

The Birch Reduction of Aromatic Compounds

Peter W. Rabideau, Louisiana State University, Baton Rouge, Louisiana

Zbigniew Marcinow, Academy of Agriculture, Wroclaw, Poland

1. Introduction

The reduction of aromatic compounds by alkali metals in liquid ammonia represents an important method for the preparation of partially unsaturated six-membered rings. The reaction was discovered by Wooster and Godfrey, (1) but the major development resulted from the efforts of A. J. Birch, (2, 3) and the reaction has since come to bear his name. Although a variety of metals

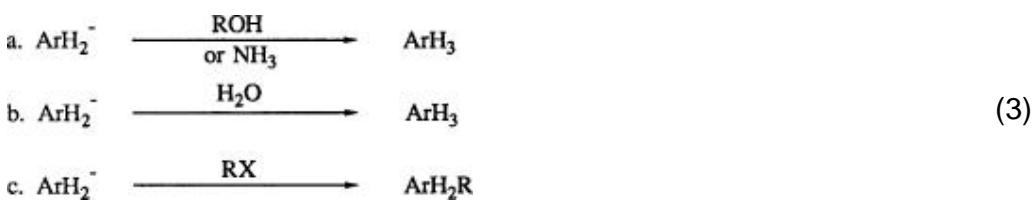

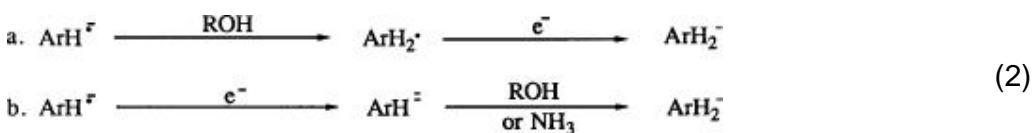

can be used, the most common are sodium and lithium, and, to a lesser extent, potassium. Cosolvents such as ether or tetrahydrofuran (THF) are often used to improve solubility, and weak acids such as alcohols may be employed during the reaction as proton sources. The latter are necessary for the reduction of benzene and its unactivated derivatives. Improvement in experimental procedures by Wilds and Nelson, (4) the application to polynuclear compounds by Hückel (5) and later by Harvey, 3f and the development of methods for the alkylation of the anions generated in this process (i.e., reductive alkylation) have made this reaction an important approach to the synthesis of a wide variety of organic compounds. (6)

2. Mechanism, Regiochemistry, and Stereochemistry

2.1. Mechanism

Alkali metals dissolve in liquid ammonia to produce deep blue solutions that behave as if they contain metal cations and solvated electrons, and provide an excellent reducing medium. (7, 8) As shown in Eq. 1, the aromatic substrate accepts an electron to produce a radical anion in equilibrium with the reactant. In the presence of an alcohol, the radical anion may be protonated to furnish a radical which quickly adds an electron resulting in a monoanion (Eq. 2a). In the absence of an alcohol, the radical anion may simply persist in low concentration, (9, 10) and the addition of a stronger acid, like water or ammonium chloride, generally destroys metal faster than protonation of the radical anions can occur. Under these circumstances, little or no product is obtained since the equilibrium is shifted to the left. With substrates such as activated benzenes and polynuclear compounds, which have relatively high electron affinities, the radical anion can accept a second electron to afford a dianion (Eq. 2b). The dianion is then protonated by alcohol, if present, or more slowly by ammonia in the absence of alcohols, to provide the same monoanion as in Eq. 2a. This scheme suggests that with highly reactive substrates in the presence of an alcohol, both radical anions and dianions may be protonated during the rate-determining step. For example, both the radical

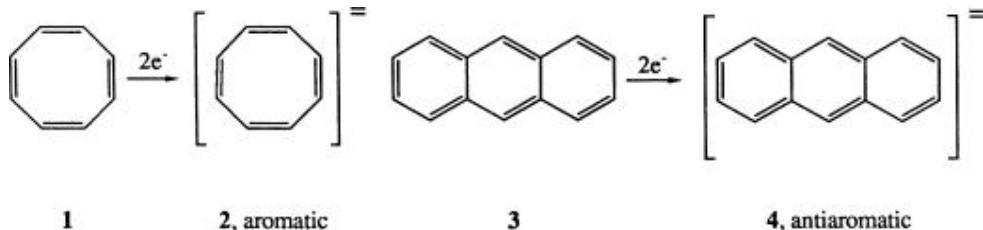

anion and the dianion are protonated in the rate-determining step when anthracene is reduced in the presence of *tert*-butyl alcohol (but not methanol, ethanol, isopropyl alcohol, or water). (8)

Depending on the basicity of the monoanion, it can be protonated by an

alcohol, if present, or by ammonia in the absence of an alcohol. Anions that are singly allylic or benzylic are protonated rapidly by ammonia. Examples include the reduction of styrene, stilbene, and phenanthrene. However, doubly benzylic anions, which are formed from anthracene, for example, appear to be persistent. Borderline basicity is provided by the dihydronaphthalene monoanion, formed as an intermediate in the reduction of naphthalene. The lithium salt is protonated in ammonia, especially at reflux temperature, whereas the sodium salt is considerably more resistant to protonation, especially at -78° . (11)

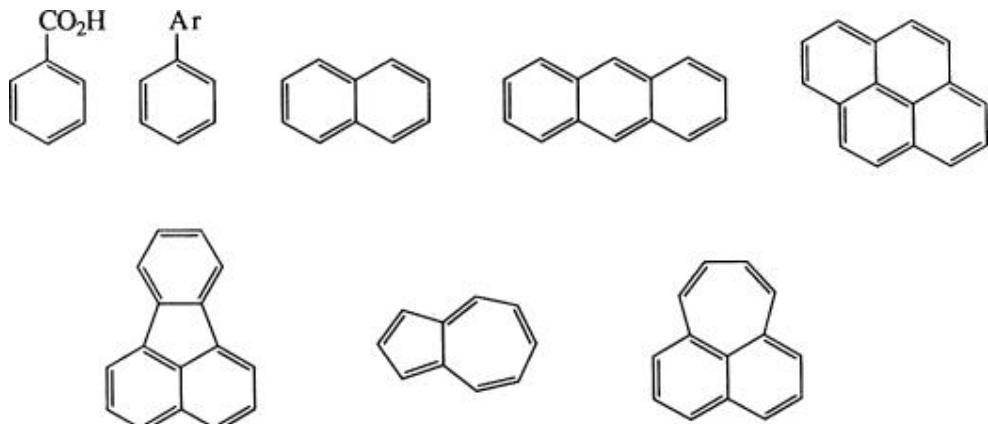

Aromatic compounds may be considered to fall into three classes with respect to their Birch reduction behavior. **Class 1:** Benzene and its unactivated derivatives, including alkylbenzenes, aryl ethers, and aminobenzenes, follow the pathway described by Eq. 2a. Alcohols are necessary for reduction to occur, and alkylation of anionic intermediates is not possible. **Class 2:** Activated benzenes such as benzoates and biphenyls, and many polynuclear aromatics with two, three, and four rings; these systems follow Eq. 2b. Alcohols are not necessary for the reduction of Class 2 systems, and, in fact, should generally be avoided since if present in amounts exceeding one equivalent, they usually cause overreduction. Alkylation of the final monoanions is possible in these cases, and unless an equivalent of an alcohol is added to prevent the amide formation which occurs when the dianion is protonated by ammonia, additional alkylation may take place. This result is due to a second deprotonation/alkylation step occurring after the initial alkylation. Complications may arise when the monoanion is itself protonated by ammonia; phenanthrene is an example. The dihydrophenanthrene monoanion is protonated by ammonia (Eq. 3a) and the resulting neutral compound, which is a biphenyl, is highly reactive under the reduction conditions. Compounds of this type are difficult to reduce without overreduction. **Class 3:** Systems which form dianions resistant to protonation by ammonia. This result is to be expected only for large polynuclear compounds or compounds that involve

Class 1 Systems

Class 2 Systems

Class 3 Systems

special stabilization such as an aromatic dianion. Cyclooctatetraene (**1**) represents a compound in which the original $4n$ π electron system is converted into a $4n + 2$ system **2** by the addition of two electrons. It is interesting to note that while conversion into an aromatic dianion assists reduction, the converse is not true. Anthracene (**3**) is converted into the (formally) antiaromatic dianion **4** by the acceptance of two electrons, yet the dianion is easily formed. (**12**) Solvation and ion triplet formation must play an important role, mitigating the electronic effects. (**13**)

Birch reduction may be accompanied by a number of side reactions. Among the most important are bond cleavage, dimerization, and substituent group reduction. Bond cleavage can result in the loss of a number of substituent groups (**3**) including benzylic oxygens in various forms; allyl, benzyl, and aryl ethers; and halogen and S-benzyl groups. Certain carbon–carbon bonds may also be cleaved during reduction, although this process is much more common in solvents other than ammonia. The mechanism of cleavage involves one of the three pathways shown in Eqs. **4–6**, depending on the nature of both the aromatic moiety and the substituent. (**14**)

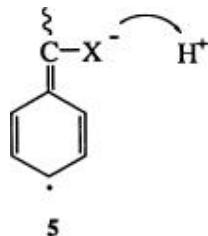

In principle, dimerization of the radical anions can also occur to provide the dianion illustrated in Eq. 7. However, this process is generally not observed under Birch reduction conditions with some exceptions. For example,

dimerization is the primary reaction pathway for pyridine radical anions in liquid ammonia when generated in the absence of alcohols. (15) Dimerization through the carbonyl carbon is also quite common with the reduction of ketones. 3k

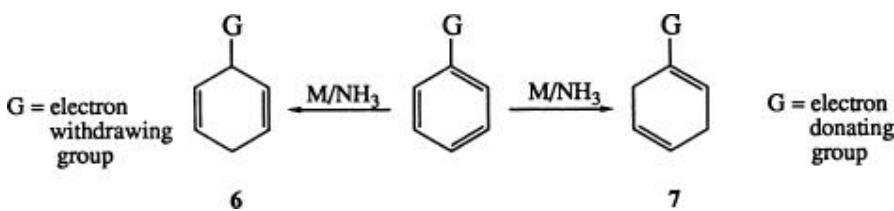

Finally, with certain substituents such as carbonyl groups, protonation of the radical anion or dianion may occur at the substituent group itself (i.e., 5) since this position may represent a site of relatively high negative charge.

This is especially true for otherwise unsubstituted benzenes or benzenes with additional substituents that are electron donors. In these cases, reduction may take place exclusively at the substituent, and the aromatic ring may not be reduced at all.

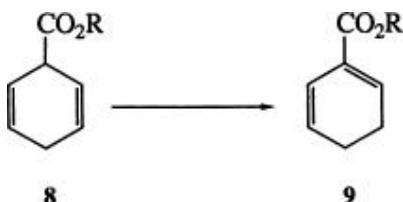

2.2. Regiochemistry

The Birch reduction of benzene derivatives generally gives nonconjugated cyclohexadienes with electron-withdrawing substituents enhancing reaction rates and occupying a saturated position in the product 6; electron-donating substituents decrease rates and occupy a vinyl position in product

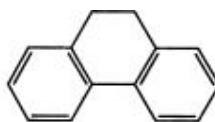

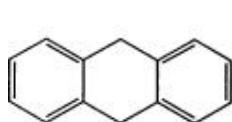

7. (3, 16-20) This behavior follows the “Birch rule:” electron-donating substituents direct reduction so that the major product has the maximum number of such groups attached to the residual double bonds, and a minimum of these groups are located at the allylic sites. [3a](#)

The observation of conjugated products in some reactions is usually the result of isomerization of an initial nonconjugated product. This is most common with carbonyl or other substituent groups that may conjugate with a double bond, as shown for the conversion of **8** into **9**.

Perhaps surprisingly, there is little difference in thermodynamic stability between 1,4-cyclohexadiene and 1,3-cyclohexadiene. With some substitution patterns, the nonconjugated isomer is actually more stable than its conjugated counterpart. [\(21\)](#) Apparently there is little stabilization in the conjugated isomer since the double bonds are not coplanar. [\(22\)](#)

With polynuclear compounds, reduction may occur 1,4 across an aromatic ring (**10** from anthracene), 1,2 across an aromatic ring (**11** from phenanthrene), or across more than one ring (**12** from pyrene). Initial protonation is considered to take place at the position of highest electron density in the

dianion. There is reasonable correlation between experimental results and predictions based on SCF MO theory [\(23-28\)](#) and electrostatic potential maps,

(17) although a number of exceptions exist. However, questions concerning protonation sites in dianions arise, (29) and the correct assignment is often provided by assuming that protonation of the dianion will take place to produce the most stable monoanion; *this appears to give a good prediction of regiochemistry whether or not the reaction is actually driven by monoanion stability.*

The effect of substituents on the regiochemistry of the reduction of polynuclear aromatic compounds is sometimes complex. In the simplest example, naphthalenes, electron donors in one ring often lead to reduction in the other ring, but this is not always true (see below). Similarly, electron-withdrawing substituents, especially at the β position, may not always lead to exclusive reduction in the substituted ring. Compounds for which the dianionic intermediates have substantial localization of negative charge at a specific site, for example the 9 and 10 positions in anthracene dianion, often are reduced with the same regiochemistry regardless of substitution pattern.

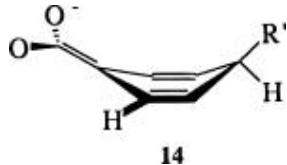

2.3. Stereochemistry

The stereochemistry of the reduction of nonrigid systems is determined by the stereochemistry of protonation of the final monoanion (Eq. 3). This is controlled by a number of factors, including the nature of R and R', and the hybridization at the anionic center. The simplest model is provided by the cyclohexadienyl anion **13**. When R' is hydrogen, protonation occurs equally

13

well from either side of the anion. Reduction of benzene-*d*₆ provides equal amounts of *cis* and *trans* (diprotio) products. (30) When R and R' are trimethylsilyl, a significant steric effect develops for protonation on the R' side, and consequently the *cis* isomer predominates by 4:1 with either metal/ammonia reduction (31) or electrochemical reduction in methylamine. (32) Predominance of the *cis* isomer is slightly less (3:1) for the electrochemical reduction of 4-trimethylsilyltoluene, as might be expected by the decrease in size of R' from trimethylsilyl to methyl. In the reduction of 4-isopropylbenzoic acid, however, the *trans* product is favored by 2:1, and with 4-*tert*-butylbenzoic acid, the *trans* isomer is formed exclusively. Clearly model **13** fails for these reactions. When R is a π substituent, the model **14**, which takes the overlap of the π

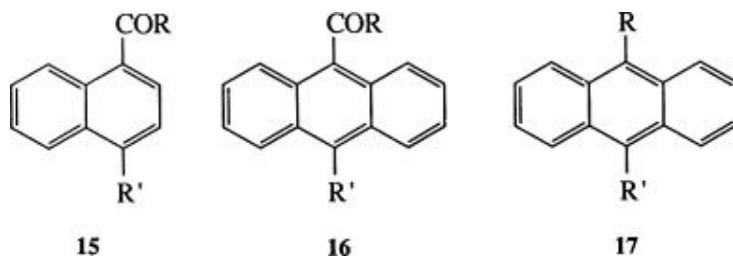

14

substituent with the anionic center into account, becomes useful. In fact, this overlap demands a nonplanar structure because of the interference of the oxygens with the nearby vinyl hydrogens. These atoms cannot all be in the same plane, and the ring folds slightly with R' occupying the pseudoaxial position. (22) This causes the vinyl hydrogens to block the bottom lobe of the anion orbital. Hence protonation is preferable from the topside; this is the case even if protonation occurs through the enol or is metal-directed.

When the 1,4-cyclohexadiene ring generated during reduction is part of a larger polynuclear system, the ability of the six-membered ring and its anion to adopt variable folding angles leads to even more complex stereochemistry. These folding angles, defined by the angle between the two planes containing the vinyl carbons, may vary from 180° (planar) to 145° (highly puckered) in the neutral compounds, (22) with a correspondingly greater tendency toward planarity in the monoanion. 3h However, enolates in polynuclear systems should be considerably more folded than **14**, since the replacement of the vinyl double bond with an aromatic ring provides an even greater steric interaction due to the *peri* hydrogens.

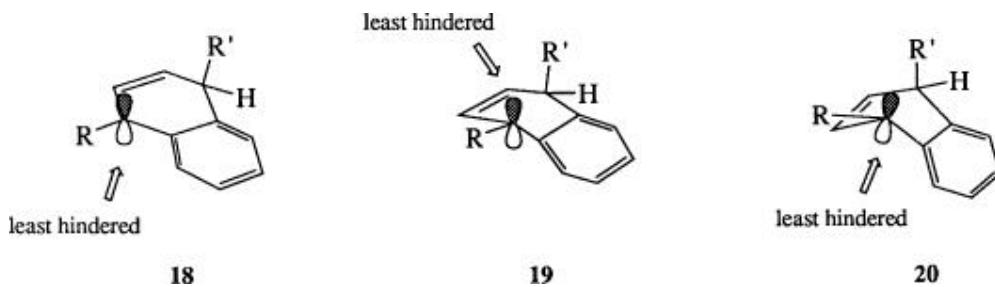

The reduction of esters **15** where R is O-*tert*-butyl and R' is either methyl or ethyl gives a slight excess of *trans* products (60:40). (33) However, when R is methyl, the methyl ketones show a predominance of the *cis* product that increases in the series Me < Et < *i*-Pr for values of R', with relative yields of 60, 70, and 75% respectively. (33) Neither the ester nor the ketone products isomerize under the conditions used for the workup of the reaction. The

change from *trans* to *cis* products may result from greater enolate character in the intermediate monoanion derived from the ketones, producing a greater degree of ring folding. Even more ring folding is expected for the anions derived from **16** (34) because of increased *peri* interactions, and reduction produces exclusively *cis* products with either ketones or esters. (33) Interestingly, 9,10-dialkylanthracenes **17** afford greater amounts of *trans*

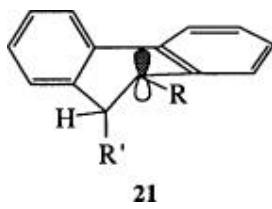

products when R and R' are primary, with a changeover to *cis* as the alkyl groups become larger. (35) Apparently the monoanion derived from **17** when R and R' are sterically small is relatively flat, in contrast to that from **16**, as suggested by both experiment (36) and theory. (37)

The pattern that emerges can be rationalized, although the prediction of product ratios remains difficult. Planar anions such as **18** are expected to show little stereoselectivity, with *cis* products favored, because of a small steric effect from R'. Systems with modest folding such as **19** will be protonated

preferentially in the pseudoaxial position to give *trans* products. With more highly folded structures like **20**, the bottom lobe of the anion orbital angles out to become more accessible, and at the same time R' is forced closer to the anionic center. Both of these effects promote protonation from the bottom to produce *cis* products. Hence even though the reasons for the observed stereochemical behavior may be understood, it remains difficult to predict product outcome when the geometry of the monoanion is not known.

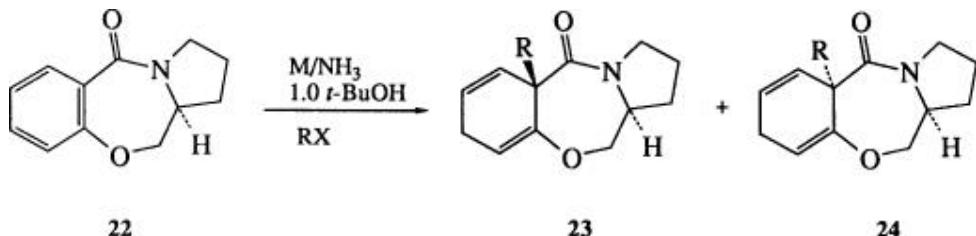

In systems for which reduction occurs in a 1,2 fashion, stereochemistry is more easily predicted since the geometry of 1,3-cyclohexadienes is better defined. (22) For example, substituents prefer the pseudoaxial position in 9,10-dihydrophenanthrenes, and the likely conformation of the monoanion can be

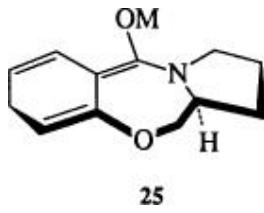

described as **21**. Of course, there may be some pyramidalization at the anionic center, depending on the nature of R, but the anion will prefer to be pseudoaxial to maximize overlap with the adjacent aromatic ring. In either case, protonation will occur from the top resulting in *cis* products, as observed. (38)

The stereochemistry of reductive alkylation, where alkyl halides are added prior to the final quench, follows generally the same pattern as reduction. However, the larger size of the alkylating agents leads to more sensitivity to

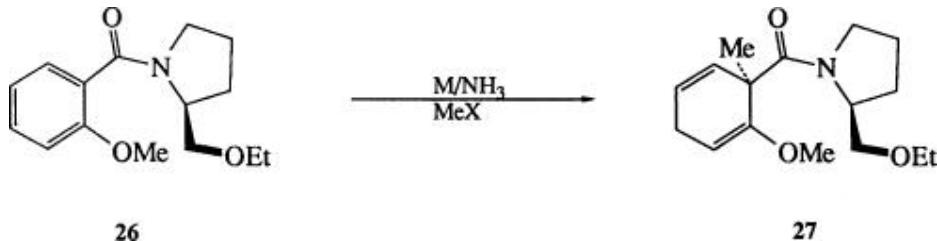

steric interference, and effects from possible prior coordination with the metal are absent. Stereoselectivity may be further increased by the use of chiral substrates, as demonstrated for the reductive alkylation of a number of chiral benzamides. (39) For example, the optically active benzoxazepinone **22** reacts

with potassium, sodium, or lithium in ammonia containing one equivalent of *tert*-butyl alcohol, followed by addition of alkyl halide, to give product ratios for **23/24** of 85:15 for R = methyl, and 98:2 to 99:1 for larger R groups.

