 50 wt% PCBM cast from TCB.

4. Conclusion

In conclusion, the F8T2:PCBM blends with thermal annealing at various temperatures leads to a tunable hole mobility. Our results demonstrate that the phase separation plays a more significant role than the one of charge mobility in terms of solar cell performance. Based on the results, too high annealing temperature is unfavorable to the performance of PV devices. Consequently, the optimal annealing temperature appears to be 70 °C and the PCE up to 2.14% can be obtained.

ABSTRACT

A novel electrically conducting polymer, poly(2-dodecyl-4,7-di(selenophen-2-yl)benzotriazole) (PSBT), containing selenophene as the strong donor and benzotriazole as the strong acceptor groups was synthesized by electrochemical polymerization. Homopolymerization and copolymerization (in the presence of 3,4-ethylenedioxythiophene (EDOT)) were achieved in acetonitrile/dichloromethane(95/5 v/v) with 0.1 M tetrabutylammonium hexafluorophosphate (TBAPF$_6$). The electrochemical and optical properties of homopolymer and copolymer were investigated by cyclic voltammetry, UV–Vis, near IR Spectroscopy. Cyclic voltammetry and spectroelectrochemistry studies demonstrated that homopolymer can be reversibly reduced and oxidized (both n- and p-doped) between -1.9 V and $+1.4$ V, at a scan rate of 100 mV/s. The homopolymer revealed a transmissive light blue color in the oxidized state, and a red-purple color in the neutral state. A transmissive light blue color was also observed in the reduced state. Homopolymer films could be fully switched between their reduced and oxidized forms in 2.4 s and 0.4 s with a percent transmittance of 32% and 56% at 511 and 1200 nm, respectively. Poly(SBT) exhibits a λ_{max} value of 511 nm and a band gap of 1.67 eV which is quite low among the selenophene-containing polymers reported so far except for poly(1,2-bis(2-seleninyl)ethane).

1. Introduction

In recent years, the design and synthesis of low band-gap polymers have been an area of intense interest since the band gap of polymer determines the intrinsic electrical and optical properties in doped state and their ability to be both p- and n-type doped [1–4]. Several ways have been developed to synthesize low band-gap polymers [5]. One of the most successful approaches is the application of an alternating sequence of donor–acceptor (D–A) units in the π-conjugated polymer chain. Alternating electron releasing and withdrawing units will consequently increase the HOMO level or lower the LUMO level which in return decrease the band gap of the molecule [6–8].

The search for organic conducting polymers started in the 1970s and up to date is largely focused on polyfuran [9], polythiophene [10], polypyrole [11] and their derivatives. Relatively little work was conducted on higher selenium-containing analogues [12–14]. In comparison, the differences in the chemistry of selenium and sulfur include the metallic character and the electronegativity of the heteroatom [15]. Hence, selenophene has a lower oxidation potential and higher electron donating character than the sulfur analogue [16]. Lower oxidation potential engenders high quality polymer films during electropolymerization by minimizing harmful effects of high polymerization potentials which causes the degradation of the polymer films [17].

In our search for low band-gap conjugated polymers, we synthesized a polymer consisting of electron rich selenophene and electron deficient benzotriazole units. The molecule contains an electron withdrawing imine (C=N) group which exhibits π-deficient nature [18]. Here we

report the synthesis, characterization and electrochromic properties of a selenium-containing polymer, poly(SBT).

The electrochemical copolymerization of SBT with EDOT was also achieved to investigate the properties of the resultant copolymer. EDOT was the choice as a comonomer due to its excellent electrochromic properties and its oxidation potential which is close to SBT.

2. Results and discussion

2.1. Monomer synthesis

The donor–acceptor type monomer (SBT) was generated through Stille coupling reaction between 4,7-dibromo-2-dodecylbenzotriazole and tributyl(2-selenophenyl)stannane with a relatively good yield of 63%. Tributyl stannyl group is located on the electron rich selenophene unit whereas, the bromo substituent is on the electron deficient benzotriazole [8,19].

2.2. Cyclic voltammetry

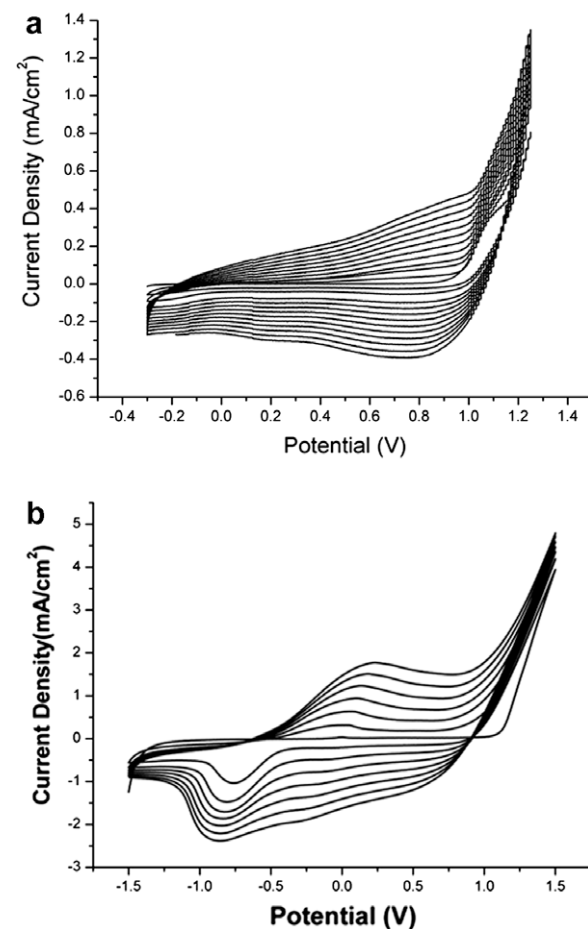
In Fig. 1 the oxidative electrochemcial polymerization of SBT is shown. An irreversible oxidation peak emerges


Fig. 3. (a) Electrochemical synthesis of poly(SBT-co-EDOT) in 0.1 M TBAPF$_6$/ACN/DCM and (b) electrochemical synthesis of PEDOT in 0.1 M TBAPF$_6$/ACN/DCM at a scan rate of 100 mV/s. (ITO working electrode versus Ag wire pseudo reference electrode.)

on the first cycle at a potential of +1.2 V versus Ag wire pseudo reference electrode (0.35 V versus SCE) indicating the formation of a reactive intermediate. The monomer oxidation potential is comparatively lower than selenophene (+1.48 V), an indication of more extensive conjugation for this monomer. As the polymerization proceeds, the peak current increases with successive scans, indicating the growth of polymer on ITO coated glass slides revealing an oxidation potential (E_{pa}) at +1.0 V and a reduction potential (E_{pc}) at +0.8 V versus the same reference electrode.

The n-doping property of the polymer was investigated using CV in a monomer free solution. The polymer deposited on Pt can reversibly be reduced and oxidized between −1.9 V and +1.4 V versus Ag wire pseudo reference electrode in TBAPF$_6$/ACN. The cyclic voltammogram of Poly(SBT) is shown in Fig. 2. A redox couple with an oxidation potential of −1.3 and a reduction potential of −1.7 V was observed which is an important indication of an n-dopable character of the film. Further supporting data on n-doping properties of the polymer was provided with spectroelectrochemistry. The scan rate dependence of the polymer films were also investigated. The current was found to be proportional to the scan rate indicating the adherence of the polymers to the electrode surface. Hence, charge transfer process was not dominated by diffusion effects [20].

A 20 μm polymer film was prepared on a platinum electrode. The polymer was peeled off and the standard four probe method was performed on the free standing polymer film where a current was supplied through the outer probes while measuring the voltage drop across the inner two. The conductivity was calculated to be 1×10^{-2} S/cm.

The electrochemical behavior of the Poly(SBT-co-EDOT) was investigated using CV in the presence of EDOT under same experimental conditions. The cyclic voltammogram of copolymer is shown in Fig. 3. A redox couple with an oxidation potential of +0.85 V and a reduction potential of +0.8 V versus same reference electrode were observed (Fig. 3a). The oxidation and reduction potentials of the material were different than those of SBT and pristine EDOT (Fig. 3b), which in fact, could be interpreted as the formation of copolymer.

The conductivity of the copolymer prepared on platinum electrode was calculated to be 2×10^{-1} S/cm.

2.3. Spectroelectrochemistry

For optoelectrochemical studies, after homogeneous polymer films were electrochemically deposited on ITO coated glass in dichloromethane/acetonitrile (5/95, v/v) with 0.1 M TBAPF$_6$, UV–Vis spectra were taken in a monomer free solution at various potentials to monitor the changes in absorbance as the polymer film is oxidized. Fig. 4 reveals spectroelectrochemistry and the corresponding colors of electrochemically prepared films at neutral and doped states. Stepwise oxidation of the polymer shows the fading of absorbance at 511 nm and typical evolution of peaks at 800 nm and 1200 nm corresponding to polaronic and bipolaronic bands, respectively. Dedoped polymer has two distinct absorption bands as expected from a donor–acceptor type polymer [21], centered at 483 nm and 511 nm. The band gap, onset of the $\pi \rightarrow \pi^*$ transition for the neutral polymer is calculated as 1.67 eV using the absorption band centered at 511 nm. Compared to neutral dedoped polyselenophene (E_g: 2.0 eV) and some other selenephone containing polymers [22], poly(SBT) exhibits lower optical band gap.

Moreover, spectroelectrochemistry studies were performed in order to prove the n-type doping process of a conjugated polymer system since formation of a redox

Fig. 4. Optoelectrochemical analysis of poly(SBT) in 0.1 M TBAPF$_6$/ACN at applied potentials between 0 V and 1.4 V.
Fig. 5. Optoelectrochemical analysis of poly(SBT) in 0.1 M TBAPF₆/ACN at applied potentials of (a) 1.25 V, (b) 0 V, and (c) −2.0 V.

couple at a negative potential in cyclic voltammetry is not adequate information. A drastic change in the NIR region was known to be one of the most important proofs of true n-type doping process [23]. As shown in Fig. 5, the optical spectrum of poly(SBT) reveals the changes in the color of the polymer film. Hence, it can be concluded that poly(SBT) is a true n-type dopable polymer [24].

Copolymer exhibits a λ_{max} value of 560 nm and a band gap of 1.54 eV (Fig. 6). On the other hand, the band gap of Poly(EDOT) and the λ_{max} of $\pi \rightarrow \pi^*$ transition were reported as 1.6 eV and 620 nm, respectively. In conclusion, the band-gap energy and absorption maxima of the copolymer are different than the values for Poly(EDOT) and Poly(SBT) as expected. In addition, the λ_{max} of the

copolymer is red shifted compared to that of the homopolymer with a lower optical band gap among such polymers.

2.4. Switching

The optical switching studies were investigated using a square wave potential step method coupled with optical spectroscopy known as chronoabsorptometry in a monomer free solution. The percent transmittance versus time was monitored at λ_{max} while the polymer on ITO coated glass slides was repeatedly switched between the reduced (0 V) and oxidized (+1.2 V) states for a residence time of 5 s. The optical contrast was measured as the difference in percent transmittance between neutral and oxidized forms and noted as $\Delta T\%$. Fig. 7 reveals the electrochromic switching properties of Poly(SBT). The optical contrast for Poly(SBT) is 32% at 511 nm and 56% at 1200 nm. The coloration efficiency which provides information about the contrast ratio acquired for a certain amount of charge introduced in the material is calculated as 143 cm²/C (at 100% of full switch at 511 nm). It is the relation between the injected and ejected charge per unit area of the electrode and the change in optical density at a specific dominant wavelength.

Switching time is an important parameter for a polymer since it indicates the speed of ions move into the polymer chains during doping process [25]. The switching time was determined by monitoring the absorption intensity at 511 nm and 1200 nm while switching the applied voltage between 0 V and +1.2 V. It is calculated at 95% of contrast ratio. The homopolymer revealed a switching time of 2.4 s and 0.4 s at 511 nm and 1200 nm, respectively. Moreover, copolymerization studies show that copolymer has fast switching times (0.48 and 0.42 s) and high optical contrasts (42% and 68%) at 560 nm and 1400 nm, respectively (Fig. 8).

Table 1
Electrochemical, electronic, and electrochromic properties

Material	E (V)	Color	L	a	b
PSBT	−2.0	Transmissive light blue	84.277	−8.847	−3.458
	0	Red-purple	79.897	8.298	7.365
	1.25	Transmissive light blue	86.947	−10.01	0.973
PSBT-co-EDOT	0.5	Purple	61.912	4.481	−10.93
	1.05	Transmissive light blue	79.328	−7.982	0.891

2.5. Colorimetry

Colorimetry is used to measure the color with an objective and quantitative practice, which allows matching of the colors in electrochromic devices. Color is made up of three attributes: hue, saturation, and luminance, and color systems, such as CIE, are used as a quantitative scale to define and compare colors. The three identifications of the colors (L, a, b) were measured and summarized in Table 1.

3. Conclusion

A novel donor–acceptor type polymer was synthesized and its electrochromic properties were investigated. Spectroelectrochemistry depicted that poly(SBT) reveals two absorption bands as expected for this type of donor–acceptor polymer, at 483 and 511 nm. The optical contrasts of the poly(SBT) film were calculated to be 32% and 56% at 511 nm and 1200 nm, respectively. Kinetic studies also revealed that the polymer films switch between their fully oxidized and fully reduced states in nearly two seconds in the visible and less than 0.5 s in the NIR regions. In addition to high optical contrasts and fast switching times, the polymer films did not reveal any degradation during kinetic studies. The colorimetry analysis showed that Poly(SBT) has a red-purple color in the neutral state and a transmissive-blue color in the oxidized state. The band gap of the Poly(SBT) is calculated as 1.67 eV which is quite low among the selenophene-containing polymers. Furthermore, the polymer has been shown to be n-dopable, as proven by reduction waves in CV and a significant change in the NIR region of spectrum upon reduction. These preliminary results are very promising for selenophene-containing donor–acceptor type polymers. Although our initial studies with 1,4-di(selenophen-2-yl)-benzene did not yield these superior characteristics, this polymer proves that use of an acceptor and a donor selenophene groups may be a key argument for the electrochromic properties of such compounds. Many other potential acceptor groups can be inserted in the structure to tune these properties to yield the best candidate selenophene-containing donor–acceptor polymer for ECD applications. Besides these promising results, it was also shown that this type of donor–acceptor monomers can be used as a comonomer for the synthesis of copolymers with superior properties. In this report EDOT was chosen as the comonomer due to its spectacular properties. The resulting copolymer

also revealed high quality characteristics as an electrochromic material.

4. Experimental section

4.1. Materials

All chemicals were purchased from Aldrich except for anhydrous tetrahydrofuran (THF) which was supplied from Acros. Tributyl(2-selenophenyl)stannane [26] was synthesized according to previously described method. All reactions were performed under argon atmosphere unless otherwise indicated (Scheme 1).

4.2. Synthesis of monomer

4.2.1. Synthesis of 2-dodecylbenzotriazole

The synthesis of 2-dodecylbenzotriazole was performed according to methodology described in literature [27]. 1,2,3-Benzotriazole (5.0 g, 42 mmol) was dissolved in methanol (50 ml) together with potassium tert-butoxide(5.0 g, 44 mmol). Bromododecane (12.2 g, 49 mmol) was added dropwise to mixture. The mixture was refluxed for 12 h and the reaction was monitored by TLC. After removal of the solvent by evaporation, the residue was washed with H_2O and extracted with $CHCl_3$. The organic extract was dried over $MgSO_4$ and the solvent was evaporated under reduced pressure. The crude product was purified by column chromatography on a SiO_2 column to obtain 2-dodecylbenzotriazole; Yield: 3.73 g, 31%, colorless oil, Rf (3:2, hexane:$CHCl_3$) 0.29. ^{1}H NMR spectrum of monomer: $C_{18}H_{29}N_3$, δ (400 MHz; $CDCl_3$; Me_4Si): 7.76 (2H, m), 7.26 (2H, m), 4.62 (2H, t, J = 7.1 Hz), 2.22 (2H, m), 1.25–1.15 (18H, m), 0.78 (3H, t, J = 6.0 Hz,) ^{13}C NMR spectrum of the monomer: ^{13}C NMR δ (100 MHz; $CDCl_3$; Me_4Si): 144.3, 126.1, 117.9, 56.6, 31.8, 30.0, 29.5, 29.5, 29.4, 29.3, 29.3, 29.0, 26.5, 22.6, 14.0.

4.2.2. Synthesis of 4,7-dibromo-2-dodecylbenzotriazole

Synthesis of 4,7-dibromo-2-dodecylbenzotriazole was achieved as described in literature [27]. 2-Dodecylbenzotriazole (4.8 g, 16.8 mmol) and an aqueous HBr solution (5.8 M, 15 ml) were added to a flask, and the mixture was stirred for 1 h at 100 °C. Bromine (5.9 g, 36 mmol) was added, and the mixture was stirred for 12 h at 135 °C and the reaction was monitored by TLC. After cooling the mixture to room temperature, an aqueous solution of $NaHCO_3$ was added and the product was extracted with $CHCl_3$. The organic extract was dried over $MgSO_4$ and the solvent was evaporated under reduced pressure. The crude product was purified by column chromatography on a SiO_2 column to obtain 4,7-dibromo-2-dodecylbenzotriazole; Yield: 4.0 g, 55%, oily at room temperature, Rf (1:1 hexane:$CHCl_3$) 0.33. $C_{18}H_{27}Br_2N_3$, δ (400 MHz; $CDCl_3$; Me_4Si): 7.36 (2H, s), 4.70 (2H, t, J = 7.0 Hz), 2.00 (2H, m), 1.28–1.12 (18H, m), 0.80 (3H, t, J = 6.9 Hz). ^{13}C NMR: δ (100 MHz; $CDCl_3$; Me_4Si): 143.7, 129.4, 109.9, 57.4, 31.8, 31.5, 30.1, 29.5, 29.5, 29.4, 29.3, 28.9, 26.4, 22.6, 14.0.

4.2.3. Synthesis of 2-dodecyl-4,7-di(selenophen-2-yl)benzotriazole (SBT)

4,7-Dibromo-2-dodecylbenzotriazole (100 mg, 0.224 mmol), and tributyl(2-selenophenyl)stannane (470 g, 1.12 mmol) were dissolved in anhydrous THF (100 ml), the
Scheme 1. Synthetic route of monomer.

solution was purged with argon for 30 min and dichlorobis(triphenyl phosphine)-palladium(II) (50 mg, 0.045 mmol) was added at room temperature. The mixture was refluxed for 18 h under argon atmosphere. Solvent was evaporated under vacuum and the crude product was purified by column chromatography on a SiO_2 column to obtain 2-dodecyl-4,7-di(selenophen-2-yl)benzotriazole; (scheme 1) Yield: 78 mg, 63%, yellow solid, Rf (2:1 hexane:CHCl$_3$) 0.45, ^{1}H NMR spectrum of monomer: $C_{26}H_{33}N_3Se_2$, δ (400 MHz; CDCl$_3$; Me$_4$Si): 8.12 (2H, d, J = 3.6 Hz), 8.01 (2H, d, J = 5.5 Hz), 7.52 (2H, s), 7.35 (2H, d-d, J = 3.8–1.5 Hz), 4.74 (2H, t, J = 7.1 Hz), 2.16–2.09 (2H, m), 1.37–1.18 (18H, m), 0.81 (3H, t, J = 6.9 Hz). ^{13}C NMR: δ (100 MHz; CDCl$_3$; Me$_4$Si): 144.1, 140.9, 130.3, 129.4, 127.2, 124.4, 122.0, 55.8, 30.8, 28.9, 28.6, 28.5, 28.4, 28.4, 28.3, 28.0, 25.5, 21.6, 13.0 (Figs. 9 and 10). m/z: 547.3 (100%), 545.1 (95%), 543.1 (55%). The details of MS spectrum are given in Fig. 11.

4.2.4. Synthesis of homopolymer by electrochemical polymerization

Polymerization of SBT was performed in the presence of 0.01 M SBT, 0.1 M TBAPF$_6$ in acetonitrile/dichloromethane (95/5 v/v) in a three-electrode cell equipped with Pt counter electrode and a Ag wire pseudo reference electrode. Polymer films were grafted on Pt foil or an ITO glass working electrode by potentiodynamic scanning wherein the potential was cycled between -0.4 V and $+1.4$ V with 100 mV/s scan rate. The free standing film was washed with ACN to remove unreacted monomer and excess TBAPF$_6$ after the electrolysis.

4.2.5. Synthesis of copolymer of SBT with 3,4-ethylenedioxythiophene (EDOT)

For the synthesis of conducting copolymer, poly(SBT-co-EDOT), EDOT was used as the comonomer. Copolymer was synthesized with a [EDOT]/[SBT] molar ratio of two. A similar oxidative electrochemical polymerization proce-
Fig. 10. ^{13}C NMR spectrum of SBT.

dure was carried out in acetonitrile/dichloromethane (95/5 v/v) via cyclic voltammetry (CV) at a scan rate of 100 mV/s. Resulting copolymer film was washed with ACN to remove unreacted monomer and excess TBAPF$_6$ after the electrolysis.

4.2.6. Equipments

Polymer film was grafted on working electrode by potentiodynamic method, wherein the potential was cycled between oxidized and neutral states at 100 mV/s without significant decomposition of the material. Electrochemical polymerization was performed in a three-electrode cell consisting of Pt foil or Indium tin oxide coated glass slide (ITO) as the working electrode, platinum wire as the counter electrode and Ag wire as the pseudo reference electrode. Polymerizations were carried out under argon atmosphere using Voltalab PST 50 potentiostat.
Fig. 9. ^{1}H NMR spectrum of SBT.
Fig. 11. MS spectrum of SBT.

Tetrabutylammonium hexafluorophosphate (TBAPF$_6$) in acetonitrile/dichloromethane (95/5 v/v) was used as the electrolytic medium. ^{1}H NMR spectra of the monomer was recorded on a Bruker-Instrument-NMR Spectrometer (DPX-400) operating at 400 MHz. ^{13}C NMR spectra were recorded at 100 MHz with CDCl$_3$ as the solvent and chemical shifts (δ) were given relative to tetramethylsilane as the internal standard. Spectroelectrochemical studies were carried out on a Varian Cary 5000 UV–Vis–NIR spectrophotometer. Colorimetry measurements were obtained by a Konica Minolta CS-100A Chroma Meter with a 0/0 (normal/normal) viewing geometry as recommended by CIE. During measurement, samples were placed in a light booth system where it was illuminated from behind by a D65 light source. A direct pyrolysis mass spectrometry (DPMS) system consisting of a 5940 Quatro micromass quadrupole mass spectrometer a mass range of 10–1500 Da was coupled to direct inter probe (T_{max} = 650 °C). In the experiment, the temperature was elevated up to 250 °C at a heating rate of 10 °C/min, and kept constant for an additional 1 min at 250 °C. Sample (0.010 mg) was pyrolyzed in the quartz glass sample vials. Pyrolysis mass spectrum was recorded using 20 eV.

ARTICLE INFO

ABSTRACT

Novel amino-alkyl containing polyfluorenes with Ir complex in pendant chain were synthesized by Suzuki polycondensation and efficient red-light-emitting devices based on the polymers that were fabricated using high work-function metal (Al or Au) as cathode. It was found that the prepared polyfluorenes exhibit good device performances, and the best device efficiency was achieved based on PFN-Irpiq1 that showed a maximal quantum efficiency (QE_{max}) of 3.7% and 1.6% for Al and Au as cathode, respectively, which was comparable to that of 5.5% for low work-function metals Ba as cathode. The efficiencies of devices from the aforementioned polymers showed a reduced roll-off upon the increase of current density, which is beneficial for the highly efficient phosphorescent dye/host-doped systems. The obtained high efficiencies with air-stable metals as cathode reflect that the copolymers have dual functions of being efficient light-emitting and electron injection ability. The results indicated that the incorporation of Ir complex into amino-alkyl containing polyfluorenes side chain is a potential approach to achieve efficient light-emitting devices with air-stable high work-function metal as the cathode.

1. Introduction

Since remarkable progress has been made in polymer light-emitting diodes (PLEDs) during the last decade, light-emitting devices with high brightness and low drive voltage could be achieved for high-efficiency, full-color applications [1]. To obtain high-efficiency, low work-function metals (such as Ca or Ba) are generally employed as cathode to facilitate electron injection. However, these metals are very sensitive to moisture and oxygen, and detrimental quenching sites might be formed near the interface between the light-emitting layer (EML) and the cathode. To circumvent such problems, many efforts have been devoted to employing environmental stable high work-function metals (such as Al, Ag or Au) as the cathode [2]. In this scenario, electron injection layers, (EIL or cathode buffer) such as metal fluoride (LiF, CsF, etc.), aluminum oxide layer, organic surfactants [3–6], or ammonium-functionalized polyfluorene derivatives [7–12] have been developed as EIL to facilitate electron injection. Recently, Huang et al. [7–11] reported a series of conjugated amino-alkyl containing polyfluorenes with various emissive wavelengths, which can significantly enhance the device performance using high work-function metal as cathode. However, the reported amino-alkyl substituted polyfluorenes [7–9] show a relative low emission efficiency, which limits their applications.

Electrophosphorescent polymers have attracted much attention since they can make use of both singlet and triplet exciton owing to a strong spin–orbit coupling, and theoretically 100% of internal quantum efficiency can be achieved. The phosphorescent conjugated polymers based

* Corresponding author. Tel.: +86 20 87114346x17; fax: +86 20 87110606.
 E-mail address: pswyang@scut.edu.cn (W. Yang).

on polyfluorene backbone with diketone pendant attached to 9-carbon position of fluorene were reported by Chen et al. [13]. The device from polymer which grafted with 1.3 mol% iridium(III)bis(2-(2′-benzothienyl) pyridinato-N,C³′) acetylacetonate complex [(btp)₂Ir(acac)] in diketone pedant at 9-position of fluorene unit has shown a high external quantum efficiency of 1.59% ph/el and a power efficiency of 2.8 cd/A at 7.0 V with a luminance of 65 cd/m² and peak a emission at 610 nm. Jiang et al. [14] reported a series of high-efficiency electrophosphorescent polymers by grafting Ir complexes into poly(fluorene-alt-carbazole) pendant chain, and QE_{ext} of 4.9% and LE of 4.0 cd/A with 240 cd/m² at a bias voltage of 7.7 V and a peak emission of 610 nm were achieved. A very similar approach of incorporated Ir complexes conjugatively into polymer main chain was reported by Zhen et al. [15,16], and yellow and red electrophosphorescent copolymers with Ir complexes on the backbone of poly(fluorene-*alt*-carbazole) (PFCz) and polyfluorene (PFO) were synthesized to achieve maximal external quantum efficiencies of 4.6% and 7.0% ph/el, respectively. However, the efficient electrophosphorescent PLED was achieved based on low functional metals Ba as cathode [14–16]. In order to employ an air-stable metal such as Au or Al as cathode for the single active layer devices, Zhang et al. [17,18] reported a series of phosphorescent polyelectrolytes and their neutral precursor, in which Ir complex was conjugatively incorporated into a polymer main chain, but the device performance does not enhance evidently. In this paper, we introduce Ir complex into amino-alkyl containing polyfluorenes side chain by a long alkyl chain. Efficient red light-emitting devices are fabricated using high work-function metal (Al or Au) as cathode.

2. Experimental section

2.1. Materials and measurements

All solvents were purified and freshly distilled prior to use according to the literature procedures. All reagents were obtained from Acros, Aldrich or TCI chemical company and used as received. All manipulations involving air-sensitive reagents were performed under high purified argon or nitrogen atmosphere.

NMR spectra were recorded on a Bruker 300 in deuterated chloroform solution operating with tetramethylsilane as reference. Weight-average molecular weight (M_w) and polydispersity index (PDI) were determined by a Water GPC 2410 spectrometer in tetrahydrofuran (THF) using a calibration curve with a standard polystyrene as a reference. Elemental analyses were performed on Vario EL elemental analysis instrument (Elementar Company). UV–vis absorption spectra were recorded on a Hitachi UV-3010 spectrometer. The PL quantum yields were determined in an integrating sphere ISO80 (Labsphere) with 325 nm excitation of HeCd laser (Mells Griot). Cyclic voltammetry was carried out on a CHI660A electrochemical workstation with platinum at a scan rate of 50 mV s⁻¹ against a saturated calomel reference electrode with nitrogen-saturated solution of 0.1 M tetrabutylammonium hexafluorophos-

phate (Bu₄NPF₆) in acetonitrile (CH₃CN) for copolymers. Glass transition temperatures (T_gs) were measured on a TA 5200M DSC instrument at a heating rate of 10 °C min⁻¹ in nitrogen. Thermogravimetric analyses (TGA) were conducted on a NETZSCH TG 209 under a heating rate of 10 °C min⁻¹.

2.2. General procedure of Suzuki polycondensation taking PFN-Irpiq05 as an example

2,7-Bis(4,4,5,5-tetramethyl-1,3,2-dixaborolan-2-yl)-9,9-dioctylfluorene [19] (**1**, 0.3213 g, 0.5 mmol), 2,7-dibromo-9,9-bis(3′-(N,N-dimethylamino)propyl)fluorene (**2**, 0.2447 g, 0.495 mmol), 3,6-dibromo-9-(iridium(III)bis(1-phenylisoquinoline-N,C2′))- 14-trifluoro-11,13-tetradecyldiketone)carbazole [15] (**3**, 6.02 mg, 0.005 mmol), and palladium(II) acetate (1.5–2 mol%) and tricyclohexylphosphine (4-6 mol%) were dissolved in the mixture of toluene (8 ml) and THF (5 ml), stirred for 30 min in argon atmosphere, then Et₄NOH (35 wt%) aqueous solution (2 ml) and deionized water (2 ml) were added. The mixture was heated to 90 °C and stirred for 48 h followed by stirring with 2-(4,4,5,5-tetramethyl-1,3,2-dixaborolan-2-yl)-9,9-dioctylfluorene (50.00 mg) 12 h. Then bromobenzene (0.2 ml) was added and stirred for another 12 h. The whole mixture was poured into methanol with stirring. The precipitated polymer was collected by filtration and purified by Al₂O₃ column chromatography with toluene as eluent to remove catalyst residue and small molecules (yield 70%). ¹H NMR (CDCl₃) δ = 7.90–7.82 (m, 4H, fluorene ring), 7.71–7.57 (m, 8H, fluorene ring), 2.30–1.95 (m, 24H, −NCH₂, −NCH₃, H-alkyl), 1.22–1.04 (m, 28H, H-alkyl), 0.87–0.72 (m, 6H). Element Anal. Found C 85.78, H 8.85, N 3.40.

3. Results and discussion

3.1. Synthesis and characterization of polymers

Copolymers derived from monomers 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene (**1**), 2,7-dibromo-9,9-bis((3′-N,N-dimethylamino)propyl)fluorene (**2**) and 3,6-dibromo-9-(iridium(III)bis(1-phenylisoquinoline-N,C²′))-14-trifluoro-11,13-tetradecyldiketone)carbazole (**3**) were prepared by Suzuki polycondensation (Scheme 1) with a feed ratio of 50:49.5:0.5, 50:49:1 and 50:48:2, and the resulted polymers are named PFN-Irpiq05, PFN-Irpiq1 and PFN-Irpiq2, respectively. The copolymers exhibit good solubility in common organic solvents such as THF, chloroform, toluene and xylene. The weight average molecular weight (M_w) of the copolymers estimated by gel permission chromatography (GPC) against the polystyrene standard with THF as eluent solvent ranges from 89,000 to 1,32,000 with a polydispersity index (PDI) (M_w/M_n) from 1.65 to 1.90. The thermal stabilities of copolymers were studied by TGA and DSC measurements. As can be seen from Fig. 1, the Ir complex containing copolymer PFN-Irpiq1 exhibits a good thermal stability with an onset of degradation temperature at around 430 °C and with a glass transition temperature
Scheme 1. Synthetic procedure of copolymers.
Fig. 1. Thermal properties of PFN-Irpiq1.

(T_g) of 93 °C. The distinct improved T_g of PFN-Irpiq1 compared to poly(9,9-dioctylfluorene) (PFO, with T_g of 72 °C) [20] might be ascribed to the intra-molecular interaction owing to the substituted amino-alkyl side chains. Likewise, other resulted copolymers also exhibit similar good thermal properties as PFN-Irpiq1.

3.2. Electrochemical properties

The electrochemical behavior of these polymers was investigated by cyclic votammetry (CV) in the solution of 0.1 M tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) in acetonitrile (CH_3CN). The copolymers show

a reversible oxidation wave with an onset at around 1.2 V of the oxidation potential of amino-alkyl containing copolymer main chain. The onset oxidation potentials are used to determine the highest occupied molecular orbital (HOMO) energy level, and the differences between the HOMO levels and the optical energy gap (E_g) are used to estimate their lowest unoccupied molecular orbital (LUMO) energy levels, where E_g is inferred from the onset absorption. HOMO and LUMO levels of polymers are calculated according to empirical formulas $E_{HOMO} = -e(E_{ox} + 4.40)$ eV [21]. The HOMO and LUMO levels of the copolymers show a little difference with a diverse Ir complex content. Table 1 summarizes the photophysical and electrochemical properties of Ir complexes and the redox potentials of the copolymers.

3.3. Photophysical properties

Fig. 2 shows the absorption spectrum a of model compound Ir complex bis-(1-phenylisoquinolyl)iridium(III)(1-

Fig. 2. Absorption of Ir(piq)$_2$(acaf) and PL of PFN.

trifluoro)acetylacetonate [Ir(piq)$_2$(acaf)] [22] and photoluminescence spectrum (PL) of poly[(9,9-bis(3′-((N,N-dimethyl)propyl)-2,7-fluorene)-2,7-(9,9-dioctyl-fluorene)] (PFN) [7]. The Ir complex shows broad absorption band from about 270 nm to more than 600 nm. The intense absorption peak below 350 nm is attributed to the spin-allowed singlet state π–π* transition of cyclometalated ligands, and the weak absorption peak at about 422 nm can be assigned to the spin-allow singlet metal-to-ligand charge transfer (^{1}MLCT) transition. The absorption peak of 486 nm is due to the triplet metal-to-ligand charge transfer (^{3}MLCT) transition. The spin-forbidden ^{3}MLCT transition is gained by mixing it with the higher spin-allowed ^{1}MLCT transition through the strong spin–orbit coupling of iridium. As can be seen from Fig. 2, fairly good overlap is found in the PL of the host PFN and the absorption of the guest Ir(piq)$_2$(acaf), thus the efficient Förster energy transfer from the PFN to the Ir complex can be expected [23].

The emission of the copolymers in Fig. 3 is dominated by the peak around 619 nm, which corresponds to the triplet emission of the Ir complex. Besides, the weak emission at 425 nm (emission from PFN) is also found in the copolymer with 0.5 mol% content of Ir complex (PFN-Irpiq 05), indicating that the energy transfer from the host PFN main chain to the low content Ir complex is incomplete. Indeed, with the increase of Ir complex content up to 2 mol%, the emission of PFN segment in copolymers is found to be quenched completely. Moreover, the emission at 425 nm is found to descend with the increase of Ir complex content in the copolymers. The PL efficiencies of the copolymers are in the range of 28.4–37.3% (Table 1), which are much higher than that of the previously reported electrophosphorescent polymers PFN-IrDPPy [13], in which neutral Ir complex is conjugatively incorporated into polyfluorenes main chain, suggesting that the incorporation of Ir complex into side chain is a better way to achieve more efficient emission.

3.4. Device performances

The light-emitting devices are fabricated in configuration: ITO/PEDOT/PVK/emissive layer/cathode. Here low work-function metal Ba (−2.8 eV) and high work-function Al (−4.3 eV) and Au (−5.2 eV) are used as cathode for comparison. As shown in Fig. 4, EL emission (Fig. 4) from the backbone of the copolymers is quenched completely although the Ir complex content is as low as 0.5 mol%. The substantial difference between the PL (Fig. 3) and EL (Fig. 4) of the copolymers implies that the excitation mechanism for the PL and EL process is different [23–25]. Under photoexcitation, singlet excited state is created on the polymer main chain and subsequently transferred to the iridium complex by Förster energy transfer [26, 27]. In contrast, since the HOMO and LUMO energy level of incorporated Ir(piq)$_2$(acaf) (which is −5.0 and −2.7 eV, respectively) lies between that of host PFN (which is −5.6 and −2.1 eV, respectively), thus for electrical excitation process, electrons and hole are readily trapped on the Ir complex sites when charge carriers are injected from the electrodes, as can be referred from the energy level diagram. In other words, charge trapping mechanism is dominant in the electroluminescent process of our devices.

Device structure: ITO/PEDOT/PVK/emissive layer/cathode.

It is interesting to note that, despite different metals with different work-functions being employed as cathodes, all copolymers exhibit a comparable device performance in terms of external quantum efficiency (QE_{ext}). The best device performance is found in PFN-Irpiq1, in which Ir complex content of 1 mol% is used as EML. The QE_{max} of 5.50%, which corresponds to a luminous efficiency (LE_{max}) of 2.44 cd A^{-1} and a maximal luminance of 750 cd m^{-2} is obtained with Ba/Al as cathode. When high work-function Al is employed, the QE_{max} and LE_{max} are 3.70% and 1.64 cd A^{-1}, respectively, with a maximal luminance of 1032 cd m^{-2}. Moreover, when noble metal Au is employed as cathode, the QE_{max} and LE_{max} could reach 1.60% and 0.71 cd A^{-1}, respectively, with a maximal luminance of 361 cd m^{-2}. It is important to note that the noble metal Au is commonly used as good hole-injection electrode and devices fabricated from traditional conjugated polymers with Au as cathode cannot emit light due to their extremely high work-function [10]. However, our devices based on PFN derivatives with Au as cathode show a remarkable efficiency, in consistence with what was reported previously [10]. The device performances in detail with different device configurations are summarized in Table 2.

Fig. 5 shows the QE_{ext} and luminance (L) as a function of current density (J) for the devices with different cathodes. It can be seen that Al and Au devices exhibit comparable overall efficiency than that with Ba device (Fig. 5). We speculate that a strong interaction between amino-alkyl moieties and high work-function metal can induce interfacial dipole [10,11], which can shift the vacuum level of the polymer upwards and is responsible for the enhanced electron injection from Al and Au. Despite that the mechanism being not fully understood, the obtained efficient devices with air-stable metals including Al or Au as cathode reveal that the copolymers have dual functions of being efficient light-emitting material and efficient electron injection ability. Furthermore, the QE_{ext} in Fig. 5 slightly decays with the increase of current density regardless of the employed cathodes, indicating that the incorporation of Ir complex into polymer side chain [15–18] is an effective way to inhibit the concentration quenching at the high current density due to the complex aggregation while depressing the triplet–triplet annihilation.

4. Conclusion

A series of novel amino-alkyl containing polyfluorenes with Ir complex in pendant chain were synthesized by Suzuki polycondensation. The devices based on the resulted copolymers using air-stable high work-function metals including Al and Au as the cathode exhibited comparable device performance with that of low work-function metals Ba as cathode. The efficiencies of device from the prepared polymers show a reduced roll-off upon the increase of current density and Ir complex content, which is positive for the highly efficient phosphorescent dye/host doping systems.

ARTICLE INFO

ABSTRACT

Organic bistable memory devices (OBDs) with MoO$_3$ as a nanocrystal inside organic layer were developed and bistability of MoO$_3$ based OBDs was investigated. High on/off ratio over 200 was obtained at a low reading voltage of 1 V. MoO$_3$ OBDs could be electrically switched between high conductance state and low conductance state over more than 100 cycles and space charge limited conduction mechanism dominated switching behavior in MoO$_3$ OBDs.

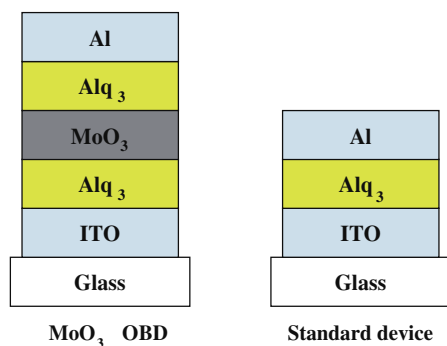
© 2008 Elsevier B.V. All rights reserved.

1. Introduction

Organic bistable memory devices (OBDs) have attracted great attention due to many advantages such as high on/off ratio, high switching speed and simple fabrication process [1–14]. In addition, it can be made into flexible form on plastic substrate [1].

There have been many studies about OBDs with bistable memory characteristics and most OBDs had nanocrystals inside organic layer as a charge trapping center [2–9]. Al has been widely used as a nanocrystal for charge trapping and it showed stable memory characteristics with various organic materials [2–4]. Au was also effective as a nanocrystal and stable memory characteristics were realized in Au based OBDs [5–9]. Uniform dispersion of Au nanocrystal was achieved by self-assembly and high on/off ratio

over 1000 was obtained [8]. Alkanethiol capping of Au nanoparticle was found to be important for bistability in OBDs and dodecanethiol capping of Au improved switching performances of OBDs [6]. Other than Al and Au, CdSe capped with ZnS nanocrystal could play a role of nanoparticle for charge trapping inside C60 [10].

In this work, OBDs with MoO$_3$ as a nanoparticle for bistable memory characteristics were fabricated and memory behavior was investigated. MoO$_3$ was introduced as an interlayer inside tris(8-hydroxyquinoline) aluminium (Alq$_3$). Detailed mechanism for bistability in MoO$_3$ OBDs was studied and it was correlated with energy level of Alq$_3$ and MoO$_3$.


2. Experimental

Device structure for OBDs was indium tin oxide (ITO, 150 nm)/Alq$_3$(50 nm)/MoO$_3$(5 nm)/Alq$_3$(50 nm)/Al(150 nm). Single layer OBDs with Alq$_3$ were also fabricated as a

Fig. 1. Device structure of Alq$_3$ organic bistable memory devices with and without MoO$_3$ nanoparticles.

standard device. Device structure of OBDs is shown in Fig. 1. Pixel size of the device was 2 mm × 2 mm with an active area of 4 mm^2. Deposition rate of Alq$_3$ was 0.1 nm/s, while MoO$_3$ was evaporated at a deposition rate of 0.02 nm/s. All materials were evaporated at a vacuum pressure under 1.0×10^{-6} Torr. The device was encapsulated with CaO getter and a glass lid. Morphology of MoO$_3$ on Alq$_3$ was observed with transmission electron microscope (TEM, Jeol) at a magnification of 100,000. Current density–voltage relationship was measured with Keithley 2400 source measurement unit. All measurements were carried out after encapsulation in air. Pulse test of the OBD was performed with a semiconductor analyzer with a pulse width of 1 μs.

3. Results and discussion

MoO$_3$ has been known as a p-type dopant and charge transfer complex formation with aromatic amine materials was reported [15]. Valence band of MoO$_3$ has been known to be 5.3–5.5 eV. Therefore, charge trapping by MoO$_3$ can be induced when it is combined with Alq$_3$ with the highest occupied molecular orbital (HOMO) of 5.8 eV and the lowest unoccupied molecular orbital (LUMO) of 3.0 eV in our cyclovoltametry measurement. Hole trapping by MoO$_3$ in Alq$_3$ matrix can be expected at the interface between Alq$_3$ and MoO$_3$ and bistable memory performances can be induced by MoO$_3$. The advantage of MoO$_3$ based memory device compared with Al embedded Alq$_3$ memory devices is that it is possible to get stable and reproducible memory performances. Al is sensitive to oxygen and it is difficult to guarantee reproducibility of device performances. MoO$_3$ is not sensitive to oxygen and memory device data are reproducible. In addition, it can be simply deposited by thermal evaporation in organic crucible at low temperature compared with other metals.

It is important to get uniform dispersion of nanoparticles to secure stable switching behavior in OBDs and morphology of MoO$_3$ on Alq$_3$ was analyzed. Fig. 2 shows TEM picture of MoO$_3$ deposited on Alq$_3$ at a thickness of 5 nm. Average size of MoO$_3$ nanoparticle on Alq$_3$ was around 30 nm and MoO$_3$ was uniformly dispersed on Alq$_3$ even though there was some scattering of particle size. Continuous film formation was not observed in TEM image of
Fig. 2. Transmission electron microscopic picture of 5 nm thick MoO$_3$ deposited on Alq$_3$.

MoO$_3$ on Alq$_3$ and island growth of MoO$_3$ dominated morphology of MoO$_3$.

Memory characteristics of MoO$_3$ OBDs were measured by scanning voltage from 0 V to 7 V after applying writing and erasing voltage to the OBD. Current density–voltage plots of MoO$_3$ OBDs are shown in Fig. 3. MoO$_3$ OBDs showed bistable memory characteristics with high conductance state (ON state) and low conductance state (OFF state). Bistability was observed during forward scans depending on the writing voltage. Current density level was gradually increased according to voltage and sharp rise of current density was observed between 2.1 V and 2.4 V. The device was changed from low conductance state to high conductance state at 2.4 V. After sharp rise of current level, negative differential resistance behavior was observed. The high current state was observed after applying 2.5 V during scan from 0 V to 7 V. Large hysteresis required for bistable memory devices was clearly observed during voltage scan from 0 V to 7 V. To elucidate the switching mechanism of MoO$_3$ OBDs, single layer device of ITO/Alq$_3$(100 nm)/Al was fabricated and its current density–voltage data were compared with those of MoO$_3$ OBDs. In contrast to MoO$_3$ OBDs, Alq$_3$ device did not show any hysteresis during voltage scans, indicating that MoO$_3$ nanoparticles are responsible for bistable current behavior in MoO$_3$ OBDs. The origin for bistable memory performances of MoO$_3$ OBDs can be found in the charge trapping by MoO$_3$. Charges can be trapped by MoO$_3$ interlayer because there is 0.5 eV energy gap between valence band of MoO$_3$ and HOMO of Alq$_3$. Therefore, the bistability mechanism can be explained by Simmons and Verderer mechanism
Fig. 3. Log (current density) -voltage curves of MoO₃ memory devices based on Alq₃. Voltage was scanned from 0 V to 7 V after switching on the device at 2.5 V and switching off the device at 4.5 V. (a) Alq₃ based organic memory device with MoO₃. (b) Alq₃ based organic memory device without MoO₃.

which is based on charge trapping and detrapping [16,17]. Large amount of charges can be trapped by MoO₃ at high voltage and reading at low voltage (1 V) after charge trapping by MoO₃ gives high conductance state. Charge transport can be facilitated because charge traps are filled with holes. A sharp increase of current density is observed after the charge traps is occupied. However, the space charge formation limits the charge transport, leading to negative differential resistance region. Reading between 0 V and

2.5 V gives high conductance state after applying 2.5 V (curve 2) and low conductance state after applying 4.5 V (curve 1). Negative differential resistance behavior of MoO₃ OBDs supports this explanation. In off state, first scan from 0 V to 7 V (curve 1) shows low conductance state and the low conductance state is changed into high conductance state at 2.4 V. However, space charge formation at a voltage higher than 2.4 V leads to the decrease of current density level. Therefore, low conductance state can be induced by applying 4.5 V at which current density level is minimum and high conductance state can be recovered at 2.5 V at which current density level is maximum in negative differential resistance region. Current density–voltage curve after switching at 2.5 V followed the curve 2. Schematic diagram describing the on and off state is shown in Fig. 4. Even though negative vias region was not shown in Fig. 3, the device could be erased at negative vias due to charge detrapping.

To study detailed process for current flow in MoO₃ OBDs, charge transport mechanism of MoO₃ OBDs was investigated. Fig. 5 shows log–log plot of current density–voltage relationship at low conductance state. Linear relationship between log (current density) and log (voltage) was observed at low conductance state, indicating space charge limited charge transport behavior by MoO₃ [18,19]. This supports space charge limited switching behavior of MoO₃ OBDs at low conductance state.
Fig. 5. Log (current density)–log (voltage) curves of Alq₃ based organic memory device with MoO₃ interlayer at low conductance state after applying erasing voltage of 4.5 V.
Fig. 4. Schematic diagram of the on and off state.
Fig. 6. Multilevel switching behavior of Alq$_3$ based organic memory device with 5 nm thick MoO$_3$ interlayer at a writing voltage of 2.5 V, 3.5 V and 4.5 V. Reading voltage was 1 V and the switching test was conducted 100 times.
Fig. 7. Switching performance test results of Alq$_3$ based organic memory device with 5 nm thick MoO$_3$ interlayer. Pulse width was 1 µs and programming voltages were 2.5 V for writing and 4.5 V for erasing with a reading voltage of 1 V.

Multilevel switching can be realized by changing the writing voltage of MoO$_3$ nanoparticles based OBDs. Fig. 6 shows the multilevel switching test results of OBDs. Reading voltage was 1 V and writing voltage was 2.5 V, 3.5 V and 4.5 V. It can be clearly seen that different current density level was obtained depending on the writing voltage. Average current density level at 1 V after switching on MoO$_3$ OBDs at 2.5 V was 0.2 mA/cm^2, while average current density level at 1 V after switching off MoO$_3$ OBDs at 4.5 V was 0.00075 mA/cm^2. Current density level of OBDs after switching OBDs at 3.5 V was 0.02 mA/cm^2. Three level switching could be effectively induced by changing the writing voltage in negative differential resistance region.

The switching test results also agree with the data proposed by Simmons and Verderber and support the charge trapping and detrapping mechanism [16]. High average on/off ratio over 200 could be obtained after programming MoO$_3$ OBDs at 2.5 V and 4.5 V with a reading voltage of 1 V. The on/off ratio was quite stable even though there was some scattering of current density level during multicycle test.

To get more detailed information about the switching behavior of the OBD, pulse voltage with a pulse width of 1 µs was applied to the OBD. Programming voltages were 4.5 V and 2.5 V, while the reading voltage was 1 V. Fig. 7 shows switching test results of the OBD with MoO$_3$ nano-

crystals. The OBD with MoO_3 nanocrystal inside Alq_3 showed good switching performances between on and off states. The on and off currents were maintained during measurements without any decrease.

4. Conclusions

In summary, bistable memory devices could be fabricated by using MoO_3 as a nanoparticle to trap charges. Stable memory characteristics could be obtained by inserting MoO_3 between Alq_3 organic layers and high on/off ratio over 200 could be realized at a writing voltage of 2.5 V and erasing voltage of 4.5 V. The high on/off ratio could be maintained even after multicycle test over 100 times.

ARTICLE INFO

ABSTRACT

Two new trifunctional thiophene based dyes suited for crosslinking were synthesised from the same structural core, i.e. 4-[[5-[(4-nitrophenyl)azo]-2-thienyl]azo]benzenamine. Crystal structure and second order nonlinear optical properties were determined on a related difunctional dye that can be considered as a representative and simplified model of the trifunctional compounds, determining on it the $\mu\beta$ value of 4950×10^{-48} esu (6111×10^{-80} $C^2\,m^4\,V^{-2}$).

The presence of three acrylic or hydroxyl functional groups in the dyes allowed to incorporate the chromophoric fragment into two different kinds of crosslinked materials possessing "frozen" long-lasting dipole order. The traditional guest-host approach used for one of them was exceeded by covalently anchoring the chromophore to a functionalised polymer in a three-dimensional unique network. In this way a promising NLO active material was obtained. The value of the d_{33} coefficient (determined by SHG measurement using the Maker fringe technique) was 11 pm/V for the poled/crosslinked film. Very good thermal and temporal stability of the chromophore poling-induced dipole alignment was attained.

1. Introduction

Compounds exhibiting disazo-thiophene groups have been extensively investigated, especially for their properties of colouring textiles and plastics or in general as dispersed pigments [1,2]. More recently, thiophene has been largely used as electron-rich molecule for a variety of optical and electrooptical applications [3–5]. Thiophene based dyes typically contain aromatic rings linked by unsaturated moieties. The influence on electron donor effects of the thiophene ring has been extensively examined [6] and the use of this heterocycle in compounds for nonlinear optics has

gained increasing consideration [7–9]. In particular, theoretical investigations indicated that the replacement of a phenyl ring with a thiophenic one significantly improves the values of molecular hyperpolarizability [10–12]. Thiophene not only behaves as one of the most effective heterocyclic rings in enhancing NLO properties of typical push–pull chromophores even in relatively short conjugated systems, but also prompts the desirable targets of high solubility of the dyes and easy processability of materials.

In this work, we report the synthesis of three functionalised derivatives having the same core, 4-[[5-[(4-nitrophenyl)azo]-2-thienyl]azo]benzenamine (**C** type compounds in Fig. 1) and their precursors (**C′** type compounds in Fig. 1).

In the new dyes the thiophene ring is interposed between two highly conjugated moieties bringing donor and acceptor substituents. The unsaturated moieties are

azo bridges, that are claimed to be the most efficient ones in push–pull systems [13].

In contrast with the extended use of thiophene in NLO active polymers and materials [14–16], only a few examples of disazo-thiophene dyes for the synthesis of NLO active materials are known [17,18]. To our knowledge no example of disazo-thiophene dye in crosslinked materials was reported.

The strategy generally used to produce NLO active materials with enduring polar order involves the synthesis of polymers crosslinkable under electric field [19,20]. Alternatively, polyfunctionalised monomers, eventually pre-polymerised, are poled and crosslinked under poling conditions to give the final network [21,22].

In our case, according to the last approach, **C$_{Triacr}$** was simply reacted with non NLO active polyfunctional monomers under an electric field. For **C$_{Triox}$** another recently proposed approach [23] was implemented. The dispersed chromophore, polyglicidyl methacrylate (PGMA) and a passive co-crosslinker were thermally seized by covalent bonding in a single network under poling conditions. The most promising crosslinked material presented in this paper was achieved in this case, getting materials with both high NLO activity and excellent temporal stability of the dipolar alignment.

The difunctional compound **C$_{Diacr}$** was tailored as a model compound for EFISH and spectroscopic measurements. X-ray single crystal diffraction analysis was also effected, in order to relate crystal structure and optical properties and to achieve information on the factors affecting solubility.

2. Results and discussion

2.1. Synthesis and characterization of dyes

Three thiophene based functionalised push–pull chromophores (**C$_{Diacr}$**, **C$_{Triacr}$** and **C$_{Triox}$** in Fig. 1) were synthesised and characterized. The dye skeleton includes a nitro acceptor group and a substituted amino donor group on

phenyl rings linked by a conjugated system made up of two azo bridges and one thiophene unit. The syntheses of similar 2,5-disazo-thiophene compounds reported in literature [18,24] is often cumbersome. We have followed a synthetic pathway somehow different and simplified respect to the previously described ones [8,15,18]. According to a previous report [8], a nitro group in 2 position on a thiophene ring can be converted into an aminic one by reduction with tin. Isolation of a SnCl$_4$-aminothiophene hydrochloride complex avoided the use of the poorly stable free 2-aminothiophene. The complex was then converted into the acetamido derivative that was successively nitrated and then deprotected to nitroamine [8]. In our case, we have directly copulated 2-hydroxy-4-nitrobenzenediazonium chloride with SnCl$_4$-aminothiophene hydrochloride, the metal group acting as a protector group in the synthesis of the first azo bridge. We built the second azo bridge by amine diazotation on this metallated intermediate after easy de-protection in mildly acid solution. Thus, such use of the not isolated intermediate complex allowed easy and fast *one-pot* synthesis of the **C'** type chromophores (Scheme 1), that were used as precursors of **C** type ones.

Starting from **C'** chromophores, three different dyes (**C** type compounds, Fig. 1) were easily obtained as acrylic or hydroxylic derivatives. The trifunctional compounds, **C$_{Triacr}$** and **C$_{Triox}$**, were designed to be employed in the synthesis of two kinds of crosslinked materials.

The three chromophores are all crystalline greenish gray solids, affording blue solutions in chloroform. The ^{1}H NMR spectra gave evidence of high purity for all products. In particular, the singlet pertaining to the thiophene proton, observed at 8.36 ppm, can be considered diagnostic. Thermodynamic data for **C** chromophores and their precursors **C'** are reported in Table 1.

According to thermogravimetrical analyses, the 5% weight loss temperatures are higher than 200 °C for all
Scheme 1. Synthetic pathway for **C'** type compounds.

Sample	T_m (°C)	ΔH (J/g)	T_{dec} (°C)[a]
$\mathbf{C'_{Diacr}}$	199.5	15.6	218
$\mathbf{C'_{Triacr}}$	169.8	20.4	213
$\mathbf{C'_{Triox}}$	160.4	11.7	222

[b] Not integrable.

compounds. DSC–TGA curves for the acrylic derivatives $\mathbf{C_{Diacr}}$ and $\mathbf{C_{Triacr}}$ are similar. Fig. 2 shows, as an example, DSC and TGA curves for $\mathbf{C_{Triacr}}$.

It can be observed that the DSC curve shows the endothermic peak related to melting immediately followed by a broad exothermic signal, probably as a consequence of thermo-induced breakage of the double bonds. A gradual partial degradation not involving significant weight loss occurs together with this transition, as confirmed by ^{1}H NMR, UV spectra, optical observation, DSC and TGA analysis effected on a thermally treated sample. This behaviour could be compared with the well known photochemical degradation reaction of phenylazo-thiophenes containing electron donors and attractors [25,26].

The OH-functionalised derivatives $\mathbf{C'_{Triox}}$ and $\mathbf{C_{Triox}}$ show a larger range of stability after melting and no degradation is detected till about 220 °C. This behaviour makes them better candidates for NLO applications.

The difunctional dye $\mathbf{C_{Diacr}}$ was most easily obtained in pure form, and was considered as a "model" suitable for X-ray and EFISH measurements.

The X-ray single crystal molecular structure of $\mathbf{C_{Diacr}}$ is shown in Fig. 3, selected bond lengths and angles are reported in Table 2.

Except for the two acrylic groups, the molecule is overall planar and a bent shape is observed. The two N=N moieties with E geometry are in mutual syn arrangement on the thiophene ring. Both acrylic groups are planar and substantially perpendicular to the mean plane of the molecule (torsion angles around C4–O3 and N6–C20 bonds are 102.6(4)° and 95.4(4)°, respectively). The nitro group is almost co-planar with the attached phenyl ring, and a clear trigonal planar geometry is observed around N6. The flat shape of the molecule and the analysis of geometric parameters are in keep with extension of conjugation to the entire molecule.

The above results indicate that the core of the dyes satisfies basic conditions required to exhibit good NLO properties. In fact, it was demonstrated that a long conjugation path is expected to enhance second order nonlinear hyperpolarizability and a bent molecular shape is claimed to favour efficient orientation of the chromophore in the material under poling conditions [27]. The bent shape, in addition to the presence of aliphatic chains, is also expected to favour solubility in common organic solvents. In fact, it is to remark that the dyes here described display good solubility in organic solvents at variance with most of the analogous rod-like all-benzenoid compounds [7], whose solubility is often to be enhanced by introduction of suited substituents [28].

EFISH measurements were effected on compound $\mathbf{C_{Diacr}}$. The $\mu\beta$ value measured by EFISH technique in chloroform solutions at $\lambda = 1.907$ μm, is 4950×10^{-48} esu (6111×10^{-80} C^2 m^4 V^{-2}). To our knowledge this is by far the highest value found for similar thiophene based dyes and is about twice higher than the ones typically displayed by analogous all-benzenoid compounds [29,30].

UV–vis spectra were also recorded on the model chromophore $\mathbf{C_{Diacr}}$ in solvents with different polarity (see Table 3) and show the existence of a relevant solvatochromic shift as well as low levels of optical absorption at some typical NLO operating wavelengths.

2.2. Polymeric networks

Covalently crosslinked polymeric networks (**NET1** and **NET2**) were obtained, respectively, from $\mathbf{C_{Triacr}}$ and $\mathbf{C_{Triox}}$.

Our attempts to react the acrylic groups of $\mathbf{C_{Triacr}}$ by radicalic activation gave variable (by changing type of initiator and reaction temperature) amounts of decomposed material. In fact, as for the radical induced reactivity of acrylic monomers, it was demonstrated [25,26] that while azobenzenes containing a push–pull donor–acceptor conjugated system are moderately robust, the corresponding 2,5-substituted azothiophenes easily undergo photodegradation reactions.

Thus, in order to avoid damage to the system during crosslinking and to preserve reproducibility of the NLO signal, we reacted $\mathbf{C_{Triacr}}$ by use of a procedure not involving radicals. It is well known [31] that primary or secondary amines easily add to vinyl bonds activated by electron attracting groups. The reaction is substantially a nucleophilic ionic addition. To obtain a network we used this reaction in bulk between $\mathbf{C_{Triacr}}$ and a secondary diamine, 4,4′-trimethylene-dipiperidine. Eventually a passive co-crosslinker was added. The two polyfunctional monomers were layered by spinning as thin films and thermally crosslinked during poling.

Constituents of the crosslinked film **NET1** are shown in Scheme 2.

By this synthetic route we easily obtained homogeneous crosslinked thin films either balancing stoichiometrically the aminic functions of 4,4′-trimethylene-dipiperidine only with the acrylic groups of **C_Triacr**, or employing also tris[2-(acryloyloxy)ethyl]isocyanurate as a non NLO active co-crosslinker. This component was added in order to dilute the system and so contrast the depressing effect of dipole–dipole interactions on poling. In this case, the total amount of aminic functions was stoichiometrically balanced by the total acrylic functions, obtaining films at 5%, 10%, 20%, 30% by weight in chromophore. Although crosslinked insoluble films were obtained, no relevant SHG signal were recorded on them. Since crosslinking started on mixing of constituents, before thermal and electrical induction, it seems reasonable that the high rate of the reaction prevents efficient poling. Studies on the mechanism of Michael reaction of acrylates with primary and secondary amines gave evidence of possible sterical control of the
Scheme 2. Constituents of **NET1** film.

reaction rate [32]. However, attempts to lower the reaction rate by use of encumbered amines did not result in substantial improvements. The failure of the use of the passive co-crosslinker supports the hypothesis of a too fast crosslinking rate [33].

The presence of hydroxylic instead than acrylic functions in **C_Triox**, should reasonably imply a more moderate reactivity of the dye, maintaining anyway good crosslinking aptitude. We recall that a recently employed approach [23] to stable NLO active materials is grounded on covalent crosslinking of a tailored polymer with the chromophore under poling conditions. We used **C_Triox** substantially in similar way, but in our case a very simple monofunctional polymer was used and the covalent link was based on fac-

ile epoxy chemistry [34] in absence of initiator. We achieved (Scheme 3) the epoxy ring-opening of PGMA by reaction with the alcoholic functions of the chromophore and of the co-crosslinker to obtain the material **NET2**.

The total amount of epoxy functions was stoichiometrically balanced by the total alcoholic functions [35]. The glass transition temperature of pure PGMA (108 °C) is low enough to allow the entire system to be fluid and steerable at relatively low temperatures (about 10–20 °C below the glass transition). In these conditions the crosslinking reaction starts without catalyst while electric field is applied. Differently than for **NET1**, in the best poling conditions (140 °C for 4 h) the crosslinking rate results to be slow enough to allow satisfactory polar order before network "freezing".

A set of crosslinked poled films was prepared according to Scheme 3 at 5%, 10%, 20%, 30%, 40%, and 54% by weight of chromophore, the latter corresponding to the stoichiometric amount in absence of co-crosslinker. Second order optical nonlinearity of **NET2** was evaluated by determining the d_{33} coefficient of the films by means of Maker fringe technique. In the above range of dye loading the value of d_{33} grows up to a maximum (at 30%), thereafter decreasing. This behaviour is in agreement with assessed theoretical expectation [36].

Fig. 4 shows the Maker fringe pattern for the 30% film, where the full-line corresponds to the best-fit curve.

In spite of the high chromophore NLO activity the SHG signal is in the average range for organic polymeric materials [37]. In fact, the d_{33} coefficient reaches a value of 11 pm/V for a 30% film poled in the best conditions. This finding could be related to the thermal epoxy ring-opening reaction that partially binds the dyes even at low temperature.

On the other hand, the nonlinear activity is well retained in time as demonstrated by thermal treatment of

Fig. 4. The Maker fringes pattern of transmitted SH signal for **NET2** (30%) poled film. Open circle and full-line curve represent the experimental data and the best-fit curve, respectively.

films with various chromophore weight. In particular, Fig. 5 shows no detectable loss of activity within the experimental error for a 30% sample kept at 85 °C in air during several days.

This excellent stability of **NET2** is not typical of simple guest-host systems and is certainly due to strong degree of crosslinking. Additional stabilising effect could also be reasonably ascribed to the rigidity of naphthalene containing bridges from the passive co-crosslinker. It is to recall that also crosslinked polyglycidylmethacrylate based NLO polymers including chromophore pendants in the polymeric chains can attain high temporal stability of the nonlinear response. In fact, the SHG signal of poled samples was reported to retain from about 80% [38] to 100% [39] of its initial value. Our system attains in simple way a similar result.

The intermolecular crosslinks deriving by the thermal reaction of the hydroxyl groups of **C$_{\text{Triox}}$** and of 2,2′-(naph-

thalene-2,7-diylbis(oxy))diethanol with the glycidyl groups of PGMA can be evidenced by FTIR spectroscopy [38]. The decrease of epoxy signal (903 cm^{-1}, see Fig. 6) is diagnostic, indicating that a consistent thermo-crosslinking has occurred in **NET2** film.

3. Experimental part

3.1. Materials and methods

Thiophene, 2-amino-5-nitrophenol, N-phenyldiethanolamine, N-methyl aniline, acryloyl chloride, 4,4′-trimethylene-dipiperidine, 2-bromoethanol, tris[2-(acryloyloxy)ethyl]isocyanurate, tin powder, are commercially available. All commercial products and solvents were used without further purification.

2,2′-(Naphthalene-2,7-diylbis(oxy))diethanol was synthesised according to the procedure reported for the 2,6-isomer [40]. The synthesis of 2-nitrothiophene [8], 2-hydroxy-4-nitrobenzenediazonium chloride [41], 2-(methyl(phenyl)amino)ethyl acrylate [42], 2,2′-(phenylazenedyl)bis(ethane-2,1-dyl)diacrylate [42], SnCl$_4$-2-aminothiophene hydrochloride [8] were performed according to literature. PGMA was obtained by a typical radicalic polyaddition in DMF at 70 °C with AIBN as initiator [42].

Optical observation was performed by using a Zeiss Axioscop polarizing microscope equipped with FP90 Mettler heating stage. Phase transition temperatures and enthalpies were measured using a DSC scanning calorimeter Perkin Elmer Pyris using a scanning rate of 10 °C/min, under nitrogen flow. UV–vis absorption spectra were recorded at room temperature by use of a Jasco V-560 Spectrophotometer. Thermogravimetric analysis was performed in air by a TA Instruments SDT 2960 Simultaneous DTA-TGA. ^{1}H NMR spectra were recorded using Varian Spectrometers operating at 200 and 300 MHz. The mass spectra of the chromophores were recorded with a MALDI TOF DE-PRO apparatus on a matrix of 2,5-dihydroxybenzoic acid. IR spectra were recorded on a FT/IR-430 JASCO spectrophotometer.

Single crystals of **C$_{Diacr}$** were obtained by slow evaporation of chloroform/hexane solution. One suitable crystal was mounted at room temperature on a Bruker–Nonius Kappa-CCD diffractometer (Mo Kα radiation, graphite monochromator, CCD rotation images, $\phi + \omega$ scans to fill asymmetric unit). The structure was solved by direct methods (SIR97 package [43]) and anisotropically refined by the full matrix least-squares method on F^2 against all independent measured reflections (SHELXL program of SHELX97 package [44]). Hydrogen atoms were introduced in calculated positions and refined as riding on their carrier atoms. Crystal data for **C$_{Diacr}$**: C$_{25}$H$_{22}$N$_6$O$_6$S, M_r = 534.55 triclinic, space group P−1, D$_{calcd}$ = 1.362 g cm^{-3}, Z = 2, a = 8.176(2) Å, b = 11.859(3) Å, c = 15.016(3) Å, α = 67.61(2)°, β = 75.52(2)°, γ = 85.57 (3)°, V = 1303.2(5) Å^3. Approximate crystal dimensions 0.57 × 0.15 × 0.08 mm. Numbers of measured and unique reflections were 15046 and 5362, respectively (R_{int} = 0.0647). Final R_1 = 0.0629, wR$_2$ = 0.1630 for 344 parameters and 2575 reflections with $I > 2\sigma(I)$ and 2.80° < θ < 26.62°. Largest difference peak and hole were 0.566 and −0.262 eÅ^{-3} [45].

3.2. Synthesis of the chromophores

3.2.1. **C′** precursors

The synthesis of **C′** precursors was performed by the same general one-step procedure, and no two-rings intermediate was isolated. As an example the synthesis of **C′$_{Diacr}$** is described.

*3.2.1.1. **C′$_{Diacr}$**.* To a solution of 2-hydroxy-4-nitrobenzenediazonium chloride (0.75 g, 2.78 mmol) in ethanol (80 mL) cooled at 10 °C, a solution of SnCl$_4$-aminothiophene hydrochloride (1.00 g, 2.78 mmol) in water (20 mL) with HCl (1 mL, 37% solution) was added under stirring. The mixture turned to dark red and was kept under stirring for about 30 min. After this time HCl (3 mL, 37%) and then a solution of NaNO$_2$ (1.28 g, 18.5 mmol) in water (10 mL) were slowly added, and the mixture was kept at room temperature for 15 min. A solution of 2-(methyl(phenyl)amino)ethyl acrylate (1.40 g, 6.82 mmol) in ethanol (20 mL) was added and the mixture was stirred at room temperature for 1 h. After this time, the mixture was poured on ice/water and pH was regulated at about five with sodium acetate, ensuing precipitation of a blue solid. The product was recovered by filtration, washed twice with water, and dried at 70 °C. The compound was dissolved in a minimum amount of acetone and the solution adsorbed on about 3 g of Florisil (100–200 mesh). The solvent was removed by mild warming in an oven, and the solid was layered on the top of a column containing about 200 g of Florisil. Elution with chloroform afforded first an orange fraction, and then the blue fractions containing the product. By concentrating the blue solution to a small volume (about 10 mL) and adding hexane the product was recovered. Two further crystallisations in CHCl$_3$/hexane (2:1) gave **C′$_{Diacr}$** as a crystalline dark green solid (dark-blue in solution). Yield: 45%.

^{1}H NMR (CDCl$_3$: Me$_4$Si; 200 MHz) δ: 3.20 (s, 3H), 3.79 (t, 2H, J = 5.8), 4.40 (t, 2H, J = 5.6), 5.86 (dd, 1H, J = 10.2, J = 1.4), 6.20 (dd, 1H, J = 17.2, J = 10.5), 6.38 (dd, 1H,

J = 17.4, J = 1.7), 6.82 (d, 2H, J = 9.0), 7.64 (d, 1H, J = 4.6), 7.85 (6H, m), and 11.73 (1H, s).

MS (*m/s*) 480.12 (*M* calc. 480.50).

3.2.1.2. **C′$_{Triacr}$**. It was obtained by employing 2,2′-(phenylazenedyl)bis(ethane-2,1-dyl)diacrylate and purified by the same pathway of **C′$_{Diacr}$**. Yield: 50%.

^{1}H NMR (CDCl$_3$: Me$_4$Si; 200 MHz) δ: 3.69 (t, 2H, J = 6.0), 4.29 (t, 2H, J = 5.7), 5.77 (dd, 2H, J = 10.5, J = 1.4), 6.01 (dd, 2H, J = 17.1, J = 10.2), 6.30 (dd, 2H, J = 17.4, J = 1.6), 6.76 (d, 2H, J = 8.7), 7.55 (d, 1H, J = 4.5), 7.66 (d, 1H, J = 4.5), 7.73 (5H, m), and 11.00 (1H, s).

MS (*m/s*) 564.14 (*M* calc. 564.18).

3.2.1.3. **C′$_{Triox}$**. It was obtained by employing *N*-phenyldiethanolamine and purified by the same pathway of **C′$_{Diacr}$**. Yield: 44%.

^{1}H NMR (DMSO; 200 MHz) δ: 3.21 (8H, m), 4.79 (2H, s), 6.79 (d, 2H, J = 9.3), 7.60 (5H, m), 7.70 (1H, s), 7.94 (d, 1H, J = 4.5), and 11.03 (1H, s).

MS (*m/s*) 456.12 (*M* calc. 456.20).

3.2.2. C dyes

C$_{Diacr}$, **C$_{Triacr}$** and **C$_{Triox}$** were obtained by alkylation of the phenolic function of the correspondent **C′** precursors. This alkylation, affording the **C** derivatives, was made with minor modifications as reported elsewhere [42]. All compounds were purified on a Florisil column.

3.2.2.1. **C$_{Diacr}$**. Yield: 87%. ^{1}H NMR (CDCl$_3$: Me$_4$Si; 200 MHz) δ: 3.16 (3H, s), 3.80 (t, 2H, J = 6.0), 4.40 (t, 2H, J = 5.9), 5.87 (dd, 1H, J = 10.2, J = 1.5), 6.10 (2H, m), 6.40 (2H, m), 6.76 (dd, 1H, J = 17.1, J = 1.0), 6.84 (d, 2H, J = 9.3), 7.62 (d, 1H, J = 4.4), 7.80 (d, 2H, J = 9.3), 7.92 (2H, m), and 8.35 (2H, m).

MS (*m/s*) 534.39 (*M* calc. 534.13).

3.2.2.2. **C$_{Triacr}$**. Yield: 90%. ^{1}H NMR (CDCl$_3$: Me$_4$Si; 200 MHz) δ: 3.82 (t, 4H, J = 5.8), 4.41 (t, 4H, J = 5.7), 5.87 (dd, 2H, J = 10.4, J = 1.0), 6.15 (5H, m), 6.45 (4H, m), 6.74 (dd, 2H, J = 17.0, J = 1.5), 6.87 (d, 2H, J = 9.2), 7.68 (dd, 1H, J = 4.4, J = 1.2), 7.87 (d, 2H, J = 9.0), and 7.80 (4H, m).

MS (*m/s*) 618.33 (*M* calc. 618.15).

3.2.2.3. **C$_{Triox}$**. Yield: 80%. ^{1}H NMR (DMSO; 200 MHz) δ: 3.24 (12H, m), 4.77 (2H, s), 4.90 (1H, s), 6.77 (d, 2H, J = 9.0), 7.67 (5H, m), 7.93 (2H, m).

MS (*m/s*) 500.42 (*M* calc. 500.15).

3.3. Poling and curing conditions of the crosslinked films

3.3.1. Preparation and poling of **NET1** film (30% in chromophore)

A solution of **C$_{Triacr}$** (0.030 g, 0.048 mmol), tris[2-(acryloyloxy)ethyl]isocyanurate (0.031 g, 0.074 mmol) and of 4,4′-trimethylene-dipiperidine (0.039 g, 0.184 mmol) in chloroform (1 mL) was filtered on a 0.2 µ PTFE filter and spin-coated on glass substrate. The film was corona poled by applying a voltage of 7 kV while temperature was raised from 25 to 110 °C. After 2 h the sample was cooled to room temperature and the electric field removed. The same pro-

cedure was followed for the systems with 5%, 10%, 20% chromophore content.

3.3.2. Preparation and poling of **NET2** film (30% in chromophore)

A solution of PGMA (0.050 g, 0.352 mmol glycidyl groups), **C$_{Triox}$** (0.030 g, 0.059 mmol) and 2,2′-(naphthalene-2,7-diylbis(oxy))diethanol (0.021 g, 0.086 mmol) in THF (2 mL) was filtered on a 0.2 µ PTFE filter and spin-coated on glass substrate. The film was corona poled by applying a voltage of 7 kV while temperature was raised from 25 to 140 °C. After 4 h the sample was cooled to room temperature and the electric field removed.

The same procedure was followed for the systems with 5%, 10%, 20%, 40% and 54% chromophore weight content.

3.4. EFISH measurements

Measurement of $\mu\beta$ nonlinearity of the chromophore **C$_{Diacr}$** was obtained by the EFISH technique. The set-up allows the determination of the scalar $\mu\beta$ product where μ is the ground state dipole moment and β the vector part of the quadratic hyperpolarizability tensor. The light source was a Q:switched Nd:Yag laser whose emission at 1.06 µm was shifted to 1.907 µm by stimulated Raman scattering. Measurements were calibrated relative to a quartz wedge: the experimental value of d_{11} = 1.2 × 10^{-9} esu at 1.06 µm was extrapolated to 1.1 × 10^{-9} esu at 1.907 µm. The projection β of the vector part of tensor β_{ijk} along the direction of the dipole moment was finally determined, neglecting the purely electronic contribution compared to the orientational part and allowing Kleinman symmetry. Measurements were made in molar chloroform solution at 5 kV. The $\mu\beta$ value for **C$_{Diacr}$**, at λ = 1.907 µm, is 4950 × 10^{-48} esu (6111 × 10^{-80} C^2 m^4 V^{-2}).

3.5. SHG measurements

SHG experimental data relative to $p \rightarrow p$ experiments (incident *p*-polarised wave → detected *p*-polarised SH signal) were recorded as the incidence function at 1500 nm wavelength (SH = 750 nm) and fitted according to Hermann and Hayden SH power equation [46]. The calibration of the experimental setup was performed through SHG measurements on a sample with known second order NLO susceptibility. A 1 mm thick X-cut quartz plate was used (d_{11} = 0.30 pm/V [47]). The conditions $d_{15} = d_{31}$ (Kleinmann symmetry [48]) and d_{31} = 1/3d_{33} [49] were assumed for the polymeric poled film and hence used in the expression of d_{eff} [47].

Measurements of nonlinear coefficient d_{33} were performed by means of the Maker fringes technique. The laser beam at fundamental frequency was provided by an optical parametric oscillator (OPO) whose wavelength could be tuned in the near-infrared range (800–1600 nm). The OPO was pumped by a Q-switched Nd:YAG laser having 10 ns pulse duration and 10 Hz repetition rate. The laser beam impinged on a variable attenuator made by a half-wave retardation plate and a polarizing beam splitter cube, allowing continuous variation of optical power impinging on the sample. The fundamental beam reflected by the

polarizing beam splitter cube was directed on a potassium dideuterophosphate (KDP) crystal, whose second harmonic signal, detected by a photodiode, was employed as a reference signal in order to take into account of the power fluctuations of the fundamental laser beam. A double Fresnel rhomb selected the proper polarization direction of the fundamental beam impinging on the sample, which was placed on a goniometric stage to allow variation of the incidence angle. A coloured filter absorbed the unwanted fundamental wavelength signal transmitted through the sample, while the second harmonic signal was detected by a high sensitivity amplified photodiode. Both the electric signals coming from photodiodes were acquired by a computer interfaced Tektronix TDS540 500 MHz bandwidth digitizing oscilloscope.

4. Conclusions

Our results show that the use of disazo-thiophene based chromophores can afford unprecedented NLO active cross-linked materials with excellent temporal stability of poling. The level of the NLO properties displayed by the "model" dye is higher than for analogous known benzenoid structures, while NLO properties of crosslinked films are in medium range displayed by similar polymeric systems. The approach used for the attainment of the material is grounded on covalent bonding of the chromophore with a simple reactive polymer. Crosslinking was attained with straightforward epoxy chemistry in absence of initiator by reaction of the dye with the monofunctional polymer. The synthesis of the trifunctional chromophores was simplified with respect to previous related protocols by direct use of tin intermediates in the coupling step.

ARTICLE INFO

ABSTRACT

The thermal stability of thin (50 nm) PEDOT:PSS films, was investigated by dc conductivity measurements, X-ray and UV photoelectron spectroscopies as a function of heating temperature and heating time. The mechanism of electrical conductivity as a function of temperature is consistent with a hopping type carrier transport. The electrical conductivity decreased, as a function of time, in agreement with a granular metal type structure, in which aging is due to the shrinking of the PEDOT conductive grains. XPS and UPS spectra indicate that conformational changes of the PEDOT:PSS film are responsible for this behaviour and a model for these modifications is proposed.

1. Introduction

Organic semiconductors are of increasing interest as new materials for optoelectronic devices. This class of semiconductors is processed from solution, offering a huge potential for low fabrication costs and flexibility. Polymer emitting diodes (PLEDs), photodiodes and solar cells are the optoelectronic applications under intense study [1]. One of the fundamental requirements for reliable operation of all organic optoelectronic devices is a stable anode interface. Indium tin oxide (ITO) has been the preferred anode for all organic optoelectronic devices due to its optical transparency and high conductivity [1–3]. However, the work function of ITO is quite low (even after special ITO treatment procedures such as plasma or oxygen treatment) [4]. The most common way to improve hole injection/collection is to incorporate a hole transporting layer (buffer layer) on top of the ITO surface [4,5]. The most common buffer layer is the poly(ethylenedioxythiophene):polystyrene sulphonate (PEDOT:PSS) [5].

Poly(3,4-ethylenedioxythiophene) (PEDOT), a π-conjugated polymer, combines high electrical conductivity with excellent optical transparency [6]. The problem with its low solubility is solved by the use of the water soluble polyelectrolyte poly(styrene sulfonic acid) PSS as a charge balancing dopant. PEDOT mixed with PSS forms an easily processible colloidal solution in water. For organic

optoelectronic applications PEDOT:PSS is an essential part of the bottom electrode providing a high selective carrier contact. The stability of PEDOT:PSS layer is of high importance and determines the lifetime performance of organic optoelectronic devices. Despite the common use of PEDOT:PSS the correlation between the electrical conductivity and the morphology and especially the irreversible structural changes occurring during thermal degradation are not fully understood [7,8]. The purpose of this investigation is to study the thermal aging of the electrical conductivity of PEDOT:PSS thin films and correlate this with the morphological, composition and electronic structure changes occurring during the thermal degradation.

2. Methods

2.1. Materials

All measurements performed on 50 nm PEDOT:PSS films coated on pristine plastic substrates (PET). An aqueous dispersion of PEDOT:PSS (CLEVIOS PH 500, H.C. Starck) was used, where the ratio PEDOT-to-PSS was 1:2.5 by weight.

2.2. Conductivity measurements

Temperature dependence d.c conductivity measurements $\sigma = \sigma(T)$ performed using a four-probe method. For the temperature dependent studies a He filled cryostat was used [9]. Samples from the same PEDOT:PSS film were thermally treated at 120 °C in a thermostated oven under environmental conditions for different times. The 0 h time includes only the annealing step during the preparation process 20 min. The conductivity versus temperature was then measured after the heat treatment at every time. These successive measurements give a set of $\sigma = \sigma(T)$ curves and the whole procedure is repeated until saturation in conductivity is observed.

2.3. X-ray photoelectron and ultra-violet photoelectron spectroscopies

X-ray photoelectron spectroscopy (XPS) was used to investigate the variation in the chemical structures of the sample surface of the PEDOT:PSS films before and after the thermal degradation, while the variation of the PEDOT:PSS valence band was investigated by ultra-violet photoelectron spectroscopy (UPS). The photoelectron spectroscopy measurements were carried out in a commercial ultra-high vacuum (UHV) system which consists of a fast entry specimen assembly, a preparation and an analysis chamber. The analysis chamber is equipped with a hemispherical electron analyzer (SPECS LH-10), a twin anode X-ray gun and a discharge lamp for X-ray and ultra-violet photoelectron spectroscopy (XPS and UPS) measurements. The base pressure was 5×10^{-10} mbar. The XPS measurements were carried out with a non-monochromatic Mg Kα line at 1253.6 eV and a constant analyzer pass energy of 36 eV, while for UPS the HeI (21.22 eV) radiation was used. The spectrometer was calibrated by the Au4f$_{7/2}$ core

level (84.00 ± 0.05 eV) for a clean Au foil. The XPS resolution, measured by the full width at half maximum (FWHM) of the Au4f$_{7/2}$, was 1.10 eV for a constant pass energy of 36 eV. The analyzer resolution for the UPS measurements is determined from the width of the Au Fermi edge and is found 0.16 eV. A negative bias of 12.30 V was applied to the sample during UPS measurements in order to separate sample and analyzer high binding energy cut-offs and estimate the absolute work function from the UV photoemission spectra.

3. Results and discussion

In Fig. 1 the d.c. conductivity σ as a function of temperature T is shown for PEDOT:PSS exposed to thermal treatment times ranging from 0 to 55 h at 120 °C. The mechanism of carrier (hole polarons) transport in PEDOT:PSS is determined by its morphology. Conductive PEDOT oligomers consisted of 5–15 repeat units are electrostatically attached to twisted long insulating PSS chains, which form grains 20–70 nm in diameter, whose surfaces are rich in PSS [10,11]. So, in PEDOT:PSS, with its granular structure of conductive PEDOT-rich grains enclosed in insulating PSS-rich shells, the electrical conductivity is not determined only from the hole polarons transport into the PEDOT segments, but also by their hopping between segments and grains.

Despite different interpretations of the temperature dependence of the experimentally obtained conductivities, typically $\sigma = \sigma(T)$ is given by

$$\sigma(T) = \sigma_0 \exp\left[-\left(\frac{T_0}{T}\right)^\alpha\right] \tag{1}$$

which generally describes a hopping transport, where T_0 is a measure of the potential barrier height, as carriers get thermally activated hopping among localized states at different energies [12–14]. On the other hand σ_0 is related to the intrinsic conductivity of the grains, their size contribution, mean volume occupied by the conducting grains in the material, etc. [15].

Fig. 1. Thermal degradation of the d.c. electrical conductivity of a 50 nm thick PEDOT:PSS film heated at 120 °C under environmental conditions for times between 0 and 55 h.

In a material consisting of conductive grains embedded into an insulating matrix, thermal degradation can be considered as a corrosion – a process which is reducing the size of the grains and consequently enhancing their distance, or equivalently increasing the potential barrier for polaron transport between them. In this case the conductivity can be described by the following equation

$$\ln \sigma = \sigma_1 \exp[-(t/\tau)^{1/2}] \qquad (2)$$

in which t is the time of the thermal treatment and τ is a parameter characteristic of the aging rate. The higher the τ value, the slower the rate of degradation [16].

In the variable-range hopping (VRH) model of transport the exponent α in Eq. (1) does not depend only on the number of the hopping process dimensions D, but also on the exponent μ of the density of states $g(E) \propto (E-E_F)^\mu$ near the Fermi energy level E_F, according to the formula $\alpha = \mu + 1/(\mu + D + 1)$ [17].

In disordered systems, in which a self-assembled network of conductive polymer, PEDOT in our case, spreads in a matrix of insulating PSS, the carrier eigenstates display spatial fluctuations described by a multifractal analysis, in which the electrical conductivity follows Eq. (1) with the exponent α decreasing systematically from 1 to 0.25 with increasing the volume fraction of the conductive component [18,19]. The exponent $\alpha = 1$ indicates a nearest-neighbor hopping (nn-H) between PEDOT particles [12]. On the other hand, hopping conductivity in granular disordered systems follows Eq. (1) with the exponent α ranging from 0.25 to 1 depending on the distribution of grain sizes. The decrease of the particle size results in the reduction of the exponent α from values about unity to 0.5 or 0.25 [20]. An exponent $\alpha = 0.25$ is consistent to a three-dimensional VRH, though an exponent $\alpha = 1/2$ can be attributed to many cases. For example, the existence of an energy gap caused by Coulomb interactions between the carriers results in a $\alpha = 1/2$. However, the non-zero density of states at the Fermi level reveals that such an energy gap does not exist in PEDOT:PSS [12]. Another explanation for the $\alpha = 1/2$ value is in the framework of the charging-energy limited tunnelling (CELT) model, where carriers tunnel between small conductive grains separated by insulating material [21,22]. From the above it is apparent that the exponent α can reveal valuable information about the conduction mechanism in PEDOT:PSS.

In Fig. 2 the exponent α of Eq. (1) is shown for increasing heat treatment time at 120 °C. For the fresh samples ($t = 0$ h) $\alpha \approx 1$ decreasing with thermal aging to the value $\alpha \approx 0.5$ at the end of it, after 55 h of heat treatment. Taken into account the morphology of PEDOT:PSS, this means that for the first stages of the heat treatment, the nearest-neighbor hopping prevails, though later the charging-energy limited tunnelling between adjacent conductive grains determines the conduction. For $\alpha \sim 1$, Eq. (1) takes the well known Arrhenius formula, from which the mean of the potential barrier height can be estimated to $E \sim 0.022 \pm 0.001$ eV for the fresh samples.

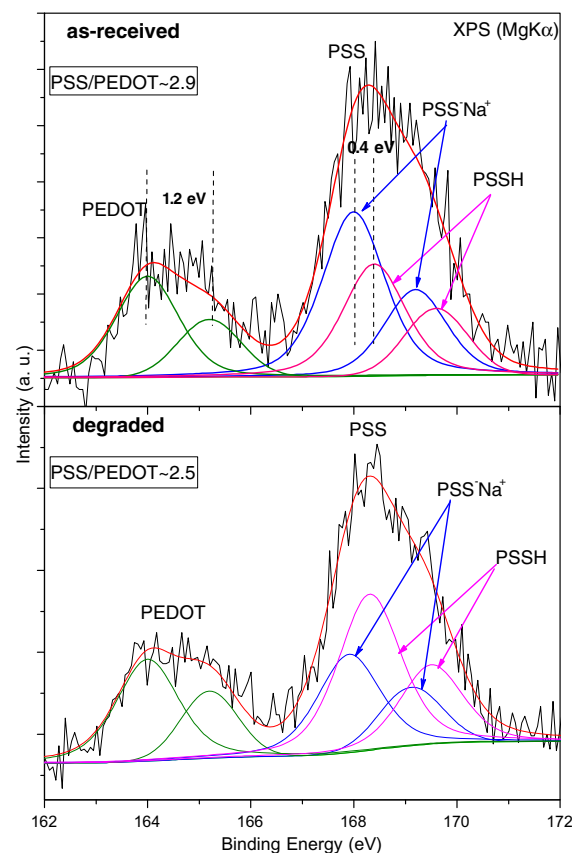
XPS and UPS were used to investigate the composition and electronic structure changes due to the thermal aging process. In Fig 3 the XPS spectra S 2p for PEDOT:PSS sam-
Fig. 2. The exponent α of Eq. (1) vs. thermal treatment time for the same PEDOT:PSS sample, as in Fig. 1.


Fig. 3. S(2p) spectra from (a) a fresh PEDOT:PSS sample and (b) from the same sample after heat treatment at 120 °C under environmental conditions for 55 min.

ples (a) fresh and (b) after heat treatment at 120 °C for 55 h are shown. In both cases the S 2p spectrum appears in two components. The component at lower binding energies is attributed to the contribution of PEDOT and in particular,

to sulphur atoms linked to carbon in the chemical structure of PEDOT and the peak at higher binding energies corresponds to the sulphur atoms in the PSS polymer. The spectra were fitted with mixed Gaussian–Lorentzian peaks after Shirley background subtraction The PEDOT component is fitted in all cases with a single spin-orbit doublet at 164.0 ± 0.1 eV and 165.2 ± 0.1 eV binding energy and a 2p3/2 to 2p1/2 ratio of 2:1, the splitting of 1.2 eV being that expected for S 2p. The contribution of PSS to the S 2p peak is due to the doping ions PSS^-H^+ (spin-orbit doublet at 168.4 eV and 169.6 eV binding energy) and to the PSS^-Na^+ salt [23,24] (spin-orbit doublet at 168.0 eV and 169.2 eV binding energy). Na^+ residues originate from $Na_2S_2O_8$ oxidizing agent used during the polymerization of PEDOT [25]. The original ratio of PSS-Na to the PSS-H in the PSS layer is found equal to 1.5 and it drops to 0.6 after the heat treatment. From them it can be seen that there is a decrease of the PSS-Na bond in the PSS chains due to thermal aging. The PEDOT-to-PSS ratio in the surface region can be calculated from the total area under the S2p core level spectra and it was found 1:2.9 for the PEDOT:PSS before thermal degradation. After thermal degradation up to 55 h at 120 °C this ratio becomes 1:2.4. As has also reported before for the fresh PEDOT:PSS the spectra indicate that there is phase segregation with an excess of PSS [25]. During this work we show that after 55 h at 120 °C the excess of PSS is slightly reduced.

In order to estimate the thickness d of the outermost PSS layer, we consider PSS and PEDOT as two separated polymers growing in the form of a "layer over layer" structure ending in a pure PSS layer and compare the intensities from the contribution to the S2p peak of each polymer. The thickness is given by the expression

$$d = \lambda \ln[(I_{PSS}/I_{PSS}^0)/(I_{PEDOT}/I_{PEDOT}^0) + 1] \tag{3}$$

where $\lambda = 2.7 \pm 0.3$ nm, is the electron inelastic mean free path, and I_x, I_X^0 are the measured and expected signal intensities from species X, respectively [23]. The above equation yields an outermost PSS layer thickness of 3.6 nm for the PEDOT:PSS before thermal degradation and 3.4 nm after thermal aging at 120 °C for 55 h, verifying that there is a thinning of the PSS layer on the surface.

From UPS spectra of the same PEDOT:PSS sample before and after the heat treatment at 120 °C, it can be seen that the density of the electronic states near the Fermi level slightly increases, although the work function of the surface decreases from 4.7 eV for the fresh sample to 3.7 eV at the end of the heat treatment. These can be attributed to the removal of the insulating PSS from the surface, which leaves an area enriched in PEDOT, from which is easier to remove carriers and as a p-doped conjugated polymer has occupied valence band states near the Fermi level [26].

From Fig. 3 it can also be seen that the peaks corresponding to the PSSH bond diminish with aging. This indicates that there is enough energy for the breaking of the electrostatic bonding between PSS and PEDOT, which gradually leads to the reeling off the PSS chains and on the other hand to the formation of PEDOT-rich clusters between the PSS chains [13,23].

Fig. 4. $\ln \sigma = f(t^{1/2})$ experimental data at 300 K for heating temperature 120 °C.

From Fig. 4 it is shown that for heating temperature 120 °C the experimental data follow very well Eq. (2). Moreover, from the fitting of the experimental data, the parameter τ takes the value 96 h and from Eq. (2) it can be calculated that the time of heating, for the conductivity of the sample to become half of its original value, is 46.1 h, in excellent agreement with the experiment, from which this time is 46.3 h. This is consistent with a granular structure of PEDOT:PSS and an electrical conductivity degradation, in which the main contribution comes from the progressive increase of the potential barriers between the conductive grains with heat treatment.

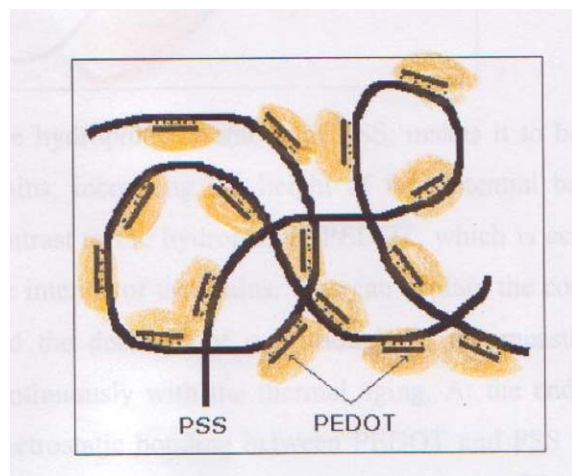
The above experimental results can be explained by the following model of conformational changes during the thermal aging. At the first stage of heating, the PSS chains are perplexed, as it is shown in Fig. 5 and the agitation of the Cl^- ions (their existence is verified by EDX spectrograms) attached weakly to the hole polarons on the PEDOT


Fig. 5. Perplexed PSS chains at the first stage of heating.
Fig. 6. The ionic bonds between PEDOT and the PSS chains start to break.

oligomers, makes them to wander further away from the polaron vicinity, increasing the mobility of the latter. This makes the grains more conductive as it is revealed from the decrease of the exponent α and the increase of σ_0.

At a second stage of the heat treatment, shown in Fig. 6, the ionic bonds between the PEDOT oligomers and the PSS chains start to break.

The remaining negative charges on the PSS chains repulse each other resulting in an improvement of their alignment. In this stage the conductive PEDOT oligomers concentrate between the aligned PSS chains forming grains of enhanced conductivity, as it is shown in Fig. 7.

The hydrophilic character of PSS, makes it to be concentrated at the surface of the grains, increasing the height of the potential barriers, as this stage progresses, in contrast to the hydrophobic PEDOT, which is accumulated in increasing numbers in the interior of the grains. This can explain the continuous decrease of the exponent α and the decrease of σ_0, although T_0, the measure of the barriers height increases continuously with the thermal aging. At the end of the heat treatment, most of the electrostatic bonding between PEDOT and PSS is removed, as it is revealed by the XPS spectrograms.

From Fig. 4 it is shown that for heating temperature 120 °C the experimental data follow very well Eq. (2). Moreover, from the fitting of the experimental data, the parameter τ takes the value 96 h and from Eq. (2) it can be calculated that the time of heating, for the conductivity of the sample to become half of its original value, is 46.1 h, in excellent agreement with the experiment, from which this time is 46.3 h. This is consistent with a granular structure of PEDOT:PSS and an electrical conductivity degradation, in which the main contribution comes from the progressive increase of the potential barriers between the conductive grains with heat treatment.

From the total areas below the peaks representing the contribution of PSS and PEDOT to the XPS peak of S2p, the PEDOT-to-PSS molar ratio in the surface region (~10 nm) for the fresh samples was estimated to 1:2.9, though for the samples at the end of the heat treatment was 1:2.4. This indicates that in fresh samples there is an excess of PSS at the surface, which is removed by the heat treatment, in agreement with previous measurements [23–25].

From UPS spectra of the same PEDOT:PSS sample before and after the heat treatment at 120 °C, it can be seen that the density of the electronic states near the Fermi level slightly increases, although the work function of the surface decreases from 4.7 eV for the fresh sample to 3.7 eV at the end of the heat treatment. These can be most likely attributed to the removal of the insulating PSS from the surface, which leaves an area enriched in PEDOT, from which is easier to remove carriers and as a p-doped conjugated polymer has occupied valence band states near the Fermi level [26]. As has already been reported by differential scanning calorimetry (DSC) and other thermal degradation studies [27,28], decrease of the work function due to the decomposition of PEDOT:PSS, as Diels–Alder reaction (SO$_2$-extrusion), starts at higher temperatures (225–230 °C) from the ones used in this study (120 °C).

4. Summary and conclusions

The aging of PEDOT:PSS films 50 nm thick was investigated by dc conductivity measurements, X-ray and UV photoelectron spectroscopies for thermal treatment at 120 °C under environmental conditions. The electrical conductivity versus T followed the formula

Fig. 7. PEDOT oligomers start to form conducting grains.

$\sigma = \sigma_0 \exp[-(T_0/T)^\alpha]$, consistent with a carrier transport of the hopping type. The exponent α, decreased with aging from a value of ~ 1 for the fresh samples to a value ~ 0.5 at the end of the thermal treatment. This indicates a change in the conduction mechanism from the nearest-neighbour hopping at the beginning of the heat treatment to the charging-energy limited tunnelling between the conductive grains as thermal aging progresses. On the other hand the electrical conductivity at room temperature vs. t, the time of the heat treatment, decreased following the formula $\sigma = \sigma_1 \exp[-(t/\tau)^{1/2}]$, in agreement with a granular metal type structure, in which aging is due to the shrinking of the conductive grains, with $\tau = 96$ h. From the last formula the time t for which σ becomes half of its original value, is calculated to be 46.1 h in agreement with the value 46.3 h obtained from the $\sigma = \sigma (T)$ curves for different t. Moreover, the XPS and the UPS spectra before and after thermal degradation revealed a slight decrease of the insulating PSS from the surface. According to the proposed model thermal aging starts with an increase of the mobility of the hole polarons in PEDOT oligomers attached to insulating PSS chains, improving conductivity into the grains, which reduces α and increases σ_0. At a second stage, the ionic bonds between PEDOT and PSS start to break, the PSS chains bearing negative charge at intervals align better themselves and PEDOT oligomers concentrate between them, further enhancing the conductivity of the grains. At the final stage the bonds between PEDOT and PSS break down, as XPS spectograms reveal. The conducting PEDOT being hydrophobic concentrates into the interior of the grains, although the insulating PSS being hydrophilic concentrates at the borders of the grains enhancing the potential barriers between the grains. These can explain the increase of σ_0 and T_0 with thermal treatment.

Polymer Research Institute, Department of Chemical Engineering, Pohang University of Science and Technology (POSTECH), Pohang 790-784, Republic of Korea

ABSTRACT

Herein, we investigate the effects of the solvents used in the passivation process on the behavior of pentacene field-effect transistors (FETs) and report on the fabrication of a passivation layer for pentacene FETs via inkjet-printing using photocrosslinkable poly(vinyl alcohol), N-methyl-4(4′formylstyryl) pyridinium methosulfate acetal (SbQ-PVA). The passivated pentacene FETs – composed of inkjet-printed SbQ-PVA containing polystyrene/SiO_2 and poly(4-vinyl phenol)/SiO_2 dual-layer gate dielectrics – retain their electrical properties for much longer periods than the unpassivated devices. Studies of the device performance show that inkjet-printed passivation is better than spin-coated passivation.

1. Introduction

In recent years, pentacene field-effect transistors (FETs) exhibiting high-performance have been reported by many research groups. The behaviors of some of these devices are comparable to those of amorphous silicon transistors [1,2]. However, although pentacene FETs show good performance in the short term, their electrical properties are significantly degraded over time by water and oxygen species present in ambient air [3–6]. Accordingly, the introduction of a passivation layer is necessary to protect the devices from the effects of water and oxygen. There are two representative ways to form a passivation layer, namely, vacuum deposition [7–9] and solution deposition [10,11]. To date, vacuum deposition processes, such as atomic layer deposition [7] and chemical vapor deposition [8,9], have been predominantly used to produce passivation layers. However, these processes have many draw-

backs, including long processing times and high costs. Solution-deposition processes, by contrast, have the advantages of allowing simple and low-cost processing in short times. Therefore, in this study, we fabricate two distinct kinds of solution-processed passivation layers by means of inkjet-printing and spin-coating. Our results show that the inkjet-printing technique has many advantages over spin-coating. In the former case, no photolithography process is required, because it is possible to pattern directly on the surface. Therefore, inkjet-printing can be conveniently applied to active-matrix displays and integrated circuits [12].

It is very important to choose appropriate solvents for the fabrication of solution-processed passivation layers, because the performance of the pentacene FETs is significantly affected by the solvent used. Gundlach et al. [13] showed that exposure of a pentacene film to solvents, such as acetone, isopropanol, and ethanol, induces a phase transition within the film from the thin-film to the bulk phase. Here, we investigate the solvent effects on the structure and morphology of pentacene films by using atomic force

---

microscopy (AFM) and X-ray diffraction (XRD). We also fabricated passivation layers for pentacene FETs, using photocrosslinkable poly(vinyl alcohol), N-methyl-4(4′formylstyryl) pyridinium methosulfate acetal (SbQ-PVA) (Polysciences, Inc.), and characterized the time-dependent electrical performance of the devices.

2. Experiments

We fabricated high-performance pentacene FETs using a heavily doped Si wafer as gate substrate (see Fig. 1a). A dual-layer composed of thermally grown 300-nm-thick SiO_2 and spin-coated 40-nm-thick polymer films of polystyrene (PS) or poly(4-vinyl phenol) (PVP) was used as gate dielectric. PVP was thermally crosslinked (at 200 °C for 2 h) using poly melamine-co-formaldehyde as crosslinking agent. Subsequently, a 50-nm-thick pentacene film was deposited onto the dielectric layer by means of organic molecular beam deposition under high vacuum (i.e., 10^{-7} Torr) and at a rate of 0.2 Å/s through shadow mask. For the top-contact geometry of the pentacene FETs, we deposited the source/drain electrodes by thermally evaporating gold through a shadow mask on the active layer. We used two kinds of shadow masks, with channel width (W)/length (L) ratios of 10 and 15.

To investigate the effects of the solvent on the crystallinity of the pentacene films, the organic-semiconductor layers were exposed to deionized (DI) water, ethanol, and toluene (by spin-coating), and the film morphologies and molecular orderings were investigated using an AFM (Digital Instruments Multimode SPM) and an XRD (Pohang Accelerator Laboratory 10C1 beam line), respectively. The polymer SbQ-PVA was dissolved in DI water and either inkjet-printed or spin-coated onto the pentacene FETs. The inkjet printer was equipped with a drop-on-demand piezoelectric print head with a nozzle size of 50 μm (manufactured by Microfab Technologies, Inc.). Uniform droplets of 1.3 wt% SbQ-PVA in DI water were gained at a frequency of 200 Hz and a substrate temperature of 50 °C. The dot-to-dot distance was 50.8 μm. An optical microscopy (OM) image of the inkjet-printed passivation layer is shown in Fig. 1b. A 200-nm-thick SbQ-PVA layer was deposited by spin-coating a 6.3 wt% solution in DI water at 1500 rpm. This film was then exposed to a fluorescent lamp for one hour and to UV light (λ = 365 nm,

power = 7 W, ENF-240C, Spectroline®) for 20 min to conduct photocrosslinking. The thickness of the film was measured with a surface profiler (Alpha-step® 500, KLA Tencor). A UV–vis–NIR spectrophotometer (Cary 5000, Varian Co.) was used to study the UV absorbance and the degree of crosslinking. The electrical characteristics of the pentacene FETs were measured with Keithley 2400 and 236 source/measure units. The capacitances were characterized using a 4284A LCR meter (Agilent Tech.).

3. Results and discussion

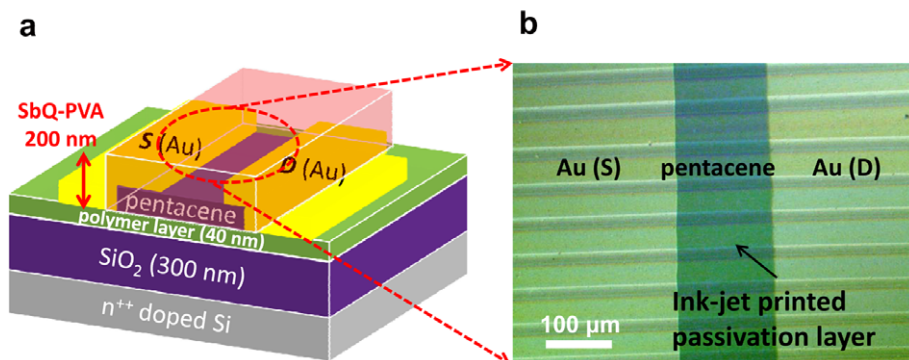
Fig. 2 shows the effects of varying the solvent on the studied pentacene films. Specifically, Fig. 2a displays the height-mode AFM topography of a nonexposed pentacene surface, and Fig. 2b–d shows images of the pentacene film after exposure to DI water, ethanol, and toluene. Fig. 2e shows XRD analyses of pentacene films before and after exposure to different solvents. After exposure to DI water, the film exhibits the morphology similar to that of the pristine pentacene layer, with a root-mean-square (Rq) roughness of 7.4 nm (see Fig. 2a and 2b). In addition, the DI water-exposed film is characterized by a thin-film phase with an interlayer spacing d_{001} of 15.5 ± 0.1 Å, which is similar to that of the pristine layer. The pentacene films exposed to other solvents exhibit high Rq roughnesses (between 15 and 30 nm). The XRD results indicate a phase transition from the thin-film to the bulk phase after ethanol and toluene exposure. Therefore, DI water is the most suitable solvent for the passivation of pentacene FETs, because the organic solvents damage the pentacene thin-film. These results coincide with those recently reported by Han et al. [11]. Thus, water-soluble SbQ-PVA can be used as a passivation layer. SbQ-PVA has powerful advantages over poly(vinyl alcohol) (PVA), which is commonly employed as a passivation layer, as the latter material is not completely adequate for this purpose due to its ultra-hydrophilic properties and high water-vapor transmission rate [14]. Therefore, an additional crosslinking agent and/or the introduction of another hydrophobic layer must be used in conjunction with PVA. SbQ-PVA can be photocrosslinked via a [2+2]-cycloaddition [15,16], which enhances its barrier properties (see Fig. 3a). Fig. 3b shows UV–vis absorption spectra of the SbQ-PVA film before and after UV exposure. The absorbance of the UV-exposed film is


Fig. 1. (a) Schematic representation of a pentacene FET and (b) OM image of an inkjet-printed passivation layer on a pentacene FET (×200).
Fig. 2. Height-mode AFM images of (a) a pristine pentacene film, (b) a DI water-exposed pentacene film, (c) an ethanol-exposed pentacene film, (d) a toluene-exposed pentacene film, and (e) XRD patterns of a pristine pentacene film and of various solvent-exposed pentacene films.

remarkably diminished relative to that of the pristine film, which verifies photocrosslinking due to quenching of the C=C double bond of the 4(4′formylstyryl) pyridinium methosulfate salts to form the [2+2]-cycloaddition products. The crosslinked SbQ-PVA film was found to be robust, even after 20 min of ultrasonication in DI water, which indicated that it had been photocrosslinked by fluorescent light.

In previous studies, the degradation of pentacene FETs was mainly due to water present in ambient air rather than to oxygen [17,18]. Therefore, we focus here on the effect of water on the degradation of the devices. Fig. 4 shows the degradation of the electrical characteristics of pentacene FETs (PS/SiO$_2$ dual-layer gate dielectrics) without, with inkjet-printed, and with spin-coated passivation layers after 10 days. The field-effect mobility (μ) was obtained from the slope of a plot of the square root of the drain current (I_D) versus the gate voltage (V_G) in the saturation regime using the following equation: $I_D = (WC_i/2L)\mu (V_G - V_{th})^2$, where I_D is the drain current, C_i is the

capacitance per unit area of dielectrics (10 nF/cm^2 at 100 kHz), and V_{th} is the threshold voltage in ambient air (with a humidity of 60–80%) at room temperature. The pentacene FETs lacking a passivation layer showed a significant decrease in mobility, from the initial value (μ_0) of 0.71 cm^2/Vs to 0.22 cm^2/Vs (30% of μ_0), as shown in Fig. 4a. Water molecules in ambient air have been reported to diffuse into the grain boundaries of the polycrystalline semiconductor layer and/or the interface between the semiconductor and the gate dielectric, thereby generating both donor- and acceptor-like traps and leading to a significant degradation of the mobility [18].

The devices containing a passivation layer did not undergo a significant change in mobility when compared with the unpassivated devices (see Fig. 4b and 4c). The changes in V_{th}, the on/off ratio ($I_{on/off}$), and the subthreshold swing (SS) were negligible. The device containing the inkjet-printed passivation layer showed a better electrical performance than that based on the spin-coated film. Since inkjet-printing allows the deposition of well-defined,

a

b
Fig. 3. (a) Chemical structures of SbQ-PVA (left) and photochemically crosslinked SbQ-PVA (right) and (b) Changes in the UV–vis absorption spectra of a SbQ-PVA film.

high-resolution lines (with dimensions of several tens of micrometers), while spin-coating takes place on the whole semiconductor area, less passivation solvent will come in contact with the semiconductor in the first case, which results in less degradation of the performance of the inkjet-printed devices.

Fig. 5 shows the transfer characteristics of pentacene FETs (PVP/SiO$_2$ dual-gate dielectrics) without a passivation layer, and with inkjet-printed and spin-coated layers. The characteristics are reported for a period of 100 days in ambient air (with a humidity of 60–80%) at room temperature. The I_D–V_G transfer curves of the pentacene FETs were obtained in the linear regime ($V_D = -6$ V). The μ_0 values for the devices without, with inkjet-printed, and with spin-coated passivation layers were 0.21, 0.22, and 0.24 cm^2/Vs, respectively. These values were calculated by fitting the experimental data to the following equation: $\mu = (L/WC_iV_D)(\partial I_D/\partial V_G)$, where C_i was 9.4 nF/cm^2 at 100 kHz. After 100 days, the relative mobility (μ/μ_0) of the pentacene FETs without a passivation layer dropped to 0.6, whereas those of the devices containing inkjet-printed and spin-coated passivation layers decreased to 0.7 and 0.65, respectively. In particular, the changes in the values of the turn-on voltage ($V_{turn-on}$), V_{th}, and I_{OFF} are much larger in the devices without passivation than those with passivation (see Fig. 6). $V_{turn-on}$ is the voltage where subthreshold current starts increasing exponentially.

These results can be attributed to the presence of absorbed water molecules on the pentacene layer close to the gate dielectrics, which act as acceptor-like traps that can be filled with injected electrons at positive V_G values, thus leading to the accumulation of negative charges. As a consequence, extra holes are required to balance the stored negative charges, and $V_{turn-on}$ and V_{th} move to more positive values. Moreover, the value of I_{OFF} at positive V_G is higher than that of the devices without acceptor-like traps [19,20].

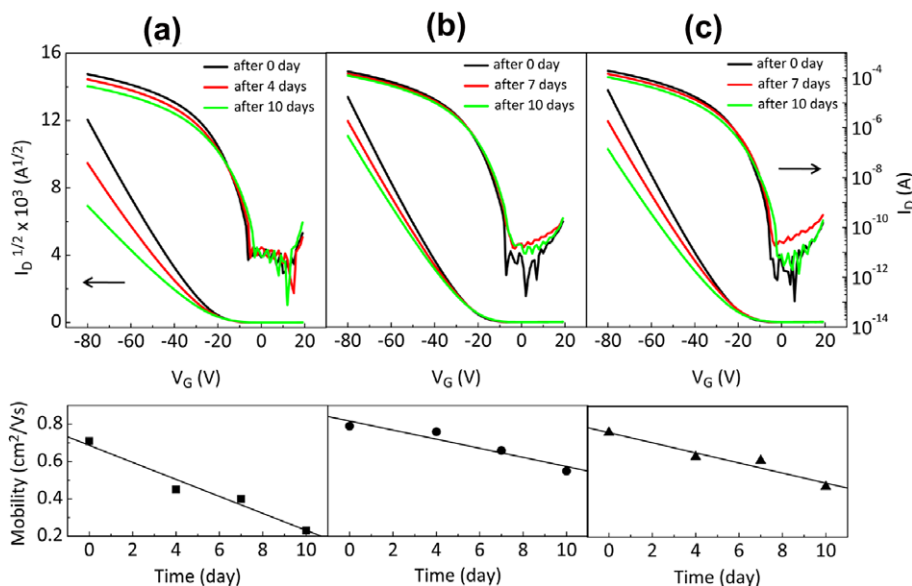
In addition to the variations in $V_{turn-on}$, V_{th}, and I_{OFF}, the time dependence of SS also shows certain differences between the passivated and unpassivated devices. The


Fig. 4. Transfer characteristics and mobility drops of pentacene FETs (PS/SiO$_2$ dual-gate dielectrics) (a) without a passivation layer, (b) with an inkjet-printed passivation layer, and (c) with a spin-coated passivation layer. The characteristics were measured for 10 days. In the top graphics, the left curves represent the square root of I_D versus V_G, whereas the right ones are I_D versus V_G.
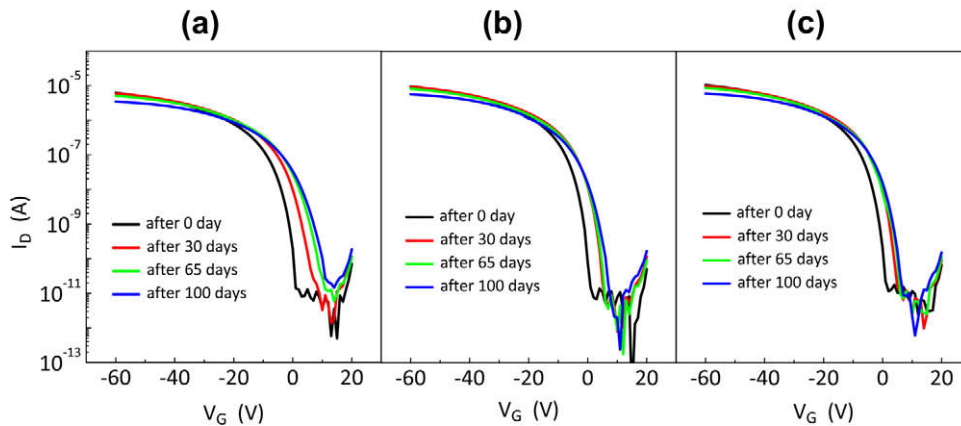

Fig. 5. Transfer characteristics of pentacene FETs (PVP/SiO$_2$ dual-gate dielectrics) (a) without passivation layer, (b) with an inkjet-printed passivation layer, and (c) with a spin-coated passivation layer. The characteristics were followed for 100 days. The I_D–V_G transfer curves were measured in the linear regime ($V_D = -6$ V).
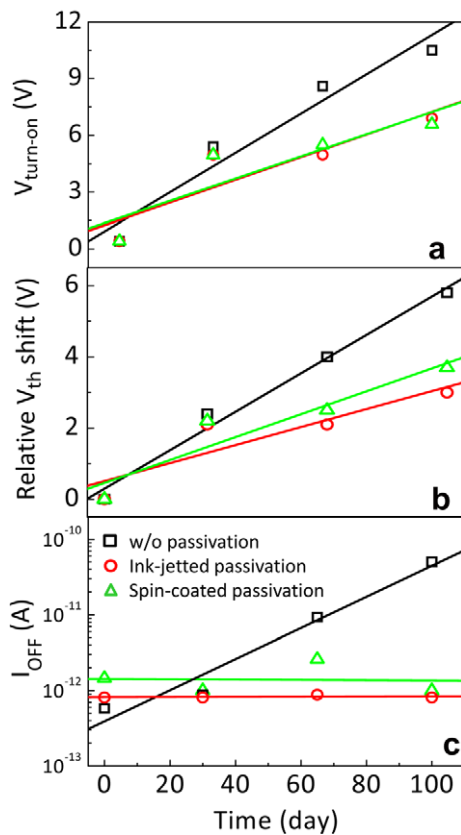

Fig. 6. Time-dependent changes of the (a) $V_{turn-on}$, (b) relative V_{th}, and (c) I_{OFF} values of pentacene FETs (PVP/SiO$_2$ dual-gate dielectrics) with and without passivation layer.

parameter SS is an important factor determining the voltage swing when a device is turned from the "off" to the "on" state and should be kept as low as possible. As mentioned above, the water molecules in the semiconductor act as trap sites, thus resulting in an increase of SS [20].

The SS value of the unpassivated device changed from 1.4 to 2.75 V/decade, whereas that of the device containing the inkjet-printed passivation layer only showed a small variation (from 1.3 to 1.7 V/decade).

We can conclude that the water-repellent properties of SbQ-PVA can protect the passivated devices from water molecules present in ambient air, so that the values of V_{th}, I_{OFF}, and SS are less affected in this case relative to the unpassivated devices. Since the FETs based on inkjet-printed passivation layers show the most stable electrical properties, we can affirm that inkjet-printing is a promising solution-processing passivation technique with the advantage that it allows direct patterning with high-resolution.

4. Summary

We investigated how the solvent used for passivation affects pentacene thin-films. The results showed that water is the most adequate solvent because it does not disrupt the pristine crystalline structure of the pentacene films. We introduced water-soluble and photocrosslinkable SbQ-PVA as a passivation material for pentacene FETs. Although this material normally dissolves well in water, it shows good water-resistant properties after photocrosslinking. Pentacene FETs containing an inkjet-printed and photocrosslinked SbQ-PVA passivation layer showed good time-dependent electrical performance, even after 100 days of aging in ambient air with 60–80% humidity. In addition, we found that inkjet-printing is a better procedure than spin-coating, because it leads to better device performance and offers additional advantages during the manufacturing process, for example, direct patterning and high-resolution.

ABSTRACT

The authors fabricated thin films by solution processes using liquid-crystalline (LC) semiconductors, 5-alkyl-5''-(4-hexyltetrafluorophenyl)-2,2':5',2''-terthiophene (2–5). Films of 5-propyl-5''-(4-hexyltetrafluorophenyl)-2,2':5',2''-terthiophene (2) show similar molecular packing as their non-fluorinated counterparts. However, the degree of molecular packing ordering from X-ray diffraction measurement is higher, and the films exhibit a more crystal-like structure. Moreover, fluorination has a remarkable effect on their mesomorphic behaviors. Films of 2 consist of large size LC domains (in the range of 100 μm) at room temperature. Thin-film transistors (TFTs) of 2 show p-type operation with good hole mobility up to 0.027 cm^2/Vs as well as improved operation stability under ambient conditions and high on/off ratio. Tetrafluorophenyl substitution leads to lowering of HOMO energy by 0.15 eV for 2 and 0.35 eV for 5, resulting in operation stability. Variable-temperature current-voltage measurements indicate intrinsic carrier transport in films of 2.

1. Introduction

In the quest for commercially successful organic field-effect transistors (OFETs), device fabrication by a solution process will be favorable due to its potential for large-area applicability and low cost production. However, the mobility of OFETs prepared by such a process is usually lower than that of devices fabricated by vacuum deposition. In addition, soluble conjugated polymers [1–3], solution-processable pentacene [4], and soluble precursors that can be converted into polycrystalline thin films [5] have been utilized to fabricate OFETs; however, a number of defects that inhibit smooth carrier transport are formed when polycrystalline thin films are formed.

Recently, liquid-crystalline (LC) semiconductors have emerged as promising materials for organic electronics [6–8]. They are solution-processable because of the thermal movement of the long alkyl chains attached to the LC molecules, which can self-assemble into large-area domains with a crystal-like structure and low defect density. Thus, the influence of grain boundaries, which seriously hinder charge carrier transport in polycrystalline materials,

E-mail addresses: funahashi@chembio.t.u-tokyo.ac.jp (M. Funahashi), n.tamaoki@aist.go.jp (N. Tamaoki).

is significantly suppressed [9]. Such capability of LCs to self-organize into ordered thin films is also favorable to electronic applications requiring homogeneity over large-area.

Bulk carrier mobility in columnar [10–12], smectic [13–16], nematic, and cholesteric [17–20] phases has been determined by the time-of-flight (TOF) technique. High carrier mobility, in excess of 0.1 cm²/Vs, has been observed in highly ordered columnar and smectic phases of LC molecules with a large π-conjugated system. It should be noted that a domain structure with size exceeding several μm is often formed in LC phases, and the domain boundary does not inhibit electronic carrier transport [9] when compared with molecular crystals. Recently, large-area LC thin-film transistors (TFTs) were fabricated [21–23] by utilizing the self-organization properties of LC semiconductors, although most LC semiconductors recrystallize at room temperature, leading to an increase in the density of defects and carrier traps.

Recently, our group developed the LC material: 5-propyl-5″-(4-pentylphenyl)-2,2′:5′,2″-terthiophene (1) [23]. It exhibits a highly ordered smectic phase at room temperature and fast ambipolar transport with the hole and electron mobility of 0.07 cm²/Vs and 0.2 cm²/Vs in the bulk state, respectively. LC thin films with a thickness of 50 nm were fabricated by the spin-coating method and they can be applied to TFTs. The hole mobility of 0.04 cm²/Vs was achieved on TFTs using this solution-processable LC semiconductor [24]. This good performance of the devices could be attributed to the highly ordered structure of the LC thin films with low defect density and domain size as compared to the channel length.

The stabilization of the LC thin films against oxidation is indispensable for the realization of practical FET devices working under ambient air for long time periods. For this, an increase in the oxidation potential by the introduction of electron withdrawing moieties is effective. The tetrafluorophenyl group has moderate electronegativity and does not deteriorate molecular linearity because of the small van der Waals radius of the fluorine atoms and its symmetry. In addition, it is known that when the terafluorophenyl moiety is introduced in LC molecules, it lowers their phase transition temperatures and increases their mobility [25]. It is expected that this property would result in the formation of large domains during LC thin-film formation. The effect of the tetrafluorophenyl group on the liquid crystallinity of phenylbithiophene derivatives [25] and conjugated polymers [26] has been studied. However, no examples of LC semiconductors with low molecular weight for TFTs exist.

In this work, we developed LC terthiophene derivatives with the tetrafluorophenyl group, 5″-(4-hexyltetrafluorophenyl)-2,2′:5′,2″-terthiophene derivatives (2–4), as well as a more electronegative LC terthiophene compound with both tetrafluorophenylene and perfluoroalkyl groups 5-perfluoro-hexyl-5″-(4-hexyl-tetrafluorophenyl)-2,2′:5′,2″-terthiophene (5), both of which are analogues of compound 1. We performed a detailed investigation of the fluorination effect on LC phase transition, molecular packing, and film structure as well as their relationship with carrier transport in the TFTs.

2. Results and discussion

2.1. Material design and synthesis

As shown in Scheme 1, 5-(4-hexyl-2,3,5,6-tetrafluorophenyl)-5″-alkyl-2,2′:5′,2″-terthiophene (2–4) and 5-(4-hexyl-2,3,5,6-tetrafluorophenyl)-5″-perfluorohexyl-2,2′:5′,2″-terthiophene (5) were synthesized by a cross-coupling reaction between 5-bromo-5″-alkyl-2,2′:5′,2″-terthiophene and 1-hexyl-2,3,5,6-fluorobenzene catalyzed by palladium (II) acetate and di-tert-butylmethylphosphonium tetrafluoroborate in N,N-dimethylacetamide, a process reported by Fagnou et al. [27], because of the low reactivity of tetrafluorophenyl borate under a conventional Suzuki coupling reaction. In contrast, nonfluorinated compound 1 can be synthesized by the conventional Suzuki coupling reaction between alkylphenylboric acid and 5-bromo-5″-alkyl-2,2′:5′2″-terthiophene [23]. Tetrafluorophenylterthiophene derivatives 2–5 were obtained in satisfactory yield and the crude products were purified by silica gel column chromatography and recrystallization from n-hexane.

2.2. Mesomorphic behaviors

The phase transition temperature was determined by differential scanning calorimetry (DSC) and the observation of optical textures under a polarized light microscope (POM). The LC phase structure was investigated by X-ray diffraction (XRD).

Compound 2 exhibits an enantiotropic nematic (N) phase and a highly ordered mesophase (M), as well as a
Scheme 1. Synthetic route of tetrafluorophenylterthiophene derivatives.
Fig. 1. (a) DSC profile of tetrafluorophenylterthiophene derivative **2**. (b) Micrographic textures in the mesophase of compound **2** at room temperature under a polarized light microscope. (c) X-ray diffraction in the mesophase of compound **2** at room temperature.

monotropic smectic A (SmA) phase. In the DSC curve of compound **2**, shown in Fig. 1(a), two peaks corresponding to an isotropic-N phase transition at 141 °C and a N-SmA at 106 °C with small transition enthalpies of 0.2 J/g as well as a peak corresponding to SmA-M transitions at 75 °C with a transition enthalpy of 8.4 J/g were observed in the cooling process. In the heating process, the curve exhibits one strong peak corresponding to the transition between the M phase and the N phases at 112 °C as well as a weak peak corresponding to the transition between the N and isotropic phases at 142 °C. When the M phase was cooled to −50 °C, no glass transition was observed. From the schlieren and fan-like textures under the observation of a polarized light microscope, the two phases that appear in the high-temperature region were identified as N and SmA phases, respectively. The result of X-ray diffraction also supports that these two phases are nematic and smectic phases, respectively. In the M phase, mosaic texture with defect lines as shown in Fig. 1b was observed. In the X-ray diffraction of the M phase of compound **2** (Fig. 1c), which appears below 75 °C in the cooling process, the strong diffraction (1 0 0) at $2\theta = 4.14°$ indicates a layer structure whose spacing is 23.1 Å. This value is slightly smaller than the molecular length (29.8 Å) with all-trans conformation, determined by MM2 calculation. And a number of peaks were observed between $2\theta = 10°$ and 30°, indicating that this phase has crystal-like 3-D structures. However, this phase exhibits fluidity above 100 °C on heating, below phase transition to the N phase, indicating that this is a mesophase with a freedom of molecular thermal movement. The optical micrographic texture revealed domains with a relatively large size exceeding several ten μm. Such a mesophase of 3-D order was observed in dithenylbenzene derivatives reported by Shimizu et al. [28]. It should be noted that this mesophase is retained below room temperature and compound **2** possessed no phase transition when it was cooled to −50 °C. The freedom of molecular thermal movement in the mesophase should cause the reorientation of molecules in the thin-film state in a thermal annealing process, resulting in large domain formation in the thin films.

Compound **3** also exhibits N, SmA, and highly ordered mesophase in both heating and cooling processes. Compound **4**, which has a long alkyl chain, exhibits a SmA and a highly ordered mesophase in a heating process. In a cooling process, an additional mesophase appears between the smectic A phase and the highly ordered mesophase. The phase transition temperatures are summarized in Table 1. The highly ordered mesophases of compounds **3** and **4** also exhibit fluidity to some extent below the phase transition

Table 1
Phase transition temperature of 5-(4-hexyltetrafluorophenyl)-5''-alkyl-2,2':5',2''-terthiophene derivatives.

	Heating	Cooling
2 R = C_3H_7	M 112 °C N 142 °C Iso	Iso 141 °C N 106 °C SmA 75 °C M
3 R = C_6H_{13}	M 114 °C SmA 130 °C N 139 °C Iso	Iso 138 °C N 130 °C SmA 90 °C M
4 R = $C_{12}H_{25}$	M_2 89 °C SmA 135 °C Iso	Iso 134 °C SmA 78 °C M_1 67°C M_2

M, M_1, and M_2 are unidentified mesophases.

temperature between the highly ordered mesophase and the SmA phase. Therefore, the mesophases should also be a kind of plastic crystal phase with some extent of molecular thermal movement.

The phase transition temperatures were lowered by ca. 50 °C as compared with the non-fluorinated counterpart 5-(4-alkylphenyl)-5''-alkyl-2,2':5',2''-terthiophene [23]. For example, compound 2 exhibited a nematic phase between 112 °C and 142 °C and a highly ordered smectic phase below 112 °C, in contrast to 5-(4-propylphenyl)-5''-hexyl-2,2':5',2''-terthiophene (1), which exhibits a nematic phase between 217 °C and 202 °C and a highly ordered smectic phase below 202 °C [23]. Such a lowering of the phase transition temperature was reported in tetrafluorophenyl-bithiophene derivatives [25].

Compound 5, which has a perfluoroalkyl chain, does not exhibit mesophases at room temperature. The phase at room temperature has a 3-D crystal-like order and no fluidity even near the phase transition to the SmA phase.

2.3. Structural characterization of mesomorphic thin films

The tetrafluorophenyl substituted compounds 2-4 show high solubility in common organic solvents. In this work, the investigation of the fabrication of the films and TFTs was focused on compound 2 due to the high similarity of molecular structure to non-fluorinated compound 1.

Homogeneous thin films of compounds 2 could be deposited on the surface of a SiO$_2$ layer treated with hexamethyldisalazane (HMDS) from their chlorobenzene solution by the spin-coating method. The polarized optical micrograph of as-prepared films of compound 2 in Fig. 2a shows the fine-threaded texture consisting of small domains with submicron size. Upon annealing at 85–90 °C for 10 min, a mosaic texture appears, corresponding to a highly ordered smectic phase (in Fig. 2b). This indicates that the thermal movement of the LC molecules caused the reorganization of macroscopic molecular alignment during the thermal annealing process below the phase transition temperature between the mesophase and the smectic A phase. This phenomenon should be associated with the freedom of molecular thermal movement in the mesophase. In particular, the films exhibited very large size of LC domains, exceeding several hundred μm, which was much larger than that in the film of non-fluorinated molecule 1 [23,24]. The tetrafluorophenyl group should increase molecular mobility in the mesophase because of weak intermolecular interaction.

The above facts were further confirmed by an atomic force microscope (AFM) observation. The film consists of large-area grains in the range of 20–50 μm (and even larger) with a lamellar structure. Fig. 2c and d show the AFM images within an individualized grain exhibiting a terrace structure on the surface. The height of the steps
Fig. 2. Polarized-light microscopic textures at room temperature of thin film of compound 2 (a) as-cast and (b) annealed at 85 °C for 10 min. (c) AFM topographic and (d) phase images of thin film of compound 2.
Fig. 3. (a) POM texture and (b) AFM topographic image of film of compound **5** from solution casting. The circled part is the less-ordered region.

separating the terraces is ca. 2.1 nm, corresponding to the thickness of one smectic layer of molecule **2** (vide infra). And the layers are thus parallel to the surface of the substrate. The large domain size is due to the higher mobility of the fluorinated molecules that originates from the weak interaction between tetrafluorophenyl groups. The high mobility of molecule **2** also causes partial dewetting of the film from the hydrophobic surface of the substrate during the annealing.

Homogenous thin films of compound **5** could not be fabricated by the spin-coating method at room temperature. Relatively homogenous films of the compound were prepared from the solution cast at 70 °C. They consist of domains with various sizes under POM observation, as shown in Fig. 3a. The AFM graph in Fig. 3b reveals the large

size domains with a layer structure. The height of the steps is 2.5 nm, corresponding to the molecular length, larger than that in the film of compound **2**. However, we found some less-ordered regions (the circled part in Fig. 3b) between the highly ordered grains. In the less-ordered regions, the layers should be perpendicular to the surface, in contrast to the ordered regions, in which the layers are parallel to the surface of the substrate. In the FET devices, carriers move within the layers, and carrier movement should be inhibited in the less-ordered regions. This may be attributed to the stiffness of the rod-like fluoroalkyl chains in molecule **5**, which hinders effective molecular assembly during film growth Table 2.

In the specular $(\theta/2\theta)$ X-ray diffraction patterns (in Fig. 4a and b), the as-deposited films of compound **2** show two distinct series of intense peaks, suggesting the presence of two different LC phases. The dominant phase (denoted as Phase I) has an interlayer spacing (d-spacing) of 2.8 nm, larger than the second phase (phase II). Such a d-spacing value is nearly the same as that in the bulk mesophase (2.83 nm), in agreement with the POM observation. After the thermal annealing, phase I disappears completely and the intensity of the reflection peak from phase II is considerably enhanced, corresponding to complete phase transition into the mesophase. The annealed film shows a

strong reflection peak at an angle of $2\theta = 3.8°$ and three higher-order reflections attributed to (00n) reflections, indicating a clear layer structure. Using Bragg law, the interlayer spacing was calculated as 2.1 nm, in agreement with the step height of the molecular layers measured by AFM. This indicates that the molecular layer in the film is parallel to the substrate surface with the tilting of the molecular long axis with respect to the surface normal. In contrast, the XRD pattern exhibits only two (00n) reflection peaks for the film from fluorine-free molecule **1** [23,24]. These results indicate that the ordering of the stacking between the layers is enhanced by the fluorination of the phenyl group. The tilt angle of molecule **2** increases to 43° as compared to 31° in the case of molecule **1** (the molecular length of compound **1** is 2.7 nm), as shown in Table 1. The interdigitation of the alkyl chains of the LC molecules also lead to the shorter layer spacing. However, similar enhancement of the molecular tilt angle was found on films of fluoroarene-thiophenes [29].

For films of compound **5** with both tetraflurophenyl and fluoroalkyl substitutions, the XRD pattern (in Fig. 4(b)) shows more higher-order (00n) reflection peaks up to $n = 6$, suggesting a highly orientated film structure. The d-spacing is 2.7 nm, as calculated from the first-order reflection at an angle of 3.8°. Compared with the films of compound **2** (with only fluorophenyl ring), the tilt angle of molecule **5** is reduced to 38° (Fig. 5).

The in-plane structure of the films was studied using grazing incidence XRD (in Fig. 4). The annealed films of compound **2** show a reflection peak at an angle of about 16° (corresponding to a d-spacing of 0.56 nm). A few reflections appear in the range of the higher angle for the film of compound **5**, suggesting a long-range ordering within the molecular layers of films of compounds **2** and **5**. However, weak intensity of the diffraction peaks (due to the limitation of intensity of X-ray source) prevents detailed structural analysis. In addition, a strong peak appears at the low angle corresponding to a d-spacing of 1.9 nm. This indicates the possible existence of a minor phase with the molecular layer perpendicular to the substrate surface. Such a phase may be located at less-ordered

Fig. 6. Optical absorption spectra of compounds **1**, **2**, and **5** as films (inset shows optical absorption in chlorobenzene).

regions between the highly ordered grains or at the dielectric-organic interface. Further investigation is required to elucidate its origin.

2.4. Absorption spectra of these compounds

Optical absorption spectra of compounds **1**, **2**, and **5** were measured both in solution and on thin films to study the effect of fluorophenyl and perfluoroalkyl-substitution on molecular packing and optical energy gap. The UV–VIS absorption spectra of the solutions (inset of Fig. 6) are free of fine structures. The absorption maximum (λ_{abs}) corresponds to the π–π^* absorption band of the conjugated π-electron system of the core. The λ_{abs} of compound **2** in chlorobenzene is located at the same position as that of fluorine-free compound **1**.

UV–VIS data for the thin films of compounds **2** and **5** are shown in Fig. 6. The baselines of the spectra exhibit non-zero-values because of the light scattering. If the influence of the light scattering is excluded, the baselines should exhibit zero. All films show a similar absorption feature with a blue-shift of the maximum and a simultaneous red-shift of the onset compared to the solution spectra. The absorption maxima of films of compounds **2** and **5** are almost the

Fig. 5. In-plane X-ray diffraction patterns of films of compounds **2** and **5** (after annealing). The crystallographic assignments of the peaks are labeled.

Fig. 7. Cyclic voltammogram of compounds **1**, **2**, and **5** in 0.05 M tetraethyl ammonium tetrafluoroborate/CH_2Cl_2 solution with an Ag/AgCl standard electrode. The scan rate was 0.01 V/min.

same and the optical band gap is estimated to be 2.6 eV for compounds **2** and **5**. This suggests a similar patterning of molecular packing in films of fluorinated molecules **2** and **5** as well as non-fluorinated material **1**.

A similar feature was observed for different kinds of oligothiophene films and it was attributed to the formation of H aggregates [22,30].

2.5. Measurement of oxidation potential

Fig. 7 shows cyclic voltammetry (CV) plots of compounds **1**, **2**, and **5**. Non-fluorinated molecule **1** and fluorinated molecules **2** and **5** exhibit quasi-reversible one-electron oxidation at 0.65 V, 0.80 V, and 0.99 V, respectively (vs. Ag/AgCl in 0.05 M TEABF$_4$/CH$_2$Cl$_2$ solution). This indicates the lowering of the HOMO energy by 0.15 eV and 0.35 eV upon substitution with the tetrafluorophenyl group and both the tetrafluorophenyl and perfluoroalkyl groups, respectively. Considering the similar optical gap for compounds **2** and **5**, as observed from the UV–VIS spectra, the LUMO level is also lowered by 0.15 eV and 0.35 eV for compounds **2** and **5** with respect to liquid crystal **1**, respectively. Considering the similar optical gap for compounds **1**, **2**, and **5**, as observed from the UV–VIS spectra, the LUMO level is also lowered by 0.15 eV and 0.35 eV for **2** and **5** with respect to **1**, respectively. This is consistent with the results of oligothiophene systems with a strong electron withdrawing tetrafluorophenyl or perfluoroalkyl group [31,32]. Such modification of the HOMO and LUMO levels will have a significant effect on the carrier transport process of organic semiconductors. The lowering of the HOMO levels of compound **2** should contribute to the stabilization of LC semiconductors for oxidation under air.

2.6. Time-of-flight measurement

The bulk carrier mobility in the mesophase of tetrafluorophenylterthiophene derivative **2** was measured by the conventional time-of-flight technique [33].

Under the application of an electric field, the photogenerated carriers drift across the bulk of the sample, inducing a transient photocurrent through the serial resistor. When the charge carriers reach the counter electrode, the induced photocurrent decays to zero. Therefore, a kink point in the transient photocurrent curve corresponds to the transit time t_T. Using Eq. (1), the carrier mobility (μ) can be calculated from the values of t_T, sample thickness d, and applied voltage V:

$$\mu = \frac{d^2}{Vt_T} \tag{1}$$

Illuminating the electrode under a positive or negative bias facilitates the determination of positive or negative carrier mobility, respectively.

When the absorption coefficient of a sample is sufficiently large, the excitation pulse is absorbed and a sheet of photo-carriers is generated at the interface between the illuminated electrode and the liquid crystal layer. In this study, a neat film of the compound exhibits a strong absorption band at around 370 and 250 nm in the smectic phase; the depth of penetration of the excitation light at 356 nm was estimated to be less than 0.5 μm, i.e., it was much smaller than the sample thickness (25 μm).

The highly ordered smectic phase of the compound has a relatively rigid structure with high viscosity; further, no change in the micrographic texture is observed when an electric field of the order of 10^5 V/cm is applied to the sample. The liquid crystal molecules in the sample are aligned parallel to the electrode surface; therefore, carrier transport within a smectic layer perpendicular to the electrode surface should be observed in the TOF measurement.

Fig. 8a shows transient photocurrents for the hole in the mesophase of compound **2** at room temperature. The obtained photocurrents are dispersive; however, transit times are estimated in a double logarithmic plot. The hole mobility is 0.07 cm^2/Vs, which is independent of the electric field and temperature between 100 and 50 °C. Below 50 °C, it decreases to 0.03 cm^2/Vs at room temperature. This decrease in the hole mobility should be attributed to the formation of defects that are caused by shrinkage when the sample was cooled, but not the intrinsic property of the liquid crystal material. If the defects are not formed with volume shrinkage, the hole mobility would be maintained constant.

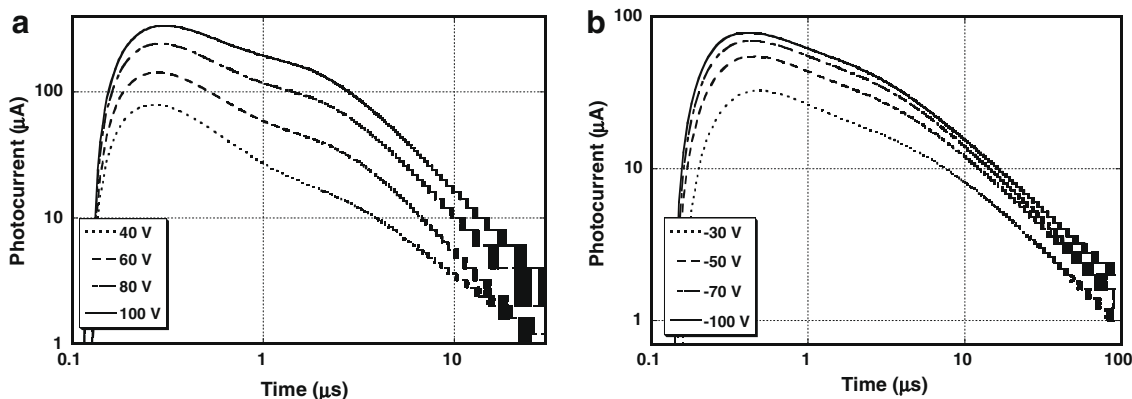

Fig. 8. Transient photocurrent curves in the mesophase of compound **2** at room temperature (a) for hole and (b) for electron. The sample thickness was 25 μm.

Fig. 8b shows transient photocurrents for the electron in the highly ordered mesophase around room temperature. The electron mobility at room temperature is 0.02 cm²/Vs, which is independent of the electric field but not the temperature. The electron mobility is lower than that of the hole, suggesting that the electron transport process should be influenced from the electron traps in the bulk state.

In the crystal phase of compound **5**, only photocurrent decay is observed. Because of the crystallinity of compound **5**, the sample contains a number of defects that form deep traps, in contrast to the low defect density of the mesophase of compounds **1** and **2**.

2.7. FET characterization

The TFTs from compounds **2** and **5** were fabricated in the top-contact configuration. As shown in the section of the structural characterization of mesomorphic thin films, molecules are perpendicular to the substrates in the mesomorphic thin films. Therefore the carriers should move within the layers consisting of the liquid crystal molecules in the channel area. Fig. 9a shows the I_D–V_D characteristics for TFTs of compound **2** measured in ambient air. The devices exhibit a typical p-type operation. The hole mobility is calculated as 1.6–2.1×10^{-2} cm²/Vs for most devices in a saturation region (see Fig. 9b). The current on/off ratio is more than 10^6. The highest value of the mobility is up to 2.7×10^{-2} cm²/Vs in the best devices. Such a value is close to that obtained from the time-of-flight (TOF) measurement in the bulk state (0.07 cm²/Vs at 50 °C), which represents the upper limit of transport properties of the TFTs [24]. This should be attributed to the formation of highly ordered LC domains with size larger than the channel length (20–30 μm) of the TFTs and thus, the effect of the grain boundary is significantly suppressed. The mobility is also comparable to that of the TFTs of non-fluorinated compound **1** [23,24]. Moreover, the TFTs of compound **2** exhibit enhanced stability of operation in ambient air. They can switch on continuously with less decay of drain current and mobility as compared to the TFTs of **1**. The devices

using compound **2** can maintain characteristics such as mobility, on/off ratio, and threshold voltage for 1 month. The on/off ratio is also higher than those of devices using compound **1** (10^5–10^6) fabricated under the same condition (on HMDS-treated SiO_2). This may be due to the strong electron withdrawing characteristics of the tetrafluorophenyl group, which raises the oxidation potential of the aromatic core to make the material less susceptible to air oxidation.

The TFTs of compound **3** and **4** also exhibited p-type operation with the lower carrier mobilities. The mobilities were 1×10^{-2} cm²/Vs for compound **3** and 8×10^{-3} cm²/Vs for compound **4**, respectively.

On the other hand, TFTs of compound **5** show a much lower performance. The hole mobility is only about 1×10^{-5} cm²/Vs and on/off ratio is 10^2. Presently, the exact origin of this low performance is not clear. One possible reason may be the existence of disordered regions and the smaller size of grains in the film, by which large amounts of electrical traps will be formed to hinder charge transport.

To evaluate the conduction mechanism and trap states in the films of compounds **2** and **5**, temperature-variable electrical characterization was performed for the TFTs from room temperature to 120 °C in a hot stage (in Fig. 10). The hole mobility of the TFTs of **2** remains nearly constant from room temperature to 70 °C and then decreases slightly (measurement was not performed at temperatures above 80 °C because of the dewetting of the film from the substrate). The threshold voltage also remains unchanged. Such behavior is in contrast to the thermally activated behavior observed on normal OTFTs of polycrystalline films [34–37], but similar to the characteristic carrier transport of LC semiconductors in the bulk, where field- and temperature-independent mobility are often observed [10–15]. This indicates that the electrical trap may not be a dominant factor to control carrier transport in such LC films, although some amount of trap states still exists at the dielectric-LC interface [38]. This should be due to the formation of highly ordered domains with a large size that exceeds the electrode gap. Such a behavior is attrib-

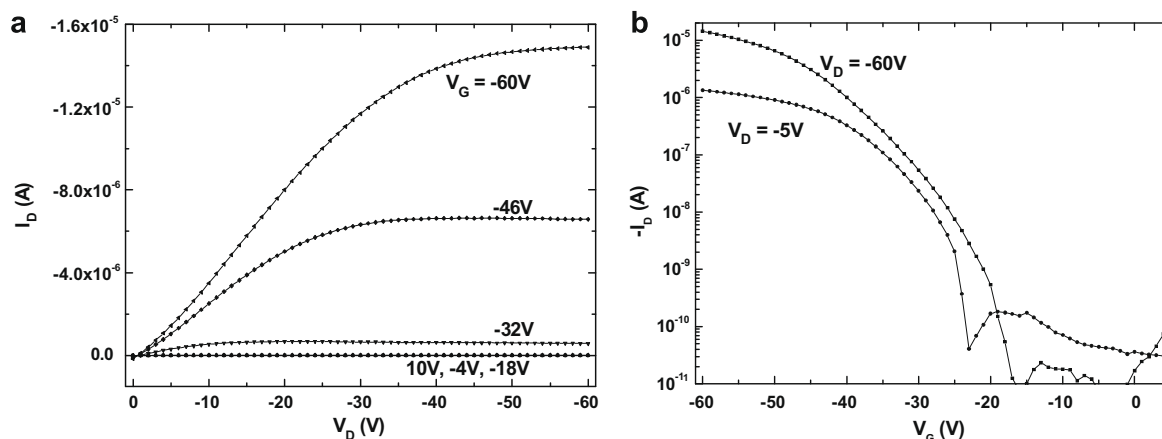

Fig. 9. (a) The output and (b) transfer characteristics of the TFT of compound **2** measured in ambient air. Channel length and width are 30 μm and 5 mm, respectively.
Fig. 10. Temperature dependence of saturation mobility and threshold voltage of TFTs based on (a) **2** and (b) **5**.

uted to self-healing of the positional disorder by thermal movement of the LC molecules. It should be emphasized that this introduction of the tetrafluorophenyl moiety should increase the mobility of the liquid crystal molecules, resulting in the formation of large domains greater than the channel length and a reduction in the defect density.

However, the mobility of the TFTs of compound **5** shows thermally activated behavior. It increases nearly exponentially with temperature ($\mu \propto \exp(E_A/kT)$) at an activation energy E_A of 50 meV. Therefore the carrier transport is trap-dominated, indicating the presence of large amounts of traps in the films. This is consistent with the microscopic observation shown above.

In this work, n-type operation was not observed in TFTs of compound **2** in ambient air and even in vacuum (10^{-3} Torr) although the gold, calcium, and samarium were used as the source and drain electrodes. This is different from the ambipolar behavior in their bulk state with an electron mobility of 0.02 cm^2/Vs, as obtained by the TOF technique. The result is also in contrast to cases of TFTs from dipentafluorophenyloligo thiophene or diperfluorohexyloligothiophene [29,39,40], in which a high electron mobility of 0.4 cm^2/Vs was obtained. It should be noted that our compound **2** showed a similar lowering of the LUMO energy relative to its non-fluorinated counterpart **1**, as observed in the cases of perfluoroarene substitution.

The absence of n-type behavior in the TFTs may be partially attributed to the high barrier of electron injection due to the relatively high-lying LUMO level of our materials. However, the dominant factor must lie in the attack by environmental oxygen because the solution processing of our TFTs was done in ambient air. For molecule **2**, an alkyl-tetrafluorophenyl group on one side of terthiophene is unable to provide sufficient screening of environmental O$_2$ or residual oxygen to the dielectric, which inhibits electron transport near the organic-dielectric interface [41]. Similarly, the absence of electron transport was observed in TFTs of oligthiophenes bearing a central tetrafluorophenylene ring [29,32]. For compound **5** with both tetrafluorophenyl and perfluoroalkyl substitutions, the absence of

n-type behavior may be attributed to a large amount of structural defects during film growth; these defects act as electron traps. Improved processing conditions (e.g., inert atmosphere) and better control of growth parameters of thin films should be provided to reduce the defect density in the LC domains as well as oxygen attack, in order to achieve n-type operation in the TFTs.

3. Experimental section

3.1. Synthesis

All solvents were used as obtained. 5-Propyl-5''-bromo-2,2':5',2''-terthiophene; 5-hexyl-5''-bromo-2,2':5',2''-terthiophene; and 5-dodecyl-5''-bromo-2,2':5',2''-terthiophene were synthesized by the procedure reported by Y. Geng et al. [42]. Other chemicals were used as obtained without further purification. ^{1}H NMR spectra were measured on a Varian NMR-300 spectrometer using chloroform-d as a solvent. IR spectra were measured using a Shimadzu IR-600 spectrometer. Mass spectra were recorded on a Voyager MALDI TOF Mass equipment.

3.2. 5-Propyl-5''-(4-hexyl-2,3,5,6-tetrafluorophenyl)-2,2':5',2''-terthiophene (2)

A mixture of 5-bromo-5''-propyl-2,2':5',2''-terthiophene, 0.49 g (1.3 mmol); 1-hexyl-2,3,5,6-tetrafluorobenzene, 0.49 g (2.1 mmol); palladium acetate, 16.6 mg (0.074 mmol); di(t-butyl)methylphosphonium tetrafluoroborate, 40.3 mg (0.16 mmol); and potassium carbonate, 2.3 g (17 mmol), was dissolved in dimethyl acetamide, 10 ml, and stirred for 2 h at 130 °C. After cooling to room temperature, water was added to the reaction mixture. The precipitates were filtered off and the crude product was purified by column chromatography on silica gel with hot hexane. Recrystallization of the product from hexane afforded 0.25 g (0.59 mmol, 46%) of pure product as yellow crystals.

^{1}H NMR (300 MHz, CDCl$_3$) δ (ppm): 0.89 (3H, t, J = 6.8 Hz), 1.00 (3H, t, J = 7.4 Hz), 1.26–1.44 (6H, m),

IR (KBr disc) 2957.3, 2927.4, 2869.6, 2858.9, 1652.7, 1477.2, 1442.5, 1394.3, 1378.9, 1251.6, 1224.6, 1196.6, 1155.2, 1123.3, 1055.8, 1024.0, 944.9, 856.2, 787.8, 735.7, 725.1, 479.2 cm^{-1}. MS (MALDI): m/z (%): 522.6 (100%), 523.6 (29.5%), 524.6 (13.6%), 525.6 (4.9%) [M$^+$] (C$_{27}$H$_{26}$F$_4$S$_3$). Anal. Calcd. for 522.68: C 62.04, H 5.01, F 14.54, S 18.40; found: C 62.52, H 4.99.

3.3. 5-Hexyl-5''-(4-hexyl-2,3,5,6-tetrafluorophenyl)-2,2':5',2''-terthiophene (3)

A mixture of 5-bromo-5''-hexyl-2,2':5',2''-terthiophene, 0.51 g (1.2 mmol); 1-hexyl-2,3,5,6-tetrafluorobenzene, 0.51 g (2.15 mmol); palladium acetate, 18.1 mg (0.081 mmol); di(t-butyl)methylphosphonium tetrafluoroborate, 46.3 mg (0.18 mmol); and potassium carbonate, 0.55 g (4 mmol), was suspended in dimethyl acetamide, 5 ml, and stirred for 2 h at 130 °C. After cooling to room temperature, water was added to the reaction mixture. The precipitates were filtered off and the crude product was purified by column chromatography on silica gel with hot hexane. Recrystallization of the product from hexane afforded 0.45 g (0.80 mmol, 67%) of pure product as yellow crystals.

^{1}H NMR (300 MHz, CDCl$_3$) δ (ppm): 0.89 (3H, t, J = 6.8 Hz), 1.00 (3H, t, J = 7.4 Hz), 1.24–1.44 (12H, m), 1.56–1.66 (2H, m), 1.72 (2H, sext, J = 7.4 Hz), 2.75 (2H, t, J = 7.8 Hz), 2.80 (2H, t, J = 7.4 Hz), 6.69 (1H, d, J = 3.6 Hz), 7.00 (1H, d, J = 3.8 Hz), 7.02 (1H, d, J = 4.0 Hz), 7.13 (1H, d, J = 3.8 Hz), 7.19 (1H, d, J = 4.0 Hz), 7.50 (1H, d, J = 4.0 Hz). ^{13}C NMR (300 MHz), CDCl$_3$ δ (ppm): 13.6, 13.7, 22.1, 22.2, 22.4, 28.3, 28.4, 28.5, 28.8, 29.8, 31.0, 31.1, 118.6, 118.8, 122.9, 123.2, 123.3, 124.5, 124.6, 130.1, 130.2, 130.3, 133.8, 134.1, 137.3, 139.1, 139.5, 145.5. IR (KBr disc) 2957.3, 2926.5, 2891.5, 2855.1, 1652.7, 1476.2, 1444.4, 1389.5, 1377.9, 1225.5, 946.9, 858.2, 787.8, 758.9, 505.3, 490.8, 476.3 cm^{-1}. MS (MALDI): m/z (%): 564.6 (100%), 565.6 (29.5%), 566.6 (13.6%), 567.6 (4.9%) [M$^+$] (C$_{30}$H$_{32}$F$_4$S$_3$). Anal. Calcd. for 564.76: C 63.80, H 5.71, F 13.46, S 17.03; found: C 64.30, H 5.70.

3.4. 5-Dodecyl-5''-(4-hexyl-2,3,5,6-tetrafluorophenyl)-2,2':5',2''-terthiophene (4)

A mixture of 5-bromo-5''-dodecyl-2,2':5',2''-terthiophene, 0.52 g (1.05 mmol); 1-hexyl-2,3,5,6-tetrafluorobenzene, 0.46 g (1.9 mmol); palladium acetate, 18.1 mg (0.081 mmol); di(t-butyl)methylphosphonium tetrafluoroborate, 49.5 mg (0.20 mmol); and potassium carbonate, 0.4 g (4 mmol), was dissolved in dimethyl acetamide, 5 ml, and stirred for 2 h at 130 °C. After cooling to room temperature, water was added to the reaction mixture. The precipitates were filtered off and the crude product was purified by column chromatography on silicagel with hot hexane. Recrystallization of the product from hexane afforded 0.45 g (0.69 mmol, 66%) of pure product as yellow crystals.

^{1}H NMR (300 MHz, CDCl$_3$) δ (ppm): 0.89 (3H, t, J = 6.8 Hz), 1.00 (3H, t, J = 7.4 Hz), 1.22–1.44 (24H, m), 1.56–1.66 (2 H, m), 1.72 (2H, sext, J = 7.4 Hz), 2.75 (2H, t, J = 7.8 Hz), 2.79 (2H, t, J = 7.4 Hz), 6.69 (1H, d, J = 3.6 Hz), 7.00 (1H, d, J = 3.8 Hz), 7.02 (1H, d, J = 4.0 Hz), 7.13 (1H, d, J = 3.8 Hz), 7.19 (1H, d, J = 4.0 Hz), 7.50 (1H, d, J = 4.0 Hz). ^{13}C NMR (300 MHz), CDCl$_3$ δ (ppm): 13.6, 13.7, 22.1, 22.3, 22.4, 28.5, 28.7, 28.8, 28.9, 29.1, 29.2, 29.3, 29.4, 29.8, 31.0, 31.2, 31.5, 118.5, 118.8, 122.9, 123.2, 123.3, 124.4, 124.5, 130.1, 130.2, 130.3, 133.8, 134.1, 137.3, 139.1, 145.5. MS (MALDI): m/z (%): 648.7 (100%), 649.7 (29.5%), 650.6 (13.6%), 651.7 (4.9%) [M$^+$] (C$_{36}$H$_{44}$F$_4$S$_3$). Anal. Calcd. for 648.92: C 66.63, H 6.83, F 11.71, S 14.82; found: C 67.04, H 6.94.

3.5. 5-Perfluorohexyl-5''-(4-hexyl-2,3,5,6-tetrafluorophenyl)-2,2':5',2''-terthiophene (4)

A mixture of 5-bromo-5''-perfluorohexyl-2,2':5',2''-terthiophene, 0.52 g (1.05 mmol); 1-hexyl-2,3,5,6-tetrafluorobenzene, 0.46 g (1.9 mmol); palladium acetate, 18.1 mg (0.081 mmol); di(t-butyl)methylphosphonium tetrafluoroborate, 49.5 mg (0.20 mmol); and potassium carbonate, 0.4 g (4 mmol), was dissolved in dimethyl acetamide, 5 ml, and stirred for 2 h at 130 °C. After cooling to room temperature, water was added to the reaction mixture. The precipitates were filtered off and the crude product was purified by column chromatography on silicagel with hot hexane. Recrystallization of the product from hexane afforded 0.45 g (0.69 mmol, 66%) of pure product as yellow crystals.

^{1}H NMR (300 MHz, CDCl$_3$) δ (ppm): 0.96 (3H, t, J = 6.9 Hz), 1.24–1.45 (6H, m), 1.69 (2H, sext, J = 6.3 Hz), 2.82 (2H, t, J = 7.5 Hz), 7.25–7.33 (4H, d, m), 7.52 (1H, d, J = 4.0 Hz), 7.69 (1H, d, J = 4.0 Hz). ^{13}C NMR (300 MHz), CDCl$_3$ δ (ppm): 13.7, 14.1, 22.6, 22.9, 24.9, 29.0, 29.3, 31.5, 32.3, 119.1, 119.3, 123.4, 123.7, 123.8, 125.0, 125.1, 130.6, 130.7, 130.8, 134.4, 134.6, 137.8, 139.5, 139.6, 145.7. IR (KBr disc) 2960.2, 2939.9, 2930.3, 2910.1, 2856.1, 1476.3, 1456.0, 1361.5, 1234.2, 1210.1, 1179.3, 1138.8, 787.8 cm^{-1}. MS (MALDI): m/z (%): 766.4 [M–S$^+$] (C$_{30}$H$_{19}$F$_{17}$S$_2$).

3.6. Characterization of mesomorphic behaviors

Phase transition behaviors of the liquid crystals were observed in micrographic optical textures under a polarized light microscope (Nikon OPTIPHOT2-POL) with a hot stage (Mettler F82HT hot stage) and thermograms were recorded by DSC (Seiko Instrument DSC-330). X-ray diffraction patterns were recorded on a Rigaku-denshi diffractometer RINT (Cu Kα: 1.541 A) with an imaging plate.

3.7. Characterization of thin-film structure

Out-of-plane and in-plane X-ray diffraction (XRD) of thin films was acquired using a Rigaku RINT-Ultima X X-ray diffractometer with Cu Kα1 (λ = 1.5418 Å). The surface morphology of thin films was measured in air using a Vecco Dimension 3100 atomic force microscope (AFM). UV-vis absorption spectra were obtained using JASCO V-570 UV–VIS–NIR spectro-photometer. The optical texture of thin films and bulk compounds was observed using an Olympus BX 60 polarized optical microscope.

3.8. Time-of-flight measurement

The time-of-flight setup comprised an Nd:YAG pulse laser equipped with a THG non-linear optical crystal (Continuum Minilite I FN, wavelength = 356 nm, pulse width = 2 ns), hand-made hot stage, source measurement unit (Advantest R-8252) as a DC voltage source, and digital oscilloscope (Tektornics TDS3044B). The liquid crystal compounds were capillary-filled into cells consisting of two ITO-coated glass plates on a hot stage heated above the mesophase–isotropic phase transition temperature. The liquid crystal cell was mounted on the hot stage. Under the application of the electric field by the DC voltage source, the pulse laser light was illuminated on the liquid crystal cell. The induced transient photocurrent was recorded in the digital oscilloscope through a serial resistor (100 Ω).

3.9. Fabrication and characterization of field-effect transistors

Thin films of compound **2** were prepared by the spin-coating method. Then, 0.5–0.7% chlorobenzene solution was spun on doped Si wafers with a 300-nm SiO$_2$ layer. Thin films of compound **5** were grown by solution casting of 0.1–0.2% solution in chlorobenzene at 70 °C. The preparation by spin-coating was not successful because the films prepared were too thin (<10 nm) and uncontinuous even at a low rotation speed of the spin coater. Prior to film deposition, the wafer was cleaned in a UV ozone cleaner and subsequently treated with hexamethyldisilazane (HMDS). After film deposition, samples of **2** and **5** were annealed in a vacuum oven at 85–90 °C and 110 °C for 10 min, respectively. Gold source and drain electrodes with a thickness of 60 nm were deposited under high vacuum (10^{-4} Pa) through a shadow mask to define the top-contact FET structure with a channel length of 20–30 μm and channel width of 5 mm. Transistor characteristics were measured using a two-channel source meter (Kethley 2612) in a light-shield box under ambient conditions with low humidity or in a vacuum of 10^{-3} Torr. The temperature-dependent electrical measurement of the TFTs was performed over a temperature range of 25 °C to 120 °C on a hot stage, where the temperature was controlled using a PID thermo-controller with an accuracy of 0.1 °C.

ARTICLE INFO

ABSTRACT

Unimolecular rectification behavior of a known amphiphilic fullerene derivative, 1,4,11,15,30-pentakis(4-hydroxyphenyl)-2H-1,2,4,11,15,30-hexahydro-[60]fullerene, (4-$HOC_6H_4)_5HC_{60}$ (referred to here as the fullerene pentapod), is reported. The HOMO and LUMO energy levels of the pentapod were determined by density functional theory calculations (B3LYP/6-31G**). It was found that the HOMO of the donor moiety and the LUMO of the acceptor are in the same fullerene cage, quite unlike the fullerene derivatives so far reported as molecular rectifiers. The molecule formed a stable Langmuir-Blodgett film at the air–water interface. Characterization of the film indicated that it constitutes mostly a monolayer of molecules with the hydrophobic C_{60} moiety pointing upwards. The LB film was transferred over Au(1 1 1) substrate and electrical conductivity of the film was measured by conducting atomic force microscopy. An asymmetric electrical rectification behavior was observed in the voltage range of ±1.0 V to ±2.0 V. Beyond a bias voltage of ±2.0 V, rectification ratio decreased steadily, until at ±2.5 V the current–voltage curve became symmetric. The observed electrical rectification behavior was ascribed to resonant electron tunneling between the Fermi level of the electrode and the molecular orbital levels of the fullerene pentapod. Charge transport in the preferred direction under a suitable applied bias was facilitated due to efficient electronic interactions of the molecular orbitals through a combined effect of homo- and peri-conjugation. This constitutes a new class of donor–acceptor system and a step forward in the field of molecular electronics.

1. Introduction

Stable molecular diodes neatly arranged without defects are a viable answer to continued quest for ultimate device miniaturization in electronics [1,2]. The possibility that a single molecule could function as a rectifier was proposed by Aviram and Ratner with an exemplary theory of rectification [3]. This initial theory, modified subsequently [4], led to a wide interest in the field of unimolecular rectification for over a decade [5]. 'Unimolecular rectification' is a conventional terminology, which in reality concerns the rectification behavior of an ordered assembly of molecules, since isolating and probing the electrical behavior of a single molecule is rather impractical. A number of systematic studies have been devoted to understand the rectification behavior of an organized array of molecules in Langmuir-Blodgett (LB) films, or self-assembled monolayers (SAM) of organic molecules. The molecules invariably contained an electron donor moiety (D) bound to an electron acceptor (A) through an insulating saturated σ- or

conjugated π-bridge. Most devices involved monolayers of such archetypal organic molecules sandwiched between two metal-electrodes, one bottom electrode plate and the tip of the atomic force microscope as the top contact electrode, or an ordered assembly of molecules in a nanopore or a nanogap connected to two electrodes [6]. Unimolecular rectification across a LB monolayer was first demonstrated for hexadecylquinolinium tricyanoquinodimethanide [5,6d,7], a D-π-A-type molecule.

Fullerenes are ideal materials for various nanoscale electronic devices. These molecules have a very strong affinity towards electrons. C_{60} is known as one of the strongest electron acceptors. When a suitable donor molecule is covalently or non-covalently bound to it, the donor–acceptor assembly shows many interesting properties with promising applications. For the rectification studies involving C_{60} derivatives, there should be an ordered assembly of preferably a monolayer of molecules over a suitable substrate. One of the deterrent factors, however, is that these molecules have a strong tendency to aggregate due to the hydrophobic fullerene–fullerene interactions [8]. This aggregation problem could easily be circumvented by attaching strong hydrophilic head groups to the fullerene [8f,9], blocking the contact of fullerene core by encapsulation [8g,10], and introducing structural constraints in the molecule [11]. Indeed, several amphiphilic fullerene derivatives are now known to form stable LB films at the air–water interface [12,13]. Similarly SAMs of fullerene derivatives, particularly those with appended thiol moiety, have produced highly ordered and densely packed structures on gold substrate [11]. The first C_{60}-based compound, dimethylaminophenylazafullerene [14], the LB film of which was sandwiched between two gold electrode layers, showed a tremendous apparent rectification ratio as high as 20,000, which was ascribed to the defects that grew at the domain boundaries. A Langmuir-Schaefer monolayer of another fullerene derivative [15] exhibited pronounced rectification with rectification ratio up to 16.5 when compared to the sample from the LB film. Interest in fullerene-based rectifier molecules with donor organic moiety
attached to the acceptor C_{60} through a suitable spacer continues unabated [16].

Herein, we report our studies on the monolayer of LB film of the fullerene pentapod formed at the air–water interface. The energy minimized structure of the molecule is shown in Fig. 1. This amphiphilic fullerene derivative is expected to form stable LB film at the air–water interface and afford a very robust structure through the five –OH groups anchored to the substrate. The electrical behavior of the film on Au(1 1 1) substrate measured using conducting atomic force microscopy (CAFM) showed that the molecule behaves as a rectifier when an appropriate bias voltage was applied. A suitable mechanism of rectification is proposed.

2. Experimental

2.1. Materials

The fullerene pentapod, $(4\text{-}HOC_6H_4)_5HC_{60}$, synthesized following the procedure reported by Nakamura and coworkers [17–19] was isolated in gram quantities in highly pure form. The compound is readily soluble in polar solvents like tetrahydrofuran, N-methyl pyrrolidinone, pyridine, and N,N′-dimethyl formamide. In nonpolar solvents like toluene solubility is low (∼0.001 g/ml). The compound is very stable towards oxidation under ambient conditions as studied by ¹H NMR monitoring the C–H peak intensity at 5.6 ppm. No change in spectral pattern was observed over a period of several weeks.

2.2. Computations

The geometry of free $(4\text{-}HOC_6H_4)_5HC_{60}$ was optimized using the density functional theory (DFT) method with the B3LYP functional [20] and the 6-31G** basis set. The HOMO and LUMO energy levels were determined on the final geometry by reading the DFT eigenvalues as well as by calculating the ionization potential ($IP = E_{CATION} - E_{NEUTRAL\ MOLECULE} \approx -E_{HOMO}$) and electron affinity ($EA = E_{NEUTRAL\ MOLECULE} - E_{ANION} \approx -E_{LUMO}$). In order to estimate roughly the error attributable to the functional-dependence of DFT, the energy levels were estimated using both B3LYP (hybrid) and PBE (GGA) functionals [21]. It should be noted that though the device in the present case is metal-organic-metal type, the shift and broadening of the energy levels due to the substrate (Au) were not taken into account in our calculations on this "free" isolated molecule. All the calculations were done with Jaguar v6.5 (Schrodinger Inc., Portland, OR).

2.3. Langmuir-Blodgett film

The LB film was cast using a PC controlled KSV MINITROUGH instrument attached to a constant temperature bath. The quality of the LB monolayer at the air–water interface was monitored by KSV Win LB computational program. A 70 μl dilute solution of the fullerene pentapod (0.0235 mg/ml in toluene) was spread on the air–water interface and the trough area decreased at a rate of 200 cm²/min. The film was transferred at a constant rate

Fig. 1. Energy minimized structure of 1,4,11,15,30-pentakis(4-hydroxyphenyl)-2H-1,2,4,11,15,30-hexahydro-[60]fullerene, $(4\text{-}HOC_6H_4)_5HC_{60}$, the amphiphilic fullerene pentapod, with molecular dimensions. Color code: grey – carbon, green – hydrogen, and red – oxygen. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

of 5 mm/min and a surface pressure of 20 mN/M onto a freshly prepared hydrophilic Au(1 1 1) substrate, which was submerged in the subphase before spreading and compressing the LB film. All the experiments were performed at 21 °C using pure deionized water as the subphase.

2.4. Atomic force microscopy

The LB film was examined by atomic force microscopy (AFM) to determine the height of the particles. The AFM images were acquired with a Nanoscope III dimension (Digital Instruments Inc. Santa Barbara, CA). Super sharp silicon taping mode with a cantilever (Nanosensor, Wetzlar-Blankenfeld, Germany) having resonance frequency of ca. 330 kHz and scan rate of 0.5 Hz was used. The tip of the cantilever has a normal radius of ca. 2 nm. The samples for AFM measurement were prepared by LB deposition method at the air–water interface over Au(1 1 1) substrate.

2.5. Ellipsometry

Variable angle spectroscopic ellipsometry measurement was done on a NFT I-ELLI 2000 ellipsometer equipped with a Nd:YAG LASER at 65°, 70° and 75° angles of incidence in the wavelength range of 300–1000 nm. The optical constants for bare gold were measured immediately before measuring the fullerene pentapod film-coated substrate. A refractive index of 1.533 was assumed for all measurements. The thickness of the film using three samples was calculated from variation of the ellipsometric parameters Δ and Ψ. Repeated measurements were made at different positions all through the substrate for obtaining accurate results.

2.6. Contact angle measurement

The wettability of the LB film was investigated by measuring the contact angle of water of a freshly prepared sample using CA-S150, KYOWA instrument. Ten microlitre of ultra pure water (Barnstead Easypure LF, 18.3 MΩ cm) was used throughout the experiment. The contact angle was read only on one side of the drop.

2.7. Conducting atomic force microscopy

Samples for CAFM measurements are the fullerene pentapod LB films transferred over Au(1 1 1) substrate. These were dried in a vacuum desiccator for 48 h prior to the electrical measurements. Precautions were taken to prevent damage to the film in view of its fragile nature by thermal radiation. Current–voltage (I–V) measurement was performed using a commercially available AFM system (PSIA, XE-100 model) with conductive AFM tips that were made from Au (20 nm)/Cr (20 nm) coating around conventional AFM tips. Two terminal DC I–V data were acquired using a semiconductor parameter analyzer (HP4145B). Voltage was applied to CAFM tip while the Au substrate was grounded. All the electrical measurements were carried out inside a covered AFM chamber through which nitrogen gas was passed to minimize the formation of contaminants on the surface of the film. From Johnson–Ken-

dall–Roberts (JKR) model [22] the radius of the contact area under the CAFM tip was estimated to be less than 10 nm [23].

3. Results and discussion

3.1. Computations

The outer diameter of C_{60} is ~1 nm estimated by taking into account the size of the π-electron cloud associated with the carbon atoms [24]. This value was taken as the diameter of the fullerene moiety in the pentapod (see Fig. 1). The five phenolic groups form a circular face, the diameter of which was ~1.78 nm. The difference between the diameters of the top fullerene moiety and bottom circular face is 0.78 nm. This is large enough to prevent fullerene–fullerene interaction among the neighboring molecules if uniformly oriented in a monolayer. Similar observations have been made for fullerene derivative C_{60}-MPPA [11] where aggregation was prevented due to the difference in size between the fullerene head group attached to a relatively larger MPAA unit.

In the study of molecular electronics, computational calculations of the molecular energy levels relative to metal-electrode energies bear specific significance. Such calculations have been made for several fullerene derivatives [14,15,25]. Even though the device in the present case is metal-organic-metal type, the shift and broadening of these energy levels due to the substrate (Au) was not taken into account in our calculations on the "free" isolated molecule. Thus, the calculated HOMO and LUMO levels, shown in Fig. 2, should be taken as approximate.

The two functionals of DFT, B3LYP and PBE, result in essentially the same electronic structure. Both of them predict the same molecular energy diagram. The HOMO and HOMO − 1 are very close in energy and hence considered as degenerate MOs, and similarly the LUMO and LUMO + 1 constitute a pair of degenerate orbitals. The energy levels taken from the B3LYP eigenvalues are as follows (in eV): −5.45 (E_{HOMO}), −5.47 ($E_{HOMO − 1}$), −5.63 ($E_{HOMO − 2}$), −5.84 ($E_{HOMO − 3}$), −5.94 ($E_{HOMO − 4}$), and −5.96 ($E_{HOMO − 5}$) for the HOMO levels; −2.47 (E_{LUMO}), −2.45 ($E_{LUMO + 1}$), and −2.32 ($E_{LUMO + 2}$) for the LUMO levels. Both functionals also predict that the frontier MOs of the molecule are essentially localized on the same C_{60} moiety, which is in sharp contrast to other fullerene derivative-based donor–acceptor systems studied for molecular rectification where the donor HOMO is located on the exocyclic group and the acceptor LUMO is on C_{60} [14–16,26].

The two functionals, however, show discrepancy in the precise locations of these energy levels (Table 1). The HOMO–LUMO gaps calculated with B3LYP are significantly larger than those calculated with PBE, as observed previously [27]. Interestingly this discrepancy becomes small when estimated from the IP and EA values. Since the PBE functional is known to underestimate the HOMO–LUMO gap, we focus on analyzing the experimental data only based on the two B3LYP values in the following discussion.
Fig. 2. Molecular orbitals of the fullerene pentapod generated by DFT calculations (B3LYP/6-31G**). (a) LUMO (−2.47 eV) (b) LUMO + 1 (−2.45 eV), (c) HOMO (−5.45 eV), and (d) HOMO − 1 (−5.47 eV). Color code: grey – carbon, white – hydrogen, and red – oxygen. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 1
HOMO–LUMO gap calculated by B3LYP and PBE functionals.

Method	E_{HOMO} (eV)	E_{LUMO} (eV)	HOMO–LUMO gap (eV)
B3LYP	−5.5	−2.5	3.0
B3LYP IP/EA	−6.3	−1.6	4.7
PBE	−4.8	−3.0	1.8
PBE IP/EA	−5.9	−1.7	4.2

3.2. LB film

The LB pressure-area isotherm of the fullerene pentapod is shown in Fig. 3. From the isotherm, the mean molecular area per molecule, A_0, obtained by extrapolating the pressure-area isotherm to zero pressure was 0.98 nm² molecule⁻¹, which corresponds to a mean diameter of 1.117 nm per molecule. The LB films of unmodified dilute C_{60} solution show a limiting area of 0.98 nm² molecule⁻¹ [8a,8c,8e], as against the theoretically predicted value of 0.866 nm² molecule⁻¹ for a monolayer of the molecule [9b,28]. This suggested that the pentapod formed a monolayer at the air–water interface rather than an irreversible aggregation of the fullerene clusters [12]. The mean molecular area at the inflection point (A_c) calculated at the collapse pressure Π_c of 33 mN/M was 0.83 nm² molecule⁻¹. Above the collapse pressure, the nature of the
Fig. 3. Pressure–area isotherm (Π-A) of the LB film at the air–water interface obtained by spreading the fullerene pentapod solution in toluene.

curve changed indicating phase transition, possibly from one closely packed structure to another. The pentapod was transferred atop the Au(1 1 1) substrate at a transfer pressure, Π_{tr}, of 20 mN/M. The mean molecular area at the transfer pressure, A_{tr}, was 0.90 nm² molecule⁻¹, from

which the mean diameter per molecule was calculated to be ~1.07 nm.

The diameter of the bottom circular face of the molecule calculated from computational measurement is ~1.78 nm. This should be the nearest neighbor distance between the molecules if they are in direct contact. However, an examination of the energy minimized structure of the molecule showed that there is enough space between the phenolic rings to allow the neighboring molecules to interdigitate as schematically shown in Fig. 4. This evidently means that the molecules could be packed more closely than 1.78 nm, i.e., even when the mean molecular diameter was 1.07 nm, the molecules could still form a monolayer without vertical stacking. It may be noted here that the molecules in the LB film though seem to interdigitate at the transfer pressure could get organized further while drying to optimize the intermolecular order. The mean molecular area of 1.07 nm is in close agreement with the nearest neighbor distance in a close-packed (1 1 1) plane of the C_{60} molecules [8e]. The LB film of C_{60}, $C_{60}O$ and $C_{61}H_2$ showed (1 1 1) close-pack arrangement for the molecules with nearest neighbor distances of 1.002, 1.003 and 1.003 nm, respectively. Hexagonal (1 1 1) face-centered cubic lattice with

neighboring distance of 0.95 nm is reported for other fullerene derivatives [29].

The thickness of the LB film, determined from ellipsometry (1.5 ± 0.01 nm) and the height image of atomic force microscopy (AFM) studies (Fig. 5), was consistent with the height of the molecule from computational measurement. Thus, the LB film is mostly a monolayer of the molecules. Water contact angle of the film on Au(1 1 1) substrate was 97°. The high contact angles of H_2O on LB film suggested the hydrophobic nature of the film, which is expected of the film with the fullerene moieties exposed to air. Thus the molecule on the substrate surface formed a homogeneous monomolecular film with the five functional groups anchored to the substrate leading to a robust structure without aggregation. Recently Nakamura and coworkers [30] have reported the photophysical properties of the monolayer of the benzoic acid derivative of a series of fullerene penta-addition derivatives, which show the same anchoring behavior to the substrate.

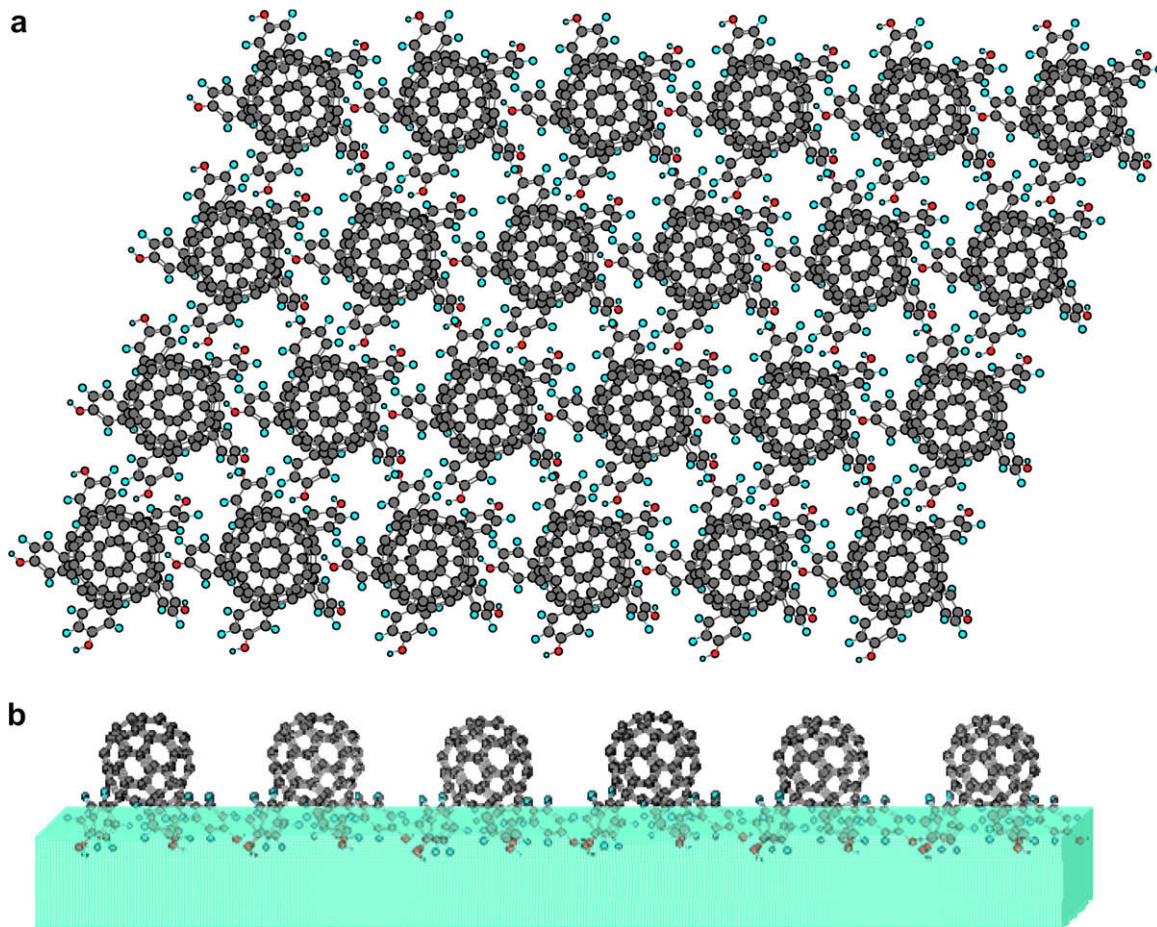
Control experiments were performed using two other fullerene penta-addition derivatives, $(C_6H_5)_5HC_{60}$ and $(4\text{-}CH_3SC_6H_4)_5HC_{60}$. From the pressure-area isotherms, A_0 was 1.98 nm^2 molecule^{-1} for $(C_6H_5)_5HC_{60}$ and


Fig. 4. Schematic arrangement of fullerene pentapods in the LB film. (a) Top view of the molecules showing the phenolic groups of neighboring molecules to interdigitate resulting in close-packing of the molecules. (b) Side view of the molecules showing arrangement at the air–water interface (shown for a single row of molecules).
Fig. 5. Atomic force microscopy picture of the $(4\text{-}HOC_6H_4)_5HC_{60}$ LB film on Au(1 1 1) substrate showing particle height of 1.445 nm.

2.09 nm^2 molecule^{-1} for $(4\text{-}CH_3SC_6H_4)_5HC_{60}$, which correspond to mean diameters of 1.587 nm and 1.631 nm per molecule, respectively. In comparison, the mean diameter of $(4\text{-}HOC_6H_4)_5HC_{60}$ was 1.117 nm per molecule. The large molecular diameters of $(C_6H_5)_5HC_{60}$ and $(4\text{-}CH_3SC_6H_4)_5HC_{60}$ imply that the derivatives are randomly oriented at the air–water interface due to their poor amphiphilic nature.

3.3. I–V measurement

The *I–V* measurements for the LB films of the fullerene pentapods performed using CAFM method [31] with gold as the top and the bottom electrodes is schematically shown in Fig. 6. The LB monolayer exhibited electrical rectification when a positive bias was applied to the CAFM tip (Fig. 7). The *I–V* characteristics showed current rectification at bias voltage of ±1.0 V measured at different monolayer junctions, with high rectification ratios (RR) registered at each junction. The LB monolayer exhibited larger current flow when a positive bias was applied to the CAFM tip. In this condition, current flows from the CAFM tip top electrode to the bottom gold electrode. The direction of electron transport as shown in Fig. 6 is opposite to that seen in previous unimolecular rectifiers using either Al or Au electrodes [6b,6d,6g,7c,14]. Our observation on the direction of rectification is consistent with elastic transport model [32] and opposite to that predicted by Aviram–Ratner inelastic transport model [3].

Fig. 8 represents the *I–V* curves of the pentapod LB film measured up to higher bias voltages of ±1.5 V, ±2.0 V, ±2.5 V, and ±3.0 V. In the bias voltages ±1.0 V, ±1.5 V, and ±2.0 V high current asymmetries were observed with rectification ratios of 1.3–48.0, 2.0–32.6, and 2.0–19.5, respectively. However, further increase of voltage sweep up to
Fig. 6. Schematic representation of the *I–V* measurement of the fullerene pentapod by CAFM. The arrow indicates the direction of electron transport when positive bias is applied to the CAFM tip (top electrode). The Au substrate (bottom electrode) is grounded.

±2.5 V led to gradual increase in current in the negative bias direction with lowering of rectification ratios to 1.0 at ±2.5 V and 0.9 at ±3.0 V. Thus current asymmetricity was substantially reduced for higher voltage sweeps. The best results were obtained at bias voltages of ±1.0 V and ±1.5 V, when there was negligible current flow in the negative bias direction. Current started flowing in the negative direction once the bias voltage exceeded ±1.5 V. The asymmetric nature persisted with gradual lowering of RR and at ±2.5 V the *I–V* curve became symmetrical (RR ≈ 1). A plausible explanation for such behavior is presented (see below).
Fig. 7. *I–V* characteristics of the LB film of the fullerene pentapod showing current rectification at bias voltage of ±1.0 V measured at different junction positions, with high rectification ratios (RR) registered at each junction.

The *I–V* measurements were taken repeatedly by changing the position of the CAFM tip and the rectification ratio for each position was recorded. It was observed that the molecule showed rectification behavior in almost 80% of the devices measured. From the statistical histograms (Fig. 9) the mean rectification ratios were 10.8 and 14.7, at bias voltages of ±1.0 V and ±1.5 V, respectively.

The *I–V* characteristics of LB films from fullerene penta-derivatives, $(C_6H_5)_5HC_{60}$ and $(4\text{-}CH_3SC_6H_4)_5HC_{60}$ were studied. For these molecules no rectification was observed in the same applied tip bias voltage ranges in which the fullerene pentapod $(4\text{-}HOC_6H_4)_5HC_{60}$ showed rectification. Evidently, in the LB films, $(C_6H_5)_5HC_{60}$ and $(4\text{-}CH_3SC_6H_4)_5HC_{60}$ are not as uniformly oriented as the highly amphiphilic $(4\text{-}HOC_6H_4)_5HC_{60}$. Furthermore, the *I–V* characteristics of the alkane thiol SAMs under a similar

experimental set up used for the present study were symmetric with a mean RR value of 1.17 [33a]. Thus, the observed current rectification behavior of $(4\text{-}HOC_6H_4)_5HC_{60}$ is a characteristic attributable to the typical structural feature of the pentapod.

3.4. Mechanism of electron transport

The mechanism of the electron transport is explained by the interaction between the molecular energy levels obtained from the DFT calculation of the fullerene pentapod and the Fermi level of the electrode. Here the work function of Au was taken as −4.6 eV though in the literature there is considerable variation of this value from −4.70 eV to −5.40 eV [34], depending upon the crystal face of Au and the method of measurement.

According to the B3LYP eigenvalues the HOMO and LUMO energies of the free molecule are separated by 2.98 eV, but this separation is expected to be smaller in the actual device as the interaction with the electrodes would broaden the molecular energy levels. At zero bias, the HOMO and HOMO − 1 levels of the free molecule are located ∼0.9 eV below the Fermi level (E_F) of Au, and the LUMO and LUMO + 1 levels are located ∼2.1 eV above the E_F.

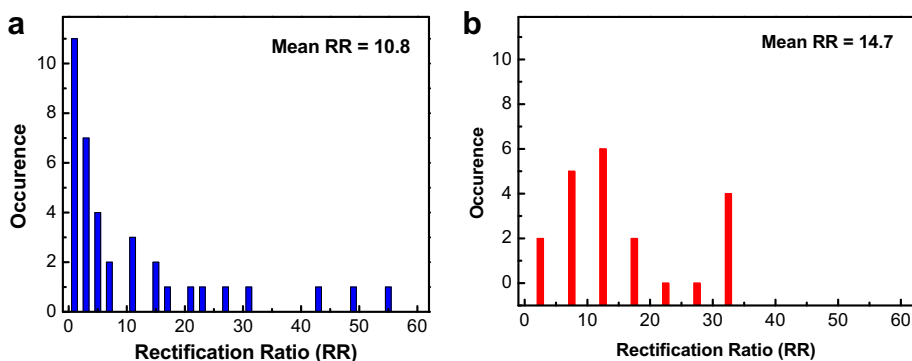
When a bias of +1.0 V is applied to the top electrode, E_F of Au goes down approximately by 1 eV relative to the cathode and becomes −5.6 eV, approaching resonance with the HOMO and HOMO − 1 levels of the molecule ($E_{HOMO} = -5.45$ eV, $E_{HOMO-1} = -5.47$ eV) (Fig. 10). Hence current flow in the forward direction is favored. When a negative bias voltage (−1.0 V) is applied to the top electrode, the E_F of Au goes up to −3.6 eV, and neither the HOMOs nor the LUMOs are aligned with the electrode energy levels, thus impeding current flow in the reverse
Fig. 8. Typical *I–V* plots measured up to a higher bias than ±1.0 V. (a) RR = 12.0 at ±1.5 V, (b) RR = 19.5 at ±2.0 V, (c) RR = 1.0 at ±2.5 V, and (d) RR = 0.9 at ±3.0 V.


Fig. 9. Statistical histograms of rectification ratio data showing mean RR values of (a) 10.8 at ±1.0 V and (b) 14.7 at ±1.5 V.
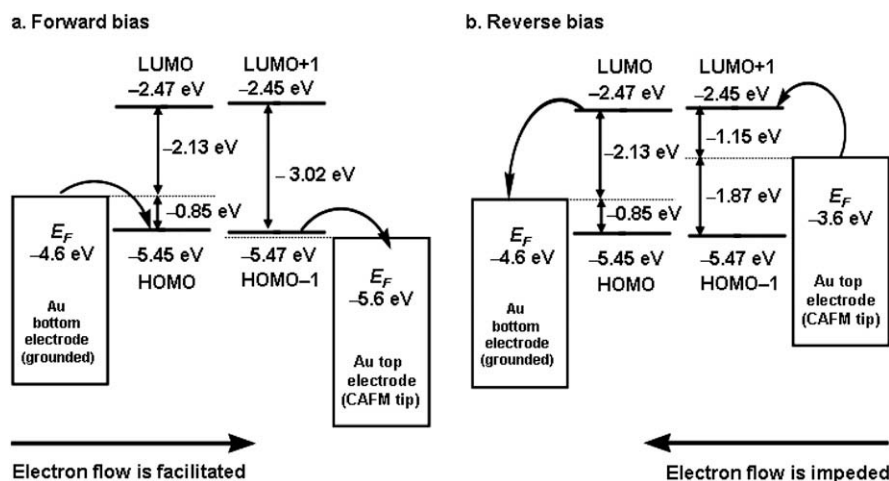

Fig. 10. Energy levels of the device under applied bias voltage. (a) A forward bias voltage of +1.0 V facilitates the electron transport from the bottom Au electrode to the top CAFM tip electrode, and (b) a reverse bias voltage of −1.0 V impedes it in the opposite direction. The HOMO and HOMO − 1 levels are of nearly similar energy and so are LUMO and LUMO + 1. Hence these are shown to take part in the electron tunneling process as though they are degenerate orbitals.

direction. When a bias voltage of +2.0 V is applied (E_F = −6.6 V), lower HOMO levels, such as HOMO − 10 ($E_{HOMO − 10}$ = −6.22 eV), become energetically favorable and participate in the current flow process. At −2.0 V the LUMO levels (E_{LUMO} = −2.47 eV, $E_{LUMO + 1}$ = −2.45 eV) approach resonance with E_F of Au (−2.6 V). Hence, some current starts flowing in the reverse direction as well. Apparently, for higher bias voltages, lower HOMO − X and upper LUMO + X levels had energies aligned to a similar extent with E_F of Au, facilitating current flow in both the directions with equal ease.

It may be pointed out here that the conventional use of the one-electron molecular orbitals from a DFT calculation may be an approximation to the many-electron states that will influence the real transport processes. Nevertheless, it is not actually the reaching of resonances that leads to the rectification but rather the approaching of resonances. Hence the explanation of charge transport in a preferred direction based on alignment of calculated orbital energies with those of the Fermi levels of the electrodes using the present method of computation, though qualitative, is a rational approach at the moment.

Besides, in the present case, there is homo-conjugation [35] between the cyclopentadiene moiety with the rest of the 50 sp^2 carbon atoms of the fullerene and peri-conjugation [36] between the p_z-π orbitals of phenolic groups and orbitals of adjoining fullerene carbon atoms. Thus, the phenolic groups, the cyclopentadiene moiety, and the rest of the fullerene molecule in the pentapod electronically interact. From the B3LYP calculation it was found that the fullerene pentapod has a high ground state dipole moment of 3.23 debye (4.53 debye calculated from PBE), and hence the molecule is quite polar. C_{60} accepts six electrons electrochemically to form hexa-anion whereas oxidation is relatively difficult [37]. The electron affinity of C_{60} is 2.65 ± 0.05 eV and the first ionization potential is 7.58 eV [38]. The values for the hydroxypentapod, calculated using B3LYP/6-31G**, are 1.6 eV and 6.3 eV, respectively (1.7 eV and 5.9 eV from PBE/6-31G**). Thus, the pentapod has retained to a significant extent the characteristic electron-withdrawing ability of C_{60}. Considering that the C_{50} moiety of the pentapod is still strongly electron-withdrawing, the direction of the dipole moment must be towards the fullerene moiety. Besides, the molecule could undergo further

polarization in this direction when a positive bias is applied to the CAFM tip electrode. Hence electron transport in the forward bias condition should be facilitated, as has been actually observed. Similar rectification behavior has been explained by polarization of the electron cloud of the molecule under an applied potential [39].

Three mechanisms, S-, A- or U-types, have been suggested to explain current rectification in metal-organic-metal devices [5,7a]. When the current passing through a molecule involves electron transfer between its own molecular orbitals, or asymmetry in the molecule itself causes asymmetry in current flow it is called the U-type of electrical rectification. Previously, the mechanism of electrical rectification in fullerene derivatives involve electron transfer in which C_{60} acts as an acceptor and exohedral functional groups attached to it act as donors [14,16,26]. The donor is attached to the acceptor by a σ-bond and there is through-bond electron transfer from the HOMO of the donor to the LUMO of the acceptor. However, in the present case, both the HOMO and the LUMO are in the same fullerene cage interacting with each other through homo-conjugation. Under a suitable applied bias, electron from the HOMO level is transferred to the LUMO level through the fullerene cage itself. This is completely a new case observation in the field of molecular rectification of the fullerene derivatives and a novel example of a true U-type unimolecular rectifier.

4. Conclusions

An amphiphilic fullerene pentapod, $(4\text{-HOC}_6\text{H}_4)_5\text{HC}_{60}$, formed well-defined LB film at the air–water interface and constitutes mostly a monomolecular arrangement with C_{60} facing upwards. The LB film transferred over Au(111) substrate afforded a robust structure through anchoring of the five phenolic –OH groups. When the device was subjected to a forward bias using the CAFM tip as the top electrode in contact with the fullerene moiety, electrons moved from the bottom negative electrode to the top electrode through the fullerene molecule. When a negative bias was applied to the CAFM tip electron transport was significantly less in the opposite direction. The rectification was appreciable up to an applied bias of ±2.0 V; decreasing thereafter until at ±2.5 V there was no rectification. Two other fullerene derivatives, $(C_6\text{H}_5)_5\text{HC}_{60}$ and $(4\text{-CH}_3\text{SC}_6\text{H}_4)_5\text{HC}_{60}$, did not show any electrical rectification. These molecules are not as uniformly oriented on the substrate surface in contrast to $(4\text{-HOC}_6\text{H}_4)_5\text{HC}_{60}$. Thus, $(4\text{-HOC}_6\text{H}_4)_5\text{HC}_{60}$ constitutes a new class of molecule, in which the donor HOMO and acceptor LUMO levels are on the same fullerene cage and hence represent true unimolecular U-type rectifier.

Prediction of the current versus voltage behavior of devices based on organic semiconductor guest–host systems

Fredrik L.E. Jakobsson, Xavier Crispin *, Magnus Berggren

Department of Science and Technology (ITN), Linköping University, S-60174 Norrköping, Sweden

ABSTRACT

Organic semiconductor blends are commonly used in organic based (opto-) electronic devices. They are composed of two types of (macro-) molecules, referred to as the guest and host. To achieve optimum device operation, the chemical nature, electronic structure, molecular order and the relative concentration of the guests and host are crucial. Here, we present simulation results of the current density versus the voltage (J–V) behavior of a two terminal device based on a variable-range hopping model in which the electronic states of the guest and host are represented by two Gaussian distributions. The J–V behavior is investigated for various energetic mismatches between guest and host states, widths of the distribution as well as the guest concentrations. Finally, a simple tool enabling easy prediction of the J–V behavior of organic host–guest diodes is derived.