This behavior may be understood by the enolate model **25**, in which the top face appears to be more accessible to the electrophile. Even greater diastereoselectivity is shown by **26**; **27** is produced with a 260:1 selectivity relative to methylation on the opposite side. (39)

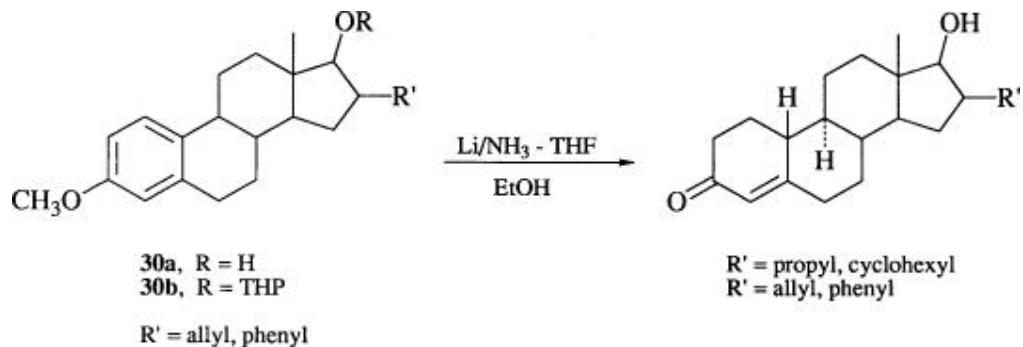

2.4. Regiochemistry and Stereochemistry—Intramolecular Effects

Although nonconjugated double bonds are generally not reduced under Birch conditions, norbornadiene and a number of related compounds are quite reactive. (40) For example, the reduction of **28** and **29** with sodium/ammonia in the presence of *tert*-butyl alcohol results in double bond reduction

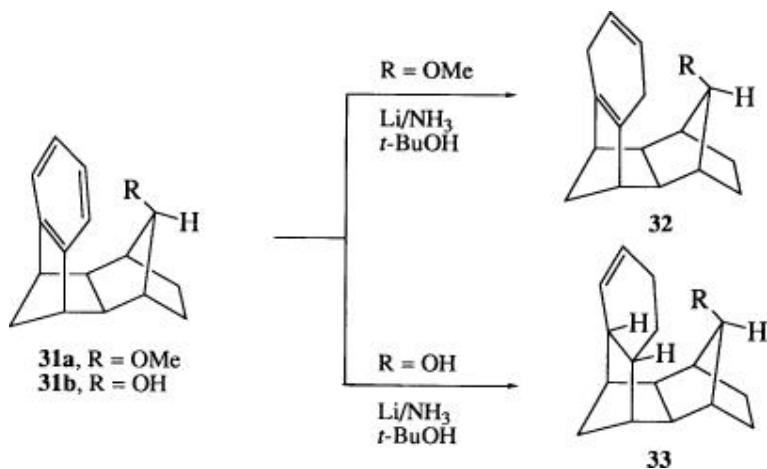

predominating over aromatic ring reduction in ratios of 2.1:1 and 10:1, respectively. This behavior is a consequence of orbital interactions through space, and orbital interactions through bonds. (41) Additional examples involve unsaturated sites separated by three, four, five, and six σ bonds. (40)

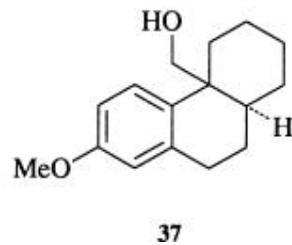

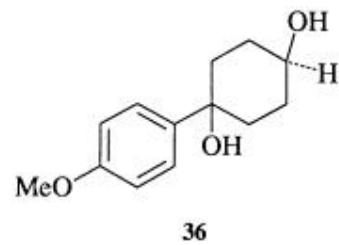

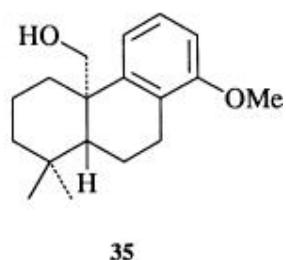

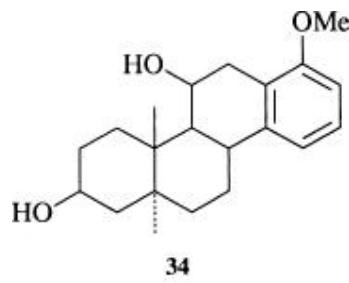

Reactivity, regiochemistry, and stereochemistry are also affected by the presence of hydroxy groups. When OR in **30** is hydroxy, an allyl or phenyl group at the 16 β position is reduced. However, when the hydroxy group is protected, as in **30b**, the 16 β substituents are left intact, suggesting the importance

of intramolecular protonation. (42) Ether **31a** reacts only slowly with lithium to produce the expected 1,4-cyclohexadiene **32**, but when R = OH,

the reaction is fast to produce **33**. Hence regiochemistry, and presumably stereochemistry, are controlled by internal protonation of the radical anion intermediate. (43) Similar rate and/or regiochemical effects are observed for the reductions of **34–37**. (44–48)

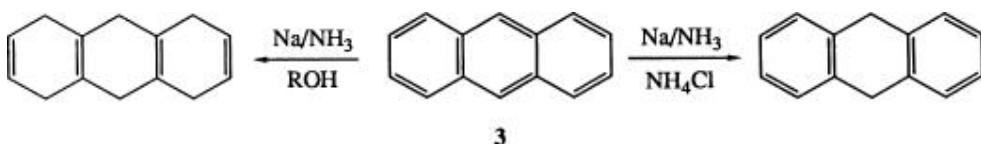

3. Scope and Limitations

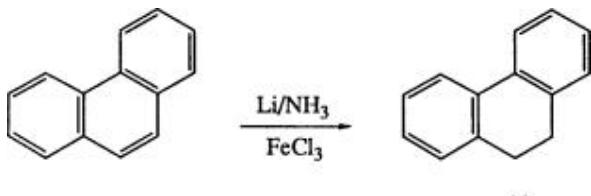

3.1. The Reduction of Polynuclear Aromatic Compounds

Polynuclear aromatic compounds are considerably more reactive than benzenes, [3f,h](#) and, as discussed under [Regiochemistry](#), the sites of reduction are controlled by the distribution of electron density in the anionic intermediates. With the exception of compounds like naphthalene, triphenylene, and perylene, where all of the rings are equivalent, this selectivity also controls which ring is reduced. Substituents may exert some control over ring selectivity. However, in a system like anthracene, where the electron density is highly localized at the 9,10 positions, reduction generally occurs at that position regardless of the nature of substituent groups.

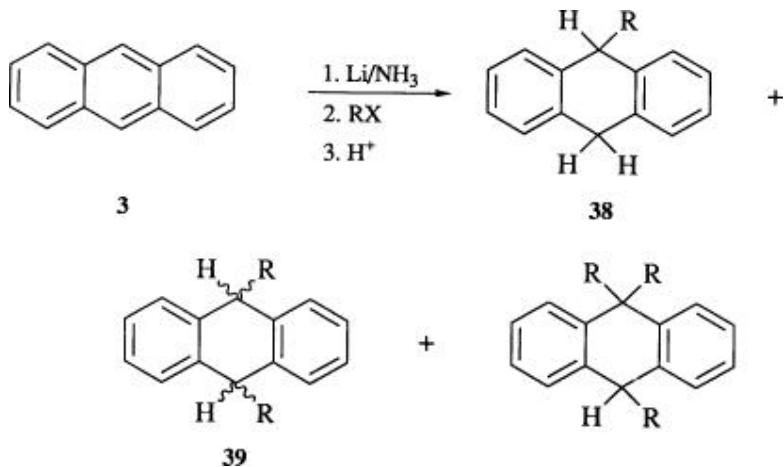

The application of classical Birch reduction procedures, including the Wilds and Nelson modification of adding the alcohol last, provides only marginal results with polynuclear aromatic compounds. [3f](#) The addition of alcohols to metal ammonia solutions of polynuclear aromatics invariably leads to reduction

beyond the stage of the addition of two hydrogens. Mixture of products at varying stages of reduction and/or isomerization products are also common. For example, anthracene (**3**) affords primarily the hexahydro isomer by reduction with sodium/ammonia in the presence of an alcohol. [\(49\)](#) Colloidal iron may be used in a number of instances to prevent overreduction, and its presence during the reduction of anthracene restricts reduction beyond the dihydro stage. [\(50, 51\)](#) However, the same results can be obtained in minutes rather than hours by avoiding the alcohol altogether and simply quenching with stronger acids like ammonium chloride. [3f,g](#) Nonetheless, iron salts are useful in systems like phenanthrene where reducible dihydro derivatives **11** are produced *in situ* via protonation with ammonia. [\(38\)](#)

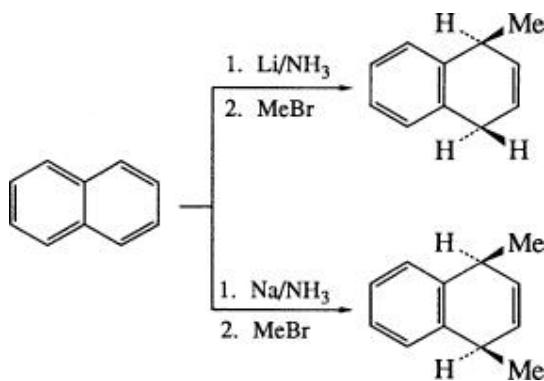

If alkyl halides are added to metal ammonia solutions of polynuclear aromatic compounds before the addition of a proton source, alkyl groups may be introduced into the reduced products. The number of alkyl groups introduced

depends on reaction conditions. 3g For example, anthracene provides mono-, di-, and trialkylated products under these conditions with *cis* and/or *trans*-39 predominating when the alkyl halide is added to the metal/ammonia solution. However, if the metal/ammonia solution is added to the alkyl halide (inverse quench), 38 is produced in 80–90% yield.

Naphthalene shows an unusual metal effect in that the use of sodium leads to >90% dialkylation whereas lithium provides >90% monoalkylation. (52) Once again, however, inverse quench leads to almost exclusive formation of the monoalkylated product. These effects, metal and addition order, are both due to a secondary reaction. As discussed above, many polynuclear aromatics produce monoanions as the persistent intermediate, and alkylation affords

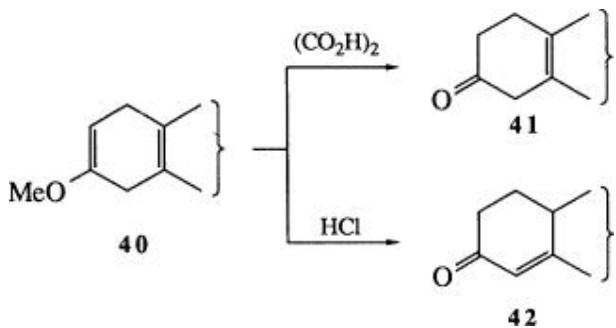

monoalkylated dihydroaromatics (Eq. 8). However, protonation of the dianion by ammonia generates amide ion and so the monoalkylated product may be deprotonated and subsequently alkylated again (Eq. 9). Since sodium

amide is more soluble than lithium amide, multiple alkylations are more common when sodium is used for the reduction. Inverse quenching into a large excess of alkyl halide consumes anions and amide so rapidly that secondary reactions are prevented. Alternatively, one equivalent of *tert*-butyl alcohol can be added to destroy the amide as it is formed.

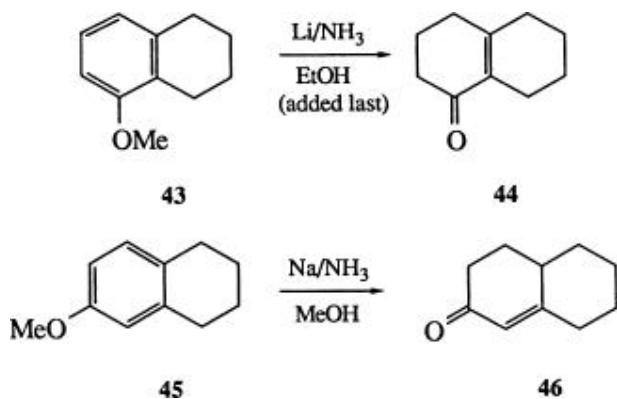

3.2. The Reduction of Aryl Ethers

In the absence of other activating substituents, anisoles are reduced to 1-methoxy-1,4-cyclohexadienes with the addition of hydrogen taking place at positions other than those occupied by the methoxy substituent (e.g., **40**). The resulting enol ethers tend to undergo rearomatization on standing, so

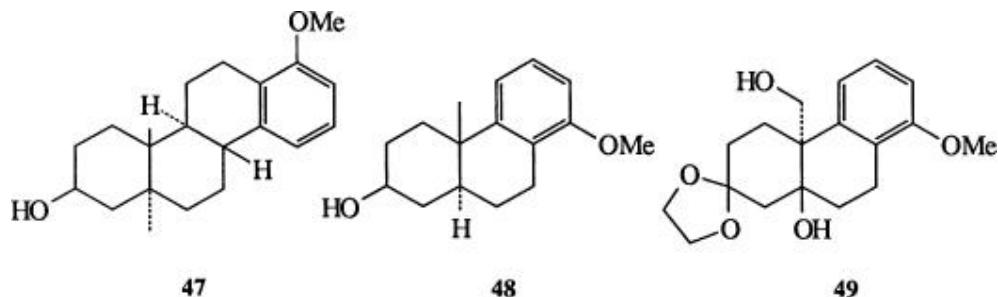

they are generally converted into the more stable ketones soon after preparation. This may be accomplished under mild conditions with oxalic acid in aqueous methanol, whereupon the double bond maintains its original position (**41**), or with hydrogen chloride to provide the conjugated ketone **42**. This technique has wide application to the synthesis of steroids where the A ring is transformed into a Δ^2 -cyclohexenone. [3g,53–59](#)

The reaction of 5-methoxytetralin (**43**) with sodium/ammonia in the presence of methanol gives only a trace of reduction products, while its isomer

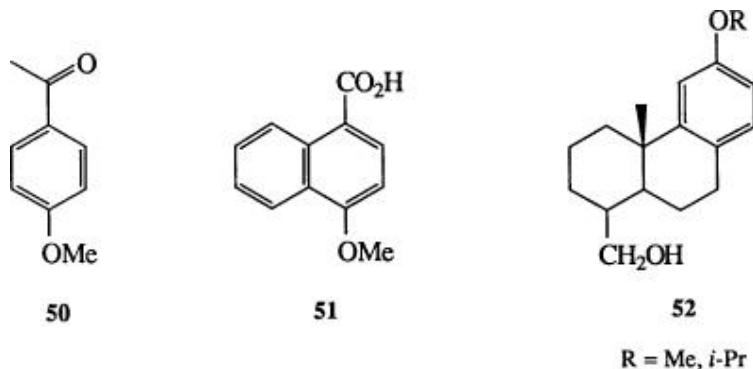

45 is successfully transformed into the enone **46** under similar conditions. (80) The diminished reactivity of **43** results from the fact that the normal course of reduction requires protonation to occur at a site bearing an alkyl substituent. However, by adding an alcohol last according to the Wilds and Nelson modification, (4) ketone **44** is isolated in 63% yield with lithium providing significantly better results than sodium. Compounds **47** (81) and **48** (82) containing the 5-methoxytetralin moiety provide poor yields of the desired enones even with

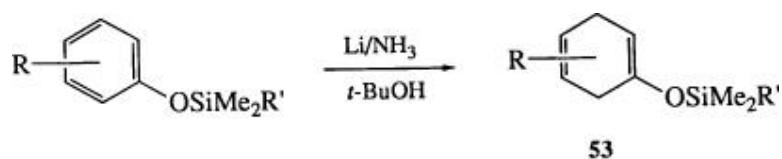

large excesses of lithium. In contrast, the unusually high reactivity of **49** is understandable in terms of an intramolecular protonation process (see above).

An important limitation in the reduction of aromatic ethers is the occasional partial or complete loss of the alkoxy group. This is especially true when the alkoxy group is *para* to an activating substituent. Both **50** (83) and **51** (84) are reduced exclusively 1,4 to the carbonyl substituent with complete loss of the methoxy group. The replacement of methoxy with larger groups (85) is only modestly successful in increasing oxygen retention as demonstrated with 12-methoxy and 12-isopropoxypodocarpe-8,11,13-trien-19-ol (**52**). (86)

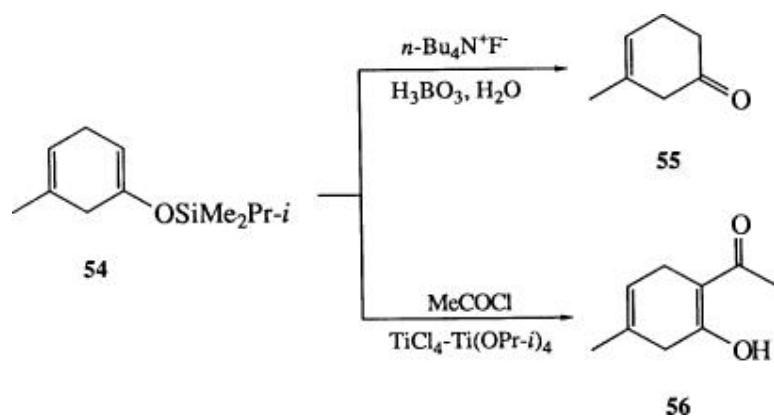

The Birch reduction of aryl silyl ethers has considerable synthetic utility. Although poor results are obtained with trimethylsilyl, *tert*-butyldimethylsilyl and isopropyldimethylsilyl phenyl ethers give good yields (80–97%) of 1,4-dihydroaryl silyl ethers **53**. (87) Further treatment of **54**, for example, with

$\text{R} = \text{H}, o\text{-}, m\text{-}, p\text{-Me}, o\text{-}, m\text{-}, p\text{-OMe}$

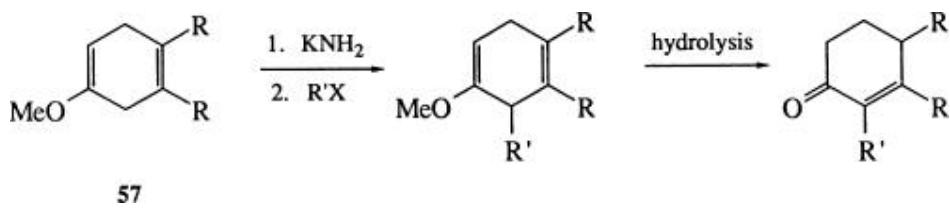

$\text{R}' = i\text{-Pr}, t\text{-Bu}$

tetrabutylammonium fluoride gives the relatively inaccessible β , γ -unsaturated ketone **55**, and titanium-mediated acylation provides cyclohexadiene **56**.

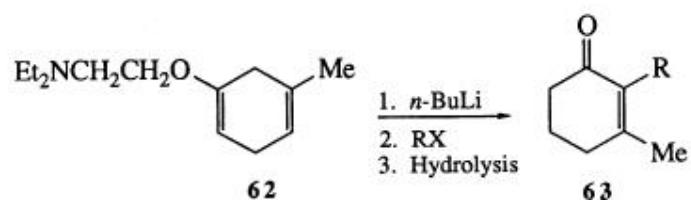

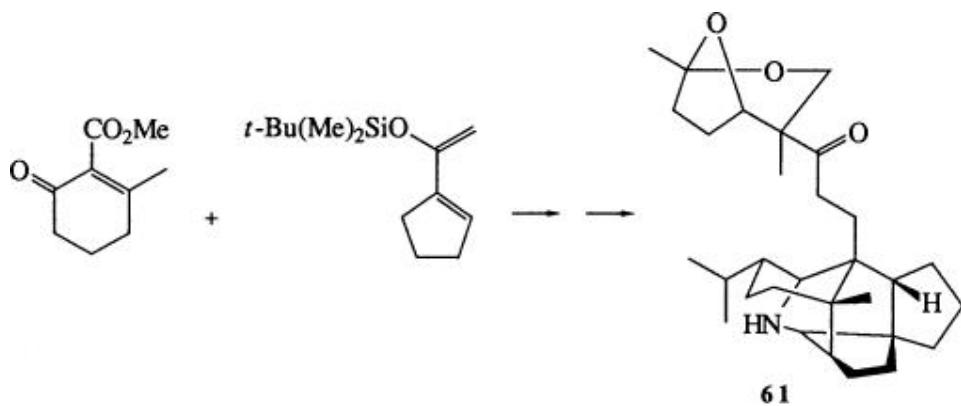

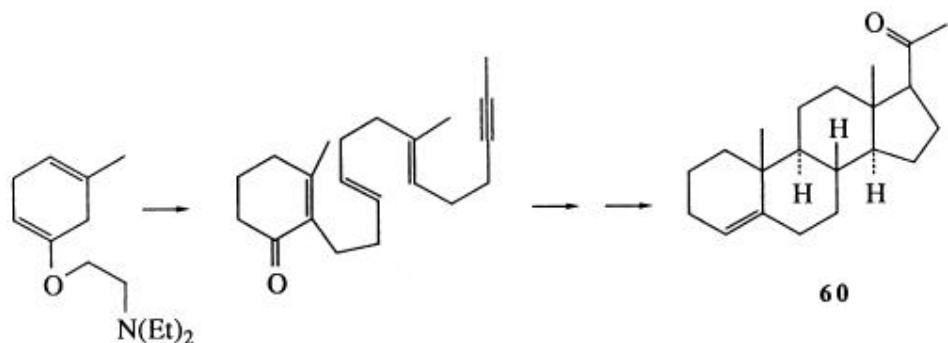

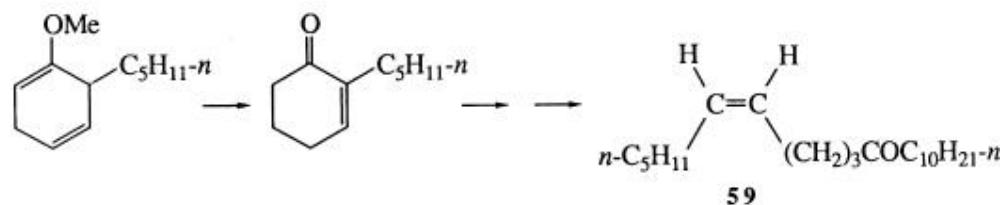

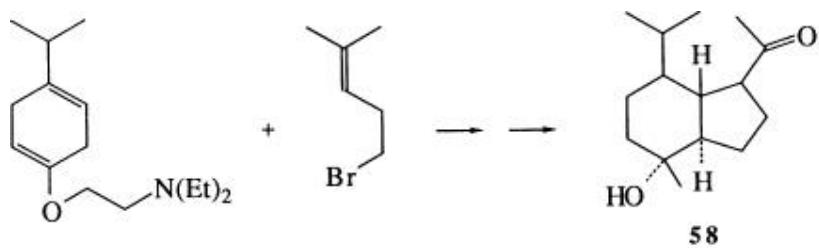

3.2.1.1. Alkylation of Dihydroaryl Alkyl Ethers

The reduction products of aryl ethers can serve as useful starting materials for synthesis. 1-Methoxy-1,4-cyclohexadienes **57** are deprotonated by potassium amide in ammonia at the allylic position next to the oxygen. (88, 89) The resulting anion is alkylated in yields of 75–85% with butyl, pentyl, or hexyl bromides, or arylated in 50–60%

yield with bromobenzene. (89) This method provides a basis for the synthesis of olopanone (**58**), (90) (Z)-heneicos-6-ene-11-one (**59**) (89) (the male sex attractant of the Douglas fir Tussock moth), and pregn-4-en-20-one (**60**). (91) A related process is used for the synthesis of the alkaloid secodaphrinphylline (**61**). (92) The protected ether derived from the Birch reduction of *m*-cresol is lithiated and then carboxylated followed by methylation of the acid and hydrolysis of the ether to produce 2-carbomethoxy-3-methylcyclohexenone. Subsequent Diels–Alder reaction with the *tert*-butyldimethylsilyl enol ether derived from 1-acetylcylopentene leads to a tricyclic keto ester that provides the necessary carbocyclic skeleton for the synthesis of **61**. With **62**, where deprotonation of the methyl ether fails, the diethylaminoethyl ether reacts with *n*-butyllithium in hexamethylphosphoric triamide (HMPA), followed by addition of alkyl halide and hydrolysis, to produce 2-alkyl-3-methylcyclohex-2-en-1-ones **63**. (93, 94)

$\text{MeCCl} = \text{CH}(\text{CH}_2)_2\text{Cl}$	(80%)

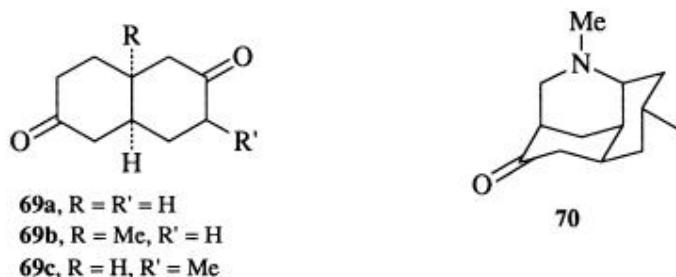

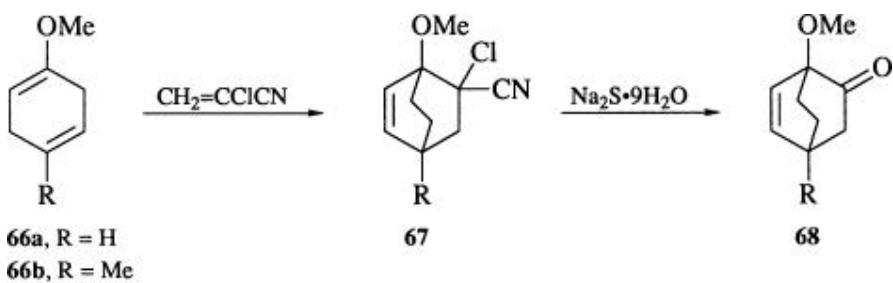

3.2.1.2. Cycloadditions

1-Methoxy-1,4-cyclohexadienes can be used as substrates in cycloadditions where prior isomerization to the conjugated isomer is accomplished in situ. This reaction is accelerated by catalysts, as illustrated by the reaction of 1-methoxy-1,4-cyclohexadiene (**64**) with acrylonitrile in the presence of dichloromaleic anhydride (DCMA) to afford adduct **65** in 75%

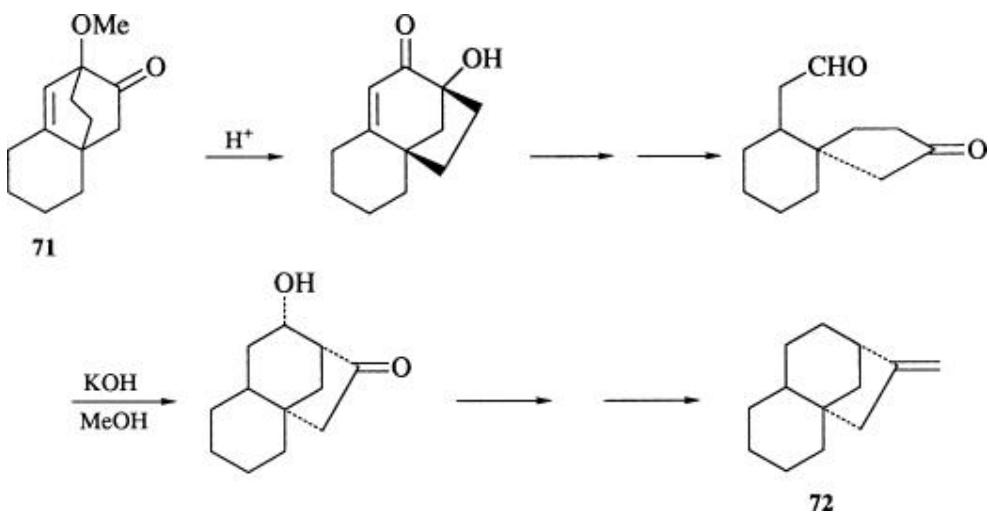

yield. (95) Under similar conditions, but in the absence of dichloromaleic anhydride, only unreacted **64** is recovered. Aluminum chloride and *p*-toluenesulfonic acid are also effective catalysts. (96)

α -Chloroacrylonitrile can also be used with complete (>99.9%) regioselectivity to produce adduct **67**, which can be converted into the bicyclic ketone

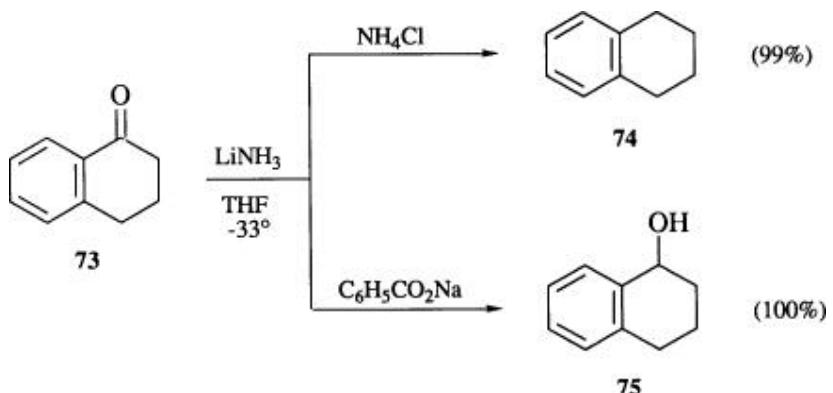

68 in over 80% yield. (97) Ketone **68** serves as a precursor to *cis*-decalin-2,6-diones **69**, (98) which can be used in the total synthesis of the lycopodium alkaloid luciduline (**70**). (99) Rearrangement of ketone **71**, available from 6-methoxy-1,2,3,4,7,8-hexahydronaphthalene and a ketene equivalent, ultimately furnishes **72**, a model of the veatchine group of diterpene alkaloids. (100)

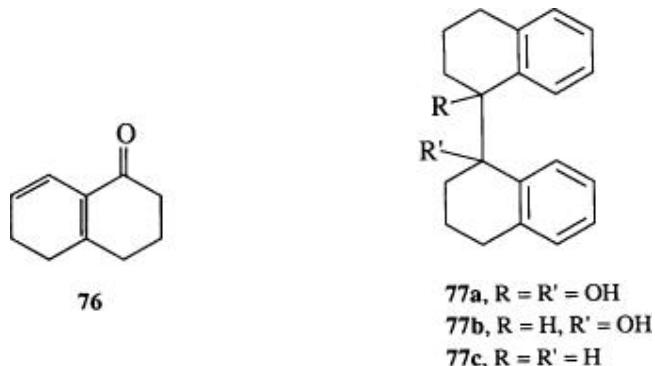

3.3. The Reduction and Reductive Alkylation of Aromatic Ketones

The Birch reduction of aromatic ketones is complicated by the fact that carbonyl reduction may take place in addition to, or in place of, aromatic ring reduction. Acetophenone reacts with potassium/ammonia in the presence of *tert*-butyl alcohol to give ethylbenzene. (101) Similarly, α -tetralone (**73**) affords

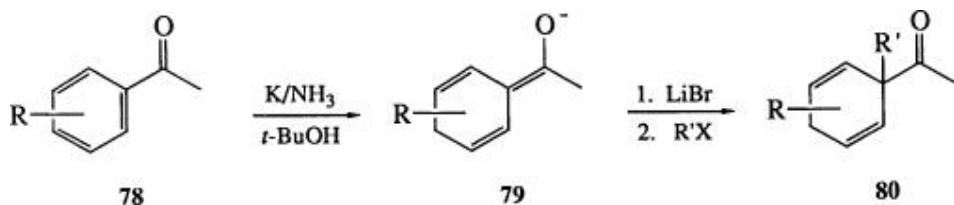

tetralin with lithium/ammonia reduction, but alcohol **75** is produced when sodium benzoate is used as a quenching agent. (102) Evidently additional reduction

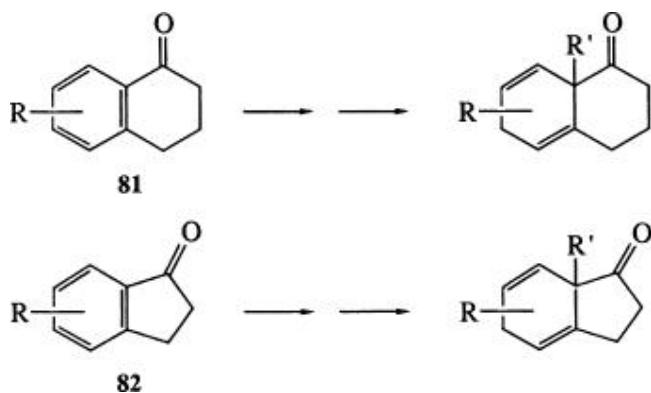

may occur during the quenching process even when relatively acidic agents like ammonium chloride are used. The reduction of a α -tetralone is also quite sensitive to the order of addition of reagents, the metal employed, and the temperature. (103) With sodium added last, the nuclear reduction product **76** is produced in 30% yield together with **74** (12%) and **75** (49%). However, the use of lithium and lower temperatures (-78°) results in a considerable amount (54–84%) of dimerization (**77**), affording a mixture of **77a**, **77b**, and **77c**.

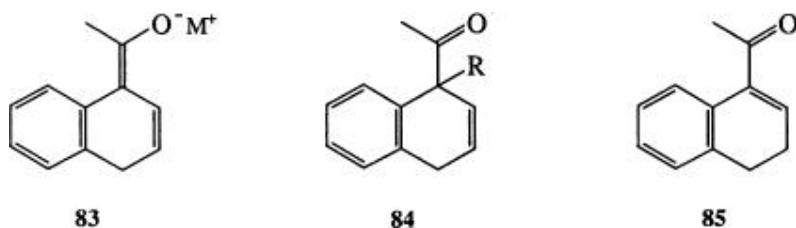

Overall reductive alkylation may be accomplished with acetophenones **78** by reduction to produce an enolate **79** which is subsequently alkylated. (83) This is best accomplished by initial reduction with potassium followed by exchange of the cation with lithium bromide prior to the alkylation step. Additional

improvements include adding the alkylating agent in aqueous tetrahydrofuran (1:1) at -78° to buffer the system and suppress dialkylation. (104) Similarly, 1-tetralones (**81**) (83, 104, 105) and 1-indanones (**82**), (106-108) including a number of methoxy derivatives, undergo reductive alkylation with $R' =$ methyl, ethyl, allyl, and benzyl halides.

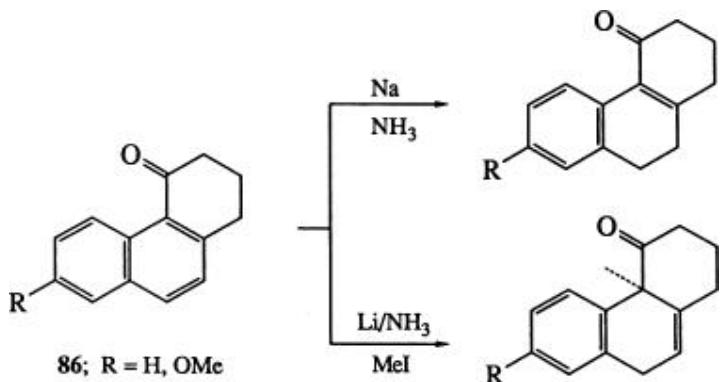

Reduction of 1-acetylnaphthalene (109-113) leads to the dienolate **83**, which can be alkylated with methyl or *n*-amyl iodide (109, 111) to produce **84**. On the other hand, protonation by ethanol affords the conjugated product **85**. (110, 111)

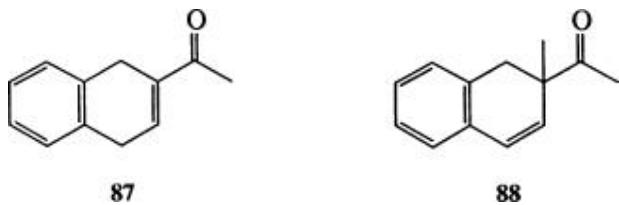

This is likely a rearrangement product since the reverse quench of **83** into aqueous ammonium chloride yields **84** ($R = H$). (113)

1-Keto-1,2,3,4-tetrahydrophenanthrenes **86**, (112, 114, 115) as well as A/B aromatic 11-keto steroids, (115, 116) react similarly to provide conjugated reduction products or nonconjugated, methylated reduction products.

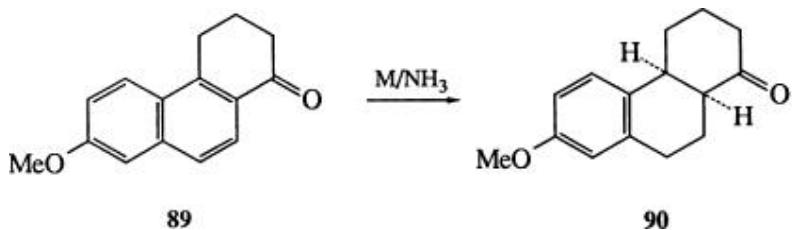

In contrast to the 1-isomer, the reduction of 2-acetylnaphthalene is more difficult to control. Both lithium and sodium reduction lead to tetrahydro

products with some reduction of the carbonyl group. However, the use of potassium for reduction, or lithium/ferric chloride for reductive methylation, affords the dihydro products **87** and **88** respectively. (111) Curiously neither the

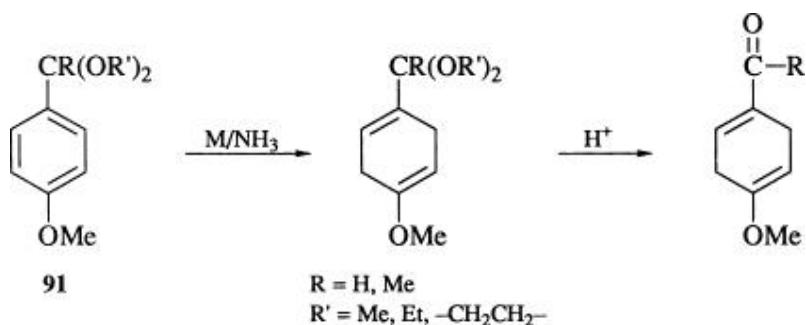

use of potassium nor ferric chloride limits the reduction of **89**, which yields the tetrahydro product **90**. (112) Preference for *cis*-fused B/C rings in the latter is presumably a consequence of protonation of the enolate from the sterically

less hindered equatorial side. Alkylation of the lithium enolate derived from **89** affords a mixture of *cis*- and *trans*-fused hexahydro isomers, and the use of sodium or potassium leads to a considerable amount of dialkylation.

Carbonyl groups may be protected during reduction by conversion into acetals, and a variety of *p*-anisaldehyde and *p*-methoxyacetophenone acetals and ketals **91** can be reduced to the 2,5-dihydro compounds in 30–80%

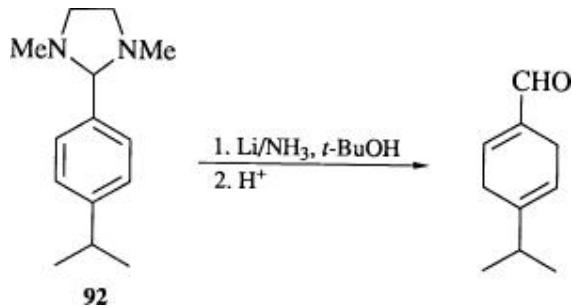

yields. (117) *p*-Isopropylbenzaldehyde can also be protected as the *N,N* β -dimethylimidazoline (**92**) in an analogous transformation. (118)

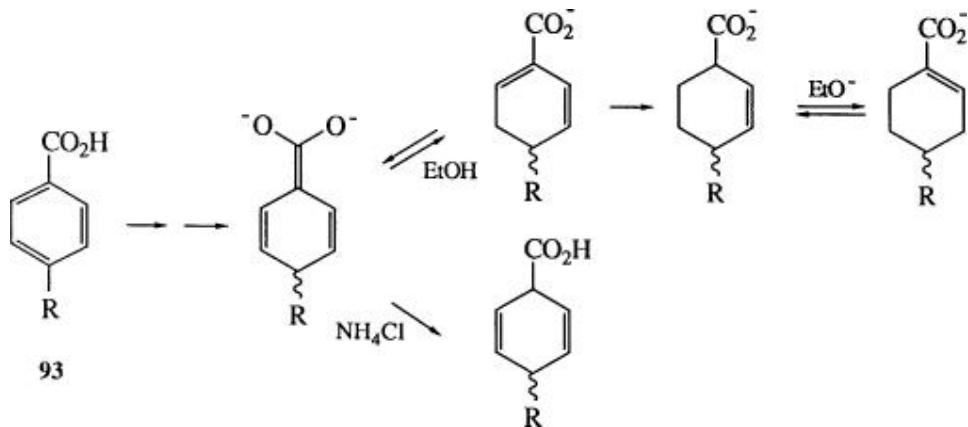

3.4. The Reduction of Aromatic Carboxylic Acids

3.4.1.1. Benzoic Acids

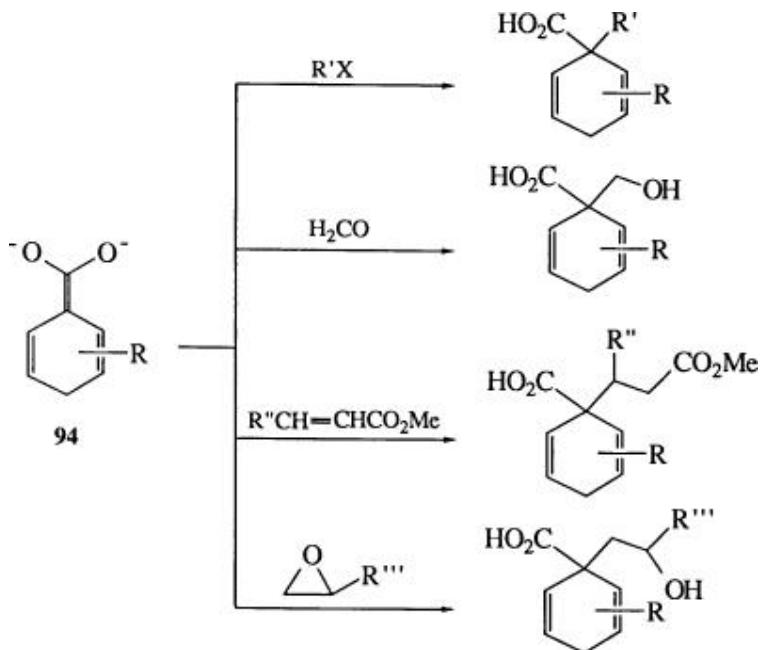

The carboxy group generally dominates regiochemistry, and is strongly activating in the Birch reduction. 3f,119 However, while classical reduction conditions produce good results with benzoic and *o*-toluic acids,

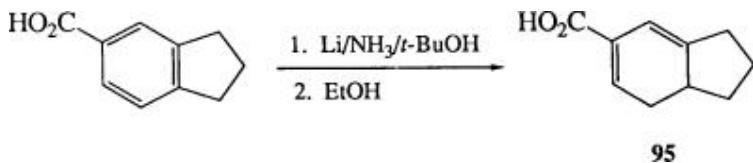

affording 1,4-dihydrobenzoic acids, (119-121) *p*-toluic acid (**93**, R = Me) gives mainly the tetrahydrotoluic acid under similar conditions. (120) With low levels of an alcohol, or in its absence together with short reaction periods followed by ammonium chloride quench, both 4-isopropyl and 4-*tert*-butylbenzoic acids

can be reduced efficiently to the 1,4-dihydro products. The former has a *cis/trans* ratio of 1:2 (122) while the latter gives only the trans isomer. (33) *m*-Alkylbenzoic acids

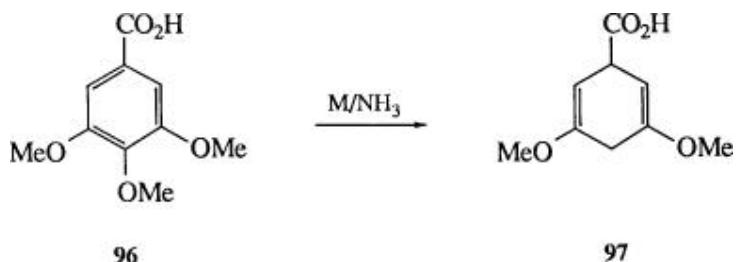

acids show similar behavior and are best reduced with water or ammonium chloride as the proton donor if 1,4-dihydro products are desired. (123) On the other hand, *o*-alkylbenzoic acids give mainly 1,4-dihydrobenzoates irrespective of the experimental procedure. In the absence of proton donors, the intermediate dianion 94 persists in solution and can be trapped with alkyl halides, (123) α , β -unsaturated esters, (124) epoxides, (125) or formaldehyde (126) to give a variety of synthetically useful products. The use of alcohols may serve as a

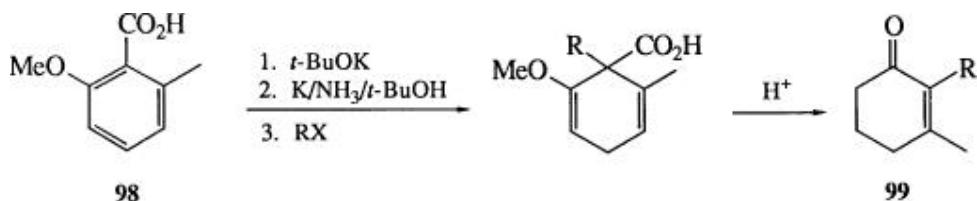

convenient method when conjugated products are desired, however, as illustrated in the synthesis of the tetrahydroindane carboxylic acid 95. (127)

The loss of alkoxy and amino groups in benzoic acids by hydrogenolysis is common especially when they are in the *para* position. For example, the

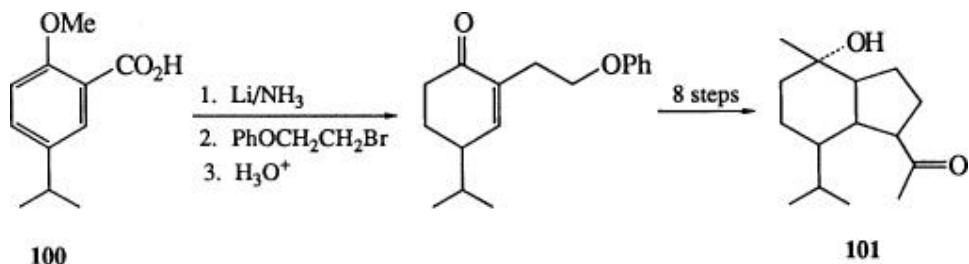

reduction of the trimethyl ether of gallic acid (**96**) leads to complete loss of the *p*-methoxy group but retention of those *meta* to the carboxy group. (120) *m*-Anisic acid is reduced smoothly with complete retention of the methoxy group. However, overreduction to the tetrahydro stage occurs with ethanol, and to a lesser extent with methanol, as the proton donor. This problem is corrected by reduction in the absence of an alcohol followed by the addition of ammonium chloride. (120, 128-130)

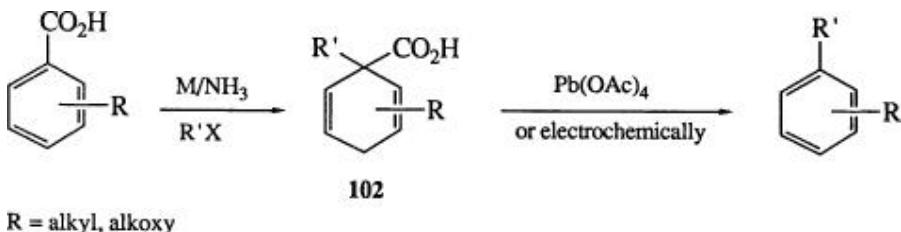

The loss of substituents can also be a problem with *o*-methoxybenzoic acids, especially when lithium is used in refluxing ammonia. (131) Some improvements involve the use of sodium instead of lithium, and the use of methanol as a proton donor. 132–133 A more general procedure, which also facilitates alkylation, involves the addition of potassium *tert*-butoxide prior to reduction by potassium metal in the presence of up to four equivalents of *tert*-butyl alcohol.

In this way 2-methoxy-6-methylbenzoic acid (**98**) can be reductively alkylated with methyl, benzyl, and 4-(1-but enyl) halides. Hydrolysis of the enol ethers leads to decarboxylation with production of cyclohexenones **99**. (134) In some

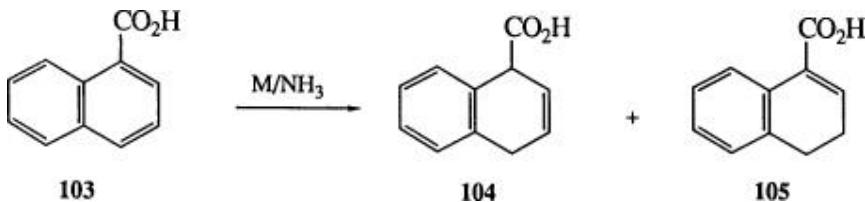

instances, it may be desirable to generate the lithium salt prior to alkylation, and such exchange is accomplished by the addition of lithium bromide. The reductive alkylation of 2-methoxybenzoic acids serves as the starting point for a number of total syntheses as illustrated for the sesquiterpenes **101**. (135) The reductive alkylation products of alkyl and alkoxybenzoic acids **102** can also undergo oxidative decarboxylation with lead tetraacetate, (136) or electrochemically, (137) to produce aromatic hydrocarbons and ethers in good yields.