1. Introduction

The introduction of guest molecules into a host matrix has become a successful approach to improve efficiency and to define new functionalities of organic electronic devices. For instance, blending donor and acceptor materials improves exciton dissociation and enables high-efficiency of photovoltaics [1]. Blending phosphorescent dyes into an electroluminescent matrix provides harvesting of triplet states, thus improving the efficiency of light-emitting diodes [2,3]. Tuning the emission wavelength in light-emitting diodes and lasers have been achieved in tailor-made blends combining luminescent dyes, or inorganic nanoparticles, and organic semiconductors [4,5]. Switchable charge

traps have been demonstrated in diodes consisting of blends of a semiconductor host and photochromic guest molecules [6,7].

Organic electronic devices are commonly fabricated in less rigorously controlled environments than traditional inorganic electronic devices, increasing the risk of contamination of the materials. Moreover, organic materials are prone to degradation if not processed and operated in inert atmosphere and under proper light conditions. The resulting organic semiconductor can be regarded as an unintentional blend of a pristine intrinsic material, the host, and an ensemble of impurity molecules or degraded molecules considered as the guest.

Several factors govern charge transport in host–guest systems. First, if the highest occupied molecular orbital (HOMO) of the guest molecule (lowest unoccupied molecular orbital, (LUMO)) is above (below) the HOMO (LUMO) of the host molecule, the guest site is energetically more favorable for holes (electrons). Therefore, in a device at thermal

equilibrium, the guest sites have a higher probability to be occupied than the host sites; the guest sites acts as a traps for the charge carriers (Fig. 1a) [8]. Second, a guest molecule with a large dipole moment reshapes the surrounding electrostatic landscape due to charge-dipole interactions. The energy of some host sites near the guest is lowered, and these sites might act as traps for carriers (Fig. 1b) [7,9]. Note however, dipole-charge interaction acts over a long range, which results in a smoother transition from the unperturbed host energy levels to the bottom of the trap. Therefore it is reasonable to assume that dipole traps might be less severe than energy level traps. Finally, in a situation where the host and guest have similar transport energy level, the difference in charge hopping rate between guess-host and host-host transitions can affect the charge transport behavior. This can originate from a different electronic coupling between guest–host and host–host, or reorganization energy between hosts and guests [10].

In order to optimize organic host–guest systems for (opto-) electronic devices, it is highly desirable to understand and to be able to predict the current-voltage behavior of devices. In this report, we focus on the case of guests acting as energy level traps and investigate how they affect the J–V behavior diodes (Fig. 1a). We assume that the dipole moments of the guest and host molecules are similar, so that the electrostatic potential felt by the host molecules is not affected by the presence of guest molecules. Furthermore, the electronic coupling between the guest and host are considered to be the same as between hosts.

In general, the J–V behavior of diodes in the presence of traps can be divided into three regimes (Fig. 1c). At low voltages (trap-limited regime (i)), the carrier concentration is significantly lower than the trap concentration. The traps are to a large extent empty and therefore the transport is strongly limited by the traps. In this regime the current density is low and proportional to V^2 and the mobility is approximately constant. For higher but intermediate voltages (trap-filling regime (ii)), the carrier concentration is high enough to increase significantly the occupancy of the traps. Equivalently, the Fermi level, E_F, is shifted towards higher energies and moves through the trap distribution. The sites that are below E_F are filled and do not contribute to the transport anymore. In other words, there are fewer active trap states to limit the mobility. Therefore the current density is increased rapidly in this region, with J–V^β and $\beta \gg 2$. β increases as the energy distribution of the trap levels is widened. As E_F is shifted above the energy levels of the traps practically all trap states are filled and the mobility is no longer suppressed by trapping (trap-free regime (iii)). In this regime, the current density follows the familiar J–V^2 behavior in the case of an otherwise constant mobility. The voltage at which the J–V behavior transits from the trap-filling to the trap-free behavior is traditionally called the trap-filled limit, V_{TFL}.

An analytical relation for the J–V behavior in the trap-filling regime was first deduced by Mark et al. [11], assuming an exponential distribution of traps extending into the band gap from the conduction band edge and freely moving carriers in the conduction band. The resulting J–V behavior follows a J–V^{r+1}/t^{2r+1} dependence, where $r = T_t/T$ is a measure of the width of the trap distribution and t is the thickness of the active layer of the device, see Fig. 1d. This model was recently extended by Mandoc et al. [12] to the case of a Gaussian distribution of the host states and an exponential distribution of the guest states, energetically well below the distribution of host states. Several numerical models have been suggested to describe the J–V behavior over the whole voltage range (i.e. for all charge transport regimes) [13–19]. The common denominator in those models is the concept of multiple-trapping [8]; i.e., the carriers move in extended states, with constant mobility, but are repeatedly trapped and released. At any given moment only carriers that are free, i.e. that does not reside at a trap site, contribute to the charge transport. Using this approach, the device behavior have been investigated for several archetypal trap distributions; e.g. discrete- [19], exponential- [17] and Gaussian- [13] trap distributions. A disadvantage with multiple-trapping models is the need to distinguish between trapped and free carries. In disordered organic materials all states are localized and there are no free charge carriers. Therefore, the concept of trapped and free carriers is ambiguous for these materials.

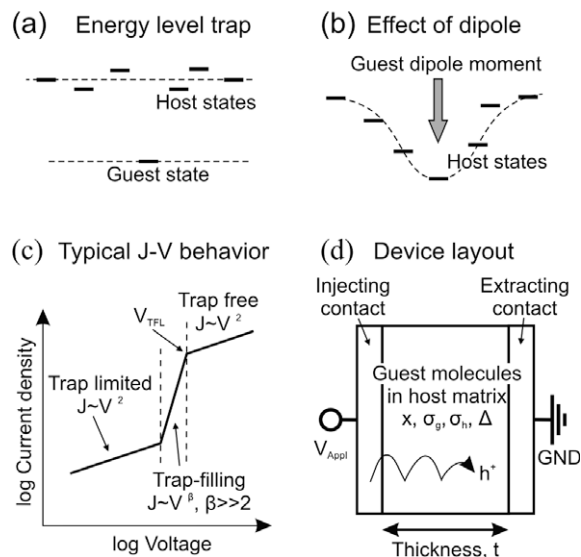
In this report, we use a carrier concentration dependent mobility model derived by Martens et al. [20] and further elaborated on by Coehoorn et al. [21,22]. In this model all carriers reside in a density of states (DOS) composed of states from the guest and the host. In this way, the occupancy of the states is explicitly taken care of in the mobility model and the concept of trapped versus free carriers is circumvented. Both the host and the guest states are represented with a Gaussian DOS distribution, and the total DOS equals the sum of the two Gaussians, see Fig. 2a. We investigate the impact of (i) the width of the Gaussian guest- and host DOS (Fig. 2b), the position of the center of the guest DOS


Fig. 1. Frontier energy levels of the organic semiconductor host–guest system where the guest molecule creates a charge trap: (a) either because its frontier level is more stable than the host; (b) or because its strong dipole moment perturbs the electrostatic landscape of the host. The general J–V characteristic of a device with one type of charge traps is depicted in (c). In (d) the device layout is shown.
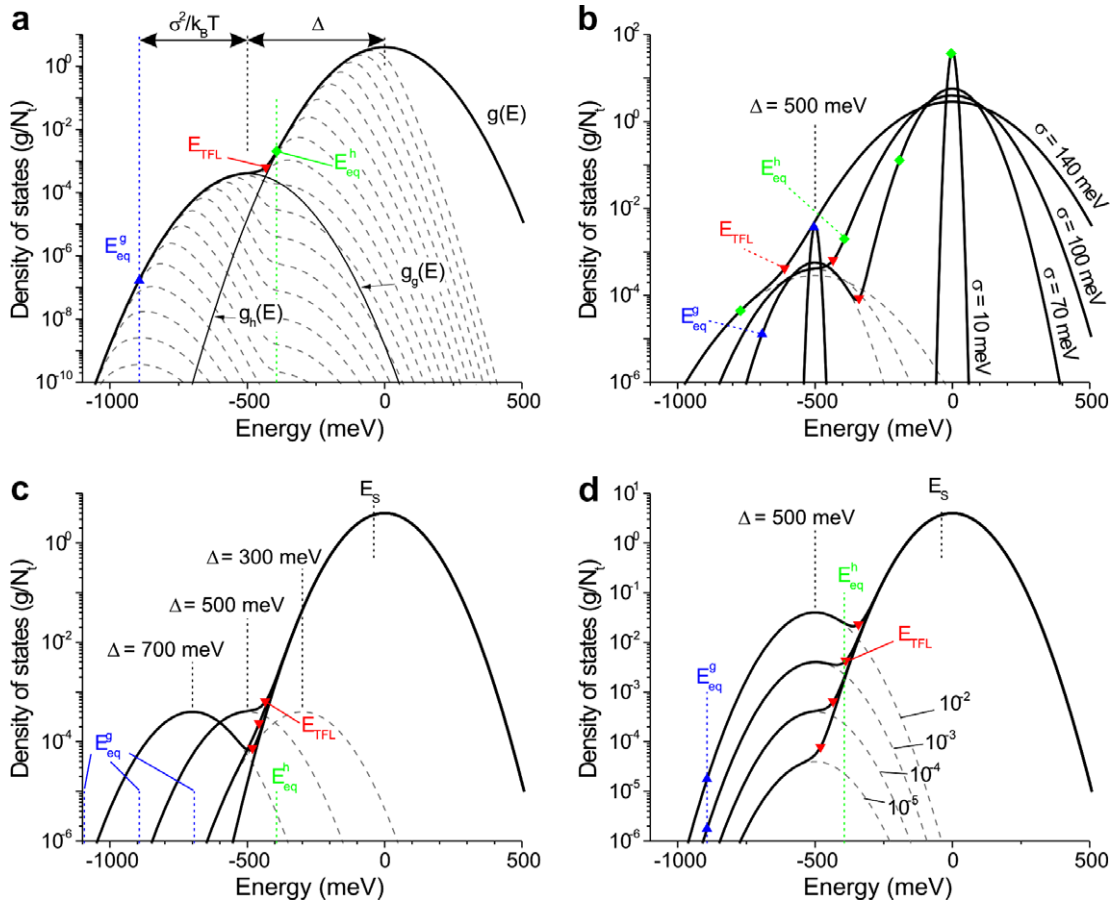

Fig. 2. (a) The total density of states, g(E), consists of the sum of the host DOS, $g_h(E)$, and the guest DOS, $g_g(E)$. In this case $\sigma_g = \sigma_h = 100$ meV, $\Delta = 500$ meV and $x = 10^{-4}$. This gives $E_{TFL} = -434$ meV, $E^h_{eq} = -394$ meV and $E^g_{eq} = -894$ meV. The ODOS is shown in dashed lines, starting with $E_F = 0$ meV for the rightmost ODOS and with decreasing E_F by 50 meV for each successive ODOS. The effects of various parameters of the organic host–guest system on the device behavior are investigated; (b) the width σ of the DOS; (c) the energy difference Δ (or trap depth) between the guest DOS and the host DOS; and, (d) the guest concentration x. In (b), (c) and (d) the total DOS is plotted in bold and the guest DOS is plotted in dashed lines. E_S is the position of the optimal transport energy, E_{TFL} marks the trap-filled limit (red down triangles). E^g_{eq} (blue up triangles) and E^h_{eq} (green rhombs) are the guest- and host equilibrium energy, respectively. with respect to the host DOS (Fig. 2c) and the concentration of guests (Fig. 2d).

2. Methodology

2.1. Mobility model

The Martens model [20] is an extension of the variable-range-hopping model introduced by Mott [23] but for arbitrary density of states. Despite its relative simplicity, the mobility is in good agreement with more sophisticated models [21,22]. The total DOS, g(E), is the sum of the guest- and host-Gaussian DOS:

$$g(E) = g_h(E) + g_g(E)$$
$$= \frac{(1-x)N_t}{\sqrt{2\pi}\sigma_h} \exp\left(-\frac{E^2}{2\sigma_h^2}\right) + \frac{xN_t}{\sqrt{2\pi}\sigma_g} \exp\left(-\frac{(E+\Delta)^2}{2\sigma_g^2}\right)$$
(1)

where $g_h(E)$ and $g_g(E)$ are the host and guest DOS, respectively; x is the concentration of guest sites, and N_t is the total density of sites. $(1-x)N_t$ and xN_t are the density of host and guest sites; σ_h and σ_g are the width of the host and guest distributions. Δ is the energy difference between the center of $g_g(E)$ and $g_h(E)$ (Fig. 2a). The energy disorder is assumed to be mainly due to electrostatic fluctuations arising from molecular electric dipoles or quadrupoles [24,25]. Furthermore, the guest molecules are considered to be well dispersed in the host matrix, i.e. no phase separation. Also, the guest and host molecules experience the same electrostatic environments and the width of both DOS distributions can be assumed to be the same ($\sigma_g = \sigma_h = \sigma$).

The charge transport is governed by carriers hopping from an initial state near the Fermi level, E_F, to a final state lying at an optimal transport energy, E_S, over an optimal spatial hopping distance, R_s. The activation energy for the hopping process can be defined as $E_A = E_S - E_F$. Given the carrier concentration, p, the Fermi level is found by solving:

$$p = \int_{-\infty}^{\infty} g(E) f_{FD}(E, E_F) dE \qquad (2)$$

where f_{FD} is the Fermi-Dirac distribution. The mobility is given by:

$$\mu = \frac{\sigma_0}{ep} \exp\left(-\alpha R_s - \frac{E_F - E_s}{k_B T}\right) \qquad (3)$$

where e is the elementary charge, T is the temperature and σ_0 is a constant prefactor. α is the inverse localization length and describes the spatial extent of the localized state. α^{-1} is proportional to the decay of the electronic density away from the molecules. In all simulations, $\alpha = (0.1a)^{-1}$ and $N_t = a^{-3}$, where a is the average site-to-site distance and is assumed to be $a = 1$ nm.

According to Mott's model, there is only one state to hop to within the optimal hopping distance R_s with energy lower than the optimal transport energy, E_s. In other words within the volume $V_s = 4\pi R_s^3/3$, there is only one available (i.e. one unoccupied) final state with energy less than E_s. This can also be expressed as $V_s N(E_s) = 1$, where $N(E_s)$ is the number of available final states per unit volume with energy less than E_s. Coehoorn et al. [22] have suggested that this should be modified to $V_s N(E_s) = B$ in order to take into account the percolative nature of charge transport in organic disordered materials. B is a parameter introduced to represent the average number of sites within the volume when percolation is achieved. In this study, $B = 1.969$ is used as suggested by Coehoorn.

The mobility is found by optimizing the right-hand side of Eq. (3) with respect to R_s and E_s. In the case of a bi-modal Gaussian distribution, this translates into first solving the following Eq. (4) to get E_s:

$$\frac{\sqrt{\frac{2}{9\pi}}\left(\frac{3B\alpha^3}{2\pi N_t}\right)^{\frac{1}{3}}\left((1-x)\exp\left(-\frac{E_s^2}{2\sigma_h^2}\right) + x\frac{\sigma_h}{\sigma_g}\exp\left(-\frac{(E_s+\Delta)^2}{2\sigma_g^2}\right)\right)}{\left((1-x)\left(erf\left(\frac{E_s}{\sqrt{2}\sigma_h}\right) - erf\left(\frac{E_F}{\sqrt{2}\sigma_h}\right)\right) + x\left(erf\left(\frac{E_s+\Delta}{\sqrt{2}\sigma_g}\right) - erf\left(\frac{E_F+\Delta}{\sqrt{2}\sigma_g}\right)\right)\right)^{\frac{4}{3}}}$$
$$-\frac{\sigma_h}{k_B T} = 0 \qquad (4)$$

R_s is then given by the relation $V_s N(E_s) = B$:

$$R_s = \left(\frac{3B_M}{2\pi N_t} \middle/ \left((1-x)\left(erf\left(\frac{E_s}{\sqrt{2}\sigma_h}\right) - erf\left(\frac{E_F}{\sqrt{2}\sigma_h}\right)\right)\right.\right.$$
$$\left.\left. + x\left(erf\left(\frac{E_s+\Delta}{\sqrt{2}\sigma_g}\right) - erf\left(\frac{E_F+\Delta}{\sqrt{2}\sigma_g}\right)\right)\right)\right)^{\frac{1}{3}} \qquad (5)$$

Finally, the mobility is found by inserting E_S and R_S into Eq. (3).

For a given σ, a realistic carrier concentration for diodes ($p < 10^{-3}N_t$) and at low- to moderate guest concentrations ($x < 10^{-2}$), both R_S and E_S are to a very good approximation constant and are positioned slightly below the center of the host DOS. Physically, this means that the final state of the jumps is within the host distribution, and therefore the limiting processes for charge transport are guest-to-host or host-to-host jumps. As the guest concentration is increased above $x \sim 10^{-1}$, E_s shifts towards the center of the guest DOS (towards $-\Delta$), indicating that hopping directly between guest states becomes important. In this paper, we assume that the guest concentration is low enough

so that direct guest-to-guest hopping can be neglected, i.e. $x < 10^{-2}$. In this case, both R_s and E_s are nearly constant and therefore the carrier concentration dependence of the mobility originates from the dependence of E_F on p, and from the relative position of E_F to E_s.

In general, the charge carrier mobility in disordered organic semiconductors depends on both the charge carrier concentration and the electric field. In the above described model by Martens, the charge carrier concentration dependence of the mobility is well modeled, while the effect to of the electric field is neglected. In our study, the charge carrier concentration is the most important parameter for the mobility in order to understand the effect of filling of deep guest (trap) states on the J–V behavior. Furthermore, the carrier concentration dependence of the mobility is much stronger than the electric field dependence in disordered organic materials at low and intermediate fields [26]. Deviations from the calculated J–V behavior can be expected at low temperatures due to the effect of the electric field on the activation barrier for charge hopping. To avoid that, all calculations are performed for a temperature set to 295 K.

2.2. Simulation of the J–V behavior

This study is restricted to the case of a single carrier device, consisting of a single organic host–guest layer with ideal ohmic contacts. The contacts can supply the bulk with unlimited amount of charges, i.e. the current is only limited by the charge transport phenomenon in the bulk of the organic material. The J–V behavior is found by simultaneously solving the drift-diffusion equation:

$$J = ep(x)\mu(p(x))E(x) - eD(p(x))\frac{dp(x)}{dx} \qquad (6)$$

and the Poisson's equation:

$$\frac{d^2\Psi(x)}{dx^2} = -\frac{e}{\varepsilon_0 \varepsilon_r} p(x) \qquad (7)$$

where ε_r and ε_0 are the relative permittivity and the permittivity of vacuum, respectively; and, Ψ is the electric potential. The diffusion coefficient is estimated through the Einstein relation $D = (k_B T/q)\mu$.

Ohmic contacts are modeled by assuming that the carrier concentration at both contacts is fixed at a sufficiently high value. No difference to the solution of Eqs. (6) and (7) is found for carrier concentrations greater than $p = 10^{25}$ m^{-3}, and therefore this carrier concentration is used as the boundary conditions at the contacts. The voltage is applied to the injecting contact and the extracting contact is grounded. These four boundary conditions can be summarized as: (i) $\Psi(0) = V_{Appl}$; (ii) $\Psi(t) = 0$; (iii) $p(0) = p_0$; and (iv) $p(t) = p_0$, where $p_0 = 10^{25}$ m^{-3} and t is the thickness of the organic layer. To eliminate the effect of filling of deep states due to diffusion from the electrodes into very thin films [15,27], all simulations have been performed for 300 nm-thick organic layers. In the following discussion, the carrier concentration in the middle of the device (i.e. $p(x = t/2)$) is considered if not else explicitly stated.

3. Results and discussion

3.1. General features of the modeled J–V behavior

3.1.1. J–V behavior in the absence of guests

In order to identify the effect of guests, it is illustrative to first consider the simple case of a single-compound system. This corresponds to a pristine host system, without guests, described by a single Gaussian DOS (Fig. 3a). To visualize the occupation of the DOS, the occupied density of states (ODOS = product of the Fermi-Dirac distribution and the DOS) is also plotted. The evolution of the mobility versus charge carrier concentration is depicted in Fig. 3c (dashed line); while the expected J–V behavior is shown in Fig. 3d (dashed line).

Let us first assume that the majority of the carriers, contributing to the charge transport, have their initial states close to the maximum of the ODOS and their final states for hopping at the transport level E_S. At high carrier concentrations, the maximum of the ODOS is to a good approximation near E_F. Hence, an increase of the carrier concentration is accompanied by a shift of E_F (and the maximum of the ODOS) towards higher energy, thus reducing the activation energy defined by E_F–E_S; the mobility increases with p.

However, at low carrier concentration, the increase of the Gaussian DOS matches the fall-off of the Fermi-Dirac distribution, in such a way that the ODOS peak stays in the same position at the so-called equilibrium energy, given by $E_{eq} = -\sigma^2/k_B T$ [28]. In this case, the activation energy for transport is instead given by E_{eq}–E_S. Since both E_{eq} and E_S are constant with p, the activation energy is constant; the mobility is independent of p. This regime of constant mobility occurs when E_F is several $k_B T$ below E_{eq}. This can also be understood mathematically by replacing the Fermi-Dirac distribution in Eq. (2) with the Boltzman distribution, which is a reasonable approximation for low values of p. The resulting carrier concentration is proportional to $p \sim \exp(E_F/k_B T)$; and consequently, the E_F–dependences in Eq. (3) cancel out and the mobility becomes constant. Note that this is a property of the Gaussian shape of the DOS [22], and it is in general not the case for an arbitrary shape of the DOS. For example, in the case of an exponential DOS, the maximum of the ODOS follows E_F also for small carrier concentrations and there is no well-defined E_{eq}.

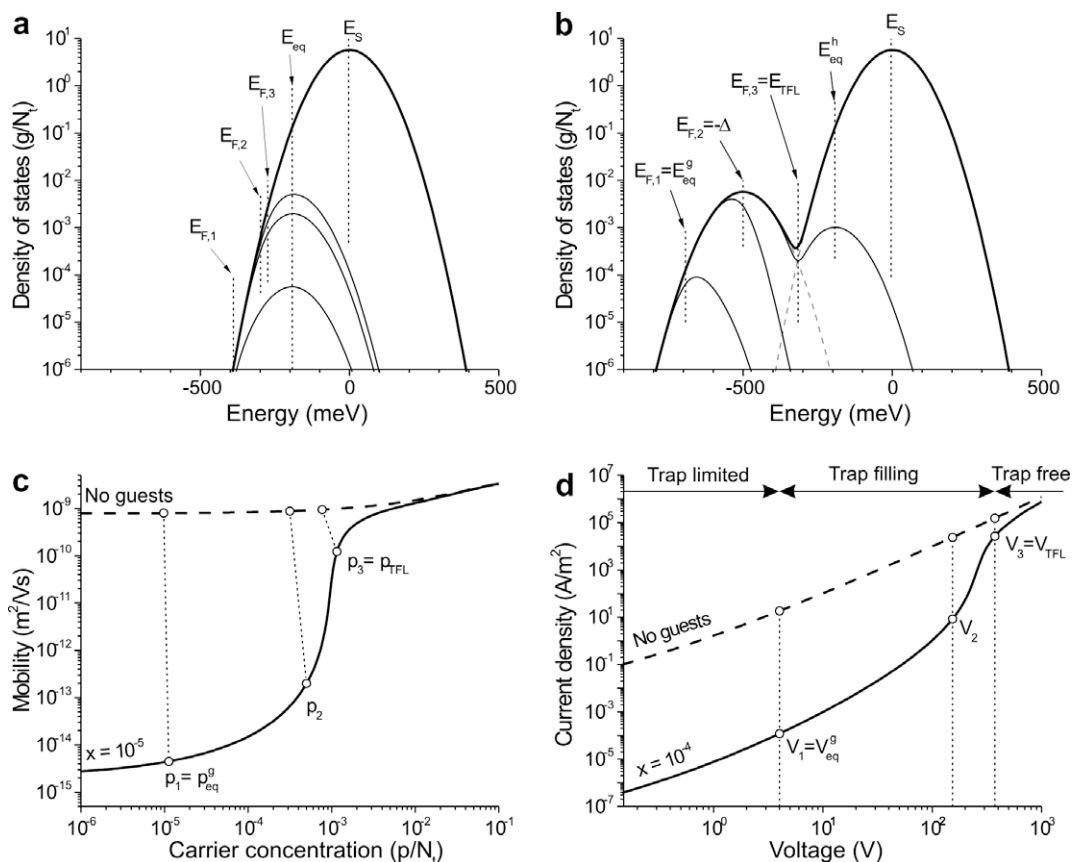
E_F is below E_{eq} for the entire voltage range in Fig. 3d (dashed line) and therefore the mobility is approximately constant. As a consequence, the J–V behavior follows the J–V^2 behavior described by the Mott-Gurney law. Note that


Fig. 3. (a) The DOS of an organic layer without guests, i.e. composed only of similar molecular levels with a certain disordered represented by the width σ = 70 meV of the Gaussian. (b) The DOS of a host–guest system described by the sum of a Gaussian host DOS and a Gaussian guest DOS located 500 meV below the center of the host DOS. Mobility and J–V behavior for the case with and without guest (c and d). Three marked Fermi-levels in (a) and (b) corresponds to the three carrier concentrations in (c) and the three voltages in (d). Note that the voltage range in (d) is much wider than what is accessible in an experiment.

in the case of Fig. 3d the width of the Gaussian DOS is only σ = 70 meV, i.e. at the lower limit reported for organic disordered materials [29]. As disorder increases the mobility becomes dependent on the carrier concentration at lower voltage, resulting in a deviation from the Mott-Gurney behavior.

3.1.2. The J–V behavior in presence of guests

Fig. 3b shows the DOS of a host–guest system described by a bi-modal Gaussian distribution. The mobility versus carrier concentration and the J–V behavior are displayed in Figs. 3c and d (solid line). The presence of guests does not modify the average density of charge carriers significantly but strongly changes the energy distribution of the carriers. The presence of guest states shifts the ODOS towards lower energy, which results in a lower E_F for the same carrier concentration as in the guest-free case. As a consequence, the activation energy for hopping increases and the mobility diminishes (Fig. 3c). The overall change in mobility due to the presence of guests depends on the degree of deformation of the total DOS caused by the guest states.

In order to explain qualitatively the mobility dependence on the carrier concentration in host–guest systems, we use a similar approach as adopted for the guest-free case. The carrier concentration sets the position of the Fermi level with respect to the defined equilibrium energy. The latter is an indicator to identify the region of constant mobility. For the host–guest system, two different equilibrium energies are worth defining (Fig. 3b):

$$E_{eq}^g = -\Delta - \sigma^2/k_B T \tag{8a}$$
$$E_{eq}^h = -\sigma^2/k_B T \tag{8b}$$

At sufficiently low carrier concentrations, the maximum of the ODOS is in the guest DOS at E_{eq}^g, and the mobility is constant as long as $E_F < E_{eq}^g$. Since E_{eq}^g is lower in energy than E_{eq} in absence of guests, the transition to a carrier dependent mobility occurs at lower E_F or equivalently at lower carrier concentrations as compared to the guest-free case. When E_F is shifted above $-\Delta$ (E_{F2}), the density of states starts to decrease again. As a consequence, a small change in carrier concentration results in a larger shift of E_F and thus a reduction of the activation barrier for the jumps (E_F–E_S). Therefore, the mobility increases strongly with carrier concentration in this region of the DOS. As the guest states are filled up, the ODOS moves into the part of the total DOS that is dominated by host states ($E_F = E_{F3}$). If the host and guest DOS are well separated and if the guest concentration is low, there is an intermediate carrier concentration regime where the mobility again becomes approximately independent on p. This occurs when E_F has passed into the host DOS but is still several $k_B T$ below E_{eq}^h. If E_F is increased above E_{eq}^h the mobility again becomes dependent on the carrier concentration.

At low voltages ($V < V_1$ in Fig. 3d), the carrier concentration is low and the carriers occupy states within the tail of the guest DOS, near E_{eq}^g. Hence, p is in the Boltzmann limit, the activation energy for hopping is high, and the mobility is effectively constant and low. This corresponds to the trap-limited regime. As the voltage is increased, E_F is shifted above E_{eq}^g, and the mobility becomes strongly carrier con-

centration dependent. This corresponds to the trap-filling regime. The increase in mobility results in a steeper slope of the J–V behavior, peaking at $V = V_2$ before it increases less steeply again. At even higher applied voltages ($V > V_3$), the guest states start to be filled up significantly, such that E_F transits into the part of the DOS dominated by the host states. At this point the slope of the J–V curve is reduced and the behavior approaches the trap-free case. This corresponds to the trap-free regime.

Since the DOS is not a discrete function, the filling of the guest states is a continuous process. Therefore the transition from the trap-filling regime to the trap-free regime is smooth and the definition of a trapped-filled limit, V_{TFL}, is ambiguous. We have chosen to define V_{TFL} as the voltage when E_F is equal to the crossing point, E_{TFL}, between the individual guest- and the host DOS. At E_{TFL}, the guest DOS and host DOS has the same magnitude; the initial states for hopping is equally probable to be a guest state as a host state. When E_F is further increased, the transport process becomes dominated by charge carriers hopping from states within the host DOS, i.e. by host-to-host hopping. Assuming that $\sigma_g = \sigma_h = \sigma$, it is straight-forward from $g_g(E_{TFL}) = g_h(E_{TFL})$ to derive the following expression for E_{TFL}:

$$TFL = \frac{\sigma^2}{\Delta} \ln\left(\frac{x}{1-x}\right) - \frac{\Delta}{2} \tag{9}$$

Note that the definition of E_{TFL} and E_{eq}^g is only meaningful as long as $E_{TFL} > E_{eq}^g$, since otherwise the difference between the trap-limited and the trap-free regimes vanishes and the guests do no longer act as traps. Above the V_{TFL}, the J–V behavior approaches the trap-free case.

The evolution of the J–V behavior as states are filled in the DOS can be summarized by:

(1) Trap-limited regime ($E_F < E_{eq}^g$; i.e., $V < V_{eq}^g$): the ODOS is in the tail of the guest DOS and the mobility is approximately constant.
(2) Trap-filling regime ($E_{eq}^g < E_F < E_{TFL}$; i.e., $V_{eq}^g < V < V_{TFL}$): the mobility is strongly p-dependent and the slope of the logJ–logV is larger than
(3) Trap-free regime ($E_{TFL} < E_F$; i.e., $V_{TFL} < V$): Most guest states are filled and the J–V behavior approaches the trap-free case.

There are two appealing reasons for this definition of the three different regimes. First, both E_{eq}^g and E_{TFL} are well-defined, which circumvents the problem with ambiguous definitions conceivable in the case of smooth transitions as with disordered materials [30]. Second, this definition is consistent with the traditional definition of the regimes, in that J follow a V^2–relationship (since the mobility is constant) in the trap-limited and trap-free regimes, and follows a considerably stronger V-dependence in the trap-filling regime.

3.2. J–V behavior and mobility for various shapes of the DOS

In the following sections the J–V behavior for varying shape of the DOS is investigated. The width of the Gaussian DOS (σ), the energy difference between the frontier levels

of the guest and host molecules in the blend (Δ) and the concentration of guest molecules in the host matrix (x) is varied one at a time.

3.2.1. Influence of the Gaussian DOS width

Tuning the width of the Gaussian partial DOS for host and guest molecules (Fig. 4a) is a way to simulate the importance of energetic disorder in molecular host–guest systems. In the case of a very ordered and homogeneous system (σ = 10 meV), E_F shifts negligibly until the guest DOS is almost filled. When the carrier concentration is further increased, the charge carriers start to occupy the host states, resulting in an abrupt shift of E_F into the host DOS. As a consequence, the activation barrier for jumps (i.e. E_S–E_F) is dramatically reduced and the mobility becomes significantly enhanced (Fig. 4b). In the J–V behavior, this appears as a narrow trap-filling regime and a steep transition from the trap-limited to the trap-free regime (Fig. 4c).

When disorder is increased to a realistic value for organic semiconductors (70–140 meV [26,29]), the trap-filling regime becomes stretched out, and the slope of the J–V behavior in the trap-filling regime becomes less steep. Since the range of carrier concentration is still the same ($10^{-6}N_t < p < 10^{-3}N_t$), the impact on the diode J–V behavior becomes less dramatic. This implies that as σ becomes larger, the J–V behavior becomes less sensitive to the presence of the guest DOS. As σ is increased, E_{eq}^g is shifted towards lower energy. Therefore, for σ > 100 meV the trap-limited regime is most likely not accessible within the electric field span of real experiments.

3.2.2. Influence of the host–guest energy mismatch

The impact of Δ on the J–V behavior depends on the width of the distributions (σ). If Δ is small compared to σ, the guest DOS is almost entirely engulfed in the host DOS and the associated effect on the charge transport is small. In Fig. 5a, four different cases are shown: no guests, Δ = 300 meV, 500 meV and 700 meV for σ = 100 meV and $x = 10^{-4}$. The host states are completely dominating the DOS when $\Delta \leqslant 300$ meV (i.e. $\sigma/\Delta \leqslant 3$). In this case, the shape of the ODOS and the position of E_F follow that of the guest-free case when V is varied. As a result, guests have very little impact on both the mobility (Fig. 5b) and the J–V behavior (Fig. 5c). For Δ values larger than 300 meV, the guest DOS is now clearly visible in the total DOS. The ODOS and E_F are at lower energy as compared to the guest-free case, resulting in an increased activation barrier for hopping and a reduced mobility. Increasing Δ from 300 meV to 500 meV decreases the current density in the trap-limited regime with three orders of magnitude and increases the slope of the log J vs. log V curve from 4.5 to 16.5 in the trap-filling regime.

3.2.3. Influence of the guest concentration

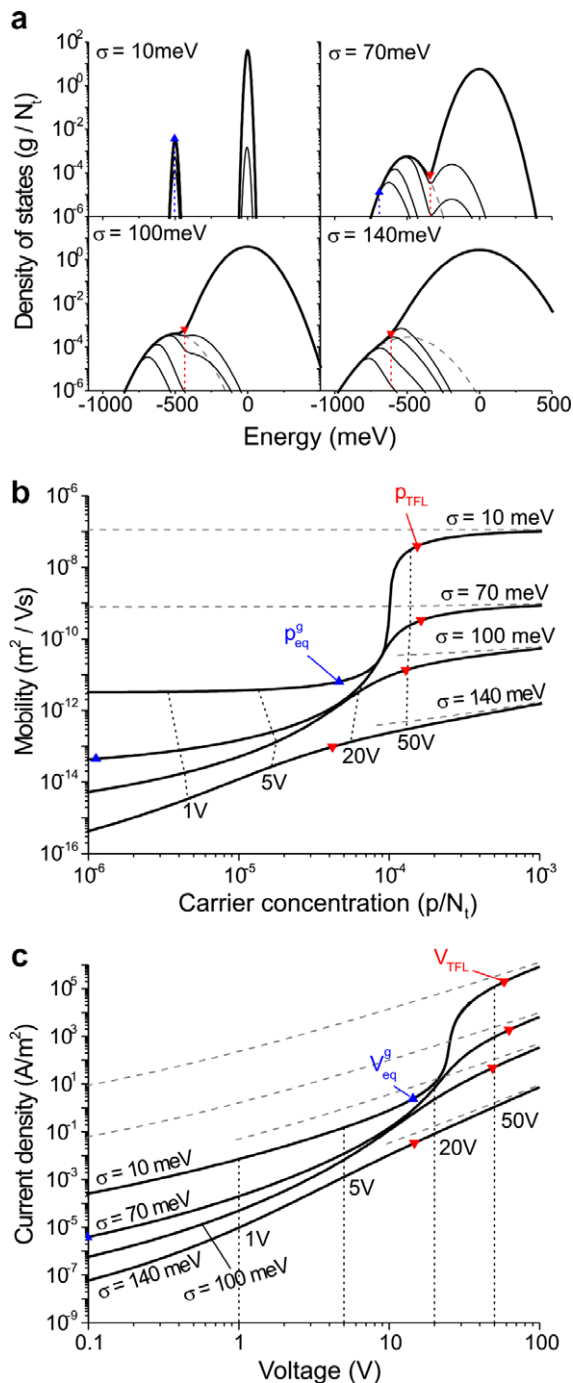
As the guest concentration is increased, the shoulder in the total DOS grows (Fig. 6a). This is accompanied with a shift of the μ–p curve towards higher carrier concentration values (Fig. 6b) and a dramatic drop of the mobility for low charge carrier concentration. The shift of the p-dependent mobility implies that the trap-limited and trap-filling re-


Fig. 4. The progression of the J–V behavior for σ = 10 meV, 70 meV, 100 meV and 140 meV. The DOS is shown in (a), and the mobility and J–V behavior in (b) and (c). The guest equilibrium point E_{eq}^g and trap-fill limit E_{TFL} are marked with blue up triangles and red down triangles, respectively. The mobility and J–V behavior in the absence of guests are shown in dashed. The ODOSs in (a) and the mobilities and concentrations at the dotted lines in (b) corresponds to the voltages at the dotted lines in (c), i.e. V = 1 V, 5 V, 20 V and 50 V.

gimes extend into higher carrier concentrations. When the carrier concentration reaches the same order of magnitude as the guest concentration, the mobility starts to increase
Fig. 5. The progression of the J–V behavior for $\Delta = 0$ meV, 300 meV, 500 meV and 700 meV, for $\sigma = 100$ meV and $x = 10^{-4}$. The DOS is shown in (a) and the mobility and J–V behavior in (b) and (c). The ODOSs in (a) and the mobilities and concentrations at the dotted lines in (b) corresponds to the voltages at the dotted lines in (c), i.e. $V = 1$ V, 5 V, 20 V and 50 V. The trap-fill limit and the host equilibrium point are marked with red down triangles and green diamonds, respectively. In this case the guest equilibrium point occurs for very low carrier concentrations and is therefore not visible in the figure.

Fig. 6. The progression of the J–V behavior for $x = 10^{-5}$, 10^{-4}, 10^{-3} and 10^{-2}, for $\sigma = 100$ meV and $\Delta = 500$ meV. The DOS is shown in (a) and the mobility and J–V behavior in (b) and (c). The ODOSs in (a) and the mobilities and concentrations at the dotted lines in (b) corresponds to the voltages at the dotted lines in (c), i.e. $V = 1$ V, 5 V, 20 V and 50 V. In all the graphs, the trap-fill limit is marked with a red down triangle and the guest equilibrium limit is marked with a blue up triangle. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article).

towards the guest-free value and eventually reaches the value of the trap-free regime. The J–V behavior in Fig. 6c follows the mobility behavior. At 5 V, the current density is

two orders of magnitude lower with a guest concentration of $x = 10^{-4}$ than in the guest-free case. V_{TFL} is shifted from

6.4 V to 48.6 V when the guest concentration is changed from $x = 10^{-5}$ to 10^{-4}.

It is worth noting two limiting cases for the example considered. First, it is unlikely that the trap-filled limit can be reached for $x > 10^{-2}$ in a diode configuration since the diode would likely break down before the transition is reached. Second, for very low guest concentrations ($x < 10^{-4}$), the current transition is so smooth that it is hardly discernable. Note that if the guest concentration is increased above $x > 10^{-2}$, guest-to-guest hopping eventually starts to dominate the charge transport process. Assuming that the guest–guest electronic coupling is on the same order as (or even higher than) the host–host elec-

tronic coupling, the mobility will then increase with the guest concentration [21]. However, as noted above, this situation is outside the scope of this study.

3.3. Prediction of the dominant regime

3.3.1. Estimation of p_{eq}^g and p_{TFL} for organic host–guest systems

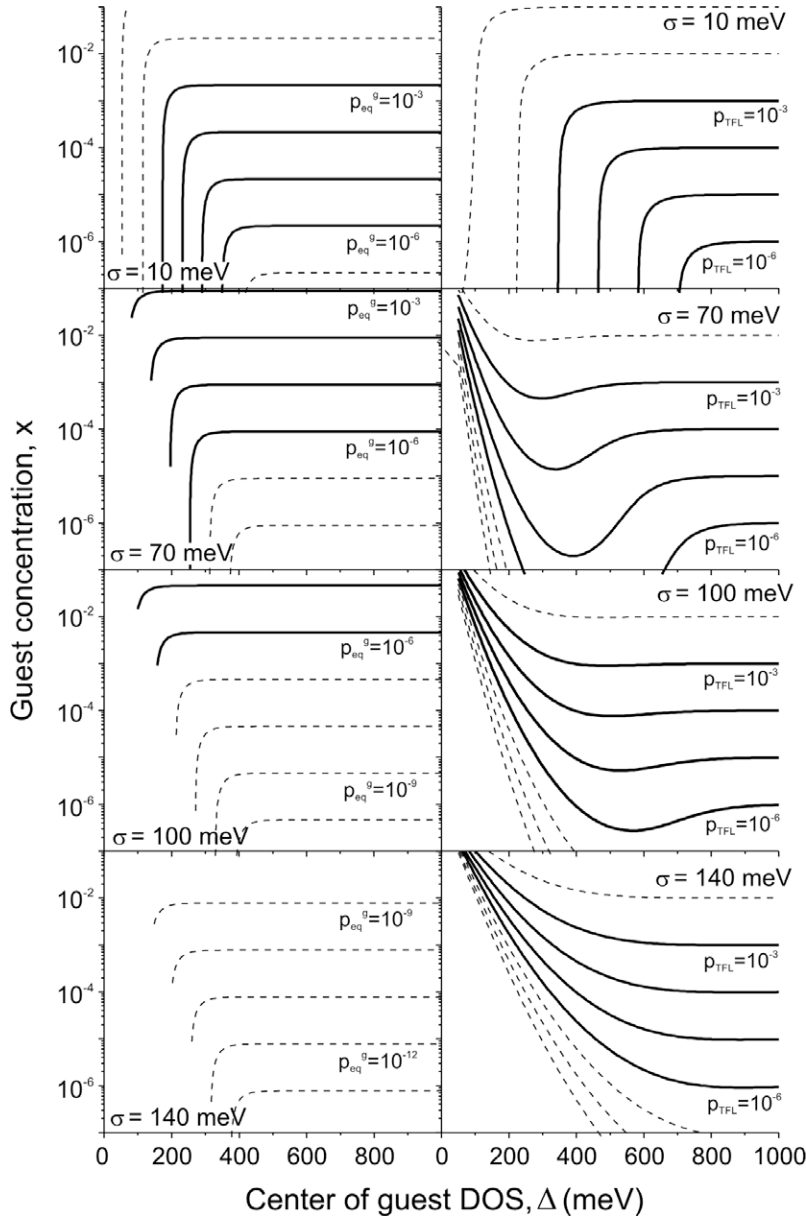
Since the J–V behavior is dramatically different in the trap-limited, trap-filling and trap-free regimes, it is desirable to be able to predict the dominant regime for a diode based on a certain organic host–guest system characterized by a set of σ, Δ and x. In order to do that, a correlation


Fig. 7. Isodensity contours of p_{eq}^g (left column) and p_{TFL} (right column) for $\sigma_h = \sigma_g = 10$ meV, 70 meV, 100 meV and 140 meV, as a function of x and Δ. The bold lines correspond to p_{eq}^g or $p_{TFL} = 10^{-3}N_t$, $10^{-4}N_t$, $10^{-5}N_t$ and $10^{-6}N_t$. The dashed lines correspond to one decade change of carrier concentration. Note that in the case of p_{eq}^g the contour lines are only plotted for $E_{eq}^g < E_{TFL}$, since otherwise the definition of E_{eq}^g is not relevant.

is needed between the range of the applied voltage and the range of accessible charge carrier densities in the device. With the definitions given above, the device is in the trap-filling regime when $E_{eq}^g < E_F < E_{TFL}$. Using Eq. (2), this condition translates into carrier concentrations as $p_{eq}^g < p < p_{TFL}$, where p_{eq}^g and p_{TFL} are the carrier concentrations when $E_F = E_{eq}^g$ and $E_F = E_{TFL}$, respectively. At lower carrier concentrations ($p < p_{eq}^g$), the device is in the trap-limited regime, while at higher carrier concentrations ($p > p_{TFL}$), the system is in the trap-free regime. The isodensity contours of p_{eq}^g and p_{TFL} as a function of Δ and x are extracted from Eq. (2) and given in Fig. 7. The difference between two neighboring lines in the figure corresponds to one decade difference in carrier concentration. In the case of p_{eq}^g, the contour lines are only plotted for $E_{eq}^g < E_{TFL}$, since otherwise the definition of E_{eq}^g is not relevant.

When the contacts are ohmic, the carrier concentration profile in the device at thermal equilibrium is determined by the build-up of charge near the injecting contact, irrespective of the transport mechanism in the bulk of the material. The amount of charge stored in the material is given by the product of the geometrical capacitance, $C_g = \varepsilon_r\varepsilon_0/t$ [F/m^2], and the applied voltage, V_{Appl}. At intermediate to high carrier concentrations, an approximation of the average charge carrier concentration, p_{av}, is then given by $p_{av} \approx C_g V_{appl}/e = \varepsilon_r\varepsilon_0 V_{Appl}/et^2$ [8]. This simple estimate of the average charge concentration is independent on the DOS parameters (σ, Δ and x), thus not rigorously accurate. However, it gives the same order of magnitude as the true value, with the shape of the DOS taken into consideration, of the carrier concentration in the center of the device. For a thickness of the organic layer of a few hundred nanometers and with an applied voltage close to the breakdown voltage of the organic layer, the realistic upper-limit for the carrier concentration in a diode is on the order of $p_{av} \approx 10^{-3}N_t$. With the same thickness, the lower limit of the carrier concentration in the device is $p_{av} \approx 10^{-6}N_t$ due to diffusion of carriers from the ohmic contacts [27]. With this motivation, we conclude that the carrier concentration in diodes under realistic voltages is in the range of $10^{-6}N_t < p < 10^{-3}N_t$. In Fig. 7, p_{eq}^g and p_{TFL} belonging to this accessible range of carrier concentrations are plotted in bold lines, while those outside this range appears as dotted lines.

For large Δ (e.g. $\Delta = 700$ meV in Fig. 5a), the guest and the host DOSs are well separated and E_{TFL} is low. Few carriers occupy states in the host DOS and most states in the guest DOS are filled, according to the definition of E_{TFL}. Consequently, $p_{TFL} \approx xN_t$ and is independent on Δ. This appears in Fig. 7 as horizontal isodensity lines for large enough Δ. When Δ diminishes (e.g. $\Delta = 500$ meV in Fig. 5a), E_{TFL} is sliding upwards along the crossing between the guest and the host DOS. As long as $E_{TFL} < E_{eq}^h$, an approximation for p_{TFL} in this intermediate range of Δ can be found using Eq. (2), according to:

$$p_{TFL} = \int_{-\infty}^{\infty} g(E)f_{FD}(E, E_{TFL})dE$$
$$\approx xN_t + N_{eff}\exp((E_{TFL} - E_{eq}^h)/k_BT) \quad (10)$$

where $N_{eff} \approx \int g_h(E)f_{FD}(E, E_{eq}^h)dE$ is the effective density of states of the host DOS at E_{eq}^h [31]. The two terms in Eq.

(10) corresponds to the charge carriers residing in the guest states (first term) and the host states (second term). As Δ decreases further, $E_{TFL}-E_{eq}^h$ becomes larger and the second term in Eq. (10) increases abruptly. In order to stay on the same isodensity contour, p_{TFL} must be kept constant by decreasing x. This appears as a downward bending of the p_{TFL} isodensity contours for intermediate Δ.

For small Δ (e.g. $\Delta = 300$ meV in Fig. 5a), the guest DOS is almost entirely engulfed in the host DOS. The number of charge carriers residing in the guest states is therefore no longer accurately described by the first term in Eq. (10). In this case, a better estimate of p_{TFL} is given by the second term alone, i.e. $p_{TFL} \approx N_{eff}\exp((E_{TFL}-E_{eq}^h)/k_BT)$. The only way to maintain p_{TFL} constant while reducing Δ is to keep E_{TFL} constant, since both N_{eff} and E_{eq}^h are constant. From Eq. (9), it follows that this can only be accomplished by increasing x. This trend is depicted as isodensity contours bending upwards towards larger x for small Δ.

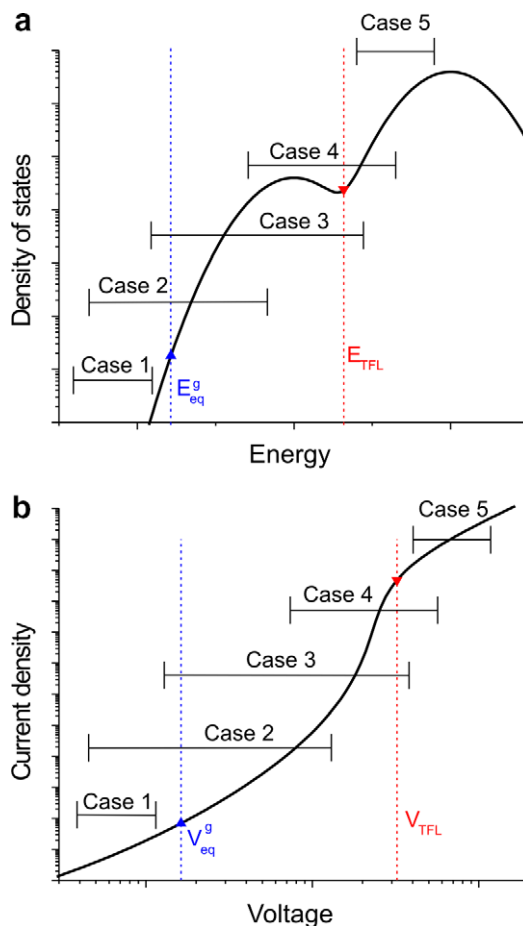
For large and intermediate Δ, $E_{eq}^g < E_{TFL}$ and most of the carriers contributing to p_{eq}^g are located on guest molecules. Therefore, the p_{eq}^g isodensity contours are constant with x


Fig. 8. Five possible cases for host–guest systems illustrated with sketches of the DOS (a) and the J–V behavior (b) of the diode. The horizontal bars represent the energy- and voltage range corresponding to the carrier concentration range of $10^{-6}N_t < p < 10^{-3}N_t$. Note that this is only a sketch and the energy- and voltage ranges are mapped onto one DOS to fit all the cases into the same figure.

in this Δ range. For small Δ, such that $E^g_{eq} > E_{TFL}$, states from the host DOS contribute significantly to p^g_{eq}. In order to keep p^g_{eq} constant while decreasing Δ, the guest concentration x is reduced and the isodensity contours diverge into vertical lines.

3.3.2. Organic host–guest systems classified in cases

On one hand, two key carrier concentrations p^g_{eq} and p_{TFL}, characterize a specific organic host–guest system, i.e. they are defined by a particular set of σ, Δ and x (see Fig. 7). On the other hand, the carrier concentration in a diode typically varies with the applied voltage from $10^{-6}N_t$ to $10^{-3}N_t$. Depending on where p^g_{eq} and p_{TFL} are located within the range of the accessible p, six different cases of organic host–guest systems can be identified. While examples for each case can be found in the previous Section 3.2, we have here chosen a simplified representation in order to be able to represent all cases in one graph. Fig. 8 is not a rigorous scientific representation of the different cases, but a sketch that helps the reader to understand the physical origin of the mobility behavior of these different organic systems. The accessible carrier concentration span ($10^{-6}N_t$–$10^{-3}N_t$) in the device is translated into the accessible energy range for the Fermi level in the DOS of each specific system, which is represented by a horizontal bar in Fig. 8. The six cases are:

(1) $10^{-3}N_t < p^g_{eq}$: Only the trap-limited regime is accessible. A requirement for a large p^g_{eq} is that E^g_{eq} is in a high-density part of the DOS, i.e. either close to the center of the guest DOS (if x is large) or well within the host DOS (a small Δ). Since E^g_{eq} is proportional to the square of σ, this is only satisfied if σ is small, i.e. for an ordered film. Interestingly, this situation is not observed in the simulations performed with realistic σ values for disordered organic semiconductor ($\sigma > 70$ meV).

(2) $10^{-6}N_t < p^g_{eq} < 10^{-3}N_t < p_{TFL}$: The J–V behavior starts in the trap-limited regime, transits into the trap-filling regime, but never reaches the trap-free limit.

(3) $10^{-6}N_t < p^g_{eq} < p_{TFL} < 10^{-3}N_t$: The J–V behavior starts in the trap-filled regime, proceeds into the trap-filling regime and eventually reaches the trap-free regime.

(4) $p^g_{eq} < 10^{-6}N_t < p_{TFL} < 10^{-3}N_t$: The trap-limited regime is not accessible; the J–V behavior begins in the trap-filling regime, and transits into the trap-free regime.

(5) $p^g_{eq} < p_{TFL} < 10^{-6}N_t$: Only the trap-free regime is accessible, i.e. the guest states have little impact on the J–V behavior.

(6) $p^g_{eq} \geqslant p_{TFL}$, or equivalently $E^g_{eq} \geqslant E_{TFL}$: The trap-filling regime vanishes and the guests no longer acts as traps.

4. Conclusions

Organic semiconductor blends, obtained by introducing guest molecules into a host matrix, have been demonstrated to improve efficiency and give new functionality in two terminal devices, like diodes. Here, the evolution of the mobility vs. charge carrier concentration and the current density-voltage behavior of the device are explained and simulated by following how the charge carriers reside in a density of states of the organic host–guest system.

An organic semiconductor host–guest system is defined by three parameters: the width of the Gaussian guest– and host DOS, the position of frontier energy levels of the guest molecules compared to those of the host molecular matrix, as well as the concentration of guests. The impact of the guest states on the J–V behavior is determined by the level of modification of the total DOS introduced by the guest DOS. Several major trends are observed: Firstly, when molecular disorder is increased, the transition from the trap-limited to the trap-free regime becomes smoother. In a strongly disordered system, the guest DOS needs to deviate strongly from the host DOS to have an impact on the J–V behavior. Secondly, the transition from the trap-limited to the trap-free regimes occurs over approximately the same voltage range, but the transition is much steeper for larger energy mismatch between guest and host frontier π-levels. Thirdly, an increase of guest concentration in the organic system shifts the J–V behavior towards higher voltages.

From the above analysis, we propose simple criteria to predict the J–V behavior of a two terminal device composed of an organic semiconductor host–guest system defined with its three parameters (σ, Δ, x). An organic host–guest system is characterized by two key charge carrier concentrations, p^g_{eq} and p_{TFL}, easily accessible in this report. The position of p^g_{eq} and p_{TFL} within the range of charge carrier concentration accessible in device [$10^{-6}N_t$–$10^{-3}N_t$] allows to predict the regimes of charge transport (trap filing, trap-filled, trap free) accessible for that specific organic host–guest system. We believe these criteria will help device scientists to select the right molecular host–guest pair and host/guest ratio to access the desired J–V behavior for a given (opto) electronic application.

ARTICLE INFO

ABSTRACT

We have fabricated solution-processed pentacene thin film transistor arrays with mobilities as high as 1.0 cm^2/V s, evaluated at a low drain voltage of -10 V. This is achieved by controlling the growth direction of the pentacene films from solution, and by optimizing conditions for drop casting. Crystal growth of the solution-processed pentacene films is found to proceed in one direction on a tilted substrate. Grazing incidence X-ray diffraction and electron diffraction reveal that the crystal growth azimuth corresponds to the direction along the minor axis of the a–b plane in the unit cell of the pentacene crystal. This directional growth method is extended to solution processing on large glass substrates with an area of 150×150 mm^2, thereby yielding transistor arrays with two-dimensional uniformity and high carrier mobility.

1. Introduction

In recent years, thin film transistors (TFTs) based on organic semiconductors have attracted significant attention because of the relatively high mobility up to 10 cm^2/Vs of single crystals and applicability to flexible substrates [1–5]. Solution processing can be applied using organic semiconductors with flexible substrates at much lower temperatures compared to conventional processes for inorganic semiconductors, thus allowing for studies using novel soluble materials [6–10]. One of the organic semiconductors under investigation, pentacene, has shown high carrier mobility comparable to amorphous silicon [11]. However, it has been typically used as the source for vacuum deposition due to its low solubility. To obtain higher solubility, it is necessary to modify the molecular structure of pentacene by adding some functional groups to the parent structure. Diels–Alder-adducted pentacene derivatives [12,13] and 6,13-bis(triisopropyl-silylethynyl) pentacene [14], for example, were investigated and exhibited high field effect mobilities of 0.1–1 cm^2/Vs.

We have investigated and reported direct solution processing of organic thin films, without the need for particular syntheses to obtain pentacene derivatives [15]. These organic thin film transistors (OTFTs) fabricated by direct solution processing also exhibited high carrier mobilities, up to 0.5 cm^2/Vs. Moreover, our solution-processed pentacene films had widespread crystalline domains up to several hundred micrometers and exhibited an interlayer spacing of $d(001)$ similar to that of the bulk phase ($d = 14.4$ Å). Although the maximum carrier mobility in our previous reports was sufficiently high to be applicable in electronic devices, such as the active-matrix of a liquid crystal display and electronic paper, little attention has been paid to controlling the quality of the films, thereby

obtaining reproducibly high carrier mobilities. To this end, it is important to clarify the crystal growth mechanism in the solution process and to extract key parameters for optimum growth conditions.

In this report, we focus on the crystal growth of pentacene from a solution, and discuss the application of directional growth of pentacene thin films. In the solution process, the surface-area-normalized amount of dropped solution and the concentration of the pentacene solution were optimized as primary parameters. The obtained TFT arrays showed uniformly high carrier mobilities, and accordingly this solution process was utilized for the preparation of transistor arrays for 5-inch-diagonal-sized liquid crystal displays (LCDs) [16].

2. Experimental procedure

Pentacene was purchased from Tokyo Chemical Industry Co. (refined product by sublimation) and used without further purification. Commercially available 1,2,4-trichlorobenzene (TCB) was used as the solvent after distillation. Pentacene was added to the TCB and heated at 200 °C to obtain 0.01–0.07 wt% solutions in a glove box under a nitrogen atmosphere. The solution was coated onto a substrate previously heated to 200 °C to form a pentacene thin film by evaporating the TCB. To enhance wetting of the solution on the substrate surface, we added polydimethylsiloxane (PDMS), obtained from Aldrich, to the pentacene solution to a concentration less than 50 ppm.

We used glass substrates with a 280 nm-thick silicon dioxide film as an insulator, which was prepared from polysilazane spin-coated over the 100 nm-thick Cr gate electrode and heated to 300 °C [16]. The source and drain electrodes were prepared using photolithography methods, electron beam deposition of 22/3 nm-thick Au/Ti, and cleaning by reactive-ion etching after a lift-off process. The bottom-contact configuration was adopted as the geometry of the electrode with a channel width (W) of 500 μm for all devices, and the channel length (L) was varied from 5 to 50 μm. The substrates were cleaned with oxygen plasma prior to the preparation of the pentacene thin films.

The electrical properties of the OTFTs were measured with a semiconductor parameter analyzer (Keithley 4200SC). The field effect mobility μ was calculated in the saturation region from the slope of the linear part of the $I_{D,sat}^{1/2}$ vs. V_G plot in the saturation region, using the following equation:

$$I_{D,sat} = \frac{WC_{ox}}{2L} \mu (V_G - V_{th})^2, \tag{1}$$

where C_{ox} is the capacitance of the insulator per unit area, V_G is the gate voltage and V_{th} is the threshold voltage, which can be estimated from the intercept of a line drawn through the linear part of the $I_{D,sat}^{1/2}$ vs. V_G plot.

In-situ observations of crystal growth were carried out using an optical microscope with a heating and cooling stage (1002LS, Japan High Tech Co. Ltd.). The dispersed pentacene in TCB was enclosed in a cell of the stage unit under a nitrogen atmosphere, and the cell was mounted on the microscope stage. The dispersion in the cell was heated initially to 200 °C to form a uniform ca. 0.07 wt% solution of pentacene. Thereafter, the solution was cooled to yield crystal growth at a cooling rate of 2 or 15 °C/min. The grown crystal domains were observed by polarized light.

Electron diffraction (ED) studies of the flat domain of the solution-processed pentacene thin films were carried out using a transmission electron microscope (TEM; HF-2000, Hitachi Ltd.). The pentacene films were covered with a water-soluble resin and were exfoliated together from the substrate. This was then floated on water to dissolve the resin, and the pentacene films left behind were picked up with a copper grid. The electron beam (λ = 0.0251 Å) was irradiated onto the sample in a perpendicular direction to the pentacene films on the copper grid. The stripe patterns on the pentacene film, corresponding to the growth direction, were checked prior to the ED analysis to confirm the direction of crystal growth.

The in-plane structure of the solution-processed thin films was investigated by grazing incidence X-ray diffraction (GIXD) [17], to confirm the relationship between the direction of the thin film formation in the process and the crystallographic structure. The GIXD measurement was performed using an ATX-GSOR diffractometer with synchrotron radiation (λ = 1.00 Å) at the BL46XU in the SPring-8. The incident X-ray beam is radiated onto the sample surface at a grazing angle (typically <0.5°). The X-ray detector is scanned in the in-plane direction to observe in-plane diffraction of the films. In this measurement, lattice planes perpendicular to the film surface can be detected. In addition, the in-plane two-dimensional azimuth of the pentacene crystalline film was subsequently analyzed by rotating the sample (ϕ axis) with a fixed angle of the detector at $2\theta_\chi$ = 18.0°, wherein the strongest diffraction was obtained in the previous measurements of the $\phi/2\theta_\chi$ scan. Here, the origin of the sample rotation was set as the direction of the stripe patterns on the thin film surface.

3. Results and discussion

3.1. Directional growth of the solution-processed film

In-situ observations of pentacene crystal growth in the TCB solvent were carried out using the optical microscope with the thermally controllable stage unit. Fig. 1 shows the crystal morphology for different cooling rates. The low cooling rate of 2 °C/min leads to plate-like crystal growth, while the high cooling rate of 15 °C/min results in dendritic pentacene crystals. The cooling rate is related to supersaturation of the solution, in other words, a fast cooling rate provides high supersaturation and vice versa. Furthermore, the plate-like crystal growth should evolve into flat domains of the solution-processed pentacene films, which always exhibit the stripe pattern. Here, we call these structures macro-stripe patterns. We have assumed that the macro-stripe patterns are related to the growth direction of the pentacene crystalline films.

The solution-processed films, in which the flat domains showed different directions of the macro-stripe patterns, were observed by a polarizing microscope. Some domains could be distinguished from the polarized image, with each domain having a different direction of the macro-stripe pattern. This implies that the macro-stripe patterns correspond to the crystal azimuth of the respective flat domains. We considered that the directionality of crystal growth is related to the evaporation direction. Drop casting was therefore carried out on a tilted substrate with a tilt angle of up to 0.5°. With a tilted substrate, the growth of the thin film proceeds approximately in one direction, since the thickness of the solution has a one-dimensional gradient. As shown in Fig. 2, the obtained films showed a directionality of the macro-stripe patterns, with the direction of the macro-stripes mostly oriented towards the direction of the thin film growth.

3.2. Growth azimuth of the pentacene crystalline film

To investigate the relationship between the growth direction and crystal azimuth in the pentacene solution-processed films, we employed TEM measurements, and the TEM images obtained are shown in Fig. 3. Another stripe pattern of ca. 0.2 μm width was observed in the TEM images; we named this the micro-stripe pattern. Although the direction of the micro-stripe patterns did not necessarily correspond to that of the macro-stripe patterns, we focused on the regions where the direction of both stripe patterns corresponded to each other in the azimuth. The inset image in Fig. 3 represents the ED pattern observed simultaneously in the TEM measurement. In addition, the obtained ED pattern was compared with ED simulation [18] using the solution-grown crystal structure reported by Campbell et al. with the lattice parameters of $a = 7.90$ Å, $b = 6.06$ Å, $c = 16.01$ Å, $\alpha = 101.9°$, $\beta = 112.6°$,

Fig. 2. Optical microscope image for the solution-processed pentacene film obtained with directional growth. The arrow represents the evaporation direction. The macro-stripe patterns were structured along the evaporation direction. The rectangles in the figure represent source and drain electrodes.
Fig. 3. TEM image of the solution-processed pentacene film. The inset image is the electron diffraction pattern observed simultaneously with TEM. The direction of the micro-stripe pattern is in agreement with the growth direction of the solution-processed pentacene film in this case (the arrow in the figure).

and $\gamma = 85.8°$ [19], in order to assign the respective diffractions. Recently, Siegrist et al. reported that the high-temperature pentacene polymorph is stable above 190 °C,

and that the unit cell parameters of this polymorph were similar to those reported by Campbell [20]. Furthermore, Della Valle et al. suggested that the structure reported by Campbell corresponds to the deepest minimum structure, using energy-minimization calculations with the quasi-Monte-Carlo sampling method [21]. These reports imply that pentacene crystal grown above 190 °C tends to have the structure reported by Campbell. In fact, the solution-processed pentacene thin film in our earlier work was found to have a structure close to that determined by Campbell [22]. Therefore, in the following, the crystal structure of pentacene will be discussed on the basis of the Campbell's structure. In the ED simulation, Campbell's structure was redefined as $a = 6.06$ Å, $b = 7.90$ Å, $c = 14.88$ Å, $\alpha = 83.26°$, $\beta = 100.54°$, and $\gamma = 85.80°$, since the original structure is not a reduced cell, namely, the c axis of the original cell is much inclined. The difference in the definition of a unit cell is displayed in Fig. 4. The ED measurement in Fig. 3 revealed that the direction of the stripe patterns on the film surface corresponded to $(1\,0\,0)$ direction in the reduced Campbell's structure, that is, the $(0\,1\,0)$ direction of the original one.

As further verification of the growth azimuth of the pentacene films, GIXD measurements were also carried out using synchrotron radiation at the SPring-8 ($\lambda = 1.00$ Å). The GIXD pattern of the $\phi/2\theta_\chi$ scan for the solution-processed pentacene film with directional growth is shown in Fig. 5a. A very strong peak is observed at $2\theta_\chi = 18.0°$, which corresponds to the d spacing of 0.32 nm. This diffraction peak is assigned to the $(1-2-1)$
Fig. 4. Crystal structure of pentacene (a) determined by Campbell et al. and (b) redefined structure in this study.
Fig. 5. (a) GIXD pattern (λ = 1.00 Å) of the solution-processed pentacene thin film with directional growth. (b) In-plane distribution of diffraction at $2\theta_\chi$ = 18.0°, fixing the position of the detector during sample rotation of the ϕ axis.

lattice plane of the reduced Campbell's structure (calculated to be $2\theta_\chi$ = 18.0°). The (1−2−1) plane is confirmed to be almost perpendicular to the (001) plane, since the angle between these planes is calculated to be 90.4° from crystal structure data of the reduced Campbell's structure. In order to avoid confusion, the (120) and (1−20) planes, which were also confirmed in the ED measurement, should be mentioned here. The calculated angle between (120) and (001) is 90.3°, almost perpendicular; however, the corresponding d spacing is 0.34 nm which should be observed at $2\theta_\chi$ = 16.8°. The (120) diffraction was actually confirmed at $2\theta_\chi$ = 16.82° with a low intensity of 10^3 cps in this measurement. On the other hand, simulations indicated that the (1−20) plane was at $2\theta_\chi$ = 18.42° (d spacing = 0.31 nm) with low intensity, and the dihedral angle toward the (001) plane was estimated to be 78.0°. The (1−20) plane cannot be detected in the GIXD measurement. Thus, it is reasonable to assign the peak at 18.0° to the (1−2−1) lattice plane. As shown in Fig. 5b, the in-plane distribution of the strong peak at $2\theta_\chi$ = 18.0° was subsequently investigated by rotating the sample (ϕ axis) with the fixed angle of detector at $2\theta_\chi$ = 18.0°. In this measurement, we set the origin of the rotation angle approximately to the direction of the macro-stripe patterns, which was visible to the eye. It was revealed that the strongest peak was obtained in the narrow angle region from −56° to −52° with the peak top at −53.6°, while several peaks were detected in the other azimuth. In addition, the angle between (100) and (1−2−1) was calculated to

be 54.9° from the crystal structure data. Since the difference in the azimuthal angle is only 1.3°, we conclude that the pentacene crystal growth from a solution proceeds along the minor axis (ca. 6 Å) in the a-b plane of the crystal structure of pentacene.

Using density functional calculations, Northrup et al. predicted an equilibrium crystal shape in terms of the surface energy of the crystal structure [23]. They employed the original Campbell's structure without any structural redefinition, and calculated the surface energies for the (001), (100), (010), (110), and (1−10) surfaces. In addition, the theoretical form of the crystal can be derived from the relative growth rates of various low-index faces, since the growth rate of the crystal face is assumed to be proportional to its surface-formation energy [24,25]. The corresponding formation energies were also calculated to be 0.15, 0.45, 0.75, 0.71, and 0.72 eV/cell respectively in Ref. [23], that is, the (010) surface has the largest surface-formation energy. Therefore, pentacene molecules in a solution are likely to cohere to the (010) surface, and this facet will disappear from the equilibrium crystal shape [23]. It is worth noting again that the (010) surface mentioned here corresponds to the (100) surface of the reduced Campbell's structure in the present study. Hence, the crystal growth was theoretically predicted to proceed preferably along the minor axis in the a-b plane of the pentacene crystal under equilibrium condition. This prediction implies that the flat domain growth in this process takes place under nearly equilibrium condition.

3.3. Fabrication of transistor array

The solution process with directional growth was applied to a glass substrate with an area of 150×150 mm^2, wherein 10,000 transistors ($W = 500$ µm) were prepared in the center region of 100×100 mm^2 area (cf. Fig. 7). The glass substrate was placed on a hot plate with a slight tilt and was sufficiently heated at 200 °C before drop casting of the pentacene solution. The direction of thin film growth was parallel to that of the channel.

First, we emphasize that wetting of the solution on the substrate is important to stably provide two-dimensional growth of thin films. Since the drop casting itself is essentially a non-equilibrium process, it was difficult to control and restrain a phenomenon such as *stick and slip movement* at the edge of dropped solution without additives. It was found that the addition of PDMS of less than 50 ppm to the pentacene solution provides preferable wetting of the solution on the substrate, and that the solution on the tilted substrate can continuously evaporate from the upper side to the lower side of the dropped solution, even in the case of large-area substrates. Moreover, the evaporation rate becomes moderate after starting the two-dimensional growth. The enhancement of wetting can be attributed to appropriate lowering of the surface tension of the solution and the interfacial tension between the solution and the substrate due to the presence of an appropriate amount of PDMS. Although the exact mechanism for the enhancement in wetting has not been fully investigated at the present stage, this treatment was clearly found to make the drop casting controllable with simple experimental parameters as described below.

We focused on the surface-area-normalized amount of dropped solution and the concentration of the solution as process parameters to control the quality of the thin films. It is possible to apply the same condition to substrates with different sizes, by defining the surface-area-normalized amount of the dropped solution. These two parameters were optimized so that the best transistor characteristics were obtained. The optimum conditions for the amount

and concentration of the dropped solution were found to be 0.058 ml/cm^2 and 0.05 wt%, respectively. In Fig. 6a, distributions of the transistor characteristics, mobility and threshold voltage in the TFT arrays fabricated using the best condition (condition 2) are displayed, and compared with conditions of 0.044 ml/cm^2 and 0.07 wt% (condition 1). The characteristics of transistors with $L = 10$ µm were evaluated at a drain voltage of -10 V, wherein 40 TFTs were randomly sampled from the TFT array of 100×100 mm^2 area. For condition 2, the characteristics converged well within a small distribution ranging from 0.2 to 1.1 cm^2/Vs for the carrier mobility (0.62 cm^2/Vs on average with standard deviation of 0.19 cm^2/Vs), and from -2.6 to -0.9 V for the threshold voltage (-1.8 V on average with standard deviation of 0.2 V), respectively. Moreover, the on/off ratio and the subthreshold slope showed good values of more than 10^4 and ranging from 0.5 to 1.1 V/decade, respectively. The transfer characteristics of OTFTs with the highest carrier mobility are shown in Fig. 6b. The maximum carrier mobility of 1.1 cm^2/Vs obtained may be one of the highest values ever reported measured at a low drain voltage in solution-processed OTFTs. In contrast, condition 1 resulted in low carrier mobility ranging from 0.01 to 0.52 cm^2/Vs with an average mobility of 0.13 cm^2/Vs.

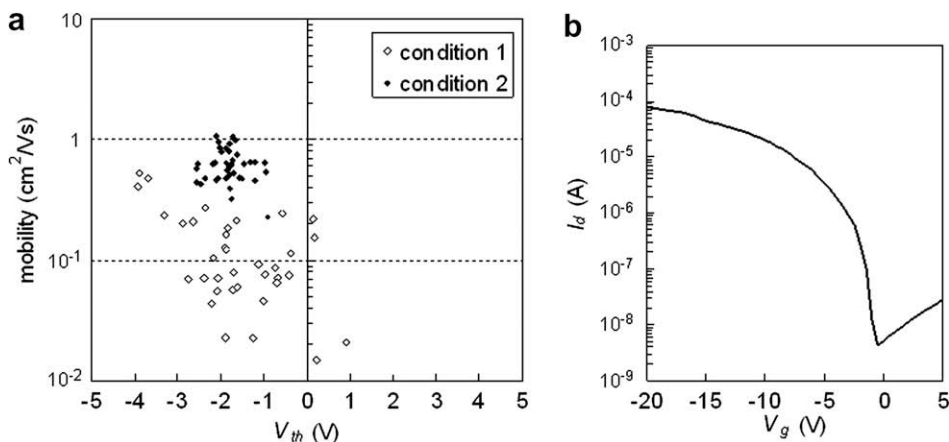
The area with lower carrier mobility in the array is comprised of dendritic domains. The formation of dendritic domains occurs at the initial stage of film growth owing to high supersaturation accompanied by fast evaporation. In addition, the smaller amount of dropped solution results in widespread dendritic domains. Solution-processed films on 150×150 mm^2 glass substrates obtained using both conditions are shown in Fig. 7. In the pictures, a part of the thin film is clouded due to the presence of dendritic domains or large roughness of the thick domains. In the case of condition 2, most of the area in the TFT arrays was covered with flat domains, and at the same time, the area of the dendritic domain was restricted to the edge of the glass substrate (Fig. 7b), while the dendritic and thick domains covered a considerable area of the substrate when condition 1 was used (Fig. 7a). In the course of the evaporation,


Fig. 6. (a) Distributions of carrier mobility as a function of threshold voltage for conditions 1 and 2. In both cases, 40 TFTs were randomly sampled from each part of the TFT array. (b) Transfer characteristic of OTFT with the best carrier mobility from the TFT array fabricated using condition 2. The geometry of TFTs was $W/L = 500/10$ µm, and the applied drain voltage was -10 V for all measurements.
Fig. 7. Solution-processed pentacene thin film on a glass substrate of area 150 × 150 mm², fabricated using (a) condition 1 and (b) condition 2. Both substrates were placed on a cover case for a 6-inch-square photomask. The outer area of the TFT array in the glass substrates was partially covered with gold in the electron beam deposition.

the increasing vapor pressure should reduce the evaporation rate to change the growth mode from dendritic growth to two-dimensional growth, owing to lowering of the supersaturation. A similar phenomenon was confirmed in the *in-situ* observations of pentacene crystal growth.

The directionally grown films have color gradation from blue to violet, as seen in Fig. 7. This color gradation is attributed to the gradient of the film thickness. The distribution of the film thickness obtained using condition 2 is displayed in Fig. 8b. The thickness was measured from cross-sectional profiling of the films, and 45 points (five points per division and nine divisions in an array) were evenly sampled from the respective area of the TFT array in the substrate. The TFT array was classified into nine divisions by separating three sections for each side, as *a–c* for the *x*-axis and 1–3 for the *y*-axis, respectively. The film growth proceeded in the direction from *a* to *c* along the *x*-axis. The thickness increased from 100 to 200 nm, accompanied by film growth, and the averaged thickness was approximately 150 nm. The distribution of the film thickness using condition 1 is also shown in Fig. 8a. The thickness gradually increased from 150 to 250 nm, accompanied by film formation, and the average thickness was ca. 200 nm. The concentration of the solution is roughly correlated with the thickness of the pentacene films. The dense solution yielded thick films particularly at the end of evaporation, resulting in large roughness of the films. The rough surface could be an impediment in the post-processing of pentacene film formation, for example the seal-

ing process for the liquid crystal layer. Thus, the intermediate concentration of 0.05 wt% was found to be desirable for application to TFT arrays [16].

The optimized process parameters thus successfully provided high quality solution-processed pentacene films, yielding high carrier mobilities. The directional growth also contributes to the high uniformity of TFT characteristics, even on large-area substrates, since the pentacene crystal has been reported to exhibit anisotropic carrier mobility both theoretically and experimentally [26,27]. This solution process was applied for the preparation of transistor arrays for 5-inch-diagonal-sized LCDs, which were also driven successfully [16].

4. Conclusions

We have successfully fabricated directional-solution-grown pentacene TFT arrays with high carrier mobilities, up to 1.1 cm²/Vs, at a low drain voltage of −10 V. In addition, the distribution of TFT performance in an array showed high uniformity for both carrier mobility and threshold voltage, which were respectively 0.62 cm²/Vs on average with standard deviation of 0.19 cm²/Vs and −1.8 V on average with standard deviation of 0.2 V.

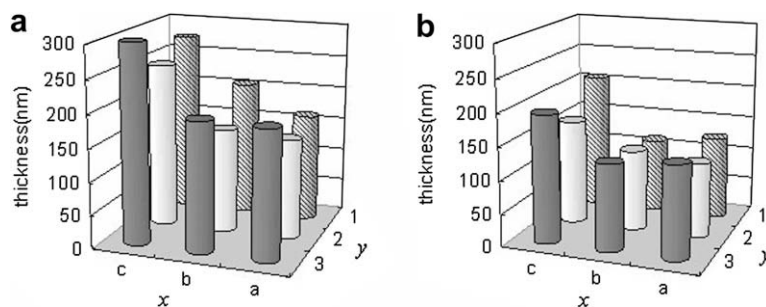
We found that the crystal growth direction in the pentacene film was accompanied by the thin film growth direction, and that crystal growth proceeded preferably along the minor axis of the *a-b* plane in the crystal structure of pentacene. We applied this phenomenon to our solution


Fig. 8. Distribution of thickness for the solution-processed pentacene film prepared using (a) condition 1 and (b) condition 2.

process by dropping the solution onto tilted substrates, thereby obtaining high directionality of film growth.

This solution process with directional growth was applied to a large glass substrate with an area of 150×150 mm^2. To enhance the wetting of the pentacene solution on the substrate, we added a small amount of PDMS to the solution. With this treatment, good wetting on the substrate was realized, thereby making the drop casting process controllable. We optimized the amount of the dropped solution and the concentration of the solution as prime parameters in the process to obtain the preferred films. This method was applicable to TFT arrays for LCDs. In summary, we have demonstrated the possibility of application of the direct solution process to electronic devises. We believe that OTFT using small molecules is the most promising candidate for flexible displays manufactured by printing technologies.

ABSTRACT

We report the dynamic admittance, both in the dark and under illumination, of heterojunctions made of poly(3-hexyl thiophene)/1-(3-methoxycarbonyl)propyl-1-phenyl[6,6]C_{61} (P3HT:PCBM) blends, which are used in efficient organic solar cells. In the dark there appears a huge low frequency negative capacitance which we associate with slow electron hole bimolecular recombination at the heterojunction interfaces. Surprisingly, under photoexcitation the negative capacitance gradually disappears with increasing light intensity. We attribute this positive photoinduced capacitance to the combined effect of (1) long lived photogenerated charges at the P3HT:PCBM interfaces that increase electron-hole bimolecular recombination rate, which in turn renders the capacitance less negative and (2) trapped photogenerated charges that increase the capacitance upon re-emission.

1. Introduction

We report a huge dark negative capacitance (NC) and its disappearance under illumination in organic bulk heterojunction devices made of poly(3-hexylthiophene)(P3HT) and 1-(3-methoxy carbonyl)propyl-1-phenyl[6,6]C_{61} (PCBM). Photovoltaic cells based on P3HT:PCBM blends are among the most efficient in this class of devices [1–4]. The NC phenomenon in various devices, such as inorganic Schottky diodes, inorganic homojunction photodetectors, organic light emitting devices and more, has been reported previously, while its origin is still under debate [5–9]. In many cases, the frequency, ω, dependence of the NC spectrum, $C(\omega)$, has been shown to be directly related to current relaxation [5,6] or electron–hole (e–h) recombination in bipolar organic devices [7,9]. The primary cause for the NC is probably different in different systems. In the present case of organic heterojunction devices, the NC is observed under bipolar charge injection conditions. At low enough frequencies the NC saturates reaching (in absolute value) up to ≈500 times the geometrical capacitance at low frequencies. The bias voltage and frequency dependencies of NC enable us to determine the e–h bimolecular recombination (BMR), which is responsible for the spectral behavior of the NC and the corresponding dynamic sample conductance.

Upon photoexcitation the NC diminishes in magnitude and the capacitance reaches even positive values under sufficiently intense illumination. We attribute this positive photoinduced capacitance to the combined effect of (1)

long lived photogenerated charges at the P3HT:PCBM interfaces that increase e–h BMR rate, which in turn renders the capacitance less negative and (2) trapped photogenerated charges that increase the capacitance upon re-emission.

2. Experimental

Thoroughly cleaned indium tin oxide (ITO) covered glass slides are used as substrate. An $L \approx 800$ nm thick photo-active layer made from a regio-regular (rr)-P3HT:PCBM solution (1:1, 2% in chloroform) was cast by the doctor blade technique on the substrate. The Al top contacts were applied by vacuum deposition, followed by an annealing step (5 min at 120 °C). The diodes (active area $A \simeq 12$ mm^2) showed a rectification ratio of $\simeq 10^4$ at ±1 V (Fig. 4, inset). Forward (positive) bias conditions are obtained when the ITO is wired (+) and Al wired (−). An HP 4284A LCR-meter operated in the frequency range $f = \omega/2\pi = 20 - 10^6$ Hz (20 mV ac voltage) was used to measure the complex admittance $Y(\omega)$, from which the capacitance $C(\omega) = ImY(\omega)/\omega$ and the conductance $G(\omega) = ReY(\omega)$ were extracted. We carefully analyzed the low frequency regime in order to make sure that the extracted $C(\omega)$ and $G(\omega)$ are not influenced by any parasitic circuit reactance [10]. The 532 nm line of a Nd:YVO$_4$ laser was used as light source for the photoinduced admittance measurements. All measurements reported here were done at room temperature.

3. Results

In Fig. 1 we display the measured frequency dependent capacitance of the ITO-P3HT:PCBM-Al device in the dark at various applied forward bias voltages. For $V_{bias} > 0.3$ V, we observe a negative contribution to the capacitance and relate it to current relaxation [5] due to e–h recombination in the bipolar injection regime [6,9]. This negative contribution becomes more dominant as the voltage increases above 0.35 V, where $C(\omega)$ becomes more negative as the

bias increases. The effect of increasing bias on NC is shown in the inset of Fig. 1 where the measured capacitance at 50 Hz, $C(50$ Hz$)$, is plotted as a function of V_{bias}. At 1.5 V, $C(50$ Hz$) \approx -200$ nF, which is (in absolute value) $\simeq 500$ times the geometrical capacitance, $C_g = \varepsilon A/L \simeq 0.4$ nF ($\varepsilon \simeq 3\varepsilon_0$ is the sample static dielectric constant and ε_0 is the vacuum permittivity).

The decrease in capacitance as f decreases below $\approx$5–10 kHz, is accompanied by a corresponding increase in the conductance, as shown in the inset to Fig. 2. The zero value $G(f \approx 0)$ corresponds to the static conductance dI/dV. Denoting $\Delta G(f) \equiv G(0) - G(f)$, the quantity $\Delta G(f)/f$ (up to $f \approx 10$ kHz) is proportional [11] to the corresponding changes in $\varepsilon''(f)$, the imaginary part of the dielectric function associated with the process. In Fig. 2, $\Delta G(f)/f$ is displayed for various bias voltages, showing the bell shaped curves characteristic to ε''. Note the shift of the curves' maximum towards higher frequencies for higher bias; this is consistent with the observed faster recombination process at higher voltages (see discussion below).
Fig. 2. The frequency dependence of $\Delta G(f)/f \equiv [G(20$ Hz$) - G(f)]/f$ for the same device as in Fig. 1, showing the typical bell shaped loss function behavior. Symbols: data points at various bias voltages (in V) as marked. Inset: $G(f)$ vs f for $V_{bias} = 1.5$ V.

Fig. 1. Frequency dependent capacitance measured on an ITO-P3HT:PCBM-Al device shown for various forward bias from 0.3 to 1.5 V (as marked). Symbols: data points, solid lines: fits to the data. The 0.3 V data is multiplied by 10 for clarity. Inset: $C(50$ Hz$)$ vs bias voltage. Black squares – data points and red stars – fit (see text).
Fig. 3. The capacitance of the ITO-P3HT:PCBM-Al device vs frequency measured under laser illumination (532 nm) at I_L = 5, 100, 250 μW, as marked ($V_{bias} \simeq 0.6$ V). For clarity, only the frequency range 0.02–15 kHz is shown. Inset (a): the photoinduced changes $\Delta C \equiv C_{light} - C_{dark}$ (in nF) at f = 50 Hz vs I_L (on a log–log plot) for $V_{bias} = 0.35$ (black square) and 0.5 V (red dots) The solid lines are fits to $\Delta C \propto I_L^{1/2}$ law. Inset (b): ΔC (in nF) at f = 50 Hz vs V_{bias} for I_L = 100 μW (red dots) and 250 μW (black square).

We now turn to the effect of photoexcitation on NC. In Fig. 3 the measured capacitances of a ITO-P3HT:PCBM-Al device under 532 nm continuous irradiation (C_{light}) are shown in the bipolar charge injection regime for various light intensities, I_L. A significant increase in the capacitance due to illumination is observed at low frequencies. Above 15 kHz up to 1 MHz the photoinduced changes in the capacitance are very small (not shown in Fig. 3). The photoinduced changes in the capacitance, $\Delta C \equiv C_{light} - C_{dark}$, are sensitive to both the light intensity and applied bias. Inset (a) to Fig. 3 shows the dependence of $\Delta C(50$ Hz$)$ on I_L at fixed V_{bias}. The observed $\Delta C \propto I_L^{1/2}$ for both $V_{bias} = 0.35$ and 0.5 V is indicative of a BMR mechanism for the photoinduced carriers. Inset (b) to Fig. 3 shows the dependence of $\Delta C(50$ Hz$)$ on V_{bias} at fixed I_L. Below $V_{bias} \approx 0.35$ V $\Delta C(50$ Hz$) \leqslant 3$–4 nF, then a sharp rise at $V_{bias} \approx 0.35$ V followed by a plateau (where $\Delta C(50$ Hz$) \geqslant 100$ nF for $I_L \geqslant 100$ μW/cm^2) above ≈ 0.6 V are evident.

4. Discussion

The negative contribution to the dark $C(\omega)$ is observed here only at $V_{bias} > 0.3$ V, under the conditions of bipolar injection. NC is more pronounced at higher forward bias voltages, where the conductance of the device is higher. The maximum frequency at which NC is observed is restricted approximately to $f < 2$ kHz at $V_{bias} = 1.5$ V where NC is most pronounced. Such low frequencies represent time scales which are much longer than the single carrier transit time in this device ($\simeq 5$ μs at 1 V). It is therefore plausible to analyze the NC as a separate process dominating the other transport processes in this frequency range. Previously, such an approach was used by Penin [5] in order to account for NC in semiconductor Schottky diodes via impact ionization of impurity atoms and in GaAs homojunctions via interface states mediated recombination [6]. In our previous publication [9] we have shown that the NC spectrum measured in organic semiconductor devices could be accurately described when treating NC as a separate mechanism in addition to the effect of space charge. In all these approaches the recombination plays an important role. Under bipolar injection conditions (with dc conductance $G_0 = dI/dV$) and for a finite recombination time, τ_r, a negative contribution (of the order of $\tau_r G_0$) to the capacitance should be expected at frequencies $\omega < \tau_r^{-1}$; this is similar to the negative contribution to the capacitance which occurs simultaneously with an increase in conductance at frequencies below the reciprocal transit time in a unipolar SCLC device. The effect of recombination on the capacitance and conductance can be summarized as follows [5,6,9]:

$$C_r(\omega) = -\frac{G_{r0}\tau_r}{1 + \omega^2\tau_r^2}; \quad G_r(\omega) = G_{r0} - \frac{G_{r0}\omega^2\tau_r^2}{1 + \omega^2\tau_r^2}, \quad (1)$$

where G_{r0} is the conductance associated with the process. As can be seen from Eq. (1), the maximum of the conductance (and most negative capacitance) occurs for $\omega \ll \tau_r^{-1}$ near $\omega \approx 0$; at higher frequencies the conductance decreases due to the diminishing carrier density ($\propto (\omega\tau_r)^{-2}$ for $\omega \gg \tau_r^{-1}$) and the capacitance becomes less negative.

It is important to note that the shorter is the recombination time, the wider is the frequency range in which NC can be observed experimentally. We can now use Eq. (1) in order to fit the data in the bipolar injection regime ($V_{bias} \geqslant 0.35$ V in Fig. 1). In the relevant range where the NC is dominant (up to 5 kHz), the fits (solid lines, Fig. 1) account very well for $C(\omega)$. In particular, we notice the experimentally observed leveling off of $C(f)$ below 30–40 Hz, that is very well accounted for by Eq. (1). Furthermore, the voltage dependence of C is also fully explained by our analysis, as can be seen in the inset to Fig. 1, where the stars denote the capacitance calculated using the parameters obtained from the frequency fits at each voltage.

The losses due to e–h recombination in the bipolar injection regime are clearly revealed in the $\Delta G(f)/f$ plots shown in Fig. 2. The changes $\Delta\varepsilon''(\omega) \equiv [G_r(0) - G_r(\omega)]/\omega = G_{r0}\omega\tau_r^2/(1 + \omega^2\tau_r^2)$ (Eq. (1)), can be ascribed to the losses due to recombination. As formally expected from the inter-relation between $C(f)$ and $G(f)$, exactly the same parameters, τ_r and G_{r0}, obtained from the $C(\omega)$ fits in Fig. 1, account accurately for the peak frequency and peak height of $\Delta G(f)/f$ in Fig. 2.

Interestingly, the voltage dependence of the fitted conductance, G_{r0}, follows exactly that of the static conductance, dI/dV, as seen in Fig. 4, where we find that $G_{r0}(V) \propto dI/dV$ for the entire bias range. The proportionality of the fitted G_{r0} (from the complex admittance experiment, Figs. 1 and 2) and the measured dI/dV (from the dc I–V experiment, Fig. 4, inset) further supports the interconsistency of the experimental results.

The recombination rate, τ_r^{-1}, extracted from the fits shows a linear dependence on V_{bias}, as shown in Fig. 4. From the dI/dV curve we see that bipolar injection (as well as NC) starts at $V_{bias} \simeq 0.35$ V; thus the actual injection voltage is $V = V_{bias} - 0.35$ V. The straight dashed line in Fig. 4 is a linear fit to the data. The linear dependence on V implies a BMR mechanism under bipolar injection, where the average BMR rate, τ_{BM}^{-1}, may then be written as [12]
Fig. 4. The recombination parameters τ_r^{-1} (left axis) and G_{r0} (right axis), extracted from the fits to the NC data of Fig. 1, are shown vs V_{bias}. The straight dashed line is a linear fit, $1/\tau_r(\text{m s}^{-1}) = 0.55 + 1.45(V_{bias} - 0.35$ V$)$. The static admittance dI/dV (multiplied by 0.3) is overlayed (right axis) on the extracted G_{r0} for comparison. Inset: current density J (in mA/cm^2) vs V_{bias} (in V).

$$\tau_{\mathrm{BM}}^{-1} = \gamma \bar{n} = \frac{4V}{L^2}\left[\frac{\mu_n \mu_p \varepsilon \gamma}{2e(\mu_n + \mu_p)}\right]^{1/2}, \qquad (2)$$

where $\gamma = \bar{v}\sigma_R$ is the BMR coefficient, $\bar{v}$ is the average e–h microscopic relative velocity, σ_R is their recombination cross section, and $\bar{n}$ is the average carrier density. The measured mobility of the carriers in annealed rrP3HT:PCBM is of the order $\mu \approx 10^{-3}$ cm^2/Vs for both electrons and holes [13]. The linear fit of the data in Fig. 4 then yields $\gamma \simeq 10^{-12}$ cm^3/s, similar to the value observed by other techniques [7,14,15]. This BMR coefficient, γ, is $\simeq 10^3$ times smaller than the Langevin BMR coefficient: $\gamma_L = 2e(\mu_n + \mu_p)/\varepsilon$. Obviously, a high recombination coefficient inhibits the efficiency of organic photovoltaic devices. The reduced BMR coefficient has been suggested to be the result of different pathways for electrons and holes in the heterojunction device [14,16]. Being confined to different phases or pathways, electrons and holes would recombine only at the interfaces between the phases. Thus the volume in which the recombination occurs is only a small fraction of the total volume in which the current flows.

Under bipolar injection, where the NC is dominant, it is surprising that by adding photoinduced carriers the NC decreases in magnitude, as shown in Fig. 3. Moreover, the reduction in NC, ΔC, increases dramatically in forward bias as seen in Fig. 3 (inset (b)). Inset (a) of Fig. 3 shows that $\Delta C \propto I_L^{1/2}$. Assuming that ΔC is proportional to the steady state density of the photogenerated carriers, the square root dependence on I_L implies that the photogenerated carriers undergo BMR process, in agreement with previous observations [14].

The photoinduced positive contribution ΔC increases sharply at the onset of bipolar injection. It may therefore be related to the phenomenon of negative capacitance, which also appears only under bipolar injection. Such inhibition of the negative capacitance may be due to an increase in recombination rate by the photoinduced carriers decreasing thereby the magnitude of the NC, according to Eq. (1). Such photo-enhancement of the BMR may not be surprising since the photoinduced charges are predominantly created at the heterojunctions, where the local electric field breaks the photoexcited excitons. The increased carrier density at the heterojunction, where most of the bimolecular recombination takes place, shortens thus the recombination time. Alternatively, positive ΔC may arise from trapped photoinduced carriers: upon re-emission from the traps the capacitance increases [17]. The effect of traps may be more evident from the maximum observed in the spectrum of $C_{\mathrm{light}}(f)$ at around $f \simeq 1$ kHz (Fig. 3 at I_L = 100 and 250 μW). It is plausible that the 532 nm illumination excites deep compensated donors or acceptors, which may then become deep traps for the injected carriers. If the emission rate from these photogenerated traps (PGT) is e_{PGT}, then the increase of the capacitance due to the traps is $\Delta C_{\mathrm{PGT}}(\omega) \propto 1/(1 + \omega^2/e_{\mathrm{PGT}}^2)$ [18]. Taking now into consideration both the effect of NC inhibition (i.e. reduced NC under light) and the PGT contribution (ΔC_{PGT}), the frequency dependent admittance data under illumination at I_L = 0.1 and 0.25 μW is very well accounted for with $e_{\mathrm{PGT}} \simeq 3 \times 10^4$ s^{-1} (Fig. 3, solid lines). Emission

rates of the same order of magnitude were previously found for deep traps in organic diodes [19].

5. Summary

In summary, we have shown that in bulk heterojunction diodes made of annealed composites of rrP3HT and PCBM and under forward bias conditions a huge (up to $\simeq 500C_g$) negative capacitance is observed. We show that finite electron hole recombination times make it possible to observe the negative capacitance in the bipolar injection regime. We extract the bimolecular recombination coefficient and show that it is ≈ 1000 smaller than the Langevin value. Under illumination, the total capacitance becomes less negative reaching even positive values at sufficient intensities. This phenomenon may arise from an enhancement of the BMR rate at the heterojunction interfaces due to the extra carrier photoinduced density at exactly these donor–acceptor interfaces. Alternatively, it may arise from trapped photoinduced carriers.

ARTICLE INFO

ABSTRACT

In this paper we show that thiolated self-assembled monolayers (SAMs) can be used to anchor source–drain gold electrodes on the substrate, leading to excellent electrical performances of the organic field-effect transistor (OFET) on a par with those using a standard electrode process. Using an amorphous semiconductor and a gate dielectric functionalized with SAMs bearing different dipole moments, we demonstrate that we can tune the threshold voltage alone, while keeping nearly unchanged the other electrical properties (hole carrier mobility, I_{on}/I_{off} ratio, subthreshold swing). This differs from previous studies for which SAMs functionalization induced significant changes in all the OFET electrical performances. This result opens doors to design organic circuits using reproducible amorphous semiconductor based OFETs for which only the threshold voltage can be tuned on demand.

1. Introduction

During the past decade, research on new materials for organic thin film transistors (OTFT) has received a fast growing interest, resulting in significant improvements of the electrical performances and leading to promising demonstrators [1]. Various organic materials have been developed due to their electronic tunability by molecular design. Good intrinsic properties are now accessible, but interestingly the interface properties of these new organic species with other materials have been less studied whilst they can lead to dramatic changes in OTFT behaviour [2].

For instance, it is possible to modulate charge injection from the electrodes into the semiconductors by modifying the surfaces of electrodes with self-assembled monolayers (SAMs) [3–6]. Chemically modifying the interface properties between organic semiconductor (OSC) and insulator can also lead to phenomena of overwhelming importance. One of the most remarkable effects was reported in 2005: Chua et al. showed that trapping of electrons at the semiconductor–dielectric interface by hydroxyl groups prevented most conjugated polymers to yield n-channel field-effect transistor conduction [7]. Interface engineering by SAMs to achieve control of channel conductance and/or

charge carrier density has been reported, but the role of the SAMs is still controversial since it can result in several effects such as (i) changes in the molecular orientation in the OSC, (ii) neutralization of surface defects, (iii) modification of surface roughness, interface dipole and surface energy. In most cases, a combination of these effects is likely, some of them being certainly dependent on both the dielectrics and the OSCs. As a consequence, several transistors parameters are modified simultaneously, and this feature prevents a clear understanding of the effect of the SAMs.

For further development of organic electronics, it is mandatory to find a way to precisely control the threshold voltage of OFET. This is a strong constraint to allow a reliable design of organic circuitries. It could be very interesting to fabricate and study organic transistors with similar electrical properties (i.e. charge carrier mobility, I_{on}/I_{off} ratio and subthreshold swing) except for the threshold voltage, this latter being precisely controlled and adjusted. Up to now, gate dielectric interface variations leading to modification of the threshold voltage came-along with charge carrier mobility changes that have mainly been attributed to modifications of the semiconductor morphology [8–10]. The chain alignment of polymeric OSCs at the interface is a well known process which can induce significant improvement of the mobility. For instance, poly-(3-hexylthiophene) (P3HT) enhancement in mobility by SAM-treated silicon oxide is linked to the highly oriented crystals at the interface between the polymer and the dielectric [11–16]. A similar effect was also observed for other molecules such as thermally evaporated pentacene [10,13,17,18], PQT-12 [18] and more recently on a fused-ring thieno–thiophene polymer [19]. For instance, surface modification of the gate dielectric by surface chemistry (using SAMs) can lead to a better π–π stacking, resulting in an increase of the charge carrier mobility.

In the meantime, threshold voltage shifts were consistently observed, depending on the chemical nature of the SAMs. Thus, it was not possible to modify selectively the threshold voltage without modification of the overall electrical performances of the OFET, due to the interplay with changes in the structural organization of the OSCs.

In order to avoid any molecular ordering or crystallization effects, we decided to study the impact of organosilane self-assembled monolayers on OTFT fabricated with an amorphous OSC material. Despite the moderate hole mobility observed with PolyTriArylAmine (PTAA), this semiconductor material presents several advantages. It is easy to handle, to spin-coat from organic solutions, and thin films of PTAA exhibit excellent stability to air and light, thus, avoiding doping side-effect [20–25].

In addition to gate dielectric functionalization, SAMs have also been investigated to modify the surface properties of metal source–drain surfaces. This treatment improves the charge injection in the OSC, it can also help getting a better structural organization in the OSC film [26]. In this paper, we present an approach in which SAMs are used underneath the source–drain electrodes as an anchoring layer. Gold electrodes are made by metal evaporation directly on thiolated self-assembled monolayers. We demonstrate electrical performances identical to the commonly used Ti/Au contacts made by lift-off. The benefit is a simplified one-step process, compatible with many substrates, including plastic ones.

Using these electrodes, we studied the effect of different SAMs at the dielectric/organic semiconductor interface on the electronic performances of the transistor, with the amorphous organic semiconductor PTAA. We demonstrate that threshold voltage can be significantly changed by choosing the orientation and magnitude of the molecule dipole, while other important parameters (charge carrier mobility, on/off ratio, subthreshold swing) are slightly affected, in contrast with previous results [8–17].

2. Thiol based SAM as anchoring layer for electrodes

Two types of devices with bottom gate/bottom contact geometry were fabricated on a heavily doped (1 0 0) silicon wafer (n^{++}, 2–5 mΩ cm) covered by a thermally grown silicon dioxide (200 nm). The source and drain electrodes of the first device were patterned by optical photolithography, followed by Ti (10 nm) and Au (90 nm) evaporation and lift-off. The second substrate was treated with piranha solution (H_2SO_4/H_2O_2, 1/1 (v:v)), followed by oxygen plasma treatment (20 mTorr, 10 sccm O_2, 10 W, 300 s) and immersion in a $HCl/H_2O_2/H_2O$ (1:1:8) mixture. The sample was then exposed to vapour-phase of 3-mercaptopropyltrimethoxysilane (MPTS) for 6 h under vacuum (10^{-2} mBar). The water contact angle measured on the SAM was 60° ± 2° (Kruss DSA-10), which is in fair agreement with reported values [27,28]. The surface morphology of the organic layer was determined by imaging using a Veeco Dimension 3100 atomic force microscope (AFM) in tapping mode. We measured a root-mean square surface roughness of ∼1 Å over a 1 μm^2 area (2.3 Å over a 10 μm^2 area), identical to the roughness of silicon oxide. Gold (90 nm) was then deposited by evaporation using photolithography techniques and etched by a solution of KI/I_2. The measured RMS roughness value of the gold electrode surface was ∼7 Å, which is much better than the roughness (∼18 Å) obtained by Au deposition on Ti. These results are consistent with those reported recently by Janes and Coll [29], and in addition to the stability tests mentioned in this paper we tried the commonly used "Scotch® tape peel test". We observed no difference between the two types of electrodes, both of them remaining unaffected by this test. A schematic device structure is presented in Fig. 1.

A 1 wt% solution of PTAA in toluene was spin-coated on both substrates and devices were annealed at 100 °C for 20 min. In both cases, uniform thin films of 50 nm, as measured by ellipsometry (Sopra ES4G spectroscopic ellipsometer) were obtained. No particular care was taken to prevent atmosphere contact since PTAA is an air-stable polymer. Electrical measurements were carried out on interdigitated source–drain transistors with channel length of 10 μm and channel width of 10,000 μm (W/L = 1000) with an Agilent 4156b semiconductor parameter analyser.

Typical transfer curves of both devices are presented in Fig. 2 in the saturation regime (V_{DS} = −60 V). The performances measured on 10 devices indicated that both

Fig. 2. Transfer curves of devices fabricated with PTAA as semiconductor, in the saturation regime (V_{DS} = −60 V) (a) Diamonds: Ti (10 nm)/Au (90 nm) (b) Circles: MPTS/Au (100 nm) (c) Triangles: MPTS/Au (100 nm) after removal of organics in the channel by O_2 plasma.

source–drain technologies led to very similar performances. The effective mobility of the devices is extracted from the slope of the current voltage characteristics according to the following equation

$$I_{ds,sat} = \frac{W}{2L}\mu_{sat}C_i(V_g - V_{th})^2 \qquad (1)$$

where L is the channel length of the device, W is the channel width, and C_i is the gate dielectric capacitance. Capacitance of the SAM was neglected with regard to the 200 nm thickness of silicon dioxide, and according to recent results [9]. Charge carrier mobility values for both types of devices were similar ($2–5 \times 10^{-4}$ cm^2 V^{-1} s^{-1}), as well as I_{on}/I_{off} ratios (>10^4). A slight change of the threshold voltage was observed, this point will be discussed thereafter.

These results demonstrate that it is possible to fabricate substrates for OTFT using thiolated SAMs to anchor gold electrodes instead of chromium or titanium. Moreover, smooth surfaces for electrodes and channel are obtained

by this technique, which might be advantageous since surface roughness may be a critical parameter for organic transistor fabrication [30,31]. No significant differences were observed between the two systems, indicating that charge injection is not altered by this unconventional fabrication process.

3. Effect of different gate dielectric functionalization

As discussed in the introduction, self-assembled monolayers are known to strongly modify the OFET characteristics, leading generally to significant changes of electrical properties, notably for charge carrier mobility.

To study the effect of SAM molecules at the interface between dielectric and PTAA, we used devices made with the previously described MPTS/Au electrodes. The remaining SAMs in the channel were removed by O_2 plasma and trialcoxy or trichlorosilane reagents were used to synthesize SAMs with different terminal groups.

Six chemically different surfaces were prepared between source and drain electrodes. The hydroxyl rich surface was obtained after oxygen plasma, and C_6F_5-$(CH_2)_3$-$SiCl_3$ (3-perfluorophenyl-propyl-trichlorosilane, PFTS), HS-$(CH_2)_3$-$Si(OMe)_3$ (MPTS), H_2N-$(CH_2)_3$-$Si(OEt)_3$ (3-aminopropyl-triethoxysilane, APTS), 4-(Ph_2N)-C_6H_4-$NHC(O)NH$-$(CH_2)_3$-$Si(OEt)_3$ (1-(4-(diphenylamino)-phenyl)-3-(2-(triethoxysilyl)-propyl)-urea, a triarylamine triethoxysilane derivative, TAATS), and CH_3-$(CH_2)_{17}$-$SiCl_3$ (octadecyltrichlorosilane, OTS) were used as starting molecules for the SAMs (Fig. 3) [32]. TAATS was synthesized in three steps [33].

APTS and MPTS were deposited under vacuum (10^{-2} mBar, respectively, 15 min and 6 h) whereas OTS, FTS and TAATS were grafted by immersion of the substrates in a 10^{-3} M organic solution for 2 h. After synthesis, SAMs were characterized by advancing water contact angle measurements. Values reported in Table 1 were in good agreement with those reported in the literature [34,35].

A similar procedure as described previously (*vide supra*) was carried out for PTAA film formation. Homogeneous OSC thin films were achieved for all SAMs, except for the OTS one. In this case, we observed dewetting of the PTAA, which may probably be related to the highly hydrophobic nature of the long alkyl chains grafted on the silicon oxide surface ($\theta = 110°$).

Fig. 4a depicts the I–V characteristics of a typical OFET with PTAA, which conformed to the conventional transistor behaviours in both linear and saturated regimes.

In this figure, the MPTS self-assembled monolayer was used. Similar curve shapes were obtained for all devices. The output curves showed good saturation behaviours with no observable contact resistance (see inset of Fig. 4a), while the transfer curve in the saturated regime shown in Fig. 4b exhibited a near quadratic increase in current as a function of gate biases (see inset of Fig. 4b). The extracted mobility in the linear regime was slightly lower than that in the saturated regime, and this was quite similar to OFETs with most organic semiconductors. Table 2

summarizes the mean mobility values in the saturation regime, threshold voltages, subthreshold slopes and current I_{on}/I_{off} current ratios, with their standard deviation observed at least on five similar structures for each SAM. No significant deviation was observed for the hole carrier mobility values, which differs strongly from the poly-crystalline materials for which mobilities can vary by a factor of a few hundreds, depending both on the chemical formula of the SAMs and on the OSC material [8,18,19]. The I_{on}/I_{off} ratios ($\sim 10^4$ to 10^5) as well as the subthreshold swing values were also in the same range, with low deviation. These results are in good agreement with the fact that the OSC remains mainly unaffected by the SAMs at the interface with the dielectric. As expected, the fact that PTAA is an amorphous material avoids any morphologic effect and, thus, any charge carrier mobility variation inherent to the crystal packing of the OSC.

In sharp contrast, the V_t values were strongly modified by the SAMs (Fig. 5).

A significant modulation was obtained, spanning over a 70 V range. PFTS SAM tends to shift positively the V_t values whereas amine derivatives (APTS and TAATS) lead to very negative values. Depending on their functional groups, SAMs are known to generate a built-in electric field [6,8], which modify the charge carrier density in the transistor channel. Fluorinated SAMs have tendency to generate local electric field that accumulates holes, and on the contrary, devices with APTS or TAATS accumulate electrons, leading to the need of a very large negative gate bias to turn on the PTAA into hole accumulation mode.

Fig. 4. Typical curves of devices fabricated with PTAA as semiconductor, with MPTS in the channel and as anchoring layer for gold electrodes (channel length = 10 µm, channel width = 10,000 µm). (a) Output characteristics at different gate voltages and zoom in the $V_{DS} = 0$ region (inset); (b) Transconductance characteristics in the saturated regime at constant source–drain voltage of −60 V and square root of the absolute value of current as a function of gate voltage (inset).

This local electric field is related to the dipole moment of the molecules. We calculated the dipole moment using MOPAC [36] and the semi-empirical method PM3. The dipole values (see Table 3) were calculated for isolated molecules with a SiH_3 group at the bottom. We considered that the leaving groups of the silane derivatives (OMe, OEt, Cl) are not present after the grafting reaction, and, therefore, no longer contribute to the molecular dipole. From these dipole moment values, we calculated the surface charge density according to the following equation

$$Q_s = \frac{N\mu_D \cos\theta}{d} \tag{2}$$

Table 2
Summarized electrical properties as a function of the channel modification.

SAM	μ (cm^2 V^{-1} s^{-1})	I_{on}/I_{off}	S (V/dec)	V_t (V)
PFTS	5.2 (±1.3) × 10^{-4}	1.0 (±2.7) × 10^4	5.0 (±0.6)	18.6 (±2.5)
MPTS	5.2 (±1.5) × 10^{-4}	3.0 (±4.4) × 10^5	2.7 (±1.1)	5.5 (±2.7)
–	1.9 (±0.8) × 10^{-4}	1.5 (±2.3) × 10^4	5.5 (±2.4)	13.1 (±5.2)

TAATS	2.0 (±0.1) × 10^{-4}	2.1 (±0.7) × 10^5	2.8 (±1.6)	−41.5 (±0.7)

where N is the surface density of molecule, μ_D the dipole moment, d the length of the molecule and θ the (average) angle between the long axis of molecule and the normal
Fig. 5. V_t as a function of the channel modification.

Table 3

Calculated dipole moment along the long axis of the molecule, molecule length and steric hindrance, calculated with MOPAC (PM3). The positive (negative) dipole points upstairs (downstairs) leading to positive (negative) charges at the surface of the monolayer. The surface charge density is calculated according to Eq. (2). Dipole moment of the APTS is calculated for the ammonium derivative. Dipole moment of the TAATS is calculated for the cationic form of the triphenylamine group.

SAM	Dipole moment (D)	Length (Å)	Area (Å^2)	Q_S (cm^{-2})
PFTS	−1.66	9.9	37	−1.2 × 10^{13}
MPTS	−1.6	7.2	23	−2.7 × 10^{13}
APTS	7	7.3	21	9.6 × 10^{12}
TAATS	7.7	18.3	61	1.4 × 10^{13}

at the surface. The lengths d were calculated for the optimized conformations of the molecules (energy minimum optimization performed with MOPAC, see Table 3).

Without a precise knowledge of the molecular organization and packing inside the SAM, we assume here that $\theta = 0$, and we consider an average molecular density $N = 2.5 \times 10^{14}$ molecules cm^{-2} ($\pm 1 \times 10^{14}$ cm^{-2}). This value corresponds to an average surface per molecule of 40 Å^2 (steric hindrance calculated with MOPAC ranges from ∼20–60 Å^2 (from APTS to TAATS, respectively). To explain the negative threshold voltage, we have to assume that APTS and TAATS molecules, or a fraction of them, are in a cationic form. In ambient and usual pH condition, only ca. 10% of the APTS molecules are in the ammonium form, and we used in Eq. (2) an effective dipole of 1/10 of the calculated one [37,38]. Similarly, we assume 50% for the TAATS which is more easily converted into its cationic form [39,40].

Fig. 6 shows the experimental threshold voltage versus the surface charge density deduced from the dipole calculation. A rough (according to the assumption done for the dipole calculation) linear relationship can be estimated (solid line). A slope of ca. -2.5×10^{-12} V cm^2 is estimated, as well as, a zero-charge threshold voltage V_{T0} of -15 V. In an organic FET working in accumulation regime, the threshold voltage corresponds to the so-called flat-band voltage of the metal–insulator–semiconductor structure. Thus, we can write

$$V_T = \Phi_{MS} - \frac{Q_B}{C_{ox}} - \frac{Q_S}{C_{ox}} = V_{T0} = \frac{Q_S}{C_{ox}} \tag{3}$$

where Φ_{MS} is the work-function difference between the gate (here Si) and the semiconductor, Q_B the bulk density of charges in the gate dielectric, Q_S the surface charge density and C_{ox} the gate oxide capacitance. Φ_{MS} cannot be easily calculated (it depends on the doping level in the semiconductor, which is not known here), but a negative V_T corresponds to $Q_B > 0$ as expected for SiO$_2$ due to the well known presence of positively-charged traps and/or a possible positive ions contamination [41].

Notice that the measured V_T in the case of the pristine SiO$_2$ (Fig. 5) is positive. This is due to the negative charges at the surface (Q_S) trapped by the hydroxyl surface groups. With a 200 nm thick oxide, the theoretical slope ($-1/C_{ox}$) is 9.4×10^{-12} V cm^2, i.e. a factor 3.7 larger than the experimental determination. In addition to the crude estimate of the dipole and charge (Section 2), another feature can explain this difference. The dipoles were calculated for isolated molecules, and it is well known that in a monolayer, the dipole is reduced due to the Coulomb interaction between the parallel dipoles. For instance, more detailed calculations have predicted a screening of the dipole by a factor of ca. 3 [42]. Such an effect reduces the surface charge density and, thus, increases the slope towards the expected value.

4. Conclusion

In conclusion, we have shown how thiolated SAMs can be used for anchoring source and drain gold electrodes. We have demonstrated that this simple process leads to OFETs with similar performances as those using standard titanium anchoring layer. We have also fabricated OFETs with an amorphous semiconductor (PTAA) deposited on a gate
Fig. 6. Measured threshold voltage shift versus the calculated surface charge. The solid line is a linear fit, $y = -15.2 - 2.54x$. The dotted line is the expected slope given by $(-1/C_{ox})$ where C_{ox} is the oxide capacitance.

dielectric functionalized by different SAMs. By virtue of the amorphous nature of the OSC, the molecular organization in the OSC is not strongly affected by the chemical nature of the SAM, and this feature allowed us to study the effect of the SAM on the threshold voltage, all the other parameters (hole carrier mobility, I_{on}/I_{off} ratio, subthreshold swing) remaining almost unchanged. By choosing molecules bearing different dipole moments, we observed an almost linear relationship between the surface charges at the monolayer/OSC interface and the threshold voltage, in agreement with the expected field-effect. This result opens the way for fabricating circuits with identical transistors, based on amorphous organic semiconductors, that can be adjusted to switch on at different selected voltages. The proposed method can also be extended to crystalline organic semiconductors by designing organosilanes that contain various dipoles embedded in the organic structure, but with an identical end group to ensure constant interface with the OSC.

ARTICLE INFO

ABSTRACT

Organic amorphous films fabricated by vacuum deposition have been widely used in organic light-emitting devices, making use of their high-performance optical and electrical characteristics and taking advantage of the easy fabrication of pinhole-free thin smooth layers of a desired thickness. However, random orientation in amorphous films often makes it difficult to utilize their best optical and electrical potential. Here the authors demonstrate that the linear-shaped molecules of fluorescent styrylbenzene derivatives are horizontally oriented in organic amorphous films fabricated by conventional vacuum deposition even when the molecules are doped in an isotropic host matrix film. The longer the molecular length is, the larger the anisotropy of the molecular orientation becomes. The weak interaction between adjacent molecules and the linear-shaped molecular structure probably cause the horizontal orientation. The fact that the horizontal molecular orientation occurs on any underlying layers shows the high versatility of the horizontal orientation for various applications. Their findings will provide a new guideline for molecular designs that can be used to improve optical and electrical characteristics of organic optoelectronic devices, such as organic light-emitting diodes and organic laser devices.

1. Introduction

Organic amorphous films fabricated by vacuum deposition have played a important role in the development of organic light-emitting diodes (OLEDs) [1] and organic laser devices [2,3]. Amorphous films that have smooth interfaces are essential in the fabrication of fine structures in devices that control as planned light and charge carriers because randomly rough interfaces—for example, due to polycrystalline texture—cause undesirable light scattering or leak current. The vacuum-deposited amorphous films also greatly contribute to the manufacture of practical pinhole-free multilayer films using simplified fabrication techniques that have in turn significantly increased the rate of development of organic thin film devices in the past 20 years.

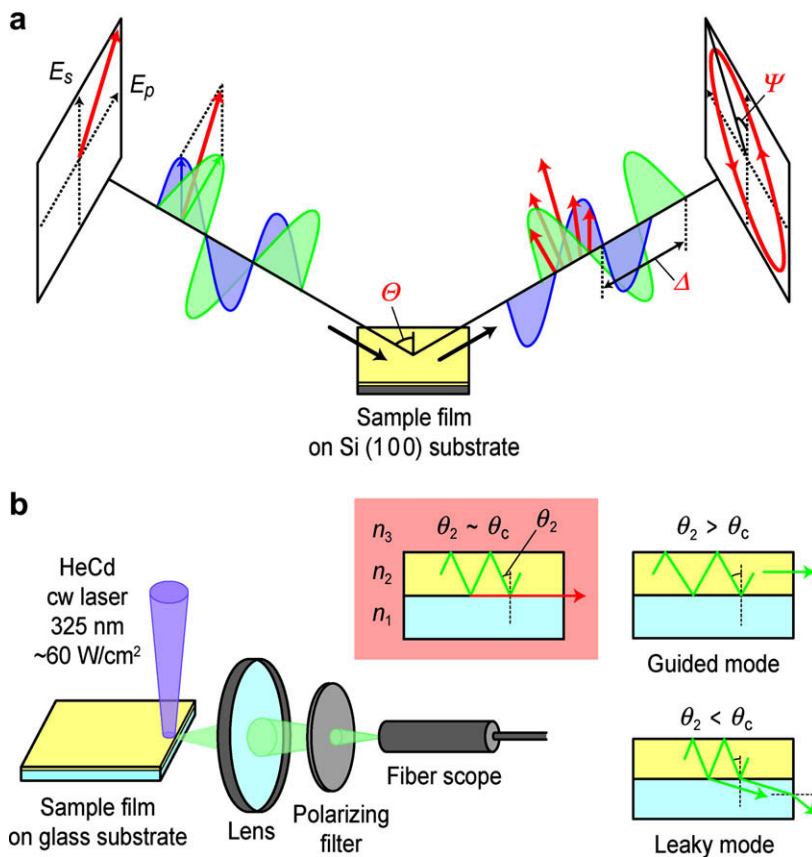
However, it has been taken for granted that the full optical and electrical potential of organic molecules cannot be achieved because the molecules in organic vacuum-deposited amorphous films are randomly oriented and the films themselves are isotropic. In OLEDs fabricated by vacuum deposition, for example, light out-coupling efficiency is limited by the randomly oriented transition dipole moments of the emitting molecules [4–6]. If we can make the orientation of the transition dipole moments of the emitting molecules in OLEDs completely parallel to the substrate, the light out-coupling efficiency becomes


Fig. 1. (Color online) Schematic illustrations of experimental setup of two independent methods for detection of anisotropy in organic amorphous films. (a) Variable angle spectroscopic ellipsometry (VASE) [7]. Linearly polarized light is incident to an organic film deposited on a Si substrate with different incident angles of Θ. The ellipsometry parameters Ψ and Δ, which represent the ratio of amplitudes of s- and p-polarized components of the incident light and the phase difference between them, respectively, are obtained for multiple incident angles and wavelengths. (b) Cutoff emission measurement (CEM). Organic films on glass substrates were optically pumped near the edges of the substrates by ultraviolet light from a cw He–Cd laser. Spectral shapes of edge emissions often significantly differ from the normal PL spectral shapes, and the peak wavelengths of the narrowed bands are in good agreement with the cutoff wavelengths of the slab waveguides composed of the glass substrate (with a refractive index of n_1), organic film (n_2) and air (n_3). The cutoff emission occurs as a boundary phenomenon between the cases where light is guided and where light is leaky, which means that the incident angle in the organic film θ_2 corresponds to the critical angle of the waveguide θ_c.

~50% higher than when the orientation of the transition dipole moments is random [6]. In organic semiconductor laser devices, the random orientation is also not favorable because the alignment of transition dipole moments of emitting molecules makes it easy for stimulated emissions to occur. Furthermore, the alignment of molecules can facilitate charge career transport because it makes the overlap of π-orbitals of adjacent molecules larger.

Although complete alignment of molecules is natural in organic single crystals, it is not easy to prepare single crystal thin films having a desired thickness and a smooth flat surface on a nm-scale by a simple fabrication technique. Therefore, instead of preparing ideal molecular single crystal films, realization of quasi-molecular orientation in smooth organic amorphous films is a right strategy to fabricate large-area organic high-performance devices with low cost. In this study, we pay attention on this viewpoint and investigate the molecular orientation in neat and doped organic amorphous films and its mechanism.

The molecular orientation in thin films can be detected by measuring the optical anisotropy in the films. One of the best methods of investigating the optical properties of thin films is spectroscopic ellipsometry [7]. In particular, variable angle spectroscopic ellipsometry (VASE) is very sensitive to optical anisotropy in films and has been widely used to determine optical constants of anisotropic films. Variable angle spectroscopic ellipsometry has also been used to investigate many kinds of anisotropic films made from spin-coated polymers [8–11], and is reliable technique for determining optical properties not only of inorganic films but also of organic films. Because a smooth surface of a film makes it easier to analyze and determine optical constants, organic amorphous films are also good subjects for VASE measurement. Recently, Lin et al. [12] first reported the application of this technique to vacuum-deposited organic amorphous films and detected uniaxial anisotropies in ter(9,9-diarylfluorene)s thin films. They also demonstrated that the molecular orientation affect the amplified spontaneous emission thresholds of the films [13].

The other method used to detect anisotropy in films is measurement of emissions at cutoff wavelengths [14] from
Fig. 2. Molecular structures of materials used in this study.

edges of substrates though it can only be applied to light-emitting films having a smooth surface [15–22]. With this method, a characteristic spectrum having a narrow band at the cutoff wavelength can be observed in the direction parallel to the substrate surface. Because the polarization characteristics of the emissions are related to the direction of the transition dipole moments of the emitting molecules, optical anisotropy in films can be detected. Using this cutoff emission measurement (CEM), anisotropy of spin-coated polymers has been investigated [15–20]. However, detailed analysis of the relation between peak wavelengths of the emissions and anisotropic refractive indices has not yet been completed.

Recently, we observed spectrally narrow emissions from organic vacuum-deposited amorphous films [21,22] and found that they originate in the cutoff phenomenon [22]. Here, we demonstrate that there are large anisotropies in vacuum-deposited amorphous films of fluorescent bis-styrylbenzene derivatives and that the ordinary refractive indices of the films of the bis-styrylbenzene derivatives are significantly higher than the extraordinary ones, showing the horizontal orientation of the molecules in the amorphous films fabricated by vacuum deposition. Using VASE, we proved the large anisotropy in the films of the bis-styrylbenzene derivatives. We also show the dependence of the anisotropy on molecular structures and underlying layers and discuss the mechanism causing the anisotropy in vaccum-deposited amorphous film. Furthermore, we demonstrate the optical anisotropy in the films of the bis-stylylbenzene derivatives by using CEM in addition to VASE. Detailed analysis of the relation between peak wavelengths of the cutoff emissions and anisotropic refractive indices is also performed. Although the two methods are completely independent of each other, as shown in Figs. 1a and b, there was excellent agreement between their results, showing the reliabilty of the results

obtained by the two methods. By using CEM on doped amorphous films, furthermore, we also found the horizontal orientation of doped molecules even in isotropic host matrix films.

2. Results and discussion

2.1. VASE analysis

Molecular structures of materials studied in this study are listed in Fig. 2. We selected styrylbenzene derivatives (materials **3**–**9**) having carbazole or diphenylamine groups at both ends of the molecules. Although it seems from the formulas that these styrylbenzene derivatives have planar structures, they actually twist to avoid steric repulsion. We also previously demonstrated that bis-styrylbenzene derivatives are laser-active materials whose doped films have extremely low ASE thresholds [23,24]. The neat films fabricated by vacuum deposition are amorphous except material **9**. Tris(8-hydroxyquinoline)aluminum (Alq$_3$, material **1**) was used as a reference having an isotropic optical property. 4,4'-bis(N-carbazole)-biphenyl (CBP, material **2**) was used as a material having a short molecular length. CBP was also used as a host material for the doped films.

Figures 3a–c show the experimental and simulated ellipsometric parameters Ψ and Δ of the Alq$_3$, CBP and 4,4'-bis[(N-carbazole)styryl]biphenyl (BSB-Cz, material **5** in Fig. 2) films with the thickness of $\sim$100 nm on silicon substrates, respectively. Their surface appearances are very smooth and they are amorphous. The values of root mean square (RMS) of the surface roughness of the Alq$_3$, CBP and BSB-Cz films measured by atomic force microscope (AFM) were 0.5, 0.9 and 0.4 nm, respectively.

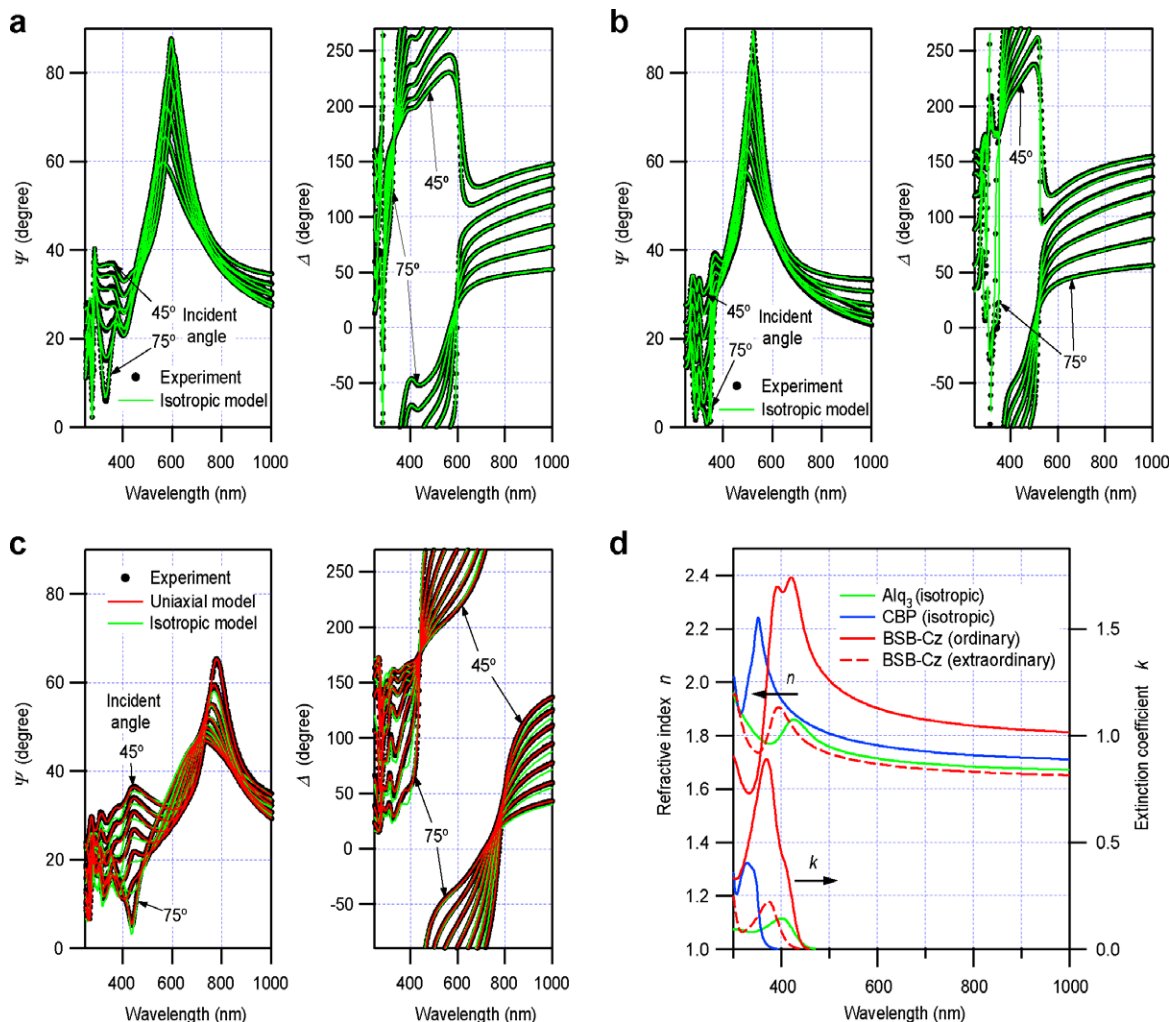
All the ellipsometric parameters of the Alq$_3$ film obtained by VASE measurement were exactly simulated using an isotropic model. As shown in Fig. 3a, the experi-


Fig. 3. (Color online) Experimental and simulated ellipsometric parameters Ψ and Δ, and determined refractive indices of organic films. (a)–(c) Experimental (black dots) and simulated (green and red lines) ellipsometry parameters at incident angles from 45° to 75° in steps of 5° in the spectral region from 245 to 1000 nm for Alq$_3$ (a), CBP (b) and BSB-Cz (c). Because only the values simulated with an isotropic model (green lines) of the BSB-Cz film are not in good agreement with the experimental values, a uniaxial anisotropic model (red lines) is also used in the case of BSB-Cz. (d) Refractive indices and extinction coefficients of Alq$_3$ (green lines), CBP (blue lines) and BSB-Cz (red solid and broken lines) films. The ordinary refractive index of the BSB-Cz film is much higher than the extraordinary refractive index, meaning that there is horizontal orientation of BSB-Cz molecules in the BSB-Cz films.

mental and simulated curves exactly overlap. As well as the Alq$_3$ film, the ellipsometric parameters of the CBP film were also simulated using an isotropic model as shown in Fig. 3b.

In contrast to the Alq$_3$ and CBP films, the ellipsometric parameters of the BSB-Cz film could not be well simulated using an isotropic model even if many oscillators were included in the analysis. Other complicated models could also not compensate the deviation. For example, we tried to simulate the parameters on the assumption of a non-uniform refractive index in the film or existence of the interface layer between the substrate and the organic layer, but a good fitting could not be obtained. The ellipsometric parameters of the BSB-Cz film could be well simulated only using a uniaxial anisotropic model. This shows the uniqueness of analysis by VASE. As shown in Fig. 3c,

the ellipsometric parameters simulated using the uniaxial anisotropic model were in excellent agreement with the experimental parameters whereas the parameters simulated using the isotropic model do not correspond well. These results demonstrate the anisotropy in the BSB-Cz film. We also checked whether the in-plane anisotropy exists in the BSB-Cz film by rotating the sample, resulting in no in-plain difference.

The degree of fitting can be relatively quantified by a mean square error (MSE) [25]. The MSE values for the Alq$_3$, CBP and BSB-Cz films obtained using the isotropic models were 5.8, 8.2 and 35, respectively. The much higher value for the BSB-Cz film means that the parameters could not be well simulated by the isotropic model. The MSE value for the BSB-Cz film obtained using the uniaxial anisotropic model was 4.2, which is comparable to that for the

Alq$_3$ film obtained using the isotropic model. The slightly higher MSE value for the CBP film than that for the Alq$_3$ film indicate the very slight anisotropy in the CBP film, as shown later. Actually, the MSE value for the CBP film became 2.8 when using a uniaxial anisotropic model.

The refractive indices and the extinction constants of the Alq$_3$, CBP and BSB-Cz films are shown in Fig. 3d. The BSB-Cz film has uniaxial anisotropy, and the ordinary refractive index is much higher than the extraordinary one. The difference between them at 550 nm (near the center of visible wavelength), Δn, is 0.23, which means a very large birefringence of the film. The validity of the obtained refractive indices is demonstrated again by CEM, as shown later. The ordinary extinction constant is also much higher than the extraordinary one.

Because the transition dipole moment of the BSB-Cz molecule is almost along the molecular long axis, the ordinary extinction constant that is higher than the extraordinary one means that the BSB-Cz molecules in the film lie nearly parallel to the silicon substrate surface. The ordinary refractive index is also much higher than the extraordinary one because π-electrons in molecules can be moved by external electric fields more easily in the direction of the molecular long axis than in the direction perpendicular to it. Furthermore, no in-plane anisotropy means that the BSB-Cz molecules lie in random directions in the film. In our separate experiment, we could not observe apparent peaks in the X-ray diffraction (XRD) patterns of the BSB-Cz film as well as the Alq$_3$ films. From these results, we conclude that the BSB-Cz film is in a "horizontally oriented amorphous state", where molecules are horizontally oriented on the substrate, but there is no crystallographic structure because the in-plain molecular orientation is random. The similar results of the horizontal molecular orientation in ter(9,9-diarylfluorene)s thin films using VASE were reported by Lin et al. [12].

We further investigated the dependence of the anisotropy on molecular structures of styrylbenzene derivatives to determine the mechanism causing anisotropy in vacuum-deposited amorphous film. The anisotropies in the amorphous films made from the materials in Fig. 2 are summarized in Table 1. Variable angle spectroscopic ellipsometry measurement and analysis of each film were carried out in the same way as for the BSB-Cz film to compare the results equally. We found that the films of all the styrylbenzene derivatives (materials **3**–**8**) also have smooth surfaces and optical anisotropies except material **9** which forms a polycrystalline state with a rough surface by vacuum deposition. First, we focused attention on molecular length because the anisotropy in vacuum-deposited polycrystalline films of paraffin changes depending on the molecular length [26,27]. By comparison of the anisotropy in the film of materials **2**–**5**, we found that a long molecular structure is essential for large anisotropy. Figures 4a–d show the optical constants of the film of materials **2**–**5** determined by VASE using uniaxial anisotropic models. The longer the molecular length is, the larger the birefringence Δn becomes.

The birefringence of the films, however, does not directly reflect the anisotropy of the molecular orientation because each molecule itself has the anisotropy of molecular polarizability. To clarify the relation between the molecular orientation and the molecular structure, we introduced an orientation order parameter S as an index of molecular orientation [28]; that is

$$S = P_2(\cos\theta) = \frac{1}{2}\langle 3\cos^2\theta - 1\rangle = \frac{k_e - k_o}{k_e + 2k_o}, \quad (1)$$

where $P_2(x)$ is the second Legendre polynomial, $\langle\ldots\rangle$ indicates ensemble average, θ is the angle between the molecular long axis and the direction perpendicular to the substrate surface, and k_o and k_e are the ordinary and extraordinary extinction coefficients at the peak wavelength, respectively. $S = -0.5$ if the molecules are completely parallel to the surfaces, $S = 0$ if they are randomly oriented, and $S = 1$ if they are completely perpendicular to the surface. The last term in Eq. (1) can be calculated using extinction coefficients determined by VASE using uniaxial anisotropic models, which is based on the assumption that the transition dipole moment of the molecule is parallel to the molecular axis. The values of S are also summarized in Table 1. The results of materials **2**–**5** clearly demonstrate the relation between the molecular orientation and the molecular length; that is, the longer the molecular length is, the larger the anisotropy of the molecular orientation becomes. From the results of materials **6** and **7**, we found that bis-styrylbenzene derivatives having diphenylamine groups at both ends are also horizontally oriented in the films. Furthermore, the difference in S of materials **5** and **8** shows that the introduction of bulky central moieties makes anisotropy small.

Interestingly, we found that the horizontal molecular orientation can occur on any underlying layers, as shown in Table 2. The large anisotropies in the BSB-Cz films on a silicon substrate, a glass substrate, a 50-nm-thick CBP layer, a 100-nm-thick Ag layer, and a 30-nm-thick smooth ITO layer with an RMS of 0.6 nm were obtained. These results are very important because they mean the high versatility of the horizontal orientation for various applications to organic devices, such as OLEDs, in which an emitting layer is usually sandwiched between electrodes and/or other organic layers.

From the above results, it is reasonable to assume that the molecular orientation in amorphous film is caused only by the weak interactions between the molecule and the underlying layer and the successive weak interaction between the adjacent molecules. As shown in Fig. 5a, in the case of a molecule which has a linear-shaped structure with no bulky substituent, such as material **9**, there is a very strong interaction between the molecules. We think that although the molecules are horizontally oriented just after deposition due to the van der Waals interaction between the molecule and the underlying layer, successive aggregation and crystallization occur due to the strong interaction between the molecules. In contrast, in the case of a molecule which has a linear-shaped structure and bulky substituents, such as BSB-Cz, the bulky substituents avoid aggregation and crystallization, resulting in keeping the horizontal orientation, as shown in Fig. 5b. The van der Waals interaction between the molecules is not so

Table 1
Ordinary and extraordinary refractive indices of films on Si substrates at wavelength of 550 nm and orientation order parameters.

Material	Molecular length (Å)	Ordinary refractive index n_o	Extraordinary refractive index n_e	Birefringence $\Delta n = n_o - n_e$	Orientation order parameter S
2 (CBP)	19	1.78	1.74	0.04	−0.07
3	21	1.83	1.76	0.08	−0.17

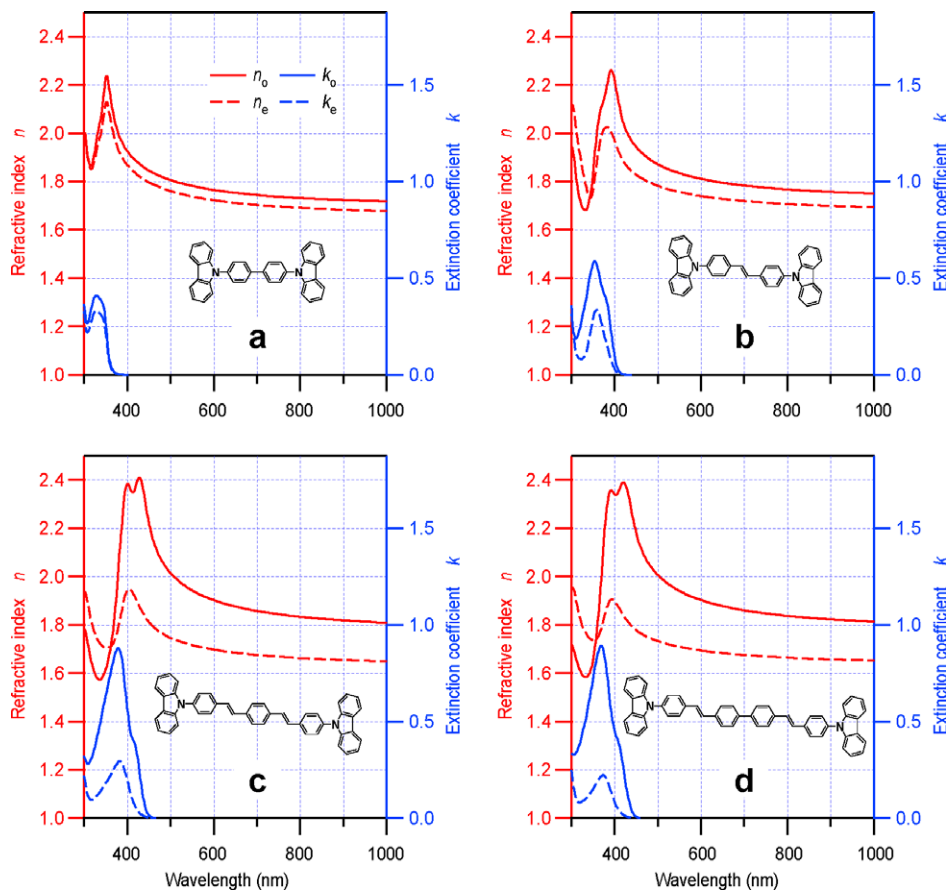

Fig. 4. (Color online) Dependence of ordinary and extraordinary refractive indices (red lines) and extinction coefficients (blue lines) on molecular length. (a) Material **2** (CBP), (b) material **3**, (c) material **4**, (d) material **5** (BSB-Cz). The longer the molecular length is, the larger the differences of ordinary and extraordinary optical constants become.

Table 2
Dependence of ordinary and extraordinary refractive indices of BSB-Cz films at wavelength of 550 nm and orientation order parameters on underlying layer.

Underlying layer	Ordinary refractive index n_o	Extraordinary refractive index n_e	Birefringence $\Delta n = n_o - n_e$	Orientation order parameter S
Si substrate	1.94	1.71	0.23	−0.33
Glass substrate	1.97	1.74	0.23	−0.45
CBP layer (50 nm) on Si substrate	1.93	1.70	0.23	−0.39
Ag layer (100 nm) on glass substrate	1.90	1.71	0.19	−0.36
ITO layer (30 nm) on glass substrate	1.93	1.76	0.18	−0.31
Fig. 5. (Color online) Schematic illustrations of horizontal molecular orientation. (a) Aggregation of molecules having linear-shaped structure without bulky substituents, (b) horizontal orientation of molecules having linear-shaped structure with bulky substituents, and (c) independent depositions of guest and host molecules on flat surface of doped film in which guest molecules having linear-shaped structure are horizontally oriented in a host matrix.

strong due to the presence of rather bulky substituents of carbazole or diphenylamine groups and the primary van der Waals interactions between the molecule and the underlying layer induce horizontal orientation to minimize the surface energy. After the formation of the horizontal orientation of the first molecular layer on the underlying layer, successive molecular orientations would occur due to the weak van der Waals interaction between the molecules without significant aggregation and crystallization.

2.2. CEM analysis

Next, we demonstrate that the molecular orientation based on the results of CEM. Figures 6a–d show cutoff emission spectra of the Alq$_3$, CBP, BSB-Cz and 6 wt%-BSB-Cz-doped CBP films with 15 different thicknesses on glass substrates under optical excitation. We observed spectrally narrow bands that were strongly polarized in transverse electric (TE) mode or transverse magnetic (TM) mode. The electric field in TE mode is polarized parallel to the substrate surface, and that in TM mode is polarized in the plain perpendicular to it. All the TE and TM spectra in Figs. 6a–d are normalized such that the peak intensities of the TE spectra become unity while keeping the ratios of the intensities of the TE and TM spectra. The ratios of the intensities of the TE and TM emissions reflect both the direction of the transition dipole moment of the emitting molecules in the organic film and the intensity of the normal photoluminescent (PL) spectrum of the film at the peak wavelengths of the narrow TE and TM emissions. In the case of the isotropic Alq$_3$ and CBP films, the intensities of the TE and TM emissions were almost identical on the whole, as shown in Figs. 6a and b. In contrast, Fig. 6c shows that the intensities of the TE emissions of the BSB-Cz films are much higher than those of the TM emissions. This result means that the transition dipole moments of the molecules in the film are nearly parallel to the polarization direction of the TE emissions. Thus, the horizontal orientation of the molecules on glass substrates is demonstrated by CEM independently of VASE.

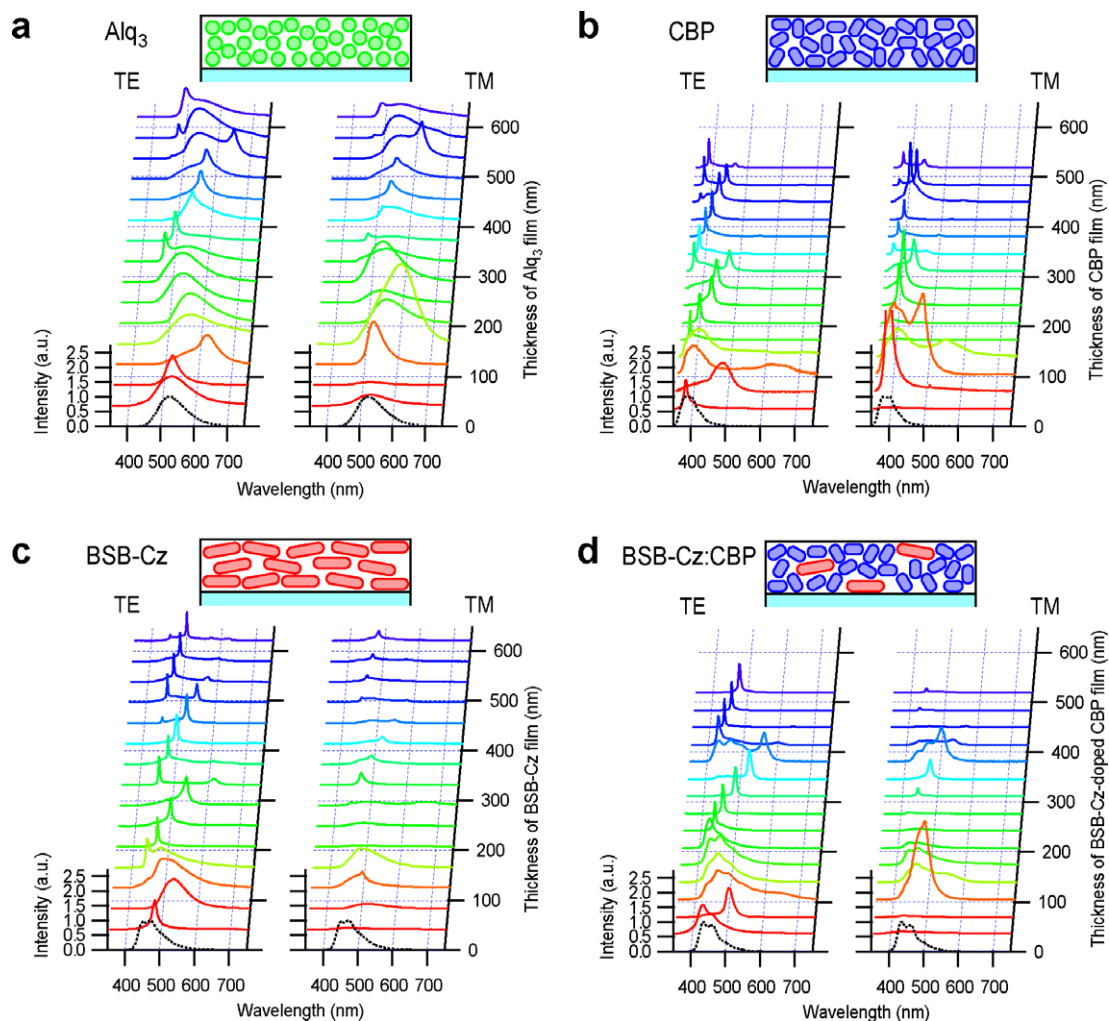
Furthermore, because the weak interaction between molecules causes the horizontal orientation, guest molecules having a linear-shaped structure can be horizontally oriented in host films. Fig. 6d shows the cutoff emissions from the edges of 6 wt%-BSB-Cz-doped CBP films. It should be noted that the TM emissions from the BSB-Cz-doped CBP films were depressed compared to the TM emissions from the neat CBP films shown in Fig. 6b. (Although the high TM intensities are apparently seen at the thicknesses of ∼100 and ∼380 nm in Fig. 6d, it does not mean random orientation or normal orientation. Because the cutoff wavelengths of TE modes at these thicknesses are accidentally out of the PL spectral region, as shown later, the absolute intensities of the TE emissions became low. Furthermore, because the cutoff wavelengths of the TM emissions are inside the PL region, the intensities of the TM emissions became *relatively* high compared to those of the TE emissions at these thicknesses.) This result shows the horizontal orientation of the guest BSB-Cz molecules even in the isotropic host matrix of the CBP film. It can be well understood with assumptions that the surface of the films is always smooth on nm-scale during co-deposition and that the depositions of each BSB-Cz and CBP molecules are independent due to the weak interaction


Fig. 6. (Color online) Dependence of cutoff emission spectrum on polarization direction and thickness of organic film. (a) Alq$_3$, (b) CBP, (c) BSB-Cz, and (d) 6 wt%-BSB-Cz-doped CBP. Insets: Schematic illustrations of molecular orientations in films. All the TE and TM spectra are normalized such that the peak intensities of the TE spectra become unity while keeping the ratios of intensities of the TE and TM spectra. Normal PL spectra are shown by black broken lines. In the case of the isotropic films (Alq$_3$ and CBP), the intensities of the TE and TM spectra are not so different on the whole. In contrast, the intensities of the TE spectra are higher than those of the TM spectra on the whole in the case of BSB-Cz and 6 wt%-BSB-Cz-doped CBP, showing the orientation of BSB-Cz molecules.

between them, as shown in Fig. 5c. The BSB-Cz molecules are horizontally deposited on the surface of the doped film, as in the case where BSB-Cz molecules are deposited on a CBP underlying layer (see Table 2).

The validity of the results obtained by VASE and CEM is also shown in Fig. 7a–d, in which the peak wavelength of the cutoff emissions and the calculated cutoff wavelength of the films with different thicknesses are both shown. The former was obtained by CEM, and the latter was obtained by calculations according to the process written in Section 4 using refractive indices obtained by VASE (shown in Fig. 3d). They were obtained by the two independent methods using different substrates. The cutoff wavelengths of the slab waveguide composed of a glass substrate, an isotropic organic film (Alq$_3$ or CBP), and air were directly calculated using Eqs. (6) and (7) in Section 4. As shown in Figs. 7a and b, the peak

wavelength of the cutoff emissions and the calculated cutoff wavelength are in good agreement with each other. The peak wavelengths shift in the spectral region of the normal PL spectrum with an increase in the film thickness, and then the narrow emission having the next mode number appear from the short-wavelength side. The peak wavelengths of the TE and TM emissions are adjacent to each other and the wavelengths of the TE emissions are slightly longer than those of the TM emissions, which are the characteristics of a slab waveguide with an isotropic layer.

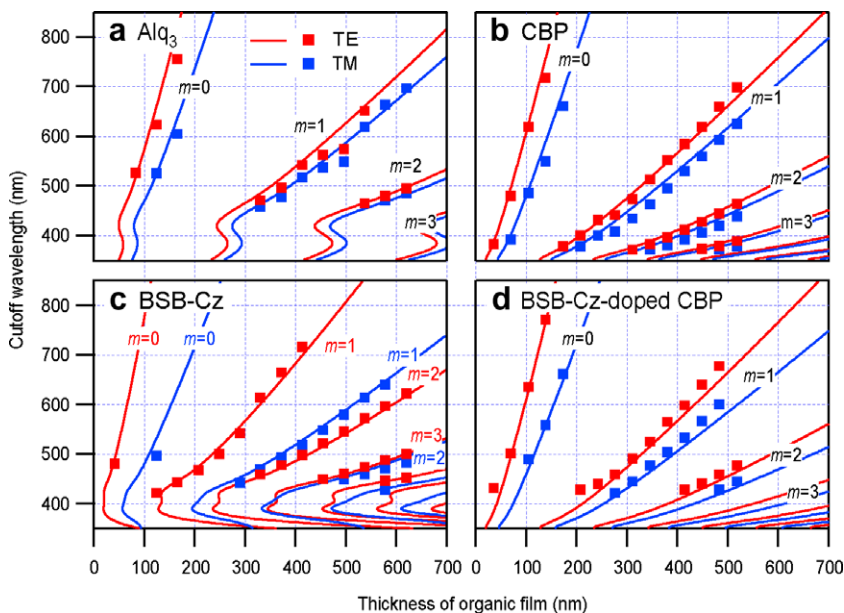
In contrast, the peak wavelengths of the emissions from the neat BSB-Cz films change in a different way, depending on the thickness, as shown in Fig. 5c. The peak wavelengths of the TE and TM emissions are not always adjacent. Here, we succeeded in simulating this behavior by a calculation in which we took into account the anisotropy in the BSB-


Fig. 7. (Color online) Agreement of experimental peak wavelengths of cutoff emissions and calculated cutoff wavelengths of slab waveguides. The peak wavelengths of the TE and TM emissions (red and blue squares, respectively) and the cutoff wavelengths calculated using the refractive indices (red and blue lines, respectively) are indicated. (a) Alq$_3$, (b) CBP, (c) BSB-Cz, and (d) 6 wt%-BSB-Cz-doped CBP. The cutoff wavelengths in (d) are calculated using isotropic optical constants of a neat CBP film. Except for BSB-Cz, the peak wavelengths of the TE and TM emissions are always adjacent to each other. This is a characteristic of a slab waveguide with an isotropic core layer. Only the peak wavelengths of the emission from the neat BSB-Cz films change in a different way depending on the thickness and can be simulated using the equation of the index ellipsoid of the anisotropic film.

Cz film according to the process using the equation of the index ellipsoid, as shown in Section 4. The peak wavelengths and the calculated cutoff wavelength exactly corresponded, demonstrating the validity of the results obtained by both VASE and CEM.

The peak wavelengths of the cutoff emissions from the BSB-Cz-doped CBP films nearly corresponded to the calculated cutoff wavelengths of the waveguide with the isotropic CBP film though slight deviations were found, as shown in Fig. 5d. The deviation of the TE modes in the short-wavelength region is due to perturbation by the doped BSB-Cz molecules because the ordinary refractive index of the BSB-Cz film is much higher than that of the CBP film. This result demonstrates the horizontal orientation of doped emitting molecules in the host film having the low ordinary refractive index, which is necessary to improve out-coupling efficiency of OLEDs. The out-coupling efficiency is affected not only by the orientation of transition dipole moments but also by the refractive index of emitting layer n_{em} with the $1/n_{em}^2$ relation [6]. Thus, a high ordinary refractive index is not favorable because it cancels out the effect of the horizontal orientation on the out-coupling efficiency. In addition, the horizontal orientation of emitting molecules in doped film is important because doping techniques are frequently used in the fabrication of OLEDs and organic laser devices to avoid concentration quenching.

3. Conclusions

In this study, we found that the linear-shaped molecules of fluorescent styrylbenzene derivatives are horizon-

tally oriented in organic amorphous films fabricated by conventional vacuum deposition even when the molecules are doped in an isotropic host matrix film. The weak interaction between adjacent molecules and the linear-shaped molecular structure probably cause the horizontal orientation. The fact that the horizontal molecular orientation occurs on any underlying layers shows the high versatility of the horizontal orientation for various applications. Our findings will lead to an improvement in optical and electrical characteristics of organic amorphous films and optoelectronic devices made from them. Moreover, there is a possibility that the horizontal molecular orientation inheres in many amorphous films having high-performance optical or electrical characteristics though it has not yet been noticed. Actually, we recently also detected the anisotropies in the films of many hole and electron transport materials having long or planar structures [29]. We think that it is meaningful to reevaluate the optical and electrical properties of organic materials in terms of their molecular orientation.

4. Experimental and calculations

All samples of organic films for ellipsometry measurement were prepared by vacuum deposition. Silicon (100) substrates were cleaned using detergent and organic solvents. Glass substrates with and without a 30-nm-thick ITO layer were cleaned using detergent and organic solvents and then subjected to UV-ozone treatment. A glass substrate with a 100-nm-thick Ag layer was also prepared by deposition of Ag on the cleaned glass substrate at an evaporation rate of ∼0.1 nm/s in a vacuum of

<1 × 10^{-3} Pa and kept without air exposure. All organic films were thermally evaporated on the substrates in a vacuum of <3 × 10^{-3} Pa at an evaporation rate of ~0.2 nm/s. A 6 wt%-BSB-Cz-doped CBP film was also fabricated by co-deposition. The thicknesses of all the samples were ~100 nm.

Surface roughness of the films was measured using an AFM (D-3000, Veeco Instruments Inc.). Out-of-plane and in-plane XRD patterns of the Alq$_3$ and BSB-Cz films on silicon substrate were measured using a high-resolution XRD diffractometer (SmartLab, Rigaku Corporation).

Variable angle spectroscopic ellipsometry was performed using a fast spectroscopic ellipsometer (M-2000U, J. A. Woollam Co., Inc.). Measurements were taken at seven multiple angles of the incident light from 45° to 75° in steps of 5°. At each angle, experimental ellipsometric parameters Ψ and Δ were simultaneously obtained in steps of 1.6 nm throughout the spectral region from 245 to 1000 nm. All measurements for one sample were done only at ~90 s.

The analysis of the data was performed using the software "WVASE32" (J. A. Woollam Co., Inc.), which can perform a batch analysis of all the data at all the different incident angles and wavelengths. The model function system of dielectric constants ε_1 and ε_2 of the organic films, which satisfies the Kramers-Kronig consistency, was composed of Gaussian and Tauc-Lorentz oscillators [30] with a Sellmeier background. Physically reasonable values were adopted as the initial values of the structural and optical parameters of the model functions. Then, the parameters were optimized to fit the simulated values of Ψ and Δ to the experimental values to minimize the value of the MSE [25]. The complex refractive indices of the films $N = n + ik$ were also calculated using the values determined for ε_1 and ε_2. Analysis using uniaxial anisotropic models [7] was also performed to determine the anisotropy in the films of the styrylbenzene derivatives. Only the amplitudes of the oscillators were independently changed in the model function systems of the ordinary and extraordinary dielectric constants. The other parameters were changed while keeping the common values in these systems. The dielectric constants of the ITO layer were estimated in advance using Drude and Tauc-Lorentz oscillators. Throughout all the above analysis, we assumed a uniform optical property of the films with a smooth surface, and complicated models, such as a surface roughness layer, a non-uniform layer, or an interface layer, were not used because they make the uniqueness of analysis low.

Molecular lengths of materials were roughly estimated from the optimized geometries obtained by density functional theory calculations using GAUSSIAN 03 program [31]. B3LYP calculations were performed using 6-31G(d) basis.

All samples of organic films for measurement of cutoff emissions were also prepared by vacuum deposition under the same conditions. The organic films, which had 15 different thicknesses, were deposited on the clean glass substrates having a refractive index of 1.524. The glass substrates with the organic film were cleaved, and the organic films were optically pumped near the edge of the cleavage face using a cw He–Cd laser (IK3102R-G, Kimmon

Electric Co.). An incident beam with a wavelength of 325 nm was focused on the surface of the organic films by a lens. The excitation energy of the beam was 60 W/cm^2. The edge emissions were collected using a multichannel spectrometer (PMA-11, Hamamatsu Photonics Co.) that has an optical fiber with a receiving diameter of 1 mm. The polarization characteristics of the edge emissions were measured through a polarizing filter placed between the sample and the end of the fiber.

The cutoff wavelengths of waveguides with an isotropic and uniaxial anisotropic organic core layers were calculated as below. The wavelength of the light that propagates in a waveguide should satisfy the phase matching condition represented by

$$\frac{4\pi n_2 d \cos\theta_2}{\lambda} + \phi_{21} + \phi_{23} = 2m\pi, \tag{2}$$

where d is the thickness of the core layer, λ is the free space wavelength of light, ϕ_{21} and ϕ_{23} are the phase shifts at interfaces 21 and 23, respectively, and m is the mode number ($m = 0, 1, 2, \ldots$) (see also Fig. 1b). The phase shifts depend on the polarization direction and are represented for the TE and TM modes by

$$\phi_{2i}^{TE} = -2\tan^{-1}\frac{(n_2^2\sin^2\theta_2 - n_i^2)^{1/2}}{n_2\cos\theta_2} \quad (i = 1 \text{ or } 3) \tag{3}$$

and

$$\phi_{2i}^{TM} = -2\tan^{-1}\frac{n_2(n_2^2\sin^2\theta_2 - n_i^2)^{1/2}}{n_i^2\cos\theta_2} (i = 1 \text{ or } 3) \tag{4}$$

respectively. If the wavelength of light is very close to the cutoff wavelength, incident angle θ_2 corresponds to the critical angle θ_c, that is

$$\theta_2 = \theta_c = \sin^{-1}(n_1/n_2). \tag{5}$$

From Eqs. (2)–(5), we obtain the cutoff wavelength for the TE and TM modes,

$$\lambda_c^{TE} = \frac{2\pi d(n_2^2 - n_1^2)^{1/2}}{\tan^{-1}\left(\frac{n_1^2 - n_3^2}{n_2^2 - n_1^2}\right)^{1/2} + m\pi} \tag{6}$$

and

$$\lambda_c^{TM} = \frac{2\pi d(n_2^2 - n_1^2)^{1/2}}{\tan^{-1}\left[\frac{n_2^2}{n_3^2}\left(\frac{n_1^2 - n_3^2}{n_2^2 - n_1^2}\right)^{1/2}\right] + m\pi}, \tag{7}$$

respectively. Here, d is the thickness of the organic film, and n_1, n_2, and n_3 are the refractive indices of the glass substrate ($n_1 = 1.524$), the organic film, and air ($n_3 = 1$), respectively. The refractive indices of the organic films n_2 in all the above equations depend on the wavelength of light. Using Eqs. (6) and (7), we can directly calculate cutoff wavelengths of a waveguide with an isotropic core layer at a certain thickness. When a core layer has a uniaxial anisotropic property, the calculations become more complicated because the refractive indices for the light of the TE and TM modes are different. The refractive index for the light of the TE mode n_2^{TE} is simply equal to the ordinary refractive index, while that of the TM mode n_2^{TE} depends on

angle θ_2 according to the equation of an index ellipsoid. They are represented by

$$n_2^{TE} = n_o, \tag{8}$$

and

$$\frac{1}{n_2^{TM}(\theta_2)^2} = \frac{\cos^2\theta_2}{n_o^2} + \frac{\sin^2\theta_2}{n_e^2}, \tag{9}$$

respectively [32]. The cutoff wavelength for the TE mode is obtained by substituting Eq. (8) into Eq. (6). To calculate the cutoff wavelength for the TM mode, it is necessary to determine angle θ_2 at each wavelength because the refractive index depends on this angle. The equation for the cutoff condition, Eq. (5), is replaced with

$$\theta_2 = \sin^{-1}(n_1/n_2^{TM}(\theta_2)). \tag{10}$$

From (9) and (10) we obtain the equation for determining θ_2,

$$n_1 - n_o n_e (n_o^2 \sin^2\theta_2 + n_e^2 \cos^2\theta_2)^{-1/2} \sin\theta_2 = 0. \tag{11}$$

Eq. (11) can be solved for θ_2 numerically at each wavelength, and the n_2^{TM} determined by Eq. (9) is substituted into Eq. (7). In this way, we can calculate the cutoff wavelength in both cases: when the core layer is isotropic and when it is anisotropic.

ARTICLE INFO

ABSTRACT

Electrical bistability is demonstrated in organic memory devices based on *tris*-(8-hydroxy-quinoline)aluminum (AlQ$_3$) and aluminum nanoparticles. The role of the thickness of middle aluminum layer and the size of the nanoparticles in device performance is investigated. Above a threshold voltage, the device suddenly switches from a low conductivity OFF state to a high conductivity ON state with a conductivity difference of several orders of magnitude. The OFF state of the device could be recovered by applying a relatively high voltage pulse. The electronic transition is attributed to an electric field induced transfer of charge between aluminum nanoparticles and AlQ$_3$. The type of charge carriers responsible for conductance switching is investigated. The charge carrier conduction mechanism through the device in ON and OFF states is studied by temperature dependent current–voltage characteristics and analyzed in the framework of existing theoretical models. The conduction mechanism in the OFF state is dominated by field-enhanced thermal excitation of charge carriers from localized centers, whereas it changes to Fowler–Nordheim tunneling of charge carriers in the ON state. The device exhibited excellent stability in either conductivity states. The results indicate the strong potential of the device towards its application as a nonvolatile electronic memory.

1. Introduction

During the past fifteen years, tremendous work has been done in the field of organic semiconductor based electronic devices. Devices such as light emitting diodes [1–3], field effect transistors [4–6] and solar cells [7–9] have shown great potential towards future technologies. Organic semiconductor based devices exhibit unique advantages such as low fabrication cost, high mechanical flexibility and versatility of the material chemical structure compared with the inorganic semiconductor devices. However, to widen the application of organic semiconductors to varieties of electronics systems, organic based memory devices are essential [10–16]. The basic feature of a memory device is to exhibit bistable behavior having two different resistance states at the same applied voltage. Ma et al. have

demonstrated memory effects in a three layer organic/metal nanoparticle/organic structure embedded between two electrodes [17]. Bozano and coworkers have studied the important role of different metal nanoparticles in a three layer memory structure [18]. During the device operation, when applied voltage exceeds a certain value, the device suddenly switches from a low conductivity 'OFF' state to a high conductivity 'ON' state, with a conductivity difference of several orders of magnitude. This high conductivity state will be memorized until an 'OFF' voltage is applied to erase it. Despite the superior performance of organic memory devices, the charge carrier transport mechanism in the 'ON' and 'OFF' states and the type of carriers responsible for bistability are not understood clearly.

In this paper, we describe the fabrication and operation of the tri-layer organic/metal/organic and the single layer memory structures sandwiched between two electrodes. The effect of the thickness of intermediate metal layer and the size of the nanoparticles in device performance is

investigated. The charge carrier conduction mechanism through the device in 'ON' and 'OFF' states is studied by temperature dependent current–voltage characteristics and analyzed in terms of existing theoretical models. The type of carriers responsible for conductance switching is also investigated.

2. Experimental

In present investigation, three different types of device structures were studied. The first type (type-I) is the tri-layer AlQ_3/Al nanoislands/AlQ_3 structure sandwiched between two electrodes (hereafter called tri-layer device), the second one (type-II) is a single AlQ_3 layer embedded between two electrodes (hereafter called single layer device), and the third type (type-III) is the ITO/Poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS)/AlQ_3/Al nanoislands/AlQ_3/Al device. For all types of devices, patterned indium tin oxide (ITO) (SPI Inc.) with sheet resistance 10 $\Omega/\square$ was used as the bottom electrode. Prior to AlQ_3 deposition, ITO substrates were cleaned thoroughly in acetone, isopropyl alcohol and de-ionized water in sequence by an ultrasonic cleaner followed by drying with nitrogen gas. For the fabrication of tri-layer structure, both the AlQ_3 and Al middle layers were deposited by thermal evaporation at a base pressure of 5×10^{-6} mbar. The thickness of the each AlQ_3 layer was about 50 nm and that of the middle Al layer was varied between 5 and 20 nm. The deposition rate of the middle Al layer was controlled by a quartz crystal thickness monitor. In order to obtain the nanoscale metal islands, a low evaporation rate of less than 0.1 nm/s was used. For the single layer device structure, AlQ_3 (100 nm) was thermally evaporated on ITO electrodes. For the fabrication of ITO/PEDOT:PSS/AlQ_3/Al nanoislands/AlQ_3/Al device, a 40 nm thick PEDOT:PSS layer was spin coated on ITO substrates from a 2.8 wt.% water solution (Aldrich). Post baking was done for 1 h at around 110 °C to remove the solvent completely. Deposition of all other layers of this device was done in the same manner as the tri-layer device. Finally, aluminum top electrode strips were deposited by thermal evaporation through a shadow mask.

The thickness of different layers was monitored by quartz crystal monitor and was verified by stylus profilometer (Veeco Dektak3). Cross sectional scanning electron microscopy (SEM) images of the device were taken using a ZEISS SUPRA 40 field emission (FE) microscope. Atomic force microscopy (AFM) (Veeco Nanoscope-IV) in tapping mode was used to evaluate the surface morphology of the middle Al layer. Fourier-transform infrared (FTIR) spectra of the middle Al layer in the wave number range 400–4000 cm^{-1} were obtained using a Nexus 870 Thermo Nicolet spectrometer. The optical transmission spectra were measured in the wavelength range 300–1100 nm using a UV–vis–NIR spectrophotometer (Perkin–Elmer Lambda 45). The dc current–voltage characteristics of the devices were obtained using a Keithley 485 Pico ammeter and an Advantest R6144 programmable dc voltage generator.

3. Results and discussion

Fig. 1 shows the cross sectional view of a typical tri-layer memory structure (type-I) sandwiched between ITO and Al electrodes. The FE–SEM micrograph clearly indicates ITO, two AlQ_3 layers and Al layer with sharp interfaces. The thickness of bottom AlQ_3, top AlQ_3, ITO and Al layers are estimated to be 70 nm, 50 nm, 400 nm and 200 nm, respectively.

The performance of organic bistable device is sensitive to metal nanoparticles and the thickness of the middle metal layer. The ON/OFF current ratio, for example, depends strongly on the size and density of the nanoparticles. Morphology and the thickness of the middle Al layer depends on the evaporation rate and is controlled by quartz crystal monitor. Films deposited with a higher deposition rate led to continuous films and, hence, non-switching devices. A deposition rate less than 0.1 nm/s resulted in island like growth and bistable devices. Detailed information about the nanostructure of the middle Al layer has been obtained by AFM. Fig. 2a illustrates the surface morphology of the middle Al layer of thickness 5 nm. It clearly shows disconnected metal islands of various sizes. The size distribution of nanoislands is estimated from this AFM image and is shown in Fig. 2b. The island size varies from 5 nm to about 25 nm with peak of the distribution at 15 nm. When the thickness of the film is increased to 10 nm, the size of nanoislands increases slightly as shown in Fig. 2c. For this film the island size distribution ranges from 8 nm to about 35 nm and peaks at 20 nm, as shown in Fig. 2d. The gaps

**Fig. 1.** Cross sectional SEM image of the tri-layer memory device, ITO/AlQ_3/Al/AlQ_3/Al (type-I).

between the islands are of the order of 3–7 nm. Coalescence of nanoislands is observed with further increase in film thickness as shown in Fig. 2e. Here the thickness of the middle Al layer is about 15 nm. A large variation in the size of the nanoislands (from 15 to 60 nm) is observed in Fig. 2f, with the peak of the distribution at 30 nm.

Though the deposition of Al nanoparticles is performed at 5×10^{-6} mbar, there is a time delay between the deposition of nanoparticles and top AlQ_3 layer. During this time a thin oxide shell is formed on the nanoparticles. Since the deposition is done under high vacuum, a large fraction of the aluminum remains as a metallic core surrounded by a thin oxide shell [18]. Formation of oxide shell was also mentioned by other authors. Ma et al. have performed *in situ* X-ray photoemission spectroscopy measurements and confirmed the formation of 16 Å oxide shell [11]. Fig. 3a shows the FTIR spectra of the middle Al layer of thickness 10 nm in the range 400–2000 cm^{-1}. The strong band observed at 538 cm^{-1} (labeled A) is assigned to octahedral Al–O stretching vibrations, whereas the broad band centered at 812 cm^{-1} (labeled B) is assigned to tetrahedral Al–O stretching vibrations [19–21]. These results clearly indicate the presence of oxide shell on the metal islands.

In addition to AFM and FTIR, UV–vis transmission spectra have been used to study the middle Al layer deposited on AlQ_3. Fig. 3b shows the transmission spectra of the middle Al layer of different thickness deposited on 50 nm thick AlQ_3 film. Transmission spectrum of pure AlQ_3 film is also shown as a reference. For the Al film that appears in normal metallic color, the transmission is relatively low in the UV–vis region. It indicates that most of the radiation from the light source is reflected away by the continuous metal film. The film containing Al nanoislands appears in deep blue color and shows relatively high transparency in the UV–vis region, as shown in Fig. 3b. The devices fabricated using this deep blue color Al films have shown bistable behavior.

Fig. 4 shows typical current–voltage (*I–V*) characteristics of the tri-layer nanoparticle memory device (type-I) on a semi logarithmic scale obtained by sweeping the volt-age from −5 to +5 V and then back to −5 V. Here the thickness of the middle Al layer is about 15 nm. Almost symmetric *I–V* characteristics are observed for both the polarities of the voltage. This figure can be used to define the key parameters of the device. Initially, the device remains in the high resistance 'OFF' state at a smaller bias. When the applied voltage reaches a threshold value (V_{th}), resistance of the device decreases abruptly and the device current increases by several orders of magnitude. The value of V_{th} is in the range 1.7–2.3 V. As shown in Fig. 4, the device current switches between the states of high and low resistance at the threshold, reaches the maximum (V_{ON}), and then goes through a negative differential resistance (NDR) region to a minimum (till V_{OFF}), after which it increases again almost exponentially. When the voltage is decreased towards zero, the current follows the upper curve and the device is set in its 'ON' state until the voltage near V_{OFF} is applied. An "N-shaped" *I–V* curve is obtained in the 'ON' state of the device. The low voltage region below V_{th} is the region of bistability, in which the state of the device can be read (V_{read}). The 'ON' state of the device is obtained by applying a voltage near V_{ON} and the 'OFF' state is recovered by applying a voltage beyond V_{OFF}.

Fig. 5 shows the current–voltage characteristics of the tri-layer devices $ITO/AlQ_3/Al/AlQ_3/Al$ (type-I) with different thickness of middle Al layer. The characteristics of the device without middle Al layer, is also shown for comparison. Both the devices show bistable properties. The bistability is attributed to the presence of metal nanoparticles in the AlQ_3 matrix. For tri-layer devices, the middle thin Al layer contains the nanoparticles. In case of single layer devices, metal nanoparticles are incorporated in AlQ_3 layer by diffusion during the evaporation of top electrode [22]. The threshold voltage is in the range 1.7–2.3 V for the devices with different thickness of middle Al layer. The ON/OFF current ratio is very small (~10) for single layer device and increases with increasing thickness of the middle Al layer till 10 nm. The devices with 10 nm thick middle Al layer have shown better switching properties with large ON/OFF current ratio (>10^5) at a read volt-

age of 1 V. If the thickness of the middle Al layer is increased beyond 10 nm, the ON/OFF ratio decreases sharply and the switching properties almost vanish at a thickness of 20 nm as shown in Fig. 5. At higher thicknesses of middle Al layer, for example at 15 nm, Al nanoparticles grow in size and join with the neighboring particles as shown in AFM image (Fig. 2f). Then the number of isolated particles that can store charge becomes less and hence the ON/OFF ratio goes down. Single layer devices exhibit lower current because of the mismatch of electrode work functions to the HOMO and LUMO levels of AlQ$_3$. The current in both ON and OFF states increases with increasing thickness of the middle Al layer. These results suggest that the nanoparticles not only induce bistability, but also contribute to the conduction process.

The retention of the ON and OFF states and device performance under electrical stress is important for practical

applications. Stress tests have been performed by subjecting the device to a low bias of 1 V over prolonged periods of time in both ON and OFF states and by recording the currents at different times. When subjected to stress test, the device in the OFF state retains its conductivity and do not undergo any transition to the ON state, as shown in Fig. 6. Similar tests have been performed on the device in the ON state. The current in both ON and OFF states remains constant even after a prolonged period of continuous stress test. It shows that there is no significant degradation of the device in both ON and OFF states, indicating the stability of both material and material/electrode interfaces.

To understand the conduction mechanism through the device in both ON and OFF states, the current–voltage characteristics at different temperatures have been measured and analyzed in the framework of existing theoretical models. Fig. 7 shows the current–voltage characteristics of the device, ITO/AlQ$_3$/Al(10 nm)/AlQ$_3$/Al (type-I), at different temperatures. The threshold voltage of the device decreases with increasing temperature. The device current in the OFF state has shown strong temperature dependence. This thermally activated charge transport may be either due to Poole–Frenkel (PF) emission of charge carriers or to the Schottky contact at the Al/AlQ$_3$ interface. The PF emission is due to the field-enhanced thermal excitation of charge carriers from localized centers or potential wells within the bulk of the semiconductor, whereas the Schottky effect results from the injection of charge carriers from the electrode into the semiconductor. In order to differentiate between these two conduction mechanisms, current–voltage characteristics are measured at both the polarities of voltage. In present study, an asymmetric electrode structure (ITO and Al electrodes) is used for the fabrication of all the devices. The difference between the work functions of ITO and Al is 0.6 eV (the work functions of ITO and Al are 4.9 and 4.3 eV, respectively). For the Schottky controlled conduction in an asymmetric electrode structure, the current–voltage characteristics should also be asymmetrical when the voltage is reversed. However, all
Fig. 6. Voltage stress test of the device in the ON and OFF states at a read voltage of 1 V.
Fig. 7. Current–voltage characteristics of ITO/AlQ$_3$/Al(10 nm)/AlQ$_3$/Al device at different temperatures.

the devices have shown symmetric current–voltage characteristics in the OFF state as shown in Fig. 4. Therefore, the current conduction is dominated by PF emission in the OFF state of the device.

This PF mechanism is further confirmed by analyzing the current–voltage characteristics. The reported values of HOMO and LUMO levels of AlQ$_3$ are around 5.8 and 3.0 eV, respectively [18,23]. In case of PF emission, the theoretical energy barrier for the emission of electrons is 1.3 eV. The current through the device in case of PF emission is given by [24]

$$I = CV \exp \left[-\frac{q}{kT} \left(\Phi - \left(\frac{qV}{\pi \varepsilon l} \right)^{1/2} \right) \right] \qquad (1)$$

where q is the electronic charge, Φ is the ionization energy of the traps, ε is the dynamic permittivity of AlQ$_3$, k is the Boltzmann constant, T is the temperature, and C is a constant. A linear relation between $\log(I/V)$ and $V^{1/2}$ is ob-

served in the OFF state of the device as shown in Fig. 8a. The experimental activation energy obtained from the temperature dependant current characteristics is 1.6 eV, which is in close agreement with the theoretical ionization energy of PF emission. These results confirm the predominance of PF emission in the OFF state of the device.

The current–voltage and current–temperature relations have changed after electrical transition to the ON state. A linear relation is observed between $\log(I/V^2)$ and $1/V$ as shown in Fig. 8b. In addition, the current in the ON state is insensitive to temperature. These results suggest that the current conduction in the ON state is probably due to Fowler–Nordheim tunneling of charge carriers through a triangular barrier. The current in case of Fowler–Nordheim tunneling is given by [24]

$$I = C_1 V^2 \exp \left[-\frac{4d(q\Phi)^{3/2}(2m^*)^{1/2}}{3qhV} \right] \qquad (2)$$

where Φ is the energy barrier height, d is the tunneling distance, m^* is the reduced mass of the charge carrier, and C_1 is a constant. Thus, the current conduction mechanism changed from the Pool–Frenkel emission in the OFF state to Fowler–Nordheim tunneling in the ON state.

In order to investigate the type of carriers (either electrons or holes) responsible for conductance switching, a hole injecting material PEDOT:PSS is deposited between ITO electrode and bottom AlQ$_3$ layer. The current–voltage characteristics of ITO/PEDOT:PSS/AlQ$_3$/Al(10 nm)/AlQ$_3$/Al device exhibit slight hysteresis and no obvious switching behavior as shown in Fig. 9. Moreover, emission of light from the device is observed after the incorporation of PEDOT:PSS layer. In case of ITO/AlQ$_3$/Al(10 nm)/AlQ$_3$/Al device, electrons injected from the Al electrode are trapped inside Al nanoislands and produces bistability. Probability of electron-hole recombination is very small because of the less number of available holes. PEDOT:PSS enhances the injection of holes into the AlQ$_3$ layer and hence increases the probability of electron-hole recombination [25]. The process of recombination results in smearing
Fig. 8. (a) Variation of $\log(I/V)$ with $V^{1/2}$ in the OFF state of the device, and (b) variation of $\log(I/V^2)$ with $1/V$ in the ON state of the device. Symbols are the experimental data and the solid lines are the fitting data using theoretical models.

Fig. 9. Current–voltage characteristics of ITO/AlQ$_3$/Al(10 nm)/AlQ$_3$/Al device with and without PEDOT:PSS layer between ITO and bottom AlQ$_3$.

out of bistability and emission of light. Thus the electrons are majority carriers and holes are minority carriers in case of our organic bistable devices.

In the light of above experimental results, we propose that the electronic transition is due to an electric field induced transfer of charge between aluminum nanoparticles and AlQ$_3$. When the applied electric field is high enough, electrons in the AlQ$_3$ may gain enough energy and tunnel through aluminum oxide shell into the core of aluminum nanoparticles. The charge on the aluminum nanoparticles may be stable due to the presence of insulating aluminum oxide shell, which prevents the recombination of charge after the removal of external electric field. The OFF state of the device can be recovered by applying a voltage near V_{OFF}, which is due to the removal of charge from the core of the aluminum nanoparticles.

4. Conclusions

In conclusion, electrically bistable devices using AlQ$_3$ and aluminum nanoparticles have been demonstrated. The effect of the thickness of middle aluminum layer and the size of the nanoparticles on device performance is investigated. It is observed that the bistability is very sensitive to nanostructure of the middle aluminum layer. For obtaining the devices with well controlled bistability, the middle aluminum layer should have island like structure, instead of continuous metal layer. These nanoislands act as the charge storage elements, which enable the nonvolatile electrical bistability when biased to a sufficiently high voltage. The charge carrier conduction mechanism through the device in ON and OFF states is studied by temperature dependent current–voltage characteristics and analyzed in

the framework of existing theoretical models. The charge conduction for the device in the OFF state is mainly due to the field-enhanced thermal excitation of charge carriers from localized centers, whereas it changes to Fowler–Nordheim tunneling of charge carriers in the ON state. Present study reveals that the electrons are majority carriers in these organic bistable devices. The devices exhibit a repeatable bistable behavior and stability in either state. These characteristics indicate that the tri-layer device has a strong potential towards its application as nonvolatile electronic memory.

Low-voltage organic ferroelectric field effect transistors using Langmuir–Schaefer films of poly(vinylidene fluoride-trifluororethylene)

Chien A. Nguyen *, Junling Wang, Lang Chen, Subodh G. Mhaisalkar, Pooi See Lee

School of Materials Science and Engineering, Nanyang Technological University, Block N4.1, 50 Nanyang Avenue, Singapore 639798, Singapore

ABSTRACT

Langmuir–Schaefer transfer was used to fabricate ultrathin films of ferroelectric copolymer, poly(vinylidene fluoride-trifluoroethylene) (70–30 mol%), for non-volatile memory application at low operating voltage. Increasing the number of transferred monolayers up to 10 led to improved film crystallinity in the "in-plane" direction, which reduced surface roughness of the semicrystalline film. Treatment of the substrate surface by plasma results in different film coverage which was subsequently found to be governed by interaction of the deposited film and surface condition. Localized ferroelectric switching was substantially attained using piezo-force tip at 10 V on 10-monolayer films. Integrating this film as a dielectric layer into organic capacitor and field effect transistor yields a reasonably good leakage current ($<10^{-7}$ A/cm^2) with hysteresis in capacitance and drain current with ON/OFF ratio of 10^3 for organic ferroelectric memory application at significantly reduced operating voltage of |15| V.

1. Introduction

Polyvinylidene fluoride (PVDF) and copolymer with trifluoroethylene P(VDF-TrFE) are well-known for their ferroelectric properties in crystalline forms [1,2]. The polymers have a vast application in sensors, actuators [3,4], and non-volatile memory [5–8]. These applications usually require a thin film fabricated by spin-coating or mechanical pressing. Crystallization of the polymer chains can be resulted from either post-process annealing or recrystallization from melting. Recently, a new method of forming P(VDF-TrFE) copolymer films has been reported using Langmuir–Schaefer transfer mechanism [9,10]. The method includes two main steps – first, compressing to form monolayer (ML) of compact polymer chains at the air-liquid interface and second, transferring the monolayer onto a substrate surface. Film thickness can be controlled by the

number of transfers at a certain compressing pressure [11]. Film crystallinity can be enhanced by annealing at temperatures below melting point similar to those of spin-coated films [12]. In addition, Langmuir–Schaefer (LS) method has a potential for realizing a polymer monolayer by aligning and packing its molecular chains without anneal crystallization.

Forming and transferring the LS-films of P(VDF-TrFE) copolymer have been intensively performed by Nalwa [9]. Different properties and characteristic of monolayer P(VDF-TrFE) can be observed including ferroelectricity, optical and energy band etc., as well as the proposed intrinsic switching polarization [9]. While Ducharme et al. have advocated for the intrinsic switching mechanism based on both experimental data and theoretical prediction [9], some other researchers have been expressing concerns regarding to the theoretical conditions of the data interpretation. Recent experimental works by Kliem et al. revealed that the switching process below a certain critical thickness could not be sufficiently explained by either intrinsic or extrinsic model alone [13]. Especially, Naber

et al. have been able to obtain the experimental evidence of ferroelectric switching with bulk characteristics for ultrathin films with thickness ranging from 3 to 10 nm [14]. They have attributed this observation to the improved surface interfacing between the metal electrodes and the ultrathin ferroelectric polymer film. The intrinsic switching mechanism in the PVDF nanostructures and ultrathin films is beyond the scope of this report. However, it can be seen that various important properties of ferroelectric materials remain to be explored in spite of the tremendous efforts and achievements have been obtained in the field.

The application of LS-transfer P(VDF-TrFE) for non-volatile memory using hybrid device with Si-technology has been shown but limited to rather thick film of 100 ML [10]. A unique feature of the LS-transfer film is being strongly governed by the interfacial interaction with substrate that leads to formation of different nanostructures by simple annealing process [15]. It has been well postulated that the nucleation in ferroelectrics substantially occurs at defects or crystal boundaries. For the mesa nanostructures or ultrathin films, the domain-wall motion is in the film plane due to the highly anisotropic dimensions. It hence allows more precise control of nucleation locations and domain-wall motion direction in the switching process. With the lateral size in the range of less than 200 nm, a group of these separately and accurately positioned nanostructures can serve as an equivalent memory element (1 bit) that can improve the storage density as well as reduce cross-talk noise between bits. These understandings are potentially useful for memory application in terms of enhanced device density and performance [10]. To date, demonstration of non-volatile memory behavior of thin LS-transfer films (<100 ML) has been lacking and the memory functionality of the ultrathin P(VDF-TrFE) is not fully explored. Furthermore, realization of organic ferroelectric field effect transistors (FeFET) with LS-transfer film has not yet been reported.

In this paper, we investigate the crystallization of the polymers upon annealing in the paraelectric phase, as a function of the number of transferred layers. We attained localized area switching using piezo-force microscopy and demonstrate a low voltage ferroelectric memory (<15 V) using 10 ML of the LS-transfer P(VDF-TrFE) film as dielectric layer in capacitors and ferroelectric field effect transistors. The electrical behavior and memory functionality is correlated to polarization properties of the LS-transfer films.

2. Experimental

P(VDF-TrFE) (70–30 mol%) was purchased from Solvay and used without purification. Copolymer pellets were dissolved in methyl ethyl ketone (MEK) at concentration of 0.1 mg/cc. The solution was then filtered by using 0.2 μm pore-size Teflon filter and promptly used for deposition to maintain a consistent concentration. N-type Silicon wafer was used as transfer substrates. The wafers were cleaned with Piranha solution ($1H_2O_2$:$2H_2SO_4$), SC2 solution ($1NH_4OH$:$1HCl$:$10H_2O$), followed by acetone, metha-

nol and DI water and blow-dried by N_2 gas. Plasma treatment was done on cleaned substrates with ambient medium for 2 min.

LS-transfer film fabrication was done using Langmuir KSV5000 trough. Ultra-purified water with resistivity of 18.2 MΩ cm was used as subphase medium. The copolymer solution was manually spread onto the subphase surface between the two automatically moving barriers with surface pressure measured by a platinum Wilhelmy plate. The monolayers were manually transferred onto substrates horizontally at 25 °C and surface pressure of 5 mN/m. All transferred samples were then annealed in the ambient at 120 °C for 1 h using a slow ramping oven (1 °C/min). Film crystallinity was determined by Rigaku X-ray diffractometer (XRD) (40 KV, 30 mA) with an incident angle of 0.5° and step of 0.02. The surface morphology of all layers was characterized by atomic force microscopy (AFM) (digital instruments) in tapping mode using nonconductive tip.

Polarization switching of the transferred films was observed by piezo-force microscopy (PFM) with conductive Si tip in contact mode. The closed circuit of sample and PFM equipment was made through the contact from the conductive tip to the LS-film surface and the back of the Si-wafer substrate using silver paste to reduce contact resistance. The surface morphology was first scanned with 10×10 μm^2 dimensions. Next a voltage of +10 V was applied to an area of 6×6 μm^2 and a reversed voltage of -10 V was lastly applied to area of 2×2 μm^2 as shown in Fig. 2. The metal-ferroelectric-semiconductor (M-F-S) capacitor devices were fabricated by thermal evaporation of gold (99.9% purity) through a shadow mask (diameter of 300 μm) onto annealed film samples. The leakage current was measured by Keithley 4200 analyzer and capacitance data was obtained by using HP4284 LCR meter (AC signal of 50 mV and 1 kHz). Ferroelectric field effect transistor (FeFET) was fabricated using Si-wafer with 5 nm thick thermal oxide. The transistor was formed by evaporation of pentacene on top of the transferred P(VDF-TrFE) layers in vacuum (5×10^{-7} torr) at 1–2 Å/s rate. It was then followed by evaporation of gold electrodes for source and drain formation using shadow mask. The transistor operation was then characterized by the Keithley analyzer in dark vacuum ambient.

3. Results and discussion

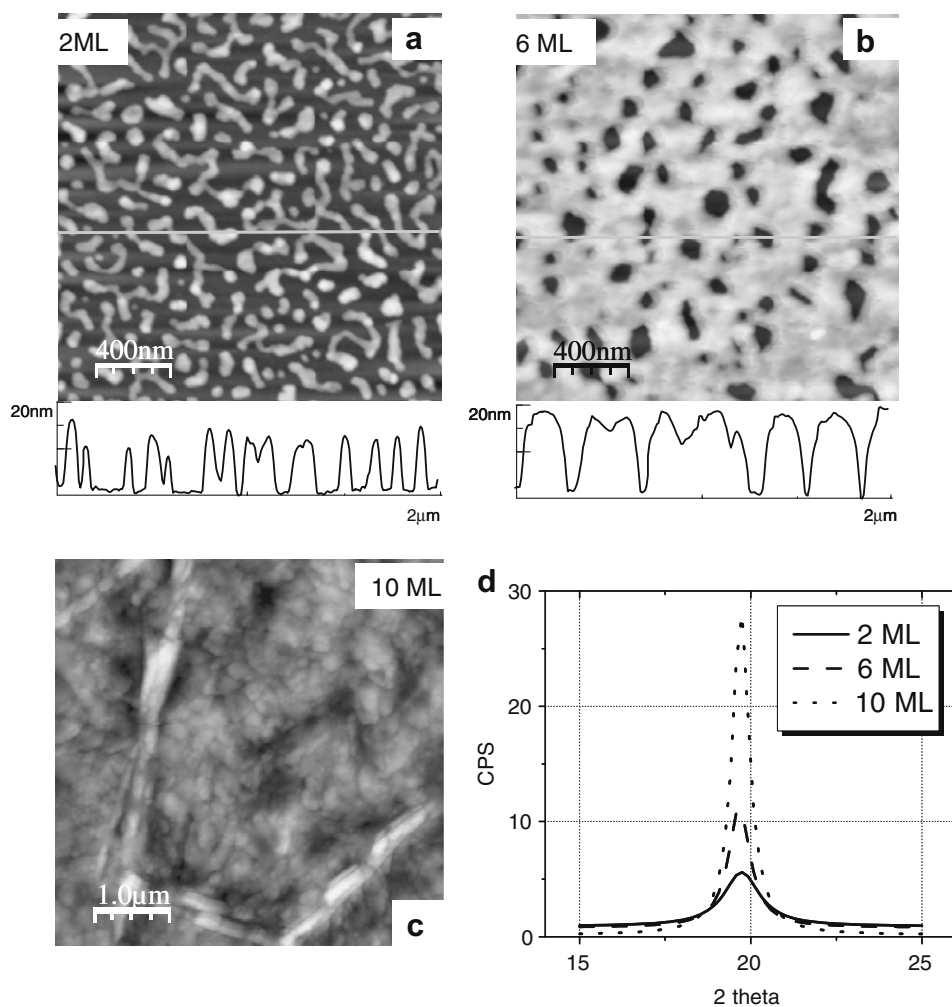
To examine the formation of continuous thin film by LS-transfer method, multiple monolayers were transferred onto cleaned Si-wafer followed by annealing as described. Fig. 1 presents the surface morphology and crystalline structure of films with thickness from 2 to 10 ML. After annealing, it can be seen that nano-mesas and nanowells were formed for 2 and 6 ML thick film, respectively, as well as fully covered film for 10 ML thick sample. Final thickness of the nano-mesa and nanowell samples is below 20 nm while that of the 10 ML sample is in the range of 20 ± 2 nm as determined by AFM line-profiling. Both the nanostructure formations and dimensions are in agreement with the previously reported data (1.8 nm per monolayer) especially in the case of fully covered film of 10 ML


Fig. 1. Changes in surface morphology and crystallinity of the LS-transfer P(VDF-TrFE) films as thicknesses were increased (a), (b) and (c) 2, 6, and 10 ML, (d) XRD data of all the three films.
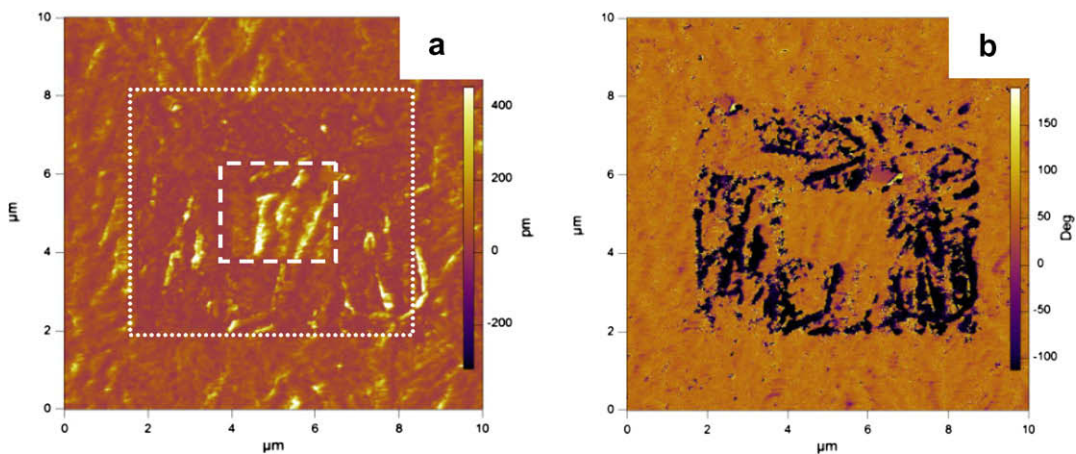

Fig. 2. PFM images of 10 ML LS-transfer sample (a) d_{33} coefficient image and (b) phase image. The dashed and dotted boxes in (a) indicate the scanning areas of different voltage application and the contrast difference in (a) and (b) represents the polarization switching.

layer [16]. The small variation in thickness suggests the crystallization of P(VDF-TrFE) copolymer occurred in a planar manner with crystallinity increasing with more transferred layers. While the 6 ML-film appears with vertical holes through the film thickness, no specific grain formation is observed on the covered regions by the copolymer. On the other hand, grain formation can be seen on the fully covered 10 ML film. The film surface mainly consists of small and round-shaped grains, which results in roughness value (RMS) less than 9 nm. Besides, occasional appearance of rod-like crystals is also observed as shown in Fig. 1c. At the locations of the rod-like grain, the vertical dimension can eventually reach up to 50 nm indicating the crystallization propagates along the normal direction to the film only after the substrate surface had been fully covered. The rod-like grains with polymer lamellas packing along the grain direction appears as vertical walls which intercept each others leading to rough topography and deep valleys usually found on thicker film fabricated by spincoating [17]. Formation of the 10 ML thin film (10 ML) with limited rod-like grain and good crystallinity (Fig. 1) is anticipated to improve the quality of multilayer ferroelectric memory device.

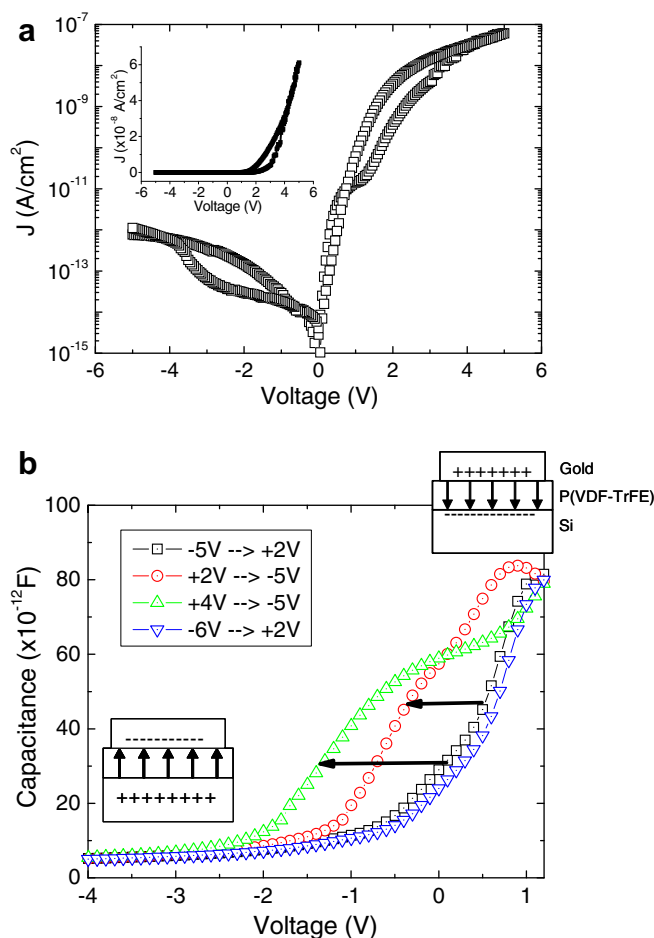
The XRD data (Fig. 1d) of 2, 6 and 10 ML samples show that both ferroelectric and paraelectric phases coexist [1,2]. Previous report [18] suggested that formation of nanostructures had only taken place in the copolymer paraelectric phase. The observation of ferroelectric phase here is hence believed to be due to the slow cooling process after annealing that resulted in paraelectric–ferroelectric phase transition even in the nanostructures. Measurement to confirm polarization properties was hence done by PFM method on all the samples shown in Fig. 1. It was found that only fully covered sample with 10 ML transferred possessed switchable regions under the tip bias application while it was unable to capture any responsive signals from samples with nanostructures (2 and 6 ML). We attribute this to the limitation of applied voltage in the PFM system (maximum applied voltage of $|10|$ V) as compared to the much higher value of intrinsic coercive field ($\sim$0.5 GV/m) which has been estimated for ultrathin (<15 nm) Langmuir–Blodgett film [19]. Polarization switching examined in a 10-ML sample on Si-wafer substrate by the d_{33} coefficient and phase images are presented in Fig. 2. The experiment was performed in two steps – first, 6×6 μm^2 (dotted box) scan with +10 V that


Fig. 3. Electrical characteristic of 10 ML M-F-S capacitor device (a) leakage current *J-V* curve. The electrode area is 7.07×10^{-4} cm^2. The inset shows the linear plot. (b) Capacitance hysteresis *C-V* curves. Two insets present the device structure with hysteresis mechanism.

registered "down" dipoles (point towards substrate) appearing as dark contrast, and then $2 \times 2 \mu m^2$ scan (dashed box) that reversed the polarization to "up" dipoles (pointing away from substrate) appears as different contrast in Fig. 2b. The bright contrast in the dashed box of Fig. 2a clearly indicates the strong dipolar response which could only be resulted from the orientation switching as compared to the outer areas where polarization was not disturbed. The stable existence of the switched region ($2 \times 2 \mu m^2$ box) after continuous scanning enables the storing of information in an ultrathin film device without the adverse effects by depolarization.