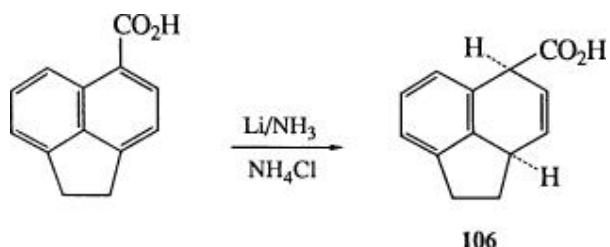

3.4.1.2. Polycyclic Aromatic Carboxylic Acids

The reduction of polycyclic aromatic carboxylic acids is especially easy when the carboxy group is located on a carbon that corresponds to a position of high electron density in the radical anion/dianion of the parent hydrocarbon. If the carboxy group is positioned at a site of low electron density relative to the parent hydrocarbon, however, reduction is often hard to control with respect to overreduction and/or isomerization.

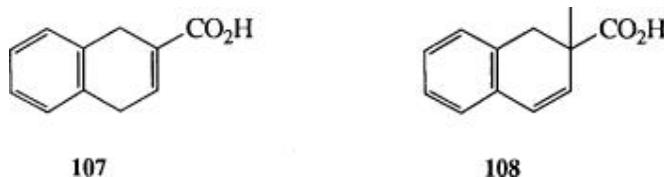

Conditions that give good results with benzoic acids, like the use of excess metal and the presence of an alcohol as a proton donor, often provide poor results with polycyclic aromatic carboxylic acids. For example, 1-naphthoic acid (**103**) provides substantial amounts of the 3,4-dihydro isomer **105** when reduced in the presence of an alcohol, **2a,138** but 1,4-dihydro-1-naphthoic acid

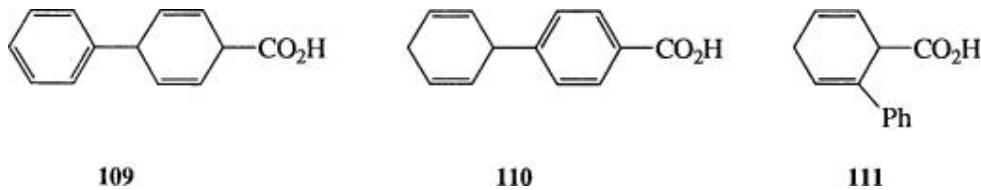

(**104**) becomes the exclusive product when ammonium chloride is used as the proton source. (84, 139) In contrast to the *trans* predominance observed for

4-substituted benzoic acids, 5-acenaphthoic acid gives the *cis* isomer **106**. (140) This result is presumably due to the added constraint provided by the five-membered ring. The reduction of 2-naphthoic acids is more difficult to control. (84, 141-144) However, the use of ferric chloride during the reduction leads to yields of ca. 75% for both reduction (**107**) and reductive methylation (**108**). (84) Interestingly, different regiochemistry is observed for these two processes.

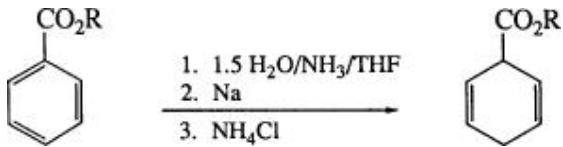

Reaction conditions are quite important in the reduction of biphenyl-4-carboxylic acid. (145, 146) However, with rapid quenching techniques, two products **109** (stereochemistry unknown) and **110** can be obtained in a ratio of 3:1

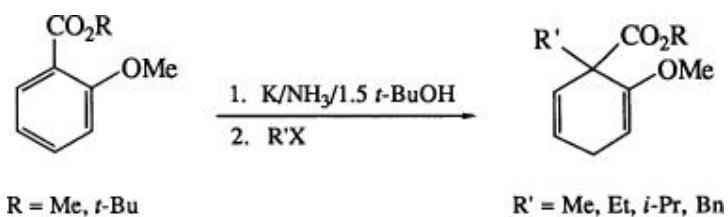

respectively. (146) In contrast, the *ortho* isomer provides a single product **111** with reduction being controlled by the carboxylic acid group. (145)

3.5. The Reduction of Aromatic Carboxylic Esters

The Birch reduction of aromatic esters is problematic in that carbonyl reduction is expected to be competitive with ring reduction (i.e., the Bouveault–Blanc procedure). However, if one or two equivalents of water, or *tert*-butyl alcohol, is added before metal addition, benzoate esters may be

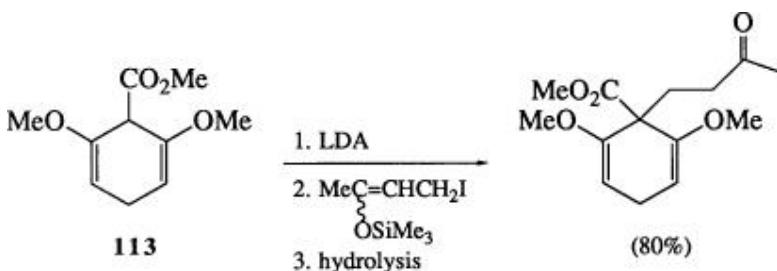

reduced in over 95% yield with sodium in ammonia, although yields are poor when 4-alkyl substituents are present or methyl esters are used. (147) However, if *tert*-butyl alcohol is used with lithium or potassium as the metal, good results are obtained with methyl benzoate. 3j This method, with potassium, also works well with reductive alkylation as illustrated for the *o*-methoxybenzoate ester

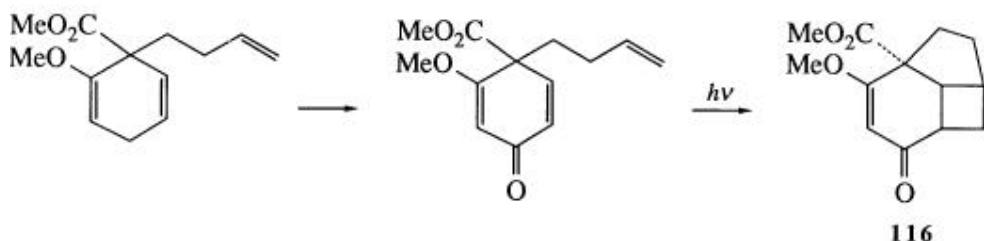

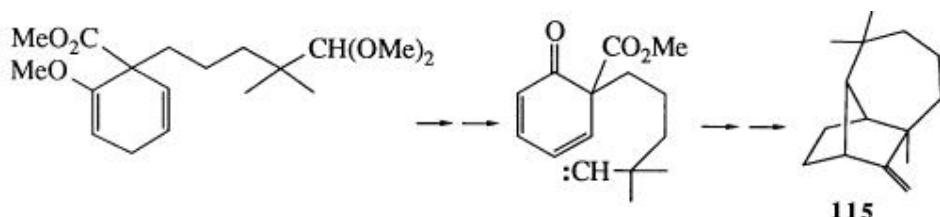

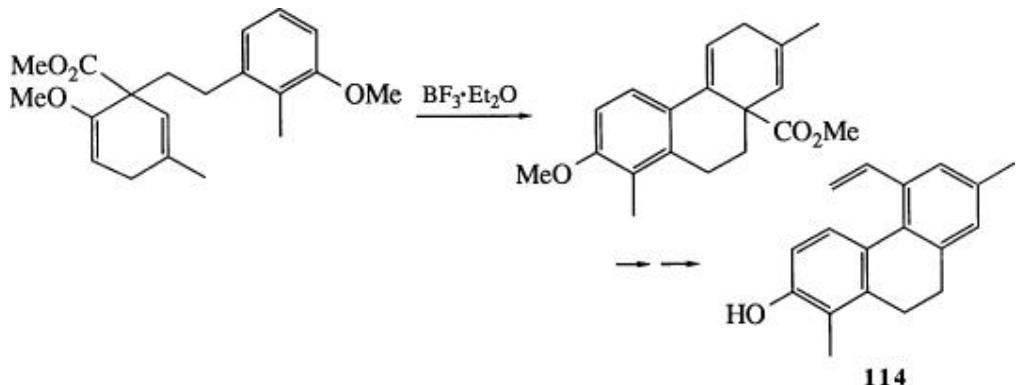

112

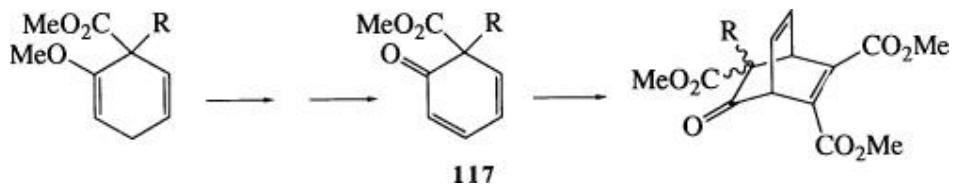

112. (134, 148) Yields are in the range 60–95% even in the presence of a 4-methyl substituent. However, in some cases it is necessary to convert the potassium enolate into the lithium enolate prior to the alkylation step, and with especially

active alkylating agents the ammonia must be removed first. 3j It is possible to carry out the alkylation step separately on the dihydrobenzoate (e.g., 113) by deprotonation with lithium *N,N*-diisopropylamide (LDA) followed by alkylation. (149) The reductive alkylation of *o*-methoxybenzoate esters provides

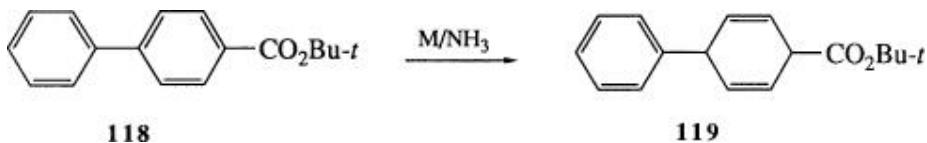

considerable opportunity for further synthetic elaboration as illustrated in the synthesis of juncunol (**114**), (**133**) (\pm)-longifolene (**115**), (**150**) and the tricyclic ketone **116**. (**151**) Similarly, conjugated dienes like **117** may be produced that serve as substrates for Diels–Alder reactions. (**152**)

In general, esters may serve as excellent alternatives to the parent carboxylic acids for Birch reduction, especially reductive alkylation. They are more

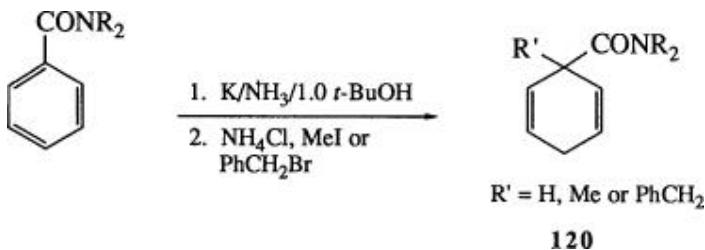

soluble; more resistant to isomerization, rearomatization, and decarboxylation; and are more easily isolated. They may also show improved regioselectivity,

as illustrated for reduction of ester **118**. The parent acid is reduced in both rings with the disubstituted ring favored by a 3:1 ratio whereas the ester gives **119** exclusively. (146)

3.6. The Reduction of Aromatic Amides

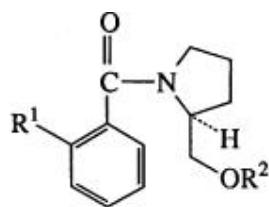

The reduction of aromatic amides is quite sensitive to conditions and can produce considerable amounts of benzaldehyde as well as dimeric products. (120, 152-157)

Best results are obtained when potassium is used in the presence of one equivalent of *tert*-butyl alcohol, and the resulting monoanion can be protonated or alkylated (**120**). (157)

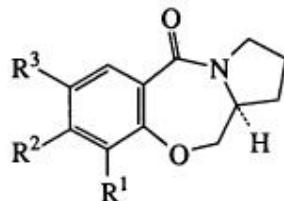

3.6.1.1. Enantioselective Reductive Alkylation of Aromatic Amides

The incorporation of L-proline as a chiral auxiliary in **121–123** allows reductive alkylations with high diastereoselectivities (39, 158-164) although the sense of stereoselection in **121** is opposite to that in **122**. (159) Birch reduction of **121**, where

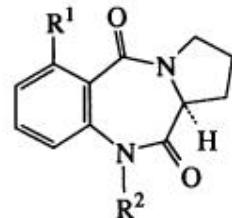

121, $R^1 = \text{OMe, Ph}$

$R^2 = \text{Me, CH}_2\text{OMe}$

122a, $R^1, R^2, R^3 = \text{H}$

122b, R^1 or R^2 or $R^3 = \text{Me}$

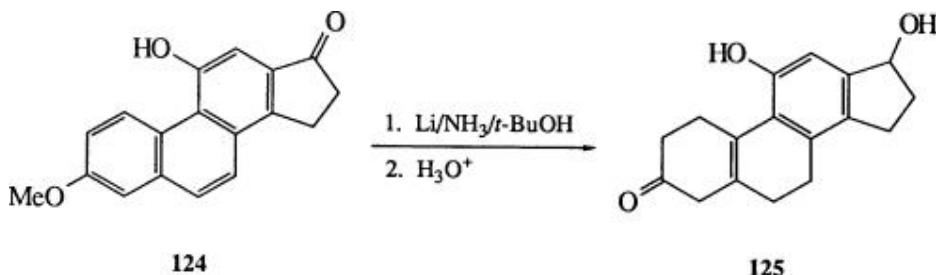

123, $R^1 = \text{H, Me}$

$R^2 = \text{H, Me}$

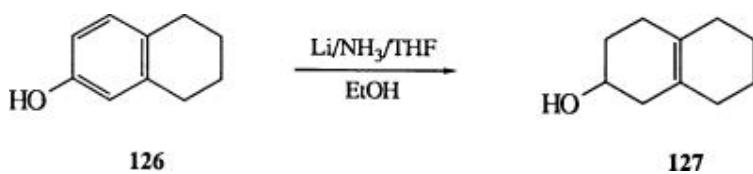

$R^1 = \text{OMe}$ and $R^2 = \text{CH}_2\text{OMe}$, followed by alkylation with methyl iodide at -78° gives diastereomeric α -methylated dihydroaromatic products in a 260:1 ratio. (39) Amide **122**, where $R^1 = R^2 = R^3 = \text{H}$, is less selective than **121** in methylation with a ratio of 85:15, but selectivity increases to 99:1 when ethyl iodide is used as the alkylating agent. This method can be used as a starting point for total synthesis as, for example, **122** in the enantiospecific preparation of ($-$)-longifolene (**115**). (150)

3.7. The Reduction of Phenols

Phenols are rather unreactive under Birch reduction conditions since the addition of an electron to a phenoxide produces a radical dianion. In polynuclear aromatics such as **124**, the aromatic ring bearing the hydroxy group is often not reduced. (165) The reduction of phenolic rings is best accomplished with high concentrations of lithium. The yield of **127** is increased from 46% to 76% by increasing the lithium concentration from 3.4 M to 4.3 M. (166) An exception to this lack of reactivity is 2-naphthol and its derivatives. **2a** Increased

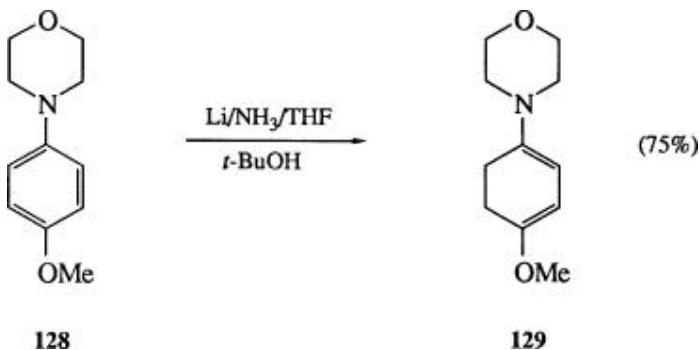

reactivity may be due to reduction occurring via the tautomeric α, β -unsaturated keto form.

3.8. The Reduction of Aromatic Amines

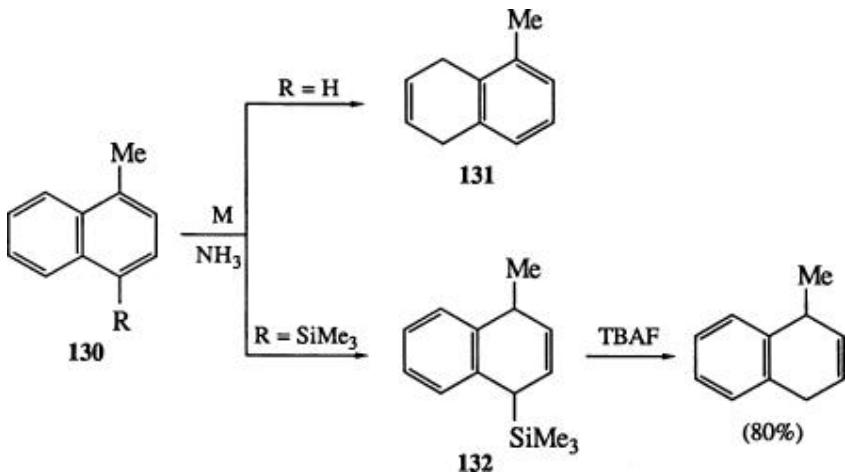

Aromatic amines undergo transformations analogous to anisoles in that the final products are ordinarily ketones and unsaturated ketones. (167, 168) In contrast to anisoles, however, the initial reduction products are usually not isolated with aryl amines, and overreduction is common. However, *N*-aryl-morpholine

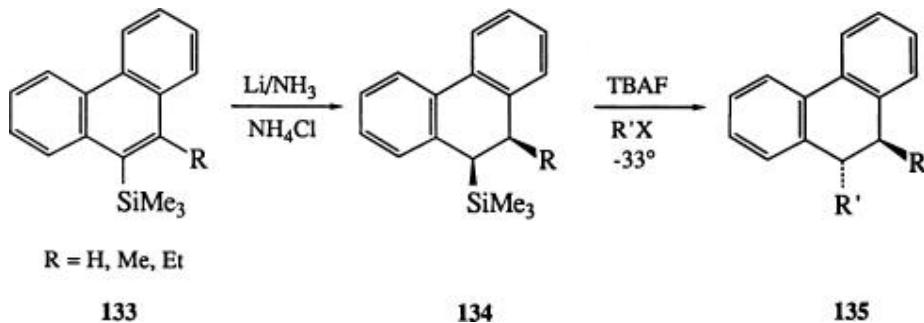

derivatives provide an important exception in that the primary reduction product is isolable. As illustrated for **128**, the products are generally conjugated cyclohexadienamines, although nonconjugated products are formed when there are substituents *ortho* to the nitrogen. (169)

3.9. The Reduction of Arylsilanes

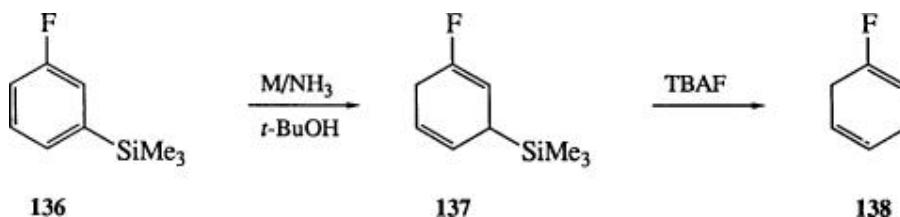

Carbanions are stabilized by an α -silyl substituent, (170) and consequently arylsilanes are reduced to provide allylic silanes in the absence of more strongly activating substituents. (171) Since allylic silyl groups are easily removed by fluoride ion, silyl substitution represents a way of controlling regiochemistry in the Birch reduction. (172-174) For example 1-methylnaphthalene (**130**),

$R = H$) is reduced in the unmethylated ring to produce 5-methyl-1,4-dihydronaphthalene (**131**). However with a 4-trimethylsilyl substituent at C-4 (**130**, $R = SiMe_3$), reduction occurs exclusively in the substituted ring to produce **132**. Subsequent removal of silicon by treatment with tetrabutylammonium fluoride (TBAF) affords 1-methyl-1,4-dihydronaphthalene in 80% overall yield. (172) The equivalent of overall reductive alkylation can also be accomplished by removal of the trimethylsilyl group in the presence of methyl or ethyl iodide. For example, the phenanthrene **133** is reduced to the benzylic silane **134**, which, in turn, can be treated with tetrabutylammonium fluoride in the presence of primary alkyl halides to produce the *trans*-9,10-dihydro derivative **135**. (173) This is especially significant since reduction of 9,10-dialkylphenanthrenes produces the *cis* isomers. Anthracenes and naphthalenes can also be alkylated in this way, and the products exhibit the same stereochemistry that they show during normal reductive alkylation in the absence of a silyl group. This result indicates that additional stereoselectivity by the replacement of silicon with RX is not possible and that the intermediate resulting from treatment with tetrabutylammonium fluoride is the carbanion and not a tight complex. (174) Silyl substitution can also be used to prevent cleavage of

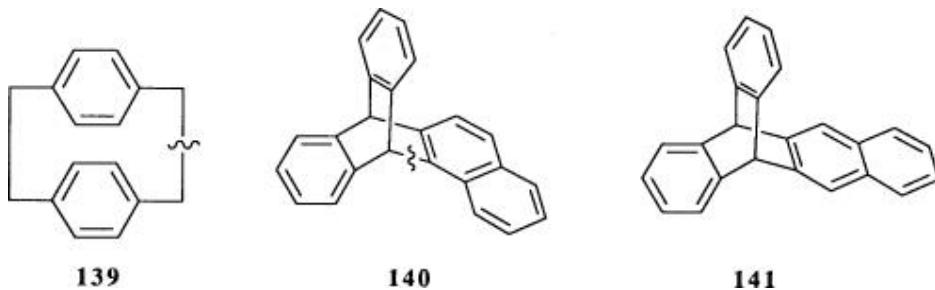

substituents that might otherwise be lost during reduction. For example, although fluorobenzene is rapidly converted into benzene and on to 1,4-cyclohexadiene under Birch reduction conditions, *m*-trimethylsilylfuorobenzene

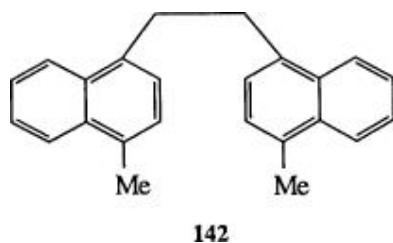

(136) is reduced with the fluorine retained. Subsequent removal of the silicon by tetrabutylammonium fluoride affords 1-fluoro-1,4-cyclohexadiene (138), which is not otherwise accessible by Birch reduction methods. (175)

3.10. Bond Cleavage and Dimerization

Dissolving metal reduction is sometimes accompanied by processes that alter the nature of the original ring system. Two such side reactions are bond cleavage and dimerization. As mentioned above, the cleavage of carbon–oxygen bonds is quite common in aryl ethers, and may become a major pathway. (176) This is especially true for alkali metal reduction in solvents other than ammonia. (177-185) Carbon–carbon bond cleavage is also possible with 1,2-diarylethyanes

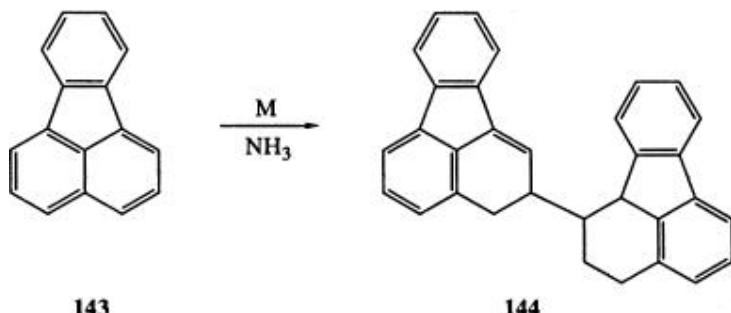

and diarylmethanes. [2.2]-Paracyclopheane (139) undergoes cleavage of the ethane bond during lithium/ammonia reduction, (186) and the 1,2-benztriptycene (140) ring opens to give 10-lithio-9-(2-naphthyl)-9,10-dihydroanthracene. (187) On the other hand, the isomeric 2,3-benztriptycene (141) does not ring open under similar conditions. (187) The competition between Birch reduction and bond cleavage in 1,2-bis(4-methyl-1-naphthyl)ethane (142) is

quite sensitive to conditions, with cleavage increasing relative to reduction in the series Li < Na < K and NH₃ < THF < HMPA. (188) It is quite significant, however, that reduction becomes the almost exclusive pathway at temperatures below –33° regardless of metal or solvent. Since this is the highest operating temperature for ammonia, effects that appear to be solvent related may in fact be more attributable to temperature.