Non-volatile memory behavior was studied using M-F-S device with 10 ML thick P(VDF-TrFE) film as a dielectric layer. Fig. 3a shows the leakage current profile which is reasonably low (less than 10^{-7} A/cm^2) for device application with the inset showing a typical diode behavior. It can be seen the current is asymmetric across the vertical axis but has the minimum value at 0 V. The asymmetric shape of the current curve is believed to be caused by different barrier heights at P(VDF-TrFE)/Au and P(VDF-TrFE)/ Si interfaces. With potential applied at the bottom electrode to the silicon substrate, higher current obtained by positive biases means the apparent barrier height of charge injection at the top electrode (Au) is lower than that at bottom one (Si). The minimum current at 0 V possibly indi-

cates the absence of detrapping current by charges existing near the interfacial regions. The memory function is hence mainly resulted from the switching polarization of the P(VDF-TrFE) dipoles as explained by the capacitance hysteresis below.

Fig. 3b presents the capacitance hysteresis data obtained by different sweeping voltages with the first curve (−5 V to +2 V) as reference curve. As voltage was swept in the reversed direction (+2 V to −5 V, dash curve), a capacitance hysteresis was obtained with a shift in flatband voltage of 0.7 V to the negative potential. This can be explained from the direction of dipole vectors. The positive bias (+2 V) at the top metal electrode caused the dipole pointing down towards the Si substrate and led to accumulation in Si. As the voltage was swept to negative bias (−5 V), the field across the device must overcome the dipolar coercive field to revert the dipole direction. As a result the charges were accumulated in the Si until coercive field was reached and led to depletion as displayed in the insets of Fig. 3b. The charge accumulation and depletion in the semiconductor can be treated as ON and OFF state, respectively, for the non-volatile memory. An estimation of the switching field for this device including voltage of |1| V over thickness of 18 nm yields a value of |56| MV/m similar to previous report [2] for spin-coated films. Furthermore, Fig. 3b also displays variability of
Fig. 4. Comparison of surface morphology of (a) spin-coated film (200 nm thick) and (b) 10 ML (~20 nm thick) LS-transfer film. Morphology of pentacene layers grown on both films are shown in (c) and (d), respectively.

flat-band voltage shift or memory window of the device with the application of different voltage amplitudes. When the "writing" voltage was increased to +4 V, the voltage shift could be extended up to 1.3 V (dot curve). To bring the device back to the original state, an "erasing" voltage was applied at −6 V (dash-dot curve). To read the data in the device, a small "reading" voltage should be used e.g. −0.5 V without destroying or reversing the polarization state, which will result in a capacitance difference of up to 40 pF for +4 V "writing" voltage. Hence this proves the versatility and applicability of thin ferroelectric polymer for low voltage non-volatile memory application.

It can be seen that the accumulation in the M-F-S device is unstable which coincides with the high leakage current in the device (Fig. 3). In order to improve the device stability during accumulation for field effect transistor, the semiconducting layer of Si is replaced with pentacene which is an organic p-type semiconductor with lower charge carrier concentration ($\sim 3 \times 10^{17}$ cm^{-3} [20]) while the n-type Si-wafer serves as an electrode. Surface morphology of the evaporated pentacene layer (50 nm thick) on spin-coated and LS-transfer (10 ML) films are shown for comparison in Fig. 4. The surface roughness of the spin-coated P(VDF-TrFE) film is about 17–20 nm as previously reported [6]. For the 10-ML LS-transfer film, pre-scans of surface morphology by AFM were performed to select regions with minimal appearance of the rod-crystallite. As a result, the effective surface roughness of the LS-film was maintained below 10 nm. The average size of pentacene grains is found from the AFM profile to be around 100 nm for both types of P(VDF-TrFE) films. However the pentacene grain-growth is seen to follow the morphology of the rod-like grains on the spin-coated film (Fig. 4c), which limits the intergrain connection in the thin (~ 50 nm) semiconductor layer. This resulted in weak semiconducting behavior of the pentacene film and negligible transistor device characteristics. In the contrary, pentacene grains on the LS-transfer film (Fig. 4d) are generally in circular shape and unaffected by the underneath surface morphology. The average small grain size is probably due to the low surface energy of the P(VDF-TrFE) copolymer [21,22].

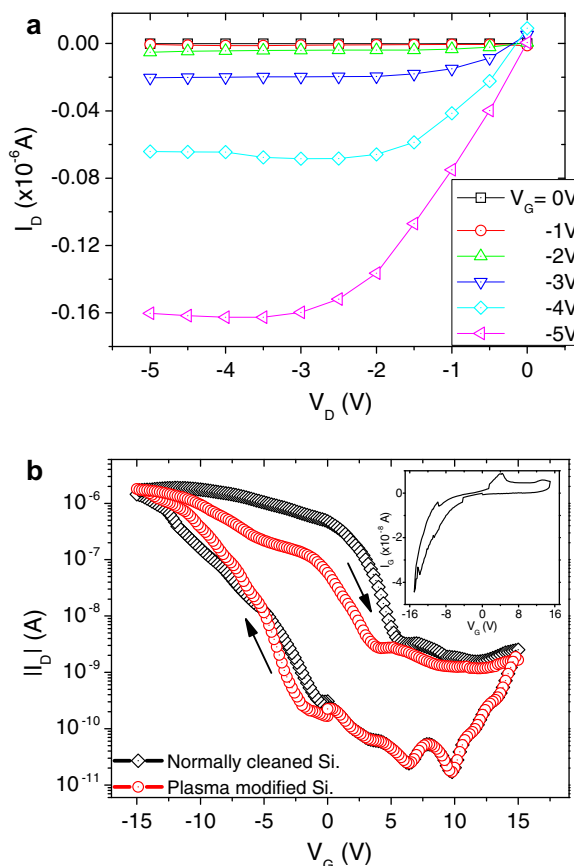
The electrical characteristics (I_D–V_D, I_D–V_G) of the FeFET device fabricated on the LS-transfer film are shown in Fig. 5. Both of drain and gate voltages were applied in ascending order for I_D–V_D. The mobility is calculated in the saturation regime from Fig. 5a yielding value of 0.003 cm^2/Vs for device with an effective capacitance of 3.1×10^{-7} F/cm^2 and channel length and width of 75 and 4000 μm, respectively. The value of mobility is likely affected by the smaller grain size [23] and the lower dielectric constant of SiO$_2$ ($\kappa = 3.9$ as compared to $\kappa = 13$ of P(VDF-TrFE)) in the composite insulating layer. The transfer characteristic shows hysteresis in drain current (ON/OFF ratio around 2×10^3 at zero gate bias) which follows the polarization switching of the copolymer dipoles and is in agreement with previously reported devices fabricated by spin-coating P(VDF-TrFE) film [5,6]. As switching current peaks seen from the inset of Fig. 5b are around $V_G = |5|$ V, a sweeping gate voltage of |15| V is hence sufficient to induce saturated polarization in the ferroelectric layer. One of the clear advantages is hence the saturating


Fig. 5. Device characteristics of pentacene transistors with 10 ML transferred dielectric layer on normally cleaned and plasma-modified Si substrates (a) I_D–V_D (device on normally cleaned Si substrate). (b) I_D–V_G measured at $V_D = -5$ V. The inset shows the gate current I_G–V_G of device on normally cleaned Si substrate.

of polarization at low bias ($\sim |15|$ V) which results in low voltage application device.

The formation of nanostructures from the first few monolayers is governed by both of the elastic and surface energy density [18]. We attempted to improve the contact formation between the LS-transferred film and the substrate surface by briefly subjecting the Si surface to ambient plasma for 2 min. The obtained result was a more hydrophilic surface (with smaller contact angle of 7.72° as compared to 25.27° of normally cleaned Si-wafer). The higher surface energy led to pattern coarsening to minimize the interface area during annealing in paraelectric phase [18]. Examination by AFM of annealed 1 ML sample on both types of treated surfaces shows different nanostructure formation. While separating nano-islands were seen on the normally cleaned sample, percolating nano-mesa with larger coverage of substrate surface was obtained for the plasma-modified sample as previously described [15]. FeFET device with 10 ML film transferred onto the plasma-modified surface shows similar drain current hysteresis and carrier mobility in the semiconductor channel as the ones on normally cleaned substrate (Fig 5b). However the ON/OFF ratio is reduced to 350 due to lower current retention at zero gate bias. It is possibly

resulted from the defects generated during plasma-modification. The plasma ion bombardment partially removed the topmost oxygen-bonding layer and left unsaturated bonds on the Si surface that makes it more susceptible to trapping of mobile charges during the transfer of first few layers. The existence of trapped charges between the SiO_2 and the P(VDF-TrFE) layer subsequently caused the non-switching polarization which induced higher drain current during strong accumulation but did not retain the current as gate voltage drop to 0 V [6]. It is hence required further improvement in the engineering of interface between substrate and the transferred films to obtain denser dielectric layer of ultrathin thickness.

4. Conclusion

We have demonstrated the fabrication of good quality ultrathin Langmuir–Schaefer films for the application in non-volatile memory device. Study of crystallinity evolution and surface morphology in the process of film formation indicates planar crystallization occurring in the LS-film with transferring of up to 10 ML. The good coverage of this film with high crystallinity of small flat grains allows the demonstration of non-volatile memory devices. The memory behavior was presented in MFS capacitor as well as FET with the retention by the dipolar polarization. Different states of data storing and erasing was demonstrated with operation voltages less than 15 V. One of the detrimental defects has been identified as mobile charge trapping at the interface that worsens the current retention when the substrate is plasma treated to improve the LS-film coverage. This hence prompt for more attention in optimizing the crystallization of the LS-film and the engineering of the surface morphology. In spite of those shortcomings, the LS-transfer method offers the advantages of simple processing conditions and small volume of consumed material. The ferroelectric LS-film is proven to be versatile and applicable for device application that requires low operation voltages.

A B S T R A C T

Efficient solution-processed electrophosphorescent devices using two blue-emitting ionic iridium complexes (complex 1 and complex 2) were fabricated, with poly(*N*-vinylcarbazole) (PVK):1,3-bis(5-(4-tert-butylphenyl)-1,3,4-oxadiazol-2-yl)benzene (OXD-7) as the host and Cs_2CO_3/Al as the cathode. Using complex 1 as the dopant, we obtained efficient blue-green electrophosphorescence from single-layer devices with a maximum efficiency of 12.2 cd A^{-1}, a maximum brightness of 12,600 cd m^{-2} and CIE (Commission Internationale de l'Éclairage) coordinates of (0.19, 0.45). And the maximum efficiency of the device based on complex 1 can be further improved to 20.2 cd A^{-1}, when a thin 1,3,5-tris(1-phenyl-1H-benzo[d]imidazol-2-yl)benzene (TPBI) layer was inserted between the light-emitting layer and the cathode. Using complex 2 as the dopant, we obtained deep-blue electrophosphorescence with the emission peak at 458 nm and CIE coordinates of (0.16, 0.22). Our work suggests that ionic iridium complexes are promising phosphors for obtaining efficient electrophosphorescence in the blue region.

1. Introduction

The past two decades have witnessed the great development of organic light-emitting diodes (OLEDs), which are promising candidates for display and solid-state lighting applications [1]. Through the recombination of holes and electrons, singlet and triplet excitons are generated in OLEDs. For OLEDs containing fluorescent dopants, only singlet excitons can generate light; while for OLEDs containing phosphorescent dopants, both singlet and triplet excitons can generate light [2]. In theory, the efficiency of electrophosphorescent devices is nearly three times higher than that of electrofluorescent devices, given that the ratio between singlet and triplet excitons generated in OLEDs is about 1:3 [2,3]. To achieve high efficiency, electrophospho-

rescent devices containing phosphorescent dopants are more favorable choices.

Phosphorescent dopants commonly used in OLEDs are transition metal complexes [2,4]. The involvement of transition metal ions is essential because they can provide strong spin-orbit coupling which allows the spin-forbidden triplet excitons to decay radiatively. Many kinds of transition metal complexes, i.e., rhenium, osmium, ruthenium, platinum and iridium complexes, have been developed and utilized as efficient phosphorescent dopants in OLEDs [4]. These transition metal complexes are mostly neutral and, thus, evaporable to fabricate vacuum-deposited devices. In recent years, ionic transition metal complexes (iTMCs), including ionic copper, ruthenium, osmium and iridium complexes, have drawn more and more attention [5,6]. The application of iTMCs in organic electroluminescence have resulted in another kind of device, named light-emitting electrochemical cells (LECs), which have

many advantages (i.e., single-layer, solution-process and air-stable cathodes) over conventional multilayer OLEDs, though they suffer from long response time and limited device stability [5,6]. To obtain highly efficient LECs, various iTMCs with controllable emission colors and high photoluminescent quantum yields (PLQY) have been developed [5,6,8]. Surprisingly, these iTMCs, despite their impressive photophysical and electrochemical characteristics, have seldom been used as phosphorescent dopants in OLEDs. For LEC devices, the light-emitting layer is composed of neat iTMCs, which results in severe excited-state quenching and, thus, depressed device performance [7,8]. It is expected that the severe excited-state quenching in LEC devices will be significantly relieved as the iTMCs are used as dopants in OLEDs. Carlson et al. reported single-layer polymer OLEDs with ionic osmium complexes as dopants, which gave red light emission with a maximum external quantum efficiency of 2.2% [9]. Zhang et al. used ionic copper complexes as dopants in multilayer polymer OLEDs, which emitted green light with a maximum efficiency of 10.5 cd A^{-1} [10]. Plummer et al. reported yellow-emitting polymer OLEDs using an ionic iridium complex as the dopant, which gave a maximum efficiency of 22.5 cd A^{-1} [11]. However, as far as we know, there is no report on blue-emitting OLEDs with iTMCs dopants till now, as iTMCs emitting light in the blue region are rare [6,8]. In this paper, we report efficient electrophosphorescent devices using two blue-emitting ionic iridium complexes as the dopants (Scheme 1). Previously, we used these two ionic iridium complexes to fabricate blue LECs and found severe excited-state-quenching in LEC devices, though blue light emission was achieved [8]. In single-layer devices with the host of poly(*N*-vinylcarbazole) (PVK):1,3-bis(5-(4-tert-butylphenyl)-1,3,4-oxadiazol-2-yl)benzene (OXD-7) and the cathode of Cs$_2$CO$_3$/Al, we obtained efficient blue-green electrophosphorescence with a maximum efficiency of 12.2 cd A^{-1}, a maximum brightness of 12,600 cd m^{-2} and CIE (Commission Internationale de l'Éclairage) coordinates of (0.19, 0.45) when complex 1 was used as the dopant. After a thin 1,3,5-tris(1-phenyl-1H-benzo[d]imidazol-2-yl)benzene (TPBI) layer was inserted between the light-emitting layer and the cathode, the maximum efficiency of the blue-green device was further improved to 20.2 cd A^{-1}. We also obtained deep-blue electrophosphorescence with the emission peak at 458 nm and CIE coordinates of (0.16, 0.22) when complex 2 was used as the dopant.
2. Experimental

2.1. Photophysical characterization

Complex 1 and complex 2 were synthesized according to our previous publication and were further purified by recrystallization from acetonitrile and ether before use [8]. Thin films with the thickness of approximate 100 nm for photophysical characterization were deposited onto quartz substrates by spin-coating from 1,2-dichloroethane solutions. Absorption spectra were recorded with a UV–vis spectrophotometer (Agilent 8453) and PL spectra were recorded with a fluorospectrophotometer (Jobin Yvon, FluoroMax-3).

2.2. Fabrication and characterization of electrophosphorescent devices

Film thickness and surface morphology of thin films were determined with the atomic force microscopy (AFM, SPA-400). The ITO substrates with sheet resistance of 15 Ω/□ were sufficiently cleaned by ultrasonication in detergent and then in deionized water and treated with oxygen plasma before use. The PEDOT:PSS layer was spin-coated in ambient atmosphere and then baked at 200 °C for 10 min, yielding a smooth film with a thickness of approximate 60 nm and a root mean square (RMS) value of 1.25 nm (for an area of 5×5 μm^2). The light-emitting layer was then spin-coated onto the PEDOT:PSS-coated substrate from a mixed solution of PVK:OXD-7:complex 1 (or complex 2) in 1,2-dichloroethane in a nitrogen atmosphere glove box. The film was then baked at 80 °C for 30 min, yielding a smooth film with a thickness of approximate 85 nm and a RMS value of 0.93 nm (for an area of 5×5 μm^2). The substrate was then transferred into an evaporation chamber, where the TPBI (if needed) was evaporated at an evaporation rate of 1–2 Å/s under a pressure of 4×10^{-4} Pa and the Cs$_2$CO$_3$/Al bilayer cathode was evaporated at evaporation rates of 0.2 and 10 Å/s for Cs$_2$CO$_3$ and Al, respectively, under a pressure of 1×10^{-3} Pa. The current–voltage–brightness characteristics of the devices were characterized with Keithley 4200 semiconductor characterization system. The electroluminescent spectra were collected with a Photo Research PR705 Spectrophotometer. All measurements of the devices were carried out in ambient atmosphere without further encapsulations.

3. Results and discussion

3.1. Photophysical characterization

Fig. 1 depicts the absorption and photoluminescent (PL) spectra of complex 1, complex 2 and PVK:OXD-7 in thin films. The intense absorptions at the ultra-violet region from 200 to 350 nm are ascribed to $^1\pi$–π^* transitions from the ligands while the relatively weak absorptions from 350 nm to the visible region are ascribed to metal-to-ligand charge-transfer transitions (MLCT) of the complexes. As Fig. 1 shows, the overlap between the emission

Scheme 1. Chemical structures of the ionic iridium complexes.
Fig. 1. Absorption and emission spectra of complex 1 (5% doped in PMMA), complex 2 (5% doped in PMMA) and PVK:OXD-7 (2:1, weight ratio) in thin films.

spectra of PVK:OXD-7 and the MLCT absorption bands of complex 1 is quite large, indicating that the Förster energy transfer from PVK:OXD-7 to complex 1 would be efficient. As for complex 2, the overlap is relatively weak. When lightly doped at 5 wt.% into poly(methyl methacrylate) (PMMA), complex 1 and complex 2 both give blue light emission with the emission peak at 476 and 452 nm, respectively. More photophysical characterizations of complex 1 and complex 2 can be found in our previous publication [8].

3.2. Electrophosphorescent devices based on complex 1

PVK:OXD-7 (2:1, weight ratio) was selected as the host for the ionic iridium complexes. The electron-transporting material OXD-7 was mixed into PVK to facilitate the electron transport in the light-emitting layer [12–14]. The device structure is ITO/PEDOT:PSS (60 nm)/PVK:OXD-7:x% complex 1 (85 nm)/Cs_2CO_3 (y nm)/Al (200 nm), where the doping concentration of complex 1 and the thickness of Cs_2CO_3 layer were varied to optimize the device performance.

Fig. 2. Current density–voltage characteristics of ITO/PEDOT:PSS (60 nm)/PVK:OXD-7:x% complex 1 (85 nm)/Cs_2CO_3 (2 nm)/Al (200 nm) with different doping concentrations (x%) of complex 1. The inset shows the corresponding brightness–voltage curves of the devices.

Fig. 2 shows the current density–voltage characteristics of devices with different doping concentrations of complex 1. The inset in Fig. 2 depicts the corresponding brightness–voltage curves of the devices. Detailed electrical characteristics of the devices are summarized in Table 1. For all devices, the thickness of the Cs_2CO_3 layer was fixed at 2 nm. As Fig. 2 shows, the current density–voltage curves shift towards the low voltages as the doping concentration of complex 1 increases. This can be explained by the energy level diagram of the device (Scheme 2). The lowest unoccupied molecular orbital (LUMO) energy level of complex 1 (−3.2 eV) is much lower than that of PVK (−2.2 eV) and comparable to that of OXD-7 (−3.0 eV). Thus, as the doping concentration of complex 1 increases, electrons are expected to be able to move along the LUMO orbitals of complex 1. Consequently, the electron transport in the device is facilitated, which explains the increased current density at a fixed voltage as the doping concentration of complex 1 increases. Noticeably, as the doping concentration of complex 1 increases, the brightness of the device at a fixed voltage also increases (see the inset of Fig. 2). The net result is that the efficiency of the devices does not vary very much as the doping concentration of complex 1 varies from 2% to 12% (Table 1). At a doping concentration of 8%, the device reaches a maximum efficiency of 10.5 cd A^{-1} and a maximum brightness of 10,080 cd m^{-2}. Besides, all devices show low turn-on voltages at around 4.0 V, indicating that both the hole injection from the ITO/PEDOT:PSS anode and the electron injection from the Cs_2CO_3/Al cathode into the light-emitting layer are efficient.

All devices show bright blue-green light emission with the emission peak at around 482 nm and CIE coordinates varying a little from (0.19, 0.45) to (0.20, 0.48) as the doping concentration of complex 1 varies from 2% to 12% (Table 1). Fig. 3 shows the electroluminescent (EL) spectra of the devices and the inset shows the corresponding PL spectra of the light-emitting layers. In the PL spectra of thin films of PVK:OXD-7:2% or 4% complex 1, the emission from PVK:OXD-7 (around 410 nm) was observed, indicating incomplete energy transfer from PVK:OXD-7 to complex 1 at a low doping concentration of the dopant. However, in the EL spectra, the emission from PVK:OXD-7 disappears completely, indicating that the charge-trapping plays an important role in the operation of the devices [15]. The charge-trapping mechanism mainly corresponds to the trap of electrons considering the low-lying LUMO energy level of complex 1 (Scheme 2).

To further improve the device performance, the thickness of the Cs_2CO_3 electron-injection layer was also optimized [16,17]. Fig. 4 depicts the current density–voltage characteristics of devices with Cs_2CO_3 layers of different thicknesses. The inset in Fig. 4 depicts the corresponding brightness–voltage curves of the devices. Detailed electrical characteristics are also summarized in Table 1. For all devices, the doping concentration of complex 1 was fixed at 8%. As the thickness of Cs_2CO_3 layer increases, the current density–voltage curves shift towards the high voltages. And, at the same time, the brightness–voltage curves shift slightly towards the low voltages. As a result, the efficiency of the device increases as the thickness of Cs_2CO_3 layer increases (Table 1). With a 4 nm thick Cs_2CO_3

Scheme 2. Energy level diagram of ITO/PEDOT:PSS/PVK:OXD-7:complex 1(or complex 2)/Cs$_2$CO$_3$/Al, where the highest occupied molecular orbitals (HOMO) and LUMO values of complex 1 (or complex 2) were calculated from their oxidation potentials in CH$_3$CN solutions together with their optical band gaps obtained from the absorption spectra [8].

Fig. 4. Current density–voltage characteristics of ITO/PEDOT:PSS (60 nm)/PVK:OXD-7:8% complex 1 (85 nm)/Cs$_2$CO$_3$ (y nm)/Al (200 nm) with different thicknesses (y nm) of Cs$_2$CO$_3$ layer. The inset shows the corresponding brightness–voltage curves of the devices.

Fig. 3. EL spectra of ITO/PEDOT:PSS (60 nm)/PVK:OXD-7:x% complex 1 (85 nm)/Cs$_2$CO$_3$ (2 nm)/Al (200 nm) with different doping concentrations (x%) of complex 1. The inset shows the corresponding PL spectra of the light-emitting layers.

between the light-emitting layer and the cathode [11,18]. As shown in Fig. 4, the brightness of the device with a TPBI layer was significantly increased compared with those of single-layer devices. After the insertion of the TPBI layer, the maximum efficiency of the blue-green device was largely improved to 20.2 cd A^{-1} (Table 1), demonstrating that complex 1 is a promising phosphor for achieving highly efficient blue-green electrophosphorescence.

3.3. Electrophosphorescent devices based on complex 2

Complex 2 with fluorine-substituted cyclometalated ligands shows further blue-shifted emission spectra (Fig. 1). As blue phosphorescent dopants with saturated color purity are rare, we used complex 2 to fabricate deep-blue electrophosphorescent devices. The device structure is ITO/PEDOT:PSS (60 nm)/PVK:OXD-7:x% complex 2 (85 nm)/Cs$_2$CO$_3$ (2 nm)/Al (120 nm), where the doping concentration of complex 2 was varied to optimize the device performance.

Fig. 5 depicts the EL spectra of the devices and the inset depicts the corresponding PL spectra of the light-emitting layers. All devices show deep-blue light emission with

layer, the device reaches a maximum efficiency of 12.2 cd A^{-1} and a maximum brightness of 12,600 cd m^{-2}.

Generally, for single-layer devices, severe exciton-quenching exists at the cathode interface, resulting in degraded device performance. To improve the performance of the device based on complex 1 further, a thin (30 nm) TPBI electron-transporting/exciton-confining layer was inserted

Fig. 5. EL spectra of ITO/PEDOT:PSS (60 nm)/PVK:OXD-7:x% complex 2 (85 nm)/Cs$_2$CO$_3$ (2 nm)/Al (200 nm) with different doping concentrations (x%) of complex 2. The inset shows the corresponding PL spectra of the light-emitting layers.
Fig. 6. Current density–voltage characteristics of ITO/PEDOT:PSS (60 nm)/PVK:OXD-7:x% complex 2 (85 nm)/Cs$_2$CO$_3$ (2 nm)/Al (200 nm) with different doping concentrations (x%) of complex 2. The inset shows the corresponding brightness–voltage curves of the devices.

the emission peak at 458 nm and CIE coordinates of (0.16, 0.22), which is, to the best our knowledge, the bluest electrophosphorescence from ionic iridium complexes. This light emission is also much bluer compared to the electrophosphorescence from the widely used blue phosphorescent dopant of bis[(4,6-difluorophenyl)-pyridinato-N,C^2] iridium(III) (picolinato) (FIrpic), which shows sky-blue electrophosphorescence with the emission peak at around 474 nm [19]. Interestingly, the PL spectra of the light-emitting layers show considerable emission intensity from PVK:OXD-7 (around 410 nm) even at a doping concentration up to 10%, indicating that the energy transfer from PVK:OXD-7 to complex 2 is not complete. This is consistent to the weak overlap between the emission spectrum of PVK:OXD-7 and the absorption spectrum of complex 2 in thin films (Fig. 1). However, in EL spectra, only light emission from complex 2 was observed, indicating that charge-trapping plays an important role in the operation of the devices based on complex 2 [15]. The charge-trapping mechanism mainly corresponds to the trap of electrons considering that the LUMO energy level of complex 2 (−3.3 eV) is much lower than that of PVK (−2.2 eV) (Scheme 2).

Fig. 6 shows the current density–voltage characteristics of the devices with different doping concentrations of com-

plex 2 and detailed electrical characteristics are summarized in Table 2. As the doping concentration of complex 2 increases, the current density–voltage curves shift towards the low voltages. Though complex 2 has a LUMO energy level (−3.3 eV) much lower than that of PVK (−2.2 eV) (Scheme 2) and, thus, would behave as strong electron traps, the doping of complex 2 would also facilitate the electron transport when the doping concentration of complex 2 is beyond the percolation where electrons are expected to be transported by directly hoping between molecules of complex 2. Noticeably, the current density of the devices based on complex 2 is much lower than that of the devices based on complex 1, suggesting that complex 2 might behave as much stronger electron traps than complex 1 does. The efficiency of the devices based on complex 2 does not vary very much either as the doping concentration of complex 2 varies from 5% to 15% (Table 2). At a doping concentration of 10%, the device reaches a maximum efficiency of 1.5 cd A^{-1} and a maximum brightness of 595 cd m^{-2}. When the film thickness of the light-emitting layer was increased to 140 nm, the efficiency of the device was improved to 2.4 cd A^{-1} at the expense of a higher driving voltage and degraded color purity (due to the microcavity effect [14,20]) (Table 2). When a thin (30 nm) TPBI layer was inserted between the light-

emitting layer and the Cs_2CO_3 layer, the device efficiency was improved to 2.5 cd A^{-1} at the expense of degraded color purity (also due to the microcavity effect [14,20]) (Table 2). The relatively low efficiency and brightness of the devices based on complex 2 are presumably due to the relatively low triplet-energy of the PVK host [21,22] or the inefficient energy transfer from PVK:OXD-7 host to complex 2 (vide supra). Further work is to dope complex 2 into a host with higher triplet-energy to improve the efficiency of the deep-blue device.

4. Conclusion

Efficient electrophosphorescent devices were fabricated using two blue-emitting ionic iridium complexes as the dopants and PVK:OXD-7 as the host. For single-layer devices, we obtained efficient blue-green electrophosphorescence with a maximum efficiency of 12.2 cd A^{-1}, a maximum brightness of 12,600 cd m^{-2} and CIE coordinates of (0.19, 0.45). After a thin TPBI layer was inserted between the light-emitting layer and the cathode, the maximum efficiency of the blue-green device was further improved to 20.2 cd A^{-1}. We obtained deep-blue electrophosphorescence with the emission peak at 458 nm and CIE coordinates of (0.16, 0.22). Our work suggests that ionic iridium complexes are promising phosphors for obtaining efficient electrophosphorescence in the blue region.

ARTICLE INFO

ABSTRACT

A novel blue emitter, **In2Bt**, featured with a rigid and coplanar distyryl-*p*-phenylene backbone flattened by two different bridging atoms (i.e. carbon and sulfur) exhibits high thermal and morphological stability ($T_g \sim 192\,^\circ C$) and ambipolar charge carrier mobilities in the range of $10^{-4} \sim 10^{-5}\,cm^2\,V^{-1}\,s^{-1}$. OLED device: ITO/PEDOT:PSS (300 Å)/α-NPD (200 Å)/TCTA (100 Å)/**In2Bt** (200 Å)/TPBI (500 Å)/LiF (5 Å)/Al (1500 Å) utilized **In2Bt** as an emitter gave a maximum brightness as high as 8000 cd m^{-2} (12 V) and saturated-blue emission with CIE chromaticity coordinates of (0.16, 0.08), which is very close to the National Television Standards Committee (NTSC) standard blue gives an enlarged palette of colors for color displays.

1. Introduction

In recent years, the development of deep blue emitters for OLED, which can match the National Television System Committee (NTSC) standard blue CIE (*x*,*y*) coordinates of (0.14, 0.08) has drawn considerable attentions [1–5]. Such a device not only can effectively reduce the power consumption of a full-color OLED but also can be utilized to generate emission of other colors through energy transfer. However, the molecular design for a deep blue emitter is quite challenging in terms of molecular structures. Molecules that can emit deep blue light normally have a restricted π-conjugated length, which consequently limits the spaces for tailoring the desired chromophore with sufficient thermal and thin film morphological stability. Thus, only few materials can meet these requirements so far [1–5]. Recently, the ladder-type oligomers and polymers [6–14], due to their rigid and coplanar structures which can enhance the π-conjugation, charge mobility, and luminescence intensity have emerged as potential materials for optoelectronic applications. In this regard, the physical properties and possible applications of ladder-type oligo- or poly(*p*-phenylene)s with various heteroatom bridges have been extensively studied [15–18]. More importantly, the physical properties of ladder-type materials can be

tailored by modulating the degree of conformational flexibility between consecutive backbone units or, more effectively, manipulating the electronic properties by flattening the π-conjugated molecular framework with heteroatoms. In this paper, we report a new blue light-emitting material based on a coplanar molecular structure, in which benzothiophene was fused to neighboring phenylene ring through intramolecular annulation via sp³-hybridized carbon atoms bearing two p-tolyl groups as peripheral substituents [19]. The non-doped OLED device shows an external quantum efficiency of 1.3% and saturated-blue emission with CIE chromaticity coordinates (0.16, 0.08), which is almost the National Television Standards Committee (NTSC) standard blue.

2. Results and discussion

Fig. 1 depicts the molecular structure of blue emitter: 7,14-dihydro-7,7,14,14-tetrakis(4-methylphenyl)-s-indaceno[1,2-b:5,6-b′]bis[1]benzothiophene (**In2Bt**) featured with a rigid and coplanar distyryl-p-phenylene backbone flattened by two different bridging atoms (i.e. carbon and sulfur). The synthesis and X-ray structural analysis of **In2Bt** have been reported by our group previously [19]. The peripheral p-tolyl substituents occupy the top and bottom faces of the main conjugated backbone prevent undesirable aggregation and improve thermal and morphological stability efficiently. We characterized the morphological and thermal properties of **In2Bt** using differential scanning calorimetry (DSC) and thermogravimetric analyses (TGA), respectively. **In2Bt** exhibits a distinct glass transition temperature ($T_g \sim 192$ °C), which allows to form homogeneous and stable amorphous films upon thermal evaporation, a critical issue for OLED application. We ascribed the amorphous behavior and high values of T_g to the rigidity of the conjugated backbone and the presence of the p-tolyl substituents, which can effectively suppress intermolecular interactions and crystallization. The aryl substituents impart the oligomers with a high tolerance to heat, as indicated by their high decomposition temperatures ($T_d \sim 408$ °C, corresponding to a 5% weight loss).
Fig. 1. Chemical structure of **In2Bt**.
Fig. 2. The optical absorption, photoluminescence (PL) spectra of **In2Bt** in solution and thin film, and the electroluminescence (EL) spectra of device using **In2Bt** as an emitter.

Fig. 2 summarizes the electronic absorption (Abs) and photoluminescence (PL) spectra of **In2Bt** in chloroform solution and as solid films. Due to the coplanar conformation of the main chromophore, the absorption spectra of **In2Bt** in dilute solution and in thin film are almost superimposable with slightly red-shifted maxima in solid state (Abs λ_{max} in solution, 375, 397 nm, and in film, 385, 402 nm). The thin film emission spectra of **In2Bt** exhibit slightly red-shifted maxima (PL λ_{max} in solution 408, 430 nm, and in film 416, 439 nm). In addition, the small Stokes shifts ($\Delta\lambda \sim 11$ nm in solution) and the mirror images of the absorption and emission spectra are consistent with the molecular rigidity observed in the solid state structures [19,20]. We estimated the $\pi-\pi^*$ band gap ($\Delta E_g \sim 3$ V) from the lowest energy absorption edges (ca. 413 nm) in the UV–Vis absorption spectra. The thin film photoluminescence quantum yield (PLQY) of **In2Bt** measured by a calibrated integral sphere (HAMAMATSU C9920) is ca. 14%. In order to gain more insight into the low PLQY of **In2Bt** in thin film, we have employed time-correlated single photon counting measurement with a time resolution of ~30 ps. Upon excitation at 390 nm and monitoring the emission at e.g. 450 nm, the observed lifetime (τ_{obs}) for **In2Bt** in thin film was determined to be 268 ps. From the PLQY and observed lifetime, the radiative (k_r) and non-radiative (k_{nr}) decay rate constants, deduced by Eq. (1), were 5.2×10^8 s⁻¹ and 3.2×10^9 s⁻¹, respectively,

$$\text{PLQY}(\Phi) = \frac{\tau_{obs}}{\tau_r} = \frac{k_r}{k_{obs}} = \frac{k_r}{k_r + k_{nr}}. \tag{1}$$

Normally, a skeleton possessing a rigid distyryl-p-phenylene backbone is expected to provide a reasonably high PLQY. The large k_{nr} (c.f. k_r) value and hence low PLQY for **In2Bt** in thin film is of fundamental interest and, to our viewpoint, can be tentatively attributed to two factors associated with the sulfur atom and/or the molecular framework. On one hand, sulfur atoms embedded inside the chromophore backbone may facilitate the non-radiative processes due to the heavy atom effect, a common phenomenon occasionally reported in sulfur-containing oligoaryls [21]. On the other hand, the soft sulfur atom pos-
Fig. 3. The cyclic voltammogram of **In2Bt**.

sesses a lower lying non-bonding orbital that may facilitate the non-radiative process via certain vibronic coupling modes. Such modes may be associated with the slightly twisted molecular plane of **In2Bt** in thin film [12]. At room temperature or upon cooling to 77 K, phosphorescence of the **In2Bt** thin film was obscure. Therefore, the former case of heavy atom enhanced spin-orbit coupling and hence the intersystem crossing is less likely. Nevertheless, at this stage, the actual deactivation mechanism is still pending for resolution. Note we also cannot eliminate the possibility that relatively low PLQY, in part, is attributed to the re-absorption problem occurring in solid states.

Fig. 3 depicts the electrochemical properties of **In2Bt** studied by cyclic voltammetry (CV). We detected one reversible oxidation potential occurred at 1.13 V (V vs. Ag/AgCl, in CH_2Cl_2 using a glassy carbon electrode with 0.1 M of nBu_4NPF_6 as electrolyte) and one reversible reduction potential at -1.87 V together with one quasi-reversible reduction at -2.25 V (V vs. Ag/AgCl in dimethyl-foramide using a glassy carbon electrode with 0.1 M of nBu_4ClO_4 as electrolyte). Thus, **In2Bt** exhibits bipolar character with excellent electrochemical stability. The HOMO energy level of **In2Bt** (ca. -5.7 eV) was calculated using a linear correlation with α-NPB (HOMO = ca. -5.3 eV), which exhibits an $E_{1/2}^{OX}$ at 0.74 V measured under the same conditions [22]. And the corresponding LUMO (ca. -2.7 eV) of **In2Bt** was then derived by subtracting the corresponding optical band gap from the HOMO energy.

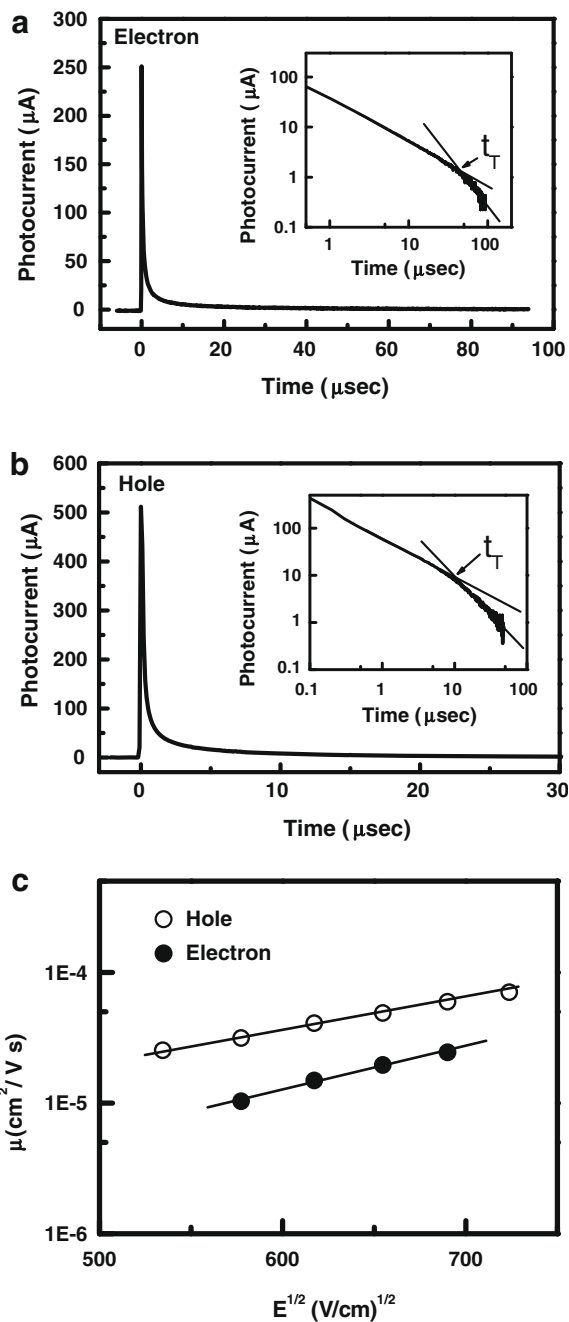
We used time-of-flight (TOF) techniques with a device structure of glass/Ag (30 nm)/**In2Bt** (2.1 μm)/Ag (200 nm) to measure the charge carrier mobilities of **In2Bt** [23]. Fig. 4a and b shows representative TOF transients for electrons and holes of under an applied field, respectively. The TOF transients reveal that **In2Bt** exhibits slightly dispersive carrier-transport characteristics. In the double-logarithmic representation (inset of Fig. 4a and b), the carrier-transit time, t_T, needed for determining carrier mobilities can be clearly extracted from the intersection point of two asymptotes. The field dependence of hole mobility μ thus determined (Fig. 4c) from the transit time t_T according to the relation $\mu = d^2/Vt_T$, where d is the sample thickness and V is the applied voltage. Apparently,


Fig. 4. TOF transients for **In2Bt** (2.1 μm thick): (a) electron, $E = 4.8 \times 10^5$ V cm^{-1}; (b) hole, $E = 4.3 \times 10^5$ V cm^{-1}. Insets are the double-logarithmic plots of (a) and (b). (c) Electron and hole mobilities vs. $E^{1/2}$.

In2Bt exhibits bipolar charge-transport properties, which has similar electron and hole mobilities in the range of $10^{-4} \sim 10^{-5}$ cm^2 V^{-1} s^{-1} ($E = 3 \times 10^5 \sim 5 \times 10^5$ V cm^{-1}) at room temperature.

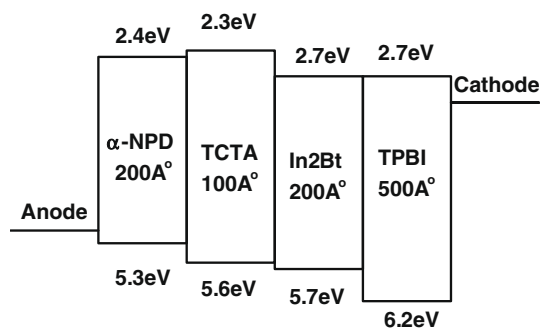
To assess the feasibility of using **In2Bt** as an emitting material, multilayer device with the configuration of ITO/PEDOT:PSS (300 Å)/α-NPD (200 Å)/TCTA (100 Å)/**In2Bt** (200 Å)/TPBI (500 Å)/LiF (5 Å)/Al (1500 Å) was fabricated.


Fig. 5. HOMO and LUMO energy level diagram of the organic materials in the device.

Here, the conducting polymer, poly(ethylene dioxythiophene)/poly(styrene sulfonate) (PEDOT:PSS) is used as the hole-injection layer [24], 4,4′-bis(*N*-(1-naphthyl)-*N*-phenyl)biphenyldiamine (α-NPD) [25] and 4,4′,4′-tri(*N*-carbazolyl) triphenylamine (TCTA) as hole-transport layers [26], **In2Bt** as an emitting layer, 1,3,5-tris(*N*-phenylbenzimidizol-2-yl)benzene (TPBI) [27] as an electron-transport and hole-blocking layer, LiF as an electron-injection layer and Al as a cathode, respectively. The energy levels alignment diagram of this blue OLED is shown in Fig. 5. The holes transport through the HTLs of α-NPD and TCTA with a stepwise increase in HOMOs into the emitting layer, and

Fig. 6. (a) Brightness and current density vs. voltage. (b) External quantum efficiency and power efficiency vs. current density.

subsequently are blocked by the higher energy barrier at the interface of **In2Bt** and TPBI. In the meantime, the electrons are injected into **In2Bt** layer from TPBI and blocked by the higher energy barrier at the interface of TCTA and **In2Bt**. Therefore, it is reasonable to anticipate that the recombination region is restricted only within the **In2Bt** layer. Consequently, a pure deep blue EL spectrum from **In2Bt** was obtained, which is corresponding well to the thin film PL spectrum (Fig. 2).

Fig. 6a shows the current density and the luminance vs. voltage for the device. The device exhibits a rather low turn-on voltage of 3 V and low operation voltage (100 cd m^{-2} at 6 V, 1000 cd m^{-2} at 8.5 V). The device exhibits unusual high currents ∼3860 mA cm^{-2} for 12 V, giving a maximal brightness of 8000 cd m^{-2}. Such high current density is ascribed to the well-matched energy levels of various functional layers used, rendering the device with a balanced holes and electrons recombination ratio. However, this device inevitably suffers from the re-absorption phenomena occurred in the solid states. The EL external quantum efficiency (EQE) shows a maximum at 1.3% (0.86 cd A^{-1}) and a maximal power efficiency of ∼0.76 lm W^{-1} (Fig. 6b). It is worthy to note that the non-doped device shows a pure deep blue emission (Fig. 2) with CIE coordinates of (0.16, 0.08), which is almost perfectly match to the National Television Standards Committee (NTSC) standard blue value. The observed external quantum yield and luminance efficiencies is comparable to commonly non-doped deep blue devices, which warrants further investigations of analogous derivatives to afford materials with improved EL properties.

3. Experimental

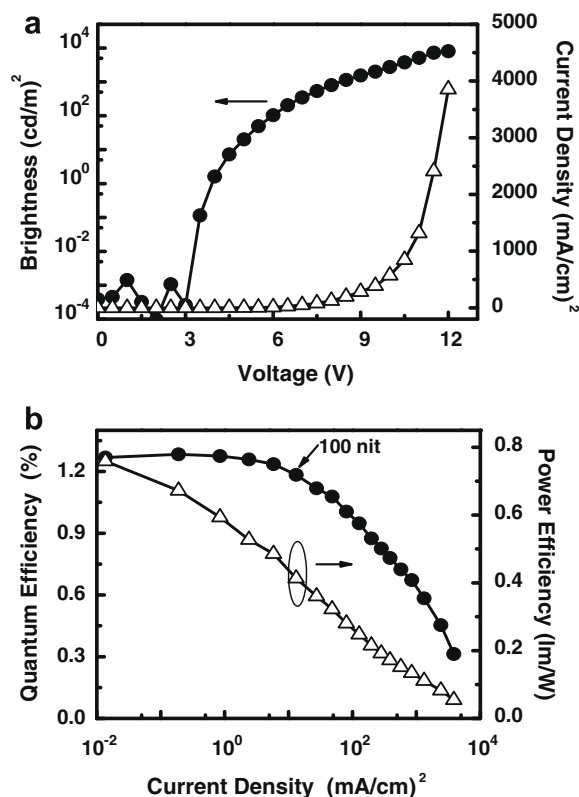
3.1. Device fabrication and measurement

All chemicals were purified through vacuum sublimation prior to use. The OLEDs were fabricated by vacuum deposition of the materials at 10^{-6} torr. onto ITO-coated glass substrates having a sheet resistance of 15 Ω/square. The ITO surface was cleaned through ultrasonication sequentially with acetone, methanol, and deionized water and then it was treated with UV-ozone. The deposition rate of each organic material was ca. 1–2 Å s^{-1}. Subsequently, LiF was deposited at 0.1 Å s^{-1} and then capped with Al (ca. 5 Å s^{-1}) by shadow masking without breaking the vacuum.

The current–voltage–brightness (*I–V–L*) characteristics of the devices were measured simultaneously using a Keithley 6430 source meter and a Keithley 6487 picoammeter equipped with a calibration Si-photodiode. EL spectra were measured using an ocean optics spectrometer.

3.2. Time-of-flight mobility measurements

The samples for the TOF measurement were prepared by vacuum deposition using the structure: glass/Ag (30 nm)/organic (2 ∼ 3 μm)/Al (150 nm), and then placed inside a cryostat and kept under vacuum. The thickness of organic films were monitored in situ with a quartz crys-

tal sensor and calibrated by a profilometer (Tencor Alpha-step 500). A pulsed nitrogen tunable dye laser was used as the excitation light source (to match the absorption of organic films) through the semitransparent electrode (Ag) induced photogeneration of a thin sheet of excess carriers. Under an applied dc bias, the transient photocurrent was swept across the bulk of the organic film toward the collection electrode (Al), and then recorded with a digital storage oscilloscope. Depending on the polarity of the applied bias, selected carriers (holes or electrons) are swept across the sample with a transit time of t_T. With the applied bias V and the sample thickness D, the applied electric field E is V/D, and the carrier mobility is then given by $\mu = D/(t_T E) = D^2/(Vt_T)$, in which the carrier-transit time, t_T, can be extracted from the intersection point of two asymptotes to the plateau and the tail sections in double-logarithmic plots.


4. Conclusions

In summary, we reported a new deep blue emitter, **In2Bt**, which is based on a coplanar distyryl-*p*-phenylene core flattened through the incorporation of two different bridging atoms (i.e. carbon and sulfur). The promising physical properties of **In2Bt** including deep blue emission, high morphological stability, and bipolar charge-transport properties allow us to use it to achieve a non-doped deep blue device. The device fabricated use **In2Bt** as deep blue emitter leads to a NTSC pure blue electroluminescence (CIE coordinates = 0.16, 0.08) with respectable device performances.

ARTICLE INFO

ABSTRACT

We synthesized new kinds of pyrene-based electron transport materials: 1,6-di(pyridin-3-yl)-3,8-di(naphthalen-1-yl)pyrene (N1PP) and 1,6-di(pyridin-3-yl)-3,8-di(naphthalen-2-yl)pyrene (N2PP). The external quantum efficiencies of the device with these electron transport materials increase by more than 50% at $1\ mA\ cm^{-2}$ compared with those of the device with representative Alq_3 as an electron transport material. The enhanced quantum efficiency is due to a balanced charge recombination in an emissive layer. Electron mobilities in N1PP and N2PP films are three times higher than that in Alq_3. Highly enhanced power efficiency is achieved due to a low electron injection barrier and a high electron mobility. We find that the luminance degradation in the blue OLEDs is correlated with the HOMO energy levels of electron transport materials.

1. Introduction

Since the first report on light emission from double-layered OLEDs by Tang and Van Slyke [1], advances in luminescent RGB materials, device structures, and manufacturing processes have led to the demonstration of full-color OLED displays that are capable of showing video rate images. There are still obstacles for the commercialization of full-color OLED displays. Among them, development of highly efficient blue emitters with sufficient operational stability should be made. Substantial performance enhancement can be achieved through synthesizing new blue luminescent organic materials by way of rational design of the photoactive chemical structure. A phosphorescent (triplet emission) blue electroluminescence (EL) with a high external quantum efficiency and a saturated blue color has been thought

to be an alternative but its instability problems remain unresolved [2–4]. Another approach to achieve maximum device efficiency is to balance charge carrier recombination, because the hole mobility in the OLED is usually much higher than the electron mobility under the same electric field [5,6]. And thus, emitting and charge-transporting materials with a high ionization potential value such as oxadiazole [7], benzimidazole [8], diarylsilole group materials [9] and electron transport materials [10,11] were synthesized and applied to OLEDs. The lifetimes of the devices made with these electron transport materials (ETMs) are short compared with those of the devices using a small molecule Alq_3. There are needs to develop emitting and charge-transporting materials with a longer lifetime and to understand the degradation mechanism. The increased luminance efficiency and the understanding of luminance degradation in OLEDs will be keys to the use of OLED technology in the next generation flat displays and light sources. Here, we report the development of the new kinds of ETMs based on

pyrene molecules and the measurement of the lifetime of ETMS and find the luminance degradation process of the blue OLEDs.

2. Experimental

2.1. Materials

Dibromo pyrene and 3-pyridinyl boronic acid were purchased from SFC Co. Ltd. All other reagents and solvents were purchased from Aldrich Chemical Co. and Fluka. Those were used as received. For absorption and emission experiments, spectroscopic grade CH_2Cl_2 (Aldrich) was used.

2.1.1. 1,6-Di(pyridin-3-yl)-pyrene

To a solid mixture of 1,6 dibromo-pyrene (7.2 g, 20 mmol) and 3-pyridinyl boronic acid (7.4 g, 60 mmol) were added a solution of 70 ml tetrahydrofuran (THF) and 10 ml toluene. After 60 ml of 2 M aqueous potassium carbonate was added to the mixture, it was degassed by bubbling nitrogen for 30 min. Finally, 0.6 mmol of tetrakis(tri-phenylphosphine)palladium (Pd(Ph$_3$)$_4$) was added to the mixture. The mixture was vigorously refluxed under nitrogen for 24 h. When the reaction mixture was cooled down to room temperature, it was poured into 200 ml methanol. After filtering it off, the crude solid was re-precipitated from chloroform and methanol. Light-yellow powder (5.3 g, 74%) was more purified by flash chromatography with chloroform. mp 249 °C. δ_H (500 MHz; CDCl$_3$; Me$_4$Si) 8.88 (2H, s), 8.73 (2H, d, J 3.5), 8.27 (2H, d, J 7.7), 8.15 (4H, m), 7.97 (4H, m), 7.52 (2H, m). Elemental analysis: Found: C, 87.27%; H, 4.35%; N, 7.97%; Calc. for C$_{26}$H$_{16}$N$_2$: C, 87.62%; H, 4.52%; N, 7.86%; M$^+$, 357.

2.1.2. 1,6-Di(pyridin-3-yl)-3,8-dibromo-pyrene

Pyridinium hydrobromide perbromide (7.97 g, 25 mmol) was added to a solution of 1,6-di(pyridin-3-yl)-pyrene (3.56 g, 10 mmol) in 1,2 dichlorobenzene (200 ml). The mixture was refluxed for 12 h. After cooling, 100 ml of methanol was slowly added and the precipitate was filtered. Pure product (3.6 g, 70%) was obtained from re-precipitation with pyridine and methanol. mp: 378 °C. δ_H (500 MHz; CDCl$_3$; Me$_4$Si) 8.89 (2H, s), 8.79 (2H, d, J 5.0), 8.50 (2H, d, J 9.5), 8.3 (2H, s), 8.16 (2H, d, J 10.0), 7.95 (2H, d, J 10.0), 7.54 (2H, m). Elemental analysis: Found: C, 60.93%; H, 2.90%; N, 5.67%; Calc. for C$_{26}$H$_{14}$Br$_2$N$_2$: C, 60.73%; H, 2.74%; N, 5.45%; M$^+$, 515.

2.1.3. 1,6-Di(pyridin-3-yl)-3,8-di(naphthalen-1-yl)pyrene (N1PP)

To a solid mixture of 1,6-di(pyridin-3-yl)-3,8-dibromo-pyrene (5.1 g, 10 mmol) and 1-naphthyl boronic acid (4.3 g, 25 mmol) were added a solution of 70 ml tetrahydrofuran (THF) and 10 ml toluene. After 60 ml of 2 M aqueous potassium carbonate was added to the mixture, it was degassed by bubbling nitrogen for 30 min. Finally, 0.05 mmol of tetrakis(tri-phenylphosphine)palladium (Pd(Ph$_3$)$_4$) was added to the mixture. The mixture was vigorously refluxed under nitrogen for 24 h. When the reaction mixture was cooled down to room temperature, it was poured into 200 ml methanol. After filtering it off, the crude solid was re-precipitated from chloroform and methanol. Light-yellow powder (4.9 g, 80%) was more purified by flash chromatography with chloroform. mp 377 °C. δ_H (500 MHz; CDCl$_3$; Me$_4$Si) 8.91 (2H, s), 8.66 (2H, d, J 4.0), 8.05 (2H, s), 8.03 (2H, d, J 7.9), 7.99 (2H, t, J 3.9), 7.96 (4H, m), 7.75 (2H, d, J 7.9), 7.65 (4H, m), 7.50 (2H, t), 7.46 (2H, d, J 7.0), 7.40 (2H, m), 7.32 (2H, t). Elemental analysis: Found C, 90.74%; H, 4.66%; N, 4.53%; Calc. for C$_{46}$H$_{28}$N$_2$: C, 90.76%; H, 4.64%; N, 4.60%; M$^+$, 609.

2.1.4. 1,6-Di(pyridin-3-yl)-3,8-di(naphthalen-2-yl)pyrene (N2PP)

Synthetic procedure is the same as in N1PP, except using 2-naphthyl boronic acid instead of 1-naphthyl boronic acid. Yellow powder (4.8 g, 80%), mp 340 °C. δ_H (500 MHz; CDCl$_3$; Me$_4$Si) 8.96 (2H, s), 8.72 (2H, d, J 4), 8.28 (2H, d, J 8.0), 8.14 (6H, m), 8.05 (4H, m), 7.94 (4H, m), 7.80 (2H, d, J 7.0), 7.59 (4H, m), 7.51 (2H, m). Elemental analysis: Found: C, 90.74%; H, 4.61%; N, 4.45%; Calc. for C$_{46}$H$_{28}$N$_2$: C, 90.76%; H, 4.64%; N, 4.60%. M$^+$, 609.

2.2. Instrument

2.2.1. Solution electrochemistry and UV–vis spectroscopy

Cyclic voltammetry was performed in 0.5 mM solution of the compounds with a Potentiostat & Galvanistat (EG&G Princeton Applied Research, Model 273A). All oxidation measurements were carried out in nitrogen-purged anhydrous CH_2Cl_2 containing 0.1 M tetraethyl ammonium tetrafluoroborate (Et$_4$NBF$_4$, Aldrich) as a supporting electrolyte. Platinum disk (2 mm in diameter), platinum wire, and Ag/AgCl (saturated) were used as the working, counter, and reference electrodes, respectively. The voltage between the working and counter electrodes was swept at a scan rate of 50 mV s^{-1}. The potentials for all the materials were the traced to the first anodic peak by using a differential pulse mode. Absorption spectra of 10^{-5} M solution of the samples were collected using a spectrophotometer (SCINCO UVS2100). The optical bandgap was determined from the absorption onset of that spectrum.

2.2.2. OLED fabrication

Patterned indium tin oxide (ITO)-coated glass substrates (NHT, 2 mm × 2 mm, 20 Ω cm^{-2}) were thoroughly cleaned, treated with oxygen plasma (150 W, 5 min, 4×10^{-2} torr). Organic materials were purified by train-sublimation method prior to device experiments. OLEDs were prepared in multiple-source thermal evaporation system at a base pressure of 3×10^{-6} torr or lower. The deposition rate, which is controlled using a deposition controller (Inficone IC/5), was 2 Å s^{-1} for organic materials, except for dopants which were co-evaporated at an appropriate rate to obtain the desired doping level. All the OLEDs were characterized by using a source-unit (Keithley 2400) and a spectroradiometer (Photo Research PR650). To determine the OLED lifetimes, the devices were driven at a constant DC current, while the emission

intensity was monitored using a silicon photodiode at room temperature.

2.2.3. Transient EL and PL

The ITO treatments and organic evaporating conditions are all the same as described in the OLED fabrication. The NPB (60 nm) as a HTL was coated on the ITO, and then electron transport materials (they also behave as emitting materials in this case, 85 nm) were coated on that. Al (100 nm) was used as a cathode. During measurement, a rectangular voltage pulse (amplitude 6–8 V, pulse duration time 3 μs) was applied to an OLED using a pulse generator (HP model 241B). The time-resolved EL from the OLED was measured by placing a miniature photomultiplier tube (PMT, Acton spectra pro 300i Hamamatsu Model 5783-02) directly on the top of the OLED. The output photocurrent from the PMT was sourced into a sensing resistor from which the transient EL signal can be displayed on a storage oscilloscope (Tektronix TDS 754B). The electron mobility was then calculated using $\mu = d/(\tau_d E)$, with d denoting the film thickness and E the applied field, assuming the field drops across the sample compound and neglecting the built-in potential. For the PL measurement, sample thin films (45 nm) were prepared on the ITO glass and Al (100 nm) was coated to protect the films from air. Fluorescence spectra upon excitation with 355 nm were collected by a PMT.

3. Results and discussion

The polycyclic aromatic hydrocarbons such as naphthalenes, anthracenes, and pyrenes, compared with other hetero-aromatic compounds, are known to be not suitable for ETMs because of their high reduction potentials, but they have good thermal stability and no absorption at longer wavelengths than 430 nm [12]. Among them, the pyrene has relatively high electron affinity values and better thermal stability [13]. Moreover, it has four possible positions for substitution reaction (1, 3, 6, and 8 positions), so we

can introduce various kinds of functional groups to it to tailor the desired electrical and optical properties. To increase the electron affinity of pyrene-based aromatic hydrocarbons, we attached two 3-pyridyl moieties at the 1 and 6 positions. Additionally, in order to ensure morphologically stable amorphous film, we introduced two naphthyl moieties into 3 and 8 positions. Expecting the positional dependence of physical properties, we used 1-naphthyl boronic acid and 2-naphthyl boronic acid to synthesize 1,6-di(pyridin-3-yl)-3,8-di(naphthalen-1-yl)-pyrene (hereafter, N1PP) and 1,6-di(pyridin-3-yl)-3,8-di(naphthalen-2-yl)pyrene (hereafter, N2PP), respectively. Synthetic routes to the new ETMs (N1PP and N2PP) are shown in Scheme 1. (The detailed description is given in Section 2.)

The molecular structures of N1PP and N2PP were confirmed by ^{1}H NMR, mass spectrometry, and elemental analysis. Thermal properties of N1PP and N2PP were investigated by means of differential scanning calorimetry (DSC). A glass transition temperature (T_g) was obtained from the second heating scan of the glassy samples cooled after the first heating up to melting temperature (T_m). The heating rate was 10 °C min^{-1}. The T_m's of N1PP and N2PP appear at 377 and 337 °C, respectively, and N1PP shows 20 °C higher T_g than N2PP (shown in Table 1). Because the 1-naphthyl group is expected to be more properly oriented towards the pyrene backbone than the 2-naphthyl group is, N1PP molecule may form a more rigid structure where the intermolecular dipole interactions are favored [14,15]. The crystallization temperature (T_c) of N1PP was observed at 250 °C by the second heating, but no T_c of N2PP was found (Supplementary information), which indicates that N2PP has more glass-like property. However, T_g's of N1PP and N2PP are high enough to keep the amorphous films from being crystallized during the device operation.

The oxidation potentials for the compounds were measured by a differential pulse voltammetry and were used for the estimation of the highest occupied molecular orbital (HOMO) levels, based upon the known linear correla-
Scheme 1. Synthetic routes of N1PP and N2PP.

tion between the two parameters [16]. Because Alq₃, N1PP, and N2PP did not undergo reversible oxidation, the potentials given for these molecules are the first irreversible anodic peak potentials, which are considered as the half-wave oxidation potentials ($E_{1/2}^{OX}$). The anodic peak potential of ferrocene measured by a differential pulse voltammetry corresponded within 30 mV to its half-wave oxidation potential obtained from the anodic peak (E_p^a) and the cathodic peak potential (E_p^c). The bandgap energies were estimated from the onset of UV–vis absorption spectra in dilute solution (Supplementary information).

N2PP (E_g = 2.9 eV) has a smaller bandgap than N1PP (E_g = 3.0 eV). HOMO's and LUMO's of N1PP and N2PP are shown in Fig. 1. Furthermore, in order to get more detailed substituent positional effect, we calculated electronic energy of N1PP and N2PP, using the density functional theory (DFT) B3LYP/6-31G* level Spartan'06 program. Dihedral angles between a naphthyl unit and a pyrene backbone in N1PP and N2PP are and 73.6° and 54.5°, respectively, The conjugation between naphthalene moiety and pyrene moiety is more favourable in N2PP than in N1PP. N2PP shows more bathochromic shift of π–π* transition as shown in Table 1. The two materials, however, show rela-

tively higher oxidation potentials and larger bandgap energy than Alq₃, as shown in Table 1.

The blue OLEDs were fabricated by high-vacuum thermal evaporation of OLED materials onto ITO-coated glass that was used as the anode. All the devices, we fabricated have the same architectures as one shown in the left-half of Fig. 1, differing in the component of electron transport layer. We tested Alq₃, newly-synthesized N1PP and N2PP as electron transport layer (ETL) or electron transport material (ETM).

Firstly, a 60-nm-thick hole injection layer (HIL) consisting of 4,4'-bis[N-[4-{N,N-bis(3-methylphenyl)amino}-phenyl]-N-phenylamino]biphenyl (DNTPD) was deposited, and followed by a 30-nm-thick 4,4'-bis [N-(1-naphthyl)-N-phenylamino]biphenyl (NPB) as a hole transport layer (HTL). Secondly, a 25-nm-thick emissive material layer (EML) was formed by co-depositing 3 wt% of 2,5,8,11-tetra(tert-butyl)perylene (TBP) as a dopant and 9,10-di-(2-naphthyl)anthracene (ADN) as a host [17]. Finally, a 25-nm-thick electron transport layer (ETL) consisting of Alq₃ for device 1 (N1PP for device 2, N2PP for device 3) was deposited. LiF (0.5 nm) and Al (100 nm) worked as an electron injection facilitating a layer and a cathode

(b) Energy diagram of multi layer devices; HOMO and LUMO levels of DNTPD, Alq₃, N1PP, and N2PP are estimated from the first oxidation potential and the absorption onset (Section 2). Those of NPB and ADN are previously reported values [22].
Fig. 2. The J–V (current–density–voltage) curves of blue devices based on different ETMs. The inset shows the external quantum efficiency as a function of current density.

Fig. 3. The electron mobilities in Alq$_3$, N1PP, and N2PP are plotted as a function of the square-root of the electric field. Their transient electroluminescent signals around 5.5 V are also shown in the inset (more specifically, applied voltages for Alq$_3$, N1PP, and N2PP devices are 5.67 V, 5.52 V, and 5.45 V, respectively).

layer, respectively. Inside a glove box, all the devices were encapsulated by a 1-mm-thick glass cover containing a humidity absorber (Dynic). Devices 1, and 2, and 3 have Alq$_3$, N1PP, and N2PP as an electron transport layer (ETL), respectively.

The current density (J)–voltage (V)–luminescence (L) characteristics of the blue OLEDs with different ETLs were measured by source-measure-units (Keithley 2400) and a spectrometer (Photo research PR650). The J–V characteristics are shown in Fig. 2 and the external quantum efficiencies as a function of J are also shown in the inset of Fig. 2. Applying approximately 10 mA cm^{-2} to the devices, the driving voltages of the devices 1, 2, and 3 are 7.05 V (10.1 mA cm^{-2}), 6.25 V (10.4 mA cm^{-2}), and 6.65 V (10.4 mA cm^{-2}), respectively. The external quantum efficiencies of the devices are 2.8%, 3.6%, and 3.5%, respectively. The required operating voltage for 10 mA cm^{-2} is in the order of device 1 > device 3 > device 2, which corresponds to the height of the electron injection barrier estimated by the electrochemical data (Alq$_3$ > N2PP > N1PP shown in the right-half of Fig. 1, i.e. N1PP has the lowest injection barrier among them.).

Additionally, the external quantum efficiencies of the device with the newly-developed pyrene-based molecules as electron transport materials increase by more than 50% at 1 mA cm^{-2} compared with those of the device with Alq$_3$ as an electron transport material. This enhancement is due to the newly-developed pyrene-based molecules as electron transport materials through an improved electron mobility and a lower injection barrier. In order to confirm this fact, we fabricated three kinds of devices to measure the electron mobility by the transient electroluminescence (EL) with ITO/NPB (60 nm)/ETM (85 nm)/Al device structure, where ETM is Alq$_3$, N1PP, or N2PP (described in Section 2) [18]. The typical transient EL signals for the three devices are shown in the inset of Fig. 3, where the time delay (τ_d) of Alq$_3$ film is 1.1 μs and both N1PP and N2PP films have about 0.3 μs of τ_d around 5.5 V. We collect τ_d by varying the electric field. The electron mobility is

plotted as a function of the square-root of the electric field and is given in Fig. 3. For the electric field at 0.7 MV cm^{-1}, the estimated electron mobility in Alq$_3$ film is 1.4×10^{-5} cm^2 (V s)$^{-1}$ that is in a good agreement with the reported value, $10^{-6} \sim 10^{-5}$ cm^2 (V s)$^{-1}$ [5,19]. Those in N1PP and

Fig. 4. (a) EL spectra of devices 1, 2, and 3 at J = 10 mA cm^{-2}. (b) Photoluminescence spectra of the vacuum-deposited amorphous thin films of Alq$_3$, N1PP and N2PP upon UV excitation at 355 nm.

N2PP films are 3.7×10^{-5} cm^2 (V s)$^{-1}$ and 4.3×10^{-5} cm^2 (V s)$^{-1}$, respectively. As expected, the electron mobilities in the newly-developed pyrene-based electron transport materials (N1PP and N2PP) turned out to be higher than that in better-known Alq$_3$, and thus enhanced the external quantum efficiency of devices 2 and 3 using N1PP and N2PP as ETLs which can be explained in terms of an efficient balanced carrier recombination in the emissive material layer (EML).

The EL spectra of the three devices at 10 mA cm^{-2} are also shown in Fig. 4a together with their PL spectra in Fig. 4b. The luminescences with 1931 Commission Internationale del' Eclairage (CIE) coordinates (x, y) of devices 1, 2, and 3 are 495 cd m^{-2} with $(0.148, 0.294)$, 627 cd m^{-2} with $(0.138, 0.276)$, and 672 cd m^{-2} with $(0.148, 0.318)$, respectively. Device 2 (with N1PP as an ETL) emits the most saturated blue color and the intense peak at 468 nm. Device 3 (with N2PP as an ETL) shows a little bit broader spectrum and the intense peak centered at 496 nm. The difference in spectral feature among these results from the enhanced blue emission. Gathering from the PL data shown in Fig. 4b, the totally enhanced portion of blue emission in device 2 with N1PP as an ETL, compared with device 1 with Alq$_3$ as an ETL, comes from an improved carrier recombination in an EML due to the HOMO energy level of N1PP as a hole barrier and three times higher electron mobility of N1PP than that of Alq$_3$ If some of the enhanced portion of the blue emission in device 2 with N1PP as an ETL come from the blue emission of N1PP itself, then the blue emission around 430 nm should be shown in the EL spectrum of device 2. In fact, it is not shown in the EL spectrum of device 2 as given in Fig. 4a. On the other hand, the excimer peaks of pyrene [20] around 500 nm are generated from both N1PP and N2PP, but N2PP having more planar structure for easier formation of excimers shows much stronger excimer peak, for device 3 with N2PP as an ETL, considering that 9,10-di(2-naphthyl)anthracene (ADN) is so ambipolar [21] that the holes passing over it can reach the ETL of N2PP, some of the enhanced portion of blue emission can be originated from N2PP and its excimer themselves.

With the newly-developed pyrene-based molecules (N1PP and N2PP) as an ETL, we get the enhanced blue emission due to 3 times higher electron mobility in those and the HOMO levels of those, compared with Alq$_3$ as an ETL. More specifically, the totally enhanced portion of the blue emission with N1PP as an ETL originates from the HOMO energy level of N1PP as a hole barrier and three times higher electron mobility, while some of the enhanced portion of the blue emission with N2PP as an ETL results from an improved carrier recombination at EML due to three times higher electron mobility and the others come from the blue emission of N2PP and its excimer themselves. We have performed an accelerated lifetime test at 2000 cd m^{-2} initial brightness for the three devices. Applied current and voltage are 52.8 mA cm^{-2} and 8.55 V for the device 1, 42.2 mA cm^{-2} and 7.25 V for device 2, and 37.3 mA cm^{-2} and 7.80 V for the device 3. The accelerated test data are given in Fig. 5. The operation times of 40% light emission reduction occurring for devices 1, 2, and 3 are 620 h, 87 h, and 517 h, respectively.
Fig. 5. Luminance deteriorations and drive voltage variation curves (ΔV) of the devices as a function of time at 2000 cd m^{-2}.

Interestingly, the lifetime of the device 2 with N1PP is shortened by a factor of 5, compared with device 3 with N2PP, even though the only difference in the two structures is the substituent (1-naphthyl or 2-naphthyl). This observation gives some light on the device degradation. According to the energy levels of each material shown in Fig. 1b, device 2 with N1PP as an electron transport layer has a hole injection barrier between an emissive material layer (EML) and an electron transport layer (ETL), but device 3 with N2PP as an ETL does not have a hole injection barrier. The holes in device 3 (with no hole injection barrier) can penetrate the ETL layer deeply and spread over larger area and disappear away with electrons than those in device 2 with N1PP as an ETL. The hole accumulation caused by a hole injection barrier accelerate the material decomposition through a higher concentration of ionized carbocation species in the emissive materials layer [22–24]. Compared to Alq$_3$ and N2PP, N1PP has the highest hole injection barrier. And thus the device 2 with N1PP as an ETM degrades faster than the others. Usually, the deterioration of the light emission is observed in company with an increase in the drive voltage. The drive voltage variations, ΔV's of devices 1, 2, and 3 at 40% light emission reduction, are 0.68 V, 1.2 V, and 1.0 V, respectively. The highest drive voltage increase ($\Delta V = 1.2$ V) is also observed in the device 2 with N1PP as an ETL, with which we can suppose that the voltage increase during the lighting process has a strong correlation with some degradation at the interface between EML and ETL as well. The luminance degradation in the blue OLEDs was correlated with the HOMO energy levels of electron transport materials. Based upon the fact that N1PP and N2PP have 3 times higher mobility than Alq$_3$ and the understanding on the device degradation with N1PP and N2PP, further works on the better devices with a longer lifetime are in progress.

4. Conclusions

In conclusion, we synthesized new kinds of pyrene-based electron transport materials: 1,6-di(pyridin-3-yl)-3,8-di(naphthalen-1-yl)pyrene (N1PP) and 1,6-di(pyridin-3-yl)-3,8-di(naphthalen-2-yl)pyrene (N2PP). The external

quantum efficiencies of the device with the newly-developed pyrene-based molecules as electron transport materials increase by more than 50% at $1\ mA\ cm^{-2}$ compared with those of the device with representative Alq_3 as an electron transport material. The enhanced quantum efficiency is due to the balanced charge recombination in an emissive layer. Electron mobilities in N1PP and N2PP films are $3.7 \times 10^{-5}\ cm^2\ (V\ s)^{-1}$ and $4.3 \times 10^{-5}\ cm^2\ (V\ s)^{-1}$, respectively. These values are three times higher than that of Alq_3. Highly enhanced power efficiency (e.g., $1.4\ lm\ W^{-1}$ for device 1 with Alq_3, $2.0\ lm\ W^{-1}$ for device 2 with N1PP, and $2.1\ lm\ W^{-1}$ for device 3 with N2PP at $2000\ cd\ m^{-2}$) is achieved due to a low electron injection barrier and a high electron mobility. We find that the luminance degradation in the blue OLEDs is correlated with the HOMO energy levels of electron transport materials.

ARTICLE INFO

ABSTRACT

Deep blue phosphorescent organic light-emitting diodes have been developed by using tris((3,5-difluoro-4-cyanophenyl)pyridine) iridium (FCNIr) as a blue phosphorescent dopant. The FCNIr showed a wide triplet bandgap of 2.8 eV for deep blue emission due to a strong electron withdrawing CN substituent in addition to F unit. Doping of the FCNIr in N,N'-dicarbazolyl-3,5-benzene gave a high quantum efficiency of 9.2% with a CIE color coordinate of (0.15, 0.16).

1. Introduction

Deep blue phosphorescent organic light-emitting diodes (PHOLEDs) are critical to get a low power consumption in organic light-emitting diodes because the efficiency of blue fluorescent device is low compared with that of red and green devices [1].

There have been many studies to develop blue PHOLEDs. Iridium(III) bis(4,6-(di-fluorophenyl)-pyridinato-N,C2′) picolinate (FIrpic) is the most well-known blue phosphorescent dopant, but its color performances were poor with a color coordinate of (0.15.0.32) [2]. Bis[2-(4′,6′-difluorophenyl)pyridinato-N,C2′]tetrakis(1-pyrazolyl)borate was also developed as a blue phosphorescent dopant, but its electroluminescence performances were not good enough as a deep blue dopant [3]. Color coordinate of (0.16, 0.26) was obtained with a quantum efficiency of about 10%. Fluorine substituted phenylpyridine derivatives were synthesized as blue dopants, but it gave a light blue emission in spite of high efficiency in soluble devices [4]. Other than these studies, a triazole based ancillary ligand structure was combined with fluorine substituted phenylpyridine

ligand structure and color coordinate of (0.16,0.24) was obtained [5].

In this work, a deep blue PHOLED with a color coordinate of (0.15,0.16) was developed by using a iridium based phenylpyridine derivative with strong electron withdrawing substituents. N,N'-Dicarbazolyl-3,5-benzene(mCP) was used as a host to get a high quantum efficiency in deep blue PHOLEDs.

2. Experimental

A device architecture of indium tin oxide(ITO, 150 nm)/N,N'-diphenyl-N,N'-bis-[4-(phenyl-m-tolyl-amino)-phenyl]-biphenyl-4,4'-diamine (60 nm)/N, N′-di(1-naphthyl)-N,N′-diphenylbenzidine(20 nm)/mCP(10 nm)/mCP: tris((3,5- difluoro-4-cyanophenyl)pyridine) iridium(FCNIr, 30 nm)/2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline(BCP, 5 nm)/tris(8-hydroxyquinoline) aluminium(Alq$_3$, 20 nm)/LiF (1 nm)/Al(200 nm) was used to fabricate deep blue devices. Blue PHOLEDs with 4,7-diphenyl-1,10-phenanthroline (BPhen) as an electron transport layer were also fabricated to study the effect of the electron transport layer on device performances of deep blue PHOLEDs. The doping concentration of FCNIr in mCP was controlled as 5%, 10% and 15%. Chemical structures and the device structure

Fig. 1. A chemical structure of FCNIr and device structures of deep blue PHOLEDs.

are shown in Fig. 1. Synthesis of FCNIr will be reported in other work. Ultraviolet–visible (UV–visible) and photoluminescence (PL) spectra of host and dopant materials were measured with JASCO FP-750 fluorescence spectrometer. Current density–voltage–luminance characteristics of the devices were measured with Keithley 2400 source measurement unit and CS-1000 spectrophotometer.

3. Results and discussion

FCNIr was designed as a deep blue phosphorescent dopant because a strong electron withdrawing group in phenyl unit of main ligand can induce a blue shift of emission spectrum [6]. Fig. 2 shows PL spectra of FCNIr and FIrpic
Fig. 2. Ultraviolet–visible absorption and photoluminescence spectra of mCP and FCNIr materials.

dopant materials. The PL emission peak of FCNIr was observed at 448 nm with a vibrational peak at 476 nm. The FCNIr showed a deep blue emission peak due to the strong electron withdrawing CN group in the phenyl unit of main ligand. An electron withdrawing group in phenyl unit shifts the highest occupied molecular orbital (HOMO) and a deep HOMO level of 5.8 eV was observed in FCNIr from photoelectron spectroscopy. UV–visible absorption and PL emission spectra of mCP are also shown in Fig. 2 and it can be clearly seen that PL emission spectra of mCP are overlapped with metal to ligand charge transfer absorption of FCNIr with a peak position between 400 nm and 450 nm. Therefore, an efficient energy transfer from host materials to FCNIr is expected. In addition, the triplet bandgap of mCP is 2.9 eV compared with 2.8 eV of FCNIr and a triplet dexter energy transfer can be induced.

Fig. 3 shows current density–voltage–efficiency curves of FCNIr doped blue PHOLEDs with BCP/Alq$_3$ and BPhen electron transport layer. The doping concentration of FCNIr was 10%. The blue PHOLED with BPhen showed a higher current density than the blue PHOLED with BCP/Alq$_3$. Bphen is known to have a high electron mobility [7], leading to high current density at the same voltage. High electron mobility of BPhen can be beneficial to the quantum efficiency in hole transport type mCP based devices. Therefore, Bphen was chosen as an electron transport layer of deep blue PHOLEDs and device performances were studied according to doping concentration.

Current density–voltage–luminance curves of deep blue PHOLEDs with Bphen electron transport layer are shown in Fig. 4a. Current density was increased as the doping concentration was increased. A maximum current density was obtained in the device with 15% doping concentration. The high current density in the highly doped device can be explained by charge trapping effect in the light-emitting layer [8]. The FCNIr has a HOMO of 5.8 eV and the lowest unoccupied molecular orbital (LUMO) of 3.0 eV. As can be seen in Fig. 1, electron is strongly trapped by FCNIr due to a LUMO gap of 0.6 eV between mCP and FCNIr. A HOMO gap between mCP and FCNIr is 0.3 eV, which is much lower than the LUMO gap between mCP and FCNIr. Therefore, electrons are strongly trapped by FCNIr and the electron transport in FCNIr doped mCP is retarded by the electron trapping effect. The electron transport is facilitated at high doping concentration because of a reduced hopping distance between dopant materials, resulting in the high current density at high doping concentration. A similar result was observed in the luminance data of blue PHOLEDs and a high luminance was obtained in the highly doped blue PHOLED due to high charge density at high doping concentration [9].

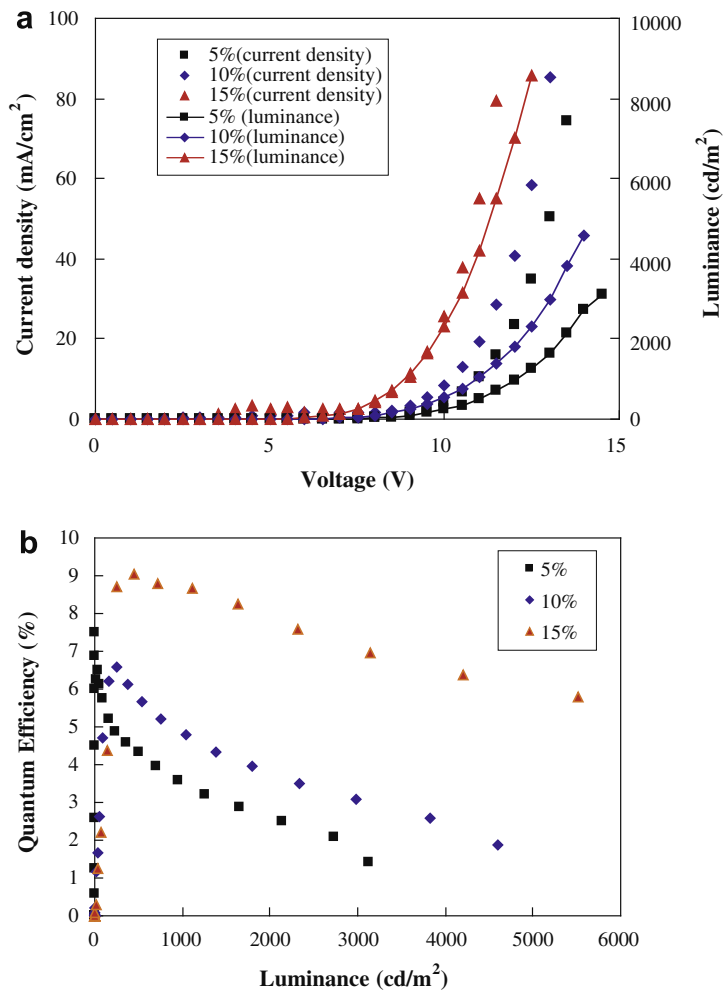
The quantum efficiency of the deep blue PHOLEDs was plotted against the luminance and it is shown in Fig. 4b. The quantum efficiency was enhanced at high doping concentration and a high quantum efficiency of 9.1% was obtained at 500 cd/m². The high quantum efficiency of deep blue PHOLEDs doped with 15% FCNIr can be explained by a charge balance in the light-emitting layer. The mCP host material is a hole transport type host material and a hole injection is better than an electron injection. Therefore, a hole density is higher than the electron density in the
Fig. 3. Current density–voltage–luminance characteristics of blue PHOLEDs with BCP/Alq$_3$ and BPhen electron transport layers.


Fig. 4. Current density–voltage–luminance curves (a) and quantum efficiency–luminance curves (b) of blue PHOLEDs with Bphen according to FCNIr doping concentration.
Fig. 5. Electroluminescence spectra of blue PHOLEDs with different FCNIr doping concentrations.

mCP based emitting layer and more electron injection enhances the charge balance. The electron transport is improved at high doping concentration due to a reduced hopping distance and the electron density is increased at high doping concentration, resulting in better holes and electrons balance in the light-emitting layer. A high current efficiency of 11 cd/A was observed in 15% FCNIr doped devices.

Electroluminescence spectra of deep blue PHOLEDs are shown in Fig. 5. The peak maximum of blue PHOLEDs was 454 nm and a shoulder peak at 482 nm was observed. The color coordinate of 5% FCNIr doped PHOLED was $(0.14, 0.15)$ compared with $(0.17, 0.33)$ of common phosphorescent blue dopant materials in our measurement. The color coordinate is better than any other data reported in the literature [2–5]. The blue PHOLED with 15% doping concentration was $(0.15, 0.16)$ with a current efficiency of 11 cd/A. Therefore, a true deep blue PHOLED with a high efficiency over 10 cd/A could be obtained by controlling the doping concentration and the electron transport layer of the blue PHOLEDs.

4. Conclusions

In summary, a true deep blue PHOLED could be fabricated by doping FCNIr in the mCP host material. A high quantum efficiency of 9.2% and a current efficiency of 11 cd/A were obtained in the deep blue PHOLED with a color coordinate of $(0.15, 0.16)$ at 500 cd/m^2.

ABSTRACT

We have demonstrated top-gate polymer field-effect transistors (FETs) with ultra-thin (30–50 nm), room-temperature crosslinkable polymer gate dielectrics based on blending an insulating base polymer such as poly(methyl methacrylate) with an organosilane cross-linking agent, 1,6-bis(trichlorosilyl)hexane. The top-gate polymer transistors with thin gate dielectrics were operated at gate voltages less than −8 V with a relatively high dielectric breakdown strength (>3 MV/cm) and a low leakage current (10–100 nA/mm² at 2 MV/cm). The yield of thin gate dielectrics in top-gate polymer FETs is correlated with the roughness of underlying semiconducting polymer film. High mobilities of 0.1–0.2 cm²/V s and on and off state current ratios of 10^4 were achieved with the high performance semiconducting polymer, poly(2,5-bis(3-alkylthiophen-2yl)thieno[3,2-b]thiophene.

1. Introduction

Research into solution-processible organic field-effect transistors (OFETs) has been dramatically increasing in the past decade motivated by applications in low-cost, large-area electronics on flexible substrates. Many studies have focused on the development of high performance polymer semiconductor materials and methods for improving their ordering to achieve high charge carrier mobility via inter-molecular hopping [1–5]. Research on gate dielectrics and their properties has attracted less attention even though the device operates through the modulation of charge carrier flow at the semiconductor–dielectric interface. Earlier works on development of solution-processible

gate dielectrics focused mainly on high permittivity [6–9] and silicon-based materials motivated by the superb properties of silicon dioxide (SiO₂) as a gate dielectric for silicon FETs [10]. However, reports of a dependence of field-effect mobility on the dielectric constant of the gate dielectric [11] and of the general observation of n-type behavior in organic semiconductors via controlling the semiconductor–dielectric interface [12] illustrate clearly the importance of selecting the right gate dielectric material. New polymer dielectrics are now considered as a key area of development for improving the performance and reliability of OFETs and to accelerate commercialization.

A key requirement for a polymer gate dielectric is the ability to form a thin film with good dielectric properties [13,14]. The thickness of the gate dielectric determines directly the operating voltage of the FET, and for devices with short channel length L the gate dielectric thickness needs to be sufficiently thin to fulfill basic transistor scaling relationships (typically $d/L < \frac{1}{4}$) [15,16]. With conventional polymer insulators such as poly(methyl

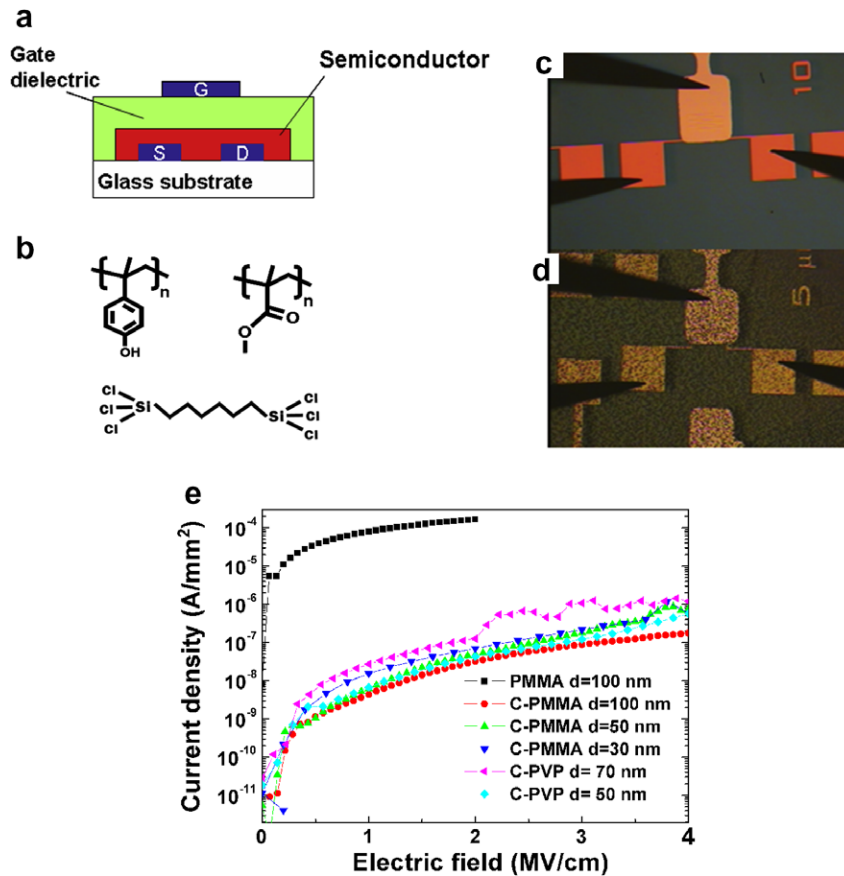

Fig. 1. (a) Chemical structure of poly(methyl methacrylate) (PMMA), poly-4-vinylphenol (PVP) and 1,6-bis(trichlorosilyl)hexane (C_6-Si) used as a base polymer and crosslinking agent for thin gate dielectrics in this study. (b) Schematic diagram of top-gated polymer transistor. Optical micrograph view of the top of poly(9,9-dioctylfluorene-*co*-bithiophene) (F8T2) transistors with (c) crosslinked PMMA (C-PMMA), and (d) crosslinked polystyrene as a gate dielectric (the size of for the square source and drain contact pads is $500 \times 500 \ \mu m$). (e) Leakage current density versus applied voltage for C-PMMA (100, 50 and 30 nm), C-PVP (70 nm and 50 nm), or PMMA (100 nm)/30 nm F8T2 films sandwiched between gold electrodes.

methacrylate) (PMMA) or polystyrene (PS) it is very difficult to achieve thin dielectrics less than 100 nm without pinholes due to their large free volume and low breakdown voltage (see Fig. 1e). Some research groups have introduced crosslinkable polymer systems with high breakdown voltage and low free volume as a thin gate insulator ($d < 50$ nm), but these are all applied in a bottom-gate architecture in which the gate insulator is formed on an underlying smooth highly doped silicon substrate as a gate electrode prior to deposition of the organic semiconductor [14,17,18].

For some technological applications top-gate device architectures are advantageous:

(i) The gate-line can be deposited at the top of device and can therefore be formed by a cheap printing process and the conductivity of gate-line can be controlled via selection of conductive inks such as a metal nanoparticle to reduce RC-delay in large-area active matrix liquid crystal displays [19].
(ii) Source–drain electrode can be formed on the substrate by high-resolution patterning processes such as photolithography, printing or imprinting without

degrading the surface properties of an underlying gate dielectric/semiconducting layer.
(iii) The presence of a gate dielectric and gate electrode on top of the organic semiconductor can provide an encapsulation effect against environmental exposure.
(iv) The top-gate architecture enables use of a staggered device configuration with lower contact resistance than what can be achieved in bottom-gate, bottom-contact devices [20].

However, there are difficulties to apply crosslinkable polymer thin gate dielectrics in top-gate architectures including (i) a high curing temperature for crosslinking causing damage to the underlying semiconductor film; (ii) the difficulty to find an orthogonal, stable solvent to avoid dissolution of the underlying semiconducting layer and (iii) increased leakage current related to the roughness of the semiconducting film, which is often higher than that of a smooth substrate such as a silicon wafer. Most systems require high curing temperatures over 150 °C for more than 30 min [13,17,18]. We show here that the crosslinkable polymer blend (CPB) system recently introduced by Yoon

et al. [14] for bottom-gate architectures is able to meet the requirements for integration into a top-gate architecture.

We have realized ultra thin polymer gate dielectrics (~30 nm) for top-gate polymer FETs via blending a conventional insulating polymer with the crosslinking agent, 1,6-bis(trichlorosilyl)hexane (C_6-Si). The main advantage of this system is that the crosslinking takes place at room-temperature spontaneously in the presence of moisture and therefore the system can be applied in top-gate configuration while avoiding damage to the underlying conjugated polymer. Using this approach we have fabricated polymer FETs operating at voltages less than −8 V with a relatively high dielectric breakdown strength and a low leakage current (10–100 nA/mm^2 at 2 MV/cm). The polymer transistors with thin gate dielectrics exhibit high yield, which is correlated with the roughness of semiconducting polymer film. High mobilities of 0.1–0.2 cm^2/V s and on–off current ratios of 10^4 were achieved with the high performance semiconducting polymer, poly(2,5-bis(3-alkyl-thiophen-2yl)thieno[3,2-b]thiophene (pBTTT).

2. Experiment

Corning 7059 glass slides were used as substrates after cleaning sequentially in an ultrasonic bath with deionised water, acetone and isopropanol for 10 min each. The gold patterns for source and drain electrode were fabricated using conventional lift-off photolithography. The semiconducting polymer, poly(9,9-dioctylfuorene-co-bithiophene) (F8T2) (Dow Chemical Company), poly(3-hexylthiophene) (P3HT) (Rieke Metal Inc.), and pBTTT (Merck Chemicals) was dissolved in anhydrous xylene (0.7 wt.%; F8T2) or trichlorobenzene (1 wt.%; P3HT and 0.5 wt.%; pBTTT), respectively. For the case of F8T2 or P3HT films, films were annealed at 100 °C for 30 min to remove the solvent after spinning (2000 rpm, 1 min (F8T2) or 3 min (P3HT)) in a glove box with low oxygen and moisture level (<5 ppm). pBTTT films were annealed at 100 °C for 30 min in the same glove box to remove the solvent and 170 °C for 10 min to achieve high molecular ordering. For thin polymer dielectrics, PMMA (Aldrich, MW = 120,000) or poly-4-vinylphenol (PVP) (Aldrich, MW = 20,000) was used without further purification. The crosslinking agent, 1,6-bis(trichlorosilyl)hexane (Acro Organics, UK), was purified by distillation under inert atmosphere. For a 30–50 nm thickness film, PMMA or PVP (15–20 mg/ml in anhydrous n-butyl acetate) was blended with 1,6-bis(trichlorosilyl)hexane (5–7 μl) and then the mixture was filtered via 0.1 μm syringe filter and spin-coated at 4000–6000 rpm onto the semiconductor. All steps except spin-coating of the gate dielectric were performed in the glove box. The film was annealed on hot plate at 100 °C for 10 min to remove solvent in air. Top-gate transistors were completed by formation of a gate electrode via inkjet printing of the conducting polymer poly(3,4-ethylenedioxithiophene) doped with poly(styrene sulfonate) (PEDOT:PSS) or evaporation of thin Au or Al films through a shadow mask. Some FETs with P3HT and pBTTT were annealed after making full devices at hotplate (80 °C, 30 min) in nitrogen filled glove box to improve on–off current ratio. The electrical characteristics were measured with HP 4155B semiconductor parameter analyzer and HP 4192A impedance analyzer in nitrogen atmosphere. The transistors parameters such as charge carrier mobility were calculated in the saturation or linear regime using the standard formalism for field-effect transistors [6]. The surface morphology of films was investigated by atomic force microscopy (Dimension 3100, Veeco Instrument Inc.) in tapping-mode.

3. Result and discussion

Fig. 1a and b displays the device configuration of our top-gated FETs and the molecular structure of PMMA and PVP used as a base polymer and C_6-Si as crosslinking agent, named as C-PMMA and C-PVP, respectively. To spin-coat a thin dielectric film on top of the semiconducting polymer layer, the base polymer was dissolved in an orthogonal solvent, anhydrous n-butyl acetate, and blended with the crosslinking agent in a glove box (oxygen and moisture concentration < 5 ppm). The orthogonal solvent was selected to provide (i) a good solubility for the insulating polymer; (ii) a poor solubility for the underlying semiconductor film to avoid dissolution and swelling; (iii) a low vapor pressure (15 mm Hg at 25 °C for n-butyl acetate) to give sufficient time for full crosslinking before evaporation of solvent and (iv) absence of hydroxyl group to avoid crosslinking with the solvent. We have tried a range of base polymers and PMMA and PVP exhibited clear and smooth films (Figs. 1c and 2a) and the best performance and yield in our top-gated polymer transistors. The proper combination of a base polymer and an orthogonal solvent was important to obtain a pinhole free, smooth film. For example, PS films deposited from n-butyl acetate with C_6-Si showed much higher surface roughness and large leakage current (Fig. 1d) in contrast to smooth PS films deposited from the same solvent but without the C_6-Si crosslinker or crosslinked PS film deposited from xylene. Details about this are well-described in another paper published recently [21]. The dissolution and swelling of a F8T2 layer in the orthogonal solvent, n-butyl acetate, was checked by measuring atomic force microscopy topographs before and after spin-coating of the pure solvent. There was no dissolution of the F8T2 film by the solvent and the roughness of film was only slightly increased from a root mean square (rms) value of 0.52 nm before to 1.1 nm after the spinning.

To investigate the minimum possible thickness that can be achieved in this way in comparison with conventional, non-crosslinked insulating polymer films, we measured the current density versus applied field characteristics of a series of 1 mm^2 Au/C-PMMA (d = 100, 50 and 30 nm)/ F8T2 (30 nm)/Au metal–insulator–semiconductor (MIS) diodes and compared these with reference structures using a 100 nm uncrosslinked PMMA dielectric layer (Fig. 1e). The ultra-thin, 30 nm C-PMMA films on F8T2 exhibited gate dielectric breakdown strength exceeding 3 MV/cm with low leakage current of <100 nA/mm^2. This is much better performance than what could be achieved with 100 nm, uncrosslinked PMMA films. The performance of the C-PMMA films is comparable to that of thermal SiO$_2$ on Si [22]. The measured capacitance values (10 kHz) are 103.3 nF cm^{-2} for 30 nm C-PMMA and 180.3 nF cm^{-2} for
Fig. 2. (a) Atomic force microscopy image of C-PMMA film on F8T2 film (5 μm × 5 μm). (b) Output and (c) transfer characteristics of top-gated F8T2 FET (W/L = 1 mm/20 μm) with C-PMMA ($t \sim 30$ nm). The gate leakage currents were measured at $V_D = -1$ V (opened square) and -10 V (closed square) at the same time. (d) Static characteristics of a resistor load inverter (W/L = 1 mm/20 μm) with a printed PEDOT:PSS resistor load (R_L = 30 MΩ) and the corresponding circuit diagram (inset).

30 nm C-PVP which is in good agreement with the theoretically expected values using dielectric constants of 3.5 and 6.4 for C-PMMA and C-PVP, respectively [14]. The possible minimum thickness was dependent of the roughness of the underlying semiconductor film and 30 nm thickness was successfully achieved for F8T2 with more than 90% yield. Yield details will be discussed below. C-PVP film on F8T2 exhibited similar properties in terms of dielectric break down strength and leakage current as C-PMMA at the same thickness (Fig. 1e).

To fabricate top-gate polymer FETs F8T2 was coated on a glass substrate in the glove box with Au source and drain electrodes pre-patterned by photolithography and then C-PMMA solution was spin-coated onto the semiconducting layer in air atmosphere. The crosslinking took place spontaneously during the spinning process with the help of moisture in air and no annealing process was necessary. (*Note:* The blending of the crosslinking agent, C_6-Si into the PMMA solution must be done in the glove box to avoid the crosslinking in the formulation before coating of C-PMMA.) The C-PMMA film (30 nm) on F8T2 exhibited a very smooth surface with less than 0.8 nm rms roughness which is similar to the surface roughness of the underlying F8T2 film (Fig. 2a). The top-gated FETs were completed by the evaporation of a metal (Au or Al) or printing of PEDOT:PSS as a gate electrode. Typical output and transfer curves are shown in Fig. 2b and c. All devices operated be-

low -8 V with a saturation mobility (μ_{sat}) of 0.005 cm²/V s typical of F8T2 [4,23] and a low threshold voltage (V_{TH}) of -1.5 V. Very low gate leakage current was observed (<1 nA) at $V_G = -6$ V and there is no significant increase of gate leakage (<10 nA) even at $V_G = -20$ V when the gate field corresponds to ~ 6 MV/cm (Fig. 4b). Inverters were realized in a simple resistor load configuration using an inkjet printed PEDOT:PSS load resistor (30 MΩ) and exhibited a good voltage gain of 2 at $V_{DD} = -8$ V (Fig. 2d). Top-gated F8T2 FETs with 50 nm C-PVP showed similar performance to that of C-PMMA devices (Fig. 3a and b).

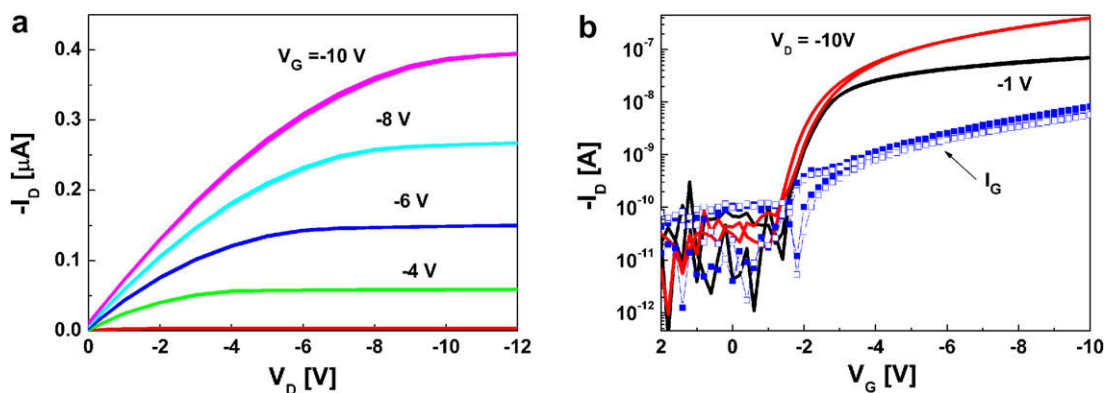
Thin polymer gate dielectrics were successfully applied also on semicrystalline polymer semiconductors, such as P3HT and pBTTT in top-gate architecture. Regioregular P3HT (molecular weight = 45,000, regio-regularity $\sim 98\%$) film showed a typical nanoribbon morphology when deposited from the high boiling point trichlorobenzene solution (Fig 4c). The rms roughness of the film was 3.5 nm, which is much increased from that of amorphous, as-deposited films of F8T2. Top-gated P3HT FETs were demonstrated successfully with 30 nm thin C-PMMA as gate dielectric. The calculated μ_{sat} was 0.007–0.01 cm²/V s which was similar to that of reference top-gate P3HT FETs with uncrosslinked PMMA [24]. The as-deposited P3HT transistors exhibit low on–off current ratio on the order of 100 presumably due to doping of P3HT during spin-coating of the gate dielectric in air (Fig 4a). The poor on–off


Fig. 3. (a) Output and (b) transfer characteristics of top-gated F8T2 FET (W/L = 1 mm/10 μm) with C-PVP ($t \sim 50$ nm). Gate current leakages were measured at $V_D = -10$ V (closed square) and -1 V (opened square) at the same time.
Fig. 4. Transfer characteristics of top-gated poly(3-hexylthiophene) (P3HT)/C-PMMA ($t \sim 30$ nm) FET (W/L = 1 mm/20 μm) measured (a) before and (b) after post-annealing (80 °C, 30 min) in a glove box. The gate leakage currents were measured at $V_D = -1$ V (opened square) and -5 V (closed square) at the same time. (c) Atomic force microscopy image of the P3HT surface morphology on glass (5 μm × 5 μm).

current ratio could be significantly improved to values of 1000 by de-doping the films via post-fabrication annealing (80 °C, 30 min) in nitrogen (Fig. 4b).

Finally, high performance top-gated polymer transistors were demonstrated with pBTTT. pBTTT FETs had been shown to exhibit a remarkably high-mobility of up to 0.6 cm²/V s on octyltrichlorosilane (OTS) treated SiO₂ in the bottom-gate configuration and the mobility was further improved to 1 cm²/V s with the low contact resistance Pt source/drain electrode [3,25]. The high performance was

attributed to their exceptional molecular ordering obtained via cooling from the liquid crystalline (LC) mesophase. The performance was shown to be highly sensitive to the surface chemistry of the substrate resulting in large difference of grain size on different surfaces [26]. Samples fabricated on a bare SiO₂ surface showed much poorer mobility (<0.005 cm²/V s) and smaller granular grain size (~50–100 nm) than samples on OTS/SiO₂ with large, terraced grains (~200 nm). Our top-gate pBTTT transistors with 30–50 nm C-PMMA exhibit high μ_{sat} values of ~0.1–
Fig. 5. (a) Transfer and (b) output characteristics of top-gated poly(2,5-bis(3-alkylthiophen-2yl)thieno[3,2-b]thiophene (pBTTT)/C-PMMA ($t \sim 30$ nm) FET (W/L = 1 mm/20 μm) measured after post-annealing (80 °C, 30 min) in glove box. The gate leakage currents were measured at V_D = −1 V (opened square) and −10 V (closed square) at the same time. Inset shows the chemical structure of pBTTT. (c) Atomic force microscopy image of the pBTTT surface morphology on glass (2 μm × 2 μm).

0.2 cm^2/V s. To the best of our knowledge this mobility is the highest value reported for a top-gate polymer FET. Fig. 5a and b shows typical transfer and output characteristics of a pBTTT top-gate FET after 30 min post-fabrication annealing. The as-deposited pBTTT devices showed poor on–off current ratio on the order of 100 similar to the behavior observed for P3HT. Overnight annealing of the devices in nitrogen leads to a slight decrease of on current but to a significant increase of the on–off current ratio to values of >10^4. The relatively large grain size of pBTTT films (>200 nm, Fig. 5c) on glass substrates explains the high-mobility values obtained in our top-gate pBTTT FETs. It is interestingly noted that we can get the large grains on glass substrate without OTS treatment and different from other group's reports that the large grains only can ob-

tained on OTS treated SiO$_2$ surface in bottom-gated FETs [3,26,27]. Even though top-gated pBTTT transistors show the relatively high performance with thin polymer gate dielectrics, the output characteristics seemed somewhat a nonlinear drain current increase near the origin (Fig. 5b). The reason of poor output characteristics does not clarified yet but it may be due to pBTTT itself because other publications also showed the similar poor output curve with thick SiO$_2$ (200 nm) [25].

Finally, we comment on the device yield due to dielectric breakdown and gate leakage of top-gated FETs with thin C-PMMA or C-PVP films. For the thinnest gate dielectrics (30–50 nm) this was strongly correlated with the roughness of the semiconductor surface and the size of the active area (see Table 1). FETs with an amorphous

Table 1
Device performance and yield due to dielectric breakdown/gate leakage of top-gated polymer transistors with 30 nm C-PMMA or C-PVP.

Gate dielectric	Channel length/width	Semiconducting polymer	μ_{sat} (cm^2/V s)	V_{TH} (V)	Yield (%)[a]
C-PMMA	20 μm/1 mm	F8T2	0.005–0.001	0 to −2	100
	10 μm/1 mm	P3HT	0.008–0.015	1 to −2	45
	5 μm/1 mm	P3HT	0.007–0.01	0 to −3	60
	5 μm/1 mm	pBTTT	0.1–0.2	−1 to −4	80
C-PVP	20 μm/1 mm	F8T2	0.005–0.001	−1 to −2	90
	5 μm/1 mm	F8T2			95

[a] The yield was determined from measurements of more than 20 transistors from four different batches. A transistor was considered to have failed if the gate leakage current was the same as the drain current of transistor.

semiconducting polymer such as F8T2 always exhibited near perfect yield due to their smooth surface morphology. However, we observed that the yield of transistors decreased for semicrystalline semiconductors, such as P3HT or pBTTT due to their significantly rougher surface morphology.

4. Conclusion

In conclusion, we have demonstrated high performance top-gate polymer FETs with ultra-thin (30–50 nm), room-temperature crosslinkable polymer gate dielectrics based on blending an insulating base polymer with an organosilane crosslinking agent. The crosslinking system can be extended to other systems with different dielectric permittivities by careful selection of the base polymer. The approach enables low-voltage operation below 10 V and high yield and is compatible with a range of state-of-the-art high-mobility polymer semiconductors.

ARTICLE INFO

ABSTRACT

This paper describes the synthesis of three triaryldiamine derivatives presenting two thermally polymerizable trifluorovinyl ether groups that can be polymerized through thermal curing to form perfluorocyclobutyl (PFCB) polymers. These PFCB polymers, studied using time-of-flight techniques for the first time, exhibited remarkable non-dispersive hole-transport properties, with values of μ_h of ca. 10^{-4} cm^2 V^{-1} s^{-1}. When we employed these thermally polymerized polymers as hole-transport layers (HTLs) in electroluminescence devices containing tris(8-hydroxyquinolate) aluminum (Alq$_3$) as the emission layer, we obtained high current densities (ca. 3400 mA cm^{-2}), impressive brightnesses (5×10^4 cd m^{-2}), and high external quantum efficiencies (EQEs = 1.43%). These devices exhibited the same turn-on voltage, but higher EQEs, relative to those incorporating the vacuum-processed model compound N,N'-di(1-naphthyl)-N,N'-diphenylbenzidine (α-NPD) (EQE = 1.37%) as the HTL under the same device structure.

1. Introduction

Organic and polymer light-emitting diodes are promising devices for use in future lighting and display applications because of their low power consumption, light weight, fast response, and wide viewing angle [1,2]. To increase their efficiency, most organic light-emitting diodes (OLEDs) are configured with a variety of functional materials into a multilayer structure—fabricated through successive vacuum deposition of small molecules—and then covered by a metal cathode. It is generally inherently difficult to form polymer-based OLEDs in multilayer structures through solution-processing techniques, such as spin-coating, because of solvent erosion of the previously deposited layers during spin-coating [3]. One of the most promising approaches toward achieving purely solution-processed multiple-layer polymer-based OLEDs is utilizing soluble precursor materials to produce insoluble polymer networks through polymerization and/or cross-linking reactions. This strategy allows the sequential deposition of various functional layers [4,5]. The flexibility of using the chemical modifications of a wide variety of materials

possessing various functional moieties—such as siloxan [6–9], norbornene [10,11], oxetane [4,5], vinyl [12,13], and tri-fluorovinyl ether [14–18] units—as polymerizable groups under UV irradiation or thermal curing allows the construction of copolymers in nearly any designated composition. For example, trifluorovinyl ether (TFVE)-containing compounds are useful as reactive monomers that undergo thermal cyclopolymerization to afford a new class of thermally stable perfluorocyclobutane (PFCB) polymers [19–21]. Taking advantage of this strategy, PFCB-based hole-transport materials have been developed to increase the efficiency of OLED devices [22–28]. This superior performance is ascribed mainly to the homogeneous surface morphology of the thermally treated thin films, as probed using atomic force microscopy (AFM). Nevertheless, to the best of our knowledge, the intrinsic charge transporting characteristic, one of the most critical factors in optoelectronic devices, of PFCB-based hole-transport materials has not been reported previously. In this paper, we report the synthesis, characterization, and application of three tri-aryldiamine derivatives attached to two thermally polymerizable trifluorovinyl ether (TFVE) groups that can be polymerized through thermal curing to form PFCB polymers. More importantly, we have used time-of-flight (TOF) techniques to study the hole-transport properties of these polymers. We have found that PFCB-based polymers possess remarkable hole-transport properties, with values of μ_h of ca. 10^{-4} cm^2 V^{-1} s^{-1}. These thermally polymerized polymers are useful as hole-transport layers (HTLs) in electroluminescence (EL) applications, as evidenced by the high external quantum efficiency of 1.43% achieved when employing one such system with tris(8-hydroxyquinolate) aluminum (Alq$_3$) as the emission layer.

2. Experimental

2.1. Synthesis

Compound 5: Compound **4** (5.08 g, 10 mmol), N-phenyl-1-naphthylamine (4.39 g, 20 mmol), Pd(OAc)$_2$ (67 mg, 0.3 mmol), and sodium *tert*-butoxide (7.68 g, 80 mmol) were dissolved in toluene (100 mL) and then tri-*tert*-butylphospine (6 mL, 0.05 M in toluene, 0.3 mmol) was added. The mixture was heated under reflux under argon for 72 h and then quenched with water. The solution was partitioned between ethyl acetate and brine. The combined organic extracts were dried (MgSO$_4$) and concentrated. The resulting solid was washed with hexane to afford a yellow product (6.41 g, 82%). M.p. 254–255 °C. IR (KBr) ν 3544 (w), 3055 (w), 1609 (m), 1592 (s), 1573 (m), 1507 (s), 1489 (s), 1464 (s), 1434 (m), 1392 (m), 1302 (m), 1269 (s), 1172 (m), 1015 (m) cm^{-1}. ^{1}H NMR (DMSO-d_6, 400 MHz): δ 9.29 (s, 2H), 7.97 (d, J = 8.0 Hz, 2H), 7.84 (d, J = 8.4 Hz, 2H), 7.76 (d, J = 8.4 Hz, 2H), 7.56–7.48 (m, 6H), 7.37 (t, J = 7.4 Hz, 2H), 7.28 (d, J = 7.2 Hz, 2H), 7.16 (t, J = 7.6 Hz, 4H), 6.92–6.84 (m, 8H), 6.78 (s, 2H), 6.51 (d, J = 8.8 Hz, 4H), 6.41 (d, J = 8.4 Hz, 4H). ^{13}C NMR (DMSO-d_6, 100 MHz): δ 155.5, 152.2, 147.5, 146.5, 142.6, 135.3, 134.7, 132.9, 130.1, 129.1, 128.4, 128.2, 126.6, 126.4, 126.3, 126.1, 123.4, 121.6, 121.1, 120.4, 120.2, 118.8,

114.6, 63.0. MS (FAB$^+$, m/z) 785 (100), 784 (65), 154 (70), 136 (65), 57 (65). HRMS (FAB$^+$, [M+H]$^+$) Calcd. C$_{57}$H$_{41}$N$_2$O$_2$ 785.3170, found 785.3165.

Compound 6: A mixture of **5** (2.93 g, 3.73 mmol) and triethylamine (3 mL, 21.6 mmol) in dry dichloromethane (260 mL) was cooled to −10 °C. Trifluoromethanesulfonic anhydride (1.9 mL, 11.2 mmol) in dry dichloromethane (90 mL) was added dropwise and then the reaction mixture was warmed to room temperature and stirred for 16 h. The reaction was quenched by pouring the mixture into ice water. The organic layer was separated and the aqueous phase was extracted twice with dichloromethane. The combined organic extracts were washed with saturated NaHCO$_3$ solution and brine and then dried (MgSO$_4$). The solvents were evaporated and the resulting residue was purified through re-precipitation from dichloromethane and methanol to afford a yellow product (3.18 g, 81%). M.p. 136–138 °C. IR (KBr) ν 3059 (w), 1609 (m), 1592 (m), 1573 (m), 1494 (s), 1468 (s), 1455 (m), 1426 (s), 1392 (m), 1271 (m), 1249 (m), 1212 (s), 1140 (s), 884 (m), 774 (m) cm^{-1}. ^{1}H NMR (DMSO-d_6, 400 MHz): δ 7.96 (d, J = 8.4 Hz, 2H), 7.85 (d, J = 8.0 Hz, 2H), 7.72 (d, J = 8.0 Hz, 2H), 7.62 (d, J = 8.4 Hz, 2H), 7.53–7.46 (m, 4H), 7.37–7.27 (m, 8H), 7.15 (t, J = 7.6 Hz, 4H), 7.00 (d, J = 8.4 Hz, 4H), 6.92–6.89 (m, 4H), 6.84 (d, J = 8.4 Hz, 6H). ^{13}C NMR (DMSO-d_6, 100 MHz): δ 149.9, 147.7, 147.2, 146.9, 145.0, 142.3, 134.7, 132.8, 129.9, 129.3, 129.0, 128.4, 126.7, 126.5, 126.4, 126.3, 126.0, 123.2, 121.8, 121.3, 121.1, 120.8, 119.6, 118.3, 116.4, 63.6. TFVE1: **1** (380 mg, 0.87 mmol), **2** (515 mg, 2.18 mmol), Pd(OAc)$_2$ (10 mg, 0.04 mmol), and sodium *tert*-butoxide (210 mg, 2.18 mmol) were dissolved in toluene (10 mL) and then tri-*tert*-butyl phosphine (1.6 mL, 0.05 M in toluene, 0.08 mmol) was added. The mixture was heated under reflux under argon for 24 h and then quenched with water. The solvent was evaporated and then the reaction mixture was extracted with dichloromethane and dried (MgSO$_4$). The crude product was purified through column chromatography (SiO$_2$; EtOAc/hexane, 1:15) to afford **TFVE1** (485 mg, 72%) as a white solid. IR (KBr) ν 3046 (w), 1600 (w), 1497 (s), 1460 (w), 1397 (m), 1311 (m), 1274 (s), 1192 (m), 1159 (m), 1136 (m) cm^{-1}. ^{1}H NMR (acetone-d_6, 400 MHz): δ 7.98 (d, J = 8.0 Hz, 2H), 7.94 (d, J = 8.0 Hz, 2H), 7.89 (d, J = 8.0 Hz, 2H), 7.55 (t, J = 8.0 Hz, 2H), 7.52–7.45 (m, 6H), 7.43–7.36 (m, 4H), 7.14–7.07 (m, 8H), 7.00 (d, J = 8.0 Hz, 4H). ^{13}C NMR (acetone-d_6, 100 MHz): δ 148.0, 146.3, 143.8, 136.2, 134.5, 131.8, 129.3, 127.9, 127.8, 127.6, 127.3, 127.2, 127.0, 124.5, 124.2, 122.3, 117.6. ^{19}F NMR (acetone-d_6, 376 MHz): δ −117.1 (dd, J = 99.6, 55.6 Hz, 2 F), −124.3 (dd, J = 108.3, 99.3 Hz, 2F), 130.6 (dd, J = 108.3, 56.4 Hz, 2F). MS (FAB$^+$, m/z) 780 (100), 467 (25), 217 (35). HRMS (FAB$^+$, M$^+$) Calcd. C$_{47}$H$_{28}$N$_4$ 780.2211, found 780.2208.

TFVE2: A flask containing **3** (2.46 g, 4.88 mmol), 1-aminonaphthalene (2.09 g, 14.6 mmol), Pd$_2$(dba)$_3$ (224 mg, 0.25 mmol), and sodium *tert*-butoxide (1.41 g, 14.7 mmol) was evacuated and recharged with argon, then dry toluene (30 mL) and tri-*tert*-butylphosphine (9.8 mL,

0.05 M in toluene, 0.49 mmol) were added. The mixture was heated under reflux for 48 h and then cooled to room temperature. The mixture was filtered through a short path of Celite and then washed with dichloromethane, and the filtrate was extract with dichloromethane and dried ($MgSO_4$). The solvent was partially removed using a rotary evaporator and then hexane (30 mL) was added to give a yellow solid that was collected through filtration and washed with hexane. The crude solid (1.9 g, 3.02 mmol) was combined with $Pd(OAc)_2$ (34 mg, 0.15 mmol), **2** (1.91 g, 7.5 mmol), and sodium *tert*-butoxide (1.44 g, 15 mmol) and then dry toluene (40 mL) and tri-*tert*-butylphosphine (6 mL, 0.05 M in toluene, 0.3 mmol) were added. The mixture was filtered through a short path of Celite and washed with ethyl acetate, and the filtrate was extracted with ethyl acetate and dried ($MgSO_4$). The solvent was removed using a rotary evaporator to give a crude product, which was purified through column chromatography (SiO_2; EtOAc:hexane, 1:20) to afford **TFVE2** (2.3 g, 49% over two steps) as a yellow solid. 2.2. Time-of-flight (TOF) mobility measurements

In the TOF method, a sheet of carriers is created near one of the contacts using a short laser pulse (nitrogen pulse laser). The sample is illuminated from the indium tin oxide (ITO) side to generate a sheet of charge carriers in the organic layer. Under the influence of an applied electric field, these carriers drift toward the counter electrode (Ag), resulting in a transient current through the sample. When the carriers reach the counter electrode, the current drops to zero; the point at which this happens corresponds to the transit time of the carriers (t_T). Depending on the polarity of the applied bias, selected photogenerated carriers (holes or electrons) are swept across the sample thickness D; the applied electric field E is then equal to V/D, and the carrier mobility (μ) is given by $D/(t_T E)$.

2.3. OLED device

The OLEDs were fabricated on ITO sheets having a resistance of 15 Ω/□. The substrates were washed sequentially with isopropyl alcohol, acetone, and methanol in an ultrasonic bath, followed by UV-ozone treatment prior to use. A hole injecting poly(ethylene dioxythiophene): polystyrene sulfonate (PEDOT:PSS) layer was spin-coated onto the substrates and dried at 130 °C for 30 min to remove residual water. The substrates were transferred to a N$_2$-filled glove box. The crosslinkable **TFVE1–3** monomers (1.2 wt%) were dissolved in THF, dip-coated atop the PEDOT:PSS layer to yield ca. 50-nm-thick films, and then cured at 230 °C for 30 min to promote crosslinking. To prepare the emissive and electron transport layer, a 60-nm layer of Alq3 was vacuum-deposited on top of the spin-coated HTL. The devices were then completed through thermal evaporation of the back electrode [LiF (0.5 nm)/Ag (100 nm)] through a shadow mask. All evaporations were performed under a vacuum of less than 10^{-6} torr. Each device pixel had an active area of 0.25π mm^2. The current–voltage–brightness (I–V–L) characteristics of the devices were measured simultaneously using a Keithley 6430 source meter and a Keithley 6487 picoammeter equipped with a calibration Si-photodiode. EL spectra were measured using an ocean optics spectrometer.

3. Results and discussion

3.1. Materials

Scheme 1 depicts the syntheses of monomers **TFVE1–3**, which were derivatives of the well-established hole-transporting material N,N′-di(1-naphthyl)-N,N′-diphenylbenzidine (α-NPD). **TFVE1**, possessing two trifluorovinyl ether (TFVE) groups linked to the terminal phenylene rings of α-NPD, was synthesized in an isolated yield of 72% through Pd-catalyzed amination of diamine **1** and compound **2** [20]. **TFVE2**, which had similar structural features to the terminal groups of **TFVE1**, but with the diarylamino groups attached to a coplanar rigid core (fluorene) to modulate the electronic properties, was synthesized through the reaction of 2,7-dibromo-9,9-ditolylfluorene (**3**) [29] with
Scheme 1. Synthesis of trifluorovinyl ether-functionalized monomers **TFVE1–3**.

1-aminonaphthalene in the presence of a catalytic amount of $Pd_2(dba)_3$ to furnish an aminated crude product that was subsequently subjected to Pd-catalyzed amination with compound **2** (49% yield over two steps). Without structural perturbation of the active chromophore, the two TFVE groups of **TFVE3** were introduced onto the peripheral biphenyl substituents of the central fluorene unit. The amination of compound **4** [30] with *N*-phenyl-1-naphthylamine in the presence of a catalytic amount of $Pd(OAc)_2$ and tri-*tert*-butyl phosphine gave compound **5** in 82% yield. The treatment of the phenol groups in **5** with trifluoromethane-

sulfonic anhydride afforded the disulfonate **6** in 81% yield. **TFVE3** was then obtained in 55% yield after Suzuki coupling of the boronic ester **7** [15] and compound **6**.

3.2. Physical properties

The morphological properties of the monomers **TFVE1–3** were investigated using differential scanning calorimetry (DSC). The introduction of two TFVE groups had a pronounced effect on the morphology. As indicated in Fig. 1, no evident glass transition could be detected for **TFVE1**; in-
Fig. 1. DSC analyses of the thermally polymerizable monomers **TFVE1–3**.

stead, we observed an endothermic peak centered at 111 °C, which corresponded to the melting point of **TFVE1**. The increased molecular rigidity of **TFVE2** led to a distinct glass transition temperature (T_g) detected at 82 °C, which remained significantly lower than that of its parent compound (127 °C) [29]. **TFVE3**, with its two TFVE groups attached to the peripheral biphenyl substituents of the central fluorene unit, possesses a value of T_g of 118 °C. The exothermic peaks of **TFVE1–3** at ca. 230 °C in the DSC traces correspond to their thermal polymerizations, consistent with the previously reported polymerization temperatures of TFVE groups [14–28]. The three TFVE monomers were soluble in common organic solvents, such as chloroform, tetrahydrofuran (THF), and toluene. After dip-coating solutions of the TFVEs in THF onto ITO substrates, the films were baked at 100 °C for 30 min to remove any residual solvent. Atomic force microscopy (AFM) reveals that the films prepared through this dip-coating process had smooth surfaces with no obvious crystallization, pinholes, or cracks (Fig. 2). After curing at 230 °C for 60 min, the films of the PFCB polymers became

insoluble in most organic solvents. The AFM images of these PFCB polymer films reveal some clusters formed after thermal polymerization at high temperature.

Fig. 3a displays UV–vis absorption and photoluminescence spectra of the thin films of vacuum-deposited α-NPD and **TFVE1–3** after thermal polymerization. The absorption spectrum (λ_{max} = 344 nm) of **TFVE1** polymer matches well with that of α-NPD, whereas polymers of **TFVE2** and **TFVE3** exhibit red-shifted absorption maxima (by ca. 40 nm), due to the coplanar structure of their cores. There were no significant changes in the absorption spectra of **TFVE1–3** after the treatment at high temperature (Fig. 3b and c). In contrast to their electronic transitions, the emission spectra of the thermally polymerized thin films of **TFVE1–3** exhibit slightly red-shifted maxima with broader half-widths of the emission peaks, relative to that of the α-NPD thin film and the thin films of **TFVE1–3** prior to thermal polymerization. These results contrast those from a previous report by Jen et al., where a thin film of a *N,N*-di(3-methylphenyl)-*N,N*-diphenylbenzidine (TPD)-based PFCB polymer exhibited an obviously red-shifted emission maximum relative to that of its monomer film as a result of strong aggregation and excimer emission [22–28]. The observed limited red shifts in the emission of **TFVE1–3** polymers and their long-wavelength tails could be attributable to the changes in the dielectric environments upon thermal treatment. The chromophores surrounded by TFVE moieties in the monomeric states should behave differently from those in the polymeric forms, in which the TFVE groups have been converted into PFCB moieties. Nevertheless, we cannot exclude the possibility of weak interchromophore interactions leading to long-wavelength emission regions in the polymer films after high-temperature thermal polymerization.

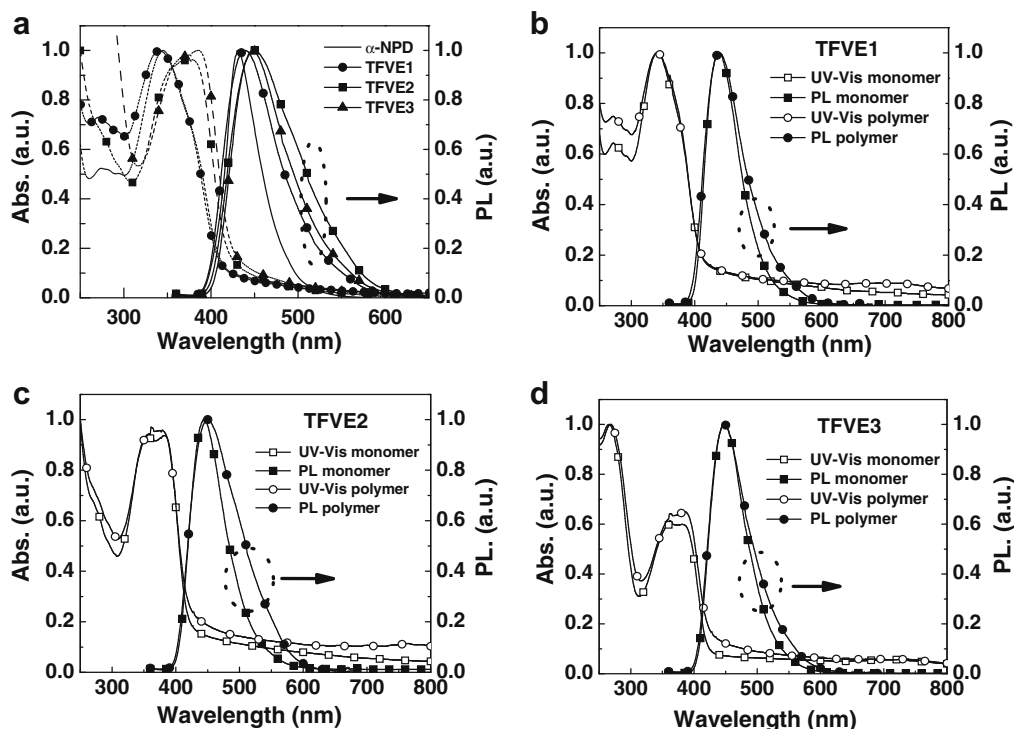
To characterize the hole transport in these thermally polymerized **TFVE1–3** polymers and to quantify their mobilities, we used time-of-flight (TOF) techniques [31]
Fig. 2. AFM images (5 × 5 μm) of **TFVE1-3** thin films before (top) and after (bottom) thermal polymerization. The indicated clusters with heights of **TFVE1** (11 nm), **TFVE2** (13 nm), and **TFVE3** (16 nm), respectively.


Fig. 3. (a) UV–vis absorption and photoluminescence spectra of thin films of thermally polymerized **TFVE1–3** and vacuum-deposited α-NPD and (b–d) comparisons of photophysical properties of **TFVE1-3** thin films before (monomers) and after thermal polymerization (polymers).

to measure the charge carrier mobility. This technique has been successfully applied to investigate the charge transport behavior of a wide range of polymers and small molecules, but it has not been applied previously to measure the charge mobility of any thermal polymerized and/or cross-linked polymers. TOF samples were prepared by dissolving appropriate weight ratios (up to 25 wt%) of the monomers **TFVE1** and **TFVE2** in THF and then dip-coating the solutions onto an ITO substrate within a glove box. For **TFVE3**, however, poor solubility in THF meant that we could not obtain a solution of sufficiently high concentration to yield a sample that was thick enough for TOF measurement. We were able to control the film thicknesses by varying the solution concentrations and the dip-coating conditions; the films were subsequently dried through baking at 100 °C for 30 min to remove the residual solvent and then curing at 230 °C for 60 min to form the polymers. We used a Dektak surface profilometer to measure the thicknesses of the **TFVE1** (ca. 760 nm) and **TFVE2** (ca. 500 nm) polymer films. The samples were then completed through thermal deposition of the back electrode [Ag (100 nm)] through a shadow mask.

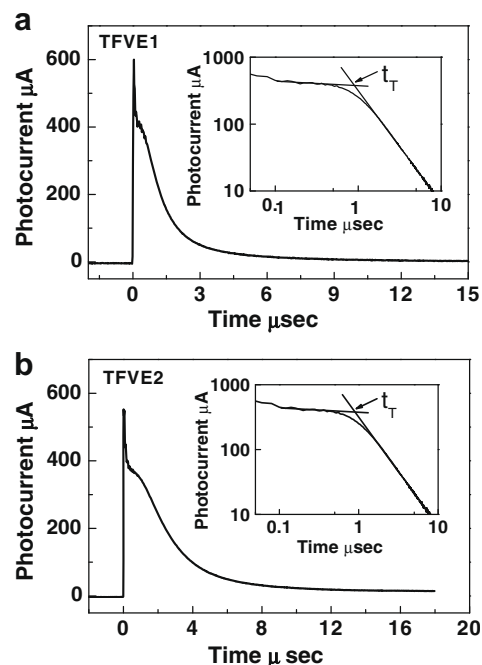
Fig. 4 displays the TOF transients of the **TFVE1** and **TFVE2** polymer films. Distinctive plateaus are visible in the typical TOF transient photocurrents, indicating the non-dispersive transport behavior of the **TFVE1** and **TFVE2** polymers toward holes. We estimated the carrier transit times t_T from the asymptotes of the log–log plots (insets to Fig. 4); from these values, we deduced the hole mobilities (μ) using the relation $\mu = d/(Et_T)$, where E and d are the applied electric field and the thickness of the organic film,


Fig. 4. Representative TOF transients for polymer films derived from (a) **TFVE1** (at $E = 5.3 \times 10^5$ cm V^{-1}) and (b) **TFVE2** (at $E = 6.1 \times 10^5$ cm V^{-1}) at room temperature. The insets present double-logarithmic plots of the data.

respectively. Fig. 5 presents the room-temperature hole mobilities of the model compound α-NPD and of the
Fig. 5. Plots of hole mobilities vs. $E^{1/2}$ for the thermally polymerized films of **TFVE1** and **TFVE2** and of a film of the model compound α-NPD obtained through thermal evaporation.

PFCB-based polymer films derived from **TFVE1** and **TFVE2** plotted against the square root of the applied electric field. The linear correlation follows the universal Poole–Frenkel relationship, $\mu = \mu_0 \exp(\beta E^{12})$, where μ_0 is the zero-field mobility, β is the Poole–Frenkel factor and E is the electric field [32]. The hole mobilities ranged from 2×10^{-5} to 10^{-3} $cm^2\,V^{-1}\,s^{-1}$ for fields varying from 4×10^4 to $1.4 \times 10^6\,V\,cm^{-1}$ and the values (μ_0 and β) of fitting data are summarized in Table 1.

The observed hole mobility ($\mu_h =$ ca. $10^{-4}\,cm^2\,V^{-1}\,s^{-1}$) of the **TFVE1**-derived polymer film was about one order of magnitude lower than that of the model compound α-NPD ($\mu_h = 1.2 \times 10^{-3}\,cm^2\,V^{-1}\,s^{-1}$) under the same electric field ($E = 3.6 \times 10^5\,V\,cm^{-1}$). In addition, as indicated by it larger value of β, the **TFVE1**-derived polymer film exhibited a stronger electric-field-dependent hole mobility. We ascribe these phenomena to the presence of the PFCB units of the **TFVE1**-derived polymer; i.e., the more rigid structure and the larger distance and steric hindrance between neighboring chromophores increased the carrier hopping distance, thus retarding hole migration. The aggregates observed in the AFM images of the thermally treated thin films might also have been another attribute responsible for the lower hole mobility. The steric effect on hole transportation was also evident from the lower hole mobility of

Table 1
The values of zero-field hole mobility (μ_0) and Poole–Frenkel factor (β) obtained by fitting the data in Fig. 5 with the Poole–Frenkel equation.

HTL	[$cm^2\,V^{-1}\,s^{-1}$]	β
α-NPD	4.18×10^{-4}	1.79×10^{-3}

TFVE2	1.46×10^{-6}	4.27×10^{-3}

the **TFVE2**-derived polymer (a 9,9-ditolylfluorene-based diamine) relative to that of the **TFVE1**-derived polymer (a biphenylene-based diamine) [33].

3.3. Device

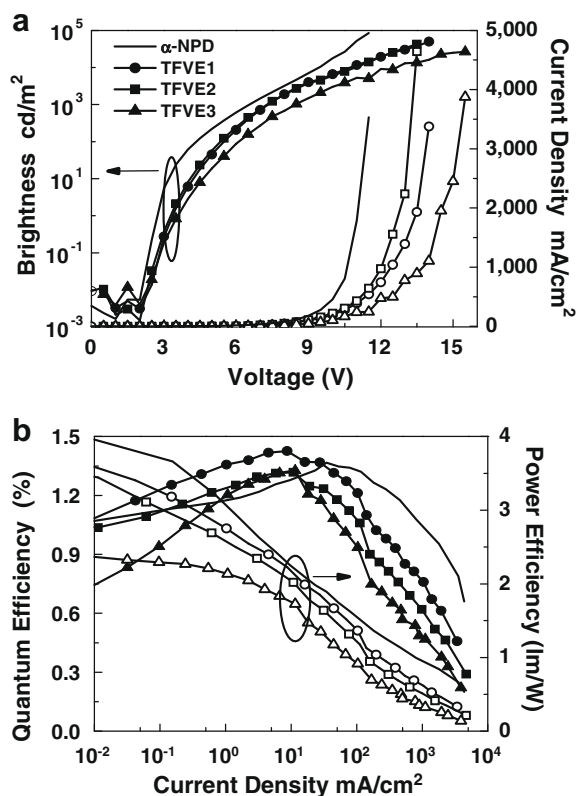
To evaluate the performances of devices incorporating the thermally polymerized **TFVE1–3** films as HTLs, we fabricated two-layer devices having the configuration ITO/PEDOT:PSS (30 nm)/polymeric **TFVE1–3** (ca. 50 nm)/Alq$_3$ (60 nm)/LiF (0.5 nm)/Al (100 nm). Uniform films were formed through first dip-coating the solution of **TFVE1–3** (1.2 wt% in THF) onto the pre-dried (130 °C for 30 min) PEDOT:PSS layer on an ITO substrate [34,35] and then polymerizing under thermal treatment at 230 °C for 30 min. Integrating the conductive HIL and the thermally polymerized HTL together resulted in a low driving


Fig. 6. Performances of typical two-layer devices incorporating thermally polymerized HTLs and α-NPD. Plots of (a) brightness (solid symbols) and current (open symbols) vs. voltage and (b) quantum efficiency (solid symbols) and power efficiency (open symbols) vs. current.

Table 2
Device characteristics of OLEDs incorporating cross-linked **TFVE1–3** and vacuum-deposited α-NPD as HTLs.

HTL	V_{on} [V]	L_{max} [cd m^{-2}]	I_{max} [mA cm^{-2}]	η_{ext} (max) [%, cd A^{-1}]	η_p (max) [lm W^{-1}]
α-NPD	2	86,000 (11.5 V)	3500	1.36, 4.4	4
TFVE1	2	50,000 (14.0 V)	3400	1.43, 4.6	3.6
TFVE2	2	43,000 (13.5 V)	4600	1.32, 4.2	3.6
TFVE3	2	26,600 (14.0 V)	3900	1.32, 4.2	2.4

voltage, cascade hole injection, and effective electron blocking/exciton confinement in the Alq_3 layer. All devices exhibited the same emission, which originated exclusively from the Alq_3 layer.

Table 2 and Fig. 6 summarize the EL characteristics of the OLEDs incorporating the thermally polymerized **TFVE1**–**3** monomers and vacuum-deposited α-NPD as HTLs. These hybrid OLEDs exhibit noteworthy properties relative to those of conventional vacuum-deposited OLEDs. For example, the thermally polymerized HTLs functioned well without decreasing the device performance [10]. As indicated in Fig. 5a, the devices turned on sharply at low voltages (ca. 2 V), probably because the HOMO and LUMO energy levels of the active triaryldiamine chromophores, which remained intact before and after thermal polymerization, were matched well with those of ITO and Alq_3. Among our three new thermally polymerizable HTL materials, the **TFVE1**-derived polymer exhibited the best performance. Fig. 5b indicates that the highest efficiency was achieved when using the **TFVE1**-derived polymer as the HTL: the maximum EQE was 1.43% (4.6 cd A^{-1}) and the maximum power efficiency was 3.6 lm W^{-1}. It is generally accepted that polymers exhibiting high morphological stability in their thin film form result in devices that can endure relatively high current densities (ca. 3400 mA cm^{-2}) and, consequently, emit an impressive maximum brightness of nearly 5×10^4 cd m^{-2} at ca. 14 V from the non-doped Alq_3. Despite the lower hole mobility of the **TFVE1**-derived polymer films, compared with that of the vacuum-deposited model compound α-NPD, the device incorporating the former as the HTL exhibited the same turn-on voltage and slightly higher EQE (1.43%) relative to that of the latter (EQE = 1.37%) under the same device structure. We attributed the higher EQE achieved in the hybrid OLED to a more balanced recombination of holes and electrons.

4. Conclusions

In summary, we have synthesized and characterized three thermally polymerizable hole-transporting materials, **TFVE1**–**3**, derived from the parent α-NPD core through the attachment of TFVE groups. The thermally polymerized monomers exhibited good thermal properties, solvent resistance, and relatively high surface smoothness. More importantly, for the first time we used TOF techniques to measure the hole-transporting characteristics of α-NPD-based PFCB polymers. We observed a hole mobility of ca. 10^{-4} cm^2 V^{-1} s^{-1} for **TFVE1**-derived polymer films, ca. one order of magnitude lower than that of the model compound α-NPD (i.e., in the absence of TFVE groups) under the same electric filed. We ascribe the lower mobilities of the PFCB-based polymers to their larger degrees of spatial and steric hindrance leading to blocking of carrier hopping. We fabricated hybrid OLEDs incorporating the **TFVE1**-derived polymer film as the HTL. These devices exhibited high current densities (ca. 3400 mA cm^{-2}), impressive brightness (5×10^4 cd m^{-2}), and high external quantum efficiency (1.43%).

ARTICLE INFO

ABSTRACT

Using a 4,4′,4″-tris(N-carbazolyl)-triphenylamine (TCTA) small molecule interlayer, we have fabricated efficient green phosphorescent organic light emitting devices by solution process. Significantly a low driving voltage of 3.0 V to reach a luminance of 1000 cd/m^2 is reported in this device. The maximum current and power efficiency values of 27.2 cd/A and 17.8 lm/W with TCTA interlayer (thickness 30 nm) and 33.7 cd/A and 19.6 lm/W with 40 nm thick interlayer are demonstrated, respectively. Results reveal a way to fabricate the phosphorescent organic light emitting device using TCTA small molecule interlayer by solution process, promising for efficient and simple manufacturing.

Solution processible organic light emitting diodes (OLEDs) are attracting much attention as potential candidates for flat-panel displays and solid state lighting, owing to their easy processing and low manufacturing cost [1,2]. Requirement for use in these applications, the high luminance at lower current density and efficient operation, are realized by the balance charge carriers injection from the electrodes into the emitting layer. Poly(3,4-ethylenedioxythiophene)-poly(4-stylenesurfonate) (PEDOT:PSS) hole injection layer on the top of indium-tin-oxide (ITO) surface is most widely used to improve the hole injection [3–5]. Further, the insertion of a thin interlayer (thickness 10–30 nm) between the PEDOT:PSS and the light emitting layer (EML) significantly improves the device efficiency and lifetime. Conjugated polymer materials such as poly(p-phenylene vinylene), poly(9,9′-dioctylfluorene) (PFO) and poly(9,9′-dioctylfluorene-alt-benzothiadiazole) [6], poly(2,7-(9,9-di-n-octylfluorene)-alt-(1,4-phenylene-((4-sec-butylphenyl)imino)-1,4-phenylene)) (TFB) [7,8], and poly(9,9-dioctylfluorene-co-bis-N,N′-(4-butylphenyl)-bis-N,N′-phenyl-1,4-phenylenediamine) (PFB) [9] were used for this purpose. To date, non-conjugated materials, poly(N-vinylcarbazole) (PVK) [9] and crosslinked non-conjugated materials [10–12] having hole transporting chemical units were mostly reported for this purpose. However, such interlayer polymers have several issues for use in practical devices such as considerably high exchange energy, 1.0–1.5 eV values, between the singlet and triplet states [13]. As a consequence, conjugated polymers

generally are not suitable as phosphorescent host materials [14]. Further, these polymers in phosphorescent OLEDs may act as a potential quencher at the interface of EML. Owing to low solubility in several organic solvents, conjugated polymers also offer a serious difficulty for the printing process and in removing the undesired material from the substrate. Although TFB is widely used as an interlayer, its low triplet emission energy (2.2–2.3 eV) causes some quenching of the phosphorescence emission in green phosphorescent devices. While 4,4′,4″-tris(N-carbazolyl)-triphenylamine (TCTA) small molecule has a good film forming properties, solubility, and high triplet emission energy (2.7 eV). We, therefore, propose that the use of small molecule material interlayer may be a good approach in solution processed phosphorescent OLEDs. In the present work, phosphorescent green light emitting devices using a solution process with a small molecule TCTA interlayer have been fabricated and studied.

The TCTA hole transport material (HTL), known to confine excitons and electrons in emitting layer and reported as a suitable host material in green phosphorescent OLEDs [15,16], usually has been deposited using the vacuum evaporation process in OLEDs fabrication. In order to acquire more knowledge about amorphous nature of spin-coated TCTA film, the vacuum thermal evaporated TCTA and the spin-coated TCTA and well known TFB interlayer films (30 nm thick) were fabricated on glass substrates. The average surface roughness (Rave) values of spin-coated and sublimated TCTA surface, measured by using Atomic Force Microscopy (AFM), are about 4.17 Å and 3.38 Å, while the surface roughness value of 5.49 Å in the spin-coated TFB interlayer is observed as shown in Fig. 1. This unlike value of surface roughness in a spin-coated TCTA film than the vacuum thermal evaporated may be attributed to the solvent evaporation during the process of spin coating. A good amorphous film formation characteristic of the TCTA has been ascribed to three dimensional molecular structure of TCTA. A Half circle shape structure of the TCTA molecule with coplanar two carbazole units and remaining one carbazole unit vertically orthogonal to the plane containing two carbazole units contributes to the amorphous molecular packing, indicating that the crystallization of the TCTA film during spin-coating and baking process is practically missing. The good surface characteristic of spin-coated TCTA film is well suited for use as an interlayer material. Furthermore, to check the possibility of use of well known TPD and NPB hole transport materials

as an interlayer in wet processed OLEDs, spin-coated TPD and NPB films (40 nm) on the glass substrate were fabricated and investigated, respectively. Evidences of non-uniform surface with high roughness due to crystallization of TPD and NPB molecules upon thermal treatment in solution processed films make them unsuitable for wet processed OLEDs.

To fabricate OLED devices, clean glass substrates of size 2 cm × 2 cm precoated with a 150 nm thick indium-tin-oxide (ITO) layer with a sheet resistance of 12 Ω/square were used. The ITO glass was cleaned by sonification in an isopropylalcohol (IPA) and acetone, rinsed in deionized water, and finally irradiation in a UV-ozone chamber. The line pattern of ITO was formed by photolithography process. The PEDOT:PSS was spin-coated on the ITO substrates pretreated with UV ozone to a thickness of 40 nm and the dried at 120 °C for 20 min on a hot plate to remove the solvent. Subsequently, the interlayer solution either TCTA or TFB 0.5 wt% in toluene (thickness of about 30 nm) was spin coated and later dried at 180 °C for 30 min on a hot plate. PVK described as an unipolar hole transporter and 4,4′-N,N′-dicarbazolebiphenyl (CBP) recognized to have bipolar transport character were used as mixed host materials in the present work. The 40 nm-thick EML host of PVK:CBP system mixed in the proportion of 1:1 and doped with 13 wt% of tris(2-(4-toltyl)phenylpyridine) iridium (Ir(mppy)$_3$) in chlorobenzene was spin-coated on the top of interlayer film. The spin-coated EML was then baked on a hot plate at 120 °C for 60 min to remove the solvent present, if any. The spin coating and baking processes were carried out in a nitrogen atmosphere glove box. Subsequently, The TPBi (2,2′,2″-(1,3,5-phenylene)tris(1-phenyl-1H-benzimidazole)) (30 nm) was deposited in organic chamber using vacuum thermal evaporation in a base pressure of 10^{-7} Torr, while LiF (1 nm) and Al (100 nm) were deposited in a metal chamber without breaking the vacuum of the system. The following devices were fabricated:

(a) Device 1: ITO/PEDOT:PSS (40 nm)/TFB (30 nm)/EML (40 nm)/TPBi (30 nm)/LiF (1 nm)/Al (100 nm), and
(b) Device 2: ITO/PEDOT:PSS (40 nm)/TCTA (30 nm)/EML (40 nm)/TPBi (30 nm)/LiF (1 nm)/Al (100 nm).

The emission area of devices was 2 mm × 2 mm. The current density–voltage (I–V) and luminance–voltage (L–V) characteristics of fabricated OLEDs were measured by using a Keithley SMU 238 and Minolta CS-100A.

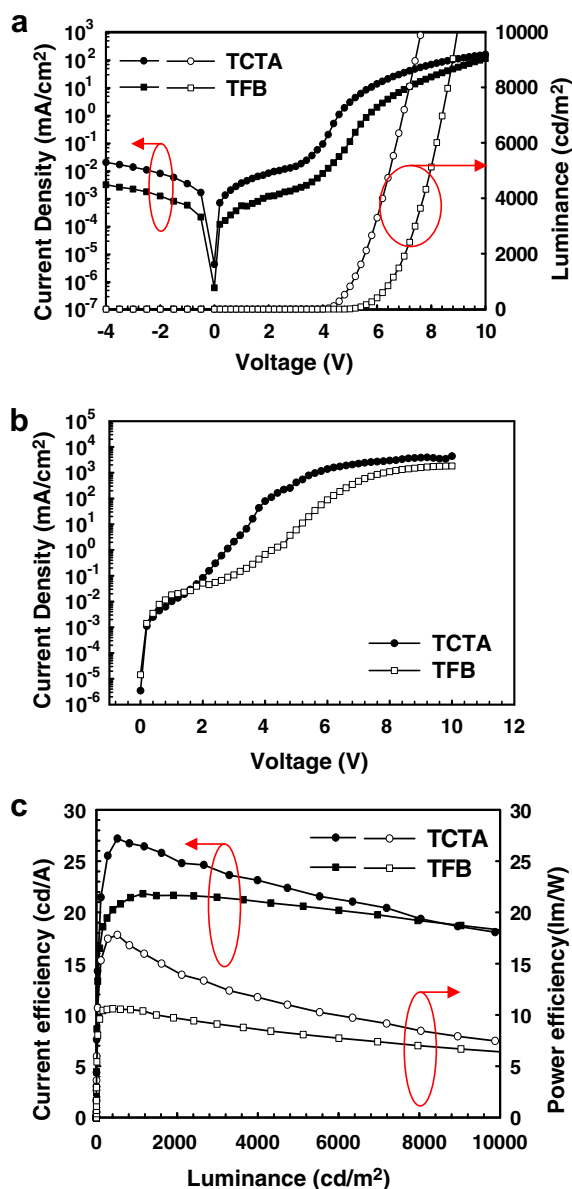
Electroluminescence (EL) spectra and CIE color coordinate were obtained by using a photo-research PR-650 spectro-radiometer.

Fig. 2a shows the luminance and current density as a function of applied voltage. The turn voltage value of 4.0 V to attain a luminance of 1000 cd/m² in device 1 with TFB interlayer is reported, while this value is 3.0 V in device 2 with TCTA interlayer. Device 2 with TCTA interlayer seems to offer a low barrier for hole injection into emitting layer. To substantiate our argument, hole only devices, having configuration of ITO/PEDOT:PSS (40 nm)/TCTA or TFB (70 nm)/LiF (1 nm)/Al (100 nm), were fabricated. As


evident from the results shown in Fig. 2b, low resistance to hole transport and conduction in hole only device with TCTA interlayer is noticed. Clearly, these results corroborate the superior electrical performance of device 2 with the TCTA interlayer. Further, to perceive whether the large difference in space charge current is still true, hole only devices were fabricated using Al cathode (work function = 4.28 eV, electron injection barrier to TFB = 2.18 eV and TCTA = 1.98 eV) which does not inject electrons either into TFB or TCTA. We have obtained results similar to LiF/Al cathode, thus substantiating the hypothesis of better transport properties of TCTA interlayer.

Fig. 2c shows the current and power efficiencies as a function luminance. Current and power efficiency values of 21.5 cd/A and 10.5 lm/W in device 1 with TFB interlayer at a luminance of 1000 cd/m² are observed, respectively, whereas these values in device 2 with TCTA interlayer are 26.5 cd/A and 16.0 lm/W. The maximum current and power efficiency values with TCTA interlayer are 27.2 cd/A and 17.8 lm/W and 21.7 cd/A and 10.6 lm/W with TFB interlayer, respectively. Better performance of the device 2 with TCTA interlayer, therefore, is of interest to manufacturers.

Furthermore, improvement of the device performance due to increase of the thickness of TCTA interlayer from 30 to 40 nm is observed. The values of current and power efficiencies of 32.0 cd/A and 15.9 lm/W at the luminance of 1000 cd/m² were measured, respectively. The maximum current and power efficiencies were 33.7 cd/A and 19.6 lm/W in this device, respectively. Further enhancement of TCTA interlayer thickness deteriorates the device performance as listed in Table 1.

To investigate the dissolution issue of interlayer, if any, in the solvent of emitting layer, thick interlayers (70 nm) of TFB and TCTA in toluene were spin coated on glass substrates and dried at 180 °C for 30 min on a hot plate. Subsequently, EML solvent chlorobenzene was spin-coated on the top of TFB and TCTA interlayes, baked on a hot plate at 120 °C for 60 min, and thicknesses of the final layers were then measured. The thickness of TFB was reduced about 8–10 nm while that of TCTA by 20–22 nm. These dissolution values of TFB and TCTA in the EML solvent are not a serious issue for making spin-coated phosphorescent OLEDs.

Table 1

Performance of ITO/PEDOT/TCTA/PVK + CBP:Ir(mppy)3 (1:1, 13 %)/TPBI/LiF/Al PHOLEDs with different interlayer thicknesses

TCTA thickness (Å)		300	400	500–600
Turn-on voltage (V)		3	3.8	4.6
At 1000 cd/m^2	Voltage	5.2	6.4	8.0
	current efficiency (cd/A)	26.5	32	18.1
	Power efficiency (lm/W)	16.0	15.9	7.1
Max.	Current efficiency (cd/A)	27.2	33.7	18.6
	Power efficiency (lm/W)	17.8	19.6	8.6

Table 2

HOMO and LUMO energy levels of interlayers, host materials and exciton blocking layers

Materials	HOMO(eV)	LUMO(eV)	Triplet energy T_1(eV)	Reference
TFB	5.3	2.1	2.2–2.3	17
TCTA	5.7	2.3	2.7	18, 19
	5.7	2.4		20
PVK	5.4	1.9		21
	5.6	2.2	2.5	22
CBP	6.1	3.0	2.6	23, 19
	5.9	2.6		20
TPBI	6.3	2.8		24
Ir(mppy)$_3$	5.4	2.4, 3.0(T_1)	2.4	25, 26

Indeed, interesting and intriguing results on the device performance with the TCTA small molecule interlayer deposited using spin coating are obtained. These results may be explained as electrons/holes charge carriers injection and transport and confinement of triplet excitons in emissive layers on the basis of the existing knowledge of energy levels of materials used in device fabrication. Highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of interlayers, host materials, phosphorescent dopant, and exciton blocking layers are summarized in Table 2 [17–26]. As the HOMO level of TCTA (-5.9 eV or -5.7 eV) is close the HOMO energy of host layer (-5.8 eV or 5.6 eV in PVK and -5.91 eV or 5.9 eV in CBP), a low hole injection barrier ($\sim$0.2 eV) into PVK + CBP:Ir(mppy)$_3$ emissive layer significantly facilitates carrier injection (Fig. 3). While holes injected from TFB into PVK + CBP:Ir(mppy)$_3$ emissive layer have to overcome a barrier of $\sim$0.3–0.6 eV, high com-

pared to TCTA. Finally, injected holes are trapped at the HOMO of Ir(mppy)$_3$ (5.4 eV) (Fig. 3). Thus, the hole injection efficiency in TCTA interlayer based device is significantly improved. The electrons injected from the cathode transport freely with a negligible barrier, recombine with the trapped holes on the Ir(mppy)$_3$ dopant molecules in the emissive layer, and finally result in an improved green phosphorescence emission. Whereas in case of TFB interlayer, the triplet energy levels of TFB are in the range of 2.2–2.3 eV, lower than the triplet emission energy of Ir(mppy)$_3$ (2.4 eV). Thus, low triplet energy of TFB provides a nonradiative path for exciton quenching and reduced the phosphorescence light emission of the PHOLEDs. No such phenomenon is observed in PHOLEDs with a TCTA interlayer as triplet emission energy of TCTA (2.7 eV). Moreover, TCTA interlayer confines excitons and electrons in the emitting layer, contributing to enhanced device performance. Furthermore, the clean emission peak in green region at 520 nm (CIE coordinates (0.33, 0.61) at 1000 cd/m^2) in the fabricated TCTA interlayer device also reveals no leakage of electrons into HTL layer (Fig. 4), thereby confining electrons in the EML.
In summary, we have fabricated TCTA small molecular interlayer based green phosphorescent devices using a spin-coating process. The TCTA has a good solubility in toluene and thin film forming properties by spin coating process. Low turn-on voltage value of 3.0 V to obtain luminance of 1000 cd/m^2 and maximum current and power efficiencies values of 27.3 cd/A and 18.0 lm/W are reported in this device, respectively. The maximum current and power efficiencies of 33.7 cd/A and 19.6 lm/W with TCTA thickness of 40 nm were reported. In conclusion, demonstration of solution processible efficient green phosphorescent OLEDs with TCTA small molecule interlayer could be a promising way for simple manufacturing process.

ARTICLE INFO

ABSTRACT

We report on the fabrication of pentacene-based thin-film transistors (TFTs) with a 230 nm-thick double polymer dielectric composed of 30 nm-thin low-*k* poly-4-vinyphenol (PVP) and 200 nm-thick high-*k* poly(vinylidene fluoride/trifluoroethylene) [P(VDF–TrFE)] dielectric on polyethersulfone (PES) films. Our 230 nm-thick double (high-*k*/low-*k*) polymer showed a good dielectric strength of ~2 MV/cm, a high capacitance of 26 nF/cm² with *k* = ~7. Based on this double polymer dielectric, our flexible pentacene TFT displayed a high saturation mobility of 1.22 cm²/V s, a threshold voltage of −2.5 V, and on/off ratio of 10³, stably operating under −5 V.

1. Introduction

Pentacene organic thin-film transistors (OTFTs) have attracted much attention, looking for practical applications such as flat-panel displays, logic devices, and radio frequency identification tag, and other portable devices in general [1–5]. Very recently, electrophoretic display or E-book emerges to be one of the most appropriate applications in such OTFT device field [6–8]. The E-book driving TFTs preferably require flexible substrate and low voltage operation, as well as device stability. In order to realize these low voltage driven OTFTs, many research groups have focused on the study about the gate dielectric layers

(for example, thin-polymers, self-assembled monolayer (SAM), high-*k* metal oxide, and thin polymer/thick high-*k* oxide hybrid layer) [9–12]. However, low voltage OTFT adopting flexible plastic substrate is still in lack of report. Moreover high mobility operations on flexible substrates are even more difficult to find from literature. It is because such device needs high-*k* polymer dielectric to support the low voltage operation while usual polymer has low-*k* dielectric properties unlike inorganic dielectrics. (But inorganic high-*k* dielectric has a limited process-compatibility with flexible plastic substrate and a limited flexibility by itself.) High-*k* polymer with smooth surface and good electric strength is quite difficult to find and further difficult to fabricate without high current leakage paths while thin low-*k* polymer is easy to be broken down under gate voltage stress [9]. One way to satisfactorily meet the condition

of low voltage operation on flexible substrate may be to adopt both low-*k* and high-*k* polymer dielectric layer in stack since the low-*k* polymer provides good electric strength and surface smoothness while the high-*k* one may make the low voltage TFT operation possible. In the present study of low voltage flexible pentacene OTFT fabrication, we thus adopt a leakage-resistant 200 nm-thick poly(vinylidene fluoride/trifluoroethylene) [P(VDF–TrFE)] as a high-*k* polymer (*k* = 6–9) beneath a 30 nm-thin low-*k* poly-4-vinyphenol (PVP) dielectric, that interfaces pentacene channel. Our pentacene OTFT demonstrates a high mobility of 1.22 cm^2/V s operating at −5 V on flexible plastic substrate.

2. Experimental section

Al gate electrodes (width 320 μm) were patterned by thermal evaporation on polyethersulfone (PES) films in a vacuum chamber. The 200 nm-thick film of P(VDF–TrFE) 75/25 mol% copolymer was coated by spin casting 6 wt% cyclohexanone solutions on Al gate pattern and the high-*k* polymer was quenched by blowing N$_2$ gas (99.9% purity) at room temperature (RT) after being cured at 160 °C for 2 h in a vacuum oven, so that the P(VDF–TrFE) has little crystalline ordering inside the film. Sequentially, the 30 nm-thick PVP layer was coated by spin casting 1 wt% solutions and was exposed under UV lamp (254 nm wavelength) for 10 min in air at RT as a curing process [13]. The 240 nm-thick PVP single layer was coated by spin casting 8 wt% solutions and was cured at 175 °C for 1 h in a vacuum oven [14]. Pentacene (Aldrich Chem. Co., 99% purity, with no other purification) active channel layer was patterned on the double polymer dielectric through a shadow mask at room temperature (RT) by thermal evaporation. Deposition rate was fixed to 1 Å/s using an effusion cell (ALPHAPLUS Co., LTE-500S) in a vacuum chamber (base pressure ∼1 × 10^{-7} Torr). The thickness of pentacene films was 50 nm as monitored by a quartz crystal oscillator and confirmed by ellipsometry. Au pads were finally deposited as source and drain electrodes by thermal evaporation in a vacuum chamber (base pressure ∼2 × 10^{-6} Torr). The nominal channel length (*L*) and width (*W*) of our pentacene TFTs were 90 and 500 μm, respectively. Fig. 1a shows the schematic cross-sectional views of our low voltage pentacene TFT with double polymer dielectric and high voltage reference TFT with single PVP. Fig. 1b is a picture displaying our flexible pentacene TFTs.

The electrical properties of the double polymer and PVP single dielectric layers were measured with 250 μm-dia Al dot/dielectric/indium–tin–oxide (ITO) glass structures by capacitance–voltage (*C*–*V*) and current density–electric field (*J*–*E*) tests. All current–voltage (*I*–*V*) properties of our TFTs and test structures were measured with a semiconductor parameter analyzer (HP 4155C, Agilent Technologies), and *C*–*V* measurements were made with a capacitance meter (HP 4284 LCR meter, Agilent Technologies, 1 MHz) in the dark and in an air ambient (relative humidity ∼40%) at RT. The dielectric surface morphologies were observed by atomic force microscopy (AFM) (XE-100, PSIA).

3. Results and discussion

Fig. 1c and d shows *C*–*V* and *J*–*E* characteristics of the 230 nm-thick PVP/P(VDF–TrFE) double and 240 nm-thick PVP single dielectric layers on ITO glass, respectively. The

(c) Capacitance–voltage (*C*–*V*) curves of 240 nm-thick PVP single and 230 nm-thick double polymer dielectric insulators on ITO glass as measured from 250 μm-dia Au dot/dielectric/electrode structures at 1 MHz (d) Current density–electric field (*J*–*E*) characteristics of both insulators.

capacitance of the double polymer and PVP single dielectric layers were 26~28 nF/cm² and 12 nF/cm², respectively. Also, the dielectric constant (k) of the double

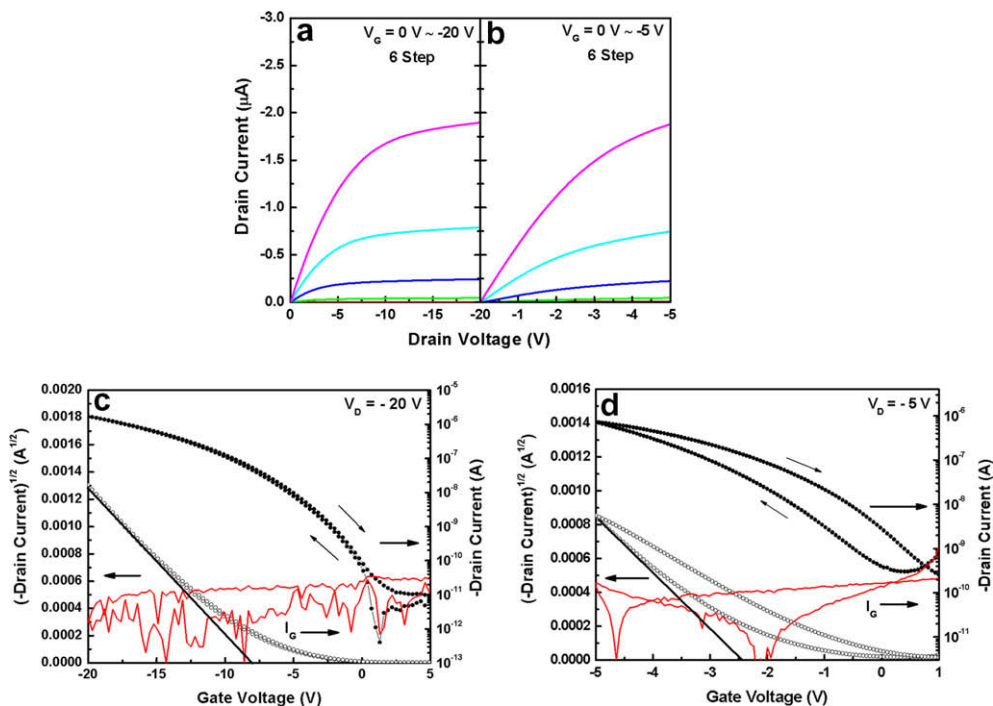
polymer and PVP single dielectric layers were ~7.1 and ~3.2, respectively, estimated from the measured capacitance values. The high capacitance of double polymer layer
Fig. 2. (a) AFM images of 240 nm-thick PVP single insulator, (b) 30 nm-thin PVP layer on 200 nm-thick P(VDF–TrFE) layer, and (c) 200 nm P(VDF–TrFE) layer deposited on ITO glass (5 μm × 5 μm).


Fig. 3. Drain current–drain voltage (I_D–V_D) output curves obtained from our pentacene TFTs with (a) 240 nm-thick PVP single layer and (b) 230 nm-thick double polymer dielectric layers. Transfer curves ($\sqrt{-I_D}$–V_G and $\log_{10}(-I_D)$–V_G) of the pentacene TFTs with (c) PVP single and (d) double polymer dielectric layers (obtained at $V_D = -20$ V and $V_D = -5$ V, respectively).

would assist the flexible organic TFT to operate in low voltage range. Similar dielectric strength of ~2 MV/cm was shown in the both double polymer and PVP single dielectric layers. In spite of generic high leakage profile of crystalline-ordered high-k polymer (data not shown here) [15], the double polymer dielectric layer composed of 30 nm-thin PVP and 200 nm-thick P(VDF–TrFE) showed quite good leakage property. It is mainly because the thin PVP layer inhibits the current leakage covering the rough surface of P(VDF–TrFE) layer, and also because our P(VDF–TrFE) layer obtained by N_2 gas-quenching after the 160 °C curing has fewer leakage paths than normal crystalline-ordered polymer, which is conventionally obtained by 135 °C curing and subsequent long term cooling for good crystalline ordering. We expect that our P(VDF–TrFE) layer is amorphous-like with little crystalline ordering. Also interesting to note is that the C–V curve of our double polymer shows broad and weak butterfly peaks in the voltage range between −20 and +20 V although the butterfly effect vanishes in low voltage range (−5 to +5 V). It is because our amorphous-like polymer still possess a little of ferroelectric property. However, those ferroelectric properties are dejected by PVP-induced depolarization during TFT gating and also subside by operating the TFT under a low voltage which is much lower than coercive voltage (~±12 V according to the present C–V data). This means that our double polymer layer can be used as a dielectric for low voltage TFT without any problem.

Fig. 2a–c shows the AFM surface images of the 240 nm-thick PVP single layer, 230 nm-thick PVP/P(VDF–TrFE) double polymer layer, and 200 nm-thick P(VDF–TrFE) single layer on ITO glass. According to the Figs. 2a, b and c, the surface roughness of PVP single, PVP/P(VDF–TrFE) double, and P(VDF–TrFE) single layers on ITO glass was 0.4, 5 and 10 nm, respectively. Although initial surface of P(VDF–TrFE) single layer was very rough, the final surface of PVP/P(VDF–TrFE) double layer became much smoother due to the thin PVP over layer.

Fig. 3a and b displays the drain current–drain voltage (I_D–V_D) output curves obtained from our pentacene-based TFTs with the 240 nm-thick PVP single and 230 nm-thick
Fig. 4. Drain current behavior of the both devices observed under (a) constant gate bias stress (vertical scale range: 5×10^{-8}–3×10^{-7} A) and (b) dynamic bias stress conditions (5 s on/off periods). On-state condition was $V_G = V_D = -2$ V for device with double polymer layer and was $V_G = V_D = -8$ V for the other device with single PVP dielectric, while off-state condition was $V_G = 0$ V at $V_D = -2$ and at −8 V for the devices with double polymer and single PVP, respectively.

double polymer dielectric layers on PES films. Similar maximum saturation current (∼2 µA) was achieved from the TFTs with single PVP dielectric and double dielectric layers but under different gate biases of −20 V and only −5 V, respectively. According to the drain current–gate voltage ($\sqrt{I_D}$–V_G) transfer curves of Fig. 3c and d, the pentacene TFT with the double polymer dielectric showed a high field mobility (saturation mobility) of 1.22 cm^2/V s at −5 V while that with PVP single dielectric layer displayed a field mobility of 0.38 cm^2/V s at −20 V. The threshold voltages(V_T) of pentacene TFTs with double polymer (Fig. 3d) and PVP single layers (Fig. 3c) were about −2.5 V and −7.5 V, respectively, but the pentacene TFT with double polymer dielectric showed a relatively large gate-bias hysteresis while the other TFT with PVP single layer did not display such hysteresis. It is very likely that the present double polymer dielectric is somewhat unstable under gate biases, because the P(VDF–TrFE) in our double polymer layer is as weak as to allow the charge injection from the gate electrode [16] or to allow the residual poling (slow polarization) effect under negative gate bias sweep [16]. In contrast the 240 nm-thick PVP single layer is known to be very stable under the gate bias stress if gone through the right curing process [14]. Since the leakage property of our double polymer containing the high-k layer is a little inferior to that of the single PVP (see J–E curves of Fig. 1), gate electron injection to the bottom P(VDF–TrFE) is quite a reasonable conjecture to explain this gate instability. The $\log_{10}(-I_D)$ −V_G curves of Fig. 3c and d showed the on/off current ratios of 3×10^3 for the double polymer dielectric device and ∼10^6 for the PVP single layer device. The maximum gate leakage current (I_G) level is kept under less than 1 nA for the both cases.

Since the TFT with double polymer layer showed such gate-hysteresis, we measured the gate stability of the two TFTs under continuous and dynamic gate-bias stress as shown in Fig. 4a and b, respectively [17]. As expected, the drain current of pentacene TFT with the double polymer dielectric layers continuously and more rapidly increased (after on: $V_G = −2$ V) or decreased (after off: $V_G = 0$ V) than that of the other TFT with thick single PVP (on: $V_G = −8$ V) as measured in repetitive 5 s periods (Fig. 4b), but according to Fig. 4a the I_D increase of the TFT with double-polymer dielectric becomes quite saturated as the stress time elapses, although its initial increase was rapid. We do not exactly know why this saturation takes place but it seems that injected electrons stay somewhere in the bottom P(VDF–TrFE) making some negative charge states, finally to play as coulomb blockade against the next coming gate electrons. Time dependent dielectric breakdown experiments on our double polymer layer are necessary as a future study but it is now regarded that our pentacene TFT with the double polymer dielectric is not so much unstable and is possibly promising as a driving component in E-book application.

4. Conclusion

In summary, we have fabricated flexible low-voltage pentacene TFTs with 30 nm-thin PVP/200 nm-thick P(VDF–TrFE) double polymer dielectric. The 230 nm-thick double polymer dielectric layer showed a good dielectric strength (∼2 MV/cm) and a high capacitance (over∼26 nF/cm^2), allowing our pentacene TFT to operate under a low voltage of −5 V along with a maximum channel mobility of 1.22 cm^2/V s and an on/off current ratio of ∼3 × 10^3. Although our TFT displayed some degree of I_D–V_G hysteresis due to the gate electron injection and remnant polarization in P(VDF–TrFE) layer, we conclude that our thick double polymer layer is quite a promising candidate as a gate dielectric for flexible low-voltage driven pentacene TFTs.

ARTICLE INFO

ABSTRACT

We report on the fabrication of rubrene thin-film transistors (TFTs) with surface-modified dielectrics adopting several kinds of self-assembled-monolayer (SAM) on SiO_2/p^+–Si substrate. With the dielectric of lower surface energy, the crystalline rubrene growth or amorphous-to-crystalline transformation kinetics is faster during in-situ vacuum post-annealing, which was performed after rubrene vacuum deposition. In the present study, hexamethyldisilazane (HMDS) was finally determined to be the most effective SAM interlayer for polycrystalline rubrene channel formation. Our rubrene TFT with HMDS-coated SiO_2 dielectric showed quite a high field mobility of $\sim 10^{-2}$ cm^2/V s and a high on/off current ratio of $\sim 10^5$ under 40 V.

1. Introduction

Rubrene transistors with crystalline channels, as fabricated by solution- or vapor-induced processes, recently attracted much attention, displaying high mobilities exceeding those of pentacene thin-film transistors (TFTs) that usually have vacuum-deposited patterned channels [1–6]. This means that rubrene TFTs may have higher potentials than those of pentacene TFTs even in patterned device form. However, until recent years rubrene TFTs could hardly draw such a desirable device performance from vacuum-deposited patterned channels [7]. It is mainly due to process-dependent difficulties of vacuum-deposition (thermal evaporation) method in obtaining crystalline channels on a dielectric substrate; this vacuum

process could hardly obtain good crystalline rubrene film because the evaporated rubrene molecules could not easily overcome the energy barrier to the planar conformation [8] In addition, considering the fact that the surface chemical state of the dielectric is important for the formation of crystalline organic semiconductor layers although those studies appeared in lack of systematic understanding or uncertain in terms of device performance [6,9]. Therefore, in order to achieve a high performance rubrene TFT with vacuum-deposited channel pattern, it is very desirable to exploit the previously-found deposition conditions [10] on an optimally-modified dielectric surface. We thus, as the first step, implemented a systematic study for the crystalline growth of vacuum-deposited rubrene film on several dielectric surfaces modified with such a variety of self-assembled-monolayers (SAMs) as Hexamethyldisilazane (HMDS), 7-octenyltrichlorosilane (7-OTS), and Trichloro(1H,1H,2H,2H-perfluorooctyl)Silane (FTS) in the

E-mail address: semicon@yonsei.ac.kr (S. Im).

order of hydrophobic tendency. Then as the next step of research, we have fabricated channel patterned rubrene TFTs with those surface-modified dielectrics to determine an optimal SAM layer leading to the best performance rubrene TFTs with enhanced mobilities.

2. Experimental section

A 200 nm-thick conventional thermal silicon oxide (SiO_2) on p^+−Si was used as substrates (or gate dielectrics). In order to modify the surface states of our dielectrics, HMDS, 7-OTS, and FTS were applied onto the substrates using the following universal methods [11–15]; prior to the surface modification of SiO_2 substrates, the substrates were cleaned with acetone, methanol, and de-ionized water in that order, and then the substrates reacted with 7-OTS and FTS solution (0.1 wt.%) using hexane as the solvent by immersion for 1 h at room temperature (RT). In HMDS coated sample case, it was coated on the SiO_2 substrates by spin casting at RT. After that, the SAM-modified samples were dried in the vacuum oven at 100 °C for 1 h.

The rubrene channel layers (Aldrich, ~99.19% purity) were initially deposited on the substrates at 40 °C by thermal evaporation. After deposition, we immediately carried out in-situ post-annealing at 80 °C for 17 h. For source/drain (S/D) of the rubrene TFTs, 100 nm-thick Au was then evaporated onto the rubrene channels at RT. Nominal channel length and width of our rubrene TFTs were 90 and 500 μm, respectively. All electrical characterizations were carried out with a semiconductor parameter analyzer (Model HP 4155C, Agilent Technologies) in the dark. Atomic force microscopy (AFM: model XE-100, PSIA) was carried out on the surfaces of our rubrene channels and SAM-treated dielectrics. Absorption measurements were also performed for HMDS-, 7-OTS-, FTS-functionalized, and unfunctionalized 80 nm-thick rubrene films on Corning glass with a Varian Cary 5G Spectrophotometer.

3. Results and discussion

Table 1 shows the information on the de-ionized water contact angles (c.a.) of pristine, HMDS-treated, 7-OTS-treated, and FTS-treated SiO_2, listed in the order of dielectric surface energy. In view of AFM image those pristine or modified dielectric surfaces appeared nearly identical (root-mean-square roughness, R_{rms}; 0.2–0.3 nm for all). The information on the c.a. is very important here because only the surface energy may influence on the rubrene channel formation and the effects from surface roughness can be ignored in our experiments.

Fig. 1a–d are the optical micrographs of rubrene surfaces obtained by thermal evaporation of rubrene molecules at a substrate temperature of 40 °C and subsequent

in-situ vacuum annealing at 80 °C for 17 h. [10] on SiO_2 substrate surfaces modified with various SAMs: (a) pristine, (b) HMDS, (c) 7-OTS, and (d) FTS. In the figures, the photos I, II, and III are ×90, ×140, and ×3.5 times magnified images of rubrene film surfaces, respectively. According to the photo I in Fig. 1a–d, the final radii of crystalline rubrene discs grown in the same post-anneal period were observed to be 300 μm, 400 μm, 500 μm, and more than 500 μm on pristine, HMDS-, 7-OTS-, and FTS-treated SiO_2, respectively, along in the inverse order of the hydrophobic tendency of dielectric surfaces. This means that the growth rate of the nuclei becomes faster with the lower dielectric surface energy. These phenomena may be understandable based on a classical nucleation and growth theory as we deploy it in a simplified manner as follows;

$$\Delta G = \pi R^2 d\Delta G_c + \pi R^2(\gamma_3 - \gamma_1) + 2\pi R d\gamma_2 \qquad (1)$$

where ΔG is the total free energy necessary for the amorphous-to-crystalline phase transition of rubrene disc, R and d are the radius and thickness of the crystalline rubrene disc, ΔG_c is bulk free energy for the phase transition, γ_1 and γ_3 are the interface energies of dielectric/amorphous and dielectric/crystalline rubrene, respectively. γ_2 is the interface energy between amorphous and crystalline rubrene. Since we want to derive a critical radius (R_c) of crystal rubrene disc, it can be determined from the following Eq. (2) if the equation satisfies the next conditional formula (3).

$$\left(\frac{\partial \Delta G}{\partial R}\right) = 2\pi(d\Delta G_c + \gamma_3 - \gamma_1)R + 2\pi d\gamma_2 = 0 \qquad (2)$$

$$\left(\frac{\partial^2 \Delta G}{\partial R^2}\right) = 2\pi(d\Delta G_c + \gamma_3 - \gamma_1) < 0$$

Here, ΔG_c and $\gamma_3 - \gamma_1$ are always negative values because crystalline phase must be more stable than amorphous phase ($\Delta G_c < 0$) and γ_3 is usually smaller than γ_1 ($\gamma_3 - \gamma_1 < 0$).

Therefore formula (3) is satisfied. We thus could derive R_c from Eq. (2).

$$R_C = -\frac{d\gamma_2}{(d\Delta G_c + \gamma_3 - \gamma_1)} \qquad (3)$$

Here γ_1 is probably almost the same for all the SAM-modified SiO_2 while γ_3 should vary with the chemical state of dielectric substrate. According to our experimental results on the growth rate, it is deduced that the γ_3 decreases with the hydrophobic tendency of dielectrics and also that with the stronger hydrophobic dielectric surface the magnitude of R_c becomes smaller. This means that the crystalline rubrene nuclei on the FTS-modified SiO_2 are relatively easy to go to the stable growth stage due to their small R_c or small energy barrier conditions compared to those of pristine SiO_2. Since the growth of the crystalline discs becomes fast once they overcome the R_c condition, it is now understandable that why the dielectrics of the low surface energy display large-sized rubrene discs here. Photo II shows a merged form of crystalline nuclei and their grain boundaries.

Table 1
Contact angle measured from (a) Pristine, (b) HMDS treated, (c) 7-OTS treated, and (d) FTS treated SiO_2.

	Pristine	HMDS	7-OTS	FTS
Contact angle	~40°	~60°	~85°	~117°
Fig. 1. Optical microscope images of rubrene thin-film surfaces prepared by in-situ vacuum annealing (at 80 °C for 17 h), which follows the rubrene film deposition at 40 °C on various SiO$_2$ substrates with (a) Pristine, (b) HMDS-treated, (c) 7-OTS-treated, and (d) FTS-treated surfaces. Photo I, II, and III are ×90, ×140, and ×3.5 magnified surface images of rubrene film.

On the one hand, it is also worthy of note from the photo III of Fig. 1a–d that the number of rubrene crystal discs dwindles with the lowered surface energy. Although why the number of crystals decreases with the surface energy decrease of dielectric is not quite clear, we can suggest an assumption that the number of nucleation sites are somewhat related to that of OH groups on the dielectric surface or that the surface OH groups play as main seeds of nucleation sites for the crystalline discs. As an extreme case, FTS-treated SiO$_2$ surface rarely allows to show any disc shape crystals but seems to show only one grain of crystalline rubrene because it has very small surface energy and thus contains only a small number of nuclei while the growth rate of the nuclei is much fast enough to cover the whole surface area during the process time after all. The next best coverage (>90%) with the crystalline phase resulted from the HMDS-modified SiO$_2$ surface. This good result might come from an optimum phase transition condition which is achievable with large numbers of nucleation site and proper growth rate as well. Since the surface coverage with the crystalline phase is important to obtain a high mobility TFT device, this nucleation and growth issue must be taken into good consideration. In the case of bare hydrophilic SiO$_2$ dielectric, the nucleation site is many but the growth speed is too slow to cover the whole area of the dielectric surface with the crystalline phase (resulting in only ∼40% coverage). In contrast, the 7-OTS-modified SiO$_2$ contains only a small number of nucleation sites while it allows the nuclei to grow so fast (∼70% coverage).

Fig. 2a–d shows AFM images of 80 nm-thick rubrene films grown on (a) pristine SiO$_2$, (b) HMDS-treated SiO$_2$, (c) 7-OTS-treated SiO$_2$, and (d) FTS-treated SiO$_2$. The AFM surface image (5 μm × 5 μm) of rubrene in a few hundred μm–dia. crystalline disc on pristine SiO$_2$ shows lamellar-like orientation and is generally similar to those of crystalline films grown on HMDS- and 7-OTS-treated SiO$_2$. (They showed (200) orientation in previous X-ray diffraction analysis [10]). It is very interesting, however, that the rubrene films on FTS-treated SiO$_2$ substrates show somewhat different AFM surface image distinguishable from those of other samples. Crystalline rubrene film grown on FTS-treated SiO$_2$ displayed rather directionless micro-grains unlike the other cases. The growth speed of rubrene crystals on FTS-modified SiO$_2$ is probably too high to keep the directional morphologies and thus the speed results in somewhat directionless or dendritic outcome as micro-grains, whose appears random and their sizes are so small (∼1 μm dia.). In addition to optical microscopy and AFM analysis, we implemented absorption measurement to again confirm the crystalline quality of the four types of 80 nm-thick rubrene films on clear glass substrate, which has correspondingly SAM-modified surfaces. As shown in this optical measurement of Fig. 2e, we clearly observed the rubrene crystalline quality with respect to the substrate hydrophobicity. As expected, HMDS- and FTS-functionalized rubrene films displayed the similarly intense peak signatures representing the best crystalline quality among the four samples while the rubrene film on bare SiO$_2$ showed weak crystalline signature. These results are quite consistent with those from optical microscopy of Fig. 1a–d, where our HMDS- and FTS-functionalized rubrene films displayed similar crystalline coverage of 90% and 100%.
Fig. 2. AFM images of rubrene thin-film deposited on (a) Pristine, (b) HMDS-treated, (c) 7-OTS-treated, (d) FTS-treated SiO$_2$, and (e) absorption spectra of those 80 nm-thick rubrene thin-films deposited on correspondingly SAM-treated glass.

In order to determine the optimum rubrene TFT with the highest performance potentials, we have fabricated four types of TFT devices adopting aforementioned SAM-modified SiO$_2$ and pristine SiO$_2$ as gate dielectrics. The inset of Fig. 3 shows 3-dimensional (3-D) schematic drawing of our rubrene TFTs and the Fig. 3 shows the drain current–drain voltage (I_D–V_D) output curves obtained from the four rubrene TFTs: TFTs on pristine, HMDS-treated, 7-OTS-trea-

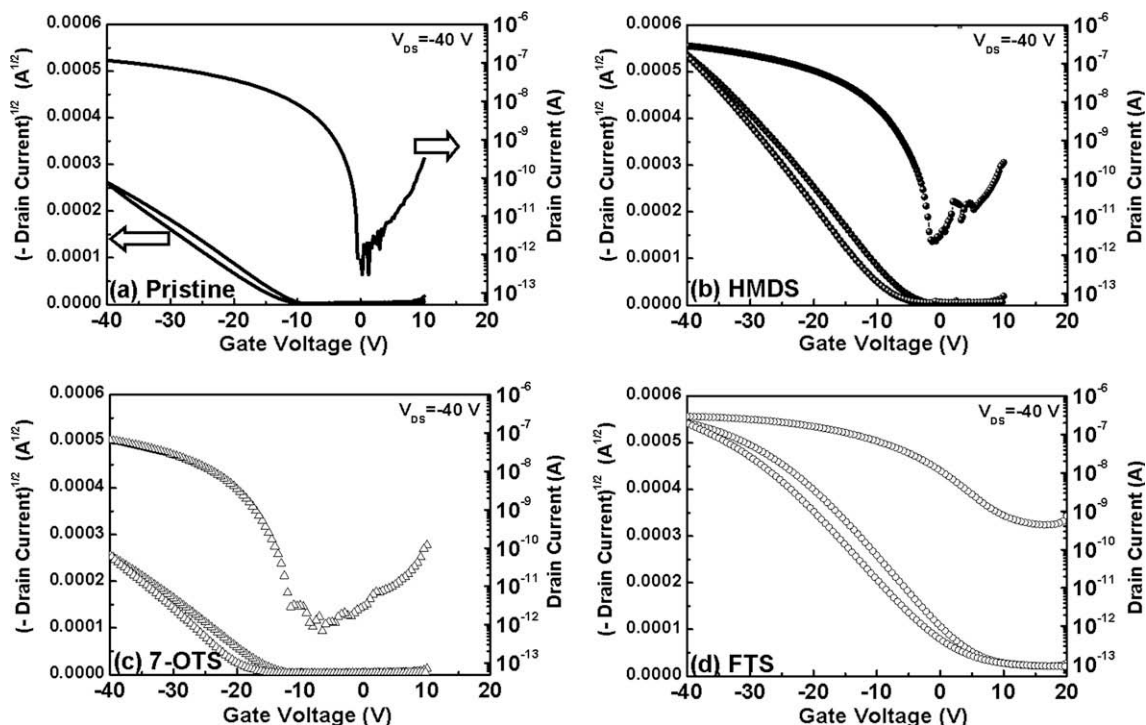
ted, and FTS-treated 200 nm-thick SiO$_2$ dielectrics. According to the output curves, rubrene TFTs with pristine and 7-OTS-treated SiO$_2$ exhibited almost the same saturation level of drain current ($I_{D,sat} \sim 60$ nA) at the gate bias (V_G) of -40 V but the $I_{D,sat}$ level of devices obtained from HMDS-treated and FTS-treated SiO$_2$ were 220 and 245 nA, respectively which are much higher than 60 nA at the same V_G. These results were reflected by the
Fig. 3. Output characteristics (I_D vs. V_D) of the rubrene TFTs with pristine, HMDS-, 7-OTS-, and FTS-treated SiO$_2$ dielectrics.


Fig. 4. $\sqrt{-I_D}$ vs. V_G and $\mathrm{Log}(-I_D)$ vs. V_G transfer curves of the rubrene TFTs with (a) pristine, (b) HMDS-, (c) 7-OTS-, and (d) FTS-treated SiO$_2$ dielectrics.

corresponding drain current-gate bias (I_D–V_G) transfer curves of Fig. 4a–d. Under a drain-source bias (V_{DS}) of −40 V our organic TFTs with (a) pristine, (b) HMDS treated, (c) 7-OTS treated, and (d) FTS-treated SiO$_2$ dielectrics exhibited the saturation field effect mobilities of 0.0020, 0.0080, 0.0024, and 0.0050 cm^2/V s, respectively (and by extending the annealing time (24 h) for the rubrene film on HMDS-treated surface, we could achieve a little higher mobility of ∼0.01 cm^2/V s). All the rubrene TFTs displayed on/off current ratio of ∼10^5 except the one with FTS-treated SiO$_2$, which showed only ∼10^3. In terms of on-state current and mobility, we could regard that the organic TFTs with HMDS- and FTS-treated dielectrics displayed good potentials toward device performance. Their high mobilities are certainly because their rubrene channels have been mostly covered by crystalline phase, which must be true in that the crystalline coverage of the HMDS- and FTS-treated cases was 90% and 100%, respectively (see Fig. 1a–d). However, in terms of the off-state current and sub-threshold swing the OTFT with FTS-treated SiO$_2$ appears less desirable than the other one with HMDS-treated SiO$_2$ dielectric, displaying two orders of magnitude higher off-current. As the AFM image of crystalline rubrene film grown on FTS-treated dielectric shown in Fig. 2d, the film contains many micro-grains as a result of the fast crystalline growth. Consequently the total grain boundary area becomes large and as a matter of fact the boundary area may play as carrier trap center. Many of trapped whole charges are de-trapped at a depletion state under a gate bias for off-state, resulting in an elevated level of off-state current.

4. Conclusion

In summary, we have implemented a systematic study for the crystalline growth of vacuum-deposited rubrene film on several dielectric surfaces modified with HMDS, 7-OTS, and FTS in the order of hydrophobic tendency, in order to achieve or determine an optimal SAM layer leading to optimum OTFT performance in both terms of mobility and on/off ratio. Our rubrene TFT with HMDS-coated SiO$_2$ dielectric showed quite high field mobility of 0.008–0.01 cm^2/V s and on/off current ratio of ∼10^5 under 40 V. We conclude that HMDS is presently the most effective and promising SAM interlayer for polycrystalline rubrene channel formation, which involves an amorphous-to-crystalline phase transition during post-annealing.

ARTICLE INFO

ABSTRACT

We report the influence of thickness and thermal annealing of the poly(3,4-ethylenedioxy-thiophene):poly(styrenesulfonate) (PEDOT:PSS) layer on the performance of bulk heterojunction solar cells made from blends of regioregular poly(3-hexylthiophene) and 1-(3-methoxycarbonyl)-propyl-1-phenyl-$(6,6)C_{61}$. Results show that the power conversion efficiency was significantly improved by inserting the PEDOT:PSS layer but was not strongly sensitive to either the layer thickness or the annealing temperature. Although the short circuit current density was enhanced slightly by annealing the PEDOT:PSS layer at high temperatures, the fill factor was slightly decreased. The trend in device performance could not be explained by the observed changes in the work function of the PEDOT:PSS layer.

Since the first reports of organic solar cells based on blends of conjugated polymers and fullerene derivatives [1,2], device performance has been greatly improved by selection of materials with suitable energy levels, control of nanomorphology [3] either during film deposition [4] or using post-fabrication procedures such as thermal annealing [5–9], and by optimisation of electrode materials [10]. Devices made from the well studied combination of poly(3-hexylthiophene) (P3HT) and 1-(3-methoxycarbonyl)-propyl-1-phenyl-$(6,6)C_{61}$ (PCBM) have been reported to produce power conversion efficiency (PCE) of

4–5% [4,7,8,10], while devices made from poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-b;3,4-b′]-dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] (PCPDTBT):PCBM blend have been reported to produce PCE of up to 5.5% [11].

Most of these high efficiency polymer:fullerene solar cells are made with a poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) layer, which is inserted between the transparent electrode, typically indium-tin oxide (ITO) and the light-absorbing organic layer. The positive effect of this PEDOT:PSS layer on device performance has been attributed to improved selectivity of the anode, on account of the higher work function relative to ITO [12], improved smoothness of the electrode/active layer contact [13], and increased photovoltage through the surface enrichment of PSS components [14]. Despite

the apparent importance of the PEDOT:PSS layer for high efficiency [4,7,8,11], the device performance has not yet been correlated to the specific properties of the PEDOT:PSS layer such as thickness, conductivity and morphology. Moreover, the literature contains quite a range of PEDOT:PSS layer thicknesses and annealing treatments, even for otherwise similar devices [6,15–18].

Here we report studies of the effect of thickness and annealing temperature of the PEDOT:PSS layer on the performance of bulk heterojunction solar cells made with blends of regioregular P3HT and PCBM. The results are considered in terms of variations in work function, conductivity and surface morphology of the PEDOT:PSS layers.

The P3HT:PCBM (50 wt.% PCBM) solution was prepared in chlorobenzene as reported previously [6]. PEDOT:PSS (Baytron P standard grade, HC Starck) layers were prepared by spin-coating onto pre-cleaned ITO-coated glass substrates [6]. For the study of thickness dependence, layer thickness was varied from 60 to 165 nm by varying spin rate, and films were then soft-baked at 50 °C for 15 min. A 70 nm thick P3HT:PCBM active layer was then deposited by spin-coating at 2500 rpm. To study annealing temperature, the thickness of PEDOT:PSS layer was fixed at 70 nm and the PEDOT:PSS coated substrates were annealed for 15 min at temperatures from 75 °C to 230 °C using a precision hot plate which has a glass cover to protect samples from moisture attack from outside. A 90 nm thick P3HT:PCBM layer was then deposited on top by spin-coating at 1500 rpm. Devices of 4.5 mm^2 were defined by thermal evaporation of aluminium top contacts through a shadow mask. In each case about 18 devices were fabricated to check the reproducibility of resulting data. In order to minimize the sample-to-sample variation of device performance we measured pixels in similar positions on each substrate. Since annealing of the active layer (after complete device fabrication) significantly affects device performance and may also affect the PEDOT:PSS layer, each device set was replicated. One set of devices was not further annealed (non-annealed or 'NAN' devices) and the other set was further annealed at 140 °C for 15 min (annealed or 'AN' devices).

The photovoltaic characteristics of devices were measured as described in Ref. 6, but with an incident light intensity of simulated solar light of 85 mW/cm^2. The work functions of the PEDOT:PSS layers were calculated from the chemical potential that was measured by using a Kelvin probe (Kelvin Control 07, Besocke Delta Phi Gmbh) by comparison to a gold reference. The surface morphology of the PEDOT:PSS layers and ITO was measured by using an atomic force microscope (AFM, Burleigh). The sheet conductivity was measured using a four point probe (Newport).

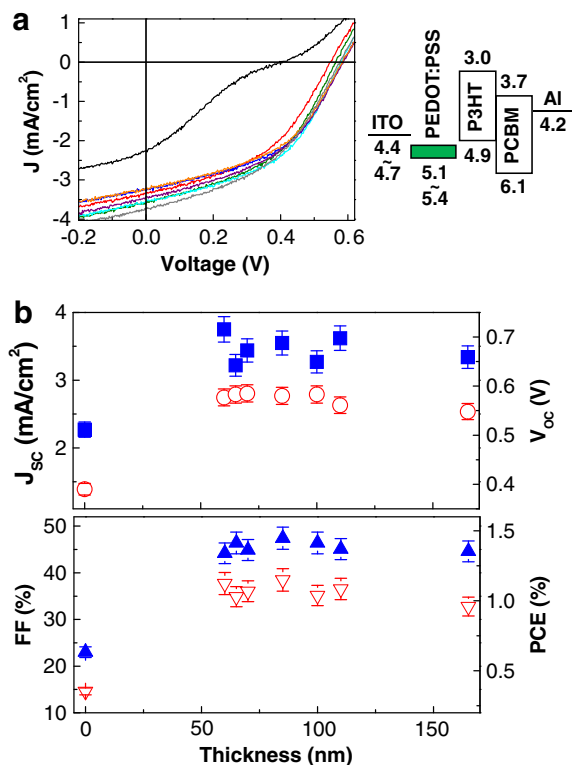
Fig. 1a shows the current density – voltage (J–V) characteristics of as-fabricated P3HT:PCBM devices with different PEDOT:PSS layer thicknesses. The data show that device performance is improved by inserting the PEDOT:PSS layer, irrespective of its thickness. This result is in good agreement with the previous result for vacuum deposited small molecule (C$_{60}$: copper phthalocyanine) solar cells [19]. Here the sigmoidal J–V shape for the device without the PEDOT:PSS layer can be attributed to an interfacial barrier


Fig. 1. (a) (Left) J–V characteristics (AM 1.5, 85 mW/cm^2) of devices with non-annealed P3HT:PCBM layer (70 nm) and non-annealed PEDOT:PSS layer of which thickness is 0 (ITO only; black line), 60 (gray line), 65 (orange line), 70 (purple line), 85 (sky blue line), 100 (blue line), 110 (green line), and 165 nm (red line). (Right) Ideal flat energy band diagram for the device with the PEDOT:PSS layer; (b) J$_{SC}$ (filled squares), V$_{OC}$ (open circles), FF (filled upward triangles), and PCE (open downward triangles) as a function of PEDOT:PSS layer thickness. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

between ITO and the active layer which can cause slow charge transfer [20]. The increased short circuit current density (J$_{SC}$) and fill factor (FF) on inclusion of the PEDOT:PSS layer are attributed to the improved efficiency of hole transfer between P3HT and PEDOT:PSS compared to hole transfer between P3HT and ITO. Because the work function of ITO is approximately 0.3–0.5 eV lower than the ionisation potential of P3HT, a barrier exists for hole injection at the ITO-P3HT interface. In contrast, the higher work function of PEDOT:PSS (measured by Kelvin probe and shown in Fig. 3) means that the contact will be ohmic for holes (see the flat energy band diagram in Fig. 1a).

The open circuit voltage (V$_{OC}$) was also observed to increase on insertion of the PEDOT:PSS layer. Since the same P3HT:PCBM layer is used for each device, this change in V$_{OC}$ can be attributed primarily to the effect of the significantly (>0.4 eV) increased work function relative to ITO: Better matching of the electrode work functions with the transport levels of the active materials allows the open circuit voltage to approach closer to the theoretical limit for any combination of donor and acceptor. As a result, the insertion of PEDOT:PSS layer improved PCE by a factor of 1.8.

Device performance was not strongly sensitive to PEDOT:PSS film thickness over the range measured (60–165 nm). The trend in J_{SC} is in moderately good agreement with theoretical calculations which predict a gradual decrease in J_{SC} of some 10% of its value as the PEDOT:PSS layer thickness is increased from 50 nm to 160 nm, with a local maximum in the region 100–140 nm, for the active layer thickness used here [17]. Only approximate agreement can be expected with such calculations for perfectly planar structures, on account of the roughness of the ITO and PEDOT:PSS layers (see below) that are used in practice. Finally, we note that the shape of J–V curves was not influenced by the PEDOT:PSS layer thickness. This indicates that the overall charge collection efficiency is not strongly affected by any variation in PEDOT:PSS film morphology due to different spin-coating speed. The linear shape of the J–V curves near V_{OC} is most likely the result of serial resistance due to relatively low conductivity of the soft-baked PEDOT:PSS films, as discussed in detail below.

Next, the effect of thermal annealing of the PEDOT:PSS layer (thickness = 70 nm) was studied for both NAN devices and AN devices. As shown in Fig. 2a and b, the J–V characteristics of neither set of devices was significantly affected by the annealing temperature of the PEDOT:PSS
Fig. 2. (a) J–V characteristics (AM 1.5, 85 mW/cm²) of devices: 'NAN' denotes the devices with non-annealed P3HT:PCBM layer (90 nm) and PEDOT:PSS layer (70 nm) annealed at 75 (black solid line), 140 (red dashed line), 230 °C (blue dash-dot line), while 'AN' represents the annealed devices of the 'NAN' devices at 140 °C for 15 min. (b) J_{SC}, V_{OC}, FF, and PCE as a function of PEDOT:PSS annealing temperature: Red open squares and blue filled circles denote 'NAN' and 'AN' devices, respectively. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

layer, although all AN devices show a much higher J_{SC} than NAN devices, as previously reported [4–6]. Both NAN and AN devices show a slight increase in J_{SC} upon annealing the PEDOT:PSS layer at high temperatures (Fig. 2b) while the FF reduces slightly. As the annealing temperature of the PEDOT:PSS film affects the intensity but not the shape of external quantum efficiency spectra (data not shown), these J_{SC} trends are unlikely to be caused by a change in morphology of the photoactive layer but may relate to the morphology or conductivity of the PEDOT:PSS layer. Therefore the effect of thermal annealing of the PEDOT:PSS layer on these properties was studied.

The work function (Fig. 3 top panel) is observed to decrease monotonically with the annealing temperature, in accordance with a previous report by Huang et al. [21]. This suggests that the surface concentration of PSS components is reduced with an increase in annealing temperature. The drop in work function cannot explain the increase in J_{SC} but is small enough (<0.15 eV) for the PEDOT:PSS – P3HT contact to remain approximately ohmic over the range of annealing temperatures explored, and therefore it is unlikely to be expected to degrade performance. In contrast, as shown in Fig. 3 (bottom panel), the conductivity is observed to increase as annealing temperature is increased above 100 °C, and then decrease as the annealing temperature is increased above 200 °C. This change in conductivity is likely due to a change in oxidation state of the polymer, where heating at temperatures between 100 and 200 °C cause an increase in oxidation state, but heating above 200 °C causes over-oxidation and degradation of the film [21–24]. Although the change in sheet conductivity at high annealing temperatures correlates with FF, possibly due to and increase in series resistance, it does not correlate to the change in J_{SC}, and so cannot explain the increase in J_{SC} at annealing temperatures in the range 160–200 °C. However, the four point probe technique is not sensitive to changes in conductivity in the direction perpendicular to the substrate, which could result in this case from changes in the vertical distribution of PSS within the layer and could also
Fig. 3. Work function (WF, top panel) and conductivity (σ, bottom panel) of PEDOT:PSS layers (70 nm thick) as a function of annealing temperature.
Fig. 4. AFM images (1 × 1 μm) of ITO surface (a; Rg = 3.3 nm) and PEDOT:PSS layer (70 nm thick) annealed at 75 °C (b; Rg = 6.9 nm), 140 °C (c; Rg = 5.8 nm), and 230 °C (d; Rg = 1.4 nm).

influence J_{SC}. Measurements of the change in surface roughness of the PEDOT:PSS layer upon thermal annealing suggest an alternative explanation for the increase in J_{SC}. AFM images (Fig. 4) show that while annealing of the PEDOT:PSS layer at 140 °C leads to fluctuations in thickness of tens of nm, a much smoother film results from annealing above 200 °C. The smoother surface should enable a more uniform interfacial contact between the PEDOT:PSS and P3HT:PCBM layers, after thermal annealing of the active layer, and so avoid local fluctuations in collection efficiency that could limit J_{SC}.

With regards to V_{OC}, thermal annealing of the PEDOT:PSS layer improved V_{OC} for NAN devices irrespective of annealing temperature. As for J_{SC}, this cannot be attributed to the enrichment of PSS components on the surface of PEDOT:PSS layer as previously reported [14]. The higher V_{OC} in AN devices than NAN devices (regardless of PEDOT:PSS annealing temperature) can be explained by the previously reported effects of thermal annealing on charge recombination kinetics [7] and on vertical distribution of components [25]. The combined trends lead to a the highest PCE (3.5%) for annealed devices at a PEDOT:PSS annealing temperature of 230 °C but no clear optimum for non-annealed devices.

In summary, the performance of P3HT:PCBM blend solar cells was significantly improved by addition of a PEDOT:PSS layer, as previously reported. The short circuit current density decreases slightly with increasing thickness of this layer (over a range 60–165 nm) in agreement with theoretical calculations. Thermal annealing of the PEDOT:PSS layer at high temperatures (200–230 °C) increased J_{SC} slightly but decreased FF. It is proposed that these influences are caused by variations in conductivity and surface roughness of the PEDOT:PSS layers with thermal annealing temperature. The work function was also

observed to decrease with an increase in annealing temperature whilst remaining high enough to provide an ohmic contact with P3HT and is consistent with the small observed trend in V_{OC}. The small variation in PCE with annealing temperature is consistent with the large variation in annealing temperature (10–230 °C) of PEDOT:PSS layers commonly used in devices reported in the literature.

ABSTRACT

In this paper, we report the fabrication of permeable metal-base organic transistors based on N,N'-diphenyl-N,N'-bis(1-naphthylphenyl)-1,1'-biphenyl-4,4'-diamine (NPB)/C$_{60}$ heterojunction as both emitter and collector. By applying different polarities of voltage bias to the collector and the base, and input current to the emitter, the ambipolar behavior can be observed. The device demonstrates excellent common-base characteristics both in P-type and N-type modes with common-base current gains of 0.998 and 0.999, respectively.

In recent years, organic transistors are technologically interesting because they could serve as the main component in cheap and flexible electronic circuits, such as flexible displays [1,2] and integrated circuits [3,4]. For the development of electronic circuits based on organic semiconductors, the transistors need to go beyond unipolarity. The simultaneous transport of both types of carriers could lead to a simplification in the design of the complementary logic circuits, allowing at the same time to reduce power dissipation and increase noise margins. As a consequence, a lot of efforts have been made towards the fabrication and optimization of ambipolar transistors [5–11].

Ambipolar organic transistors have been fabricated by applying blends [5–7], bilayers of holes and electrons transporting materials [8], interface dopant [9] and electron injection electrodes [10]. Recently, transistor with vertical structure achieving ambipolar characteristics by inserting a transition-metal-oxide layer at the source/organic interface to form a unique nanoscale structure was reported [11]. In this letter, we fabricated another type of vertical structure organic transistors, namely permeable metal-base organic transistors, based on N,N'-diphenyl-N,N'-bis(1-naphthylphenyl)-1,1'-biphenyl-4,4'-diamine (NPB)/C$_{60}$ heterojunction as the emitter and the collector, and Al/Al:Ca/Al base electrode. It is found that the devices showed ambipolar behavior with common-base current gains of 0.99 for both, P-type and N-type modes, respectively.

Fig. 1a shows the schematic diagram of the studied device structure. The patterned ITO glass substrate was first cleaned and dried, and then put in a vacuum chamber.

Fig. 1. (a) The schematic diagram of the proposed ambipolar PBT structure. (b) Ambipolar device operating modes for *P*-type. (c) Ambipolar device operating modes for *N*-type.

At a pressure of $\sim5 \times 10^{-4}$ Pa, a 5 nm thick vanadium oxide (V_2O_5) film, a 10 nm C_{60} film, a 50 nm NPB film, a 5 nm Al film and a 15 nm Ca:Al alloy film were evaporated in sequence on ITO. Amongst, the heterojunction consisting of C_{60}/NPB was used as the collector, and the V_2O_5 was used as the buffer layer to enhance the injection of charge carriers. Ca and Al were co-evaporated to form the Ca:Al alloy layer. The evaporation rates of aluminum and calcium were 0.2 nm/s and 0.1 nm/s, respectively. At this time, taking out the samples and annealing them at 120 °C for five minutes in air. After annealing, the samples were putted in the vacuum again. When the vacuum achieved $\sim5 \times 10^{-4}$ Pa, then a 5 nm Al, 50 nm NPB, 10 nm C_{60}, 5 nm V_2O_5 and 120 nm Al films were in turn deposited to finish the fabrication of the devices. Thus the NPB/C_{60} heterojunction forms the emitter and the Al/Ca:Al/Al forms the base. All the organic layers and V_2O_5 were deposited at a rate of 0.2 nm/s with the substrate temperature maintained at room temperature. The device area defined as the overlap of three electrodes was 6 mm². The electric characteristics measurements were performed in the dark using two Keithley 2400 Sourcemeters. For the measured results throughout this work, we use the following definition, $V_{BE} \equiv V_B - V_E$; $V_{CB} \equiv V_C - V_B$, and when the device is in *P*-type mode, I_E and I_C are positive, whereas the input/output currents are negative, this device operates in *N*-type mode. The subscripts E, B and C denote emitter, base and collector, respectively. Fig. 1b and c show the operating modes for *P*-type and *N*-type cases, respectively.

By applying different polarities of voltage biases between the collector and the base, and the input current to the emitter, the ambipolar behavior can be observed. In Fig. 2a and b, the common-base characteristics are plotted for *P*- and *N*-type devices. When operated as a *P*-type device with the measurement shown in Fig. 1b, the device demonstrates excellent common-base characteristics, as shown in Fig. 2a. For increasingly negative $-V_{CB}$, there is a sharp increase in negative I_C for holes injection from the collector through the C_{60}/NPB heterojunction to the base. When $-V_{CB}$ increases to positive values, the I_C meets a plateau soon and keeps the value $I_C \cong I_E$ afterward. The device also gives out fine *N*-type common-base characteristics, as presented in Fig. 2b, when working in *N*-type mode in Fig. 1c. It can be observed that $-I_C$ is negative and large at $V_{CB} = -6$ V, accounting for the presence of electrons injection between the collector and the base, and increases with the increasing of V_{CB} up to a saturation value close to the selected $-I_E$. The insets depict output current I_C dependence on input current I_E at $V_{CB} = 0$ V, which offer the calculation of the common-base gain $\alpha \equiv \frac{\partial I_C}{\partial I_E}$, to be about 0.998 and 0.999 for *P*- and *N*-type modes, respectively. These high common-base gains indicate that whether charge carriers are injected by the emitter are able to be transferred through the C_{60}/NPB heterojunction and cross the base, being collected by the collector.

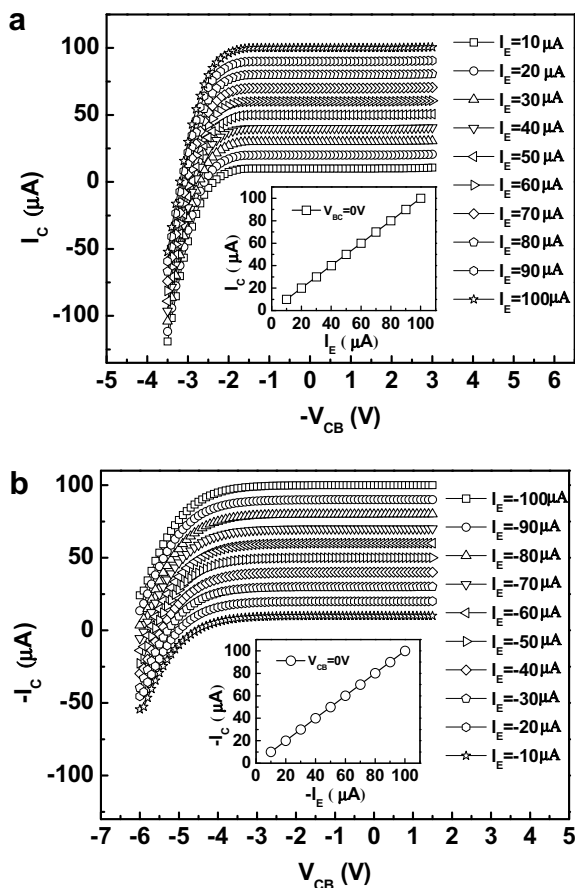
Fig. 3 shows the variation of V_E necessary to maintain I_E constant during the V_{CB} scan. As can be seen, $|dV_{EB}/dV_{CB}| \cong 1$ at different values of I_E, ranging from 100 μA (bottom) to −100 μA (top) at steps of −10 μA, indicating that the device operates as PBT both in *P*-type and *N*-type modes [12]. As known, the process that charge transfer between the emitter and collector occurs mainly through small openings in the base layer, rather than by ballistic transport across it, is the principle behind PBTs [12]. In our devices, openings formed by annealing. Annealing caused the base layer Al:Ca to be oxidized partially and result in a ultra thin oxidized surface and pin-like-oxide penetrated into the base layer due to the easier oxidation of the calcium in air with respect to aluminum. Obviously, the pin-like-oxide can act as the efficient openings, thus the carriers transport from the emitter to the collector, rather than shield by the thick base electrode [13].


Fig. 2. (a) Common-base characteristics of the ITO/V_2O_5/C_{60}/NPB/Al/ Al:Ca/ Al/NPB/C_{60}/V_2O_5/Al device operating at *P*-type mode. (b) Common-base characteristics of the device operating at *N*-type mode. The insets show I_C as a function of I_E at V_{CB} = 0 V.
Fig. 3. $-V_{BE}$ ($-V_{CB}$) characteristics of the ITO/V_2O_5/C_{60}/NPB/Al/Al:Ca/Al/ NPB/C_{60}/V_2O_5/Al device at different I_E values.

Moreover, the ambipolar PBTs exhibit good air stability. After 33 days exposed to environmental atmosphere, the devices were measured again and there was no observable

changes in common-base characteristics. *P*-type PBTs based on NPB as emitter and collector showed different behavior, i.e., did not demonstrate any performance expected for PBTs after only 5 days stored in air. We consider that the air stability of the ambipolar PBTs can be attributed to the utilization of C_{60}/NPB heterojunction with the air-stable C_{60}.

It can be seen that the ambipolar characteristics can not be achieved when the C_{60}/NPB heterojunction is not used in such devices. It is well known that heterojunctions can well be used to improve the performance of organic optoelectronic devices due to the possibility of control of the charge injection, transport and confinement by the change of energy barriers [14,15]. Obviously, the C_{60}/NPB heterojunction plays an important role in the achievement of the ambipolar characteristics in our PBTs, also contribution to the long term stability of the devices, which constitute a key point when practical applications are considered.

For further understanding of the origin of ambipolar properties, we fabricated diodes based on C_{60}/NPB heterojunction with structures of Al(1)/NPB/C_{60}/V_2O_5/Al(2) and Al(1)/NPB/C_{60}/Al(2). Here the devices are defined as positive bias when Al (1) is set as anode and Al (2) as cathode, whereas the devices are negative biased. *I–V* characteristics of the two diodes are shown in Fig. 4. It can be seen that the device with V_2O_5 shows higher current than that of the device without V_2O_5 under positive and negative bias. This indicates that there are more electrons or holes to be injected into the device in Al(1)/NPB/C_{60}/V_2O_5/Al(2). In the case of positive bias, hole injection of the two devices are identical, obviously the more currents in Al(1)/NPB/C_{60}/ V_2O_5/Al(2) owe to the more electrons injection from Al(2) electrode. While negative biased, electron injection of the two devices are same, the more currents in Al(1)/NPB/C_{60}/ V_2O_5/Al(2) evidently attribute to holes injection from Al(2) to C_{60}/NPB. That is to say, the utilization of V_2O_5 greatly enhances electron injection and favors hole injection, which had been proven in our previous works [16,17]. All above should be account for ambipolar properties of the devices based on NPB/C_{60} heterojunction. The deep understanding of the organic heterojunction will be helpful for further developing environmentally stable, or even long operational lifetime encapsulated high performance PBTs.
Fig. 4. *I–V* characteristics of the diodes based on C_{60}/NPB heterojunction. The inset shows the structure of the devices.
In summary, vertical architecture ambipolar permeable metal-base organic transistors were realized by using C_{60}/NPB heterojunction as the emitter and collector. The device demonstrates excellent common-base characteristics both in *P*-type and *N*-type modes with common-base gains of 0.998 and 0.999, respectively. This opens an effective method to fabricate ambipolar organic PBTs.

ARTICLE INFO

ABSTRACT

We have used particle induced X-ray emission analysis and particle induced gamma-ray emission analysis to determine the elemental impurity concentrations in poly[(2,5-bis(3-decylthiophen-2-yl)thieno[2,3-b]thiophene] samples that have undergone different washing and extraction procedures to remove impurities. Field-effect transistors (FETs) were fabricated from the materials and their electrical characteristics show no significant differences between the devices made from different material samples. Reducing the metal residue levels below the ones measured in the starting material (300 mg/kg Fe, 7 mg/kg Zn, 3000 mg/kg Pd and 12000 mg/kg Sn) does not improve the FET performance. This suggests that it is not necessary to completely remove metal residues in the polymer for FET applications.

1. Introduction

During the last few years semi-conducting polymers have attracted a considerable amount of attention due to their potential electronic applications in field-effect transistors, solar cells, light emitting diodes, electronic memories and other devices [1–4]. The advantages of polymers over conventional inorganic semi-conductors, such as silicon and germanium, include solution-processability, large area fabrication, low costs and flexibility. One of the requirements on organic semi-conductors for use in organic field-effect transistors (OFETs) is a high chemical purity level, since impurities can act as charge-trapping sites [2]. However, the effects of impurities in semi-conducting polymers on OFET performance are not well understood.

In organic semi-conductors the charge carriers are more localized than in their inorganic counterparts; resulting in a smaller radius of influence for impurities [5]. Depending on the nature of the impurity it can influence device performance in different ways. Charged impurities could act as dopants that interact coulombically with localized

---

carriers, resulting in a broadened density-of-states which could reduce the charge carrier mobility [6]. Charge neutrality must be maintained when ionized moieties are introduced into the system. One way to accomplish this is by electrochemical doping, where the dopants injects mobile majority carriers, giving rise to an increased energetic disorder [6]. Another possibility is to introduce a neutral entity whose electron affinity allows for charge transfer from the semiconductor to the dopant [7]. Metallic residues in the material acting as charge-trapping sites could also produce hysteresis in a device [8], while any impurities acting as bulk traps will increase the off-currents [9]. The drain voltage dependence of the subthreshold current is also affected by interface-traps. Scheniert et al. have suggested that this effect is caused by recharging of incompletely ionized acceptors or traps in the interface and in the bulk [10]. It is also possible that the impurities are charge neutral and chemically inert, having no effect on the device performance.

To the best of our knowledge, only a few studies of the effects of impurities in semi-conducting polymers on electronic device performance have been published [5,8,11]. Urien et al. performed Particle Induced X-ray Emission (PIXE) analysis on poly(3-hexylthiophene) (P3HT), revealing several impurity atom species and an increase in organic field-effect transistor (OFET) performance upon removal of these impurities [5]. They did not, however, quantify the levels of impurities. Kawamura et al. reported a decrease in OFET off-currents upon the removal of Zn and Ni impurities from P3HT, suggesting the metal residues acted as bulk traps [11]. Sonar et al. presented a study of poly(9,9-dioctylfluorene) fabricated by two different methods and purified a number of times, resulting in different Pd and Ni levels [8]. They concluded that it is not necessary to remove all traces of palladium to obtain satisfactory device performance, suggesting that complete removal of metal residues from semiconductors may not be necessary for OFET applications.

In this article, we aim to investigate the effects of impurities in poly[(2,5-bis(3-decylthiophen-2-yl)thieno[2,3-b]thiophene] on the electronic properties of OFETs. Eight batches of the polymer were obtained after different purification and extraction steps, resulting in samples containing different impurity levels. PIXE and PIGE were chosen for the elemental analyzes due to their ability, when combined, to give the concentrations of most elements present in a solid target [12].

In recent years an external ion beam set-up has been developed at the Åbo Akademi University [13]. Equipped with a high precision beam current monitor [14] and a computer controlled XY-stage the set-up offers accurate determinations of elemental concentrations and distributions in solid materials. Hence, the PIXE and PIGE analysis can be performed on a small amount of dry polymer mate-

rial, thus avoiding contaminations from solvents and interference from the substrate. The small amount of material required also makes these methods suitable for testing materials produced on laboratory scale. The methods are also fast, and cover a wide range of concentrations.

2. Materials

The polymer, poly[2,5-bis(3-decylthiophen-2-yl)thieno[2,3-b]thiophene], was prepared by a microwave-assisted Stille coupling as illustrated in Fig. 1 [15]. Sample 1 was obtained by direct precipitation of the reaction mixture, and materials 2 to 4 by sequential washing in acetone, petrol and methanol *via* Soxhlet extraction. Material sample 4 was then split into four batches that all underwent different purification procedures to yield samples 5 through 8. The extraction methods are summarized in Table 1. A more detailed description of the synthetic method and the subsequent extraction methods can be found in the experimental section below.

The purpose of the different purification and extraction methods was to test the relative effectiveness of each of these steps and identify which steps were critical for the reduction of metal impurity content. Furthermore, by gaining a deeper understanding of which steps were critical for the removal of metal impurities, a more efficient standard purification protocol could be constructed for polymers prepared by this synthetic method.

Poly[(2,5-bis(3-alkylthiophen-2-yl)thieno[2,3-b]thiophene] materials demonstrate excellent air stability in FET devices [16]. This is due to the deeper and more stable HOMO energy level of the polymer class that results in a material that is much less susceptible to oxidative doping compared to P3HT. For poly[(2,5-bis(3-decylthiophen-2-yl)thieno[2,3-b]thiophene], the HOMO level energy was determined by photoelectron spectroscopy AC-2 measurements and measured as HOMO = -5.3 eV [21].

3. Elemental analysis

About 15 mg of the polymer sample material was pressed to a pellet (diameter 13 mm). Pure graphite was used as backing material to minimize the amount of sample material [17]. The samples were irradiated with a 3 MeV proton beam from the Åbo Akademi MGC-20 cyclotron. The acquisition time was about 500 s with a beam current of 10 nA. All irradiations were performed in air to avoid heating and charge build-up. A strong ion luminescence from the irradiated spot on the polymer samples was observed in the beginning of the proton irradiation but faded away within a few seconds. This phenomenon indicates some changes in the molecular structure but does not affect the elemental concentration measure-

Table 1

Summary of the purification and extraction procedures used for the material samples, and the number (M_n) and weight (M_w) average molecular weights for the samples.

Sample	Starting sample	Procedure	M_n	M_w
1		Re-precipitation	36200	73200
2	1	Acetone Soxhlet extraction	38000	76700
3	2	Petrol Soxhlet extraction	33800	74400
4	3	Methanol Soxhlet extraction	35900	73900
5	4	Re-precipitation	35000	77200
6	4	Silica treatment	31200	62000
7	4	Thiol–silica treatment	33800	64000
8	4	Thiourea–silica treatment	38000	65100

ments. The radiation emitted from the sample during the irradiation was measured with an IGP X-ray detector for PIXE analysis and with an HPGe gamma detector for PIGE analysis. The integrated charge on the target needed for quantification was determined from measurements of light induced in air by the proton beam [14]. The obtained PIXE spectra were analyzed using the GUPIX software package [18]. The calibration was checked using the USGS granite CRM G-2. The sodium and magnesium concentrations were obtained from peak height analyzes of the gamma spectra using the SAMPO 90 program [19]. The calibration method and the calculation of the limits of detection have been described earlier [20].

4. Results and discussion

4.1. Elemental analysis

Fig. 2 shows a typical PIXE spectrum, it has clear peaks from S, Fe, Br, Pd and Sn. Detailed results of the PIXE analysis are shown in Table 2. Sulfur can be found in the polymer backbone and bromine in the ends of the polymer chain, the other elements are considered to be impurities. Sample number 1 is the crude polymer, containing the highest level of impurities. The high ratio between bromine and sulfur in the starting material, compared to the
Fig. 2. Energy spectrum of sample 3 as an example of a typical spectrum for the polymer. The K_α peaks correspond to transitions from the L- to the K-shell, transitions from higher shells gives the K_β peaks.

other samples, suggests that it either contains free bromine impurities (either ionic or organic) or low weight polymers (with a high ratio of bromine end groups) that were removed in the subsequent cleaning steps. The acetone Soxhlet extraction removed almost 90% of the impurities, the result of which can be seen in column 2 of Table 2. The following petrol Soxhlet extraction reduced the zinc and palladium contents but increased the tin and iron levels. The methanol Soxhlet extraction reduced the iron and tin content (column 4 of Table 2), but increased the palladium level slightly. Sample 6 contained about the same iron than the precursor material 4, the other extraction procedures resulted in slightly higher iron concentrations in the samples (5, 7 and 8). Sample 7 displayed a higher zinc concentration than material 4; in the others (5, 6, and 8) it was unaffected. All extraction procedures reduced the palladium content, the thiourea–silica treatment the most. The tin concentration in sample 8 was reduced from the starting sample 4, in the other three it increased. The increase in impurity concentrations might be due to impurities transferred from the solvents used in the purification, or more plausibly from the removal of polymer material in the purification that was less rich in these impurities. The silica and the thiourea–silica treatments gave the best results. The silica treatment gave the lowest levels of iron and zinc, and low levels of palladium; the lowest total impurity level was obtained with the thiourea–silica treatment, which also gave the lowest level of tin.

The additional information from the PIGE analysis was that sample 5 contained 17 mg/kg and sample 7 contained 30 mg/kg of sodium. The sodium contents in the rest of the samples were below the limit of detection (7 mg/kg). The concentrations of manganese were below the limit of detection (330 mg/kg) for all samples.

4.2. Homogeneity analysis

The homogeneity of the elemental composition was determined by performing additional PIXE analysis on two different material samples. Nine points on each sample were analyzed and the elemental concentrations at each point calculated. Average concentrations and standard deviations for the samples are shown in Table 3. If the relative standard deviation (RSD), the ratio between the standard deviation between the points and the average concentration, is less than or roughly of the same size as the statistical error of the PIXE measurement the impurity concentration is considered homogeneous. In sample 3 the zinc impurities were homogeneously distributed, since the RSD was only 5,5% compared to the statistical error of 16,5%. For the other impurities in material 3, the RSD for Fe (15,4%), Pd (30,3%) and Sn (26,8%), exceeded the statistical errors (6,1%, 2,3% and 7,7%), thus the distribution of these impurities were considered inhomogeneous. For sample 7 the RSD for both Pd (5,5%) and Sn (8,2%) were of the same order as the statistical errors (3,3% and 4,9%), and therefore considered homogeneously distributed. The RSD for both Fe (30,8%) and Zn (59,4%) were larger than the statistical errors (14,9% and 6,2%), suggesting an inhomogeneous distribution of these impurities. The Zn and Fe levels are close to the limit of quantification ($\sim 3^*$ limit of

Sum	15694	1791	1896	1837	1235	1103	1304	973		

detection), which partially explain the high RSD. Sample 7 is more homogeneous than sample 3, suggesting that the additional cleaning and extraction steps improve the homogeneity of the material.

4.3. OFET characteristics

Typical transfer curves (I_d–V_g traces) for the devices are shown in Fig. 3a and 3b. All devices displayed the same I–V

Table 3
Average concentrations (C_{ave}) in mg/kg and standard deviations (σ) in impurity concentrations for materials 3 and 7. The RSD-column contains the ratio between the standard deviation and average concentration in per cent. The error column contains the statistical error from the PIXE analysis for the first measurement point.

	C_{ave} [mg/kg]	σ [mg/kg]	RSD [%]	Error [%]	LOD
				For point #1	
Material 3					
Fe	123.7	19.0	15.4	6.1	11.1

Sn	721.2	58.9	8.2	4.9	18.1

characteristics, except for a small variation in the turn-on-voltage. On/Off ratios of 10^4–10^5 were routinely achieved for the devices. The on-currents in the saturated regime (Fig. 3a) were typically on the order of 10^{-6} A, and slightly lower in the linear regime (Fig. 3b). In the off-state, the currents regularly reached levels of 10^{-9}–10^{-10} A. The variations in on-currents seen in Fig. 3a and b are due to the turn-on-voltage shift between the devices. The conductivity in the off-state can be increased by impurities in the semiconductor, resulting in leak currents to the gate and low on/off-ratios [21]. Off-currents in devices made from the same sample material display fluctuations on the same order of magnitude as devices made from different samples. We therefore conclude that the differences in off-currents in Fig. 3a are statistical. We also found that manual patterning of the devices, i.e. reducing the area of the semi-conductor, reduced the off-current with up to one order of magnitude.

Sonar et al. reported that metal residues, especially palladium, causes hysteresis in poly(9,9-dioctylfluorene) OFET devices [8]. Their devices displayed less hysteresis when fabricated from polymers containing 2000 mg/kg palladium than from polymers with higher palladium levels (3300 mg/kg or 4000 mg/kg). We did not observe this kind of behavior in our transistors. Little or no hysteresis could be observed while operating the devices in the on-state, and there were no systematic difference between the devices.
Fig. 3. Typical transfer curves for the material samples, measured at a constant drain bias of (a) −50 V and (b) −5 V. The channel length, L, was 35 μm and the width, W, 1.5 mm.
Fig. 4. Typical field-effect mobilities. The linear mobilities were measured at a constant drain voltage of $V_d = -5$ V and the saturated at $V_d = -50$ V. The error bars show the maximum deviation between the measured mobility values and average mobilities.

The field-effect mobilities measured in both the linear and saturated regimes are plotted as a function of the total impurity concentrations in Fig. 4. The linear mobilities typically ranged from ∼0.008 to 0.01 cm²V⁻¹s⁻¹ and the saturated from ∼0.01 to 0.03 cm²V⁻¹s⁻¹, the latter agrees with earlier reported mobilities [16]. The linear mobilities are lower than the saturated, but no systematic difference in the mobilities with respect to the measured impurity concentrations could be observed.

The SiO₂-semiconductor interface is very sensitive to the device fabrication methods [21,22] and small variations in fabrication parameters might lead to different results. It has been shown that plasma treating the SiO₂-surface for different times introduces different amounts of charges to the surface [21], such charges will shift the turn-on voltage [23]. Turn-on voltage as a function of impurity concentration for some typical devices is shown in Fig. 5. V_0 is very sensitive to device fabrication, which explains the offset between the turn-on voltages for the two series. All devices in the same series were fabricated at the same time under the same conditions, making the turn-on voltages comparable within the same series. No clear trends can be observed in the turn-on voltage with regards to the impurity concentrations.

5. Conclusions

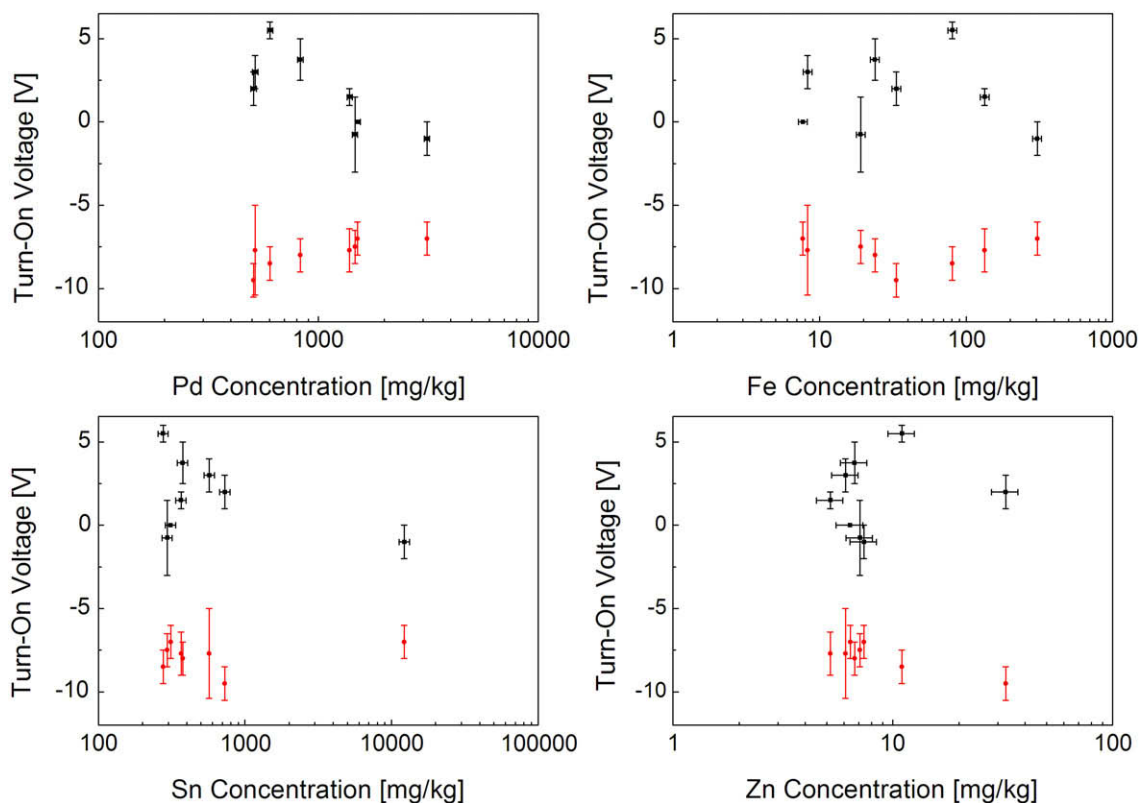
We have used PIXE and PIGE to determine the elemental concentrations in poly[(2,5-bis(3-alkylthiophen-2-yl)thieno[2,3-b]thiophene] samples that have undergone successive washing and extraction procedures to remove impurities. The levels of impurities in each sample were measured and FETs were made from the materials. Analysis of the homogeneity of impurity levels showed that the successive cleaning and extraction procedures improved the homogeneity of the Sn and Pd impurities. Characterisation of the FETs shows that there were no significant


Fig. 5. Turn-on voltages as function of impurity concentrations for two series of devices. The error bars show the maximum deviation between the measured turn-on-voltages and average turn-on-voltages.

differences between the devices made from different material samples. We have shown that reducing the metal residue levels below the one measured in sample 1 (300 mg/kg Fe, 7 mg/kg Zn, 3000 mg/kg Pd and 12000 mg/kg Sn) does not improve the FET performance. The methods presented in this article could be used to study most semicrystalline polymer semi-conductors, to determine if present day large-scale synthesis provides sufficiently pure materials for organic transistor applications.

6. Experimental

6.1. Polymer synthesis

A 20 ml glass vial was charged with a stirrer bar, 5,5'-dibromo-4,4'-didecylbithiophene (0.967 g, 1.6 mmol), 2,5-bis(trimethylstannyl)thieno[2,3-b]thiophene (0.745 g, 1.6 mmol), tris(dibenzylideneacetone)dipalladium (0) (29 mg, 2 mol.%), tri(o-tolyl)phosphine (39 mg, 8 mol.%) and chlorobenzene (16 mL). The glass vial was purged with nitrogen and securely sealed. The glass vial was placed into a microwave reactor (Emrys Creator, Personal Chemistry Ltd) and heated to 180 °C. A temperature ramp was used such that the vial was heated with stirring at 140 °C for 120 s, then at 160 °C for 120 s and finally at 180 °C for 15 min. Elapsed time was only calculated once the temperature had been reached. Bromobenzene (33 μL, 20 mol.%) was added *via* syringe and the reaction mixture heated at 160 °C for 60 s in the microwave reactor. Tributylphenyltin (107 μL, 20 mol.%) was added *via* syringe and the reaction mixture heated at 160 °C for 60 s in the microwave reactor.

6.2. Purification and extraction methods

The reaction mixture was precipitated into a mixture of 37% hydrochloric acid (50 mL) and methanol (500 mL) and stirred for 1 h. The polymer was collected by filtration, washed with water followed by methanol, and dried under vacuum to yield sample 1. Sample 1 was washed (*via* Soxhlet extraction) with acetone for 24 h and dried under vacuum to yield sample 2. Sample 2 was further washed (*via* Soxhlet extraction) with petrol 40–60 for 24 h and dried under vacuum to yield sample 3. Sample 3 was further washed (*via* Soxhlet extraction) with methanol for 24 h and dried under vacuum to yield sample 4. A bulk solution of sample 4 was formulated in hot chloroform (100 mL). A portion of the sample 4 bulk solution (25 mL) was precipitated from methanol (200 mL), and the polymer was collected by filtration, washed with methanol, and dried under vacuum to yield sample 5. Another portion of the sample 4 bulk solution (25 mL) was stirred at 50 °C over silica (1 g) for 1 h under N_2. The solution was filtered through a plug of cotton wool, which was washed with hot chloroform. The filtrate was precipitated from methanol (200 mL). The polymer was collected by filtration, washed with methanol, and dried under vacuum to yield sample 6. A portion of the sample 4 bulk solution (25 mL) was also stirred at 50 °C over thiol-functionalized silica (1 g) for 1 h under N_2. The solution was filtered through a plug of cotton wool, which was washed with hot chloroform. The filtrate

was precipitated from methanol (200 mL). The polymer was collected by filtration, washed with methanol, and dried under vacuum to yield sample 7. Another portion of the sample 4 bulk solution (25 mL) was stirred at 50 °C over thiourea-functionalized silica (1 g) for 1 h under N_2. The solution was filtered through a plug of cotton wool, which was washed with hot chloroform. The filtrate was precipitated from methanol (200 mL). The polymer was collected by filtration, washed with methanol, and dried under vacuum to yield sample 8.

6.3. OFET fabrication

The poly[(2,5-bis(3-decylthiophen-2-yl)thieno[2,3-b]thiophene] samples were received from Merck Chemicals Ltd. Molecular weight determinations were carried out in chlorobenzene solution on an Agilent 1100 series HPLC using two PL Mixed B columns in series and the system was calibrated against narrow weight PL polystyrene calibration standards. 10 mg/ml solutions were made in 1,2-dichlorobenzene from each polymer sample under dry nitrogen atmosphere in a glove box. The solutions were heated on a hot plate at 80 °C for 2 h.

Thin-film organic field-effect transistors were fabricated on doped silicon substrates with 300 nm thermally grown silicon oxide (SiO_2), where the substrate served as a common gate electrode. The capacitance of the insulating SiO_2 layer, C_i, was calculated to be 11.5 nF(cm)$^{-2}$, assuming the permittivity of SiO_2 to be 3.9 nF. Prior to organic film deposition the substrates were ultrasonicated at 60 °C in H_2O, acetone and IPA successively for 10 min. The substrates were etched for 30 s in an O_2-plasma and treated with a silylating agent octadecyltrichlorosilane at 10 mM concentration in toluene for 15 min at 60 °C, before the film deposition. Semi-conductor films were deposited on the substrates in dry nitrogen atmosphere in a glove box by spin coating at 2000 rpm for 78 s and annealed at 100 °C for 60 min on a hot plate inside the box. About 30 nm thick Au electrodes were vacuum evaporated on top of the semiconductor film using a custom built evaporator inside the glove box. All transistors were fabricated with top-electrode bottom-gate configuration with a channel length, L, of 35 μm and channel width, W, of 1.5 mm. Several series of devices were fabricated to verify the reproducibility of the results. All samples in one series were manufactured at the same time, making the elemental concentrations in the material the only difference between the samples.

6.4. Electrical characterization

Electrical characterization of the devices was performed in a custom built probe station inside the glove box. An Agilent 4142B parameter analyzer controlled via Labview on a PC was used to conduct the measurements. Characterization of the transistors was conducted at constant drain bias, V_d, −5 V for the linear regime and −50 V for the saturated. The gate voltage, V_g, was swept from +20 V to −50 V in steps of 1 V and the drain current, I_d, was measured. Standard methods were used to calculate the field-effect mobilities and threshold voltages [22]. V_0 is graphically

calculated as the gate voltage where I_d starts growing exponentially.

ARTICLE INFO

ABSTRACT

Tetracene-based organic thin-film transistors (OTFTs) were prepared using a neutral cluster beam deposition (NCBD) method. The effect of surface modification with an amphiphilic surfactant, octadecyltrichlorosilane (OTS), on the formation of thin films and the geometric influence of channel length and width on the transistor characteristics were systematically examined. The estimated trap density and temperature-dependence of the field-effect mobility in the range of 10–300 K demonstrated that surfactant pretreatment decreased the total trap density and activation energy for hole-transport by reducing structural disorder in the active layer. In particular, the room-temperature hole mobilities of 0.162 and 0.252 cm^2/Vs for untreated and OTS-pretreated devices were among the best to date for polycrystalline tetracene-based transistors using SiO_2 gate dielectric layers without any thermal post-treatment.

1. Introduction

Compared to conventional electronic devices made of inorganic materials, organic-based semiconductor electronics have many advantages, such as their large-area coverage, structural flexibility, and low-cost fabrication. The performance of some organic thin-film devices is comparable to that of hydrogenated, amorphous Si-based devices [1–7]. Organic thin-film devices utilizing fused-ring polycyclic aromatic hydrocarbon compounds have been extensively investigated. This is well-demonstrated by the polyacene-based devices including tetracene, a Π-conjugated molecule consisting of four aligned condensed benzene rings (Fig. 1) in organic thin-film transistors (OTFTs), light-emitting transistors and solar cells [8–14]. De Boer et al. fabricated the transistors based upon the

free-standing tetracene single crystals by applying the physical vapor deposition method under temperature-gradient conditions to obtain a high room-temperature mobility of 0.4 cm^2/Vs [8]. Gundlach and co-workers studied the polycrystalline tetracene-based transistors using the amphiphilic surfactant, octadecyltrichlorosilane (OTS), and obtained a mobility as high as 0.1 cm^2/Vs [9].

In fabricating high-performance OTFTs, both preparation of highly crystalline active layers and systematic optimization of device structures are important prerequisites. Various techniques such as traditional vapor deposition and solution processing methods have been proposed to produce high-quality thin films. Conversely, the neutral cluster beam deposition (NCBD) method is less popular but highly promising [15–21]. The NCBD scheme utilizes weakly bound clusters produced when the organic vapor-phase molecules sublimated by resistive heating undergo adiabatic expansion into a high vacuum. Due to the large translational energy of cluster beams with high

directionality, the collision of clusters with the substrate results in efficient decomposition into individual molecules, and the subsequent migration leads to very smooth, uniform thin films. The NCBD scheme has demonstrated significant enhancement in the surface morphology, crystalline quality, and film packing density. In particular, the distinctive advantage of low substrate-temperature deposition cannot be accomplished simply by employing conventional deposition techniques.

In this paper, we describe our systematic investigation of the performance of tetracene-based OTFTs prepared by the NCBD method. No comparative study examining the effects of surface pretreatment and geometry on device performance and transport characteristics has been reported to the best of our knowledge. We first focused on the effects of surface modification with an amphiphilic OTS surfactant on the morphology, crystallinity, and packing density of tetracene thin films. Secondly, we investigated the influence of the geometric dimensions upon device characteristics to optimize the transistor structure for higher performance. Finally, the transport mechanisms were examined in the temperature range of 10–300 K. The strong correlation of device performance with structural and morphological properties of the active layers is discussed.

2. Experiment

Fig. 1 displays molecular structures of the tetracene and OTS, and a schematic diagram of a top-contact transistor along with the bias condition. The substrates used in this study consisted of a highly doped, n-type Si wafer coated with an aluminum layer as the gate electrode and thermally grown 1000 Å-thick SiO_2 layers as the gate dielectric. The substrates were first cleaned by a series of sequential ultrasonic treatments in acetone, hot trichloroethylene, acetone, HNO_3, methanol, and deionized water, and finally blown dry with dry N_2 [22]. The substrates were finally exposed to UV (254 nm) for 15 min [23]. Such a rigorous cleaning procedure significantly increased device performance. For surface modification, the cleaned substrates were immersed in a 1×10^{-3} M solution of OTS in n-hexane (Aldrich Co.) for 24 h at room temperature.

The active layers of the tetracene thin films were prepared by a homemade NCBD apparatus previously described in detail [15], and therefore, only a relevant account is presented here. The as-received tetracene sample (Sigma–Aldrich Co.) was placed inside the enclosed, cylindrical, crucible cell with a diameter of 1.0 and 1.0 mm-long nozzle. The sample was sublimated by resistive heating between 520 and 550 K, and then the tetracene vapor underwent adiabatic, supersonic expansion into the high-vacuum drift region at a working pressure of 3×10^{-6} Torr. The resultant, highly-directional, weakly bound neutral cluster beams were produced at the nozzle throat and deposited directly onto the substrates with an average thickness of ca. 500 Å, and a deposition rate of 5 Å/s. Electron-beam evaporation using a rectangular-shaped shadow mask was utilized to produce 500 Å-thick Au source and drain electrodes. To determine the influence of the geometric dimensions on device performance, the devices were prepared with several channel lengths (L) of 200, 660, 800, and 1400 μm, at a fixed channel width (W) of 500 μm. Depending on the channel length, the four different kinds of devices were grouped into class I, II, III and IV, respectively.

The thickness, contact angle, surface morphology, and structural properties were characterized using an alpha-step surface profile monitor, a contact angle goniometer, atomic force microscopy (AFM), and X-ray diffractometry (XRD). The current–voltage (I–V) characteristics of the OTFTs and their temperature-dependence were measured by an optical probe station connected to a HP4140B pA meter-dc voltage source unit and a 10 K-closed cycle refrigerator at a base pressure of 1×10^{-2} Torr over the temperature range of 10–300 K. Various parameters were derived from the fits of the I–V characteristics.

3. Results and discussion

3.1. Comparison of surface morphological and structural properties

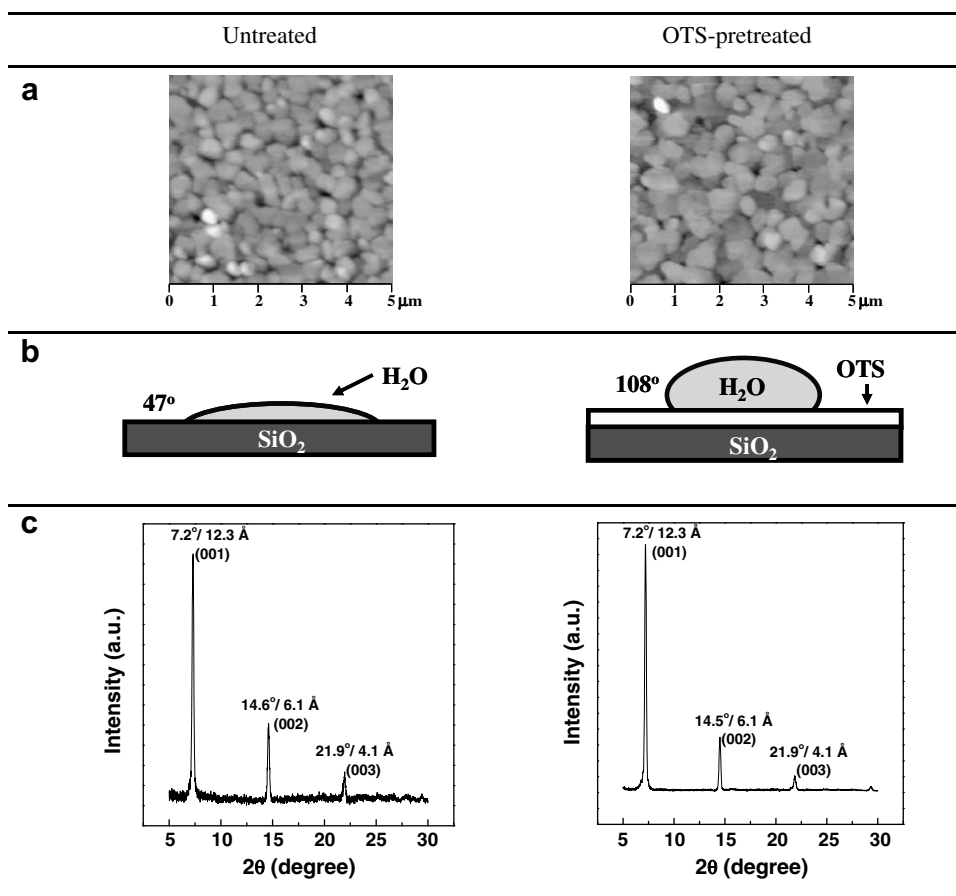
Surface analysis using an AFM apparatus in the non-contact mode was employed to characterize the morphology of the tetracene active layers. Fig. 2a shows the 2-dimensional AFM images taken over an area of 5×5 μm^2 for the untreated and OTS-pretreated tetracene films at a nominal thickness of 500 Å. Both films were completely covered with highly packed grain crystallites. Compared to the data obtained at the same deposition rate using the conventional vacuum sublimation method [12], our grain size appeared larger in both untreated and


Fig. 2. Comparison of (a) 2-dimensional AFM micrographs (5×5 μm^2), (b) contact angles with water, and (c) XRD spectra for the 500 Å-thick tetracene thin films prepared on untreated and OTS-pretreated SiO$_2$ substrates at room temperature using the NCBD method.

OTS-pretreated films. The increase can be ascribed to the characteristics of the neutral cluster beam method, in which the larger energetic cluster seeds enhance the formation of grain crystallites on the early stages of growth. The quantitative values of the root-mean-square roughness of the films were obtained by conducting section analyses over at least four areas in the 5×5 μm^2 films using the built-in software of the AFM apparatus. The roughness values for the untreated and OTS-pretreated tetracene films were measured to be 40 and 30 Å on the average, respectively.

The pretreated tetracene films showed a lower roughness and a higher packing density, suggesting that the amphiphilic OTS molecules capable of forming bonds with hydrophobic tetracene and hydrophilic SiO$_2$ provided favorable deposition conditions. This result is also consistent with the contact angle measurement in Fig. 2b. The surface pretreatment increased the contact angle with water from 47° to 108°, indicating that the OTS-covered substrate surface becomes highly non-polar and leads to a significant reduction in the structural mismatch at the interface during the initial accumulation of tetracene molecules.

The effect of the surface pretreatment was also clearly demonstrated in the X-ray diffraction measurements ob-

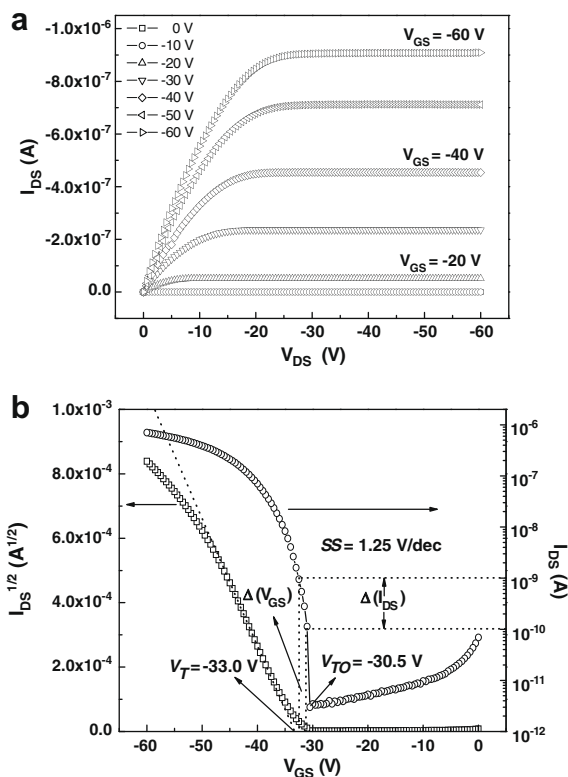
tained using Cu Kα radiation in a symmetric reflection, coupled θ–2θ scanning mode. Fig. 2c shows the comparative XRD results for the 500 Å-thick tetracene thin films deposited on the untreated and OTS-pretreated SiO$_2$ substrates at room temperature. Tetracene single crystals are known to have a triclinic structure with two molecules in the unit cell [24–27]. The strong and sharp first-order peak, as well as distinctive higher-order multiple peaks, can be fitted to a series of (001) reflection lines with multiple d spacing. The interplanar spacing d_{001} from the peak positions is determined to be 12.3 Å for both films, which is in good agreement with the previous XRD reports of d_{001} = 12.1 and 12.4 Å for as-deposited tetracene films [17,24,25]. The higher signal-to-noise in the XRD patterns of OTS-pretreated films suggests that the amphiphilic surfactant appears to substantially affect the growth of tetracene films and the packing between tetracene crystallites as a well-ordered monolayer template, which is consistent with the results shown in the AFM micrographs. The observed, unique advantage of the facile growth of smooth crystalline films through the low substrate-temperature mechanism is characteristic of the NCBD method. In addition, the formation of well-packed tetracene films is very likely to improve performance of the OTFT devices due to


Fig. 3. (a) Current–voltage characteristics at various gate voltages for the OTS-pretreated tetracene-based transistors in class IV. (b) Variation of $I_{DS}^{1/2}$ (left axis) and $\log(I_{DS})$ (right axis) vs. V_{GS} at a constant $V_{DS} = -60$ V.

more favorable hopping of the polaron charge carriers between the grain crystallites.

3.2. Comparison of mobilities, geometry effects and trap densities

A comparative characterization analysis of top-contact, tetracene-based transistors grouped into the 4 classes, I, II, III, and IV, depending on W/L, was performed. The I–V characteristics of untreated and OTS-pretreated transistors were similar to those for typical p-type semiconductors and complied well with the standard field-effect transistor equations working in the accumulation mode. Fig. 3 demonstrates the typical plots of drain-source current (I_{DS}) as a

function of the drain-source voltage (V_{DS}) for various gate-source voltages (V_{GS}). At a fixed V_{GS}, I_{DS} increases linearly with V_{DS} in the low V_{DS} regime, and then the I_{DS} tends to saturate in the large V_{DS} regime due to the pinch off in the accumulation layer. In the saturation regime, I_{DS} increases with V_{GS} and satisfies the following relationship

$$I_{DS} = \frac{WC_i\mu}{2L}(V_{GS} - V_T)^2$$

where C_i is the capacitance per unit area of the SiO$_2$ gate dielectric, μ the field-effect mobility, and the channel lengths (L) of 200, 660, 800, and 1400 μm are at a fixed channel width (W) of 500 μm. For thermally grown, 1000 Å-thick SiO$_2$, the value for C_i is known to be 34.5 nF/cm^2. From the analysis of the observed I–V characteristics, several device parameters such as μ, current on/off ratio (I_{on}/I_{off}), threshold voltage (V_T), subthreshold slope (SS), and trap density (N_{trap}) could be deduced.

Various derived device parameters are listed in Table 1 and were obtained for more than 160 untreated and OTS-pretreated transistors: on the average, 20 devices for each of eight different groups belonging to classes I–IV. In the case of the mobility data, the maximum mobilities (μ_{eff}) are listed with the average mobilities (μ_{eff}^{avg}) with the standard deviation. Three characteristic features with respect to the device performance can be found in Table 1.

Firstly, the whole groups of the NCBD-based transistors in this study showed room-temperature mobilities greater than 4.5×10^{-2} cm^2/Vs, and the surface modification with OTS always enhanced the mobilities. Although the devices in class I showed lower mobilities compared to other class devices, still, these mobilities were comparable to or higher than those from typical tetracene-based transistors, which ranged between ca. 1×10^{-4} and 0.12 cm^2/Vs [9,28]. The observed high mobilities can be rationalized that after the surface pretreatment, the formation of the smooth tetracene active layer, with higher structural organization, induces more efficient charge-carrier transport *via* face-to-face intermolecular interactions between the Π–Π stacks. The outcome of the pretreatment also suggests that the grain boundary-scattering of hole carriers in the tetracene active layers was the key obstacle to favorable charge conduction, as in poly-silicon- and pentacene-based transistors [22]. Furthermore, one of the critical factors determining device performance was the production of highly ordered thin films with good film connectivity, which was consistent with the AFM images and XRD diffractograms described in the previous section.

Table 1
Device parameters deduced from current–voltage characteristics.

	W/L	Surface pretreatment	μ_{eff} (cm^2/Vs)[a]	$\mu_{eff}^{avg} \pm \sigma$ (cm^2/Vs)[a]	I_{on}/I_{off}	V_T (V)	SS (V/dec)	N_{trap} (10^{12}/cm^2)
Class I	500 μm/200 μm	untreated	5.7×10^{-2}	0.045 ± 0.011	10^5	−37	1.21	1.25
		OTS	0.126	0.098 ± 0.014	10^6	−40	0.78	0.96
Class II	500 μm/660 μm	untreated	9.1×10^{-2}	0.064 ± 0.018	10^5	−34	1.32	0.93
		OTS	0.148	0.11 ± 0.02	10^6	−33	0.84	0.85
Class III	500 μm/800 μm	untreated	0.124	0.10 ± 0.02	10^5	−38	1.58	0.81
		OTS	0.208	0.15 ± 0.02	10^6	−26	0.85	0.74
Class IV	500 μm/1400 μm	untreated	0.162	0.12 ± 0.03	10^5	−37	1.59	0.62
		OTS	0.252	0.19 ± 0.03	10^5	−33	1.25	0.48

[a] The hole mobility data in the text represents the maximum values (μ_{eff}). Considering the distributions of the OTFT characteristics derived, most of the μ_{eff} values lie within $\mu_{eff}^{avg} \pm 2\sigma$ (standard deviation).

Secondly, the geometric configuration effect on the mobilities was examined for the four different W/L ratios of the untreated and OTS-pretreated devices in classes I–IV. Fig. 4 represents the summarized results of the dimension effect on the mobilities whereby the obtained data showed that, at a constant channel width, the field-effect mobility increased as the channel length became longer (with decreasing W/L ratio), irrespective of surface modification. The maximum hole mobilities of 0.162 and 0.252 cm²/Vs for untreated and OTS-pretreated devices in class IV were among the best for the polycrystalline tetracene-based OTFTs reported to date for a SiO₂ gate dielectric layer. We note that the W/L ratio of our devices is less than $W/L = 10$ which is recommended to ignore a contribution of stray currents in these devices. As a result the mobilities might be slightly overestimated. However, when extrapolating the mobilities in Fig. 4 to smaller channel lengths of $W/L > 10$ where the stray current contribution is negligible, the observed mobilities of 0.1 cm²/Vs are still equal or slightly higher than those reported previously.

Thirdly, the total trap density was also consistent with the device performance and surfactant pretreatment effect. The traps can be identified as structural disorders and/or defects. The N_{trap} value was estimated by the following relationship:

Fig. 4. Variation of field-effect mobilities as a function of channel length for untreated and OTS-pretreated tetracene-based transistors.

Fig. 5. Temperature-dependence of the field-effect mobilities for (a) OTS-pretreated, and (b) untreated tetracene-based transistors in class IV.

$$N_{trap} = \frac{C_i |V_T - V_{TO}|}{e}$$

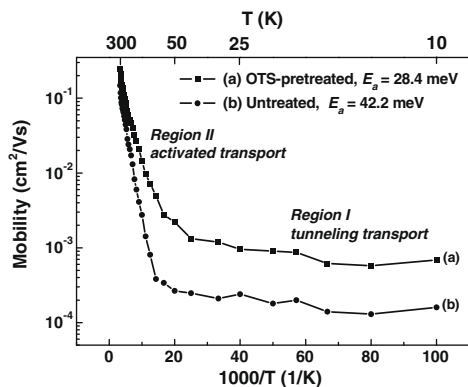
where e the elementary charge and V_{TO} is the turn-on voltage, at which the drain current starts to increase exponentially as indicated in Fig. 3 [29]. There have been no other tetracene-based devices to which our current N_{trap} results can be directly compared. In Table 1, the surface modification with OTS clearly reduced the trap densities in all active layers. It should be noted that the tetracene thin films were deposited on SiO₂ substrates at room temperature without any thermal post-treatment. In comparison to the previous reports involving thermal post-treatment, the observed low trap densities of the OTS-pretreated thin films can be attributed to the characteristic growth of well-connected, polycrystalline thin films produced by the weakly bound neutral cluster beams.

3.3. Comparison of transport characteristics

The temperature-dependence of the field-effect mobility was examined over a wide temperature range from 300 to 10 K. Fig. 5 represents the typical behavior of the mobilities as a function of temperature in class IV. Two domains in both logarithmic plots were observed: temperature-dependent region II (50 K < T < 300 K) and temperature-independent region I (10 K < T < 50 K). In low-temperature region I, the conduction of the majority hole carriers can be described by a so-called tunneling process occurring at the Au–(OTS-)tetracene interfaces. On the other hand, region II is attributed to a thermally activated transport mechanism, where the hole conduction is governed by thermal overcoming of the shallow traps present in the tetracene active layers. The behavior in region II was well fitted to the Arrhenius relation:

$$\mu_{eff} \propto \exp(-E_a/kT)$$

where E_a and k are the activation energy and Boltzmann constant, respectively. From the analysis of the slope of the logarithmic plot, the activation energies were estimated to be 42.2 and 28.4 meV for the untreated and OTS-pretreated devices.

The low activation energies derived from the temperature-dependence are consistent with the aforementioned device characteristics. Since the origin of the thermal activation process lies mainly in overcoming the traps produced by the structural imperfections in the active layers, the low activation energies derived in Fig. 5 correlated strongly with the good crystallinity of the tetracene thin films and the low trap densities in Table 1. The high quality of the NCBD-based thin films is also evidently manifested in the comparison to those reported elsewhere. For instance, Newman et al. examined device performance of bottom-contact, single crystal, tetracene-based transistors and reported that the mobility over the range of 220 K < T < 270 K was thermally activated with an E_a of 49–51 meV [30]. In the case of OTS-pretreated, pentacene-based transistors prepared by thermal evaporation, Minari et al. reported an E_a of 54.8 meV [31]. The lower activation energy and trap density observed in this study strongly imply that the higher quality of the surface-modified NCBD


films eventually results in highly effective hole conduction between the well-connected polycrystalline grains, as well as the excellent mobilities in the tetracene-based transistors.

4. Summary

Tetracene-based, top-contact OTFTs fabricated using a neutral cluster beam deposition method were characterized. In comparison to untreated thin films, surface modification with an amphiphilic OTS surfactant improved growth of tetracene active layers, as manifested in the contact angles, AFM, and XRD measurements. The trap density and temperature-dependence of the field-effect mobility in the range of 10–300 K demonstrated that the OTS pretreatment decreased the total trap density and activation energy for hole conduction by reducing structural disorder in the active layer. The influence of device configuration on the transistor characteristics was systematically examined: the field-effect mobility increased as the channel length became longer at a constant channel width. In particular, room-temperature hole mobilities as high as 0.162 and 0.252 cm^2/Vs for untreated and OTS-pretreated devices were among the best to date for polycrystalline tetracene-based transistors using SiO_2 gate dielectric layers without any thermal post-treatment.

Department of Organic Device Engineering, Yamagata University, Yonezawa, Yamagata 992-8510, Japan

ABSTRACT

We synthesized π-conjugated lithium phenolate complexes, lithium 2-(2-pyridyl)phenolate (LiPP), lithium 2-(2′, 2″-bipyridine-6′-yl)phenolate (LiBPP), and lithium 2-(isoquinoline-1′-yl)phenolate (LiIQP). These complexes showed lower sublimation temperatures of 305–332 °C compared to 717 °C of LiF. The organic light-emitting devices (OLEDs) using these complexes as an electron injection layer exhibited high efficiencies which are comparable to that of the device using LiF. Especially, a 40-nm thick film of LiBPP or LiPP was effective as an electron injection material, providing low driving voltages, while such a thick film of LiF serves as a complete insulator, resulting in high driving voltages.

1. Introduction

In organic light-emitting devices (OLEDs), aluminum metal has been widely used for cathode because of its high stability in air and easy processability. However, work function of Al (4.2 eV) as an anode is not low enough to inject electrons into organic layer at low driving voltages. In the first report on an efficient OLED by Tang and Van Slyke, Mg:Ag alloy was used to improve electron injection from cathode [1]. Later, Li:Al alloy and double layer cathode of Li/Al were found to reduce driving voltage drastically [2]. These effects are due to lower work function of Li than that of Mg. Insertion of thin inorganic Li salt layer, such as Li_2O [3] or LiF [4], between organic layer and cathode Al was found to be also very effective to reduce electron injection barrier to the organic layer, and now it is widely used. LiF is expected to be reduced to Li by thermally activated hot Al in successive deposition, and interacts with an electron-transporting material like an electron donor [5]. That is why the thickness of LiF has to be very thin, no thicker than 1 nm, to be fully reacted by Al and not to leave unreduced insulating part of LiF. High temperature is also required to evaporate LiF under vacuum. Such thin thickness and low processability are disadvantages, especially in industrial process and large area deposition. On the other hand, organic π-conjugated ligands can be helpful to reduce evaporation temperature in a deposition process, and give charge-transporting ability to the complex. We previously reported that lithium quinolinolate complex (Liq) serves as an excellent electron injection material (EIM), and its thickness is much less sensitive to a performance of the device than that of LiF, because of an electron-transporting ability of Liq [6].

Scheme 1. Synthetic route of the lithium complexes. Reagents and conditions: (i) 2-hydroxyphenylboronic acid, Pd(PPh$_3$)$_4$, K$_2$CO$_3$ aqueous, toluene, ethanol, reflux, 8 h and (ii) LiOH·H$_2$O, methanol, r.t., 1 h.

In this paper, we report new series of Li complexes, such as lithium 2-(2-pyridyl)phenolate (LiPP), lithium 2-(2′, 2″-bipyridine-6′-yl)phenolate (LiBPP), and lithium 2-(isoquinoline-1′-yl)phenolate (LiIQP), and their improved electron-transporting ability in OLED due to their more extended π-conjugated ligand than that of Liq.

2. Results and discussion

2.1. Synthesis, thermal and optoelectrochemical properties

Phenol ligands **1**–**3**, substituted 2-pyridyl or 2-quinolyl group on ortho position, were synthesized by Suzuki coupling of 2-hydroxyphenylboronic acid and the corresponding bromopyridine or chloroquinoline. Complexation reactions of the phenols and lithium hydroxide in methanol were straightforward, and the yields were quantitative (Scheme 1). All these complexes were further purified by train sublimation, and characterized with ^{1}H NMR and elemental analysis. Melting points of the complexes were relatively high (>300 °C) although their molecular weight is only around 200, probably because of their strong molecular interaction derived from their ionic property (Table 1). The complexes were sublimable, and the sublimation temperatures T_ss of the complexes were estimated from 10 wt% loss temperature in thermal gravimetric analysis under vacuum (Fig. 1). The lithium phenolate complexes showed much lower T_ss around 300 °C, while LiF showed a high T_s of 717 °C. These T_ss are nearly 100 °C lower than their decomposition temperatures, suggesting that the

complexes are not decomposed and do not release lithium ion or neutral atom during the thermal evaporation process.

UV–vis and photoluminescence (PL) spectra of the film on quartz substrates are shown in Fig. 2. LiPP showed a widest π–π* energy gap derived from the ligand **1**, which is estimated from the absorption edge, and LiBPP showed the narrowest gap, derived from the ligand **2**. The photoluminescence of the complexes was blue to green, and the order of λ_{max} is consistent with the order of energy gap from UV spectra. The highest occupied molecular orbital (HOMO) levels of the complexes, or the ionization potentials (I_ps), determined from photoelectron spectrometer surface analysis, were 5.56–5.70 eV, and the lowest unoccupied molecular orbital (LUMO) levels, estimated by the difference of I_p and optically obtained energy gap, were 2.49–2.68 eV.

2.2. OLED performance

The OLEDs with the configuration of an ITO/N,N′-bis(naphthalen-1-yl)-N, N′-bis(phenyl)benzidine (α-NPD) (50 nm)/tris(8-quinolinolato) aluminum (Alq₃) (70 nm)/EIM (0.5–7.0 nm)/Al (100 nm) were fabricated. The device performance is summarized in Table 2. The devices without EIMs:ITO/α-NPD (50 nm)/Alq₃ (70 nm)/Al (100 nm) showed much higher driving voltage and much lower efficiencies compared with those with EIMs. These results demonstrated that the electron injection from Al cathode (4.2 eV) was not blocked by the higher LUMO levels of the lithium complexes, but was rather facilitated, although the LUMO levels of the EIMs (2.5–2.7 eV) are higher than that of Alq₃ (3.2 eV). This improvement of the electron injection is probably because of the low barrier height for the electron injection from the Al cathode, which are the results from the lithium metal doping of the EIL materials

at the cathode interface. As reported [6], the lithium ion in the organic lithium complexes can be reduced by thermally activated Al to release lithium metal, which dopes the EIL materials at the interface to form the gap states. When a thin layer, <3.0 nm, of the lithium complexes was used as an EIM, the turn-on voltages at 1 cd/m² in the all devices were around 3–4 V, and the driving voltages at 100 cd/m² were 6–8 V. The efficiencies are comparable to those of the device using LiF as an EIM. On the other hand, the life time of the devices using these lithium phenolate complexes was the same as that of the device using LiF, and so there was no negative effect of the phenolate ligand for the device stability. These results reveal that the three lithium complexes can be alternative to LiF as an EIM.

In contrast to LiF, these complexes have a π-conjugated ligand, which may act as a charge-transporting moiety. To investigate the electron-transporting ability of the complexes, the devices with a thick EIM layer, having a structure of an ITO/NPD (50 nm)/Alq₃ (70 − x nm)/EIM (x = 20 or 40 nm)/Al (100 nm), were fabricated. Fig. 3 shows the dependency of driving voltage on the thickness of EIM. As the thickness of LiPP increased from 3.0 to 40 nm, the turn-on voltage at 1 cd/m² increased by 8.8–13.2 V. On the other hand, the turn-on voltage with LiBPP and LiIQP increased only by 2.1 and 2.6 V, respectively, with increase of the thickness from 3.0 to 40 nm. At 100 cd/m², LiBPP and LiIQP also showed less increase in the driving voltage compared with that of LiPP. These results show that LiBPP and LiIQP may have higher electron-transporting mobility than LiPP, resulting from their wider π-conjugation.

The EL emissions of the devices were green and ascribed to the emission of Alq₃. However, the EL spectra with a thick LiPP layer exhibited a shoulder peak around 430 nm derived from LiPP emission (Fig. 4). The shoulder peak was increased as the thickness of LiPP increased from 20 to 40 nm. These shoulder peaks indicate that all injected holes were not consumed through recombination in Alq₃ because of a poorer electron-transporting ability of LiPP, and some of the holes reached into LiPP layer to give a blue emission of LiPP (Scheme 1).

When BCP (bathocuproine), which has a more crystalline feature than Alq₃, was used as 0.5 nm of thin ETL between Alq₃ and EIL (device: ITO/NPD (50 nm)/Alq₃ (60 nm)/BCP (10 nm)/EIM (LiF or LiPP) (0.5 nm)/Al (100 nm)), LiPP showed a slightly poorer electron injection compared with LiF. This result is probably because LiF having smaller molecular size than LiPP could make a better contact with rough BCP surface, while there were no differences between LiF and LiPP for the electron injection to amorphous Alq₃ layer. Further investigation on the effect of roughness of ETL and on the size of the lithium complexes is ongoing.

3. Conclusion

π-Conjugated lithium phenolate complexes, lithium 2-(2-pyridyl)phenolate (LiPP), lithium 2-(2′, 2″-bipyridine-6′-yl)phenolate (LiBPP), and lithium 2-(isoquinoline-1′-yl)phenolate (LiIQP), were synthesized. The complexes

were readily sublimated under vacuum, compared with LiF. The organic light-emitting diodes (OLEDs) using these complexes as an electron injection layer exhibited a facilitated electron injection from Al cathode to Alq$_3$ emitting layer, as well as the device using LiF, and even in 40 nm of thick film, LiBPP and LiPP were still effective because of their electron-transporting π-conjugated ligand.

4. Experimental

4.1. Materials

6-Bromo-2, 2′-dipyridyl was synthesized according to the literature. 2-Hydroxyphenylboronic acid was purchased from Wako Chemical.

4.2. Measurements

The ^{1}H NMR spectra were measured in deuterated solvents with JEOL ECX 400 MHz spectrometers. Elemental analyses were carried out in the Elemental Analysis Service, Yamagata University, Japan. Mass spectra were obtained by a JEOL JMS-K9 mass spectrometer. Thermal gravimetric analysis was performed on SII EXSTAR 6000 and TGA/DTA 62000. Ionization potentials were measured with Photoelectron Spectrometer Surface Analyzer (RIKEN KEIKI AC-3). UV–visible absorption spectra were recorded with a Shimadzu UV-3150 spectrometer. PL spectra were recorded using a Jobin Yvon Fluoromax-2 fluorometer. The EL devices were fabricated on indium tin oxide (ITO) coated glass substrates, ultrasonicated sequentially in detergent, methanol, 2-propanol, and acetone and exposed under UV–ozone ambient for 20 min. NPD and Alq_3 materials were deposited by thermal evaporation under 2×10^{-4} Pa. EIM and aluminum were finally deposited under 1×10^{-3} Pa as a cathode through a shadow mask, and its active area is 5×5 mm^2. Layer thickness calibration was performed using Dektak 3 surface profilometer. The EL spectra were measured on a Hamamatsu photonic multichannel analyzer PMA-11. The current–voltage (I–V) characteristics and luminance were measured using Keithley 2400 Source Meter and Konika Minolta CS-200, respectively. External quantum efficiencies were calculated assuming Lambertian emission pattern and considering all spectral features in the visible.

Ligand 1: A mixture of 2-bromopyridine (5.21 g, 33.0 mmol), 2-hydroxyphenylboronic acid (4.14 g, 30.0 mmol), toluene (120 ml), ethanol (60 ml), aqueous potassium carbonate (2.0 mol/l, 30 ml) and tetrakis(triphenylphosphine)palladium (0) was heated at 80 °C for 8 h under nitrogen. The mixture was allowed to cool to room temperature, and then toluene was added. The organic layer was washed with water, dried over magnesium sulfate and filtered. The solvent was removed in vacuo, and the residue was purified by column chromatography over silica using a chloroform–hexane mixture (1:1) as eluent to give **1** (3.4 g, 66%). ^{1}H NMR (400 MHz, d_6DMSO, ppm), 8.62 (1H, d, J = 4.1 Hz), 8.21 (1H, d, J = 8.6 Hz), 8.03–8.00 (2H, m), 7.43 (1H, t, J = 6.1 Hz), 7.30 (1H, t, J = 7.5 Hz), 6.91 (2H, t, J = 4.1 Hz). EI–MS (m/z) calcd. 171.2. found 171. Elemental analysis calcd. for $C_{11}H_9NO$: C, 77.17; H, 5.30; N, 8.18. found: C, 77.08; H, 5.39; N, 8.17.

Ligand 2: A mixture of 6-bromo-2, 2′-dipyridyl (5.05 g, 21.5 mmol), 2-hydroxyphenylboronic acid (3.27 g, 23.7 mmol), toluene (100 ml), ethanol (50 ml), aqueous potassium carbonate (2.0 mol/l, 24 ml), and tetrakis(triphenylphosphine)palladium (0) was heated at 70 °C for 8 h under nitrogen. The mixture was allowed to cool to room temperature, and then toluene was added. The organic layer was washed with water, dried over magnesium sulfate, and filtered. The solvent was removed in vacuo, and the residue was purified by column chromatography over silica using a chloroform–ethyl acetate mixture (9:1) as eluent to give **2** (4.8 g, 90%). ^{1}H NMR (400 MHz, d_6DMSO, ppm) 8.77 (1H, d, J = 4.5 Hz), 8.32–8.26 (2H, m), 8.19–8.13 (2H, m), 8.09–8.03 (2H, m), 7.53 (1H, dd, J = 7.7, 5.0 Hz), 7.34 (1H, t, J = 7.7 Hz), 6.98–6.94 (2H, m). EI–MS (m/z) calcd. 248.3. found 248. Elemental analysis

calcd. for $C_{16}H_{12}N_2O$: C, 77.40; H, 4.87; N, 11.28. found: C, 77.34; H, 4.93; N, 11.32.

Ligand 3: A mixture of 1-chloroisoquinoline (5.20 g, 31.8 mmol), 2-hydroxyphenylboronic acid (5.21 g, 37.8 mmol), toluene (100 ml), ethanol (60 ml), aqueous potassium carbonate (2.0 mol/l, 38 ml) and tetrakis(triphenylphosphine)palladium (0) was heated at 70 °C for 8 h under nitrogen. The mixture was allowed to cool to room temperature, and then toluene was added. The organic layer was washed with water, dried over magnesium sulfate, and filtered. The solvent was removed in vacuo, and the residue was purified by column chromatography over silica using a toluene–ethyl acetate mixture (9:1) as eluent to give **3** (5.5 g, 78%). ^{1}H NMR (400 MHz, d_6DMSO, ppm) 9.67 (1H, s), 8.53 (1H, d, J = 6.0 Hz), 7.99 (1H, d, J = 8.2 Hz), 7.81 (1H, d, J = 6.0 Hz), 7.76–7.71 (2H, m), 7.57 (1H, t, J = 7.6 Hz), 7.35–7.27 (2H, m), 7.01–6.94 (2H, m). Contact effects in organic thin-film transistors (OTFTs) sensors are here investigated specifically respect to the gate field-induced sensitivity enhancement of more than three orders of magnitude seen in a DHα6T OTFT sensor exposed to 1-butanol vapors. This study shows that such a sensitivity enhancement effect is largely ascribable to changes occurring to the transistor channel resistance. Effects, such as the changes in contact resistance, are seen to influence the low gate voltage regime where the sensitivity is much lower.

1. Introduction

The scientific and technological driving force towards the development of performing conducting polymer (CP) based solid state sensors is still very strong despite this field has been initiated more than 30 years ago [1]. Recently, organic thin-film transistor (OTFT) sensors have risen the interest of the scientific community for their enhanced level of performance [2–6]. In this configuration, highly repeatable responses were measured by properly gate biasing the device [2,3] whereas broad chemical selectivity was conferred either by covalently bound side groups [7] or by means of CP blends [8]. Besides, an important assessment of their selectivity capabilities was achieved with a chiral OTFT, that exhibited field-effect

amplified sensitivity allowing detection of optical isomers in the tens part-per-million (ppm) concentration range [9], *i.e.* with a three order of magnitude sensitivity improvement [10,11].

This report aims to demonstrate that the sensing process, in particular the field-induced sensitivity enhancement, can be largely ascribed to changes of the channel resistance R_{ch}, eventually ruling out dominating contributions from of the contact resistance (R_c) or leakage current variations. The results reported can also shed light on the origin of the contact resistance in OTFTs.

2. Experimental methods

2.1. Organic thin-film transistors fabrication

The transistors used for this study have a bottom-gate structure and consist of a highly *n*-doped silicon wafer

---

(resistivity: 0.02–1 Ω/cm) coated by a 300 nm thick SiO_2 thermal oxide (dielectric capacitance per unit area: C_i = 10 nF cm^2). Each sample was fabricated on a cleaved wafer piece of *ca.* 2 cm^2. The silicon substrate with a gold pad acts as the gate contact (G) while the silicon dioxide is the gate dielectric. The SiO_2 surface was alkyl functionalized by treatment in 1,1,1,3,3,3-hexamethyldisilazane saturated vapors for 24 h. The dielectric surface was covered by a α,ω-dihexyl-hexathiophene (DHα6T) thin-film deposited by thermal evaporation at a base pressure of 8×10^{-7} with the substrate kept at room temperature. A series of 30 gold source (S) and drain (D) contacts were defined, by thermal evaporation through a shadow mask, directly on the organic films. Before the measurements, the OTFTs were annealed under a vacuum of 10^{-5} Torr at 100 °C for 30 min. Transistors were produced with different channel lengths (distance between the two probed pads), namely: L = 0.2 mm, 0.6 mm and 1 mm, while the channel width (the pads' longer dimension, W), was kept constant at 4 mm. The sensors were fabricated and measured in a standard laboratory environment and operated at room temperature. The synthetic approach for preparing the α,ω-dihexylsexithiophene comprised a Stille coupling between the 5,5′-bis-trimethylstannyl-2,2′-bithiophene and the 5-bromo-5′-hexyl-2,2′-bithiophene. The product precipitated from the reaction medium as a red powder and was purified from soluble byproducts by subsequent Soxhlet washing with methanol, chloroform, acetone and *n*-hexane.

2.2. Sensing measurements

The analyte, in a nitrogen stream and at a controlled concentration, was delivered through a nozzle (positioned at a fixed distance of few mm from the device channel surface) directly onto the active layer surface, as depicted in Scheme 1. The I_{ds}–V_g transfer characteristics were measured by biasing the device in a common source configuration by sweeping V_g (from positive to negative potentials) at a fixed V_{ds}, namely −50 V. The current, I_{ds}, flowing in the channel region was measured in nitrogen and in a flux of controlled butanol concentration in N_2, obtained through a system of computer controlled flow meters. The response measurements were performed at relatively high analyte concentrations (3750–11,250 ppm) as this condition allowed to better discriminate the effects of the contact resistance variation. Both the transfer characteristics (measured in N_2 and in the analyte atmosphere), lasted for 45 s with a total flux of 200 ml/min. Before starting

each run the unbiased device was conditioned by exposure to the analyte atmosphere for 45 s.

3. Results and discussion

The system investigated is a α,ω-dihexylsexithiophene (DHα6T) OTFT with a bottom-gate top contact configuration (Scheme 1). Such a device has been widely investigated for 15 years now [12–17] and can, in many respects, be taken as a model system. The DHα6T thin-film, exhibiting a morphology formed of a three dimensional percolation-type network, with nano-sized crystalline domains separated by voids of comparable size [18], acts both as transistor channel material and as sensing layer. In agreement to what already reported for OTFTs exposed to volatile organic compounds, changes in the drifting source-drain current were seen upon exposure of the DHα6T OTFT to 1-butanol and the response and recovery times were generally quite short, falling in the 10–100 s of seconds range at most [2,3]. Weak chemical interactions are likely to occur between the DHα6T thin-film and the alcohol molecules, the latter being eventually partitioned between the solid (the DHα6T thin-film) and the gaseous phase. Since diffusion of the molecules into the crystalline grains is unlikely, such molecules largely percolate through the voids around the grains till the interface with the dielectric is reached. The analyte molecules are physisorbed at the grains surface and this can enhance the potential barriers at the boundaries [19], generating also charge trapping effects. The degree of physisorption is a function of the chemical affinity between the active layer and the analyte [7], and it occurs in the DHα6T bulk, as well as at the interface with the dielectric, were the two-dimensional transport takes place.

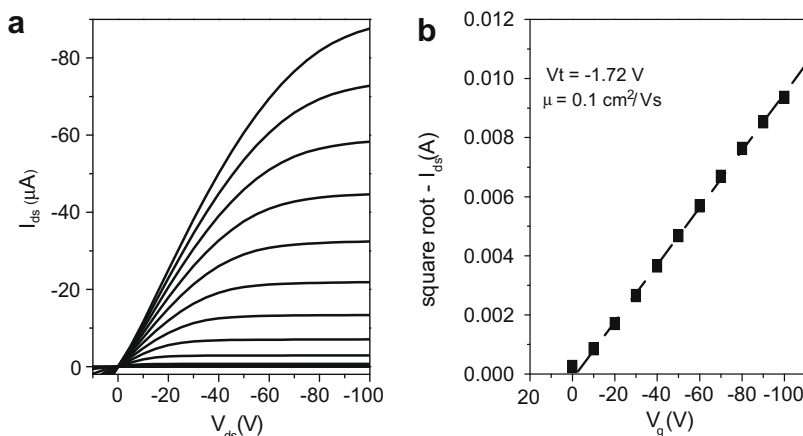
Typical DHα6T OTFT current–voltage characteristics in the inert N_2 atmosphere are reported in Fig. 1a. Here, the source-drain current (I_{ds}) is reported as a function of the source-drain bias (V_{ds}) for different gate biases (V_g). As DHα6T is a p-type semiconductor, negative values of V_{ds} and V_g ($|V_g| > |V_t|$) drive the device in the *on-state* (accumulation mode), while V_g values below the threshold voltage, V_t, generate a regime of charge depletion (*off-state* or depletion mode) [2]. The field-effect mobility (μ) and the threshold voltage, V_t, are graphically extracted from the relevant square root of I_{ds} *vs.* V_g plot (Fig. 1b) resulting in μ = 0.1 cm^2/Vs, V_t below −2 V while a current amplification of 10^4 can be achieved. These figures of merit are state of the art values for DHα6T [12–15], although best mobility
Scheme 1. DHα6T thin-film transistor sensor structure upon exposure to 1-butanol vapors along with biasing details.


Fig. 1. (a) DHα6T current–voltage characteristics in a nitrogen flux. Gate voltages go from 20 V to −100 V in steps of −10 V. (b) The relevant square root of source-drain current as a function of the gate bias is reported (*L* = 0.2 mm).

values can reach 0.5–1 cm^2/Vs [16,17]. Data reported in the supporting information show I_{ds} values at zero V_{ds} biases at different V_g. It is apparent that the highest leakage current (I_{ds} values at zero V_{ds}) is at most of *ca.* 60 nA. Since the I_{ds} currents measured reach 100 μA, the sum of the leakage currents is below 0.1% of I_{ds}, this being a figure generally considered as adequate.

The field-effect mobility in a OTFT is generally gate bias dependent and can be better estimated by considering the channel conductance

$$g_{ds} = \frac{\partial I_{ds}}{\partial V_g} \qquad (1)$$

measured at low drain voltages ($V_{ds} < −5$ V) [20]. In this case being $V_{ds} \ll V_g$, g_{ds} can be expressed as follows:

$$g_{ds} = \frac{\partial I_{ds}}{\partial V_{ds}} \approx \frac{W}{L} \mu C_i (V_g − V_t) \qquad (2)$$
Fig. 2. DHα6T OTFT channel conductance, g_{ds}, plotted as a function of the gate bias.

This equation is, at first approximation, valid also for non-constant mobility. In Fig. 2 the data for the channel conductance, g_{ds}, extracted from the *I–V* characteristics of Fig. 1 at low source-drain voltage ($0 < V_{ds} < |−5$ V$|$), are reported as a function of V_g. The extracted mobility is of 0.07 cm^2/Vs in this case. The data modeling within this framework allows also to give a first estimate of the contact resistance effects. In the case of zero contact resistance Eq. (2) holds, at low V_{ds} (linear region). Introducing a series resistance as contact resistance, R_c, results in changing V_{ds} by a $V_{ds} − I_{ds} R_c$ and Eq. (2) becomes

$$g_{ds} \approx \frac{W/L \cdot C_i \mu (V_g − V_t)}{1 + W/L C_i \mu R_c (V_g − V_t)} \qquad (3)$$

The transport in the channel region appears as not limited by the contact resistance, since g_{ds} shows a quite good linear dependence from V_g (correlation factor of 0.9997). A slight deviation from linearity at higher V_g biases is indeed observed and this calls for further investigations. To quantitatively extract the contribution of the contact resistance the transfer line method, TLM [21,22] was used. Accordingly, the *I–V* characteristics of a set of three DHα6T OTFTs, with channel lengths of $L = 0.2$, 0.6 and 1 mm were measured in N$_2$. The total device resistance, R, was extracted from the linear region ($0 < V_{ds} < |−10$ V$|$) for each of the three OTFTs. In Fig. 3 the data are reported as ($R * W$) vs. L at different V_g voltages. According to the transfer line method, the total resistance, R, is the sum of the channel resistance, R_{ch}, and the contact resistance R_c, the latter being graphically extrapolated at $L = 0$.

In Fig. 4 the contact (R_c) and channel (R_{ch}) resistances of DHα6T OTFTs with different channel lengths are plotted vs. V_g. As expected, in longer channel devices the contact resistance weights much less, while in the shorter channel devices they are of comparable size, at least at higher gate biases. This provides preliminary evidences that contact related effects are not dominating the *on-state* OTFT transport properties. Besides, the curves in Fig. 4 exhibit contact resistance at high V_g biases falling in the $10^5 \, \Omega$ cm range. Although lower R_c have been reported in some cases for
Fig. 3. The total device resistances (R) extracted from the I_{ds}–V_{ds} curves ($0 < V_{ds} < |-10\,V|$ and $V_g = -20\,V$, $-40\,V$, $-60\,V$, $-80\,V$, and $-100\,V$) of DHα6T OTFTs of different channel lengths exposed to nitrogen. W is the transistor channel width.
Fig. 4. DHα6T OTFT contact and channel resistances as extracted from the plots in Fig. 3.

pentacene organic semiconductors [22,23], values in the $10^5\,\Omega$ cm are typical for thiophene based materials contacted with gold electrodes [24,25].

The same DHα6T OTFT devices were then exposed to saturated vapors of 1-butanol. A comparison of the device I–V and transfer characteristics in nitrogen and butanol are reported in Fig. 5. The DHα6T OTFT I_{ds}–V_g, transfer characteristics, are reported in Fig. 5a, along with the relevant log-plot (Fig. 5b), while typical device I_{ds}–V_{ds} characteristics are reported in panel (c) and (d). The black solid curves in Fig. 5a and b show the current drifting in the channel region between the source and the drain contacts at a fixed drain-source bias ($V_{ds} = -50\,V$) while sweeping V_g between 20 V and $-100\,V$. Generally, as it is apparent in Fig. 5 and as already widely reported, a *on-state* I_{ds} decrease occurs upon exposure of a thiophene based OTFT to alcohol vapors [3,25]. This can be explained by the elicited poten-

tial barrier increase at grain boundaries upon exposure to the analyte or, equivalently, by a charge trapping effect. However, a closer inspection of Fig. 5b, reveals that for gate biases falling below a cross-over point, a I_{ds} current increase occurs upon exposure to the analyte. This effect has been seen consistently in most sensing OTFT, using differently substituted thiophene as well as phenylene-thiophene based organic semiconductor, when exposed to organic vapors as well as to inorganic species [9]. It can be also seen on a recently published report, by a different laboratory [6]. In this case a doping effect can be postulated as an increase of the *off-current* is seen. Sample dependent features were for instance the gate bias at which the cross-over took place and in the intensity of the current differential change.

The response of the OTFT sensor ΔI was defined as follows:

$$\Delta I = I_{ds}(N_2) - I_{ds}(1 - \text{butanol}) \tag{4}$$

In Fig. 5b it can be seen that different ΔI values can be measured at different V_g biases and as I_{ds} are negative values, ΔI is negative above the cross-over while is positive below. The DHα6T I–V characteristics, exposed to butanol at different concentrations, were measured for devices with different channel lengths and plots, similar to those reported in Fig. 3, were constructed. The relevant data are reported in Fig. 6a. Also in this case the R_{ch} and R_c data are extracted by the TLM and a comparison of the contact and channel resistances in N_2 (data as in Fig. 4) and in butanol are given in Fig. 6b and c, respectively. In Fig. 7 the relevant R_{ch} and R_c variation are reported and the following features can be outlined. The ΔR_c values can be several times lower then ΔR_{ch}, especially for longer channel devices. This holds true also for the relative percentage variations as $\Delta R_c/R$ is ca. 8% while $\Delta R_{ch}/R$ can be as high as 20%. Moreover, the variations of the contact and channel resistances, upon exposure to 1-butanol vapors, go in opposite directions as ΔR_{ch} are negative values while ΔR_c are positive ones.

Such a result allows establishing some correlations. As already mentioned, a cross-over point, discriminating negative and positive ΔI current changes, was identified in the transfer characteristics (curves in Fig. 5b being a typical example). It is straightforward to associate negative resistance changes to negative current variations and *vice versa*. This means that, when a negative ΔI is seen, it is the channel resistance that is changing, while when ΔI is positive, contact resistance variations are dominating. Therefore, the plot of the OTFT sensor transfer characteristics, measured in an inert and in the analyte atmosphere, gives an indication of the voltage range in which the contribution of contact effects dominates. To better understand the interplay occurring between the channel and the contact resistance changes in OTFT sensors a modeling of the data is in progress.

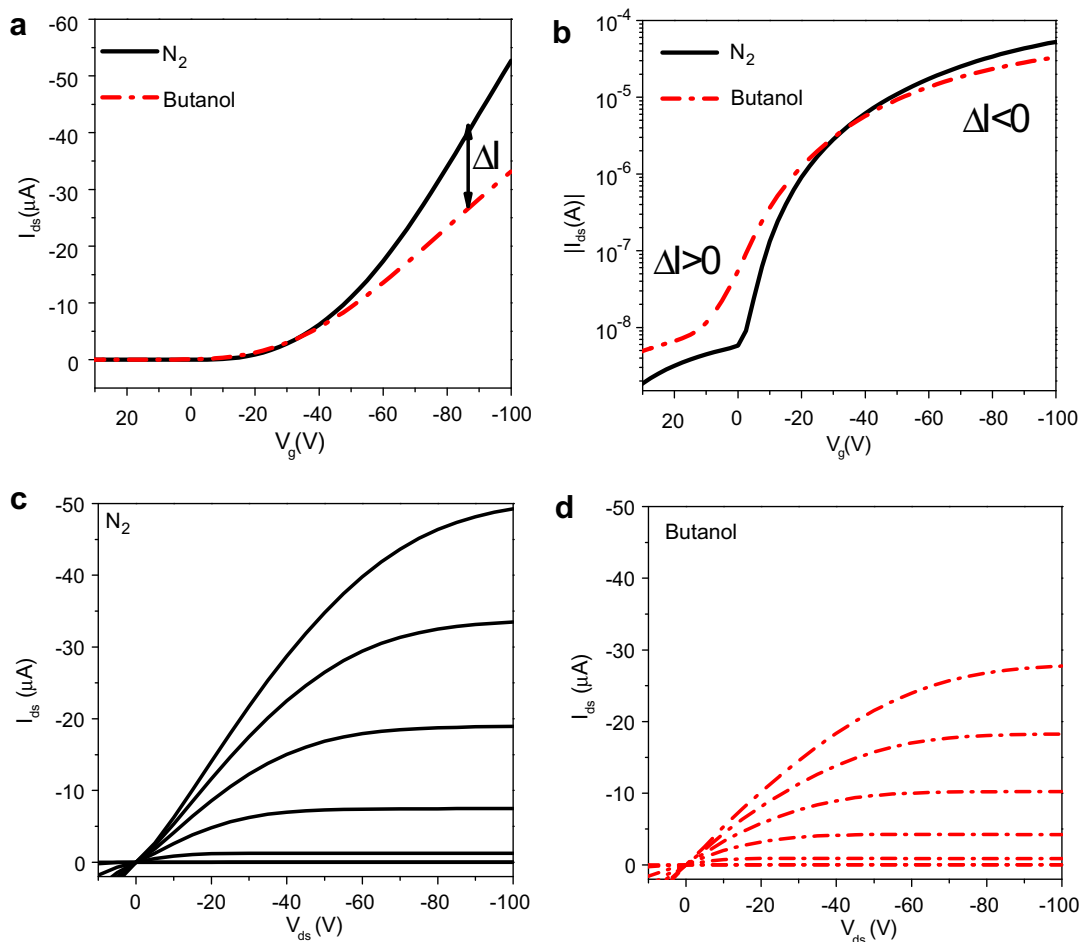
As a further step, the DHα6T OTFT transfer characteristics have been measured also in atmospheres of butanol vapors at different concentrations. The ΔI values were evaluated at different gate biases and at constant concentration as shown in Fig. 5b. The ΔI values at a fixed V_g bias


Fig. 5. DHα6T OTFT transfer characteristics in N_2 and 1-butanol are reported in panel (a). Panel (b) shows the relevant log-plot. *I–V* characteristics curves in N_2 and 1-butanol are reported in panels (c) and (d), respectively. The OTFT channel length is $L = 0.2$ mm and the analyte concentration is 11,250 ppm.

and at different concentration constitute the data points for one calibration curve, the slope (*m*) of each curve being the device sensitivity. The relevant *m* data are given in Fig. 8 for $L = 0.2$ mm and $L = 1.0$ mm DHα6T OTFTs. The occurrence of a gate field dependent sensitivity is apparent and a sensitivity enhancement of more than three orders of magnitude is seen when the device is driven from the *off* to the *on*-state. Similar data were gathered for a phenylene–thiophene [9], as well as for differently substituted thiophene oligomers exposed to organic and inorganic species, showing that this can be a general property of OTFT sensors. Fig. 8 further shows that the slope values too can be positive (hollow red points) and negative (solid black points). Also in this case it is possible to associate the negative slopes to the channel resistance variation, while the positive ones to the contact resistance changes. This means that contact resistance changes dominate in the low gate voltage regime while channel resistance variations are responsible for the much higher sensitivity at gate biases that drive the transistor in the *on-state*. Since red points values are consistently orders of magnitude lower than negative ones, the contact resistance variations affect the field-enhanced sensitivity only negligibly. Besides, it is also

important to outline that the associated standard error on the response repeatability is much lower in the *on regime* than in the *off-one*. All the evidences provided so far show that the enhanced sensitivity observed is in fact not dominated by contact related effects. Such effects are present, but influence the TFT sensor low gate voltage regime. Interestingly, in this operating regime an OTFT is much more likely to behave as a chemiresistor. As to the leakage is concerned, it has been shown in the Supplementary information file that the leakage is limited to 0.1% of the maximum I_{ds} current, while the total relative current variation can be as high as 20%. Therefore, leakage current contribution to the total current variation is negligible too.

A final remark is due on the sensing mechanism. Upon exposure of the OTFT active layer to a volatile organic vapor a partition of the analyte molecules between the solid and the gaseous phase occurs. The chemical affinity between the analyte and the active layer modulates the degree of physisorption of the analyte molecules at the grains' surface. This in turn can enhance the potential barriers at the grain boundaries, eventually lowering the intensity of the drifting source-drain current, as seen in preliminary evidences [19,26]. This effect involves the

whole bulk of the DHα6T film down to the interface with the gate dielectric where the two-dimensional transport occurs [27]. The two-dimensional nature of the sensing mechanism was demonstrated too, as ΔI responses were seen to be active layer thickness independent [9]. The field-induced sensitivity enhancement, can be seen as correlated to the comparably larger number of charges drifting in the device's channel in the *on-state* accumulation regime with the respect to the charges, drifting in the bulk, in the device *off state*. The data reported can also contribute to shed light on the origin of contact effects in OTFTs. A simple thermionic emission is generally postulated although this hypothesis is not supported by evidences such as the contact activation energy being much smaller than the estimated potential barriers determined by pho-

toemission spectroscopy. Also the channel potential measurements by Kelvin probe force microscopy and the four-probe methods, indicate that the contact resistances and temperature dependences associated with the individual source and drain electrodes are nearly identical [21]. Alternatively, the transport through the contacts can be limited by a disordered depletion region near the contacts, this being even more plausible in top contact devices. It is received that the charged carrier transport in OTFTs proceeds through thermionic emission through grains [28]. The data in Fig. 8 shows that, upon exposure to an alcohol, the contact resistance and the channel one change in opposite fashion, implying that they can be generated by two different mechanisms. This can be of further support to the hypothesis that the carrier diffusion through a disordered depletion region is the dominant contributing mechanism to OTFT contact resistance. A doping near the contacts could also be favored by the amorphous nature of the organic semiconductor in this region.

4. Conclusions

A systematic study is reported on the role of contact resistance effects on OTFT sensors, in particular as it concerns the gate field-induced sensitivity enhancement. The *on-state* sensitivity enhancement is largely ascribable to changes occurring in the transistor channel transport and effects, such as contacts resistance or leakage current variations do not dominate the *on-state* sensor behavior. Their effect is seen in the low gate voltage regime where sensitivities are much lower. Besides, the evidences reported bring further support to the hypothesis of the OTFT contact resistances being mainly due to carried diffusion though a disordered depletion region.

ABSTRACT

Ideal host-guest system for emission in phosphorescent OLEDs with only 1% guest doping condition for efficient energy transfer have been demonstrated in the present investigation. Using a narrow band-gap fluorescent host material, bis(10-hydroxybenzo[h] quinolinato)beryllium complex ($Bebq_2$), and red dopant bis(2-phenylquinoline)(acetylacetonate)iridium ($Ir(phq)_2acac$), highly efficient red phosphorescent OLEDs (PHOLEDs) exhibiting excellent energy transfer characteristics with a doping concentration of 1% were developed. Fabricated PHOLEDs show a driving voltage of 3.7 V, maximum current and power efficiencies of 26.53 cd/A and 29.58 lm/W, and a maximum external quantum efficiency of 21%. Minimized electron or hole trapping at the phosphorescent guest molecules and efficient Förster and Dexter energy transfers from the $Bebq_2$ host singlet and triplet states to the emitting triplet of $Ir(phq)_2acac$ guest appear to be the key mechanism for ideal phosphorescence emission.

1. Introduction

Since the initial report by Baldo et al. [1], phosphorescent organic light-emitting devices (PHOLEDs) have been attracting much attention owing to their potential use in general illumination and flat panel displays. Phosphorescent based devices fabricated by doping host materials, having high-energy triplet states, with phosphorescent guest materials can theoretically produce 100% internal quantum efficiency (IQE). This is achieved by harvesting both singlet and triplet excitons generated by electrical injection which is four times that of fluorescent organic light-emitting devices (OLEDs) [2–4]. Förster and/or Dexter energy transfer processes [5] between host and guest molecules play an important role in confining the triplet energy excitons in the phosphorescent guest. This determines the triplet state emission efficiency in PHOLEDs. Förster energy transfer [6] is a long range process

(up to ~10 nm) due to dipole–dipole coupling of donor host and acceptor guest molecules, while Dexter energy transfer [7] is a short range process (typically ~1–3 nm) which requires overlapping of the molecular orbital of adjacent molecules (intermolecular electron exchange).

The phosphorescence emission in the conventional host-guest phosphorescent system occurs either with Förster transfer from the excited singlet S_1 state of the host to the excited singlet S_1 state of the guest and Dexter transfer from the excited triplet T_1 state of the host to the excited triplet T_1 state of the guest or direct exciton formation on the phosphorescent guest molecules, resulting in a reasonable good efficiency. However, emission mechanism in phosphorescent OLEDs whether due to charge trapping by guest molecules and/or energy transfer from the host to the guest, is not clearly understood. Till date, several researchers have reported that the charge trapping at guest molecules is the main cause for the emission of PHOLEDs.

Amongst well-known iridium (III) and platinum (II) phosphorescent emitters, iridium (III) complexes have been shown to be the most efficient triplet dopants employed in highly efficient PHOLEDs [8,9]. Usually, wide

energy gap 4,4′-bis(N-carbazolyl)-1,1′-biphenyl (CBP) is used as a host material for red (~2.0 eV) or green (~2.3–2.4 eV) phosphorescent guests [10,11]. Such a wide energy gap host has the advantage of a high T_1 energy of 2.6 eV [12] or 2.55 eV [13] and long triplet lifetime >1 s, [12] while the optical band-gap value (E_g) is 3.1 eV [8].

Fig. 1a shows both the energy level diagram of fac-tris(2-phenyl-pyridinato)iridium(III) (Ir(ppy)₃) green and the tris(1-phenylisoquinoline)iridium (Ir(piq)₃) red phosphorescent complexes used in doping the CPB host. However, the wide band-gap host and narrow E_g guest system often cause an increase in driving voltage due to the difference in HOMO and/or LUMO levels between the guest and host materials [11]. Thus, the guest molecules are thought to act as deep trapping centers for electrons and holes in the emitting layer, causing an increase in the drive voltage of the PHOLED [14]. The dopant concentration in such a host-guest system is usually as high as about 6–10% by weight (wt%) because injected charges should move through guest molecules in the emitting layer. Therefore, self-quenching or triplet–triplet annihilation by guest molecules is an inevitable problem in host-guest systems with high doping concentrations. Earlier, Kawamura et al. had reported that the phosphorescence photoluminescence quantum efficiency of Ir(ppy)₃ could be decreased by ~5% with an increasing in doping concentration from 2% to 6% [15]. Consequently, the selection of suitable host candidates is a critical issue in fabricating high efficiency PHOLEDs.

In this study, the minimized charge trapped host-guest system is investigated by using a narrow band-gap fluorescent host material in order to address device performance and manufacturing constraints. Here, we report an ideal host-guest system that requires only 1% guest doping condition for good energy transfer and provides ideal quantum efficiency in PHOLEDs. We also report that strong fluorescent host materials function very well in phosphorescent OLEDs due to efficient Förster energy transfers from the host singlet state to the guest singlet and triplet mixing state which appears to be the key mechanism for phosphorescence emission.
2. Experimental

N,N′-Di(4-(N,N′-diphenyl-amino)phenyl)-N,N′-diphenyl-benzidine (DNTPD) as a hole transporting layer, CBP and bis(10-hydroxybenzo [h] quinolinato)beryllium complex (Bebq₂) as host materials, bis(2-phenylquinoline)(acetyl-acetonate)iridium (Ir(phq)₂acac), tris(1-phenylisoquino-line)iridium (Ir(piq)₃) as red dopants, aluminum (III) bis(2-methyl-8-quinolinato)-4-phenylphenolate (BAlq) as a hole blocking layer and tris-(8-hydroxyquinoline)alumi-num (Alq₃) as an electron transporting layer were purchased from Gracel and Chemipro Corporation and were used. To fabricate OLED devices, clean glass substrates pre-coated with a 150-nm-thick indium tin oxide (ITO) layer with a sheet resistance of ~12 Ω/□ were used. Line patterns of ITO were formed on glass by photolithography process. The ITO glass was cleaned by sonification in an isopropylalcohol and acetone, rinsed in deionized water, and finally irradiation in a UV–ozone chamber. All organic materials were deposited by the vacuum evaporation technique under a pressure of ~1×10^{-7} Torr. The deposition rate of organic layers was about 1 Å/s. Then, LiF and Al were deposited in another vacuum deposition system without breaking vacuum. Deposition rates of LiF and Al were 0.1 Å/s and 5–10 Å/s, respectively. The current density–voltage (J–V) and luminance–voltage (L–V) data of PHOLEDs were measured by Keithley SMU 238 and Minolta CS-100A, respectively. The OLED area was 2 mm² for all the samples studied in this work. Electroluminescence (EL) spectra and CIE coordinate were obtained using a Photo-research PR-650 spectroradiometer.

3. Result and discussion

Fig. 1b shows an energy band diagram of the fluorescent host and orange–red phosphorescent dopant materials used in the device fabrication. The simple bilayer PHOLED comprises a DNTPD hole transport layer (HTL), a Bebq₂ narrow band-gap fluorescent host and an electron transport layer (ETL) plus Ir(phq)₂acac dopant. Bebq₂ and other beryllium complexes are known to have excellent electron transport characteristics with a high electron mobility of ~10^{-4} cm²/Vs [16,17] and a narrow band-gap. Earlier, Hamada et al. [18] used Bebq₂ as an emitter to produce high luminance in OLEDs. More recently, we have demonstrated green [19] and red [20] emitting phosphorescent devices utilizing beryllium complexes as host and ETL. In the present investigation, the fabricated PHOLED was:

$$\text{ITO/DNTPD(40 nm)/Bebq}_2 : \text{Ir(phq)}_2\text{acac(50 nm, 1\%)}$$
$$\text{/LiF(0.5 nm)/Al(100 nm)}$$

Fig. 2a and b and Table 1 (device B) illustrate the electrical performance of the fabricated phosphorescent device. A luminance of 1000 cd/m² was obtained with a driving voltage of 3.7 V, and a current and power efficiency

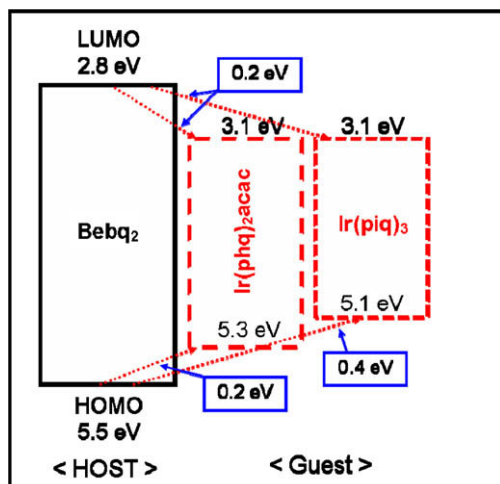

Fig. 1b. An Energy level diagram of the $Bebq_2$ fluorescent host and ($Ir(phq)_2acac$) and $Ir(piq)_3$ red phosphorescent dopant materials. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

of 20.53 cd/A and 23.14 lm/W, respectively. Furthermore, the maximum current and power efficiency were 26.53 cd/A and 29.58 lm/W, respectively. The external quantum efficiency (EQE) value of 21% in the fabricated PHOLED slightly exceeded the theoretical limit of about 20% derived from simple classical optics. Moreover, this can be further improved by optimizing the output coupling. These remarkable results brought some pleasant surprises.

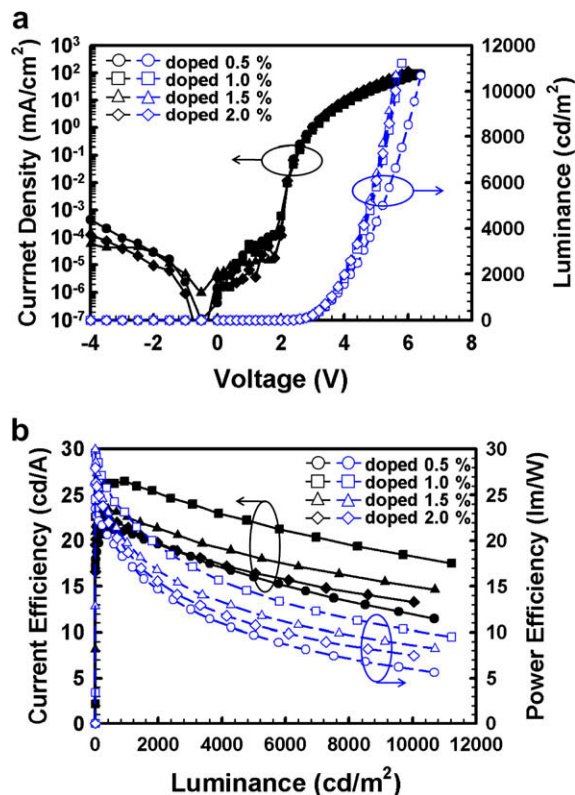
Indeed, because of the extraordinarily low doping concentration (~1%) by contrast with most phosphorescent devices (6–10 wt%) we never expected the enhanced performance of the $Bebq_2$:$Ir(phq)_2acac$ PHOLEDs. In order to investigate the origin for the enhanced performance, we fabricated several PHOLEDs by varying the doping concentration from 0.5% to 2% in the host-guest system. Current and luminance as a function of voltage are presented in Fig. 2a, while current and power efficiencies as a function of luminance are presented in Fig. 2b. This data provides evidence for: (1) complete energy transfer from the fluorescent host to phosphorescent guest, except at extremely low doping concentrations (~0.5%); (2) no significant difference between measured I–V characteristics for identical


Fig. 2. (a) A J–V–L plot and (b) current and power efficiencies as a function of luminance from red PHOLEDs doped with different concentrations (0.5–2%) of $Ir(phq)_2acac$. devices but with different dopant concentrations lying between 0.5 and 2 wt%; and, (3) the quenching of both luminance, and current and power efficiencies with higher doping concentrations (~2 wt%). A summary of the key electrical and optical parameters (Table 1) reveals excellent device performance for doping concentration as low as 0.5–2%, in contrast with conventional PHOLEDs which require a guest concentration typically in the range of 6–10 wt%. Therefore, a highly efficient simple bilayer PHOLED structure with a $Ir(phq)_2acac$ guest doping concentration as low as 1% in the narrow band-gap $Bebq_2$ fluorescent host is demonstrated here for the first time. Previously,

EQE (%) (maximum)	16.6	21.0	18.9	18.6

(ppy)$_2$Ir(acac):Ir(piq)$_3$ (0.3–1 wt%) red [11] and CBP:Ir(phq)$_2$acac (6 wt%) orange–red PHOLEDs [21] demonstrated an EQE of 9.2% with a power efficiency of 11.0 lm/W and a power efficiency of 17.6 cd/A with an EQE of 10.3% at 600 nit, respectively.

Fig. 3 provides evidence of energy transfer from the Bebq$_2$ fluorescent host to the Ir(phq)$_2$acac phosphorescent guest by comparing the electroluminescence (EL) spectra of PHOLEDs as a function of Ir(phq)$_2$acac doping concentration from 0.5% to 2%. The strong red light emission peak at 605 nm for all EL curves at 1000 nit is attributed to the phosphorescence of Ir(phq)$_2$acac. The Commission Internationale de l'Eclairage (CIE) colour emission coordinates are (0.61, 0.38), (0.62, 0.37), (0.62, 0.37), (0.62, 0.37) for doping concentrations of 0.5, 1.0, 1.5, and 2.0 wt% of Ir(phq)$_2$acac, respectively. A slight emission at 500 nm due to the Bebq$_2$ host plus a dominant doping peak at 605 nm when the doping concentration is extremely low (~0.5%), suggests an incomplete energy transfer from the Bebq$_2$ host to the Ir(phq)$_2$acac guest. Furthermore, it indicates that the recombination of injected holes and electrons occurs at host molecule sites and then the excited energy is rapidly transferred from the host to the guest. The presence of a clean EL peak (no emissions at 500 nm) in other devices with doping concentrations of Ir(phq)$_2$acac > 0.5% indicates a complete energy transfer from the host to the guest.

To understand the phosphorescence emission mechanism more precisely in the Bebq$_2$:Ir(phq)$_2$acac host-guest system, we fabricated and studied a series of PHOLEDs. Firstly, we used the well-known wide band-gap CBP host material instead of Bebq$_2$ and fabricated the device with a structure: NPB (40 nm)/CBP:Ir(phq)$_2$acac (30 nm, 10%)/ BAlq (5 nm)/Alq$_3$ (20 nm)/LiF (0.5 nm)/Al (100 nm). At a luminance of 1000 cd/m^2 the resultant operating voltage was 7.1 V with current and power efficiencies of 14.41 cd/A and 6.28 lm/W, respectively, and an EQE of 11.5%,. Furthermore, the maximum current and power efficiency values were 14.43 cd/A and 8.99 lm/W, respectively. Obviously, the two fold increase in driving voltage is a consequence of the trapping of injected holes and electrons at deep Ir(phq)$_2$acac molecules in the CBP:Ir(phq)$_2$acac system. Direct charge trapping on the Ir(phq)$_2$acac guest

molecules seems to be the key mechanism for phosphorescence emission in this host-guest system.

Later, a PHOLED device was fabricated using Ir(piq)$_3$ red emitting phosphorescent doping instead of Ir(phq)$_2$acac and a Bebq$_2$ host. The fabricated device was: DNTPD (40 nm)/Bebq$_2$:Ir(piq)$_3$ (50 nm, 4 wt%)/LiF (0.5 nm)/Al (100 nm). A weak emission peak at 500 nm in the EL spectra due to the Bebq$_2$ host arises at a doping concentration of 4 wt% (significantly high by comparison with an Ir(phq)$_2$acac doping concentration ~0.5 wt%), accompanied by a strong peak at 620 nm (CIE coordinates $x = 0.67$ and $y = 0.32$) due to an Ir(piq)$_3$ doping molecule (Fig. 4). At luminance of 1000 cd/m^2, the corresponding operating voltage, current and power efficiencies were 3.5 V, 8.41 cd/A and 7.34 lm/W, respectively. Furthermore, the maximum current and power efficiency values were 9.38 cd/A and 11.72 lm/W, respectively. Increasing the Ir(piq)$_3$ concentration to 6 wt% suppresses the Bebq$_2$ host emission and results in a clean EL red emitting peak at 620 nm due to the Ir(piq)$_3$ doping molecules. However, the device performance deteriorates with increasing doping concentration due to the self-quenching process.

The primary mechanism for phosphorescence emission in the Bebq$_2$:Ir(piq)$_3$ host-guest system (Fig. 1 b) appears to be due to energetically favorable electron transport and hole trapping at deep trapping centers in Ir(piq)$_3$ molecules. Thus, an appropriate selection of host and phosphorescent dopant materials plays a significant role in determining the emission mechanism in phosphorescent devices. These results on phosphorescent emission in Bebq$_2$:Ir(phq)$_2$acac host-guest systems are very interesting and intriguing. The mechanism of phosphorescence emission is not believed to be due to direct charge trapping in Ir(phq)$_2$acac phosphorescent guest molecules. Now an attempt is made here to explain these results on the basis of the existing knowledge of Förster and Dexter energy transfer processes in host-guest systems.

The Bebq$_2$ host material produces a strong fluorescence emission but no phosphorescence emission signature even at 77 K. The efficient use of Bebq$_2$ host in the described phosphorescent devices is an extraordinary phenomenon since strong fluorescent host materials are believed to provide poor phosphorescent performance. Therefore, we suspect efficient Förster energy transfer between the host
Fig. 3. EL spectra as a function of dopant concentration: Ir(phq)$_2$acac of an ITO/DNTPD (40 nm)/Bebq$_2$:Ir(phq)$_2$acac (50 nm, 0.5–2%)/ LiF(0.5 nm)/ Al(100 nm) PHOLEDs at 1000 cd/m^2.

singlet and the metal-to-ligand charge-transfer (MLCT) state of the iridium (III) metal complex. Earlier, Förster energy transfer in phosphorescent OLEDs was postulated by Gong et al. and Ramos-Ortiz et al. in solid photoluminescence studies [14,22]. To investigate Förster energy transfer from the Bebq$_2$ host to the Ir(phq)$_2$acac, time resolved spectroscopy and a Stern–Volmer plot in THF solution measurements techniques were employed. The singlet fluorescent lifetime of Bebq$_2$ is 5.0 ns. From the slope of the linear Stern–Volmer plot (Fig. 5), the calculated energy transfer rate is $k_q = 8 \times 10^{12}$ s^{-1} M^{-1}, indicating that the energy transfer from the excited singlet state of the host to the dopant triplet occurs quantitatively and ideally. Furthermore, the strong spin orbital coupling induced by the transition metal ion indicates that a narrow energy gap exists between the ^{1}MLCT and ^{3}MLCT states ($\sim$0.3 eV) and opens a pathway for efficient energy transfer from the singlet to the emitting triplet states. Therefore, two channels for Förster energy transfer from the host singlet to the ^{1}MLCT and ^{3}MLCT states of the iridium complex are available as shown in Fig. 6. Overlapping of the host emission and dopant absorption spectra substantiates the hypothesis of efficient Förster energy transfer from the host singlet to the guest emitting triplet states via two channels (Fig. 7). Furthermore, the strong fluorescent quantum efficiency of 0.39 in the host (Bebq$_2$) in solution, obtained using a relative quantum yield measurement, favors Förster energy transfer.
Fig. 6. Förster and Dexter energy transfer mechanism in the Bebq$_2$:Ir(phq)$_2$acac system.
Fig. 7. Spectral overlapping of the photoluminescence spectrum from Bebq$_2$ and the absorption spectrum from Ir(phq)$_2$acac.

The Förster radius (R_0), critical distance for the concentration quenching, was estimated as 1.3 nm (similar to a previously reported value [23]) using the following equation:

$$R_0^6 = \frac{9000(\ln 10)k^2\Phi_{PL}}{128\pi^5 N_A n^4} \int_0^\infty F_D(\lambda)\varepsilon_A(\lambda)\lambda^4 d\lambda$$

where k^2 = orientation factor, Φ_{PL} = photoluminescence quantum efficiency, N_A = Avogadro's number, n = refractive index, $\int_0^\infty F_D(\lambda)\varepsilon_A(\lambda)$ = spectral overlap integral between donor photoluminescence ($F_D(\lambda)$), and $\varepsilon_A\lambda$ = acceptor absorption, and λ = wavelength.

The triplet exciton energy transfer from the Bebq$_2$ host to ^{3}MLCT is governed by Dexter energy transfer. The rate constant of Dexter energy transfer [23] is:

$$K_{ET} = KJ\exp(-2R_{DA}/L)$$

where K is related to the specific orbital interaction, J is a spectral overlap integral, and R_{DA} is donor–acceptor separation relative to their van der Waals radii, L. The ideal Dexter radius is the distance between the host and dopant molecule diameter considering overlapping molecular orbitals in adjacent molecules [24].

Using the equation: R = [(molecular density in film) × mol% of the dopant in a film]$^{-1/3}$ as reported by Kawamura et al. [23] yields an average distance of about 58.5 Å and 44.9 Å between Ir(phq)$_2$acac molecules for doping concentrations of 0.5% and 1.0%, respectively (Fig. 8). By considering the host (13.6 Å) and dopant (13.7 Å) diameters calculated using a molecular modeling program (DMOL3) [25] and van der Waals interaction distance (usually very small within $\sim$2 Å) for the ideal Dexter energy transfer condition, the estimated distance between the host and guest molecules is about 15.6 Å (i.e. the half diameters of the host and dopant molecules are, 13.7/2 Å plus 13.6 Å/2, including a 2 Å van der Waals interaction distance). In solid state films, the minimum doping concentration is desirable to prevent triplet quenching processes.

Considering that two host molecules are located between two dopant molecules, an ideal Dexter condition (Fig. 8b), all host molecules are adjacent to a dopant molecule and dopant molecules are well separated in the host
Fig. 8a. Förster and Dexter energy transfer conditions as a function of doping concentration and distance between two dopants.

matrix. In such a host and guest molecule arrangement, the separation between two dopant molecules appears to be about 46.9 Å. However, when the doping concentration is 0.5%, the estimated separation between Ir(phq)$_2$acac molecules is 58.5 Å, suggesting that more than two host molecules are located between two dopant molecules (Fig. 8b). If the doping concentration is increased to 1%, the separation between dopant molecules is less than 46.9 Å, which results in an efficient energy transfer from the Bebq$_2$ host to the emitting triplet state of Ir(phq)$_2$acac via Dexter processes. The triplets generated due to the Bebq$_2$ host molecules diffuse an average of only 15.6 Å, with a doping concentration of 1 wt%, until they are harvested by Ir(phq)$_2$acac (Fig. 8b). If the doping concentration is increased to greater than 1%, the device performance deteriorates due to quenching processes of

triplet excitons caused by two closely separated dopant molecules.

The influence of the Förster quenching process in the described system is not serious at all doping concentrations (Fig. 8a). The singlet exciton energies generated by charge injection in host molecules can be transferred to triplet states of dopant molecules by the efficient Förster energy transfer. In our system, the rate constant of Förster energy transfer is much faster than that of the intersystem crossing of host singlet states. Typical intersystem crossing rate constants fall within the range $\sim 10^6$–10^8 s^{-1} [26]. Thus, strong fluorescent materials, such as Bebq$_2$, are excellent as host materials in PHOLEDs.

4. Conclusions

In conclusion, we have demonstrated here an ideal host-guest energy transfer and quantum efficiency conditions with a dopant concentration of approximately 1% in phosphorescent OLEDs. We also report that strong fluorescent host materials function very well in phosphorescent OLEDs. The operating mechanism for the phosphorescence emission is twofold: Firstly, an efficient Förster energy transfer process from the host singlet exciton to the ^{1}MLCT and ^{3}MLCT states of the guest. And, secondly, Dexter energy transfer process from the host triplet exciton to the ^{3}MLCT state of the guest. The extremely low doping concept for highly efficient PHOLEDs has potential uses in future display and lighting applications.

ARTICLE INFO

ABSTRACT

We investigated highly efficient phosphorescent organic light-emitting diodes (OLEDs) based on an orange–red emission iridium complex as the guest and five green emission iridium complexes as the host material, respectively. For comparison, a device using a common fluorescent host CBP (4,4′-bis(*N*-carbazolyl)-1,1′-biphenyl) has also been fabricated. Results show that the steric hindrance and exciton transporting property of the iridium complex host are found to be critical to this kind of doping system, a proper steric hindrance and improved exciton transporting ability result in reducing of triplet–triplet annihilation, thus improving of the device performance. In addition, all devices using iridium complexes as host have better performance than that of CBP, which arised from the fact that those green emission iridium complexes have a lower triplet excited energy befitting for energy confinement and a higher highest occupied molecular orbital (HOMO) level for hole injection.

1. Introduction

Recently, electrophosphorescent materials such as iridium, platinum, ruthenium, and osmium complexes, which use both singlet and triplet excitons, have received a great deal of attention due to their potential application in flat-panel displays [1–13]. The heavy metals such as iridium in the complex forms are known to induce intersystem crossing by strong spin-orbit coupling, leading to mixing of the singlet and triplet excited states. Thus, iridium complexes were known to have high photoluminescence efficiency with a relatively short excited state lifetime, which minimizes annihilation of triplet emissive states. Up to now, high brightness and efficiency of iridium complexes based OLEDs were achieved by using a host:guest

system to improve energy transfer and avoid triplet–triplet annihilation. Thus many host materials have been investigated, such as 4,4′-bis(*N*-carbazolyl)-1,1′-biphenyl (CBP) [6,14,15], 4,4′,4″-tris(*N*-carbazolyl)-triphenylamine (TCTA) [16], 3-phenyl-4-(1′-naphthyl)-5-phenyl-1,2,4-triazole (TAZ) [17], and 9-{4-[5-(4-tert-butylphenyl)-[1,3,4]oxadiazol-2-yl]-benzyl}-9H-carbazole (t-CmOxa) [18]. However, most employed hosts were fluorescent materials, while the host:guest based OLEDs using phosphorescent materials as hosts are rare but their performances seem to be amazing [19,20].

In this study, we report a series of green-emission iridium complexes used as the host for an orange–red iridium complex guest for highly efficient OLEDs. In particular, we describe the electroluminescent (EL) properties of OLEDs based on five iridium complexes Ir(ppy)$_2$(acac) [bis (2-phenylpyridinato-*N,C*^{2}) iridium (acetylacetonate)] [21], Ir(ppy)$_2$(dmd) [bis(2-phenylpyridinato-*N,C*^{2}) iridium

(5,5-dimethylhexane-2,4-diketonate)], Ir(ppy)$_2$(tmd) [bis (2-phenylpyridinato-*N,C*^{2}) iridium (2,2,6,6-tetramethyl-heptane-3,5-diketonate)] [6], Ir(ppy)$_2$(CBDK) [bis(2-phenylpyridinato-*N,C*^{2}) iridium (1-(9H-carbazol-9-yl)-5, 5-dimethylhexane-2,4-diketonate)] [22], and Ir(ppy)$_2$ (FBDK) [bis[2-phenylpyridinato-*N,C*^{2}) iridium (1-(9-methyl-fluoren-9-yl)-6,6-dimethylheptane-3,5-diketonate)] used as hosts for the guest Ir(DBQ)$_2$(acac) [bis(dibenzo[f,h]quinox-alinato-*N,C*^{2}) iridium (acetylacetonate)] [2], and compare these results with the device using CBP as the host. The choice of these OLEDs provided us an opportunity for tracing the effect of the host: considering Ir(ppy)$_2$(acac) as a reference, we investigated the effect of structural change of the iridium complex on the performance of this class of host:dopant system, such as exciton transporting ability and molecular steric hindrance; while considering CBP as a reference, we traced the differences between fluorescent and phosphorescent hosts.

2. Experimental

2.1. General information

^{1}H NMR spectra were recorded on an ARX-400 NMR spectrometer, chemical shift data for each signal were reported in ppm units with tetramethylsilane (TMS) as internal reference, where δ (TMS) = 0. Elemental analyses were performed on a VARIO EL instrument. The UV–vis absorption spectra were measured with Shimadzu UV–3100 spectrometer. The photoluminescence (PL) spectra were recorded on an Edinburgh Analytical Instruments FLS920 spectrometer after removing the oxygen by bubbling of nitrogen through the solution. Electrochemical measurements were recorded by a similar method reported before [23].

2.2. Materials

Ir(ppy)$_2$(acac) [21], Ir(ppy)$_2$(tmd) [6], Ir(DBQ)$_2$(acac) [2], Ir(ppy)$_2$(CBDK) [22], Hdmd [24], HFBDK [23], and tris (8-hydroxyquinolinolinolato)aluminium (AlQ) [25] were synthesized according the literature. Both *N,N*′-diphenyl-*N*, *N*′-bis(1-naphthyl)-1, 1′-diphenyl-4, 4′-diamine (NPB) and 2, 9-dimethyl-4, 7-diphenyl-1, 10-phenanthroline (BCP) were purchased from Aldrich. NPB, BCP and AlQ were all subjected to gradient sublimation prior to use.

2.3. Synthesis of Ir(ppy)$_2$(FBDK)

[(ppy)$_2$Ir(μ-Cl)]$_2$ [26] (0.536 g, 0.5 mmol), sodium carbonate (0.53 g, 5.0 mmol) and HFBDK (0.367 g, 1.1 mmol) were dissolved in 2-ethoxyethanol (30 mL). The reaction mixture was refluxed under a nitrogen atmosphere for 12 h and an excess of water was added after cooling the solution to room temperature. The resulting precipitate was collected by filtration and pumped dry. The solid was chromatographed using dichloromethane as eluent. ^{1}H NMR (400 MHz, CDCl$_3$), δ: 8.34 (d, 1H, *J* 7.3 Hz), 8.29 (d, 1H, *J* 6.6 Hz), 7.84 (d, 1H, *J* 8.0 Hz), 7.78 (d, 1H, *J* 8.0 Hz), 7.65–7.71 (m, 4H), 7.58 (d, 1H, *J* 8.9 Hz), 7.51 (d,

1H, *J* 8.9 Hz), 7.22–7.31 (m, 6H), 7.04 (t, 1H, *J* 13.0 Hz), 7.00 (t, 1H, *J* 14.5 Hz), 6.83 (t, 1H, *J* 14.9 Hz), 6.78 (t, 1H, *J* 14.9 Hz), 6.69 (t, 1H, *J* 16.2 Hz), 6.65 (t, 1H, *J* 14.8 Hz), 6.37 (d, 1H, *J* 8.6 Hz), 6.26 (d, 1H, *J* 8.6 Hz), 4.99 (s, 1H, CH), 1.96 (t, 2H, *J* 18.4 Hz, CH$_2$), 1.39 (t, 2H, *J* 16.3 Hz, CH$_2$), 1.32 (s, 3H, CH$_3$), 0.79 (s, 9H, t-Bu); MS (TOF) m/z calcd. for C$_{45}$H$_{41}$IrN$_2$O$_2$, 834, found, 834. Anal. calcd. for C$_{45}$H$_{41}$IrN$_2$O$_2$, C 64.80, H 4.95, N 3.36. found: C 64.75, H 4.96, N 3.42.

2.4. Synthesis of Ir(ppy)$_2$(dmd)

The synthesis of Ir(ppy)$_2$(dmd) is similar to Ir(ppy)$_2$(FBDK) except the Hdmd (0.156 g, 1.1 mmol) was instead of HFBDK (0.367 g, 1.1 mmol). ^{1}H NMR (400 MHz, CDCl$_3$), δ: 8.49 (d, 1H, *J* 4.9 Hz), 8.43 (d, 1H, *J* 5.1 Hz), 7.85 (d, 1H, *J* 8.1 Hz), 7.80 (d, 1H, *J* 8.0 Hz), 7.67–7.73 (m, 2H), 7.56 (d, 1H, *J* 7.7 Hz), 7.51 (d, 1H, *J* 7.7 Hz), 7.09 (t, 2H, *J* 13.1 Hz), 6.78 (t, 2H, *J* 10.7 Hz), 6.66–6.71 (m, 2H), 6.40 (d, 1H, *J* 8.5 Hz), 6.23 (d, 1H, *J* 8.4 Hz), 5.32 (s, 1H, CH), 1.81 (s, 3H, CH$_3$), 0.87 (s, 9H, t-Bu); MS (TOF) m/z calcd for C$_{30}$H$_{29}$IrN$_2$O$_2$, 642, found, 642. Anal. Calcd for C$_{30}$H$_{29}$IrN$_2$O$_2$, C 56.14, H 4.55, N 4.36. Found: C 55.20, H 4.46, N 4.42.

2.5. Computational details

All calculations have been carried out using Gaussian 03 package [27]. Ground state geometries of all the complexes were fully optimized with no symmetry or internal coordinate constrains. The hybrid density functional B3P86 [28,29] was used for all the calculations. For geometry optimization, the standard basis set 6–31g* [30,31] was used and for single point energy calculations, a larger "triple-ζ" basis 6–311g* was employed.

2.6. Device fabrication and testing

Patterned anode used in our laboratory was commercially available with a sheet resistance of 7 Ω/sq. Before loading into a deposition chamber, the ITO coated glass were cleaned with organic solvents, deionized water and finally treated with ultraviolet (UV) ozone. The organic and metal layers were deposited in different vacuum chamber with a base pressure better than 8×10^{-5} Pa. The emissive area of the devices as defined by the overlapping area of the cathode and the anode was 9 mm^2. All electric testing and optical measurements were performed under ambient conditions. The EL spectra were measured with a Spectra Scan PR650. The current–voltage (*I–V*) and luminance–voltage (*L–V*) characteristics were measured with a computer controlled Keithley 2400 Sourcemeter unit with a calibrated silicon diode.

3. Results and discussion

3.1. X-ray crystal structure

Single crystals of Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), and Ir(ppy)$_2$(FBDK) were all grown from an ethanol/chloroform

solution by slow evaporation at room temperature and characterized by X-ray diffraction analysis to establish their exact configuration [32]. Details of crystallographic data are given in Table 1.

The ORTEP diagram only for Ir(ppy)$_2$(FBDK) is shown in Fig. 1 as an example. The Ir(ppy)$_2$(LX) (LX = dmd, tmd, or FBDK) molecule consists of two phenylpyridine fragments as cyclometalated ligands and one β-diketonate as an ancillary ligand ranging in a distorted octahedral geometry around the iridium atom. The coordination geometries of these three complexes are the same as that reported for the chloride–bridged dimer complex [(ppy)$_2$Ir(μ-Cl)]$_2$ [33] and Ir(ppy)$_2$(acac) [6,21]. However, the average single molecular volume varied from 552 [21,34] to 894 [34] Å^3
Fig. 1. ORTEP diagram of Ir(ppy)$_2$(FBDK). The measurement temperature was 113(2) K and the thermal ellipsoids for the image represent 30% probability. The hydrogen atoms are omitted for clarity.

as the steric hindrance of β-diketonate increased from the small acac to the bulky FBDK.

3.2. Photophysical characterization

The UV–vis absorption and photoluminescence spectra of Ir(ppy)$_2$(acac), Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), Ir(ppy)$_2$(CBDK), and Ir(ppy)$_2$(FBDK) in CH$_2$Cl$_2$ solution are shown in Fig. 2. For these Ir(ppy)$_2$(LX) complexes, the difference in UV–vis absorption is only the transitions attributed to the different β-diketonates, while the singlet (∼410 nm) and triplet (∼460 nm) metal-to-ligand charge transfer (MLCT) transitions [6] are the same as those showing in 400–500 nm region. The maximum emission bands for Ir(ppy)$_2$(acac), Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), Ir(ppy)$_2$(CBDK), and Ir(ppy)$_2$(FBDK) in CH$_2$Cl$_2$ solution examined at room temperature are at 518, 522, 523, 518, and 520 nm, respectively. These similar emissions are all likely to be ^{3}MLCT based transitions [21]. The phosphorescence quantum yields for Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), and Ir(ppy)$_2$(FBDK) were deduced to be 0.31, 0.28, and 0.24, respectively, which are a little lower than that of Ir(ppy)$_2$(acac) (0.34 [6]), and a little higher than that of Ir(ppy)$_2$(CBDK) (0.19 [22]).

The UV–vis absorption spectrum of Ir(DBQ)$_2$(acac) in CH$_2$Cl$_2$ solution, photoluminescence spectra of neat Ir(ppy)$_2$(LX) films, and Ir(DBQ)$_2$(acac)/Ir(ppy)$_2$(LX) blend films doped with ∼7 mol% Ir(DBQ)$_2$(acac) are shown in Fig. 3. The absorptions at 440 and 530 nm can be assigned to ^{1}MLCT and ^{3}MLCT based transitions [2]. The maximum emission bands for neat Ir(ppy)$_2$(acac), Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), Ir(ppy)$_2$(CBDK), and Ir(ppy)$_2$(FBDK) films are 532, 532, 531, 529, and 531 nm, respectively. Since all five Ir(ppy)$_2$(LX) have a maximum emission band around 530 nm, the triplet excited state (T$_1$) energies were estimated to be ∼2.3 eV, which is higher than that of Ir(DBQ)$_2$(acac), ∼2.0 eV. Furthermore, these observed emission bands fairly overlap with the ^{3}MLCT absorption of Ir(DBQ)$_2$(acac), which indicates that there may be good energy transfer between Ir(ppy)$_2$(LX) and Ir(DBQ)$_2$(acac). By gradually increasing the concentration of Ir(DBQ)$_2$(acac) in Ir(ppy)$_2$(LX) host at 0, 1, 3, 5, 7, 9, and 11 mol%, respectively, pure emission was observed only when the concentration of the guest was up to ∼7 mol%. The blend films doped with ∼7 mol% Ir(DBQ)$_2$(acac) emitted red light with maximum intensity at wavelengths 621, 619, 615, 615, and 615 nm for Ir(ppy)$_2$(acac), Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), Ir(ppy)$_2$(CBDK), and Ir(ppy)$_2$(FBDK), respectively. The phosphorescence of Ir(ppy)$_2$(LX) was quenched, indicating that the triplet energy of Ir(ppy)$_2$(LX) were efficiently transferred to Ir(DBQ)$_2$(acac).

3.3. HOMO and LUMO Investigation

Because the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) energy levels of the host are one of the most important factors for OLEDs, herein we investigated the HOMO and LUMO properties of these five iridium complexes both by cyclic voltammetry and density functional theory (DFT) calculations.

The oxidation potential for an iridium complex in HPLC grade CH_2Cl_2 solution can be obtained via cyclic voltammetry [23], then the HOMO was deduced by assuming the energy level of ferrocene/ferrocenium to be −4.8 eV [35]. Estimated from the UV–vis absorption spectrum, the energy bandgap of the iridium complex was obtained, thus the LUMO was calculated to be the sum of the energy bandgap and HOMO. Using the strategy mentioned above, the oxidation potentials for Ir(ppy)$_2$(acac), Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), Ir(ppy)$_2$(CBDK), and Ir(ppy)$_2$(FBDK) are estimated to be 0.35, 0.30, 0.25, 0.32, and 0.26 V higher than that of the ferrocene/ferrocenium couple, respectively. Thus the HOMO energy levels were deduced to be 5.15, 5.10, 5.05, 5.12, and 5.06 eV, respectively. The five iridium

complexes possess similar ^{3}MLCT absorption bands whose edges reach the green-wavelength region with an absorption band limit of approximately 520 nm, and have the same bandgap of 2.36 eV; thus the LUMO energy levels are 2.79, 2.74, 2.69, 2.76, and 2.70 eV for Ir(ppy)$_2$(acac), Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), Ir(ppy)$_2$(CBDK), and Ir(ppy)$_2$(FBDK), respectively. The cyclic voltammograms are compared in Fig. 4. The electrochemical data and energy levels of the complexes are summarized in Table 2, from which we can see that the HOMO and LUMO energy levels of the iridium complexes are similar.

Computational investigations have been proved to be very helpful in understanding the HOMO and LUMO properties of iridium complexes [20,21]. Herein, DFT calcula-
Fig. 2. UV–vis absorption and photoluminescence spectra of Ir(ppy)$_2$(LX) (LX = acac, dmd, tmd, CBDK, or FBDK) in CH_2Cl_2 solution.
Fig. 3. UV–vis absorption spectrum of Ir(DBQ)$_2$(acac) in CH_2Cl_2, photoluminescence spectra of neat Ir(ppy)$_2$(LX) films, and Ir(DBQ)$_2$(acac)/Ir(ppy)$_2$(LX) (LX = acac, dmd, tmd, CBDK, or FBDK) blend films doped with ∼7 mol% Ir(DBQ)$_2$(acac).

tions were carried out on these five iridium complexes. The HOMO and LUMO of Ir(ppy)$_2$(CBDK) are plotted in Fig. 5 as an example. Results show that in all five iridium complexes, the HOMO consists of a mixture of phenyl-π and Ir-d orbitals, while the LUMO orbital is localized primarily on the pyridine-π orbitals. That the HOMO and LUMO do not involve the β-diketonate fragments may be the best explanation for the observed phenomenon that they have similar HOMO and LUMO energy levels.

3.4. Electroluminescent properties

To understand the EL properties of Ir(DBQ)$_2$(acac) doped in the phosphorescent hosts and compare these results with a common host CBP, six devices (**I–VI**) using Ir(ppy)$_2$(acac), Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), Ir(ppy)$_2$(CBDK), Ir(ppy)$_2$(FBDK), and CBP as a host material, respectively, were fabricated with the same configuration of ITO/NPB (50 nm)/Ir(DBQ)$_2$(acac): Host ($\sim$7 mol%, 30 nm)/BCP (10 nm)/AlQ (30 nm)/Mg$_{0.9}$Ag$_{0.1}$ (200 nm)/Ag (80 nm), in which NPB is used as the hole-transporting layer, and BCP and AlQ are used as the hole-blocking layer and electron-transporting layer, respectively. The Mg:Ag layer is used as the cathode with a Mg:Ag mass ratio of 9:1, and with an 80-nm thick Ag cap. The chemical structures of the materials and the structure of the EL devices are shown in Fig. 6. The EL performances of those devices are summarized in Table 3.

The EL spectra of device **I** are shown in Fig. 7 as an example. The observed emission is attributed to the guest Ir(DBQ)$_2$(acac) at low voltages while an combined orange–red light from the host Ir(ppy)$_2$(acac) and guest was observed at higher applied voltages. The emission color changes from red to orange–red due to the increasing Ir(ppy)$_2$(acac) emission at higher current density, accompanied with the CIE chromaticity coordinates (x, y)

Table 2
Electrochemical potentials and energy levels of the iridium complexes.

Iridium complex	E^{ox} (V)[a]	E_g (eV)[b]	HOMO (eV)[c]	LUMO (eV)[d]
Ir(ppy)$_2$(acac)	0.35	2.36	5.15	2.79
Ir(ppy)$_2$(dmd)	0.30	2.36	5.10	2.74
Ir(ppy)$_2$(tmd)	0.25	2.36	5.05	2.69
Ir(ppy)$_2$(CBDK)	0.32	2.36	5.12	2.76
Ir(ppy)$_2$(FBDK)	0.26	2.36	5.06	2.70

[e] The maximum power efficiency and applied voltage.

IV, and (0.59, 0.41) at 23 V for device V. The device VI in which CBP was used as the host has a pure EL spectrum that originates from Ir(DBQ)$_2$(acac), and the CIE chromaticity coordinates does not change significantly from a value around (0.61, 0.39). The pure EL spectra of device VI may be attributed to a wide E_g between the host and guest leading to a completely energy transfer even at higher current density. Based on the reason mentioned above, pure EL spectra can be forecasted for all devices if a red-shifted guest, such as tris(1-phenylisoquinolinolato-C^2,N)iridium(III) [Ir(piq)$_3$], was used here [20,36].

Figs. 8 and 9 show the luminance–voltage and current–voltage curves for devices I–VI, respectively. The turn-on voltage is 3.8 V (1.86 cd m^{-2}), 4.3 V (1.08 cd m^{-2}), 3.2 V
Fig. 7. Electroluminescent spectra of device I at different applied voltages.

(1.34 cd m^{-2}), 3.0 V (1.85 cd m^{-2}), 5.0 V (2.20 cd m^{-2}), and 6.5 V (1.83 cd m^{-2}) for devices **I**, **II**, **III**, **IV**, **V**, and **VI**, respectively. Devices **I–V** using Ir(ppy)$_2$(LX) as host have lower turn-on voltages compared to device **VI**, in which CBP was used as the host. While among these devices based on Ir(ppy)$_2$(LX) host, devices **III** and **IV** have lower turn-on voltages. This phenomenon can also be observed when comparing luminance and current density under the same applied voltage. For example, for an applied voltage of 8 V, the luminance (current density) is 102.3 cd m^{-2} (0.756 mA cm^{-2}), 58.0 cd m^{-2} (0.534 mA cm^{-2}), 531.1 cd m^{-2} (2.84 mA cm^{-2}), 618.2 cd m^{-2} (6.50 mA cm^{-2}), and

14.8 cd m^{-2} (0.092 mA cm^{-2}) for devices **I**, **II**, **III**, **IV**, and **V**, respectively, which are higher than that of device **VI**, 7.5 cd m^{-2} (0.056 mA cm^{-2}). Moreover, devices **III** and **IV** have higher luminance and current density among devices **I–V**.

Fig. 10 shows the lumen efficiency as a function of current density for devices **I–VI**. All the devices **I–V** using iridium complexes as host have higher lumen efficiency than device **VI** based on CBP host. Among these devices **I–V**, devices **III** and **IV** exhibit the highest lumen efficiency. Device **III** displays a maximum brightness of 22360 cd m^{-2} at 16 V, a maximum external quantum efficiency of 12.6%, the highest power efficiency of 22.6 lm W^{-1} (3.4 V, 2.70 cd
Fig. 8. Luminance–voltage curves for devices **I–VI**.
Fig. 9. Current–voltage curves for devices **I–VI**.
Fig. 10. Lumen efficiencies as function of current density for devices **I–VI**.

m^{-2}, 0.011 mA cm^{-2}), and the highest current efficiency of 24.5 cd A^{-1}. In addition, when the brightness of device **III** was increased to 531.1 cd m^{-2} (2.84 mA cm^{-2}) it still had a power efficiency of 4.0 lm W^{-1} and current efficiency of 18.7 cd A^{-1} (external quantum efficiency 5.3%). Even at 10180 cd m^{-2} (181.2 mA cm^{-2}) the external quantum efficiency of 2.9% was kept. Device **IV** displays a maximum brightness of 17660 cd m^{-2} at 15 V, a maximum external quantum efficiency of 12.7%, the highest power efficiency of 22.0 lm W^{-1} (3.5 V, 4.41 cd m^{-2}, 0.018 mA cm^{-2}), and the highest current efficiency of 24.5 cd A^{-1}. The device **IV** also has excellent performances at higher current density or luminance. For example, when the brightness of device **IV** was increased to 127.8 cd m^{-2} (1.13 mA cm^{-2}) it still had a power efficiency of 5.9 lm W^{-1} and a current efficiency of 11.8 cd A^{-1} (external quantum efficiency 5.8%). Even at 375.5 mA cm^{-2} (>13,000 cd m^{-2}) the external quantum efficiency of 3.2% was maintained.

By comparing the electroluminescent properties of these devices, key factors that may influence the performances of this doped system could be emphasized. One is the steric hindrance of the host material. Comparing devices **I**, **II**, and **III** it can be seen that device **III** shows the best performance. This may arise from a larger distance between the central ions, which correspondingly reduce the triplet–triplet annihilation of the host [23]. However, the rule for steric hindrance is not the larger the better. The performance of device **V** can compare with device **III** only at higher current densities. It is likely that too large steric hindrance of the host material is not beneficial for exciton transportation. Another factor is the carrier-transporting property. When devices **IV** and **V** are compared, one can find that the performance of the former is much better than the later. This can be attributed to a carbazole group introduced to the β-diketone, which not only enhances its hole-transporting ability but also reduces the triplet–triplet annihilation [22,23]. In addition, it is interesting to observe that the performances of those devices using iridium complexes as hosts are much better than that of CBP, performing lower driving voltages and higher efficienies. The lower driving voltages were resulted from the easier hole injection from NPB to iridium complex based host because Ir(ppy)$_2$(LX) series have a higher HOMO level compare to that of CBP [37]. And the higher efficiency was arised from the efficient energy transfer from Ir(ppy)$_2$(LX) to guest because they have a lower tripet excited level compare to that of CBP, which confined energy better on the guest molecules [38].

4. Conclusion

In summary, phosphorescent OLEDs using an orange–red emitting iridium complex Ir(DBQ)$_2$(acac) as the guest and five green-emitting iridium complexes Ir(ppy)$_2$(acac), Ir(ppy)$_2$(dmd), Ir(ppy)$_2$(tmd), Ir(ppy)$_2$(CBDK), or Ir(p-py)$_2$(FBDK) as the host, respectively, were demonstrated. Results show that these devices have better performance than that of the device based on CBP hosts. Moreover, the steric hindrance and exciton transporting property of the host are found to be the most important factors to this kind of doped system.

ARTICLE INFO

ABSTRACT

In this paper, we described a new category of solution processable small molecule organic light emitting materials, the pyrene functioned diarylfluorenes: 2PE-PPF and DPE-PPF. They emit blue light in solution and green light in film, and show high thermal stability with the 5% weight loss temperature (T_d) over 400 °C. The glass transition temperature (T_g) for 2PE-PPF and DPE-PPF is 102 °C and 147 °C, respectively. These molecules are interesting molecular glass and they have good film forming abilities. Smooth and uniform film could be obtained by spin-coating. This character enables them able to be used in solution processed OLEDs by spin-coating or jet-printing. Single layered device using 2PE-PPF as the active material shows a turn-on voltage of 3.2 V, brightness over 8000 cd/m^2 and current efficiency up to 2.55 cd/A. Double layered device by inserting TPBI as the hole-blocking electron-transporting layer increases the maximum efficiency to 5.83 cd/A.

1. Introduction

Since the pioneering work by Tang and Friend in 1987 and 1990 [1], organic/polymeric light emitting diodes (OLEDs) have come to the commercial stage. Despite this progress, there are still many opportunities to improve the technology for both materials and devices. In OLEDs applications, amorphous materials are required for charge transporting and light emitting purpose. The amorphous materials with high thermal and morphological stability enable the fabrication of thermally stable OLEDs to increase device service time [2]. The materials with a low glass transition temperature and strong tendency to crys-

tallize are not proper for OLEDs because they will form grain boundaries which limit the charge transport and shorten the device lifetime [3].

Many stable amorphous molecules have been reported as functional materials in OLEDs for charge transporting/ blocking and light emitting purpose, such as 4,4',4"-Tris- (carbazol-9-yl)- triphenylamine (TCTA) [4], 2,2',7',- tetrakis-(N,N-diphenylamino)-9,9'-spirobifluorene (spiro-TAD) [5], 1,3-bis[5-(*p*-tert-butylphenyl)-1,3,4-oxadiazol-2-yl]- benzene (OXD-7) [6], 2,2',2"-(1,3,5-benzenetriyl) tris[1-phenyl-1H-benzimidazole] (TPBI) [7] and many chromophores. [8] They have good thermal and morpho-logical stability, as well as good film forming ability by vacuum deposition. For solution processed devices, the active materials are usually polymers, which could form smooth and uniform films without pinholes. The most famous examples are polyfluorenes blue emitters [9] and

Poly(phenylenevinylene) (PPV) series green and red light emitting polymers [10]. Yet, light emitting polymers could not be purified by common purification methods such as column chromatography, recrystallization and vacuum sublimation. This drawback limits their purity, especially those defects and catalyst residues, which strongly quench light emission and trap injected carriers [11].

Recently, a new category of monodisperse materials: dendrimers [12], starbursts [13] and nanocomposites [14], have emerged as promising light emitting materials. They have well defined chemical structure, high purity, and could be deposited by cheap and efficient solution process. However, their synthesis and purification are quite laborious. An alternate solution to combine the advantage of small molecule and polymer is to develop efficient solution processable small molecules, which could be easily synthesized and purified, and have good film forming ability by spin-coating. Oligofluorenes are interesting solution processable molecules [15], yet their T_g is low. Structure modification is needed to increase their T_g to enhance thermal and morphological stability [16]. For the unique advantages of solution processable small molecular light emitting materials, there is a current need to gain more understanding of the correlation between molecular structure and device function. It is important to design and synthesis new molecules to accelerate their practical application.

In this article, we report a new methodology to design solution processable amorphous light emitting molecular glass. Pyrene is used as the building block for its high photoluminescence efficiency, high carrier mobility and enhanced hole-injection ability compared to fluorene based materials [17,18]. To endow the molecules high T_g, the diarylfluorene building block was employed [19]. We have recently reported several pyrene functioned fluorene molecules for vacuum deposited blue OLEDs, in which the C9 position of fluorene unit was modified by attaching a pyrene group [18]. This approach was also employed here for it could improve the thermal stability and increase the T_g. Diarylfluorene moiety is very rigid and its derivatives usually show low solubility and high tendency to crystallize. To overcome these problems, one 2-ethylhexyloxyl solubilizing chain was introduced to the para- position of C9 substituted benzene group. Pyrenyl-ethenylene groups were kinked to the C2 and C7 position of diarylfluorene unit to extend the conjugation length and give rise to the emission color [20]. The resulted molecules show blue emission in dilute solution and green emission in film. They have good solubility and could form smooth and uniform films by spin-coating. Although a 2-ethylhexyloxyl chain is presented in the molecules, their T_g is still above 100 °C, which is comparable to polyfluorenes (The T_g of fluorene copolymers lies between 80 and 100 °C [21]. For poly (9, 9-dihexylfluorene), the T_g is 103 °C [22]). The synthetic procedure is quite easy and the target molecules could be purified by silica gel column. This design combines the synthetic simplicity and solution processability. In the device work, the molecules show green emission with high brightness and efficiency. These advantages make them interesting amorphous molecular glass for optoelectronic applications.

2. Experimental section

2.1. General experimental information

All reactions were monitored by TLC using pre-coated glass sheets purchased by Yantai Huiyou Silica Gel Developing Co. Ltd. (0.20 mm with fluorescent indicator UV254). Column chromatography was carried out using flash silica gel from Qingdao Haiyang Chemical Co. Ltd. (200 ∼ 300 mesh). ^1H NMR was recorded using a Varian spectrometer at 400 MHz. Molecular masses were determined by a SHIMADZU matrix-assisted laser desorption/ionization time-of-flight mass spectrometer (MALDI-TOF-MASS). Elemental analyses were performed on a Vario ELIII elemental analyzer. Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) were performed using a purged nitrogen atmosphere at a heating rate of 20 °C/min. Absorption and photoluminescence (PL) emission spectra of the materials were measured in dichloromethane using a SHIMADZU UV-3150 spectrophotometer and a SHIMADZU RF-5301PC spectrophotometer, respectively. Cyclic voltammetry (CV) was performed on an Eco Chemie's Autolab. The quantum chemical calculations were performed using Gaussian 03, B.04 program. Fluorescent life time was measured with an Edinburgh FL-920 spectrometer. The AFM analysis was performed on DI MultiMode NanoScope IIIa Vecco. WAXRD was performed on Bruker Advance 8 powder XRD spectrometer.

Synthesis of trimethyl(pyren-1-ylethynyl)silane (2): To a 100 ml flask, 1.0 g (5.0 mmol) 1-bromopyrene, 0.24 g (0.25 mmol, 5%) $Pd(PPh_3)_4$, 47.5 mg (0.25 mmol, 5%) CuI was added. The flask was protected by N_2. Then 30 ml degassed Et_3N and 30 ml toluene was added. After stirred for several minutes, 10 ml (15 mmol) ethynyltrimethylsilane was added. The reaction was kept under 70 °C for 12 h. Silica-gel chromatograph yields yellow solid product 1.2 g (yield 80%). ^1H NMR (400 MHz, $CDCl_3$) δ (ppm): 8.59 (d, 1H), 8.09 (m, 8H), 0.56 (s, 9H).

Synthesis of 1-ethynylpyrene (3): To a 100 ml flask, 1.2 g trimethyl(pyren-1-ylethynyl)silane (2) (4 mmol) was added. Then 30 ml THF and 30 ml MeOH were added. When compound 2 was dissolved, 5 g K_2CO_3 was added. The reaction was stirred under room temperature overnight. Silica-gel chromatograph yield brown product 0.77 g (yield 86%). ^1H NMR (400 MHz, $CDCl_3$) δ (ppm): 8.57 (d, 1H), 8.04 (m, 8H), 3.69 (s, 1H).

*Synthesis of 2-Bromo-9-(4'-(2"-ethylhexyloxyphenyl))-9-pyrenylfluorene (4a) and 2,7-Dibromo-9-(4'-(2"-ethylhexyloxyphenyl))-9-pyrenylfluorene (4b) follows our previous procedure. For 4a: ^1H NMR (400 MHz, $CDCl_3$) δ (ppm): 8.16 (d, J = 7.6 Hz, 1H); 8.10 (d, J = 7.6 Hz, 1H); 7.92–8.06 (m, 5H); 7.81 (d, J = 7.6 Hz, 2H); 7.70 (d, J = 8.0 Hz, 3H); 7.54–7.64 (broad, 1H); 7.38 (td, J = 7.6 Hz, 0.8 Hz, 1H); 7.23 (td, J = 7.6 Hz, 0.8 Hz, 1H); 3.80 (d, 5.6 Hz, 2H); 1.64–1.74 (m, 1H); 1.25–1.53 (m, 8H); 0.91 (s, 6H). For 4b: ^1H NMR (400 MHz, $CDCl_3$) δ(ppm): 8.17 (d, J = 7.6 Hz, 1H); 8.12 (d, J = 7.6 Hz, 1H); 7.94–8.08 (m, 5H); 7.78–7.92 (broad, 2H); 7.67 (d, J = 8.0 Hz, 4H); 7.51 (d, J = 8.0 Hz, 2.0 Hz, 2H); 3.80 (d, J = 6.0 Hz, 2H); 1.62–1.78 (m, 1H); 1.24–1.52 (m, 8H); 0.91 (s, 6H).

Synthesis of 2PE-PPF: To a 50 ml flask, compound 4a (0.65 g, 1 mmol), compound 3 (0.27 g, 1.2 mmol), tetrakis(triphenylphosphine) palladium (30.0 mg), and cuprous iodide (10.0 mg) was added. The flask was degassed and protected under N_2, and then degassed toluene (15 ml) and diisopropylamine (15 ml) was injected. The reaction mixture was stirred at 70 °C for 48 h, and then cooled to room temperature. The solvent was stripped off under reduced pressure. The residue was purified by column chromatography on a silica-gel column, yield solid yellow product 0.64 g (yield 80%). ^1H NMR (400 MHz, CDCl$_3$) δ (ppm): 8.56 (d, J = 9.2 Hz, 1H); 8.10–8.16 (m, 6H); 7.96–8.35 (m, 12H); 7.93–7.89 (m, 3H); 7.81 (d, J = 7.6 Hz, 1H); 7.68 (s, 1H); 7.44 (t, J = 7.2 Hz, 1H); 7.31–7.26 (m, 2H); 6.84 (broad, 2H); 3.82 (d, J = 4.8 Hz, 2H); 1.65–1.78 (m, 1H); 1.31–1.54 (m, 8H); 0.92 (m, 6H). ^{13}C NMR (100 MHz, CDCl$_3$) δ (ppm): 158.53, 153.35, 140.46, 139.43, 132.06, 131.70, 131.45, 131.39, 131.29, 130.64, 129.92, 129.76, 128.61, 128.46, 128.30, 128.00, 127.70, 127.64, 127.44, 126.61, 126.52, 126.39, 126.21, 125.78, 125.43, 125.19, 124.95, 124.70, 124.52, 122.92, 121.04, 120.79, 118.00, 115.07, 96.24, 89.38, 70.69, 66.46, 53.70, 39.69, 30.80, 29.38, 24.13, 23.32, 14.38, 11.43. MALDI-TOF-MS (m/z): Anal. calcd. for $C_{61}H_{46}O$ 795.0; found 795.4. Anal. calcd. C, 92.16; H, 5.83; found C, 92.11; H, 5.92.

Synthesis of DPE-PPF: To a 100 ml flask, compound 4b (0.73 g, 1 mmol), compound 3 (0.54 g, 2.4 mmol), tetrakis(triphenylphosphine) palladium (60.0 mg), and cuprous iodide (20.0 mg) was added. The flask was degassed and protected under N_2, and then degassed toluene (30 ml) and diisopropylamine (30 ml) was injected. The reaction mixture was stirred at 70 °C for 48 h, and then cooled to room temperature. The solvent was stripped off under reduced pressure. The residue was purified by column chromatography on a silica-gel column, yield solid yellow product 0.78 g (yield 77%). ^1H NMR (400 MHz, CDCl$_3$) δ (ppm): 8.54 (d, J = 9.2 Hz, 2H); 8.09–8.19 (m, 9H); 7.92–8.05 (m, 20H); 7.79 (d, J = 8.0 Hz, 2H); 7.34 (broad, 2H); 6.88 (d, J = 8.8 Hz, 2H); 3.82 (d, J = 6.0 Hz, 2H); 1.65–1.78 (m, 1H); 1.31–1.54 (m, 8H); 0.92 (m, 6H). ^{13}C NMR (400 MHz, CDCl$_3$) δ (ppm): 158.66, 153.62, 139.66, 132.06, 131.82, 131.72, 131.44, 131.26, 130.67, 129.76, 129.70, 128.48, 128.33, 127.76, 127.70, 127.42, 126.76, 126.39, 126.25, 125.80, 125.74, 125.52, 125.29, 125.00, 124.69, 124.64, 124.49, 123.40, 121.12, 117.87, 115.15, 96.14, 89.82, 70.70, 66.47, 39.67, 30.78, 29.35, 24.11, 23.29, 14.34, 11.40. MALDI-TOF-MS (m/z): Anal. calcd. for $C_{79}H_{54}O$ 1019.3; found 1019.5. Anal. calcd. C, 93.09; H, 5.34; found C, 93.01; H, 5.42.

Device fabrication and testing: LED was fabricated on pre-patterned indium–tin oxide (ITO) with sheet resistance 10–20 Ω/□. The substrate was ultrasonic cleaned with acetone, detergent, deionized water, and 2-propanol. Oxygen plasma treatment was made for 5 min as the final step just before film coating. Onto the ITO glass was spin-coated a layer of polyethylenedioxythiophene-polystyrene sulfonic acid (PEDOT: PSS) film with thickness of 40 nm from its aqueous dispersion. PEDOT: PSS film was dried at 80 °C for 12 h in the vacuum oven. The solution of the polymer was prepared under nitrogen atmosphere and spin-coated on to PEDOT: PSS layer. Typical thickness of

the emitting layer was 80 nm and heated at 60 °C for 30 min. Then a thin layer of 4 nm barium or 2 nm CsF as the electron injection cathode and the subsequent 120 nm thick aluminum protection layers were thermally deposited by vacuum evaporation through a mask at a base pressure below 4×10^{-4} Pa. The cathode area defines the active area of the device. The typical active area of the devices in this study is 0.17 cm^2. The EL layer spin-coating process and the device performance tests were carried out within a glove box under nitrogen atmosphere. Current–voltage (I–V) characteristics were recorded with a Keithley 236 source meter. EL spectra were measured by a PR 705 photometer (Photo Research). The external quantum efficiencies were determined by a Si photodiode with calibration in an integrating sphere (IS080, Labsphere).

3. Results and discussion

3.1. Synthesis and characterization

The pyrene functioned diarylfluorenes, 2PE-PPF and DPE-PPF, were synthesized according to the procedure sketched in Scheme 1. Compound 2 was synthesized by Sonogashira reaction (82% yields) from 1-bromopyrene [23], then the TMS protecting group was eliminated by using KOH in THF/CH$_3$OH solution. The intermediate 4 was prepared according the procedure in our previous publication with excellent yield [18b]. The Sonogashira coupling reaction was employed between the pyrene ethylene and monobromide 4a or dibromide 4b to achieve the target compound 2PE-PPF and DPE-PPF with 80% and 77% yields, respectively. They showed good solubility in common solvents such as dichloromethane, THF and toluene. Both the two compounds in this report were purified by silica column chromatography. They were fully characterized by ^1H and ^{13}C NMR, MALDI-TOF-MASS and elemental analysis. The results were consistent with the proposed structures.

3.2. Photophysical properties and electrochemistry

The UV–Vis absorption and photoluminescence spectra of the two materials were measured both in CH$_2$Cl$_2$ and in film, the corresponding data were summarized in Table 1. In solution absorption spectra, the onset absorption edge showed a red shift about 28 nm from 2PE-PPF to DPE-PPF. This was due to the increasing of conjugation length, resulting from a more conjugated pyrenyl-ethylene group at the C7 position of fluorene moiety in DPE-PPF (Fig. 1). The absorption spectra of the two molecules both in solution and in film were dominated by a series of peaks, which result from the combination of fluorene, pyrene and pyrenyl-ethylene groups. The peak at about 350 nm came from the pyrene unit at the C9 position of fluorene unit [18b]. Peaks at longer wavelength were due to the absorption from pyrenyl-ethylene functioned fluorene backbone. In the solid state absorption spectra, the absorption edges red shifted about 20 nm compared to solution absorption for each molecule. The phenomena indicated strong intermolecular aggregation existed in film. The

[b] LUMO = HOMO − ΔE (solution state band gap).

absorption peak of C9-pyrene red shifted about 5 nm compared to solution absorption. This red shift was less pronounced compared to the red shift of absorption edges, indicating the intermolecular aggregation comes from the conjugated backbone. The intermolecular interaction of C9-pyrenes was very weak. The diarylfluorene was highly twisted in structure, and it could hamper the molecular aggregation to some extent. Thus we believe the strong red shift of the absorption edges comes from the π-π stacking of C2 and C7 functioned pyrenyl-ethenylene group.

The solution emission spectra of 2PE-PPF and DPE-PPF displayed well structured emission band with the maximum at 412 and 439 nm, respectively (Fig. 2). In the solid state emission, both the two materials red shifted to the green emission region and the peaks are broad and structureless, which was typical excimer emission. 2PE-PPF showed a peak at 514 nm, and DPE-PPF showed a peak at 495 nm, Although DPE-PPF had a longer main chain conjugation, its film state emission located at the short wavelength region [24]. This was on the contrary to the absorption spectra. Pyrene had a strong tendency to form aggregation. This explained the remarkable red shift in emission from solution to film. The lower energy emission for 2PE-PPF was attributed to the aggregation nature of pyrene-ethenylene group at C2 position of fluorene unit. DPE-PPF was larger and more rigid in molecular structure. In the film forming process, it was less prone to form well packed aggregates than 2PE-PPF. The stronger aggregation

Fig. 3. Fluorescent life time measurement of 2PE-PPF and DPE-PPF films.

in 2PE-PPF caused its emission shifted to lower energy band. This explanation was supported by the observation of emission shoulders and tails. For 2PE-PPF, its emission shoulder and tail was stronger at lower energy region compared to DPE-PPF, indicating lower energy emission species existed in 2PE-PPF.

Fluorescent lifetime of 2PE-PPF and DPE-PPF films was measured with an Edinburgh FL-920 spectrometer [25]. The excitation source was a nanosecond flash lamp operating in the atmosphere of H_2 gas (0.40–0.50 bar, 1.2 ns FWHM, 40 kHz repetition rate), whose output was filtered through a monochromator prior to the sample excitation. All fluorescent lifetimes were determined from the data using the Edinburgh Instruments software package. The film was pumped under 240 nm excitation and probed at their maximum emission wavelength. The fluorescence decay was plotted in Fig. 3. The fluorescent lifetime was deduced by bi-exponential fitting. For 2PE-PPF, τ_1 = 2.23 ns, τ_2 = 7.62 ns; for DPE-PPF, τ_1 = 1.04 ns, τ_2 = 5.13 ns. The lifetime decreased from 2PE-PPF to DPE-PPF [26].

The electrochemical behavior of the materials was investigated by cyclic voltammetry (CV) with a standard three electrodes electrochemical cell in a 0.1 M tetra-n-butylammonium hexafluorophosphate (Bu_4NPF_6) in acetonitrile at room temperature under nitrogen with a scanning rate of 80 mV/s. A glassy carbon working electrode, a platinum counter electrode and an $Ag/AgNO_3$ (0.1 M) reference electrode were used. The oxidation onset potentials were measured to be 0.66 V and 0.60 V for 2PE-PPF and DPE-PPF, respectively. The corresponding HOMO energy levels were thus estimated to be -5.37 eV and -5.31 eV for 2PE-PPF and DPE-PPF by the method – (Eox + 4.71) reported by Li et al. [27]. This indicates that the pyrene center could improve the HOMO level, and thereby heighten the hole-affinity and hole-injection ability than conjugated fluorene derivatives (for polyfluorene, the HOMO level is -5.80 eV [28]). The LUMOs can be estimated by LUMO =

HOMO + ΔE (band gap) method. The band gap was calculated from the solution absorption edges. The corresponding data were also summarized in Table 1.

3.3. Electronic structure

To gain deep insight into the materials, quantum chemistry was employed to investigate the electronic structure of the molecules. To minimize calculation cost, the 2-ethyl-hexyloxyl group was substituted by methoxyl group in the calculation. The grand state geometry of the molecules was fully optimized by AM1 and B3LYP/6-31G methods [29]. The energy of highest occupied molecular orbital (HOMO)/lowest unoccupied molecular orbital (LUMO) and energy gap was listed in Table 2. In the B3LYP calculation, the resulting data were much more close to experimental observation, because the DFT calculation took good account on the correlation effect [30]. In the molecular perspective, the energy level of HOMO for both molecules was around -5.0 eV, indicating they had good hole-injection ability. And the energy gap decreased with the adding of the pyrenyl-ethenylene group, this was easy to understand because the conjugation was increased. It was interesting to note that from 2PE-PPF to DPE-PPF, with the adding of a pyrenyl-ethenylene group, the energy level of HOMO increased and the LUMO decreased, indicating

Table 2
The calculated HOMO, LUMO, and the energy gap (ΔE/eV) by AM1 and DFT-B3LYP/6-31G methods.

Methods	2PE-PPF			DPE-PPF		
	HOMO	LUMO	ΔE	HOMO	LUMO	ΔE
AM1	−7.967	−1.196	6.771	−7.931	−1.294	6.637
B3LYP/6-31G	−5.077	−1.887	3.190	−4.990	−2.063	2.928
Fig. 4. HOMO-LUMO orbitals of 2PE-PPF and DPE-PPF.

adding such a group enhanced both the hole-injection and electron injection. The HOMO and LUMO orbitals were shown in Fig. 4. They all localized on the main chain backbone, the C9-pyrene group had no contribution. This was because it was linked to the fluorene unit via a conjugation breaking manner.

3.4. Thermal and morphological properties

The thermal stability of the two materials was evaluated by thermogravimetric analysis (TGA) in nitrogen atmosphere. Thermal decomposition temperatures (5% weight loss temperature, T_d) for 2PE-PPF and DPE-PPF were 409 °C and 436 °C, respectively. The TGA results indicated that the materials were stable enough to be used as EL materials. The phase-transition properties of the two materials were determined by DSC in nitrogen atmosphere at a heating rate of 20 °C/min, the result was shown in Table 3. The T_g of 2PE-PPE was 102 °C, and the T_g of DPE-PPF was 147 °C. No melting temperature (T_m) was found for the two materials upon heating to 300 °C, revealing that 2PE-PPF and DPE-PPF were amorphous materials. Stable amorphous molecular materials were highly needed for long lifetime OLEDs. For solution processed OLEDs, this need was much more urgent. Solution processable light emitting molecules usually had a low T_g. This was because they were often substituted by long alkyl or alkoxyl chains to enhance the solution processability (For the *n*-pentyl-substituted fluorene pentamer, the T_g is 72 °C [15]; for

the low generation triazatruxene-centered starburst oligofluorenes, the T_g is 51 °C [13a]). For a small molecule bearing 2-ethylhexyloxyl solubilizing chain with the molecular weight of 795, while still keeping a T_g higher than 100 °C, this was very rare. The thermal stable amorphous molecular glass could make the spin-coated film bearing a much stable morphology under annealing or device operation.

The amorphous characteristics of 2PE-PPF and DPE-PPF were further studied by powder wide-angle X-ray diffraction (WAXRD), and pyrene was also examined for comparison. The WAXRD pattern was shown in Fig. 5. For pyrene, a series of sharp peaks were recorded with high intensity. For 2PE-PPF and DPE-PPF, similar weak and broad amorphous peaks at $2\theta = 14$, 21 (corresponding d values were 6.5 and 4.2 Å) were found, which were attributed to the π-π stacking of pyrene segments. The WAXRD experiment indicated by kinking pyrenyl-ethenylene group with fluorene could effectively reduce the crystalline nature of pyrene to get amorphous materials.

2PE-PPF and DPE-PPF had good solubility in common solvent such as THF, toluene, chlorobenzene and CHCl$_3$. We dissolved the materials in chlorobenzene with the concentration of 40 mg/ml, and spin-coated on the glass substrates with the speed of 3200 rpm/min. The thickness of obtained film was about 80 nm. The film was heated at 80 °C in nitrogen for 30 min. The morphology of the film was examined by AFM using typical tapping mode, as shown in Fig. 6. For 2PE-PPF, very smooth and uniform film without pinholes was obtained. For DPE-PPF, the film was not as smooth as 2PE-PPF, and some pinholes were found, which was not ideal for device because the pinholes would cause large leakage current [31].

Table 3
Thermal properties of 2PE-PPF and DPE-PPF.

Molecules	Molecular weight	T_g/°C	T_d/°C
2PE-PPF	795.02	102	409
DPE-PPF	1019.27	147	436

Fig. 6. AFM morphology of spin-coated film on glass substrate: (a) 2PE-PPF; (b) DPE-PPF.

3.5. Electroluminescence

Because of the good thermal stability and excellent film forming ability, 2PE-PPF was chosen as the active material in solution processed devices. Single layered device with the configuration of [ITO/PEDOT: PSS (40 nm)/2PE-PPF (80 nm)/Ba (4 nm) /Al (120 nm)] was fabricated (Device 1). It showed bright green emission with the peak at 522 nm. The turn-on voltage was 4.2 V, the maximal brightness was 3544 cd/m^2 and the maximal current efficiency reached 0.9 cd/A. The device performance was sum-marized in Table 4. The electroluminescence spectra were presented in Figs. 7 and 8 and the *I–V–L* characteristic was shown in Figs. 9 and 10.

Single layered device was optimized by using CsF/Al as cathode with the device configuration of [ITO/PEDOT: PSS (40 nm)/2PE-PPF (80 nm)/CsF (2 nm)/Al (120 nm)] (Device 2). The device showed bright green emission with the peak located at 528 nm, little red shifted compare to Device 1. The emission color remains quite stable with increasing the current. While increasing the current from 1 mA to 20 mA, the emission remained identical (Fig. 8). Compared

Table 4
Electroluminescence properties of 2PE-PPF based devices.

Device	Structure	Turn-on (V)	Brightness (cd/m²)	LE (cd/A)	EQE (%)	CIE 1931
1	PEDOT/2PE-PPF/Ba	4.2	3544	0.90	0.36	(0.36, 0.54)
2	PEDOT/2PE-PPF/CsF	3.2	8325	2.55	1.12	(0.39, 0.54)
3	PEDOT/2PE-PPF/TPBI/Ba	6.2	2579	5.83	2.32	(0.28, 0.54)
4	PEDOT/PVK: 2PE-PPF/CsF	2.4	4262	2.06	1.13	(0.19, 0.30)
Fig. 7. Electroluminescence of devices with different structure.
Fig. 8. Electroluminescence stability of Device 2.

to Device 1 using Ba electrode, Device 2 showed better performance. The turn-on voltage was reduced to 3.2 V, indicating that the CsF/Al cathode have better electron injection than Ba cathode [32], this could be seen from direct comparison of I–V characteristics of the two devices (Fig. 9). The brightness and current efficiency both increased to a great extent. For Device 2, the maximal current efficiency reached 2.55 cd/A (Fig. 10), and it remained quite stable with increasing the current density. The interesting efficiency-current density relationship was

similar to our previous pyrene functioned material based OLEDs by vacuum deposition, [18] indicating 2PE-PPF was a promising light emitting material. The maximal brightness for Device 2 was over 8000 cd/m², it was strong enough for lightening application. Based on this investigation and our previous work [13a], we found that for pyrene based materials, CsF was a more efficient cathode than barium in electron injection. This was because the Ba was still an injection limited cathode for 2PF-PPF. While using a thin layer of CsF, with the presence of Al capping cathode, free low work function alkali metal would be generated at the 2PE-PPF/CsF interface and the CsF layer produced an interfacial dipole. The combination of these two reasons lowered the Schottky barrier at the interface and enhanced the electron injection [33].

The device performance was further optimized by employing [1,3,5-tris (N-phenylbenzimidazol-2-yl)benzene] (TPBI) as the electron-transporting/hole-blocking layer. Double layered device using 2PE-PPF as the emitting material was fabricated with the structure of [ITO/PEDOT: PSS (40 nm)/2PE-PPF (80 nm)/TPBI (20 nm)/Ba (4 nm)/Al (120 nm)] (Device 3). Compared to Device 1 and 2, the emission blue shifted a little and its emission band was narrowed in FWHM (full-width at half-maximum). This was due to the adding of TPBI exciton blocking layer [34]. The turn-on voltage for Device 3 was increased to 6.2 V, this was due to the adding of 20 nm TPBI layer. The maximal brightness was over 2500 cd/m², and the light efficiency was improved to 5.83 cd/A, which was quite high for solution processed small molecule OLEDs. We believe further optimization could improve the device performance and fully explore the potential of the material.

The fluorescence molecules could be used as the bulk emitter in a neat film. It could also be used as the dopant in the electroluminescent devices. Because 2PE-PPF had strong aggregation in neat film, it would be interesting to study the optoelectronic properties of the isolated molecules. We blended 2PE-PPF into PVK to study its optoelectronic response in blends. 2PE-PPF was 20 wt% compared to PVK in the blend. To increase the electron-transporting properties, [2-(4-bi-phenylyl)-5-(4-tert-butylphenyl)-1,3, 4-oxadiazole] (PBD) was added (30 wt% compared to PVK) [35]. The configuration of the device was [ITO/PEDOT: PSS (40 nm)/PVK: 2PE-PPF (80 nm)/CsF (2 nm)/Al (120 nm)] (Device 4). The turn-on voltage was 2.4 V, the maximal brightness was over 4200 cd/m² and the peak efficiency reached 2.06 cd/A, as shown in figures 8, 10 and 11. 2PE-PPF worked as an efficient dopant in PVK and the intermolecular aggregation was strongly reduced. The emission shifted to the sky blue region with the CIE 1931 coordinates of (0.19, 0.30) (For Device 2, the CIE 1931 coor-
Fig. 9. I–V–L curve of devices 1(black line), 2(red line), 4(blue line). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

dinates were (0.39, 0.54)). The electroluminescence spectra were not the same as that of solution state photoluminescence, it was because in the solid state solution, the concentration for 2PE-PPF was still very high, and the electrical excitation was different from optical excitation in nature. These two reasons made the electroluminescence not the same as the solution state photoluminescence.

4. Conclusion

In this paper, we demonstrated a promising molecular glass with high thermal and morphological stabilities for optoelectronic applications. The pyrene functioned diarylfluorenes, especially 2PE-PPF, is easy to be obtained by simple synthetic procedures and could be purified by column chromatography. The solid state emission comes from the pyrene excimer, which is broad and structureless and

red shifted a lot from the solution state photoluminescence. Although the molecule is very small, and contains only one alkoxyl solubilizing group, it has good film forming ability, smooth and uniform film could be obtained by spin-coating. They have quite high T_d and T_g, which grant their service longevity in device operation. This material extends the device fabricating method of molecular glass. Single and double layered devices show efficient green emission, and the emission color remains quite stable with increasing the current. CsF is observed to be the optimal cathode for the material. Single layered device using CsF as the cathode shows a maximal current efficiency up to 2.55 cd/A and the maximal brightness over 8000 cd/m², which is quite high for a solution processed small molecule OLEDs. The efficiency of single layered device remained quite stable when current density increased. This feature is very interesting in OLEDs application.

ARTICLE INFO

ABSTRACT

It has been found that cesium hydroxide (CsOH) doped tris(8-hydroxyquinoline) aluminum (Alq_3) as an interfacial modification layer on indium-tin-oxide (ITO) is an effective cathode structure in inverted bottom-emission organic light-emitting diodes (IBOLEDs). The efficiency and high temperature stability of IBOLEDs with CsOH:Alq_3 interfacial layer are greatly improved with respect to the IBOLEDs with the case of Cs_2CO_3:Alq_3. Herein, we have studied the origin of the improvement in efficiency and high temperature stability via the modification role of CsOH:Alq_3 interfacial layer on ITO cathode in IBOLEDs by various characterization methods, including atomic force microscopy (AFM), ultraviolet photoemission spectroscopy (UPS), X-ray photoemission spectroscopy (XPS) and capacitance versus voltage ($C–V$). The results clearly demonstrate that the CsOH:Alq_3 interfacial modification layer on ITO cathode not only enhances the stability of the cathode interface and electron-transporting layer above it, which are in favor of the improvement in device stability, but also reduces the electron injection barrier and increases the carrier density for current conduction, leading to higher efficiency.

1. Introduction

Interfacial phenomena represent a challenge and important area in organic light-emitting diode science and technology, and they have been the subjects of recent theoretical and experimental studies [1–10]. At present, a variety of interfacial treatments have been applied to both the cathode/organic and anode/organic interfaces, influencing interfacial stability and charge injection, and leading to varying degrees of the improvement in device performances in terms of luminance, efficiency and lifetime [11–14]. For representative vapor-deposited multi-layer structure OLEDs, a significant increase in luminance and efficiency occurs upon the insertion of an interfacial layer (i.e. LiF [15], NaF [16], CsF [17], NaCl [18], alkali metal acetates [19], MgO [20], Liq [21], Cs_2CO_3 [22], C_{60} [23], and Cs:$POPy_2$ [24]) between the cathode and electron-transporting layer. Numerous mechanisms, including band bending, tunneling injection, LiF and CsF dissociation upon Al deposition, decrease of the Al surface potential, lowering the effective Al work function, as well as ETL protection during cathode deposition, have been suggested to explain the improvement in device performance.

As known, inverted bottom-emission organic light-emitting devices (IBOLEDs) are of considerable interest for display applications due to their easily integrating with either Si or organic thin film transistors for active-matrix displays [25]. However, generally, the structure of IBOLED

has an indium-tin-oxide (ITO) as the bottom cathode. A dogged issue of using ITO as the cathode is the high electron injection barrier due to the high work function of ITO, even though inserting interfacial layers. Although the problem can recently be overcome by evaporating an ultrathin layer of magnesium (Mg) or introducing a lithium (Li) or cesium (Cs) doped 4,7-diphenyl-1,10-phenanthroline (BPhen) layer onto ITO [26–28]. There yet exist problems, for example, the ultrathin Mg and active Li and Cs are rather difficult to handle and deposit, and the introduction of the Mg layer affects the transparency of ITO. Therefore, there is a continuing need to develop more effective electron interfacial layer materials, especially using ITO as the cathode.

Chen et al. [29] ever reported that introducing a Cs_2O:Bphen interfacial layer on ITO significantly enhanced the efficiency and lifetime of IBOLEDs, comparable with the conventional bottom-emission OLEDs. The improvement in device performance was attributed to the reduction in electron injection barrier from ITO, leading to the effective injection of electrons. Recently, we found [30] that cesium hydroxide (CsOH) doped Alq_3 as interfacial layer on ITO cathode could also significantly enhance the efficiency of IBOLEDs. More importantly, it was found that the device using CsOH:Alq_3 as the electron injection layer achieved 30–40% higher efficiency than that with Cs_2CO_3:Alq_3 interfacial layer. However, the origin of the improvement in efficiency via the modification role of CsOH:Alq_3 interfacial layer on ITO cathode in IBOLEDs is not yet understood well, and the complete studies on the effects of the CsOH:Alq_3 interfacial layer on the device stability of IBOLEDs are not still given.

In this paper, we carried out systematic studies on the role of CsOH:Alq_3 as interface modification layer on ITO cathode in the improvement of the efficiency and high temperature stability in IBOLEDs by atomic force microscopy (AFM), ultraviolet photoemission spectroscopy (UPS) and X-ray photoemission spectroscopy (XPS) and capacitance versus voltage (C–V). It is clearly seen that the CsOH:Alq_3 interfacial modification layer not only improves the stability of the interface at cathode and electron-transporting layer above it, leading to the stability at high temperature, but also reduces the electron injection barrier height, resulting in higher electron injection efficiency. More importantly, the free carrier density in CsOH:Alq_3 film is greatly enhanced with respect to Cs_2CO_3:BCP, Cs_2CO_3:Alq_3 films. As a result, the more electrons are injected, which is attributed to the higher efficiency compared to the case of Cs_2CO_3 doping.

2. Experimental

The used device structure in this study was ITO/CsOH:Alq_3 (20 wt%,10 nm)/Alq_3 (20 nm)/10-(2-benzothiazolyl)-2,3,6,7-tetrahydro-1,1,7,7-tetramethyl-1H,5H,11H-benzo[l]-pyrano-[6,7,8-i,j]quinolizin-11-one (C545T):Alq_3(0.6%, 20 nm)/N,N′-di(naphthalene-1-yl)-N,N′-diphenyl-benzidine (NPB)(40 nm)/MoO_3 (6 nm)/Al (120 nm). For comparison, ITO/Cs_2CO_3 (3 nm) or Cs_2CO_3:BCP (30 wt%, 10 nm), Cs_2CO_3:Alq_3 (5 wt%, 10 nm)/Alq_3(20 nm)/(C545T):Alq_3

(0.6%,20 nm)/NPB(40 nm)/MoO_3 (6 nm)/Al (120 nm) devices were also investigated. The aforementioned structures of devices have been optimized. The inverted bottom-emission organic light-emitting diodes (IBOLEDs) and thin films for the thermal treatment studies were prepared by thermal evaporation in a high-vacuum system with pressure of less than 5×10^{-4} Pa. In order to study the influence of the cathode interfacial layer on the stability of the cathode interface and electron-transporting layer, the substrate temperature referred to the temperature of evaporating the electron interfacial layer and transport layer. For an example of the devices fabricated at high substrate temperature, the electron interfacial layer and transport layer were prepared when the substrate temperature reached 170 °C or 190 °C, and then the light-emitting layer and other layers were evaporated after the substrate temperature was reduced to about 85 °C. For the thin films fabricated at high substrate temperature, thermal treatment was the same as the fabrication processes of devices. In our experiments, the commercial ITO-coated glass with a sheet resistance of around 10 Ω/□ was used as the cathode. The evaporation rates for organic layer and Al were 0.2 nm/s and 1 nm/s, respectively, which were monitored by frequency counter and calibrated by Dektak 6M Profiler (Veeco). The overlap between ITO and Al electrodes was 16 mm² as the emissive size of devices. For the measurements energy levels and morphologies of Alq_3, Cs_2CO_3/Alq_3, Cs_2CO_3:BCP/Alq_3, Cs_2CO_3:Alq_3/Alq_3 and CsOH:Alq_3/Alq_3 thin films at different substrate temperatures, they were deposited on ITO-coated glass substrates. The current–voltage–luminance characteristics were measured by a Keithley source measurement unit (Keithley 2400 and Keithley 2000) with a calibrated silicon photodiode. All the devices were measured without encapsulation at room temperature.

The morphology was measured by atomic force microscopy (AFM) (SIINT, SPA400). The electron concentration was measured by C–V (Agilent E 4980A). The interface electronic structure and variation in the work function were performed by XPS with Al kα X-ray source (1486.6 eV) and UPS with He discharge lamp (UV light of 21.22 eV) (Thermo ELECTRON CORPORATION, ESCALAB 250). The resolution of the spectra was 0.3 eV for XPS, 0.1 eV for UPS. The UPS measurements were performed with a −4 V bias voltage applied to the sample in order to enable the measurement of the secondary electrons cutoff.

3. Results and discussion

3.1. Electroluminescence properties of IBOLEDs

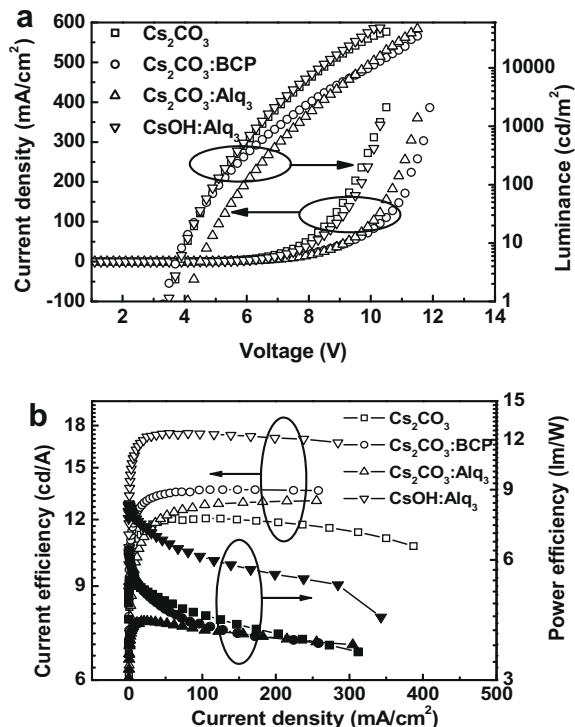
The electroluminescence (EL) performances of IBOLEDs with different interfacial modification layers on ITO cathode at different substrate temperatures were firstly investigated in detail. Fig. 1a and b show the current density–luminance–voltage, current efficiency–current density–power efficiency characteristics of devices with Cs_2CO_3, Cs_2CO_3:BCP, Cs_2CO_3:Alq_3 and CsOH:Alq_3 modification layers at room substrate temperature, respectively.


Fig. 1. Luminance–voltage–current density (a), current efficiency–current density–power efficiency (b) of ITO/cathode buffer layer/Alq$_3$/Alq$_3$:C545T/NPB/MoO$_3$/Al at room substrate temperature.

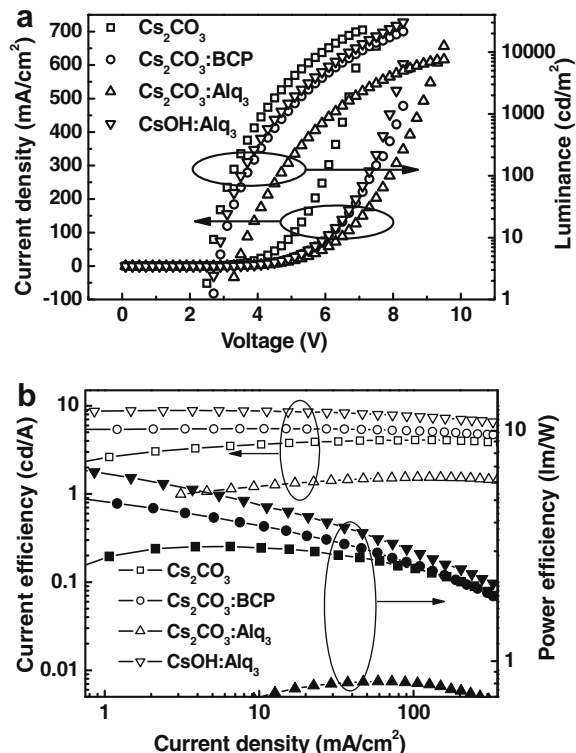
Fig. 2. Luminance–voltage–current density (a), current efficiency–current density–power efficiency (b) of ITO/cathode buffer layer/Alq$_3$/Alq$_3$:C545T/NPB/MoO$_3$/Al at substrate temperature of 170 °C.

The EL properties of ITO/Alq$_3$/Alq$_3$:C545T/NPB/MoO$_3$/Al device without the modification layer structure are not shown in Fig. 1 because the luminance and current efficiency are lower than 100 cd/m^2, 1 cd /A, respectively, due to high electron injection barrier between ITO cathode and Alq$_3$. It is clearly seen that the device with CsOH:Alq$_3$ interfacial layer shows more efficient EL performances than the case of Cs$_2$CO$_3$, Cs$_2$CO$_3$:BCP and Cs$_2$CO$_3$:Alq$_3$ as the interfacial layers. The device with CsOH:Alq$_3$ interfacial layer shows higher luminance and current density than devices with the case of Cs$_2$CO$_3$:BCP and Cs$_2$CO$_3$:Alq$_3$ as the interfacial layer at the same voltage. As shown in Fig. 1b, the higher current efficiency and power efficiency are obtained in device with CsOH:Alq$_3$ interfacial layer than in devices with Cs$_2$CO$_3$, Cs$_2$CO$_3$:BCP and Cs$_2$CO$_3$:Alq$_3$ as the interfacial layers. The maximum current efficiency and power efficiency, respectively, reach 17.4 cd/A and 8.3 lm/W in device with CsOH:Alq$_3$ interfacial layer. They are significantly higher than 12.1 cd/A and 5.3 lm/W of device with Cs$_2$CO$_3$ as the interfacial layer, 13.6 cd/A and 6.4 lm/W of device with Cs$_2$CO$_3$:BCP as the interfacial layer, and 13.0 cd/A and 4.2 lm/W of device with Cs$_2$CO$_3$:Alq$_3$ as the interfacial layer. These indicate that CsOH:Alq$_3$ should be an excellent electron injection interfacial material.

To further demonstrate the validity of CsOH:Alq$_3$ as interfacial layer, the EL performances of devices with different interfacial modification layers fabricated at different substrate temperatures are compared. Fig. 2 shows the EL performance characteristics of the devices with Cs$_2$CO$_3$,


Cs$_2$CO$_3$:BCP, Cs$_2$CO$_3$:Alq$_3$ and CsOH:Alq$_3$ modification layers at substrate temperature of 170 °C. It can be seen that the device with CsOH:Alq$_3$ interfacial layer yet shows higher luminance and power efficiency, reaching 32,300 cd/m^2 and 7.24 lm/W, approximately equal to the luminance and power efficiency of device fabricated at room substrate temperature. However, the EL efficiencies of the devices with Cs$_2$CO$_3$, Cs$_2$CO$_3$:BCP and Cs$_2$CO$_3$:Alq$_3$ as the interfacial layer are greatly reduced. Especially, the EL efficiencies of the devices with Cs$_2$CO$_3$ or Cs$_2$CO$_3$:Alq$_3$ as the interfacial layer are reduced to 4.09 cd/A (3.14 lm/W) and 1.54 cd/A (0.816 lm/W), obviously lower than the cases of room substrate temperature.

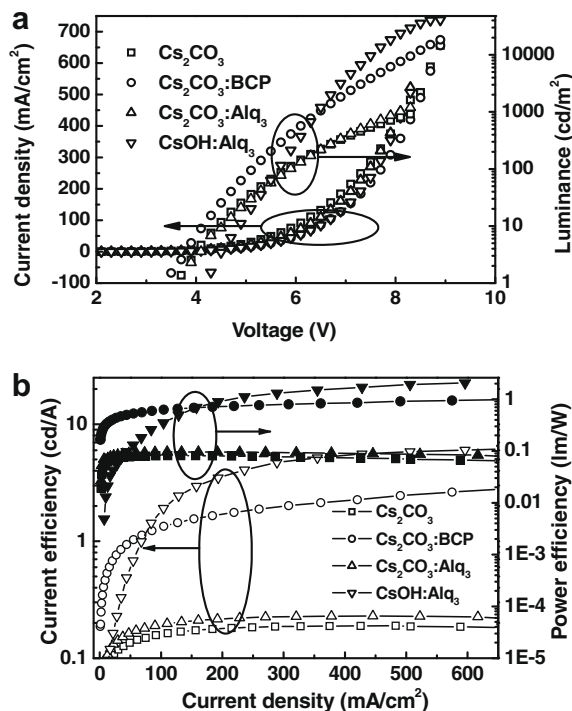
The reduction difference in luminance and EL efficiency is further obvious at higher substrate temperature. As the case of the devices fabricated at substrate temperature of 190 °C, which is above the glass transition temperature of Alq$_3$, the EL performances are shown in Fig. 3. It can be seen that the device based on Cs$_2$CO$_3$ or Cs$_2$CO$_3$:Alq$_3$ as the interfacial layer hardly emits light, whereas the EL efficiencies of device with Cs$_2$CO$_3$:BCP interfacial layer are reduced to 2.98 cd/A and 0.98 lm/W. However, as shown in Fig. 3, the device with CsOH:Alq$_3$ interfacial layer may still operate well with efficiencies of 6.27 cd/A and 2.06 lm/W. All of these results demonstrate that the CsOH:Alq$_3$ is an ideal cathode interfacial layer material in enhancing EL efficiency and high temperature stability of IBOLEDs.