Dimeric and oligomeric products may also result from the reduction reaction,

and in some cases this represents a major pathway. For example, fluoranthene (**143**) reacts with either sodium or lithium in ammonia to give

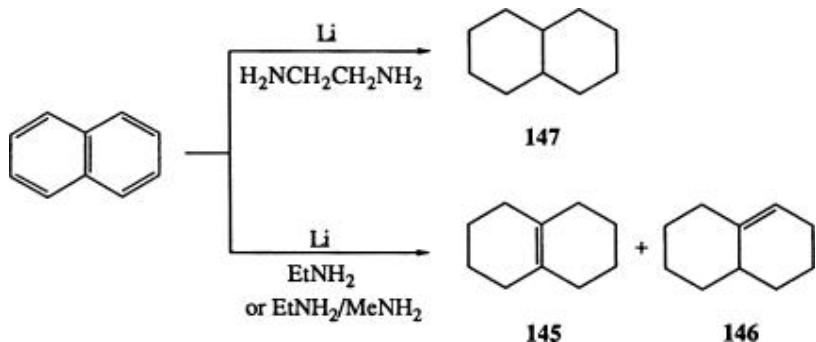

the dimer **144** in 30–52% yield together with polymeric material. (189) Similarly, the reduction of naphthalene can produce substantial amounts of dimer and trimer, especially with prolonged reaction times. (190) These processes do not involve dimerization of radical anions, as might be expected, but rather result from monoanion addition to neutral alkenyl aromatics. (189, 190)

3.11. Comparison with Other Methods

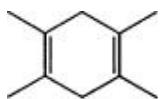

3.11.1.1. Benkeser Reduction

The use of lithium in primary amines, ethylenediamine, or mixtures of primary and secondary amines serves as an alternative to the classic Birch reduction procedure. Known as the Benkeser reduction, this system provides a more powerful reducing medium than metals in ammonia. (191) For example, whereas benzene gives 1,4-cyclohexadiene by Birch reduction, treatment with lithium in ethylamine provides mainly cyclohexene plus some cyclohexane. (192) Similarly, naphthalene, which under suitable metal ammonia reduction conditions affords 1,4-dihydronaphthalene almost quantitatively, (11) gives the octahydro products **145** and **146** in equal amounts by reduction with lithium in ethylamine. (192) When the solvent is changed to a mixture of ethylamine and methylamine, the selectivity (193) increases with **145** as the major product (80%). With ethylenediamine, reduction proceeds even further to produce decalin (**147**). (194) Polynuclear aromatic compounds normally

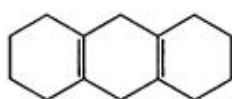

undergo reduction beyond the dihydro stage with lithium–amine systems and often yield a mixture of products. Reduction of these compounds beyond the addition of two hydrogens must result from protonation of the anionic intermediates by the amines. However, this need not suggest greater acidity in this medium as compared with ammonia, but probably results from the higher temperatures normally employed. The conjugation of dienes by the lithium salts of amines is well known. (195) In any event, Benkeser reduction does not serve as a substitute for the Birch reduction, but may be the method of choice when more highly reduced materials are desired or for the reduction of isolated double bonds.

The use of calcium in low-molecular-weight amines sometimes provides cleaner results than lithium. For example, the dienes **148** and **149** can be

148

149

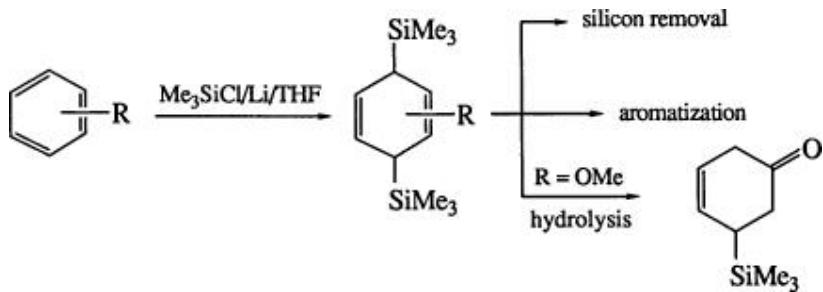

obtained by calcium–methylamine–ethylenediamine reduction of durene and anthracene respectively. (196) The addition of *tert*-butyl alcohol to such systems, however, gives products similar to those of the Birch reduction in a number of cases. For example, anisole and the isomeric xylenes are all reduced to the expected 1,4-cyclohexadienes with calcium/amines/*tert*-butyl alcohol with yields in the 75–90% range. (197)

3.11.1.2. Reduction in other Solvents

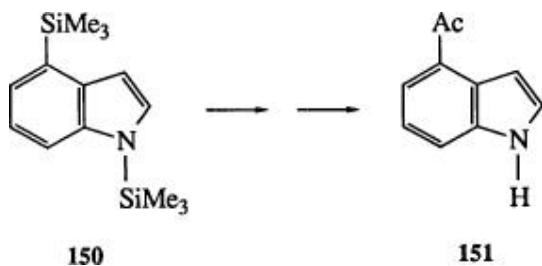

Electron addition to aromatics and other unsaturated cyclic compounds can also be accomplished by the use of alkali metals in solvents other than ammonia or amines, most notably tetrahydrofuran and HMPA. (198) This procedure seldom offers any advantage over metal/ammonia procedures, since reactions in these solvents are often quite slow. However, in the absence of ammonia or an alcohol as a proton source, the intermediates are radical anions or dianions, and alkylations may be possible that cannot be achieved in the presence of ammonia. Alloys such as Cs/K/Na in tetrahydrofuran reduce benzene, toluene, and xylene, generally producing tetrahydrobiphenyls as the major products. (199) Crown ethers enhance the solubility of alkali metals in tetrahydrofuran, (200) and the system sodium–potassium alloy/18-crown-6/tetrahydrofuran has been used for the reduction of benzoic acid and anthracene. (201, 202) The addition of sodium metal to polynuclear aromatics in a refluxing alcohol also represents a method for ring reduction, but it is not expected to have much general utility. (203)

3.11.1.3. Reductive Silylation

Benzene (204, 205) and its alkyl, (205) methoxy, (206, 207) and hydroxy derivatives (207) react with lithium in tetrahydrofuran in the presence of chlorotrimethylsilane to produce 3,6-bis(trimethylsilyl)-1,4-cyclohexadienes. This process, which may require extended reaction periods of a number

of days, can be accelerated by sonication as demonstrated for the reductive silylation of phenol. (207) 1,4-Cyclohexadiene, free of its conjugated isomer, can be prepared by the reductive silylation of benzene followed by silicon removal with aqueous potassium hydroxide in carbitol. (208) Rearomatization, affording an overall route to silylated aromatics, is also quite facile. For example, this

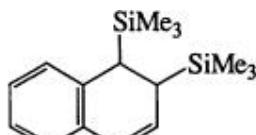

methodology can be used for the preparation of the silylated indole **150** with further conversion to the acyl derivative **151** by *ipso* Friedel–Crafts acylation. (209)

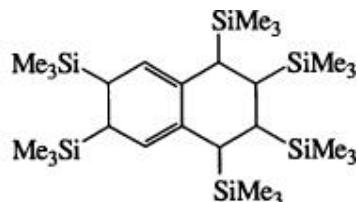

Naphthalene undergoes reductive silylation with sodium in tetrahydrofuran to provide both 1,2- and 1,4-dihydro isomers **152** and **153**, (210) whereas the use of potassium leads to a tetrasilylated compound. (211) With lithium/tetrahydrofuran (212)

152

153

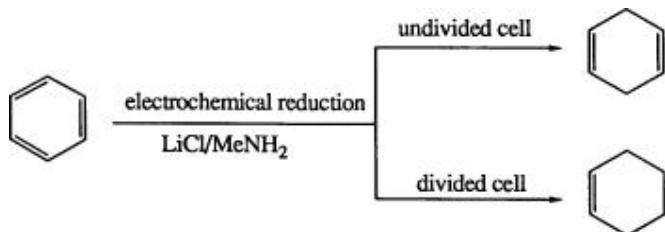

154

or magnesium/HMPA, (213) silylation proceeds further to give 154, which can be rearomatized with the loss of two silyl groups to provide 1,4,6,7-tetrakis(trimethylsilyl)-1,2,3,4-tetrahydronaphthalene, providing a source of tetrafunctional naphthalenes by subsequent electrophilic substitution on silicon.

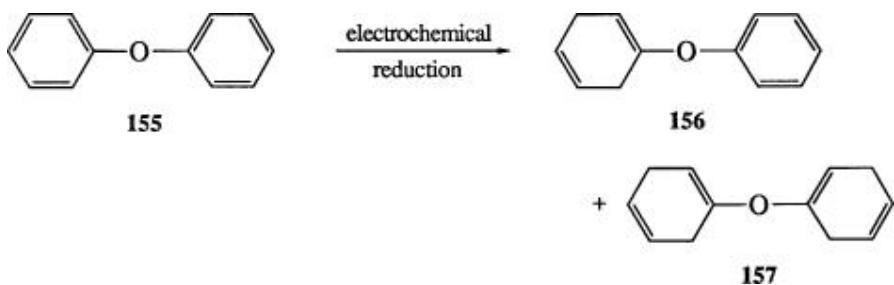

3.11.1.4. Electrochemical Reductions

Reactions similar to the Birch reduction can also be performed electrochemically. (214, 215) Benzene is reduced by electrochemical reduction using lithium chloride as the electrolyte to provide 1,4-cyclohexadiene in an undivided cell, but cyclohexene in a divided cell. (191, 216) The latter result is presumably due to the presence of lithium dimethylamide,

formed in the divided cell, that causes isomerization and further reduction of the initial product. Ethyl, isopropyl, and *tert*-butylbenzene can be similarly reduced producing 1-alkyl-1,4-cyclohexadienes in yields of 75–96% in the undivided cell.

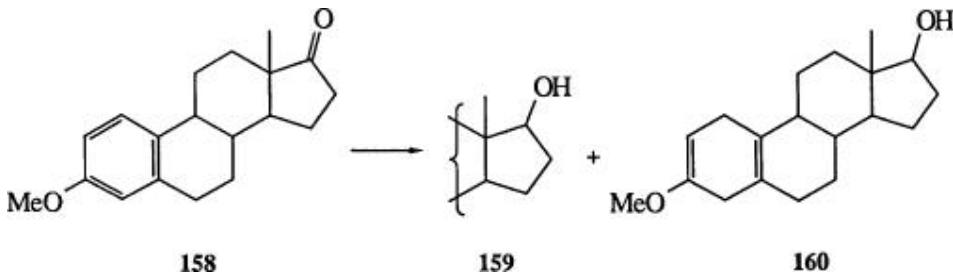

Efficient preparative electroreductions can be performed at mercury pool cathodes in solutions containing tetraalkylammonium electrolytes with a variety of solvents including acetonitrile, *N,N*-dimethylformamide (DMF), alcohols, ethers, sulfolane, and HMPA. (215) The use of aqueous solutions can

also produce interesting results. For example, diphenyl ether (**155**) is reduced to phenol and benzene by either Birch reduction or electrochemical reduction in dry *N,N*-dimethylformamide. However, with cathodic reduction in aqueous tetrahydrofuran, **156** and **157** are produced in combined yields of over 50%. (217)

Another interesting example is estrone 3-methyl ether (**158**) since it cannot be satisfactorily reduced by Birch reduction. By varying the current, the carbonyl and the aromatic ring can be selectively reduced producing either **159** or **160** in yields of over 80%. (218)

Polynuclear aromatic hydrocarbons can also be reduced electrochemically; in some instances results are quite comparable to Birch reduction and in others they are not. For example, preparative electrolysis of anthracene provides 9,10-dihydroanthracene in 90% yield. However, phenanthrene gives a mixture of dihydro, octahydro, and decahydro derivatives. (215)

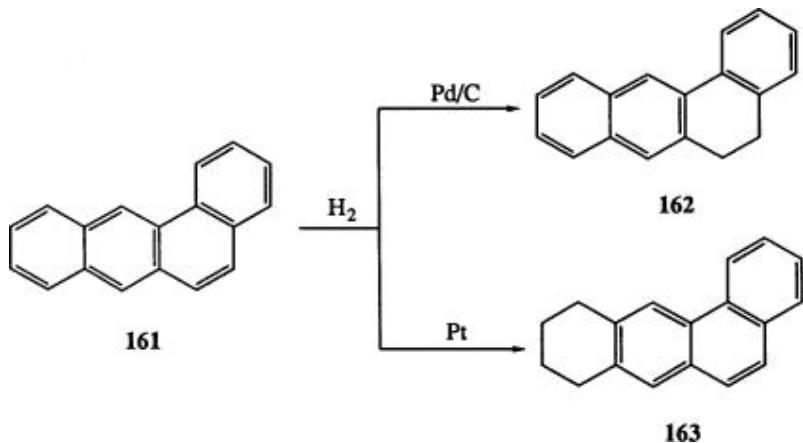

3.11.1.5. Catalytic Hydrogenation

Although aromatic rings can be reduced by catalytic hydrogenation, reduction normally proceeds far beyond the stage of dissolving metal reduction. (219) Thus while a useful procedure, catalytic hydrogenation

does not usually serve as an alternative to Birch reduction. Hydrogenation is often unpredictable and difficult to control. Either heterogeneous or homogeneous catalysts can be used, but in both cases the usual products from the hydrogenation of benzene derivatives are cyclohexanes. However, this method can be applied to polynuclear aromatics with exceptionally good results in some instances. For example, benz[a]anthracene (**161**) can be hydrogenated under mild conditions (20–50 psig, ambient temperature) to

provide **162** in 97% yield when palladium on charcoal is used as the catalyst, and **163** in 95% yield using a platinum catalyst at slightly higher hydrogen pressures. (220)

4. Experimental Conditions

4.1. Liquid Ammonia

Anhydrous ammonia is a toxic gas with a pungent odor, and all operations must be conducted in an efficient fume hood. Liquid anhydrous ammonia is available commercially in steel cylinders, and it can be removed in either liquid or gaseous form. However, ammonia from steel cylinders is often contaminated with iron, thereby providing a catalyst for the formation of alkali metal amides. This problem is especially important when sodium or potassium is employed, or when prolonged reaction times are necessary, and has led to the practice of double distillation – ammonia is removed as a gas and condensed into a preliminary vessel where it is dried with sodium until a blue color persists. It is then distilled into the reaction vessel. A simpler method is to pass the ammonia through a drying tube containing barium oxide (10–20 mesh).

Liquid ammonia has a boiling point of -33.4° , and an efficient condenser is required. A Dewar condenser containing a slurry of dry ice in isopropyl alcohol will normally suffice. A positive pressure of inert gas is also required, and argon or helium are preferred since nitrogen reacts with lithium metal.

4.2. Metals

The metals most frequently employed for Birch reduction are sodium, lithium, potassium, and, to a lesser extent, calcium and magnesium. Lithium is the most reactive, and also the most soluble in ammonia. Coupled with the fact that lithium is also less sensitive than sodium or potassium to iron-catalyzed reaction with ammonia, it is often the metal of choice. Lithium amide is also less soluble than either sodium or potassium amide, and this can reduce the amount of secondary isomerization products. With polynuclear compounds, however, the greater tendency for lithium salts to be protonated by ammonia can lead to overreduction, and sodium sometimes gives the best results.

Although alkali metals are quite soluble in ammonia ultimately producing so-called “metallic” or “bronz” phases, Birch reductions are most often done under dilute conditions. Ranges of 0.1–0.5 g metal per 100 mL of ammonia are common, and scaling up, when it includes more concentrated metal solutions, sometimes results in lower yields. Hence the ramifications of highly concentrated solutions of alkali metals in amine and ether solvents remain unclear. (221)

4.3. Cosolvents and Proton Donors

Cosolvents are often added to aid solubility. They are usually ethers, with diethyl ether, tetrahydrofuran, and glymes being the most common. However, since the anionic intermediates, as well as the products, are often more

soluble than the starting materials, only slight solubilization is necessary. Product outcome is occasionally affected by the nature of the cosolvent, but this may be more a function of ion pairing than solubilization. In any event, the routine use of diethyl ether or tetrahydrofuran in a ratio ranging from 1:3 to 1:2 relative to excess ammonia is probably prudent.

It is sometimes necessary to add acidic substances that may serve as proton sources. Generally, alcohols like ethanol and *tert*-butyl alcohol are employed for this purpose although occasionally stronger acids like water may be employed. The most serious problem normally comes about when a proton source is added where it is not required. This is true for almost all polynuclear aromatics as well as for a number of activated benzenes.

4.4. Reaction Procedures

The purity of starting materials remains a question. Carefully purified ammonia, cosolvents, proton donors, and aromatic substrates are sometimes critical. On the other hand, commercial anthracene can be reduced almost quantitatively without purification, and with “wet” ether as a cosolvent. As a general rule, the reduction of highly reactive substrates with short reaction times and rapid quenching (e.g., ammonium chloride) will not be overly sensitive to these considerations. Nonetheless, routine purification of materials is recommended. Commercial anhydrous tetrahydrofuran can be further dried by distillation from sodium benzophenone ketyl. Metals should be freshly cut under oil with their surfaces scraped clean, and then rinsed with petroleum ether. Additional details for the handling and purification of lithium, sodium, and potassium may be found in *Reagents for Organic Synthesis*. (222)

The order of addition can be quite important. There are several possibilities: the substance to be reduced dissolved in cosolvent containing an alcohol may be added to the ammonia already containing the metal, the alkali metal may be added last to the other reagents, or the alcohol may be added last. Of these methods, adding the metal last in small pieces is generally recommended.

The final quenching process is also important, and two general types of materials may be used: acidic materials like alcohols, water, or ammonium chloride, or electron-transfer agents like sodium benzoate or dienes followed by water. It is best to understand what is being accomplished in the final quench. This generally means one or more of the following possibilities: destroy excess metal, protonate anionic intermediates, and shift equilibria. If the quench is done slowly, as is the case with alcohols, metal is destroyed slowly and so excess metal during the quench can produce overreduction. A potential problem with electron-transfer reagents is that they can accept an electron from an anionic intermediate. This is not likely, however, except for dianions which are rare in ammonia. The addition of saturated ammonium chloride as fast as possible while keeping frothing under control is a good

general method. Where extreme sensitivity to overreduction during the quenching process exists, it is possible to pump the ammonia solution into dilute ammonium chloride (i.e., inverse quench).

Rapid workup is sometimes important, and allowing the quenched ammonia solution to stand for long periods to evaporate ammonia may be detrimental. When the amounts of ammonia are a few hundred mL or less, the quenched reaction mixture (no more violent frothing upon addition of water) may be poured into an excess of water (good hood) containing some ether, and then gently poured into a separatory funnel mounted on a ring stand (good hood, do not shake the funnel!). The water layer is then removed and more water is added to the separatory funnel *without shaking*. This water layer is drained off, and after two or three of these operations, the separatory funnel can be shaken without developing much pressure, and product isolation can proceed as usual.

For reductive alkylations, the alkylating agent in dry ether is added dropwise from a pressure equalizing dropping funnel. If reactive alkyl halides are added too quickly, violent evaporation of ammonia can result, and stoppers will be blown out.

4.5. Apparatus

Reactions are ordinarily conducted in a three-necked round-bottom flask with a sealed mechanical stirrer or equipped for magnetic stirring. In either case, glass or polyethylene stir blades or stir bars are preferred since Teflon darkens with repeated use in metal/ammonia solutions. The use of blackened stir bars does not seem to interfere with the reaction, however. The flask should be fitted with an inert gas inlet with a tee connection to a mercury bubbler and a Dewar condenser. If magnetic stirring is used, the third neck may be stoppered and used for the addition of reagents. With a flow of inert gas (stopper removed) the apparatus should be dried with a burner flame. After cooling, the Dewar condenser should be charged with dry ice/isopropyl alcohol, and the flask should also be cooled with a dry ice bath. Ammonia gas is then passed in through a drying tube containing 10–20 mesh barium oxide. Once the desired amount of ammonia is collected (usually estimated by premarking the flask), the bath can be removed if the reaction is to be run at reflux (ca. –33°), or otherwise remain if a lower temperature (ca. –78°) is desired. The aromatic substrate, dissolved in cosolvent, is then added via the stoppered neck. It may simply be poured in or added with a pressure equalizing addition funnel. The metal is added last in small pieces through the same inlet, and sometimes best results are obtained when this is done over a period of a few minutes.

5. Experimental Procedures

5.1.1.1. 1,2-Dimethyl-1,4-cyclohexadiene (Reduction of a Monocyclic Aromatic Hydrocarbon) (223)

To a flask containing 2.5 L of liquid ammonia were added slowly 450 g of anhydrous ether, 450 g (10 mol) of absolute ethanol, and 318.5 g (3.0 mol) of *o*-xylene in that order. Then 207 g (9.0 mol) of sodium was added in pieces over 5 hours. The ammonia was allowed to evaporate overnight, and 800 mL of ice water was slowly added with stirring. The organic layer was washed three times with 800-mL portions of water and dried over magnesium sulfate. Distillation through a 20-cm Vigreux column gave 250–300 g (77–92%) of a fraction boiling at 70–72° (48 mm).

5.1.1.2. 9,10-Dihydroanthracene (Reduction of a Polycyclic Aromatic Hydrocarbon) (224)

A solution of 0.36 g (2 mmol) of anthracene in 20 mL of tetrahydrofuran was added to 40 mL of anhydrous ammonia at –78° under an argon atmosphere. Lithium metal (35 mg, 5 mmol) was then added in pieces and the reaction mixture was stirred for 20 minutes. Saturated ammonium chloride solution was then added as quickly as possible to discharge the deep blue color. Ether (150 mL) was added, and washing, drying, and evaporation afforded pure 9,10-dihydroanthracene, mp 108°. The yield was essentially quantitative.

5.1.1.3. 7,12-Dihydrobenz[a]anthracene (The Use of Ferric Chloride to Control Reduction) (225)

A solution of benz[a]anthracene (1.14 g, 5 mmol) in 76 mL of dry tetrahydrofuran was added to 150 mL of anhydrous ammonia containing 40 mg of ferric chloride. Lithium wire (85 mg, 12 mmol) was added to the solution at reflux temperature, and after 2 hours the deep blue color was discharged by the addition of ethanol. After evaporation of the ammonia and dilution with water, the product was isolated by filtration. Dissolution in acetone, filtration, and removal of the solvent provided 7,12-dihydrobenz[a]anthracene (1.08 g, 70%, mp 111–112°).

5.1.1.4. 17 β -Hydroxy-16 β -methylestr-4-en-3-one (Conversion of an Anisole into a Cyclohexene-3-one) (42)

Anhydrous ammonia (300 mL) was added to 16 β -methyl-3-methoxyestra-1,3,5(10)-trien-17 β -ol (1.2 g, 4.2 mmol) in ethanol (5 mL) and tetrahydrofuran (50 mL) at –50°, followed by lithium ribbon (2.3 g) in ca. 0.3-g portions over 2 hours with stirring. After stirring an additional 1 hour, ammonia was evaporated in a slow stream of nitrogen, and the residue was extracted with ether. The extracts were washed with water, dried over Na₂SO₄, and the solvent was evaporated to give crude crystals (1.13 g). To a stirred solution of this enol ether in methanol (25 mL) was added 6 M HCl (3 mL).