Fig. 3. Luminance–voltage–current density (a), current efficiency–current density–power efficiency (b) of ITO/cathode buffer layer/Alq$_3$/Alq$_3$:C545T/NPB/MoO$_3$/Al at substrate temperature of 190 °C.

3.2. Morphology of electron-transporting layer

For insight into the origin of the observed great improvement in device performance due to the utilization of the CsOH:Alq$_3$ interfacial layer, the effects of different interfacial layers on the morphology of electron-transporting layer Alq$_3$ at different substrate temperatures were studied in detail by atomic force microscope (AFM). The atomic force microscopy images of Alq$_3$ (20 nm) (I), Cs$_2$CO$_3$ (3 nm)/Alq$_3$ (20 nm) (II), Cs$_2$CO$_3$:BCP (30 wt%, 10 nm)/Alq$_3$ (20 nm) (III), Cs$_2$CO$_3$:Alq$_3$(5 wt%, 10 nm)/Alq$_3$ (20 nm) (IV) and CsOH: Alq$_3$ (20 wt%,10 nm)/Alq$_3$ (20 nm) (V) films on ITO are shown in Fig. 4. It is clearly seen that the spots grow larger in some areas and spread to almost all regions of the samples for the case of ITO/Alq$_3$ and ITO/Cs$_2$CO$_3$:Alq$_3$/Alq$_3$ fabricated at substrate temperature of 170 °C, and the spots become severe as the substrate temperature increases to 190 °C. Although the Alq$_3$ film above Cs$_2$CO$_3$ and Cs$_2$CO$_3$:BCP interfacial layer keeps a basically featureless morphology with a small root mean square (RMS) roughness of 1.1 nm, 1.2 nm, respectively, in case of 170 °C substrate temperature, which are smaller than the RMS of 1.5 nm of Alq$_3$ without cathode buffer layer. However, the RMS roughness of Alq$_3$ film above Cs$_2$CO$_3$ and Cs$_2$CO$_3$:BCP interfacial layer reaches 5.5 nm, 9.9 nm as the substrate temperature is up to 190 °C. This indicates that the Alq$_3$ films above these interfacial layers are crystallized, which will degrade the performances of IBOLEDs. Differently, the CsOH:Alq$_3$ interfacial layer keeps the stable morphology of Alq$_3$ film above it, even at substrate temperature of 190 °C. A relatively flat surface with RMS roughness of 0.7 nm and 3.4 nm at 170 °C and 190 °C is obtained. These studies show that CsOH:Alq$_3$ as the interfacial layer greatly improves the stability of the morphology of Alq$_3$ film above it, which should favor the high temperature stability of IBOLEDs.

3.3. Electron injection barrier at interfaces

It is known that the improvement mechanism of Cs$_2$CO$_3$ or Cs$_2$CO$_3$ doping as an interfacial layer is attributed to the enhancement of electron injection due to the reduction of electron injection barrier [31–34]. One reason is that the Cs$_2$CO$_3$ tends to decompose into CsO$_2$ and CO$_2$ to form X–O–Cs complex during evaporation, thus enhancing the electron injection [32]. Another is that the metallic Cs is diffused into the Alq$_3$ surface to form an efficient electron injection contact during the thermal evaporation of Cs$_2$CO$_3$ [33]. Furthermore, the increase of free electron density is also considered as to be one of the main reasons in the enhancement of electron injection in the case of Cs$_2$CO$_3$ doping [34]. Similar processes may occur in the case of CsOH doping. However, as we can see, the CsOH doped Alq$_3$ as the interfacial layer significantly enhances the device efficiency with respect to Cs$_2$CO$_3$ and Cs$_2$CO$_3$ doped Alq$_3$. In order to clearly elucidate the advantage of the CsOH doped Alq$_3$ as the interfacial layer, the effect of CsOH:Alq$_3$ on interfacial barrier is investigated by UPS. Fig. 5a and b show the UPS spectra of Cs$_2$CO$_3$ (2 nm), Cs$_2$CO$_3$:BCP (2 nm), Cs$_2$CO$_3$:Alq$_3$ (2 nm) and CsOH:Alq$_3$ (2 nm) on ITO interface as well as ITO. As shown in UPS spectra, the work function (ϕ_{buffer}) of ITO is calculated to be 4.70 eV, and the work function of ITO with Cs$_2$CO$_3$, Cs$_2$CO$_3$:BCP, Cs$_2$CO$_3$:Alq$_3$ and CsOH:Alq$_3$ modification layer is reduced to 4.00 eV, 4.38 eV, 4.40 eV, and 4.50 eV, respectively. This lower work function due to the modification of interfacial layer has been ascribed to the formation of interfacial dipoles (ID$_1$ = vacuum$_{cathode\ buffer\ layer}$ − vacuum$_{ITO}$), which reduces the vacuum level, leading to lower electron injection barrier, thus facilitating electron injection.

Furthermore, the UPS spectra of ITO/Alq$_3$ (2 nm), and ITO/Cs$_2$CO$_3$ (3 nm), Cs$_2$CO$_3$: BCP (10 nm), Cs$_2$CO$_3$:Alq$_3$ (10 nm), or Alq$_3$:CsOH (10 nm)/Alq$_3$ (2 nm) films are performed, as shown in Fig. 5c and d. It can be calculated that the interfacial dipole (ID$_2$ = vacuum $_{Alq3}$ − vacuum$_{cathode\ buffer\ layer}$) of 0.20 eV is generated at ITO/Alq$_3$, the interfacial dipoles of −0.10 eV, −0.96 eV, −0.96 eV, −0.64 eV are formed for Cs$_2$CO$_3$/Alq$_3$, Cs$_2$CO$_3$:BCP/Alq$_3$, Cs$_2$CO$_3$:Alq$_3$/Alq$_3$ and Alq$_3$:CsOH/Alq$_3$, respectively. Therefore, the utilization of the interfacial modification layer induces lower vacuum level of Alq$_3$ to reduce further electron-injection barrier height compared to that without interfacial modification layer.

The detailed values extracted from the Fig. 5 are shown in Fig. 6. In energy diagrams, the band bending effects are negligible because the change of HOMO is almost the same as the change of the vacuum level. From the optical band gap (2.7 eV for Alq$_3$) and HOMO energy level, the evolution of the lowest unoccupied molecular orbital (LUMO) of Alq$_3$ can be determined. As the energy diagram shown in Fig. 6, the electron injection barrier from ITO to Alq$_3$ is 1.73 eV for
Fig. 4. Atomic force microscopy images of Alq$_3$ (I), Cs$_2$CO$_3$/Alq$_3$ (II), Cs$_2$CO$_3$:BCP/Alq$_3$ (III) and Cs$_2$CO$_3$: Alq$_3$/Alq$_3$ (IV) CsOH: Alq$_3$/Alq$_3$ (V) films fabricated at substrate temperature of 170 °C (A), and 190 °C (B).
Fig. 5. UPS spectra ITO, ITO/Alq$_3$, ITO/Cs$_2$CO$_3$, ITO/Cs$_2$CO$_3$:BCP, ITO/Cs$_2$CO$_3$:Alq$_3$, and ITO/Alq$_3$:CsOH shown in (a) and (b), ITO/Alq$_3$, ITO/Cs$_2$CO$_3$/Alq$_3$, ITO/ Cs$_2$CO$_3$:BCP/Alq$_3$, ITO/ Cs$_2$CO$_3$:Alq$_3$/Alq$_3$, and ITO/Alq$_3$:CsOH/Alq$_3$ shown in (c) and (d).

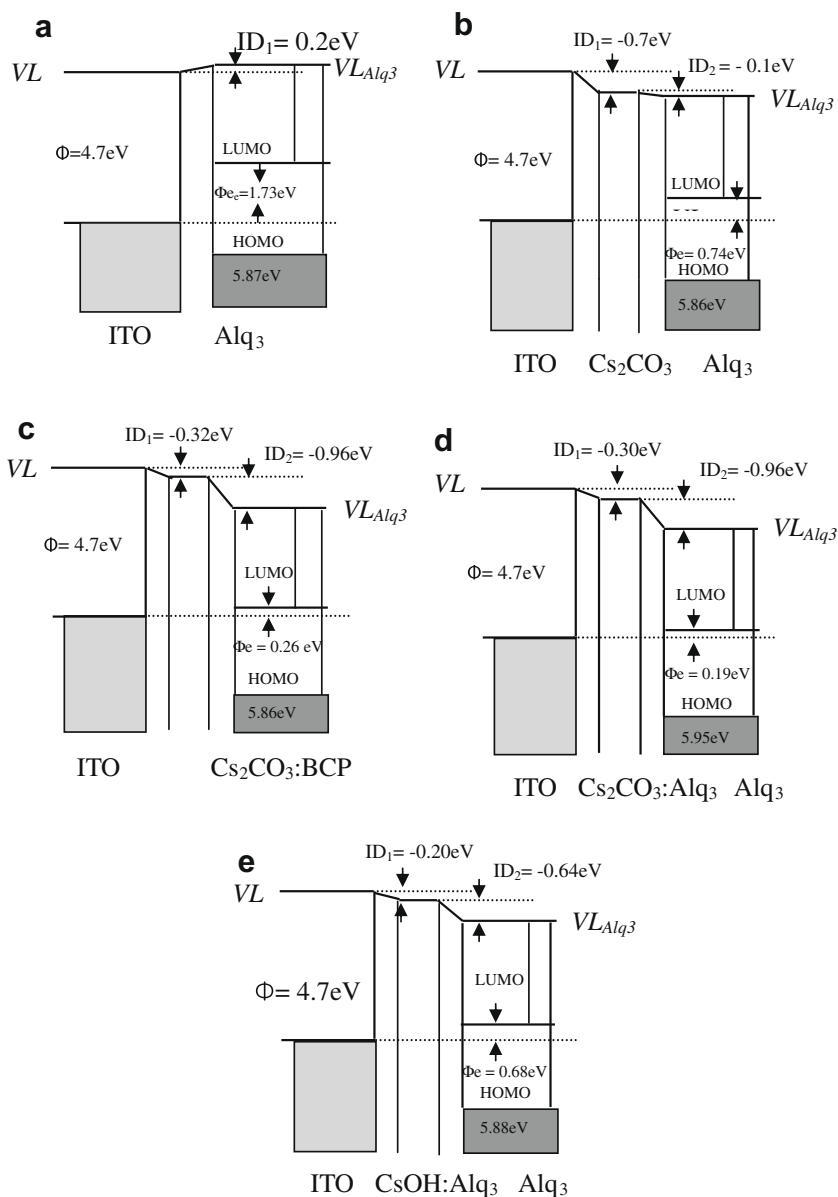
the case of ITO/Alq$_3$, whereas the electron injection barriers are reduced to 0.74 eV, 0.26 eV, 0.19 eV and 0.68 eV, respectively, as inserting Cs$_2$CO$_3$, Cs$_2$CO$_3$:BCP, Cs$_2$CO$_3$:Alq$_3$ and CsOH:Alq$_3$ interfacial layers between ITO and Alq$_3$.


Fig. 6. Schematic energy diagrams of ITO/Alq$_3$ (a), ITO/Cs$_2$CO$_3$/Alq$_3$ (b), ITO/Cs$_2$CO$_3$:BCP /Alq$_3$ (c), ITO/Cs$_2$CO$_3$:Alq$_3$/Alq$_3$ (d), ITO/Alq$_3$:CsOH/Alq$_3$ (e) extracted from the UPS.

Obviously, these cathode interfacial modification layers greatly reduce the electron injection barrier, which should be benefit for the improvement of EL efficiency.

The XPS spectra of ITO, ITO/Cs$_2$CO$_3$:Alq$_3$ (2 nm), ITO/Cs$_2$CO$_3$:Alq$_3$ (30 nm), ITO/CsOH:Alq$_3$ (2 nm), and ITO/CsOH:Alq$_3$ (30 nm) films are shown in Fig. 7. It can be seen that the In and Sn binding energies shift to lower level after deposition of 2 nm Cs$_2$CO$_3$:Alq$_3$ or CsOH:Alq$_3$ film on ITO compared to that of bare ITO. Meanwhile, the Cs peak in the case of deposition of 2 nm Cs$_2$CO$_3$:Alq$_3$ or CsOH:Alq$_3$ film keeps higher binding energy than that in the case of 30 nm Cs$_2$CO$_3$:Alq$_3$ or CsOH:Alq$_3$ film. This indicates that there occurs electron transfer from CsOH (Cs$_2$CO$_3$) to ITO,

resulting in the vacuum level shift down. Furthermore, the reaction between ITO and CsOH (Cs$_2$CO$_3$) may also form the Sn or In–O–Cs complex [32], which further lowers the work function of ITO. As the experiment shown, the utilization of CsOH:Alq$_3$ interfacial layer greatly reduces the electron injection barrier from ITO, which is similar to that of Cs$_2$CO$_3$ modification with respect to the case of bare ITO. However, the electron injection barrier is not further reduced due to the modification of CsOH:Alq$_3$ compared to the modification of Cs$_2$CO$_3$:Alq$_3$ and Cs$_2$CO$_3$:BCP. This indicates that the large enhancement in EL efficiency is not mainly originated from the reduction of the electron injection barrier as using CsOH:Alq$_3$ to modify ITO.
Fig. 7. XPS spectra of ITO, ITO/Cs$_2$CO$_3$:Alq$_3$ (2 nm), ITO/Cs$_2$CO$_3$:Alq$_3$ (30 nm), ITO/CsOH:Alq$_3$ (2 nm) and ITO/CsOH:Alq$_3$ (30 nm).

3.4. Free electron density

To elucidate the main origin of the improvement in EL efficiency due to the utilization of CsOH:Alq$_3$ interfacial modification layer, the capacitance–voltage characteristics of ITO/Alq:Cs$_2$CO$_3$ (100 nm), BCP: Cs$_2$CO$_3$ (100 nm), Alq:CsOH (100 nm)/Al were performed. As we know, capacitance-voltage characteristics have been widely used to investigate the electrical and charge transport properties in organic diodes. For one-sided injection organic diodes, i.e. one side contact is ohmic, the other side is injection limited, which controls the charge injection and forms the depletion layer, then the free charge carriers can be determined well by the capacitance–voltage characteristics [35–39]. In this case, the capacitance can generally be described as [40]:

$$\frac{1}{C^2} = \frac{2(V_{bi} - V)}{A^2 q \varepsilon \varepsilon_0 N_A} \tag{1}$$

where q is elementary charge, V_{bi} is the built-in potential, ε is the relative dielectric constant, ε_0 is the vacuum permittivity, A is effective area of device, and N_A is the active concentration of free charge carriers. $1/C^2 - V$ plots with different doped layer are shown in Fig. 8. It is found that the fitted lines are in good agreement with $1/C^2$ versus the bias voltage curves, where all the relative coefficients
Fig. 8. $1/C^2$ vs. V_{bias} plots of different doped layers.

(R) are above 0.98. The free carrier density can be easily extracted from the slope. The calculated carrier density values are summarized in Table 1. It is surprisingly found that the free carrier density is strongly dependent on the dopants in doped layers as determined by capacitance–voltage measurements. For example, the CsOH:Alq$_3$ film shows the highest value, which is much 10 times higher than Cs$_2$CO$_3$: Alq$_3$ and 20 times higher than Cs$_2$CO$_3$:BCP. The large increase of the free carrier density in the CsO-

Table 1

	k_A	R	N_A (10^{16} cm^{-3})
Cs$_2$CO$_3$:BCP	1.179E16	0.984	16.25
Cs$_2$CO$_3$:Alq$_3$	6.768E15	0.999	27.17
CsOH:Alq$_3$	4.669E14	0.993	393.81

[a] The relative dielectric constant ε is assumed to be 3, and the active area of device is 16 mm^2. For C–V measurements, 0.03 V signal oscillating at 1 kHz was added to dc bias.
Fig. 9. XPS spectra of Alq$_3$ (30 nm), Cs$_2$CO$_3$:Alq$_3$ (30 nm), and CsOH:Alq$_3$ (30 nm) films.

H:Alq$_3$ film should be attributed to the most effective electron injection.

The larger increase of the free electron density in CsOH:Alq$_3$ film could be well elucidated by XPS spectral measurements. Fig. 9 shows the XPS spectra of the Alq$_3$ (30 nm), Cs$_2$CO$_3$:Alq$_3$ (30 nm) and CsOH:Alq$_3$ (30 nm) films. It can be seen that a new peak appears and Al peak shifts to higher binding energy value in the Cs$_2$CO$_3$:Alq$_3$ and CsOH:Alq$_3$ films. This indicates that there occurs charge transfer between the Cs$_2$CO$_3$ and Alq$_3$ or CsOH and Alq$_3$. Furthermore, the Al peak of CsOH:Alq$_3$ film shifts to higher binding energy than that of Cs$_2$CO$_3$:Alq$_3$ film, indicating that the more charge transfer states are formed between CsOH and Alq$_3$. As known, the formed charge transfer state generally exhibits a high conductivity [41]. This should be used to explain the reason that the higher free carrier density occurs in CsOH:Alq$_3$ film. It can be seen that the electron injection properties strongly depend on the dopant structures and electron transport materials. The detailed mechanism investigation should be benefit for the understanding of the electron transport properties in doping organic films, thus further optimizing device performances.

4. Conclusions

We have studied the origin of the improvement in EL efficiency and high temperature stability via the modification role of CsOH:Alq$_3$ interfacial layer on ITO cathode in inverted bottom-emission organic light-emitting diodes (IBOLEDs) in detail. The studies clearly demonstrated that the CsOH:Alq$_3$ interfacial modification layer on ITO cath-

ode significantly enhanced the stability of the cathode interface and reduced the electron injection barrier from ITO cathode. More importantly, inserting the CsOH:Alq$_3$ between ITO and electron-transporting layer greatly increased the free carrier density leading to the more effective electron injection.

ARTICLE INFO

ABSTRACT

We have observed, respectively, a negative differential resistance (NDR) and switching conduction in current–voltage (I–V) characteristics of organic diodes based on copper phthalocyanine (CuPc) film sandwiched between indium-tin-oxide (ITO) and aluminum (Al) by controlling the evaporation rate. The NDR effect is repeatable, which can be well controlled by sweep rate and start voltage, and the switching exhibits write-once-read-many-times (WORM) memory characteristic. The traps in the organic layer and interfacial dipole have been used to explain the NDR effect and switching conduction. This opens up potential applications for CuPc organic semiconductor in low power memory and logic circuits.

1. Introduction

Organic molecular semiconductors have been intensively studied for more than twenty years due to their envisioned applications in flexible, low-cost and light-weight organic optoelectronics [1–4]. The physical processes of electrical transport in organic semiconductors (charge injection, transport, and space charge effects) have also been widely explored [5], which are quite different from the crystalline inorganic semiconductors. Considering the injection process can be viewed as a supply vs. demand problem, the current–voltage (I–V) characteristics in organic devices are generally dominated by the charge injection or transport processes in organic semiconductor. On the other hand, it was found experimentally that some or-

ganic devices showed negative differential resistance (NDR) characteristics [6–11] that have tremendous potential in the applications of low power memory and logic circuits, or irreversible switching currents which possibility of obtaining write-once-read-many-times (WORM) memories for archiving non-editable databases [12–14]. These devices based on organic semiconductors could satisfy the requirement in the low end of the market and some of them have been reported in recent years.

In this paper, we realized a single-layer diodes with repeatable NDR and switching exhibiting WORM memory in I–V characteristics based on copper phthalocyanine (CuPc), a macrocyclic metal complex, which has been one of the most popular organic semiconductors with high thermal and chemical stability suitable for thin film preparations [15], and widely reported in electrical transport and switching in organic devices [4,16–18]. It was found experimentally that the CuPc exhibits distinctly different I–V characteristics by merely changing the evaporation

rates of the CuPc. Our results demonstrate that CuPc is a hopeful organic semiconductor as memory medium in organic diodes for the applications in low power information storage and logic circuits.

2. Experimental details

The fabricated device in this study was a single-layer sandwich structure. Indium-tin-oxide (ITO) coated on glass substrate was used as one of the electrodes. CuPc was firstly thermally evaporated on ITO coated glass substrate at a controlled evaporation rate. The high, normal, and low deposition rate (H, N and L for short) of CuPc was, respectively, 0.50, 0.10, and 0.05 nm/s. Then 150 nm aluminum (Al) was thermally deposited on the CuPc film as another electrode. If using calcium (Ca)/Al electrode, 10 nm Ca was first deposited and then 150 nm Al was capped on Ca. For the case of molybdenum oxide (MoO_3)/Al electrode, 3 nm MoO_3 layer was firstly deposited. The thickness of CuPc film was about 400 nm. All of the deposition processes were carried out in a vacuum of 10^{-4} Pa. The I–V characteristics were performed by Keithley 2400 sourcemeter controlled by a computer, and the positive electric voltage was defined the Al electrode as positive bias. The atomic force microscope (AFM) measurements were carried out on a scanning probe microscope (SPA-300HV, Seiko Instruments, Inc.). All the electrical measurements were done in ambient condition without any device encapsulation.

3. Results and discussion

It was experimentally found that a large NDR is observed in I–V characteristics only when the organic layer was deposited by high rates and the applied voltage starts from certain negative voltage. Fig. 1 shows the typical I–V characteristics of the ITO/CuPc (H)/Al device between voltages of −16 to 16 V. As sweeping the voltage from −16 to positive bias, the current is initially high, and increases with bias voltage. When the bias voltage reaches a certain value, the current starts decrease with the bias, forming a NDR region. Finally, the current remained at a low current state from 16 V back to 0. It can be seen that a high current state (ON state) and a low current state (OFF state) exist simultaneously at the same voltage in the positive region. It should be noted that the ON state and NDR characteristic can be recovered from the low current state by simply applying a negative bias voltage. However, the devices ITO/CuPc (N)/Al, whose organic layer deposited with normal rate, have no similar NDR I–V characteristics, as shown in the insert of Fig. 1.
Furthermore, it can be seen that the occurrence of the hysteretic NDR and the ON/OFF current ratio depend strongly on the magnitude of the applied reverse start voltage in ITO/CuPc (H)/Al. As shown in Fig. 2, a higher negative start voltage leads to the occurrence of the larger hysteresis and higher ON/OFF current ratio, whereas the hysteresis and NDR vanish if the sweep voltage from negative is less than a critical value. The insert of Fig. 2 shows the currents of ON and OFF states at 3 V and the ON/OFF current ratio as a function of the negative sweep voltages. The maximum ON/OFF current ratio is over 4600. It is noteworthy that the ON state current and ON/OFF current ratio are also greatly dependent on the sweep rate. Fig. 3 shows the I–V characteristics of the ITO/CuPc (H)/Al device at different sweep rates after applying −16 V reverse bias voltage for 3 s. It can be seen that a faster sweep rate results in larger ON current and larger ON/OFF current ratio.

The similar hysteresis and NDR phenomenon in I–V characteristics are also observed in ITO/CuPc (H)/Ca/Al devices. However, as inserting an electron-blocking layer of MoO_3 between CuPc and Al to fabricate devices of ITO/CuPc (H)/MoO_3/Al, the NDR is disappeared and the hysteresis is greatly reduced. Fig. 4 gives the comparison in I–V characteristics of three different devices of ITO/CuPc (H)/Al, ITO/

Fig. 4. Comparison of I–V characteristics of the ITO/CuPc/Ca/Al, ITO/CuPc/MoO$_3$/Al and ITO/CuPc/Al devices.
Fig. 6. The retention ability of the memory device ITO/CuPc (H/L)/Al. The currents of the ON and OFF states were measured continuously under a constant bias of 1.0 V.

CuPc (H)/Ca/Al and ITO/CuPc (H)/MoO$_3$/Al. This indicates that the electron injected in the device during the application of negative voltage plays an important role in the NDR properties.

However, it was found that the device ITO/CuPc (H/L)/Al with a 20 nm low-deposited CuPc layer between 270 nm high-deposited CuPc and Al electrode exhibit switching conduction in I–V characteristics [19]. Fig. 5 shows the typical I–V characteristics of the device ITO/CuPc (H/L)/Al, which were measured by scanning the voltage from 0 to V_{max} (10 V) and then to 0. The current in ON state is increased linearly with the voltage and decreased abruptly as switching transition at a critical bias (about 4.8 V). Then the device remains the OFF state as the voltage sweeping to high value and back to 0. This OFF state will be retained permanently in the subsequent voltage sweeps. The typical ON/OFF current ratio observed in the sweep I–V characteristics at 1.0 V, as shown in Fig. 5, is over 5.6×10^5. It was interestingly noted that the a repeatable NDR effect can be observed in the I–V characteristics in the case of OFF state, as shown in the insert of Fig. 5. Fig. 6 shows the retention ability of the memory device, in which the cur-

rents of the ON and OFF states were measured continuously under a constant bias of 1.0 V. It can be seen that the device remains good stability without any degradation.

We further studied the I–V characteristics of the ITO/CuPc (H/L)/Al device, and found that the currents of OFF states were injection limited, as previous reported [20,21], whereas the ON state currents are ohmic conduction. This means that a perfect ohmic contact at the interface of CuPc (L)/Al is formed as the currents transit to ON state from OFF state, i.e. the change of the injection barrier height leads to the ON–OFF state transition.

It is worthy noting that the voltage value shifts away zero as the current reaches the maximum value in the case of ITO/CuPc (H)/Al. This should indicate the existence of space charges in devices. Furthermore, as shown above, only by applying certain negative voltage bias can lead to the NDR. The bias polarity dependence demonstrates that the NDR characteristics in our devices should be due to the interface

effects [22], directly related to the interfacial traps [23], leading to the formation of space charge due to trapping.

To clearly demonstrate the mechanism of the NDR and switching conduction, the energy band diagrams of the devices at forward bias are depicted in Fig. 7. For the case of ITO/CuPc (H)/Al devices, some electrons are injected and trapped in CuPc near the side of Al at sufficient negative bias (ITO as anode and Al as cathode). In this state, when the voltage is swept to the positive value, the electric field at the Al/CuPc interface increases due to the existence of the trapped electrons, resulting in the band bending, thus greatly decreasing the injection barrier of holes, leading to high hole current, as shown in Fig. 7a. However, with the increase of forward voltage, the trapped electrons are released and neutralized by injected holes. In this case, the band bending will be gradually flatted, and the current will decrease due to the increase of hole injection barrier, forming the NDR region, which can be seen in Fig. 7b. When the voltage is swept faster, the current is larger because the processes of trapping electron releasing and injection barrier rising are slow. As the voltage keeps on increasing and sweeping back to zero, the current will remain at the low current state. Obviously, the processes are reproducible by simply applying a negative voltage.

The same operational mechanism can be observed in ITO/CuPc (H)/Ca/Al device. In this device, the low electron injection barrier of the Ca electrode with respect to the case of Al electrode leads to more electrons to be trapped in CuPc near Ca electrode, resulting in larger NDR. However, for the case of ITO/CuPc (H)/MoO₃/Al devices, the MoO₃ interfacial layer possesses a blocking role of electrons [24]. In this case, no more trapped electrons by applying negative bias voltage can make the processes of the band bending and band flatting with bias. Therefore, the NDR effect is disappeared. Accordingly, we can conclude that the interfacial traps and electron trapping are the main reasons of the NDR formation in our devices.

In the device ITO/CuPc (N)/Al, the hole injection barrier under positive voltage can also greatly decrease due to the existence of the trapped electrons, resulting in the band bending, leading to high hole current. However, there are much more traps because the trap concentration in the CuPc film will increase when the deposition rate decreasing [25]. It is much more difficult to release sufficient trapped electrons for flatting energy band and increasing the injection barrier. That is why the forward currents of the device with normal rate evaporated CuPc are larger and have no NDR effects, as shown in Fig. 7c.

As known, a very low deposition rate of organic molecules generally results in the much larger grain size [19]. It is well established that metal atoms can migrate inside the organic layer during the evaporation of a top electrode
Fig. 7. Energy band diagrams (the side of anode) of the devices in the paper: (a) ON state of ITO/CuPc (H)/Al, (b) OFF state of ITO/CuPc (H)/Al or ITO/CuPc (H/L)/Al, (c) ITO/CuPc (N)/Al, and (d) OFF state of ITO/CuPc (H/L)/Al.
Fig. 8. AFM morphology images of the CuPc films with L, N, and H deposition rate on ITO, respectively.

and such an interdiffusion increases if the surface of organic film shows a larger gain size. As a result, a huge interface dipole is easily formed [26,27]. Fig. 8 show the AFM images of the morphology of CuPc films with L, N and H deposition rate, respectively. As seen, the film fabricated by low deposition rate indeed shows larger grain size. Therefore, in the case of ITO/CuPc (H/L)/Al device, since the interface dipole oriented in a suitable direction greatly pushes up the energy band of CuPc with respect to the vacuum level of metal, the barrier for hole injection is significantly reduced from a rectifying Schottky contact to an Ohmic contact. Then the hole injection from Al into organic layer is easier, forming the high ON state, as shown in Fig. 7d. This interface dipole can be destroyed due to a high space field caused by access hole injection, resulting in great increase of the barrier height for the hole injection, as shown in Fig. 7b. At this time, the hole injection is rather difficult due to higher barrier, leading to a abruptly decrease in current, and the destruction of the interface dipole under a critical bias voltage is irreversible. However, the injection barrier in the OFF state device may be temporarily decreased a little by the trapped electrons after negative biased, which is similar as the ITO/CuPc (H)/Al device.

4. Conclusions

We have observed, respectively, a repeatable NDR effect and switching conduction in the *I–V* characteristics of organic diodes based on CuPc film sandwiched between ITO and Al by the control of the CuPc deposition rate. It is found that a high deposition rate of CuPc results in a repeatable negative differential resistance (NDR), where a low deposition rate of CuPc near the metal electrode then leads to unrenewable switching property. The traps in the organic layer and interfacial dipole could well be used to explain the NDR effect and switching conduction. It is believed that these interesting characteristics could lead to more deep understanding of devices based on CuPc.

ARTICLE INFO

ABSTRACT

We have studied the phenomena resulting from the combination of a hole-conducting *poly*(phenylene vinylene) (PPV) based light emitting polymer with a highly efficient electron injection layer of caesium carbonate (Cs_2CO_3) in light emitting diodes. A strong dependence between the thickness of the applied Cs_2CO_3 and the electro-optical performance of the diodes is detected and already with ultrathin Cs_2CO_3 layers high efficiency diodes are achieved. The Cs_2CO_3 is shown to diffuse into the polymer layer leading to an increased electron density but also quenching of both electro and photoluminescence when the amount of applied Cs_2CO_3 is increased. During electrical stressing the electron density decreases assumably through degradation of the *n*-doping and quenching Cs_2CO_3 species inducing an unusual increasing luminescence behavior.

1. Introduction

Ever since their discovery polymer light emitting diodes (PLEDs) have raised great attention due to their potential in fabrication of low-cost light emitting devices [1,2]. Due to their solution processability and mechanical flexibility, PLEDs offer a possibility to be applied on flexible substrates with traditional roll-to-roll printing methods [3]. The potential applications for these devices include ultra-thin, ultra-light, low power consumption displays and lighting elements. Although some products containing PLED displays are already commercially available, a lot of research and development is still ongoing in order to enhance the efficiency and especially the long-term stability of the materials involved in these polymer based devices.

The standard structure of a PLED consists of a transparent substrate and anode on which a hole-injection layer (HIL) is applied from solution. The HIL is then covered with a light emitting polymer (LEP) film followed by a vacuum deposited low work function metal electron injection layer (EIL) and a protective higher work function metal cathode. This asymmetric electrode structure is designed to supply the injection of both electrons and holes in the LEP-layer in order to achieve as efficient exciton formation as possible. Besides the injection of the charge carriers, also their transport in the LEP must be sufficient enough to ensure fast response times and low power consumption of the devices.

"Superyellow–PPV" (PDA-132 from Merck KGaA) is known as an efficient alkoxy-phenyl-substituted *poly*(phenylene vinylene) (PPV) based light emitting polymer [4].

Like PPV-polymers in general, also SY is a hole-dominant polymer meaning that the hole mobility is higher than the mobility of electrons along the polymer chains [5–7]. Applying a low work function metal, like barium in this study, on top of the SY improves the electron injection from the aluminum cathode and thus also the diode performance significantly. Even though the electron injection is improved, due to the low electron mobility and the presence of electron traps in the PPV-polymer, the emission zone is still located in the vicinity of the cathode leading in to a partial loss of excitons via non-radiative energy transfer to the metal cathode [5,8]. Therefore, more efficient electron injection would be required to push the emission zone further away from the cathode thus minimizing the quenching and resulting in diodes with even higher efficiency due to the better balance between the charge carriers. Caesium carbonate (Cs_2CO_3) has been reported to result in very low work function surfaces when fabricated via thermal evaporation [9]. Recently, Cs_2CO_3 has also been shown to efficiently function as a solution processed electron injection layer in PLEDs as well as an *n*-dopant in the electron transport layer in vacuum deposited small molecule based OLEDs [10–14].

In this work, a thin layer of Cs_2CO_3 was applied between the SY and aluminum by thermal evaporation to explore the effects initiated by a highly efficient electron injection layer being deposited on top of a highly efficient, hole-dominated LEP. As expected, diodes with higher efficiency were achieved with a SY–Cs_2CO_3 structure in comparison to the traditional SY–Ba structure. The strong increase in the electron injection of the Cs_2CO_3 diodes is apparently caused by a highly conductive, *n*-doped layer resulting from the charge transfer reaction between Cs_2CO_3 and SY, where by the magnitude of the reaction and resulting effects depend strongly on the amount of the applied Cs_2CO_3. This conclusion can be drawn from the LIV, impedance and photoluminescence measurements of the diodes with Ba and Cs_2CO_3 cathodes. Impedance spectrometry (AC-field with varying frequency) is a powerful tool for investigation of the interfaces between organic layers and the effects of an *n*-doped layer on conductance and capacitance behavior have been shown in literature [15]. The tendencies in the impedance spectra measured for our Cs_2CO_3 diodes align perfectly with the published study [15] implying that *n*-doping of the SY and the following increase in the number of intrinsic electrons indeed is the source of the more efficient electron injection. Further indications on the formation of an *n*-doped region are the quenching of the intensity and the shift of the maximum both in electro- and photoluminescence spectra. With the help of the simulated EL-spectra the shift in the maximum is concluded to result from the alteration in the location of the emission zone. A quenching, *n*-doped region would also consequentially explain the quenching of the intensity in the EL and PL spectra.

For industrial applications the long-term stability of the light emitting devices is of outmost importance and therefore the behavior of the Cs_2CO_3 diodes during electrical stressing was investigated both electrically and optically. It is shown that the behavior of the highest efficiency Cs_2CO_3-diodes during electrical stressing is comparable to the behavior of the Ba-cathode. Interestingly, with thicker Cs_2CO_3 layers, after an initial decay the light-output of the diodes increases strongly reaching a maximum near the initial luminescence. We attribute this behavior to result from a better charge carrier balance and the simultaneous decrease in the number of the quenching Cs_2CO_3 species in the SY-layer. These conclusions are drawn based on the results from LIV, impedance and photoluminescence measurements before, during and after the electrical stressing.

2. Experimental

The *poly*(3,4-polyethylenedioxythiophene) *poly*(styrene sulfonate) (PEDOT:PSS) used in this study was Baytron® PVP CH 8000 purchased from H.C. Starck. Superyellow (SY) (PDA-132) (5 mg/ml in toluene) was acquired from Merck KGaA as a ready-to-use solution and was used as received. The caesium carbonate Cs_2CO_3 was purchased from Sigma–Aldrich and stored in an inert atmosphere due to its highly hygroscopic nature.

The light emitting devices studied in this work consisted of glass-substrate/ITO/PEDOT:PSS (120 nm)/SY (100 nm)/Ba or Cs_2CO_3/Al and were processed as follows. The indium tin oxide (ITO) covered glass-substrates were cleaned in ultrasonic bath followed by drying and reactive ion etching (RIE) treatment. PEDOT:PSS was spin-coated on ITO and baked in order to avoid water contamination of the following layers. The SY-polymer was spin-coated on PEDOT:PSS from toluene in an inert N_2-atmosphere followed by a heat treatment. Cs_2CO_3 and the protecting aluminum electrode were thermally evaporated on the substrates. The applied thicknesses of Cs_2CO_3 were 0.05, 0.10, 0.15, 0.25, 0.50, 0.75, 1.0 and 1.50 nm measured with a calibrated oscillating quartz crystal. Theoretically, one monolayer of Cs_2CO_3 molecules is formed with about 0.50 nm layer thickness. The thickness of the reference barium layer used in this study was 3 nm. After the cathode deposition, the diodes were encapsulated in an inert argon atmosphere followed by measurements in atmospheric conditions. The active area of the devices was 4 mm².

The current–voltage characteristics of the diodes were measured with a computer controlled Keithley 238 high current source measure unit and the luminescence and spectra with a calibrated spectral camera Photo Research PR650. The influence of the varying location of the emission zone on the EL spectrum was simulated with commercially available optical simulation software *etfos* (FLUXiM) [16]. In order to study the interfacial properties of the SY-dielectric, impedance spectroscopy in a frequency range of 5 Hz–10 MHz was performed with a Hewlett Packard 4192A LF Impedance Analyzer.

3. Results and discussion

3.1. Diode performance dependency on the amount of applied Cs_2CO_3

3.1.1. LIV characteristics

When Cs_2CO_3 is used as an electron injection layer on the hole-dominant superyellow polymer, already with ul-

tra-thin layers a significant change in the LIV-characteristics of the diodes is detected. At a constant bias of 4.0 V, the current density of the diodes with only aluminum and 0.05 nm Cs_2CO_3 is almost equal (Fig. 1a). However, the light-output at a constant 25 mA/cm^2 current density of the device with only Al as cathode material is roughly two orders of magnitude lower in comparison to the Cs_2CO_3 diode (Fig. 2b). The unsubstantial difference in the current density but the significant difference in the luminescence indicates that the current is still hole-dominated in both devices (0 nm Cs_2CO_3 device behaves like a single carrier device) but already an infinitesimal amount of Cs_2CO_3 improves the electron injection into the SY-polymer in such a way that a substantial improvement in the light-output is detected. This behavior is in-line with the previously reported comparison between the Al and Ca cathodes [8]. As can be seen in Fig. 1a, when the thickness of the Cs_2CO_3 layer is further increased, the current density at 4.0 V bias is also increased reaching its maximum at 0.50 nm after which the current density decreases going above the values of the reference Ba as the layer thickness of Cs_2CO_3 reaches 1.50 nm.

Similarly with the current density plot in Fig. 1a, a curve with a maximum can also be seen in the efficiency versus Cs_2CO_3 thickness plot at 4.0 V bias (Fig. 1b). The optimum ratio between the required voltage and the achieved light-output and therefore also the maximum efficiency (over a
third higher power efficiency [lm/W] at 4.0 V than reference Ba, Fig. 1b) is achieved with a layer thickness of 0.15 nm which corresponds not even to one monolayer of Cs_2CO_3.

The efficiency optimum can also be seen in the electroluminescence (EL) spectra of the devices detected at a constant current density of 25 mA/cm^2 (Fig. 2) as a significant increase in the EL-intensity when the Cs_2CO_3 thickness is increased from 0 nm to 0.15 nm. As the Cs_2CO_3 layer thickness increases above 0.15 nm, besides a decrease in the EL-intensity also a shift in the emission maximum towards higher wavelengths is detected (Fig. 2b). The λ_{max} for Ba and 0–0.15 nm Cs_2CO_3 layers is located at 552 nm whereas the λ_{max} for thicker Cs_2CO_3 layers is located at 596 nm. The onset of this red-shift can already be detected in the EL-spectrum of the 0.15 nm Cs_2CO_3 as an increase of another peak next to the maximum.

3.1.2. Impedance and photoluminescence behavior

In order to investigate the change in the electrical properties of the Cs_2CO_3 diodes further, impedance spectroscopy measurements were performed [15]. During these measurements a small harmonic AC-voltage is applied and both the amplitude and the phase difference of the AC-current are detected as a function of frequency (f). The complex admittance (Y which is the inverse of the impedance) can then be written as a function of conductance (G) and capacitance (C) using the equation $Y = G(\omega) + i\omega C(\omega)$, where $\omega = 2\pi f$. While the DC-driven measurements (Figs. 1 and 2) provide information about the charge injection and transport properties in the devices, the information gained from the AC-measurements at zero applied bias is more related to the number of the intrinsic charge carriers in the device. As already mentioned, Cs_2CO_3 has been shown to function as a very efficient n-dopant in small molecule based OLEDs [11,13,14]. An n-doping reaction would result in a formation of a charge-transfer complex and a following movement of the Fermi-level of the bulk material towards the donor-states introduced by the n-dopant [17]. Knowing that these doping states are immediately charged with electrons during deposition, the assumed n-doping reaction between SY and Cs_2CO_3 should be detected as an increase in the number of intrinsic electrons in the layer.

In our measurements, a small 100 mV AC-pulse in the 5 Hz–10 MHz frequency range was applied between the electrodes and the detected capacitance and conductance as a function of frequency for different Cs_2CO_3 thicknesses are shown in Fig. 3. From the curves it is clear that after the Cs_2CO_3 thickness exceeds 0.15 nm, both the capacitance and the conductance of the SY-layer increase significantly at low frequencies. The strong increase in capacitance and conductance at low frequencies indicates that the applied Cs_2CO_3 indeed forms a charge-transfer complex with SY thereby introducing doping states on which the electrons are then able to diffuse or tunnel with the oscillating field [15]. This n-doping is further enhanced by increasing the amount of applied Cs_2CO_3 and thus also the intrinsic electron density in the SY layer. As the frequency of the AC-pulse increases above 2×10^5 Hz (above 2×10^6 Hz for 1.50 nm Cs_2CO_3), the mobile intrinsic electrons are no

longer fast enough to follow the oscillation of the field and the dielectric (SY-polymer) response takes over both the capacitance and the conductance. This can be seen as an alignment of the capacitance and conductance curves at higher frequencies.

Gommans et al. [15] have reported similar results with another PPV-derivative as light emitting polymer and pure caesium metal as the cathode material. They concluded that the enhancement in capacitance and conductance is caused by the diffusion of the Cs atoms and following *n*-doping of the PPV-layer. This reaction was reported to lead into an increased hole transit time (resulting from a change in the field distribution inside the device due to band bending and potential drop at the cathode interface) and improved electron injection and/or higher electron mobility. In our study, diffusion profiles are not measured but from a simple calculation of the dielectric thickness derived from the geometrical capacitance ($C = \varepsilon_0 \varepsilon A/d$), the calcu-

lated SY thickness at 1 kHz frequency for the thicker Cs_2CO_3 layers is only half of the SY thickness calculated to the Ba-diode. This significant decrease in the electrically visible layer thickness of the dielectric indicates a strong diffusion of the Cs_2CO_3 into the polymer layer.

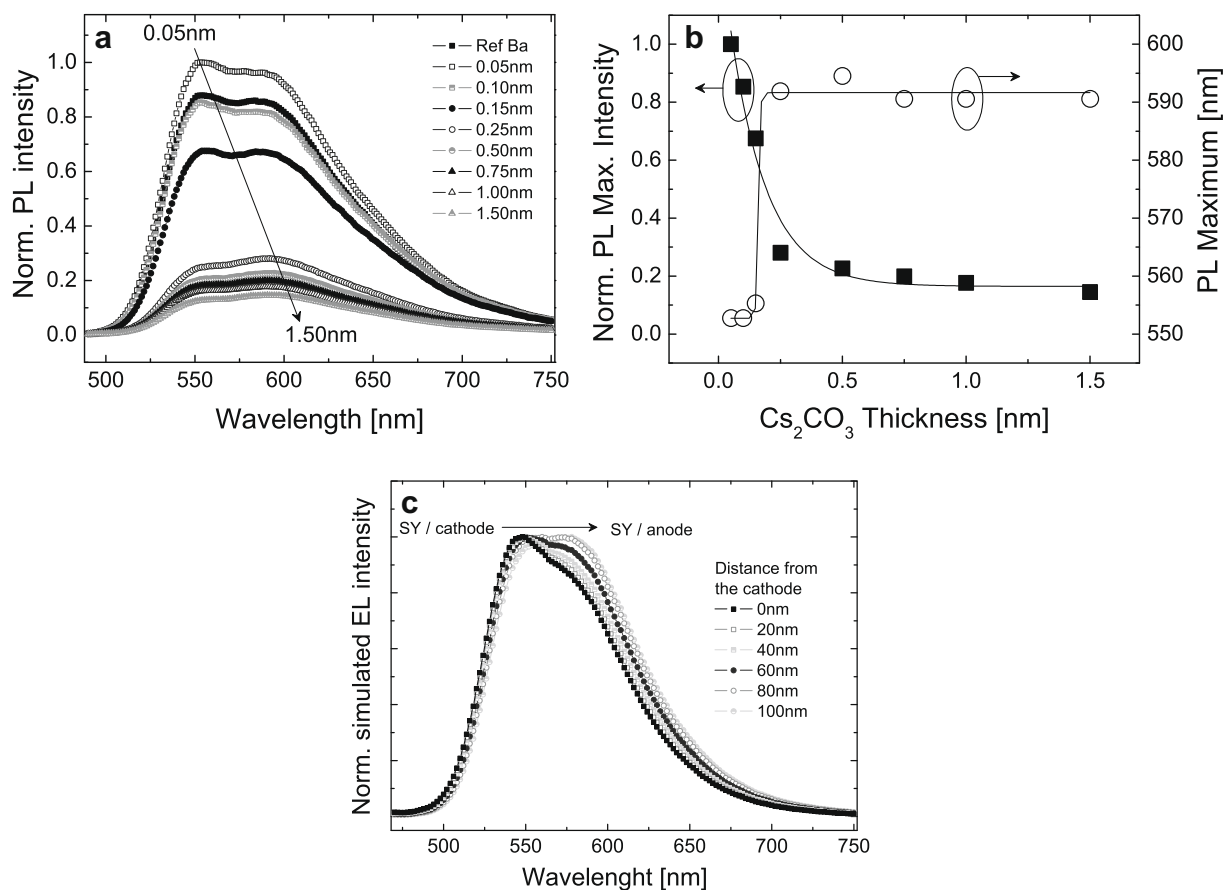
Another indication of the diffusion of Cs_2CO_3 in the SY-layer is the quenching of the photoluminescence (PL) intensity (Fig. 4a and b). In previous studies it has been shown that both *p*- and *n*-type dopants quench the EL and PL intensities as they are diffused into the emissive layer via exciton-dopant (in EL and PL) and exciton-polaron (in EL) type quenching [18]. Unlike in the case of electroluminescence, where charge injection and charge transport contribute to the exciton distribution (emission zone) and thus to the emission spectrum, in the PL the response consists of the emission from homogenously distributed excitons in the layer. As shown in Fig. 4b, the PL intensity maximum of these homogenously distributed excitons decays expo-


Fig. 4. The measured (a) PL-spectra for diodes with 0.05–1.50 nm Cs₂CO₃ and reference Ba and (b) the PL-intensity and the location of the PL-maximum as a function of Cs₂CO₃ thickness. (c) The EL-spectra simulated from the PL-spectrum of a pure superyellow-layer.

nentially as a function of increasing Cs_2CO_3 thickness indicating clearly that the more Cs_2CO_3 is applied the more the PL-emission is quenched. The mechanism for this non-radiative decay of the photoexcited excitons is assumed to be the exciton-dopant quenching [18].

In order to simulate the red-shift detected both in EL and PL spectra, a Gaussian-shaped 10 nm half-width emission zone was moved from the interface of the cathode towards the interface of the anode and was used as an input parameter for the optical simulation software (*etfos*) [16]. The shape, width and the position of the emission zone was chosen based on the hypothesis that Cs_2CO_3 diffuses into the SY layer and quenches the emission starting from the cathode as a function of the amount of applied Cs_2CO_3. A red-shift similar to the measured PL- and EL-spectra (in Figs. 4a and 2a, respectively) can be detected if the emission zone is shifted in the optical simulation. As the emission zone is located at the SY-cathode interface, the simulated EL-spectrum has a similar shape than the spectra measured for Ba and 0.05–0.10 nm Cs_2CO_3. Whereas if the emission zone is located at the anode interface, the λ_{max} shifts towards higher wavelengths resembling the tendency of the PL- and EL-spectra measured for thicker Cs_2CO_3 layers.

The red-shift detected in the PL-emission (Fig. 4a and b) is indeed a strong indication that by quenching the PL-

emission starting from the cathode interface, the diffused Cs_2CO_3 leads into a formation of a gradually narrowing photo-emissive layer. If this quenching region would not exist, the excitons would emit homogenously from the whole SY-layer and the shape and intensity of the PL-spectrum would remain the same for all cathodes and cathode thicknesses.

Based on the results from DC-, AC- and photo-excitation measurements a theory that Cs_2CO_3 diffuses into the SY-layer forming a charge-transfer complex via an *n*-doping reaction is applicable. The magnitude of this *n*-doping is dependent on the amount applied Cs_2CO_3 increasing the intrinsic electron density and decreasing the PL-intensity with increasing quantity of Cs_2CO_3. The long-term effects resulting from the diffused Cs_2CO_3 are discussed in detail in the following chapter.

3.2. Long-term stability of the diodes with Cs₂CO₃ and Ba cathodes

3.2.1. LIV characteristics

The long-term stability of the SY-diodes with different Cs_2CO_3 thicknesses was investigated in a lifetime measurement setup where the diodes were driven at a constant DC-

current corresponding to a certain initial luminescence. For diodes with a Cs_2CO_3 thickness exceeding 0.25 nm, unusual increasing luminescence-curves were measured. Whereas in the case of Cs_2CO_3 layer thickness below 0.25 nm the lifetime behavior was normally decreasing and aligned with the behavior of the Ba-diodes. In order to further investigate the unusual behavior of the thicker Cs_2CO_3 diodes in comparison to the thinner Cs_2CO_3- and Ba-diodes during stressing, the device with 0.50 nm Cs_2CO_3 is discussed here more in detail.

The behavior of the luminescence and driving voltage of the diodes with 0.15 nm Cs_2CO_3, 0.50 nm Cs_2CO_3 and reference Ba are displayed in Fig. 5. The decay of the luminescence and the increase of the driving voltage of the Ba- and 0.15 nm Cs_2CO_3 devices are standard behavior for SY-diodes and similar curves have also been reported elsewhere [19]. The luminescence of the Ba-diodes (and 0.15 nm Cs_2CO_3) decays rapidly during the first hours of the measurement losing about 30% of its initial brightness. This has been reported to be due to the morphological changes of the PPV-film [20]. After this rapid decrease, the luminescence continues to decrease very slowly until

reaching its half-lifetime (50% of the initial brightness) after several thousands of hours. The luminescence over time for the 0.50 nm Cs_2CO_3-device shows similar rapid decrease in the beginning of the stressing but starts to increase again already after 30 h of stressing. The luminescence continues to increase until after reaching its maximum value at 1000 h, a decrease begins leading into a device failure after 1600 h of stressing.

After the initial rapid increase, the driving voltage of the Ba-diode (and 0.15 nm Cs_2CO_3) continues to increase slowly during stressing (Fig. 5b). The gradually increasing driving voltage of the 0.50 nm Cs_2CO_3-diode is faster than that of the Ba-diode (and 0.15 nm Cs_2CO_3) and after 550 h lifetime, the Cs_2CO_3-diode already consumes more voltage for its constant current than the Ba-diode.

The increasing luminescence behavior seen in Fig. 5a resembles the published luminescence curves of the polymer light emitting electrochemical cells (PLEC). In PLEC-devices, under the influence of an applied electric field, the ionic species mixed into the polymer move to the electrode interfaces thereby enhancing the charge injection and leading to a relatively slow formation of a light emitting junction. The formation of this light emitting junction is detected as an increasing luminescence under electrical stressing. If such an ion drift were to happen also in the studied devices during stressing, a decrease in the driving voltage would be expected due to the enhanced charge injection [19]. This is however not the case but the driving voltage of the 0.50 nm Cs_2CO_3 device (that shows the increasing luminescence) increases with increasing stressing time indicating that the injection and/or transport in the devices rather degrades than improves during electrical stressing. This could mean that the charge-transfer complexes providing the electrons to the LUMO of the SY, degrade during stressing weakening the electron injection and/or transport and thus increasing the resistance and driving voltage in the layer.

Fig. 6 shows the electroluminescence spectra of the SY-devices with Ba, 0.15 nm Cs_2CO_3 and 0.50 nm Cs_2CO_3 cathodes measured during stressing. For Ba and 0.15 nm Cs_2CO_3 the spectra remain unchanged whereas a significant blue shift is detected in the emission maximum of the 0.50 nm Cs_2CO_3-diode with increasing stressing time (Fig. 6c). According to the optical simulations shown in Fig. 4c, this shift could result from a movement of the emission zone from the interface of the anode towards the interface of the cathode. Previously, an identical blue shift was detected as the Cs_2CO_3 layer thickness decreased from 1.50 nm to 0.05 nm (Fig. 2a). The shift in the emission zone and the increasing driving voltage could result from the decreasing electron contribution in the SY-layer during electrical stressing. As Gommans et al. [15] reported the doping reaction changes the field distribution in the device leading to an increased hole transit time. If the doping reaction between SY and Cs_2CO_3 degrades during stressing, that would also result in a gradually decreasing hole transit time. The decreasing hole transit time could then at least partly induce the shift in the location of the emission zone and thus also a shift in the EL-maximum.

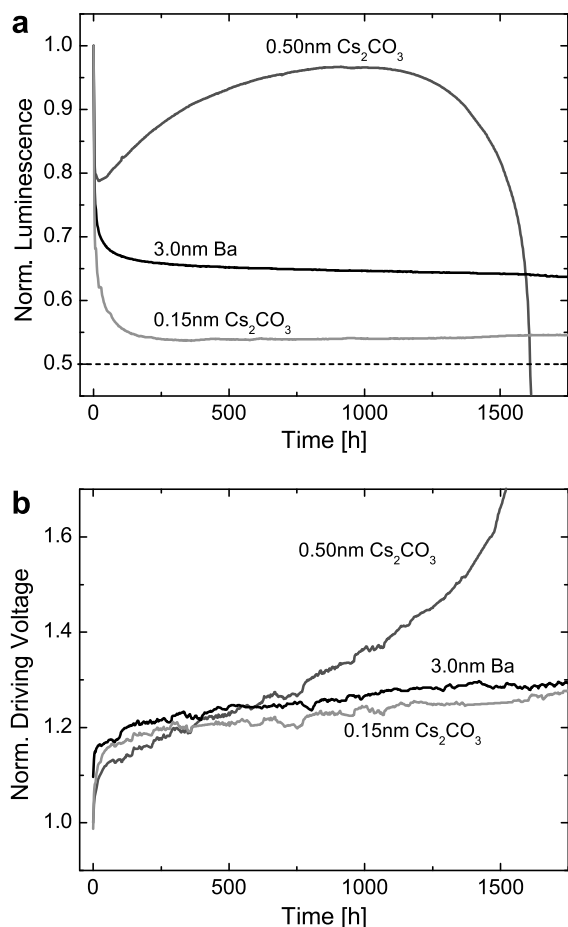
The shift in the EL-spectrum is neither visible in the diode with Ba-cathode (Fig. 6a) nor with the thinner


Fig. 5. (a) Luminescence and (b) driving voltage behavior during lifetime for Ba, 0.15 nm Cs_2CO_3 and 0.50 nm Cs_2CO_3 cathodes measured at a constant 22 °C temperature. The diodes were driven at a constant DC-current calibrated to correspond 1000 cd/m^2 initial luminescence.

0.15 nm Cs$_2$CO$_3$ (Fig. 6b). This suggests that the emission zone in the Ba- and 0.15 nm Cs$_2$CO$_3$ devices remain unchanged during stressing.

3.2.2. Impedance and photoluminescence behavior

While the conductance (and the capacitance, not shown here) of the 0.50 nm Cs$_2$CO$_3$ diode in the low frequency range is strongly decreased during stressing (Fig. 7c), the conductance of the Ba-reference and 0.15 nm Cs$_2$CO$_3$ diodes remain relatively constant during the measured time (Fig. 7a and b).

The decreasing conductance, the increasing driving voltage and the shift in the emission zone are all indications of the decrease in the electron contribution during electrical stressing in the 0.50 nm Cs$_2$CO$_3$ diode. Knowing that before stressing, the SY-diode with 0.50 nm Cs$_2$CO$_3$ has a very high density of electrons on the cathode side of the polymer which then gradually decreases during stressing and assuming that the hole transit time in the SY decreases as the doping degrades, it can be assumed that the ratio between the charge carriers changes from electron domination via optimal balance to a hole domination. This variation in the charge carrier balance could at

least partly explain the increasing luminescence of the Cs_2CO_3 diode during stressing, the maximum luminescence representing the optimal charge carrier balance.

The slight decrease in the conductance of the unstressed Cs_2CO_3 diode visible in Fig. 7c could be either due to the repeated DC-measurements and following degradation of the n-doping, or due to storage instability. The storage stability of the SY–Cs_2CO_3 diodes is currently under further investigation.

Interestingly, the PL-spectrum of the 0.50 nm Cs_2CO_3 diode measured after the operational lifetime shows a strong increase in the PL intensity and also a blue shift in the spectral maximum (Fig. 8c) in comparison to a diode that has not been electrically stressed. This implies that

the Cs_2CO_3 species which resulted into a quenched PL-spectrum (Fig. 4a and b) before electrical stressing are indeed no longer active in the SY-layer after stressing. Because no EL is detected at this point anymore we assume that the SY parts reacted with Cs_2CO_3 have lost their conjugation leading into an electrical isolation of the still conjugated and emissive SY-chains. Also the electron injection is presumably decreased because of the decreasing number of the active Cs_2CO_3. Thus after the complete degradation of the diffused Cs_2CO_3 species, the electron injection into the still conjugated parts of SY is no longer possible which leads into a complete disappearance of the electroluminescence. This decrease in the number of quenching units during stressing could also, together with the optimized charge balance, logically explain the increasing luminescence behavior (Fig. 5) of the thicker Cs_2CO_3 devices.

In comparison to the PL-intensity before and after stressing, both the stressed Ba-diode and the stressed 0.15 nm Cs_2CO_3 diode reach 70% from the intensity of the corresponding unstressed device. Also the stressed 0.50 nm Cs_2CO_3 diode reaches about 75% from the intensity of the unstressed Ba-device. This is in good agreement with the EL-behavior where the electroluminescence is decreased to about 70% of the initial light-output (Fig. 5). The result also implies that after the initial morphological changes the SY-polymer is very stable against electrical stressing and goes through identical changes independently of the applied cathode material.

4. Conclusions

We have investigated the effect of introducing a Cs_2CO_3 interlayer as a cathode in PLED devices with a well known highly efficient PPV-derivative as a light emitting polymer. The Cs_2CO_3 cathode strongly influences both the electrical and optical properties of the devices leading to a higher density of electrons and to a shift in the electroluminescence and photoluminescence emission maxima. These phenomena are dependent on the applied Cs_2CO_3 layer thickness leading to more pronounced effects with increasing thickness. When the amount of the applied Cs_2CO_3 is optimized, diodes with higher efficiency than the reference Ba but similar long-term behavior are obtained. After electrical and optical analysis of the Cs_2CO_3 diodes before, during and after electrical stressing we conclude that as the amount of Cs_2CO_3 is increased above the optimum, Cs_2CO_3 diffuses in the SY-layer reacting with the conjugated double bonds forming an n-doped region on the cathode side of the polymer. This n-doping degrades during electrical stressing leading to a decrease in the intrinsic electron density and in the number of quenching units. These two phenomena result in a better charge carrier balance and weaker quenching of the emission in the device and thus into a shift in the emission zone. Consequently, an increasing luminescence curve and increased photoluminescence intensity during stressing are measured for the diodes with thicker Cs_2CO_3 layer.

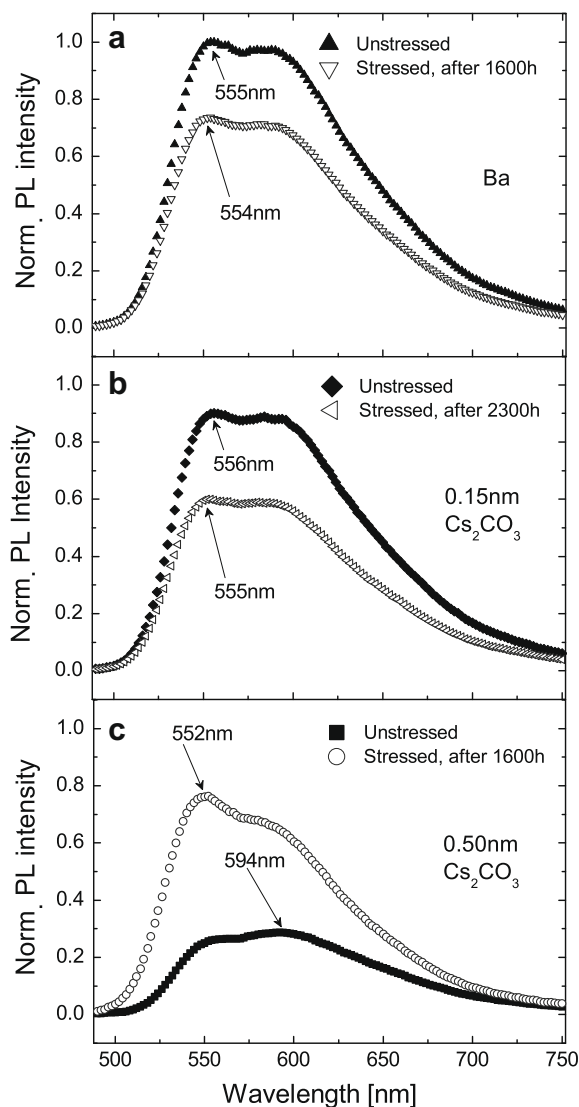
The results disclosed in this study are used to explain the functional principle of the Cs_2CO_3-cathode with a PPV-derivative as an emitting polymer. The outcome and


Fig. 8. PL intensity before and after a stressing period for (a) Ba, (b) 0.15 nm Cs_2CO_3 and (c) 0.50 nm Cs_2CO_3 diodes. The intensities are normalized to the PL-maximum of the unstressed Ba-diode in (a). "Unstressed" indicates to the pixel which has not been under an influence of a DC electric field and "Stressed" to a pixel that has been electrically stressed.

the experimental route will serve as a useful guideline for the future studies on other light emitting polymers and the Cs_2CO_3-cathode initiated effects on them.

ARTICLE INFO

ABSTRACT

We have fabricated high performance polycrystalline pentacene-based thin-film transistors using several dielectrics with different surface properties, including inorganic oxide and polymeric materials. These materials provide excellent samples for the analysis of charge transport properties, particularly the impact of the grain boundary and the molecular structural quality within the grain on the efficient charge transport. The carrier transport in polycrystalline organic films with grain structures is often interpreted using the grain boundary model. Assuming a large amount of charges are trapped at the boundaries, the model neglects the microstructural quality inside a grain. According to joint experimental and theoretical Raman spectra and normal modes analysis on these pentacene films, we present a new observation that the microscopic hopping transport parameters, i.e., intermolecular interactions and reorganization energy, in polycrystalline films govern the carrier transport. An obvious, positive correlation is found between the mobility and the molecular vibrational characteristics, especially the intermolecular vibrational coupling energy, under all varieties of grain size morphology. MicroRaman mapping methodology reveals that the grain size of pentacene films should not be taken for granted in structural quality and efficient charge transport. The microstructural qualities inside the grain play an important role in efficient charge transport.

1. Introduction

The use of organic semiconductors as active elements in optoelectronic devices has become prevalent, such as in thin-film transistors (TFTs), light-emitting diodes, solar cells, sensors, switches and others devices [1–3]. The charge transport properties of organic semiconductors [2–4] will have a critical role in integrating organic materials into useful devices and further optimizing device per-

formance. In particular, the organic TFT (OTFT) is one of the current hot topics in the research field of organic electronics applications, and the behavior of the charge transport can be investigated in these devices. Recently, the performance of OTFTs based on small molecule organic semiconducting materials, such as oligoacenes, oligothiophenes, and their derivatives, have demonstrated high carrier mobilities (μ) of above 1.0 and have surpassed that of amorphous silicon [2,5]. For most OTFT device applications, these small molecules are generally and easily deposited upon gate dielectrics using thermal evaporation to form thin-films. However, these organic thin-films are particularly challenging because of their polycrystalline

nature with a grainy texture morphology [1,2,5]: they do not form a single-crystal but instead are rife with multiple polymorphisms [6], grain boundary (GB) effects [7,8], orientation defects [9], static disorder [4c], and defects/impurities [10]. Despite existence of extensively studies devoted to the analysis of structure–carrier transport relationships of organic semiconducting films, carrier transport properties in polycrystalline films remain unclear, in particular, the role of GB and molecular microstructural quality within the grain.

Concerning the polycrystalline media, including inorganic materials (e.g., silicon, CdSe, etc.) and organic materials (e.g., oligoacenes, oligothiophenes, etc.), a grain boundary model has been proposed to research the charge transport mechanisms [7,11,12]. The μ in a polycrystalline material could be described as

$$\frac{L_G + L_{GB}}{\mu} = \frac{L_G}{\mu_G} + \frac{L_{GB}}{\mu_{GB}} \qquad (1)$$

where L_G and L_{GB} are the average lengths of the grain and GB, respectively; μ_G and μ_{GB} are the intragrain and the GB mobilities, respectively. The μ qualities appear to be dominated by GB effects, assuming a large amount of charges are trapped at the boundary. For a small grain size, where $L_{GB} \gg L_G$ and $\mu_{GB} < \mu_G$, μ is approaching the value of μ_{GB}. Under this assumption, the microstructural quality within the intragrain can be neglected. Grain size dependent μ values in oligothiophene [7] and pentacene [8] films have been reported. It has become demanding work to develop growth methods for realizing the super large grain (e.g., 100 μm for pentacene [13]), producing single-crystalline films [14], or fabricating nanoscale OTFTs that enable charge transport in a single grain and eliminate GBs [15]. However, in some cases there was no direct relationship between μ and grain size in organic films [5b,16]. Recently, we observed a tiny grain (~0.1 μm) pentacene OTFT with excellent electrical characteristics, including a μ above $1.0 \, \mathrm{cm^2 \, V^{-1} \, s^{-1}}$, an on/off current ratio larger than 10^6, and a subthreshold slope as low as 0.8 V/dec [17]. These results suggest that GBs may not act as a dominating mobility- and device performance-limiting mechanism. There are several interesting questions raised by the above discussion. For one, the traps are quite likely to reside in GBs rather than being uniformly distributed over the film according to the GB model, but what is the microstructural quality inside the grain? Is it acceptable to presume that there are single-crystal-like and/or trap-free microstructures inside the grain and that these should, therefore, be disregarded entirely?

In this study, to clarify the above questions, we applied microRaman spectroscopy to investigate the correlations between microscopic structural characteristics and charge transport properties in pentacene thin-films deposited on several dielectrics with different surface properties, including inorganic silicon dioxide (SiO₂) and polymeric insulators. We discuss the structural characteristics of polycrystalline pentacene films in view of a molecular picture of charge transfer processes in π-conjugated organic semiconductors. Such transport processes can be described using two key microscopic parameters [4]: intermolecular electronic coupling (transfer integrals, J_{ab}) and reorganiza-

tion energy (λ_{reorg}). The J_{ab} is proportional to the intermolecular interactions and thus inversely proportional to the effective separation, R, between adjacent molecules. The λ_{reorg} is a measure of the strength of the interaction between the electronic structure and the vibrational states of the molecule and of the material. In order to ensure an efficient carrier transport process, the J_{ab} must be maximized, while the λ_{reorg} needs to be minimized [4]. In this paper, we show that microRaman spectroscopy provides a powerful and convenient tool for analyzing the actual microstructure and the microscopic transport parameters of organic films within the active channel of OTFTs. At the same time, the relevant information of J_{ab} and λ_{reorg} can be derived and related to the measured μ in the OTFTs. Furthermore, microRaman mapping offers the ability to identify the quality of both the intragrain and GB microstructures of these films. Finally, the implications of crystal and grain size data obtained from X-ray diffraction (XRD) and atomic force microscopy (AFM) scans, respectively, are also discussed.

2. Experimental section

Preparation of gate dielectrics: Four type gate dielectrics were used as follows: (i) thermally grown SiO₂ (denoted TSiO₂): a heavily doped Si wafer was used as the gate electrode substrate. A 300 nm SiO₂ layer was thermally grown on the substrate acted as the gate dielectrics; (ii) plasma-enhanced chemical vapor deposition (PECVD) grown SiO₂ (denoted PSiO₂): heavily doped Si wafer or glass substrates (with the indium–tin–oxide gate electrode upon the substrate) were used as the gate electrode substrate. Then, a 300 nm SiO₂ gate dielectric layer was prepared by PECVD at 800 mtorr and 380 °C. The gases used were He, O₂, and tetraethylorthosilicate with corresponding gas quantities of 100, 3500, and 175 sccm, respectively; (iii) poly(methyl methacrylate) (PMMA): an approximately 60 nm PMMA (molecular weight $(M_w) = 5.4 \times 10^5 \, \mathrm{g \, mol^{-1}}$, Scientific Polymer Products, Inc.) layer was deposited by spin coating directly onto a SiO₂ layer using a 1 wt% PMMA solution from *p*-xylene, and then was baked for 2 h at 120 °C; (iv) polyimide (PI, Nissan Chemical Co.): an approximately 80 nm PI layer was deposited by spin coating directly onto a SiO₂ layer, and then was baked for 60 min at 220 °C. In this study, the root-mean-square surface roughness of TSiO₂, PSiO₂, PMMA, and PI were 1.6, 2.8, 0.5, and 0.8 nm, respectively, and the surface free energies were 59, 62, 49, and 39 mJ m⁻², respectively.

Preparation of pentacene films: Pentacene was purchased from Aldrich Chemical Company and was used as received without further purification. All of the pentacene was thermally evaporated upon dielectrics with a thickness of ca. 65 nm at a deposition rate of approximately 0.5–1 Å s⁻¹ and a pressure of 2×10^{-5} torr. The pentacene active layer was patterned using a shadow mask around the measured OTFTs to minimize the leakage. The thickness of pentacene films were calibrated using an AFM and monitored via the frequency shift of a quartz oscillator.

OTFT fabrication and electrical characteristics measurements: A bottom gate staggered transistor structure with rectangular gold top-contacts was used (also see Fig. 1).
Fig. 1. Schematic cross-section of the thin-film transistor test structure and herringbone packing of the pentacene molecules grown upon the gate dielectric surface.

In the final step, the gold source–drain electrodes were deposited to form an electrode upon the surface of the pentacene film through a shadow mask in order to complete the top-contact OTFT device. The devices were then transferred to a dry nitrogen-atmosphere glove box to minimize the influence of H_2O from the ambient air upon the electrical properties of devices [12c]. The electrical characteristics of OTFTs were measured by a Keithley 4200-SCS semiconductor parameter analyzer in the glove box under dark conditions. In the saturation regime, the saturated field-effect mobility (μ_{sat}) was calculated by fitting the metal-oxide-semiconductor field-effect transistor charge-sheet model equation described below [2,18]:

$$I_{DS} = \frac{W\mu_{sat}C_i}{2L}(V_G - V_{th})^2, \quad \text{if } (V_G - V_{th}) \leqslant V_D \quad (2)$$

where I_{DS} is the drain-to-source current, C_i is the gate capacitance, V_D is the drain bias, V_G is the gate bias, V_{th} is the threshold voltage, respectively, and W/L is the channel width-to-length ratio.

Analytical methods: The surface morphology and root-mean-square surface roughness were measured using AFM (Digital Instrument Multimode SPM AS-12VMF). The surface free energy was analyzed using the OCA15 contact angles goniometer (Dataphysics Co.). Raman spectra of pentacene films, produced by lattice phonons, were obtained using a Jobin Yvon LabRam HR spectrometer. A 532 nm solid state laser and a 633 nm He–Ne laser served as the excitation light source and were kept below 0.5 mW to prevent thermal damage to the pentacene thin-film. The spatial resolution of the beam spot was around 1 μm, attained using a $100\times$ objective microscope lens. The spectrometer resolutions are 0.4 and 0.2 cm^{-1} for using 532 and 633 nm excitation lines, respectively. Every Raman spectrum was taken an average of five spectra and at least three spectra were measured for each sample. MicroRaman mapping measurements were generated by measuring Raman spectra for each with lines of over 5 μm in step sizes of 0.1 μm. The pentacene films on various substrates were studied by XRD (Rigaku D/Max-2500 diffractometer) in the symmetric reflection coupled θ–2θ arrangement. XRD patterns were obtained using a 18 kW rotating-anode X-ray generator (Cu Kα radiation, $\lambda_{K\alpha1} = 1.5406$ Å) and a wide-angle graphite monochromator. The data were collected with a step size of 0.01° with a scanning rate of 1°/min. A Si single-crystal (1 1 1) wafer was used to estimate the effect of the instrumental broadening in XRD experiments. The observed FWHM of the (1 1 1) peak at ca. 28° 2θ is 0.061° under the same instrumental conditions.

Quantum mechanical calculations: The GAUSSIAN 03 program [19] was used to perform the density functional theory (DFT) calculations. The BLYP method (Becke's 1988 exchange functional combined with the LYP correlation functional of Lee, Yang and Parr) [20] was used for geometry optimization, Raman spectrum, and normal modes calculations. In all cases, the 6-31G(d) basis set was used. The observed Raman modes were assigned based on the calculation. However, it should be noted that the theoretical calculated frequencies were scaled with a factor of 0.9613 to fit the experimental obtained frequencies, as recommended by Scott and Radom [21]. Comparison of theoretical and experimental Raman spectra, the agreement between theory and experimentation is generally very good [22]. Therefore, the contributions of each vibrational mode to the reorganization energy were calculated from the normal mode analysis using the same 6-31G(d) basis set. The λ_{reorg} is proportional to the extent of the molecular geometry change between the neutral-state and charge-state, including the inner- (λ_i) and outer- (λ_o) sphere contributions. The λ_i (intramolecular) arises from the molecular geometry modifications that occur when an electron is added to or removed from a molecule. The vibrational term λ_i is a sum of contributions from the Raman active normal modes [4,23],

$$\lambda_i = \sum \lambda_v = \frac{1}{2}\sum \Delta_k^2 v_k = \sum S_k h v_k \quad (3)$$

In the harmonic approximation, the vibrational reorganization energy, λ_v, depends on the dimensionless displacement, Δ_k, and v_k is the vibrational frequency of mode k. The displacement Δ_k along normal mode k is between the equilibrium positions of the two electronic states, i.e., the ground and cation states. The Huang–Rhys factor S_k is the distortion parameter and h is Planck's constant. Calculated optimized geometries of neutral and cation states and the normal mode coordinates were used to derive the vibrational term λ_i [23]. The numerical procedure consists of the following steps: (i) the optimized neutral (q_k^g) and cation (q_k^e) geometries at charge 0 and charge +1, respectively, are determined. The vector $\Delta q = (q_k^e - q_k^g)$ describes the geometry change upon electronic excitation in the mass weighted Cartesian coordinates; (ii) the normal mode coordinates and the force constants are determined; (iii) the normal mode displacements, Δ_k, are obtained by projecting the displacements Δq onto the normal mode vectors. By substituting the calculated quantities into Eq. (3), the S_k, λ_v, and λ_i are obtained. The partition of the reorganization energy into the contributions of each vibrational mode is listed in Table 1.

3. Results and discussion

Carrier mobilities in pentacene-based OTFTs: We used a typical bottom gate configuration with a gold top-contact OTFT [2] (see Fig. 1a) to study the charge transport properties for the pentacene films grown on several dielectric surfaces with different surface properties. The measured

output and saturation transfer characteristics are shown in Fig. 2. When the pentacene was grown on a SiO$_2$ surface, it showed a very low output on-current. The output on-current was improved by nearly two orders of magnitude when pentacene was grown on the PI surfaces. The μ_{sat} was extracted from the slope (see Fig. 2b) using Eq. (2). When the pentacene was deposited on a SiO$_2$ surface, the device generally displayed a poor μ_{sat} of around 0.01–0.4 cm^2 V^{-1} s^{-1}. The obtained μ_{sat} values of pentacene films in this work that grown on a native SiO$_2$ surface are consistent with previous studies done by other researchers [2,5,16]. However, when pentacene films were grown upon polymeric surfaces, the corresponding devices displayed excellent performance with μ_{sat} values that were generally above 1.0 cm^2 V^{-1} s^{-1}. In particular, the mobility of penta-

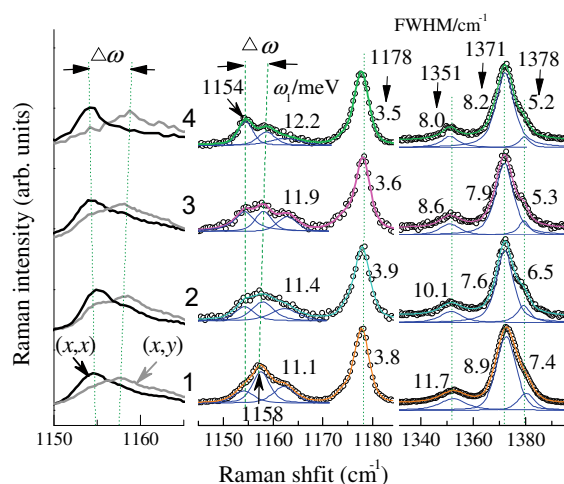
(a) Typical output characteristics: drain current (I_{DS}) versus source–drain voltage (V_{DS}) curves. (b) Saturated electrical-transfer characteristics: $I_{DS}^{1/2}$ versus gate voltage (V_G) curves. The solid lines indicate the linear fitting results. Calculated saturated field-effect mobilities (μ_{sat}) were also shown.


Fig. 3. Non-polarized (λ_{exc} = 532 nm, right-panel) and polarized (λ_{exc} = 633 nm, left-panel) Raman spectra of pentacene films grown on (1) TSiO$_2$, (2) PSiO$_2$, (3) PMMA, and (4) PI surfaces. The polarizations of the incident and detected light are parallel (x, x) and perpendicular (x, y) to each other. The Gaussian/Lorentzian functions used for the deconvolution are presented by a thin solid line. The thick solid lines represent the overall fit, while the open cycles to the experimental data. The dashed lines serve as guidelines. The intermolecular vibrational coupling energy (ω_1) and the full width at half-maximum (FWHM) of selected bands were also shown.

cene on PI was above 1.6 cm^2 V^{-1} s^{-1}, which is close to two orders of magnitude improvement when compared to pentacene grown on a TSiO$_2$ dielectric.

Raman scattering analysis: The Raman spectra of the corresponding pentacene films are shown in Fig. 3. The bands at 1158 (A_g) and 1178 (A_g) cm^{-1} are related to C–H in-plane bending modes, and the 1351 (A_g), 1371 (A_g), and 1379 (B_{3g}) cm^{-1} bands belong to the aromatic C–C stretching modes. These modes are shown in Fig. 4. A molecule under solid phase, Raman selection rules can be changed due to the static field-effect arising from the crystalline environment, and also due to the dynamic effect (called correlation field or Davydov splitting [24]) arising from the nonidentical spatial orientation of anisotropic molecules in the crystal and from the intermolecular forces between molecules. First, we have focused on a significant splitting $\Delta\omega$ that occurred between ca. 1158 (v_0 band) and ca. 1155 cm^{-1} (v_1 band) and was explained by Davydov splitting [25]. Evidently, the relative intensity ratio of v_1 and v_0 bands (I_{v_1}/I_{v_0}) has explicitly changed by altering polarizations of incident and scattered light either parallel (x, x) or perpendicular (x, y) to each other (see Fig. 3, left-panel). We have observed that the v_1 and v_0 bands have the following features [22,26]: (i) compared with other Raman modes, the relative intensity of the v_1 band was much more sensitive in response to the 633 nm excitation line that corresponds to the Davydov component in the absorption spectrum; (ii) the $\Delta\omega$ was sensitive to the unit cell volume (i.e., the R) due to that $\Delta\omega$ could be enlarged at low temperatures; (iii) the $\Delta\omega$ was related to the intermolecular coupling parallel to the a–b lattice plane direction (also see Fig. 1), which is said to be parallel to active channel direction in OTFT geometry.

Fig. 4. Shows a representation of the selected A_g and B_{3g} vibrational modes of pentacene as determined by a DFT/B3LYP at 6-31G(d) calculation of an isolated pentacene. The vectors representing the atom displacements in the Cartesian coordinates are multiplied by a factor of three.

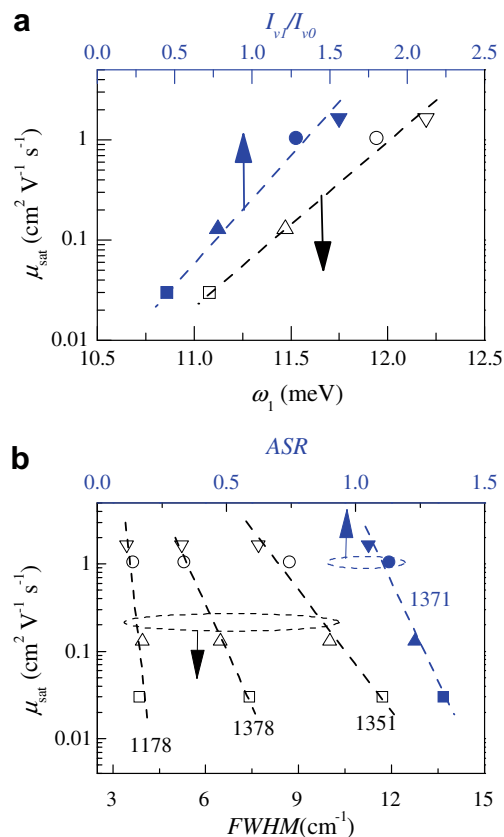
Recently, we have shown that the Davydov splitting of the Raman mode could be used to study the intermolecular interactions between molecules in films [22,26]. The intermolecular vibrational coupling energy, ω_1, could be estimated by a simple coupled-oscillator model due to that the transfer of energy from internal vibrations to external vibrations (phonons) is equivalent to the damping of internal vibrations. In the weak-coupling regime, the splitting of the characteristic frequencies is given by $\Delta\omega = v_0 - v_1 = \omega_1^2/2\omega_0$, where ω_0 is the frequency of the internal molecular band. The peak centre of v_0 and v_1 bands could be obtained according to a curve-fitting procedure reported previously [27], thus obtaining the $\Delta\omega$. Alternatively, the obtained $\Delta\omega$ could be further checked by using polarized Raman measurements (see Fig. 3, left-panel). Herein, both methods were used to determine the average value of ω_1 based on at least six values from different locations. The results of ω_1 calculation are also shown in Fig. 3, indicating that pentacene films on polymeric surfaces have a higher value, e.g., $\omega_1 \sim 12$ meV. Such polycrystalline organic films do not have clear phonon modes in the low-frequency spectral region ($<200 \text{ cm}^{-1}$) due to the lack of long-range order [22]. Hence, the observed differences in ω_1 among these films bear useful information in identifying microstructural differences. Most importantly, in Fig. 5a, we can observe a linear relationship between μ_{sat} and ω_1 on a semi-logarithmic scale. A clear relationship between the μ_{sat} and I_{v_1}/I_{v_0} has also been discovered. The magnitude of Davydov splitting is directly dependent upon the R [22,24]. Consequently, there are good reasons to believe that the charge carrier mobility can be scaled to ω_1.


Fig. 5. Relationships between saturated field-effect mobility (μ_{sat}) and vibrational characteristics of pentacene films grown on different dielectric surfaces: ($\square$) TSiO$_2$; ($\triangle$) PSiO$_2$; ($\circ$) PMMA; and ($\triangledown$) PI. (a) The μ_{sat} versus the intermolecular vibrational coupling energy (ω_1) and the relative intensity ratio of v_1 to v_0 bands (I_{v_1}/I_{v_0}). The standard deviations of the ω_1 and the I_{v_1}/I_{v_0} are within 0.15 meV and 6%, respectively. (b) The μ_{sat} versus the FWHM of 1178, 1351, and 1379 cm^{-1} bands and asymmetric ratio (ASR) of 1371 cm^{-1} band. The standard deviations of the FWHM of 1178, 1351, and 1379 cm^{-1} bands are within 0.1, 0.5, and 0.2 cm^{-1}, respectively. At least three spectra were measured for each sample from different locations. Solid lines indicate the linear fitting results.

Raman spectroscopy provides a powerful tool not only for analyzing the molecular packing and orientation of organic molecules in thin layers and the thin-film uniformity (homogeneity) in a specific direction, but also for obtaining information on λ_{reorg} [4b,28]. When pentacene was grown on polymeric surfaces, the films had a narrow full width at half-maximum (FWHM) of 1178, 1351, and 1378 cm^{-1} bands (see Fig. 3, right-panel). According to DFT calculations (also see Fig. 4), the 1178 cm^{-1} band is the strongest C–H in-plane vibrational mode and is related to the motion of H-atoms located on both sides of the pentacene molecule. The 1351 cm^{-1} band is the aromatic C–C stretching vibration and is strongly related to the completeness of the film parallel to the dielectric surface [22]. The 1379 cm^{-1} band is due to the asymmetric C–C stretching vibration along the short molecular axis also in the molecular plane. The smaller FWHM of these bands indicated that the films have a higher environmental unity for molecular vibrations occurring parallel to a dielectric sur-

face (or called the horizontal direction, i.e., along the direction of the active channel of OTFT, also see Fig. 1) due to better molecular packing.

During the carrier transfer process, the total free energy of reaction could contribute to the FWHM of the vibronic bands that involve the excitation process and lead to an unsymmetrical shape; thus, $\lambda_{reorg} \sim$ (FWHM of the vibronic bands)^2 [4b,28]. We found that the larger the ω_1 was in the experimental pentacene films, the smaller the FWHM of the vibration modes became. However, the FWHM of the strongest C–C band at 1371 cm^{-1} does not show the same trend (see Fig. 3, right-panel). In fact, we have observed that the FWHM of this band decreased with the increase of pentacene film thickness [22]. DFT normal-coordinate displacement analysis suggested that the 1371 cm^{-1} band (see Fig. 4) are more sensitive to the film quality in the vertical direction than that in the horizontal direction. Examining many pentacene films grown on various surfaces with the same thicknesses, we found that the FWHM of the 1371 cm^{-1} band is highly related to the FWHM of the (001) diffraction peak from XRD scans (see Fig. 6). We could further quantify the degree of asymmetry of the 1371 cm^{-1} band using an asymmetry ratio (ASR) [29] that is described as the ratio of the blue half to the red half of the FWHM. In general, the vibration modes have a higher ASR in an amorphous (disordered) region than in a crystalline (ordered) region, since the crystalline environment causes a shift of vibrational frequencies and possible splittings. Pentacene films grown on PI and PMMA have smaller ASRs of 1.05 and 1.13, respectively, than the obtained values of 1.34 and 1.23 on TSiO$_2$ and PSiO$_2$, respectively. After an annealing process, which aims to improve the crystal quality, the band becomes more symmetrical.

In Fig. 5b, one can see that the μ_{sat} is inversely proportional to the FWHM of these vibrational modes at 1178, 1351, and 1378 cm^{-1} and the ASR of 1371 cm^{-1}. According to the DFT computational results, the main contributions to the λ_i of a single molecule in the dimensionless situation come from a few normal modes, especially in the 1178 (17%), 1371 (28%), and 1498 (38%) [30] cm^{-1} bands (see Table 1). In single-crystals and thin-films, we have to consider the λ_o due to external environmental influences. A simulation approach suggests that λ_i has a strong dependence on the local intermolecular coupling; thus, the
Fig. 6. XRD spectra of the corresponding pentacene films on different dielectric surfaces: (1) TSiO$_2$, (2) PSiO$_2$, (3) PMMA, and (4) PI. The FWHM of the (001) peak were also shown.

embedded pentacene molecule in a single-crystal has a lower λ_i value than that of a free molecule [31]. For conjugated oligomers and polymers, it has been reported [32] that the λ_{reorg} decreases with increasing degrees of interchain and intrachain orders. However, in an OTFT, we need to consider the influence of molecular packing and orientation on the vibrations as well as the direction of charge transport in the active channel. Consequently, the analysis results from these normal modes suggests that pentacene grown on PI and PMMA surfaces have a superior microstructure with closed molecular packing, thus lowering the λ_{reorg}, especially in the direction along the current flow.

X-ray diffraction analysis: As shown in Fig. 6, we have also studied the crystal structure of the corresponding pentacene films. All the films consist of only the (00l) lattice plane and show a dominant "thin-film" phase [33] with almost identical d_{001} spacing (~15.4 Å). The results indicated that the pentacene molecules are slightly tilted to the plane of dielectric surface and form a herringbone pattern within the layers [6]. The structural parameters, including the paracrystal size (L_{00l}, i.e., the mean dimension of the crystallites perpendicular to the (00l) plane) and the fluctuation factor (g_{ll}, i.e., the distance fluctuation between successive planes of the family (00l) or the degree of distortions of crystal structure), were calculated according to the paracrystal theory, repeating the methodology used before [33,34]. The estimated parameters are listed in Table 2. Contribution to the FWHM from instrumental broadening is negligible compared to the magnitude of the observed FWHM values. Therefore, the calculated crystallite size L_{00l} is a minimum. As displayed in the table, the pentacene films on PSiO$_2$, PMMA, and PI all have similar values for the FWHM of the (001) diffraction peak, L_{00l}, and g_{ll}. The obtained L_{00l} and g_{ll} values were similar to those reported in other publications [33]. In contrast, the pentacene film on TSiO$_2$ has significantly inferior crystal quality. From the present case, it is difficult to draw clear correlations between out-of-plane XRD data and μ_{sat}. For OTFTs with top-contact configurations, the charge transport runs through the path that includes the channel near the dielectric surface at horizontal direction and the way from source and drain electrodes to the channel at the vertical direction (also see Fig. 1). Since there is only the (00l) lattice plane in the XRD pattern, we should mention the importance of crystal quality in the vertical direction of the substrate. It is established that the quality of vertical growth does not always determine the quality of horizontal growth for pentacene films. Sometimes we

could observe a good correlation between mobility and L_{00l} [16d]. Large L_{00l} and low g_{ll} would help the charges pass through the pentacene film easily, thus leading to lower bulk film resistance and higher output on-current.

Upon further analysis of these pentacene films at low thicknesses (ca. 1–2 monolayers), it was found that the films on polymeric surfaces still have higher coverage associated with a larger ω_1 (e.g., 10.5 and 10.3 meV for 50 Å pentacene films on PI and PMMA surfaces, respectively) and narrower FWHM of the Raman modes than those on the SiO$_2$ surface (e.g., ω_1 of 9.1 meV for 50 Å pentacene films on SiO$_2$ surfaces, respectively) [22]. It should be noted that the results do not fully reflect the real situations of the films for charge transport, since several monolayers could possibly be incomplete layers, which is common for organic films. However, the subsequent growth of pentacene films at a higher thickness was strongly influenced by the bottom-most layer, i.e., the formation of a more completed bottom-most layer will benefit pentacene growth, thus higher mobility for real device applications (in general, a-few-10-nm thick organic films).

MicroRaman mapping analysis of grain structures: The microstructural quality inside the grain and near the GBs is another concern. The v_0 and v_1 bands featured within the grain and near GBs were investigated using microRaman mapping scans. In Fig. 7 (upper-panels), we could see that the pentacene films grown on PSiO$_2$ display larger grain sizes than those on PMMA surfaces. First, Raman line-mapping analyzes (spot size ~1 μm with step 0.1 μm) were performed for a pentacene film on PSiO$_2$ as shown in Fig. 7a (lower-panel). The intensities of v_1 and v_0 bands were normalized to the intensity of the strongest C–C bands at 1371 cm^{-1} (as an internal standard) to eliminate the thickness variation effects due to granular morphology. We observed that both the relative intensities of v_1 and v_0 bands exhibit a wavy shape with scan position. The pinnacle and valley positions of the v_1 band intensity were used to calculate the highest (ω_1^H) and the lowest (ω_1^L) intermolecular vibrational coupling energy, respectively. The positions with stronger v_1 and v_0 intensities are always associated with larger ω_1, indicating a large contribution from the molecules within the grain. Because there are large quantities of pentacene molecules within the grain they form a more orderly crystal structure compared to that in GB. For a classical treatment, Raman scattering intensity is proportional to the density of scatters or molecules per cubic centimeter [35]. Moreover, only the pentacene in a crystal lattice can contribute to the ω_1 [24]. Hence, the lowest v_1 and v_0 intensities along with lower ω_1 occur at the positions near GBs. Based on the Raman mapping, the estimated grain size distributions at ca. 0.5–1 μm are consistent with those obtained by AFM observations. Furthermore, the larger sizes of grains demonstrate the higher Raman intensities.

Fig. 7b (lower-panel) displays the Raman mapping of the pentacene film on PMMA featuring a very small grain size of ca. 0.1 μm, which is far smaller than the spatial resolution of the Raman beam spot (ca. 1 μm). Thus the grain and GB locations could not be recognized clearly although the mapping measurements had a step of only 0.1 μm. Whether due to grains or GBs, the film on PMMA had a

Table 2
Thin-film phase structural parameters of the pentacene films grown on various dielectric surfaces.

Dielectric surfaces	d_{001}-spacing (Å)	FWHM of (001) peak (degree)	L_{00l}[a] (Å)	g_{ll}[a] (%)
TSiO$_2$	15.5	0.18	263	2.84
PSiO$_2$	15.4	0.12	363	1.60
PMMA	15.4	0.12	354	1.53
PI	15.4	0.14	350	1.75

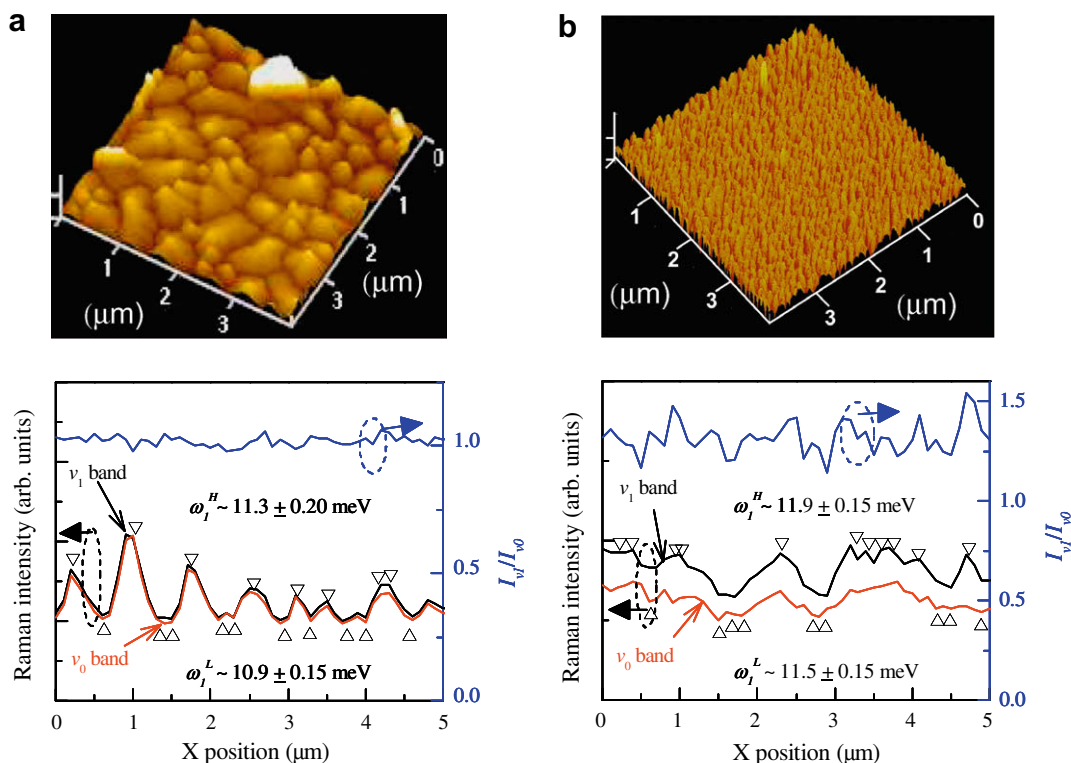
[a] L_{00l} and g_{ll} are the mean dimension of the crystallites perpendicular to the (00l) plane and the distance fluctuation between successive planes of the family (00l), respectively.


Fig. 7. AFM images (upper-panels, 4 μm × 4 μm) and Raman mapping spectra (λ_{exc} = 633 nm) (lower-panels) of pentacene films grown on (a) PSiO$_2$ and (b) PMMA. Lower-panels: relative Raman intensities of v_1 and v_0 bands, respectively, normalized to the intensity of the strongest C–C band at 1371 cm^{-1} (left-axes) and relative intensity ratio of v_1 to v_0 bands (I_{v_1}/I_{v_0}) (right-axes) as a function of scan length. Downtriangles and uptriangles indicate the positions used for calculating the highest (ω_1^H) and the lowest (ω_1^L) intermolecular vibrational coupling energy, respectively.

higher I_{v_1}/I_{v_0} and larger ω_1 than that on PSiO$_2$ featuring large grains. The results imply that the microstructure qualities inside the grain (i.e., the higher density crystals with close packing and thus highly ordered microstructures) of pentacene film on PMMA are far superior to that on PSiO$_2$. At the early stage growth, other researchers [36] have observed that the pentacene on PMMA had higher first monolayer coverage than on the SiO$_2$ surfaces. Although the formed grain is bigger on the PSiO$_2$, we suggest that with looser crystal packing comes worse microstructures. Evidently, the intragrain mobility is lower than that expected in single-crystals [37], thus Matsubara et al. [8b] suggested that there exist some limiting factors of charge transport other than the GBs. It should be noted that in Refs. [7,8], these researchers only used SiO$_2$ as the dielectric surface and their OTFTs have an inferior μ below 0.5 cm^2 V^{-1} s^{-1}. This is valid if the density of formed crystals inside the grain was at a similar level. Indeed, we also observed an apparent grain size dependent μ in pentacene OTFTs when one kind of surface, e.g., SiO$_2$, was used. We argue that the GB model does not apply to the case where the density of crystals inside the grain has large disparities among the specimens. This viewpoint could be supported by using a higher M_w of PMMA, intended to increase the density of polymer chains on the surface, thus leading to the formed pentacene film becoming more dense and forming high a density crystal (since the polar functional groups on the PMMA surface could produce an extra

attraction force for the pentacene molecules). For instance, when using PMMA with a higher M_w, we observed a higher value of μ_{sat}. Investigations into the effects of the M_w of polymer insulators (e.g., PMMA) on the electrical characteristics of pentacene OTFTs will be reported elsewhere. On the other hand, the pentacene film grown on PMMA has tiny grain morphology, thus someone may suggest that grain boundaries act as charge traps and consequently degrade OTFT characteristics, as well as the OTFTs may exhibit a larger hysteresis effects in the current–voltage characteristics. Interesting, we have not observed relationship between grain size and hysteresis effect in pentacene films. To the contrary, adding an extra PMMA layer upon SiO$_2$, the hysteresis effects of pentacene-based OTFTs were reduced as compared to that only using SiO$_2$ [38]. Moreover, Uemura et al. have not observed hysteresis effects in the pentacene-based OTFTs by only using PMMA as gate dielectric [39]. The results suggest that the GBs should not be treated as an only dominant carrier transport/performance constraint factor in polycrystalline pentacene-based OTFTs.

For organic polycrystalline films with grain morphology, there are many influencing factors on charge carrier transportation. In the past, the GB effect is thought to be a significant limiting factor on charge transport taking dominance over others. As can be observed in the study, the microstructural quality within the grain, i.e., molecular packing, has a remarkable influence on μ in pentacene

polycrystalline films. Recently, Matsubara et al. [8b] treated the carrier transport behavior in pentacene polycrystalline films on SiO_2 by a polycrystalline model with the diffusion theory that a mean free path of a charge carrier is smaller than the barrier width at GB. According to their GB model, the apparent μ can be influenced both by the barrier height at the GB (grain size-dependent part) and the mobility in grain (in-grain-relevant part). Previous research papers are mainly concerned with the discussion of the grain size-dependent part on the charge transport, in which GB elimination is the main focus. Besides, we suggest the improvement of the in-grain-relevant part, e.g., the microstructural quality within the grain, is also very important in order to achieve ultrahigh μ of organic polycrystalline films. Our observations do not contradict to previous reports from the point that the μ is still limited by the GB region.

4. Conclusions

To summarize, despite the use of different dielectrics with various surface properties, we report a clear relationship between the mobility and the ω_1 in the pentacene films regardless of grainy morphology. The microstructural qualities inside the grains must be considered case by case. In other words, the inferior microstructures may have a large grain appearance. Here, we have shown that microRaman mapping based on Davydov splitting, probing the intermolecular vibrational coupling on a micrometer scale, clearly shows that the grain morphology should not be taken for granted, for both structural quality and efficient charge transport. The GB effects (assuming large amounts of charge traps at the GBs) are found not to be a dominant performance factor, thus suggesting that the traps may be randomly distributed over the films. Our observations give a possible reason why some experimental efforts could not make carrier transport more efficient in samples featuring large grains, in a single grain, or within the grain. After all, eliminating GBs is still important since the microstructures are still inferior to inside the grain. However, the most important thing is to improve the microstructural qualities inside the grain, which was not addressed in previous studies. Furthermore, the microRaman mapping methodology we proposed here can also be used to check most organic semiconductors, both in films and in single-crystals, since there exist two types of molecular orientations in a unit cell. For example, the Davydov splitting in Raman spectroscopy has been observed in a n-type perylene tetracarboxylic dianhydride [40]. Consequently, we believe that the basic understanding of carrier transport properties of an organic film at the microscopic level will significantly contribute to the development of organic thin-film devices and the advancement of relevant technologies.

ARTICLE INFO

ABSTRACT

We demonstrate highly efficient white emission polymer light-emitting diodes (WPLEDs) from multilayer structure formed by solution processed technique, in which alcohol/water-soluble polymer, poly [(9,9-bis(3′-(N,N-dimethylamino)propyl)-2,7-fluorene)-alt-2,7-(9,9-dioctylfluorene)] (PFN) was incorporated as electron-injection layer and Al as cathode. It was found that the device performance was very sensitive to the solvents from solution of which the PFN electron-injection layer was cast. Devices with electron-injection layer cast from methanol solution show degraded performance while the best device performance was obtained when mixed solvent of water and methanol with ratio of 1:3 was used. We attribute the variation in device performance to washing out the electron transport material in the emissive layer due to rinse effect. As a result of alleviative loss of electron transport material in the emissive layer, the optimized device with a peak luminous efficiency of 18.5 cd A^{-1} for forward-viewing was achieved, which is comparable to that of the device with same emissive layer but with low work-function metal Ba cathode (16.6 cd A^{-1}). White emission color with Commission International de I'Eclairage coordinates of (0.321, 0.345) at current 10 mA cm^{-2} was observed.

1. Introduction

White organic light-emitting devices (WOLEDs) are of intense interest because of their potential applications in full-color flat-panel displays, solid-state lighting source and backlights for liquid-crystal displays [1–3]. Various approaches towards realizing WOLEDs have been reported, which include doping of RGB fluorophors or phosphors in a small molecule or polymer host [4–8], synthesis of a single polymer incorporating RGB emitting moieties in the polymer backbone or side chain [9,10], use of excimer or exciplex formed by one or two dopants [11–13], multilayer device with consecutive evaporations of RGB-emitting compounds [14,15]. So far, efficiency of WOLEDs based on vacuum deposited technology have exceeded that of the incandescent light bulb (12–17 lm W^{-1}) [1]. In contrast, only a few demonstrations with high efficiency exceeding this benchmark were reported for WPLEDs [16,17], and for most of white emission PLEDs, their power efficiencies are still much lower tan 10 lm W^{-1} mainly due to unbalanced charge injection, unsatisfactory charge transport and weak confinement of electron and hole [15]. Therefore, one of the most critical factors in achieving high efficiency for a given polymer is to obtain balanced electron and hole injection and effective confinement over the charge carrier. To minimize the injection barrier height for electron, low work-function metals are usually employed as cathode [18,19]. However, since the low-work function metals are susceptible to degradation upon water vapor and oxygen, high work-function metal, thereby more stable electron injection cathodes are desirable, if they can provide comparable device efficiency. Over the past years, significant efforts have been made to develop

a new electron injection cathode from high work-function metals in order to reach a high environmental stability, easy fabrication in combination with high device efficiency and a low operating voltage. For example, Park et al. reported the use of the ionomer-type and salt-type electron-injection layer with air-stable metal Al as cathode [20,21]. Recently, several groups reported that thin film of alcohol- or water-soluble conjugated polymer in combination with air-stable metals (such as Al, Ag, and Au) can be used as efficient electron injection cathode for PLEDs with high efficiency of green or red-emitting devices [22–29]. And more recently, Zhang et al. have developed a novel method in which a thin layer of poly[9,9-bis(6′-(diethanolamino)hexyl)-fluorene] (PFN-OH) spin-coated from water/ethanol mixed solvent was used as electron-injection layer for WPLEDs consisting of two phosphores (blue Ir complex and orange Os complex) doped into poly(N-vinylcarbazole) (PVK), the device efficiency is much higher than that with PFN-OH cast from neat ethanol, to improve the performance of white phosphorescent PLEDs by manipulating the morphology of the electron-injection layer through solvent processing [17].

In this letter, we demonstrate that analogous concepts can be applied to fabricate highly efficient multilayer WPLEDs based on blue and red Ir complexes, FIrpic and Ir(piq), respectively, in which a water/alcohol-soluble polymer, poly[(9,9-bis(3′-(N,N-dimethylamino)propyl)-2,7-fluorene)-alt-2,7-(9,9-dioctylfluorene)] (PFN) [24] was used as electron-injection layer, and air-stable, high work-function metal Al was used as cathode. We also found out that the device performance was very sensitive to the solvent composition from which PFN layer was cast, which is consistent with previous report [17]. We proposed that washing out of electron transport materials, 1,3-bis[(4-tert-butylphenyl)-1,3,4-oxadiazolyl] phenylene (OXD-7) component in the EML layer upon spin-coating of PFN layer from methanol solution is an important reason responsible for degradation of such device performance. Addition of water into PFN methanol solution prevents erosion of Ir complexes/PVK layer undernearth and makes efficient electron injection from bilayer cathode possible. This implies that multilayer configuration is an effective approach for producing low-cost, and large-area size white PLEDs by spin-coating.

2. Experimental details

Devices configurations used in this study is ITO/poly (ethylendioxythiophene):poly (styrene sulfonic acid) (PEDOT:PSS) (40 nm)/PVK:OXD-7:FIrpic (5%):Ir(piq) (0.25%) (70–80 nm)/cathode, in which PVK (70 wt%)/OXD-7 (30 wt%) form the host matrix, iridium bis(2-(4,6-difluorophenyl)-pyridinato-$N,C^{2'}$) picolinate (FIrpic, blue emission) and iridium bis(1-phenylisoquinoline) (acetylacetonate) (Ir(piq), red emission) are efficient triplet emitters. PVK was purchased from Aldrich, Ir(piq) were obtained from America Dyes Sources, respectively, and used as received. FIrpic, OXD-7 and PFN were synthesized in our laboratory. The chemical structure of PFN is shown in Scheme 1. PEDOT:PSS (Baytron P 4083, Bayer AG) was purchased from H. C. Starck, Inc.
Scheme 1. Chemical structure of the water soluble polymer (PFN).

The fabrication of devices followed well-established processes [25]. Patterned indium tin oxide (ITO) coated glass with a sheet resistance of 15–20 Ω/square were cleaned by a surfactant scrub, then underwent a wet-cleaning process inside an ultrasonic bath, beginning with deionized water, followed by acetone and isopropanol. After oxygen plasma cleaning for 4 min, a 40 nm-thick PEDOT:PSS anode buffer layer of was spin-cast on the ITO substrate and then dried by baking in vacuum oven at 80 °C overnight. The emitting layer, with thickness in the 70–80 nm range, was then deposited on top of PEDOT layer, by casting from a chlorobenzene solution containing PVK (60 wt%):OXD-7 (30 wt%):FIrpic (10 wt%):Ir(piq) (0.5 wt%), followed by thermal annealing at 120 °C for 30 min. A Tencor, Alfa-Step 500 surface profiler was used to determine thickness of the PEDOT and EL polymer films. Deposition of PFN layers and determination of their thickness follows a previously published paper [24,25] and thickness control is adjusted by spin speed between 600 rpm to 2500 rpm. In a word, the thickness of PFN was determined by a surface profiler (Alfa Step-500, Tencor) in combination with extrapolation from an absorbance–thickness curve assuming a linear dependence of absorbance at 380 nm of PFN peak on the film thickness. Prior to making the co-solvent solution, the solubility of PFN in methanol and water was checked, respectively. It was found when dissolved into methanol, with a few drops of acetic acid added and heating up to 60 °C, a concentration of 10–15 mg/ml was reached, yielding a clear solution with no sign of saturation. Nevertheless, the solubility decreases rapidly in water, for instance, even dissolving 2 mg of PFN in 1 mL of water requires heating, apparently due to the reduced solvent polarity. Given these conditions, when we handled with water/methanol (6v/1v) co-solvent solution, or any other co-solvent solution, we made PFN methanol solution first, for example, in a concentration of 2–5 mg/ml. Depending on the water/methanol blending ratio, corresponding amount of water is added to form the targeted diluted solution. When water was added in the prepared PFN methanol solution, the resulted mixed solution became slightly ropy whereas remained clear. Finally, 4 nm barium and 100 nm aluminum layer were evaporated with a shadow mask at a base pressure of 3×10^{-4} Pa. The thickness of the evaporated cathodes was monitored by a quartz crystal thickness/ratio monitor

(Model: STM-100/MF, Sycon). The structure of electron-only devices we studied in this letter is ITO/Ba(20 nm)/EML(70–80 nm)/PFN(20 nm)/Al(120 nm). 20 nm barium layer were evaporated on the ITO substrate with a shadow mask at a base pressure of 3×10^{-4} Pa. The overlapping area between the cathode and anode defined a pixel size of 17 mm^2. Except for the deposition of the PEDOT layers, all the fabrication processes were carried out inside a controlled atmosphere of nitrogen dry-box (Vacuum Atmosphere Co.) containing less than 10 ppm oxygen and moisture. The current–luminance–voltage (I–L–V) characteristic was measured using a Keithley 236 source-measurement unit and a calibrated silicon photodiode. The forward-viewing luminance was calibrated by a spectro-photometer (SpectraScan PR-705, Photo Research) and the forward-viewing LE was calculated accordingly. Throughout the whole manuscript, reported value of luminance and LE are for forward-viewing direction only. The external quantum efficiency of EL was collected by measuring the total light output in all directions in an integrating sphere (IS-080, Labsphere). The photoluminescent spectra was recorded by a single-grating monochromator (Instaspec IV, Oriel Co.) equipped with a CCD detector,

and electroluminescent spectra was collected by a PR-705 photometer. The photovoltaic measurement was carried out under white-light illumination using a xenon lamp (150 W, Oriel) as a light source.

3. Results and discussion

Fig. 1a display the forward-viewing luminous efficiency–current density (LE–J) characteristics of the devices with different cathodes (Al, Ba/Al, PFN (methanol)/Al, PFN (water/methanol, 1v/3v)/Al, respectively). All the thickness of PFN was fixed at its optimized value of 20 nm. It was found that that the maximal LE of the device with neat Al as cathode is only 0.59 cd A^{-1}, which is consistent with the fact that Al has a work-function of 4.3 eV and a big electron injection barrier exists at the PVK/Al interface. On the other hand, it is interesting to note that changing the solution composition for PFN coating can make a substantial impact on the device performance. The maximal LE of the device with PFN (water/methanol, 1v/3v)/Al as cathode can be as high as 18.5 cd A^{-1}, while a maximal luminance of 8672 cd m^{-2} was obtained at 12.6 V (Fig. 1b). This is comparable to that of device with low work-function metal Ba as cathode (a peak forward-viewing LE of 16.6 cd A^{-1} and a maximal luminance of 7823 cd m^{-2} at 13.2 V, respectively). We also note that insertion of additional Ba between PFN (water/methanol, 1v/3v) layer and Al have minor effect on the device performance further indicating that the enhancement is originated from the incorporation of PFN layer itself. On the other hand, the maximal LE of device with the PFN (methanol)/Al device is only 1.0 cd A^{-1} with a maximal luminance of 351 cd m^{-2} at 10.6 V. We also note that the turn-on voltage (defined as voltage at which luminance of 1 cd m^{-2} was detected) of the device with the PFN (methanol)/Al is quite high (6.3 V), while for the device with PFN (water/methanol, 1v/3v)/Al, lower turn-on voltage of 4.8 V was observed, close to that of Ba/Al device (3.9 V).

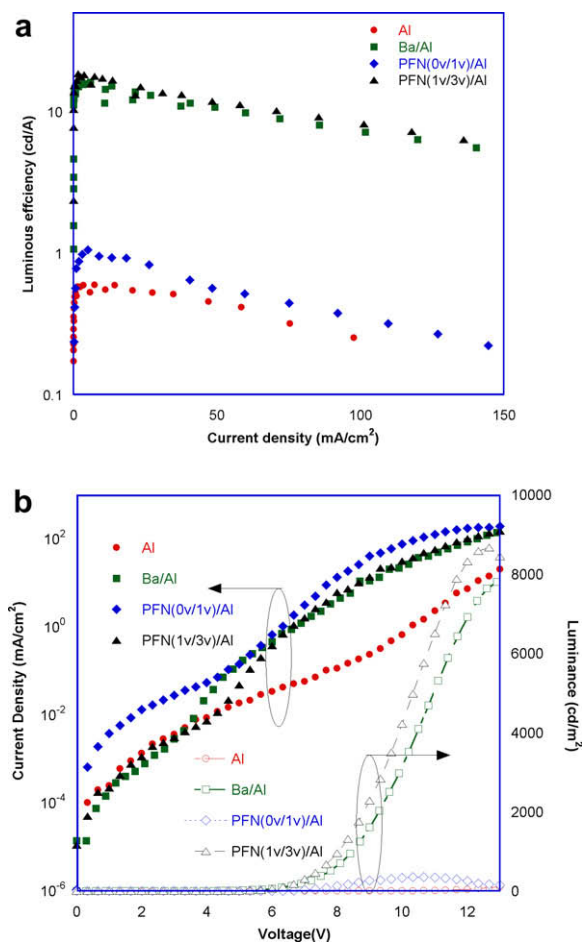
J–L–V characteristics of the devices with the four types of cathodes are presented in Fig. 1b. It is obvious that the


Fig. 1. LE-J (a) and J–L–V (b) characteristic of the devices with different cathode (Al, Ba/Al, PFN (methanol)/Al, PFN (water/methanol, 1v/3v)/Al cathodes, respectively.
Fig. 2. Photovoltaic characteristics of the white emission PLEDs with different cathode.

PFN (water/methanol, 1v/3v)/Al bilayer cathode provides an efficient electron injection due to reduced electron injection barrier height [25,26] and the device performance with such bilayer cathode was dramatically enhanced over plain Al cathode devices. On the other hand, despite its poor device performance, the PFN(methanol)/Al device exhibit the maximal current density over any other devices at any voltage studied, suggesting that its device performance is limited by imbalanced charge carriers transport rather than by injection of electron itself. This is supported by built-in potential measurement [23,25] shown in Fig. 2. As deduced from the *J–V* cure under illumination from solar simulator, the built-in across the device shift from 1.30 V for a plain Al device to about 1.60–1.70 V for the PFN(W/M)/Al, PFN(M)/Al and Ba/Al cathode device. This reveals that the built-in potentials of all of the three types of devices are very close (with difference of only 0.05 V), indicating electron injection barrier height of these devices are similar. In order to further clarify the influence of solvent composition on the charge transport properties of the device, it is necessary to compare the sole current of electron. Therefore, hole carrier flux must be suppressed by a large barrier to form an electron-only device. Since highest occupied molecular orbital (HOMO) of PVK is −5.8 eV, an hole injection barrier of 3.0 eV is expected when using low work-function metal such as Ba (2.8 eV) as anode. Two sets of electron-only devices in configuration like ITO/Ba(20 nm)/EML(70–80 nm)/PFN(20 nm)/Al(120 nm) were fabricated with PFN layers processed from two types of solvents, respectively, and their *J–V* characteristics is shown in Fig. 3. In order to obtain reliable anode/polymer contact with extra high injection barrier height, prior to spin-coating of EML, 20 nm of barium film was evaporated on precleaned ITO substrate with a shadow mask at a base pressure of 3×10^{-4} Pa. More importantly, anhydrous grade chlorobenzene (Aldrich) containing negligible water (less than 0.005 wt%) was used as solvent for the EML solution to alleviate ero-sion. Negligible emission from the resulted devices further confirmed that electron is the dominant charge carrier in the devices. In addition, diodes characteristics shown in Fig. 3 also confirmed that it is not likely the 20 nm of barium be oxidated by the residue water completely. It is found that electron current density through PFN (water/methanol, 1v/3v)/Al device is significantly higher than that of PFN(methanol)/Al device, which must be results of the better electron transport properties in the former device keeping in mind that the electron injection barriers are the same for these two type of devices. In addition, the fact that insufficient electron transport in the PFN(methanol)/Al device results in higher total current density through the device can be understood if one take into account the fact that electron accumulation at the internal interface can gives rise to a significant redistribution of the electric field inside the device [30]. Furthermore, imbalanced charge transport in the bulk of PFN (methanol)/Al was also supported by the EL spectra of the PFN (methanol)/Al device (Fig. 4), which will be discussed later.
It is also worthy to point out that changing the ratio between water and methanol can significantly affect on the device performance of the WPLEDs. Table 1 presents the influence of various solvent ratios (from 6:1 to 1:10 by volume, water to methanol) on peak LE, peak luminance and CIE coordinates (at 10 mA cm^{-2}) the devices. It can be seen that the best device performance (highest LE) is obtained when water/methanol ratio is 1v/3v.

Fig. 4 displayed the EL spectra of the white PLEDs with different cathodes (Al, Ba/Al, PFN(methanol)/Al, PFN(water/methanol, 1v/3v)/Al) at a current density of 10 mA cm^{-2},which corresponded to CIE coordinates of (0.366,0.362), (0.320,0.369), (0.205,0.328), and (0.321, 0.345), respectively, very close to ideal white emission point (0.33, 0.33). For all of the EL spectra, two intense peaks around 470 nm and 620 nm and a small shoulder peak at 500 nm were clearly observed, which can be

Fig. 5. LE–J characteristics of PLEDS based on green emitting poly [2-(4-(3′,7′-dimethyloctyloxy)-phenyl)-p-phenylenevinylene] as active layer and Al, PFN (methanol)/Al and PFN (water/methanol, 1v/3v)/Al as cathode, respectively.

Fig. 6. The normalized spectral difference between the neat film and those treated by methanol and UV–Vis absorption spectra of OXD-7. Inset: the UV–Vis spectra of the EML, equivalent film treated by methanol and co-solvent (water/methanol, 1v/3v), respectively.

assigned to the emission from FIrpic and Ir(piq). However, the device with PFN (methanol)/Al as cathode shows additional emission peak at 420 nm, which can be attributed to the EL emission of PFN layer itself, indicating that the exciton recombination zone shift towards cathode side as a result of imbalanced charge carrier transport in such device and accumulated electron at PFN/emissive layer interface. In contrast, PLEDs with single emissive component (i.e. phenylenevinylene or polyfluorene derivative) does not show such dependence on the solvent from which PFN layer was spin-cast. As clearly seen from Fig. 5, with green emitting poly[2-(4-(3′,7′-dimethyloctyloxy)-phenyl)-p-phenylenevinylene] (P-PPV) as emissive layer, both PFN(M)/Al and PFN(W/M)/Al cathode device show significant enhancement with a peak luminous efficiency around 16 cd A^{-1} when compared with the plain Al device (~0.40 cd A^{-1}). We speculate that in the white emission device with PFN (methanol)/Al device, methanol dramatically affect on electron transport in the device by washing away OXD-7, resulting in imbalanced electron transport, therefore leading to degraded device performance. Since FIrpic had been shown to exhibit bipolar transport properties [31], the reduced electron transport properties in the device had even greater impact on the excitation of Ir(piq),

leading to a significantly reduced red emission from Ir(piq). Furthermore, since charge trapping is the dominant process in the electrical excitation of these devices [8], and Ir(piq) serve as hole traps due to its high HOMO level, it is expected that a reduced electron transport will significantly influence the excitation of the Ir(piq), fully consistent with the observation shown in Fig. 4.

The emission color of the device with PFN (water/ethanol, 1v/3v)/Al as cathode showed minor color shift upon change of applied current density, for example, as the current density increase from 5 mA cm^{-2} to 10, 20, and 50 mA cm^{-2}, CIE coordinates shifted from (0.325,0.345) to (0.321,0.347). EL spectra for device with PFN (water/methanol, 1v/3v)/Al at different current density are also shown in the inset of Fig. 4.

In order to get insight into the strong dependence of device performance on the solvent composition, UV–Vis spectra of neat EML and equivalent film treated by methanol and mixed solvent (water/methanol, 1v/3v) were compared (inset in Fig. 6). As shown in Fig. 6, it was found that the spectral difference between the neat film and those treated by methanol is consist with the UV–Vis spectra of OXD-7, while in contrast, UV–Vis spectra of the neat film and the film treated with mixed solvent (water/methanol, 1v/3v) was nearly identical, thus confirm removal of the small molecule in the EML in somehow upon drop casting of PFN from methanol solution atop. The mechanisms of alleviative erosion of PVK:OXD-7:Ir complexes upon incorporation of water into PFN methanol solution is not clear so far and will be investigated in the follow-up study.

4. Conclusions

In summary, highly efficient white emission polymer light-emitting diodes was fabricated from multilayer structure formed by solution processed technique using a water/alcohol-soluble polymer as electron-injection layer, and air-stable, high work-function metal Al was used as

cathode. To obtain optimized device performance, 25% amount of water was added into PFN methanol solution to prevent erosion of Ir complexes/PVK layer undernearth and makes efficient electron injection from bilayer cathode and transport possible. The maximal luminance efficiency of the resulting device increase immensely from 0.59 cd A^{-1} for device with neat Al cathode, 1.0 cd A^{-1} for device with PFN spin-coated from methanol to 18.5 cd A^{-1} for devices with optimized PFN/Al cathode, which is comparable to those obtained using Ba cathode. We found that washing out of electron transport materials, OXD-7 component in the EML layer upon spin-coating of PFN layer from methanol solution is an important reason responsible for degradation of such device performance. Addition of water into PFN methanol solution prevents erosion of Ir complexes/PVK layer undernearth although the mechanism is not clear so far. Using air-stable metals as cathode makes these white emitting PLEDs promising candidates for lighting applications. Our study implies that multilayer configuration is an effective approach for producing low-cost, and large-area size white PLEDs by spin-coating.

ARTICLE INFO

ABSTRACT

Space-charge limited current transport in organic devices, relevant to the operation of a range of organic optoelectronic devices, is analyzed in the frequency domain. The classical multiple trapping picture with one transport state and one trap level is used as the basis for the descriptions. By varying the energetic and kinetic properties of the traps, we show that the admittance and the capacitance spectra are considerably modified depending on the interplay between the trap-limited mobility and the trap kinetics. We point out that capacitance steps at low-frequency, usually found in experiments, are observed only for slow traps.

1. Introduction

The discovery of electroluminescence in organic materials [1] launched a vast research effort for improving the performance and stability of organic semiconductors applied in optoelectronic devices such as organic light-emitting diodes (OLEDs) [2]. Polymer-based OLEDs are quite appealing for their easy processability by spin coating and ink-jet printing techniques [3]. However, further understanding of the physical behavior of such materials is needed. For instance, the description of the charge transport in organic layers by space-charge limited current (SCLC) model requires to include field [4–6] or density-dependent [7] mobility according to the percolation models [8]. Experimentally, the determination of transit times in single-carrier devices has been widely used to measure the mobility by time-of-flight (TOF) [9] and impedance spectroscopy techniques [10,11], among others [12]. It has also been recognized that the role of energetic disorder is crucial for an adequate knowledge and control of the

properties of organic transport layers. Transport in a single-carrier device has been often rationalized in terms of an extended state and a distribution of traps in the bandgap [13–15]. In this approach, the traps produce a decrease of the transport rate in the extended states [16]. However, in general the dynamics of traps is far more complex, since the traps relaxation intersects with the transport features throughout the layer [17]. While the trapping-diffusion dynamics can be solved completely in homogeneous situations [18], the typical carrier distribution at high injection currents in an organic layer in the SCLC regime is highly inhomogeneous [19].

The aim of this paper is to go beyond a quasistatic approximation to the trap-limited mobility (in which free and trapped charge remain in local equilibrium [13,20]) and to treat rather generally an apparently simple problem, a two level system composed of a transport state and a single trap level. The advantage of this model is that we can fully classify the different dynamic regimes of the system by the interplay of the relevant kinetic constants. This gives us physical insight in the interpretation of more general systems with a distribution of localized levels (e.g., exponential or Gaussian) which can be calculated

numerically, a method also applied to dual-carrier devices [10,21,22]. However, the latter systems are beyond the scope of this paper.

The problem treated in this paper has been already considered some decades ago by Dascalu [23,24] and Kassing [25,26], for the particular case of a slow-shallow trap (i.e., when the transit time is shorter than trapping time) and this case is also solved numerically in the present paper. In addition, we consider the dynamic results in the frequency domain for fast traps, and also for deep traps. By formulating a general analytical model valid for a fast-shallow trap, we find a delay in the transit time (and thus, a mobility decrease) due to multiple trapping, as measured by means of impedance techniques [27].

The paper has the following structure. Firstly, a mathematical description is presented of the single-trap model, secondly, physical implications according to the applications of the model are discussed, and finally, we provide the main conclusions.

2. Single-trap model

The SCLC for single-carrier transport (neglecting diffusion) of electrons in a transport level with density n_c that drift in the electric field F, a trap level of occupancy f_t and total density N_t, is described by: the continuity equation, the drift–current equation, Poisson equation and the trap dynamics equation, respectively [9,18]

$$\frac{dJ}{dx} = 0 \tag{1}$$

$$J = q\mu_0 n_c F + \varepsilon_r \varepsilon_0 \frac{\partial F}{\partial t} \tag{2}$$

$$\frac{dF}{dx} = \frac{q}{\varepsilon_r \varepsilon_0}(n_c + N_t f_t) \tag{3}$$

$$\frac{\partial f_t}{\partial t} = c n_c [1 - f_t] - e f_t \tag{4}$$

Here q is the elementary charge, μ_0 is the mobility, $\varepsilon_r \varepsilon_0$ the dielectric constant, and c and e are the coefficients for electron capture and release, respectively. The potential can be calculated by integrating the electrical field along the thickness L

$$V = \int_0^L F dx \tag{5}$$

The population of the extended states at the energy level E_c, for a non-degenerate semiconductor, relates to the Fermi level E_F as

$$n_c = N_c e^{(E_F - E_c)/k_B T} \tag{6}$$

where N_c is an effective density of states in the transport level (conduction band). Assuming that the trap level at energy E_t reaches equilibrium with the extended states (with the same Fermi level), the trap occupancy is given by

$$f_t = \frac{1}{1 + e^{(E_t - E_F)/k_B T}} \tag{7}$$

In steady state, Eq. (4) gives

$$f_t = \frac{1}{1 + e/(c n_c)} \tag{8}$$

Therefore, the detailed balance condition provides the following relationship for the trap emission and capture coefficients:

$$e = c N_c e^{(E_t - E_c)/k_B T} \tag{9}$$

Let us denote steady-state by $\bar{x}$ and small perturbation by $\hat{x}$ applied at a certain angular frequency ω. Therefore every electrical variable can be expressed as $x = \bar{x} + \hat{x}$ to linearize the whole system of equations up to the first order [28,29]. As shown in Ref. [17], by solving Eq. (4) for a small perturbation, we obtain

$$\hat{f}_t = \frac{1}{\bar{n}_c} \frac{\bar{f}_t(1 - \bar{f}_t)}{1 + i\omega/\omega_t} \hat{n}_c \tag{10}$$

This term gives the contribution to the spectra of the capacitance and conductance of the trap. The trap frequency is defined as

$$\omega_t = \frac{e}{1 - \bar{f}_t} \tag{11}$$

This is the maximum frequency that the trap is acting as such, since at higher frequencies the trap cannot follow the ac perturbation, as will be described in Section 3. Inserting Eq. (9) in Eq. (11), we find the dependence of ω_t on the trap energy and the occupation, as

$$\omega_t = \frac{c N_c e^{(E_t - E_c)/k_B T}}{1 - \bar{f}_t} \tag{12}$$

It should be remarked that in the SCLC regime, $\bar{f}_t$ is position-dependent along the organic layer. The impedance is defined as the quotient of potential to current density,

$$Z(\omega) = \frac{\hat{V}(\omega)}{\hat{J}(\omega)} \tag{13}$$

$\hat{V}(\omega)$ is determined by spatial integration of $\hat{F}(\omega)$ from the solution of the above described model. The boundary conditions at the injecting contact used to solve the electrical variables along the thickness in dc and ac conditions are [30,31]

$$\bar{n}_c(x = 0) = N_c \text{ and } \hat{F}(x = 0) = 0 \tag{14}$$

Capacitance and conductance are defined as follows:

$$C'(\omega) = \text{Re}\left[\frac{1}{i\omega Z(\omega)}\right] \tag{15}$$

$$g(\omega) = \text{Re}\left[\frac{1}{Z(\omega)}\right] \tag{16}$$

3. Results and discussion

In this section we show the results of the calculations of the capacitance and the conductance spectra for different trap properties and voltages, compared to the trap-free case. We first describe the latter case as a reference, and then discuss variations of energetics (E_t), by considering a shallow and a deep trap level, and the trap kinetics (c),

for a fast and a slow trap. The different configurations are given in Table 1.

3.1. Trap-free

The well-known trap free SCLC model with constant mobility is given by the analytical expression for stationary and impedance responses as [32]

$$J = \frac{9}{8}\varepsilon\mu_0\frac{V^2}{L^3} \tag{17}$$

$$Z(\omega) = \frac{6}{g_0(i\omega\tau_0)^3}\left[1 - i\omega\tau_0 + \frac{1}{2}(i\omega\tau_0)^2 - \exp(-i\omega\tau_0)\right] \tag{18}$$

where the transit time, the geometrical capacitance and the conductance are, respectively,

$$\tau_0 = \frac{4}{3}\frac{L^2}{\mu_0 V} \tag{19}$$

$$C_g = \frac{\varepsilon}{L} \tag{20}$$

$$g_0 = \frac{dJ}{dV} = \frac{3}{\tau_0}C_g \tag{21}$$

For low-frequency, the admittance is

$$Y(\omega) = g_0 + i\omega\frac{3}{4}C_g \tag{22}$$

and for high-frequency it is

$$Y(\omega) = \frac{2}{3}g_0 + i\omega C_g \tag{23}$$

It is well-known that the capacitance spectrum makes a step from $\frac{3}{4}C_g$ to C_g at around the transit time frequency, i.e., when the small perturbation of charge carriers injected by the frequency perturbation voltage is able to arrive at the collecting contact. However, in experimental data, this ideal behavior is usually distorted, mainly at low-frequencies, by the trap contribution to capacitance.

3.2. Steady-state characteristics of organic layers with shallow and deep traps

Experimental measurements of J–V curves have been used to determine the transport properties in organic layers [33,34]. Simulations of current density–voltage curves and the Fermi level distributions are displayed in Fig. 1 for two different trap energy levels configurations. These results are well understood and described in the literature [35]. For a shallow trap, the trap population is much less than the population of the transport level, hence the electric field distribution is not significantly altered, causing only a slight variation in the Mott–Gourney square law

$$J \approx \frac{9}{8}\varepsilon\theta\mu_0\frac{V^2}{L^3} \tag{24}$$

where θ is a carrier-density dependent factor of trapped and free charge defined as [27]

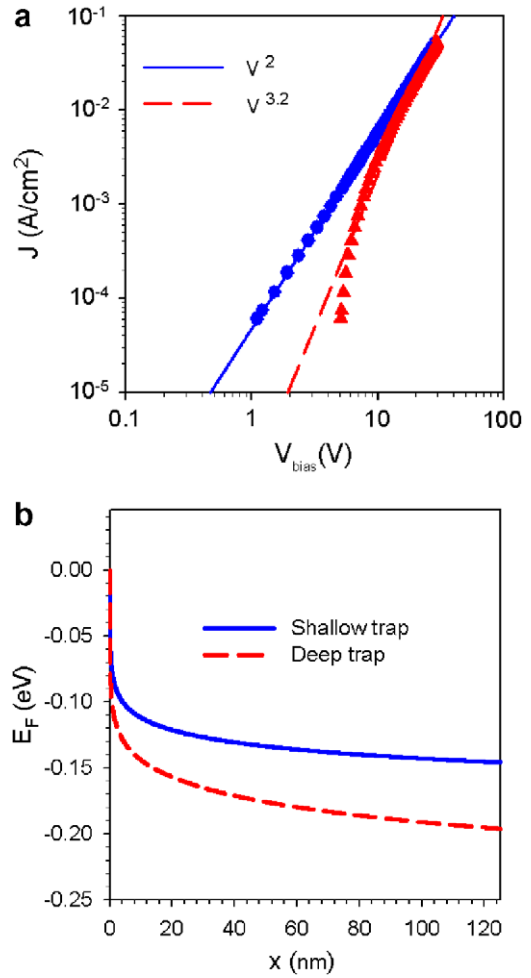
$$\theta^{-1} = \left(1 + \frac{\langle\bar{n}_t\rangle}{\langle\bar{n}_c\rangle}\right) \tag{25}$$


Fig. 1. Model simulations of shallow ($E_c - E_t = 0.1$ eV) and deep ($E_c - E_t = 0.5$ eV) trap configurations represented by blue solid lines and red dashed lines. (a) Current density voltage-characteristics for a shallow trap and a deep trap are plotted by blue dots and red triangles. Fittings provide the exponent of the voltage. (b) Fermi level representations at 6 V along the thickness, for a shallow trap (blue solid line) and a deep level (red dashed line). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

with the brackets denoting an average over the thickness of the film. For a deep trap, the occupancy of the trap level increases and the trapped charges play a crucial role in the current density–voltage curves. At low bias, most carriers are trapped, thus significantly altering the carrier and electric field distributions with respect to trap-free case, leading to an abrupt increase of the current slope, $J \propto V^m$ with $m \geqslant 2$. At high bias, the trapping sites are already filled and all the additional injected carriers are located in the transport level. This situation bends the curve from a higher voltage exponent than 2, towards a square law dependence.

3.3. Dynamic characterization of shallow traps

Let us now focus our attention on the dynamic properties of the electrical variables (capacitance and

conductance) in the case of the shallow trap. A general outline of the simulation results is displayed in Fig. 2. To accurately determine the *ac* transit times τ_{ac}, it is worth to apply the representation of negative differential suscep-
Fig. 2. Simulation spectra for shallow traps at 2 V. Fast traps are plotted by pink lines, slow traps by orange dashed lines and trap-free spectrum by black. (a) Capacitance spectra normalized to C_g for fast and slow traps. Low-frequency increase is displayed for slow traps whereas not for the fast ones. (b) Conductance spectra normalized to g_0 for fast and slow traps. (c) Negative differential susceptance $-\Delta B(\omega)$ normalized to C_g to extract transit times. In the case of fast trapping, *ac* transit time is $\tau_{ac} = 1.36\tau_0$ ($\tau_0 = 221.6\ \mu s$) with $\theta^{-1} \approx 1.40$, whereas for slow trapping no deviation from the trap free is observed. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

tance $(-\Delta B(\omega) = \mathrm{Im}(Y(\omega)) = -\omega(C'(\omega) - C_g))$, that provides peaks at certain frequencies $f_{\max}$ such that [36]

$$\tau_{ac} \approx 0.72 \cdot f_{\max}^{-1} \tag{26}$$

Fig. 2a shows the capacitance spectra (normalized to C_g) for the trap-free case, as a reference, and a shallow trap with two different trap kinetics, fast and slow (as specified below). At low-frequencies, the presence of a shallow trap in the organic layer implies (1) a deviation of the capacitance spectra for the slow case, and (2) of transit time for the fast one. At high frequencies, all the spectra converge to C_g with smooth and decaying oscillations as theoretically expected. In experiments, a slight decrease of the capacitance occurs due to the dielectric relaxation of the material [37].

As for conductance, Fig. 2b, the normalized low-frequency value decreases by a factor θ and the calculated *ac* transit time (normalized to τ_0) is increased by θ, although only for fast traps, thus in Fig. 2b we obtain for low-frequencies $g = 0.71g_0$ and for high frequencies, $g = 2\theta g_0/3$. All these behaviors will be modeled and explained in terms of a quasi-equilibrium between the two states (trapping and transport levels) in the forthcoming subsections.

3.4. Fast-shallow traps

When the trap kinetics is fast, quasi-equilibrium prevails between carriers in the trap and transport levels. In this case we expect the standard formula of Rose [27] for trap limited transport to be valid

$$\mu = \theta\mu_0 \tag{27}$$

and therefore, the trap-limited transit time is

$$\tau = \theta^{-1}\tau_0 \tag{28}$$

In order to check Eq. (27), in Fig. 3 changes in the population of the traps were imposed by modifying N_t. The resulting capacitance spectra are well described by the trap-free case formulas by using the trap-limited values τ and g *instead* of τ_0 and g_0. In particular we obtain

$$g = \frac{dJ}{dV} = \frac{3}{\tau}C_g = \theta g_0 \tag{29}$$

The inset of Fig. 3 shows that Eq. (28) is indeed satisfied.

The physical interpretation of this situation is given in terms of the interplay between trapping and detrapping and the carrier transit time. If fast-shallow traps are present in an organic layer, a delay in the transit time is expected and thereby, a mobility decrease. An experimental method to corroborate whether this kind of energetic disorder exists, consists on the evaluation of the *ac* transit time from admittance spectroscopy, Eq. (26), and the *dc* transit time, Eq. (19). The possible deviation should be attributed to the presence of fast-shallow traps.

3.5. Slow-shallow traps

If the trapped charge is not able to achieve the quasi-equilibrium with the carrier concentration in the transport
Fig. 3. Simulated capacitance spectra steps for fast-shallow traps at 6 V ($\tau_0 = 73.8$ μs) with varying trap densities, from left to right: $N_t = 8 \times 10^{17}$, 4×10^{17}, 2×10^{17}, $0\,\mathrm{cm}^{-3}$. Inset shows an identification of the transit times between the models discussed in the text, and the ac conductance calculation.

levels, the spectra present a large low-frequency capacitance that increases above the $3C_g/4$ value, Fig. 4. When exceeding the trap frequency ω_t of Eq. (11), capacitance rapidly decreases as trapping action ceases for the rest of the frequency range. In contrast to the previous case, here carriers are able to cross the organic layer and reach the collecting contact before being trapped, avoiding any delay and following the trap-free transit time τ_0. Dascalu and Kassing have given the analytical expression for the impedance in this situation [23–26]

$$Z(\omega) = \frac{6\alpha}{g_0} \sum_{k=0}^{\infty} \frac{\Gamma(\theta\alpha + 1)}{\Gamma(\theta\alpha + k + 2)} \frac{(-i\omega\tau_0)^k}{k+3} \qquad (30)$$

with α being

$$\alpha(\omega) = 1 + \frac{\omega_c}{\omega_e} \frac{1}{1 + i\omega/\omega_e} \qquad (31)$$

Here $\omega_c = c(N_t - \langle \bar{n}_t \rangle)$ and $\omega_e = \beta(\langle \bar{n}_c \rangle + N_c e^{(E_t - E_c)/k_B T})$ are the reciprocal lifetimes for electrons in the conduction band and in the trap level, respectively. For low-frequency with $N_t \gg \langle \bar{n}_t \rangle$, we have the approximation [26]

$$Y(\omega) = g + i\omega \frac{C_g}{\omega_e \tau_0} \qquad (32)$$

being $g = \theta g_0$ and for high-frequency

$$Y(\omega) = \frac{2}{3}g + i\omega C_g \qquad (33)$$

The low-frequency capacitance increase is usually found in experiments for single-carrier devices [11,38,10] and, according to our model, due to the slow-shallow trap contribution. The model also predicts a coincidence in transit times by ac and dc techniques unlike the previous case.

In Fig. 5, it is shown that the low-frequency capacitance dependence with the voltage exhibits a peak when quasi-Fermi level crosses the trap energy level (E_t) corresponding to a maximum in the trap contribution to the capacitance, Eq. (10). The low-frequency conductance is similar to the trap-free value at high voltages since free charges dominate the injected carrier concentration.

3.6. Limit between fast- and slow-shallow traps

In the previous subsection, we have shown two extreme behaviors dominated either by transit or trapping time. It is interesting to establish the conditions that determine which regime prevails. Let us define the trap and transit time frequencies as

$$\langle \omega_{tr} \rangle \approx \frac{cN_c e^{(E_t - E_c)/k_B T}}{1 - \langle \bar{f}_t \rangle} \qquad (34)$$

$$\omega_{tt} = 2\pi/\tau_0 \qquad (35)$$

Fig. 4. Model representations of the capacitance spectra for slow-shallow traps at voltages 6, 4 and 2 V, from top to bottom. The trap-free spectrum is pictured in black.
Fig. 5. Calculations of the low-frequency capacitance (violet solid line) and conductance (cyan dashed line) versus voltage at 1 Hz. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

If the trap frequency is larger than the reciprocal transit time, the fast trap regime with the multiple trapping transit time $\tau = \theta^{-1}\tau_0$ is present. In the opposite situation, the slow trap regime occurs with the trap-free transit time τ_0 value.

Inserting Eqs. (34) and (35) in $\langle\omega_{tr}\rangle \approx \omega_{tt}$, it is possible to quantify a critical capture coefficient c_c as

$$c_c \approx \frac{2\pi}{\tau_0} \frac{1 - \langle\bar{f}_t\rangle}{N_c e^{(E_t - E_c)/k_B T}} \qquad (36)$$

According to the parameters of Table 1, this quantity is estimated as $c_c \approx 10^{-13}$ cm^3/s. If a trap capture coefficient is lower than this critical value the trap is slow, whereas if it is higher, the trap is fast. In Fig. 6, normalized transit times are plotted versus normalized trap frequency and both transit time regimes are depicted showing a narrow transition from the trap-free formula to the multiple trapping one.

As pointed out at the end of Section 3.4, to experimentally determine if shallow traps of an organic layer are slow or fast, the technique consists in comparing the transit times from ac (Eq. (26)) and dc (Eq. (19)). A coincidence would give us the slow result whereas a deviation indicates the presence of fast traps.

Table 1
Material parameters used in the simulation of transport in an organic layer.

L (nm)	N_c (cm^{-3})	μ_0 (cm^2/(Vs))	E_t (eV)	N_t (cm^{-3})	c (cm^3/s)
125	10^{19}	4.7×10^{-7}		10^{17}	
Trap properties		Shallow	−0.1	Fast	10^{-12}
		Deep	−0.5	Slow	10^{-14}
Fig. 6. Simulations of normalized transit times calculated from the ac conductance method versus normalized trap frequency at 6 V and $N_t = 3 \times 10^{17}$ cm^{-3}, describing a step up from the classical transit time $\tau_0 = 73.8$ μs to the multiple trapping one, $\tau_{ac} = \theta^{-1}\tau_0$ with $\theta^{-1} \approx 2$. Classical transit time occurs for normalized trap frequency ($\omega_{tt} = 85$ kHz) $\langle\omega_t\rangle/\omega_{tt} < \theta$ and multiple trapping for $\langle\omega_t\rangle/\omega_{tt} > 1$ according to dotted vertical marks.

3.7. Comparison between dynamic and static capacitance

Dynamic capacitance, obtained from admittance spectroscopy at low-frequencies, is frequently compared to the well-known static one [13]. In SCLC, the low-frequency capacitance has a value of $3C_g/4$ [32,39], whereas the static capacitance is set at $3C_g/2$ [13]. This reduced factor of 1/2 in the dynamic capacitance is attributed to the three contributions to the ac current (velocity modulation, density modulation and displacement term) [26]. In a two level system with a shallow trap, the static capacitance is calculated by integrating the charge stored in the device per voltage unit as [13]

$$C_{st} = \frac{q}{V}\left(\int_0^L \bar{n}_c(x)dx + \int_0^L \bar{n}_t(x)dx\right) \qquad (37)$$

where V is the bias applied along the organic layer. In Fig. 7, the static capacitance is plotted versus bias-voltage. It is observed that the value remains at $3C_g/2$ as in the trap-free case. At low voltages, the capacitance contribution essentially comes from the majority of the charge stored in the shallow trapping sites whereas at high voltages the capacitance is mainly due to free charge.

3.8. Dynamic characterization of deep traps

In contrast to the shallow trap energy level, where occupation is quite low, in the case of a deep trap, the opposite situation occurs as occupation is approaching the unity. This deviation strongly determines the contribution to the impedance from the trap dynamics Eq. (4). The trap levels are so heavily occupied that the temporal variation of $\bar{f}_t$ is governed by the emitting rather than the trapping term. The numerical solution for the capacitance and the conductance is shown in Fig. 8a and b displaying distinct features with respect to the trap-free spectrum: a
Fig. 7. Model calculations of the static capacitance versus voltage for a shallow trap (black squares). Free carrier contribution (solid and empty triangles) and trap carrier contribution (solid and empty circles) to static capacitance. Solid and empty symbols are for $N_t = 1 \times 10^{17}, 5 \times 10^{17}$ cm^{-3}, respectively.

determine the dynamical properties of carrier transport and storage depending on energy (shallow and deep) and kinetics (fast and slow) of the trap. For a fast-shallow trap, an analytical model is provided and validated by means of the multiple trapping formula for mobility $\mu = \theta\mu_0$, where θ depends on the steady-state solution (trapped and free charge). For a slow-shallow trap, the available analytical model has been revised. Both regimes, fast and slow, have been characterized depending on the dominance of either trapping or transit processes and an experimental method has been also provided by comparing *dc* and *ac* transit times. A deep trap results in a decrease in the low-frequency capacitance (with respect to the trap-free case) and also in a delay in the transit times.

ARTICLE INFO

ABSTRACT

In this paper, low surface energy separators with undercut structures were fabricated through a full-solution process. These low surface energy separators are more suitable for application in inkjet printed passive-matrix displays of polymer light-emitting diodes. A patterned PS film was formed on the P4VP/photoresist film by microtransfer printing firstly. Patterned Au-coated Ni film was formed on the uncovered P4VP/photoresist film by electroless deposition. This metal film was used as mask to pattern the photoresist layer and form undercut structures with the patterned photoresist layer. The surface energy of the metal film also decreased dramatically from 84.6 mJ/m^2 to 21.1 mJ/m^2 by modification of fluorinated mercaptan self-assemble monolayer on Au surface. The low surface energy separators were used to confine the flow of inkjet printed PFO solution and improve the patterning resolution of inkjet printing successfully. Separated PFO stripes, complement with the pattern of the separators, formed through inkjet printing. The separators also realized the patterning of cathodes. A passive-matrix display device was obtained through the assistant patterning of low surface energy separators.

1. Introduction

Organic light-emitting diodes (OLEDs) have exhibit tremendous potential in flat panel displays (FPDs) since their high brightness, low power consumption, wide viewing angle and good contrast [1–5]. FPDs of polymer light-emitting diodes (PLEDs) attracted more attention in this field because of the color tunability of polymer materials within the entire visible spectrum, simpler manufacture processing, suitable for large area and soft substrate and so on. The light-emitting polymer with different color need to be patterned in a full color display of PLEDs. Many methods have been used to pattern the light-emitting polymers, such as screen printing [6,7], transfer printing [8], inkjet printing [9–11] and photo-induced polymerization patterning [12].

Thereinto, inkjet printing is a most potential technique for application because of its simple and high efficient patterning process, suitable for solution process, easy to integration and automatization. To improve the patterning resolution of inkjet printing to up to par of patterning of FPD of PLEDs, high-resolution pattern with low surface energy was used to confine the wettability and flow of inkjet printed liquid and improve the patterning resolution of inkjet printing [13–17]. The high-resolution pattern normally formed by photolithography. Then, the pattern can be modified by fluorinated self-assembled monolayer (SAM) [14,15] or CF$_4$ plasma treating [16,17] to decrease its surface energy. Thereinto, modification by fluorinated SAM can be a simple and high selective approach.

Another element need to be patterned is cathode for the FPD of PLEDs. Separators with undercut structure are the effective method to pattern the cathode in passive-matrix display of FPD [18,19]. The separators with undercut structures have been fabricated by photolithography [20–24] or soft lithography [25–27]. Photolithography has good stability and repeatability. But multilayer resist configuration or special photolithography process is needed which complicate the patterning process. Soft lithography is simple, high efficient and low cost compared with photolithography because of its characteristic, such as suitability with roll-to-roll printing and solution process, simpler patterning equipment and so on.

In this paper, based on transfer printing of soft lithography, a full-solution process was used to fabricate undercut structures with low surface energy. At first patterned PS film was formed on P4VP/photoresist films by microtransfer printing. Metal film was formed on the uncovered P4VP film by electroless deposition, which was simple and high efficient compared with traditional deposition and patterning process of metal films. This metal film pattern can be used as mask to pattern the photoresist and fabricate undercut structures, which can be used as separators to pattern metal cathode in the passive-matrix display. It also can be modified by fluorinated SAM to form separators with low surface energy, which can be used to assist the patterning of inkjet printing. Special separators, which were suit to assist the patterning of passive-matrix displays of inkjet printed PLEDs, were obtained.

2. Experimental

2.1. Materials

The positive photoresist was purchased from Suzhou Ruihong Electronic Chemical Co., Ltd., China. Polystyrene (PS, Mw: ∼31600, T_g = 103 °C) and poly(4-vinylpyridine) (P4VP, Mw: ∼60,000, T_g = 137 °C) were purchased from Aldrich. Polydimethylsiloxane (PDMS, Sylgard™ 184) was purchased from Dow Corning. ITO glass (glass slide with indium-tin-oxide films) was purchased from Chinese South Glass Holding (CSC) Co., Ltd. The hole-injection materials of poly(styrene sulfonic acid)-doped poly(3,4-ethylenedioxy-thiophene) (PEDOT, Baytron P VP.Al4083) was purchased from H. C. Starck GmbH. Poly(9,9-di-n-octylfluorene) (PFO) was synthesized as shown in Ref. [28]. PS was dissolved in toluene with a concentration of 1.5 wt%. P4VP was dissolved in chloroform with a concentration of 0.8 wt%. PFO was dissolved in the mixture of iso-propylbenzene and cyclohexylbenzene (iso-propylbenzene/cyclohexylbenzene = 8/2 (w/w)) with a concentration of 0.8 wt%.

2.2. Patterning of metal film

The PDMS mold with a stripes pattern was obtained as our previous work reported [27]. Then PS film was spin coated on the PDMS mold at 2000 rms. Photoresist film was spin coated at 2000 rms on the ITO glass substrate and then baked at 110 °C for 3 min. P4VP film was spin coated on the photoresist-coated ITO glass substrate at

2000 rms subsequently. The PDMS mold and the P4VP/photoresist-coated ITO glass substrate were baked at 110 °C for 2 min. Then the PDMS mold was placed on the P4VP/photoresist-coated ITO glass substrate and baked at 110 °C for 3 min sequentially. The PDMS mold was removed from the P4VP/photoresist-coated ITO glass substrate when their temperature dropped to ∼80 °C. The PS film would remain on the P4VP film at the contact region. A patterned PS film formed on the P4VP film.

The glass substrate with the patterned PS film was dipped into Na_2PdCl_4/water solution (0.2 mg/ml) for 1 min. The Pd^{2+} was absorbed at the uncovered P4VP film. Subsequently, the glass substrate was dipped into $NaBH_4$/water solution (0.5 mg/ml) to reduce the Pd^{2+}. Then the glass substrate was dipped into electroless deposition solutions of nickel (Ni) for 2 min and gold (Au) for 30 s, respectively. The Au-coated Ni film deposited at the uncovered P4VP film. The components of the electroless deposition solutions were shown in Table 1.

2.3. Undercut structures fabrication and surface modification

The glass substrate with the patterned metal film was etched by oxygen reactive ion etch (O_2-RIE) at a power of 120 w and an oxygen flux of 100 sccm for 5 min to remove the PS and P4VP layer at the regions uncovered by metal film. Then the substrate was exposed to UV light and realized the UV-exposure of photoresist at the regions uncovered by metal film. The undercut structures consist of the metal film and the patterned photoresist, formed after developing process.

The glass substrate with the undercut structures was placed in the vapor atmosphere of fluorinated mercaptan (Heptadecafluoro-1-decanethiol, Aldrich) for 30 min at room temperature. The fluorinated mercaptan formed SAM on the gold surface and decreased its surface energy. Then the undercut structures were used as separators to assist the deposition of inkjet printed solution and to pattern the cathode of passive-matrix display.

2.4. Inkjet printing of PFO films and fabrication of PLEDs

The overall inkjet printing system consists of inkjet print head and its controller, a translation stage equipped with a hot plate for heating the substrate, and software to control the translation stage. The inkjet print head was manufactured by Microdrop Technique GmbH (Germany), with nozzle diameter of 70 μm. The PEDOT was spin coated on the substrate with the low surface energy separators at 3000 rms for 60 s and then baked at 100 °C for 15 min to give a thickness of ∼40 nm. The PFO solution was inkjet printed into the grooves between the separators and formed PFO film. Then Ca/Al cathode was deposited on the PFO film by physical vapor deposition to complete the fabrication of PLEDs.

2.5. Characterization

The absorption and reduction of Pd^{2+} was proved by X-ray photoelectron spectra (XPS). The patterned PS film, metal film, undercut structures and inkjet printed polyflu-

orene film were all observed by optical microscope. The undercut structures were also observed by ESEMFEG scanning electron microscopy (XL30 ESEM, FEI Company). The surface energy of the metal film was measured by contact angle measuring system (Krüss DSA10-MK2, Germany). The brightness-voltage characteristics of the PLEDs were recorded using a computer-controlled sourcemeter (Keithley 2400) at room temperature under ambient conditions.

3. Result and discussion

Fig. 1 shows the over all patterning process of undercut structures with low surface energy. The first key step of the fabrication process is the patterning of PS film on the P4VP film. Microtransfer printing was used to pattern the PS film. In this patterning step, the PS-coated PDMS mold was placed on the P4VP/photoresist -coated glass substrate. The PS film contacted with the P4VP film at the protruded regions of the PDMS mold, as shown in Fig. 1(a). When the PDMS mold and the glass substrate were heated to 110 °C, which temperature was higher than the glass transition temperature (T_g) of the PS (T_g = 103 °C) slightly, the PS film and the P4VP film formed a stick because of

the movement of PS molecule. The movement of PS molecule frozen when the temperature was dropped to ∼80 °C. And the stick between the PS film and the P4VP film became stronger. The PS film remained on the P4VP film in the stick regions after the PDMS mold was removed from the glass substrate because of the low surface energy of the PDMS mold. A patterned PS film was obtained on the P4VP/photoresist-coated glass substrate. Fig. 2(a) shows the optical image of the patterned PS film.

The second step is the absorption of Pd^{2+} and electroless deposition of metal film. The patterned PS film was used as a mask to define the region of absorption of Pd^{2+}. Previous work has proved that P4VP and Pd^{2+} can form complex [29]. Fig. 3 shows the XPS analysis of the P4VP surface with patterned PS film after different treatment. It is obviously that absorption of Pd^{2+} has occurred on the P4VP surface. And a part of Pd^{2+} was reduced to Pd after the reduction step. This was proved by the decreased intensity at ∼338.5 ev and the slight increased intensity at ∼335.7 ev. The reduced Pd can be used as catalyzer to catalyze the electroless deposition of metal film.

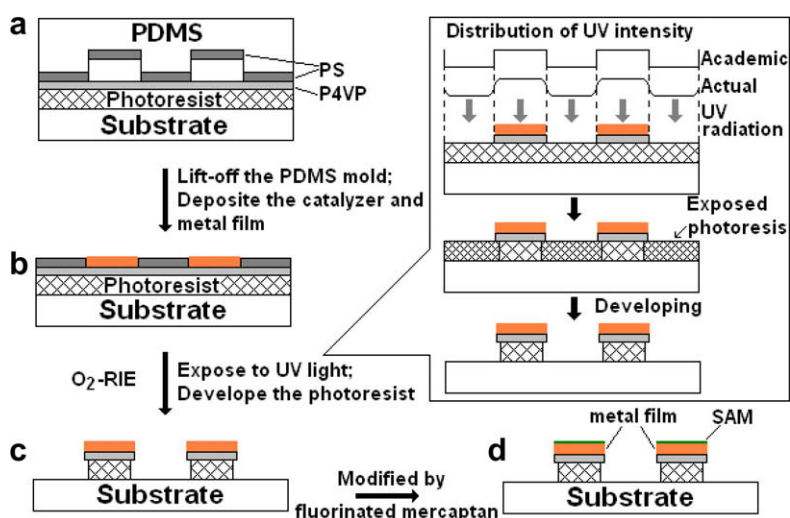
Fig. 2(b) shows the optical image of the Au-coated Ni film through electroless deposition. The electroless deposition of metal film has happened at the uncovered P4VP


Fig. 1. The patterning process of undercut structures: (a) form patterned PS film on the P4VP/photoresist-coated substrate; (b) deposit metal film on the uncovered P4VP surface by electroless deposition; (c) expose the substrate to UV light and then develop to obtain the undercut structures; (d) modify the surface of the undercut structures by SAM of fluorinated mercaptan. Insert: detailed description of the UV exposing and developing process.
Fig. 2. Optical images of P4VP/photoresist-coated substrate with (a) patterned PS film and (b) electroless deposited metal film. (c) Optical image of patterned stripes with undercut structures and (d) its SEM image of the cross-section.

surface selectively. This also proved that the absorption of Pd^{2+} occurred at the uncovered P4VP surface. And the reduced Pd catalyzed the electroless deposition effectively. So patterned metal film, complement with the pattern of PS film, was obtained. The patterned PS film can also be used as hydrophobic layer to avoid the edge diffusion of metal film in the electroless deposition process. This ensured that the electroless deposited metal film pattern was confirmed with the uncovered P4VP regions.

The patterned metal film was used as mask to realize the selective UV-exposure of the photoresist layer at the regions uncovered by metal film. The UV-exposed photoresist layer can be dissolved and removed at the following developing process. The remained photoresist pattern was same with the pattern of the metal film. In the developing process, a lateral dissolving of photoresist would occurred at the edge of the unexposed regions because of the lateral nonideal exposure caused by the UV diffraction at corresponding region [30], as shown in the insert of Fig. 1. So the undercut structures, consist of the up-layer of the patterned metal film and the bottom-layer of the patterned photoresist, formed after the developing process. Fig. 2(c) and (d) show the optical and SEM images of the patterned undercut structures. It is obviously that a lateral dissolving has happened at the unexposed region. The undercut structures formed because of this lateral dissolving. These undercut structures can be used as separators to pattern the cathodes in the passive-matrix display.

The metal film can be modified by SAM of fluorinated mercaptan to decrease its surface energy. The metal film was placed in the vapor atmosphere of fluorinated mercaptan for 30 min at room temperature. A SAM of fluorinated mercaptan formed on the surface of metal film because of the chemical action between mercaptan and Au atom. The surface energy of the metal film decreased from 84.6 mJ/m^2 to 21.1 mJ/m^2 after the modification of SAM of fluorinated mercaptan. Fig. 4 also shows the contact angle between water and the metal film with or without the SAM of fluorinated mercaptan. The contact angle between water and the metal film has increased from 20.3° to 100.6°. The surface energy of the metal film has decreased dramatically through the SAM modification. This low surface energy separators can be used to confine the flow of the inkjet printed solution and improve the patterning resolution of inkjet printing.
Fig. 3. Surface analysis of P4VP/photoresist-coated substrate by X-ray photoelectron spectra.
Fig. 4. Contact angle of water on the Au/Ni-coated substrate (a) with and (b) without the SAM of fluorinated mercaptan.

To demonstrate their application, the undercut structures with low surface energy were used as separators to assist the inkjet printing of PFO solution and pattern the cathodes of passive-matrix display of PLEDs. Photolithography and wet-etching were used to realize the patterning of ITO anode firstly. The patterned ITO stripes have a width
Fig. 5. Optical images of (a) spin-coated PEDOT film on substrate with low surface energy separators and inkjet printed PFO film on PEDOT-coated substrate (b) without and (c) with low surface energy separators. (d) Fluorescent image of inkjet printed PFO film on the substrate with low surface energy separators. SEM images of the cross-section of the separators with (e) PEDOT film and (f) PEDOT/PFO film.

of 200 μm with a space of 50 μm. Then a group of parallel stripes with undercut structures and low surface energy were fabricated used the method described above. The stripes, which were vertical with the ITO anode, were used as confined pattern to assist the inkjet printing and separators to pattern the cathodes. The stripes have a width of 50 μm with a space of 200 μm. So the dimension of the light-emitting region in every pixel of the passive matrix was 200 μm × 200 μm.

The PEDOT film was spin coated on the substrate with the low surface energy separators firstly. Fig. 5(a) and (e) show the optical and SEM images of the substrate with spin-coated PEDOT film. When the PEDOT film was spin coated on the substrate, the PEDOT/water solution dewetted from the separators surface because of its low surface energy. So the PEDOT film just deposited in the grooves between the separators and formed separated PEDOT stripes after the spin-coating process. The PEDOT film has obvious edge deposition at the edge of the grooves which caused by the morphology of the separators. The PFO solution was then inkjet printed into the grooves at ambient atmosphere and formed PFO film. Fig. 5(b) and (c) show the optical images of inkjet printed PFO film on PEDOT-coated substrate without and with low surface energy separators. Compared Fig. 5(b) with (c), low surface energy separators confined the wetting and spreading of inkjet printed solution effectively and improved patterning resolution. Fig. 5(d) and (f) also show the fluorescent image of the inkjet printed PFO film and the SEM image of the cross-section of low surface energy separators. The fluorescence of PFO film emitted from the regions of grooves only. There was no emitting of fluorescence at the regions of separators. The PFO film just formed in the grooves because of the confined flow of inkjet printed solution by separators with low surface energy. Separated PFO stripes were obtained by inkjet printing. There are also edge deposition of inkjet printed PFO film at the edge of the grooves which caused by the coffee-ring effect in the evaporating and drying process of PFO solution [31,32].

A thin layer of calcium (10 nm) followed by a layer of aluminum (100 nm) is deposited on the PFO/PEDOT/ITO coated glass substrate through a physics vapor deposition. The Ca/Al cathodes separated by the separators and formed stripes pattern which were vertical with the ITO stripes. A passive-matrix display device was obtained. Fig. 6 shows the optical image of light-emitting matrix and its bright-

ness-voltage curve. It is obvious that the patterned matrix of polymer light-emitting diodes have formed through inkjet printing. Certainly, there are some dead pixels in the light-emitting matrix which may be caused by the defects of the inkjet printed PFO film.
4. Conclusion

A full-solution process was explored to fabricate separators with undercut structures and low surface energy. By microtranfer printed PS film as mask, patterned metal film was formed on the P4VP/photoresist film by electroless deposition. This metal pattern was used as mask to pattern the photoresist layer and form undercut structures with the patterned photoresist layer. The metal film can also be modified by SAM of fluorinated mercaptan to form low surface energy separators. The low surface energy separators were used to assist the deposition of inkjet printed PFO solution successfully. Separated PFO stripes formed through inkjet printing. The separators also realized the patterning of cathodes. A passive-matrix display device was obtained which proved the suitability of the low surface energy separators in the application of inkjet printed passive-matrix display of PLEDs.

ABSTRACT

We report a highly efficient electrophosphorescent bis(2-phenylquinoline) (acetylacetonate) iridium(III) [Ir(2-phq)$_2$(acac)]-based red organic light-emitting diode. The emission layer consists of a periodic thin layer of guest material of Ir(2-phq)$_2$(acac) separated by host material of 4,4′-Bis(carbazol-9-yl)biphenyl. The guest and host thicknesses were optimized independently to obtain the best performance. The current efficiency reaches to a maximum of 16.2 cd/A then drops to 15 and 11 cd/A at brightness of 10 and 100 cd/m^2, respectively. By reducing the thickness of the host layer, the power efficiency was further improved. Device with a maximum power efficiency of 8.3 lm/W was obtained. We also found that the concentration quenching in Ir(2-phq)$_2$(acac) is dominated by molecular aggregation. Excitonic quenching by radiationless Förster process is miniscule.

1. Introduction

Organic light-emitting diode (OLED) has emerged as one of the most important display technologies for the future. Various techniques have been reported in literature to optimize the electroluminescence processes in OLED, including: balancing the carrier transport and injection [1,2], confining the excitons [3], doping the transport [4] and emission layers [5], and the most recent electrophosphorescence [6].

By harvesting the triplet excitons, electrophosphorescence enables improvement of the efficiency by four times. With further improvements in carrier balance and exciton confinement, both green [7] and yellow [8] emitting devices have reached the efficiency close to their maximum

theoretical limit. Red phosphorescent OLED, however, still has room for improvement. Li et al. reported a red phosphorescent OLED with a current efficiency of 13 cd/A at a current density of 20 mA/cm^2 [9]. Ho et al. reported a maximum external quantum efficiency of 12% photon/electron at low current density but drops to 3% photon/electron at 200 mA/cm^2 for their saturated red OLED [10].

In phosphorescent OLED, the emission layer (EML) is normally made of a host-guest system formed by co-evaporating a small amount of guest molecule in the matrix of host material [5,6]. Most excitons are formed in the matrix host which then transfer the energy to the guest molecules where final emission takes place. Host–guest system minimizes concentration quenching of guest molecules to enable high quantum yield.

Red emitting organic molecules suffer from a tremendous concentration quenching [11]. As the concentration of the emitting guest molecules increases, the quantum

Fig. 1. Schematic diagram of fluorescent OLED fabricated with sequential doping with *N* cells and the molecular structures of the materials used in this work.

efficiency of the device drops significantly. Concentration quenching is originated from molecules aggregation [12] and long range dipole–dipole interaction between the guest molecules [13–15]. Molecular aggregation results in a much red-shifted emission spectrum followed by a significant drop in the efficiency [12]. On the other hand, excitonic quenching by long range dipole–dipole interaction only results in efficiency reduction without emission shift [13–15]. Depending on the molecule, the dominant factor is either molecular aggregation or dipole–dipole interaction. Since conventional doping only allows one parameter to be varied, the guest–host ratio, the effect of molecular aggregation or dipole–dipole interaction can not be controlled separately.

Recently we have introduced a technique termed sequential doping that allows two independent parameters to be varied for a better control of device performances [14]. In sequential doping, the EML consists of periodic thin layers of guest separated by the host. In this architecture, device performance can be tuned by adjusting the thicknesses of the guest and host layers independently. For molecules with a severe excitonic quenching due to molecular aggregation, the thickness of the guest layers can be minimized. On the other hand for molecules that suffer a large dipole–dipole quenching interaction, one may increase the thickness of the host layers for better device performance.

Reineke et al. showed a similar EML structure to the sequential doping, but compared to a neat film of guest molecules, they prepare the guest containing layers by co-evaporation of host and guest [16]. This method has been able to improve the efficiency roll-off with the critical current density increases from 140 to 270 mA/cm² by confining the exciton within the guest molecule. In spite of the better roll-off performance, the device reported by Reineke et al. shows a lower EQE value. The lack of guest molecules available for emission results in appearance of host emis-

sion and reduction in EQE due to incomplete energy transfer. Also the interlayer host thickness used is fixed at 2 nm. At such distance, the excitonic quenching by long range dipole–dipole process becomes significant.

In this letter, we utilized the sequential doping method to produce a highly efficient red OLED and to investigate the quenching mechanism in bis(2-phenylquinoline) (acetylacetonate) iridium(III) [Ir(2-phq)$_2$(acac)]. Device with a maximum current efficiency of 16.2 cd/A (8.4% photon/electron) is reported. Interestingly the power efficiency can be improved by minimizing the thickness of the host layer. Using 3 nm of host layers, device with a maximum power efficiency of 8.3 lm/W is achieved. We also found that molecular aggregate dominates the exciton quenching in Ir(2-phq)$_2$(acac).

2. Experimental

Here, we employed *N,N′*-di(naphth-2-yl)-*N,N′*-diphenyl-benzidine [NPB] as the hole transporting layer, 4,4′-Bis(carbazol-9-yl)biphenyl [CBP] as the host, Ir(2-phq)$_2$(acac) as the guest, and 2,9-dimethyl-4, 7-diphenylphenanthroline (BCP) as the hole blocking layer and tris-(8-hydroxyquinoline) aluminum [Alq$_3$] as the electron transporting layer. Fig. 1 shows the schematic of the sequential doped device and the molecular structures of the materials used in this work.

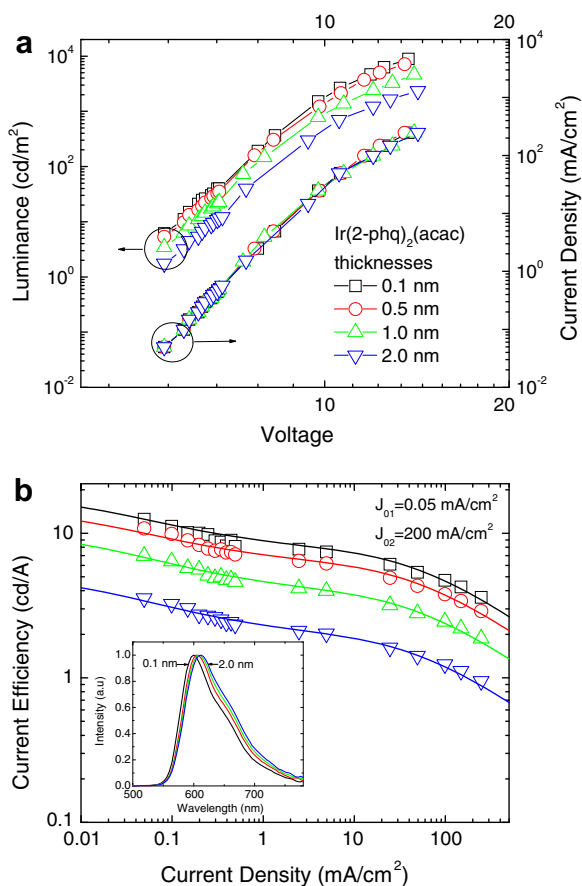
The routine cleaning procedures, including ultra-sonication in acetone, ethanol, and rinsing in de-ionized water, were firstly carried out to clean ITO glass (50 Ω/square). Before deposition, the ITO was treated by oxygen plasma at 10 Pa for 2.5 min. The ITO substrates were then transferred to the main chamber under high vacuum for device fabrication. The deposition rate (thickness) is measured by a crystal sensor quartz oscillator combined with a frequency meter. Evaporation of organic materials and metals


Fig. 2. (a) *J–V* and *L–V* curves for devices with various Ir(2-phq)2(acac) thicknesses (six cells). (b) Current efficiency versus current density for devices in (a). The efficiency roll-off can be fitted with a double TT annihilation model (with J_{01} and J_{02} of 0.05 and 200 mA/cm^2, respectively). was carried out in a high vacuum condition of about 2×10^{-4} Pa at a deposition rate of 0.5–4 Å/s.

Electroluminescence (EL) spectra of the fabricated devices were measured with a PR650 Spectra Scan spectrometer. Luminance–current density–voltage (*L–J–V*) characteristics were recorded simultaneously with the measurements of the EL spectra by attaching the spectrometer to a programmable Keithley 236 source measurement unit. Assuming a Lambertian emission pattern, we calculated the EQE from the luminance, current density and EL spectrum. All measurements were carried out at room temperature under ambient atmosphere without any encapsulation.

3. Results and discussion

3.1. Variation of guest's thicknesses

We fabricated devices with a structure of NPB/ [Ir(2-phq)$_2$(acac) (*x* nm)/CBP (5 nm)] (6 cells)/ Ir(2-phq)$_2$-(acac) (*x* nm)/ BCP/ Alq$_3$, where *x* varies from 0.1, 0.5, 1, to 2.0 nm. Six cells were used to make sure the EML thick-

ness is larger than 20 nm to obtain a good carriers confinement [3]. Fig. 2a shows the current density and luminance versus voltage curves for devices with various guest thicknesses (*x*). It can be seen that the current density does not vary much, while the luminance drops significantly as the guest thickness increases. This means the Ir(2-phq)$_2$(acac) molecules do not trap or block charges significantly enough to influence the current flow. On the other hand, the large drop in the luminance for thicker guest layer can be attributed to molecular aggregation. Fig. 2b shows the current efficiency versus current density for various guest thicknesses. As the thickness of the guest layers increases, the degree of aggregation increases accordingly, resulting in a decrease in efficiency.

It can also be seen from Fig. 2b that the efficiency drops as the current increases. The efficiency roll-off is caused by biexcitonic interaction of triplet–triplet (TT) annihilation [17]. In the presence of triplet–triplet annihilation, the efficiency (η) becomes

$$\eta = \eta_0 \frac{J_0}{4J} \left(\sqrt{1 + \frac{8J}{J_0}} - 1 \right) \tag{1}$$

where η_0 is the maximum efficiency, J is the current density and J_0 is the critical current density. The efficiency in Fig. 2b, however, cannot be fitted with a single TT annihilation model. Instead it can be fitted with a double TT annihilation process of

$$\frac{\eta}{\eta_0} = k_1 \frac{J_{01}}{4J} \left(\sqrt{1 + \frac{8J}{J_{01}}} - 1 \right) + k_2 \frac{J_{02}}{4J} \left(\sqrt{1 + \frac{8J}{J_{02}}} - 1 \right) \tag{2}$$

where k_1 and k_2 are constants, J_{01} and J_{02} represent the first and second critical current densities, respectively. Similar feature of double TT annihilation has been observed previously in various different OLEDs utilizing CBP as the host material [17]. The reason behind this phenomenon is not clear; however it may be related to exciton formation processes. At a low current injection, the excitons are only formed at the heterojunction interfaces. Therefore the TT annihilation is severe due to the thin recombination region. As the current increases, the exciton starts to be formed throughout the EML, increasing the effective recombination region, hence reducing the TT annihilation.

It can be seen from Fig. 2b that the data can be fitted nicely with double TT annihilations model. J_{01} and J_{02} values are independent of the guest thickness. This suggests that the TT annihilation is dominated by interaction between the planar guest layers since the host thickness is fixed. Later we shall see that variation of the host thickness changes the value of the critical current density.

Inset of Fig. 2b shows the emission spectrum of the device in Fig. 2a. It can be seen that the emission red-shifts with the increase in guest thickness. The emission peak shifts from 600 nm to 612 nm for Ir(2-phq)$_2$(acac) thickness of 0.1 nm to 2.0 nm, respectively. This also supports the argument on molecule-aggregation. When two similar molecules are positioned close one another such that their electronic wavefunctions start to overlap, a new state is formed with different spectral properties compared to the molecular spectrum. In most cases the emission spec-
Fig. 3. CIE color coordinates of devices in Fig. 2.

trum is broaden and red-shifted with a much lower quantum efficiency than that of the molecule itself [12]. The large drop in the efficiency and shift of the emission spectrum show that $Ir(2\text{-}phq)_2(acac)$ molecules tend to form inefficient aggregates.

Fig. 3 shows the Commission Internationale de l'Eclairage (CIE) coordinate for devices in Fig. 2. It can be seen that there is a slight shift in CIE coordinate from ($x = 0.61$, $y = 0.38$) to ($x = 0.63$, $y = 0.36$) for devices with $Ir(2\text{-}phq)_2(acac)$ thickness from 0.1 nm to 2.0 nm. The CIE coordinate is very close to that of the National Television System Committee (NTSC) standard red color ($x = 0.674$, $y = 0.326$) [9].

3.2. Variation of host's thicknesses

We then varied the host thickness using a structure of $NPB/[Ir(2\text{-}phq)_2(acac)$ (0.1 nm)$/CBP$ (y nm)] (6 cells)$/Ir(2\text{-}phq)_2(acac)$ (0.1 nm)$/BCP/Alq_3$, where y varies from 3, 7, 10, to 15 nm. Fig. 4a shows the current density and luminance versus voltage curves for devices with various thicknesses of host layers. It can be seen that the current density and the luminance shift toward higher voltage as the thickness of the host increases. This is understandable due to a thicker device structure. The maximum luminance increases slightly with the host thickness. Fig. 4b shows the current efficiency for devices in Fig. 4a. It can be seen that the current efficiency increases slightly with the host thickness.

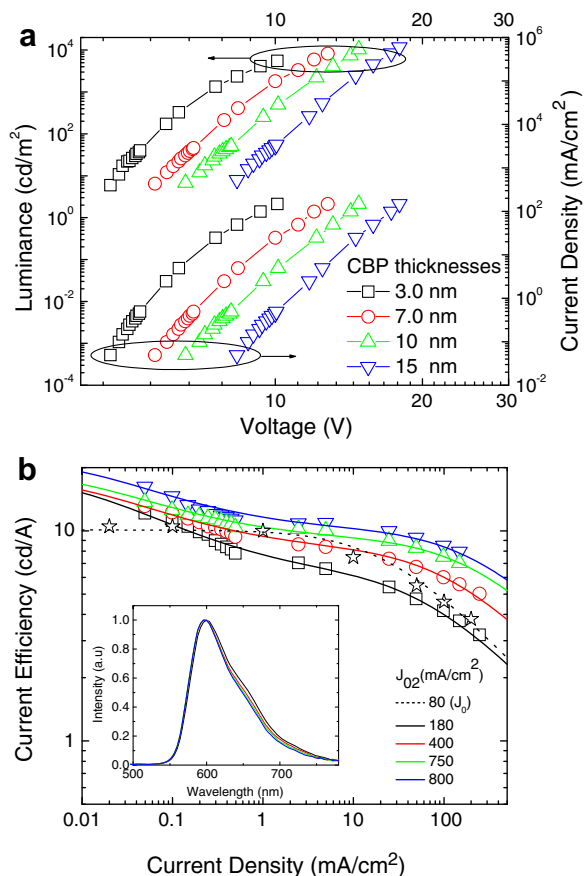
Similar to previous observation, the efficiency drops with the increase of current density. The efficiency rolloff in Fig. 4b can only be fitted with double TT annihilation model as shown by the solid line. The value of J_{01} is fixed at 0.05 mA/cm². On the other hand J_{02} drops from 800 to 180 mA/cm² when CBP thickness reduces from 15 to 3 nm. The maximum value of J_{02} even exceeds that of the optimized device reported by Reineke et al. of 400 mA/cm², which indicates the advantage of using our sequential doping method for this study [18]. The variation of J_{02} with CBP thickness shows that the TT annihilation processes oc-


Fig. 4. (a) *J–V* and *L–V* curves for devices with various CBP thicknesses (six cells). (b) Current efficiency versus current density for devices in (a). Also shown here is the current efficiency of device from Ref. [10] (stars). Inset in (b) shows the normalized emission spectra for devices in (a). Symbols in (a) also apply in (b).

cur between the guest layers as mentioned before. When the guest layers are separated adequately, the TT annihilation is minimized as evidenced by the increase in the critical current density.

The TT annihilation between the $Ir(2\text{-}phq)_2(acac)$ within the planar guest layer is also minimized due to the large intermolecular spacing between the molecules. To estimate the intermolecular spacing of the $Ir(2\text{-}phq)_2(acac)$ layer, we assume that 0.1 nm of $Ir(2\text{-}phq)2(acac)$ layer corresponds to 0.1 monolayer of $Ir(2\text{-}phq)_2(acac)$ film. Assuming that a monolayer square lattice of $Ir(2\text{-}phq)_2(acac)$ has intermolecular spacing of 1 nm [15,19], the intermolecular spacing of a 0.1 monolayer can be estimated as $a = 1$ nm $\times \frac{1}{\sqrt{0.1}}$. We further assume that, two molecules may be closely spaced forming aggregate (dimer), the intermolecular spacing ranges between 3 and 6 nm. At this distance, the $Ir(2\text{-}phq)2(acac)$ molecules are isolated, therefore minimizes the TT annihilation.

To our best knowledge this is the first time that $Ir(2\text{-}phq)_2(acac)$ molecule was incorporated as a red OLED. In the literature, a similar molecule of bis(1-phenylisoquinoline) (acetylacetonate)iridium(III) [Ir(piq)_2(acac)] has

also been used for red OLED [10]. The current efficiency of a Ir(piq)$_2$(acac) device fabricated using the conventional co-evaporation method was included in Fig. 4b represented as stars. The emission layer consists of 4 wt.% Ir(piq)$_2$(acac) doped into CBP host. It is clear that the performance of the device fabricated using the conventional method is worse. The maximum current efficiency reaches up to 10.1 cd/A and drops to 4.5 cd/A at a current density of 100 mA/cm^2. The J_0 value is much lower of 80 mA/cm^2 [20].

Inset of Fig. 4b shows the emission spectrum of the device in Fig. 4a. No significant change was observed in the emission spectrum for devices with various thicknesses of CBP, which indicates the absence of molecular aggregate. The slight drops of the current efficiency for device with thinner layer of host material may arise from an increase in interaction between the guest molecules.

Previous studies have shown that Förster type interactions between the guest molecules result in excitonic quenching in host–guest system [13–15]. The long range interaction between the electronic and vibrational modes between two molecules is enabled by dipole–dipole interaction which applies up to a range of 20 nm [21]. In our case, it is clear that the long range excitonic quenching is much less significant than the aggregation effects. It can be seen that only a slight drops in current efficiency is observed for device with different CBP thicknesses (drops from 16.2 to 12.1 cd/A for CBP thicknesses of 15 to 3 nm, respectively). This means that the radiationless Forster radius between the Ir(2-phq)$_2$(acac) molecule is small.

Table 1 summarized the performances for devices reported in this work. It worth mentioning that the current efficiency obtained in this work (16.2 cd/A) is one of the best for red OLED based on small molecule with CBP host. Furthermore, the current efficiency shows only a small roll-off with current density. At high current density of 100 mA/cm^2 the current efficiency still reaches 8.7 cd/A. At brightness values of 10 and 100 cd/m^2, the current efficiency reaches 15 and 11 cd/A, respectively.

From Table 1 it can be seen that the best power efficiency (8.3 lm/W) is obtained for device with a thinner layer of CBP layer (3 nm) which corresponds to EML thickness of 18 nm. In OLED it is known that reducing the thickness of EML significantly reduces the efficiency due to

inadequate number of emitter molecules, which results in emission saturation [3]. Therefore sufficient EML thickness is required to achieve high power efficiency. In our case, the numbers of guest emitter molecules are fixed with variation of host thickness. Therefore the decrease of the efficiency is not due to emission saturation but increase intermolecular interaction between the guest molecules. The slight drop in current efficiency is followed by a significant reduction in operating voltage, which in overall increases the power efficiency as the thickness of the host reduces.

Inset of Fig. 5 shows the operating voltage for devices with various CBP thicknesses at a current density of 25 mA/cm^2. It can be seen that the voltage increases linearly with CBP thickness, indicating that the electric field is constant throughout the CBP layer. The electric field within the CBP can be obtained from the slope of the fitting straight-line. Fig. 5 plots the average electric field and the CBP electric field at various current densities. The average electric field is determined by dividing the operating voltage with the total thickness of the device with EML thickness of 18 nm. It is clear that for a fixed current density the electric field in the CBP is almost two times higher than the average electric field. There-
Fig. 5. Current density versus the average and CBP electric-field. Inset shows the operating voltage for devices with various CBP thicknesses at a current density of 25 mA/cm^2.

fore minimization of the CBP thickness effectively reduces the operating voltage and increases the power efficiency since the number of emitting guest molecules is unaltered.

It is worth mentioning that the device structure has the potential for further optimization, such as the usage of Alq_3 as the host, LiF [2] or CsF [22] cathodes, electron-blocking layer [4], corrugated substrate [23], or microcavity [24] and optimization of number of cells in order to further reduce the operating voltage and increases the current efficiency of the device.

4. Conclusion

In conclusion, we have introduced sequential doping method for efficient phosphorescent red OLED. The method presented here has an advantage since it allows two independent parameters to be varied for optimization. Device with current efficiency of 16.2 cd/A has been produced. Interestingly, the power efficiency increases with reduction of the host thickness. Device with a power efficiency of 8.3 lm/W is achieved. The excitonic quenching in thin layer of $Ir(2-phq)_2(acac)$ was mainly due to appearance of aggregation state. We also observed a small amount of excitonic quenching due to inter-molecular energy transfer among $Ir(2-phq)_2(acac)$ molecules, i.e. by long range Förster process between the $Ir(2-phq)_2(acac)$ molecules in different layers.

ARTICLE INFO

ABSTRACT

We report on the deposition of para-sexiphenyl (PSP) on poly(diphenyl bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylate) (PPNB) by hot wall epitaxy (HWE). The surface polarity of the substrate, PPNB, can be increased by UV-illumination via a photo-Fries rearrangement. The influence of the changed surface polarity on the surface morphology and the structure of the PSP layers were studied by atomic force microscopy (AFM), X-ray diffraction (XRD) and grazing incidence X-ray diffraction (GIXD). The observation of growth spirals and islands, providing mono-layer step heights of standing PSP molecules, underline a high crystallographic order of the films which is confirmed by XRD analysis. GIXD experiments show a strong preferential (001) orientation of the PSP layers with better alignment on substrates with smaller surface polarity. The γ- and Baker-crystal structures are present in the films grown at low substrate temperatures, but only Baker structure was found in the films deposited at high substrate temperatures. However the main influence on the growth of PSP, is caused by the polarity change induced by pre-treating the PPNB substrate by UV-illumination.

1. Introduction

Surface morphology and crystalline order are determining the electrical and optical properties such as mobility or electroluminescence of organic semiconducting films. Therefore it is of great importance to understand the growth kinetics of organic materials on surfaces with well controlled properties that could be potentially used for the fabrication of optoelectronic devices. Para-sexiphenyl (PSP) ($C_{36}H_{26}$), a six units oligomer of para-phenylene, is a promising candidate as an electro active layer in organic LED displays due to its blue luminescence with high quantum yield [1,2]. Moreover, it is classified as a wide band gap organic semiconductor (3.1 eV) with photoluminescence in the blue visible range and polarisation dependent absorption and emission if the PSP films are highly ordered [3].

The hot wall epitaxy (HWE) technique was adapted for the deposition of organic materials. Highly ordered organic thin films can be obtained with this technique because it allows organic molecules to find the most suitable arrangement before settling into the crystal lattice [3,4]. Organic thin films grown by HWE have shown outstanding electrical and optical properties [5,6]. HWE grown PSP films have been already deposited on different substrates such as KCl

and muscovite mica and extensive morphological and structural characterization has been performed [7,8]. It is generally shown that the nature of the substrate and the growth conditions such as substrate temperature and deposition rate are determinant parameters for the molecular packing of the films.

In this contribution, an amorphous polymer poly(diphenyl bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylate) (PPNB) containing photoreactive aryl-ester groups was used as substrate. Upon illumination with UV-light of $\lambda < 280$ nm these ester groups isomerise to the corresponding hydroxyketones in the so-called photo-Fries reaction [9,10]. Fig. 1 shows the generally accepted mechanism [11–13]. As a first step photolysis proceeding from an exited singlet (S1) state leads to the cleavage of the C–O bond. The photogenerated radicals can recombine and yield a derivative of cyclohexadienone as the "cage product" (ortho and para product). Tautomerism then gives the hydroxyketone, which is the rearranged acyl migration product. Besides the release of free phenols as "escape" product, decarboxylation occurs as competing reaction [14,15].

The photo-Fries rearrangement is also observed in polymeric materials [16–18]. Recently, we have shown that the photoreaction in PPNB (Fig. 2) yields up to 21% hydroxyketones as photoproducts [19]. The UV induced reaction leads to a large increase of the refractive index as well as a change in surface polarity. This enhanced polarity and the generated new functional groups can be used for selective post-modification reactions [20]. As a consequence we expected a clear influence of the enhanced surface polarity on the growth mechanism of PSP layers.

2. Experimental

PPNB was synthesized as described previously [19]. A 10 mg/ml solution of PPNB in CHCl$_3$ was prepared and stirred for 12 h. Subsequently, the solution was spin cast onto Si-substrates with a native 1.7 nm (±0.4 nm) thick oxide layer, resulting in 80 nm (±10 nm) film thickness of PPNB which was verified by ellipsometric measurements. Finally, the film was dried at 40 °C in vacuum.

In order to provide equivalent growth conditions while depositing PSP on UV-exposed and non-irradiated surfaces each substrate was divided in two regions. One half of the substrate was exposed for 20 min to UV-light (254 nm) while the other half was covered with a chromium mask.
Fig. 2. Structure of PPNB.

The unfiltered light of an ozone-free mercury low pressure UV lamp (Heraeus Noblelight; 254 nm) was used. For these experiments, the light intensity (power density) at the sample surface was measured with a spectroradiometer (Solatell, Sola Scope 2000TM, measuring range from 230 to 470 nm). The integrated power density for the spectral range 240–270 nm was 1.41 mWcm^{-2}. The illumination process was performed under inert gas atmosphere (nitrogen with a purity >99.95%) in order to avoid unwanted oxidation reactions. The surface tension γ of the illuminated and non-illuminated part was determined by measuring the contact angle with a Drop Shape Analysis System DSA100 (Krüss GmbH, Hamburg, Germany) using water and diiodomethane as test liquids (drop volume ∼20 μl). The contact angles were obtained by means of the sessile drop method and they were measured within 2 s. Based on the Owens–Wendt method, the surface tension γ as well as the dispersive and polar components (γ^D and γ^P) were calculated [21]. The surface polarity is expressed as the ratio γ^P/γ and is given in percent (%). AFM investigation of the surface roughness (before and after 1 h annealing at 160 °C) resulted in RMS values between 0.2 and 0.6 nm no difference could be observed for the as prepared and illuminated parts of the substrate.

After the illumination process the substrates were transferred via a load lock to a HWE evaporation chamber working at a dynamic vacuum of 9×10^{-6} mbar. The working principles of a HWE system can be found elsewhere [22]. In order to reduce surface contaminations a 15 min in situ preheating procedure was applied. The substrate temperature during preheating is chosen the same as the growth temperature in order to permit constant thermal conditions during the whole deposition process. The preheating process also allows to remove any adsorbed species (H$_2$O, O$_2$ etc.) from the surface of the substrate. A complete series of samples was prepared varying growth
Fig. 1. Mechanism of photo-Fries rearrangement.

time (5–60 min) and substrate temperature (85–160 °C) whereas the source- (240 °C) and wall-temperature (260 °C) were kept constant resulting in a deposition rate of ~0.55 nm/min. All steps of the sample preparation procedure are shown schematically in Fig. 3.

For the structural characterization, specular scans were performed on a SIEMENS D501 diffractometer using Cu K$_\alpha$ radiation in Bragg–Brentano geometry equipped with a secondary graphite monochromator. Complementary to studies in our laboratory, grazing incidence X-ray diffraction (GIXD) was performed at the G2 line, Cornell high energy synchrotron source. The angle of incidence was optimised for maximum scattering intensity, values between to 0.19° and 0.23° were used.

At the beam line a diffractometer in κ-geometry was operated with radiation of a wavelength of 0.12681 nm. Reciprocal space maps were taken with an one-dimensional detector collecting the scattered intensity in q_z-direction. Simultaneously an angular range of 6° was picked up with a resolution of 0.1°. The surface parallel component of the scattering vector (q_{xy}) was varied by the goniometer in steps of 0.1°. Since the PSP crystallites do not have any specific in-plane orientation the GIXD measurements could be performed without sample rotation.

The vertical crystal size (in perpendicular direction to the substrate surface) was determined from the specular scans taking the integral width of the diffraction peaks. No corrections for the instrumental line broadening were used, since only relative changes in the peak width are of interest. The lateral crystal size (in parallel direction to the substrate surface) was determined from the GIXD pattern by using the Scherrer formula. The crystal sizes obtained from Williams–Hall plots reveal that the line broadening arises dominantly by size effects, this reveals that Scherrer formula can be applied [23,24].

Atomic force microscopy (AFM) studies of the deposited films were performed using a Digital Instruments Dimension 3100 in the tapping mode. The AFM characterization was performed on an area of 100 μm^2 with a SiC tip.

3. Results and discussion

In Table 1 the contact angle data of the non-illuminated and of the illuminated parts of the substrate are summa-rized. Due to the illumination of the substrate the contact angle of water decreases from 88 ± 1° to 83 ± 3° while the contact angle of diiodomethane increases from 34 ± 1° to 43 ± 2° demonstrating that the surface becomes more hydrophilic. The overall surface tension decreases slightly upon illumination, due to a large decrease of the dispersive component. However, the polar component becomes higher, leading to an increase of the surface polarity from 2.3% to 6.5%.

Using AFM in tapping mode, a detailed surface morphology analysis of the sample series was performed. The influence of the polymer substrate on the surface properties of the grown PSP is analysed depending on substrate temperature, deposition time and UV-illumination of the substrate before deposition of PSP.

Fig. 4 depicts a chart with the AFM images (100 μm^2) of films grown at 85 °C, 100 °C, 130 °C and 160 °C varying the deposition time from 5 to 20 and 60 min. The height scale (z_0) is presented at the bottom of each image. The morphology of the PSP film grown on the UV-illuminated side and on the as prepared surface are shown on the right and left side of each image, respectively. A clear morphological difference between non-illuminated and UV-illuminated regions can be observed. While on the non-illuminated side a more homogeneous PSP film is formed, UV-irradiation of the substrate prior to HWE leads to island formation. This can be clearly deduced in the height distribution from the AFM scans. The UV-treated side always shows two peaks in the height histogram, while the as prepared parts give only one. That means that the AFM tip reached the substrate in the first case between the islands, which does not occur for as prepared samples. This effect in the surface morphology can be attributed to the increase in surface polarity of the substrate, resulting from the photochemical reaction of PPNB, due to the fact that the preparation conditions of the sample where identical and the only change was the UV treatment.

Increasing the deposition time of PSP from 5 to 60 min is leading to a lateral expansion of the single islands. In the same way, an increase in size of the observed structures results from an increase of the substrate temperature. In Fig. 5 more detailed AFM images of the two regions of the sample grown at 160 °C for 20 min (Fig. 4-IVb) are pre-
Fig. 3. Description of the sample preparation.

Table 1

Contact angle (sessile drop) of PPNB before and after UV-illumination, calculated values of the surface tension γ using the Owens–Wendt method as well as the dispersive and polar components (γ^D and γ^P) and the surface polarity [21]. The surface polarity is expressed as ratio $\gamma^P/\gamma \times 100$.

PPNB	θ H$_2$O (°)	θ CH$_2$I$_2$ (°)	γ (mJ^{-2})	γ^D (mJ^{-2})	γ^P (mJ^{-2})	Surface polarity (%)
Pristine	88 ± 1	34 ± 1	43.4	42.4	1.0	2.3(0.2)
UV-illumination[a]	83 ± 3	43 ± 2	40.6	38.0	2.7	6.5(0.3)

[a] λ = 254 nm, illumination time 20 min, power density 1.4 mW cm^{-2}.

sented. On the one hand, on the non-illuminated part (Fig. 5a, Fig. 4-IVb left) we can observe a closed film with growth spirals, which are characteristic for screw dislocations [25,26]. On the other hand, in the UV-illuminated side (Fig. 5c, Fig. 4-IVb right), crystallites with terraces of up to hundreds of nanometres in length can be observed. A substrate temperature of 160 °C seems to be the optimal growth parameter to observe such differences in morphological features. Fig. 5b and d shows the scan profiles indicated in Fig. 5a and c as black solid lines. The step heights of the observed features are in good agreement with the expected thickness of one mono-layer of standing PSP molecules corresponding to 2.6 nm. Similar results are found for other small organic molecules grown on different sub-

strates [27]. The resulting surface morphology and the observation of step heights corresponding to standing PSP molecules gives a clear hint that the PSP layers have a high degree of crystallographic order. Moreover, it is demonstrated that it is possible to influence the crystal morphology of PSP via a pre-treatment of the substrate by illumination.

In order to deduce additional information concerning the crystal structure of the samples detailed X-ray studies were performed, taking as a motivation the results obtained form the morphology studies. The thicker samples, grown at substrate temperatures between 85 °C and 160 °C (60 min of deposition time) were selected for diffraction experiments to ensure a higher intensity.
Fig. 4. Atomic force microscopy images of para-sexiphenyl on PPNB pre-treated with UV-light (right side of each image) and as prepared (left side) for different substrate temperatures and different deposition times.
Fig. 5. AFM images and scan profiles along the indicated dark lines of the PSP crystallites deposited on the as prepared (a and b) and UV-illuminated (c and d) PPNB surface.
Fig. 6. Specular X-ray diffraction of PSP films grown on the as prepared surface (a) and on the UV-illuminated surface (b). The substrate temperature during the thin film growth was varied between 85 °C and 160 °C. The curves are vertically shifted for clarity.

The specular scans of the PSP films, deposited on the as prepared surface and on the UV-illuminated surface, are depicted in Fig. 6a and b, respectively. The film grown at a substrate temperature of 160 °C (Fig. 6a) shows a diffraction peak series, arising from an interplanar distance of 2.6 nm. Please note that the 6th order reflection observed at $q_z = 14.51 \text{ nm}^{-1}$ shows enhanced intensity. The peak positions in the specular scan together with the indexed diffraction pattern of the reciprocal space map obtained by GIXD (not shown), reveal that the present crystal structure can be identified as the well-known "Baker" structure [28]. This crystal structure is a layered herringbone structure with lattice constants of $a = 0.8091$ nm, $b = 0.5565$ nm, $c = 2.6241$ nm and $\beta = 98.17°$. The reflections of the specular scan can be indexed as 00L arising from the crystallographic 001 plane parallel to the PPNB substrate. This plane with the herringbone structure has the lowest surface energy of the Baker structure [29]. In a real space picture the orientation of the molecules within the PSP crystals appears with up-right standing molecules with the long molecular axes tilted 17° to the surface normal.