After stirring at room temperature for 30 minutes, the reaction mixture was extracted with ether. The extracts were washed with water, dried over Na_2SO_4 , and the solvent was evaporated to give crude crystals. Recrystallization from ether–hexane (1:1) gave 17β -hydroxy- 16β -methylestr-4-en-3-one (0.98 g, 85%) as colorless needles, mp 228–229°.

5.1.1.5. *trans*-3 α , β

-Methyl-3-(1-methoxyethoxymethoxyethyl)-2,3,3a,4,5,6,9,9b-octahydro-1H-benz[e]inden-7(6H)-one (Conversion of an Anisole into a Cyclohexen-4-one) (226)

A solution of *trans*-7-methoxy-3 α , β

-methyl-3-(1-methoxyethoxymethoxyethyl)-2,3,3a,4,5,9a-hexahydro-1H-benz[e]indene (942 mg, 2.71 mmol) in 25 mL of dry tetrahydrofuran and 4 mL of ethanol was added to 65 mL of liquid ammonia at –78°. Lithium (128 mg, 18.3 mmol) was added and the mixture was stirred for 20 minutes. Ethanol (10 mL) was then added dropwise, and the solvent was evaporated. The residue was diluted with water (30 mL), extracted with ether, and then washed with saturated aqueous sodium chloride and evaporated. The residue was dissolved in ethanol (29 mL) and water (3 mL), and this solution was treated with oxalic acid (328 mg, 3.64 mmol) for 3 hours at room temperature. The mixture was neutralized with 10% aqueous sodium hydroxide and the solvent was evaporated. The residue was diluted with water (30 mL) and extracted with ether, and the extract was washed with saturated aqueous sodium chloride. The residue upon workup was chromatographed using hexane–ethyl acetate (4:1) to afford *trans*-3 α , β -methyl-3-(1-methoxyethoxymethoxyethyl)-2,3,3a,4,5,6,9,9b-octahydro-1H-benz[e]inden-7(6H)-one (838 mg, 92%) as an oil. ^1H NMR (CCl_4): δ 0.70 (s, 3H), 1.13 (d, 3H), 3.29 (s, 3H), 3.40–3.73 (m, 4H), 4.63 (d, 2H).

5.1.1.6. *2,4-Bis[(methoxycarbonyl)oxy]-17-(methoxycarbonyl)morphinan-6-one (Reduction of a 1-Benzylidihydroisoquinoline followed by Cyclization of the Resulting Enol Ether)* (227)

1-[3,5-Bis(benzyloxy)benzyl]-6-methoxy-3,4-dihydroisoquinoline hydrochloride (75 g, 0.15 mol), 850 mL of tetrahydrofuran, and 850 mL of *tert*-butyl alcohol were placed in a 5-L three-necked flask equipped with a dry ice condenser, a mechanical stirrer, and a stopper. Ammonia (2.2 L) was condensed in, and Li (11.5 g, 1.6 mol) was added in small pieces slowly until a blue color was obtained and maintained for 3 hours. Excess lithium was decomposed by addition of 75 mL of ethanol and ammonium chloride (200 g, large excess) and the ammonia was allowed to evaporate slowly overnight under a slight pressure of nitrogen. The residual solvents were evaporated and ether (1 L) and concentrated HCl (1 L) were added slowly with cooling. The reaction mixture was stirred initially at 25° and then in a bath at 50° for 24 hours. The reaction mixture was filtered, concentrated under reduced pressure to a volume of 1.5 L, and made just basic with KOH (initially solid and then 4 M

aqueous solution). A solution of CICO_2CH_3 in CH_2Cl_2 was added slowly to the basic reaction mixture until the aqueous layer turned acidic. The mixture was extracted with methylene chloride (1 L). The aqueous layer was made alkaline with 2 M KOH, and it was again treated with $\text{CICO}_2\text{CH}_3/\text{CH}_2\text{Cl}_2$ until it became acidic. The layers were separated, and the aqueous layer was extracted with CH_2Cl_2 . The combined CH_2Cl_2 layers were stirred with anhydrous K_2CO_3 and CICO_2CH_3 at room temperature overnight. The reaction mixture was filtered, and the filtrate was extracted with saturated NaHCO_3 , dried over Na_2SO_4 , and concentrated to a brown oil (130 g). Purification by flash chromatography over silica gel [40–63 μm , 900 g, in $\text{CH}_2\text{Cl}_2/\text{CH}_3\text{CN}$ (4:1)] gave 64.5 g (96%) of 2,4-bis[(methoxycarbonyl)oxy]-17-(methoxycarbonyl)morphinan-6-one as a pale yellow oil, which solidified on standing in the refrigerator. An analytical sample was obtained by recrystallization from *i*-PrOH: mp 133–135°.

5.1.1.7. 2-Methyl-2-cyclohexenone (Reduction of a 2-Alkylpyridine Followed by Hydrolysis and Aldol Condensation) (228)

2-Vinylpyridine (10.5 g, 0.1 mol) and absolute ethanol (36.8 g, 0.8 mol) in 300 mL of anhydrous ether was added quickly to a solution of lithium (3.45 g, 0.5 mol) in 1 L of ammonia. After disappearance of the blue color, the ammonia was evaporated in a stream of nitrogen, and the residue was dissolved in 480 mL of ethanol. A solution of sodium hydroxide (12.0 g) in 240 mL of water was then added, and the resulting system was stirred at room temperature under nitrogen for 2.5 hours. The solution was acidified by the addition of 10% HCl, and the resulting solution was extracted four times with 200-mL portions of ether. The combined ether layers were washed twice with saturated NaHCO_3 , once with saturated brine, and then dried over anhydrous sodium sulfate. Evaporation of the solvent followed by distillation of the residue afforded 6.97 g (63%) of 2-methyl-2-cyclohexenone, bp 61–62° (10 mm).

5.1.1.8. 2-(Phenoxyethyl)-4-isopropylcyclohexenone (Reductive Alkylation of an Anisic Acid Followed by Hydrolysis) (135)

Ammonia (400 mL) was distilled into a solution of 2-methoxy-5-isopropylbenzoic acid (19.5 g, 0.1 mol) in 100 mL of tetrahydrofuran at –78°. Lithium was added in pieces until a deep blue color persisted. β -Bromophenetole (110 mmol, 22.1 g) in 50 mL of tetrahydrofuran with 1 mL of dibromoethane was added immediately in one portion, and after stirring briefly, the cooling bath was removed allowing the ammonia to evaporate under a stream of nitrogen. 1,2-Dichloroethane (100 mL) and water (100 mL) were then added, and the two-phase mixture was refluxed for 2 hours. The organic layer was separated and the aqueous layer extracted twice with methylene chloride. The combined organic phase was dried over K_2CO_3 , concentrated in vacuo, and distilled through a short-path apparatus to give 14.2 g (55%) of 2-(phenoxyethyl)-4-isopropylcyclohexenone as a colorless oil, bp 155–170° (0.4 mm).

5.1.1.9. 1-Acetyl-1-methylcyclohexa-2,5-diene (Reductive Alkylation of a Monoaromatic Ketone. Exchange of the Potassium Counterion of the Enolate for Lithium Prior to Alkylation) (83)

A solution of acetophenone (5.2 g, 43 mmol) and *tert*-butyl alcohol (52 mmol) in 20 mL of tetrahydrofuran was added to 140 mL of anhydrous ammonia at -78° . Potassium (3.7 g, 95 mmol) was added in pieces over 1–5 minutes, and stirring was continued for an additional 10 minutes. Anhydrous lithium bromide (95 mmol) was then added, and the mixture was stirred at -78° for 40 minutes. The ammonia was then evaporated over several hours and the resulting paste was methylated by the addition of methyl iodide (13.5 g, 95 mmol) with stirring at 0–10° for 40 minutes. Salt solution was added followed by extraction with ether. Further washing followed by drying over sodium sulfate, evaporation, and distillation, gave pure 1-acetyl-1-methylcyclohexa-2,5-diene (4.8 g, 80%), bp 72.2° (18 mm).

5.1.1.10. 2-Methoxy-1-methylcyclohexa-2,5-diene-1-carboxylic Acid (Addition of Potassium *tert*-Butoxide prior to Reduction to Suppress Overreduction and Loss of a Methoxy Group) (134)

Potassium *tert*-butoxide (5.6 g, 0.05 mol) was added to a stirred solution of 2-methoxybenzoic acid (7.6 g, 0.05 mol) in dry tetrahydrofuran (50 mL), followed by *tert*-butyl alcohol (4.0 mL, 0.05 mol) and liquid ammonia. The mixture was cooled to -70° , and potassium metal (4.89 g, 0.125 mol) was added in small pieces until a deep blue color persisted for more than 5 minutes. The color was discharged by the addition of a drop of 1,3-pentadiene, then a solution of methyl iodide (15.5 mL, 0.25 mol) in tetrahydrofuran (50 mL) was added. The ammonia was removed in a stream of 3, and 200 mL of sodium chloride solution was added. The product was extracted with methylene chloride while the pH of the mixture was progressively reduced to 4 by the addition of 1 M HCl. Drying (Na_2SO_4), evaporation of solvent, and distillation gave 2-methoxy-1-methylcyclohexa-2,5-diene-1-carboxylic acid (4.6 g, 84%) as a homogeneous colorless gum. ^1H NMR: δ 1.24 (s, 3H), 2.80 (brs, 2H), 3.52 (s, 3H), 4.81 (t, 1H), 5.64–5.83 (m, 2H).

5.1.1.11. Ethyl 1,4-Dihydrobenzoate (Reduction of an Aromatic Carboxylic Acid Ester Containing 1.25 Equivalents of Water) (229)

Ethyl benzoate (7 g, 46 mmol) and water (1.2 mL, 69 mmol) were dissolved in 75 mL of tetrahydrofuran and added to 150 mL of anhydrous ammonia under inert gas at -78° . Sodium metal (2.67 g, 116 mmol) was then added in pieces and the reaction was stirred for 25 minutes. The mixture was then pumped through a glass tube into a large excess of NH_4Cl solution, and the product was separated by ether partition. Microdistillation afforded ethyl 1,4-dihydrobenzoate (64%) as a colorless oil: bp 54–56° (0.35 mm).

5.1.1.12. (2'S,
6R)-1-Methoxy-6-methyl-6-([2'-*(methoxymethyl)pyrrolidinyl*]carbonyl)-1,4-cycl
ohexadiene (*Reductive Alkylation of a Chiral Benzamide*) (39)

A solution of 1-([2S]-methoxymethylpyrrolidinyl]carbonyl)-2-methoxybenzene (0.25 g, 1.0 mmol) in dry tetrahydrofuran (5 mL) and *tert*-butyl alcohol (74 mg, 1.0 mmol) was cooled to -78°, and anhydrous ammonia (60 mL) was added to the reaction mixture. Potassium (86 mg, 2.2 mmol) was added to the stirred solution in small pieces. Methyl iodide (0.28 g, 2 mmol) was added, and resulting yellow solution was stirred for 1 hour at -78°. After addition of NH₄Cl (~0.5 g), the mixture was warmed slowly while the ammonia was removed with a stream of nitrogen. Brine (~20 mL) was added, and the mixture was extracted with chloroform (3 × 20 mL). The combined organic extracts were washed with 10% sodium thiosulfate (20 mL), water (20 mL), and brine (20 mL), and then dried over anhydrous magnesium sulfate. Evaporation of solvents provided the crude product as a 260:1 mixture of diastereomers (GC analysis). Flash chromatography (silica gel, ethyl acetate–hexane, 3:2) gave (2'S,

6*R*-1-methoxy-6-methyl-6-([2'-(methoxymethyl)pyrrolidinyl]carbonyl)]-1,4-cycl
ohexadiene (0.23 g, 85%) as a colorless oil. ¹H NMR (CDCl₃): δ 1.42 (s, 3H), 1.68–2.00 (m, 4H), 2.73–3.01 (m, 2H), 3.22–3.38 (m, 5H), 3.53 (s, 3H), 3.60–3.68 (m, 2H), 4.32 (m, 1H), 4.67 (t, 1H), 5.53 (dt, 1H), 5.77 (m, 1H).

6. Tabular Survey

The computer search of *Chemical Abstracts* covers the literature to the end of 1988, although some later papers as well as those that appeared to mid-1989 have also been included. About 40 compounds reported in patents without indication of experimental condition are not included in the tables. Tables I to VII contain examples of reduction of aromatic compounds according to their functionality. A similar division is followed for Tables VIII to XII covering reductive alkylation reactions. All compounds which contain heteroatoms in a ring (not necessarily in the aromatic ring) are treated as aromatic heterocycles. Table XIII contains examples of reduction (or reductive alkylation) of aromatic amines, alcohols, acetals, phosphines, and nitriles which were sporadically reported in the literature. Within each table the compounds are listed according to increasing carbon atom numbers using the *Chemical Abstracts* convention. Carbon atom(s) and hydrogens of R in the ester group CO₂R as well as benzyl (OBn), methanesulfonyl (OMs), tetrahydropyranyl (OTHP), or acetyl (OAc) groups which undergo hydrolysis during reduction are not counted. The reaction condition columns include the type of metal (number given in parentheses represents molar equiv. of metal per 1 mol of aromatic reactant, if reported), solvent, reaction time, and temperature (°C) if provided in references. The reaction temperature is given only if it differs from the reflux temperature of ammonia (−33°). The notation M/ NH₃ indicates that the substrate was added to the metal–ammonia solution, while NH₃/M means that the metal was added last. In the quenching agent column, other reactants are also given that are required to convert the primary reduction product into the one actually isolated. Alkylating agents are listed according to increasing carbon atom numbers. Yields are given in parentheses and are based on either isolation or GC analyses (marked with asterisk). A dash (—) indicates that no yield information was reported. In some cases, yields have been calculated by the authors from the literature data. Numbers not in parentheses are the product ratios. When a reaction has been reported in more than one publication, the conditions producing the highest yields are given, and the reference to that paper is listed first.

The following abbreviations are used in the tables:

Ac	acetyl
Am	amyl
Bn	benzyl
Bu	butyl
DME	1,2-dimethoxyethane
DMF	N,N-dimethylformamide

DMSO	dimethyl sulfoxide
equiv	equivalent
Et	ethyl
HMPA	hexamethylphosphoric triamide
LDA	lithium diisopropylamide
M	metal
Me	methyl
MEM	methoxyethoxymethyl
Ms	methanesulfonyl
Ph	phenyl
Pr	propyl
THF	tetrahydrofuran
THP	tetrahydropyran-2-yl
TMEDA	<i>N,N,N',N'</i> -tetramethyl-ethylenediamine
Ts	<i>p</i> -toluenesulfonyl

^a The reaction mixture was pumped (with argon pressure) through a glass tube into a large excess of saturated ammonium chloride solution.^b After stirring the reaction mixture for 20–30 min a trace of FeCl₃ was added and the temperature allowed to increase from -78° to reflux (ca -33°) for the time indicated.^c The yield represents a mixture of *cis* and *trans* isomers.^d A solution of water (6 mmol) in THF (76 mL) was added over 10 min (half quench) to the product of lithium-*p*-terphenyl interaction (without cosolvent), followed by addition of excess of solid NH₄Cl.

^a Metal and alcohol were added slowly in alternating proportions to the reaction mixture.

^b Alcohol was added slowly to the reaction mixture until the color disappeared.

^c The use of 1,2:5,6-di-O-isopropylidene- α -D-glycopyranose (G) as the proton source caused asymmetric reduction.

^d The mixture, after removal of the ammonia, was mixed with dry methanol. Hydrogen chloride gas was passed into the solution until the pH became 1.

R = C₂H₄O₂ ketal

^a 2-Methoxybenzoic acid with Li (3)/NH₃ showed (NMR) about 70% loss of OMe. The presence of MeOH produces 2-methoxy-1,4-dihydrobenzoic acid with little loss of OMe.

^b Sodium metal was added to the reaction mixture over 3 h.

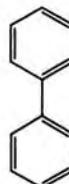

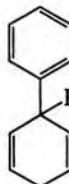

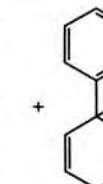

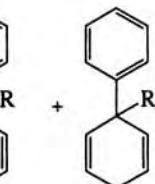

^c An ammonia-THF solution of this compound was treated with 1 equiv. of t-BuOK before normal Birch reduction.

^a The reaction mixture was pumped (argon pressure) through a glass tube into a large excess of alkyl halide in THF (inverse quench).

^b The yield represents a mixture of *cis* and *trans* isomers.

^c The yields were based on biphenyl converted and measured by peak area on GLC.

^d A solution of water in THF (half quench) was added to the reaction mixture over 10 min, then a stream of methyl bromide was passed through a column of 50% silica gel-sand into the reaction vessel until the color of the solution was discharged.

^a The ammonia was evaporated during 1-4 h, and the resulting pasty mixture was alkylated by adding alkyl halide and stirring the mixture at 0-10° for 40 min.

^b Yields were measured by peak area on GC; the difference from 100% represents starting material, propio- and isobutyrophenone.

^c The resulting blue solution was mixed with anhydrous lithium halide (2.2 equiv) and stirred at -78° for 40 min.

^d After 20 min, alkyl halide and aqueous THF (1:1) were added simultaneously to the reaction mixture.

^e The yield represents a mixture of both isomers.

^a After stirring for 1 h the solution was treated with *tert*-butyl alcohol. Lithium wire was again added to maintain the blue color, and after 20 min ammonium chloride was added.

^b After addition of alkyl halide the resulting solution was stirred for 1 h at -78°. It is essential to quench the alkylation reaction mixture with excess ammonium chloride before evaporation of ammonia.

^c The yield represents a mixture of *cis* and *trans* isomers.

^d The solution was cooled to -70° and dry methyl iodide was added dropwise. After 15 min the colorless solution was treated with solid ammonium chloride.

^a After stirring for 1 h, solid ammonium chloride (1.2 equiv) was added and then the mixture was stirred for an additional 30 min. Then excess alkylating agent was added slowly into the reaction mixture and it was stirred for an additional 1 h.

^b The deep blue-green solution was cooled to ca -70° and the appropriate alkylating agent was introduced from a syringe.

^c Before alkylation 1,3-pentadiene (2-3 drops) was added to the reaction mixture to destroy the excess metal.

^d The yield represents a mixture of *cis* and *trans* isomers.

R = C₂H₄O₂ ketal

^a After addition of alkyl halide, the resulting yellow solution was stirred for 1 h at -78°. It is essential to quench the alkylation reaction mixture with excess NH₄Cl before evaporation of ammonia.

^b An ammonia-THF solution of this compound was treated with 1 equiv of *t*-BuOK before normal Birch reduction. Pretreatment with one equiv of base completely prevents hydrogenolysis in most cases.

^c Before alkylation 1,3-pentadiene (2-3 drops) was added to the reaction mixture to destroy excess metal.

^d Alkyl halide and 1,2-dibromoethane were added in one portion to the reaction mixture.

^e The ammonia was removed before alkylation.

^f The resulting 1,4-dihydro derivative was subsequently alkylated by treatment with lithium diisopropylamide (LDA) at -78° (0.5 h, THF) followed by alkyl halide.

^g The resulting blue solution was mixed with anhydrous lithium halide and stirred at -78° for 40 min.

^h The ammonia was evaporated during 1-4 h and the resulting pasty mixture was alkylated by adding alkyl halide and stirring the mixture at 0-10° for 40 min.

ⁱ After 20 min alkyl halide and aqueous THF (1:1) were added simultaneously to the reaction mixture.

^j Metal was added to the reaction mixture in small portions over 2 h.

^k The yield represents a mixture of *cis* and *trans* isomers.

R¹, R² = *o*-MeC₆H₄

R¹, R² = *p*-Me₂NC₆H₄

^a After addition of alkyl halide the yellow solution was stirred for 1 h at -78°. It is essential to quench the alkylation reaction mixture with excess NH₄Cl before evaporation of ammonia.

^b The reaction was performed with a high concentration of lithium in ammonia (ca 4 M).

^c Ethanol was added to the reaction mixture at 30-min intervals until the solution was decolorized (ca. 1.75 h).

^d Slightly better yields were obtained if the naphthoxide anion was formed by reaction of the substrate with sodium hydride before addition to a solution of the metal in ammonia.

7. Acknowledgments

We thank the Division of Chemical Sciences, Office of Basic Energy Sciences of the U.S. Department of Energy for financial support. We are also eternally grateful to Sharon Fricke who prepared the manuscript. Finally, special thanks to Professor Ronald G. Harvey.

The Mitsunobu Reaction

David L. Hughes, Merck Sharp and Dohme Research Laboratories, Merck and Co., Inc.,
Rahway, New Jersey

1. Introduction

Alkyl and aryl phosphites and phosphines react with compounds having weak heteroatom–heteroatom bonds, such as S—S, O — O, etc., and with azo compounds to form reactive phosphonium salts. These phosphonium salts in turn promote “redox” condensation reactions with compounds having active hydrogens. The condensation reaction of alcohols using the redox couple of a triaryl- or trialkylphosphine and a dialkyl azodicarboxylate has become known as the Mitsunobu reaction, based on his pioneering work in the late 1960s. (1-3) The overall reaction is summarized in Eq. 1, wherein the alcohol (R^1OH) and acidic compound ($H-Nu$) are condensed to form product (R^1-Nu), while triphenylphosphine is oxidized to triphenylphosphine oxide and the azodicarboxylate is reduced to the hydrazine.

Although the typical redox combination is diethyl azodicarboxylate (DEAD) and triphenylphosphine, many other combinations have found selected use. The reaction is generally limited to primary and secondary alcohols, although tertiary alcohols react in a few intramolecular 4a and intermolecular 4b-d reactions. For secondary alcohols the reaction usually proceeds with clean inversion of stereochemistry. The acidic component of the reaction (denoted as $H-Nu$ in Eq. 1) generally has an aqueous $pK_a < 15$, with intramolecular reactions providing the exceptions. Examples of $H-Nu$ include oxygen nucleophiles such as carboxylic acids and phenols; nitrogen nucleophiles such as imides, hydroxamates, and heterocycles; sulfur nucleophiles such as thiols and thioamides; and carbon nucleophiles such as β -ketoesters.

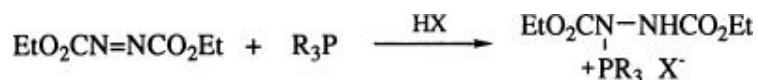

Major reviews of the Mitsunobu reaction were published in 1981 by Mitsunobu (5) and in 1983 by Castro. 6a The former review concentrated on reactions using DEAD/triphenylphosphine, while the latter review focused on reactions in which halogens replaced the hydroxy group using reagents such as triphenylphosphine/carbon tetrachloride, triphenyl phosphite/iodomethane, and triphenylphosphine/N-halosuccinimide. Reactions involving the DEAD/triphenylphosphine redox system are the principal subject of this review,

with emphasis on the literature between 1981 and 1988.

2. Mechanism

In his 1981 review Mitsunobu proposed that the dehydration reactions of alcohols using DEAD and R_3P proceed in three steps: (1) reaction of R_3P with DEAD in the presence of the acid component to form a salt wherein a phosphorus–nitrogen bond is formed; (2) reaction of the DEAD– R_3P adduct with the alcohol to form an activated oxyphosphonium ion intermediate; and (3) displacement via an S_N2 process to form the inverted product and the phosphine oxide. (5) The mechanistic details of each step are discussed below.