At a substrate temperature of 115 °C, a considerable shift of the 00L reflections appears (Fig. 6a), which is most clearly visible at the 002 reflection at $q_z = 4.61 \text{ nm}^{-1}$. A change in the crystal structure can be concluded. The new crystal structure can be assigned to the γ-phase of PSP. This polymorph phase is also a layered herringbone structure [30]. In difference to the "Baker" structure, the long molecular axes of the PSP molecules are oriented perpendicular to the surface normal. The GIXD pattern allow an indexation of the γ-phase with lattice constants of $a = 0.776$ nm, $b = 0.558$ nm, $c = 2.85$ nm and $\beta = 106.3°$. The GIXD investigations of these samples confirm the simultaneous appearance of Baker and γ-phase for PSP crystals grown on the as prepared surface, however only the γ-phase was found at the UV-illuminated substrate.

The overall intensity of the 00L diffraction peaks decreases with decreasing substrate temperature. In case of the films prepared on the as prepared surface (Fig. 6a) strong diffraction peaks are observed for layers grown at a substrate temperature of 160 °C, but no clear peaks are present for layers grown at 85 °C. This decrease of intensity is even more pronounced for films grown on the UV-treated surface (Fig. 6 b). This fact is clearly related to the mosaicity of the PSP layers: at lower substrate temperatures the 001 planes of PSP crystallites are much weaker oriented, than at high substrate temperatures. This fact is experimentally observed in the GIXD pattern where the thin films grown at 160 °C show comparable sharp diffraction spots as it is expected for a two-dimensional powder. The films grown at 115 °C show segments of circles (onset of Debye–Scherrer rings), which reveal a much higher mosaicity of the PSP crystals. The different mosaicity is also reflected in the different intensity of the 00L diffraction peaks between films grown on the as prepared and the UV-illuminated surface (compare Fig. 6a and 6b).

The vertical crystal size was determined from specular scans. Reliable values could be obtained only for the thin films grown at a substrate temperature of 160 °C. The small intensities of the 00L peaks for layers grown at lower

substrate temperatures, did not allow a crystal size determination. The PSP crystallites grown on the as prepared and on the UV-illuminated surface show a vertical crystal size of 70 nm and 60 nm, respectively.

Specific results of GIXD measurements are shown in Fig. 7. The figure shows the scattered intensity as a function of q_{xy} obtained from cuts through the reciprocal space maps at $q_z = 1.5 \, nm^{-1}$. The strongest diffraction peaks of both PSP crystal structures (Baker as well as γ – structure) are visible. The lateral crystal size was determined from the peak widths. At a substrate temperature of 160 °C (Fig. 7a) the lateral crystal size was estimated with 40 nm which is comparable for films on both types of substrates. At a substrate temperature of 115 °C, a lateral crystal sizes of 40 nm and 20 nm is obtained for films grown on as prepared and UV-treated substrates, respectively. The lateral crystal size is not in the same range as the island size observed in AFM images, which means that the islands can contain grain boundaries, not observable by AFM.

The strongly preferred orientation of PSP crystallites with the 001 plane parallel to the substrate surface is known for isotropic surfaces such as glass or native oxide single crystal surfaces [31,32]. It is reported that the crystal orientation becomes more pronounced with increasing substrate temperature [33]. This tendency is also clearly seen on the PPNB substrate. This results from the fact that the PSP molecules become more mobile on the surface and are thereby able to arrange in larger crystallites. An additional contribution to this effect may stem from the fact that PPNB has a glass transition temperature (T_g) of 96 °C. While below T_g the PPNB polymer is in a glassy state, at temperatures above T_g molecular motion on the scale of its repeating unit takes place. Therefore, the substrate can adapt its surface with the 001 facet of PSP crystals which have a lateral extension of 40 nm. With increasing sub-

strate temperature the softness of the substrate increases which causes that the PPNB thin film becomes more homogenous while the impinging PSP molecules become more mobile on the surface resulting in a better alignment of the 001 planes of PSP crystallites relative to the substrate.

Recently, Kim et al. reported that depositing pentacene on polymeric substrates below T_g results in better quality thin films than when the deposition temperature is above the glass transition temperature of the substrate [34]. At first glance these findings seem to follow the opposite trend of our observations. However, the temperature range investigated in Ref. [34] ended shortly above the glass transition and no data on higher temperatures are given. In our study, the samples around the glass transition temperature also exhibit a low order (samples prepared at 85 °C and 115 °C) compared to the samples prepared at higher substrate temperature (samples prepared at 130 °C and 160 °C). In these samples, the effect that at higher substrate temperatures higher quality films are obtained [33], seems to be predominant.

As already discussed the size of the PSP crystals is slightly smaller in the films grown on the UV-treated substrates than on the as prepared ones, 20 and 40 nm for the lateral crystal size (detected at $T_s = 115 \, °C$) and 60 and 70 nm for the vertical crystal size (detected at $T_s = 160 \, °C$). This fact correlates with AFM results which detects smaller lateral as well as vertical dimensions of the islands on the UV-treated surface. Moreover, the PSP thin film morphology shows a clear difference between the as prepared and the UV-treated surface. Elongated islands are observed at the UV-treated surface, especially at high substrate temperatures, while the typical island morphology of sexiphenyl is observed on the as prepared surface [32,35]. Different mechanisms of crystal formation, like spiral growth caused by screw dislocations at the as prepared surface, can be suggested. This can be correlated to the different surface polarity of the illuminated side of the substrate compared to the non-illuminated side. It is obvious that on the pristine surface (which contains ester groups and is non-polar) the interaction between the PSP and the polymer is enhanced. However, on the illuminated side, these ester groups are photochemically converted into hydroxyketones which results in a more polar surface. Higher polarity disturbs the favourable interaction between PSP and the substrate, and consequently more island formation during the growth process is observed.

No clear conclusion can be made for the observed polymorphism. The γ-phase can be classified as a surface mediated polymorph of sexiphenyl [30,36], as it is also known for other rod-like conjugated molecules like pentacene or sexithiophene. These phases are observed on silicon oxide surfaces at elevated substrate temperatures [33,37,38]. The appearance of the γ-phase of sexiphenyl on the polymeric substrate in a temperature range close to the glass transition temperature of the substrate layer can be induced by the smooth but not too flexible surface of the polymer, favouring the formation of a surface mediated polymorph structure at lower substrate temperatures.
Fig. 7. Line scans of the grazing incidence X-ray diffraction pattern taken at $q_z = 1.5 \, nm^{-1}$. The results of the thin films grown at a substrate temperature of 160 °C (a) and of the 115 °C (b) are depicted for the non-illuminated and the UV-treated polymer surface.

4. Conclusions

Para-sexiphenyl films were successfully deposited on PPNB at different temperatures and deposition times. Careful AFM investigations demonstrate that PSP shows different growth morphology when deposited on UV-illuminated and as prepared PPNB substrates. Features such as terraces or screw dislocations with step heights corresponding to standing PSP molecules highlight the high order of the layers.

The lateral and vertical sizes of the PSP crystallites were estimated from the specular scans and line scans of the GIXD measurements. For the samples grown at $T_s = 160\ °C$ lateral and vertical crystal sizes of up to 40 and 70 nm were obtained, respectively. While for the samples grown at 115 °C values of 20 nm and 40 nm for the lateral size of the as prepared and UV-treated substrates were respectively evaluated. The grown films show a strong 001 orientation with a better alignment on the as prepared than on the UV-treated substrate. It is also shown that at lower T_s the 001 planes of PSP crystallites are much weaker oriented relative to the surface than at high T_s. It is suggested that the strong preferred orientation of PSP crystallites with the 001 plane parallel to the substrate surface is related to the fact that the impinging PSP molecules become more mobile on the surface and is due to the effects caused by depositing at temperatures above the glass transition temperature of PPNB ($T_g = 96\ °C$). The specular scans together with the indexed diffraction pattern of the reciprocal space maps obtained by GIXD reveal the presence of two different crystal structures of PSP. The formation of Baker structure only was observed if elevated substrate temperatures were used ($T_s \geqslant 130\ °C$) and the simultaneous appearance of Baker and γ-phase was obtain when using low substrate temperatures.
We have shown that a change in polarity of amorphous polymer films of PPNB does significantly influence the growth of PSP films prepared by HWE. The polarity change of the polymer film was generated by a photochemical reaction, the photo-Fries rearrangement of the aryl-ester units. In this reaction, the phenyl ester groups of PPNB undergo upon irradiation with UV-light a rearrangement reaction to the corresponding hydroxyketones which leads to an increase in surface polarity. Consequently, it is clearly demonstrated, that the growth on PSP can be modified by a simple and easily reproducible pre-treatment of the substrate surface and by the deposition conditions. This procedure can potentially control the optical and electrical properties of the films deposited on the different parts of the substrate thus opening new perspectives for the fabrication of devices by using the UV treatment of the substrates as pre-structuring process.

ARTICLE INFO

ABSTRACT

The presence of impurities in organic semiconductors is an important limitation for the performance of related devices. Here, we investigate with density-functional theory calculations the effect of water and oxygen-related species on the properties of the prototype system of rubrene, the current record-holder organic semiconductor in terms of carrier mobilities. We identify the most stable impurity structures, with species in either substitutional or interstitial configurations, and we analyze their complex role in changing the shape and profile of rubrene energy bands. In certain cases the impurities either give rise or help annihilate carrier traps, and we discuss the relevance of our findings for the optimization of rubrene-based electronic systems.

The absence of inter-molecular covalent bonding in organic semiconductors carries significant advantages such as flexibility and versatility of film growth, but it also relates to increased likelihood for impurity insertion. An understanding of the atomic-scale mechanisms that control the presence of extrinsic species and their effect on the properties of organic electronic materials is, therefore, essential for the optimization of related devices. The issue is even more pressing for materials like rubrene which has attracted a lot of interest recently [1–11] because its films show carrier mobilities that surpass those of any other organic semiconductor.

Rubrene is an oligoacene derivative which is formed by four phenyl rings linked (Fig. 1) on the side of a tetracene back-bone (TBB). In the crystalline orthorhombic form [12,13], large portions of the TBBs of neighboring molecules face off in parallel, while other parts of the crystal contain more open space. Impurities may be incorporated in either region and, indeed, experimental studies [14–18] have already reported oxygen-related effects on the electronic properties of rubrene samples. In addition to oxygen, water and hydrogen are known as key impurities in conventional Si-based devices [19–22], but also in organic electronic materials, for example in pentacene [23–27]. It can thus be expected that these species play an important role also in rubrene-based systems.

In this article, we use quantum-mechanical first-principles calculations to elucidate several prominent impurity effects in rubrene crystals. In particular, we examine

oxygen impurities in ketone configurations, with or without hydrogen atoms attached, and we find that they can lead to distinct peaks formed out of the valence band of rubrene. We also find that it is energetically favorable for water molecules to enter rubrene crystals and that they can either appear in physisorbed configurations between phenyl groups, or they can dissociate to H atoms and hydroxyl groups attached on the TBB. An isolated hydroxyl group is shown to give rise to energy levels deep in the band gap of rubrene, an effect that is ameliorated upon the arrival of a H impurity.

The results were obtained using density-functional theory (DFT) calculations, with a local-density approximation (LDA) exchange-correlation (xc) functional [28],

plane waves as a basis set (the energy cutoff was set at 400 eV) and ultrasoft pseudopotentials to represent the ionic cores [29], as implemented in the code VASP [30]. As in a previous study that discussed the effect of hydrogen and interstitial oxygen atoms in rubrene [31], the energetics of impurity incorporation were studied with supercells that contain four molecules and which were constructed based on the experimental data for the unit cell [13] of rubrene. $2 \times 2 \times 2$ k-grids and the Monkhorst-Pack method for Brillouin zone sampling [32] were employed for total energy calculations, whereas to obtain the electronic density of states (DOS) we used larger $6 \times 6 \times 6$ k-meshes and the tetrahedron sampling method [33].
Fig. 1. Amplitude of the highest occupied (HOMO), lowest unoccupied (LUMO), and HOMO-1 orbitals of rubrene.

Fig. 2. Chemical structure and amplitude of the HOMO and LUMO for ketone impurities in a rubrene molecule. The arrows show the positions of the O atom that replaces a H atom in the defective molecule.

We start with results on substitutional oxygen impurities in rubrene crystals. We first consider an O impurity that replaces a H atom in a rubrene molecule and forms a ketone group with a double bond to the corresponding C atom. The most stable ketone configurations are shown in Fig. 2. Other defects with the C=O bond at different C sites have energies higher by 0.2–0.3 eV. If we assume that H and O atoms are exchanged with H_2 and O_2 molecules, respectively, then the formation of the ketone defect of Fig. 2b is an exothermic reaction with an energy gain of 0.73 eV.

In Fig. 2, we show the amplitudes of the highest occupied molecular orbitals (HOMO) and the lowest unoccupied molecular orbitals (LUMO) of rubrene molecules with ketone substitutional groups on their TBB's. For comparison, the HOMO, the HOMO-1, and the LUMO of a defect-free molecule are included in Fig. 1. The figures clearly show that the defects change the frontier orbitals considerably. This effect is more pronounced for the HOMO of Fig. 2b, where a substantial decrease in the weight of the wavefunction is noticed for the parts of the molecule away from the impurity.

The plots of frontier orbitals that are included in Fig. 1 and DFT results [34] on the projected density of states of rubrene demonstrate that the tetracene units have a dominant role in the formation of the valence and conduction bands of this organic semiconductor. As a result, any orbital changes similar to the ones depicted in Fig. 2 that disrupt the TBB stacking and the respective intermolecular electronic coupling are bound to have a considerable effect on the electronic properties of the crystal. Indeed, in comparison to the electronic density of states of defect-free rubrene, the DOS plots of Fig. 3 for 4-molecule supercells with isolated ketone groups show that the valence and conduction bands of the defective crystal split up and change their relative positions.

An especially important effect is noted for the ketone configuration of Fig. 2a: a distinct peak appears in the DOS and its distance of about 0.22 eV to the bands below is very close to the experimental value [15,16] of 0.25 eV for O-related carrier traps in rubrene. We should note that, the well known DFT band gap problem results in the theoretical underestimation of the energy separation between the HOMO and LUMO states, and introduces an uncertainty about the absolute position of defect levels. An approach like *GW* (wherein the electronic self-energy is given by the Green's funtion *G* and the screened interaction *W*) can enhance the accuracy of the calculated values, but its use for large supercells requires excessive computational power. In fact, though DFT results on impurity energy levels lack in absolute accuracy, they are normally reliable in predicting the nature of impurity effects and, in particular, whether defects introduce deep or shallow levels in a semiconductor band gap.

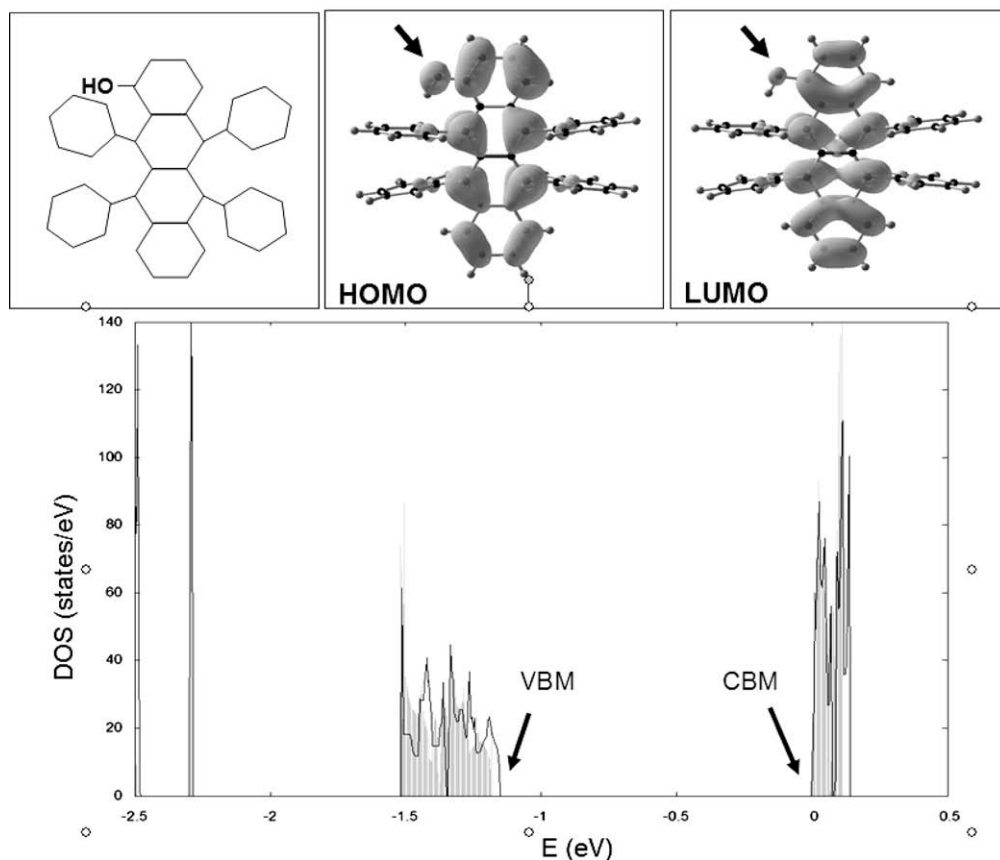
As noted above, hydrogen is a typical impurity in many types of systems [22,20]. In its most stable configuration in rubrene [31] hydrogen is attached to the C atom that links the TBB to a phenyl group. The interaction of this H-structure with a ketone-containing molecule can lead to the formation of the hydroxyl group depicted in Fig. 4, an exothermic process that releases 1.6 eV of energy. The differences between the HOMO's and LUMO's of rubrene
Fig. 3. Effect of ketone impurities on the electronic density of states (DOS) of a rubrene crystal. Dark (black) and light (green) lines for one defective rubrene molecule of the type of Fig. 2a and c, respectively, per 4 rubrene molecules in the crystal. The DOS for defect-free rubrene is shown with light impulses. The arrow shows the conduction band minimum (CBM). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)


Fig. 4. Chemical structure and amplitude of the HOMO and LUMO for passivated ketone impurities (shown with arrows) in a rubrene molecule (upper part) and effect on the electronic DOS (lower part). molecules with substitutional hydroxyl and those of defect-free rubrene molecules are much less pronounced compared to the case of ketone impurities. As a result, the effect of OH species on the electronic DOS of a rubrene crystal is also less pronounced. For example, the passivation of the ketone of Fig. 2a with a H atom results in a more compact form for the electronic DOS (Fig. 4) in the range of the valence band and the 0.2 eV peak of Fig. 3 disappears.

In addition to substitutional configurations, oxygen species may enter rubrene in interstitial structures, either as isolated atoms, or in pairs. The most stable configurations of extra O atoms are epoxy groups, wherein O atoms form triangles of bonds with two C atoms of the TBB of rubrene. The structural details of epoxy groups and their effect on the electronic properties of rubrene have been reported in Ref. [31]. In Fig. 5, we show a number of other configurations of a pair of O atoms in rubrene. They include variants of peroxy bridges, which have been suggested as likely oxidized rubrene configurations in previous studies [2,14], and non-dissociated O_2 molecules. All these structures are considerably less stable than the epoxy pairs since their energies are higher by at least 1.2 eV. We note that following the removal of one of the two O atoms in the configurations of Fig. 5a–c, the remaining O impurity relaxes to form bonds with two C atoms of rubrene, creating thus an isolated epoxy group.

We now turn our attention to the effect of water-related impurities in rubrene crystals. In Fig. 6a, we show the most stable configuration for a non-dissociated water molecule inside rubrene. The molecule physisorbs with a significant energy gain of 0.38 eV compared to an H_2O species in vacuum. It gets trapped in the space between two side phenyl groups of a rubrene molecule, with the two O–H bonds pointing to two different C atoms. The distances between the H atoms of water and the two C atoms of the phenyl moieties are approximately equal to 2 Å. In another physisorbed configuration, which is similar to Fig. 6a and has an energy gain of 0.30 eV compared to vacuum, only one of the water O–H bonds points to a phenyl group, while the other O–H bond is directed to the space between neighboring molecules. When one of the O–H bonds points to the end of a TBB and the other to a neighboring molecule the energy gain for H_2O insertion drops to 0.23 eV.

In addition to physisorbed configurations of non-dissociated H_2O molecules in a rubrene crystal, we found stable impurity structures that can be viewed as the result of the breakup of water species. One such configuration is shown in Fig. 6b; it comprises a hydroxyl group and a hydrogen impurity that are both attached on the same rubrene molecule and the C sites that link the TBB to phenyl groups. This chemisorbed structure is, in fact, more stable than
Fig. 5. Metastable configurations with oxygen impurities in endoperoxide or molecular configurations in rubrene. The energies of these configurations are at least 1.2 eV higher in energy than the epoxy pairs discussed in Ref. [31] [C: gray, O: dark gray (red), H: white spheres]. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
Fig. 6. Water-related impurities in a rubrene crystal: (a) a physisorbed water molecule, (b) vicinal OH and H impurities after dissociation of H_2O, and (c) chemical structure of (b). Only the defective molecule is shown for clarity. The energy of (b) is lower than that of (a) by 0.2 eV [C: gray, O: dark gray (red), H: white spheres]. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

the physisorbed configurations of the type of Fig. 6a by at least 0.2 eV of energy.

As might be expected, the physisorption of an H_2O molecule in the configuration of Fig. 6a has a minimal effect on the electronic DOS of rubrene. The corresponding DOS curve is depicted in Fig. 7. The dissociation of an H_2O species, on the other hand, in the structure of Fig. 6b has a more discernible effect; it splits the valence band in two parts, and it introduces an isolated peak between this band and the one below it. Overall, the effect of attaching the OH
Fig. 7. Effect of water-related impurities on the electronic DOS of a rubrene crystal. The arrows show the valence band maximum (VBM) and the conduction band minimum (CBM). The DOS for defect-free rubrene is shown with light impulses. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

and H species at C sites between a rubrene TBB and the side phenyl groups is similar to the corresponding change [31] in the DOS in the case of a configuration with two H atoms at the same positions.

A water-related impurity that introduces a more pronounced change in the DOS is an isolated hydroxyl group attached at the OH position of Fig. 6b. As shown in Fig. 8, the introduction of an OH species on a rubrene molecule breaks the symmetry of the impurity-free HOMO and LUMO. For this reason, it can be expected that this defect gives rise to changes in the DOS away from the bands of pristine rubrene. This qualitative argument is validated by the results of Fig. 8 for the DOS of the cell with an OH impurity, which show that the isolated hydroxyl species introduces a level that lies deep in energy band gap of rubrene, almost at the midgap position.

The attachment of a H atom on the molecule of Fig. 8 leads to the formation of the structure of Fig. 6b and an energy gain of 1.6 eV. In other words, the dissociation of the latter H–OH complex to H and OH species in rubrene carries an energy penalty of 1.6 eV. The role of H in the formation of the H–OH group is similar to its role in the creation of stable H–H complexes [31] in rubrene. In fact, the similarity extends as well to the effect of H on the electronic properties of rubrene: whereas isolated H and OH species introduce states deep in the energy band gap, H–OH complexes and H–H pairs lack such deep levels. Hydrogen has, therefore, a dual role in creating and annihilating carrier traps in rubrene.

The incorporation of impurities and, especially, the formation of levels in their energy band gap is fundamentally important in semiconductor physics. For example, oxygen species have been identified as acceptor states in rubrene [15] and impurities control the behavior of pentacene-based transistors under bias stress [35] and photo-oxidation [36]. Impurities like ketone groups may be incorporated in a rubrene molecule during synthesis, while other defects like water species may enter a rubrene crystal during growth or operation of rubrene-based devices. In addition, the pronounced effects of impurities on the shape and position of the valence and conduction bands of rubrene may provide mechanisms [31] for effective defect engineering in this prototype organic semiconductor. Finally, another possible role for impurities in rubrene that can be explored in the future relates to mechanisms of selective adsorption and of nucleation similar to the ones that have been suggested [37,38] or observed [39] for pentacene growth on substrates.

In summary, we examined the stability of water and oxygen-related impurities in rubrene and we showed that they have pronounced effects on the electronic properties of the host crystal, including the possibility of formation or annihilation of carrier traps. It is energetically favorable for water molecules to enter this system in either physisorbed or chemisorbed configurations, and ketone or hydroxyl groups create shallow and deep levels in the energy band gap of rubrene.

ARTICLE INFO

ABSTRACT

A stable self nano-aggregated bathocuproine film was fabricated and introduced atop of a conventional organic light emitting diode for enhancing top emission. It leads to a 2.7–2.1-fold enhancement on top emission at applied voltage from 4 to 9 V which is much larger than the 1.5–1.3-fold enhancement for a device overlaid with an amorphous bathocuproine film. The more effective outcoupling of this method probably arises from surface plasmon modes being scattered by only the nanostructured surface, and thus without phase cancellation, at the bathocuproine/air boundary. Moreover, this method nearly preserves the original electroluminescent spectra and has no damage on electrical properties.

1. Introduction

Organic light-emitting diodes (OLEDs), typical structures of which consists of an anode, organic materials and a metallic cathode, have been attracting considerable attention because of their application to flat-panel displays. One problem that occurs though is that a large fraction of the power generated by excitons within the organic emissive layer is lost to surface plasmon (SP) modes, which are surface free electron density oscillations confined to the metallic electrode/organic layer interface and can not radiate out due to its larger wave vector than that of a freely propagating photon. Calculations have shown that as much as 40% of the light produced in a typical OLED based on small molecules may be lost via this decay route [1], and an even more significant SP loss for top electrolu-

minescence (EL) devices [2], that are practical and suitable for high-resolution active matrix displays; while the emitted light extraction efficiency is limited to be as low as ∼20% [3–5]. Therefore, many fabrication methods, such as the incorporation of appropriate sub-wavelength scale periodic corrugations fabricated by holographic techniques [6], solvent assisted micromolding [7] and nanoimprint lithography [8,9], have been employed to outcouple SP modes to improve light extraction. For top EL devices in particular, the recovery of significant SP loss has been anticipated to be a desirable and powerful way to enhance light output [10]. In this work, a nano-aggregated bathocuproine (BCP) film has been layered in a simple manner on top of an Ag cathode of a conventional OLED based on tris-8-hydroxyquinoline aluminum (Alq_3) to enhance top emission. This method avoids currently costly and complex fabrication processes and more importantly does not damage the electrical properties of the device. Its top emission intensity increases by a factor of 2.7–2.1 compared with that of the equivalent device without such a nanostruc-

tured layer, while a similar device capped with an amorphous BCP layer exhibits 1.5–1.3 times enhancement. The experimental data emphasize the excellent outcoupling capability of a nano-aggregated BCP film on a single side of an Ag cathode, an arrangement ensuring no phase cancellation when scattering SP modes. Furthermore, this method does not modify the original EL spectra because of nonperiodic BCP nanostructures. All these properties are desirable for application in OLED displays.

2. Experimental

2.1. Nano-aggregated BCP layer formation

A 50 nm thick Ag film was deposited on a quartz substrate by vacuum evaporation, and then an 80 nm layer of BCP was deposited on Ag/quartz; meanwhile a sample of BCP (80 nm)/quartz was fabricated for comparison. The two samples were kept in vacuum at room temperature for 24 h, and then a stable self nano-aggregated BCP films were obtained. The top surface morphography of all the samples were measured by atomic force microscopy (AFM), as shown in Fig. 1.

2.2. Photoluminescence (PL) and lifetime measurements

To properly apply a nano-aggregated BCP film to an EL device, we first need to investigate the formation mechanism of such nanostructures and the SP resonance supported by these nanostructures. The relevant experiments are outlined as follows. The PL spectra of amorphous BCP film on quartz and nano-aggregated BCP films on both quartz and Ag film were recorded by a Hitachi F2500 fluorescence spectrophotometer in air at room temperature with ~15% relative humidity (RH). The fluorescence decay dynamics for nano-aggregated BCP films on quartz and on Ag film were studied at 383 nm (monomer emission) and 492 nm (excimer emission). The samples were excited by a femtosecond laser and then the fluorescence was recorded by a Hamamatsu streak camera system synchronized with laser repetition rate. For the above samples, intensity decays at 524 nm, viz. the wavelength of PL enhancement maximum, were investigated by an FL920 fluorometer. All the lifetime data were attained by using deconvolution methods with exponential functions.

2.3. EL device fabrication and characterization

Such a nano-aggregated BCP film was introduced onto an EL device with the aim to improve top emission. The device, composed of glass/180 nm indium tin oxide (ITO) anode/40 nm 4,4-bis[N-(1-naphthyl)-N-phenylamino] biphenyl (NPB) hole transport layer/40 nm tris-8-hydroxyquinoline aluminum (Alq$_3$) emitting layer/2 nm Ca for enhancing electron injection/28 nm Ag metallic cathode, was fabricated by vacuum deposition without thickness optimization. The active device region was confined to a 12.56 mm^2 area by a shadow mask during cathode evaporation. For comparison, half the area of the Ag cathode was covered by a 30 nm layer of BCP. The top EL properties of the device were measured immediately after vacuum evaporation, during which time the fresh BCP film was still amorphous. And the top EL properties were measured again after the nano-aggregated structures were formed in BCP film by preserving in vacuum at room temperature. The current density–voltage-luminance and spectral characteristics were simultaneously recorded using a programmable array 3645A power supply and Photo research PR650 spectrophotometer. All measurements were carried out on an unencapsulated device in air with ~15% RH at room temperature.

3. Results and discussion

Fig. 1a shows the amorphous BCP film on a quartz substrate examined immediately after vacuum evaporation revealing a surface roughness of 1.2 nm. Surface roughness of 9.9, 9.6 and 0.6 nm are found, respectively, for nano-aggregated BCP film on quartz (Fig. 1b), for nano-aggregated BCP film on Ag film (Fig. 1d), and for Ag film on quartz (Fig. 1c). Nano-aggregated BCP films on quartz and on Ag film exhibit similar topography. As shown in Fig. 2, compared with the emission spectrum of an amorphous BCP film on quartz, which displays only the monomer band (~383 nm), the spectral profile of a nano-aggregated BCP film on quartz, exhibits a slight decrease in monomer emission with a concomitant emergence of an emission band (~492 nm). This emission (~492 nm) substantially increases in the PL spectrum of a nano-aggregated BCP film on Ag film. In general, many aromatic hydrocarbons are subject to excimer formation, a diffusion-controlled process; the corresponding fluorescence band has red shift relative to that of the monomer and does not show vibronic bands [11]. These features can be observed in the PL spectra of nano-aggregated BCP films, indicating that BCP molecules, which themselves contain aromatic groups, have probably formed excimers. To further verify the existence of these excimers, the fluorescence decay dynamics for nano-aggregated BCP films on quartz and on Ag film were analyzed. As shown in Fig. 3, the intensity decay at 492 nm exhibits rise-times of 186 and 167 ps for nano-aggregated BCP films on quartz and on Ag film, respectively, with negative exponential prefactors. These values are close to the lifetimes of 251 and 236 ps for nano-aggregated BCP films on quartz and on Ag film, respectively, associated with the fast monomer decay at 383 nm. Because fast monomer decay lifetimes correspond to rise-times indicative of excimer formation [12], the emission band (~492 nm) occurring in the PL spectra of nano-aggregated BCP films on both quartz and Ag film should originate from excimers. Based on the AFM results and excimer presence reflecting molecular diffusion, we can deduce the formation mechanism of this nano-aggregated BCP film as follows [13]. The vacuum evaporation produces a film in non-equilibrium, and thus molecules diffuse and agglomerate to minimize the total surface energy. Finally, the original film arrives at an equilibrium state, i.e., forming a stable nanostructured film.

To ascertain the range of wavelengths of the SP resonance supported by the nano-aggregated BCP film, the

Fig. 5. Current density–voltage characteristics of the device for the first measurement, viz. before BCP aggregation (open triangle △), and for the second measurement, viz. after BCP aggregation (inverse open triangle ▽). Top emission luminescence-voltage characteristics for both measurements, and the corresponding EL spectra at 8.4 V (shown in the inset). For the first measurement: top emission from amorphous BCP film (solid square ■) and from Ag cathode (open square □); for the second measurement: top emission from nano-aggregated BCP film (solid circle ●) and from Ag cathode (open circle ○).

A). The PL intensity increases over a broad range of green emission wavelengths and the PL enhancement ratio reaches a maximum (~6.5 times) at 524 nm. We also calculated the PL enhancement ratio resulting from the reflection and interference of exciting light, as well as that of fluorescence, arising from the presence of Ag film, as shown in the inset of Fig. 4 (curve B). Those small values (~2 times) can not explain the larger experimental enhancement, which indicates the existence of another PL enhancement mechanism. Meanwhile, the intensity decays at 524 nm in Fig. 4 show both a reduced mean time (τ_{mean} = 5.3 ns) and an amplitude-weighted lifetime ($_<\tau_>$ = 3.8 ns) for a nano-aggregated BCP film on Ag film as compared with a quartz control sample (τ_{mean} = 14.6 ns, $_<\tau_>$ = 7.0 ns). The increased fluorescence, accompanied by the decreased lifetime in the presence of flat Ag film overlaid with a nanostructured layer, can be attributed to the resonant coupling of spontaneous emission into SPs, which can compete with nonradiative decays and can be scattered out to the far field by nanostructures, thus enhancing the output of light [14–18].

Accordingly, we introduced such a nano-aggregated BCP film onto a typical OLED based on the green emitter, Alq₃, to improve top emission. As shown in Fig. 5, the curves of current density–voltage and top emission luminance-voltage from the bare Ag cathode for the device, both before and after BCP aggregation, are nearly identical for both measurements, indicating almost no degradation of electrical properties occurring. The inset of Fig. 5 depicts the EL spectrum at 8.4 V for both measurements. The top emission spectral shape from the nano-aggregated BCP film, the amorphous BCP film and the bare Ag cathode are almost the same. This result can be expected from non-periodic nanostructures and is favorable for OLEDs applications.

A previous report has demonstrated that a capping layer can enhance the light output in top-emitting OLEDs

due to the reduction of an Ag cathode reflection [19]. As shown in Fig. 6, a similar phenomenon is observed in that the top EL intensity from the amorphous BCP film increases by a factor of 1.5–1.3 compared with that from the bare Ag cathode, while the top EL intensity from the nano-aggregated BCP film exhibits a 2.7–2.1-fold enhancement over applied voltage range of 4–9 V. To compare outcoupling capabilities, the outcoupling enhancement factor g is defined as: $g = \frac{(E_{nanostructured} - E_{amorphous})}{E_{amorphous}} \times 100\%$, where $E_{nanostructured}$ and $E_{amorphous}$ are top EL enhancements from nano-aggregated and amorphous BCP films, respectively. The calculated outcoupling enhancement factors demonstrate that the outcoupling capability of the nano-aggregated BCP film is ~60% higher than that of the amorphous film. Because the absorption band of the nano-aggregated BCP
Fig. 6. Top EL enhancement for ITO/NPB/Alq₃/Ca/Ag/with amorphous (square) and nano-aggregated (circle) BCP film compared with ITO/NPB/Alq₃/Ca/Ag as a function of voltage. The inset shows a schematic drawing of the EL device as well as a photo of top emission from bare Ag cathode and from nano-aggregated BCP film for the second measurement.

film does not overlap the EL emission band of Alq$_3$, there is no PL from the overlaid nanostructured BCP layer to contribute to an enhanced light output. The improvement of the top emission from the nano-aggregated BCP film may be attributed to two factors [10,20,21]. First, the Ag cathode is thin enough to allow the fields of the SP modes associated with each metal interface to overlap. Organic materials with similar refractive indices on both sides of the Ag cathode enable those SP modes to interact due to wave vector matching of each SP mode, thus allowing the energy to transfer across the metal. Second, a pathway opens to recover energy in the SP modes as free light. In symmetric nanostructures used in previous studies, SP modes may be scattered by either metal surfaces of the cathode and light mediated via these two routes are out of phase [22], decreasing the strength of emission. In this work, the single nanostructured surface on one side of the Ag cathode ensures the absence of phase cancellation, thus supporting the more effective scattering of SP modes into free radiation. In general, the recovery of the trapped energy from the SPs relies on suitable surface corrugation. It has been reported that a surface depth modulation of approximately 30–40 nm can efficiently scatter SPs as light [23], and even the surface roughness on the order of 7–10 nm can scatter SPs [24]. Therefore, we believe that the nano-aggregated BCP film with a depth modulation of about 30–40 nm can offer similar recovery.

4. Conclusion

Nano-aggregated BCP film, which is easily obtained, has been incorporated into a typical OLED based on Alq$_3$ and has been found to increase top emission by a factor of 2.7–2.1, compared with a typical OLED overlaid with amorphous BCP film, which exhibited only an enhancement of 1.5–1.3 times in top emission. Thus the outcoupling capability of the nano-aggregated BCP film is ~60% higher than that of the amorphous film. Moreover, this non-periodic nanostructured layer has proved beneficial in preserving the EL spectrum of the light emitting device, and its introduction won't have damage on current injection. All these properties are favorable in OLED applications.

ARTICLE INFO

ABSTRACT

Polar polymers (polyfluorene copolymers, PFN–PBT) with different polarities are utilized to modify the surface of tantalum pentoxide (Ta_2O_5) insulator in *n*-channel organic thin-film transistors (OTFTs). A high mobility of 0.55 cm^2/Vs, high on/off current ratio of 1.7×10^5, and low threshold voltage of 2.8 V are attained for the OTFT with the modification polymers, the performances of which are much better than those of OTFT with only Ta_2O_5 insulator. The performances of the OTFT with only Ta_2O_5 insulator are only 0.006 cm^2/Vs in mobility, 5×10^3 in on/off ratio, and 12.5 V in threshold voltage. Furthermore, it is found that the threshold voltage of the OTFTs with PFN–PBT modification layer is easily tuned by polarities of the polymers. Further studies show that self-assembly dipole moments in the polymers play an important role in the improvement of the OTFT performances.

1. Introduction

In recent years, organic thin-film transistors (OTFTs) have received more and more attention due to their potential applications in low-cost and flexible electronics such as organic light-emitting diodes (OLEDs) and organic complementary circuits [1,2]. The performances of *p*-channel (hole transporting) OTFTs based on pentacene can be comparable to those of amorphous silicon transistors [3]. However, the performances of *n*-channel (electron transporting) OTFTs are not as good as those of *p*-channel OTFTs. So to improve *n*-channel OTFTs performances is urgent for many applications, such as in complementary circuit.

To date, most of *n*-channel OTFTs are based on low dielectric-constant materials (e.g., SiO_2 [4,5] or insulating polymers [6,7]) as the gate insulators, which may lead to high operating voltage or high threshold voltage. There-fore, to reduce the operating voltage or threshold voltage is an important issue in investigation of OTFTs. Tantalum pentoxide (Ta_2O_5) is one of the most promising materials for gate insulators due to its high dielectric-constant (ε_r = 20–35) [8–12] which would result in low operating voltage or low threshold voltage in OTFTs. However, the Ta_2O_5 insulator has the problem of seriously trapping electrons at the interface between Ta_2O_5 and *n*-type active semiconductors [13], which may cause low electron mobility and poor electrical stabilities in *n*-channel OTFTs.

In this work, we use polar polymers to modify the surface of Ta_2O_5 insulators, and achieve great improved performances in *n*-channel OTFTs.

2. Experimental

The polar polymers used as the modification layers are based on Poly[(9,9-bis(3′-((*N,N*-dimethyl)-*N*-ethylammonium)propyl)-2,7-fluorene)-alt-2,7-(9,9-dioctylfluorene)]

(PFN, Fig. 1a), which is widely utilized in polymer light-emitting diodes to improve electron injection from the cathode into emission polymers due to its strong molecule polarity [14,15]. Here, polar PFN and its copolymers (Fig. 1b) are firstly used to fabricate OTFTs.

The copolymers (PFN–PBT) (Fig. 1b) were synthesized in our lab from monomers of 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene (1), 2,7-dibromo-9,9-bis(3′-(N,N-dimethylamino)propyl)fluorene (2), and 4,7-bis(5-bromo-N-methylpyrrol-2-yl)-2,1,3-benzothiadiazole (3), processed by using Pd-catalyzed Suzuki coupling methods. The co-monomer feed ratios of 3 to 1 + 2 are 1:99 and 5:95 and the corresponding polymers are named PFN–PBT1 and PFN–PBT5, respectively. Higher feed ratio copolymers are poor soluble in methyl alcohol solvent. The active material is N,N′-didodecyl-3,4,9,10-perylene tetracarboxylic diimides (PTCDI, Fig. 1c), a typical n-type semiconductor [16].

The schematic structure of the OTFTs with top contact configuration is shown in Fig. 1d. A 600 nm thick tantalum (Ta) film was deposited on a cleaned glass substrate by a DC magnetron sputtering. The Ta_2O_5 insulator was prepared by anodizing Ta. The anodizing process was performed as follows: the glass substrate with a Ta layer was immersed in a 0.01 wt.% citric acid solution. Ta acts as the anode of the circuit and platinum electrode is the cathode. A constant current density of 0.2 mA/cm^2 was established at the beginning with increasing the voltage up to about 100 V. The current would experience an exponential decay process when the voltage keeps constant (100 V) during anodizing [8], and then Ta_2O_5 film with 200 nm thick was formed. The polymers of PFN, PFN–PBT1, and PFN–PBT5 were dissolved in methyl alcohol at the concentration of 5 mg/ml (a small amount of acetic acid was added in the methyl alcohol to improve the solubility). Then the solution was deposited, respectively, onto the Ta_2O_5 film by spin-coating to form a 40 nm-thick polymer film. The polymer films were naturally dried in N_2 atmosphere overnight at room temperature. PTCDI was thermally evaporated onto the polymer films with a thickness of 50 nm. The initial deposition rate was controlled between 0.01 and 0.05 nm/s to form a 10 nm thick film. Then the rate was increased to about 0.2 nm/s for another 40 nm, because the first 10 nm-thick PTCDI is a key issue in optimizing performances of OTFTs. Finally the Al source and drain electrodes with 80 nm thick were thermally deposited through a shadow mask onto the PTCDI film. The transistor channel length and width were 0.1 and 10 mm, respectively. The OTFT characterization was performed in N_2 atmosphere by using a probe station and a semiconductor parameter analyzer (Agilent 4155C). The capacitance–voltage (C–V) measurements were carried out by using a HP4192A impedance analyzer.

3. Results and discussion

3.1. Device characteristics for PTCDI OTFTs

Leakage current density vs. gate voltage (V_G) is shown in Fig. 2. Clearly, the current density is remarkably reduced to 10^{-10} A/cm^2 order in minimum for the device structure with PFN or its copolymers. It is noted that the V_G values corresponding to the lowest leakage current density are not at zero but at a positive values in V_G range ($V_G > 0$) for the structure with PFN and its copolymers, which suggests the existence of an internal electric field induced by PFN or its copolymers, which will be discussed below.

Fig. 3a–d show the output characteristics (I_D vs. V_D) obtained from OTFTs based on Ta_2O_5, Ta_2O_5/PFN, Ta_2O_5/PFN–PBT1, and Ta_2O_5/PFN–PBT5 insulators, respectively. All types of the transistors show n-channel behavior with operating voltages lower than 16 V. In the transistor fabricated by using Ta_2O_5 only, the drain current (I_D) remarkably decreases in higher drain voltages (V_D), indicating that the electron carriers are trapped seriously at the PTCDI/Ta_2O_5 interface or in bulk of Ta_2O_5 layer. Fortunately, in the transistors fabricated by using Ta_2O_5/PFN, Ta_2O_5/PFN–PBT1, and Ta_2O_5/PFN–PBT5, the output characteristics demonstrate typically saturated behavior, and the saturated I_D reaches as high as 114 μA when the gate voltage (V_G) is biased at 16 V for the OTFT based on Ta_2O_5/PFN insulator. Similarly, saturated current I_D is about 45 and 39 μA at V_G = 16 V for OTFTs based on Ta_2O_5/PFN–PBT1 and Ta_2O_5/PFN–PBT5 insulators, respectively. This implies that the electron transport properties are greatly improved when using a PFN, or PFN–PBT1, or PFN–PBT5 modification layer.

Fig. 4 shows I_D vs. V_G, and corresponding $|I_D|^{1/2}$ vs. V_G for the OTFTs with Ta_2O_5, Ta_2O_5/PFN, Ta_2O_5/PFN–PBT1, and Ta_2O_5/PFN–PBT5 insulators, respectively. Clearly, the on/off ratio reaches as high as 1.7×10^5 for the device with Ta_2O_5/PFN insulator while it is only 5×10^3 for the one based on Ta_2O_5 only. It should be noted, the subthreshold swing (SS) tends to increase in the transistors with the modification layer from PFN to PFN–PBT1 to PFN–PBT5, which is different from the case of the transistors with modified surface of SiO_2 insulators [17]. It indicates fewer traps at the interface of PFN/PTCDI, or PFN–PBT1/PTCDI, or PFN–PBT5/PTCDI than those at the interface of Ta_2O_5/PTCDI. The detailed information for SS and on/off ratios is listed in Table 1.

The threshold voltages (V_T) as illustrated in Fig. 4b for the transistors with Ta_2O_5, Ta_2O_5/PFN, Ta_2O_5/PFN–PBT1, and Ta_2O_5/PFN–PBT5 insulators are 12.5, 2.8, 4.8, and 6 V, respectively. Clearly, the V_T decreases when Ta_2O_5 insulator is modified by PFN or its copolymers, and tuned by PBT contents in PFN–PBT copolymers. We ascribe the V_T changes to dipole moments formed at the interface of PFN/PTCDI or PFN–PBT/PTCDI, as discussed below.

The electron mobility (μ) in the saturated current regime is calculated as follows:

$$I_D = \frac{W \mu C_i}{2L}(V_G - V_T)^2 \tag{1}$$

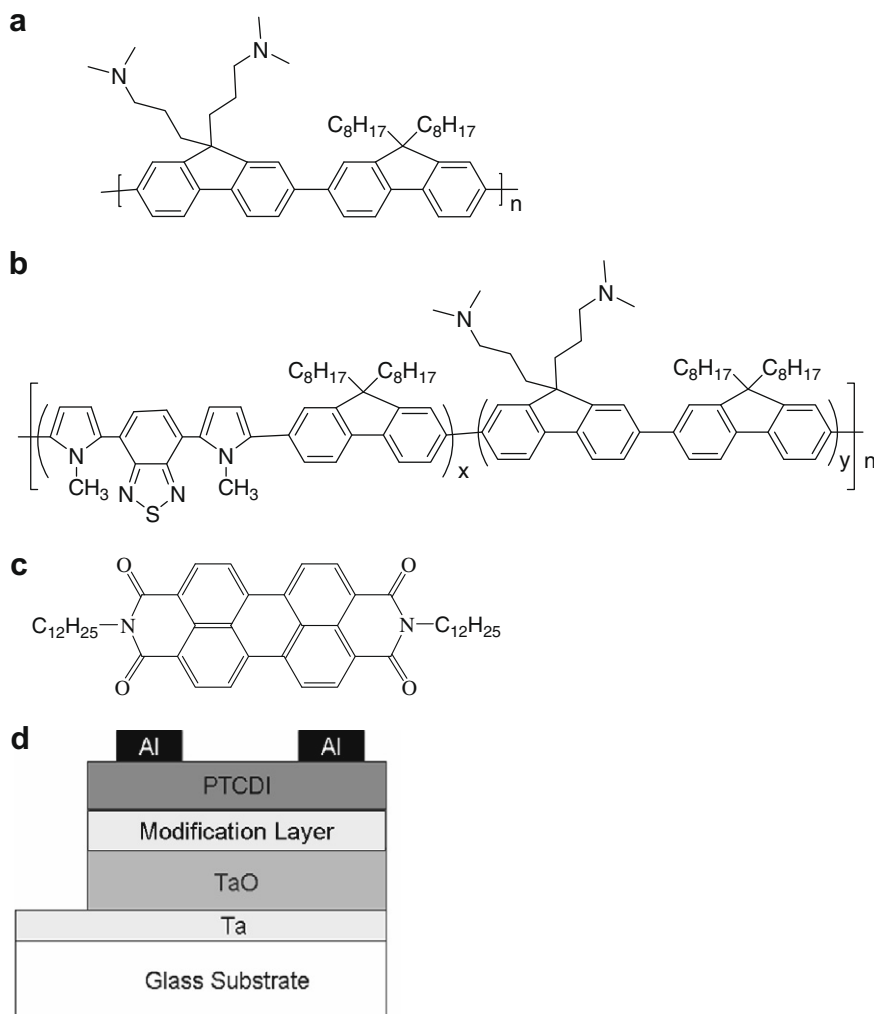
where L is the channel length, W the channel width, and C_i the capacitance per unit area of the dielectrics. The capacitances are 51.3 nF/cm^2 for Ta_2O_5, 43.1 nF/cm^2 for Ta_2O_5/PFN, 44.3 nF/cm^2 for Ta_2O_5/PFN–PBT1, 43.8 nF/cm^2 for Ta_2O_5/PFN–PBT5 dielectric layers, respectively, measured by an impedance instrument. The electron mobility of the OTFTs fabricated on Ta_2O_5/PFN reaches as high as 0.55 cm^2/Vs which is almost 100 times large compared to


Fig. 1. Chemical structure of (a) PFN, (b) PFN–PBT, (c) PTCDI, and (d) schematic cross-section of the OTFTs.

that of the transistor with Ta_2O_5 insulator (0.006 cm^2/Vs). This value is higher than that reported before [16], and can be comparable to those of many p-channel OTFTs [17]. Table 1 summarizes the data of μ and V_T, suggesting that the PFN or PFN–PBT modification layer can greatly improve the performances of the n-channel OTFTs. Meanwhile, during comparing the mobilities of the OTFTs with PFN, PFN–PBT1, and PFN–PBT5 modification layers, we find that the PBT monomer seems disadvantageous for the n-channel OTFT performances (Table 1), probably it is due to the non-polarity of PBT monomers.

3.2. Interface structure between insulator and PTCDI

We now discuss the reasons for V_T changes with different polymer modification layers. We believe that the changes attribute to the different polarities of PFN, PFN–PBT1, and PFN–PBT5. In order to conform the speculation, we measure the water-contact angle of Ta_2O_5, PFN, PFN–PBT1, and PFN–PBT5 surfaces, respectively, as shown in Table 1. We can see that PFN has the smallest water-contact angle and the angles increase with increasing PBT contents, suggesting that PFN has the strongest polarity and the polarity is reduced as the PBT content increases. Further-
Fig. 2. Leakage current density vs. gate voltage (V_G) for the capacitors with the structures of Ta/Ta_2O_5/Al, Ta/Ta_2O_5/PFN/Al, Ta/Ta_2O_5/PFN–PBT1/Al, and Ta/Ta_2O_5/PFN–PBT5/Al.

more, we speculate that the polar PFN or PFN–PBT may form self-assembly electric dipolar layer between PFN or PFN–PBT and PTCDI because of PFN and its copolymers containing the amino polar groups, similar case has been discussed by Wu in light-emitting diodes [14]. The speculation can be confirmed via measuring small angle X-ray diffraction (XRD). Fig. 5 displays the results of the samples of PTCDI deposited on Ta_2O_5, PFN, PFN–PBT1, and PFN–PBT5, respectively. No diffraction peaks are observed in Ta_2O_5/PTCDI structure. As for PFN /PTCDI structure, a peak located at $2\theta = 2.58°$ is observed, indicating the existence of an ordered structure with a spacing of $\sim$34.2 Å, which is consistent with that reported in Ref. [13]. Similarly, a peak located at $2\theta = 3.48°$ (corresponding to a spacing of $\sim$25.4 Å) for the PFN–PBT1/PTCDI structure, and a peak at $2\theta = 3.80°$ (corresponding to a spacing of $\sim$23.2 Å) for the PFN–PBT5/PTCDI structure appear, showing decreased

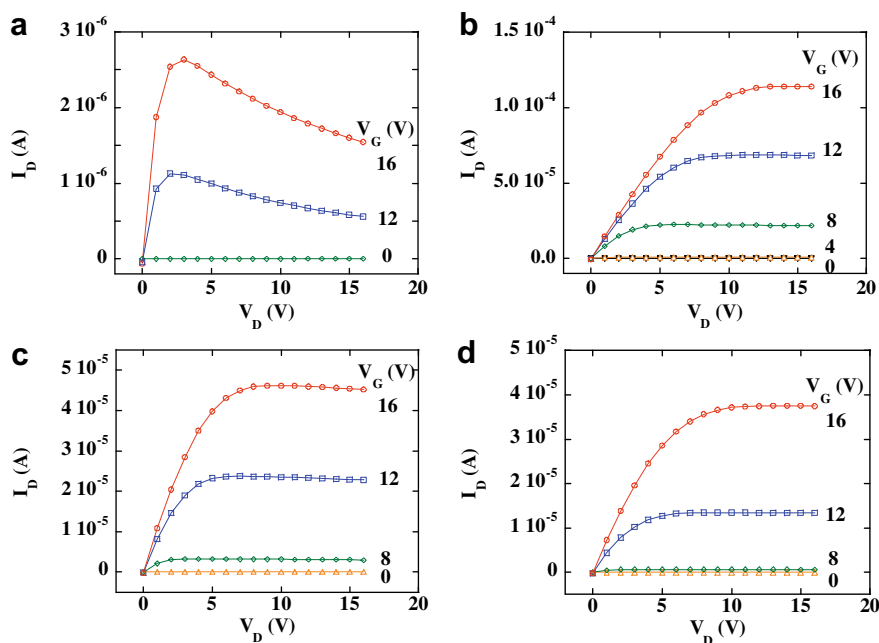
both the spacing in the ordered layer and the diffraction intensities with increasing the PBT contents. It means that the dipoles are less ordered when the PBT contents increase, which would weaken the self-assemble electric dipole field. The changes of the intensity of the self-assemble electric dipole field will cause the V_T changes. The situation is quite similar to the statement of Campbell et al. [18]. They found that the dipole moment strength depends on the functional group of the investigated molecule. When such molecules form a self-assemble layer, the molecular dipoles will give rise to a net polarization to influence on the surface potential [19]. So, when PFN or PFN–PBT copolymers to modify non-polar Ta_2O_5 insulator, the dipole field in the PFN or PFN–PBT copolymers would provide a surface potential which produces a similar effect as applying a (positive) gate voltage (Fig. 6). It means that a lower gate bias is high enough to turn on the OTFTs, i.e.,


Fig. 3. Output characteristics for PTCDI OTFTs with insulators of (a) Ta_2O_5, (b) Ta_2O_5/PFN, (c) Ta_2O_5/PFN–PBT1, and (d) Ta_2O_5/PFN–PBT5.
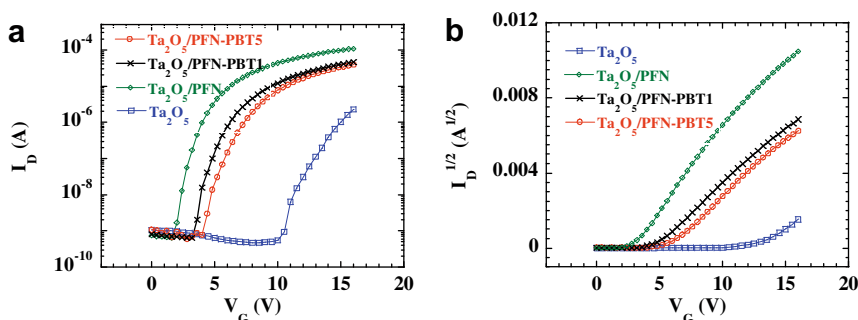

Fig. 4. Plots of (a) I_D vs. V_G, and (b) corresponding $|I_D|^{1/2}$ vs. V_G for PTCDI OTFTs with insulators of Ta_2O_5, Ta_2O_5/PFN, Ta_2O_5/PFN–PBT1, and Ta_2O_5/PFN–PBT5 biased at $V_D = 16$ V.

Table 1
Summarized properties of the transistors with various surface modification polymers.

Insulators	V_T (V)	SS (V/dec)	μ (cm²/Vs)	On/off ratio	Θ[a] (deg)
Ta₂O₅	12.5	1.2	0.006	5 × 103	90.6
Ta₂O₅/PFN	2.8	0.6	0.55	1.7 × 105	29.0
Ta₂O₅/PFN–PBT1	4.8	0.7	0.30	7.5 × 104	38.4
Ta₂O₅/PFN–PBT5	6.0	0.9	0.26	6 × 104	52.0

[a] Θ is the contact angle of water on different substrates.
Fig. 5. X-ray diffraction patterns of (a) PTCDI (50 nm in thickness), (b) PTCDI (50 nm)/Ta₂O₅, (200 nm) (c) PTCDI (50 nm)/PFN–PBT5 (40 nm), (d) PTCDI (50 nm)/PFN–PBT1 (40 nm), and (e) PTCDI (50 nm)/PFN (40 nm).

the V_T is lowered. The discussion coincides with the tendency of V_T changes (Table 1).

3.3. Traps at the interface

The traps at the insulator/semiconductor interface could strongly affect the performances of the OTFTs. As known, Ta₂O₅ insulator can seriously trap electrons [13]. Therefore, to reduce the interface-traps is an important issue in fabricating *n*-channel OTFTs based on Ta₂O₅ insulators. Fortunately, the interface-trap densities could be reduced greatly by modifying Ta₂O₅ surface with PFN or PFN–PBT copolymer layer, and the electron mobility would be enhanced.

In order to investigate the trap densities at the interfaces of Ta₂O₅/PTCDI and polymer/PTCDI, capacitance–voltage (C–V) measurement on Ta/Ta₂O₅/PTCDI/Al and Ta/Ta₂O₅/polymer/PTCDI/Al structures has been carried out. The frequency and the amplitude for the AC component of the bias to the Ta electrode were 100 kHz and 50 mV, respectively. The DC component was swept between −16 and +16 V. The hysteresis swept forward and reverse reflects the trap density at the insulator/PTCDI interface or in the bulk of insulators.

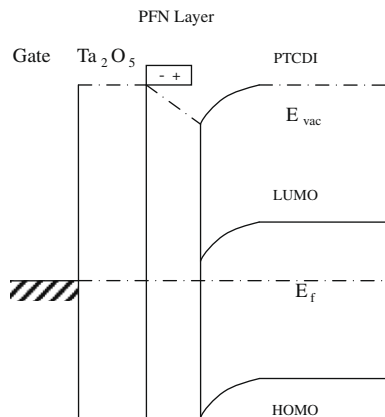
Fig. 7 shows the C–V characteristics. The shifts of the flat-band voltages (ΔV) are 8.2, 1.4, 1.9, and 3.3 V for Ta₂O₅/PTCDI, PFN/PTCDI, PFN–PBT1/PTCDI, and PFN–PBT5/PTCDI interface, respectively. Assuming that ΔV originated from trapped electrons at the insulator/PTCDI interface, the density of interface-traps (N) can be estimated by the following equation [17,20]:


Fig. 6. Schematic energy level diagram of OTFTs with PFN modification layer (LUMO: the highest occupied molecular orbital energy level, HOMO: the lowest unoccupied molecular orbital energy level, Evac: vacuum energy level, Ef: Fermi level).

$$N \approx C_i \Delta V / q \qquad (2)$$

where C_i is the capacitance per area of the insulator and q is the elementary charge. Using this formula, we are able to estimate the trap density to be 3×10^{12} cm⁻² for Ta₂O₅/PTCDI, 5×10^{11} cm⁻² for PFN/PTCDI, 7×10^{11} cm⁻² for PFN–PBT1/PTCDI, and 1×10^{12} cm⁻² for PFN–PBT5/PTCDI interfaces. As seen, the trap density is the smallest for the PFN/PTCDI interface. According to the data, we may conclude that the stronger polarity of the polymer modification layers will lead to fewer traps at the interface and higher electron mobility for the *n*-channel PTCDI OTFTs.

3.4. Gate bias stress effects

One of the obstacles for a commercialization of OTFTs is gate bias stress effects. The effects are often investigated by applying a fixed gate voltage for an extended time, followed by a measurement of the shift of the transfer characteristic [21].

Fig. 8 shows the V_T shift due to the gate bias stress. During the measurement, the gate bias was stressed at 16 V at the interval between every two sweeps, and the transfer curves were recorded at a drain bias of 16 V with the gate bias sweeping from −8 to 16 V. Five transfer curves were
Fig. 7. C–V characteristics for Ta/Ta₂O₅/PTCDI/Al, Ta/Ta₂O₅/PFN/PTCDI/Al, Ta/Ta₂O₅/PFN–PBT1/PTCDI/Al, Ta/Ta₂O₅/PFN–PBT5/PTCDI/Al structures.
Fig. 8. V_T shifts under gate bias stress for PTCDI OTFTs with Ta_2O_5, PFN/Ta_2O_5, PFN–PBT1/Ta_2O_5, and PFN–PBT5/Ta_2O_5 insulators.

recorded with interval time of 60 s. Clearly, very little V_T shift occurs in the OTFTs with PFN or PFN–PBT modification layer during the gate bias stress, while the OTFT without PFN or PFN–PBT layer displays large shift. The result is consistent with the hysteresis (ΔV) in $C–V$ measurements. It should be noted that the effects of H_2O and O_2 on the electrical instability can be neglected, because all of the measurements were carried out in a dry nitrogen atmosphere. Thus, the improvement in the electrical stability is most probably due to the reduction of the interface-trap density.

4. Conclusion

We fabricated *n*-channel PTCDI OTFTs using Ta_2O_5 as the insulator. The performances of OTFTs are significantly improved by using polar PFN and PFN–PBT polymers to modify the surface of Ta_2O_5. The electron mobilities of the OTFTs with PFN modification layer are increased by almost two orders (0.55 cm^2/Vs) compared to that of the transistor with only Ta_2O_5 insulator (0.006 cm^2/Vs). The drain current is as high as 114 μA. The reason for the improvement was discussed to be ascribed to the formation of self-assembly dipole moments in the polymers. The polarity of PFN–PBT can strongly influence on the performances of OTFTs. Strong polarity of the polymers can decrease both electron-trap density at the interface of insulator/ PTCDI and the gate bias stress effect, and finally increase electron mobilities of OTFTs. The threshold voltages of the OTFTs decrease with increasing the polarity of PFN–PBT, the stronger the polarity of the polymer is, the lower the threshold voltages of the OTFT are. We believe that it is an available way to improve the *n*-channel OTFT performances by using polar polymers to modify Ta_2O_5 insulator surface.

ABSTRACT

We demonstrate organic photovoltaic (PV) and ultraviolet (UV) photodetector devices using 1,3,5-tris(3-methylphenyl-phenylamino)-triphenyamine and 1,3,5-tris(N-phenyl-benzimidazol-2-yl)-benzene to function as the donor (D) and the acceptor (A), respectively. Two types of structural devices, a planar heterojunction of layer-by-layer and a bulk heterojunction with a D/A blend layer are fabricated, respectively. Under UV-365 irradiation, the PHJ device offers a power conversion efficiency of ~10%, while the BHJ device behaves with a responsivity of 135 mA/W at −4 V bias. The BHJ device can also obtain a high exciplex electroluminescence (EL). The dependencies of PV and EL performances on exciplex formation were also discussed.

© 2008 Elsevier B.V. All rights reserved.

Ultraviolet (UV) sensitive photovoltaic (PV) diodes can be used for environment monitoring, combustion flames, UV curing monitors, developing areas, and so on [1–7]. Moreover, the devices, especially the visible–blind (VB) device, also has potential applications in solar astronomy, missile plume detection, space-to-space transmission, and sterilization monitors. The wide-band-gap inorganic photodetectors based III-nitrides [2], SiC [3] and II–VI materials [4] are constructed on expensive substrates such as sapphire [5] or SiC [3], and the associated fabrication techniques are troublesome and costly. Differing from inorganic systems, organic UV photodetectors have undergone rapid development in recent years, which can be as-cribed to simpler fabrication processes, lighter weight and lower costs [6,7]. However, organic UV photodetectors still exhibit lower responsivity, such as a peak responsivity of 30 mA/W [6]. Organic PV performances rely intensively on electrical properties including energy levels and the carrier mobility of the donor (D) and acceptor (A) materials and the diode structure. For this reason, we will select a new material system in which the D material has a low ionization potential (IP) and the A material presents a higher electron affinity (EA) and electron-mobility. 1,3,5-*tris*(3-methylphenyl-phenylamino)-triphenyamine (m-MTDATA) is a well-known effective D materiel due to its lower IP (5.1 eV) and high hole mobility of 3×10^{-5} cm^2/Vs [8]. It has also been studied on various exciplex-type devices [9–11]. However, the efficiency of m-MTDATA based PV devices shows lower performance which may be due to the unmatched energy alignment between m-MTDATA and

bathocuproine (BCP) [11]. Compared with BCP as an acceptor, 1,3,5-tris(N-phenyl-benzimidazol-2-yl) benzene (TPBi) presents a higher electron mobility (EM) over BCP and tris-(8-hydroxy-quinoline) aluminum (Alq_3) [12]. Its electron mobility increases three times than that of BCP when the applied electrical field increased only two times, which lead to a decisive PV performance. TPBi is generally used as the exciton blocking and electronic transporting material to substitute BCP/Alq_3 layers in the field of OLED fabrications. In this Letter, a new PV diode was constructed where m-MTDATA and TPBi serve as D and A, respectively, and BCP was also employed as the exciton blocking layer (EBL).

All devices were fabricated on cleaned glass substrates pre-coated with conducting indium–tin–oxide (ITO) anode with a sheet resistance of 25 Ω/sq, and the substrates were treated by UV ozone in a chamber for 15 min after solvent cleaning. The organic films were thermally evaporated in high vacuum (<10^{-6} Torr) using previously calibrated quartz crystal monitors to determine the deposition rate and the film thickness. The organic layers were deposited at a rate of 2 Å/s. The evaporating rate of LiF and Al cathode were controlled to be 0.5 Å/s and 10 Å/s with the thickness of 10 Å and 2000 Å, respectively. A 365 nm UV light with a power of 0.426 mW/cm^2 was employed to illuminate both types of diodes at zero bias and various reverse biases.

Fig. 1 shows the chemical structures of the used materials and the schematic energy level diagram of the PHJ device. The function of three layers has been expatiated in the preamble. About 10 Å LiF was used as the complex cathode with Al to further increase the performance [13,14]. To compare the performance of the diodes, two types of devices were constructed. One is device-A with a structure of ITO/m-MTDATA(350 Å)/TPBi(500 Å)/BCP(120 Å)/LiF(10 Å)/Al. The other is device-B with a structure of ITO/m-MTDATA(300 Å)/m-MTDATA:TPBi (1:1, 100 Å)/TPBi(450 Å)/BCP(120 Å)/LiF(10 Å)/Al, which were called the planar heterojunction (PHJ) and bulk-heterojunction (BHJ) devices hereafter, respectively.

Fig. 2a shows I–V characteristics of the PHJ and BHJ devices. According to the figure, the open-circuit voltage (V_{OC}), short-circuit current density (J_{SC}), and fill factor (FF) for PHJ and BHJ devices were 2.26 and 2.22 V, 46.1 and 46.7 μA/cm^2, 37.5% and 31.3%, yielding a power conversion efficiency (η_p) of 9.15% and 7.63%, respectively. Compared with previous reports [15], the η_p of 9.15% is highest found until now. The above data depicts that η_p is higher for PHJ than for BHJ structure devices. It is

interesting that this result is very different from the previous relationship in which the blend-device (BHJ) generally provides a higher PV property than that of a bilayer (PHJ) device reported in Yang's work [16]. The discrepancy in the phenomena of PV efficiency can be understood as follows. First of all, BHJ devices can provide a large interface area where photoinduced charge transfer by excitons into separated electrons and holes can efficiently occur. In this case, excitons are always generated within a diffusion length (∼3–10 nm) of a donor–acceptor interface, potentially leading to higher cell efficiency than a planar heterojunction. Secondly, m-MTDATA is an amorphous film. It possesses a denser film structure and finer surface morphology than CuPc microcrystalline [17]. Because the charge mobility is higher in crystalline than in amorphous materials, the existence of crystalline structures is important for ensuring a low cell series resistance [16]. Thirdly, the mean distance between neighboring molecules of the same species in the mixed layer is larger than that in their respective homogeneous layers. The hopping mobilities are expected to decrease upon intermixing on the molecular scale. Both the second and third reasons lead to a larger internal series resistance in our BHJ device, which result in a lower *FF*, i.e., the *FF* is lower for the BHJ-device (0.313) than for the PHJ-device (0.375), consequently a lower η_p for the BHJ-device. In other words, the introduction of the blend layer produces a pair of contradictory processes

and results in a trade-off in which the highest η_p can be obtained. However, when the thickness of blend layer decreases from 20 to 2 nm, the η_p increases linearly and the maximum photocurrent is highest only at 10 nm. This suggested that the method of mixing D:A could be unfit for our system, and the causes will be illuminated at the latter of part of this paper.

Fig. 2b shows the normalized absorption and photoluminescence (PL) spectra of neat m-MTDATA, TPBi and BCP neat films on quartz substrates as well as the photocurrent spectral response of the PHJ-device. In the insert of Fig. 2b, it shows that both types of devices offer the same photocurrent spectral responses which mainly correspond with the absorption of m-MTDATA film. It proved that most of the excitons were generated in the m-MTDATA layer. An absorption peak of TPBi is located at 315 nm, at which the photons can be completely absorbed by ITO glass, leading to a smaller contribution of spectral response in TPBi layer. The spectral response is located at the band from 300 to 400 nm, which is just at the VB UV spectral position. We also found that these two types of diodes have a higher photoelectric detector effect under the irradiation of 365 nm UV light.

Fig. 3a depicts the dark-corrected photocurrent response as a function of the different reverse bias for the two types of devices. It is clearly shown that generation rate of the free carrier is prominently enhanced with the increase of the reverse bias voltage and gradually reach a
Fig. 3. (a) Dark-corrected photocurrent response as a function of different reverse biases for the different structure detector devices. (b) Dependence of photocurrent response on the 365 UV irradiation intensity at zero bias.

saturation value. The BHJ device has a higher photocurrent and saturation photocurrent density than the PHJ one, which is due to a higher amount of intermolecular contact between the D/A, which proves that the generation and disassociation ratio of the exction in the BHJ device is easier than that of the PHJ. The difference between the photocurrents gradually increases with the increase of the reverse bias which indicates that the external electric field gradually plays a leading role over the built-in electric field. But the case is different when the thickness of the mixed layer is increased to 20 nm. That is, at lower reverse bias, the responsivity is higher for the PHJ device than for the BHJ one because the built-in field plays a dominating role in exciton dissociation. But as the reverse bias increases, the external electrical field plays a dominant role in exciton dissociation for the BHJ device, because the external electrical filed could overcome the disadvantageous influence of the higher resistance at the blend layer while taking advantage of the much higher photogenerated exciton ratio, thus the photocurrent will be higher than that of the PHJ one but lower than the optimized BHJ device with a 10 nm blend layer (see Fig. 3a).

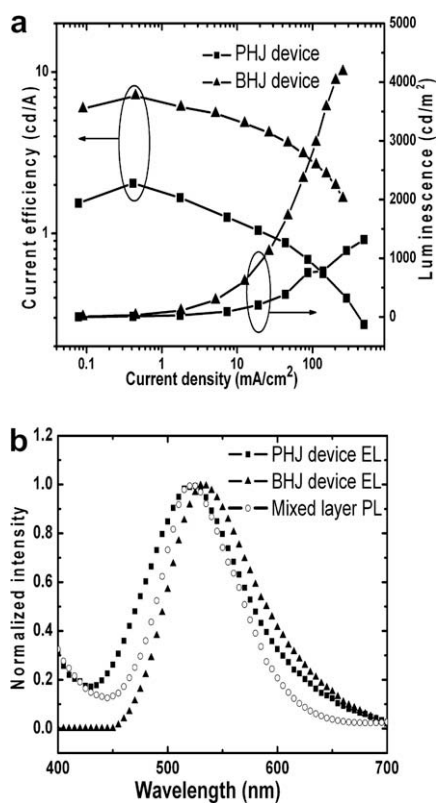
The dependence of the photocurrent response on the incident UV light intensity under zero bias was shown in Fig. 3b. From the slope of the fitted line, the responsivities of 100 and 85 mA/W for the PHJ and BHJ detectors were attained, respectively, which is three times higher than that reported by Ray's [6] and can be compared with that of

Fig. 4. (a) Plot of current efficiency and luminance as a function of current density for PHJ device and BHJ device. (b) The EL spectra of PHJ and BHJ devices and the PL spectrum of BHJ device.

GaN (~100 mA/W) and of SiC (130 mA/W) based on inorganic UV detectors [2,3]. When the reverse bias rises to 4 V, the responsivity of the BHJ structure based the detector can up to 135 mA/W, and the photodetector presents a constant at broad irradiation density range with only a sharp spectral response as shown in the insert of Fig. 2b.

Fig. 4a provides the current efficiency and luminance as a function of current density for the two devices. Fig. 4b indicates the EL and PL spectra of the PHJ and BHJ-structure devices. Both the PHJ and BHJ devices show a bright green emission peak at 520 nm, which are completely different from the emission spectrum of m-MTDATA and TPBi monomers, proving it is caused by exciplex [10]. Exciplex is formed at the intermolecular interface between the excited state of m-MTDATA and the ground state of TPBi molecules [18]. We note that the emission of the BHJ and PHJ devices exhibit the maximum current efficiencies of 7.14 and 2.05 cd/A, and the peak luminance of 4182 and 1319 cd/m^2, at 8.2 V and 7.5 V biases, respectively. That means these two types of devices have an EL effect and a PV effect, which were connected by exciplex and will be explained as below. There is a weak emission at blue waveband even extending to UV area in PHJ EL device and it increases with applied voltage. It is because the exciplex formation takes place only at the interface between m-MTDATA and TPBi. The increasing in the applied voltage leads to an increase in the number of injected holes and electrons, which recombine not only at the interface but also in the bulk of the TPBi layer, which can be proved from the PL spectrum of TPBi.

It is well known that the energy level offset of D and A at heterojunctions interface plays a very important role in the operation of the PV diode because exciton dissociation occurs at the D/A interface, while exciplex can be formed in the same place in some system. Based on our previous experiments [9,10,19], the formation of exciplex would be easier in the BHJ than for the PHJ structure device as there is a higher number of D/A molecular interactions. That is, the intensity of exciplex EL is higher for the BHJ device. Compared with the EL result, there is a contrary dependence on the PV performance in our system. That is, the PHJ device offers higher PV properties and better EL performance but its PL of exciplex is almost indetectable (data not shown), which is due to less contact and interaction among D/A molecules, while the BHJ device offers lower PV properties and better EL performance and its intensive PL of exciplex which is due to much more contact and interaction between D/A molecules (see Fig. 4b).

We deduced that there would be a competitive process between exciplex formation and photo-generated free charge carriers. Thus we supposed that they have a common precursor, which is most likely a similar non-emissive geminate pair. The PL of exciplex competes with the PV effect, which leads to a lower PV effect. The dynamic physical process may be like this: When the PV device was irradiated by a photon of a suitable energy, photo-generated excitons diffuse to the interface of the heterojunction and converse into non-emissive geminate pairs, and they are the generated common precursor. They will transform either into exciplex and emit photons or free charge carriers that drive the external circuit load. However, the


dynamic factors that decide what the common precursor will change into are still confusing.

In conclusion, we have fabricated a high efficiency PHJ-PV device with the η_p of 9–10%. This diode could be used as a photodetector for its sharp response in VB-UV and a responsivity of 100 mA/W at zero bias. A maximum responsivity of 135 mA/W was achieved in the BHJ device with a 10 nm blend layer with 1:1 D:A at a −4 bias, while this device has peak current efficiency and maximum luminance of 7.14 cd/A and 4182 cd/m^2 under electrical excitation. A new dependence of the PV and EL performances on the exciplex formation was discovered in our small molecular system, which will inspire us to design more efficient organic electronic diode devices.

ABSTRACT

In this work we present a permeable-base transistor consisting of a 60 nm thick N,N'-diphenyl-N,N'-bis(1-naphthylphenyl)-1,1'-biphenyl-4,4'-diamine layer or a 40 nm thick 2,6-diphenyl-indenofluorene layer as the emitter, a Ca/Al/Ca multilayer as the metal base, and p-Si as collector. In the base, the Ca layers are 5 nm thick and the Al layer was varied between 10 and 40 nm, the best results obtained with a 20 nm thick layer. The devices present common-base current gain with both organic layer and silicon acting as emitter, but there is only observable common-emitter current gain when the organic semiconductor acts as emitter. The obtained common-emitter current gain, $\sim$2, is independent on collector-emitter voltage, base current and organic emitter in a reasonable wide interval. Air exposure or annealing of the base is necessary to achieve these characteristics, indicating that an oxide layer is beneficial to proper device operation.

1. Introduction

The concept of the modern metal-base transistor (MBT) is almost 50 years old [1,2], but it was not widely explored because such devices constructed in the inorganic semiconductor/metal/inorganic semiconductor vertical structure suffered from severe limitations. These devices present complex production procedures showing poor electrical characteristics, despite the promise of operation at higher frequencies than bipolar transistors [3,4]. The interest on MBTs received a new impulse after many research groups used the approach of the substitution of the inorganic semiconductors by organic ones. By doing this, not only the fabrication process became easier, but

new possibilities of flexible [5,6] and hybrid organic/inorganic integrated devices were opened [7–10].

The MBT structure, which is a vertical stack of ultra-thin layers, is specially suitable for organic semiconductor applications. In this architecture high currents can be attained at low voltages due to the short paths for charge carriers, of the order of tens of nanometers, reducing the limitations imposed by the low charge carrier mobilities usually observed in organic semiconductors.

The MBT is constructed in the semiconductor/metal/semiconductor vertical structure, constituting a three-terminal device, named emitter, base and collector. In the case of inorganic semiconductors, the transistor is formed by two Schottky junctions, one is forward-biased (emitter/base junction) and the other is reverse-biased (base/collector junction), the emitter and collector semiconductors traditionally being crystalline ones. However, when organic semiconductors are used, the junction can be more

complex due to its amorphous and disordered character, interface polarization, etc. [11,12]. In general, these junctions are asymmetrical in order to increase the base transport factor, to improve current gains and to prevent a high leakage current or minority charge carrier injection. Additionally, as the charge carriers must be transported from the emitter through the base to reach the collector, a thin metal layer is required as the base and a low electron scattering is desired to improve device performance. In such ultra-thin base layers, typically of a few tens of nanometers, the existence of pinholes directly connecting emitter and collector is quite common. When this happens, the device is called permeable-base transistor (PBT) as characterized by the interdependence between emitter-base and collector-base voltages due to its inability of electric field shielding, analogous to the solid-state triode [13]. Using newly developed techniques, PBTs with controlled pinhole size and distribution and showing high current gains and on/off ratios have been demonstrated [14–17].

Recently, several PBTs containing organic materials were designed using different approaches, including electrochemically deposited metal base layer [18], bi-metal base layer [19], conducting polymer base layer [20] and organic collector and emitter layers [21,22], and all aimed at achieving improved electrical characteristics. Despite the high common-emitter current gains and low operational voltages already achieved, these devices suffer from high leakage currents and current gains dependent on emitter-collector voltage and base current, which leads to low on/off ratios and severely restricts practical applications related to signal amplification and modulation.

In this work we report the construction of hybrid PBTs with constant common-emitter current gain, i.e., independent of collector voltage and base current. The devices are constructed using a Ca/Al/Ca layered base. In addition, we compare two organic semiconductors with different band gaps as an emitter, observing only a slight dependence of device characteristics on the emitter materials and thus confirming the importance of the base structure for achieving high performance devices.

2. Experimental

The hybrid transistors were prepared onto p-type Si (100) substrate (resistivity 1–10 Ω cm). The silicon substrates were immersed in a 35% hydrofluoric acid (HF) aqueous solution to remove surface oxide. In the sequence, an insulating poly(methyl methacrylate) (PMMA) thick layer was deposited by spin-coating on part of the p-Si, in order to further prevent the direct contact between the emitter and collector electrodes, in the same geometry as reported elsewhere [24].

The deposition of the Ca/Al/Ca three-layer metal base was sequentially made without vacuum break on the p-Si polished side. The Ca layer thickness was maintained constant at 5 nm for all devices, while devices having different thickness δ_{Al} of the Al layer (δ_{Al} = 10, 15, 20 or 40 nm) were prepared. After the Ca/Al/Ca base deposition the vacuum is broken, exposing the three-metal layer to air and allowing oxidation of the highly reactive Ca layer. These samples are not submitted to any thermal treatment. However, addi-
Fig. 1. Scheme of the structure in which the devices are constructed. O.S. means organic semiconductor, DPIF or NPB. (a) top view, the PMMA covers the entire silicon wafer, except inside the broken line rectangle, which lies under the base and emitter layers; (b) side view, layer-by-layer structure of the devices. The p-Si/Al corresponds to the collector, the Ca/Al/Ca to the base and the O.S./V_2O_5/Al to the emitter.

tional devices were made in which an δ_{Al} = 20 nm three-metal base was annealed in air at 120 °C for 5 min just after its deposition, being the sequence of device construction the same.

The organic emitter, a 60 nm thick layer of N,N′-diphenyl-N,N′-bis(1-naphthylphenyl)-1,1′-biphenyl-4,4′-diamine (NPB), or a 40 nm thick layer of 2,6-diphenylindenofluorene (DPIF), was further deposited by thermal sublimation in vacuum. To improve the hole injection into the organic semiconductor emitter layer, a 5 nm layer of nominally V_2O_5 was deposited on top of the NPB layer [23,24] prior to the top contact metal electrode deposition, which consisted of a 120 nm thick Al layer. The resulting devices have an effective area of ∼9 mm². Another 120 nm thick Al layer was deposited on the silicon unpolished backside to act as the back contact for the collector terminal. The layers thickness were controlled during device preparation using a quartz oscillator and all base and emitter related depositions were made at a base pressure lower than 6×10^{-6} torr. Fig. 1 presents the geometry in which the devices are constructed (Fig. 1a) together with the final structure of the transistors (Fig. 1b).

Two- and three-terminal electrical measurements carried out in the dark using two Keithley 2400 Sourcemeters were made in both, common-emitter and common-base mode. Furthermore, the devices were measured again after a period under air exposure to investigate degradation.

3. Results and discussion

As reported elsewhere [24], the energy levels of the involved materials favors holes as majority charge carriers. The metal work functions [25], the valence and conduction
Fig. 2. Energy levels of materials used in this work and chemical structure of DPIF and NPB. O.S. means organic semiconductor, DPIF (full line) or NPB (broken line).

band energies of Si [26], and HOMO and LUMO levels of NPB [27] and DPIF [32] are summarized in Fig. 2. Both, NPB and DPIF are used in p-type conduction hybrid devices and their HOMO levels differ by approximately 0.1 eV. However, it must be pointed out that the Ca/Al/Ca layer was exposed to air after evaporation in all cases, so that the actual Ca work function during device operation can significantly differ from that presented in the figure, since the work function of CaO is around 1.7 eV [28].

Although the detailed energy level structure of this Ca/Al/CaO layer is difficult to predict, it plays an important role in device operation, as freshly-prepared devices do not work properly, their characteristics being not reproducible. However, after some days under air exposure, the device characteristics become more stable and the results highly reproducible. The following results for the NPB-based devices were acquired after four days device exposure to air, and for the DPIF-based devices the results were acquired one day after air exposure. However, the base of the DPIF-based device was submitted to the mentioned thermal treatment.

In the presentation of the electrical characteristics of the devices we will use the subscripts E, B and C to denote emitter, base and collector currents I and voltages V, respectively. Additionally, we define V_{ij} $V_i - V_j$ (i,j = E, B or C).

We made two-terminal current *versus* voltage measurements between each of the three terminals, i.e., collector/base, emitter/base and emitter/collector, maintaining the unmeasured electrode unconnected to the measurement setup. Fig. 3 presents these measurements for a δ_{Al} = 20 nm device, using NPB (Fig. 3a) or DPIF (Fig. 3b) as organic emitter. Considering the first device, it can easily be seen that the collector-base characteristic curve presents rectification. However, it seems not to follow a Schottky junction behavior. Instead, a series resistance appears to limit the injected current, possibly due to the oxidized Ca layer. The emitter-base characteristic curve also presents rectification. As expected from Fig. 2, the injection is favored when the emitter is positively biased, due to the different energy barriers for hole injection from V_2O_5/Al and Ca/CaO. Furthermore, the injected current is higher than the collector-base current for voltages V > 2 V, favoring its use as the emitter electrode. The emitter-collector charac-
Fig. 3. Two terminal current *versus* voltage characteristics of δ_{Al} = 20 nm devices using as organic emitter (a) NPB and (b) DPIF.

teristic curve shows almost no rectification. Moreover, this current is lower than the previous ones, possibly due to the necessity of the charge carriers to transpose the base layer through pinholes. These results are similar to those obtained in δ_{Al} = 40 nm devices, while for all other devices (δ_{Al} < 20 nm) the base was not able to transport charge. Therefore, 20 nm is a critical thickness in this structure. The same behavior is observed for a device using DPIF as organic emitter (Fig. 3b), although different current values are achieved.

Fig. 3 presents the NPB-based device characteristics while operating in common-base mode. Interestingly, these devices can operate using the NPB or the p-Si as emitter electrode, as presented in Fig. 3a and b, respectively. The inset presents the measured I_C versus V_{CB}, for different I_E values, for devices with δ_{Al} = 20 nm. As can easily be seen, in this operation mode there is no leakage current, i.e., I_C (I_E = 0) = 0 in both cases. With NPB as the emitter (Fig. 4a), the I_C saturation value is not close to I_E, indicating a common-base current gain α lower than the ideal value, which equals 1. The plot of the I_C versus I_E at V_{CB} = 0 V allows the calculation of $\alpha = \frac{\partial I_C}{\partial I_E}\big|_{V_{CB}=const.}$ [29]. The slope of this straight line gives α = 0.67, being lower than the previously reported values on p-type hybrid tran-

Fig. 5. Common-base characteristic curves of a δ_{Al} = 20 nm DPIF-based device in case of (a) DBIF operating as emitter and; (b) p-Si operating as emitter. Inset: emitter current ranging from 0 to 50 μA in steps of 10 μA.

sistors [24,30], but is highly reproducible. Furthermore, the devices suffer from a very slow degradation process, because after eleven days air exposure, α dropped to 0.60, a fall of only ~10%. The δ_{Al} = 40 nm device presented α = 0.62. In contrast, when the p-Si is the emitter (Fig. 4b), the saturation I_C is close to I_E, indicating a nearly ideal α = 0.99 at V_{BC} = 3 V. These devices support a maximum I_E of the order of 50 μA, higher currents leading to saturation of I_C at ~50 μA.

The common-base characteristic curves of DPIF-based devices are presented in Fig. 5, for the organic material acting as emitter (Fig. 5a) and collector (Fig. 5b). These characteristics are very similar to those observed in the NPB-based devices for both emitters, DPIF and p-Si: low leakage currents and similar saturation currents, which lead to α similar to that observed in NPB-based devices. This is a very interesting result because changing the organic emitter does not influence the device characteristics, despite energy level differences, and thus strongly indicates that in this system the base layer is the key terminal and determining factor to high device performance. It is reasonable to attribute this characteristic to the small difference in HOMO energies, 0.1 eV between NPB and DPIF, when compared to the energy difference between

CaO work function and NPB- or DPIF-HOMO, of the order of 3.5-3.6 eV. In all cases permeable-base characteristic was observed through the typical dependence of $\partial V_{BE}/\partial V_{CB}$ = 1 at a constant I_E [29]. Despite the fact that the total thickness of the metallic base is much thicker than the Fermi-Thomas length, across which an electric field is screened, we attribute the permeable-base characteristic of these devices to the roughness of the base layer, which can be of the same order as the layer thickness, creating natural pinholes that allow the direct connection of emitter and collector [24,30].

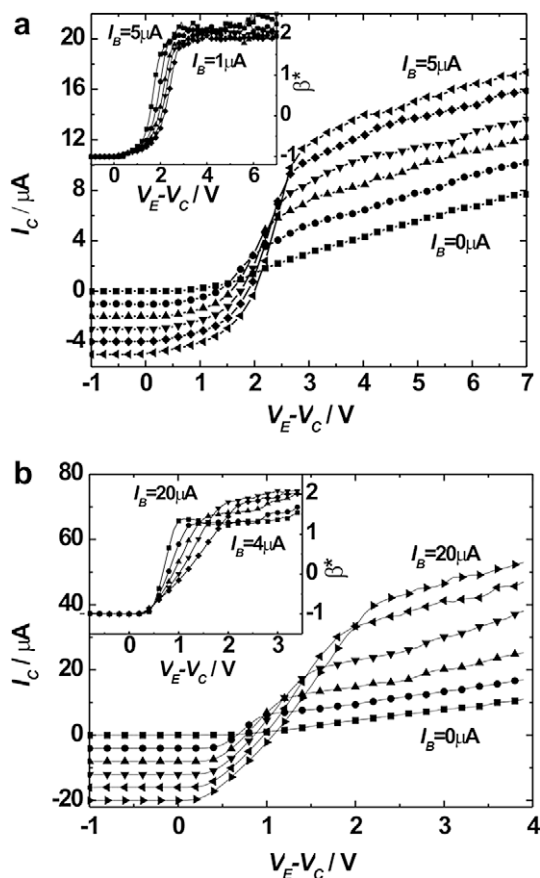
The common-emitter characteristics for δ_{Al} = 20 nm NPB- and DPIF-based devices are presented in Figs. 5a and b, respectively. These measurements show that, independent on the organic material used as emitter, the leakage current $I_L = I_C (I_B = 0)$ is low compared to previously reported hybrid p-type transistors [24,31,32], leading to higher on/off ratios. Additionally, it is easy to see that in both cases the difference between two I_C curves remains constant as V_{CE} changes, which leads to a constant common-emitter current gain $\beta = \frac{\partial I_C}{\partial I_B}\Big|_{VCE=const.}$. Due to the stepwise character of our measurements, we considered the related quantity β^* defined as $\beta^* = \frac{I_C - I_L}{I_B}$. The obtained results are constant, $\beta^* \cong 2$, independent on I_B and on the


Fig. 6. Common-emitter characteristic curves of a δ_{Al} = 20 nm (a) NPB-based device and; (b) DPIF-based device. Base currents ranging from (a) 0 to 5 µA in steps of 1 µA and; (b) 0 to 20 µA in steps of 4 µA. organic emitter material, as can be seen in the insets of Fig. 6. However, a small dependence of β^* on I_B in the DPIF-based device can be observed: β^* increases as I_B increases, reaching a saturation value of about 2 at $I_B \cong 12$ µA. Despite the low value, it represents an important achievement because previously reported permeable-base hybrid transistor devices show common-emitter current gain dependent on base current and collector voltage, restricting practical applications. Most of those reported devices show very high gains at very low base currents, but the gain strongly diminishes as the base current increases. Moreover, the operation voltage of our devices is low, near 3 V, with a low "turn-on" voltage of about 2 V. The same operation and "turn-on" voltages are achieved in the δ_{Al} = 40 nm NPB-based device, but in this case β^* drops to 1.6. In both devices, the maximum supported I_B is ~20 µA. Higher currents lead to saturation of I_C and, consequently, to lower β^*, possibly due to the low conductivity of the organic emitter, which cannot provide enough current to the collector, as demanded by the base. It is important to notice that these values of α and β follow in all cases exactly the expected relation $\beta = \frac{\alpha}{1-\alpha}$, also valid for bipolar transistors [33].

At last, it was not possible to observe a common-emitter current gain when operating the devices using the organic materials as collector. Probably, this is because in order to operate in the active-forward mode while in the common-emitter configuration, the voltages required to drive the charge carriers through the collector are much higher than those used in the measurements. As a consequence, devices degrade before achieving the required operational condition.

As mentioned earlier, the reported characteristics are observed only after the devices are exposed to air. The most plausible hypothesis is that the Ca layer oxidizes completely, considering its thickness and period of air exposure. This could explain the dramatic change in the electrical properties in a fresh-prepared device and its late stability. In order to help supporting this hypothesis, we made a δ_{Al} = 20 nm NPB-based device and submitted it to a thermal treatment in air at 120 °C during 5 min. The obtained results were exactly the same as those presented above for long time air exposure devices. This result strengths the hypothesis that an isolating layer between emitter and base is a key factor to improve device characteristics, as already reported elsewhere [7,21,22,34] for all-organic transistors, since higher temperature is expected to lead to faster oxidation.

Finally, despite the similarity in the structure of these devices and the one presented in previous work [24], the device characteristics are very different. The difference can be partially attributed to the substitution of the Ag by the Al in the base layer. However, the oxidation of the Ca layer cannot be neglected, as it may play an important role in defining device characteristics. The strong mismatch between CaO work function and NPB- and DPIF-HOMO probably imposes severe constraints for charge transport from NPB or DPIF through the Ca/CaO to the Al, effectively acting as an energy barrier and leading the device base to operate as a high impedance terminal. However, due to the high conductivity of the Al layer in the base, this high impedance base is able to act as an equipotential surface, producing a homogeneous potential drop in the NPB or DPIF layer between Al top metal electrode and Al in the base.

4. Summary

In conclusion, we have demonstrated hybrid organic/inorganic metal base transistors with low leakage current in common-emitter mode and with a highly reproducible common-emitter current gain independent on both base current and collector voltage. These devices are stable when operated in air. Furthermore, a critical thickness of 20 nm is necessary for the proper base operation. A key factor to the stable device operation is related to the oxidation of the Ca base layer, since a device submitted to a short thermal treatment presents the same characteristics as those exposed to air for longer periods. Additionally, the observed nearly identical characteristics of the devices differing only by the organic emitter lead to a conclusion that in this system the base plays a key role in device characteristics.

ARTICLE INFO

ABSTRACT

Multiwalled carbon nanotubes (MWNTs) were solubilized in water by wrapping them non-covalently with poly(4-styrene sulfonate) (PSS). The PSS-wrapped MWNTs exhibited a high conductivity $(2.0 \times 10^2 \, \text{S/cm})$ when compared to other solution-processed electrodes. Ultraviolet photoelectron spectroscopy results show the PSS-wrapped nanotubes have a work function of 4.83 eV, which is 0.36 eV higher than that of untreated MWNTs. We fabricated triisopropylsilylethynyl pentacene field-effect transistors (FETs) using the PSS-wrapped MWNTs as source/drain electrodes and found that the field-effect mobility of the thus obtained devices was $0.043 \, \text{cm}^2 \, \text{V}^{-1} \, \text{s}^{-2}$. This mobility is four times higher than that of similar FETs containing gold electrodes $(0.011 \, \text{cm}^2 \, \text{V}^{-1} \, \text{s}^{-2})$.

In the past decade, there has been a growing interest in organic field-effect transistors (OFETs) because of their potential commercial applications as driving units in low-cost, large-area, and bendable electronics, for example, for the development of flexible displays, radio-frequency identification tags, smart cards, and so forth [1,2]. Intensive studies performed on OFETs using solution-processed small molecules and polymers, such as triisopropylsilylethynyl pentacene (TIPS-PEN), poly(3-hexylthiophene), and poly(2,5-bis(3-alkylthiophen-2-yl)thieno[3,2-b]thio-phene), as the active layer have made it possible to achieve device performances comparable to those of amorphous-silicon transistors [3–5]. The electrode materials used in such OFETs must be highly conductive and flexible and exhibit a high work function (for p-type transistors) to ensure a good performance of the devices. Furthermore, the electrode materials should be solution-processable and printable to allow the fabrication of low-cost logic devices. To date, several materials, including poly(3,4-ethylenedioxy-thiophene):poly(styrene sulfonate), polyaniline, silver paste, and conductive polymer–carbon nanotube composites, have been tested as possible electrodes for OFETs [6–9]. However, these materials have not been shown to be good enough to replace the gold electrodes due to the
Fig. 1. Electrical conductivities of MWNT/PSS films as a function of the MWNT:PSS ratio. The inset at the bottom shows 20-ml vials containing PSS-wrapped MWNTs (left) and untreated MWNTs (right) in water.

low conductivity of the conductive polymers and the low work function of the silver paste.

Multiwalled carbon nanotubes (MWNTs), composed of co-axially arranged single-walled carbon nanotubes of different radii, are good candidates to be used as electrodes in OFETs. This is because of their high conductivity and mechanical strength [10,11]. However, their poor solubility and low work function have complicated their use. In this
work, we solubilized MWNTs in water by simply wrapping them with poly(4-styrene sulfonate) (PSS) [12]. The wrapping of the MWNTs with the water-soluble polymers was thermodynamically driven to eliminate the hydrophobic interface between the tubes and their aqueous medium [12–14]. In addition to the good solubility of the PSS-wrapped MWNTs in water, we also found—via ultraviolet photoemission spectroscopy (UPS) measurements—that their work function was high enough to allow their use as electrodes in OFETs. Using the PSS-wrapped nanotubes as source/drain electrodes, we fabricated solution-processed TIPS-PEN OFETs and examined their device performances.

The MWNTs were obtained from Carbon Nano-material Technology Co. Ltd. and used as received. PSS was purchased from Aldrich ($M_w \approx 75,000$). The nanotubes were dispersed in a 2 wt.% solution of PSS in water (at a concentration of 20 mg/ml) by ultrasonication for 30 min. The homogeneous dispersion of the as-prepared PSS-wrapped MWNTs was stable and no phase separation with aggregation of nanotubes was observed—not even after two weeks. The conductivity of a PSS-covered MWNT film formed by drop-casting on a glass was calculated from the sheet resistance measured using the four-point probe method (KEITHLEY 2400 source meter). The film thickness was measured with a surface profiler (alpha step 500, TENCOR) at different MWNT:PSS ratios. Scanning electron microscopy images of both the PSS-wrapped MWNTs and the nanotube powder were obtained using a field-emission scanning electron microscope (FESEM, Hitachi S-4800) operating at 3 kV. All the materials, namely, the untreated MWNTs, the polymer (PSS), and the PSS-wrapped MWNTs spin-coated on the gold substrate, were characterized by UPS (Escalab 220IXL) with an He(I) emission of 21.2 eV to measure their work function. During the UPS measurements, a −5.0 eV bias was applied to improve the transmission of low-kinetic-energy electrons and ensure the determination of the energy of the low-kinetic-energy edge.

OFETs with bottom-contact configurations, where the source/drain electrodes are built before depositing the

Table 1

Work functions of MWNTs, PSS, PSS-wrapped MWNTs, and Au calculated from UPS measurements.

	MWNTs	PSS	PSS-wrapped MWNTs	Au
Work function	4.47 eV	4.58 eV	4.83 eV	5.01 eV

semiconductor layer, were fabricated on heavily doped silicon wafers covered by thermally grown 300-nm-thick silicon-dioxide layers. The substrates were modified with hexamethyldisilazane (HMDS) after rinsing with acetone and cleaning with a UV–ozone cleaner, GCS-1700 (AHTECH LTS, Korea), for 20 min. In order to pattern the source/drain electrodes, the substrates were irradiated with an O_2 plasma (at 70 W for 6 s) through a shadow mask. Then, the PSS-wrapped MWNTs were spin-coated on these substrates. In this way, source/drain electrode patterns composed of PSS-wrapped MWNTs were formed on the irradiated areas. This patterning method has been described in previous reports [7,15,16]. Before spin-coating the PSS-wrapped MWNTs, we added glycerol to the modified nanotube solution (at a concentration of 0.8 g/ml) to obtain a clear pattern (it should be noted that glycerol does not affect the conductivity of the PSS-wrapped MWNTs). The electrode-patterned substrates were dried in a vacuum oven for one hour at 60 °C. A solution of TIPS-PEN in tolu-

ene (1 wt.%) was then dropped onto the patterned substrates and dried under ambient conditions. The electrical characteristics of the OFETs were measured in air using Keithley 2400 and 236 source/measure units.

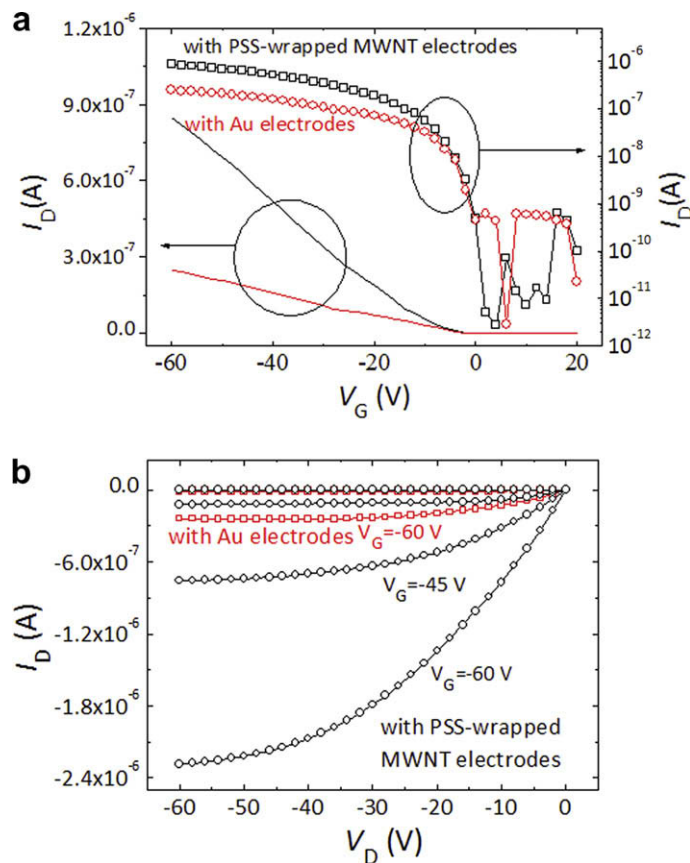
The conductivities of MWNT/PSS films at different ratios of MWNTs and PSS—measured using the four-point probe method—are shown in Fig. 1. Upon varying the ratio of PSS and MWNTs from 2:1 to 4:1, and then to 8:1, we observe a decrease in the conductivity, which is caused by the excess of PSS. At an MWNT:PSS ratio of 1:1, the conductivity becomes saturated (at 2.0×10^2 S/cm). However, at a ratio of 1:2, aggregates of MWNTs are observed due to a lack of PSS wrapping the tubes. Therefore, we can roughly say that a MWNT:PSS ratio of 1:1 is optimal in this case. The PSS-wrapped MWNTs (with a MWNT:PSS ratio of 1:1) are homogenously dispersed in water, even after 2 weeks. However, if the MWNT content exceeds the PSS content, nanotube aggregates start to precipitate at the bottom of vial, as shown in the inset of Fig. 1. The surface


Fig. 4. (a) I_D–V_G transfer characteristics in the linear regime (drain voltage, $V_D = -6$ V) for TIPS-PEN OFETs containing source/drain electrodes composed of PSS-wrapped MWNTs and gold. (b) I_D–V_D output characteristics of both devices. The values of W and L are 1000 and 100 μm, respectively.

of the pristine MWNTs is smooth (see Fig. 2a), whereas that of the PSS-wrapped nanotubes is rough, with the polymers helically wrapping the surface of the MWNTs. Fig. 2b shows the successful fabrication of PSS-wrapped MWNTs with a MWNT:PSS ratio of 1:1.

The work functions of pristine MWNTs, the polymer (PSS), and PSS-wrapped nanotubes were determined from the UPS experiments shown in Fig. 3 and summarized in Table 1. The work function of the pristine nanotubes was found to be 4.47 eV, a value that is quite consistent with that reported previously [17]. The work function of the PSS-wrapped MWNTs was 0.36 eV above that of the pristine nanotubes. Since the work function of the surface of a PSS bulk film spin-coated on a gold substrate is 4.58 eV, we can conclude that the increased work function does not come from the PSS bulk. Ago et al. showed that carboxylic-acid groups introduced at the surfaces of MWNTs by acid oxidation increase the work function of the nanotubes from 4.4 to 5.1 eV due to the presence of oxygen-induced surface dipole moments [17]. Similarly, the increased work function observed here may originate from a negative dipole moment at the pendent group (benzene sulfonate) of the wrapping polymer, which is oriented away from the nanotube [18]. The increased work function of the PSS-wrapped MWNTs (i.e., 4.83 eV) is comparable to that of gold, the material generally used for source/drain electrodes in OFETs due to its high work function, which is comparable to the highest occupied molecular orbital (HOMO) of an organic semiconductor. Consequently, since the PSS-wrapped MWNTs exhibit good conductivity and a high work function, as well as good solubility, they represent good candidates to be used as electrodes in OFETs.

Fig. 4a shows typical drain current–gate voltage (I_D–V_G) transfer curves for TIPS-PEN OFETs fabricated using source/drain electrodes composed of PSS-wrapped MWNTs and gold. The carrier mobility was calculated in the linear regime from the slope of a plot of the drain current versus the gate voltage. This was done by fitting the data to the following equation: $I_D = (WC_i/L)\mu(V_G - V_{th})V_D$, where I_D is the drain current, μ is the carrier mobility, V_{th} is the threshold voltage, and V_D is the drain voltage (namely, −6 V). The measured capacitance, C_i, was 10 nF/cm^2. The carrier mobility of the pentacene OFETs containing the PSS-wrapped MWNTs was 0.043 ± 0.006 cm^2/V s whereas that of the devices based on gold substrates was 0.011 ± 0.004 cm^2/V s. Ohmic contact behavior was observed for the devices based on the modified nanotubes (see Fig. 4b), which implies that the contact resistance between the PSS-wrapped MWNTs and TIPS-PEN is negligible.

The mobility of OFETs containing PSS-wrapped MWNT electrodes is about four times higher than that of gold-based devices, even though the work function of gold is slightly higher than that of the modified nanotubes. In previous reports, a large downward vacuum level shift was observed between pentacene and gold [19,20] due to the high induced density of interface states (IDIS) originated from the strong local orbital exchange and the potential correlation between the metal and the semiconductor

[19–21]. This large vacuum level shift also leads to a large hole-injection barrier between pentacene and gold, despite the high work function of gold. In contrast, the electrodes having an organic surface show a smaller vacuum level shift—or no shift at all—between the electrode and pentacene. This is because no strong local orbital exchange or potential correlation are expected on the organic surface [20,22,23]. From this viewpoint, a large downward vacuum level shift at the interface between TIPS-PEN and the metallic surface of gold leads to a large hole-injection barrier. In contrast, the organic surface of PSS causes a small vacuum level shift between the PSS-wrapped MWNT electrode and TIPS-PEN, thus leading to a smaller hole-injection barrier. Since a smaller hole-injection barrier implies a smaller contact resistance in the OFETs [23,24], we can assume that the higher mobility of the devices containing the PSS-wrapped MWNT electrodes comes from their lower contact resistance relative to that of the transistors containing gold electrodes.

In conclusion, we have fabricated PSS-wrapped MWNT electrodes exhibiting a high work function (of 4.83 eV), high conductivity (of 2.0×10^2 S/cm), and good solubility in water. The good performance of TIPS-PEN OFETs fabricated using these electrodes as source/drain electrodes demonstrates that PSS-wrapped MWNTs are a competitive material for the fabrication of OFET electrodes.

ARTICLE INFO

ABSTRACT

In this work, we tested an approach towards novel organic materials that can permanently increase conductivity upon thermal or photo treatment, and potentially, change from insulator to conductor or semiconductor. Using dichlorodicyanoquinone (DDQ) doped thermo and photo responsive pentacene precursors as model systems, we found that conductivity of the thermal responsive material increased over 2 orders of magnitude to 10^{-3}–10^{-2} S/cm after thermal treatment, while that of a photo responsive material did not significantly increase after photo irradiation even though the composites are same. Based on the results of conductivity measurement, SEM, XRD, UV–Vis, and FT–IR, the phenomena are attributed to that the crystalline morphology of thermally generated pentacene/DDQ thin films favored charge transfer while the amorphous morphology of the photo generated material favored solid-state Diels–Alder reaction. The result implies that the mechanism of solid-state reaction can be altered by controlling morphology.

Current research on organic electronic materials focuses on organic semiconductors and conductors. Our group is working on a novel type of organic electronic material that can permanently increase conductivity upon photo or thermal treatment, and potentially, change from insulator to conductor or semiconductor. Such materials may be applied to improve the interface between insulator, semiconductor and conductor. More interestingly, they have potential to largely simplify the process of multilayer interconnection; and allow ink-free printing of microcircuit with high resolution.

Substantial conductivity increase after intense UV irradiation and multistep processing has been reported in early works aimed at photo patterning of conducting polymer [1–4]. We are developing a systematic approach that can control electric property in a wide range with mild photo and/or thermal process. The approach is based on

the fact that nonconjugated organic materials are insulating; conjugated polymers or oligomers are semiconducting; and effectively doped conjugated polymers or oligomers can be highly conducting in the presence of a suitable morphology. Thus, converting nonconjugated structure to conjugated, or activating an ineffective dopant, i.e. converting a precursor dopant that is not oxidizing or reducing enough for charge transfer to a dopant that can induce charge transfer efficiently, can largely increase conductivity.

Inspired by the previous works that utilized precursor chemistry to solve solubility problems associated with aromatic polymers and oligomers [5–12], we utilized retro-Diels–Alder chemistry for converting nonconjugated structure to conjugated in the presence of an effective dopant. This process can potentially convert an insulating material to a conducting material, and thus largely increase conductivity. While the idea is straightforward, the process is complicated since it involves solid-state reaction, morphology change, and consequent change of

charge transfer and transport. Successful development of such materials requires understanding how factors including structures of polymers or oligomers, dopants, morphology and processing procedures affect solid-state reactions and charge transport. In this communication, we demonstrate a large conductivity increase using dichlorodicyanoquinone (DDQ) doped pentacene precursors as a model system. The factors that affect the conductivity change are carefully analyzed. In addition, we observed intriguing competition between charge transfer and solid-state reaction of pentacene and DDQ.

To demonstrate conductivity increase upon thermal and photo treatment, thermal responsive pentacene precursor **1** [9] and photo responsive pentacene precursor **2** [10] were doped by DDQ and spin cast into thin films. The idea is that **1** and **2** will be converted from nonconjugated structures to pentacene by thermal and photo treatment, respectively, followed by charge transfer between pentacene and DDQ, which will largely increase the conductivity. (Scheme 1)

Precursor **1** was developed by Afzali et al for solving the low solubility problem in preparing thin films of pentacene by solution process [9]. Thin films with charge mobility as high as 0.1 cm^2 V^{-1} S^{-1} were achieved after pentacene was generated from **1** via a retro-DA reaction at ~150 °C. It must be pointed out that, as described below, the conductivity of **1** is at least 2 orders of magnitude higher than the pentacene generated from it. Simply converting **1** to pentacene decreases conductivity though increases the charge mobility, which may be due to that ionic conductivity is predominant in low conductivity range. Precursor **2** can be converted to pentacene in solution or solid-state under UV–vis irradiation (Scheme 1) [10,13].

A solution of **1** and DDQ in CH$_2$Cl$_2$ was spin cast to thin films (concentration: ~2% total solid weight; spin rate: 1000 rpm; substrate: ITO or glass.) The molar ratio of DDQ/precursor was varied between 1:5 and 1:1. The conductivity was measured by a Keithley 2400 source meter using four-point technique and I–V scan. Thin films of **1** and DDQ showed a conductivity of 10^{-6}–10^{-5} S/cm which was close to or slightly higher than that of the undoped **1** (2 × 10^{-6} S/cm). Baking the film at 150 °C under N$_2$ induced the retro-DA reaction and changed the color of the film from light yellow to blue or greenish blue. The in-film retro-DA reaction was monitored by attenuated total
reflection infrared (ATR-IR) and UV–vis spectroscopy. The aliphatic C–H stretch disappeared in IR after thermal treatment, which indicated that the retro-DA reaction is close to completion [9]. The change of UV–vis spectra between 350 nm and 900 nm is similar to that of the undoped **1** (Fig. 1a). No charge transfer band can be undoubtfully assigned in this range. However, the conductivity increased more than two orders of magnitude after heated for 15 min. The conductivity stayed in the same order of magnitude after a couple of days. The highest conductivity increase was ~570 fold (3.6 × 10^{-5} S/cm to 2.0 × 10^{-2} S/cm) obtained from 1:3 DDQ/pentacene. The magnitude of conductivity change was reproducible with commercial DDQ and **1**. Additionally, a film of **1** without DDQ showed that a low conductivity of ~10^{-8}–10^{-7} S/cm after heated under the same condition, which is consistent with the fact that undoped pentacene has very low conductivity [14]; heating a mixture of **1** and FeCl$_3$ and NOSbF$_4$ [15] also substantially decreased conductivity, which confirmed that the conductivity increase was indeed caused by interaction between pentacene and DDQ.

Photoresponsive pentacene precursor **2** was synthesized according to a literature procedure [10]. Compound **2** was thermally stable. No decomposition was observed upon stationary heating at 150 °C. Thin films of undoped **2** and DDQ doped **2** showed conductivity of 10^{-6} S/cm. UV–vis spectrum of **2** showed an absorption peak at 470 nm, while neither pentacene nor DDQ strongly absorbs at this wavelength. The 470 nm absorption is due to the diketone structure of the DA adduct **2**. Therefore we irradiated a thin film of DDQ doped **2** under nitrogen with a 472 nm LED bundle [16]. The 470 nm absorption peak disappeared after irradiation which indicated that conversion from **2** to pentacene was close to completion
Fig. 1. (a) UV–vis spectra of DDQ doped **1** before and after thermal treatment. (b) UV–vis spectra of DDQ doped **2** before and after irradiated at 472 nm. Disappearance of the absorption at 470 nm after irradiation indicated that the precursor **2** had completely changed into pentacene.

Scheme 1. Thermal and photo responsive composites based on DDQ doped pentacene.

[11] (Fig. 1b). While conductivity increase was observed as expected, the magnitude is much less than that of the thermal system. The conductivity only increased ~5 fold in the best case.

The low conductivity increase of the photo generated pentacene/DDQ films may be attributed to three possible reasons: incomplete conversion from **1** to pentacene, inefficient charge transport due to undesirable morphology, and inefficient charge transfer between pentacene and DDQ due to undesirable molecular orientation. Prolonged irradiation did not increase (or decrease) conductivity which implies that the low conductivity increase was unlikely due to incomplete conversion. Scanning electron microscope (SEM) was applied to study the morphology of the thin films. After photo irradiation, bumps with diameter of ~300 nm and average height of ~25 nm appeared on the surface (Fig. 2). The height of the bump was measured by AFM. Elemental analysis of the bumping areas

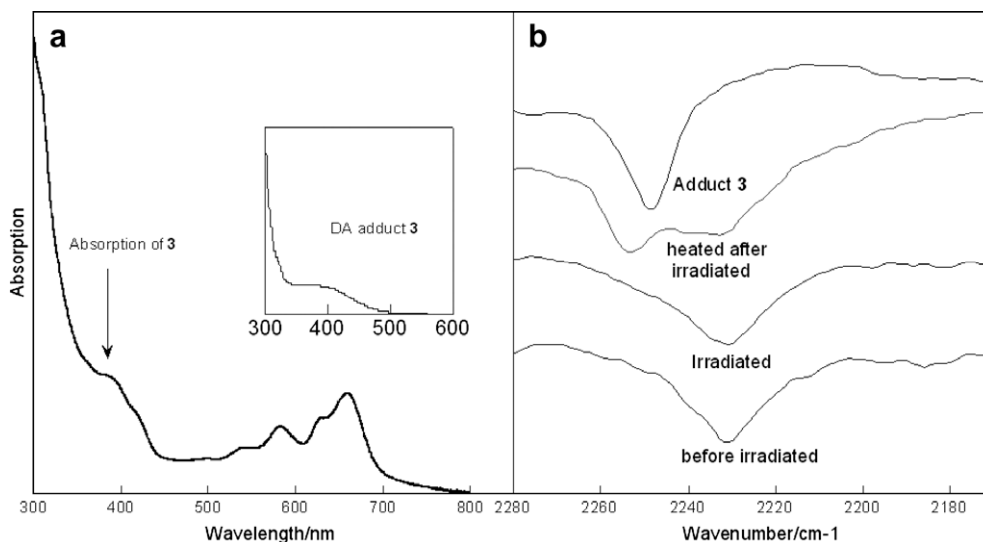
and the adjacent areas by SEM did not show apparent difference, which indicated that the bumps are not aggregates of pure DDQ or pentacene. Since irradiation was at room temperature in nitrogen filled glove box, thermal mechanisms and air oxidation are also ruled out. Therefore, bumping must be due to release of CO during the retro-DA reaction (Scheme 1). Small CO molecules aggregated in the film before evaporated out, which caused the bumps. SEM of the thermal responsive films also showed morphology change after the retro-DA reaction. However, instead of bumps, crystalline domains appeared on the surface. (Fig. 2) This may be due to that the size of the N-sulfinyl dienophile released during the thermal reaction is much larger than CO, which makes them difficult to move and aggregate in the film. In addition, the thermal process provided energy for generated pentacenes to align themselves and fill the space left by the released dienophiles for reaching a low energy state stabilized by intermolecu-
Fig. 2. SEM of thermal generated (a) and photo generated (b) pentacene/DDQ films. The films before thermal or photo treatment looked smooth and did not show any special feature (Supporting information Figures 3 and 4).


Fig. 3. UV–vis (a) and FTIR (b) of the photo generated pentacene/DDQ films after heated at 150 °C for 10 min. The spectra of the pure DA adduct **3** are also showed.

lar π–π interactions. The difference in crystallinity was further proved by both X-ray diffraction (XRD) and UV–vis spectroscopy. Only the thermally treated thin films of **1** and DDQ showed the 001 peak of pentacene in XRD (Supporting information). Moreover, UV–vis indicated that pentacene generated from **2** by photo irradiation is disordered and amorphous. The coulomb interaction between a pentacene molecule and its surrounding is weak, which lead to low intensity of the Davydov doublet [17] (Fig. 1).

3
To improve the crystallinity of the photo generated films, a film of **2** and DDQ was heated at 150 °C for 10 min after photo irradiation. While the pentacene absorption in UV–vis became similar to that of the thermally generated films (Fig. 3) and SEM showed that the bumps became flat, no conductivity increase was observed. IR and UV–vis spectra showed that substantial amount of DDQ/pentacene DA adduct **3** was generated by the annealing process. (Fig. 3) This is an unexpected observation since the films of **1** and DDQ did not show notable absorption of **3** in UV–vis or IR after being heated at the same condition. Upon prolonged heating for over 1 h, only a small shoulder on the CN stretch peak of DDQ appeared in the IR, which may be due to the formation of **3** (Supporting information).

All the results can be attributed to that the morphology of DDQ and pentacene in the thermally generated films favored charge transfer interaction while that of the photo generated films favored solid-state Diels Alder reaction. Morphology includes both long-range alignment (crystallinity) and short-range relative molecular orientation between pentacene and DDQ. The precursor **1** and **2** interact differently with DDQ which may lead to different relative orientation between pentacene and DDQ after retro-DA reaction. While it is well known that molecular orientation is important for both bimolecular reaction and charge transfer, [18] the long-range alignment may also play an important role since it affects the energy levels of the donor and acceptor, and the subsequent charge separation [19]. Charge transfer will result in positively charged pentacene and negatively charged DDQ, which suppresses DA reaction since DA reaction normally requires electron-rich diene and electron-deficient dienophile. It is possible that the amorphous morphology of the photo-generated films cannot stabilize the charge transfer state as the crystalline morphology of the thermally generated ones and consequently favors the DA reaction.

In conclusion, we have demonstrated an approach towards organic materials that can permanently increase conductivity upon thermal or photo treatment. Over two orders of magnitude conductivity increase to 10^{-2} S/cm was achieved by thermally converting a DA adduct to pentacene in the presence of DDQ. The photo generated materials did not show large conductivity increase though the composition was the same as the thermally generated ones. This is attributed to undesirable morphology including long-range alignment and short-range molecular orientation. The observation that different morphologies can favor either charge transfer or solid-state reaction is both intriguing and important since it implies that the mechanism of a solid-state reaction can be altered by controlling the morphology. It is worth pointing out that two orders of magnitude conductivity increase is much less than the potential of the general approach described here. Future work will focus on further understanding the fundamentals by modeling the interactions between the precursors and dopants, measuring charge density and charge mobility, designing new oligomers and polymers as well as dopants, and testing processing conditions for desirable morphology.

Appendix A. Supplementary data

SEM of the thin films before thermal and photo treatment; XRD of a pentacene/DDQ film generated from thermal treatment; FTIR of thermally generated pentacene/DDQ. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.orgel.2008.12.003.

ABSTRACT

The device performances of spin-coated and stamp transfer printed devices were compared. There was little difference of morphology between the spin-coated and stamp transfer printed devices. However, the stamp transfer printing process was better than the spin-coating process in terms of current density, light-emitting efficiency and lifetime. In particular, the lifetime of the stamp transfer printed device was doubled compared with that of the spin-coated device.

Polymer light-emitting diodes (PLEDs) have advantages over small molecule based organic light-emitting diodes (OLEDs) such as an easy fabrication process, less material consumption and scalability to large size. In particular, the PLEDs is superior to small molecule OLEDs for large size applications because large size PLEDs can be easily fabricated by a solution coating process.

Spin-coating and ink-jet printing has been typically used as film-forming methods in PLEDs [1]. The spin-coating is a simple method to form a thin polymer film and the ink-jet printing has been used as a color patterning method of PLEDs [1–3]. Other than the two methods, the laser induced thermal imaging has also been used in PLEDs [4,5]. A light-emitting polymer film spin-coated on a donor film was transferred from the donor film to the substrate with a hole transport layer by an excimer laser irradiation. The pattern transfer process depended on the interfacial adhesion between the light-emitting polymer and the hole transport layer. Even though the efficiency was not de-

graded by the laser transfer process, it is not good for the lifetime of the device. A stamp transfer printing method has also been developed as a film-forming method of polymers [6–8]. A polymer pattern could be effectively transferred by the stamp transfer printing method even though detailed device performances of the stamp transfer printed device were not reported.

In this work, the device performances of the stamp transfer printed PLEDs were compared with those of the spin-coated PLEDs. The extension of lifetime by the stamp transfer printing process was demonstrated in this work.

A device structure of indium tin oxide(ITO, 150 nm)/polyethylene-3,4-dioxythiophene:polystyrenesulfonate-(PEDOT:PSS, 100 nm)/yellow emitting layer(30 nm)/LiF/Al was used to study the effect of coating process on device performances of PLEDs. Polyphenylenevinylene based supper yellow polymer from Merck was a yellow emitting material. The spin-coating of the yellow polymer was carried out from 0.3 wt% toluene solution, while the stamp transfer printing of yellow polymers was carried out by spin-coating of the 0.3 wt% yellow polymer solution on Si substrate and a subsequent transfer printing of yellow
Fig. 1. Atomic force microscopic images of spin-coated and stamp transferred yellow polymer films. (a) Spin-coated film, (b) stamp transferred film.

polymer from the Si substrate to an ITO substrate using polydimethylsiloxane (PDMS) stamp. The PDMS stamp was fabricated by curing Sylgard® 184 from Dow Corning Co. at 95 °C for 2 h. The yellow polymer film was separated from the Si substrate by contacting the cured PDMS stamp with the yellow polymer coated Si substrate at room temperature. Then, the yellow polymer was transferred from the PDMS stamp to the PEDOT:PSS coated substrate by pressing the PDMS stamp on the substrate at 120 °C for 10 s. Hole only devices of spin-coated and stamp transfer printed yellow devices were fabricated to study the effect of film-forming process on the hole injection of yellow devices.

Morphology of spin-coated and stamp transfer printed yellow polymer films was analyzed with atomic force microscope and a non-contact method was used to get images from the films. Current density-voltage-luminance characteristics of the devices were obtained by Keithley 2400 source measurement unit and a CS 1000 spectrophotometer.

The transfer of the polymer film was carried out from Si substrate using a PDMS stamp. The use of Si substrate for the film transfer is advantageous because the interfacial adhesion between Si and polymers is poor, leading to easy detachment of polymer film. In addition, a smooth polymer film with a low surface roughness can be coated and transferred to the substrate. The temperature during the transfer process was critical to the film transfer and the film transfer was not perfect below 100 °C and it was optimized at 120 °C.

The morphology of polymer films is critical to the device performances and the surface morphology of a transferred yellow film was analyzed with an atomic force microscope to compare the surface roughness of spin-coated and stamp transferred films (Fig. 1). Mean surface roughness of spin-coated film was 0.4 nm with a peak to valley value of 9 nm, while the transferred film showed a mean surface roughness of 0.5 nm and a peak to valley value of 6 nm. There was little difference of the mean surface roughness between spin-coated and stamp transferred films and they showed similar morphology even though some spikes were observed in spin-coated films. The transfer printed polymer film was transferred from Si substrate which has a smooth surface, resulting in the low surface
Fig. 2. Current density-voltage curves of hole only devices of spin-coated and stamp transfer printed yellow polymers.

roughness. This indicates that the film morphology of spin-coated polymer film is not affected by the stamp transfer printing process. A smooth surface film morphology was maintained during processing. Therefore, it can be expected that device performances may not be degraded by the stamp transfer process.

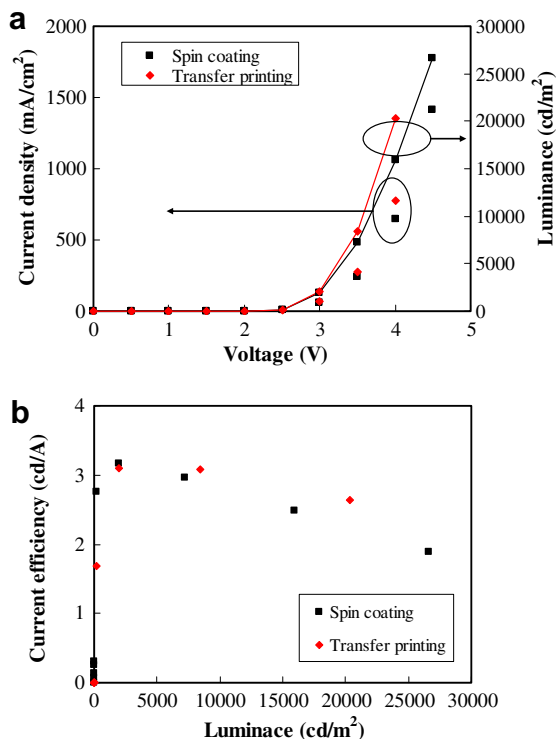
To study the effect of the stamp transfer process on device performances, the device performances of hole only devices of the yellow polymer fabricated by a spin-coating process and the stamp transfer process were compared. Fig. 2 shows current density-voltage curves of the hole only devices of the yellow polymer. The current density of the yellow device fabricated by the stamp transfer process was not decreased compared with that of the spin-coated devices. The current density was rather increased by 20%. The small increase of current density in the transfer printed device may be due to intimate interface formation between PEDOT:PSS and yellow polymer during transfer printing process at 120 °C. The interfacial contact can be improved because of pressure and heat applied during the transfer printing process [5]. Considering the similar film morphology of spin-coated and transfer printed films, the high current density of transfer printed films is due to improved hole injection rather than efficient electron injection. The interface between PEDOT:PSS and the


Fig. 3. Current density-voltage-luminance curves of spin-coated and stamp transfer printed yellow devices. (a) Current density-voltage-luminance, (b) current efficiency-luminance.

yellow polymer may be influenced by the film-forming process and the hole injection was different [9].

Fig. 3 compares device performances of yellow polymer devices prepared by the spin-coating process and the stamp transfer printing process. The stamp transfer printing process was better than the spin-coating process in terms of current density as expected from the hole only device data. Hole injection was efficient in the stamp transfer printed device, resulting in high current density in the stamp transfer printed device. Luminance was also high in the stamp transfer printed device due to high current density.

Current efficiency was also improved in the stamp transfer printed device. Although maximum current efficiency was similar in the two devices prepared by the different process, efficiency roll-off was serious in the spin-coated device, resulting in a high efficiency at high luminance in the stamp transfer printed device. The high efficiency of the stamp transfer printed device may be due to good interfacial contact between PEDOT:PSS and the yellow polymer. In our previous work about the device performances of laser transferred PLEDs, the use of high energy laser irradiation increased the current efficiency of PLEDs. At high laser dose, the temperature was high and additional pressure by laser contributed to the high efficiency. Similarly, the pressure and heat applied during the transfer process of polymers might enhanced the interfacial contact between the transferred polymer and the hole transport layer.
Fig. 4. Lifetime curves of spin-coated and stamp transfer printed yellow devices.

The lifetime of the stamp transfer printed and spin-coated devices was also compared and it is shown in Fig. 4. The lifetime was measured at a constant current density of 40 mA/cm^2. The lifetime of the stamp transfer printed device was much better than that of the spin-coated device. The lifetime may depend on the interface considering the similar surface roughness and the similar efficiency at the lifetime test condition. Intimate interface formation by the stamp transfer process may be responsible for the improved lifetime of the stamp transfer printed device. The low voltage rise during lifetime measurement supports this explanation. The voltage rise typically depends on the internal resistance increase during driving which is originated from the interface [10]. Therefore, the low voltage rise during measurements implies that the increased lifetime of the stamp transfer printed device is due to good interfacial contact between PEDOT:PSS and the yellow polymer.

To clarify the origin of the improved lifetime in the stamp transferred device, the lifetime of the spin-coated device with and without stamp pressing was compared. The lifetime data of the two devices are shown in Fig. 5. The lifetime of the spin-coated device was almost doubled after pressing stamp on the spin-coated yellow film. This
Fig. 5. Lifetime curves of spin-coated devices with and without stamp pressing.
Fig. 6. Electroluminescence spectra of spin-coated and stamp transfer printed devices.

indicates that the stamp press process at 120 °C is responsible for the enhanced lifetime in the stamp transfer printed device. Improved interfacial contact by the stamp press process may contribute to the improved lifetime. Therefore, it can be concluded that the stamp transfer printing process is better than the spin-coating process in terms of device performances.

EL spectra of the spin-coated and the stamp transfer printed devices are shown in Fig. 6. The two devices showed the same spectra, indicating that the film coating process did not greatly affect the emission behavior of the yellow devices.

In conclusion, the device performances of the stamp transfer printed device were better than that of the spin-coated device. In particular, the lifetime of yellow devices were greatly improved by using the stamp transfer printing process. Therefore, it can be expected that the stamp transfer printing method can be effectively used as a film coating method of polymers in organic electronic devices.

ARTICLE INFO

ABSTRACT

Flexible, plastic chemical sensors were fabricated using a thin polymer gate dielectric layer and polymer electrodes patterned via selective wetting directly on the surface of the organic semiconductor film. Low-voltage transistors based on DDFTTF with PEDOT:PSS electrodes had a mobility as high as 0.05 cm^2/Vs with an on–off ratio of 1.2×10^4 on ITO/PET substrates. These devices demonstrated stable operation in water with sensor characteristics similar to those reported on rigid silicon substrates, with sub-ppm detection for cysteine and 2,4,6-trinitrobenzene (TNB).

Recent progress in organic materials has given a great deal of promise to plastic electronics, especially for organic light-emitting diodes (OLEDs) [1] and radio-frequency identification cards (RFIDs) [2–4]. The rapid progress of the field has been, in part, due to improvements in fabrication processes and new material design, with noticeable improvements in electronic properties for the semiconducting [5–7], conducting [8] and insulating [9–12] components. Recently, organic field-effect transistors (OTFTs) have gained considerable attention with the demonstration of potentially scalable patterning processes [13–18] and improved semiconductor and gate insulator performance, laying the groundwork for low-power circuits [11] and devices [19].

Due to the versatility of chemical synthesis, organic materials have a niche application in chemical sensors based on OTFTs [20], in which the semiconductor functions simultaneously as the active transport layer and the sensing component. Functional derivatives of organic semiconductors have already demonstrated utility in chemical and biological sensors based upon the ability to impart specific

functionality to direct the interaction with target analytes [21,22]. However, most devices used a rigid, planar substrates and required high operating voltages. The development of low-cost, disposable sensors for environmental monitoring, health diagnostics or detection of chemical warfare agents requires incorporation of simple processing on inexpensive, large area substrates. The ability to detect chemical species in water adds another degree of versatility to OTFT sensors, allowing for in situ measurements with these applications for non-volatile species. For example, detection of amino acid concentrations in situ could have a profound impact on disease detection and prevention [23], while the ability to monitor munitions disposal is important for maintaining safe water supplies [24]. In this report, we combine the fundamental advantages of organic materials for the demonstration of flexible, transparent chemical sensors based on plastic thin-film transistors in aqueous solutions.

Our OTFT sensors are fabricated using organic and polymeric materials with simple processing on a conductive indium tin oxide (ITO) film on polyethylene terephthalate (PET) substrates. These devices were operable at low bias in vapor and liquid solutions enabled by the use of a

cross-linked gate dielectric layer [9]. Additionally, we show the chemical sensing performance of these devices is comparable to that of OTFTs fabricated on rigid, planar substrates, with detection of cysteine and trinitrobenzene (TNB) down to 100 parts per billion.

The fabrication scheme for the flexible OTFTs is shown in Fig. 1. A previously reported polymer dielectric film, [9] poly(4-vinylphenol) (PVP) cross-linked with 4,4′-(hexafluoroisopropylidene)diphthalic anhydride (HDA), was deposited via spin-coating directly on the ITO surface at 3000 rpm and cured at 100 °C for 2 h, resulting in a film with a thickness of 35 nm and a capacitance of 115 nF/cm^2. Fig. 2B shows the atomic force micrograph (AFM) of the PVP–HDA surface with a surface roughness of 2.6 nm, moderately rougher than that reported on a planar surface. DDFTTF, an organic semiconductor demonstrating long-term stability in water, was thermally deposited on the cross-linked polymer film at a rate of 0.2–0.3 Å/s and a substrate temperature of 105 °C to a thickness of 30 nm. Top-contact electrodes were deposited on the semiconductor surface using two methods. Gold (40 nm) was deposited via thermal evaporation (1.0 Å/s) and PEDOT:PSS was deposited via selective wetting.

The surface energy of the organic semiconductor surface can be considerably modified as shown by a decrease in water contact angle (First Ten Angstroms FTA200 equipped with a CCD camera) upon UV-ozone exposure.

Without any treatment, the DDFTTF surface is very hydrophobic (112°), due to the vertically-aligned, densely-packed alkyl chains. After treating the organic semiconductor surface with UV-ozone for 12 min, the water contact angle decreases substantially from 112° to 23° (shown in Supporting information, figure S1), due to the complete removal of the alkyl chains. Using X-ray photoelectron spectroscopy (SSI S-Probe Monochromatized XPS Spectrometer, Al(ka) radiation (1486 eV)), we showed that a dodecyl silane monolayer is completely removed from a silicon oxide surface after 12 min (Supporting information figure S2).

The unique contrast in surface energy is the premise for the deposition of poly(3,4-ethylenedioxythiophene) poly(styrenesulfonate) (PEDOT:PSS) [25] via selective wetting. Immediately after UV-ozone exposure, the substrate with a patterned DDFTTF surface (with features varying from 50 μm to 400 μm) is briefly held in a solution vortex [26] of PEDOT:PSS (Baytron P, 1.2–1.4% aqueous solution, Bayer Corp.) diluted with water and ethylene glycol (EG) at a ratio of 47:47:6, 90:0:10, or 50:50:0 (Baytron P:water:EG). As the substrate is withdrawn from the solution, the contrast in surface energy results in the deposition of PEDOT:PSS solution on the regions previously exposed to UV-ozone. The substrates are then placed on a hot plate at 90 °C for 1 h to dry the film. The addition of ethylene glycol is known to lead to a significant increase
Fig. 2. (A) AFM images ($10 \times 10 \ \mu m^2$, phase left, height right) of the top-contact PEDOT:PSS electrode interface with DDFTTF. The line profile (red line in height image) shows good conformity of the PEDOT:PSS electrodes that are actually smoother than the top surface of the DDFTTF film. (B) AFM ($10 \times 10 \ \mu m^2$, height) of the PVP–HDA surface on an ITO/PET substrate.

in the conductivity of PEDOT:PSS films [27]. We found that ethylene glycol can either be directly added to the PEDOT:PSS formulation as described above or the sample can be subsequently treated by dipping it into ethylene glycol. In the latter case, the significant surface energy contrast between DDFTTF and the already deposited PEDOT:PSS electrodes leads to an exclusive wetting of the ethylene glycol on the PEDOT:PSS electrodes (Supporting information, figure S4). Both treatments resulted in a reduction of the surface resistivity of the PEDOT:PSS electrodes by several orders of magnitude (compared to untreated PEDOT:PSS electrodes) to values as low as 20 Ω/sq.

Atomic force micrographs (AFM) (Digital Instruments Nanoscope IV operated in tapping mode ($\sim$350 kHz frequency, Si tip)) images of the PEDOT:PSS electrodes on the DDFTTF surface are shown in Fig. 2A. The PEDOT:PSS makes a good, conformal contact with the surface of the DDFTTF film (see line profile, red line in height image), partially filling the pores on the top surface of the DDFTTF film. The resultant PEDOT:PSS electrode surface is therefore significantly smoother than the top surface of the DDFTTF film.

Aside from the top-contact gold electrodes, the resultant devices shown in Fig. 3 are both flexible and transparent, highlighting the advantageous properties of organic

materials. Fig. 3C and D show optical micrographs of PEDOT:PSS electrodes patterned on the semiconductor surface. While the DDFTTF surface was patterned with UV-ozone using a shadow mask with channel lengths (L) of 50 μm and 100 μm, and respective channel widths (W) of 1 mm and 2 mm for a W/L ratio of 20, the final electrodes had a W/L ratio ranging between 4 and 6 for $L = 50$ and 100 μm. As the solvent (water and ethylene glycol) evaporated, the polymer in solution was drawn to the center leaving slight remnants along the periphery of the UV-ozone treated regions while maintaining the defined L, shown by the light extensions of the electrodes in the images. The lighter regions of the electrodes, however, were not conductive. The feature size can potentially be reduced by stamping hydrophobic masks [28], for example, using a PDMS elastomeric template for dimensions down to 10 μm [29].

5,5′-Bis-(7-dodecyl-9H-fluoren-2-yl)-2,2′-bithiophene, DDFTTF, was chosen for the semiconductor layer based on its proven stability in ambient and water [9], thin-film transistor characteristics, and long alkyl side chains that promote molecular packing and water stability. Previously, we showed that thin evaporated films of DDFTTF grow perpendicular to the substrate with highly two-dimensional films promoted by the interactions between the alkyl side
Fig. 3. Digital photograph of an OTFT with PEDOT:PSS electrodes on black and white text (A) and a flexed OTFT with gold electrodes (B); optical micrographs of OTFTs with PEDOT:PSS electrodes with 50 μm (C) and 100 μm (D) channels. Panel C shows the device on a dark surface while D shows the device on a white surface, illustrating the transparency. Note that the electrodes are invisible when the light is focused on the substrate.

chains [30–32]. Additionally, it is well known that the charge transport occurs within the first 5 nm (in proximity to the dielectric) [33], therefore, the gentle UV-ozone surface modification of the film should not affect the transport properties, as shown in the following section.

OTFTs with top-contact gold and PEDOT:PSS were electrically characterized in ambient and water to determine their suitability for sensing in water environments. By incorporating a thin, cross-linked polymer gate dielectric, we were able to operate at gate and source-drain biases below 1 V. The OTFTs fabricated with gold electrodes ($W/L = 20$) on DDFTTF showed a mobility of 0.06 cm^2/Vs with an on–off ratio of 4×10^3. The rough ITO surface, and correspondingly rough dielectric surface, lead to the decreased electrical performance compared to using rigid, planar substrates. OTFTs fabricated with PEDOT:PSS electrodes ($W/L = 4$–6) performed comparable to those with gold electrodes with a mobility of 0.05 cm^2/Vs with an on–off ratio of 1.2×10^4. Although the performance of the two systems was quite similar, the OTFTs with PEDOT electrodes had a lower on-current due to the shorter electrode width from the solution deposition process. A slight increase in leakage current was observed for OTFTs on ITO/PET (3 nA at 1 V) as compared to devices on planar silicon substrates (0.2 nA at 1 V), both of which are much less than the source-drain current. The influence of bending on the OTFT performance for devices fabrication with small molecule organic semiconductors and polymer dielectrics has been reported previously [9,34,35], and we expect similar mechanical properties for these sensors.

Electrical characterization in water is performed by placing a droplet of deionized water across the entire electrode (channel) region. It was critical to reduce the source-drain bias (V_{DS}) to -0.6 V in order to limit the ionic conduction through water. The transfer characteristics of the OTFT

with gold electrodes are shown in Fig. 4A in ambient (black) and water (grey). The influence of water on the electronic properties is similar to that reported in a previous report, with a slight increase in the mobility (0.12 cm^2/Vs), positive threshold shift, and a reduction in the on–off ratio due to the finite ionic current through water. The output characteristics under water are shown in Fig. 4D. As mentioned above, a slight leakage current is observed as a result of using a thin insulating layer on a rough electrode surface. Similar plots for the OTFT with PEDOT:PSS electrodes are shown in Fig. 4C and D. Interestingly, only a small change in transfer characteristics is observed when exposing these devices to water. Other than an increase in the off-current, as previously discussed, and a marginal increase in mobility, the characteristics are nearly identical. This is most likely due to the fact that the semiconductor was previously exposed to water during the PEDOT:PSS deposition process.

We demonstrated chemical sensing by adding a small volume of analyte solution to a droplet of water spanning the source and drain electrodes. Based on the sensitivity to various analytes in a previous report, we investigated the influence of cysteine, trinitrobenzene (TNB), and pH on the OTFT performance. In the sensing trials, the source-drain and gate electrodes are continuously biased at -0.6 V (in the saturation regime), and a droplet of analyte solution is added after current stabilized (approx. 30–60 s). The relative drain current change, $\varDelta I_{DS} = I_{DS}/I_{DS-0}$ (I_{DS-0} is the drain current baseline before the analyte addition) is plotted versus time for each analyte system. We observed similar $\varDelta I_{DS}$ responses on the flexible ITO/PET substrates as we previously observed on silicon for cysteine solutions and pH [9], which was performed on OTFTs with PEDOT:PSS electrodes.

Top-contact OTFTs with PEDOT:PSS electrodes were covered in water (5 μl) and biased according to the condi-
Fig. 4. Fig. 5. (A) Optical micrograph of an OTFT under operation in water. (B) ΔI_{DS} of an OTFT with PEDOT:PSS electrodes when exposed to solutions of TNB with concentrations as low as 100 ppb, (inset) resistive current of PEDOT electrodes in air, water, and 100 ppb TNB solution. (C) ΔI_{DS} ($I_{DS}/I_{DSbaseline}$) when exposed to solutions of cysteine with various concentrations, (inset) relative saturation current change with concentration for OTFTs fabricated on silicon and ITO/PET substrates. (D) ΔI_{DS} with solution pH on ITO/PET substrates with PEDOT:PSS electrodes, (inset) ΔI_{DS} as a function of change in [H$^+$] concentration.

tions described. Fig. 5A shows the droplet of water spanning the channel region. After establishing a baseline, 2 μl of 300 ppb TNB was added to the droplet, and an increase in I_{DS} was observed. The same procedure was done using 3 parts per million (ppm) TNB, and the composite current characteristics are shown in Fig. 5B in the form of ΔI_{DS} versus time. A higher degree of noise relative to the signal is observed due to the contact between the gold wire probes and the soft, conducting polymer electrodes. Previously, we observed a decrease in current when the OTFTs (silicon substrates and gold electrodes) were exposed to TNB; however, with the polymer electrodes we observed an increase in current. To explain this, we measured the resistive current of the electrodes in water and in the saturated (300 ppb) TNB solution. Indeed, the conductivity of the electrodes increases by an average of 31% in the TNB solution due to a charge transfer between the analyte and conducting polymer [36,37], indicating, in this case, that a change in contacts plays a major role. Therefore, when using electrode materials, such as conducting polymers, that can dope and de-dope under specific solution conditions, it is important to consider the influence of the analyte on the electrode conductivity. In fact, the use of polymer doping/de-doping can be used to fabricate organic electrochemical transistors [38].

We also investigated the influence of pH on the polymer electrode conductivity since the conductivity has been shown to vary with acidity [39] or alkalinity [40]. However, we observed a change in resistive current of less than 3% when exposing the polymer electrode to solutions of pH 3 (based on HCl) and pH 11 (based on NaOH). Therefore, the ΔI_{DS} response was similar for OTFTs fabricated with gold and PEDOT:PSS electrodes (Fig. 5D). The inset shows a plot of ΔI_{DS} versus change in hydronium ion, H^+, concentration. It is important to note that the parasitic current between the S-D electrodes in negligible for the acidic or basic solutions under the bias conditions applied [9].

Fig. 5C shows the drain current response to solutions of cysteine with concentrations ranging from 0.1 ppm to 10 ppm. For comparison, the inset of Fig. 5C shows the concentration dependent OTFT drain current change (I_{DS} at saturation minus I_{DS} of the baseline, divided by I_{DS} of the baseline) for plastic and rigid substrates.

With the demonstration of chemical sensing using organic thin-film transistors fabricated on flexible substrates, we have taken a step toward the realization of low-cost, disposable sensors. In our fabrication process, we maintain the requirements of low input power and device stability in air and water environments. Our fabrication process relies on the simplicity of solution methods with the ability to deposit a polymer insulating layer and patterned polymer electrodes from solution without damaging the organic semiconductor or plastic substrate. However, consideration must be given to the choice of electrode material, which can potentially influence the OTFT response toward certain analytes.

Fabrication of high efficiency and color stable white organic light-emitting diodes by an alignment free mask patterning

Kyoung Soo Yook, Soon Ok Jeon, Chul Woong Joo, Jun Yeob Lee *

Department of Polymer Science and Engineering, Dankook University, Jukjeon-dong, Suji-gu, Yongin-si, Gyeonggi-do, Seoul 448-701, Republic of Korea

ABSTRACT

Small molecule based white organic light-emitting diodes were fabricated by using an alignment free mask patterning method. A phosphorescent red/green emitting layer was patterned by a metal mask without any alignment and a blue phosphorescent emitting layer was commonly deposited on the patterned red/green emitting layer. A white emission could be obtained due to separate emission of red/green and blue emitting layers. A maximum current efficiency of 30.7 cd/A and a current efficiency of 26.0 cd/A at 1000 cd/m^2 were obtained with a color coordinate of (0.39, 0.45). In addition, there was little change of emission spectrum according to luminance because of balanced red/green and blue emissions.

1. Introduction

White organic light-emitting diodes (WOLEDs) have attracted great attention from many researchers for their application as a display and a general lighting. WOLEDs have advantages over red, green and blue pattered device such as a simple process and the ease of fabrication. However, WOLEDs suffer from low efficiency, color shift at high luminance and poor color stability.

There have been many studies to develop WOLEDs with a high efficiency and a good color stability. A red, green and blue stacked structure [1–9] and a single layer emitting structure doped with red, green and blue dopants were reported [10–13]. The stack structure has a merit of high efficiency and good color stability, while the single layer emitting structure has a problem of poor color stability even though high efficiency can be obtained. Other than the stacked and single layer mixed structures, a color converting structure has also been developed to get white

emission using a blue emitting layer and color converting materials [14,15]. Another method to realize white devices is to use a single white emitting material which can emit red, green and blue colors [16–18].

In the case of common WOLED structures, it was difficult to manage the light emission from each color because RGB materials are included in a single layer or in a single stack structure. In addition, color stability could not be obtained because there was an exciton movement or charge leakage between emitting layers depending on the luminance of the device [1]. These problems can be overcome by designing a device structure with separated RGB or RB regions [19].

A combination of RGB separate emission and a diffuse film was effective to get white emission and white color could be easily controlled by managing the luminance of each RGB pixel. However, each RGB pixel had to be precisely patterned to get controlled white emission. The RGB patterning by a fine metal mask after mask and substrate alignment was required. Although a high efficiency and controlled light emission could be obtained from the device, the device fabrication process was complicated due to mask alignment process.

In this work, a simple device fabrication method which can achieve controlled white emission without any mask alignment process was developed. A separate emission without any mask alignment can be achieved by a device structure with a patterned red/green layer and a common blue layer. The common blue layer would be stacked on the patterned red/green emitting layer in some region and it will exist as a blue single layer in the region without the red/green layer. The blue layer can play a role of hole blocking layer of the red/green emitting layer and the device performances of red/green and blue emitting layers can be separately managed. Three color devices could be fabricated by the method and stable white device performances were demonstrated from three color white devices.

2. Experimental

One pixel in this work was patterned by metal mask and it had red and blue emitting units. Red emitting region had a stack structure of indium tin oxide(ITO, 150 nm)/poly-3,4-ethylenedioxythiophene:polystyrenesulfonate(PEDOT:PSS, 60 nm)/ N, N′-di(1-naphthyl)-N,N′-diphenylbenzidine(NPB, 10 nm)/ 4,4′,4″-tris(N-carbazolyl)triphenylamine(TCTA, 10 nm)/N, N′-dicarbazolyl-3,5-benzene(mCP, 10 nm)/TCTA:3-phenyl-4-(1′-naphthyl)-5-phenyl-1,2,4-triazole (TAZ): iridium(III) tris(2-phenylpyridine)(Ir(ppy)$_3$):iridium(III) bis(1-phenylquinoline) acetylacetonate(Ir(pq)$_2$-acac)(20 nm, 10%, 1%)/2-diphenylphosphorylspirofluorene(SPPO1): iridium(III) bis(4,6-(di-fluorophenyl)-pyridinato-N,C2′) picolinate (FIrpic) (30 nm, 15%)/4,7-diphenyl-1,10-phenanthroline(Bphen, 5 nm)/tris(8-hydroxyquinoline) aluminum(Alq$_3$, 20 nm)/LiF (1 nm)/Al (200 nm). Blue emitting region had a structure of ITO/PEDOT:PSS(60 nm)/NPB(10 nm)/TCTA(10 nm)/mCP(10 nm)/SPPO1:FIrpic(30 nm, 15%)/Bphen(5 nm)/Alq$_3$(20 nm)/LiF(1 nm)/Al(200 nm). Pixel size was 2 mm by 2 mm and the open width of stripe type metal mask was controlled to investigate the effect of the emitting area of red/green and blue colors on the device performances of pixel divided white devices. Two devices with different relative emitting area were fabricated. Relative emitting areas of red/green to blue were 1:1(device I) and 2:1(device II). Current density–voltage–luminance characteristics and electroluminescence (EL) spectra of PHOLEDs were measured with Keithley 2400 source measurement unit and CS 1000 spectrophotometer.

3. Results and discussion

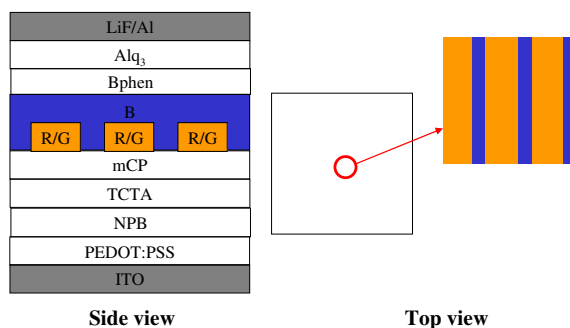
It is required to use hole blocking type blue phosphorescent emitting layer to get high efficiency and pure red/green emission in red/green emitting layer [20]. Therefore, a new electron transport type blue phosphorescent host material based on spirofluorene and phosphine oxide was synthesized. The 2-(diphenylphosphoryl)spirofluorene (SPPO1) was synthesized by the reaction of diphenylphosphonylchloride with 2-bromospirofluorene followed by oxidation with H$_2$O$_2$. The SPPO1 had a triplet bandgap of 2.8 eV and the highest occupied molecular orbital (HOMO) level of 6.5 eV. The HOMO level was deep enough for effec-


Fig. 1. Schematic diagram of the pixel structure.

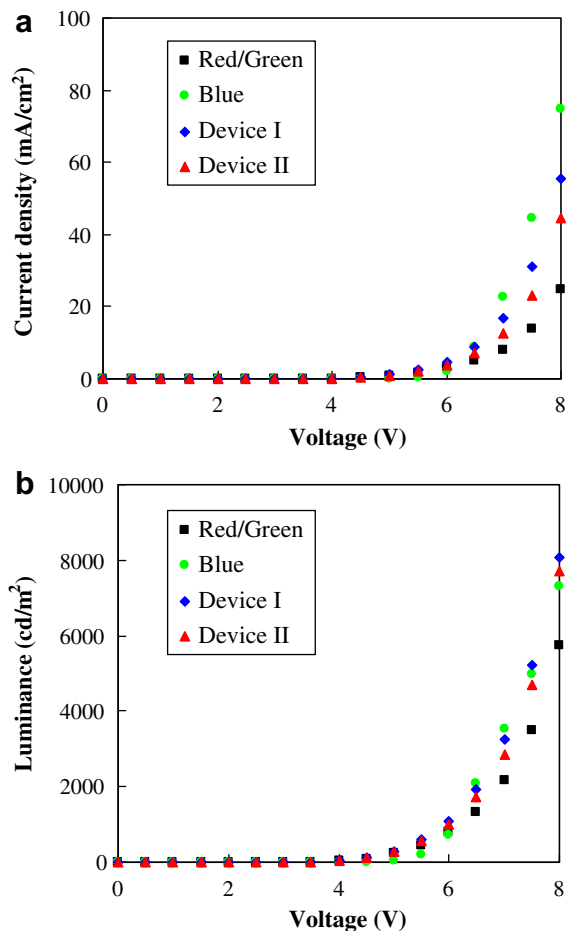
tive hole blocking and the triplet energy of SPPO1 was wide enough for efficient energy transfer to FIrpic with a triplet bandgap of 2.6 eV. Therefore, the FIrpic doped SPPO1 layer can play a role of hole blocking layer on red/green emitting layer. Schematic diagram of the pixel structure is shown in Fig. 1. The relative area of the red/green emitting region was 50% in device I, while it was 66% in device II.


Fig. 2. Current density–voltage and luminance–voltage curves of red/green, blue and white devices. (a) Current density–voltage and (b) luminance–voltage.

Standard devices with red/green emitting layer and blue emitting layer were also fabricated in addition to the white device with divided red/green and blue pixel region. Fig. 2 shows the current efficiency–voltage and luminance–voltage curves of red/green, blue and two white devices. The current density was high in the blue device, while red/green device showed the lowest current density. The low current density in the red/green device can be explained by the thickness of red emitting layer. Total thickness of the emitting layer in the red/green device was 50 nm compared with 30 nm of the blue device, resulting in low current density. The white devices showed an intermediate current density value of red/green and blue devices. The current density was high in the device with large area for blue emission because of high current density in the blue device. The luminance of the devices also followed the same trend as current density.

Quantum efficiency and current efficiency of the red/green, blue and white devices are shown in Fig. 3. The red/green device with blue emitting layer stacked on red/green emitting layer showed a quantum efficiency of 12.6% and a current efficiency of 28 cd/A at 1000 cd/m^2. Compared with the red standard device without the blue emitting layer, the efficiency was not degraded. The similar efficiency of the red/green device may be due to hole blocking properties of the SPPO1 with the HOMO level of

6.5 eV. The blue standard device showed a quantum efficiency of 13% and a current efficiency of 29 cd/A at 1000 cd/m^2. The SPPO1 can be a good host material for FIrpic because of a wide triplet bandgap of 2.8 eV and a wide singlet bandgap of 3.8 eV. An exothermic energy transfer can be induced by using the SPPO1 host and a high quantum efficiency of 12% was obtained. The white device showed a little lower quantum efficiency value than red/green and blue devices. A maximum current efficiency of 30.7 cd/A and a current efficiency of 26 cd/A at 1000 cd/m^2 were achieved in the white device II. Relative area of the red/green emitting region to blue emitting region in the white pixel affected the efficiency of the white device and high efficiency was observed in the device II with larger red/green emitting area compared with blue emitting area. This is due to a rather large efficiency roll-off and high current density of the blue device. Local current density is high in the blue emitting region due to high current density through blue emitting layer (Fig. 2). The blue emitting region contributes to the efficiency of the white device and the luminance of the blue emitting region is relatively high compared with that of red emitting region. Therefore, the luminance of the blue emitting region is higher than 1000 cd/m^2 even at 1000 cd/m^2 white emission in the pixel. In the case of the blue emission, a rather large efficiency roll-off was observed, leading to relatively low quantum efficiency in the white device. The quantum efficiency was increased as the relative area of blue emitting region was decreased because of less contribution of the efficiency roll-off behavior on the white emitting characteristics.

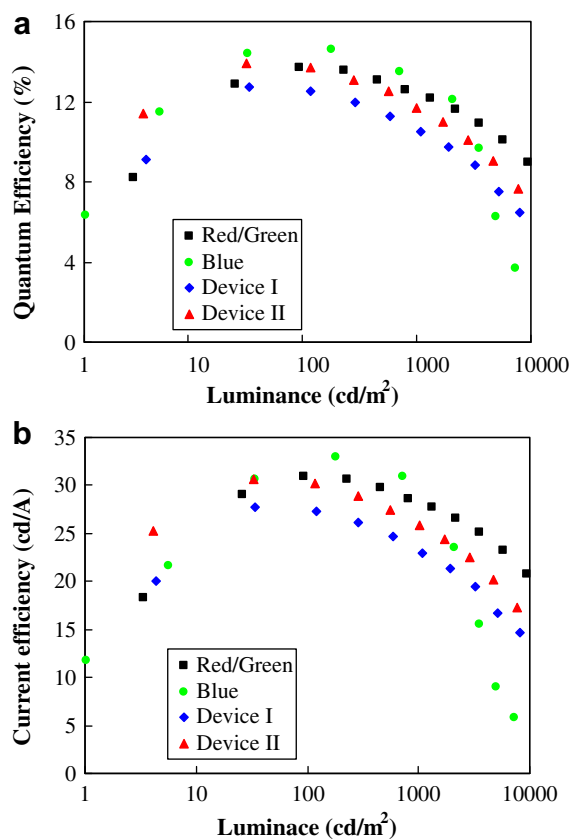
Fig. 4 compares EL spectra of red/green, blue and white devices. The red/green device showed a red/green emission with little blue emission from the blue emitting layer stacked on the red/green emitting layer. This indicates that most excitons are generated inside the red/green emitting layer and the blue emitting layer does not contribute to the red/green light emission. The blue layer just acts as a hole blocking layer even though there is a little hole leakage through FIrpic in the blue emitting layer. The HOMO level of SPPO1 is suitable for hole blocking and holes cannot be injected from red/green emitting layer to SPPO1 layer. Therefore, red/green emission with little blue emission


Fig. 3. Quantum efficiency and current efficiency of red/green, blue and white devices. (a) Quantum efficiency–luminance and (b) current efficiency–luminance.
Fig. 4. Electroluminescence spectra of red/green, blue and white devices.
Fig. 5. Electroluminescence spectra of white organic light-emitting diodes according to luminance. (a) Device I and (b) device II.

was observed from the red/green emitting layer. In the case of blue device, only blue emission from FIrpic doped SPPO1 layer was observed. The blue device showed a peak maximum at 474 nm and a strong shoulder at 499 nm which is overlapped with green emission peak of the red/green device. The white device showed both red/green and blue emissions because it had red/green emitting region and blue emitting region. The relative intensity of the red/green and blue emissions were dependent on the relative area of the red/green and blue emitting region and the blue emission was strong in the device with large area for blue emission. Color coordinate of device I was (0.33, 0.43), while the color coordinate of device II was (0.38, 0.45). More blue emission was observed in device I due to large blue emitting area.

One merit of using the patterned pixel structure for white light emission is the color stability through independent red/green and blue emissions. The red/green and blue emissions are separate, which makes it easy to keep good color stability in the device. Fig. 5 shows the EL spectra of device I and device II according to luminance. The EL

spectra were not greatly changed within the luminance range from 100 to 5000 cd/m^2. The white device with the patterned pixel structure does not have the problem of exciton leakage or charge leakage through the interface between emitting layers in common stacked white devices. Detrapping of charges in a single layer white device is also not observed in this patterned pixel structure, resulting in constant EL spectra irrespective of luminance. The color coordinate of the device I was (0.35, 0.44) at 100 cd/m^2 and it was (0.34, 0.44) at 5000 cd/m^2. The color coordinate was kept stable even at 10,000 cd/m^2 and it was (0.35,0.45). Similar data were obtained in the device II and the color coordinate was changed from (0.40, 0.45) to (0.38, 0.45) by changing luminance from 100 to 5000 cd/m^2. It was (0.39,0.46) at 10,000 cd/m^2.

4. Conclusions

In summary, a white device with patterned red/green and blue region inside a pixel was effectively fabricated by using a fine metal mask without any alignment. Red/green and blue emissions were independently controlled in a single pixel and good color stability was observed. A high current efficiency of 30.7 cd/A was achieved in the white device with a color coordinate of (0.39, 0.45).

ARTICLE INFO

ABSTRACT

For efficient hole-extraction in solution processed organic solar cells the transparent indium-tin oxide (ITO) electrode is invariably pre-coated with a thin layer of the high work function conducting polymer poly(3,4-ethylenedioxythiophene) doped with poly(styrene-sulfonate). Herein we show that thin films of partially oxidised multi-wall and single-wall carbon nanotubes are equally effective at facilitating hole-extraction in efficient ($\sim$2.7%) bulk-heterojunction organic solar cells based on poly(3-hexylthiophene) (P3HT): [6,6]-phenyl-C_{61} butyric acid methyl ester (PCBM) blends. Crucially, in contrast to PEDOT:PSS, deposition is from aqueous solutions of low acidity (pH 6–7) ensuring compatibility with ITO and other emerging conducting oxides. Furthermore, thin oxidised carbon nanotube films offer greater transparency in the near-infrared as compared to PEDOT:PSS films of comparable thickness. The functionality of these nano-structured films is demonstrated in relatively large area devices ($\sim$0.35 cm^2) and the performance rationalised based on measurements of the electronic structure and morphology.

1. Introduction

Organic solar cells (OSCs) [1] have strong potential as a low cost path to harvesting electrical energy from sunlight and in recent years a great deal of progress has been made in the search for low cost, transparent and flexible substrate electrodes for this application [2,3]. One particularly promising material system is that of carbon nanotube (CNT) films, which can be prepared by filtration [3a–f], densification of nanotube yarns [4a,b] or spraying [5], although it is yet to be seen which processing technology will dominate. Whilst the electrical conductivity of these

films is far below the axial conductivity of individual CNTs it is now approaching that of commercial ITO glass for comparable transparency (i.e. <100 Ω/sq at >80% transparency) [3f]. With the exception of the pioneering work of Zhang et al. [4], which pertains to the densification of dry CNT yarns, all other processing methods involve deposition from relatively dilute dispersions typically achieved using a surfactant to de-bundle and solubilise the CNTs without damaging their highly conductive graphitic structure. In the context of OSC applications optimal performance is only realised when the CNT electrode is coated with a thin layer of the high work function [6] conducting polymer poly(3,4-ethylenedioxythiophene) doped with poly(styrenesulfonate) (PEDOT:PSS) which reduces the sheet resistance [3d] and planarizes [3e] the porous CNT film.

OSCs fabricated on CNT electrodes without PEDOT:PSS were reported by Lagemaat et al. to exhibit inferior open-circuit voltage (V_{oc}) and short-circuit current density (J_{sc}) as compared to devices employing PEDOT:PSS [5]. Notably, the work function of the pristine CNTs in that work, whilst comparable to ITO glass, was lower than that of PEDOT:PSS. Consequently, optimal alignment of the electrode Fermi level with the highest occupied molecular orbital (HOMO) of the adjacent donor material was unlikely to be realised.

Thin films of PEDOT:PSS are widely regarded as efficient hole-extracting layers (HELs) in OSCs, combining a high work function, good optical transparency, high electrical conductivity and ease of processing from solution [6,7]. The primary drawback of PEDOT:PSS is its acidity, which is believed to etch the surface of ITO liberating oxygen and metal ions which contaminate the adjacent photoactive organic layer to the detriment of device performance [8a–c]. In this paper we show that thin films of both multi-wall and single wall carbon nanotubes (MWCNTs and SWCNTs, respectively) that have been extensively oxidised via acid treatment to render them soluble in water, are as effective as PEDOT:PSS for hole-extraction in efficient archetypal OSCs based on poly(3-hexylthiophene) (P3HT): [6,6]-phenyl-C_{61} butyric acid methyl ester (PCBM) blends supported on ITO glass. The monochromatic internal quantum efficiency of OSCs employing PEDOT:PSS in conjunction with P3HT:PCBM photoactive layers is reported to be as high as ∼90% at optimum wavelengths [7a] making this material system an excellent benchmark against which other HELs can be compared [9]. Importantly, in this study both PEDOT:PSS and acid oxidised CNT films were supported on ITO glass to ensure that the bulk conductivity of the transparent electrode was the same in all devices. Care was also taken to ensure that the different HELs were of comparable transparency across the range of wavelengths over which P3HT-PCBM absorbs light (400–675 nm) [7b] and that the photoactive layer thickness was the same in all devices. In this way differences in the performance of OSCs employing different HELs could be decoupled from variations in the transparency and conductivity of the substrate electrode and rationalised solely in terms of their respective electronic structure and morphology.

2. Experimental

MWCNT (>90 wt.%) and SWCNT (>90 wt.%) grown by chemical vapour deposition were obtained commercially (Nanocyl) and used as received. Stable dispersions of SWCNTs and MWCNTs in de-ionized water were prepared by ultrasonically dispersing CNT in a 3:1 mixture of concentrated sulphuric and nitric acids for ten minutes. The mixture was refluxed at 130 °C for 60 min or 25 min for MWCNT and SWCNT respectively, before diluting with HPLC grade de-ionized water. The very low pH of the resulting solution destabilizes the CNTs causing them to flocculate. To accelerate this process the dispersion was centrifuged and the acid supernatant decanted off. The remaining solid was repeatedly washed with de-ionized water over a 50 nm polycarbonate filter until the washings were pH 6–7. Before allowing the oxidised nanotubes to dry the entire filter paper was submerged in a small quantity of de-ionized water whereupon they spontaneously disperse to form a concentrated dispersion. The resulting dispersion was centrifuged to remove residual aggregates. In order to determine the actual CNT loadings in solution a sample of known volume was completely dried and weighed. The resulting black solutions required no further preparative treatment and were stable for >6 months.

CNTs were characterized using a Philips CM200 ST transmission electron microscope (TEM) with a LaB_6 filament and 200 kV accelerating voltage. Transmission spectra were obtained using a UV-Vis Varian Cary 5000 UV-Vis-NIR spectrometer. The XPS measurements were carried out in an Omicron multi-probe system, with a base pressure in the 10^{-10} mbar range. The analysis chamber was equipped with a ThermoVG XRE32 twin anode X-ray source and an Omicron EA 125 electron energy analyser. The XPS was measured using the Mg k (1256.3 eV) anode of the source operated at 300 W with a 6mm circular diameter analyser entrance slit and electron pass energy of 20 eV. The zero of the binding energy scale of the XPS is such that the Au 4 $f_{7/2}$ peak is at 83.9 ± 0.1 eV. Field-emission scanning electron microscopy imaging was conducted with a Zeiss SUPRA 55-VP using an accelerating voltage of 500–600 V. Atomic force microscope (AFM) measurements were made using a Dimension 3100 AFM under ambient conditions. Raman scattering spectra were obtained using a Renishaw Raman Scope 1000 and laser excitation wavelength of 785 nm. Kelvin probe measurements performed in air were referenced to freshly cleaved highly orientated pyrolytic graphite (HOPG). Thick CNT films (>1 micron) were used for the work function measurements to ensure no contribution from the underlying substrate. Sheet resistance measurements of o-CNT and PEDOT:PSS films were made on glass microscope slides of comparable roughness and hydrophilicity to ITO glass using the four point probe method.

Devices were fabricated on ITO coated glass (PsiOTec) with a nominal sheet resistance of 15 Ω sq^{-1}. The ITO substrates were cleaned using a three stage ultrasonic cleaning procedure: toluene; an aqueous solution of Decon-90; and acetone. Immediately prior to use the ITO substrates were oxygen plasma treated. o-SWCNT or o-MWCNT films were prepared by the drop-then-spin method with a spin speed of 2250 r.p.m. onto clean ITO substrates followed by heating at 120 °C in air for 20 min to remove residual water. The drop-then-spin method, which is widely used for PEDOT:PSS, ensures a high degree of uniformity of large areas. Conductive grade (1 S/cm) 1.3 wt% dispersion of PEDOT (0.5 wt.%):PSS (0.8 wt.%) in water was spin cast at 6000 rpm prior to baking at 120 °C for 20 min in air. Poly(3-hexylthiophene): [6,6]-phenyl-C_{61} butyric acid methyl ester blends in dichlorobenzene with loadings 20 mg ml^{-1} each were spin cast onto substrates at 600 r.p.m. and allowed to dry in an open Petri-dish in a nitrogen filled glove-box for 20 min. The P3HT:PCBM coated substrates were heated at 110 °C in a nitrogen atmosphere for 10 min to remove residual solvent before transferring to a vacuum system. The thickness of

the P3HT:PCBM layer was measured directly using a Dektak profilometer to be 210–230 nm. The electron extracting electrode, comprising a 10 nm calcium layer followed by 80 nm aluminum was deposited at $<10^{-5}$ mbar with deposition rates of 0.1 nm s^{-1} and 0.3–4 nm s^{-1}, respectively. The thickness of the evaporated layers was monitored using a calibrated quartz crystal microbalance. The photoactive device area was ~35 mm^2. Devices were tested using an Oriel solar simulator under AM 1.5 G spectral illumination of 100 mW cm^{-2} (1 sun). The output power of the simulator was measured using an NREL calibrated silicon reference cell. All measurements were made in the air immediately after device fabrication.

3. Results and discussion

Treatment of CNTs using nitric [10] or hydrochloric acid [10,11] under relatively mild conditions is an established method for removing metal catalyst particles without altering CNT dimensions. Conversely, sulphuric acid is known to shorten CNTs via scission of the sidewalls and ends and so is not normally used as part of a purification procedure [12]. Both of these treatments introduce oxygen containing groups at pre-existing or new defect sites, which – crucially for the current application – help to increase the solubility in water. When nitric and sulphuric acids are used together at elevated temperature (70–130 °C), oxidation and chopping proceed rapidly, decorating the CNT ends and sidewalls with a high concentration of oxygen containing groups which render the CNTs highly soluble in water and alcohols. In this work the oxidation procedure has been optimised to strike a balance between achieving stable concentrated dispersions of CNTs via surface oxidation and the requirement to maintain the integrity of the tubular structure.

Acid oxidation of CNTs is known to result in the formation of oxygen containing moieties, including CO– (e.g. alcohol, ether), C=O (e.g. aldehyde, ketone) and COO– (e.g. carboxylic acid, ester) [13]. Using X-ray photoelectron spectroscopy (XPS) (Fig. 1) and high-resolution transmission electron microscopy (HRTEM) (Supporting information) we have studied the effect of the acid treatment described herein on MWCNTs with diameters ~10 nm. The relative proportions of these groups based on atomic percentages determined from peak fitting to the C1 s XPS peak are 5:4:8, making COO– the most abundant moiety. From this data it is possible to estimate the COO– density to be 3–4 nm^{-2}, or 7.3×10^{20} -9.7×10^{20} sites/g of MWCNTs, which is in excellent agreement with the value of 7.6×10^{20} sites/g determined by titration of acid oxidised MWCNTs with NaOH. [14] Furthermore, only the outer 2–3 layers were appreciably modified by the acid treatment – determined by HRTEM (Supporting information) – and so the oxygen containing moieties are essentially confined to the MWCNT surface.

In SWCNTs all constituent atoms are located at the CNT surface and so defects formed in the side walls tend to propagate, chopping the SWCNT into shorter lengths [12,15a,b]. As a result the oxygen containing groups are believed to be concentrated at the ends of acid oxidised SWCNTs [12,15a,b]. The increased susceptibility of SWCNTs to oxidation required that the oxidation time be reduced from 60 min for MWCNTs to 25 min for SWCNTs. After treatment with acid there was no trace of residual metal catalyst using energy dispersive X-ray analysis. To probe the effect of acid oxidation on the SWCNTs Raman scattering (Fig. 2) was employed in conjunction with HRTEM (Supporting information).

In the low frequency region of the Raman spectrum radial breathing modes (RBM) in resonance with the laser photon frequency can be probed to obtain information about the tube diameters present [16]. In this case there are numerous peaks, some of which appear as shoulders on more intense neighbours corresponding to contributions from SWCNTs of different radii. The relationship between SWCNT diameter (d_t) and the RBM frequency is
Fig. 1. C1s XPS spectrum of o-MWCNT. Dots correspond to experimental data points and dashed/solid lines are fitting to curves.
Fig. 2. Raman spectra of single-walled carbon nanotubes before and after acid oxidation using 785 nm laser excitation.

given by d_t(nm) $\sim$223.7 cm^{-1}/ω_{RBM} from which the diameter range present is estimated to be 0.8–1.5 nm [16]. Using a Kataura plot [17], which relates the SWCNT diameter to the electronic transition energies calculated using the first-neighbour tight binding method, it is possible to assign o-SWCNT diameters in the ranges 0.8–1.1 nm and 1.2–1.5 nm to semiconducting and metallic respectively. Assuming a transfer integral of 2.9 eV and a carbon-carbon distance of 0.142 nm, the energy gap between the valence and conduction bands (E_g) in the semiconducting SWCNTs present ranges between $\sim$0.8–1.0 eV. Notably the Raman modes of metallic tubes are broadened by the interaction with free electrons, whilst the lines for semiconducting tubes should have a Lorentzian profile, making the latter easier to resolve. Such a large diameter distribution is not unexpected for SWCNTs grown by chemical vapour deposition (CVD) since the CNT diameter is to a large extent determined by the catalyst size, which is difficult to control on the nanometre scale. Upon acid oxidation some RBM peaks increase in intensity whilst others decrease. These changes can be attributed to changes in the degree of bundling and inter-tube contact area and/or the effect of chemical functionalisation which cause tubes with different radii to come into resonance with the laser photon frequency whilst others move away [18].

Raman scattering is also an effective probe of disorder in sp^2 carbons such as graphene [19] and CNTs. The band characteristic of well ordered graphite ($E_{2\,g} \sim 1582$ cm^{-1}) is split into a number of components in the spectrum of CNTs due to their cylindrical symmetry [18]. Disorder appears as a broad band at $\sim$1300 cm^{-1} (D-band) and is activated by any change in the periodicity of the sp^2 network such as missing carbon atoms or surface functionality resulting from chemical treatment. In Fig. 2 it is evident that the relative intensity of the D band is fractionally increased, broadened and up-shifted upon acid oxidation consistent with a decrease in structural order resulting from the incorporation of oxygen containing moieties into the sp^2 lattice. The G band is also slightly up-shifted consistent with previous reports pertaining to the effective of electronegative functionality on the Raman spectra of SWCNTs [20]. Throughout the remainder of this paper, SWCNTs and MWCNTs acid treated according to the protocol reported herein will be abbreviated as o-SWCNT and o-MWCNT, respectively.

An important property of CNTs for OSC and OLED applications is their work function, since the difference between the CNT Fermi level and the relevant energy level of charge carriers in an adjacent organic semiconductor sets the barrier for injection or extraction. Table 1 gives the work function of o-SWCNT, o-MWCNT, PEDOT:PSS and ITO glass

cleaned according to the procedure described herein, measured using the Kelvin probe method. These measurements are referenced to freshly cleaved HOPG [21]. Importantly, since the Kelvin Probe method measures the spatial average of the work function, the values for o-MWCNT and o-SWCNT given in Table 1 were made on relatively thick (>1 μm) films supported on non-conducting glass substrates, ensuring that the underlying substrate did not contribute to the measurement. Notably, the work function of the same films supported on ITO glass was identical to that on plain glass, verifying the credibility of the measurement [22].

The work function of PEDOT:PSS coated ITO glass is entirely consistent, within the experimental error, with that recently reported in the literature [23]. The work function of o-MWCNT is $\sim$0.5 eV higher than that of HOPG (4.475 eV) [21] and of untreated MWCNTs [13]. We consider that such a large increase is due to modification of the CNT surface potential by the high density of electronegative oxygen containing moieties which decorate the outermost layers only, since MWCNTs are essentially metallic in nature [13] and the inner walls remain intact. The work function of o-SWCNTs ($\sim$5.06 eV) is slightly higher than that reported for untreated SWCNT (4.7–4.9 eV) [13,24]. However, since in SWCNTs all constituent atoms are located at the CNT surface the interpretation of the increase in work function is more complex than in the case of o-MWCNTs. We attribute the observed increase in work function to a lowering of the Fermi level in the semi-conducting SWCNTs due to p-type doping by the electronegative oxygen containing moieties formed upon acid treatment.

For application in OSCs thin films of o-SWCNTs and o-MWCNTs were prepared by the drop-then-spin casting method onto ITO glass from 2.7 mg ml^{-1} dispersions. The nanotube film thicknesses – determined by the dispersion concentration and spin speed – were selected to ensure that their transparency, thickness and conductivity was comparable to that of PEDOT:PSS films typically used in OSCs. The film thickness was measured directly using an AFM by carefully scoring films with a moist probe without scratching the underlying ITO (Fig. 3a). Notably, from the cross-section it is evident that the narrow strips between channels (A and C) have the same peak-to-peak roughness as the step edge of the widest channel (D), evidence that nanotubes are removed by the probe rather than displaced to the edges which would otherwise artificially increase the step height at the edge of the channel. The effective thickness of both films, based on the peak-to-peak roughness, was $\sim$30 nm. SEM images of o-SWCNT and o-MWCNT films drop and spin cast onto ITO glass are shown in Fig. 3b and c. These images are representative of a number of measurements at different sites on a number of different samples, from which it can be concluded that the films are uniform and relatively dense because the distinctive polycrystalline surface of the underlying ITO glass is not evident. Upon close inspection it is clear that both films comprise dense mats of entangled individual CNTs, with the difference in density reflecting the difference in nanotube dimensions.

Fig. 4a shows the transparency of the PEDOT:PSS, o-MWCNT and o-SWCNT coated ITO glass substrates. In all

Table 1
Summary of work function measurements made of commercial ITO (100 nm) on glass, PEDOT:PSS ($\sim$45 nm) on ITO glass, and thick films (>1 μm) of o-SWCNT and o-MWCNT films on plain glass using the Kelvin probe method referenced to freshly cleaved HOPG [21].

	ITO glass	PEDOT:PSS	MWCNT (oxidised)	SWCNT (oxidised)

cases the substrates were illuminated from the glass side, as is the case in an OSC. The highlighted region is that over which P3HT:PCBM absorbs light, from which it can be seen that, to a good approximation, the same photon flux is incident on the photo-active layer in all devices. It is clear from Fig. 4 that the oxidised CNT films have greater transparency at near infra-red wavelengths (>700 nm) at which a significant proportion of the terrestrial solar spectrum is located. This would prove to be a distinct advantage for the growing body of photoactive materials that harvest light in the near infrared, although this is not the case for P3HT:PCBM.

With improvements in the recorded efficiency of OSCs, the requirement to measure these values accurately has become increasingly important. A number of leading research groups have highlighted common sources of error when measuring device efficiency [25,26]. Arguably the greatest potential source of error relates to the accurate measurement of device area owing to shadowing [25] and edge effects [26] particularly when the device area is very small. The vast majority of reports in the literature pertain to devices with areas $\leqslant 0.1$ cm^2. In this study we have taken care to minimise these errors by both increasing the device area to ~0.35 cm^{-2} and by masking off the edges of the device with a mat black mask to minimise edge effects. Furthermore, the calcium/aluminium electron extracting electrode was deposited using a rotating substrate stage to eliminate shadow effects. Devices were tested under standard test conditions of 100 mW cm^{-2} AM1.5 G irradiance using an NREL traceable calibrated silicon solar cell.

In order to draw meaningful conclusions from a direct comparison of the performance of OSCs employing different hole-extracting electrodes it is critical to have knowledge of any difference in the thickness or roughness of the photoactive organic layer between cells employing different electrodes. The thickness of the photoactive layer can depend on properties of the substrate surface such as hydrophilicity and surface roughness particularly when deposited using the spin coating method. In this case the thicknesses of the P3HT:PCBM films deposited under identical conditions on ITO, ITO/PEDOT:PSS, ITO/o-MWCNT and ITO/o-SWCNT were 246 ± 15 nm. A thickness variation of ±15 nm across different samples with the same substrate electrode is consistent with that previously reported by Li et al. [27] using identical deposition procedure. The peak-to-valley roughness of P3HT:PCBM films deposited using the slow dry method employed herein is known to be ~100 nm, which corresponds to ~50% of the mean film thickness [27]. The peak-to-valley roughness of P3HT:PCBM films deposited on PEDOT:PSS, o-SWCNT and o-MWCNT films in this work was ~100 nm, and fractionally smaller, ~70 nm, on the virgin ITO glass substrate. This small difference, combined with the fact that these features are much smaller than the wavelength of visible light, make it unlikely that any significant differences in device performance can be attributed to variations in the extent to which light is scattered by the reflective back contact.

The OSCs employing a PEDOT:PSS HEL at the interface between the ITO electrode and bulk-heterojunction exhibit increased open circuit voltage (V_{oc}), short circuit current

(J_{sc}) and fill factor (FF) as compared to ITO alone (Fig. 5: V_{oc} = 0.61 V *vs.* 0.57–0.60 V; J_{sc} = 6.8–7.3 mA cm^{-2} *vs.* 6.3–6.6 mA cm^{-2}; FF = 0.61–0.62 *vs.* 0.5–0.55). The V_{oc} of devices employing o-MWCNT or o-SWCNT HELs was identical to that of devices using PEDOT:PSS and fractionally larger than in devices employing plasma cleaned ITO glass alone.

Whilst the factors that determine V_{oc} in OSCs are not yet fully understood this result indicates that V_{oc} is weakly dependent on the positive contact (cathode) work function and that the optimal value lies between that of ITO (4.73 eV) and PEDOT:PSS (4.94 eV) which correlates with the ionisation energy of P3HT (4.65–4.85 eV) [28]. Interestingly, in the simplest case where the vacuum level is aligned across the interface (i.e. in the Schottky-Mott limit) there would be a modest barrier ($\geqslant 0.2$ eV) to hole-extraction by o-MWCNTs and o-SWCNTs, which would be expected to deteriorate device performance as compared to OSCs employing PEDOT:PSS or plasma cleaned ITO alone. Clearly, this is not the case and so the simplistic assumption of vacuum level alignment across the interface between oxidised CNTs and P3HT is unlikely to be valid. In cases where the work function of the HEL is higher than the ionisation energy of P3HT and when the former has accessible states above the Fermi level (as in the case of o-MWCNTs and metallic o-SWCNTs) ground state charge transfer from the HOMO of P3HT to the HEL is expected [29]. The effect of such charge transfer across the interface would be to pin the electrode Fermi level close to the P3HT HOMO level [29], thus removing any energy barrier to hole extraction that would otherwise exist across interfaces with o-SWCNT or o-MWCNT. The implication for device performance of such an interaction would be an insensitivity of V_{oc} to the work function of the hole-extracting electrode for HELs having work functions equal to or greater than the ionisation energy of P3HT, which is observed to be the case.

In bulk-heterojunction OSCs free carriers are generated throughout the light absorbing organic layer and so charge carrier extraction is primarily driven by the built-in
Fig. 5. Typical current–voltage characteristics of OSCs incorporating various HELs at the ITO/P3HT:PCBM interface under one sun (AM1.5 G) irradiance. Inset: Schematic energy level diagram depicting pinning of the Fermi level of o-MWCNT and o-SWCNT to the HOMO of P3HT as a result of a ground state charge transfer interaction.

electric field that results from asymmetry in the anode and cathode work functions. The fact that in all devices the J_{sc} changes very little as the electric field is increased beyond the maximum built-in potential by an applied bias of up to 0.5 V (i.e. in the 3rd quadrant response) is evidence that in all cases the field is sufficient to sweep out the photogenerated carriers to the external circuit. The J_{sc} in devices utilizing ITO glass alone was consistently lower than those using o-MWCNT, o-SWCNT or PEDOT:PSS HELs. Khodabakhsh et al. [30] have previously shown that the J_{sc} in discrete heterojunction OSCs increases as the work function of the hole-extracting electrode approaches the ionisation energy of the donor material. The observation of a larger J_{sc} in OSCs incorporating o-SWCNT, o-MWCNT and PEDOT:PSS as compared to ITO glass only is therefore consistent with improved alignment between the Fermi level of the electrode (in this case the HEL modified ITO glass) and the HOMO of P3HT. The fractionally lower J_{sc} in cells incorporating o-MWCNTs as compared to PEDOT:PSS can be attributed to the lower transparency across the part of the solar spectrum that P3HT:PCBM absorbs (400–700 nm) [7b]. However, in narrower band gap devices, which harvest a greater proportion of the near infrared spectrum, this disadvantage would be off-set.

The high and comparable shunt resistance (defined as the gradient of the JV characteristic at J_{sc}) of all the device structures reported herein is compelling evidence that the incorporation of o-CNT layers does not increase leakage due to filamentary short circuits. The primary advantage of incorporating an o-CNT or PEDOT:PSS HEL is the large ($\sim$50%) reduction in cell series resistance (defined as the gradient of the JV characteristic at J = 0 mA cm^{-2}) as compared to those using plasma-cleaned ITO glass only. The sheet resistance of the $\sim$30 nm thick o-MWCNT and o-SWCNT films supported on plain glass was found to be very high and comparable to that of the $\sim$45 nm thick films of PEDOT:PSS: $\sim$10^7 Ω sq^{-1}. Such a high sheet resistance is consistent with the very low film thickness utilised ($\sim$30 nm) and disruption of the pi-conjugation in the CNT walls as a result of acid treatment. Consequently, the observed reduction in device series resistance cannot result from an increase in the conductivity of the electrode due to the presence of the o-CNT or PEDOT:PSS layers. It can also be assumed that the resistance to transport though the photoactive layer and ITO electrode is the same in all device structures and so the observed reduction in device series resistance must be attributed to a difference in contact resistance. In the context of OSCs the interaction between the photoactive organic layer and the supporting substrate electrode is a weak van der Waals type interaction and so the difference in contact resistance may be correlated with a difference in molecular conformation at the interface. Conjugated molecules including polythiophenes [31] are known to adopt a parallel orientation with respect to the graphitic wall of CNTs a configuration that would be expected to minimise the contact resistance, although in this instance the nature of the interaction is complicated by the presence of surface bound oxygen containing moieties. The low series resistance and high shunt resistance in devices incorporating CNTs results in a high *F.F.* (o-MWCNT $\sim$0.64, o-SWCNT $\sim$0.63), comparable to that uti-

lising PEDOT:PSS (0.61–0.62) and, to our knowledge, the largest *F.F.* for an OSC employing CNTs in any capacity [2c,3b,4,5,32a–c]. Importantly, the power conversion efficiency in devices employing o-SWCNT and o-MWCNT films is identical to that achieved using PEDOT:PSS films: $\sim$2.7%.

MWCNTs are essentially metallic in nature having a small but finite density of states at the Fermi level [13]. Consequently they are equally capable of conducting both electrons and holes and so offer predictable functionality as reliable high work function nano-wires, simplifying the interpretation of functionality as well as design in a device context. Conversely, the electronic structure of o-SWCNTs is more complex than that of o-MWCNTs primarily due to the presence of both semi-conducting and metallic SWCNTs, which co-exist in bulk samples regardless of the method of synthesis. From the spread of Raman active radial breathing modes (Fig. 2) it is evident that the sample comprises a distribution of SWCNT diameters with $E_g \sim 0.8$–1.0 eV. The result is a complex multi-level energy structure of metallic and semiconducting o-SWCNT. Clearly, from the performance of devices incorporating o-SWCNTs this complexity is not disadvantageous. A possible explanation is that the Fermi level in the semiconducting o-SWCNT is close to the valance band edge due to p-type doping by oxygen defects, enabling holes to move easily between metallic and semiconducting o-SWCNTs. This does not however rule out the possibility of significantly better performance should the type selection of the SWCNT be more precise.

4. Conclusion

In conclusion we have shown that thin films of extensively oxidised single wall and multi-wall carbon nanotubes can be utilised as high work function, solution processable hole-extraction layers in efficient OSCs. An important advantage over PEDOT:PSS – the most widely used hole-extraction layer in OSCs – is that they are processed from a pH neutral aqueous dispersion, reducing the likelihood of adverse chemical reaction with conducting oxide electrodes. Furthermore, absorption measurements show that films of acid oxidised carbon nanotubes of comparable thickness to PEDOT:PSS offer greater transparency at near infra-red wavelengths over which a significant portion of the terrestrial solar spectrum is located. As such we have demonstrated that extensively oxidised carbon nanotubes are a new tool in electrode design for low cost OSCs pointing the way to the realisation of wholly carbon nanotube based conformable hole-extracting electrodes in OSCs.

Table of contents

Thin films of extensively oxidised single-wall and multi-wall carbon nanotubes offer a path to efficient hole-extraction in state-of-the-art solution processed organic solar cells, as high work function solution processable hole-extraction layers with the advantages of low acidity and high transparency in the near infra-red.

ARTICLE INFO

ABSTRACT

Ultraviolet transfer embossing is optimized to fabricate bottom gate organic thin-film transistors (OTFTs) on flexible plastic substrates, achieving significant improved device performance (μ = 0.01–0.02cm^2/Vs; on/off ratio = 10^4) compared with the top gate OTFTs made previously by the same method (μ = 0.001–0.002 cm^2/Vs; on/off ratio = 10^2). The performance improvement can be ascribed to the reduced roughness of the dielectric-semiconductor interface (R_{rms} = 0.852 nm) and thermally cross-linked PVP dielectric which leads to reduced gate leakage current and transistor off current in the bottom-gated configuration. This technique brings an alternative great opportunity to the high-volume production of economic printable large-area OTFT-based flexible electronics and sensors.

1. Introduction

Organic thin-film transistors (OTFTs) are receiving increasing interest in the area of printed low-cost and large-area electronics on flexible substrates for applications such as electronic paper, solar panels and flexible sensors [1–3]. To lower the cost of organic electronics, it is important to develop fabrication processes that do not rely on clean room and that are compatible with solution processable dielectric materials and organic semiconductors [4]. Cold welding methods, both subtractive and additive, developed by Forrest's group [1,5,6] are capable to transfer metallic patterns on submicrometer scale by applying high pressure to form metallic bonds at the conformal contact area. In the additive cold welding method, a strike layer for facilitating the bonding process requires a gentle etching or simple sputtering process to be removed. Inkjet printing is an alternative technique to photolithography that has recently reached submicron scale resolution [7]; this process, however, requires a chemically modified ink to fabricate ultra-hydrophobic electrodes and post-printing sintering at a high temperature to increase the conductivity of the electrodes. Screen printing and micro contact printing (μCP) have been actively investigated by different research groups [8], but these techniques are limited to low resolution of $\sim$20 μm. Nanotransfer printing (nTP), developed by rogers' research group as advances of

μCP, offers a better resolution (∼100 nm) comparing to μCP [9,10]. The process utilizes the surface chemistry or noncovalent forces between the receiving surface and transferred metal to form the source and drain electrodes in OTFTs [11,12].

Our lab has previously demonstrated a fast and efficient OTFT fabrication process employing ultraviolet (UV) transfer embossing at room temperature with a resolution (∼2 μm) comparable to lithography process [13]. UV transfer embossing is fast, does not require clean room and can achieve small micron-resolution. The embossing template fabrication itself does require clean fabrication conditions, but once it is made, it may be used repeatedly to produce OTFTs under less stringent conditions. However, our previous top gate devices, regardless of using P3HT or poly(3,3‴-didodecyl quaterthiophene) (PQT-12) (see Supplementary material) as organic semiconductors, have relatively low device performance of mobility (μ) of 0.001–0.002 cm^2/Vs and on/off ratio of 10^2 [13]. The poor performance is attributed principally to the roughness between the PVP dielectric and the semiconductor; this is propagated from the relatively rough PET substrate surface through the thin semiconductor film. The high roughness at the dielectric-semiconductor interface significantly perturbs the structure of the semiconductor and forms many electron traps. Further, the top-gated configuration, which requires deposition of the organic semiconductor prior to deposition of the poly(4-vinylphenol) (PVP) dielectric, prevents thermal cross-linking of the dielectric since that

would damage the underlying semiconductor (the typical cross-link temperature for PVP is above 150 °C, which would degrade the semiconductor [14]), with the consequence of high leakage current through the dielectric layer.

In this letter we report our optimization of the UV transfer embossing process by fabricating bottom gate devices with a resolution of ∼2 μm which exhibit much improved device performance. Bottom gate devices allow deposition of PVP dielectric before semiconductor deposition. Fig. 1 shows a schematic illustration of the fabrication process for bottom gate devices by our UV transfer embossing process.

2. Experimental

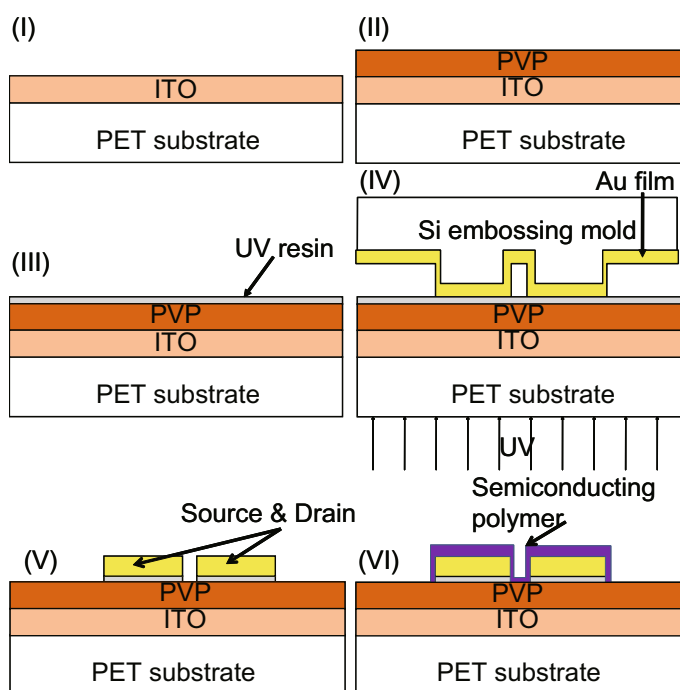
The UV embossing resin was a mixture of epoxy bisphenol-A diacrylate (Ebecryl 600), dipropylene glycol diacrylate (SR 508) and trimethylolpropane triacrylate (SR 351) with weight ratio of 12:5:3 diluted (50 wt%) in isobutylmethylketone (IBMK). Ebecryl 600 was supplied by UCB chemicals and SR 508 and SR 351 were supplied by Sartomer. Our UV resin mixture offers a fast curing response, good adhesion and superior cured film strength. This formulation was chosen also because the contact between UV resin and PVP thin-film was good enough for the deposition of UV resin on PVP via spin-coating. PVP and methylated poly(melamine-co-formaldehyde) (MPMF, used as PVP cross-linking agent) with weight ratio of 4:1 were dissolved in dimethyl formamide (DMF) to give a 8 wt% solu-


Fig. 1. Schematic illustration of the UV transfer embossing process in fabrication of bottom gate devices: (I) ITO coated PET films are cleaned in detergent, (II) PVP with MPMF is spin-coated on top of ITO and cross-linked in an oven followed with O$_2$ plasma treatment, (III) UV resin is spin-coated on PVP, (IV) Si embossing mold and UV resin coated substrate are brought into contact and exposed to UV light, (V) source and drain electrodes are transferred onto PVP after demolding and (VI) semiconducting polymer is drop-coated to complete device fabrication.

tion. The solution was filtered with a polytetrafluoroethene (PTFE) syringe filter with 0.2 μm pore size. The embossing template was fabricated, passivated and coated with Au film in the same manner as reported in our previous work [13].

Poly(ethylene terephthalate) (PET) films coated with indium tin oxide (ITO) supplied by Sigma–Aldrich were cleaned by sonication in detergent. ITO served as the transistor gate electrode. The PVP solution was spin-coated onto the ITO coated PET substrate at 500 rpm for 3 min. The dielectric layer was then cross-linked in air at 200 °C for 2 h. For high-volume production, PVP dielectric could also be sufficiently cross-linked at 200 °C for 15 min as it turns insoluble in acetone and chlorobezene. Since reduced cross-linking time is critical for the mass production, we conducted this process and successfully fabricated proper transistor devices. O_2 plasma treatment at power of 400 w and O_2 pressure of 200 m Torr were applied to PVP dielectric for 10 s. UV resin was then spin-coated onto the PVP thin-film at 3000 rpm for 2 min. The UV resin coated substrate was immediately brought into contact with a gold coated embossing template and exposed to UV light through the transparent substrate, ITO gate electrode and PVP thin-film. After removal of the template, the adhered gold patterns formed source and drain electrodes. The whole construct was rinsed with ethanol or isopropyl alcohol to remove the uncured UV resin. The transistor channel formed after removal of the uncured UV resin which is in the uncontacted areas and inhibited from curing by oxygen. The fabrication process was completed by drop coating of PQT-12 solution in chlorobenzene and annealing at 125 °C for 15 min in a vacuum oven.

3. Results and discussion

O_2 plasma treatment is a key step for the successful transfer of electrodes onto the hydrophobic PVP surface. Fig. 2a and b shows transferred gold electrodes on PVP thin-film without (a) and with (b) O_2 plasma treatment. Without plasma treatment, the gold electrodes were only partially transferred. It is known that O_2 plasma treatment can activate a surface, make it hydrophilic and greatly improved the adhesion of cured UV resin to the PVP, which was necessary for the gold electrodes to remain on the construct after removal of the UV embossing template. Fig. 2c and d shows micrographs of water droplets on untreated and plasma-activated PVP surfaces. The O_2 plasma treatment reduces the water contact angle from $76 \pm 1°$ to $19 \pm 2°$.

The transfer embossed electrodes were characterized by high resolution scanning electron microscope (HR-SEM) and atomic force microscope (AFM). Fig. 3a shows the top view of the gap between two patterned electrodes on PVP dielectric film. The measured length of the gap, which is the channel length of the transistor device, is 3.0 ± 0.1 μm and the ratio between the length of the gap and roughness of the electrodes is estimated to be 30:1, resulting in a roughness of around 100 nm. The relatively high roughness is believed to arise from the mechanical breakage in the Au film at the edge of the mold during demolding. Fig. 3b shows a 3D AFM image of the patterned electrodes, focusing on the gap between two electrodes. The measured gap of 3.0 ± 0.3 μm in length between the two electrodes was obtained. These results indicate that the technology described in this work is capable of achieving a resolution as low as ~3 μm.

The device performance of OTFT fabricated by this transfer embossing technology was measured in air using an Agilent 5270B parameter analyzer with a cascade probe station. Fig. 4a shows a representative drain current versus drain voltage (I_d–V_d) curve and Fig. 4b shows the transfer characteristics (I_d–V_g) curve. The devices achieved a much better performance than the prior top gate devices we have

reported. The calculated carrier mobility ranged from 0.01–0.02 cm^2/Vs in the saturation regime, which is more than 1 order of magnitude higher than our previous top gate devices [13]; the on/off ratio reached as high as 10^4, which is 2 orders of magnitude higher than that in our previous report [13].

The electrical properties at the interface of transfer embossed Au electrode/semiconducting polymer was studied with standard TLM method [15]. The total contact to contact resistance (R_{total}) can be divided into sheet resistance(R_{sh}) in the channel and the contact resistance(R_c) at the electrodes. At low drain voltage [15],

$$R_{total} = R_{sh} + R_C = \frac{L}{W\mu C_i(V_G - V_T)} + R_C,$$

and by normalizing resistance with channel width [16],

$$R_{total}W = \frac{L}{\mu C_i(V_G - V_T)} + R_C W,$$

where W, μ, L, C_i, V_G and V_T are channel width, charge mobility, channel length, capacitance per unit area of dielectric layer, gate voltage and threshold voltage, respectively. The width-normalized contact resistance can be evaluated at $L = 0$. Devices with four different channel

Fig. 5. Plot of width normalized total contact to contact resistance as a function of channel length to obtain contact resistance values.
Fig. 6. AFM morphology of (a) ITO coated PET substrate and (b) cross-linked PVP.

lengths were fabricated and tested. Fig. 5 shows the plot of width normalized R_{total} as a function of L. A straight line is fitted to four corresponding total contact to contact resistances. The interception between the fitting line and Y axis gives a width normalized contact resistance of around 500 KΩ cm when $V_G = -20$ V. The moderate contact resistance is believed to be caused by the roughness produced at the demolding step.

To investigate the cause of the improvement in charge carrier mobility, atomic force microscopy (AFM) was used to study the dielectric-semiconductor interface. Fig. 6a and b shows the surface morphology of ITO coated PET substrate and cross-linked PVP, respectively. The root mean square roughness (R_{rms}) of ITO coated PET substrate was 3.7 nm. With proper spin-coating parameters for the PVP thin-film, R_{rms} of the dielectric surface was reduced to 0.9 nm. It is well-known that the mobility in OTFTs is affected by morphology and grain size of the semiconductor film [17]. The semiconductor film morphology is in turn partly driven by the substrate surface [18]. Therefore, substrate roughness, to some extent, determines the quality of interface and further affects transistor characteristics [19,20]. In our earlier top gate devices, the PET substrate showed a regular ripple-like morphology ($R_{rms} = 6.7$ nm), which was a typical surface morphology of a polymer substrate. The spin-coated semiconductor film was very thin and closely conformed to this morphology; the roughness of semiconductor film only reduced modestly to $R_{rms} = 4.4$ nm [13]. In the present bottom-gated configuration, the PVP film is thick enough (800–1000 nm) to cover

up the rough surface of the ITO film and produce a very smooth ($R_{rms} = 0.9$ nm) dielectric interface. We propose that the increased mobility is a consequence of this significant roughness reduction at the dielectric-semiconductor interface.

The bottom gate device structure makes it possible to cross-link the PVP thin-film at high temperature without affecting the quality of semiconductor layer, which is deposited after PVP has been cross-linked. Generically, cross-linking of polymer systems enhances mechanical strength and stiffness and increases the resistance to solvents [21,22]. In our experiments, PVP thermally cross-linked with MPMF also shows high solvent resistance to chlorobenzene and, as a result of the cross-linking process, the gate leakage current is reduced below nA scale and the off current is as low as 0.1 nA, leading to the increase of on/off ratio. These results agree well with others' reports in which leakage current through PVP cross-linked with the proper amount of MPMF is more than two orders of magnitude lower than uncross-linked PVP film [23] and transistor off current is found to decrease by 2 orders of magnitude with prolonged cross-linking time [24]. Based on our optimized process, real, commercially interesting OTFT applications such as low-cost, large-area sensor systems become feasible.

4. Conclusions

In summary, our UV transfer embossing process is optimized by using bottom-gated configuration so that the resulting OTFT has greatly improved mobility and on/off ratio of 0.01–0.02 cm^2/Vs and 10^4, respectively. The bottom-gated configuration permits thermal cross-linking of the PVP dielectric and hence lower gate leakage current and off current. The increased mobility is proposed to result from significant roughness reduction at the dielectric-semiconductor interface. The improved OTFT performance makes this technique feasible for medium performance and/or disposable applications such as electronic paper and large-area environmental sensors.

ARTICLE INFO

ABSTRACT

In this article, we report the effects of the thickness of metal and oxide layers of the Al/WO₃/Au interconnecting structure on the electrical and optical characteristics of the upper and bottom units of the two-unit stacked organic-light-emitting-devices (OLEDs). It is found that light emission performance of the upper unit is sensitive to the transmittance of semitransparent Al/WO₃/Au structure, which can be improved by changing the thickness of each layer of the Al/WO₃/Au structure. It is important to note that the introduction of WO₃ between Al and Au significantly enhances the current efficiency of both the upper and bottom units with respect to that of the corresponding Al/Au structure without WO₃. In addition, the emission spectra of both the upper and bottom units are narrower than that of the control device due to microcavity effect. Our results indicate that the Al/WO₃/Au interconnecting structure is a good candidate for fabricating independently controllable high efficiency stacked OLEDs.

1. Introduction

Independently controllable and dependently controllable stacked organic-light-emitting-device (OLED) structures have been widely studied to improve the emission efficiency [1–6,8,9]. Each OLED unit of the independent controllable stacked OLEDs can be individually biased and operated. The performance of the stacked OLEDs strongly depends on the carrier conduction into the emissive units. For independently controllable stacked OLEDs, the interconnecting electrode plays a special role for OLED performances because the electrode has the dual functions of hole injection for the upper OLED unit and electron injection for the bottom unit simultaneously. Thus, serious at-

tempts have been put on exploring high performance interconnecting electrodes. To realize the role, the interconnecting electrode generally utilizes structures based on thin semitransparent metal layer or transparent indium-tin oxide (ITO), such as, Mg:Ag/indium zinc oxide [6] and Cs:BCP/indium-tin oxide(ITO) [7], apart from LiF/Ca/Ag and LiF/Al/Au [8,9]. ITO might cause damage to the underlying organic thin films because it is usually deposited by means of magnetron sputtering process. Metal electrodes can contribute to good carrier injection when the Fermi level can match with the highest occupied molecular orbit (HOMO) and the lowest unoccupied molecular orbit (LUMO) of the organic material for hole and electron injection, respectively. However, the transmittance of metal is generally low which may cause problems. Therefore, it is urgent to develop new connecting layers.

In this article, we shall discuss the effects of the Al/WO₃/Au interconnecting electrode. The interconnecting

[1] Currently visiting the University of Hong Kong.

electrode can be proved to be an efficient interconnecting structure for uses in high efficiency stacked OLEDs with good transmission and to improve the color purity. We will investigate the effects of the thickness of each metal and oxide layers of the interconnecting structure on the electrical and optical properties of each unit in the stacked OLEDs. To ease the study, the two-units of the stacked OLEDs are identical which are integrated by Al/WO₃/Au and Al/Au connecting layers as detailed in next section. Each unit in the stacked OLEDs can be independently biased.

2. Experiment

Fig. 1 shows the schematic diagram of the independently controllable stacked OLEDs (Device A) and control OLED (Device B) used in this study. The structure of Device A is ITO /MoO₃ (8 nm)/4,4′-N,N′-bis[N-(1-naphthyl)-N-phenyl-amino]biphenyl (NPB) (50 nm)/(tris (8-hydrooxy uinoline) aluminum(III) (Alq₃):C545T (30 nm)/Alq₃ (30 nm)/LiF(1 nm)/Al/WO₃/Au/MoO₃ (5 nm)/NPB (50 nm)/ Alq₃:C545T (30 nm)/Alq₃ (30 nm)/LiF (1 nm)/Al(140). Device B is ITO/MoO₃ (8 nm) /NPB (50 nm)/Alq₃:C545T (30 nm)/Alq₃ (30 nm)/LiF (1 nm)/Al (150 nm). All devices were fabricated on indium-tin oxide (ITO) coated glass with a sheet resistance of 15 Ω/□ and the thermally deposited LiF/Al was used as cathode. ITO substrate was cleaned and then treated by UV ozone. The deposition was carried out at a pressure less than 3×10^{-4} Pa without vacuum breaks. The organics and metal oxide were evaporated at the rate of 0.2–0.3 nm/s, and the metal of Au was evaporated at the rate of 0.1 nm/s and Al at the rate of 0.8–1 nm/s. The OLEDs had an emissive area of 16 mm². The current density–voltage–luminance (J–V–L) characteristics were measured by using a computer controlled sourcemeter (Keithley 2400) and multimeter (Keithley 2000) with a calibrated silicon photodiode. The electroluminescence (EL) spectra were measured by JY SPEX CCD3000 spectrometer. All the measurements were carried out in ambient atmosphere at room temperature. Al/WO₃/Au structures with different thicknesses of Al, WO₃ and Au were also deposited on glass substrates for transmission studies.

3. Results and discussion

Fig. 2 depicts J–V–L characteristics and current efficiency of the upper unit of the stacked OLEDs with various thicknesses of Al, Au and WO₃ layers as the interconnecting electrode. It can be seen that the current injection generally increases when the total thickness of metal layers (Al and Au) increases. However, inserting WO₃ layer between the Al and Au layers make the current injection decrease as shown in Fig. 2a. The current injection of the device with Al/WO₃/Au (2 nm/3 nm/ 16 nm) is lower than that of the device with Al/Au (2 nm/16 nm). When the thickness of WO₃ is further increased, hole injection enhances due to the modifying effect of the oxide layer on the Al layer which is similar to the case reported by Lee [10]. They used C₆₀ as the adjacent buffer layer of Al layer for improving hole injection in OLEDs. Despite that the total metal thickness of the OLED with Al/WO₃/Au (2 nm/3 nm/16 nm) is the thicker than that of the OLED with Al/WO₃/Au (1 nm/5 nm/ 14 nm) (see Fig. 2a), the carrier injection of the device with Al/WO₃/Au (1 nm/5 nm/14 nm) is higher than that of the devices with Al/WO₃/Au (2 nm/3 nm/16 nm). This is attributed to the increase of the oxide thickness. For example, at $J = 100$ mA/cm², the driving voltages of OLEDs with Al/WO₃/Au structures of (1 nm/5 nm/ 14 nm), (2 nm/3 nm/16 nm), and (2 nm/3 nm/15 nm) are 13.9, 14, and 14.5 V, respectively.

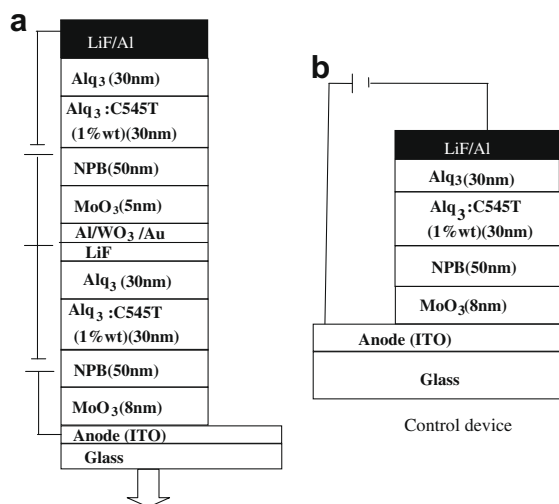
Fig. 2b shows the brightness–efficiency–current density plots of the upper unit of Device A. At any current density, the brightness of the OLEDs with various Al/WO₃/Au structures is higher than that of the corresponding Al/Au OLEDs. For example, at current density of 20 mA/cm², the brightness reaches 2700 cd/m² for Al/WO₃/Au (2 nm/3 nm/ 16 nm) OLED, which is larger than 2033 cd/m² for Al/Au (2 nm/16 nm) OLEDs and close to 2752 cd/m² for the control OLED. By using Al/WO₃/Au (1 nm/5 nm/14 nm) structure, the brightness increases to 2900 cd/m² at current density of 20 mA/cm², this means that the current efficiency is further improved. The inset of Fig. 2b shows the current efficiency versus current density of the OLEDs with various Al/WO₃/Au and Al/Au structures as well as the control device. The maximal current efficiency are 14.6 cd/A (for the OLED with Al/WO₃/Au thicknesses = 1 nm/5 nm/ 14 nm, respectively), 14.3 cd/A (2 nm/3 nm/15 nm), 13.2 cd/A (2 nm/3 nm/16 nm), 12.6 cd/A (1 nm/5 nm/ 17 nm), and 11 cd/A (the OLED with Al/Au thickness = 2 nm/16 nm, respectively), and 10.9 cd/A (2 nm/ 17 nm). It is clearly observed that the current efficiency of the upper unit of the Al/WO₃/Au OLEDs is greater than that of the control device as well as the upper unit of Al/ Au OLEDs with same Al and Au thicknesses. One of the reasons of the lower current efficiency of the upper unit of Al/ Au OLEDs is due to the low optical transmittance which will be discussed below.


Fig. 1. Schematic diagram of the independently controllable stacked OLED (Device A) and control OLED (Device B).
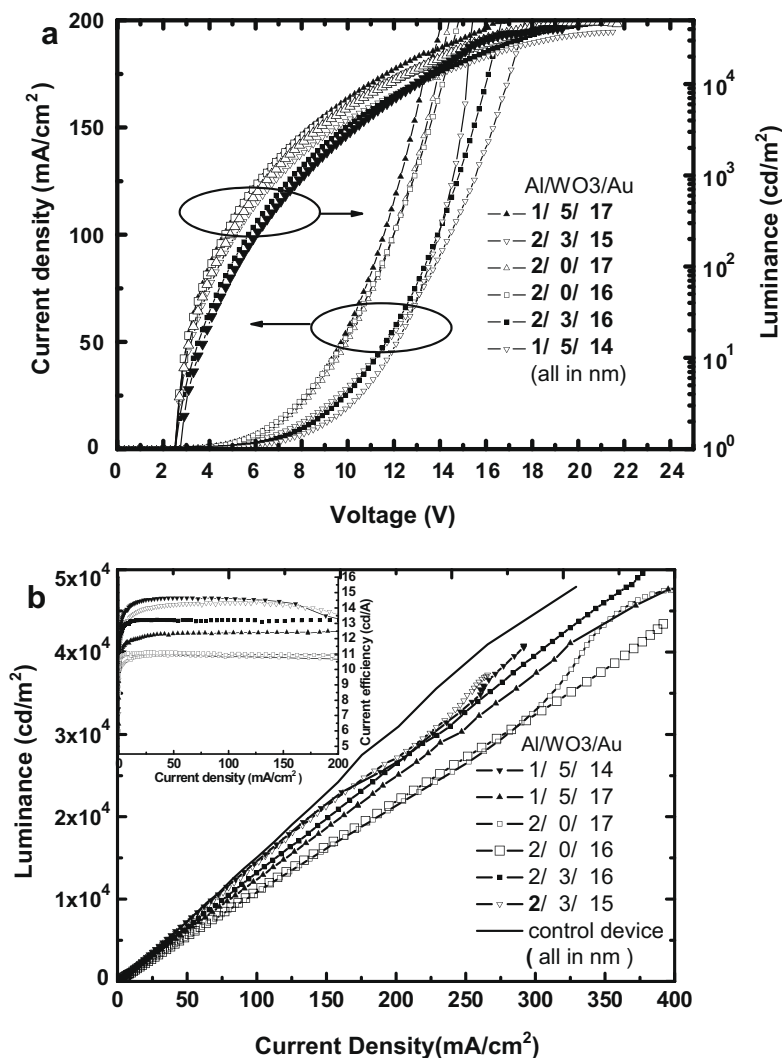

Fig. 2. (a) Current density–brightness–voltage characteristics of the upper unit of the Al/WO₃/Au and Al/Au stacked OLEDs. (b) Current density–brightness characteristics of the upper unit of the Al/WO₃/Au and Al/Au stacked OLEDs and the control OLED. The inset show the current density–current efficiency characteristics of the upper OLED unit of the Al/WO₃/Au and Al/Au stacked OLEDs and the control OLED.

To achieve efficient light emission from the upper unit in the stacked device, the intermediate connecting layers shall have high enough transmission and low absorption [11,12]. Here we study the transmittance of Al/WO₃/Au/MoO₃ as depicted in Fig. 3. The results clearly indicate that the transmittance of the Al/WO₃/Au structure is indeed enhanced with respect to the corresponding Al/Au structure without WO₃. One of the possible reasons is the improvement of transmission of the opaque metallic structure through the coupling of the SP modes to radiative modes [13,14]. It has been reported that coupling of SP modes can occur by inserting an insulating layer between two metal films to form metal/insulator/metal [15] which can enhance the radiation. These results are important for improving of device performance. For the upper unit, the light will propagate through the interconnecting structure and bottom unit before emitting to the outside environment from the ITO glass, the increase of the transmittance
Fig. 3. Transmittance spectra of various thicknesses Al/WO₃/Au and Al/Au.

of the interconnecting structure results in improvement of brightness. Although the introduction of thin WO_3 layer reduces the injection current, the improvement of the brightness not only overcomes the reduction but also enhances the emission efficiency. The maximal power efficiency of upper units of the $Al/WO_3/Au$ stacked OLEDs reaches about 11 lm/W, when that of the Al/Au stacked OLEDs is 9 lm/W and the efficiency of the control device is 8.9 lm/W. In addition, the structure $Al/WO_3/Au$ is similar to a capacitor structure. Since a layer of WO_3 between Al and Au layers serves as a dielectric layer. There is no direct contact between the Au and Al; thus the positive charge exists on the positive anode and the negative exists on the cathode. These results indicate that both Al/Au and $Al/WO_3/Au$ are excellent dependently interconnecting electrodes for upper emitting unit in stacked OLEDs and the introduction of WO_3 further improve the performance of the stacked OLEDs. Consequently, the metal/oxide/metal structures

can serve useful interconnecting structures for improving the stacked OLEDs performance.

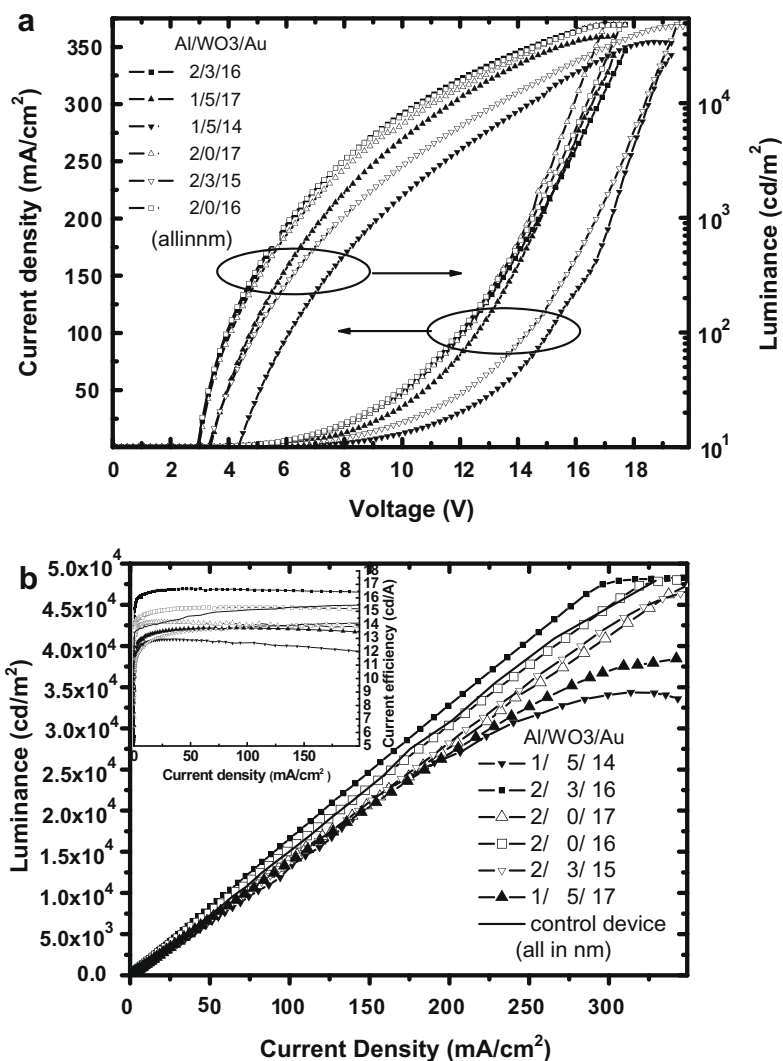
Regarding the bottom unit of the stacked OLEDs, Fig. 4 shows the J–V–L characteristics and current efficiency. The thin WO_3 oxide has no obvious influence on the current injection of the bottom devices. The driving voltage of the bottom OLED with Al/Au structure of (2 nm/16 nm), $Al/WO_3/Au$ structures of (2 nm/3 nm/16 nm), and (1 nm/5 nm/17 nm) at $J = 100$ mA/cm^2 are 12.1, 12.1, and 12.7 V, respectively (see Fig. 4a). It is interesting to note that the current efficiency and brightness of corresponding devices are improved as shown in the inset of Fig. 4b. For example, at current density of 20 mA/cm^2, the brightness is 3354 cd/m^2 for $Al/WO_3/Au$ (2 nm/3 nm/16 nm) OLEDs, which is higher than 3019 cd/m^2 for the corresponding Al/Au (2 nm/16 nm) OLEDs and 2752 cd/m^2 for the control device. The maximal current efficiency the devices are 16.7 cd/A ($Al/WO_3/Au$ thicknesses = 2 nm/3 nm/16 nm), 14.3 cd/A (2 nm/3 nm/


Fig. 4. (a) Current density–brightness–voltage characteristics of the bottom units of the $Al/WO_3/Au$ and Al/Au stacked OLEDs. (b) Current density–brightness characteristics of the bottom units of the $Al/WO_3/Au$ and Al/Au stacked OLEDs and the control OLED. The inset show the current density–current efficiency characteristics of the bottom units of the $Al/WO_3/Au$ and Al/Au stacked OLEDs and the control OLED.

15 nm), 13.8 cd/A (1 nm/5 nm/17 nm), 12.9 cd/A (1 nm/ 5 nm/14 nm), 15.3 cd/A (Al/Au thicknesses = 2 nm/16 nm), and 14.2 cd/A (2 nm/17 nm). The current efficiency of the bottom device depends on the thickness of the oxide layer and the metal layers. In addition, with the same metal thickness, the current efficiency (16.7 cd/A) of stacked OLEDs with the interconnecting electrode of Al (2 nm)/WO$_3$ (3 nm)/Au (16 nm) has been improved compared to the current efficiency (15.3 cd/A) of stacked OLEDs with the interconnecting electrode of the Al/Au (2 nm/16 nm) device, which should be attributed to microcavity effect enhancement and the transmittance improvement of Al/WO$_3$/Au (2 nm/ 3 nm/16 nm) OLEDs (see Fig. 4b). However, the current efficiency of the Al/WO$_3$/Au OLEDs with structure of (1 nm/5 nm/17 nm) and (1 nm/5 nm/14 nm) are lower than that of the Al/Au (2 nm/16 nm) structure which indicate that the increase of the Al thickness favors the electron injection. It has been reported that the electron injection at the organic/metal contact is mainly controlled by the work function [16,17]. The Al in the interconnecting structure, which has lower work function, provides the electron injection for the bottom unit. One can modify the thickness of each metal and oxide layer to fulfill the performance of a particular OLED design.

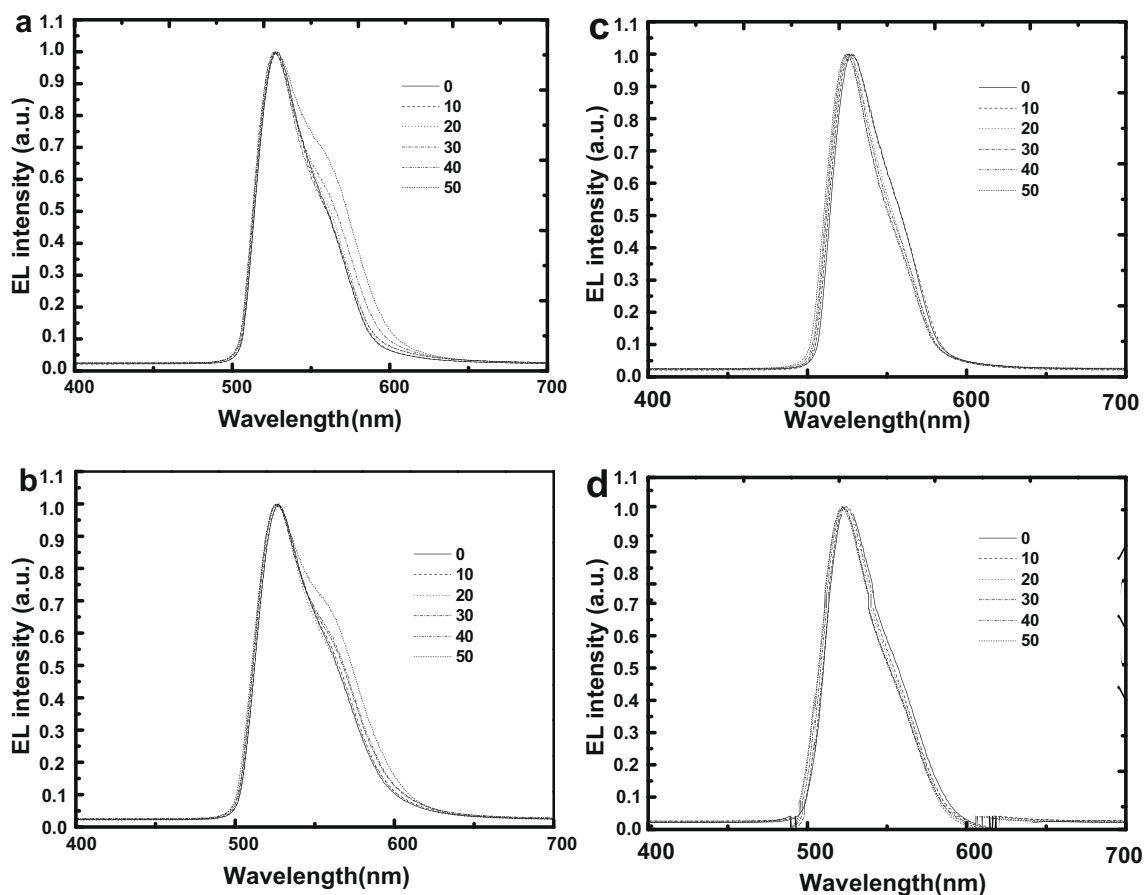
Due to the utilization of semitransparent interconnecting layer, the microcavity effect exists in upper and bottom units of the stacked OLEDs. Fig. 5a and b shows the EL spectra from upper units of Al/WO$_3$/Au (2 nm/3 nm/16 nm) and Al/Au (2 nm/16 nm) OLEDs, Fig. 5c and d shows that from bottom units. All devices emit green color with the peak at about 526 nm, but both the bottom and upper units of Al/WO$_3$/Au OLEDs show narrower EL spectrum than that of the Al/Au OLED. The full-width at half-maximum (FWHM) of the upper and bottom units of Al/WO$_3$/Au OLED are 43 and 40 nm respectively, and that of Al/Au OLED 52 and 50 nm respectively, which is narrower than 69 nm of the one-unit control device. Obviously, the narrowing phenomenon is due to the microcavity effect, and the utilization of WO$_3$ between Al and Au, indicating that the Al/WO$_3$/Au possesses the more effective microcavity optical confinement role [18] than the Al/Au which should be favor in the improvement of device efficiency. Furthermore, it can be seen that the microcavity effect does not produce any significant angular dependence in the emission spectrum for both bottom and upper units of the Al/ WO$_3$/Au stacked OLEDs, although the emissive spectra of the upper units of the both OLEDs slightly red shift and widen at 50° as shown in Fig. 5a and b.


Fig. 5. EL spectra of device respectively, from the upper units of (a) Al/WO$_3$/Au (2 nm/3 nm/16 nm) stacked OLEDs and (b) Al/Au (2 nm/16 nm) stacked OLEDs as well as the bottom unit of (c) Al/WO$_3$/Au (2 nm/3 nm/16 nm) stacked OLEDs and (d) Al/Au (2 nm/16 nm) stacked OLEDs with various viewing angles.

4. Conclusion

An independently external bias interconnecting structure for improving the efficiency of both the upper and bottom units of stacked OLEDs has been reported and discussed. The connecting structure is composed of a thin metal oxide sandwiched between Al and Au layers. Our results show that the utilization of metal oxide between Al and Au significantly improves the transmittance of the interconnecting structures, and thus the device efficiency. The spectra of both the upper and bottom emitting unit are also narrow down compared to the control device. Besides the angular dependence of spectrum caused by microcavity effect is not significant. The concept of introducing oxide layer between metal layers can be applied to other metal multilayered structures. By adjusting the thickness of each layer of the interconnecting structures, one can tailor the performance of the top and bottom units of the stacked OLEDs to meet the special requirement. Furthermore, such interconnecting layered structure can be easily fabricated by simple thermal evaporation, and can be easily applied the structures for fabricating real-time color-tunable stacked OLEDs for realizing high-resolution, independently addressable, stacked red–green–blue pixels in color displays.

ABSTRACT

The transfer of benchtop knowledge into large scale industrial production processes represents a challenge in the field of organic electronics. Large scale industrial production of organic electronics is envisioned as roll to roll (R2R) processing which nowadays comprises usually solution-based large area printing steps. The search for a fast and reliable fabrication process able to accommodate the deposition of both insulator and semiconductor layers in a single step is still under way. Here we report on the fabrication of organic field effect transistors comprising only evaporable small molecules. Moreover, both the gate dielectric (melamine) and the semiconductor (C_{60}) are deposited in successive steps without breaking the vacuum in the evaporation chamber. The material characteristics of evaporated melamine thin films as well as their dielectric properties are investigated, suggesting the applicability of vacuum processed melamine for gate dielectric layer in OFETs. The transistor fabrication and its transfer and output characteristics are presented along with observations that lead to the fabrication of stable and virtually hysteresis-free transistors. The extremely low price of precursor materials and the ease of fabrication recommend the evaporation processes as alternative methods for a large scale, R2R production of organic field effect transistors.

1. Introduction

Macroelectronic devices, such as flexible or conformable displays, smart cards, sensors etc. are impelling the emerging field of organic electronics [1,2]. Materials employed in such applications include small molecule semi-conductors, as used for example in current organic light emitting diode displays (OLEDs) as well as polymeric organic semiconductors that have proven to be favorable in organic solar cells [3]. Advantageously, these soluble materials offer the possibility to be processed by cost-efficient roll-to-roll (R2R) printing technologies [4,5]. As has been demonstrated in the packaging industry, R2R processing is also compatible with vapor deposition methods that generally apply not only for small organic molecules [6] but also for polymers [7].

While small molecules can be purified to a high degree, polymers and solvents are more likely to present impurities. Solution based processing may require extensive cleaning steps, to avoid contamination of the devices with ionic impurities [8]. In the field of organic field-effect transistors (OFETs), such impurities may give rise to unwanted ionic electret effects, causing bias stress degradation or hysteresis in transfer characteristics [9]. Though the hysteresis in the transfer characteristics of OFETs may be used as an advantage in non-volatile memory elements [10,11], it is detrimental in transistors designed for integrated organic circuits and sensors [12]. Therefore alternative routes for production of key components in OFETs are desirable. These include not only the deposition of the active semiconductor material, but also the fabrication of the insulating dielectric layer [7]. Advantageously, small molecule evaporable materials allow fabrication to be pursued by vapor deposition only [13], enabling therefore high purity production of organic electronic devices. Importantly, small molecule materials allow the forming of well defined interfaces between the organic semiconductor and the organic dielectric when growth conditions are optimized. Consequently, thermal oxide growth and wet chemical steps which are used in classical inorganic semiconductor technology would no longer be required. Moreover, since there are no dangling bonds, the organic-organic interface in such devices may also provide for low interface trap densities in comparison to inorganic-inorganic interfaces like the ones present in silicon-metal oxide-semiconductor transistors [14]. As a result, vacuum processed small molecule OFETs may represent a viable alternative route for the R2R processing of organic electronics [6].

Here we report on vacuum processed small molecule OFETs with vacuum evaporated melamine as gate dielectric and C_{60} as semiconductor material. We describe the vacuum evaporation of melamine, the structural and dielectric properties of the evaporated melamine thin film dielectrics, the fabrication of the vacuum processed small molecule OFETs and their electrical characterization.

The first synthesis of 1,3,5-triazine-2,4,6-triamine (*i.e.* $C_3H_6N_6$) can be traced back to the German scientist Justus von Liebig, who first synthesized the material in 1834 by heating an intimate mixture of ammonium chloride and potassium thiocyanate [15]. He called the fusion product melamine. Perceived initially as an expensive chemical, melamine attracted significant commercial interest one century later, for applications including fabric impregnation, adhesives and moulding powders containing cellulosic fibers, fillers and pigments. The reaction of melamine with formaldehyde to produce a thermosetting resin firmly established the industrial interest towards the duroplasts. Nowadays, melamine represents one of the most common molecular units of our daily life owing to its excellent chemical stability, low fabrication cost and simple synthesis route. In addition, melamine possesses a considerable number of attractive properties, like excellent optical transmission; very good fire and abrasion resistance; excellent chemical inertness including stability to heat, light, moisture and various chemicals attack. All these features pushed melamine as a front runner in applications including cross-linking additives for coatings of

automotive and household parts; flame retardant additives for foams in furniture and mattresses; various moulded plastic wares; laminates for kitchen cabinets, floors and table tops; concrete plasticizers; resins for textile and paper finishing and others [16]. However, despite intensive academic interest shown in the second part of the last century towards elucidating the electronic and structural properties of melamine [17–19], no report has surfaced to date with respect to the suitability of melamine for large scale industrial production of electronic devices.

Melamine crystallizes in monoclinic crystal structure in which each molecule is linked to its neighbours by eight hydrogen bonds [18,20–23]. Melamine crystals have a melting point of 350 °C and start sublimating at a temperature greater than 270 °C in a vacuum of 10^{-5} torr, the recrystallized product consisting of melamine and possibly a series of fused products of pyrolysis referred elsewhere as melam (*i.e.* $C_6H_9N_{11}$), melem (*i.e.* $C_6H_6N_{10}$) and melon (*i.e.* $C_6H_3N_9$) [19,24]. Melon is the final condensate obtained during the melamine pyrolysis and was recently investigated by several groups for the inexpensive route of fabrication of carbon nitride (*i.e.* C_3N_4) [24,25]. The above mentioned thermal behaviour therefore recommends melamine as a suitable material for the deposition of the dielectric layer in fully evaporated organic field effect transistors.

2. Experimental

Transistors are built on 1.5×1.5 cm glass substrates. Melamine is evaporated through a square mask on top of an evaporated aluminium stripe acting as gate electrode for the transistor. After the evaporation of the organic semiconductor layer, the transistors are placed on top of a patterned mask and aluminium is used to define the source and drain electrodes. All the aluminium electrodes (gate, source and drain) are 60 nm thick. For the batches built on Cr/Au gate electrodes, the thickness of the two successively evaporated metal layers was 10 nm and 50 nm, respectively. The ITO gate electrodes for the batches featuring this gate material were patterned by etching the ITO glass with "aqua regia" (*i.e.* an aqueous etching solution containing 36% hydrochloric acid, 65% nitric acid, and water in the volume ratio 0.92:0.08:1). Melamine was purchased from Aldrich Inc. and purified by two successive recrystallizations in a glass tube in an open furnace. The closed side of the tube was inserted in the furnace heated at 300 °C and the open end connected to a vacuum pump and a pressure of 10^{-2} bar established. The low fractions of melamine impurities evaporated first and were drained into vacuum and the rest of the material condensed at the end of the tube exiting the furnace. The recrystallization was repeated one more time in order to increase the purity of the material. We observed that the quality of the transistors built from precursor material recrystallized more than twice was no different to that of the transistors produced from the twice-recrystallized material. Attempts to build transistors from the "as received material" proved successful in the sense that transistor behaviour was observed in both output and transfer curves, however the evaporation of

melamine was marred by an unsteady sublimation rate at fixed temperature, presumably due to the evolution of ammonia containing impurities. The organic materials were evaporated successively in the same vacuum typically of 1×10^{-6} bar in an EDWARDS High Vacuum (Manor Royal, Crawley, Sussex), from crucibles containing melamine and C_{60}. The distance measured from the plane of the crucible holder to the one of the sample holder during the evaporation of the organic layers was always 15 cm in this work. We observed that altering this distance had a great influence on the quality of the melamine layer condensed on the substrate. Higher distances (up to 25 cm in total) offered a much better dielectric behaviour of the melamine layer in terms of breakthrough voltage, but also a considerably higher film roughness leading therefore to undesired transistor characteristics like more pronounced hysteresis, higher threshold voltage and modest on-off ratio. All the transistor samples within this work that were built on glass

substrates have gone through a post-production heat treatment at temperatures in the range of 100 to 125 °C, on hot plate in glove box under nitrogen. The transistor samples prepared on 1.5×1.5 cm PET foils have been treated at 80 °C for four hours under the same environmental conditions. The channel length L of the OFETs is 100 μm and the channel width W is 1 mm. The area of the overlapping top and bottom electrodes of the MIM capacitor built for the dielectric measurements is 6.25 mm². The electrical characterization of all transistor batches was performed in inert environment (i.e. nitrogen filled glove box). The dielectric measurements of the MIM capacitor were performed in a sample chamber under argon gas, without any prior heat treatment of the melamine sample after thermal evaporation. For the steady state current-voltage measurements, an Agilent E5273A instrument was employed, whereas a Novocontrol Alpha Analyzer was used for the dielectric spectroscopy investigation. For both the

transfer and the output characteristics, a sweep rate of 66 mV s^{-1} was employed, and the instrument featured a timing of 1 s for each of the hold, delay and step delay times respectively. For the calculation of the electron mobility in the OFETs, an experimentally measured value of capacitance per unit area (C_{0d} = 3.85 nF/cm^2) was employed. For the calculation of interface trap state density, the transistor displayed in this work in Fig. 7a–b was inserted in the measurement cell for dielectric measurements and the capacitance vs. voltage measurements performed with the Novocontrol Alpha Analyzer. The measurement was performed connecting the electrical wires to the bottom gate and to only one of the top electrodes, neglecting the finite influence of the nearby floating top electrode for the calculation of the interface trap density of states. An active area of 1.2 mm^2 for the metal-insulator-semiconductor-metal (MIS) structure was considered, as well as a value for the capacitance per unit area of the dielectric insulator (C_{0d} = 3.85 nF/cm^2). Implementing during the measurement the active area of the measured structure and considering the corresponding value of depletion capacitance offered by the instrument, a depletion capacitance per unit area (C_{dep} = 3.3 nF/cm^2) was used to compute the calculation for the interface trap density of states, and a value of subthreshold swing (S = 4 V/dec) extracted from the ratio of the derivatives of gate voltage to logarithm of source-drain current [26]. The FTIR measurements were performed on a BRUKER OPTICS (EQUINOX 55) attenuated total reflection spectrometer with all analyzed samples in KBr pellet mode. Precursor powder (collected after the second

with no heat treatment performed after the deposition. A thin layer of 5 nm Au layer was thermally evaporated on the top of melamine thin film to avoid charging of the dielectric during the SEM scanning. X-ray diffractograms were obtained using a Bruker AXS X-ray diffractometer (Cu Kα), on precursor powder (two times recrystallized) and thin films of 1.25 and 6.25 μm, respectively, which were thermally evaporated on glass slides, with no heat-treatment following thermal evaporation of melamine. Topographical surface investigations were performed by analyzing the Atomic Force Microscope (AFM) images of the surface of the samples obtained from a Digital Instruments Dimension 3100 microscope working in tapping mode. As in the case of SEM measurements, the samples were not submitted to heat treatment at the end of melamine deposition. Thickness measurements of the melamine and C_{60} layers were initially performed with the aid of the AFM microscope and all the values reported here confirmed by a DekTak profilometer.

3. Results and discussion

3.1. Structural and dielectric characterization of melamine

In this work we used no solution processing; instead both types of small molecules (*i.e.* melamine and C_{60}) have been successively evaporated without interrupting the vacuum in the evaporation chamber. A schematic of both melamine and C_{60} small molecules is displayed, as an inset of Fig. 1 showing schematically a fully evaporated OFET structure. Fig. 2a and Fig. 2b show atomic force microscopy (AFM) images of 1.25 μm thick melamine films evaporated on aluminium electrodes and 75 nm thick C_{60} films deposited on top of the evaporated melamine, respectively. The melamine grains are of elongated shape and randomly oriented. Most of the grains have lengths ranging from 350 to 700 nm, and the width is around 150 nm. The surface of the film displays a considerable peak-to-valley ratio in the range of 60 nm and an average root-mean-square

(RMS) roughness equal to 15 nm. The C_{60} layer built on top of the melamine film shows randomly oriented grains with no clearly defined shape. The surface of the C_{60} film displays a somewhat reduced roughness as compared to the melamine film; the peak-to-valley ratio and RMS values are situated in the range of 40 and 10 nm respectively.

Further analysis of the evaporated material was performed by means of Fourier transform infrared spectroscopy (FTIR) and X-ray diffraction (XRD). For the two investigations, 1.25 μm thick melamine films have been evaporated on KBr pellets and glass slides, respectively. The FTIR spectra of the precursor and evaporated melamine are displayed in Fig. 3a and b, respectively, and the characteristic peaks are assigned in very good agreement to the literature data summarized in Table 1 [17,22,23]. It is interesting to point out the vibrational peak centered at ~1370 cm^{-1} which is not characteristic to the melamine crystal structure reported elsewhere [17,18,22,23]. Lotsch and Schnick attribute this peak to the v(C–N) vibrational mode in melam-type structures [27]. However, in our work despite repeated FTIR characterization, we were not able to observe the other type of vibration (*i.e.* δ(NH) centered at ~1250 cm^{-1}), which the above mentioned group further attributed to melam. This may be due to the transitory nat-

ure of melam which is a low-temperature de-amonation product of melamine, formed upon linking of two molecules of melamine and the subsequent release of one mole of ammonia [19,27,28].

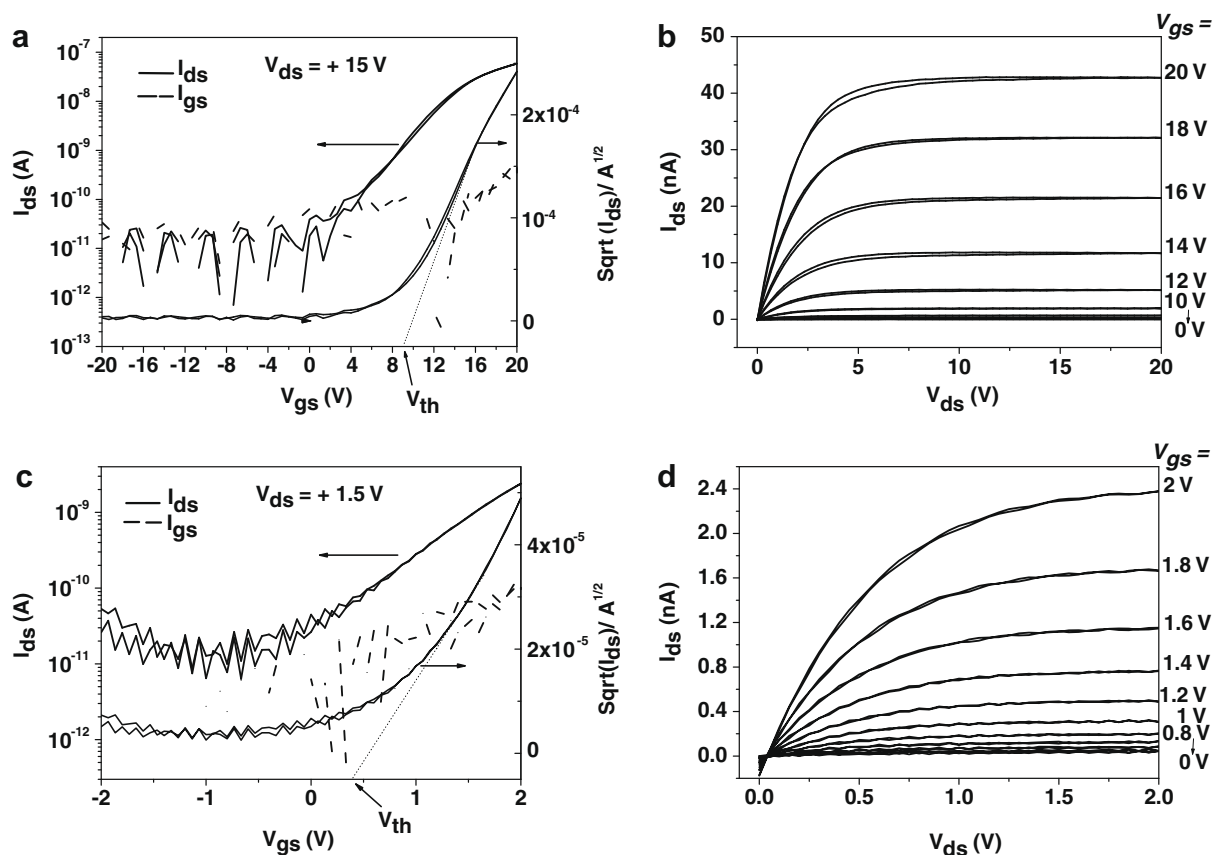
The melamine structure of the evaporated film is also confirmed by the X-ray diffraction pattern of the precursor powder and evaporated thin films, respectively (see Fig. 4a–c). The X-ray pattern of the precursor melamine powder is in excellent agreement with data published elsewhere, and the planes are indexed conforming to the pattern available in the standard card (No. 24-1654) of the instrument [20,24,25,27–31]. In agreement with observations of Jahromi and Moosheimer [31], we also presume that melamine grows in a columnar fashion originating from various nucleation centers distributed randomly on the substrate (*i.e.* aluminium stripe). Fig. 4c displays a five-fold thicker evaporated film with respect to the one shown in Fig. 4b and shows that the thin evaporated films are preferentially oriented as compared to the precursor powder. Scanning electron microscopy analysis of a 1.25 μm thick evaporated melamine film on glass slide (Fig. 5) revealed the presence of nanometer size cracks in some regions of the film. The cracking, however, was sporadic and there were extensive crack-free regions of at


Fig. 7. Transfer and output characteristics of a transistors featuring 1.5 μm melamine and 75 nm C_{60} with 60 nm thick top and bottom aluminium electrodes acting as gate and source/drain respectively (a), (b); Transfer and output characteristics of a transistor displaying 400 nm melamine and 75 nm C_{60}, with 60 nm thick aluminium top and bottom electrodes acting as gate and source/drain respectively (c), (d). Both I_{ds} and I_{gs} current values are displayed on the left axis in transfer characteristics. All transistors were subjected prior to the measurement to a heat-treatment in glove box, under nitrogen, at a temperature of 125 °C for one hour.

least 100 μm^2. The variation in the amount of cracking throughout and between samples could be attributed to differences in thickness between different regions of the evaporated films, since the induced stresses during the thermal cooling stage of the film at the end of evaporation may vary with film thickness. The presence of such cracks could be therefore responsible for the high leakage currents observed during the transistor characterization of some of the fabricated devices within different batches.

The dielectric spectrum of a 600 nm thick evaporated melamine film in a metal-insulator-metal (MIM) configuration is displayed in Fig. 6. The applied voltage bias across the MIM structure was in the range of −20 V to +20 V and the scanned frequency spanned between 10 kHz and 10 Hz. The dielectric response of the measured sample is independent of the applied voltage and virtually dispersion free in the range of frequencies measured. In the range of frequencies investigated, a dielectric constant of 4.25 for the evaporated thin film of melamine has been measured.

3.2. Transfer and output characteristics of small-molecule transistors

Fig. 7 displays the transfer and output characteristics of melamine-C$_{60}$ transistors that are entirely grown by vapor deposition. We observed that for thicknesses of the dielectric material in the range of 1 μm to 1.5 μm, the transistors are stable and reproducible, offering a change in the source to drain current in excess of 3 orders of magnitude and leakage between 2 to 3 orders of magnitude lower than the driven current. Noteworthily, our best performing device working at 15 V, displayed more than 4 orders of magnitude on-off ratio and a leakage over 3 orders of magnitude below the source-drain current. On the other side of the scale, a thin melamine layer of only 400 nm acts as a gate dielectric in a transistor working at only 2 V and featuring 2 orders of magnitude on-off ratio, with an acceptable leakage current of more than one order of magnitude below the source-drain current. We also observed that heating the devices on the top of a hot plate at a temperature of 100-125 °C for one hour further improves the transistor characteristics: the hysteresis vanishes, the leakage current decreases substantially, and the on-off ratio improves sometimes up to one order of magnitude when compared to the "as-fabricated" devices. We propose that the reason for this improvement rests in the finite diffusion of melamine molecules that arrests melamine film cracks. Some of the devices displaying an initial leakage within one order of magnitude below the drive current could be transformed in valuable devices after heat treatment, ultimately displaying leakages in excess of two orders of magnitude below the source-drain current. Thirty transistor batches with an aluminium gate in a bottom gate configuration were deposited on glass substrates, with four to six fabricated devices per batch. The measured transistors were subsequently subjected to the heat treatment exemplified above. The typical electron mobility calculated in the saturation regime for the heat treated transistors like the ones exemplified in Fig. 7a–d lies between 0.1 and 0.3 cm^2/Vs, averaged over samples produced in the same batch. The method employed for the mobility calculations

was reported elsewhere [26]. The electron mobility range and the transistor characteristics in this work correlate well with typical mobilities in OFETs featuring C$_{60}$ as organic semiconductor layer [32–34]. It is worth mentioning that these transistor characteristics are obtained on a rough dielectric layer as depicted in the AFM pictograms. The considerable roughness of the dielectric films is responsible for a late opening of the devices (*i.e.* high and positive threshold voltage, evidenced by the transfer graphs) as well as low mobility and relatively modest on-off ratio, since it is expected that at low positive gate voltages, the electric charges are trapped in the valleys where the potential energy is minimized [12]. The calculation of the interface trap density of states is performed with the aid of the relation [14]:

$$S = \frac{kT}{q} \ln 10 \left(1 + \frac{C_{dep} + C_{it}}{C_{0d}} \right) \tag{1}$$

where S is the subthreshold swing, C_{dep} is the depletion capacitance per unit area measured from independent C(V) measurements, C_{0d} is the insulator capacitance per unit area and C_{it} is the capacitance contribution per unit area of the charged interface traps, the latter being in fact expressed as:

$$C_{it} = q^2 D_{it} \tag{2}$$

with D_{it} the interface trap density of states and q-the elementary charge.

Performing the calculations for the particular case of the device shown in Fig. 7a–b, one obtain for D_{it} a value of 1.5×10^{12} cm^{-2} (eV)$^{-1}$. Furthermore, considering typical trap energies of 0.2 eV below the conduction band edge of C$_{60}$, this would correlate with a value of interface trap density $N_{it} = 3 \times 10^{11}$ cm^{-2}, very close with similar values reported for organic-organic interfaces featuring pentacene as a semiconductor [14]. Various other transistor batches were produced on Cr/Au, Cu and indium-tin-oxide (ITO) as gate material and the devices were completed with Al for the source and drain electrodes. We observed that the characteristics of the transistors featuring ITO and Cr/Au as gate electrodes lie within the batch-to-batch variation and are very similar to the ones featuring Al gate. However regarding the copper gate, the transistors showed significantly lower on-off ratio as well as pronounced hysteresis which may be due to the strong interaction between copper and amino moieties, a fact observed in our previous work and also by others [7,35–36]. In another embodiment, an ordinary xerographic foil (1.5 × 1.5 cm) of polyethylene terephtalate (PET) was used as a substrate on which an aluminium stripe was evaporated and the OFET was built in a similar way to the samples fabricated on glass substrate, resulting in a device displaying similar transistor characteristics.

4. Conclusion

In summary, we have developed organic field effect transistors having both the insulator and the semiconductor layers consisting of small evaporable molecules *i.e.* melamine and buckminsterfullerene, respectively. The characteristics of the transistors are stable and reproduc-

ible even several months after fabrication and the method offers the versatility to produce devices displaying adjustable operation voltage. The fabrication route substantiates further the vacuum evaporation method as suitable for large scale industrial processing (roll-to-roll production) of organic field effect transistors.

ARTICLE INFO

ABSTRACT

We report the enhanced performance of poly(3-hexylthiophene)/[6,6]-phenyl-C_{61} butyric acid methyl ester (P3HT/PCBM) bulk heterojunction solar cells with wet deposited interfacial gold nanostructures on their indium tin oxide (ITO) surfaces. To produce localized surface plasmons at the ITO surfaces, gold nanostructures were fabricated through the layer-by-layer deposition of gold nanorods onto the ITO substrates and transformed into nanodots through a thermally induced shape transition. The incorporation of plasmonic gold nanodots on the ITO surface was found to result in an increase in the power conversion efficiency from 3.04% to 3.65%, which is due to the presence of the resulting plasmon field.

1. Introduction

Organic solar cells have recently been intensively investigated with the aim of increasing their efficiency [1–7]. In particular, devices containing blends of poly(3-hexylthiophene) (P3HT) and [6,6]-phenyl-C_{61}-butyric acid methyl ester (PCBM) have been widely studied and have consistently been reported to produce efficiencies over 4% [2–4]. The recent development of metal nanoparticles with surface plasmon excitation has been used to further improve the performance of both silicon and organic solar cell devices [8–14]. Metallic nanoparticles are well known for their strong interactions with visible light, which arise because of the localized surface plasmon resonances (LSPR) of the collective oscillations of the conduction electrons within the particles. Excitation of LSPR within metal nanoparticles can create strong near-field electromagnetic fields and far-field propagating waves that enhance the light absorption and photocurrent of organic photovoltaic devices [11–14]. Recent studies have shown that hybrid organic photovoltaic devices with metal particles incorporated in the photo-active region have enhanced light absorption and photocurrent [13,14]. However, the power conversion efficiency (PCE) in these cases might be restricted by exciton quenching with nonradiative energy transfer and the differences between the electronic properties of the metal nanoparticles and the conjugated molecules in the hybrid material. In contrast, this undesirable quenching does not occur in interfacial metallic nanostructures between poly(3,4-ethylene dioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) and indium tin

oxide (ITO) substrates. Previous attempts to fabricate gold and silver nanostructures have used physical deposition techniques [11–13]. Wet chemistry approaches provide particularly efficient methods for the fabrication of well-dispersed metallic nanostructures with control over the size, shape, and density of particles [16,20,27]. There have been no previous studies of the effects of plasmon excitation in bulk heterojunction polymer solar cells containing interfacial gold nanoparticles fabricated with simple wet chemistry method rather than vacuum deposition.

In this study, we report a simple method for the fabrication of interfacial gold nanostructures through the thermally-induced shape transformation of anisotropic gold nanoparticles on ITO substrates, and investigate how the resulting surface plasmons affect the optical properties of the conjugated polymer and the PCE of bulk heterojunction polymer solar cells. These results are useful for understanding the role of surface plasmons in the performance of organic photovoltaic devices.

2. Experimental

For the fabrication of the photovoltaic devices, a multi-layer film of gold nanorods was prepared by the layer-by-layer electrostatic assembly approach, and the particle density of the gold nanorods on the ITO substrate was controlled by varying the number of deposition cycles [15,18]. The resulting films were annealed at 400 °C for 5 min to remove the insulating polyelectrolyte layers. In the wet chemistry approach, gold nanorods can be synthesized using the seed-mediated growth method described by Nikoobakht and El-Sayed [16]. First, the gold nanorods are capped with a bilayer of cetyltrimethyl ammonium bro-mide, which is positively charged [15,16]. The positively charged surfaces of the gold nanorods are then converted to negatively charged surfaces by exposing them to 1 mM poly(sodium-4-styrenesulfonate) (PSS) polyelectrolyte solution. In the gold nanorod deposition, positively charged 10 mM linear polyethyleneimine (PEI) is used as an adhesive layer on the ITO substrate. After the ITO substrate has been modified with PEI, repeated depositions of PSS-coated gold nanorods and PEI result in the formation of gold nanorod multilayer films on the ITO substrate. The conductive ITO film deposited with gold nanostructures was measured by using a scanning electron microscopy (SEM, Hitachi 4800). Optical spectra were acquired using Cary 5000 UV–vis spectrometer (Varian) and photoluminescence (PL) spectra were recorded by using the front face geometry of P3HT films by a spectrofluorometer (Jasco FP-6500) with the 500 nm excitation wavelength.

In order to investigate the effect of surface plasmons on the performance of P3HT/PCBM bulk heterojunction polymer solar cells, an active layer composed of 1 wt% P3HT (Rieke Metals)/PCBM (Nano-C) blend (1:0.8) in chlorobenzene was spin cast onto PEDOT:PSS (Baytron P AI 4083) coated ITO substrates with gold nanodots and treated at 150 °C for 10 min. The devices were completed by evaporation of a metal top electrode (LiF/Al), as shown schematically in the inset of Fig. 4a. For comparison, the control devices were also fabricated under the same experimental procedures with those of gold nanodots. Current density–voltage (J–V) characteristics were measured under AM 1.5 solar illumination (with reference to a standard Si cell calibrated with NREL) at an intensity of 100 mW/cm^2 with an Oriel 1 kW solar simulator by using a programmable Keithley 4200 measurement source under inert nitrogen

gas. The incident photon to current conversion efficiency (IPCE) as a function of wavelength was measured with a photomodulation spectroscopic setup (model Merlin, Oriel).

3. Results and discussion

Fig. 1 clearly shows the difference in the particle density of the gold nanorod multilayer films between the case of two layers of deposited gold nanorods (low density) and the case of five layers of gold nanorods (high density). Most of the gold nanorods are present in isolation with a few aggregates. Fig. 1a and b show a sequence of SEM images of gold nanorods changing their shape during thermal heating at 400 °C for 5 min. Thermally-transformed gold nanodots with an average size of 30 nm are then present uniformly on the ITO substrate. These SEM results confirm that the initially anisotropic nanorods have been converted into isotropic particles. The changes in the structure of the gold nanorods occur via diffusion of surface atoms from the regions of high curvature at the ends of the nanorods toward the straight cylindrical faces because of the structural instability of gold nanorods [17,18]. This trend is in agreement with changes in the shape of the UV–vis spectrum, in which a single plasmon band centered near 530 nm is present after heating instead of the two distinct plasmon bands in the original spectrum (Fig. 2).

Fig. 3a shows the absorption spectra of P3HT thin films on PEDOT:PSS-coated quartz substrates with and without gold nanodots, and the inset in Fig. 3a shows the absorption difference, ΔA ($A_{\text{sample}} - A_{\text{P3HT}}$). Because of the lack of distinct features in the absorption spectrum of the thick P3HT film on the gold nanodots, which is attributed to the high extinction coefficient of P3HT, a relatively thin 20 nm P3HT film was spin cast onto the quartz substrate instead of the ITO substrate. Since the plasmon region of the gold nanodots matches the absorption spectrum of P3HT, the absorbance of P3HT with gold nanodots in-

Fig. 3. (a) Optical absorption spectra and (b) PL spectra of P3HT thin films for P3HT/PEDOT:PSS/Au/quartz structures. The inset in (a) shows the differential absorption ΔA ($A_{\text{sample}} - A_{\text{P3HT}}$) spectra of the samples.

creases with the gold nanodot particle density. As a result, the differential absorption spectrum shown in the inset of Fig. 3a is very similar to the absorption spectrum of gold nanodots shown in the inset of Fig. 2, and the differential absorbance increases with the gold nanodot density. The weaker P3HT absorbance in the plasmon region is overwhelmed by the stronger plasmon excitation, which results in a profile similar to the surface plasmon band shapes.

The PL spectra of the same samples at room temperature are shown in Fig. 3b. The intensity of the PL spectrum of the P3HT film with gold nanodots is significantly stronger than that of the P3HT film without gold nanodots. The surface plasmons on the metal surface create a far-field propagating wave that penetrates into the P3HT layer via the excitation of surface plasmon resonances in the vicinity of the gold nanoparticles [9,19,20,27]. The large enhancement of the PL with increases in the gold nanodot density indicates that the propagating plasmon field results in an increase in the radiative relaxation of electronic states in the conjugated polymer. It is therefore clear that the PL enhancement of P3HT arises from the strong coupling between the excitonic state of P3HT and the plasmonic field

Fig. 4. *J*–*V* characteristics of polymer solar cells with and without gold nanodots (a) under illumination with 100 mW/cm^2 AM1.5 simulated light, (b) in the dark, and (c) IPCE spectra of these devices. A schematic diagram of the bulk heterojunction solar cell device with gold nanodots is shown in the inset in (a).

Table 1
Summary of device characteristics.

	J_{SC} (mA/cm^2)	V_{OC} (V)	FF	PCE (%)
P3HT/PCBM control	10.74	0.57	0.50	3.04
With gold nanodots (low density)	11.13	0.58	0.57	3.65
With gold nanodots (high density)	10.74	0.57	0.56	3.43

PCE of 3.65% with an open-circuit voltage (V_{OC}) of 0.58 V, a short-circuit current density (J_{SC}) of 11.13 mA/cm^2, and a fill factor (FF) of 0.57 was obtained for the device with a low density of gold nanodots. The IPCE data follow the same trend (Fig. 4c). The results demonstrated a substantial enhancement over the entire excitation spectral range, in which the improved IPCE was mainly observed from 500 nm to 600 nm. This agrees with the improved light harvesting via plasmon excitation of gold nanodots. Fig. 4b shows the corresponding *J*–*V* curves of these devices in the dark. This lack of change in the *J*–*V* curves in the dark strongly indicates that the total series resistance of the diode devices is unchanged with incorporation of interfacial gold nanodots. Fig. 4a and b provide further evidence that the significant change in *J*–*V* curve shape under illumination will therefore primarily originate from a change in bulk resistance of active layer under the plasmon-field interaction, not a change in sheet resistance of the electrode with metal nanoparticles.

According to the Mie theory [19], the total Mie extinction is a sum of contribution from absorption and scattering components associated with surface plasmon mode of the particles. For small gold particles unlike silver ones, the total extinction cross section consists of a large absorption and small scattering cross section. Thus, the transmission of incident light in proximate gold nanodots is largely absorbed than forward scattered at resonance condition. Because of the strong near-field absorption and far-field scattering characteristics of gold nanoparticles, there is competition between the loss of transmitted photon energy and the enhancement of incident light intensity coupling by a far-field scattering plasmon wave [19,20,24]. For this reason, J_{SC} changes negligibly from 10.74 mA/cm^2 to 11.13 mA/cm^2.

However, the enhancement of the PCE from 3.04% to 3.65% on the addition of a low particle density of gold nanodots is a consequence of an increase in FF. This result suggests that the improved FF results from the efficient charge transfer of excitons in P3HT because of the presence of the surface plasmon field. Several mechanisms by which localized surface plasmon fields can enhance the relaxation processes of excited-state excitons have been proposed as the possible interpretations of the plasmon effect [19–23]. When the strong coupling between a surface plasmon and an exciton occurs, the surface plasmon can shorten the excitonic lifetime and modify the dynamic properties of excited state excitons, which mean that the excitons do not have time to find their minima in the excitonic materials. According to these interpretations, the intense electromagnetic field of plasmon can increase the population of

of the gold nanodots, which is due to the propagating oscillation of the surface plasmon dipole.

The *J*–*V* characteristics under illumination of these solar cells with and without a layer of interfacial gold nanodots are shown in Fig. 4a, and a summary of their performance is given in Table 1. An enhanced efficiency was observed for the device with interfacial gold nanodots. A highest

'hot' exciton, the exciton with excess thermal energy being necessary to overcome the coulombic attraction of the initially generated radical pairs, in the P3HT films due to the acceleration of the radiative relaxation of P3HT exciton at plasmon resonant energy. Recently, Ohkita et al. [25] reported that this 'hot' exciton has a high probability of dissociation into free polarons for efficient charge separation. It was suggested that an increase of 'hot' exciton of P3HT might result in the enhanced charge dissociation yield without geminate recombination losses. Therefore, the plasmon-field interaction at resonant energies may be sufficient to facilitate the relaxation processes of P3HT electronic states for participating in the efficient charge dissociation, for which there is kinetic competition between geminate recombination to ground and charge dissociation. This model is supported by our results for the plasmon effect in P3HT/PCBM blend films, which implies that strong coupling between the plasmon and excitonic systems results in efficient charge dissociation at the excitation energies that overlap with those of the surface plasmon oscillations.

On the other hand, when there is a high particle density of gold nanodots, the randomly distributed gold nanoparticles generate 'hot-spots' due to their dipole–dipole electromagnetic interactions [26,27]. These hot-spots generate new hybridized plasmons below the surface plasmon frequency that complicate the propagation of the electromagnetic field into the active layer. Despite the stronger propagating plasmon field of gold nanodots with a high particle density, the excitons of P3HT cannot interact efficiently with the plasmon, resulting in a lower efficiency than that of the low particle density sample.

4. Conclusions

In conclusion, we have demonstrated that thermally-transformed gold nanodots deposited on the ITO substrate with the layer-by-layer technique enhance the far-field propagating plasmon field via surface plasmon excitation. The PCE was found to be increased from 3.04% to 3.65% by the incorporation of the plasmonic gold nanostructures because of the presence of the plasmon field proximate to the gold nanodots. These results suggest that the strong coupling between the organic excitons and plasmons of the gold nanostructures results in more efficient charge transfer in the bulk heterojunction blend. These results can contribute to our understanding of plasmonic interactions between conjugated polymers and metal nanostructures in polymer solar cells, and related experiments are under way.

ABSTRACT

We have studied the effect of active layer thickness on the performance and environmental stability of the 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS pentacene) thin-film transistor. The organic thin-film transistors (OTFTs) were fabricated by inkjet printing using a solution based TIPS pentacene. To get thick organic semiconductor, the surface of gate insulator was treated with n-octyltrichlorosilane (OTS-C_8) before jetting. The on-currents of the OTFT with ~ 1 μm active layer decreases a little in air, but the OTFT with 0.05 μm TIPS pentacene shows a significant degradation in drain currents.

Organic thin-film transistors (OTFTs) are of increasing interest for low cost, large-area electronic applications such as active-matrix displays, electronic paper and flexible microelectronics [1–3]. Among solution processed organic semiconductors, thiophene and pentacene derivatives exhibit good TFT performance. However, device stability under air should be improved to apply printed OTFTs to flexible displays.

The lifetime of the OTFTs having no passivation layer is usually short when they are exposed to ambient air due to the interaction of organic semiconductor with oxygen and moisture [4]. It results in the degradation of TFT performance. Therefore, in order to achieve OTFTs with long lifetime, the OTFTs should be protected from the environmental moisture and oxygen [5]. The studies on the environmental stability of OTFTs indicate that some specific gases such as moisture and oxygen affect the TFT performance significantly.

In this paper, we report the environmental stability of unpassivated OTFT made of the 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS pentacene) using inkjet printing. The on-currents of the OTFT with ~ 1 μm active layer degrade a little in air, but the OTFT with 0.05 μm TIPS pentacene shows a significant degradation in drain currents. The thick active layer has a self-passivation effect by intrinsic organic semiconductor even though the surface region is affected by H_2O or O_2, leading to keep the on-currents in air.

We used a piezoelectric type of Litrex Corp. 80.L equipment with spectra SE-128 printing head for inkjet printing [6]. The printer has an optical module which can inspect the substrate condition and analyze the volume, velocity and angle deviation of in-flight drops. We have optimized the parameters in order to make stable droplets with good

repeatability and to remove satellite drops before printing onto the substrate.

Fig. 1a shows the schematic cross-sectional view of a bottom contact TIPS pentacene OTFT used in the present work. As gate electrode, AlNd (100 nm) was deposited on polyethylenenaphthalate (PEN) substrate and patterned by photolithography. The gate insulator, photo-definable poly(4-vinylphenol) (P-PVP) having a dielectric constant of 3.6 and 450 nm thickness, was spin coated from the P-PVP precursor, and then developed after UV exposure. Then, the sample was cured in a vacuum oven to harden the pattern [7]. An Au layer (50 nm) was deposited on

Fig. 1. A cross-sectional view of an OTFT studied in the present work (a); FIB image of thin TIPS pentacene TFT (b); thick TIPS pentacene TFT (c) on the channel region.

the gate insulator and patterned as source/drain electrodes. The W/L, ratio of channel width to channel length, of the OTFTs was fixed to 236 μm/6 μm for all the OTFTs studied in this work.

To define a TFT region in a pixel and to keep the organic semiconductor inside of the TFT region, a bank was formed by poly(vinylalcohol) (PVA). Then, we treated the gate dielectric surface with O_2 plasma to make it clean and hydrophilic. Finally, TIPS pentacene was inkjet printed using the overlap jetting at 90 °C [8]. After printing, the OTFT substrate was cooled down to 26 °C with the cooling rate of ~0.5 °C/min. Measurement of the TFT performances were carried out at room temperature under ambient air and the sample was stored in ambient air.

It is found that boiling point of the solvent is important because the drying time upon jetting affects the structure of organic semiconductor [9]. Note that it increases with increasing boiling point. Therefore, cyclohexanol (viscosity of 41 cP) was mixed to 1,2,4-trichlorobenzene (viscosity of ~1 cP) and then more uniform TIPS pentacene layer could be achieved [10]. The boiling points for cyclohexanol and trichlorobenzene are 160 and 214 °C, respectively. And the sample was treated by n-octyltrichlorosilane (OTS-C_8) to make hydrophobic surface before TIPS pentacene printing. The surface energy of PVP dielectric decreases sufficiently by OTS-C_8 treatment, and thus printed drops could not spread out on the PVP surface, leading to a thick active layer. The thickness of the TIPS pentacene was changed between 50 nm and 1000 nm by increasing the drop number from 15 to 60 and surface treatment as well. Fig. 1b and c shows the cross-sectional view of FIB images of TIPS pentacene on the channel, from which the thickness can be decided.

Fig. 2 shows the optical image of a TIPS pentacene TFT before and after printing. The inkjet printed TIPS pentacene OTFT using mixed solvent shows more uniform layer in the channel [10]. But the optical images are very different between the two; the films of thin and thick TIPS pentacenes. The TFT channel is transparent for thin TFT as shown in Fig. 2b and the thick one is black as can be seen in Fig. 2c.

Fig. 3 shows the transfer characteristics of the TIPS pentacene TFT by inkjet printing [8]. The thin TIPS pentacene TFT on plastic exhibited an on/off current ratio of ~10^5, a threshold voltage of 1 V, a gate voltage swing of 1.6 V/dec. and a field-effect mobility of 0.006 cm^2/Vs in the saturation region. On the other hand, the thick TIPS pentacene TFT on plastic exhibited an on/off current ratio of ~10^6, a threshold voltage of −1 V, a gate voltage swing of 0.8 V/decade and a field-effect mobility of 0.02 cm^2/Vs in the saturation region.

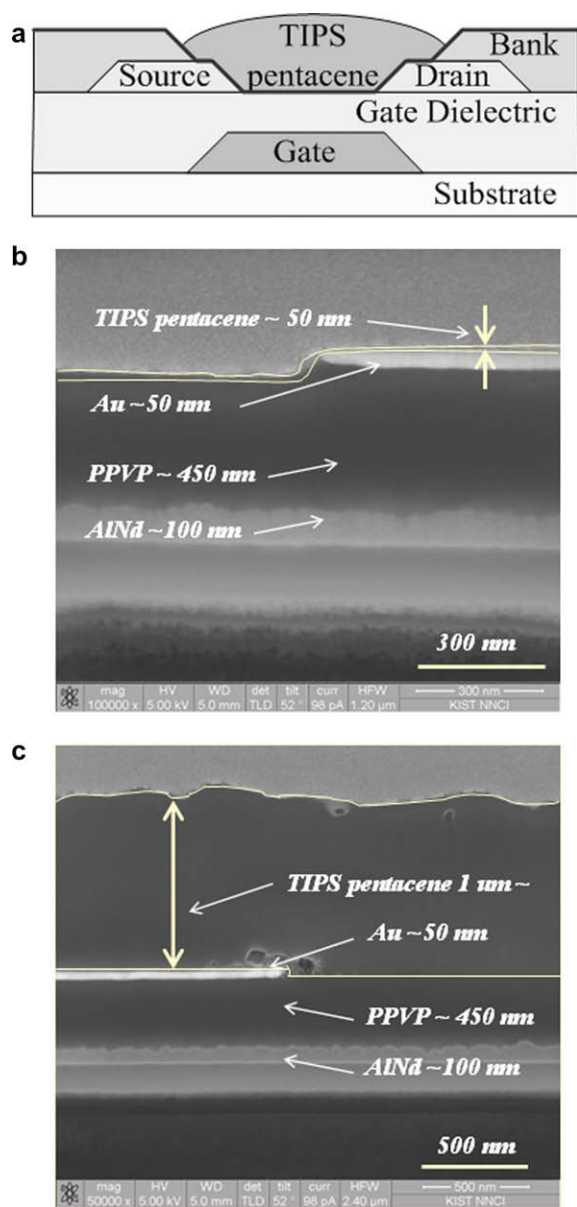
It is found that the performance of the TFT using a mixed solvent is worse than that using a single aromatic solvent. Note that aromatic solvents have π–π stacking showing relatively good electrical conduction because TIPS pentacene has π-electron conjugated segments. Therefore, when we dissolve the TIPS pentacene in aromatic solvent, electric conduction in TIPS pentacene is enhanced as a result of π–π interaction. However, when we used cyclohexanol solvent, non-aromatic solvent, the solvent molecules solvate non-conjugated segments of polymer and thus films with lower electrical conduction are obtained. Note


Fig. 2. Optical images of TIPS pentacene TFTs on the channel regions: before printing of TIPS pentacene (a); after thin TIPS pentacene jetting (b); after thick TIPS pentacene jetting (c).
Fig. 3. The transfer characteristics of the thin and thick TIPS pentacene TFTs printed by overlapping method.

that we used the mixed solvent of cyclohexanol and tri-chlorobenzene so that the performances of OTFTs are not as good as before [6]. The non-aromatic solvent, cyclohexanol, can deteriorate the OTFT performance even though the uniformity can be improved by adding it.

Fig. 4 shows the performances of the TIPS pentacene TFTs before and after 1400 h in ambient air using thin (a,b) and thick (c,d) active layers; transfer (a,c) and output characteristics (b,d). The thin TIPS pentacene TFT shows the drop in currents over the whole region. Its performance after 1400 h exhibited an on/off current ratio of $\sim 10^5$, a threshold voltage of 2 V, gate voltage swing of 0.6 V/decade and field-effect mobility of 0.0016 cm^2/Vs in the saturation region. The turn-on-voltage (V_{on}) shifts to the negative direction and field-effect mobility decreases significantly.

It is found that H$_2$O trapping is more significant than O$_2$ doping under ambient air and O$_2$ effect is dominant over H$_2$O trapping in dry air [11]. The H$_2$O absorbed by exposure to ambient air creates new trapping sites for the carriers. Therefore, H$_2$O absorbed by exposure to ambient air decreases the electrical conductivity of TIPS pentacene TFT. The overall drop of the drain currents after air exposure appears to be due mainly to the H$_2$O absorption in organic semiconductor.

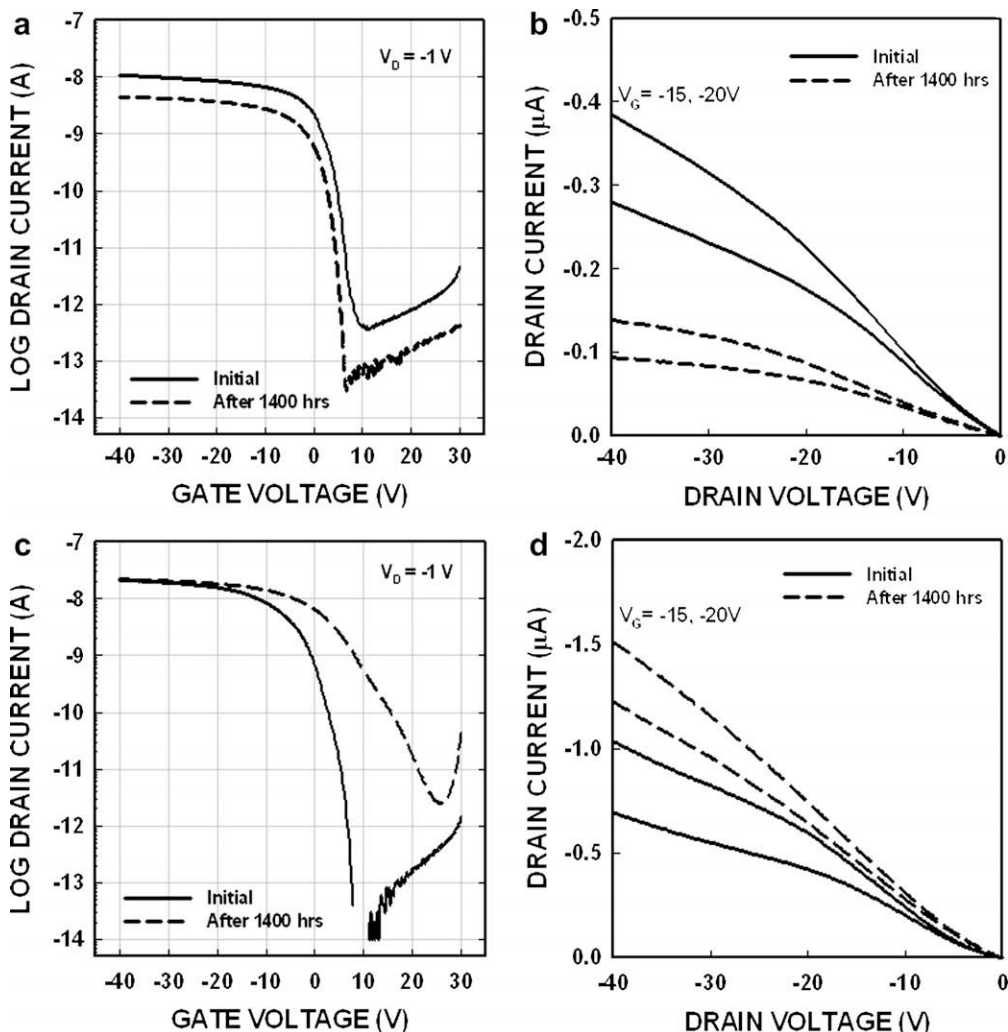
For the thick TIPS pentacene, formed by using OTS-C$_8$, the TFT exhibited an on/off current ratio of $\sim 10^6$, a threshold voltage of 2 V, a gate voltage swing of 2.0 V/decade and a field-effect mobility of 0.015 cm^2/Vs in the saturation region as shown in Fig. 4c. The on-current shows almost no change in ambient air even though a large shift in V_T from -1 V to 2 V. The significant increase of off-current (I_{off}) can be seen for thick TIPS pentacene TFT after long exposure to air because of O$_2$ doping effect into the TIPS pentacene layer. Increase of the subthreshold slope can be seen together with V_T shift. We compared the output characteristics of the OTFTs before and after long time exposure to air. A thin TIPS pentacene TFT shows a significant decrease in currents as shown in Fig. 4b, but the TFT with a thick TIPS pentacene shows a little increase in the drain currents as shown in Fig. 4d. However, the ohmic contact behavior


Fig. 4. The degradations of the TIPS pentacene TFTs using thin (a,b) and thick (c,d) layers before and after 1400 hours in ambient air; transfer (a,c) and output (b,d) characteristics.

seems to be not much different before and after the degradation in air. Therefore, it is concluded that the degradation in the drain currents is due to the bulk effect.
Fig. 5. The degradation in the field-effect mobility in the saturation region for both OTFTs in log-log scale.

The drain current (I_D) decreases and threshold voltage increases with time (t) in ambient air and the time dependence of field-effect mobility (μ_{fe}) can be described as

$$\mu_{fe} = \mu_{feo}t^\alpha \tag{1}$$

where μ_{feo} is the field-effect mobility in air at $t = 1$ s and the constant α is the slope obtained from the plot of log μ_{fe} versus log t.

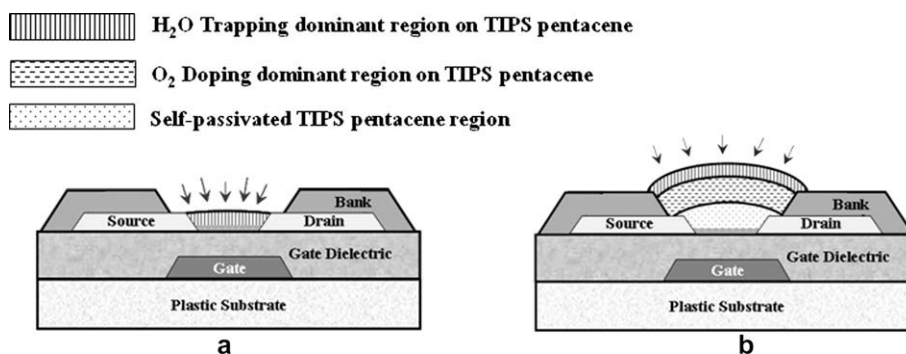
Fig. 5 shows the data indicating the plots of the μ_{fe} versus lifetime (t) in log-log scale. From the slope, the TFT with a thick TIPS pentacene exhibited the α of -0.041, and that for the TFT with 0.05 μm active-layer -0.16. On the other hand, that for the TFT with vacuum-deposited pentacene shows -0.78 [5]. Therefore, it is concluded that the environmental stability depends strongly on the thickness of active layer. The thick active layer protects the channel region against O_2 and H_2O adsorptions from ambient air. Note that the absorption of H_2O and O_2 in the active layer, especially in the channel region, degrades the TFT performance significantly.


Fig. 6. Cross-sectional views of the TIPS pentacene TFT channels dividing 2 and 4 regions using thin (a) and thick (b) TIPS pentacene layers, respectively.

Fig. 6 shows a model explaining the degradation of drain currents of OTFT with thin (a) and thick (b) active layers. The active layer can be divided into 2 for thin and 4 sub-layers for thick active-layers. These are channel and H_2O trapping dominant regions for a thin active layer as shown in Fig. 6a. The H_2O absorbed by exposure to ambient air affects the whole channel region. On the other hand, the thick organic semiconductor can be divided into 4 sub-layers; channel, intrinsic pentacene, O_2 doping dominant and H_2O trapping dominant regions as shown in Fig. 6b.

Thick TIPS pentacene has a H_2O trapped region on the surface, as the case in the thin TIPS pentacene TFT. The middle region just beneath the H_2O trapped one appears to be O_2 doping dominant region because O_2 can diffuse deeper than H_2O [11], and the region between the O_2 doping and channel regions is intrinsic organic semiconductor layer having a high resistivity. This can be a passivation layer to protect the channel layer from vapor and O_2 diffusion.

As shown in Fig. 4c, the on-currents are quite stable due to self-passivation effect. But the V_T shift increases the currents in the subthreshold region. These variations are attributed to the influence of the O_2 doping region. Note that the width of accumulation by gate bias decreases with increasing bias potential.

In conclusion, we have studied the effects of active layer thickness on the performance and environmental stability of the TIPS pentacene TFT. The OTFT was fabricated by ink-jet printing using a TIPS pentacene solution. The OTFT with a thin active layer shows the decreases in transfer charac-

teristics because of the H_2O diffuses into the whole active layer, but the OTFT with thick active layer exhibited a little change in on-currents because the channel can be protected from air and O_2 diffusion by a thin intrinsic organic semiconductor between channel and O_2 doped sub-layer.

ABSTRACT

A new architecture for flexible light-emitting devices with color-controlled emission is described. The various layers in these novel three-terminal devices are fabricated by casting soluble conjugated polymers from solution. The light-emitting three-terminal device (LET) can be described as comprising two polymer light-emitting diodes (LEDs) connected back-to-back with an internal common electrode. By controlling the bias voltages between the common buried electrode and the two outer electrodes, the LET can be turned on/off, and the emission color can be switched and modulated. Thus, the LET architecture provides a route to flexible displays that can be fabricated by printing technology with pixels that are color-switchable and color-tunable.

1. Introduction

High information content displays for future applications must be lower in cost, thinner, lighter and mechanically flexible. These demanding features are required to enable paper-like, portable "roll-up" and disposable displays [1–3]. Moreover, since such displays must have a device structure that is sufficiently simple to be compatible with low-cost manufacturing, it is important to reduce the number and complexity of circuit elements by integrating multiple functions into the components within each pixel.

We report here that we have successfully demonstrated a new architecture for flexible polymer-based, three-terminal devices with all layers cast from solution. The light emitting three-terminal device (LET) can be described as comprising two polymer light-emitting diodes (LEDs) connected back-to-back with an internal common electrode. By controlling the bias voltages between the common buried electrode and the two outer electrodes, the device can be turned on/off, and the emission color can be switched and modulated.

Plastic electronic devices made from semiconducting and metallic polymers offer a number of potential advantages, including lightweight, flexibility, and fabrication by printing/coating methods that enable low-cost manufacturing [4–6]. Moreover, multifunctional devices have been demonstrated, including light-emitting transistors [7,8], light-emitting solar cells (LESCs) [9] and light-emitting photo-diodes [10].

The pixels within high information content active matrix electroluminescent displays require two main functions: light generation from a LED and on/off switching by a field-effect transistor (FET). Full color is obtained by dividing each pixel into three sub-pixels which emit red, green and blue, respectively. Demonstration of a flexible three-terminal light emitting device that can be turned on/off and color-controlled by applied voltages is, therefore, of interest.

Voltage controlled color change has been demonstrated by using polymer blends [11] or multilayer stacks [12,13] for EL, or by using voltage controlled thermochromism [14]. Vertical-type color-controlled light emitting devices (CCLEDs) have been demonstrated using independently stacked electrode and emitting layers [15,16]. Light emitting transistors were shown to function as an LED and a transistor in series [17,18].

\Vertical-type CCLEDs are particularly interesting because the emission of each emitting layer can be controlled independently, thereby maximizing display resolution with high color purity. In addition, they also exhibit a high aperture ratio for light-emission compared with a device having a narrow light emitting region [7,18]. In spite of such advantages, however, known vertical-type CCLEDs are hard to consider as components for next generation flexible displays because of the inflexibility of their components and the relative complexity of fabrication (vapor deposition of many layers of small molecule organic semiconductors). With the LET described in here, we have successfully addressed the challenge of creating flexible CCLEDs fabricated by solution processing.

2. Results and discussion

2.1. LET structure

Fig. 1 shows the structure of the LET together with the molecular structures and the electronic structures of the component materials. The LET is equivalent to two polymer LEDs connected back-to-back with poly(3,4-ethylenedioxythiophene)-poly(styrene sulfonate), PEDOT:PSS, as the internal common electrode. The first diode with structure Al/poly [2-(4-(3',7'-dimethyloctyloxy)-phenyl)-p-phenylenevinylene](P-PPV)/PEDOT:PSS (Bottom) emits green light. The second diode with structure PEDOT:PSS/poly(2-methoxy, 5-(2,-ethyl-hexoxy)-1,4-phenylene vinylene) (MEH-PPV)/Al (Top) emits orange-red light. The function of the PEDOT:PSS layer is analogous to that of the polyaniline network layer in the polymer grid triode (PGT) [19,20]. Since the PEDOT:PSS electrode is continuous, there is no direct current path between the two outer electrodes. Thus, the LET described here is equivalent to two back-to-back diodes in contrast to the polymer grid triode (the latter can, in principle, exhibit gain).

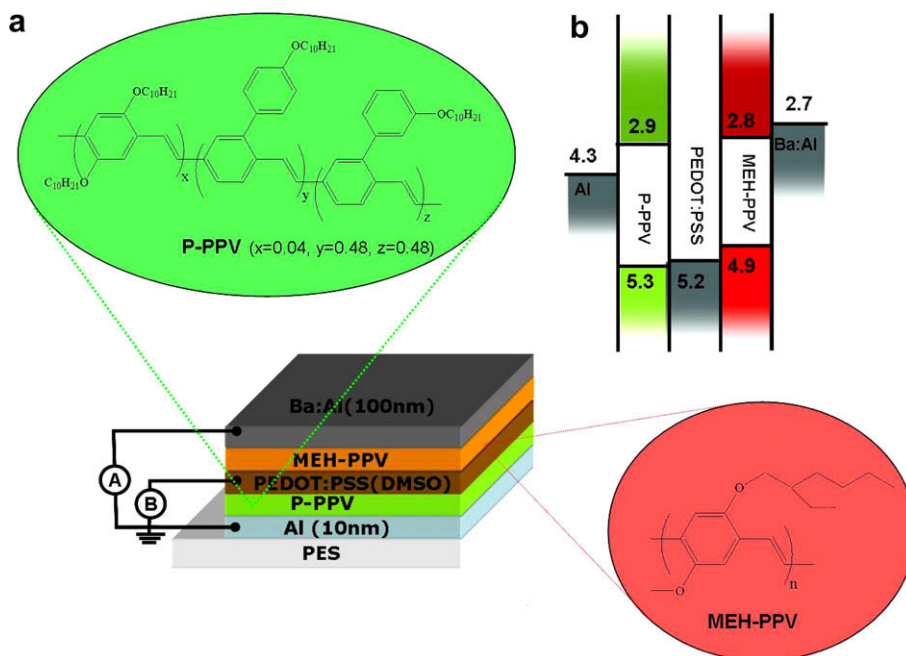
Three different conducting materials were used as electrodes, each with a different work function: Al ($\sim$4.3 eV), Ba:Al ($\sim$2.7 eV) and PEDOT:PSS ($\sim$5.2 eV) (see Fig. 1b). Semitransparent Al with a thickness of 10 nm is used as a low work function metal for injecting electrons into the bottom PLED, while Ba:Al (100 nm) is used for injecting electrons into the top PLED. The high work function semitransparent PEDOT:PSS conducting polymer is used as the internal anode for hole injection into both the top and bottom PLEDs. Because the Al electrode is grounded, the Ba:Al


Fig. 1. (a) Schematic of the device cross-section: the device consists of two polymer light emitting diodes, Al/P-PPV/PEDOT:PSS and PEDOT:PSS/MEH-PPV/Ba:Al, connected back-to-back. The P-PPV diode emits green light; the MEH-PPV diode emits red-orange light. (b) Energy level diagram.

and PEDOT:PSS electrodes can also be switched to perform either the functions of anode or cathode under different applied bias conditions.

The water-soluble PEDOT:PSS layer enables the fabrication of the multilayered device architecture. Because P-PPV and MEH-PPV are insoluble in water and PEDOT:PSS is insoluble in organic solvents, the various layers remain intact with no intermixing. The emission from MEH-PPV in the top LED must pass through the PEDOT:PSS layer and the P-PPV layer; the former is semitransparent and the absorption edge of the latter is at a photon energy above that of the emission from MEH-PPV. Earlier work has demonstrated that P-PPV shows high luminous intensity in single devices using Al as the cathode material [21,22].

The semitransparent Al electrode (thickness of ~10 nm) was deposited on a polyethersulfone (PES) substrate by thermal evaporation in a vacuum of about 5×10^{-7} Torr. The P-PPV was spin-cast (2000 rpm) from solution [1 wt.% in chlorobenzene (CB)] on top of the Al electrode, and baked at 80 °C for 60 min in a glove box. Because the P-PPV film is hydrophobic, we have deposited a thin layer of TiO_x [23–25] onto the P-PPV film before depositing hydrophilic PEDOT:PSS layer. The dilute TiO_x precursor solution was spin-cast onto the P-PPV emitting layer at 6000 rpm for only 5 s and the PEDOT:PSS solution was immediately dropped onto the TiO_x film. Since a continuous film of TiO_x is not typically formed under such spin-casting conditions, the TiO_x (amphiphilic) acts principally as a "glue" that assures adhesion between the P-PPV (hydrophobic) and PEDOT:PSS (hydrophilic) layers.

Highly conductive PEDOT:PSS (Baytron PH 500) solution mixed with DMSO solvent [26] was dropped on the TiO_x-treated P-PPV film without substrate spinning and then baked at 30 °C for 3 h. This results in higher conductivity for PEDOT:PSS (the extended annealing at 30 °C increases the degree of crystallinity of PEDOT:PSS). The MEH-PPV solution was spin-cast on top of the PEDOT:PSS layer. Finally, Ba (10 nm):Al(100 nm) was deposited by thermal evaporation in a vacuum of about 5×10^{-7} Torr.

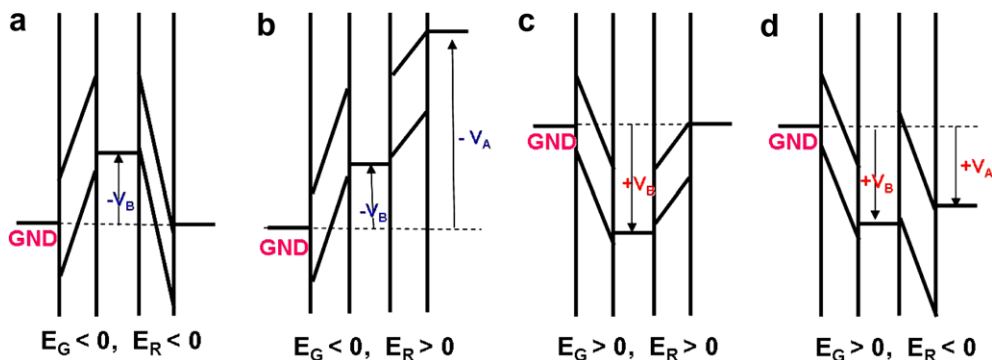
Since the LET has three-terminals, there are three different current pathways: I_1, I_2 and I_3 as shown Fig. 2a. I_1 is the current between the PEDOT:PSS and Al electrode, I_2 is the current between the PEDOT:PSS and Ba:Al electrode, and I_3 is the current between the Ba:Al and Al electrode. I_1, I_2 and I_3 a are determined by the electric field (E-field) generated by the combination of V_A voltage (Ba:Al to Al electrode) and V_B voltage (PEDOT:PSS to Al electrode). In the zero-bias condition shown in the energy diagram of Fig. 2b, the E-field in each layer results from the difference between the work functions of the two neighboring electrodes (E_G for P-PPV and E_R for MEH-PPV). We assume
Fig. 2. (a) Schematic of current paths in the device. I_1, I_2 and I_3 represent the hole currents between the PEDOT:PSS and Al electrode, PEDOT:PSS and Ba:Al electrode, and Ba:Al and Al electrode, respectively. (b) Energy band diagram for zero-bias condition.


Fig. 3. Energy band diagram for different bias conditions (see text).

the direction of E-field as positive from PEDOT:PSS to both outside electrodes.

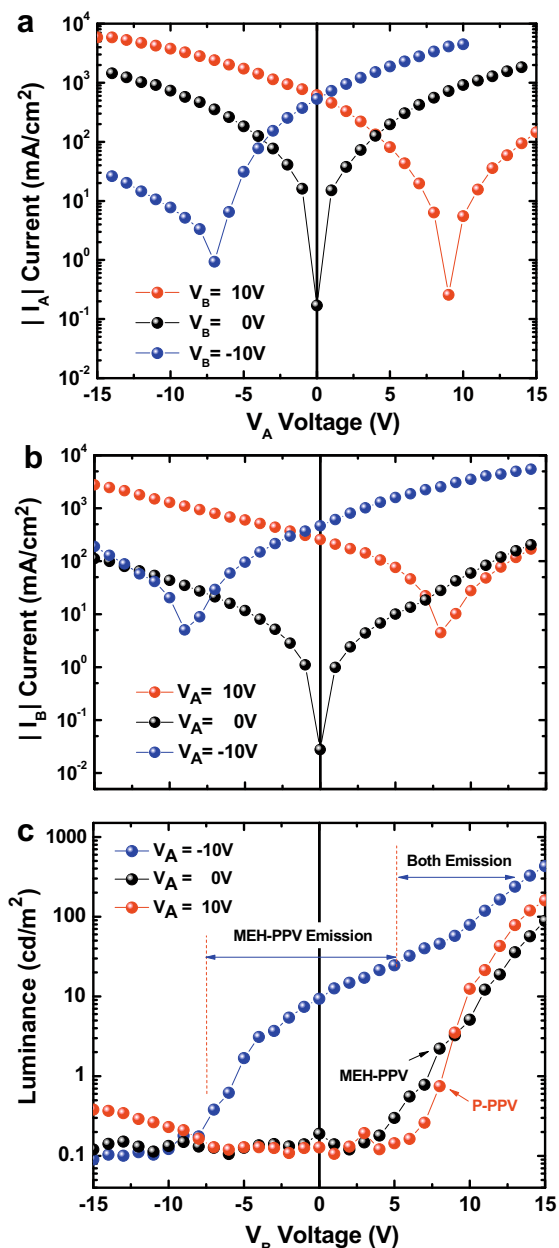
Fig. 3 shows four different combinations of E_G and E_R in the device. Fig 3a represents zero (or small) bias; Fig. 3a is similar to Fig. 2b in that both diodes are in reverse bias. Under the conditions described by Fig. 3b, the first diode is back-biased while the second diode is forward biased. In Fig. 3c, both diodes are in forward bias. In Fig. 3d, the first diode is in forward bias and the second diode is in reverse bias.


Fig. 4. Current-density versus voltage and luminance versus voltage curve characteristics under different combination of E_G and E_R electric field. I_A and V_A indicate the current and voltage between the Al and Ba:Al electrode and I_B and V_B between the PEDOT:PSS and Al electrode.

2.2. LET performance

This device operating concept described above is verified by the measurements of current density (I) – voltage (V) characteristics at various external biases. A plot of I_A (current from Al to Ba:Al, see Fig. 2a) versus V_A voltage under various V_B is shown in Fig. 4a. For $V_B = 0$, the $I–V$ curve exhibits general PLED characteristics except symmetric curve shape [27]. The current increases with increasing voltage. Control of the $I_A–V_A$ characteristics by the application of V_B is shown in Fig. 4a. With $V_B = 10$ V (red line), I_A is negative below $V_A < 9$ V and $I_A \neq 0$ even for $V_A = 0$ V. In contrast, when V_B is biased at -10 V (blue line), I_A is positive above $V_A > -7$ V and current flows even at $V_A = 0$ V.

This tendency is also observed in the control of the $I_B–V_B$ (current and voltage from Al to Ba:Al, see Fig. 2 a) characteristics by the application of V_A in Fig. 4b. For $V_A = 10$ V (red line), I_B is negative below $V_B < 8$ V and $I_B \neq 0$ even for $V_A = 0$ V. In contrast, when V_A is biased at -10 V (blue line), I_B is positive above $V_B > -9$ V and current flows even at $V_B = 0$ V.

Since I_A is determined by the combination of V_A and V_B (E_G and E_R), these current behaviors can be understood by the comparison of the energy level diagrams shown in Fig. 3a–d. For $V_B = 10$ V and $V_A < 9$ V in Fig. 4a, both E_G and E_R are positive (corresponding to Fig. 3c). Consequently holes are injected from PEDOT:PSS to Ba:Al. This corresponds to $I_A < 0$ because Ba:Al is the anode. For $V_B = -10$ V and $V_A > -7$ V in Fig. 4a, therefore, both E_G and E_R are negative (corresponding to Fig. 3a).

On the other hand, I_B has two current pathways, I_1 and I_2 (see Fig. 2a). Thus holes from PEDOT:PSS can be injected to Al [I_1] and Ba:Al [I_2]. For $V_A = -10$ V and $V_B > -9$ V in Fig 4b, the holes are injected from PEDOT:PSS to Ba:Al (corresponding to Fig. 3b). Under high +V_B, especially, the holes are injected from PEDOT:PSS to both Al and Ba:Al. This corresponds to the same E-field configuration shown in Fig. 3c. For $V_A = 10$ V and $V_B < 9$ V in Fig. 4b, holes are withdrawn at PEDOT:PSS from Ba:Al. This hole injection from Ba:Al is caused by the strongly reversed bias E_R (see Fig 3a). Under these conditions, $I_B < 0$. When V_B increases from negative to positive, the negative I_B current decreases. Moreover, when $V_B > 9$ V, $E_G > 0$ (corresponding to Fig 3d) and holes are injected from PEDOT:PSS to Al. Therefore I_B changes sign from negative to positive. These experimental results are fully consistent with the device operating concept shown in the energy diagrams of Fig. 3a–d. The data clearly indicate that one can not only control I_A by controlling V_B at fixed V_A, but also I_B by controlling V_A at fixed V_B.

2.3. Color switching

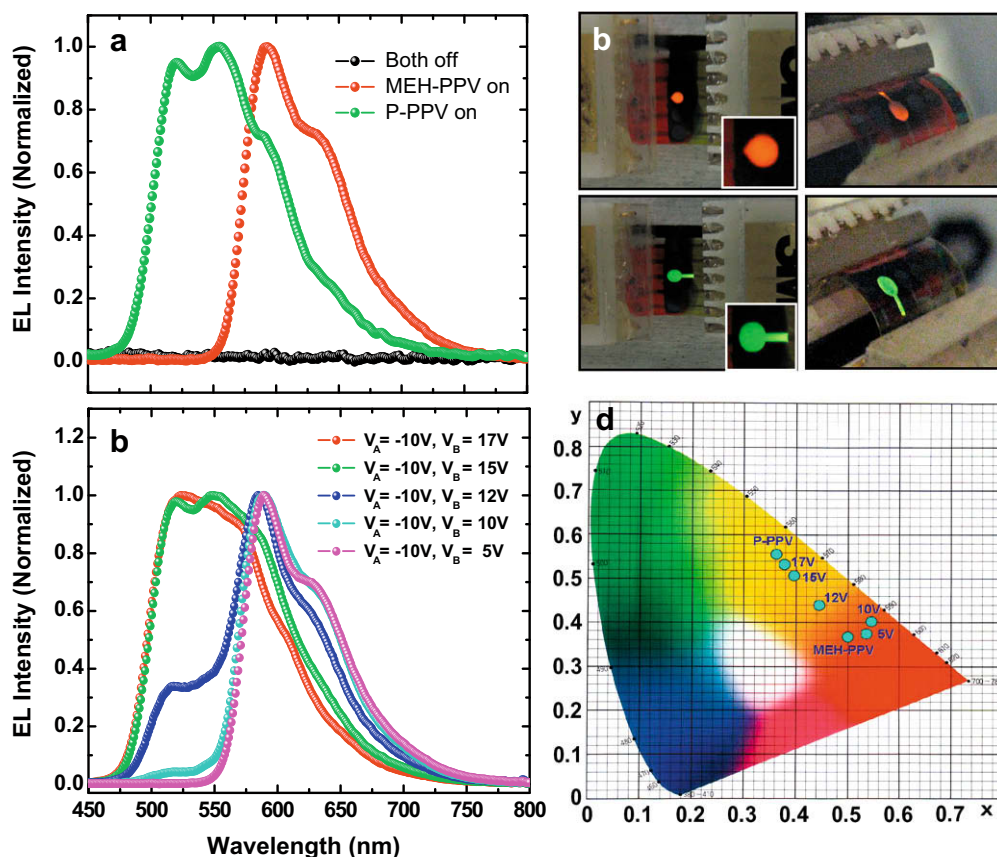
Since the energy barrier corresponding to the difference between the workfunction of PEDOT:PSS and the LUMO levels of two emitting polymers is much higher than those of PEDOT:PSS and the HOMO levels, electron injection from the PEDOT:PSS layer into the emitting layers is inhibited [27]; i.e. the device can usually emit the light under positive E_G or positive E_R.


Fig. 5. (a) Electroluminescent spectra of the device for various V_A and V_B combinations. The emission spectrum can be switched from that of P-PPV to that of MEH-PPV. (b) Photos of color switching from the LET. The LET fabricated on PES is flexible. (c) EL spectra for various V_B at fixed V_A voltage. The EL spectra are dramatically changed for different V_B. (d) Evolution of color coordinates. The chromaticity coordinates on a CIE diagram can be changed from $x = 0.5$, $y = 0.37$ to $x = 0.37$, $y = 0.5$ by controlling the V_A and V_B voltage.

Because both E_G and E_R can be changed in both sign and magnitude by the combination of V_A and V_B, the device can function as a color switch. Fig. 4c shows the luminance (L_B) – voltage (V_B) characteristics at various external V_A biases. For $V_A = 10$ V (red line) and $V_B = 10$ V ($E_R < 0$, $E_G > 0$) in Fig. 4c, holes are injected into the P-PPV layer and electrons are injected into the P-PPV layer from Al. Consequently the device emits light from the P-PPV layer. For $V_A = -10$ V (blue line) and $V_B = 0$ V ($E_R > 0$, $E_G < 0$), however, holes are injected from PEDOT:PSS into MEH-PPV and electrons are injected into MEH-PPV from Ba:Al. Thus the device emits light from MEH-PPV layer. Since the emission of each layer is governed by a combination of both I_A and I_B currents, the calculation of luminous efficiency defined by luminance intensity for injected current is non-trivial. Here, for simplicity, we use the current I_B as the basis for calculating the luminous efficiency. For $V_B = 15$ V, the luminous efficiency was 0.05 cd/A for the P-PPV layer and 0.03 cd/A for the MEH-PPV layer.

Fig. 5a shows the electroluminescent spectra of the device with various combinations of V_A and V_B. When $E_G > 0$ and $E_R < 0$ ($V_A = 10$ V and $V_B = 10$ V), the LET exhibits the typical green emission of P-PPV. However,

when $E_G < 0$ and $E_R > 0$($V_A = -10$ V and $V_B = 0$ V), the emission color switches to orange-red corresponding to that of MEH-PPV. The LET does not emit under $E_G < 0$ and $E_R < 0$.

Fig. 5b directly illustrates the color switching with color photos obtained by varying V_A and V_B (orange-red color or green color from a single LET). In addition, since the device consists of ductile metals and polymers layer fabricated on top of the plastic PES substrate, the LET is flexible (total device thickness of ~200 μm).

Interestingly, for $E_G > 0$ and $E_R > 0$, the device can emit both colors simultaneously and the intensity of each color can be controlled by varying V_B and V_A. Because the emission color can be changed continuously by varying the ratio of emission from MEH-PPV and P-PPV(see the blue line in Fig 4c), the LET can function as a color-tunable device. The EL spectra of the device for various V_B at fixed V_A are shown in Fig. 5c. The spectra change dramatically for different V_B. As a consequence, the color of the device gradually changes continuously from orange-red to green. The corresponding chromaticity coordinates on a CIE (Commission Internationale de l'Eclairage) 1931 diagram, see Fig. 5d, change from $x = 0.5$, $y = 0.37$ to $x = 0.37$, $y = 0.5$.

3. Conclusion

We have successfully demonstrated a flexible, light emitting and color-switchable polymer-based three-terminal devices. The LET functions as a color switch and a color modulator. By varying the bias voltages between the common internal electrode and the two outer electrodes, the LET can be turned on/off, the emission color can be switched, and the color (and brightness) can be modulated. Moreover, the multilayer LET structure can be fabricated with each layer cast from solution.

ARTICLE INFO

ABSTRACT

C_{60} and picene thin film field-effect transistors (FETs) in bottom contact structure have been fabricated with poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT:PSS) electrodes for a realization of mechanical flexible organic FETs. The C_{60} thin film FETs showed n-channel enhancement-type characteristics with the field-effect mobility μ value of 0.41 cm^2 V^{-1} s^{-1}, while the picene thin film FET showed p-channel enhancement-type characteristics with the μ of 0.61 cm^2 V^{-1} s^{-1}. The μ values recorded for C_{60} and picene thin film FETs are comparable to those for C_{60} and picene thin film FETs with Au electrodes.

1. Introduction

Mechanical flexibility is one of the most important advantages in organic thin film FETs from viewpoints of next-generation ubiquitous electronics. For a realization of flexible FET devices, C_{60} and pentacene thin film FETs with many kinds of plastic substrates and polymer dielectrics have been investigated during a past decade [1–4]. Furthermore, in addition to plastic substrates and polymer gate dielectrics, source/drain/gate contact electrodes are indispensable to be replaced from conventional metal to conducting polymers for a complete mechanical flexibility.

Several studies on transport characteristics for organic thin film FETs with conducting polymers have been performed so far [5–9]. Cosseddu et al. recently reported ambipolar transport in C_{60}/pentacene FET with representative conducting polymer, poly(ethylnedioxythiophene)/poly(styrenesulfonate) (PEDOT:PSS), electrodes on poly-(ethylene terephthalate) (PET) substrate fabricated by use of soft lithography (micro contact printing) technique [9]. Actually, the ambipolar FET characteristics with the n-channel μ value of 3.5×10^{-4} cm^2 V^{-1} s^{-1} and p-channel μ value of 0.01 cm^2 V^{-1} s^{-1} are observed in this device.

The n-channel μ value originating from C_{60} thin films was lower by three orders of magnitude than those for standard C_{60} FETs with Au electrodes on SiO_2/Si and parylene/PET substarates [4,10–12].

Furthermore, the best μ value among p-channel organic thin film FETs with conducting polymer electrodes fabricated in bottom contact structure was at most 0.01 cm^2 V^{-1} s^{-1}, which was realized in pentacene thin film FET with PEDOT:PSS electrodes [8], although the very high μ value of 0.05–0.3 cm^2 V^{-1} s^{-1} is exceptionally reported by Halik et al. [6]; very recently the high μ value of 0.2 cm^2 V^{-1} s^{-1} is realized in pentacene thin film FET with PEDOT:PSS-coated Au electrodes in bottom contact structure [13]. On the other hand, the best μ value in top contact structure was 0.3 – 0.7 cm^2 V^{-1} s^{-1}, which was also realized in pentacene thin film FET with PEDOT:PSS electrodes [8,9]. Therefore, the μ values in bottom contact structure are still low in comparison with that in top contact structure. For a design of complementary MOS (CMOS) integrated circuit with mechanical flexibility, n-channel and p-channel organic thin film FETs with conducting polymer electrodes are required with the high μ value in bottom contact structure.

In this study, we have fabricated and characterized the C_{60} and the new aromatic hydrocarbon, picene, thin film FETs with PEDOT:PSS electrodes in bottom contact structure. First, we expected a high n-channel μ value for C_{60} thin film FET with PEDOT:PSS electrodes fabricated by use of an air-controlled dispensing system. Second, we expected a high p-channel μ value for picene thin film FET with PEDOT:PSS electrodes because a very high μ value of 1.0–3.2 cm^2 V^{-1} s^{-1} was recently recorded in picene thin film FET with Au electrodes in top contact structure [14,15]. As a consequence, we have realized the high μ value of 0.41 and 0.61 cm^2 V^{-1} s^{-1} for C_{60} and picene thin film FETs with PEDOT:PSS electrodes, respectively, in bottom contact structure.

2. Experimental

Device structures of C_{60} and picene thin film FETs with PEDOT:PSS electrodes are shown in Fig. 1a. Commercially available C_{60} (Matsubo Co.: purity of 99.98%) and picene synthesized by ourselves [14] were used for fabrication of FET devices; ^{1}H NMR spectrum (not shown) of picene showed no impurity. Commercially available Si/SiO$_2$ are cleaned and treated to form hydrophobic surface according to procedures described elsewhere [12], and heavily doped Si was used as gate electrode in FET devices. Thickness of SiO$_2$ was 400 nm and capacitance per area C_0 was 8.63×10^{-9} F cm^{-2}. Source/drain electrodes of PEDT:PSS were formed on gate dielectric by use of an air-controlled dispensing system (Musashi Engineering Co.: SHOTMASTER 300). Two commercially available PEDOT:PSS reagents (Baytron PH500 and Baytron PHCV4, H. C. Stark GmbH) were used for the formation of PEDOT:PSS electrodes; in this letter, PEDOT:PSS (Baytron PH500) and PEDOT:PSS (Baytron PHCV4) are represented as PEDOT:PSS-A and PEDOT:PSS-B, respectively. The granule size is reported to be larger in PEDOT:PSS-B (200–500 nm) than PEDOT:PSS-A (20–60 nm). Finally, C_{60} or picene thin films with thickness of 50 nm were formed on these substrates.

3. Results and discussion

The photos of the C_{60} and picene FETs with PEDOT:PSS-A electrodes on Si/SiO$_2$ substrate are shown in Fig. 1a. The FET parameters of μ, on-off ratio and threshold voltage V_{TH} are determined from the transfer curves ($I_D^{1/2}$–V_G plots at V_{DS} = 100 V) in saturation regime, which are measured in forward-measurement mode (forward transfer curve) and the reverse measurement mode (reverse transfer curve): the parameters are determined for picene thin film FET from the transfer curve ($|I_D|^{1/2} - |V_G|$ plots at V_{DS} = -100 V). The C_{60} thin film FET was annealed from 353 to 393 K at 20 K step for each 18 h under 10^{-6} Torr, after transferring the device from evaporation chamber to measurement vessel, so that O_2 and H_2O are removed from channel region, and then the FET characteristics were measured under vacuum of 10^{-6} Torr at 300 K. On the other hand, the characteristics of picene thin film FET were measured at 300 K under vacuum of 10^{-6} Torr and under 500 Torr of O_2 without any annealing.

Fig. 1b and c show output and transfer characteristics of C_{60} FET with source/drain PEDOT:PSS-A electrodes on Si/SiO$_2$ substrate measured under 10^{-6} Torr of vacuum at 300 K after an annealing up to 393 K. Typical n-channel enhancement-type output curves are observed in C_{60} FET
Fig. 1. (a) Device structure (bottom contact type) of C_{60} and picene thin film FETs with PEDOT:PSS electrodes on gate dielectrics. Photos of these devices are also shown. (b) Output and (c) transfer curves measured at 300 K under vacuum of 10^{-6} Torr after annealing up to 393 K for C_{60} FET with PEDOT:PSS-A electrodes. For C_{60} FET with PEDOT:PSS-A electrodes shown in Fig. 1, channel length and width are 370 μm and 3.3 mm, respectively.

device (Fig. 1b). The μ, on-off ratio and V_{TH} and were 0.13 cm^2 V^{-1} s^{-1}, 1.3×10^7 and 47 V, respectively, for the forward transfer curve (Fig. 1c), while their values were 0.29 cm^2 V^{-1} s^{-1}, 1.3×10^7 and 66 V for the reverse transfer curve (Fig. 1c). The μ value, 0.29 cm^2 V^{-1} s^{-1}, is larger by three orders of magnitude than that, 3.5×10^{-4} cm^2 V^{-1} s^{-1}, reported by Cosseddu et al. [9] and it is comparable to those, 0.08–0.55 cm^2 V^{-1} s^{-1}, for the standard C$_{60}$ FET with Au electrodes on Si/SiO$_2$ [4,10–12]. The high V_{TH} value suggests an existence of large trap states in mid-gap position between highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO), which are formed in interface between C$_{60}$ and SiO$_2$ gate dielectric. On the other hand, the relatively high μ values obtained in this FET suggest very small shallow trap states in the interface.

A hysteresis between forward and reverse transfer curves is observed, as seen from Fig. 1c. Nevertheless, it is important to say that the hysteresis found in the transfer curve (e.g. Fig. 1c) obtained by data acquisition at 300 K under 10^{-6} Torr after an annealing of the FET device at 353–393 K under 10^{-6} Torr is smaller than that in the transfer curve (not shown) measured at 300 K under 10^{-6} Torr without any annealing. Recently, we investigated air and O$_2$-exposure effects on FET characteristics of p-channel FET device with thin films of picene [14,15]. These investigations clarified that the hysteresis is closely associated with H$_2$O introduced into channel region. Therefore, the hysteresis observed in transfer curve of C$_{60}$ FET with PEDOT:PSS-A electrodes may also be associated with H$_2$O. As seen from Fig. 2a, the μ value in C$_{60}$ FET with PEDOT:PSS-A increases rapidly by the annealing above 350 K whose temperature is consistent with the critical temperature where the hysteresis decreases rapidly in transfer curves (not shown). As a consequence, we can present the scenario that a reduction of H$_2$O-induced trap states by the annealing of device under vacuum produces both the decrease of hysteresis and the increase in μ.

The output characteristics (Fig. 1b) show a smooth carrier injection from source electrode to C$_{60}$ thin films because liner (Ohmic) I_D–V_{DS} plots are observed in low V_{DS} region. This suggests an existence of small barrier height or Ohmic contact between PEDOT:PSS-A and C$_{60}$ thin films. As seen form Fig. 2b, the work function, φ_m, of PEDOT:PSS was determined to be 5.2 eV (Fermi level ε_F of –5.2 eV) from the onset energy of photoemission (not shown), whose value is close to that, 5.1 eV, of Au [16]. Since the LUMO and HOMO levels of C$_{60}$ are −3.6 eV and −6.0 eV, respectively [17], this energy diagram predicts a large carrier injection barrier height for n-channel conduction owing to the large energy difference (1.6 eV) between ε_F of PEDOT:PSS-A and LUMO level. Nevertheless, such a large carrier injection barrier height was not observed in the output characteristics. This suggests that the junction between PEDOT:PSS-A and C$_{60}$ thin films is largely deviated from the electronic structure expected in pure metal-semiconductor junction. This result may be caused by charge transfer, formation of electric dipole and orbital hybridization at the interface between C$_{60}$ and PEDOT:PSS. Thus, the use of PEDOT:PSS-A electrodes led to smooth carrier injection as well as high μ value in C$_{60}$ thin film FET.

The output and transfer characteristics of C$_{60}$ FETs with PEDOT:PSS-B electrodes were measured under the same conditions as those in C$_{60}$ FET with PEDOT:PSS-A electrodes. The μ, on-off ratio and V_{TH} were 0.07 cm^2 V^{-1} s^{-1}, 1.3×10^7 and 35 V, respectively, for forward transfer curve, and 0.41 cm^2 V^{-1} s^{-1}, 1.2×10^7 and 73 V for reverse transfer curve in C$_{60}$ FET with PEDOT:PSS-B, which are measured at 300 K after annealing up to 393 K. These values are almost the same values as those for C$_{60}$ FET with PEDOT:PSS-A. As a consequence, the difference in granule size between PEDOT:PSS-A and B never affected the FET characteristics. The values of μ, on-off ratio and V_{TH} for C$_{60}$ FETs fabricated in this study are listed in Table 1.
Fig. 2. (a) Plots of μ as a function of annealing temperature in C$_{60}$ FET with PEDOT:PSS-A electrodes; the values correspond to the average ones for two devices measured. (b) Energy diagram of Au, PEDOT:PSS, C$_{60}$ and picene. The φ_m was 5.2 eV for both electrodes of PEDOT:PSS-A and PEDOT:PSS-B.

Table 1
FET parameters in C$_{60}$ FET with PEDOT:PSS electrodes.

Annealing temp. (K)	μ (cm^2 V^{-1} s^{-1})	On-off ratio	V_{TH} (V)
Forward (PEDOT:PSS-A)[a]			
Non-annealing	0.01	8.9×10^5	55
353	0.04	2.7×10^6	58
373	0.08	7.6×10^6	50

393	0.41	1.2×10^7	73

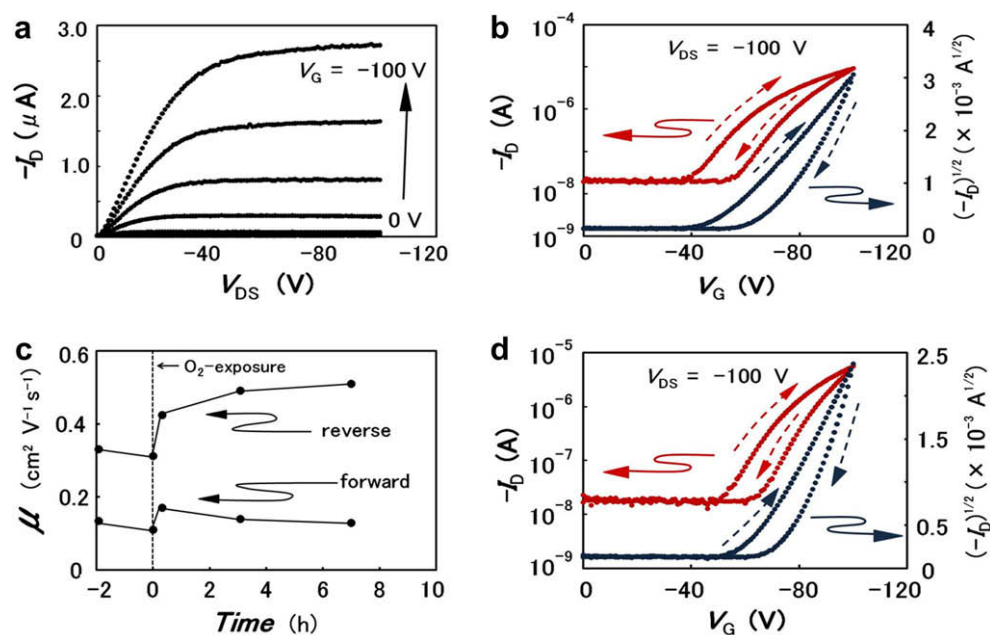
[a] The values of C$_{60}$ FET with PEDOT:PSS-A electrodes correspond to the average ones for two devices measured. The annealing time is 18 h.


Fig. 3. (a) output and (b) transfer curves measured at 300 K under vacuum of 10^{-6} Torr, and (c) O_2-exposure time dependence of μ in picene thin film FET with PEDOT:PSS-A electrodes. (d) Transfer curves for picene thin film FET with PEDOT:PSS measured under 500 Torr of O_2; the O_2-exposure time is 7 h. For picene thin film FET with PEDOT:PSS-A electrodes shown in Fig. 3, channel length and width are 300 μm and 2 mm, respectively.

Fig. 3a and b show the output and transfer curves for picene thin film FET with PEDOT:PSS-A electrodes fabricated in bottom contact structure. The curves were measured at 300 K under vacuum of 10^{-6} Torr after a dynamical pumping under vacuum of 10^{-6} Torr for 60 h. The output curves show typical p-channel enhancement-type FET characteristics. The transfer curve shows a large hysteresis between the forward and reverse curves, in the same manner as the picene thin film FET with Au electrodes fabricated in top contact structure [14,15]. The hysteresis originates from the existence of H_2O in the channel region of thin films [14]. The μ, on-off ratio and V_{TH} are determined from the forward transfer curve to be 0.13 cm^2 V^{-1} s^{-1}, 510 and 50 V, respectively, while those are determined from the reverse transfer curve to be 0.44 cm^2 V^{-1} s^{-1}, 470 and 73 V. The μ values are larger than those (0.11 cm^2 V^{-1} s^{-1} for forward curve and 0.27 cm^2 V^{-1} s^{-1} for reverse curve) under vacuum reported previously for the picene FET with Au electrodes in top contact structure [14]. This result suggests a smooth hole injection based on a lowering of the contact resistance by replacement of Au to PEDOT:PSS electrode [14,15]. Furthermore, the fact that we have never observed the FET operation in picene thin film FET device with Au electrodes fabricated in the bottom contact structure supports more smooth hole injection from PEDOT:PSS electrode to picene thin films than from Au electrode.

The energy difference between ε_F of PEDOT:PSS (−5.2 eV) and HOMO level of picene thin film (−5.5 eV) is 0.3 eV [14] whose value is slightly smaller than that, 0.4 eV, between ε_F (−5.1 eV) of Au and the HOMO level (Fig. 2b). Since the slight difference is not likely to be responsible for the difference of efficiency of hole injection, we may expect the factors such as the charge transfer, for-

mation of electric dipole and hybridization of orbitals as an origin for the smooth carrier injection from PEDOT:PSS electrode, instead of the direct energy mismatch with HOMO level of picene thin films.

After a dynamical pumping of the picene FET under vacuum of 10^{-6} Torr at 323 K for 18 h, 500 Torr of O_2 gas was introduced into the measurement vessel. As seen from Fig. 3c, before an introduction of O_2 gas, the μ values were 0.11 and 0.31 cm^2 V^{-1} s^{-1}, respectively, for the forward and the reverse transfer curves. After an introduction of O_2 gas, the μ increases drastically to 0.17 cm^2 V^{-1} s^{-1} for the forward transfer curve and 0.42 cm^2 V^{-1} s^{-1} for the reverse transfer curve within a few minutes. The μ value for the reverse transfer curve increased up to 0.51 cm^2 V^{-1} s^{-1} at 7 h after the O_2 gas exposure, while the μ value determined from the forward transfer curve a little reduces from the maximum value (0.17 cm^2 V^{-1} s^{-1}); the transfer curves are shown in Fig. 3d. The values of μ in picene FETs fabricated in this study are listed in Table 2, together with the on-off ratio and V_{TH} values.

As seen from Table 2, the V_{TH} values were 61 and 81 V for the forward and reverse transfer curves at 7 h after O_2-exposure, respectively. These values slightly decrease in comparison with the values of 71 V (forward transfer curve) and 83 V (reverse transfer curve) before O_2-exposure. Thus, the enhancement of μ and the reduction of V_{TH} by O_2-exposure is found in the picene thin film FET with PEDOT:PSS electrodes in bottom contact structure. The increase in μ is already reported in picene thin film FET with Au electrodes in top contact structure [14,15], but it should be noticed that the decrease in V_{TH} by O_2-exposure has not yet been reported. The decrease in V_{TH} observed for picene thin film FET with PEDOT:PSS

Table 2
FET parameters in picene FET with PEDOT:PSS-A electrodes.

O_2-exposure time (h)[a]	μ ($cm^2\,V^{-1}\,s^{-1}$)	On-off ratio	V_{TH} (V)
Forward			
−1.9	0.13	2.2×10^2	72
0.0	0.11	1.9×10^2	71
0.3	0.17	3.1×10^2	69
3.1	0.14	3.4×10^2	63
7.0	0.13	3.7×10^2	61
Reverse			
−1.9	0.33	1.9×10^2	82
0.0	0.31	1.6×10^2	83
0.3	0.42	3.1×10^2	80
3.1	0.49	3.0×10^2	80
7.0	0.51	3.8×10^2	81

[a] The O_2-exposure time of −1.9 h refers to 1.9 h before O_2-exposure. The O_2-exposure time, 0.0 h, means just before O_2-exposure.

electrodes in bottom contact structure suggests that not only shallow trap states in picene thin films are affected by O_2 gas but also middle trap states are affected. The quick response of this picene thin film FET for O_2 gas exposure may open a way for an application toward flexible and portable O_2 gas sensor.

The highest μ values for picene thin film FET with PEDOT:PSS electrodes was $0.61\ cm^2\,V^{-1}\,s^{-1}$ for the reverse transfer curve (not shown), recorded for another device which was stored in air for one week. The μ value of $0.61\ cm^2\,V^{-1}\,s^{-1}$ is comparable to that, $0.3–0.7\ cm^2\,V^{-1}\,s^{-1}$, for pentacene thin film FET with PEDOT:PSS electrodes in top contact structure [8]. The μ value of $0.61\ cm^2\,V^{-1}\,s^{-1}$ is higher by a factor of 60 than that, $0.01\ cm^2\,V^{-1}\,s^{-1}$, for the previous standard pentacene thin film FETs with PEDOT:PSS electrodes in bottom contact structure [8,9]. Furthermore, this value is higher by a factor of two than the best μ value, $0.3\ cm^2\,V^{-1}\,s^{-1}$, for pentacene thin film FET with PEDOT:PSS electrodes in bottom contact structure reported by Halik et al. [6].

4. Conclusion

We have fabricated high-performance C_{60} and picene thin film FETs with PEDOT:PSS electrodes in bottom contact structure. The best μ values in this study were $0.41\ cm^2\,V^{-1}\,s^{-1}$ in n-channel C_{60} thin film FET and $0.61\ cm^2\,V^{-1}\,s^{-1}$ in p-channel picene thin film FET. The μ value of $0.41–0.61\ cm^2\,V^{-1}\,s^{-1}$ is the best record in organic thin film FETs with conducting polymer electrodes fabricated in bottom contact structure [5–9]. Here it should be noted that the V_{TH} value of C_{60} and picene thin film FETs with PEDOT:PSS electrodes are very high (>40 V). For a reduction of V_{TH}, it is important to modify the interface be-

tween gate dielectrics and active layers to reduce the trap states in mid-gap position. This is the next important study in a development of high-performance organic thin film FET with conducting polymer electrodes. In this study, we have used Si/SiO_2 substrate for the C_{60} and picene thin film FETs. However, for the realization of complete flexible organic FET devices, the plastic substrate and polymer gate dielectric must be used in addition to the conducting polymer electrodes. Since we have already fabricated high-performance C_{60} thin film FET with PET substrate and parylene gate dielectric [4], the C_{60} and picene thin film FETs with plastic substrate and polymer gate dielectric as well as conducting polymer electrodes may be easily fabricated in the next step. This study shows that the practical CMOS integrated circuits can be designed with C_{60} and picene as active layers and PEDOT:PSS for electrodes.

ARTICLE INFO

ABSTRACT

Recently, it has been demonstrated that for organic semiconductors with a Gaussian density of states (DOS) and with on-site energies that are spatially uncorrelated the hopping mobility of charge-carriers can be strongly carrier-density-dependent (extended Gaussian disorder model, EGDM). In the literature, it has been argued that for some materials, the on-site energies are actually spatially correlated. In this paper, we develop a full description of the mobility in a correlated Gaussian DOS (extended correlated disorder model, ECDM), using a master-equation method. We show that the mobility is less strongly carrier-density-dependent than in the EGDM, but that the field dependence is more pronounced. The field dependence is found to be described by a Poole-Frenkel factor, as has been deduced from empirical analyses of experimental data, but only in a limited field range. As an example of an application, we present a comparison between analyses of the current–voltage–temperature $J(V,T)$ characteristics of a poly-phenylene-vinylene (PPV) based hole-only device using the EGDM and the ECDM. For both cases, excellent fits can be obtained, but with the EGDM a more realistic value of the intersite distance is found than in the case of the ECDM. We view this as an indication that site-energy correlations do not play an important role in PPV.

1. Introduction

The interest in electronic devices based on disordered semiconducting organic materials is rapidly increasing. Important applications are organic light-emitting diodes (OLEDs) [1,2] organic field-effect transistors [3], and organic photo-voltaic devices [4]. It is of crucial importance to understand the charge-carrier transport in these materials in order to design and synthesize appropriate materials and to improve the efficiency and lifetime of devices. Many investigations have addressed the mobility μ of charge-carriers in these materials, since this is one of the important parameters controlling the performance of devices.

Charge transport in polymers and organic small-molecule materials occurs by thermally assisted tunneling – hopping – between localized molecular states. In several studies, the dependence of μ on temperature T and electric-field E, due to this hopping process, has been investigated [5–10]. Bässler and co-workers introduced a model with an uncorrelated Gaussian distribution of the random energies of hopping sites, which became known as the "Gaussian disorder model" (GDM). They found a temperature dependence of the mobility of the form $\mu \propto \exp[-(T_0/T)^2]$ and a Poole-Frenkel behavior $\mu \propto \exp[\gamma\sqrt{E}]$ for the electric-field dependence in a rather limited range of electric-fields [5,6]. Gartstein and Conwell argued that in order to obtain a Poole-Frenkel behavior in a broad range of electric-fields, as observed in time-of-flight mobility measurements, it is necessary to assume correlation

between the site energies, leading to what is now known as the "correlated disorder model" (CDM) [7]. Indeed, their simulations, which assume static fluctuations of the site energies due to the interaction of a charge-carrier with permanent and induced dipoles, show that the concept of correlation between the energies of spatially close sites leads to an extended range of validity of the Poole-Frenkel law [7]. Dunlap et al. developed a one-dimensional analytical model with correlations caused by randomly oriented dipoles, which yields a Poole-Frenkel E dependence of μ in agreement with time-of-flight measurements of molecularly doped polymers [8]. An extension of this model to three dimensions was developed by Novikov et al. [9]. Apart from dipoles, long-range thermal fluctuations in the molecular geometries of a polymer were suggested as a possible cause for correlation in the disorder [10]. Recently, it has also been suggested that the Poole-Frenkel dependence on the electric-field is caused by carrier heating [11]. In an early study the assumption of a Poole-Frenkel field dependence of the hole mobility appeared to lead to a good description of the current–voltage $J(V)$ characteristics of hole-only devices of PPV(poly-phenylene vinylene)-based polymers [12].

In organic field-effect transistors, where the carrier-density is relatively high (up to on average 0.01–0.1 carriers per site), a dependence of the mobility on the charge-carrier-density p was taken into account in the modeling [13]. In sandwich-type hole-only devices containing, e.g., PPV-based or polyfluorene-based polymers used in OLEDs, the carrier-densities are typically much smaller, *viz.* 10^{-5}–10^{-4} carriers per site, except in a thin region near the anode interface. Nevertheless, it was concluded during the last few years that it is also for such devices and in OLEDs important to take the dependence of μ on p into account [14–16]. By changing the thickness of the polymer layer it was demonstrated that by only assuming a dependence of μ on E of the Poole-Frenkel type it is not possible to fit the $J(V)$ characteristics of hole-only devices with different thicknesses without changing the fit parameters, but that a consistent set of fits can be obtained by assuming a dependence of μ on p [15,16]. Several theoretical and computational approaches were employed to describe this carrier-density dependence of the mobility [10,17–19]. From a numerical solution of the master-equation within the GDM for the occupation probabilities of an array of hopping sites Pasveer et al. obtained a dependence of μ on T, E, and p that was shown to lead to excellent agreement of calculated and measured $J(V,T)$ characteristics of hole-only devices of PPV-based polymers [18]. We call this the "extended" Gaussian disorder model (EGDM), in order to indicate that the carrier-density dependence of the mobility is taken into account. It was found that only at high voltages and low temperatures the dependence of μ on E plays a role.

Pasveer and co-workers concluded that it is not necessary to assume correlations in the site energies in order to obtain for the PPV-based hole-only devices studied agreement with measured $J(V)$ characteristics. However, this does not yet proof that the site energies are uncorrelated, as it has not yet been established whether the experiments performed are sufficiently sensitive to the occurrence of correlations. In this paper, we first provide the required theoretical basis for addressing this question, *viz.* by deriving from master-equation calculations and percolation theory (Section 2) a full description of the temperature, electric-field and carrier-density dependence of the mobility (Section 3). To be definite, we will consider correlated disorder as caused by random dipoles, since this is the most commonly accepted model. We show that the carrier-density dependence of the mobility is weaker than in the EGDM, but that the field dependence is stronger. As an application of our results, we re-analyse in Section 4 the $J(V)$ characteristics of the PPV-based hole-only devices studied already in Ref. [18] within this extended version of the CDM ("ECDM"), by making use of a drift–diffusion device model. For the device considered, a very good description of the $J(V)$ characteristics can also be obtained within the ECDM, but with a much smaller intersite distance than obtained within the description using the EGDM. In Section 5 a summary and conclusions are given.

2. Methods

As in Ref. [18], we determine the charge-carrier mobility μ of carriers on an array of hopping sites, representing a disordered semiconducting organic material, by considering the master-equation for the mean-field occupation probabilities of these sites:

$$\sum_{j \neq i}[W_{ij}p_i(1 - p_j) - W_{ji}p_j(1 - p_i)] = 0. \tag{1}$$

Here p_i is the time-averaged probability that site i is occupied by a charge-carrier and W_{ij} is the transition rate for hopping from site i to j. The factors $1 - p_i$ account for the fact that only one carrier can occupy a site, due to the high Coulomb penalty for the presence of two or more carriers at the same site. We assume hopping of carriers from site to site as a thermally assisted tunneling process and coupling to a system of acoustical phonons, leading to the Miller–Abrahams transition rates [20]:

$$W_{ij} = \begin{cases} v_0 \exp[-2\alpha R_{ij} - \beta(\varepsilon_j - \varepsilon_i)] & \varepsilon_j \geqslant \varepsilon_i, \\ v_0 \exp[-2\alpha R_{ij}] & \varepsilon_j < \varepsilon_i, \end{cases} \tag{2}$$

where $\beta \equiv 1/k_B T$, with k_B the Boltzmann constant; v_0 is an intrinsic rate, $R_{ij} \equiv |\mathbf{R}_j - \mathbf{R}_i|$, with $\mathbf{R}_i$ and $\mathbf{R}_j$ the site positions; α is the inverse localization length of the localized wave functions under consideration and ε_i is the on-site energy of site i. The energy differences in Eq. (2) are supposed to contain a contribution $-eER_{ij,x}$ due to an electric-field E applied in the x direction, where e is the charge of the carriers.

As in Ref. [18] we solve Eq. (1) by an iteration procedure comparable to the one proposed by Yu et al. [10], starting from the zero-field Fermi–Dirac distribution. We take a regular cubic lattice of sites with lattice constant a and periodic boundary conditions. For the inverse localization length we take the same value as in Ref. [18]: $\alpha = 10/a$. The effect of changing α is predominantly a change of the prefactor of the mobility, which is not a matter of concern here, and a slight change in the temperature dependence of the mobility. We refer to Ref. [19] for a more detailed dis-

cussion of the role of α. For very low temperatures, it is known that variable-range hopping becomes important in conjugated polymers [21], i.e. hopping events further than to the nearest neighbor take place. We verified that for the temperature range considered in the present paper it is sufficient to take into account hops not further than to the third nearest neighbor, corresponding to a maximum distance of $\sqrt{3}a$. Once Eq. (1) has been solved, the carrier mobility can be obtained from

$$\mu = \frac{\sum_{ij} W_{ij} p_i (1 - p_j) R_{ij,x}}{N E}, \tag{3}$$

with N the number of charge-carriers in the system.

In order to obtain a density of states with a selected standard deviation σ and with spatially correlated on-site energies, we take the energy on each site equal to the electrostatic energy resulting from a distribution of randomly oriented dipole moments of equal magnitude, d, on all other sites. It is well-known that this procedure leads to a distribution of energies that is to a good approximation Gaussian [22,23], with a width proportional to d. The energy on site i is thus given by the expression

$$\varepsilon_i = -\sum_{j \neq i} \frac{e \mathbf{d}_j (\mathbf{R}_j - \mathbf{R}_i)}{\varepsilon |\mathbf{R}_j - \mathbf{R}_i|^3}, \tag{4}$$

where the summation is over all sites j in a cube centered around site i and of a size equal to that of the simulation box, and where ε is the permittivity. For large inter-site distances R, the correlation function between the energies of different sites has the form [9]

$$C(R) \equiv \langle \varepsilon_i \varepsilon_j \rangle \quad \propto \quad \frac{a}{R} \sigma^2, \tag{5}$$

where $\langle \cdots \rangle$ denotes an ensemble average.

For large values of the disorder parameter $\hat{\sigma} \equiv \sigma / k_B T$ it was not always possible to obtain a converged solution of Eq. (1) for small fields. We found that for such cases accurate results can be obtained from a numerical percolation approach. For Miller–Abrahams transition rates, the mobility can then be obtained by considering the conductivity of a random-resistor network with a conductance G_{ij} between each pair of hopping sites, given by [24]

$$G_{ij} = \frac{e^2}{k_B T} \nu_0 \exp(-s_{ij}), \tag{6}$$

with

$$s_{ij} = 2\alpha R_{ij} + \frac{|\varepsilon_i - \varepsilon_F| + |\varepsilon_j - \varepsilon_F| + |\varepsilon_i - \varepsilon_j|}{2 k_B T}, \tag{7}$$

where ε_F is the Fermi energy. We first determine numerically the exponent of the critical percolation conductance, s_c, i.e. the value of the exponent s such that the bonds with $s_{ij} < s_c$ just form a percolating network between one side of a simulation box and the other. We then replace all bonds with a conductance $G_c = (e^2 / k_B T) \exp(-s_c)$, evaluate the conductivity, and from that the mobility. We found that at moderate values of $\hat{\sigma}$ the mobility evaluated in this way agrees, after multiplication with an overall "geometrical" factor [24], very accurately with the low-field mobility as calculated within the master-equation approach, when-

ever the latter approach converged. For large values of $\hat{\sigma}$, for which we could not obtain convergence of the latter approach, this percolation approach is also expected to give accurate results. A similar numerical percolation approach was successfully applied to the case of an (uncorrelated) exponential distribution of site energies [25].

3. Temperature, electric-field, and carrier-density dependence of the mobility

We calculated the mobility for various values of $\hat{\sigma}$ as a function of the carrier-density and the electric-field, using the master-equation and percolation method discussed in Section 2, employing sufficiently large arrays such that finite-size effects could be neglected. For the master-equation approach array sizes up to $50 \times 50 \times 50$ were used and for the percolation approach sizes up to $100 \times 100 \times 100$. Averages were taken over a sufficiently large number of different disorder configurations, such that μ was obtained with an accuracy better than 10%.

In Fig. 1a, we display the carrier-density dependence of the mobility in the zero-field limit for various values of $\hat{\sigma}$, in units of $\mu_0 \equiv a^2 \nu_0 e / \sigma$, as calculated within the ECDM. Only for $\hat{\sigma} = 2$, 3, and 4 we were able to obtain converged results for the master-equation approach. A geometrical factor of 0.12 brings the results obtained with the percolation approach on top of the master-equation results for these values of $\hat{\sigma}$. We expect the percolation results multiplied with this geometrical factor to be accurate for the entire range of values of $\hat{\sigma}$ studied. We note that in OLEDs the carrier-densities can be situated in the entire range for which the results are given. In Fig. 1b, we display the corresponding results obtained within the EGDM, as calculated in Ref. [18] with the master-equation approach. At low carrier-densities, the dependence of the mobility on $\hat{\sigma}$ is for the ECDM weaker than for the EGDM, in agreement with studies in the low-density limit for the GDM [6] and the CDM [9]. We observe that for the ECDM also the dependence on the carrier-density is weaker than for the EGDM. Roughly, the difference can be modeled as a change in $\hat{\sigma}$.

In Fig. 2a, we display the mobility calculated within the ECDM as a function of $E^{1/2}$, at a relatively low carrier-density, $p = 10^{-5}/a^3$ (main panel), and a relatively high carrier-density, $p = 0.05/a^3$ (inset). The field is expressed in units of $\sigma / (ea)$. For a typical organic semiconductor, with $\sigma = 0.1$ eV and $a = 1$ nm, a voltage of 10 V applied across a 100 nm thick device leads to an average reduced field $E_{red} \equiv eaE / \sigma = 1$. In agreement with previous studies of the CDM [7,8] we find indeed a Poole–Frenkel (PF) behavior $\mu \propto \exp[\gamma \sqrt{E}]$, but only in a limited range of intermediate electric-fields. At very small fields the PF behavior has to break down since μ should be an even function of E around $E = 0$ with a first derivative equal to zero at $E = 0$. Indeed, we find at very small fields a deviation from the PF behavior. At very large fields only energetically downhill hops occur and all curves collapse onto a $\mu \propto 1/E$ dependence. This regime is found to set in around $E_{red} = 1$. In Fig. 2b, we give for the same carrier-densities the mobility as calculated within the EGDM, displayed as a function of E. In agreement with general theoretical considerations of
Fig. 1. Dependence of the mobility on the charge-carrier-density at vanishing electric-field for (a) the ECDM, calculated with the master-equation approach (filled symbols) and the percolation approach (half-filled symbols), and (b) the EGDM (only master-equation approach, Ref. [18]). The curves correspond to the parameterization given for the ECDM in the present paper (the flattening of the parameterization at high densities is discussed in the Appendix) and given for the EGDM in Ref. [18].

Gaussian disorder with algebraically decaying correlation functions [8] ($\propto 1/R^p$, leading to $\ln\mu \propto E^{p/(p+1)}$), the field dependence obtained from the EGDM is of the form $\ln\mu \propto E$ for a broad range of fields ($p = \infty$). The transition to the high-field $\mu \propto 1/E$ regime sets in at a significantly higher reduced field than for the ECDM, in particular for small carrier-densities.

In order to make applications of the master-equation results within a drift–diffusion device model possible, we have developed an empirical parameterization scheme for the mobility. First, separate expressions for the mobility in the low-field regime ($E_{\mathrm{red}} \lesssim 1$) and in the high-field regime ($E_{\mathrm{red}} \gtrsim 1$) are established. Subsequently, these expressions are combined, yielding a fully general expression for the mobility function $\mu\,(T,p,E)$.

In the low-field regime, the mobility can be written as

$$\mu_{\mathrm{low}}(T,p,E) = \mu_0(T)g(T,p)f(T,E,p),\tag{8}$$

with $\mu_0(T)$ the mobility in the zero-carrier-density limit and zero-field limit, and with g and f dimensionless mobility enhancement functions. The function $g(T,p)$ gives the carrier-density induced enhancement of the zero-field mobility with respect to the value in the zero-carrier-density limit. The function $f(T,E,p)$ gives the field-induced enhancement of the mobility with respect to the mobility at zero field. In the low carrier-density (Boltzmann) limit, the zero-field mobility is only dependent on the temperature, as in the EGDM, and is for the range $2 \leqslant \hat{\sigma} \leqslant 6$ to a good approximation given by

$$\mu_0(T) = \mu_0 c_1 \exp(-0.29\hat{\sigma}^2),\tag{9}$$

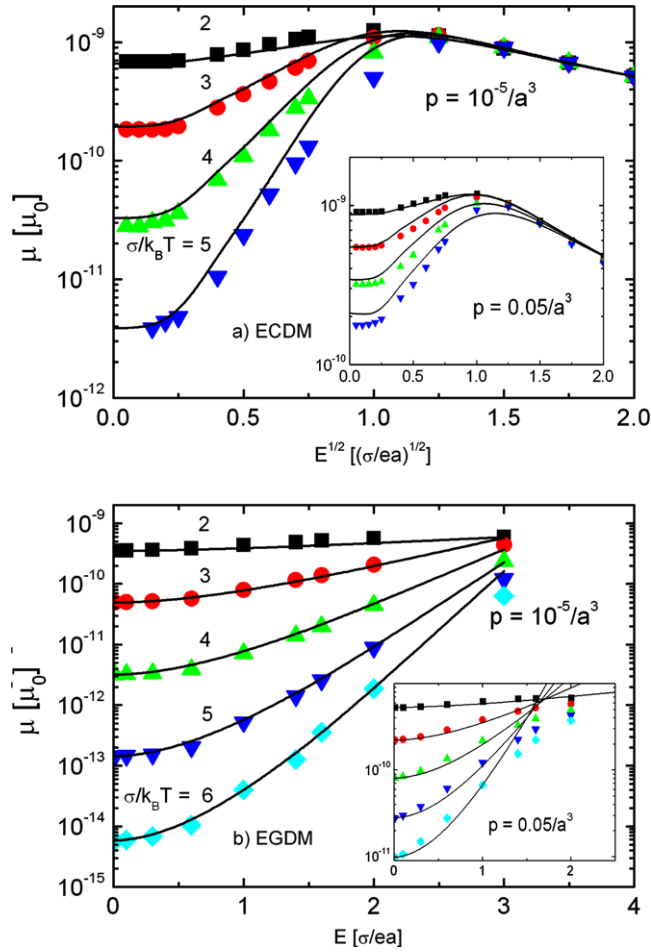
where the fit constant $c_1 = 1.0 \times 10^{-9}$ is of the order of the exponential factor describing the wavefunction overlap between two neighbor molecules, $\exp(-2\alpha a) = \exp(-20) = 2.06 \times 10^{-9}$. For the disorder parameter range studied, the temperature dependence given by Eq. (9) coincides approximately with the temperature dependence $\mu \propto \exp[-0.42\,\hat{\sigma}^2]$ obtained in Ref. [18] for the EGDM, after shifting $\hat{\sigma}$ by approximately -1.2. Effectively, the energy-level landscape is thus, for a given value of σ, smoother than in the EGDM. This is a result of the correlated nature of the energy-level landscape in the ECDM: close to each


Fig. 2. Dependence of the mobility on the electric-field at a low (main panel) and high (inset) carrier-density, calculated with the master-equation approach, for (a) the ECDM and (b) the EGDM. The curves correspond to the parameterization given for the ECDM in the present paper and given for the EGDM in Ref. [18].

occupied state many low-lying states are present, to which hopping processes that contribute significantly to the conductivity can take place. In the Appendix, a phenomenological parameterization for the functions $g(T,p)$ and $f(T,E,p)$ is given. The density-dependent function g is quite similar to that obtained earlier for the EGDM. The field-dependent function f describes the mobility in the three transport regimes indicated already briefly above.

In the high-field regime, the mobility-determining hops are all "down-hill", so that the mobility is not anymore dependent on the degree of disorder and on the temperature. The mobility is then described by

$$\mu_{\text{high}}(p,E) = c_2 \frac{av_0}{E}(1 - pa^3) = \frac{c_2}{E_{\text{red}}}\mu_0(1 - pa^3), \quad (10)$$

with $c_2 = \exp(-2\alpha a)$. For the parameters used in this study, $c_2 = \exp(-20) = 2.06 \times 10^{-9}$. The $(1 - pa^3)$ factor is included in order to describe for high carrier-densities in a phenomenological way the inhibiting effect of the occupation of final states on the mobility.

A description of the mobility at any field, including the region around $E_{\text{red}} = 1$, is obtained by joining the expres-

sions given above for low- and high-fields using the phenomenological expression

$$\mu(T,p,E) = \left((\mu_{\text{low}}(T,p,E))^{q(\hat{\sigma})} + (\mu_{\text{high}}(p,E))^{q(\hat{\sigma})}\right)^{1/q(\hat{\sigma})}, \quad (11)$$

with

$$q(\hat{\sigma}) = \frac{2.4}{1 - \hat{\sigma}}. \quad (12)$$

As can be seen from the drawn lines in Figs. 1a and 2a, this parameterization is very satisfactory, for the parameter range studied. We note that the parameterization of the electric-field dependence was not only optimized for the low and high carrier-densities for which the results are given in Fig. 2a, but also for master-equation results for a range of intermediate carrier-densities. The parameterization of the results for the EGDM can be found in Ref. [18] and is indicated by the drawn lines in Figs. 1b and 2b. An important difference between the parameterization for the two models is that the electric-field dependence of the ECDM comes in via a factor $f(T,E,p)$ that depends both on T and p, whereas for the case of the EGDM it comes in via a factor $f(T,E)$ that is independent of the

carrier-density p. In particular, the electric-field dependence of the ECDM decreases with increasing carrier-density. The reason for this is that in the case of correlated disorder broad "valleys" of energetically low-lying sites exist that gradually fill up with increasing carrier-density. Hence, the electric-field needed for escape of the carriers with the highest energy in each valley decreases with increasing carrier-density.

It is of interest to compare the field dependence of the mobility obtained from the master-equation method with the results of an analytic scaling analysis carried out by Parris et al. [26]. These authors focused on the PF regime. In that regime, the mobility is assumed to be due to the rate of certain critical forward hops. It is assumed that the backward hop rate can already be neglected. The authors considered the typical critical (rate-determining) hop distance and hop energy (thermal activation energy). Within a somewhat simplifying summary of their approach, it may be stated that they argued that a spatial correlation between the on-site energies, obeying Eq. (5), gives rise to an effective $-1/R$ dependence of the energies of sites at distance R from the low-energy sites in the tail of the Gaussian DOS at which most carriers are located. The application of an electric-field decreases the depth of this potential well as experienced by forward hops, due to the additional potential proportional to $-R$. This leads to a decrease of the escape time and hence to an increase of the conductivity. Eq. (15) in Ref. [26] gives the resulting analytic expression for the electric-field dependence of the mobility[1]

$$\mu = \mu_0 \exp(\hat{\sigma}^{3/2}\sqrt{2E_{\text{red}}}). \tag{13}$$

Within the PF regime and in the zero-carrier-density limit, our parameterization (Eq. (A.6) with $h(E_{\text{red}}) = 1$) approaches for $E_{\text{red}} \gg 1$ and $\hat{\sigma} \gg 1$ the field dependence given by Eq. (13). However, in the field range within which PF behavior is found, $0.16 < E_{\text{red}} < 0.8$, and for a more extended range of disorder parameters, the full form of Eq. (A.6) provides a much better description of the actual mobility function.

At very small fields, the PF behavior breaks down as a result of the fact that the conductivity is then not only determined by the rate of forward hops, but also by a non-negligible rate of backward hops. We find that the mobility in the very-small-field (vsf) regime is well described by the expression

$$\mu_{\text{vsf}} \propto \frac{\exp\left(\frac{ed_0E}{k_BT}\right) - \exp\left(-\frac{ed_0E}{k_BT}\right)}{E}, \tag{14}$$

with $d_0 \approx 4 \times a$ for the entire $\hat{\sigma}$-range studied. In particular for large disorder ($\hat{\sigma} > 4$) and small carrier-densities ($p = 10^{-5}/a^3$), the agreement between Eq. (14) and the parameterization given by Eqs. ((A.6), (A.8), and (A.9)) is excellent. We view this as an indication that the critical hop distance, which within the theory for the PF regime given in Ref. [26] goes to infinity with decreasing field, actually converges to

a fairly large but fixed finite value, which is within a factor of order unity equal to d_0. Due to the presence of the field the thermal activation energy for forward (backward) hopping to sites at a distance d_0 decreases (increases) by an energy ed_0E. The two terms in the numerator of Eq. (14) are proportional to the contributions to the average carrier velocity from forward and backward hopping carriers.

4. Application to a PPV-based hole-only device

As an example of an application we consider the question whether the ECDM is able to describe the $J(V)$ characteristics of the PPV-based hole-only sandwich-type devices studied in Ref. [18] as successfully as the EGDM. We perform our analysis for a device based on poly[4′-(3,7-dimethyloctyloxy)-1,1′-biphenylene-2,5-vinylene] (NRS-PPV), with a layer thickness of $L = 560$ nm, sandwiched in between an indium tin oxide (ITO) electrode used as anode and an evaporated gold electrode used as cathode. In Ref. [18] it was shown that the $J(V)$ characteristics of this device, measured at 298, 272, 252, and 233 K, can be well described within the EGDM, using a drift-only device model and assuming excellent charge-carrier injection (no injection barrier at the ITO injecting contact). The lattice constant a and the standard deviation σ of the Gaussian DOS were treated as fitting parameters and an optimal fit was obtained with $a = 1.8$ nm and $\sigma = 0.14$ eV. Here, we re-analyse these experimental data for PPV-based devices by (i) employing the EGDM within a model that goes beyond the model used in Ref. [18] by also taking the diffusion contribution to the current density into account and by allowing for a built-in voltage V_{bi} between the two electrodes, and by (ii) carrying out a similar analysis using the ECDM.

The drift–diffusion method used is described in detail in Ref. [27] for the case of the EGDM. Within this method, the diffusion coefficient is calculated from the mobility using the generalized Einstein equation, taking the effects of a finite carrier-density into account. Only a modest modification of the method, in order to include the field *and* density dependence of the function $f(T,E,p)$ in Eq. (8), was needed to make it suitable in conjunction with the ECDM. As in

---

[1] We believe that Eq. (15) in Ref. [26] contains a sign error of the argument under the exponential function and we have corrected this in Eq. (13).

Table 1
Optimal combinations of materials parameters used for fitting the $J(V)$ characteristics of a NRS-PPV hole-only device with a thickness $L = 560$ nm at four different temperatures, with a mobility as predicted by the ECDM and the EGDM, and a temperature dependence given by Eq. (15). The bold numbers indicate the parameter combination for which the best overall fit was obtained, and for which the fit results are shown in Fig. 3a and b.

a [nm]	σ [eV]	μ_0^* [m²/Vs])	C
ECDM			
0.8	0.10	1.1×10^{-8}	0.56
0.6	0.11	1.3×10^{-8}	0.46
0.4	0.14	3.8×10^{-8}	0.33
0.3	**0.18**	$\mathbf{3.8 \times 10^{-7}}$	**0.27**
0.2	0.22	0.6×10^{-5}	0.25
EGDM			
3.2	0.085	1.3×10^{-8}	0.77
2.7	0.093	1.6×10^{-8}	0.67
1.8	**0.14**	$\mathbf{2.5 \times 10^{-7}}$	**0.44**
1.2	0.20	0.9×10^{-4}	0.41

Ref. [18], we assume that the ITO anode is a perfect injector. The injection barriers for holes at the anode and cathode are $\varphi_1 = 0$ and $\varphi_2 = eV_{bi}$. The carrier-densities at the electrode interfaces $i = 1, 2$ are obtained under the assumption of local thermal equilibrium at the electrode planes, so that they are equal to the thermal-equilibrium density within a Gaussian DOS, with the Fermi energy $\varepsilon_F = -\varphi_i$ (with ε_F defined with respect to the top of the Gaussian DOS). Like in Ref. [18], we take the relative dielectric constant of the polymer equal to $\varepsilon_r = 3$. For both models, the temperature dependence of the mobility in the zero field and zero density limit has the form

$$\mu_0(T) = \mu_0^* \exp[-C(\sigma/k_B T)^2], \qquad (15)$$

as discussed already in Section 3 (Eq. (9) for the ECDM).

Table 1 gives for selected values of the inter-site distance a the parameters σ, μ_0^*, and C for which optimal fits were obtained using the ECDM and EGDM. The combinations of fit parameters that yielded the best overall fit are given in bold numbers. The corresponding values of the fitted built-in voltage V_{bi} were 1.7 and 1.1 V for the ECDM and EGDM, respectively. These values of V_{bi} are larger than would be expected on the basis of the small difference between the vacuum work functions of ITO and Au. This is indicative of the occurrence of important organic–metal interactions at the polymer/Au interface, as have been revealed earlier for many other organic/metal interfaces [28].

For the ECDM and EGDM parameter combinations for which the best fits were obtained the corresponding fits are displayed in Fig. 3a and b, respectively. It may be seen that both with the ECDM and the EGDM excellent fits to the measured $J(V)$ characteristics can be obtained. We note that within both models the mobility at any temperature is described using only three parameters, viz. a, σ and μ_0, each with a clear physical meaning.

The optimal fit values of a as obtained from the ECDM and EGDM are very different, viz. 0.3 and 1.8 nm, respectively. The value of a found for the ECDM may be
Fig. 3. Experimental current–voltage characteristics (symbols) at various temperatures for a NRS-PPV hole-only device with a thickness $L = 560$ nm, and best fits (lines) with (a) the ECDM mobility and (b) the EGDM mobility model, using the parameters given in Table 1 (bold numbers) and with the built-in voltage V_{bi} as given in the main text.

considered as unrealistically small, in view of the fact that in NRS-PPV the use of side-branches is expected to give rise to a larger typical distance between neighboring polymer chains. Furthermore, intra-chain hopping between the rather long conjugated segments is also expected to be associated with a larger a-parameter. The distance between two subsequent monomer units is equal to approximately 0.7 nm, and the conjugation length is believed to be at least five monomer units. This suggests that in the PPV-derivative studied correlations between the site energies are insignificant. The comparison between the values obtained for σ and C does not change this point of view. For σ, the optimal values obtained from the ECDM and EGDM are very similar, viz. 0.18 and 0.14 eV, respectively, each with an uncertainty of ±0.03 eV.[2] For C, the values that yield the best fits ($C = 0.27$ for the ECDM and $C = 0.44$ for the EGDM) are both very close to the values predicted within each model ($C = 0.29$ for the ECDM and $C = 0.42$ for the EGDM). We note that we have treated C as a free parameter upon making the fits. The reason is that different values of C can be found in literature, both for the (E)CDM [9], as well as for the (E)GDM [6,19]. Also, the precise value of the inverse localization length α (for which we have assumed $\alpha = 10/a$) can have some influence on the value of C [19].

We envisage that more certainty about the validity of the analysis given above can be obtained by extending this work to a series of devices with a wide range of layer thicknesses and by investigating the consistency of the analysis using the results of transient experiments (e.g. dark injection, admittance or time-of-flight experiments).

5. Summary and conclusions

In summary, using a master-equation and percolation approach, we have extended the correlated disorder model (CDM) to include the dependence of the mobility on the charge-carrier-density, in addition to the dependence of the charge-carrier mobility on temperature and electric-field. This leads to what we have called the extended correlated disorder model (ECDM). In this model, the on-site energies and the correlation in these energies are assumed to follow from the interaction of the charge-carriers with randomly oriented dipoles. We have provided an accurate parameterization of these dependencies that can be used in device studies of disordered semiconducting materials, such as small-molecule semiconductors and conjugated polymers.

As an application of our results, we modeled the $J(V)$ characteristics of a hole-only device of a conjugated PPV-based polymer (NRS-PPV), measured at various temperatures, by solving a drift–diffusion equation with a mobility and diffusion coefficient as obtained from the ECDM and as obtained from the previously investigated extended Gaussian disorder model (EGDM). We found that both with the ECDM and the EGDM excellent fits between the calculated and measured $J(V)$ characteristics can be obtained. The

most remarkable distinction between the two sets of optimal fit parameters is an observed large (factor ∼5) difference between the effective lattice parameter a. We view the more realistic intersite distance found using the EGDM ($a \approx 1.8$ nm) compared to the value found using the ECDM ($a \approx 0.3$ nm) as a first indication that in the PPV-derivative studied correlations between the site energies are absent or play a minor role. The parameterizations for the ECDM given in the present paper may be used to investigate the possible role of correlations in other conjugated polymers and small-molecule semiconductors.

Acknowledgments

Appendix Carrier-density, and electric-field dependence of the mobility in the low-field regime

In the low-field regime ($E_{red} \equiv eaE/\sigma \lesssim 1$), the mobility is expressed in the form given by Eq. (8). Using the numerical data shown in Fig. 1a for the range $2 \leqslant \hat{\sigma} \leqslant 6$, and inspired by Refs. [8,18,19], we parameterize the carrier-density-dependent mobility-enhancement function as follows

$$g(T,p) = \exp[(0.25\hat{\sigma}^2 + 0.7\hat{\sigma})(2pa^3)^\delta] \quad \text{for } pa^3 < 0.025,$$
(A.1)

$$g(T,p) = g(T, 0.025a^{-3}) \quad \text{for } pa^3 \geq 0.025,$$
(A.2)

with

$$\delta \equiv 2.3 \frac{\ln(0.5\hat{\sigma}^2 + 1.4\hat{\sigma}) - 0.327}{\hat{\sigma}^2}$$
(A.3)

Eq. (A.1) describes the increase of the mobility with increasing carrier-density. This effect becomes significant when the carrier-density is not anymore in the Boltzmann regime. Defining the cross-over density, $p_{cross-over}$, as the density at which the mobility is enhanced by a factor of 2, it follows from Eq. (A.1) that to a good approximation

$$p_{cross-over,ECDM} = \frac{1}{2}a^{-3}\exp(-\frac{\hat{\sigma}^2}{2.3})$$
(A.4)

Within the EGDM, the (exact) expression for the cross-over density is [19]

$$p_{cross-over,EGDM} = \frac{1}{2}a^{-3}\exp(-\frac{\hat{\sigma}^2}{2})$$
(A.5)

The basic assumption made in the derivation of the latter expression (Eq. (13) in Appendix A of Ref. [19]) is that at the cross-over density the carriers that contribute to the mobility still occupy predominantly states within the tail of the Gaussian density of states (DOS), so that only hops

---

[2] The results obtained for less-ideal $a - \sigma$ combinations, given in Table 1, show how an uncertainty in σ is correlated to an uncertainty in a.

that involve a large increase in energy, towards a rather high effective transport level, contribute significantly to the mobility. Our calculations show that this assumption is not strictly true anymore for the ECDM.

At very high carrier-densities, the calculations reveal a weakening of the density dependence, and even a small decrease. We have not attempted to make a detailed fit to the density dependence of the mobility in this transport regime. Instead, we have introduced a cutoff carrier-density, $p_{cutoff} = 0.025/a^3$, above which the mobility is taken to be constant (Eq. (A.2)). We note that above densities of approximately 0.01–0.1 per site, the precision of the methods used is expected to be somewhat lowered due to the neglect of the long-range part of the Coulomb interaction [29]. For applications to single-layer OLEDs, such as discussed in Section 4, this uncertainty is in practice of little importance, as in such devices high carrier-densities occur only in very thin regions near one or both electrodes. Even a relatively large uncertainty in the (high) conductivity of the organic layers in these thin regions is of little influence on the calculated $J(V)$ characteristics.

The field-dependent mobility-enhancement function $f(T,E,p)$ is expressed in terms of the reduced field, E_{red}. Within the low-field regime, we distinguish two subregimes. In the very-small-field regime, defined as $0 \leqslant E_{red} < 0.16 \equiv E_{red}^*$, forward *and* backward hops contribute to the mobility. For larger fields, the presence of the electric-field makes the (negative) contribution to the mobility from backward hops already insignificant. In the main text we have called this the Poole-Frenkel (PF) regime. The mobility-enhancement function is then parameterized as

$$f(T, E_{red}, p) = \exp \left[h(E_{red})(1.05 - 1.2(pa^3)^{r(\hat{\sigma})})(\hat{\sigma}^{3/2} - 2) \right.$$
$$\left. (\sqrt{1 + 2E_{red}} - 1) \right], \tag{A.6}$$

with

$$r(\hat{\sigma}) = 0.7\hat{\sigma}^{-0.7}, \tag{A.7}$$

and $h(E_{red}) = 1$. Within the very-low-field regime, the derivative of the mobility with respect to the field should vanish at zero field. This is accomplished in a phenomenological way by using Eq. (A.6) with

$$h(E_{red}) = \frac{4}{3} \frac{E_{red}}{E_{red}^*} for \quad E_{red} \leq E_{red}^*/2, \tag{A.8}$$

and

$$h(E_{red}) = \left[1 - \frac{4}{3} \left(\frac{E_{red}}{E_{red}^*} - 1 \right)^2 \right] for \quad E_{red}^*/2 \leq E_{red} \leq E_{red}^*. \tag{A.9}$$

The function $h(E_{red})$ is continuous and differentiable for all values of E_{red}, so that also $f(T, E_{red}, p)$ and $\mu(T, p, E_{red})$ are continuous and differentiable.

ARTICLE INFO

ABSTRACT

Thin anthracene films were studied with photoemission electron microscopy, using both a Hg discharge lamp and a femtosecond Ti:Sapphire laser for generation of the photoelectrons. In threshold photoemission, under illumination of the surface with the Hg lamp, anthracene islands appear dark due to the high work function of anthracene. Under illumination with frequency doubled femtosecond laser pulses ($\lambda = 400$ nm) two photon photoemission takes place, and the anthracene islands each exhibit a characteristic brightness. We find that the brightness of the islands in two photon photoemission (2PPE) is modulated by the S_1-exciton in anthracene that serves as the intermediate state in 2PPE. Whenever the $\vec{b}$-axis of the unit cell within a particular anthracene island is aligned with the in-plane component of the electric field of the laser pulses, the island exhibits a maximal two photon photoemission yield. Based on exciton sensitive microscopy we find that the orientation of molecules in each island is different and that the anthracene film as a whole is textured.

1. Introduction

The technological improvements of organic light emitting devices (OLEDs) [1] have been very rapid in recent years, with the first applications in flat-panel displays already on the market [2]. Light that is emitted from such OLED displays originates from exciton states inside the emissive organic layer. Light is emitted whenever the exciton's electron and hole recombine. Accordingly, the wavelength of the device is determined by the energy of the exciton. Furthermore, the molecular ordering, the grain size distribution, and grain boundaries in the active layers play a crucial role for transport of the charge carriers into the recombination zone and affect the efficiency of the recombination process. The morphology and composition of the films will thus ultimately limit the device's performance [3].

Some of the organic semiconductors that have successfully been used in blue OLEDs are anthracene ($C_{14}H_{10}$) and

its derivatives [4–6]. Anthracene is a polycyclic aromatic hydrocarbon that consists of three linearly fused aromatic rings. In our previous work we have studied the growth of anthracene on Si(1 1 1) [7] and demonstrated that under suitable deposition conditions, large and textured anthracene films could be grown. In contrast, here we address the interplay of the morphology of monolayer thin anthracene films with electronic excitations of the molecule. Anthracene exhibits several excitonic states that are closely linked to the crystal lattice. Studying of the interplay of morphology and excitons in anthracene will provide a better understanding of the underlying OLED action in anthracene and add to our knowledge of excited electronic states in polyacenes in general. The lowest energy exciton in bulk anthracene is a singlet state with an excitation energy of $E \approx 3.1$ eV [8]. In the present work we use femtosecond laser pulses with a wavelength appropriate to excite the singlet exciton in monolayer thin anthracene films, and we use nonlinear photoemission microscopy (PEEM) to directly image the occupied singlet exciton in individual anthracene islands. The contrast in PEEM is in this case based on a two photon photoemission (2PPE)

process, as the photon energy of the $\lambda = 400$ nm fs-laser pulses is not sufficient for threshold photoemission from the highest occupied molecular orbital (the ionization potential of bulk anthracene is 5.65 eV [9]).

First attempts to understand the nature of the 2PPE process in anthracene were already performed in the 1960s [10] with spatially averaging 2PPE spectroscopy in anthracene bulk crystals, and the singlet exciton was identified as the responsible intermediate state. The 2PPE process is since then believed to originate from a two-exciton excitation that decays into a free electron. Exploitation of the 2PPE process in PEEM to directly observe the exciton in a heterogeneous and polycrystalline film, however, has not been attempted until now.

2. Experimental

The 2PPE PEEM experiments were performed in the ultra high vacuum (UHV) spectroscopic photoemission electron microscope (ELMITEC PEEM III), located at the University of Duisburg-Essen. The microscope is equipped with a cooling option and allows the *in-situ* growth of anthracene thin films inside the microscope. The high vapor pressure of anthracene ($\sim 10^{-7}$ mbar at RT [11]) requires a growth temperature well below room temperature ($T \approx -40$ °C). During annealing to room temperature after growth, anthracene re-evaporates from the surface, and accordingly, all images shown here were recorded at the low deposition temperature.

Anthracene (Sigma–Aldrich, zone-refined, 99%) was deposited from a resistively heated ceramic crucible after degassing of the source material for several days. The high vapor pressure of anthracene required differential pumping of the evaporator to sustain UHV conditions during and in between the experiments.

Si samples were cut from a precision oriented Si(111) wafer, and were wiped with ethanol before mounting into the sample holder. After transfer to UHV they were degassed for at least 3–4 h at $T \sim 500$ °C and were then repeatedly flash-annealed to $T \sim 1250$ °C to thermally desorb the protective oxide. For the anthracene deposition the samples were cooled to about $T \approx -40$ °C. The temperature was monitored with a thermocouple.

For threshold photoemission experiments, an ordinary Hg discharge lamp was used. For the 2PPE experiments, however, a light source with a higher photon density is needed. Femtosecond laser pulses with a pulse energy of about 9 nJ and a pulse duration of 20 fs [12] were generated by a $\lambda = 800$ nm Ti:Sapphire laser oscillator (FEMTOLASERS GmbH [13]). The repetition rate was 80 MHz.

The laser pulses were frequency doubled in a beta-barium-borate (BBO) crystal to yield blue light with a wavelength of $\lambda = 400$ nm, i.e., a photon energy that matches one of the exciton energies of anthracene.

As the fs-pulses must pass through a UHV-window to reach the sample, correction of the dispersion of the pulses by two prisms [14] is mandatory. In the PEEM, we obtain $\lambda = 400$ nm pulses with a pulse duration of $\tau < 40$ fs, as verified by a second order interferometric pump-probe auto-correlation trace. Details of the femtosecond laser setup are published elsewhere [15].

To adjust the laser intensity, a $\lambda/2$-plate in combination with a Brewster polarizer was used. A second $\lambda/2$-plate provides control over the polarization of the pulses. Fig. 1 illustrates the definition of the polarization direction of the laser pulses with respect to the PEEM sample geometry. Due to the grazing incidence geometry of $\phi = 74°$ of the light on the sample surface, different polarizations of the laser pulses translate into electrical field components at the sample surface as follows: during the interaction of s-polarized pulses with the surface, the electric field vector $\vec{E}$ lies completely in the surface plane. In p-polarization, the electric field of the laser pulses is parallel to the optical table and during interaction with the surface, the electric field vector has a component in the surface plane and a component perpendicular to the surface as well [16]. An important fact to consider during PEEM experiments on organic materials is the possibility of light-induced film damage [17]. Interestingly, we find that under illumination with 400 nm laser pulses the films remain stable for hours.

3. Results and discussion

We have previously studied the growth dynamics of anthracene thin films on Si(111) with PEEM [7]. During deposition, a covalently bound layer of flat lying molecules is formed on the surface [18]. Subsequent layers grow on top of this initial layer and form fractal-shaped islands with a fractal dimension of $d \approx 1.6$, indicating a diffusion limited aggregation [19] growth mechanism. It is remarkable that despite the low deposition temperatures fractals with a diameter of several tens of micrometers can be observed. As the growth dynamics, the islands shapes, and the islands sizes are similar to the case of pentacene on Si [20,17], one expects that – as in the case of pentacene – the molecules in higher layers stand upright.

Panels (a) and (b) of Fig. 2 show PEEM images of a two molecular layer high anthracene island under illumination with different light sources and compares the image con-
Fig. 1. The orientation of the laser beam relative to the objective lens of the PEEM for the 2PPE experiment and the definition of the relevant angles. The incidence angle of the laser beam on the surface is ϕ. The polarization angle is θ. In s-polarization, the electric field vector of the laser lies completely in the surface plane. In p-polarization, the electric field-vector has an in-plane and an out-of-plane component.
Fig. 2. (a) An anthracene island with the nucleating second layer imaged by the Hg discharge lamp. (b) The same island after illumination with the blue pulsed laser $E = 3.1$ eV. (c) The determination of the emission exponent (EP) for each pixel results in a power map. The black spot that can be found on the lower left in each image resembles a damaged region on the multichannel plate of the PEEM.

trast obtained with threshold photoemission to the 2PPE case. In Fig. 2a the Hg discharge lamp was used to illuminate the sample. The layer of flat lying molecules separating the islands is over exposed, while the first and second layer of standing-up anthracene molecules appear dark, with weak contrast. We speculate that during the formation of the first layers the surface dipole varies and thus causes the observed reduction of the brightness for higher layers. If the surface is illuminated with $\lambda = 400$ nm fs-laser pulses, the situation is completely different, as displayed in panel (b) of Fig. 2. Here, the layer of flat lying molecules appears darker than higher layers. Also, the brightness of the islands increases with the film thickness.

To investigate the photoemission process, we record the photoelectron yield Y as a function of the laser intensity I, that is expected to follow a power law [21]:

$$Y \sim I^N, \tag{1}$$

where N reflects the order of the photoemission process and is a measure of how many photons are needed to generate one photoelectron. For a 2PPE process, $N = 2$ is expected. Furthermore, to verify that the order of the photoemission mechanism is homogeneous throughout the observed area on the surface, we record images at different laser intensities and determine N for every pixel of

the image. The resulting power map [22] in panel (c) of Fig. 2 displays the value of N as a function of the film's morphology. Except some noise (and a burnt spot in the imaging channel plate), no morphological features of panel (b) are visible in panel (c) and we find $N = 2$ for all areas of the surface. We conclude that we indeed observe a 2PPE process in all areas on the surface and that – based on the photon energy of the laser pulses of 3.1 eV – the anthracene singlet exciton is the intermediate state for the 2PPE process in the bright islands.

Fig. 3 shows two images of the same anthracene island under different polarization of the laser pulses (see Fig. 1 for a definition of the polarization directions). In panel (a) of Fig. 3, the surface is illuminated with p-polarized laser pulses. The monolayer-height island is bright, and even a 10 µm large second layer island is visible. Also, many small islands exist that can be found on both the substrate and the larger islands. These islands nucleate from the residual gas during the measurement, as the cooling is still running, the sample temperature is still decreasing, and the vacuum in the chamber is only slowly recovering from the higher anthracene partial pressure during the deposition.

In panel (b) of Fig. 3 the surface is shown under illumination with s-polarized laser pulses. In comparison to
Fig. 3. Two images of the identical anthracene island recorded with (a) p-polarized and (b) s-polarized laser pulses. The gray scale of the two images has been adjusted to obtain maximum contrast. The arrows at the bottom left of the panels indicate the direction of the in-plane component of the exciting electric field vector of the laser pulses.
Fig. 4. (a) Sketch of the orientation of anthracene molecules within the unit cell [23] and (b) the exciton energies for optical excitation in the principal directions of the unit cell [24]. Letters (a)–(c) represent excitations along the three unit cell vectors from (a).

panel (a), in which the same area on the surface is displayed, the contrast is inverted: the island is now dark and the second layer on top of the island is hardly visible.

Fig. 4 shows the orientation of anthracene molecules within the unit cell and the energetic levels of the excitons in the principal directions of the crystal lattice for bulk anthracene, with data from the literature [23,24]. In the bulk, anthracene forms monoclinic crystals [25] with two molecules per unit cell (Fig. 4a). The angle between the $\vec{a}$- and the $\vec{b}$-axis is $\gamma = 90°$ and the molecules form a herringbone stacking where the long axis of the molecules is almost aligned with the $\vec{c}$-axis. That the molecules stand up on the surface [7] implies that the $\vec{a}$- and $\vec{b}$-axis lie within the surface plane, while the $\vec{c}$-axis sticks out of the surface. More precisely, the $\vec{c}$-axis stands perpendicularly on the $\vec{b}$-axis and forms the monoclinic angle of $\beta = 124.7°$ [26] with the $\vec{a}$-axis.

The exciton levels for bulk anthracene are sketched in Fig. 4b. The first singlet exciton S_1 is located at $E = 3.1$ eV [27], which matches exactly the photon energy of the laser pulses in our experiments. The S_1 exciton, however, can only be excited by an electric field that is aligned with the $\vec{b}$-axis of the anthracene unit cell [28]. Excitation with fields aligned with the $\vec{a}$- or $\vec{c}$-axis would require light with an energy of $E = 3.3$ eV [29] or $E = 4.2$ eV (S_2-exciton) [28], respectively. Obviously, as the photon energy of our illumination source is insufficient to create an excitation along the $\vec{a}$- or the $\vec{c}$-axis, only the S_1 exciton can be excited by the laser pulses. As such excitation requires an electric field along the $\vec{b}$-axis, the island brightness in PEEM is a measure of the projection of the exciting electric field of the laser pulse on the $\vec{b}$-axis of the island. By the knowledge of the polarization of the laser pulses, one can thus determine the orientation of the $\vec{b}$-axis within the unit cell and from this conclude the azimuthal orientation of each island. This is a powerful *in-situ* method for the determina-

tion of the orientation of molecules in textured anthracene films.

Fig. 5 shows an image of several anthracene islands under illumination with p-polarized laser pulses. The islands display different brightnesses that vary from black to white and go through different gray levels. The brightness, however, is homogeneous throughout each island, and inhomogeneities of the brightness within one island are caused exclusively by nucleation of higher layers on top of the islands, or by coalescence of islands of different orientations, as in marked as feature "A" in Fig. 5. Using our
Fig. 5. Determination of the molecular orientation of individual anthracene islands. The in-plane component of the electric field of the laser pulse that was used to record the image is indicated at the lower left. Various orientations of the in-plane component of the electric field vector of the laser pulses were used to determine the orientation of the unit cell vectors for the islands. In all islands, the molecules are standing up on the surface. Feature A marks a grain boundary between two islands with different orientations that was formed by coalescence of two anthracene islands during growth.

argument that the photoemission yield reflects the projection of the electric field vector on the $\vec{b}$-axis of the crystal, we conclude that the islands are mono crystalline and that within each island the orientation of the molecules is the same, while the molecular orientation differs from island to island. For the brightest islands the orientation of the molecules is such that the $\vec{b}$-axis of the unit cell is aligned with the in-plane component of the exciting electric field. If, on the other hand, the $\vec{b}$-axis of the crystal and the in-plane component of the exciting electric field are perpendicular to each other, the islands appear black. In Fig. 5 the orientations of the unit cells of the anthracene island is displayed as an overlay. We will now describe how the orientation of the $\vec{b}$-axis of the unit cell – as plotted in the overlay of Fig. 5 – can be determined from the polarization dependence of each anthracene island.

Fig. 6 shows the 2PPE yield of a selected anthracene island as a function of the polarization angle θ of the laser pulses. To explain the polarization dependence of the yield curve, we have to consider three contributions. First, we have to consider the number of photons that are absorbed by the sample under our experimental conditions. This number varies with both the polarization angle θ, and the (fixed) incidence angle of the light on the surface $\phi \approx 74°$. As can be easily calculated from the dielectric function of Si, ϕ is close to the Brewster angle of Si, and depending on the polarization of the laser pulses, a big portion of the light is simply reflected. The reflectivity reaches its maximum for s-polarization, because in this case the entire electric field lies within the sample surface. As a result, the integral intensity of images recorded with s-polarized light is always lower than the intensity of images recorded with other polarizations. Because for p-polarization ($\theta = 0$) the Brewster reflectivity is low, the 2PPE yield is high. During any variation of the polarization angle θ, the 2PPE yield decreases, and images recorded with p-polarized laser pulses have the highest intensity of all. To properly obtain the orientation of the $\vec{b}$-axis of the unit cells within the anthracene islands, we correct the measured
2PPE yield by subtracting the measured background intensity of the area between the islands (the 2PPE signal of the disordered layer of flat-lying molecules) from the island intensity. The result of a proper background subtraction of the island photoemission yield of Fig. 6 is shown in the inset of Fig. 6.

Second, again caused by the grazing incidence geometry, both the in-plane component and the out-of-plane component of the electric-field of the laser pulses are a function of the polarization angle θ. For a surface in the (y, z) plane, we obtain for the projection of the electric field of the laser pulses into the (y, z) plane, i.e., for the in-plane component of the electric field vector

$$\vec{E}_{proj}(\theta, \phi) \sim (0, -\sin(\phi) \cdot \cos(\theta), \sin(\theta)). \tag{2}$$

In this notation, the x-axis is perpendicular to the substrate surface.

The third contribution to the 2PPE signal originates from the information of interest, namely the projection of the in-plane component of the electric field, as given in Eq. (2) on the $\vec{b}$-axis of the crystal. We obtain a maximum of the 2PPE yield, whenever the in-plane component $\vec{E}_{proj}$ of the electric field of the laser pulses is – for a particular island – aligned with the $\vec{b}$-axis of the anthracene unit cell. In the other extreme, when the in-plane component of $\vec{E}_{proj}$ is parallel to the $\vec{a}$-axis of the crystal (i.e., oriented perpendicularly to the $\vec{b}$-axis), we obtain no 2PPE signal at all.

Within this simple model, the expected photoemission signal of an anthracene island on the surface can be estimated by the knowledge of the polarization angle θ, by the fixed incident angle $\phi = 74°$ for the projection of the laser pulses onto the surface plane, and by the angle α for the projection of $\vec{E}_{proj}$ on the $\vec{b}$-axis of the anthracene island. This last projection can be expressed by the scalar product $\vec{E}_{proj} \cdot \vec{e_b}$, where $\vec{e_b} = (0, \cos(\alpha), \sin(\alpha))$ is a unit vector along the $\vec{b}$-axis of the unit cell of the anthracene island. We obtain for the 2PPE yield

$$I_{2PPE} = (E_0 \cdot (\sin(\alpha) \cdot \sin(\theta) - \cos(\theta) \cdot \sin(\phi) \cdot \cos(\alpha)))^4 \tag{3}$$

with E_0 as a proportionality factor for the electric field amplitude. The inset of Fig. 6 shows the measured and background-subtracted 2PPE intensity of a one molecular layer high island (as points) with a fitted intensity curve (solid line) that is calculated using Eq. (3) with α and E_0 as the only free parameters. The agreement between the fit and the data points is excellent. For the particular island shown in Fig. 6, the fit of the corrected data points indicates a maximum for $\alpha = 40°$, which allows the determination of the absolute orientation of the $\vec{b}$-axis of the unit cell of the anthracene island.

To analyze the distribution of the azimuthal orientation of the islands with respect to the substrate we will now perform a statistical analysis of the angle α for a larger number of islands. For this purpose, small anthracene islands were grown, and for every pixel of each island the orientation of the $\vec{b}$-axis was determined by the procedure explained above. Each island was then assigned the average orientation angle α, where the spread of the values throughout each island was used to estimate the accuracy of the method. Fig. 7 shows a histogram of the number of

Fig. 6. The typical dependence of the 2PPE yield as a function of the polarization of the laser pulses. Inset: the same curve after proper background subtraction. The maximum of the curve in the inset indicates the situation where the angle α between in-plane component of the exciting laser field and the $\vec{b}$-axis of the anthracene island is zero.
Fig. 7. The distribution of the number of anthracene islands that exhibit a particular projection angle α after a fit with Eq. (3) of the background subtracted 2PPE data. The error bars in the x-direction are obtained from the average uncertainty of the fit of Eq. (3) for every pixel of the island. Error bars in the y-direction represent the standard deviation.

islands that exhibit a particular orientation. The featureless and homogeneous distribution curve indicates that the azimuthal orientation of the islands on the surface is completely random. Apparently, the molecular orientation in the islands is not at all influenced by the 3-fold symmetry of the Si(1 1 1) surface. The same behavior has also been observed with low energy electron diffraction for the slightly longer but similar molecule pentacene. The azimuthal degree of freedom for the islands to orient on the surface is caused by the flat-lying wetting layer of molecules that in both cases, pentacene and anthracene, lies below the fractal-shaped islands [7,20] and shields the growing layer from the substrate [30].

We will now discuss the azimuthal orientation of anthracene unit cells in higher layers with respect to the orientation of the unit cells in the layers below them. The second layer island in Fig. 3a is representative of many islands that we analyzed. In all cases, the polarization behavior, i.e., the angle α, of the second layer is identical to the polarization behavior of the first layer islands on which the second layer islands are nucleated. Apparently, as the $\vec{b}$-axis is aligned in the same way in the first and second layer, the higher layers form an epitaxial relation with the layers below them. Such concept of an epitaxial relationship can, however, not be extended to the interaction between the anthracene islands and the substrate. As was already shown in Fig. 7, the orientation of the first layer islands with respect to the substrate is completely random.

4. Conclusion

Anthracene films deposited on Si(1 1 1) appear dark in regular threshold photoemission with a Hg discharge lamp, caused by the high ionization potential of the films. In 2PPE PEEM, however, anthracene islands appear in different shades of gray, depending on the polarization of the laser pulses. The contrast in 2PPE PEEM is caused by the coupling of our $\lambda = 400$ nm laser pulses to the S_1-exciton of the anthracene islands. The excitation of the S_1 state, however, is only possible with electric fields that are aligned

with the $\vec{b}$-axis of the anthracene unit cell. Together with our previous PEEM studies of the anthracene growth dynamics [7], we conclude that anthracene islands on Si(1 1 1) – after a chemisorbed interfacial layer of flat-lying molecules is formed – consist of standing up molecules wherein the $\vec{a}$- and the $\vec{b}$-axis of the monoclinic anthracene unit cell is aligned within the surface plane.

The selectivity of 2PPE PEEM to the S_1-exciton, i.e., the $\vec{b}$-axis of the anthracene unit cell, forms the basis of a novel exciton-based contrast mechanism in 2PPE PEEM and provides a powerful *in-situ* technique for the determination of the orientation of molecules in textured anthracene films. Such information is usually not attainable with regular threshold photoemission. An important issue to be taken into consideration in the interpretation of our results, is a modification of the S_1-exciton level that may be caused by differences of the film's crystallographic properties compared to anthracene bulk. The S_1-excitation energy used in this work represents the bulk exciton value and a slight change of the energy of the S_1-exciton is not important for the interpretation of our results, as long as the exciton can be excited by $\lambda = 400$ nm laser pulses. Using tunable fs laser sources in combination with PEEM, i.e., by using fs amplifiers and optical parametrical oscillators to generate the illuminating light, one could perform a spatially resolved *in-situ* determination of the energetics of the S_1-exciton in heterogeneous anthracene films.

Exciton sensitive PEEM shows, that the islands are randomly oriented, but that the second layer of anthracene islands has a perfect epitaxial relationship with the first layer. This implies that if one managed to build devices consisting of single anthracene islands, or if it was possible to control the orientation of the islands in the first layer, OLEDs that emit polarized light might become possible.

In conclusion, 2PPE PEEM is an excellent technique to directly perform microscopy on excitons in thin films, if the photon energy of the laser matches the energy of the exciton of interest. While optical transmission measurements can be used to obtain similar information [31], the use of visible light in a transmission geometry is not surface sensitive and is usually performed in a less controlled environment. In contrast, here we used femtosecond laser pulses in 2PPE PEEM and demonstrated the capability to perform exciton-sensitive microscopy on molecular monolayers in a UHV environment, with video rate and even during growth. Using the combination of PEEM and femtosecond laser pulses in a pump-probe setup will provide the possibility to study exciton dynamics in single anthracene islands as a function of their size and height and will offer new insight into the interplay of the exciton dynamics and the morphological features of an organic thin film. Such investigations are currently under way.

ARTICLE INFO

ABSTRACT

A novel donor–acceptor type conducting polymer based on BODIPY dye as acceptor and EDOT units as donor parts is synthesized electrochemically. The unique combination of BODIPY and EDOT units provides an ambipolar (n- and p-doping processes) low band gap material (**4**). This is the first example of p–n junction in an organic π-conjugated material where BODIPY unit is incorporated directly in the main chain. Furthermore, the polymer film exhibits electrochromic behavior upon p-doping: a color change from light violet (neutral) to indigo (oxidized).

1. Introduction

Organic π-conjugated materials, in particular polymers, have attracted considerable attention due to their low cost, easy processing, compatibility and tunable intrinsic properties (electronic, optical, conductivity and stability) offered by the structural design [1,2]. One of the best ways [3] to manipulate the electronic structure is combining an appropriate electron-donating moiety with an electron acceptor. This donor–acceptor strategy in the design of π-conjugated materials did not only allow a fine tuning of highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels, band gap (E_g) and absorption–emission spectra of the system [4–9], but also provided access to a variety of advanced technological applications in the field of sensors [10–12], nonlinear optics [13], molecular electronics [14–16], photovoltaics [17–21],

light emitting diodes (LEDs) [22–25], field effect transistors (FETs) [26–29], displays and electrochromics [30–34].

On the other hand, 4,4-difluoro-4-bora-3a,4a-s-indacene (BODIPY) dyes have found diverse use as fluorescent switches, chemosensors, artificial light harvesters, etc. due to their intriguing properties (i.e. absorbtion in the visible region, sharp fluorescence, thermal and photostability) [35,36]. Considering the fact that the intriguing features and the rich chemistry of BODIPY could be amplified to create viable combinations with polymerizable electroactive units, it was assumed that these materials hold promise for new applications in material science. Recently, from our endeavours in this regard, we have been able to show that a switchable multielectrochromic material which gave fast response to external stimulus could be obtained from a dithienylpyrrole bearing BODIPY unit in the backbone (**1**) (Fig. 1) [37]. Furthermore, copolymers derived from **3** represented environmentally robust electroactive materials that have multielectrochromic behaviors [38]. It is also noteworthy that BODIPY dyes can be used to enhance the nonlinear optical properties of some copolymers [39].

In an effort to extend our work [34,40–42] to the design and synthesis of BODIPY based materials, we herein wish

Fig. 1. BODIPY based compounds **1**–**3**.

to report the synthesis and characterization of a donor–acceptor type system, **2**, consisting of BODIPY as the central acceptor unit and 3,4-ethylenedioxythiophene (EDOT) as the donor parts. EDOT was the choice as donor part due to its low oxidation potential which minimized the detrimental effect of high polymerization potentials such as the degradation of the polymer film. It is of worth to note that this unique system (**2**) provided an ambipolar [43,44] low band gap [45–55] material (**4**) by electrochemical polymerization. To the best of our knowledge, this is the first example of p–n junction in an organic π-conjugated material where BODIPY unit is incorporated directly in the main chain. Furthermore, the comparison of **2** with thiophene analogue **3**, and spectro-electrochemical properties of the polymer film **4** were presented.

2. Results and discussion

2.1. Synthesis and redox behavior of **2**

The syntheses of **2** and **3** were based on Stille coupling reactions of dibromo BODIPY **5** [38] with 2-(trimethylstannyl)-3,4-ethylenedioxythiophene (**6**) and 2-(trimethylstannyl)thiophene (**7**), respectively, as outlined in Scheme 1. The characterization of compounds was based on ^{1}H, ^{13}C NMR and FTIR spectral data along with the combustion analysis.

First, the redox behavior of **2** was determined and compared to that of **3** in order to elaborate the effect of donor part in the system. Cyclic voltammetry studies revealed that both **2** and **3** exhibited amphoteric redox behaviors. As shown in Fig. 2, **2** and **3** had irreversible anodic peaks
Fig. 2. Cyclic voltammogram of **2** (—) and **3** (- - -) in DCM/TBAH (0.1 M) at 20 °C, scan rate of 100 mV/s, Pt disk working electrode.

at 1.14 and 1.19 V, respectively, ascribed to the oxidation of the external units. As expected, **2** has somewhat lower oxidation potential than **3** due to the electron rich nature of EDOT units when compared to thiophene.

On the other hand, reversible reduction waves for the formation of radical anion of the central BODIPY units in **2** and **3** were observed in the negative side of the voltammograms at E^{o}_{red} = −0.92 and −0.79 V, respectively [57,58]. These results suggested that the interaction between BODIPY and external units in the donor–acceptor system was in line with the electronic nature of the donor parts, since electron rich EDOT units made the reduction of BODIPY in compound **2** more difficult when compared to **3**. This interaction was also reflected by the electronic absorption spectra, which showed a bathochromic shift along with some widening of the absorption band of BODIPY (Fig. 3).

Scheme 1. Synthesis of **2** and **3**.
Fig. 3. Electronic absorption and emission spectra of **2** (solid line) (λ_{ex} = 540 nm) and **3** (dash–dot–dash line) (λ_{ex} = 530 nm) in DCM.
Fig. 4. (a) Repeated scan electropolymerization of **2** and (b) cyclic voltammogram of n- and p-doped polymer film of **4** in DCM/TBAH (0.1 M) at 20 °C, scan rate of 100 mV/s, Pt disk working electrode.
Furthermore, the emission of both compounds was also shifted to near infrared region.

2.2. Electropolymerization of **2**

Next, the electrochemical polymerization of the compounds was investigated. Unfortunately, all of our attempts to get the corresponding polymer film from a solution of **3** under various conditions have failed [38]. To our delight, however, the growth of a conducting polymer film on the surface of the electrode was achieved with **2** to give **4** by repetitive anodic scans which provided a gradual increase in the current density (Fig. 4a). The as-prepared polymer film was electrochemically characterized in a monomer-free electrolyte solution (Scheme 2).

Cyclic voltammogram of the polymer film exhibited two reversible and well-defined redox couples with half peak potentials (E_{ox}^o) at +0.86 and +1.08 V (Fig. 4b). The linearity between the value of peak currents and the scan rates (*I–V* curve) revealed a nondiffusional redox process of a well-adhered electroactive polymer film (Fig. 5). Apart from p-doping process, the polymer film was also highly active in n-doping process with a half peak potential of −0.84 V arising from the BODIPY unit which was directly conjugated with the donor parts.

It is noteworthy that the band gap (E_g) of the polymer was found to be 1.33 eV from the onset of redox waves in the voltammogram (Fig. 4b) that made **4**, a good candidate for device applications.

2.3. Electro-optical properties of the polymer **4**

The electro-optical properties of the polymer film were examined by recording the changes upon doping process. First of all, the polymer film was electrodeposited on ITO electrode by repeated cyclic polymerization after which the thickness of the polymer film could be increased in each cycle without deactivation of the electrode surface. The as-prepared polymer film was switched between its redox states several times in monomer-free electrolyte solution to equilibrate the redox behavior after washing with DCM to remove the unreacted monomers and/or oligomeric species.

The polymer film **4** had a broad absorption band centered at 596 nm ($\pi–\pi^*$ transition) with a shoulder at

Scheme 2. Electrochemical polymerization of **2** to give **4**.

(a) Scan rate dependence of the polymer film in 0.1 M TBAH/DCM at different scan rates, a: 20 mV/s; b: 40 mV/s; c: 60 mV/s; d: 80 mV/s; e: 100 mV/s; f: 120 mV/s; g: 140 mV/s; h: 160 mV/s; i: 180 mV/s; j: 200 mV/s. (b) Relationship of anodic and cathodic current peaks as a function of scan rate for **4** in 0.1 M TBAH/DCM.
Fig. 6. UV–vis absorption spectra of **4** on ITO at various applied potentials between 0.0 and +1.25 V in 0.1 TBAH/DCM.

490 nm in the neutral state (0.0 V) (Fig. 6). The UV–vis spectrum of **4** covers the whole visible region (400–930 nm) and from the onset of the end of this broad absorption band (930 nm), a band gap of 1.33 eV, which is in agreement with the E_g value obtained from the CV data (1.33 eV), was calculated for **4**.