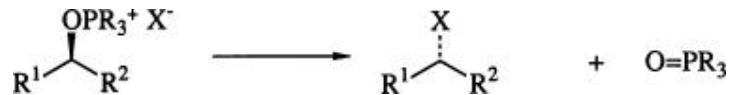

STEP 1: ADDUCT FORMATION

STEP 2: ALCOHOL ACTIVATION

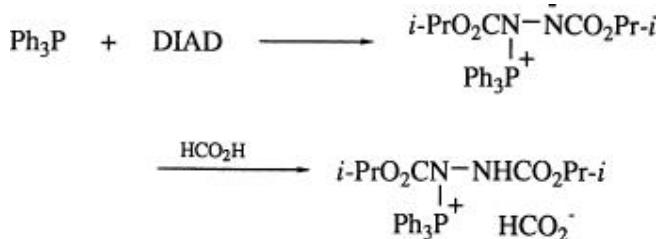

STEP 3: S_N2 REACTION

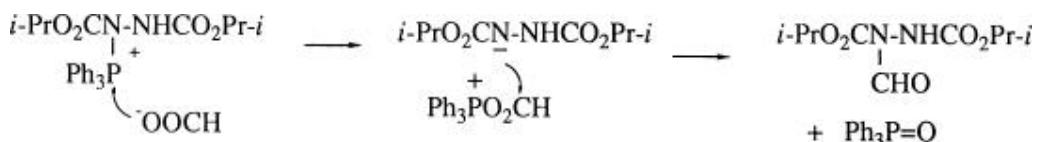

2.1.1. Step 1: Adduct Formation

The reaction of triphenylphosphine and DEAD or diisopropyl azodicarboxylate (DIAD) in methylene chloride or tetrahydrofuran proceeds rapidly to form a colorless zwitterionic adduct, which in the presence of formic acid yields the azaphosphonium formate. The reaction is irreversible since treatment

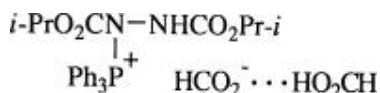

of the adduct with tri-*n*-butylphosphine does not lead to phosphine exchange.
6b

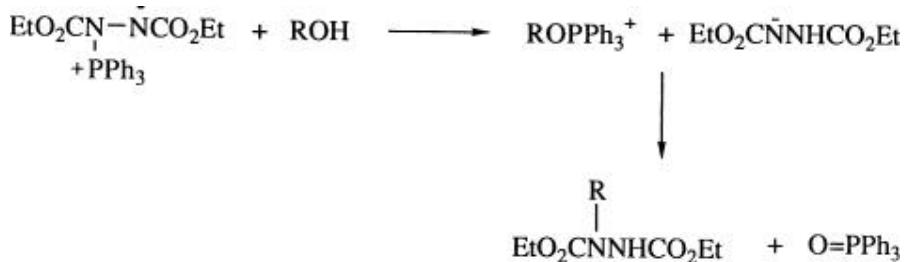

The azaphosphonium formate is unstable with respect to formation of the *N*-formyl hydrazide (10 minutes at 25°) and triphenylphosphine oxide. Acetic acid behaves similarly. (7) This mode of adduct decomposition could be a major

reason for poor yields in Mitsunobu reactions run with sterically small acids having nucleophilic carboxylates when the reagent ratios are 1:1:1. The Mitsunobu reagent can be stabilized by employing triphenylphosphine:DIAD:formic acid in a ratio of 1:1:2, wherein the extra mole of acid hydrogen bonds to the formate ion to reduce its nucleophilicity and afford a reagent having a *t*_{1/2} of 15 hours at 25°. (7) When the Mitsunobu reagent is formed in the presence

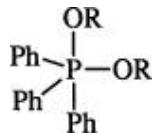

of a sterically unhindered alcohol and no carboxylic acid, *N*-alkylated products arise. (7)

The Mitsunobu reagent has been shown to have a P — N bond, as opposed to a P — O bond or heterocyclic structure, by IR C = O stretching frequencies and ^{31}P NMR isotope shifts induced by ^{15}N -DIAD. (8, 9)

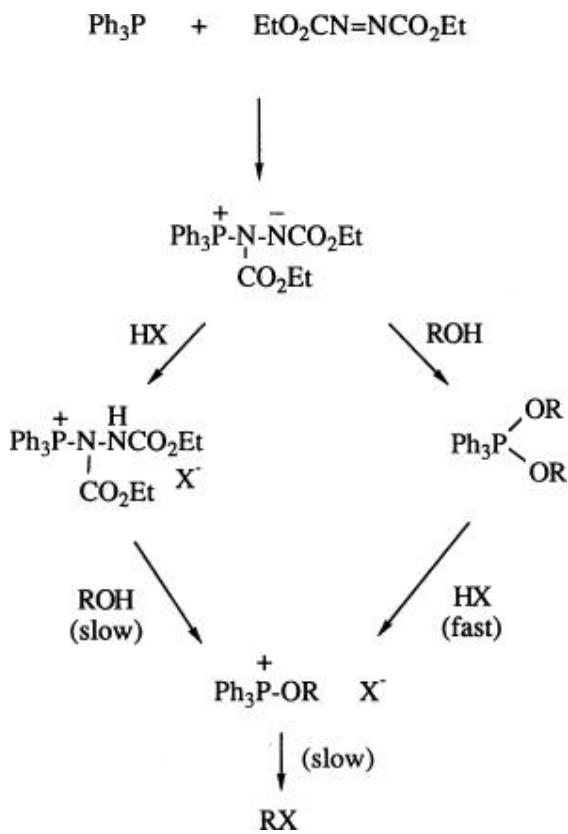

2.1.2. Step 2: Alcohol Activation

The structure of the activated alcohol species in the Mitsunobu reaction is still under debate, and is dependent on the nature of the substrate and reaction conditions. In his 1981 review Mitsunobu proposed that the activated species was an oxyphosphonium salt. (5) As support for this mechanism, stable oxyphosphonium salts were subsequently isolated and characterized from Mitsunobu reactions involving hindered carbohydrate alcohols, (10) and they have been generated electrochemically. (11) However, the existence of the oxyphosphonium salt intermediate has been questioned. NMR studies of the reaction of triphenylphosphine, DEAD, and alcohols indicate that the key intermediate is the pentavalent dialkoxyphosphorane. (12-14) Using 3,4-dichlorophenol

as the alcoholic component, a diaryloxyphosphorane can be isolated as a crystalline compound. (15) Treatment with an acid affords an ester and triphenylphosphine oxide, leading to the claim that the activated species in the Mitsunobu reaction must be the phosphorane, which on reaction with an acid affords the ester, an alcohol for recycle, and phosphine oxide.

Since the phosphorane was generated in the absence of the acid component of the system, a revised mechanism for the reaction was proposed. (16a) In the presence of the acidic component the reaction proceeds as postulated by Mitsunobu via the oxyphosphonium ion intermediate, with formation of that intermediate and its subsequent $\text{S}_{\text{N}}2$ reaction being the slow steps. However, in the absence of acid, the dialkoxyphosphorane is formed. Addition of acid results in the rapid formation and subsequent reaction of the oxyphosphonium salt, and regeneration of a mole of the alcohol. This is recycled via the original

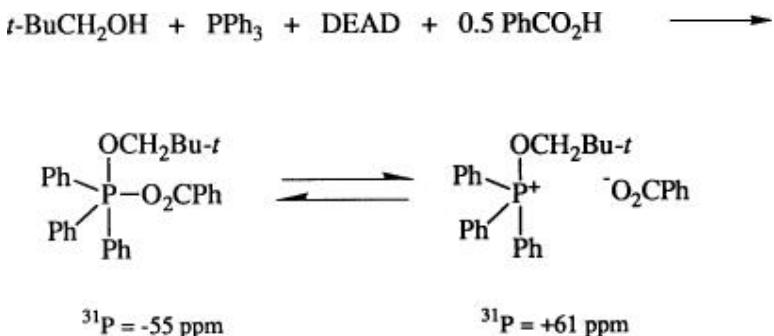

mechanism since acid is present. Thus under these conditions part of the reaction proceeds via the phosphorane and part via the oxyphosphonium salt.

Two subsequent studies have shown that even in the presence of acid, phosphoranes can be formed. [16b,c](#) When one equivalent each of benzoic acid, triphenylphosphine, and DEAD, and two equivalents of ethanol are mixed at -78° in tetrahydrofuran, peaks corresponding to both the phosphorane and the oxyphosphonium salt are observed by ^{31}P NMR. [16b](#) In a similar experiment with isopropyl alcohol, the oxyphosphonium salt is the major species, with only a trace of the phosphorane observable. [16b](#) Similarly, with the hindered neopentyl alcohol and diacetone glucose, both phosphorane and oxyphosphonium salt were observed at 0° in the presence of benzoic acid. [16c](#) These data suggest that an equilibrium mixture of phosphorane and oxyphosphonium salt exists, with the nature of the alcohol, solvent, and acid determining the equilibrium concentrations.

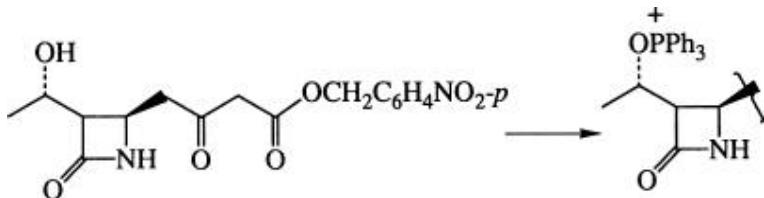

In addition, a third species, an (acyloxy)alkoxyphosphorane, has been suggested, based on NMR data. [16d](#) When neopentyl alcohol is treated at 0° in tetrahydrofuran with one equivalent of triphenylphosphine and one equivalent of DIAD, followed by 0.5 equivalent of benzoic acid, a ^{31}P NMR peak is observed at -11 ppm. This peak is roughly midway between that expected for an oxyphosphonium salt ($+60$ ppm) and that expected for a

phosphorane (-50 to -60 ppm). As the temperature is lowered, the peak becomes broader and coalescence occurs at -90° . At -100° two peaks appear, a downfield peak at $+61$ ppm ascribed to the oxyphosphonium salt, and an upfield peak at -55 ppm ascribed to the (acyloxy)alkoxyphosphorane. The equilibrium

constant between the two species was found to be highly sensitive to solvent and proton sources. Polar solvents such as acetonitrile favor the ion pair. The ion pair is also favored by addition of protic sources such as excess alcohol, benzoic acid, or diisopropyl hydrazine-1,2-dicarboxylate. [16d](#)

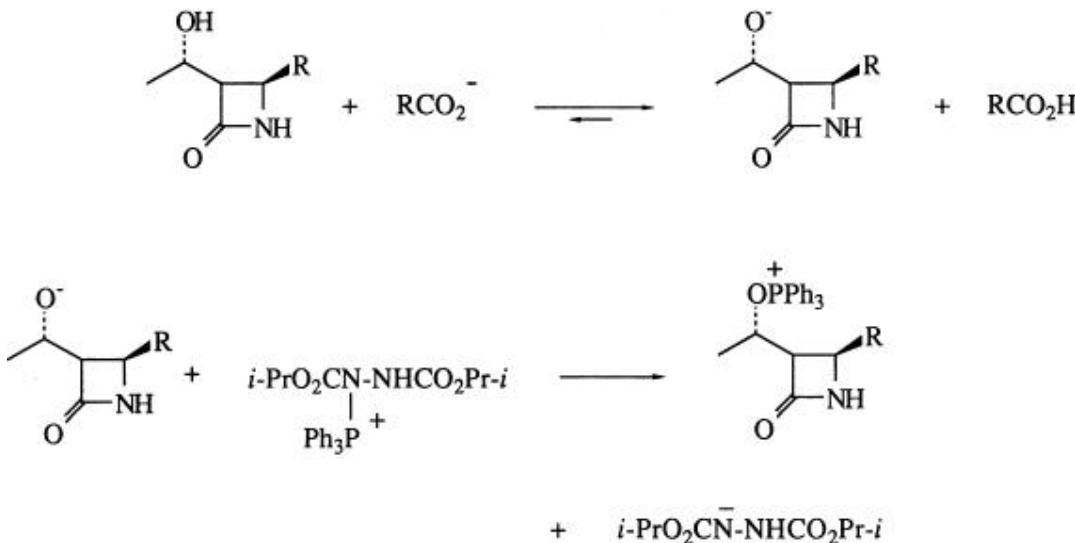

Although three activated alcohol species may be involved as intermediates in the Mitsunobu reaction, the oxyphosphonium salt is most likely the key intermediate involved in the displacement of triphenylphosphine oxide leading to product. In a study of the Mitsunobu reaction used to invert the hydroxy center in a thienamycin total-synthesis intermediate, the oxyphosphonium intermediate is the only activated alcohol species observable by NMR. [\(7\)](#) The parameters controlling its formation were clarified.

Three factors control the rate of alcohol activation via the oxyphosphonium salt: (1) the basicity of the carboxylate generated in the formation of the Mitsunobu reagent; (2) the extent of hydrogen bonding to the carboxylate; and (3) substituent effects in the triarylphosphine. [\(7\)](#)

The carboxylate functions as a base to deprotonate the alcohol before $-\text{Ph}_3\text{P}$ transfer takes place. Examination of the rate of oxyphosphonium ion

intermediate formation as a function of pK_a of the acid component affords a linear plot of pK_a vs. log rate with a slope of 1.25, indicating a high degree of sensitivity of the activation to carboxylate basicity. Using very strong acids with weakly basic carboxylates, such as trifluoroacetic acid, results in very slow formation of intermediate. Use of formic acid in the azetidinone intermediate

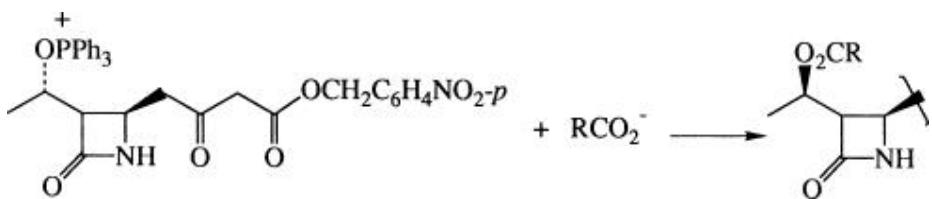

inversion and increasing the $\text{HCOOH}/\text{HCOO}^-$ ratio from 0.54 to 2 affords a 170-fold decrease in the rate of oxyphosphonium ion formation. The principal cause of this effect is the solvation of the formate on by formic acid, thereby reducing the effective basicity of the formate ion. This is the same effect that is used to stabilize the Mitsunobu reagent. The two effects must be properly balanced for a successful Mitsunobu reaction.

With substituted triarylphosphines, a classical Hammett effect is noted for the rate of activated species formation, with a rho of 1.5. (7)

2.1.3. Step 3: S_N2 Reaction

With the azetidinone intermediate as a substrate and formate as the nucleophile, the Mitsunobu reaction proceeds with at least 200:1 stereochemical inversion. The reaction of the oxyphosphonium intermediate with various carboxylates shows only a small effect of carboxylate basicity on the S_N2 reaction rate ($\beta_{\text{Nu}} = 0.1\text{--}0.15$). This indicates that the transition state for the displacement has considerable S_N1 character with much bond breaking and little bond formation. Thus, although formate is excellent for formation of the oxyphosphonium ion intermediate and trifluoroacetate is poor, they behave similarly in the S_N2 step. (7) An unusual salt effect occurs in the S_N2

reaction. The reaction appears to be zero in formate as the rate of S_N2 reaction remains relatively constant when the concentration of formate ion is increased. However, in the presence of a swamping salt, the reaction displays normal second-order kinetics. Since the ionic intermediates in the S_N2 reaction afford neutral products, addition of excess formate to this step stabilizes the intermediates, and fortuitously, the rate enhancement expected by addition of formate is balanced by the retardation caused by the increase in ionic strength.

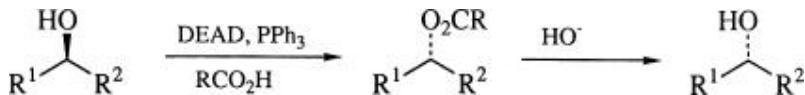

In summary, the effectiveness of the Mitsunobu reaction is quite surprising given the complexity of its mechanism. The poor yields obtained in many of the reactions reported in the literature can be traced to the failure to successfully execute one of the three key steps in the reaction.

3. Scope and Limitations

3.1. Carbon–Oxygen Bond Formation

3.1.1.1. Ester Formation

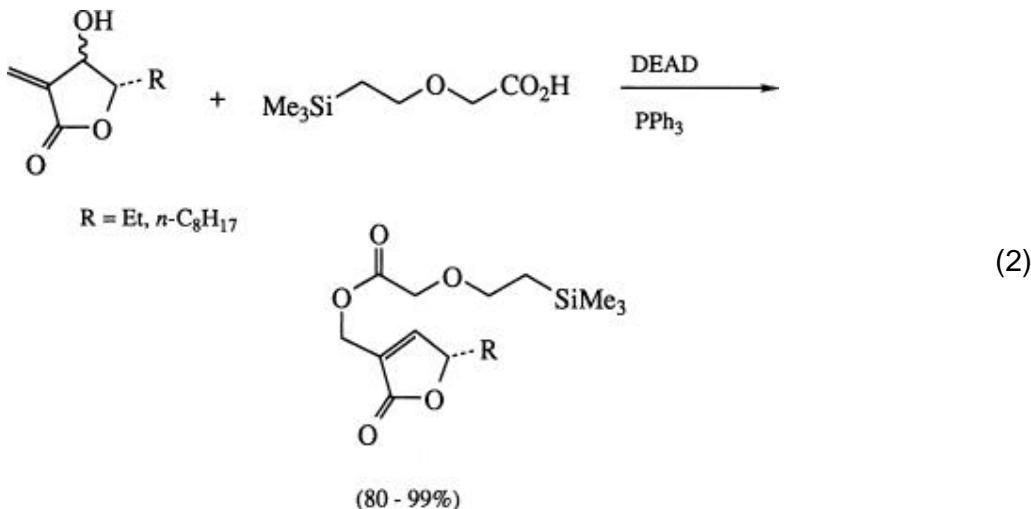

The major use of the Mitsunobu reaction is to invert optically pure secondary alcohols via formation of inverted esters. The reaction is compatible with a wide range of functional and protecting groups,

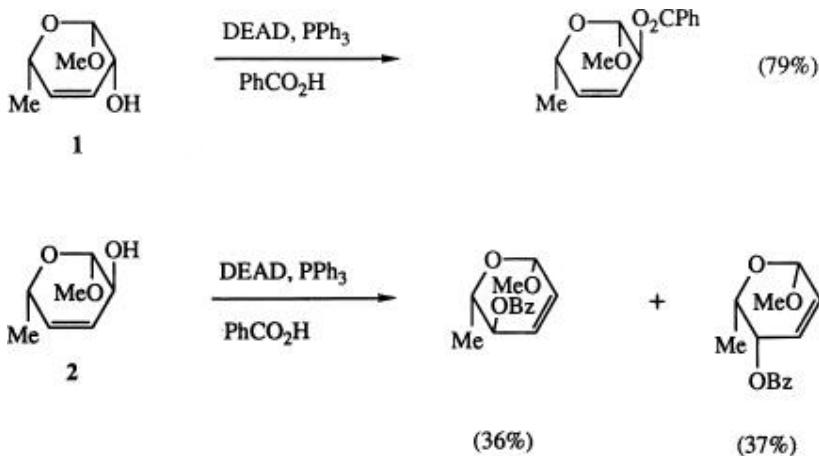

including β-lactams; (17-32) acetals; (33-42) azides; (43) thioethers; (20, 26, 31, 44-47) trimethylsilyl (TMS), (48, 49) triethylsilyl (TES), (50, 51) and *tert*-butyldimethylsilyl (TBS) ethers; (52-58) chlorides; (55, 59) iodides; (59-61) acetylenes; (62-65) C — Si bonds; (66-69) carbobenzyloxy (Cbz); (70, 71) *tert*-butoxycarbonyl (*t*-Boc); (72-74) tetrahydropyranyl (THP), (75-78) sulfones; (28, 57, 58, 79) O-alkyl oximes; (80) dithianes; (76, 81-83) allenes; (84) trichloroethyl; (85) cyclopropenes; (86) C — Hg bonds; (87) trityl; (88, 89) dichlorocyclopropanes; (90) nitriles; (91-93) methoxyethoxymethyl (MEM) and methoxymethyl (MOM) ethers; (48, 49, 94, 95) 1,2-dioxetanes; (96) diazo; (22) nitro; (22-24, 31, 97-99) and tosyl. (100, 101)

3.1.1.2.1. Esters of Allyl Alcohols

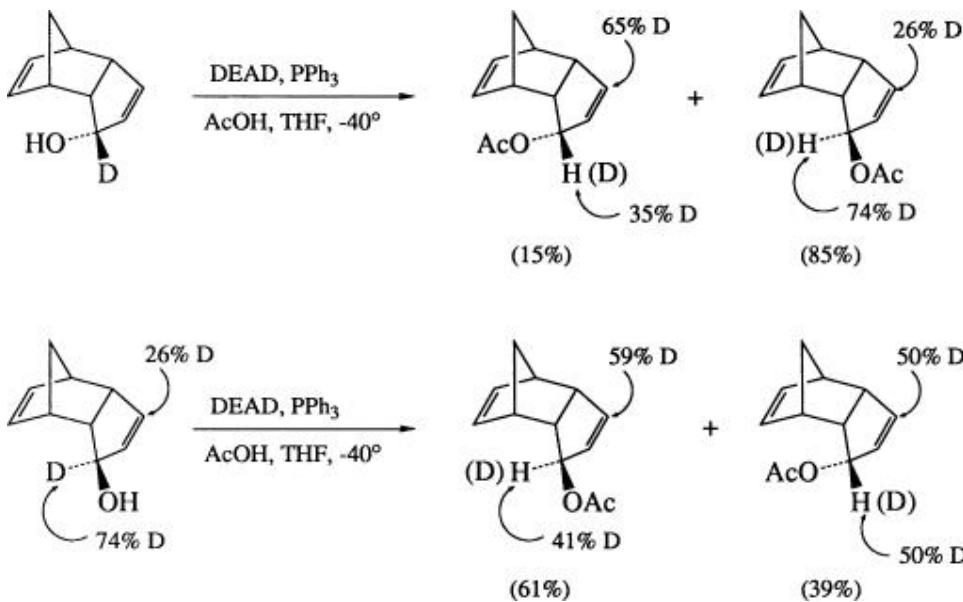

Mitsunobu reaction of allyl alcohols generally provides the inverted S_N2 product. (35, 38, 40, 44, 48, 49, 54, 55, 76, 77, 80, 83, 84, 91, 102-120) However, in a few cases, S_N2 (Eq. 2) (69, 91, 121-124) or S_N1 products (124) are observed.

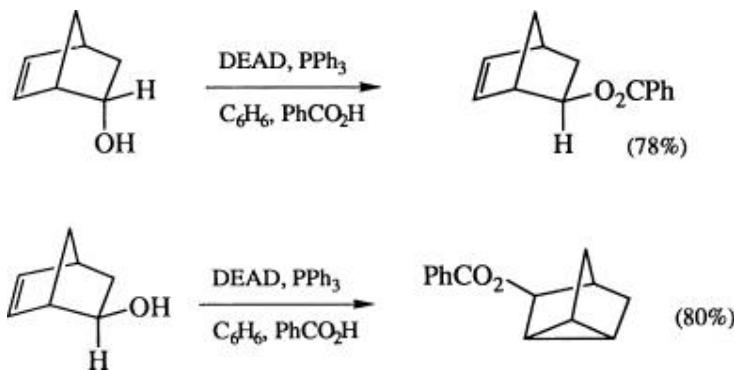

The 1,2-*cis*-pyranoside **1** forms the S_N2 product in 79% yield, but the 1,2-*trans* pyranoside **2** forms the epimeric S_N1' product in equal amounts. (123) The latter reaction apparently proceeds through the allyl carbocation owing to steric hindrance to the incoming nucleophile and to ionization assistance from the anomeric effect of the *trans* methoxy group. Similar results are observed with phthalimide as nucleophile on a similar pyranoside.