However, it was noted that the absorption band at 596 nm shifted to a high energy level (567 nm) with a concomitant increase in intensity upon p-doping process and a new absorption band appeared at 759 nm due to the polaron formation (Fig. 6). Further oxidation shifted the $\pi-\pi^*$ transition band at 567–623 nm, which confirms the presence of BODIPY units in the polymer backbone since BODIPY units in donor–acceptor system has a band at 542 nm, and the intensity of bipolaron band (1100 nm) increased whereas the polaron band disappeared. During the p-doping process, the polymer film **4** exhibited electrochromic behavior: a color change from light violet (neutral) to indigo (oxidized).

3. Conclusion

In summary, a novel donor–acceptor type polymer based on BODIPY dye as acceptor and EDOT units as donor parts was synthesized electrochemically. This unique combination of BODIPY and EDOT units provided an ambipolar (n- and p-doping processes) material (**4**) which had a low band gap 1.33 eV. To our best knowledge, this is the first example of p–n junction in an organic π-conjugated material where BODIPY unit is incorporated directly in the main chain. Furthermore, the polymer film exhibited electrochromic behavior upon p-doping: a color change from light violet (neutral) to indigo (oxidized). Considering the fact that the intriguing features and the rich chemistry of BODIPY can be amplified to create a huge number of viable combinations, these materials hold promise for new applications in photovoltaics, LEDs, ambipolar field effect transistors, p–n junction and so forth. Efforts to get solution processable variants of **4** are currently underway in our laboratories and the results will be reported in due course.

4. Experimental

4.1. General

All chemicals were purchased from Aldrich and used without any further purification. About 0.1 M tetrabutylammonium hexafluorophosphate (TBAH) dissolved in freshly distilled dichloromethane (DCM) was used as electrolyte solution. A platinum disk (0.02 cm^2) and a platinum wire were used as working and counter electrodes, respectively, as well as Ag/AgCl in 3 M NaCl(aq) solution as a reference. Repeated electropolymerization was used to obtain polymer films and then the coated working electrode was

washed with DCM to remove unreacted monomers. In order to elaborate the electrochemical behavior of the polymer film, the coated working electrode was transferred in monomer-free electrolyte solution of 0.1 M TBAH/DCM. Indium–tin oxide (ITO, Delta Tech. 8–12 Ω, 0.7 cm × 5 cm) electrodes were used to investigate the electro-optical properties of the polymer film. In spectro-electrochemical studies, a platinum wire as counter electrode and a Ag wire as a pseudo-reference electrode (calibrated externally using 5 mM solution of ferrocene/ferrocenium couple) were used. To obtain reproducible data in electroanalytical and optical studies, the polymer films coated on Pt and/or ITO electrodes were switched between redox states several times by equilibrating the redox behavior.

NMR spectra were recorded on a Bruker NMR Spectrometer (DPX-400) in CDCl$_3$. Electroanalytical measurements were performed using a Gamry PCI4/300 potentiostat–galvanostat. The electro-optical spectra were monitored on a Hewlett–Packard 8453A diode array spectrometer. The syntheses of **5** were described elsewhere [38]. Organostannanes **6** and **7** were obtained from the reactions of EDOT and/or thiophene, respectively, with BuLi and trimethyltin chloride in THF by following a literature procedure [56].

4.2. Representative procedure for the synthesis of **2** and **3**

To argon degassed solution of **5** (0.27 g, 0.51 mmol) and stannyl compound (**6** and/or **7**, 1.01 mmol) in dry toluene (40 mL) was added Pd(PPh$_3$)Cl$_2$ (0.07 g, 20% mmol) and the mixture was heated under reflux until all the starting materials were consumed (TLC). The flask was cooled and the solvent was removed under reduced pressure. The residue was filtered through a short pad of silica gel by eluting with hexane-CH$_2$Cl$_2$ (1:1, v/v) to give the product (**2** and/or **3**).

ABSTRACT

Small molecular organic light-emitting diodes (OLEDs) can be fabricated by spin-coating and thermo-evaporation of organic materials. In this work, X-ray photoelectron spectrometry (XPS) and secondary ion mass spectrometry (SIMS) are used to examine the microstructure of emissive layers in organic LEDs prepared with different technique using *in situ* C_{60}^+ sputtering. It is found that the Ir-containing guest molecule is enriched at the bottom-interface and a concentration gradient results from spin-coating while the opposite molecular distribution is observed with thermo-evaporation. Such a difference in microstructure affects the carrier-injection and carrier-transportation and is key to the dramatic difference ($\sim 3.5\times$) in the efficiency of the resultant OLED devices.

1. Introduction

The fabrication of small molecular organic light-emitting diodes (OLEDs) can be categorized into wet- and dry-processes that consist of spin-coating and thermo-evaporation of organic materials, respectively. Typically, dry-processed devices exhibit much higher efficiency [1–5] but wet-process also draws great attention for easier fabrication. Recently, emissive layers (ELs) of highly efficient green OLEDs were fabricated with a bis[5-methyl-7-trifluoromethyl-5H-benzo(c)(1,5)naphthyridin-6-one]iridium(picolinate) ((CF₃BNO)₂IrPLA) guest in a 4-4′-bis(carbazol-9-yl)biphenyl (CBP) host using these two techniques. While keeping other fabrication procedures the same, it was found that devices with the EL prepared via the wet-process yield much higher (70 lm W⁻¹) efficiency than the dry-process counterpart (21 lm W⁻¹) [6]. The reason to this enhancement in efficiency with wet-process needs to be examined.

Because of the high molecular weight and low decomposition temperature of the (CF₃BNO)₂IrPLA, it is considerably more difficult to evaporatively deposit than CBP. As a result, it is accepted that the concentration of the materials in the deposited film can be different from that of the evaporation source. In addition, during the sublimation, the vapor pressures of the molecules change with time so that the ratio of the molecules in the deposited film could change with the film thickness. In contrast, spin-coating

consists of drying a homogeneous solution so that homogeneous thin-film is expected. However, there is no direct evidence of the assumed distribution of molecules due to a lack of appropriate analytical techniques.

Due to its high sensitivity, XPS and SIMS are the most common techniques for studying the surface of materials. Combined with in situ ion sputtering, the depth-distribution of elements close to the surface can be profiled. Monoatomic argon sputtering is the most accepted technique for removing surface contaminants and obtaining information about the depth-distribution of a species within a sample. However, this erosion technique is known to cause severe damage to organic samples and cannot be used to analyze organic materials [7]. Recently, buckminsterfullerene (C_{60}) ion guns were used to sputter materials away for studying surface compositions [7]. Molecular dynamics (MD) calculations suggested that C_{60}^+ ions are more efficient in removing material [8] and leaving behind a relatively thin damage layer [9] than monoatomic ions. Experimental results have also confirmed the reduction in surface damage using C_{60}^+ sputtering compared with Ar^+ sputtering [10]. The application of C_{60}^+ profiling to thick organic films is further extended by concurrently applying a low-energy Ar^+ ion beam [11].

Although it is found that this analysis technique causes comparable damage to inorganic specimens [12] and the damage to the specimens is fluence-dependent [13], it provides a direct method for analyzing the distribution of materials in organic electronics with high depth resolution and is adopted in this work to examine the microstructure of ELs prepared with different method. It is found that the chemical composition of the EL-blend is non-homogeneous. In particular, spin-coating yields significant phase segregation as a function of depth. The Ir-containing guest molecule was found to be enriched at the bottom-interface. For a thermally-evaporated EL, the molecular distribution was the opposite of that obtained with spin-coating. Such a graded microstructure as a result of a different fabrication process dramatically affects the charge-injection and charge-transportation [14–22]; hence, the efficiency is up to $3.5\times$ higher with a spin-coated EL.

2. Experimental

2.1. Fabrication of EL films

In the wet-process (spin-coating), $(CF_3BNO)_2IrPLA$ doped (16%) CBP solution was prepared by dissolving the materials in dimethoxyethane at 80 °C. The resultant well-mixed solution was then spin-coated at 6000 rpm under nitrogen. In the dry-process (thermo-evaporation), the resultant solution prepared above was slowly dried at 70 °C under vacuum to obtain the deposition source. This pre-mixed material was then vapor-deposited at 2×10^{-3} Pa.

2.2. ToF-SIMS measurements

The experiments were performed with a PHI TRIFT IV ToF-SIMS system. The pulsed primary ion source was Bi_3^{2+}

operated at 30 kV (4 nA DC) with 100 μm × 100 μm rastering area at an incident angle of 35°. A flooding electron beam (28 V) was used for charge compensation. A Wien-filtered C_{60}^+ sputter gun was operated at 10 kV, 3.2 nA with an incident angle of 42° and rastered on an area of 1.5 mm × 1.5 mm.

2.3. XPS measurements

The experiments were performed with a PHI 5000 VersaProbe (Chigasaki, Japan) XPS system. A micro-focused (25 W, 100 μm) Al · Kα X-ray was used, and the take-off angle of the photoelectron was 45°. A dual-beam charge neutralizer (7 V Ar^+ and 30 V flooding electron beam) was used for charge compensation. The Ar^+ sputter source was operated at 0.2 kV, 300 nA with an incident angle of 45°. The C_{60}^+ ion source was operated at 10 kV, 10 nA with an incident angle of 70°. Both ion beams were simultaneously rastered over an area of 2 mm × 2 mm.

The surface potential was measured with a Veeco Innova (Woodbury, NY) atomic force microscope using a conductive 75 kHz cantilever in the lift-mode. The magnitude of the AC on the tip is 2 V. The dipole moment was calculated with Gaussian 03 revision D.02 using the B3LYP density function theory (DFT). The LANL2DZ basis set was employed for Ir atoms, and the 6-31G∗ basis set was employed for all other atoms.

3. Results and discussion

Using concurrent in situ C_{60}^+ and Ar^+ sputtering in XPS, Fig. 1 shows the elemental depth profile of ELs prepared with both dry- and wet-processes. In general, the intensity of Ir and C decreased with sputter time and the intensity of In increased with sputter time, indicating that the EL was removed and the ITO exposed. It is clear that the EL prepared via the dry-process is slightly thicker than via the wet-process. The integration of signal intensity throughout the sputtering revealed comparable amounts of Ir in both samples. Therefore, the EL prepared with the dry-process has a similar amount of Ir-compound compared with that prepared with the wet-process. In other word, the change
Fig. 1. XPS elemental depth profiles of emissive layers prepared with thermo-evaporation (dry-process) and spin-coating (wet-process).

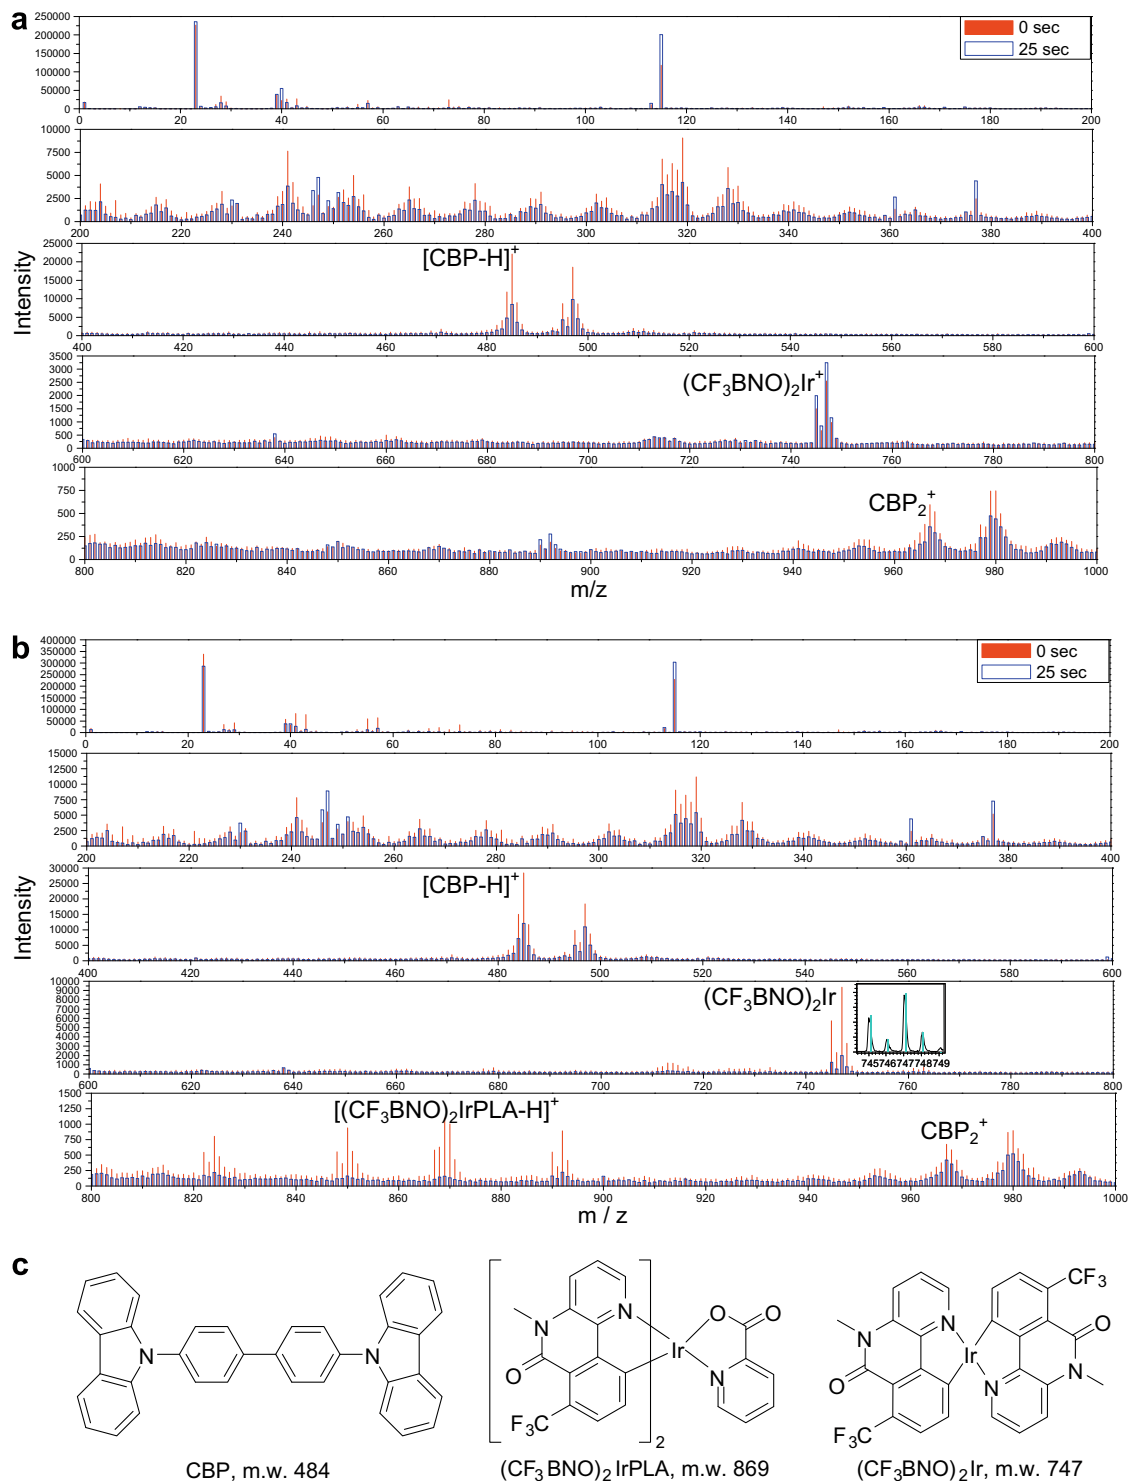
in overall chemical composition due to the evaporation process is insignificant because the evaporated film and the evaporation source, whose composition is identical to the spin-coated film, have comparable Ir-content.


Fig. 2. Positive ion spectra of (a) spin-coated emissive layer and (b) thermo-evaporated emissive layer after sputtering by C_{60}^+ for 0 and 25 s. The enlarged pattern near m/z = 747 shows the spectra with the isotopic ratio of Ir. (c) Molecular structures and fragments observed in SIMS.

Comparing the slopes of the Ir and C intensity, the steeper Ir signal of the thermo-evaporated specimen indicated that the concentration of Ir-compound is higher at the top surface. This concentration gradient could be explained by the evaporation process. Since the $(CF_3BNO)_2IrPLA$ has a higher sublimation point than CBP, the initial vapor pressure of $(CF_3BNO)_2IrPLA$ is lower. In addition, as the evaporation source losses CBP preferentially and the temperature increases during the continuous heating of the evaporation source, the relative vapor pressure of $(CF_3BNO)_2IrPLA$ increases, so the concentration of $(CF_3BNO)_2IrPLA$ is higher at the end of the evaporation process. As the result, the Ir concentration is higher at the out-most surface.

In contrast, the Ir intensity of the spin-coated specimen increased dramatically at an early stage of the profiling then decreased as the film was removed by ion sputtering. Furthermore, the Ir intensity was higher near the bottom-interface compared with the thermo-evaporated specimen. Therefore, it can be concluded that the concentration of $(CF_3BNO)_2IrPLA$ is higher at the bottom-interface and significantly lower at the top-most surface. Such a change in composition could be explained by the polarity of the molecules.

Although the wet-process consists of drying a homogeneous solution of $(CF_3BNO)_2IrPLA$ and CBP, the dipole moments of $(CF_3BNO)_2IrPLA$ and CBP are 8.5502 and 0.0022 Debye, as calculated using the density function theory (DFT). Since the substrate is polar (PEDOT:PSS coated ITO or bare ITO), the polar Ir-guests diffuse toward the bottom-interface during the drying, and non-polar CBPs migrate to the air interface. The segregation of molecules at the nano-scale thus occurs during the drying process. Similar infiltration of Ir-guest into PEDOT:PSS is reported before [23]. To further confirm the microstructure of the host-guest mixture in ELs prepared with different methods, time-of-flight SIMS (ToF-SIMS) was also used to analyze the specimen. This allowed for an examination of whether the sputtering caused damage to the remaining surface, generating artifacts in the XPS depth profile.

Fig. 2 shows secondary positive ion spectra of ELs prepared with the wet- and dry-processes, and the specimens were sputtered with C_{60}^+ ions for 0 s (as-prepared EL) and 25 s (about 10 nm of the EL was removed by the ion beam at this stage). The pattern at m/z = 747 matches with the natural isotopic ratio of the Ir-complex (inset in Fig. 2b) and the pattern at m/z = 485, 747, 869 and 870 can be assigned to the $[CBP-H]^+$, $[(CF_3BNO)_2Ir]^+$ fragment, $[(CF_3BNO)_2IrPLA]^+$ and $[(CF_3BNO)_2IrPLA-H]^+$, respectively. Comparing the spectra before and after C_{60}^+ ion sputtering, the overlapping pattern indicates that the damage to the molecular structure due to C_{60}^+ ion sputtering is negligible. The only difference observed at different sputter stages is the relative intensity of peaks related to CBP and $(CF_3BNO)_2IrPLA$, due to the difference in molecular ratios at different depths of the EL.

It has generally been believed that due to the high molecular-weight and low decomposition temperature, the Ir-containing guest does not easily deposit via thermo-evaporation. The major concern was that the molecular concentration of the evaporated film would be different from its source. In addition, thermo-decomposition of molecules could occur during the evaporation process, and the EL could contain decomposed fragments that degrade its efficiency. However, comparing the SIMS spectra of ELs prepared using different methods (Fig. 2), the pattern is almost identical aside from the difference in relative intensity associated with ratios of host to guest molecules. Because the spin-coating would not alter the molecular structure or overall ratio, this result indicates that thermo-evaporated EL contains identical molecules to that of the evaporative source, and the Ir-guest was not decomposed during the evaporation. Therefore, the change in the device performance cannot be simply explained by the difficulty in depositing the Ir-guest.

Fig. 3 shows the intensity of $[CBP-H]^+$, $[(CF_3BNO)_2Ir]^+$ fragment as a function of sputter time. Similar to the elemental depth-profile in XPS (Fig. 1), the enrichment of Ir-guest near the outer surface is observed with the dry-process while the amount of Ir-guest is higher near the bottom-interface with the wet-process. Moreover, the total intensity from the Ir-fragment throughout the sputtering is comparable for ELs prepared using different methods. This result confirms that the overall ratio of CBP and $(CF_3BNO)_2IrPLA$ is similar in the ELs prepared via different process.

In addition to the distribution of molecules along the depth of the EL, the planar distribution is another important factor in understanding its microstructure. Scanning electrical potential microscopy (SEPM) is used to analyze the planar distribution of the work-function. Because the work-function of CBP and $(CF_3BNO)_2IrPLA$ is 6.0 and 5.1 eV, respectively, planar segregation of materials would yield clear contrasts in the SEPM image. However, the SEPM images (Supporting Information) reveal a weak contrast on the order of mV. This result indicates that the distribution of CBP and $(CF_3BNO)_2IrPLA$ is rather uniform on the surface and the different fabrication processes do not significantly affect the planar distribution of materials.

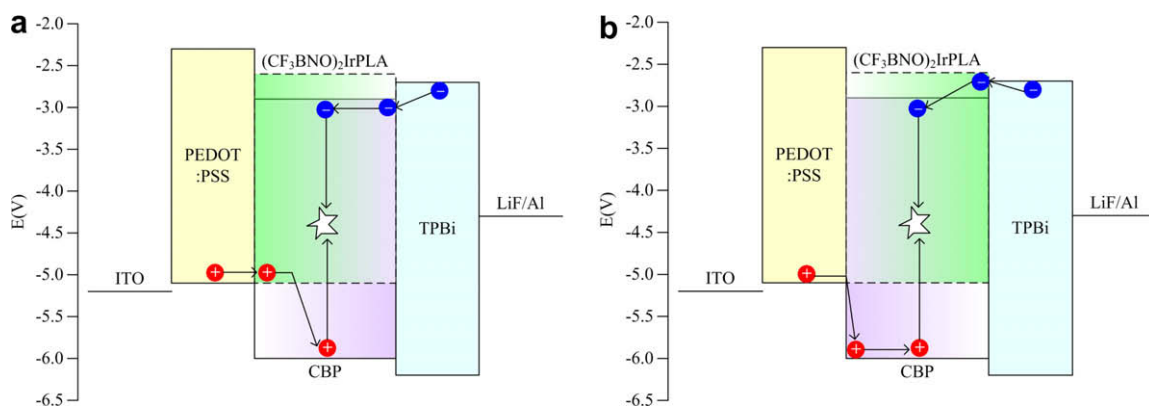
Since the overall composition is similar for both process and the planar distribution of molecules is also similar, the dramatic difference in the device performance (70 lm W^{-1} and 21 lm W^{-1} for wet- and dry-process, respectively [6]) can only be attributed to the difference in the microstruc-
Fig. 3. ToF-SIMS depth profiles of emissive layers prepared with thermo-evaporation (dry-process) and spin-coating (wet-process).


Fig. 4. Energy diagram and the route of charge carriers of OLED with EL prepared with (a) wet-process and (b) dry-process. The shade of CBP and $(CF_3BNO)_2IrPLA$ indicates its relative concentration.

ture of the EL along the vertical axis, *i.e.* the depth-distribution of Ir-guest in the CBP-host. Fig. 4 shows the energy diagram of the OLED device and the route of charge-carrier that generates excitons in the host. Considering the HOMO of PEDOT:PSS, $(CF_3BNO)_2IrPLA$, CBP, and TPBi, the enriched $(CF_3BNO)_2IrPLA$ near HTL in a spin-coated EL makes the hole easier to inject to the EL through the HOMO of the Ir-guest and can be considered as an alternative channel for hole transportation in the EL [18]. As a result, the observed turn-on voltage of spin-coated EL (3.5 V) is lower than thermo-evaporated EL (4.6 V). In addition, the hopping distance of the holes increases as the concentration of $(CF_3BNO)_2IrPLA$ decreases during the transportation toward the cathode so that holes are trapped and confined in the EL [19]. As the result, the device efficiency of a spin-coated EL is much higher ($\sim3.5\times$) than a thermo-evaporated EL.

Similarly, considering the LUMO of PEDOT:PSS, $(CF_3BNO)_2IrPLA$, CBP, and TPBi, the graded EL also helps the electron injection to the CBP-rich interface, and the electron transport gradually decreases during the movement toward the $(CF_3BNO)_2IrPLA$-rich interface, hence the electrons are also trapped in the EL. This enhancement in carrier-injection and carrier-transportation favors carrier-recombination in the EL and is the key to its high efficiency.

Notably, the molecular distribution of the EL prepared with the dry-process is opposite that of the wet-process. Since the energy barriers for hole-injection into CBP is higher than that for $(CF_3BNO)_2IrPLA$, the hole injection into EL is comparatively suppressed due to the deficiency of $(CF_3BNO)_2IrPLA$ near the interface. Meanwhile, from the viewpoint of electron-injection, electrons would hardly inject into the enriched $(CF_3BNO)_2IrPLA$ because its injection barrier is higher than that of CBP. The impeded carrier-injection would then result in fewer carriers in the EL. In addition, because of the change in chemical composition, the hopping distance of carriers decreases during transportation so that they are not trapped in the EL. As the result, there will be lower carrier-recombination in the EL, hence fewer excitations, and a dramatic change in the efficiency results.

4. Conclusion

XPS and ToF-SIMS are used to study the microstructure of the emissive layer in an organic light-emitting diode with *in situ* C_{60}^+ ion sputtering. The C_{60}^+ ion sputtering has been confirmed here to cause no appreciable damage to the molecular structure of the remaining materials. It is also found that the wet-process (spin-coating) yields an EL with a significant variation in Ir-guest distribution along the depth, *i.e.* enriched Ir-guest near the bottom and deficient Ir-guest near the outer surface. For the dry-process (thermo-evaporation), the distribution of molecules is opposite to that observed with the wet-process. Such graded EL structure changes the transportation properties of charge carriers and is the key to the high-efficiency of the OLED.

ABSTRACT

We synthesized solution-processable iridium complexes having bulky carbazole dendrons, *fac*-tris[2-{3-(3,5-bis(3,6-di-*n*-butylcarbazol-9-yl)phenyl)Phenyl)pyridine]iridium (III) (mCP)$_3$Ir and *fac*-bis[2-{3-(3,5-bis(3,6-di-*n*-butylcarbazol-9-yl)phenyl)phenyl}pyridine][2-{3-(3,5-di(4-pyridyl)phenyl)phenyl}pyridine]iridium (III) (mCP)$_2$(bpp)Ir. Photoluminescence quantum efficiencies (PLQEs) of (mCP)$_3$Ir and (mCP)$_2$(bpp)Ir in their diluted solutions were 91% and 84%, respectively. They showed high PLQEs of 49% for (mCP)$_3$Ir and 29% for (mCP)$_2$(bpp)Ir even in a neat film. The triplet exciton energy level of the dendronized ligand (2.8 eV), 2-[3-{3,5-bis(3,6-di-*n*-butylcarbazol-9-yl)phenyl}]pyridine **10**, and the dendron (2.9 eV), 3,5-bis(3,6-di-*n*-butylcarbazol-9-yl)benzene **7**, are enough higher than that of the core complex Ir(ppy)$_3$ (2.6 eV). External quantum efficiency (EQE) of single layer light-emitting device with (mCP)$_2$(bpp)Ir was much higher than that of (mCP)$_3$Ir because of better affinity of (mCP)$_2$(bpp)Ir to cathode metal. When an electron transporting and hole-blocking material was used, the EQEs of double layer devices were dramatically improved to 8.3% for (mCP)$_3$Ir and 5.4% for (mCP)$_2$(bpp)Ir at 100 cd/m^2.

1. Introduction

Organic light-emitting devices (OLEDs) have attracted a great attention because of their potentials for next generation of flat panel displays and general lighting [1]. Solution processes such as ink-jet printing are considered to have an advantage of low cost over the vacuum process for manufacturing of large area displays or lighting.

As solution-processable materials, phosphorescent iridium dendrimer complexes have recently been reported [2]. The phosphorescent dendrimers have well-defined structures, and can be purified by general purification technique. In contrast, structural defects in polymers cannot be removed and those defects could result in poor device

stability. The phosphorescent dendrimer consists of an emitting central core and surrounding dendrons. These dendrons have roles of transporting charge carriers and suppressing intermolecular interactions between emitting iridium cores, which cause photoluminescence quenching in a neat film [3]. In addition, solubility of the dendrimer metal complexes are generally better than that of the conventional metal complexes. One of the requirements for dendron is to posses the higher triplet excited energy level than that of core complex Ir(ppy)$_3$ (2.6 eV) not to quench triplet emission from the core complex.

We previously reported on high electroluminescence efficiency of carbazole-substituted phosphorescent dendrimer complex (mCP)$_3$Ir in solution-processed OLED [4]. In this paper, we discuss the synthesis detail of (mCP)$_3$Ir and another novel dendrimer complex (mCP)$_2$(bpp)Ir (Chart 1), which has carbazole dendrons in two of three ligands. The ligand has a 4-pyridine-substituted dendron to

improve electron injection from cathode metal [5]. Suppression of concentration-quenching and efficient exciton confinement by the bulky dendrons having higher triplet energy than that of Ir(ppy)₃ were studied. The energy level of the dendrimers and solution-processed OLED properties are also reported.

2. Results and discussion

2.1. Synthesis and thermal properties

Scheme 1 shows synthetic schemes of (mCP)₃Ir and (mCP)₂(bpp)Ir. Alkyl carbazole **2** was synthesized by palladium catalyzed Suzuki coupling reaction with *n*-butylboronic acid and dibromocarbazole **1**. 3-Bromophenylboronic acid **3** selectively reacted with 2-bromopyridine to give 2-(3-bromophenyl)pyridine **4**, and corresponding boronic ester **5** was given by palladium catalyzed borylation of **4**. Carbazole attached ligand **7** was obtained by palladium catalyzed C–N coupling with **2** and dibromo compound **6** [2j]. The dendrimers were prepared from the two step of complexation [6]. First, a mixture of iridium chloride trihydrate and excess of **7** afforded dichloro bridged dimer complex **8**. Second, the dimer **8** was clacked by the ligand **7** with silver trifluoromethane sulfonate to give a homoleptic dendrimer complex (mCP)₃Ir [2g]. Pyridine-substituted heteroleptic dendrimer complex (mCP)₂(bpp)Ir was synthesized by Suzuki coupling with 4-pyridylboronic acid pinacol ester and dibromo complex **9**, which was obtained by the clacking of the dimer **8** with another phenylpyridine compound **6**. Carbazole dendron **10** and pyridine substituted ligand **11** were synthesized for photoluminescence (PL) measurement. The two dendrimer complexes were fully characterized by ¹H NMR, matrix-assisted laser desorption/ ionization time-of-flight (MALDI) mass spectrometry (MS), and elemental analysis.

The dendrimers showed high thermal stability. The 5% weight loss temperature ($T_{d5\%}$) was 468 °C for (mCP)₃Ir and 445 °C for (mCP)₂(bpp)Ir, compared with 400 °C of Ir(ppy)₃. This improvement of the thermal stability may result from the protection of core complex by outer bulky dendrons. Glass transition was not observed in differential scanning calorimetry (DSC) measurement in 50–335 °C.

2.2. Photophysical properties

The UV–visible absorption and PL spectra of the Ir complexes are shown in Fig. 1. The strong absorption ranging from 250 nm to 360 nm of the dendrimers are ascribed to the singlet π–$\pi*$ transitions of the dendronized phenypyridine ligand, and the weak absorption around 360–500 nm comes from metal-to-ligand charge transfer (MLCT) transitions [7]. The absorption of (mCP)₂(bpp)Ir around 250–360 nm are weaker than that of (mCP)₃Ir, because the number of carbazole dendron unit of (mCP)₂(bpp)Ir is smaller than that of (mCP)₃Ir. Photoluminescence spectra of the two dendrimers and Ir(ppy)₃ were nearly identical, which show that the substitution of the dendrons to the *m*-position of 2-phenylpyridine ligand does not affect the emission characteristics of the Ir(ppy)₃ core complex [2j]. Photoluminescence quantum efficiencies (PLQEs) of the dendrimers in the neat film are important parameter to estimate the dendrimer's shielding effect to the core (Table 1) [8]. PLQEs of the toluene solution and the 2 or 15 wt% doped PMMA films were measured by using an integrating sphere system under 325 nm excitation. In the diluted solutions, all complexes showed high PLQE, 91% for (mCP)₃Ir and 84% for (mCP)₂(bpp)Ir, which are comparable to 85% of Ir(ppy)₃. This result demonstrated that the dendron is optically inert and does not affect the emission efficiency of Ir(ppy)₃ core. In the 2 wt% doped films, all of them showed high PLQEs as well: 90%
Scheme 1. Synthetic procedure of (mCP)₃Ir, (mCP)₂(bpp)Ir, **10**, and **11**: (i) *n*-butylboronic acid, Pd(PPh₃)₄, P(*t*-Bu)₃, K₂CO₃ *aq.*, toluene, N₂, 85 °C, (ii) 2-bromopyridine, Pd(PPh₃)₄, K₂CO₃ *aq.*, THF, N₂, reflux, (iii) bis(pinacolato)diboron, KOAc, PdCl₂(dppf), N₂, DMF, 85 °C, (iv) 1,3,5-tribromobenzene, Pd(PPh₃)₄, Na₂CO₃ *aq.*, EtOH, toluene, N₂, reflux, (v) **2**, Pd₂(dba)₃, P(*t*-Bu)₃, NaO-*t*-Bu, toluene, N₂, reflux, (vi) IrCl₃·3H₂O, H₂O, 2-ethoxyethanol, N₂, 130 °C, (vii) **7**, CF₃SO₃Ag, diglyme, N₂, 130 °C, (viii) **6**, CF₃SO₃Ag, diglyme, N₂, 130 °C, (ix) 4-pyridylboronic acid pinacol ester, Pd(PPh₃)₄, K₂CO₃ *aq.*, EtOH, toluene, N₂, reflux, (x) **2**, Pd₂(dba)₃, P(*t*-Bu)₃, NaO-*t*-Bu, toluene, N₂, reflux, (xi) **6**, 4-pyridylboronic acid pinacol ester, Pd(PPh₃)₄, Na₂CO₃ *aq.*, EtOH, toluene, N₂, reflux.

for (mCP)₃Ir, 86% for (mCP)₂(bpp)Ir, and 95% for Ir(ppy)₃ [9]. In the 15 wt% doped film, Ir(ppy)₃ showed a very low PLQE of 15% because of severe concentration-quenching effect. On the other hand, the dendrimers exhibited much higher PLQEs of 49% for (mCP)₃Ir and 29% for (mCP)₂(bpp)Ir even in the neat films. These results showed that these dendron substituents are partially effective to suppress concentration-quenching in a neat film of an iridium complex. There are two reasons why concentration-quenching happened even after the substitution of the dendrons. First, these dendrimers are facial isomers, therefore a some space around pyridyl groups of Ir(ppy)₃ core are opened and the three dimensional structure of the dendrimer complexes is like a hemisphere [8b]. There are spatial rooms for the core complex of the dendrimers to contact each other. Second, the substituted dendrons are

not enough large to suppress the interaction between the core complexes completely. Adachi et al. reported that an average distance between iridium complexes in a doped film critically influenced on PLQE [10]. Förster type energy transfer between Ir(ppy)₃ cores through an overlap of the emission and the absorption causes a decrease of neat film PLQY. If the average distance between iridium complexes is shorter than Förster radius, a strong quenching occurs. The stronger quenching of (mCP)₂(bpp)Ir in the neat film than that of (mCP)₃Ir is due to the shorter average distance between the cores derived from a less number of bulky carbazole dendron of (mCP)₂(bpp)Ir than that of (mCP)₃Ir. More branched and larger dendrons and their dense substitution to the core complexes are desirable to achieve the more effective suppression of concentration-quenching [2j,8].
Fig. 1. UV–visible and PL spectra (excited at 400 nm) of Ir(ppy)$_3$ (closed circle), (mCP)$_3$Ir (open circle) and (mCP)$_2$(bpp)Ir (closed square) at room temperature in chloroform solution.

Table 1
PLQEs of the dendrimer complexes in a solution and film.

Compound	Φ_{sol}[a] (%)	$\Phi_{2wt\% \ film}$[b] (%)	$\Phi_{neat \ film}$ (%)	$(\Phi_{sol} - \Phi_{film})/\Phi_{sol}$ (%)
(mCP)$_3$Ir	91	90	49	46
(mCP)$_2$(bpp)Ir	84	86	29	65
Ir(ppy)$_3$	85	95	15[c]	82

[a] Toluene solution (2.0 × 10^{-6} mol/L).
[b] 2 wt% Doped PMMA film.
[c] 15 wt% Doped PMMA film.
Fig. 2. Phosphorescence spectra of Ir(ppy)$_3$ (closed circle), **7** (open circle), and **10** (open triangle) in a neat film (Ir(ppy)$_3$: at room temperature, excited at 400 nm; **7** and **10**: at 4 K, excited at 337 nm).

The triplet exciton energy level (T_1) of the dendron determined by the edge at shorter wavelength side of phosphorescence spectrum at 4 K well supported the exciton confinement of the emitting core. T_1 of the dendronized ligands, 2.8 eV of **7** and 2.9 eV of **10**, are higher than 2.6 eV of Ir(ppy)$_3$ (Fig. 2). T_1 of **11** was not able to determined because its film was crystallized at 4 K, but the life time of photoluminescence of 2 wt% Ir(ppy)$_3$ in the film of

11 showed single exponential decay, indicating that the T_1 level of **11** was high enough to confine the energy of Ir(ppy)$_3$ core.

2.3. Electrochemical properties

Ionization potential (I_p) of the compounds was measured by ultraviolet photoelectron spectroscopy. I_p of (mCP)$_3$Ir and (mCP)$_2$(bpp)Ir were 5.5 eV and 5.6 eV, respectively, and these are lower than 5.9 eV of **10**, and slightly larger than 5.3 eV of Ir(ppy)$_3$. These results suggest that highest occupied molecular orbital (HOMO) level of the dendrimers are derived from Ir(ppy)$_3$ core rather than carbazole dendron, and those higher HOMO level than that of Ir(ppy)$_3$ are due to the electron withdrawing effect of the dendron to the Ir core complex [11]. In cyclic voltammetry measurements, the dendrimers, (mCP)$_3$Ir and (mCP)$_2$(bpp)Ir, showed two redox waves in anodic scan. The first redox at 0.20–0.34 V is ascribed to the redox of Ir(ppy)$_3$ core, and the second at 0.75–0.79 V is ascribed to the redox of carbazole dendron (Fig. 3). These results demonstrated that these dendrimers have independent two energy levels corresponding to the Ir(ppy)$_3$ core and the dendron, respectively, and these two π systems are not fully conjugated. Lowest unoccupied molecular orbital (LUMO) level of (mCP)$_3$Ir, (mCP)$_2$(bpp)Ir and Ir(ppy)$_3$, estimated by the energy gap and HOMO level, were 2.7 eV, 2.8 eV and 2.6 eV, respectively. LUMO level of the dendron **10** was 2.5 eV, higher than that of Ir(ppy)$_3$.

2.4. OLED performance

Single layer devices with the configuration of ITO/ poly(3,4-ethylenedioxythiophene)(PEDOT): poly(styrene sulfonic acid) (PSS) (40 nm)/(mCP)$_3$Ir or (mCP)$_2$(bpp)Ir (120 nm)/LiF (1 nm)/Al (100 nm) and double layer devices with the configuration of ITO/ PEDOT: PSS (40 nm)/(mCP)$_3$Ir or (mCP)$_2$(bpp)Ir (60 nm)/bis-4,6-(3,5-di-3-pyridylphenyl)-2-methylpyrimidine (B3PYMPM) [5d] (60 nm)/LiF (1 nm)/Al (100 nm) were fabricated. Electroluminescence
Fig. 4. Electroluminescence spectra of (mCP)$_3$Ir (closed circle) and (mCP)$_2$(bpp)Ir (closed square) in the double layer devices.

Fig. 6. EQE – current density plots of single layer devices of (mCP)$_3$Ir (closed circle) and (mCP)$_2$(bpp)Ir (closed square), and double layer devices of (mCP)$_3$Ir (open circle) and (mCP)$_2$(bpp)Ir (open square).

spectra of double layer devices were shown in Fig. 4. These spectra were identical to the photoluminescence spectra and the spectra of single layer devices. Higher driving voltages of (mCP)$_2$(bpp)Ir than those of (mCP)$_3$Ir in current density are probably due to the larger hole injection barrier to the HOMO level of dipyridylphenyl dendron compared with the barrier to the HOMO level of dicarbazolylphenyl dendron (Fig. 5). Hole injection barriers from PEDOT: PSS to the HOMO levels of these dendrimers are quite small compared with electron injection barriers from aluminum to the LUMO levels. Therefore, hole current should be dominant in single layer devices. However, in contrast to the result of the current density – voltage plots of the single layer device, (mCP)$_2$(bpp)Ir in the single layer device showed lower driving voltages than that of (mCP)$_3$Ir in the luminance – voltage plots. As well as the luminance, external quantum efficiencies (EQEs) of the single layer device with (mCP)$_2$(bpp)Ir were much higher than those of (mCP)$_3$Ir (Fig. 6). EQE at 100 cd/m^2 with (mCP)$_2$(bpp)Ir was 0.23%, and that with (mCP)$_3$Ir was 0.014%. This improvement showed that the pyridine groups of (mCP)$_2$(bpp)Ir are effec-

tive to the better electron injection from cathode metal to the dendrimer because of their better affinity to LiF of cathode [5e].

The double layer devices were fabricated using B3PYMPM as an electron transporting and hole-blocking material on the dendrimer emitting layer. The current density increased and driving voltages decreased compared with the single layer devices due to the improved electron injection by the electron transporting layer (ETL). Especially, their efficiencies were drastically improved to 8.3% for (mCP)$_3$Ir and 5.4% for (mCP)$_2$(bpp)Ir at 100 cd/m^2. These high efficiencies resulted from improved charge recombination by the efficient hole block of B3PYMPM layer, whose HOMO and LUMO levels are 6.8 eV and 3.2 eV, respectively. These drastic improvements of efficiencies by ETL also supported that the current of the single layer devices was hole dominant. The higher efficiency of (mCP)$_3$Ir than that of (mCP)$_2$(bpp)Ir is derived from the higher PLQE of (mCP)$_3$Ir. The roll-off of EQE in high current density region in double layer devices may be because of
Fig. 5. Luminance – voltage (left) and current density – voltage (right) plots of single layer devices of (mCP)$_3$Ir (closed circle) and (mCP)$_2$(bpp)Ir (closed square), and double layer devices of (mCP)$_3$Ir (open circle) and (mCP)$_2$(bpp)Ir (open square).

imbalance of injected electrons and holes. This carrier imbalance is caused by electron leakage to PEDOT: PSS layer through the dendrimer complex layer that is why an insertion of interlayer having electron blocking property between PEDOT: PSS and the dendrimer layer would be necessary to improve EQE and its roll-off behavior.

3. Conclusions

We synthesized solution-processable iridium complexes $(mCP)_3Ir$ and $(mCP)_2(bpp)Ir$ having bulky carbazole dendrons. The dendrimers exhibited still high PLQEs, 49% for $(mCP)_3Ir$ and 29% for $(mCP)_2(bpp)Ir$ even in the neat films. T_1 level of the dendronized ligand and the dendron are enough higher than that of the core complex $Ir(ppy)_3$. The EQE of single layer light-emitting device with $(mCP)_2(bpp)Ir$ was much higher than that of $(mCP)_3Ir$ because of better affinity of $(mCP)_2(bpp)Ir$ to LiF of cathode. The EQEs of double layer devices with ETL were dramatically improved to 8.3% for $(mCP)_3Ir$ and 5.4% for $(mCP)_2(bpp)Ir$ at 100 cd/m^2.

4. Experimental

NMR spectra were recorded on a JEOL ECX-400 400 MHz spectrometer. UV–visible spectra were recorded on a Shimadzu UV3150 spectrometer and photoluminescence spectra were recorded on a Horiba Jobin Yvon Fluoromax-2 spectrofluorometer. Ionization potentials were measured by Riken Keiki AC-3. Mass spectra were recorded on a JEOL JMS-K9 for electron impact-ionization (EI) or an Applied Biosystems Voyager DE-PRO for matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) from dithranol (DITH) in linear or reflection mode. Elemental analyses were carried out in the Elemental Analysis Service, Yamagata University. Gel permeation chromatography was carried out using Nippon Bunseki Kogyo LC-9204 with JAIGEL 2H and 2.5H columns. Thermal gravimetric analysis was performed on a SII thermogravimetric analyzer TG / DTA 6200. Glass transition temperatures were measured on a Perkin Elmer differential scanning calorimeter Diamond DSC. Electrochemistry was performed on ALS / H CH Instruments Electrochemical analyzer 660B. All measurements were made at room temperature on samples dissolved in dry dichloromethane with 0.1 M tetrabutylammonium tetrafluoroborate as a supporting electrolyte. The dry dichloromethane was purchased from Kanto Kagaku Co. The solutions were deoxygenated with argon. A platinum working electrode, platinum wire counter electrode and Ag/Ag$^+$ reference electrode was used. The ferrocene/ferricenium couple was used as an internal standard. All potentials are quoted relative to ferrocene / ferricenium couple. $Ir(ppy)_3$ film for PL measurement were deposited under 2×10^{-5} Pa to give a thickness of about 80 nm. Films for PL and PLQE measurement were obtained by spin-coating on quartz substrate from 1,2-dichloroethane solution with a concentration of 25 g/L at 1000 rpm for 30 s to give a thickness of about 130 nm. For PLQE measurement in solution, $Ir(ppy)_3$ was dissolved in toluene at the concentration of 1×10^{-5} mol/L, and the dendrimers

were dissolved in toluene at the concentration of 2×10^{-6} mol/L. Their PLQE was measured using an integrating sphere of Hamamatsu Photonics A10094 with a xenon lamp at 325 nm at room temperature. The integrating sphere was purged with nitrogen during measurements. On preparing OLEDs, PEDOT: PSS was spin-coated as an anode buffer layer on pre-cleaned ITO substrate. On the top of PEDOT: PSS layer, dendrimers were spin-coated from 1,2-dichloroethane solutions. B3PYMPM was deposited on the top of the dendrimer layer under 5.8×10^{-5} Pa. Finally, electron injection layer, LiF and Al cathode were successively deposited under 2.4×10^{-3} Pa. Luminance measurements were carried out with a Konica Minolta CS200 luminance meter and electroluminescence spectra were taken by Hamamatsu Photonics PMA-11 optical multi-channel analyzer at room temperature.

3,6-Dibutylcarbazole (**2**): A mixture of 3,6-dibromocarbazole (**1**) (13.3 g, 40.9 mmol), potassium carbonate (28.2 g, 204 mmol), *n*-butylboronic acid (10.0 g, 98.1 mmol), tetrakis(triphenylphosphine)palladium(0) (0.238 g, 0.206 mmol), tri-*tert*-butylphosphine (0.30 ml, 1.2 mmol), deionized water (65 ml), toluene (175 ml) was heated at 85 °C under nitrogen for 24 h. After being allowed to cool to room temperature, the organic layer was extracted with diethyl ether and washed with deionized water, dried over anhydrous sodium sulfate. The solvents were completely removed to give white solid and purified by column chromatography over silica gel with chloroform–*n*-hexane (0:1–1:1) as eluent to give white solid of **2** (6.85 g, 60%). (Found: C, 86.95; H, 7.41; N, 5.35. $C_{20}H_{25}N$ requires C, 87.09; H, 7.57; N, 5.35%); d_H(400 MHz, CDCl$_3$) 1.24 (6H, t, *J* 7.3, $2 \times CH_2CH_2CH_2CH_3$), 1.62–1.69 (4H, m, $2 \times CH_2CH_2CH_2CH_3$), 1.92–1.97 (4H, m, $2 \times CH_2CH_2CH_2CH_3$), 3.01 (4H, t, *J* 7.5, $2 \times CH_2CH_2CH_2CH_3$), 7.50 (2H, d, *J* 8.2, ArH), 7.65 (2H, d, *J* 8.2, ArH), 8.18 (2H, s, ArH), 11.2 (H, s, NH). d_C(100 MHz, CDCl$_3$) 14.2, 22.6, 34.7, 35.9, 110.4, 119.7, 123.6, 126.6, 134.0, 138.4. *m/z* [EI] 380 (M$^+$).

2-(3-Bromophenyl)pyridine (**4**): A mixture of 3-bromophenylboronic acid (**3**) (3.00 g, 14.9 mmol), 2-bromopyridine (3.03 ml, 29.9 mmol), tetrakis(triphenylphosphine)palladium(0) (0.695 g, 0.601 mmol), potassium carbonate (4.11 g, 29.8 mmol), deionized water (15 ml), tetrahydrofuran (40 ml) was heated at reflux under nitrogen for 24 h. After being allowed to cool to room temperature, the organic layer was extracted with diethyl ether and washed with deionized water, dried over anhydrous sodium sulfate. The solvents were completely removed to give brown oil and purified by column chromatography over silica gel with chloroform–*n*-hexane (1:1) as eluent to give light yellow oil. The oil was distilled under 90 °C, 50 mmHg to give light yellow oil of **2** (2.01 g, 58%). (Found: C, 56.71; H, 3.41; N, 5.75. $C_{11}H_8BrN$ requires C, 56.44; H, 3.44; N, 5.98%); d_H(400 MHz, DMSO-D6) 7.67 (1H, t, *J* 6.7, ArH), 7.73 (1H, t, *J* 7.8, ArH), 7.90 (1H, d, *J* 8.2, ArH), 8.17 (1H, t, *J* 7.8, ArH), 8.29 (1H, d, *J* 7.8, ArH), 8.35 (1H, d, *J* 8.7, ArH), 8.55 (1H, s), 8.95 (1H, d, *J* 5.5, ArH). d_C(100 MHz, DMSO-D6) 122.1, 123.9, 125.0, 126.9, 130.6, 132.5, 133.2, 139.0, 142.4, 151.2, 155.7. *m/z* [EI] 233: (M$^+$).

2-[3-{(4,4,5,5-Tetramethyl)-1,3,2-dioxaborolan-2-yl}phenyl]pyridine (**5**): A mixture of **4** (1.00 g, 4.27 mmol), bis(pina-

colato)diboron (1.19 g, 4.70 mmol), [1,1-bis(diphenylphosphino)ferrocene]dichloropalladium(II) dichloromethane complex (1:1) (0.105 g, 0.128 mmol), potassium acetate (1.26 g, 12.8 mmol), *N,N'*-dimethylformamide (20 ml) was heated at 85 °C under nitrogen for 18 h. After being allowed to cool to room temperature, the solvent was completely removed. The residue was purified by column chromatography over silica gel with chloroform–ethyl acetate (1:1) as eluent to give **5** (0.860 g, 86%) as a white crystal. (Found: C, 72.45; H, 7.26; N, 4.90. $C_{17}H_{20}BNO_2$ requires C, 72.62; H, 7.17; N, 4.98%); d_H(400 MHz, DMSO-D6) 1.65 (12H, s, 4 × CH_3), 7.69 (1H, t, *J* 6.2, ArH), 7.83 (1H, t, *J* 7.5, ArH), 8.05 (1H, d, *J* 7.3, ArH), 8.20 (1H, t, *J* 7.0, ArH), 8.28 (1H, d, *J* 8.2, ArH), 8.50 (1H, d, *J* 8.2, ArH), 8.75 (1H, s, ArH), 8.99 (1H, d, *J* 5.0, ArH). *m/z* [EI] 281 (M⁺).

2-[3-(3,5-Dibromophenyl)phenyl]pyridine (**6**): A mixture of **5** (2.33 g, 8.29 mmol), 1,3,5-tribromobenzene (7.84 g, 24.9 mmol), tetrakis(triphenylphosphine)palladium(0) (0.387 g, 0.335 mmol), sodium carbonate (1.15 g, 10.8 mmol), deionized water (5.5 ml), ethanol (5 ml), toluene (20 ml) was heated at reflux under nitrogen for 26 h. After being allowed to cool to room temperature, the organic layer was extracted with diethyl ether and washed with deionized water, dried over anhydrous sodium sulfate. The solvent was completely removed. The residue was purified by column chromatography over silica gel with chloroform as eluent to give **6** (2.64 g, 82%) as a white crystal. (Found: C, 52.42; H, 2.62; N, 3.54. $C_{17}H_{11}Br_2 N$ requires C, 52.48; H, 2.85; N, 3.60%); d_H(400 MHz, DMSO-D6) 7.71 (1H, t, *J* 6.2, ArH), 7.92 (1H, t, *J* 7.9, ArH), 8.10 (1H, d, *J* 6.8, ArH), 8.18 (1H, s, ArH), 8.23 (1H, t, *J* 7.7, ArH), 8.32 (2H, s, ArH), 8.47 (2H, d, *J* 8.1, ArH), 8.66 (1H, s, ArH), 9.01 (1H, d, *J* 4.5, ArH). d_C(100 MHz, CDCl₃) 120.9, 122.7, 123.5, 125.9, 127.1, 127.8, 129.3, 129.6, 132.9, 137.1, 139.1, 140.4, 144.8, 150.0, 157.0. *m/z* [EI] 389 (M⁺).

2-[3-{3,5-Bis(3, 6-dibutylcarbazol-9-yl)phenyl}phenyl] pyridine (**7**): A mixture of **2** (2.53 g, 9.05 mmol), **6** (1.47 g, 3.77 mmol), tris(dibenzylideneacetone)dipalladium(0) (0.0934 g, 0.102 mmol), tri-*tert*-butylphosphine (0.210 ml, 0.867 mmol), sodium *tert*-butoxide (1.45 g, 15.1 mmol), toluene (180 ml) was heated at reflux under nitrogen for 36 h. After being allowed to cool to room temperature, the organic layer was extracted with diethyl ether and washed with deionized water, dried over anhydrous sodium sulfate. The solvent was completely removed and purified by column chromatography over silica gel with chloroform as eluent to give white brown solid **7** (2.32 g, 78%). (Found: C, 86.25; H, 8.90; N, 4.99. $C_{57}H_{59}N_3$ requires C, 85.97; H, 9.02; N, 5.01%); d_H(400 MHz, DMSO-D6) 1.23 (12H, t, *J* 7.5, 4 × $CH_2CH_2CH_2CH_3$), 1.65–1.67 (8H, m, 4 × $CH_2CH_2CH_2CH_3$), 1.94–1.96 (8H, m, 4 × $CH_2CH_2CH_2CH_3$), 3.05 (8H, t, *J* 7.5, 4 × $CH_2CH_2CH_2CH_3$), 7.58 (4H, d, *J* 8.1, ArH), 7.66 (1H, t, *J* 4.7, ArH), 7.84 (4H, d, *J* 8.2, ArH), 7.94 (1H, t, *J* 7.7, ArH), 8.09 (1H, s, ArH), 8.16 (1H, t, *J* 6.8, ArH), 8.26 (1H, d, *J* 7.7, ArH), 8.35 (4H, s, ArH), 8.40–8.45 (3H, m, ArH), 8.48 (1H, d, *J* 7.7, ArH), 8.81 (1H, s, ArH), 8.96 (1H, d, *J* 4.6, ArH). *m/z* [EI] 786: (M⁺).

fac-Bis[2-{3-(3,5-bis(3,6-di-*n*-butylcarbazol-9-yl)phenyl)phenyl} pyridine][2-{(3-(3,5-dibromophenyl)phenyl)-Phenyl)phenylpyridine]iridium(III) (**9**): A mixture of **7** (3.43 g, 4.36 mmol), iridium chloride trihydrate (0.638 g,

1.81 mmol), deionized water (30 ml), 2-ethoxyethanol (125 ml) was heated (oil bath temperature: 130 °C) under nitrogen for 25 h. After being allowed to cool to room temperature, deionized water was added and filtrated. Then aqueous potassium carbonate (0.33 M, 30 ml) was added and sonicated for 5 min and washed with deionized water. The solvent was completely removed and purified by column chromatography over silica gel to remove the residual ligand with dichloromethane–*n*-hexane (4:1) as eluent to give ocherous solid (2.38 g). A mixture of the obtained chloro-bridged dimer (2.38 g), **6** (0.774 g, 1.99 mmol), silver trifluoromethanesulfonate (0.204 g, 0.794 mmol), diglyme 100 ml was heated (sand bath temperature: 130 °C) under nitrogen for 6.8 day. After being allowed to cool to room temperature, purified by column chromatography over silica gel with dichloromethane–*n*-hexane (3:4) as eluent to give brown oil. The oil was distilled under 110 °C, 50 mmHg. The solvent was completely removed and purified by gel permeation chromatography with 1,2-dichloroethane as eluent to give **9** (0.543 g, 14%) as a yellow solid. (Found: C, 73.14; H, 5.91; N, 4.55. $C_{131}H_{126}Br_2IrN_7$ requires C, 73.17; H, 5.91; N, 4.56%); d_H(400 MHz, CD₂Cl₂) 0.91 (24H, t, *J* 6.3, 8 × $CH_2CH_2CH_2CH_3$), 1.20–1.50 (16H, m, 8 × $CH_2CH_2CH_2CH_3$), 1.50–1.80 (16H, m, 8 × $CH_2CH_2CH_2CH_3$), 2.76 (16H, t, *J* 6.1, 8 × $CH_2CH_2CH_2CH_3$), 6.80–7.10 (6H, m, ArH), 7.10–7.30 (10H, m, ArH), 7.30–8.10 (38H, m, ArH). [MALDI: DITH] (*m/z*) 2149.49 (MH⁺).

3,5-Bis(3,6-dibutylcarbazol-9-yl)benzene (**10**): A mixture of **2** (0.306 g, 1.10 mmol), 1,3-dibromobenzene (0.055 ml, 0.458 mmol), tris(dibenzylideneacetone)dipalladium(0) (0.0114 g, 0.0124 mmol), tri-*tert*-butylphosphine (0.025 ml, 0.11 mmol), sodium *tert*-butoxide (0.176 g, 1.83 mmol), toluene (20 ml) was heated at reflux under nitrogen for 24 h. After being allowed to cool to room temperature, the organic layer was extracted with diethyl ether and washed with deionized water, dried over anhydrous sodium sulfate. The solvent was completely removed and purified by column chromatography over silica gel with chloroform–*n*-hexane (2:1) and with chloroform–*n*-hexane (0:1 to 1:1) as eluent to give colorless oil **10** (0.262 g, 90%). (Found: C, 87.41; H, 8.26; N, 4.31. $C_{46}H_{52}N_2$ requires C, 87.29; H, 8.28; N, 4.43%) d_H(400 MHz, DMSO-D6) 1.18 (12H, t, *J* 7.3, 4 × $CH_2CH_2CH_2CH_3$), 1.56–1.66 (8H, m, 4 × $CH_2CH_2CH_2CH_3$), 1.88–1.95 (8H, m, 4 × $CH_2CH_2CH_2CH_3$), 3.01 (8H, t, *J* 7.5, 4 × $CH_2CH_2CH_2CH_3$), 7.54 (4H,d, *J* 8.2, ArH), 7.72 (4H, d, *J* 8.6, ArH), 7.98–8.05 (3H, m, ArH), 8.20 (1H, t, *J* 8.0, ArH), 8.30 (4H, s, ArH). d_C(100 MHz, CDCl₃) 14.3, 22.6, 34.7, 35.9, 109.6, 119.9, 123.8, 124.8, 125.2, 126.9, 131.1, 135.0, 139.4, 139.9. *m/z* [EI] 634: (M⁺).

2-[3-{3,5-Di(4-pyridyl)phenyl}phenyl]pyridine (**11**): A mixture of **6** (0.500 g, 1.29 mmol), 4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)pyridine (0.792 g, 3.86 mmol), tetrakis(triphenylphosphine)palladium(0) (0.120 g, 0.104 mmol), sodium carbonate (0.355 g, 3.35 mmol), deionized water (1.7 ml), ethanol (2.3 ml), toluene (9.3 ml) was heated at reflux under nitrogen for 19 h. After being allowed to cool to room temperature, the organic layer was extracted with diethyl ether and tetrahydrofuran. The extracted fraction was washed with deionized water, dried

over anhydrous sodium sulfate. The solvent was completely removed and purified by column chromatography over silica gel with ethyl acetate–methanol (10:3) as eluent to give white solid **11** (0.380 g, 76%). (Found: C, 84.24; H, 4.79; N, 10.87. $C_{27}H_{19}N_3$ requires C, 84.13; H, 4.97; N, 10.90%); d_H(400 MHz, DMSO-D6) 7.97 (1H, t, J 5.0, ArH), 7.98 (1H, t, J 7.7, ArH), 8.22–8.35 (6H, m, ArH), 8.45–8.58 (5H, m, ArH), 8.82 (1H, s, ArH), 9.02 (5H, d, J 5.9, ArH). d_C(100 MHz, CDCl$_3$) 121.0, 122.1, 122.7, 125.0, 126.2, 126.8, 126.9, 128.0, 129.7, 137.1, 140.0, 140.5, 140.9, 143.3, 148.0, 150.0, 150.7, 157.2. m/z [EI] 386: (M$^+$).

(mCP)$_3$Ir: A mixture of **7** (0.300 g, 0.381 mmol), iridium chloride trihydrate (0.0561 g, 0.159 mmol), deionized water (2.7 ml), 2-ethoxyethanol (12 ml) was heated (oil bath temperature: 130 °C) under nitrogen for 24 h. After being allowed to cool to room temperature, deionized water was added and filtrated. Then aqueous potassium carbonate (0.35 M, 5.8 ml) was added and sonicated for 5 min and washed with deionized water. After it was dried, the crude product was directly used for next step without further purification. A mixture of the obtained chlorobridged dimer (0.262 g), **7** (0.434 g, 0.552 mmol), silver trifluoromethanesulfonate (0.0491 g, 0.191 mmol), diglyme 5.0 ml was heated (sand bath temperature: 130 °C) under nitrogen for 64 h. After being allowed to cool to room temperature, dichloromethane was added and the solution was washed with brine and deionized water, dried over anhydrous sodium sulfate. The solvent was completely removed and purified by column chromatography over silica gel with dichloromethane–n-hexane (1:2) as eluent to give **(mCP)$_3$Ir** (0.174 g, 43%) as a yellow solid. (Found: C, 80.52; H, 7.05; N, 5.01. $C_{171}H_{174}IrN_9$ requires C, 80.62; H, 6.88; N, 4.95%); d_H(400 MHz, CD$_2$Cl$_2$) 1.23 (36H, t, J 7.2, $12 \times CH_2CH_2CH_2CH_3$), 1.30–1.50 (24H, m, $12 \times CH_2CH_2$-CH_2CH$_3$), 1.50–1.80 (24H, m, $12 \times CH_2CH_2CH_2CH_3$), 2.76 (24H, t, J 7.5, $12 \times CH_2CH_2CH_2CH_3$), 6.97 (3H, t, J 6.1, ArH), 7.03 (3H, d, J 7.3, ArH), 7.17–7.28 (15H, m, ArH), 7.44–7.55 (12H, d, ArH), 7.57 (3H, d, J 6.1, ArH), 7.63–7.71 (8H, m, ArH), 7.86–8.50(24H, m, ArH). d_C(100 MHz, CD$_2$Cl$_2$) 13.8, 22.5, 34.5, 35.7, 109.7, 119.36,119.37, 119.6, 122.0, 122.5, 122.8, 123.6, 126.8, 128.6, 131.4, 134.9, 136.8, 137.7, 139.5, 140.1, 145.0, 145.5, 147.5, 162.0, 166.0. [MALDI: DITH] (m/z) 2545.8: (MH$^+$).

(mCP)$_2$(bpp)Ir: A mixture of **9** (0.400 g, 0.186 mmol), 4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)pyridine (0.305 g, 1.49 mmol), tetrakis(triphenylphosphine)palladium(0) (0.0174 g, 0.0151 mmol), potassium carbonate (0.0668 g, 0.483 mmol), deionized water (0.24 ml), ethanol (18 ml), toluene (35 ml) was heated at reflux under nitrogen for 62.5 h. After being allowed to cool to room temperature, purified by column chromatography over silica gel with chloroform–methanol (20:1) as eluent to give ocherous solid. The solid was purified by gel permeation chro-

matography with 1,2-dichloroethane as eluent to give (mCP)$_2$(bpp)Ir (0.316 g, 79%) as a yellow solid. (Found: C, 78.73; H, 6.52; N: 5.80. $C_{141}H_{134}IrN_9$ requires C, 78.88; H, 6.29; N, 5.87%); d_H(400 MHz, CD$_2$Cl$_2$) 0.92 (24H, t, J 7.3, $8 \times CH_2CH_2CH_2CH_3$), 1.30–1.45 (16H, m, $8 \times CH_2CH_2$-CH_2CH$_3$), 1.60–1.75 (16H, m, $8 \times CH_2CH_2CH_2CH_3$), 2.75 (16H, t, J 4.1, $8 \times CH_2CH_2CH_2CH_3$), 6.91–7.08 (6H, m, ArH), 7.14–7.30 (11H, m, ArH), 7.42–7.82 (21H, m, ArH), 7.84–8.12 (20H, m, ArH), 8.64 (4H, d, J 5.5, ArH). [MALDI: DITH] (m/z) 2146.91 (MH$^+$).

Organic-based devices with an 8×8 array structure using titanium dioxide nanoparticles (TiO_2 NPs) embedded in poly(9-vinylcarbazole) (PVK) film exhibited bistable resistance states and a unipolar nonvolatile memory effect. TiO_2 NPs were a key factor for realizing the bistability and the concentration of TiO_2 NPs influenced ON/OFF ratio. From electrical measurements, switching mechanism of PVK:TiO_2 NPs devices was closely associated with filamentary conduction model and it was found that the OFF state was dominated by thermally activated transport while the ON state followed tunneling transport. PVK:TiO_2 NPs memory devices in 8×8 array structure showed a uniform cell-to-cell switching, stable switching endurance, and a high retention time longer than 10^4 s.

1. Introduction

Several types of organic electronics, including organic light emitting diodes, transistors, solar cells, and nonvolatile memory devices, have attracted considerable attention due to a variety of advantages such as printability, flexibility, low processing cost, and easy fabrication [1–4]. Among these organic electronics, organic memory devices have been investigated as a promising alternative to the conventional semiconductor-based nonvolatile memory devices [5–10]. In particular, organic memory devices employing nanoparticles in the active memory materials have been extensively studied due to easily controllable processing factors such as different kinds of particles, particle size, and concentration of particles [11–13]. Much research has been done to construct organic memory devices with

high specifications including highly reproducible electrical characteristics, a large ON/OFF ratio, and a long retention time by optimizing these processing factors [11–14]. Bozano et al. showed that different types of nanoparticles (NPs) in hybrid organic–inorganic switching devices could tune the memory performance parameters such as threshold voltages and the ON/OFF ratio [14]. As compared with the organic memory devices with metallic NPs, relatively few studies have been conducted on the organic memory devices containing semiconducting NPs [15,16]. Memory devices with the hybrid organic–semiconducting NPs composites have been particularly attractive due to their unique advantages of low cost, inert chemical properties, and feasibility of various chemical compositions [15,16]. Li et al. reported data for bistability and operating mechanisms of memory devices fabricated with core/shell-type CdSe/ZnS NPs and chemically self-assembled ZnO NPs [15,16]. However, the detailed memory performances such as cell-to-cell uniformity, distribution of threshold voltages, and endurance cycles, which must be considered

for realistic memory device application, have not been thoroughly investigated.

In this study, we report on the operation and performance of unipolar resistive switching devices involving titanium dioxide nanoparticles (TiO$_2$ NPs) embedded in a poly(9-vinylcarbazole) (PVK) matrix layer in an 8 × 8 cross-bar array structure. The switching mechanism and the charge transport were studied by electrical measurements. The statistical distribution of the ON and OFF states in the 8 × 8 cell array was investigated to quantify cell-to-cell uniformity. Endurance cycle and retention tests were also performed to evaluate the performance of the memory devices.

2. Experimental

Organic memory devices using TiO$_2$ NPs embedded in poly(9-vinylcarbazole) (PVK) in the 8 × 8 cross-bar array structure were fabricated on indium tin oxide (ITO) (sheet resistance of ∼8 Ω/□) on glass substrates. ITO-coated glass substrates were pre-cleaned with a typical ultrasonic cleaning process. ITO electrodes with 8 line patterns of 100 μm line-width were prepared as bottom electrodes (Fig. 1) by conventional photolithography and a subsequent etching process. PVK (molecular weight ∼1,100,000) and TiO$_2$ NPs (anatase 5 nm) were used to make a mixture (PVK:TiO$_2$ = 200:1, 150:1,100:1,10:1, and 1:1 solution volume ratios) of PVK solution (5 mg/ml) and TiO$_2$ NPs solution (2 mg/ml) dissolved in 1,2-dichloroethane. The PVK:TiO$_2$ NPs solution was spin-coated at 4000 rpm for 40 s in a N$_2$-filled glove box and the thickness of the resulting film was measured to be ∼60 nm (for the case of PVK:TiO$_2$ = 150:1 volume ratio). To improve film

uniformity and remove residual solvent from the film, a baking process was performed on a hotplate in the N$_2$-filled glove box at 150 °C for 2 min. Then, Al (100 nm thick) electrodes were deposited using an e-beam evaporator at a pressure of ∼10^{-7} torr. Fig. 1a shows a schematic of the ITO/PVK:TiO$_2$ NPs/Al memory devices in the 8 × 8 cross-bar array structure. An optical image of the fabricated memory devices is displayed in Fig. 1b. Fig. 1c shows a schematic cross-sectional view, illustrating the PVK:TiO$_2$ NPs composite layer sandwiched between ITO and Al. Aggregates of TiO$_2$ NPs, having a diameter of 20–40 nm, were found within PVK matrix and the size of individual TiO$_2$ NP was found as 3 to 7 nm as shown in the inset of Fig. 1d. As the PVK:TiO$_2$ NPs volume ratio changed from 200:1 to 1:1 (i.e., the TiO$_2$ NPs concentration was increased), stronger aggregation of NPs was observed.

3. Results and discussion

3.1. Switching characteristics

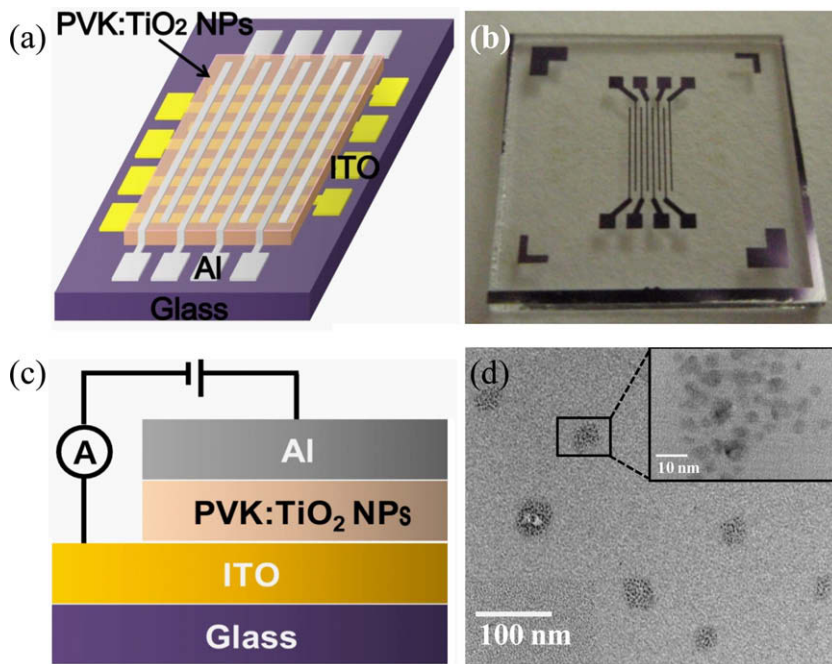
Fig. 2a shows current–voltage (I–V) characteristics of a memory cell in the 8 × 8 cross-bar array devices consisting of the ITO/PVK:TiO$_2$ NPs (volume ratio 150:1)/Al structure. As the voltage was swept to a positive bias, the memory device exhibited an abrupt increase of current by three orders of magnitude near 3.4 V (set voltage), indicating an electrical resistance transition from a high resistance state (OFF state) to a low resistance state (ON state) (1st sweep). When the applied bias was higher than the set voltage, the device still remained in the ON state until 5.7 V (reset voltage). Beyond the reset voltage, a sharp decrease in the current occurred, showing a negative differential resistance


Fig. 1. (a) Schematic and (b) optical image of ITO/PVK:TiO$_2$ NPs/Al memory devices in an 8 × 8 array structure. (c) Schematic of the cross-sectional view of ITO/PVK:TiO$_2$ NPs/Al structure. (d) TEM image of a composite film with PVK:TiO$_2$ NPs volume ratio of 150:1.
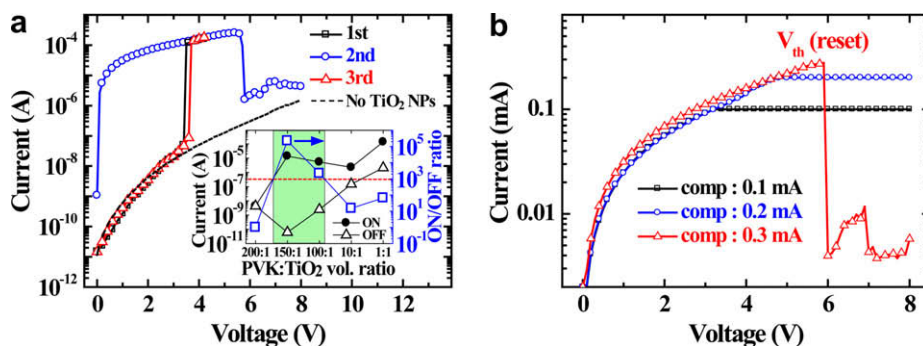

Fig. 2. (a) *I–V* characteristics of a ITO/PVK:TiO_2 NPs (volume ratio of 150:1)/Al memory device (line + symbol curves) and ITO/PVK/Al device without TiO_2 NPs (dashed line). The inset shows ON and OFF currents (left axis) and ON/OFF ratio (right axis) measured at 0.5 V as a function of PVK:TiO_2 NPs volume ratio. (b) Turn-off process as a function of compliance current.

(NDR) behavior (2nd sweep). The NDR phenomenon has been reported elsewhere in other polymer-based memory devices [11,17]. The current beyond the NDR region (>5.7 V) appeared to continue on a trend extending from OFF state. When the *I–V* characteristics were measured again (3rd sweep), the device exhibited an almost equivalent track of the current that was shown during the 1st sweep, indicating a rewritable memory effect. Therefore, the device could be set from OFF to ON (writing) by applying a voltage slightly higher than the set voltage and reset from ON to OFF (erasing) by a voltage beyond the NDR region. In this system, the switching can be achieved by successive application of voltages of the same polarity, which is typical unipolar memory effect. From the *I–V* characteristics described above, two different resistances at the same voltage could be obtained below the set voltage and remained stable even after the power was turned off, indicating the nonvolatile memory effect. However, devices made with just PVK without TiO_2 NPs showed no resistive switching behavior (dashed line in Fig. 2a). These effects clearly demonstrate that TiO_2 NPs play an important role in the electrical bistability phenomenon.

To investigate the role of TiO_2 NPs in the bistable switching, we performed *I–V* measurements on devices with different TiO_2 NPs concentration. The ON and OFF state currents measured at 0.5 V are plotted as a function of PVK:TiO_2 NPs volume ratio, as shown in the inset of Fig. 2a (left axis). It can be seen clearly that the OFF current gradually increased with increasing TiO_2 NPs concentration while the ON current remained nearly constant regardless of TiO_2 NPs concentration. These different concentration-dependent features between ON and OFF currents eventually resulted in the large variation in the ON/OFF ratios, as summarized in the inset of Fig. 2a (right axis). Especially, NPs concentrations in the range from ~150:1 to 100:1 volume ratio was observed to realize organic memory devices with high ON/OFF ratio more than three orders of magnitude. Therefore, the TiO_2 NPs concentration can be a critical factor for determining ON/OFF ratio, one of the key parameters of the memory operation. Contrary to OFF currents, ON currents show relatively little variation regardless of TiO_2 NPs concentration. It reveals that high current states are attributed to the introduction of TiO_2 NPs.

Specifically, the conduction process of ON state is consistent with the filamentary conduction model [18]. The model invokes the formation of filaments in the PVK polymer, exhibiting ohmic conduction without thermal activation. The fracture of the filaments is probably a consequence of Joule heating, raising the temperature of a part of the filament. The Joule heating effect gives rise to atomic reorganization. In our device, the filamentary paths are not only made by defects or structural disorder within the PVK polymer. TiO_2 NPs also become involved in formation of the filamentary paths. Growth of the filamentary paths may occur mainly in the localized region where TiO_2 NPs are distributed. TiO_2 NPs serve as one element source of materials which constitute the high conducting paths. It is reasonable to assume that the filament consists of TiO_2 NPs and some kind of defect within the PVK. Note that others have reported the bistability switching in PVK materials [19]. However the electrode materials, device structures, PVK layer thickness, and charge conduction behavior are different from our devices [20], which may explain different switching properties.

PVK is well known as a hole transporting material [21]. Some reports on polymer memory devices using PVK or PVK composite with NPs suggested that holes can serve as major carriers to cause the memory effect [19,22]. Furthermore, hole injection barrier of PVK is much lower than electron injection barrier because of the relatively high highest occupied molecular orbital (HOMO) energy level of PVK. Thus, holes will be the major charge carriers responsible for the memory effect. PVK mainly functions as matrix where filamentary paths are formed.

Fig. 2b shows the turn-off process as a function of compliance current. Once the ON state was formed, the OFF state could be obtained only when enough compliance current was applied to the devices. The turn-off process of the memory devices could be triggered only by the appropriate compliance current. In Fig. 2b, the device did not turn to the OFF state if the compliance current was set at 1 mA or 2 mA, but it successfully turned to the OFF state when the compliance current was set larger than 3 mA. A similar compliance dependency of the turn-off process has been reported for the case of memory devices with the Al/PVK/Al structure previously [19]. Our device showed considerable noise fluctuations beyond the NDR region. The noise

might have been closely related with rupturing and regrowing of conducting filaments inside the PVK polymer on the filament model [18]. The number of mobile carriers and their mobility would have provoked noise fluctuations. The considerable noise fluctuations generally occurred within the NDR region which displayed a gradual decrease of current [18,23], whereas the noise of our devices appeared after the NDR region (Fig. 2b). Note that some reports suggested that the bistability of the organic nonvolatile memory devices is attributed to the effect of an interfacial oxide layer such as Al_2O_3 [24,25]. In order to minimize the possible effect of the thin native oxide, the Al top electrode was deposited on the composite film with a delay time as small as possible. In addition, to minimize O_2 and H_2O effects, all electrical measurements were performed in a nitrogen filled glove box.

To obtain further information about the switching characteristics of the devices, we examined the correlation between the set current (current at the set voltage) and the reset current (current at the reset voltage). As shown in Fig. 3, we found that the reset current gradually increased as increasing the set current. This correlation between reset and set currents can also be used to understand the mechanism of memory operation associated with the filamentary conduction model [19,26]. It is expected that the higher set current will form stronger filaments. On the other hand, if the stronger filaments are formed, it is hard to break the filamentary current path, and thus the higher reset current should be expected.

3.2. Charge transport mechanism

The charge transport mechanism was studied by temperature-variable I–V measurements in a vacuum pressure of $\sim 10^{-3}$ torr. Fig. 4 is the Arrhenius plot of the ON and OFF state currents in the temperature range from 150 to 300 K. The ON and OFF currents were read at 2 V while the temperature was swept at a speed of 2 K/min. The OFF current can be explained by a thermally activated transport with an activation energy of ~ 66 meV. In contrast, the ON current was almost temperature-independent, exhibiting negligible activation energy of ~ 3 meV. It was found that the log–log plot of the ON current clearly exhibited the form of I–V, indicating ohmic characteristics (Fig. 4 inset). These features of the ON current are mainly attributed to charge

Fig. 4. Arrhenius plot of ON and OFF currents at temperature range from 150 to 300 K for a ITO/PVK:TiO_2 NPs (volume ratio of 150:1)/Al device. The inset shows the log–log plot of I–V characteristics in the voltage range of 0 to 2 V at 300 K.

tunneling through filamentary paths induced by high electric field [18,24,27]. Consequently, bistable resistance switching of PVK:TiO_2 NPs devices accompanies the change of charge conduction mechanism from thermally activated transport (OFF state) into tunneling transport (ON state).

3.3. Memory performance

For practical memory device applications, the cell-to-cell uniformity of memory array devices is critical. Fig. 5 shows the cumulative probability data of ITO/PVK:TiO_2 NPs/Al memory devices, exhibiting a good cell-to-cell uniformity. Our memory devices have a narrow distribution in both the ON and OFF states. Particularly, the OFF state showed less variable resistance due to the insulating property of the PVK polymer. The statistical distribution of both the set and reset threshold voltages was obtained from repetitive sweeping operation of a single cell, as shown in the inset of Fig. 5. Both distributions of the set and reset threshold voltages were fitted with Gaussian functions with 3σ (three standard deviations), shown as black curves in the inset. The set voltages were mainly distributed from 2.5 to 4 V, and the reset voltages ranged widely from 5 to

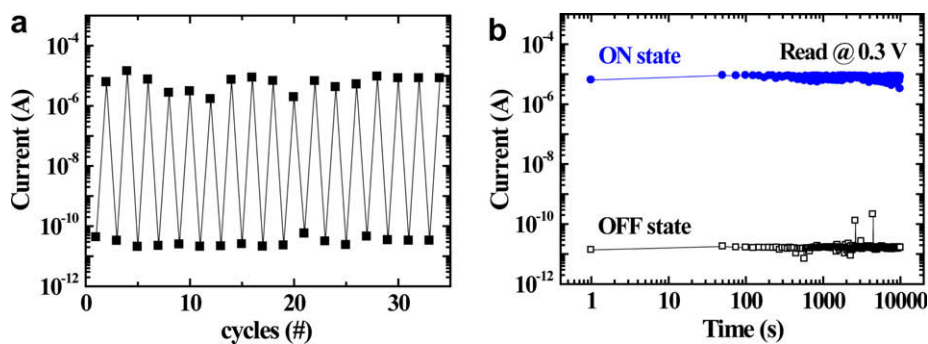
Fig. 3. Reset current (left axis) and set resistance (right axis) as a function of set current for a ITO/PVK:TiO_2 NPs (volume ratio of 150:1)/Al memory device.
Fig. 5. A cumulative probability data set of ITO/PVK:TiO_2 NPs (volume ratio of 150:1)/Al memory devices, exhibiting a good cell-to-cell uniformity. The inset shows the distribution of set and reset threshold voltages from repetitive sweep cycles from a single working cell. Both distributions were fitted with Gaussian functions with 3σ (three standard deviations), shown as black curves in the inset.


Fig. 6. (a) Endurance cycles obtained by repetitive sweeping and (b) retention time characteristics of the two resistance states under 0.3 V constant voltage stress.

7.5 V, showing a difference of ~1 V. Thus, the distribution of each threshold voltage was fairly separated enough to be utilized for potential memory application. The substantial distribution of switching voltages is especially important for determining the operative voltages of resistance-based memory devices which can be definitely distinguished between the OFF and ON state.

The performance evaluation of the memory devices was checked by endurance and retention tests. Fig. 6a shows the sweep endurance of the PVK:TiO$_2$ NPs memory devices. The initial state for the device was OFF, and, after sweeping by 4.3 V, the ON state was achieved. The state of the devices (ON or OFF) could be determined by measuring the current at a read voltage of 0.3 V. Two stable resistance states with a high ON/OFF ratio were achieved, which can provide improved information storage ability by precise control over the ON and OFF states. In addition, the retention test result is shown in Fig. 6b. The PVK:TiO$_2$ NPs memory devices presented reasonably good retention characteristics for 10^4 s without significant current degradation, maintaining an ON/OFF ratio of over 10^5. However, the formed filamentary paths will become gradually weak. It indicates that the device cannot keep the ON state any more after a long time.

4. Conclusions

In summary, we demonstrated unipolar nonvolatile resistive switching devices with an 8×8 array structure based on composites of PVK and TiO$_2$ NPs. The TiO$_2$ NP induced the bistability and its concentration within PVK was a critical factor to control ON/OFF ratio. From electrical characterizations, the switching was mainly governed by the filamentary conduction mechanism and the transport accompanied the change from thermally activated transport (OFF state) into tunneling transport (ON state). The PVK:TiO$_2$ NPs memory devices showed uniform cell-to-cell switching, stable endurance, and good retention, which feature a potential application for nonvolatile memory devices.

ABSTRACT

In spite of huge progress in improving the internal quantum efficiency of organic light-emitting diodes (OLEDs), these devices still suffer from poor light out-coupling. Loss mechanisms are for example waveguiding in the organic layers and the substrate as well as the excitation of surface plasmons at metallic electrodes. Their relative strength and the mutual dependence on the OLED structure have been studied both experimentally and by numerical simulation. Here, we consider the impact of the radiative quantum efficiency of the emitter material on predictions of light extraction from OLEDs. Competing processes resulting in non-radiative recombination of charge carriers usually reduce the emitter quantum efficiency in a real device. We show that optical simulation leads to erroneous conclusions when neglecting these competing processes. Furthermore, we demonstrate a method, which allows determining both the radiative quantum efficiency and the charge recombination factor via simulation based analysis of experimental data. This analysis of device efficiency is applied on a set of red-emitting electrophosphorescent devices.

1. Introduction

Organic solid state lighting technology is on the verge of creating commercial applications in the lighting sector. The possibility of producing a flat large area lighting panel drives the development of creative products and opens exciting fields of application. However, one evident drawback is still the low light out-coupling efficiency of organic light-emitting diodes (OLEDs). The external device efficiency is significantly reduced by various optical loss channels. Considering a conventional coplanar bottom-emitting OLED based on an ITO coated glass substrate a major part of the generated radiant power is lost to thin film waveguided modes (or ITO/organic waveguided modes), surface plasmon polariton modes of the metal cathode and sub-strate waveguided modes. Furthermore a small fraction of the generated radiation is absorbed by the materials of the different layers.

The modification of the substrate surface directed towards the ambient environment is a basic approach to increase external device efficiency. Diffuse layers (i.e. scattering particles in a transparent matrix [1–4]), micro-structured films (e.g. microlens arrays [5]) or roughened substrates [6] are well-known techniques for this purpose. Application of a diffusor or sandblasting the substrate are low cost approaches which could be used in future mass production.

Although, external device efficiency could be increased by such methods, substrate surface modification cannot be utilized, when a reflecting off-state appearance of the bottom-emitting OLED is desired. The optimum configuration of such a device differs from the one of a device with substrate surface modification: Maximum light has to be directed into the light escape cone of the substrate in the

case of a non modified substrate. On the other side maximum radiant power has to be coupled from the thin film stack into the substrate when using substrate surface modification. Here, we neglect aspects regarding the target emission color (e.g. there is a wavelength dependence of the enhancement factor of light out-coupling, which leads to a change in emission color after applying the substrate surface modification [7]).

Recently, we have studied optical loss mechanisms and the light extraction efficiencies of OLEDs by means of a dipole model [8]. We have shown that experimental data on the angular dependent emission spectra of green bottom-emitting OLEDs are in excellent agreement with optical simulations. Furthermore, we have demonstrated the influence of different device parameters, like organic layer thicknesses and the position of the emission layer, on the coupling of the emitting dipoles to different optical channels in an OLED. In this article we consider the impact of the radiative quantum efficiency of the emitter material on predictions of external device efficiency obtained from optical simulation in more detail. The radiative quantum efficiency q of an emitting dye is defined as the quantum efficiency in an unbounded space filled by the dye and its host. Non-radiative recombination of charge carriers, e.g. by bimolecular recombination processes or interaction with charge carriers, reduces the value of q. The intention of this paper is twofold: First we will demonstrate that optical simulations neglecting the impact of these competing processes on q lead to erroneous results not only in terms of the total amount of light extracted from an OLED, but also concerning the optimal device architecture to achieve this. Secondly, we will show that even if the radiative quantum efficiency of an emitter material is not known beforehand, it can be extracted by an analysis of experimental data based on optical simulation.

2. Method

2.1. Experimental

The structure of the red-emitting electrophosphorescent OLEDs used for this study was 113 nm indium tin oxide (ITO)/203 nm hole transporting layer (HTL)/10 nm electron blocking layer (EBL)/7 nm emission layer (EML)/ 10 nm hole blocking layer (HBL)/electron transporting layer (ETL)/200 nm Ag-cathode (see Fig. 1). The thickness of the ETL was varied in the range from 48 to 110 nm. The peak wavelength of the photoluminescence spectrum of the red-emitting phosphorescent dye was 593 nm.

The ETL and HTL were doped by materials improving electron and hole transport, respectively. The diodes were fabricated as follows: The organic stack was deposited on ITO coated glass substrates (refractive index 1.52) using standard evaporation technique from crucibles. The evaporation rate was 1 Å/s at a base pressure of 10^{-7} mbar. Following evaporation of the Ag-cathode, the devices were encapsulated with a glass lid and getter. The ETL and its dopant, the HTL and its dopant, and the matrix of the EML and its red dye were applied by co-evaporation. The active area of the OLEDs was 4 mm². Additionally single layers were deposited on silicon substrates. To ensure
Fig. 1. Structure of the red-emitting electrophosphorescent OLEDs used in this study. The thickness of the ETL has been varied in the range between 48 and 110 nm.

accurate optical simulation, the complex index of refraction of the samples as a function of wavelength was determined by means of standard spectral ellipsometry for all organic layers.

The current density–voltage (j–V) characteristics of the devices used in this study were measured by means of a Keithley 238 as current source and a Keithley 6514 as voltmeter. The experimental j–V characteristics of the devices with thinnest (48 nm) and thickest (110 nm) ETL are plotted in Fig. 2. Both characteristics do not differ significantly, which can be attributed to appropriate n-doping. As will be shown below, the optical properties of the device are strongly affected by the thickness variation of the n-doped ETL, while there is almost no change in the electrical properties of the diode.

In order to collect both directly emitted light and light coupled from the active layers into the substrate, the bottom-emitting OLEDs with planar substrate (4 mm² active area) was coupled to the center of a glass hemisphere (diameter 25 mm, refractive index 1.52) by using a refrac-
Fig. 2. Current density vs. voltage characteristics of devices with ETL thickness of 48 and 110 nm.

tive index matching gel obtained from Cargille Laboratories. The configuration effectively makes the emission angle in glass equal to the emission angle in air. Thus nearly all photons hit the surface of the glass hemisphere at normal incidence. This allows the measurement of the OLED emission within the substrate at angles exceeding the critical angle of total internal reflection between glass and air [9,10]. The emission of the OLED equipped with the glass hemisphere was measured in an integrating sphere, which was connected to a fiber spectrometer (Instrument Systems CAS 140B). The Comission Internationale de l'Éclairage (CIE) color coordinates related to the measured spectra of the different devices are given in Table 1. Additionally, the graph in Fig. 3 shows the external quantum efficiency as a function of current density as obtained from the measurements of the device with 72 nm ETL in the integrating sphere.

2.2. Optical modeling

The optical modeling of OLEDs must consider near-field phenomena and the photonic mode density due to the use of thin organic films. Traditional device simulation is based on the dipole model developed by Chance, Prock and Silbey (CPS) for molecular fluorescence and energy transfer near interfaces [11,12]. This model was extended to the near-field optics of OLEDs by various authors [13–17], where an exciton within the OLED is modeled as a point dipole driven by the reflected electromagnetic waves inside a microcavity.

The simulations presented in this work are also based on this traditional approach of emissive dipoles. The dipoles, embedded in the multilayer stack of an OLED, are treated as forced damped harmonic oscillators [13,14]

$$\frac{d^2 p}{dt^2} + \omega_0^2 p = \frac{e^2}{m} E_r - b_0 \frac{dp}{dt}, \tag{1}$$

where p is the electric dipole moment, ω_0 is the resonant angular frequency in the absence of damping, m is the effective mass, e the electric charge, E_r is the reflected electric field at the dipole position and b_0 is the radiative decay rate in the absence of any interfaces. Both the dipole and the reflected field oscillate with the same complex frequency $\Omega = \omega - ib/2$ as:

$$p = p_0 \exp(-i\Omega t) \quad \text{and} \quad E_r = E_0 \exp(-i\Omega t) \tag{2}$$

where ω and b are the frequency and decay rate in the presence of interfaces. Then the modified decay rate is obtained as:

Table 1
CIE color coordinates related to the emission measured in an integrating sphere. The devices were operated at a current density of 7.5 mA/cm².

ETL thickness (nm)	CIE x	CIE y
48	0.612	0.387
56	0.612	0.386
64	0.613	0.385
72	0.614	0.384
98	0.616	0.383
110	0.617	0.380
Fig. 3. Plot of the measured external quantum efficiency as a function of current density for the device with an ETL thickness of 72 nm.

$$b = b_0 + \frac{e^2}{m\omega p_0} \text{Im}(E_0). \tag{3}$$

This equation shows that the change of the decay rate inside the microcavity is determined by the magnitude of the reflected electric field at the position of the emitting dipole. It is calculated using the Hertz vector and solving the Helmholtz equation by an expansion into plane waves (for details see e.g. Lukosz et al. [18]). Thereby all layers in this multilayer stack are treated as infinite in two dimensions, having a certain thickness in the third direction. The interface between two layers is assumed sharp and without roughness. Using a transfer matrix method the Fresnel coefficients are calculated by taking the optical constants and thicknesses of the different layers of the OLED stack into account, as well as the position of the dipoles within the OLED, which is assumed to be sharp as well. The modified decay rate for arbitrary dipole orientation can then be expressed as a combination of parallel and perpendicular contributions $b_\parallel$ and $b_\perp$, respectively, which are calculated numerically by integrating over all in-plane wave vector values of k_x from 0 to ∞ (for details see Chance et al. or Barnes [12,14]). Thereby the radiative quantum efficiency of the emitter (denoted as q) enters as a material parameter. Finally the orientation of the dipoles (parallel or perpendicular to the substrate, weighted 2:1 for isotropic dipole orientation) yielding

$$b_{iso} = \frac{2}{3} b_\parallel + \frac{1}{3} b_\perp \tag{4}$$

and the emission spectrum of the emitter is taken into account. As a result we obtain a polychromatic power dissipation spectrum, i.e. the contribution of modes with in-plane wave vector component k_x to the spontaneous emission decay rate of the dipoles at each wavelength. (An example of such a power dissipation spectrum for a green fluorescent device calculated by this method can be found in our recent publication [8].)

The power dissipation spectra can be split up into four regions depending on the magnitude of the in-plane wave vector component k_x as compared to the vacuum wavelength λ and the (effective) refractive index n of the medium, where the produced radiation is traveling. Region 1

with $k_x < 2\pi n_{air}/\lambda$ represents the light which can leave the OLED directly ('direct emission'). Region 2, where $2\pi n_{air}/\lambda < k_x < 2\pi n_{glass}/\lambda$ is valid, denotes the amount of light which is emitted to the glass substrate and is trapped there due to total internal reflection ('emission to substrate'). For even larger values of k_x the radiation of the dipoles does no longer reach the glass substrate but is waveguided in the organic layers and the adjacent ITO electrode ('waveguiding', region 3) with $2\pi n_{glass}/\lambda < k_x < 2\pi n_{ITO+org}/\lambda$, where $n_{ITO+org}$ denotes an effective refractive index of the ITO and organic layers taken together. Finally, for $k_x > 2\pi n_{ITO+org}/\lambda$, the emitting dipoles couple to surface plasmon polaritons (SPPs) traveling at the organic–cathode interface ('plasmons', region 4). We note that, in principle, waveguided modes and SPPs (apart from very small distances between the emitting dipoles and the metal electrodes ($\leqslant 25$ nm) not being relevant here) contribute to an enhancement of the spontaneous emission decay rate, although it is usually not possible to extract the energy contained in these modes [8]. Integrating over the different regions in the polychromatic power dissipation spectrum leads to the amount of power coupled into the different modes. Additionally the transmission of the generated light (i.e. 'direct emission' + 'emission to substrate') through the OLED stack is calculated from the optical constants and thickness of each layer with a transfer matrix method. Thus by comparing the internal and the transmitted power of these two modes, the total amount of light absorbed in the OLED stack is determined.

To confirm the outcome of the simulations the power dissipation spectra can be compared to the experimental angular emission spectra of the OLEDs, optionally with the distinction between s- and p-polarization. This has been done in Ref. [8] for a green bottom-emitting device and is thus not shown here.

3. Results and discussion

3.1. Effect of the radiative quantum efficiency

In this section we discuss the impact of the radiative quantum efficiency of the emitter material q on predictions of the external quantum efficiency of organic light-emitting diodes. In general the optical performance of OLEDs depends on several factors. For example, the layer thicknesses mainly have an influence on the waveguided modes, whereas the location of the emission zone (i.e. in terms of the model: *the location of the dipole layer*) determines the fraction of power dissipated by the waveguided modes and the fraction coupled to surface plasmon polaritons (SPPs) [8]. Simulations of the red-emitting OLEDs described above have been performed using the model presented in Section 2.2. Here the emission zone was assumed to be located at the interface between EML and HBL. This can be concluded from the excellent hole transporting properties of the host material used for the EML. Furthermore the free emitter spectrum is needed as input for the simulations. Here, we define the free emitter spectrum as the emission spectrum of the emitter in an unbounded space filled with the material(s) forming the EML. The free emitter spectrum has been extracted from
Fig. 4. Plots of the relative contributions of the different optical loss channels as a function of the ETL thickness. The data was obtained from simulation, where the radiative quantum efficiency was set to $q = 1$.

the electroluminescence spectrum emitted in the direction perpendicular to the substrate by applying optical simulation on the measured data.[1] The computed contributions of the different loss channels as a function of ETL thickness are plotted in the graph of Fig. 4. The radiative quantum efficiency q was set to be one in the calculations, i.e. the presence of processes resulting in non-radiative recombination of electrons and holes was neglected. The variation of the ETL thickness not only influences the waveguided modes (plots (2) and (5) in Fig. 4), but the dipole layer position with respect to the cathode as well. This leads to changes in the contribution of the SPP losses (6). The coupling to SPPs is reduced drastically as the dipole layer moves further away from the cathode. At the same time the fraction of ITO/organic waveguided light (5) increases. Furthermore, the total amount of absorbed light (4) increases with increasing ETL thickness. As all other layer thicknesses have been kept constant, this is mostly due to the absorbing n-dopant of the ETL. The direct emission into air (1) shows a maximum at 75 nm ETL thickness. The amount of light coupled from the active layers into air and substrate (3) has its maximum at 105 nm ETL thickness. This configuration has to be chosen if optimum efficiency based on substrate surface modification is desired. However, we have already shown in another article that the optimal dipole layer position also depends on the radiative quantum efficiency q [8]. We will discuss the role of q in more detail in the following.

The radiative quantum efficiency q of an electroluminescent dye is defined as the quantum efficiency of electroluminescence in an unbounded space filled by the dye and its host. Competing processes resulting in non-radiative recombination of charge carriers reduce the radiative quantum efficiency. Possible competing processes include impurity quenching [19], triplet–polaron annihilation [20] or triplet–triplet annihilation [21]. The importance of the latter two is evident from the current–density

---

[1] To obtain the free emitter spectrum we first simulated the zero degree emission from the OLED using a white spectrum (constant intensity over all wavelengths) and subsequently divided the outcome by the measured EL-spectrum.

dependent roll-off of the external quantum efficiency shown in Fig. 3.

The radiative quantum efficiency is given by:

$$q = k_r/(k_r + \sum k_{nr}) \tag{5}$$

where k_r is the radiative decay rate in an unbounded emitter material and $\sum k_{nr}$ is the sum of the decay rates of all competing processes. In the optical cavity formed by an OLED device the radiative decay rate and the spatial distribution of the emitted radiation can be altered (see Section 2.2), if a fundamental mode of the system is resonant with the free emission spectrum [8,15]. (Please note, that in the terminology used here, waveguided modes and SPPs are not considered as non-radiative, because the exciton is *a priori* generating radiation – even though, it is hard to get that radiation out of the device.) Hence, the fraction of radiative decay in the OLED cavity can differ from the value q in the unbounded emitter space. This effective fraction of radiative decay in the EML of the device is given by:

$$q_{eff} = \frac{k_r^*}{k_r^* + \sum k_{nr}} \to q_{eff}(q) = \frac{q}{q + \frac{k_r}{k_r^*}(1-q)} \tag{6}$$

where k_r^* is the radiative decay rate determined by the boundary conditions of the electromagnetic field in the optical cavity. Such cavity effects on the radiative quantum efficiency are well explored for emitting dipoles in the vicinity of metal surfaces [11,12,22], but only rarely discussed in the context of OLEDs [16,23]. In many cases, device simulations assume q to be just a multiplicative factor, which is first taken to be unity and then scaled to match the measured external quantum efficiency of a device. As we will show below, this approach leads to erroneous results when the position of the emitter in the OLED cavity is varied.

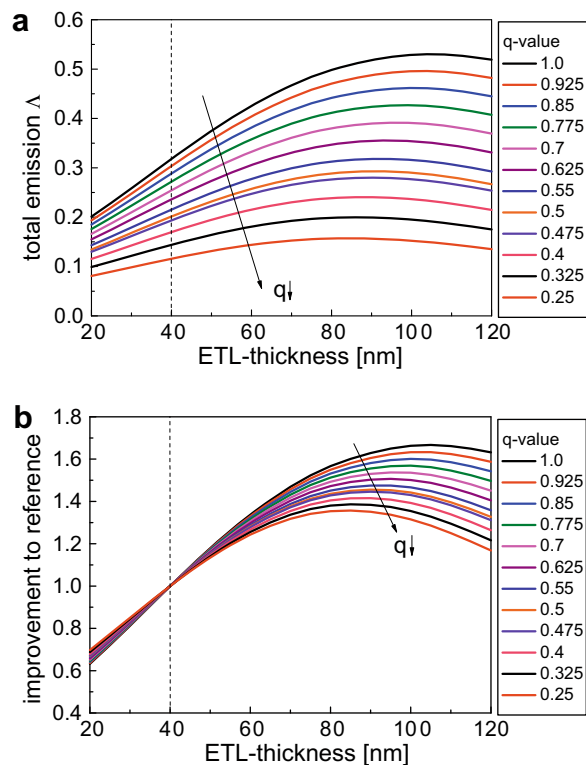
Considering the layer structure of the red-emitting OLEDs described above, q_{eff} as a function of the ETL thickness is plotted for different values of the radiative quantum efficiency q in Fig. 5. The effective radiative quantum efficiency q_{eff} is significantly enhanced for smaller values of the ETL thickness. The enhancement is higher for lower values of the radiative quantum efficiency q. Fig. 6a shows


Fig. 6. (a) Plot of the generated light coupled from the active layers to the outside world (total emission Λ = air + glass). The data was obtained by simulation assuming different values of q. (b) Λ as a function of ETL thickness normalized on the values at 40 nm ETL thickness. The plot gives the efficiency improvement in comparison to the reference device with 40 nm ETL.

the corresponding simulation results for the amount of light Λ coupled from the active layers to the outside world (i.e. the sum of the direct emission and the substrate waveguided light). Λ corresponds to the power fraction of *all* excitons generated in the emission layer which can leave the device. It can be seen, that both the values of Λ and the progression of the maxima depend on q. The ETL thickness, where the maximum of light accessible by substrate surface modification is located in each curve, increases for higher values of q. For a given value of q the location of this maximum is given by the trade-off between effective radiative rate and SPP losses, which are both dependent on the distance between the emission zone and the metal cathode (compare the curves in Fig. 5 to plot (6) in Fig. 4). Additionally the data shown in Fig. 6a has been normalized to the values for an ETL thickness of 40 nm (Fig. 6b), which was taken as reference configuration. Hence, the data of Fig. 6b give the improvement of Λ in comparison to the reference configuration. Again the achievable improvement depends on the radiative quantum efficiency q. Higher improvement can be obtained based on higher values of q, but at the same time the optimum device configuration moves to larger ETL thickness. This, however, implies that neither the optimum ETL thickness nor the achievable efficiency improvement of Λ can be predicted based on optical simulation alone, if the

Fig. 5. Effective fraction of radiative decay in the emission layer as a function of layer thickness for different values of the radiative quantum efficiency q.

radiative quantum efficiency q is not known beforehand, which is usually the case for new or undisclosed emitter systems.

White-emitting OLEDs usually comprise two or more emitting layers. Consequently exact simulation based prediction of emission color (or change in emission color) of such a device is challenging without knowledge of the radiative quantum efficiencies of the individual emitting components, since the resulting white spectrum relies on the effective decay rate of the different emitters. However, optical simulation may be used to obtain the radiative quantum efficiency from experimental data as will be shown in the following section.

3.2. Device analysis based on optical simulation

In this section we apply the above mentioned methodology to determine both the radiative quantum efficiency and the charge recombination factor via simulation based analysis of external quantum efficiencies of a series of devices with different ETL thickness.

The light generated by the red-emitting OLEDs and coupled from the active layers into the substrate has been measured by placing the devices equipped with a glass hemisphere into an integrating sphere. The external quantum efficiency (EQE) of this configuration is derived from the measurements of the light output and applied current:

$$\eta_{EQE} = N_{ph}/N_e \tag{7}$$

where N_{ph} is the number of photons emitted by the device divided by the number of electrons injected, N_e. When the measured *quantum* efficiency is brought in correlation with simulation results, one should keep in mind that the prediction of Λ based on our model is a *power* contribution. However, the color of the emission detected in the integrating sphere is almost not affected by the variation of the ETL thickness of the red-emitting devices (Table 1), i.e. there is only little redistribution of the emission spectrum. Hence, the following equation can be used to fit the measurements of the EQE as a function of ETL thickness d:

$$\eta_{EQE}(d) = \gamma \cdot \eta_{s/t} \cdot q_{eff}(q) \cdot \eta_{out} = \gamma \cdot \eta_{s/t} \cdot \Lambda_q(d), \tag{8}$$

where γ is the efficiency with which electrons and holes combine to form excitons (charge recombination factor), η_{out} is the light extraction efficiency, $\eta_{s/t}$ is the fraction of excitons that is formed in a spin state capable of radiating (for phosphorescent materials such as the red-emitting dye of the considered devices this is unity) and q_{eff} is the effective quantum efficiency depending on q as discussed above. In principle, fitting Eq. (8) to the experimental thickness variation allows to extract both q and γ We note that the charge recombination factor might change with the thicknesses of the layers and applied bias, however, as we only change the thickness of the n-doped ETL, which has almost no influence on the j–V characteristics (see Fig. 2), it seems reasonable to assume the same value of γ for all layer thicknesses.

The measured external quantum efficiency as a function of ETL thickness is plotted in Fig. 7. The devices were

operated at a current density of 7.5 mA/cm^2 when performing the measurements in the integrating sphere. Additionally five plots of the fit-function given in Eq. (8) are shown in the same graph, where only the quantum efficiency q is varied and the charge recombination factor is kept fixed as $\gamma = 1$. As the EQE scales linearly with the charge recombination factor and as γ can not be higher than one we can conclude from Fig. 7 that the quantum efficiency of the emitter must be at least $q = 0.275$ or higher.

As discussed above, q determines the curve progression, i.e. the position of the maximum. Thus assuming a higher value for q can lead to a better correlation with the experimental data, but requires a charge recombination factor smaller than one (see Eq. (8)). This is shown in Fig. 8 for different combinations of q and γ From this figure we conclude that the quantum efficiency q for this red phosphorescent emitter is about (33 ± 5)%. Still higher values of q result in a mismatch of the curve progression, which can not be scaled by the linear factor γ. The best fit result (red solid line in Fig. 8) is obtained for $q = 0.325$ and

Fig. 7. Black squares: measured external quantum efficiency as a function of ETL thickness (device operation at current density of 7.5 mA/cm^2). The error bars represent the standard deviation resulting from the measurements of several devices with the same ETL thickness. Solid lines: corresponding simulations for different quantum efficiencies q with a fixed charge recombination factor $\gamma = 1$.

Fig. 8. Black squares: measured external quantum efficiency as a function of ETL thickness (same data as in Fig. 7). Solid lines: corresponding simulations for different combinations of quantum efficiency q and charge recombination factor γ (see Eq. (8)).
Fig. 9. Black squares: measured external quantum efficiency as a function of ETL thickness (device operation at current density of 150 mA/cm^2). Solid lines: corresponding simulations for different quantum efficiencies q with a fixed charge recombination factor $\gamma = 1$.
Fig. 10. Black squares: measured external quantum efficiency as a function of ETL thickness (same data as in Fig. 9). Solid lines: corresponding simulations for different combinations of quantum efficiency q and charge recombination factor γ (see Eq. (8)).

$\gamma = 0.87$. For an accurate determination of both q and γ for sure, more experimental data points are required. However, our method, combining simulations and experimentally derived EQE, shows that a simultaneous determination of both quantities is possible.

Next, we confirm our method by 'adjusting' a lower value of the radiative quantum efficiency. As can be seen in Fig. 3, device efficiency decreases with increasing current density. This is expected due to the enhancement of triplet–polaron and triplet–triplet annihilation at higher values of current density, i.e. the rate of competing non-radiative processes is enhanced by increasing the operational current density. The graph in Fig. 9 shows the external quantum efficiency as a function of ETL thickness as derived from the measurements of the devices operated at a high current density of 150 mA/cm^2. Again, first the simulation results for $\gamma = 1$ are shown, yielding a lower limit of q of at least 0.20. The adaption to the curve progression is shown in Fig. 10. The best fit of the experimental data in the case of $j = 150$ mA/cm^2 is obtained for $q = 0.25$ and $\gamma = 0.85$. (Again the value of γ should be taken only as an estimate.) Compared to the above case this low-

er radiative quantum efficiency reflects the expected enhancement of non-radiative recombination at higher current density, resulting in a lower EQE (Fig. 3). Our method therefore demonstrates the ability to extract the quantum efficiency of an emitter embedded inside an OLED even for different current densities.

4. Summary and conclusion

In conclusion we have discussed the impact of the radiative quantum efficiency of the emitter material on predictions of the external quantum efficiency of organic light-emitting diodes. We have shown that simulation based prediction of external efficiency (or efficiency improvement) is not possible without knowledge of q. Moreover, not only does the value of EQE depend on this quantity, but also the optimum position of the emission zone for achieving the highest light extraction efficiency. For a given value of q the location of the maximum is given by the trade-off between effective radiative rate and other losses like SPPs or waveguided modes, which are both dependent on the distance between the emission zone and the metal cathode. Furthermore, simulation based prediction of the resulting emission color (or change in emission color) of devices with several emitting layers is challenging without knowledge of the radiative quantum efficiencies of the individual emitting components.

In turn we have demonstrated that both the radiative quantum efficiency of an emitter inside an OLED stack and the charge recombination factor can be determined via simulation based analysis of experimental data. This analysis of device efficiency was successfully applied on a set of red-emitting electrophosphorescent devices.

ABSTRACT

We report operational and environmental stability of solution-processed organic thin film transistors (OTFTs) using the small molecule organic semiconductor 6,13-bis(triisopropyl-silylethynyl) pentacene (TIPS-pentacene). Typical drop-cast TIPS-pentacene OTFTs show strong molecular ordering and relatively stable characteristics with air and illumination compared to vapor-deposited pentacene OTFTs. For short channel length devices, TIPS-pentacene OTFTs undergo significant degradation with bias-stress, possibly due to operation at large drive currents and large local power dissipation as well as built-in charges in the channel area.

1. Introduction

Although a great deal of improvement has been achieved in vapor phase and solution-processed OTFTs [1–5], organic transistors still have the significant shortcoming of performance degradation due to environmental and operational instability of the organic active layer [6,7]. Extensive research efforts have been focused on synthesizing organic semiconductor materials with environmental and operational stability, high mobility, and good current modulation, in addition to improving OTFT performance by device engineering and optimizing processing conditions [8–10]. Because electronic applications of OTFTs may require good stability in threshold voltage and mobility, the factors that limit operational and environmental stability of devices must be understood and controlled along with the factors that limit device performance.

Many studies have investigated the stability of OTFTs fabricated from vapor-deposited polycrystalline pentacene and solution-coated polymers [11–13]. Previous reports have shown that ambient O_2 may degrade pentacene TFT performance by oxidation of the pentacene molecule, while water and other polar molecules can generate traps at grain boundaries, which reduce mobility and current modulation, and cause threshold voltage changes [11,12]. Large operational power density, combined with exposure to an air ambient, has also led to performance degradation of bias-stressed OTFTs [14].

2. Experimental

In this report, both the operational and environmental contributions to stability of solution-processed 6,13-bis(triisopropyl-silylethynyl) pentacene (TIPS-pentacene)
Fig. 1. Cross-sectional image and typical I_D–V_{GS} characteristics of fabricated TIPS-pentacene OTFTs from 1 wt% toluene solution ($L = 35\ \mu m$, $W = 220\ \mu m$).

OTFTs are investigated. The TIPS-pentacene OTFTs in this study were fabricated on thermally oxidized, heavily doped silicon wafers with gold source and drain electrodes. Self assembled monolayers (SAMs) of pentaflorobenzenethiol (PFBT, Aldrich) and hexamethyldisilazane (HMDS, Aldrich) were formed on the Au source/drain electrodes and gate dielectric, respectively, to modify surface energy, film wetting, and contact characteristics [5]. TIPS-pentacene active layers were deposited from 1–2 wt% solutions by drop-casting in a solvent-rich ambient. Best results were obtained using toluene or chlorobenzene, yielding devices with best mobility of more than 1.2 cm^2/V s and strong molecular ordering in the organic thin films [5]. After fabrication, TIPS-pentacene OTFTs were exposed to air with and without illumination, or stored in vacuum for periods of up to four weeks. To simplify comparison, the devices in these studies were fabricated on a substrate which was then divided into several pieces for the different environmental experiments. Fig. 1 shows the cross-section image of the fabricated OTFT and log(I_D) versus V_{GS} characteristics for $V_{DS} = -40$ V. Typically, the turn-on position of the original devices are more positive than usual for these devices. It is not fully understood but we believe somewhat impurity related charges in organic semiconductor and interface charges in gate dielectric may be related to those devices.

3. Results and discussion

As shown in Fig. 2, over time all devices showed threshold voltage shifts towards normally-on devices, along with increases in sub-threshold slope. The addition of illumination increased the magnitude of these shifts. Devices stored under a vacuum without illumination for the same period showed little change in threshold voltage or sub-threshold slope. The normal humidity and illumination used in the experiments was 30–50% RH and 400–600 lux, respectively. In air and dark conditions, the devices typically showed slightly decreased mobility and increased (that is, more depletion mode) threshold voltages and sub-threshold slopes while maintaining almost same saturation current. With exposure to air and illumination the devices showed an increase in drain current and sub-threshold slope, with a larger (more positive) shift of threshold voltage compared to devices operated under air exposure in the dark. Similar to vapor-deposited pentacene, it appears that the combination of oxygen and light leads to degradation of charge transport possibly by introducing traps or defects inside film from oxygen doping effects and inducing oxidation of molecules.

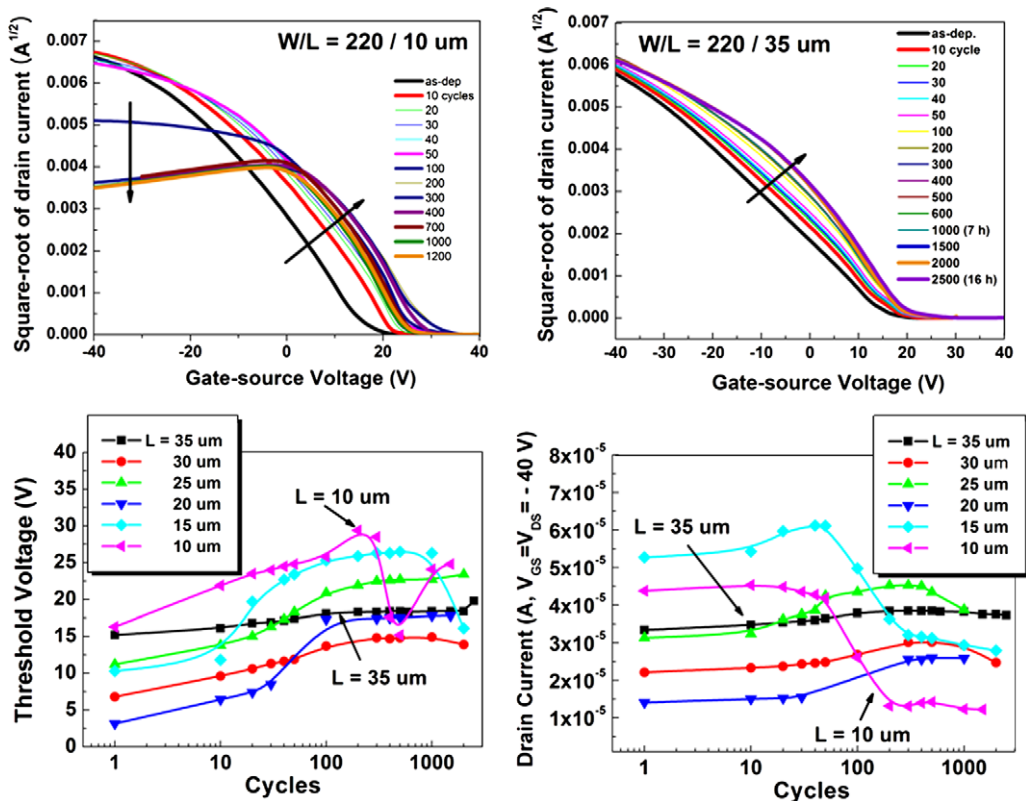
For an operational stability test, a bias-stress was applied to TIPS-pentacene OTFTs and their electrical characteristics were measured. The application of 30 V for V_{GS}
Fig. 2. Typical self life-test results of TIPS-pentacene OTFTs from 1 wt% toluene solution with environmental conditions ($L = 20\ \mu m$, $W = 220\ \mu m$).


Fig. 3. (a) Typical repeated cycling test (L = 10, 35 μm, W = 220 μm) and (b) channel length dependent repeated cycling test results of TIPS-pentacene OTFTs from 1 wt% toluene (W = 220 μm).

and −40 V for V_{DS} for more than 2000 s led to a slight increase and fluctuation in the OTFT off current. For the corresponding on current test, −40 V was applied for both V_{GS} and V_{DS} and the current behavior was measured as a function of time. The on current was quite stable and only small positive shifts in threshold voltage, with little or no change in mobility, sub-threshold slope, or on/off current ratio, was observed. As a second test, the I–V characteristics of devices with air plus illumination exposure were repeatedly measured. For this test, devices were repeatedly stressed by measuring the I_D–V_{GS} characteristics in saturation for up to 2000 cycles (about 14 h) with no delay of reverse bias between scans. For these tests the drain voltage was set to −40 V and the gate voltage was swept from −40 to 40 V. Relatively long channel (>20 μm) OTFTs had changes with operation similar to, but greater than, devices with only environmental exposure. Shifts were observed in the threshold voltage and the sub-threshold slope, but little or no change was observed in mobility and current on/off ratio.

Fig. 3 illustrates the results for the repeated cycling test, including the results from channel length dependent cycling testing. As shown in Fig. 3a, shorter channel length devices had somewhat greater shifts in threshold voltage and also showed a decrease in mobility and a significant current drop with repeated cycling. As expected, the largest changes in threshold voltage and drain current were observed in the shortest channel devices which have the

highest drain currents per unit channel area. When V_{DS} of −1 V was applied during the cycling test, the current and threshold voltage degradation of the shorter channel devices were much more limited but we could still observe slight degradation of the device's performance. The drain current and threshold voltage degradation appears to be partially related to operation at large drive currents and may be related to large local power dissipation at source contact. In addition to the contact-related effects, built-in gate charge which is naturally influenced more in shorter

Fig. 5. Molecular and stacking structure of vapor-deposited pentacene and solution-processed TIPS-pentacene.

channel devices also may be related to the more degradation of current and threshold voltage in those devices. As Kagan et al. [14] pointed out, device scaling using thinner gate dielectric may be helpful to reduce the operational power, resulting in improvement of operational stability.

Fig. 4 compares the environmental stability of solution-processed TIPS-pentacene OTFTs (this study) and literature results for vapor-deposited pentacene OTFTs. Inset of this figure is the optical micrograph of solution deposited TIPS-pentacene OTFTs used in this experiment. Because contact effects tend to dominate over other degradation effects in shorter channel devices, relatively long channel devices (>20 µm) were used for this comparison to minimize the contact effects. Compared to literature results [16,17] for vapor-deposited pentacene OTFTs (channel lengths of 100 and 30 µm, respectively), solution-processed TIPS-pentacene OTFTs typically show improved mobility stability with time for air exposure conditions. Most of results for the environmental stability test of vapor-deposited pentacene without encapsulation layer typically have shown the mobility degradation of more than 30% in air ambient over 4 weeks [11,16–19]. Previous investigations have shown pentacene oxidation at the central aromatic ring may be one of the pathways for degradation of pentacene OTFTs.

As shown in Fig. 5, in TIPS-pentacene, the functional groups at the 6 and 13 positions of the TIPS-pentacene molecule may hinder this oxidation, resulting in relatively stable mobility in air ambient. Another possibility for the increased air stability could be due to the different crystal structure of TIPS-pentacene. Pentacene in vapor-deposited thin films packs in a herringbone stacking with molecular backbone spacing of ~4 Å which is larger than the spacing for 2-dimensional π stacked solution deposited TIPS-pentacene (~3.5 Å) [8]. The larger spacing may allow moisture or oxygen to diffuse into crystal more easily, resulting in poorer stability. These stability results are in marked contrast to the simple thin film stability tests performed by Maliakal and co-workers [15], which showed solution-cast TIPS-pentacene films to be an order of magnitude less stable than vapor-deposited pentacene films. The difference may be explained by the poor molecular ordering in the films studied earlier, which UV–vis studies showed to be amorphous. We demonstrate here that highly crystalline films [5] of solution-cast TIPS-pentacene are in fact somewhat more stable than vapor-deposited pentacene films.

4. Conclusion

In summary, environmental and operational stability tests of solution-processed TIPS-pentacene OTFTs with a variety of exposure ambient and operation conditions were performed. The results demonstrate that solution-processed TIPS-pentacene OTFTs can have more stable device characteristics with both environmental exposure and device operation than is typically observed for vapor-deposited pentacene OTFTs. In addition to recent researches regarding improvement of operational and environmental stability of OTFTs including device scaling [14], passivation layer on organic semiconductors [20], top-gate structures [21], and blending polymer with small molecular organic semiconductors [22], the stability in mobility and current on/off ratio found in this study is encouraging for the use of TIPS-pentacene and similar OTFTs in low-cost and large-area electronic applications.

ARTICLE INFO

ABSTRACT

Highly efficient fluorescent white organic light-emitting diodes (WOLEDs) have been fabricated by using three red, green and blue, separately monochromatic emission layers. The red and blue emissive layers are based on 4-(dicyanomethylene)-2-tert-butyl-6-(1,1,7,7-tetramethyljulolidin-4-yl-vinyl)-4H-pyran (DCJTB) doped N,N'-di(naphthalene-1-yl)-N,N'-diphenyl-benzidine (NPB) and p-bis(p-N,N-diphenyl-amino-styryl) benzene (DSA-ph) doped 2-methyl-9,10-di(2-naphthyl) anthracene (MADN), respectively; and the green emissive layer is based on tris(8-hydroxyquionline)aluminum(Alq_3) doped with 10-(2-ben-zothiazolyl)-2,3,6,7-tetrahydro-1,1,7,7-tetramethyl-1H,5H,1[H-(1)-benzopyropyrano(6,7-8-i,j)quinolizin-1]-one (C545T), which is sandwiched between the red and the blue emissive layers. It can be seen that the devices show stable white emission with Commission International de L'Eclairage coordinates of (0.41, 0.41) and color rendering index (CRI) of 84 in a wide range of bias voltages. The maximum power efficiency, current efficiency and quantum efficiency reach 15.9 lm/W, 20.8 cd/A and 8.4%, respectively. The power efficiency at brightness of 500 cd/m^2 still arrives at 7.9 lm/W, and the half-lifetime under the initial luminance of 500 cd/m^2 is over 3500 h.

1. Introduction

White organic light-emitting diodes (WOLEDs) are of considerable interest in recent years due to their potential applications in full color displays, backlight for liquid crystal displays and solid-state lighting sources [1–3]. For the application in solid-state lighting sources, high efficiency and long operation lifetime are required. Phosphorescent WOLEDs generally are more efficient due to its demonstrated potential for achieving 100% internal emission efficiency by employing the participation of triplet emission [4–10]. However, in comparison with fluorescent WOLEDs, phosphorescent WOLEDs typically have shorter operational lifetime [10]. Also, because of the short operational lifetimes of blue electro-phosphorescent devices, the color

stability of all-phosphor-doped WOLEDs is limited. Therefore, the development of all-fluorescent WOLEDs with high efficiency and long lifetime is very important.

However, the fabrication of high efficiency all-fluorescent WOLEDs is still difficult due to the waste of the triplet excitons formed from the majority of recombination events [11–13]. To fully achieve optimum efficiency and color rendition from different fluorescent emission molecules in WOLEDs, besides developing more efficient electro-fluorescent host and guest materials, some effective new architectural approaches seem to be rather important [14,15]. In this letter, we achieved high performance fluorescent WOLEDs by introducing three red, green and blue fluorescent emission layers, separately [9,16]. The red, green and blue fluorescent dopants, respectively, are doped in three separate hosts, and it is found that the introduction of the thin green emission layer between the red and blue emission layers significantly improves the efficiency and spectral color due to the effective control

of the location of the exciton recombination zone. By optimization, the resulting WOLEDs emit a maximum power efficiency of 15.9 lm/W and show current efficiency of 20.8 cd/A. The color rendering index (CRI) reaches 84. At the initial brightness of 500 cd/m^2, the lifetime is over 3500 h.

2. Experimental procedures

The resulting WOLEDs were fabricated on a cleaned glass substrate precoated with, 180 nm-thick, 10 Ω/sq, indium-tin-oxide (ITO). The optimized device in this study was ITO/copper phthalocyanine (CuPc) (15 nm)/N,N'-di(naphthalene-1-yl)-N,N'-diphenyl-benzidine (NPB)(80 nm)/NPB: 0.5 wt% 4-(dicyanomethylene)-2-tert-butyl-6-(1,1,7,7-tetramethyljulolidin-4-yl-vinyl)-4H-pyran (DCJTB) (20 nm) /tris(8-hydroxyquionline) aluminum (Alq$_3$):0.5 wt% 10-(2-benzothiazolyl)-2,3,6.7-tetrahydro-1,1,7,7-tetramethyl-1H, 5H,1[H-(1)-benzopyropyrano(6,7-8-i,j)quinolizin-1]-one (C545T)(3 nm)/2-methyl-9,10-di(2-naphthyl) anthracene (MADN):0.8 wt% p-bis(p-N,N-diphenyl-amino-styryl) benzene (DSA-ph)(40 nm)/bis(2-methyl-8-quinolinolato-N1,O8)-(1,1′-biphenyl-4-olato) aluminum (BAlq$_3$) (10 nm)/LiF/Al. To demonstrate the role of the thin green emissive layer, the device of ITO/CuPc (15 nm)/NPB (80 nm)/NPB:0.5 wt% DCJTB (20 nm)/MADN:0.8 wt% DSA-ph (40 nm)/BAlq$_3$ (10 nm)/LiF /Al was fabricated and the devices with different green layer thicknesses were also studied for comparison. In the devices, the CuPc, NPB and BAlq$_3$ were used as hole-injecting, hole-transporting, and hole-blocking/electron-transporting layers, respectively. The DCJTB, C545T and DSA-ph were red, green and blue dopants, respectively. The ITO coated glass was used as the anode and the stacked LiF/Al as the cathode. All layers were prepared by thermal evaporation in a high-vacuum system with pressure of less than 3×10^{-4} Pa without breaking the vacuum. The evaporation rates were monitored by a frequency counter, and calibrated using a Dektak 6 M profiler. The current–luminance–voltage characteristics were measured by using a Keithley source measurement unit (Keithley 2400 and Keithley 2000) with a calibrated silicon photodiode. The devices are encapsulated in nitrogen glove box. The device area is 5×5 mm^2. Fig. 1 shows the energy level diagram of the studied devices.

3. Discussion and results

Fig. 2a shows the normalized electro-luminescent spectra of the device with green emissive layer at different driving voltages. Three separate peaks, respectively, at 453, 515 and 590 nm, corresponding to the emissions from DSA-ph, C545T and DCJTB, are clearly observed. The EL spectra show stable and high quality white light emission. There is nearly no color shift with the bias voltages as the Commission Internationale de L'Eclairage (CIE) coordinates are (0.42, 0.41) at 7 V and (0.41, 0.42) at 11 V, and the color rendering indexes (CRI) are 82 and 84, respectively, at 7 V and 11 V. This apparent resistance to the color change under the different voltages well indicates the balanced charge carrier injection and transport for exciton recombination in the three separate emissive regions. Obviously, the designed device structure is greatly effective to obtain stable white emission. Fig. 2b gives a 2-in. WOLED lighting panel, showing better illumination quality. Although the device without green emissive layer also shows white emission, as the EL spectra at different voltages shown in Fig. 2c, the EL spectrum includes two peaks with 460 nm and 570 nm, which are from DSA-ph and DCJTB, respectively, and the CRI is low, only 74.

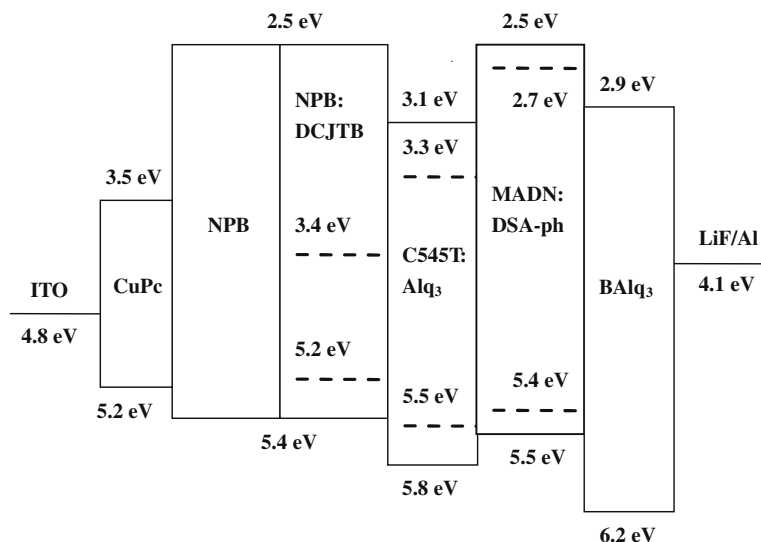
The most importance is that the introduction of the thin green layer also significantly improves the device EL performance. Fig. 3a and b displays the current density–luminance–voltage characteristics of the devices with and without green emissive layer in forward direction. The current efficiency, power efficiency, quantum efficiency and current density characteristics of the devices with and without green emissive layer are plotted in the inset of


Fig. 1. Energy level diagram of the fabricated white OLED.

Fig. 3a and b, respectively. For the case of device with green emissive layer, the turn-on voltage (defined as the voltage at the luminance of 1 cd/m²) is 2.9 V. The maximum luminance reaches 45000 cd/m² at the current density of 270.0 mA/cm² and 16 V. At 9 V bias, the luminance reaches 1000 cd/m², which is a typical value for lighting purposes. The maximum current efficiency, power efficiency and quantum efficiency arrive at 20.8 cd/A, 15.9 lm/W and 8.4%, respectively. At a luminance of 1000 cd/m², the device emits a current efficiency of 19.4 cd/A, showing a

power efficiency of 6.8 lm/W (7.8% quantum efficiency). However, the device without green emissive layer emits

Fig. 3. Current density–luminance–voltage characteristics of the devices with (a) and without (b) green emissive layer in forward direction. The inset gives the current efficiency, power efficiency, quantum efficiency and current density characteristics of the devices with and without green emissive layer (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.).

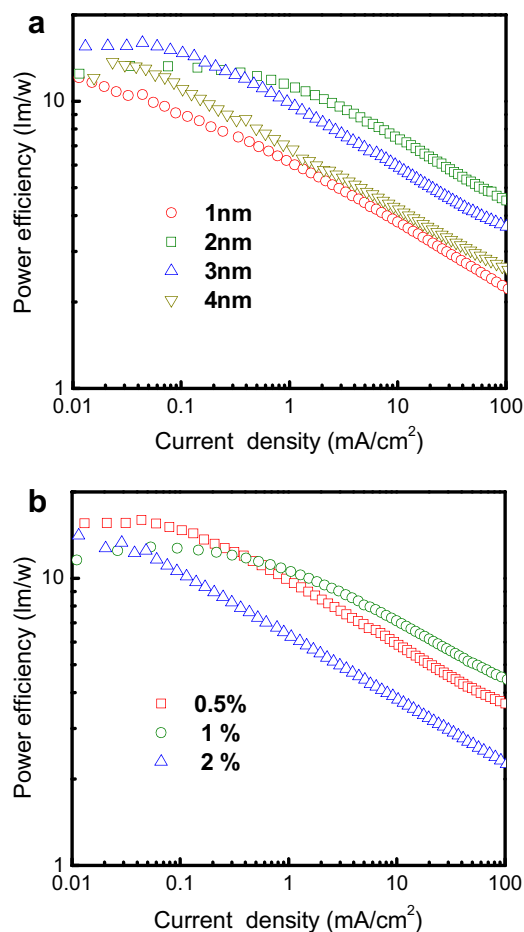
Fig. 4. Lifetime measurement of the resulting WOLEDs. The stability is measured with an initial luminance of 500 cd/m² at a constant current density of 2 mA.


Fig. 5. Power efficiency as a function of current density in devices with different thicknesses of green emissive layer (a) and different concentrations of C545T in green emissive layer (b) (For interpretation of the references in colour in this figure legend, the reader is referred to the web version of this article.).

the luminance of 25,000 cd/m² at the current density of 270.0 mA/cm². The maximum current efficiency, power efficiency and quantum efficiency are 16.9 cd/A, 9.3 lm/W and 4.5%, respectively. At the luminance of 1000 cd/m², the power efficiency reduces to 5.7 lm/W. Obviously, the utilization of the proper green emissive layer enhances the EL efficiency. Especially, the reduction in efficiency at higher luminance is greatly suppressed, as shown in Fig. 3.

Furthermore, the white device with green emissive layer also exhibits good stability. Fig. 4 shows the result of the lifetime measurement of the resulting white device.

The lifetime measurement was made at room temperature after setting the initial luminance of the device at 500 cd/m². The half-lifetime under the initial brightness of 500 cd/m² is over 3500 h. The whole improvement in the performances of the resulting WOLEDs should be related to the utilization of the reasonable device structure.

Actually, the thickness of the C545T doped Alq_3 layer and concentration of C545T in Alq_3 also have larger effect on the device performances. Fig. 5a and b shows the power efficiency as a function of current density in devices with different thicknesses of green emissive layer and different concentrations of C545T in green emissive layer, respectively. It is clearly seen that 2–3 nm thick $C545T:Alq_3$ layer and less than 1% concentration of C545T in Alq_3 lead to the higher EL efficiency. Table 1 summarizes the efficiency and lifetime results in the context of what has been published for all-fluorescent white OLEDs. It can be seen that the unique three-emissive layer structure with proper energy level match not only makes our white OLED high efficiency and luminance, but more importantly, also results in our white OLED showing longer lifetime with respect to other reported white OLEDs based on all-fluorescent organics [9,13,16].

It is clearly found that the introduction of the proper green emissive layer C545T doped Alq_3 between the red emissive layer and the blue emissive layer greatly enhances the EL efficiency and CRI. This could be well explained by the energy level diagram shown in Fig. 1. Obviously, the energy positions of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of Alq_3 determine the tuning role in the transport and recombination of the injected electrons and holes in emissive regions. The injected holes from anode ITO will be transported into DCJTB doped NPB emissive layer across the CuPc hole injection layer and the NPB hole transport layer, and due to the block role of the thin Alq_3 layer, some holes will remain in the DCJTB doped NPB layer and the some will be injected into the DSA-ph doped MADN blue emissive layer across the C545T doped Alq_3 green emissive layer, and finally are blocked in the blue emissive layer by the $BAlq_3$ layer. Relatively, the injected electrons from the LiF/Al cathode will be injected into the C545T doped Alq_3 green emissive layer across the $BAlq_3$ and the DSA-ph doped MADN blue emissive layers, and these electrons will be accumulated in the green emission region because of the blocking role of NPB. If so, the holes in the blue emissive region will recombine with the electrons in the blue DSA-ph molecules as the electrons transport across the blue emissive region, and finally leading to the emission of blue DSA-ph molecules, whereas the electrons blocked in the C545T doped Alq_3

Table 1
Summary of efficiency and lifetime of all-fluorescent white OLEDs published in literatures and this work.

	Power efficiency (lm/W)	Current efficiency (cd/A)	Lifetime (h)	Reference
1	11.4 (100 cd/m²)	20.8 (100 cd/m²)	Over 3500 (500 cd/m²)	This work
2	6.0 (10 mA/cm²)	10.9 (10 mA/cm²)	100 (5000 cd/m²)	[17]
3	9.5 (100 cd/m²)	10.6 (100 cd/m²)		[18]
4	17.1 (100 cd/m²)	17.6 (100 cd/m²)	61 (500 cd/m²)	[13]

green emissive region will be trapped by the C545T molecules and recombine with the trapped holes in the C4545T molecules as the holes are transported across the C545T doped Alq_3 layer, resulting in the green emission. Furthermore, due to the low LUMO of DCJTB and the high LUMO of NPB, some electrons in the C545T doped Alq_3 green emissive region will be directly injected into the DCJTB molecules and recombine with the trapped holes in DCJTB from NPB, finally leading to the red emission of the DCJTB molecules. Clearly, the transport of the electrons and holes in the emissive layers is well tuned by the thin C454T doped Alq_3 layer.

4. Conclusions

We have demonstrated highly efficient fluorescent white organic light-emitting diodes composed of three separate fluorescent emission layers. The introduction of the thin C545T doped Alq_3 layer between the red and blue emission layers well controls the location of the exciton formation regions. The sequence of red, green and blue emission layers and the refined control of the exciton recombination region have been shown to significantly improve the EL performances of the fabricated WOLEDs. The WOLEDs emit a maximum power efficiency of 15.9 lm/W and show a maximum current efficiency of 20.8 cd/A. The color rendering index (CRI) reaches 84. At the initial brightness of 500 cd/m^2, the lifetime is over 3500 h.

ARTICLE INFO

ABSTRACT

Use of a polyfluorene derivative (WPF-oxy-F) as the cathode interfacial layer was investigated for low-cost and high-efficiency organic solar cells (OSCs) based on poly(3-hexylthiophene) (P3HT) and 1-(3-methoxycarbonyl)-propyl-1-phenyl-(6,6)C_{61} (PCBM). Insertion of the WPF-oxy-F interfacial layer between the P3HT/PCBM active layer and the metal cathode increased overall power conversion efficiency from 2.95% to 3.77% primarily due to the improved open circuit voltage and enhanced fill factor, resulting from a reduction of the metal work-function through the introduction of WPF-oxy-F.

1. Introduction

Conjugated polymer-based organic solar cells (OSCs) have received significant attention because they are a cost-efficient and flexible power source. As a result, OSCs have undergone considerable development and the organic syntheses and fabrication methods used in their production have been significantly improved [1–11]. Among the available polymer solar cell systems, poly(3-hexylthiophene) (P3HT) and 1-(3-methoxycarbonyl)-propyl-1-phenyl-(6,6)C_{61} (PCBM) blends have efficiencies of up to 4–5%; however, further improvement in efficiency is required for practical applications [9–11].

Typically, P3HT and PCBM based bulk-heterojunction (BHJ) solar cells have a sandwich-like structure consisting of an indium tin oxide (ITO) anode, a photoactive layer, and an Al metal cathode. Here, to achieve high-performance OSCs, the interface between the electrode and active layer must be an Ohmic contact to minimize the contact resistance and to maximize the open circuit voltage (V_{oc}) [12,13]. A preferred and simple method to enhance the contact between the electrode and the active layer is modification of the electrode by insertion of a buffer layer. For example, the insertion of poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) between the ITO anode and active layer is commonly used in OSCs to enhance hole collection and increase V_{oc} [14]. In the case of cathode modification, it was suggested that a thin LiF layer improves cell efficiency through the formation of an interfacial dipole that reduces the

work-function of Al for better electron collection [15]. However, LiF is not an ideal interfacial layer in polymer-based cells for the following reasons: the LiF layer must be very thin (<1.2 nm) [15], which is difficult to achieve; and, vapor deposition of LiF in a vacuum is not well-suited for use in high-throughput roll-to-roll manufacturing, which is the most significant advantage of polymer-based cells [16].

Recently, the use of metal oxides, such as TiO_x and ZnO, as an efficient buffer layer led to significantly enhanced cell efficiency [17–19], and OSCs with SAM-modified ZnO showed dramatic improvements in efficiency, mostly due to enhancements in V_{oc} and fill factor (FF) resulting from the formation of a favorable interfacial dipole [12,13]. In particular, Zhang et al. demonstrated that a solution-processed poly(ethylene oxide) (PEO) layer can form internal dipoles at the active layer/Al interface, resulting in enhanced the power conversion efficiency (PCE) and V_{oc} [16]. This organic-based interfacial layer that can be created using a simple solution-based process may be desirable for the realization of low-cost and high-efficiency OSCs. However, until very recently, only a few approaches for an organic-based interfacial layer in OSCs have been reported and, to date, insertion of an organic-based cathode interfacial layer into P3HT/PCBM-based OSCs has not been achieved.

The aim of the present study was to realize a low-cost and high-efficiency organic solar cell by insertion of an organic-based cathode interfacial layer into the cell using a simple solution-based process. We investigated the use of a water-soluble polyfluorene derivative (WPF-oxy-F) as the cathode interfacial layer in polymer solar cells, which was synthesized using a palladium-catalyzed Suzuki coupling reaction [20]. Herein, we demonstrate that simply by spin-coating the WPF-oxy-F, the overall power conversion efficiency of solar cells was increased, mainly resulting from the enhanced V_{oc} and FF.

2. Experimental

The structure of the solar cell and the chemical structure of the WPF-oxy-F are presented schematically in Fig. 1. To fabricate the OSCs, glass substrates coated with ITO (Samsung Corning Co., Ltd.) having a sheet resistance of ~10 Ω/sq were cleaned and PEDOT:PSS (Baytron P VPAI 4083) was spin-coated onto ITO followed by drying at 120 °C for 10 min, with a thickness of ~20 nm. A solution of 30 mg of P3HT (Rieke Metals) and 15 mg of PCBM (Nano-C) in 2 ml of chlorobenzene was then spin-coated on top of the PEDOT:PSS layer, forming the active layer with a thickness of ~80 nm. The WPF-oxy-F, dissolved in methanol at a concentration of 1mg/ml, was spin-coated onto the active layer. Finally, aluminum (100 nm) was thermally evaporated on the WPF-oxy-F layer in a vacuum at 10^{-6} Torr. For comparison, solar cells without the WPF-oxy-F layer were also fabricated using experimental procedures identical to those used to make the cells with the WPF-oxy-F layer. Photocurrent–voltage (I–V) measurements were performed using a Keithley 4200 instrument under 100 mW/cm^2 illumination from a 1 KW Oriel solar simulator with an AM 1.5 G filter in a N_2-filled glove box. A calibrated silicon reference solar cell certified by the National Renewable Energy Laboratory (NREL) was used to confirm the measurement conditions.

3. Results and discussion

First, we investigated the effect of the WPF-oxy-F layer and its thickness on the performance of OSCs without thermal annealing of the active layers. A reference cell containing only Al and cells with a WPF-oxy-F layer spin-coated at either 6000, 4000, or 2000 rpm were fabricated. The thicknesses of WPF-oxy-F layers spin-coated at various speeds were as follows: ~3 nm at 6000 rpm, ~4 nm at 4000 rpm, and ~6 nm at 2000 rpm. The photocurrent density–voltage (J–V) characteristics of the cells with a WPF-oxy-F layer are shown in Fig. 2, and detailed information on V_{oc}, short-circuit current density (J_{sc}), FF, and PCE, calculated from the J–V curves in Fig. 2a, is presented in Table 1. As shown in Fig. 2b, V_{oc} values in all cells with a WPF-oxy-F layer were increased by 110 mV. V_{oc} was relatively constant at ~0.68 V, independent of the thickness of the WPF-oxy-F layer, while FF and J_{sc} were slightly reduced as the thickness of the WPF-oxy-F layer increased. Thus, the cell with the WPF-oxy-F layer that was spin-coated at 6000 rpm had the highest efficiency. Furthermore, compared with the efficiency of the reference cell, the efficiency of each cell with a WPF-oxy-F layer was dramatically enhanced.

Fig. 2. Current density–voltage (J–V) curves (a) and J–V curves plotted on a log scale (b) of the organic solar cells with WPF-oxy-F layers of variable thickness and of the reference cell.

Fig. 3. J–V characteristics (a) and J–V curves measured in the dark (b) of organic solar cells with and without WPF-oxy-F. The inset shows the dark J–V curves for the negative-voltage region, plotted on a log–log scale.

These results could be explained by a reduction of the metal work-function through the introduction of the WPF-oxy-F layer, leading to better electron transport and collection [12,16,21]. However, the overall cell performance was relatively poor due to the absence of thermal annealing of the active layer. Although annealing-free systems would be more suitable for the realization of flexible and large-area OSCs [6], at the present time, the annealing procedure seems to be needed for high-efficiency OSCs.

To obtain detailed information about the function of the WPF-oxy-F buffer layer in cells, cells with and without the WPF-oxy-F spin-coated at 6000 rpm were compared under illumination and in the dark, as shown in Fig. 3. In addition, to further improve the relatively low cell performance

shown in Fig. 2, a heat treatment to the as-prepared active layers was applied at 110 °C for 10 min in nitrogen ambient [7,8]. As demonstrated in Fig. 3a, the performance characteristics of the reference cell were as follows: V_{oc}, 0.52 V; J_{sc}, 10.45 mA/cm^2; FF, 54.3%; and, PCE, 2.95%. In contrast, the performance characteristics of the cell with the WPF-oxy-F were: V_{oc}, 0.63 V; J_{sc}, 9.86 mA/cm^2; FF, 60.7%; and, PCE, 3.77%. Compared with cell performance without a heat treatment to the as-prepared active layers, the cell performances with the heat treatment were all enhanced except for V_{oc}. The decrease in V_{oc} after thermal annealing was attributed to enhanced crystallinity of the P3HT polymer film. In fact, it is demonstrated that the enhancement in P3HT crystallinity resulting from heat

WPF2000	0.68 (0.67 ± 0.01)	5.85 (5.7 ± 0.3)	43.7 (42 ± 2)	1.74 (1.6 ± 0.2)

treatment induced an upward shift of the highest occupied molecular orbital (HOMO) level of the P3HT polymer, ultimately leading to a reduction in V_{oc} [22]. However, the difference in V_{oc} between the reference cell and the cell with the WPF-oxy-F was still maintained, irrespective of the heat treatment. Here, the increase in V_{oc} that results from introduction of the WPF-oxy-F interfacial layer can be tightly linked to the reduction of the metal work-function. For better studies, we directly investigated a change of the Al work-function by using a Kelvin probe (KP 6500 Digital Kelvin probe, McAllister Technical Services. Co., Ltd.), which can detect the contact potential difference (V_{CPD}) and the work-function difference ($\Delta\Phi = e \times V_{CPD}$, where e is the electron charge between the probe and the sample. In fact, the V_{CPD} of Al/Glass underneath the WPF-oxy-F was 1.407 V, while the V_{CPD} of Al/Glass showed 1.288 V. It means that the Φ of Al with the WPF-oxy-F layer was reduced by 0.119 eV compared with the Φ of Al, which is consistent with the enhanced V_{oc} of the cell with the WPF-oxy-F layer. Thus, it is believed that the WPF-oxy-F layer effectively induces an interfacial dipole pointing away from the metal surface that reduces the work-function of Al [12,16,23–25].

The reduction of the Al work-function could help electron transport from the active layer to the cathode, resulting in a lower interface resistance and a higher FF [12,16]. In fact, the series resistance (R_s) of the OSC with WPF-oxy-F, calculated from the inverse slope near V_{oc} in the J–V curves shown in Fig. 3b, was decreased to ~29% compared with that of the reference cell. In addition, in the inset of

Fig. 3b, the OSC with the WPF-oxy-F had a smaller leakage current at a negative-voltage. This result indicates that the WPF-oxy-F layer is both an efficient shield for the P3HT/PCBM active layer from the physical damage caused by hot Al atoms and an efficient buffer layer that reduces hole-electron recombination loss at the P3HT/Al interface [18,21]. From these results, it is clear that the enhanced efficiency shown in Fig. 3a, especially improved V_{oc} and FF, originated from a reduction of the metal work-function through the introduction of the WPF-oxy-F layer, leading to better electron transport and collection [12,16].

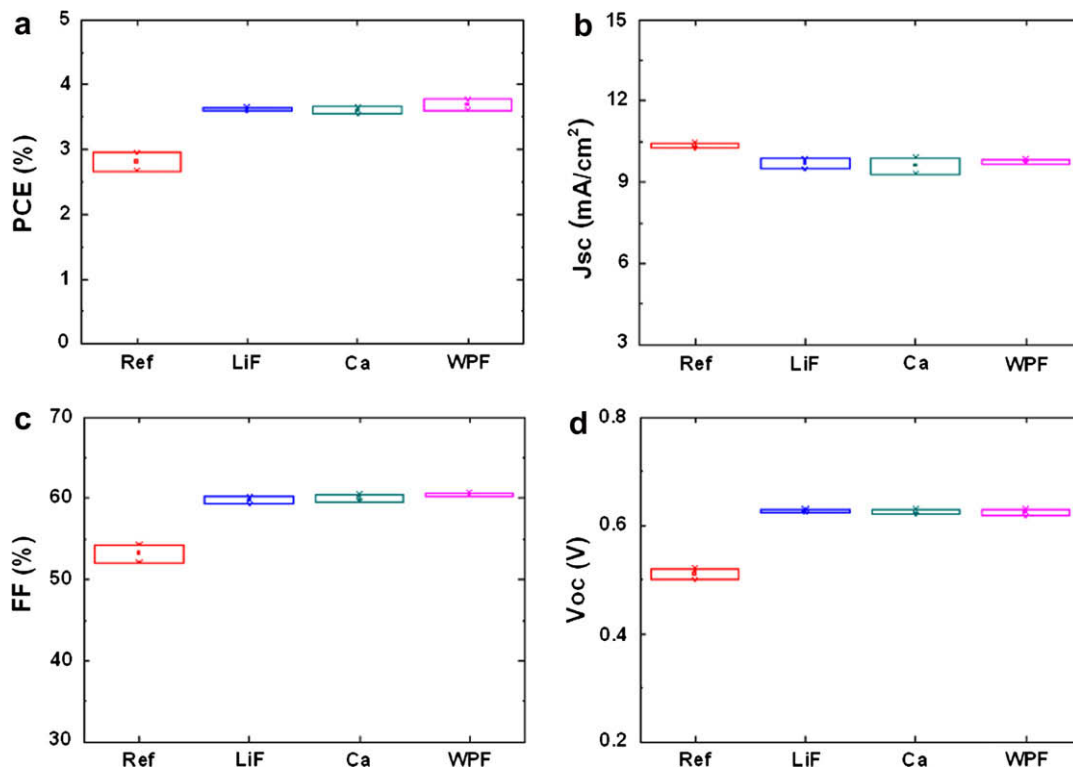
Another objective of the use of an organic-based interfacial layer in the OSCs is to enable the replacement of low-work-function and highly reactive metals such as Ca and Ba as well as the replacement of LiF. Thus, we fabricated several identical OSCs that varied only in their respective cathode. The performances of the OSCs with Al, LiF/Al, Ca/Al, and WPF-oxy-F/Al as cathodes are compared in Fig. 4. Compared with efficiencies of the reference cell with Al, the efficiencies of cells with LiF, Ca, and WPF-oxy-F were all enhanced, and in cells with LiF, Ca, and WPF-oxy-F, most of the increase in the cell efficiency comes from the enhanced FF and V_{oc}, as shown in Fig. 4c and d, respectively. As demonstrated in Fig. 4, the overall photovoltaic characteristics of the cell with the WPF-oxy-F were comparable to those of cells with LiF and Ca, indicating that the WPF-oxy-F has a similar function in the solar cell as LiF and Ca. In addition, the qualitative similarity of the photovoltaic characteristics shown in Fig. 4 indicates the possibility to substitute the LiF or Ca with the WPF-


Fig. 4. Comparison of the performance (a) PCE, (b) J_{sc}, (c) FF, (d) V_{oc} of the solar cells with Al, LiF/Al, Ca/Al, and WPF-oxy-F/Al.

oxy-F. Furthermore, when considering the simplicity of depositing a WPF-oxy-F layer, it is believed that the WPF-oxy-F is better suited than LiF or Ca for fabrication of low-cost and high-efficiency photovoltaic cells.

4. Conclusion

In conclusion, we demonstrated that the polyfluorene derivative (WPF-oxy-F) can be used as an efficient cathode interfacial layer for low-cost and high-efficiency OSCs based on P3HT and PCBM. Introduction of the WPF-oxy-F layer increased cell efficiency from 2.95% to 3.77%, resulting from a reduction in the metal work-function for better electron transport at the active layer/Al interface. Furthermore, the overall photovoltaic characteristics of the cell with the WPF-oxy-F were comparable to those of cells with LiF and Ca, indicating that the WPF-oxy-F shows potential as a practical replacement for LiF or Ca. The organic-based interfacial layer fabricated using a simple solution process will advance the realization of low-cost and high-efficiency OSCs. More detailed studies on the relationship between the performance of OSCs with stable and high work-function metals, such as Ag and Au, and water-soluble polyfluorene derivatives with different internal dipoles are currently underway.

ABSTRACT

Using extraction of photogenerated charge carriers by linearly increasing voltage (photo-CELIV), we investigated two key transport parameters in photovoltaic materials based on the donor APFO-3 and acceptor PCBM: the mobility and lifetime of photogenerated charge carriers, in bilayers of varying geometry and in blends with various acceptors loading. We find that mobility depends strongly on delay time for shorter delay time in all devices. The observed recombination kinetics is found to be monomolecular. The mean lifetime of charge carriers is 2–3 µs in blends and is slightly greater than 4 µs in bilayer devices. In addition, the implications of mobility and lifetime values on the collection efficiency of the devices are presented.

1. Introduction

Organic solar cells have become a center of attention because they are considered to be a potential low cost renewable energy sources [1–3]. There are several challenges to be overcome to realize this potential in practical devices. Among the challenges, increasing power conversion efficiency is paramount. In general the overall efficiency of organic solar cells is influenced by four main processes; absorption (creation of bound electron-hole pairs (excitons)), charge generation (dissociation of exciton to free carriers), recombination and/or collection of carriers to their respective electrodes [1].

Recently conversion efficiency above 6% was reported [4]. This remarkable improvement of polymer solar cells was reached by using conjugated polymer–fullerene heterojunctions (HJ) and improved device architecture in a

tandem cell. A doubling of the efficiency of organic solar cells was also achieved by folding two planar cells, similar or spectrally different, towards each other [5]. In HJ solar cells the photogenerated excitons dissociate at the donor/acceptor interface via an ultrafast electron transfer from the donor (polymer) to the acceptor [6]. In order to dissociate, excitons must be created within the exciton diffusion length from the interface. There are two categories of HJ solar cells, bilayer HJ and bulk HJs. Bulk HJ solar cells have interpenetrating donor/acceptor interface, which provides large interface area for exciton dissociation and hence increase free carrier generation compared to bilayer HJ. On the other hand, numerical simulations show that collection efficiency of charge carriers is higher in bilayers [7], while still the overall efficiency is better in bulk heterojunctions.

In studies using transient optical spectroscopy, the different neutral and charged species formed by photoexcitation of bulk heterojunctions of APFO3 and PCBM have been followed during the ps–µs time interval after excitation. A full kinetic model has been proposed, where geminate

recombination is an important loss mechanism at long times [8]. It is desirable to follow the fate of these charge carriers as we enter the time slot where electrical transport can be directly followed. This is our ambition in the present study. Collection efficiency and loss through recombination of free carriers are controlled by the mobility of free carriers. Therefore, better knowledge of mobility and carrier lifetime will certainly help further improvement of efficiency of polymer solar cells.

In this work we report the mobility and lifetime of photogenerated carriers in donor/acceptor blends with various compositions, and in donor/acceptor bilayer photovoltaic devices and their significance for conversion efficiency. We used the photo-CELIV technique [9], which enables determination of mobility and recombination rate of free carriers simultaneously. The donor polymer used was APFO-3 (poly [2,7-(9,9-dioctyl-fluorene)-alt-5, 5-(4′,7′-di-2 thienyl-2′,1′,3-benzo-thiadiazole)]). The acceptors are PCBM ([6,6]-phenyl-C_{61}-butyric acid methyl ester) in blends and C_{60} in bilayer.

2. Experimental

Devices studied in this work are bilayers and blends with a configuration of ITO/APFO-3/C_{60}/Al and ITO/(APFO-3:PCBM) blend/Al, respectively. Solutions of APFO-3:PCBM blend in chloroform with a PCBM content of 80%, 60%, 40% and 0% (pure APFO-3) with concentrations 75 mg/ml, 40 mg/ml, 25 mg/ml and 15 mg/ml were spin coated on pre cleaned glass substrate coated with ITO. Then aluminum was thermally evaporated on the film in a vacuum chamber at a pressure of 2.6×10^{-6} mbar, to complete the device fabrication. Bilayer devices were made the same way as that of pure polymer devices, except C_{60} was thermally evaporated on top of the polymer in a vacuum chamber at 5.2×10^{-6} mbar prior to aluminum deposition. The thicknesses of the active layers vary from sub 100 nm to 200 nm. The areas of the active layers were 4–5 mm^2.

The technique used in this study was photo-CELIV, which employs excitation of charge carriers by absorbed laser light followed by extraction of carriers by linearly increasing voltage [9]. Generated carriers either undergo recombination or are collected by the built in electric field at the junction between electrode and active material. If the built in electric field is fully compensated, the only means through which the generated carrier concentration decays is recombination. These charges, which are created and forced to stay in the layer by an offset field, can then be extracted by linearly increasing voltage.

The devices were illuminated from the ITO side by a 3–5 ns pulse of a Nd: YAG laser at 530 nm excitation wavelength. After a given delay time the reverse bias, triangular shaped voltage pulse, with a slope of $A = 2 \times 10^5$ V/s was applied by a digital function generator (Stanford Research DS 345) by connecting aluminum to the positive terminal and ITO to negative terminal. An offset voltage of 0.4–0.7 V was used. The delay time between laser light and onset of extraction was varied by a TTi TGP110 10 MHz Pulse generator. The transients were recorded by a digital storage oscilloscope (Tektronix TDS 340A) for different delay times using a 50 Ω load resistance.

From the transients, the mobility and carrier concentration with varied delay time were calculated. The mobility of carriers is related to the time at which the extraction current reaches its maximum by Eq. (1) [9]:

$$\mu = \frac{2d^2}{3At_{max}^2 \left(1 + 0.36 \frac{\Delta j}{j(0)}\right)} \tag{1}$$

where A is the increasing speed of extraction voltage, d is the thickness of the active layer, $j(0)$ the displacement current density between the electrodes, Δj is the maximum conductive current density ($\Delta j = j_{max} - j(0)$), and t_{max} the time at which the transient reaches maximum. The displacement current density is $j(0) = \frac{\varepsilon \varepsilon_0 A}{d}$, where $\varepsilon \varepsilon_0$ is permittivity of the material. The photo generated charge carrier concentration for the different delay times were calculated by integrating the conduction current over the extraction time given by Eq. (2).

$$n = \frac{1}{ed} \int_0^T (j(t) - j(0)) dt \tag{2}$$

3. Results

Fig. 1 shows transient curves obtained from photo-CELIV measurements; (a) bilayer and (b) blend of 1:4 weight ratios APFO-3:PCBM. The extraction current decreases as delay time is increased for all devices. The time at which the maximum of extraction is reached also increased with increasing delay time. The mobility calculated using Eq. (1) for various delay times are displayed in Fig. 2a for bilayer and b for blends of different compositions of APFO-3 and PCBM. Calculated concentration of carriers versus delay time is plotted and shown in Fig. 3a and b. The curves are fitted to exponential decay of the form given by Eq. (3):

$$n(t) = n(0)e^{\frac{-t}{\tau}} + n_1 \tag{3}$$

where n_1 is the concentration of carriers that remain in the layer in the given extraction time, $n(0)$ is the concentration of carrier with delay time close to zero. τ is the mean lifetime of photogenerated carriers. Table 1 shows the average mean lifetime of several devices and, by a rough estimation, the minimum thickness a carrier can traverse with the slowest mobility driven by the weakest built in field, where the field is estimated by the applied voltage.

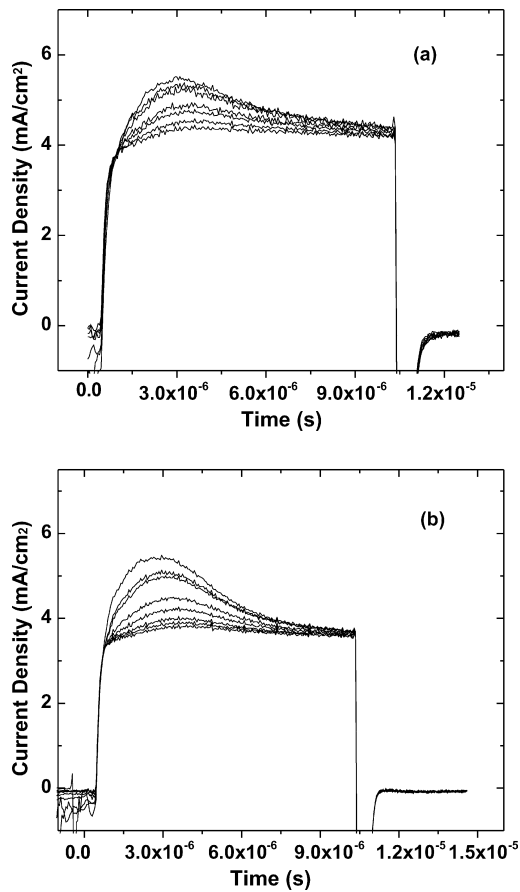
Accurate measurements of both mobility and concentration are affected by offset voltage and thickness measurement. The offset voltage, applied to compensate the built in potential, was not exactly equal to the built in potential. The difference between the offset voltage and built in potential will extract carriers, which will result in significant photo current prior to the application of the triangular pulse. The thicknesses of devices were calculated from displacement current given by taking the approximate value 3 for the dielectric constant of the material. They were also measured mechanically by profilometer (DekTak 3030) and the values of both measurements agree well. However, inevitable error in measuring thickness due to


Fig. 1. Photo-CELIV transients of (a) APFO-3/C$_{60}$ bilayer device (b) APFO-3:PCBM (1:4) ratio blend at different delay times. The extraction current decreases from shorter delay time to longer delay time.

Fig. 2. (a) Photo-CELIV mobility versus delay time of (a) bilayer devices with different thickness of polymer films and (b) for blend devices. The thickness C$_{60}$ in bilayer is 45 nm for all devices.

roughness affects the absolute concentration and mobility values, but does not affect the variation of mobility and concentration as a function of delay time.

4. Discussion

The charge transport mechanism in disordered organic systems depends upon the morphology, order, and molecular structure. In such systems the energy distribution of the HOMO (highest occupied molecular orbital) and the LUMO (lowest unoccupied molecular orbital) levels can be well approximated by a Gaussian distribution [10] as in Eq. (4) where σ is the standard deviation energy levels.

$$g(E) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{E^2}{2\sigma^2}\right) \tag{4}$$

Charge carriers transport in such system is via hopping transport between localized states, in which carriers have to hop from one localized state to another following the Miller-Abraham hopping rate given in Eq. (5),

$$v_{ij} = v_0 \exp(-2\gamma R_{ij}) \begin{cases} \exp\left(-\frac{\varepsilon_j - \varepsilon_i}{kT}\right), & \varepsilon_j > \varepsilon_i \\ 1 & \varepsilon_j < \varepsilon_i \end{cases} \tag{5}$$

where v_{ij} is the hopping rate between sites i and j with energies ε_i and ε_j. The first exponential in Eq. (5) describes the electronic wave function overlap and the second describes a Boltzmann factor for sites upward in energy. Carriers need to absorb thermal energy, which amounts to energy difference of the two sites j and i for an upward jump. The rate for downward movement is only limited by the first exponential term, i.e. only the spatial disorder controls the downward jump.

The decrease in mobility as indicated in Fig. 2a is attributed to the relaxation of carriers toward the tail of the density of states (DOS). Carriers that are excited to higher energy have higher mobility or higher probability to move, compared to those in the lower energy states in the distribution. The disordered nature of the material gives a high density of traps to which carriers continue to relax, until they eventually recombine with opposite carriers.

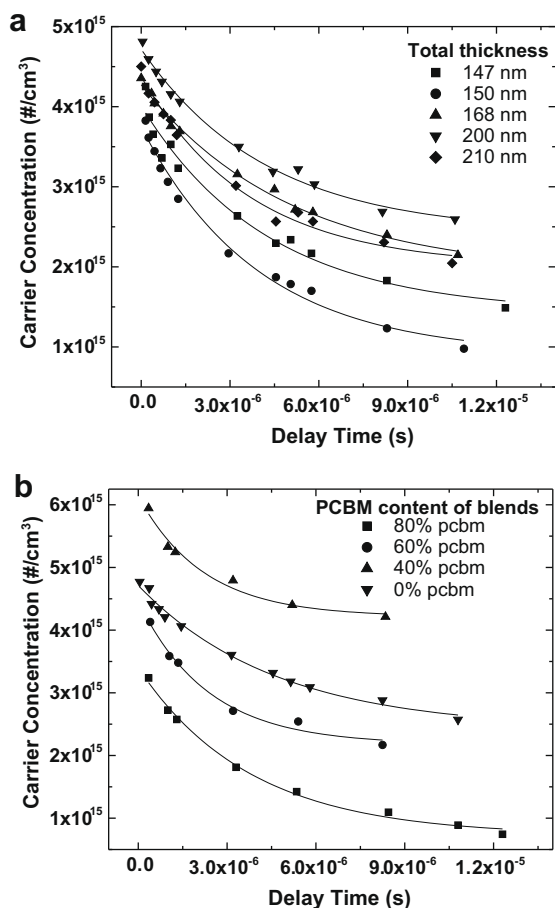
The extraction current is negligible in the dark, implying the density of intrinsic charge carrier density is so small that it cannot be detected with this experiment. All the carriers extracted are photogenerated which means that both carrier types are extracted. In all devices


Fig. 3. Charge carrier concentration plotted versus delay time (a) bilayer devices (b) different composition of APFO-3:PCBM blends. The solid lines in both (a) and (b) are the curve fits using Eq. (2).

Table 1
Mean lifetime of charge carriers and extraction depth by built in field.

Devices	Mean life time (τ) (s)	$\mu \times \tau \times E$ (nm)
Pure	$(2.3 \pm 0.7) \times 10^{-6}$	61
Bilayer	$(4.1 \pm 0.6) \times 10^{-6}$	91
Blend (80% PCBM)	$(2.7 \pm 0.4) \times 10^{-6}$	110
Blend (60% PCBM)	$(2.3 \pm 0.5) \times 10^{-6}$	94
Blend (40% PCBM)	$(2.2 \pm 0.6) \times 10^{-6}$	90

investigated only one peak is observed, which indicates that the mobility of electron and hole are comparable or else very different. From mathematical considerations, there needs to be a factor ≈ 3 in difference between the electron and hole mobility, in order to observe two resolved peaks in geometries and under measurement conditions pertinent to samples resembling well functioning solar cells. In reality the peaks usually are less well defined and so the required difference is probably larger still. Furthermore, the mobility range possible to observe with a CELIV pulse is about three orders of magnitude in the relevant samples, due to RC- and signal amplitude effects,

which means that the actual window for observing both mobilities is rather limited. More often than not, it is thus the case that only one extraction peak is observed. It is not possible to ascertain if it is one or both mobilities, neither which one, that should be associated with the peak.

By examining mobility values obtained through other means, and based on some general assumptions regarding different measurement techniques [11,12], we infer that it should be possible to make an APFO-3:PCBM blend sample of suitable thickness and suitable stoichiometry so as to observe two resolved mobility peaks in CELIV. Since this has proved difficult, another possibility is to use a bilayer to determine which peak it is that is observed. If a suitable excitation wavelength is selected so that almost all carrier generation in a photo-CELIV experiments occurs in the polymer layer, a systematic variation of the layer thicknesses could give the desired information. Unfortunately, the reported electron mobilities [13] in C_{60} are so high that manageable thicknesses have almost no effect on the peak position. Moreover, it can be argued that density of electrons and holes are equal. For equal number of both carriers, the decay of carrier density may follow the Eq. (6), which depends linearly and nonlinearly on concentration n [14]:

$$\frac{dn}{dt} = -(An + Bn^2) \tag{6}$$

where A is the monomolecular recombination coefficient, describing recombination through defects (traps). The recombination rate is directly proportional to the density of carriers. B is the coefficient of describing the direct radiative or non-radiative recombination of an electron in LUMO to holes in HOMO, which is therefore a bimolecular process and hence proportional to the square of the carrier density.

Clearly, both types of recombination can happen at the same time, but depending on the intrinsic properties of the material, one may be the dominant process. For instance, if a material has low trap density and high charge density bimolecular outweighs the monomolecular recombination. On the other hand, if a material has high trap density and low concentration of carriers, monomolecular recombination dominates. In line with the above argument, the results displayed in Fig. 3 show that the recombination type is predominantly monomolecular type, which is the result of the disordered nature of the material i.e., high trap density.

The mean lifetime in bilayer structures is longer compared to pure and blend materials (see Table 1). This is because the photogenerated carriers generated at the interface, stay apart for a longer time in the different materials (polymer and C_{60}) by internal electric field, which is oriented in one direction, whereas in blends the orientation of junctions is quite random and therefore the internal electric field does not induce cumulative barriers to carriers. The result in Table 1 shows the minimum distance that carriers can traverse during their lifetime driven by internal field. It can therefore be concluded that in sub 100 nm thick devices carrier collection is not a limiting factor.

5. Conclusion

Photo-CELIV technique has been used to investigate mobility and lifetime of photo generated charge carriers in blend and bilayer structures of photovoltaic devices. It is found that the mobility decreases very fast for shorter delay time and slower for longer delay time in all blends and bilayer devices. This decrease in mobility is ascribed to the relaxation of carriers to lower energy states in the distribution of energy states. Monomolecular recombination is found to be dominant in all APFO-3 based devices with acceptors used here, which is attributed to intrinsic energetic and spatial disorder of the material. The mean lifetime of photogenerated carriers is longer in bilayer structures as a result of a built in barriers at bilayer interface. Finally, the overall efficiency of sub 100 nm devices is not significantly limited by the collection of charge carriers.

ARTICLE INFO

ABSTRACT

Solution processable organic thin-film transistors (OTFTs) were fabricated using 6,13-bis(triisopropyl-silylethynyl) pentacene (TIPS-pentacene) and low-temperature processable polyimide gate dielectric. The TIPS-pentacene OTFT with the dielectric was found to have a field-effect mobility of 0.15 cm^2/Vs, which is comparable to that of OTFT with an inorganic dielectric. The OTFTs with the polyimide dielectric did not show any significant performance degradation as time passed. A field-effect mobility of the OTFTs in 60 days was found to be almost identical to that of pristine OTFT. The combination of TIPS-pentacene and our polyimide gate dielectric can be one of the potential candidates for the fabrication of stable OTFTs for large-area flexible electronics.

During the past decades organic thin-film transistors (OTFTs) have attracted tremendous attention as a component for flexible display such as organic light emitting devices (OLEDs) [1], e-paper [2] and radiofrequency identification devices [3] due to their good compatibility with commercially available flexible substrates, low-temperature processability and flexible controllability of their electronic properties. Pentacene is one of the most promising and widely investigated organic semiconductors for OTFTs as an active layer. Field-effect mobility of pentacene OTFTs was found to be as high as 1.0 cm^2/Vs at room temperature [4,5], which is already in the level of conventional hydrogenated amorphous silicon based field-effect transistors. But, pentacene thin-film was usu-ally obtained using a vapor deposition method, which is not suitable for the fabrication of large-area flexible device because its solubility in conventional organic solvents is limited and thus solution process can not be employed.

One of the effective approaches to solve such problem is to design soluble semiconductor with same or even better charge transport properties than pentacene. Several soluble semiconductors have been proposed for the fabrication of OTFTs by many research groups [6–14]. Among them 6,13-bis(triisopropyl-silylethynyl) pentacene (TIPS-pentacene) has attracted huge attention for the fabrication of OTFTs since it is highly soluble in organic solvent and face-to-face stacking in crystalline form is optimal for Π-orbital overlap [6]. However, OTFTs with TIPS-pentacene reported so far were fabricated using inorganic gate dielectric such as surface modified silicon dioxide [7–11], which

is not suitable for the fabrication of flexible devices which requires solution processes.

Poly(4-vinylphenol) (PVP) is one of representative polymeric gate dielectrics for OTFTs and their characteristic has been studied extensively by many research groups [15–17]. However, the PVP can be damaged by the organic solvents such as dichlorobenzene and toluene used to dissolve TIPS-pentacene for solution processes. That is, when the TIPS-pentacene thin-film was formed on top of the PVP by drop-, spin- or dip-coating method, there is a possibility for the surface of the PVP to be roughened and/or swollen by the good solvent. In addition, thin-film formation of cross-linked PVP requires high temperature around 200 °C [15–17]. Therefore, it is necessary to use a low-temperature processable polymeric gate dielectric with a high chemical resistance to organic solvent for flexible electronic devices. In addition, it should be thermally stable enough to endure the heat generated during device fabrication and operation. In this letter, we report long-term stable TIPS-pentacene OTFTs with a polyimide gate dielectric, which is a well-known class of material with a high chemical and thermal stability and good electrical properties. For comparison, we have fabricated TIPS-pentacene OTFTs with a cross-linked PVP. In addition, we have investigated a long-term stability of the TIPS-pentacene OTFTs as a function of time.

TIPS-pentacene was prepared based on the procedures reported by Anthony et.al. and purified several times by using re-crystallization and column chromathography [6]. Polyimide gate dielectric (BTDA-DADM), which is not soluble in o-dichlorobenzene that was used as a solvent for TIPS-pentacene, was prepared via two synthetic routes reported elsewhere [18]. As a first step polyimide precursor, poly(amic acid), was prepared though a conventional polycondensation reaction from 1, 2, 3, 4-butanetetra-carbox-ylic dianhyde (BTDA) and 4, 4-diaminodipheyl methane (DADM). Subsequently, the obtained poly(amic acid) was converted directly to its corresponding polyimide by a chemical imidization. Fig. 1 shows the chemical structure of TIPS-pentacene (a) and BTDA-DADM (b). The geometry of OTFTs for all electrical characterizations was a bottom gated top-contact as shown in Fig. 1c. Photo-lithographically patterned indium tin oxide on a glass substrate was used as a gate electrode and was cleaned by the following process; sonication in detergent, deionized water, acetone and isopropanol in that order for 15 min at room temperature. Prior to deposition of gate dielectric, the ITO/glass substrate was further cleaned using UV ozone. The BPDA-DADM in N-methylpyrrolidone (NMP) solution was spin-coated on top of the gate electrodes and then soft-baked at 90 °C for 1 min on a hot plate in air. The film was baked further at 175 °C for 1 h in vacuum (ca. 10^{-2} torr) oven to remove completely the residual solvent. Although the post baking temperature can be lowered down to 125 °C, we employed 175 °C in order to directly compare with cross-linked PVP which was post-baked at 175 °C in this study. The thickness was controlled to about 220 nm. The active layer was prepared by blending a polymeric binder, poly(α-methyl styrene) (0.1 wt%), and TIPS-pentacene (0.1 wt%) in o-dichlorobenzene. Although the active layer can be formed by simple solution processes such as spin-coating and drop- coating, drop coating method was used in this study since it gives better molecular ordering and device performance than the other [7]. The active layer was drop-coated using a long syringe needle at room temperature and then was baked at 90 °C for 1 h in vacuum oven to evaporate the solvent thoroughly. TIPS-pentacene OTFTs were then completed by thermally evaporating 60 nm-thick source and drain gold electrodes on top of the active layer through a shadow mask. The channel
Fig. 1. Chemical structure of (a) 6,13-bis(triisopropyl-silylethynyl) pentacene (TIPS-Pentacene), (b) BTDA-DADM prepared though a conventional polycondensation reaction from 1, 2, 3, 4-butanetetra-carboxylic dianhydride (BTDA) and 4, 4-diaminodipheyl methane (DADM) and (c) geometry of TIPS-pentacene OTFTs with BTDA-DADM gate dielectric.

length (L) and width (W) are 50 µm and 3 mm, respectively. The thickness of the gate dielectric and active layer was determined using a surface profiler (AMBIOS XP-100). Optical microscopy (OM) image was taken with an OLYMPUS BX51. The output (for drain current vs drain voltage, I_{ds} vs V_{ds}) and transfer (for drain current vs gate voltage, I_{ds} vs V_{gs}) characteristics curves of the OTFTs were measured using an HP4145B semiconductor analyzer in air without any encapsulation.

The output curves of the TIPS-pentacene OTFTs with the BTDA-DADM gate dielectric at V_{gs} (from 0 V to −40 V with a step of −10 V) were shown in Fig. 2a. It showed typical p-type characteristics with a clear transition from linear to saturation behavior. At a given V_{gs}, I_{ds} initially increased linearly with small negative V_{ds} and then saturates due to a pinch-off of the accumulation layer located in the interface between TIPS-pentacene and BTDA-DADM. The inset of Fig. 2a shows OM image of channel region of the device and it was found that the active layer was bridged well between source and drain electrodes. Fig. 2b shows its corresponding transfer characteristic curve, where V_{gs} is swept from +20 to −40 V and V_{ds} is set at −30 V. The field-effect mobility (μ) is extracted from the plot of $\sqrt{I_{ds}}$ versus V_{gs} in a saturation regime based on the following equation:

$$I_{ds} = \frac{WC_i}{2L}\mu(V_{gs} - V_{Th})^2$$

where I_{ds} is the drain current, W and L are, respectively, the channel width and length. V_{gs} and V_{Th} are the gate voltage and the threshold voltage, respectively. C_i is the capacitance per unit area of the dielectric layer which was measured by using metal-dielectric-metal device and was found to be 125 pF/mm². V_{Th} of the device in the saturation regime was determined from the plot of the square root of the drain current ($\sqrt{I_{ds}}$) and the gate voltage (V_{gs}) by extrapolating the measured data to $I_{ds} = 0$. The inverse subthreshold swing (ss), which is a measure of how sharply the device transits from the off to the on state, is given by $ss = \left[\frac{d\log(I_{ds})}{dV_{gs}}\right]^{-1}$. The calculated μ and V_{Th} for the OTFT were 0.15 cm²/Vs and −2.7 V, respectively. The value of ss and current modulation ratio (I_{ON}/I_{OFF}) were 0.7 V/dec, 1.46×10^6, respectively. The extracted performance parameters of the TIPS-pentacene OTFTs with the BTDA-DADM gate dielectric were comparable to that of OTFTs with silicon dioxide gate

dielectric [10]. This indicates that BTDA-DADM is good gate dielectric for the fabrication of OTFTs based on soluble semiconductor including TIPS-pentacene.

In addition, we have fabricated TIPS-pentacene OTFT with a cross-linked PVP (inset of Fig. 3a) as a gate dielectric using the same process described above in order to compare the performance of TIPS-pentacene OTFT with the BTDA-DADM gate dielectric. The cross-linked PVP gate dielectric solution was prepared by dissolving PVP (10 wt%) and poly(melamine-co-formaldehyde) methylated (5 wt%) as a cross-linking agent in propylene glycol monomethyl ether acetate (PGMEA), and stirred vigorously for 2 h to give homogenous solution. Prior to its deposition to the substrate, the solution was filtered by a PTFE membrane filter with a pore size of 0.20 µm. The solution was spin-coated and soft-baked at 90 °C for 1 min on a hot plate in air and baked further at 175 °C for 1 h in vacuum (ca. 10^{-2} torr) oven. C_i of the cross-linked PVP dielectric layer was found to be 61 pF/mm². The output and transfer curves of the TIPS-pentacene OTFTs at various gate and drain voltages were shown in Fig. 3a and b, respectively. The calculated μ and V_{Th} for the OTFTs were 1.07×10^{-3} cm²/Vs and −2.4 V, respectively. The value of ss and current modulation ratio (I_{ON}/I_{OFF}) were 1.91 V/dec, 1.23×10^4, respectively. Overall performance of TIPS-pentacene OTFTs with the BTDA-DADM was better than that of OTFTs with the cross-linked PVP. It may be due to the better interface formation between TIPS-pentacene and BTDA-DADM gate dielectric since the insoluble polyimide, BTDA-DADM, is stronger than cross-linked PVP in a o-dichlorobenzene used as a solvent to dissolve TIPS-pentacene.

In order to investigate long-term stability of the TIPS-pentacene OTFTs with the BTDA-DADM, we measured their electrical properties as time passed: right after fabrication, after 2, 4, 10, 30 and 60 days. The OTFTs were stored in a specially designed box which was slightly vacuumed (550 torr) in order to control their exposure condition precisely. The electrical measurement for the OTFTs was carried out in ambient condition at room temperature. Fig. 4a shows transfer characteristic curves of the OTFTs as a function of time. They are almost identical to each other except for small change of I_{OFF} and $|V_{Th}|$ as time passed. Fig. 4b–d shows μ, ss, I_{ON}, I_{OFF}, $|V_{Th}|$ plotted as a function of a time. The performance parameters of the
Fig. 2. Electrical characteristics of the TIPS-Pentacene OTFTs with BTDA-DADM gate dielectric right after fabrication. Output curves (a) were recorded by sweeping V_{ds} from 0 to 40 V with a step of −10 V and transfer curves (b) were recorded by sweeping V_{gs} from 20 to −40 V at a fixed V_{ds} = −30 V (left y-axis, logarithmic scale; right y-axis, square root of I_{ds}). Output curves (a) were recorded by sweeping V_{ds} from 0 to −40 V with a step of −10 V and transfer curves (b) were recorded by sweeping V_{gs} from 20 to −40 V at a fixed V_{ds} = −30 V (left y-axis, logarithmic scale; right y-axis, square root of I_{ds}).
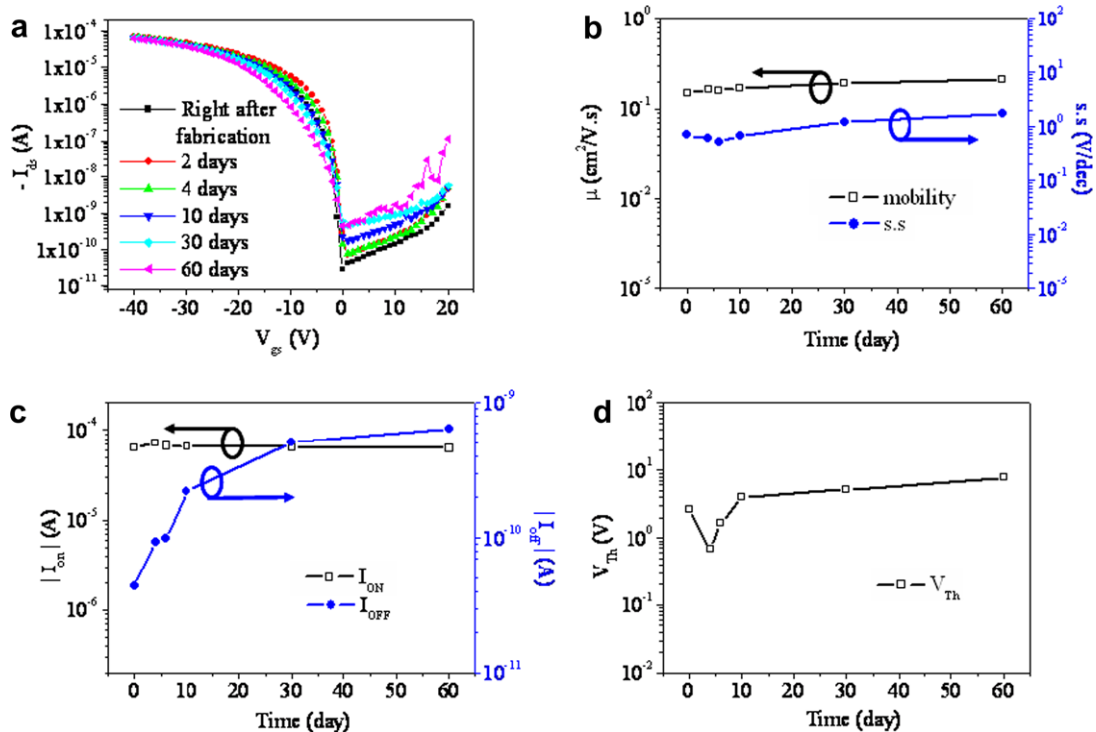

Fig. 4. (a) Transfer curves of the TIPS-Pentacene OTFTs with BTDA-DADM gate dielectric as time passed: right after fabrication, after 2, 4, 10, 30 and 60 days. The transfer curves were recorded by sweeping V_{gs} from 20 to −40 V at a fixed V_{ds} = −30 V. The plot of field-effect mobility (left y-axis) and subthreshold swing (right y-axis) (b), I_{ON} (left y-axis) and I_{OFF} (right y-axis) (c), and threshold voltage (d) as a function of time.

OTFTs are extracted from the transfer characteristic curves with a fixed V_{ds} (V_{ds} = −30 V) in a saturation regime. The μ and ss value of the OTFTs did not show any significant change up to 60 days (Fig. 4b). The μ of the OTFTs right after fabrication was 0.15 cm²/Vs and it increased gradually as time passed and was found to be 0.21 cm²/Vs in 60 days. We believe that the slightly improved μ may be due to crystalline structure formation as time passed by

self-organization at room temperature, which was also observed soluble acene OTFTs [19]. The ss value for the OTFTs was around 0.7 V/dec up to 10 days and it increased to 1.69 V/dec in 60 days. However, any significant change was not observed as time passed. As shown in Fig. 4c and d, the I_{OFF} of the OTFTs was increased from 4.4×10^{-11} (right after fabrication) to 6.4×10^{-10} (after 60 days) although their I_{ON} was not changed at all. $|V_{Th}|$ of OTFTs in-

creases from 2.67 V (right after fabrication) to 7.8 V (after 60 days) as time passed. This indicates that as time passed the interface between TIPS-pentance and the gate dielectric was slightly damaged by moisture and oxygen from device storage environment. This behavior was also observed for pentacene OTFTs which was exposed to moisture and oxygen [20,21]. However, compared to the pentacene OTFTs with silicon dioxide gate dielectric, the performance of our TIPS-pentacene OTFTs with the BTDA-DADM gate dielectric showed much better performance stability.

In conclusion, we report a fabrication of TIPS-pentacene OTFTs using a low-temperature processable polyimide gate dielectric and an investigation on their long-term stability. The calculated μ, $s.s.$, current modulation ratio (I_{ON}/I_{OFF}) and V_{Th} for the pristine OTFTs with BTDA-DADM were 0.15 cm^2/Vs, 0.7 V/dec, 1.46×10^6 and -2.7 V, respectively. The performance is comparable to that of TIPS-Pentacene OTFTs with silicon dioxide gate dielectric and better than that of TIPS-Pentacene OTFTs with cross-linked PVP. In addition, we found that the performance of the TIPS-Pentacene OTFTs with the BTDA-DADM could be maintained for long period of time without any significant performance degradation. This study reveals that the combination of TIPS-pentacene and our polyimide gate dielectric, BTDA-DADM, can be one of the potential candidates for the fabrication of stable OTFTs for large-area flexible electronics.

ABSTRACT

A surface-segregated thin layer of poly(dimethylsiloxane)-*block*-poly(methylmethacrylate) (PDMS-*b*-PMMA) formed by self-organization during spin-coating was utilized as an interfacial buffer layer in organic photovoltaic cells. X-ray photoelectron spectroscopy revealed that PDMS-*b*-PMMA mixed into the coating solution spontaneously accumulated at the surface of the active layer due to the low surface energy of PDMS. The introduction of the PDMS-*b*-PMMA layer in bulk-heterojunction cells of poly(3-hexylthiophene):[6,6]-phenyl C_{61}-butyric acid methyl ester resulted in an improvement of the power conversion efficiency (PCE) of the cells from 3.05% to 3.56% on average. The highest PCE of 3.86% was achieved with 0.4 mg ml^{-1} of PDMS-*b*-PMMA. These results indicate that the PDMS-*b*-PMMA layer formed by self-organization provides a facile and versatile approach to improve the photovoltaic performance, possibly by suppressing charge carrier recombination at the organic/metal interface.

Control of charge carrier transport at heterointerfaces in multilayer structures is one of the most important issues in the improvement of organic photovoltaic cells (OPVs). It has been reported that insertion of buffer layers between the organic layer and the electrodes improves the device performance. To date, inorganic materials such as LiF [1,2], TiO_x [3–5], ZnO [6–8], and the like [9–12], and organic materials such as naphthalene tetracarboxylic anhydride [13], poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) [2,14,15] among others [16] have been employed for this purpose. However, the deposition of the buffer layers requires performance of multi-step processes, these processes being either dry (vacuum evaporation) or wet (repeated coating using an orthogonal solvent), which could detract from the advantage of the ease of fabrication of OPVs. Recently, we proposed a new con-

cept of utilizing self-organized surface-segregated layers [17] for the buffer layers in OPVs. In this method, a small amount of a low surface energy material (i.e., a fluoroalkyl-attached fullerene compound) is mixed into the solution used to form the active layers. During the spin-coating, the low surface energy material becomes segregated at the liquid–air interface driven by the total energy minimization of the system. The photovoltaic device performance was improved by the introduction of the fluoroalkyl fullerene compound, which was attributed to surface dipole formation at the organic/metal interface.

In this work, we report on the use of a conventional low surface energy material for spontaneous buffer layer formation: poly(dimethylsiloxane) (PDMS). Analogous to fluoroalkyl-attached fullerene compounds, poly(dimethylsiloxane)-*block*-poly(methyl methacrylate) (PDMS-*b*-PMMA) can form surface-segregated layers during the solution coating processes due to the low surface energy of the PDMS block, while the PMMA block makes the polymer solid and thus easy to handle. Green et al. reported that in the structure of silicon solar cells known as MINP

devices [18–20], surface passivation by means of an ultra-thin SiO_2 layer disposed under the metal contacts prevents charge recombination at the semiconductor/metal interface and thereby improves the open-circuit voltage (V_{OC}). Furthermore, in organic light emitting diodes, insertion of a SiO_2 buffer layer blocks hole transport [21], resulting in enhancement of brightness and efficiency. Keeping this interfacial passivation with SiO_2 in mind, we can expect a similar effect in OPVs by using very thin layers of PDMS, which can prevent reverse hole flow and consequently improve the efficiency of solar cells. In addition, PDMS would provide wider range of solubility in common solvents compared to the fluorocarbon compounds, which could be advantageous for designing various molecules having the surface segregation property.

The OPV cells used in this study were fabricated as follows. ITO-coated glass substrates (Geomatech, Japan. $10\,\Omega\,\square^{-1}$) were sequentially washed by sonication in detergent, water, acetone, isopropanol and water for 20 min, and were finally exposed to UV-ozone for 5 min. The ITO-coated substrates were then coated with a 50 nm layer of PEDOT:PSS (Battron P, H.C. Starck) by spin-coating, followed by baking at 150 °C for 5 min under a N_2 atmosphere. A bulk-heterojunction layer was spin-cast onto the PEDOT:PSS layer at a coating speed of 500 rpm for 60 s from a chrolobenzene solution containing 10 mg ml^{-1} of poly(3-hexylthiophene) (P3HT, Rieke Metals, USA), 6.5 mg ml^{-1} of [6,6]-phenyl C_{61}-butyric acid methyl ester (PCBM, Frontier Carbon Corp., Japan) and 0.0–1.0 mg ml^{-1} of PDMS-b-PMMA (M_n = 8000 for PDMS and M_n = 4000 for PMMA, M_w/M_n = 1.09, Polymer Source, Canada). Finally, 60 nm of Al was thermally deposited on top of the organic layer under a vacuum of $\sim 10^{-4}$ Pa. After the cathode deposition, the devices were annealed at 150 °C for 30 min under a N_2 atmosphere. The active area of the devices was defined by a photo mask as 0.06 cm^2. The I–V characteristics of the OPV devices were measured under irradiation of simulated solar light (PEC-L11, Peccell Technologies, Inc., Japan). The photovoltaic parameters were obtained by taking the averages of four devices. The light intensity was calibrated with a standard silicon solar cell with a filter (BS520, Bunkou Keiki, Japan) to 100 mW cm^{-2}. X-ray photoelectron spectra (XPS) were measured using a JPS-90SX (Nihon Denshi, Japan). Film thickness was measured by surface profilometry (Dektak 6M, ULVAC, Japan).

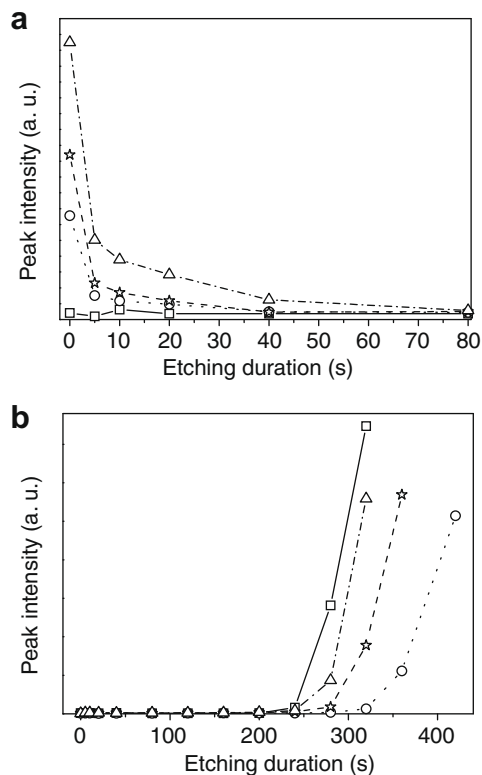
Fig. 1 shows the results of XPS measurements performed on the spin-coated films of P3HT:PCBM with different PDMS-b-PMMA concentrations. The sample surfaces were repeatedly etched away using an Ar$^+$ beam in the sample chamber of an XPS instrument. Fig. 1a and b shows the signal intensities of silicon and indium, respectively, as functions of the etching durations. Before the etching, silicon peaks can be seen for each sample, superimposed on the spectrum of PDMS-b-PMMA (Fig. 1a). For the samples with 0.1 mg ml^{-1} and 0.4 mg ml^{-1} of PDMS-b-PMMA, heights of the silicon peaks are considerably decreased after etching for 5 s. These results indicate that most of the silicon exists in the region extending to less than ca. 1.5 nm from the surface when the concentration of PDMS-b-PMMA is lower than 0.4 mg ml^{-1}, assuming an etching rate of 0.3 nm (see below). When the concentration of PDMS-b-PMMA was in-


Fig. 1. XPS depth profiles of (a) Si 2p$_{3/2}$ and (b) In 3d$_{5/2}$ on the surface of an organic layer spin-cast from a chrolobenzene solution of 10 mg ml^{-1} of P3HT and 6.5 mg ml^{-1} of PCBM mixed with 0.0 mg ml^{-1} (squares), 0.1 mg ml^{-1} (circles), 0.4 mg ml^{-1} (stars) or 1.0 mg ml^{-1} (triangles) of PDMS-b-PMMA.

creased to 1.0 mg ml^{-1}, the silicon peak is reduced to one-third after etching for 5 s and almost disappears after 40 s, indicating that PDMS-b-PMMA covers the surface and also exists in a region extending ca. 12 nm from the surface, assuming the same etching rate (see below). These results of the depth profiling clearly show that PDMS-b-PMMA mixed into the active layer solution was segregated at the air/organic interface spontaneously during the spin-coating because of its low surface energy.

The addition of PDMS-b-PMMA in the solutions also affected the film thickness of active layer, measured by surface profilometry as shown in Fig. 2. The active layer was 70 nm thick without PDMS-b-PMMA, while it became ca. 1.5 times thicker with 0.1 mg ml^{-1} of PDMS-b-PMMA. This thickness difference is obvious in optical density of the active layers. With a higher concentration of PDMS-b-PMMA (0.3–1.0 mg ml^{-1}), the thickness returns to ca. 70 nm. The XPS depth profile of indium peak intensity (Fig. 1b) gives the rate of Ar$^+$ beam etching as ca. 0.3 nm s^{-1} and also supports the thickness change of the organic films when mixed with PDMS-b-PMMA. This tendency of the film thickness change was observed in four different series of the experiments. The reason for this complex change in the film thickness is not clear, but the presence of PDMS-b-PMMA in the solution might cause a change in the factors such as solution viscosity, solvent drying rate or wet-

tability that could work competitively to determine the film thickness.

Fig. 3 shows the performances of OPVs with various concentrations of PDMS-b-PMMA. For the device without PDMS-b-PMMA added to the solution, a short-circuit current (I_{SC}) of 8.31 ± 0.08 mA cm^{-2}, a V_{OC} of 0.57 ± 0.01 V and a fill factor (FF) of $65.1 \pm 1.3\%$ were shown, resulting in a power conversion efficiency (PCE) of $3.05 \pm 0.09\%$. When 0.1 mg ml^{-1} of PDMS-b-PMMA was added to the solution, FF dropped slightly to $62.4 \pm 0.8\%$, while I_{SC} re-