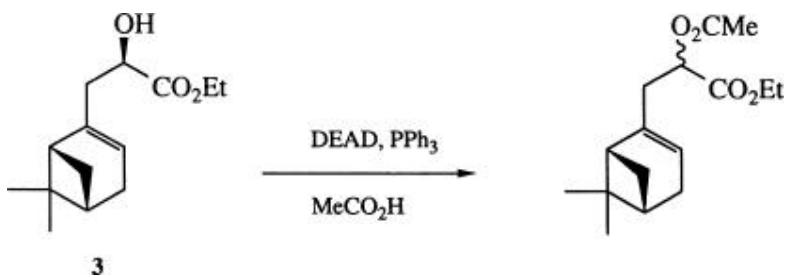

Reaction of dicyclopentadienols results in mixtures of inversion and retention products. 124b Deuterium labelling experiments show that extensive scrambling occurs during the reaction, indicating that competing direct and allylic substitution are occurring. The lack of concentration effects on the ratio of inversion to retention rules out the possibility that retention occurs by an S_N1 mechanism (unimolecular) and inversion by an S_N2 mechanism (bimolecular). The reaction probably proceeds through an allylic cation with steric effects determining the location of nucleophile capture. 124b

2-*endo*-Norbornenol reacts with benzoic acid under typical Mitsunobu conditions to provide the *exo* benzoate in 78% yield. [124c](#) In contrast, the *exo* alcohol furnished only the nortricyclic benzoate in 80% yield, presumably by π participation.

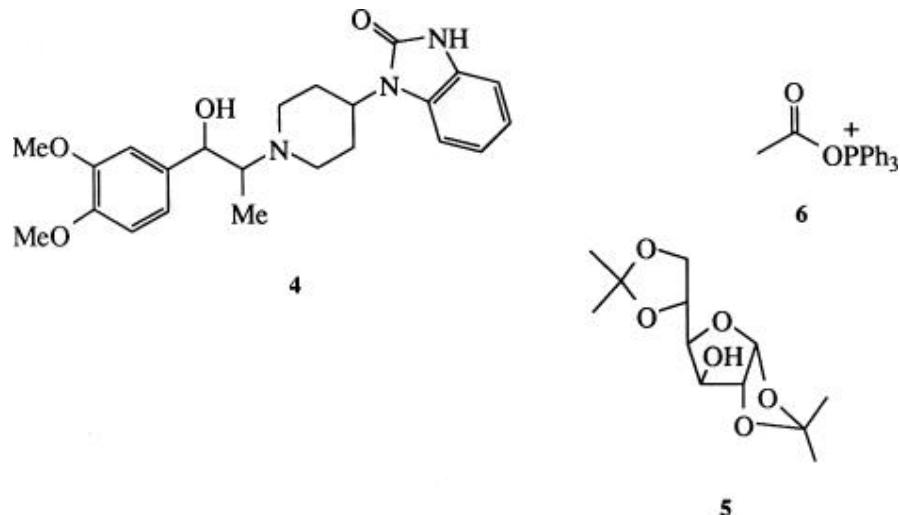

3.1.1.2.2. Esterification of Secondary Alcohols—Retention or Epimerization
 In a few cases secondary alcohols do not proceed with inversion because of an acidic epimerizable center or steric hindrance. The α -hydroxy ester **3** esterifies with complete epimerization. ([125](#)) Preparation of the α -methoxy- α -trifluoromethylphenylacetate (MTPA) ester of 2-hydroxy-3-butanone gives 9% racemization, ([126](#))

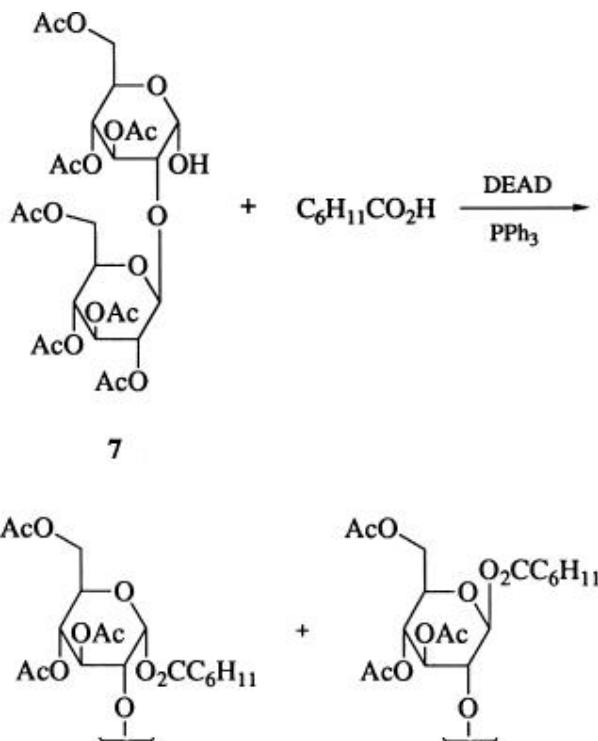

but no racemization occurs in the preparation of these esters with α -hydroxyesters. [127–128](#)

Steric hindrance results in retention of configuration in the reactions of **4** [129–130](#) and **5**. [\(131\)](#) It is postulated that the carboxylic acid is activated to form **6**, which then acylates the alcohol. With hemiacetal **7** complete epimerization

occurs at room temperature, whereas complete inversion occurs at -50° when cyclohexanecarboxylic acid is used to form the ester. [\(50\)](#)

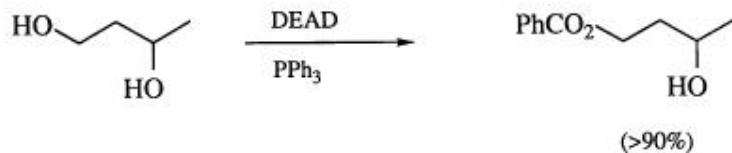

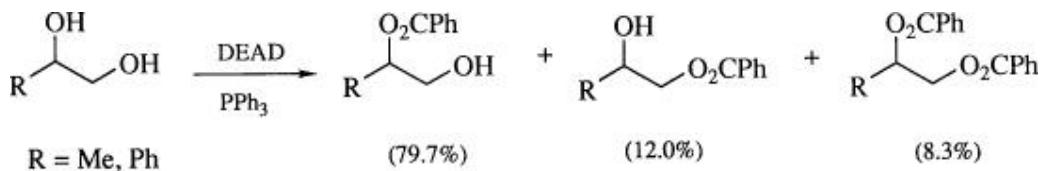

3.1.1.2.3. Aryl Esters

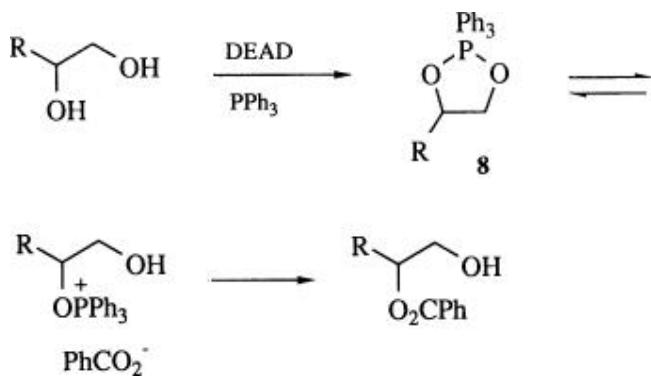

Phenols and carboxylic acids in the presence of triphenylphosphine/ DEAD react to form aryl esters in 67–96% yields. Phenols having both electron-withdrawing and electron-donating groups form esters with acetic acid and benzoic acid in high yields, but do not react with trifluoro- and trichloroacetic acids. (132)

3.1.1.2.4. Polyhydroxylic Compounds

Selective reaction can sometimes be obtained with compounds containing several hydroxy groups. Unexpectedly, 1,2-propanediol and styrene glycol undergo predominant reaction at the secondary center instead of the primary center. (133) 1,3-Diols are esterified predominantly at the primary center. (133) The 1,2-diols form the phosphorane **8**

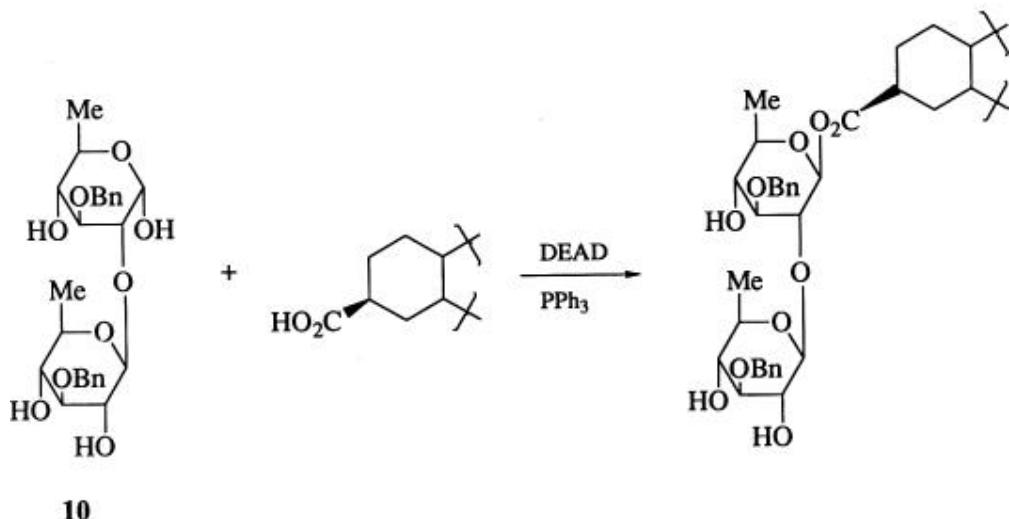

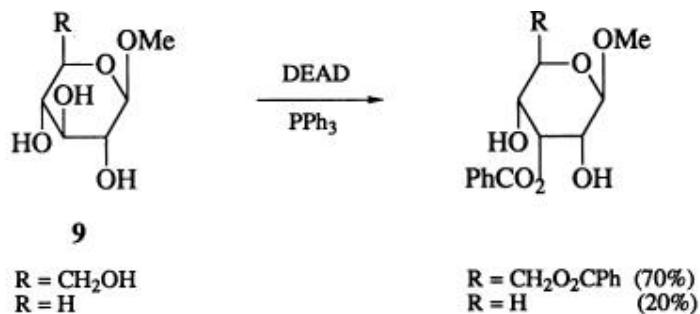

which opens via protonation of the least hindered oxygen to produce the oxyphosphonium salt and leads to esterification of the secondary center. 1,3-Diols form no phosphorane. Instead, the oxyphosphonium salt from the primary alcohol is formed preferentially, leading to ester formation at the primary center. (133)

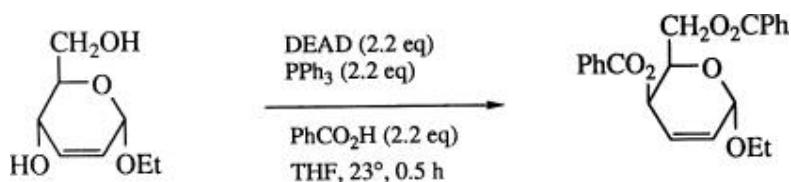

In steroids containing secondary hydroxy groups at the 3 position and at the 7 and/or 12 positions, selective esterification with inversion occurs only at the 3 position. (134-136)

The 3 position of pyranoside **9** is selectively esterified, presumably because of steric effects. (137) The hemiacetal **10** reacts selectively at the more reactive

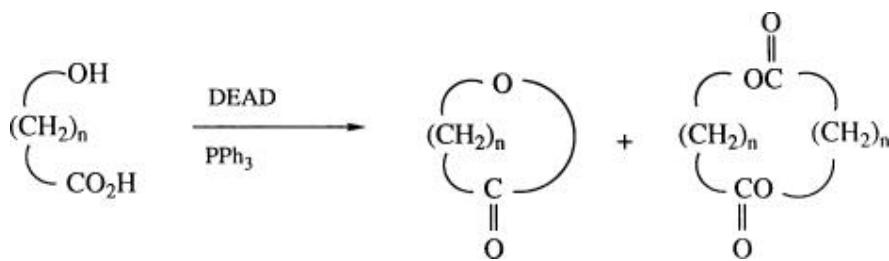

anomeric position to give the inverted ester in 40% yield. (50) Compounds that contain two primary hydroxy groups, 138–139 two secondary hydroxy groups, (37, 43, 78) or a primary and a secondary hydroxy group, (33, 55, 140, 141) are esterified at both centers, given sufficient reagent and reaction time.

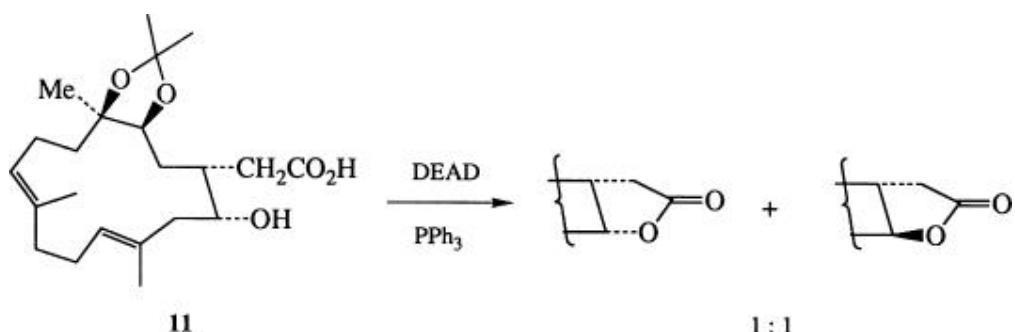

3.1.1.2.5. Lactones

Lactones are prepared by intra- or intermolecular reactions of compounds containing both an alcohol and a carboxylic acid. High dilution favors the intramolecular reaction. As with esterification, inversion at the

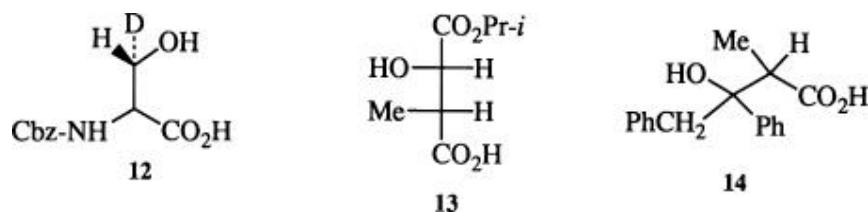

hydroxy center usually occurs, indicating that the hydroxy group is activated and displaced in an intramolecular S_N2 reaction. An exception to this is hydroxy acid **11**, which undergoes complete epimerization. (142) In this case,

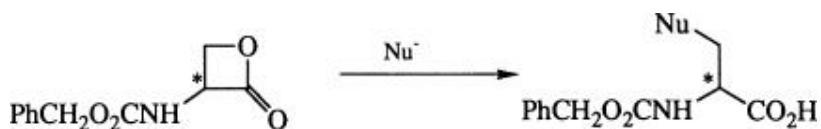

competing carboxy group and hydroxy group activation may be occurring.

Either alkenes or β -lactones result from reaction of β -hydroxy acids, depending on substrate structure and solvent polarity.

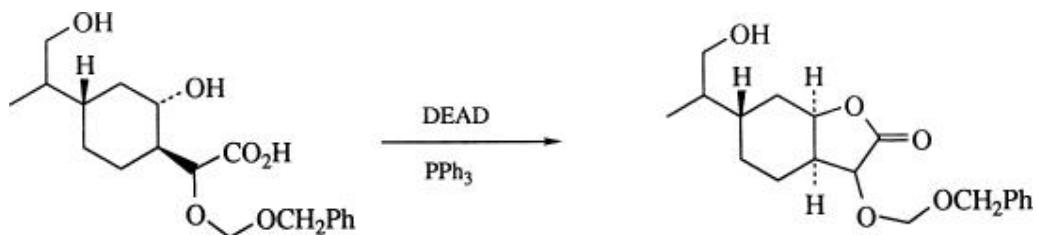

β -Lactones are prepared in good yields at –78°. Stereochemical studies indicate that lactonization of primary (**12**) and secondary (**13**) alcohols proceed by hydroxy group activation (inversion), while tertiary alcohols (**14**) proceed via carboxy group activation (retention). (143-146) β -Lactones prepared from D-

or L-serine derivatives **12** are useful chiral intermediates for formation of a wide variety of α -amino acids. (147-149)

Lactonization of a secondary alcohol is possible in the presence of a primary alcohol under high dilution conditions. (150) Mitsunobu conditions have been

used in the preparation of the natural product macrolactones gleosporone, (151) milbemycin β_3 , (152, 153) colletodiol, (154) vermiculin, (155) and griseoviridin. (156, 157)

3.1.1.2.6. Polymers

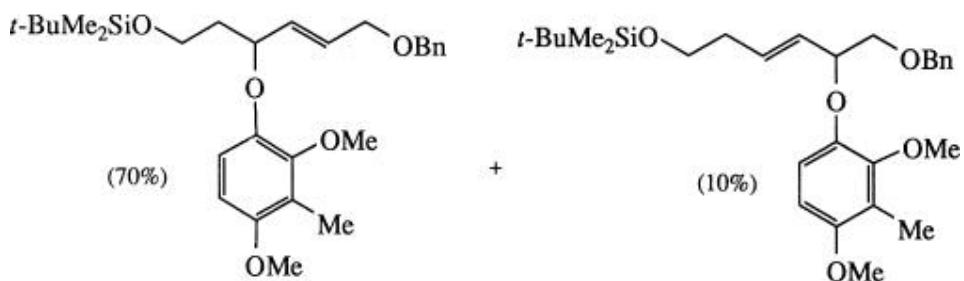

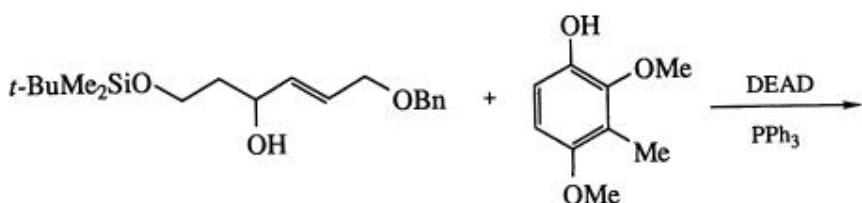

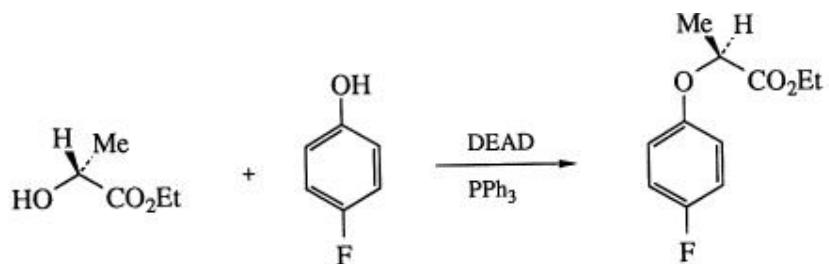

N-Protected amino acids react with *p*-alkoxybenzyl and diphenylmethanol resins to form polymeric esters. (158, 159)

3.1.1.3. Ether Formation

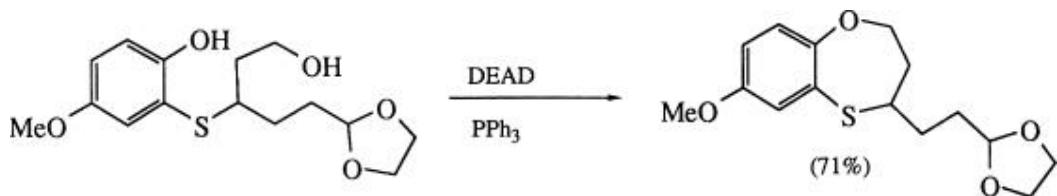

Alkyl aryl ethers, enol ethers, and cyclic dialkyl ethers can be prepared using the Mitsunobu reaction.

3.1.1.3.1. Alkyl Aryl Ethers

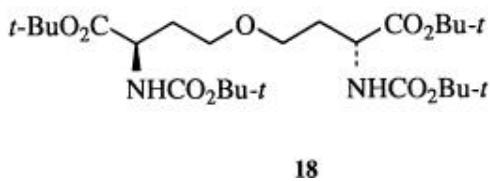

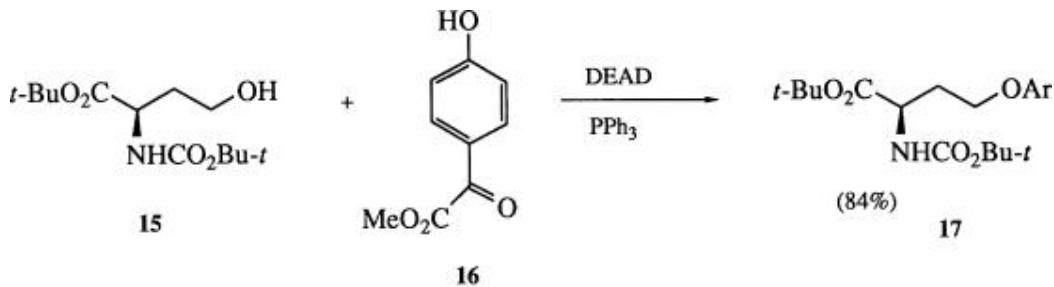

Reaction of a phenol with primary or secondary alcohols in the presence of DEAD/triphenylphosphine produces an alkyl aryl ether. (160, 161) For reaction of secondary alcohols, there is inversion at the hydroxy carbon, (162) indicating that the reaction occurs by activation of the alcohol followed by S_N2 displacement by the phenol. In the reactions of allyl alcohols the S_N2' reaction sometimes competes with the S_N2 reaction. (163)

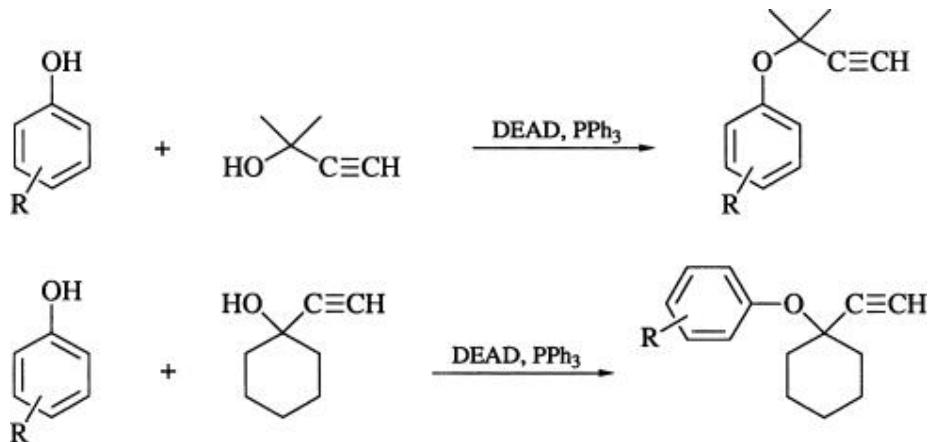

Intramolecular reactions are used to form 6- and 7-membered cyclic ethers.
[\(164-167\)](#)

Reaction of alcohol **15** with phenol **16** gives the coupling product **17** in good yield only when the concentrations of the alcohol and the DEAD/triphenylphosphine adduct are kept low during the reaction. [\(168\)](#) This prevents coupling of the alcohol with itself to form alkyl ether **18**, which otherwise forms in 30–35% yield.

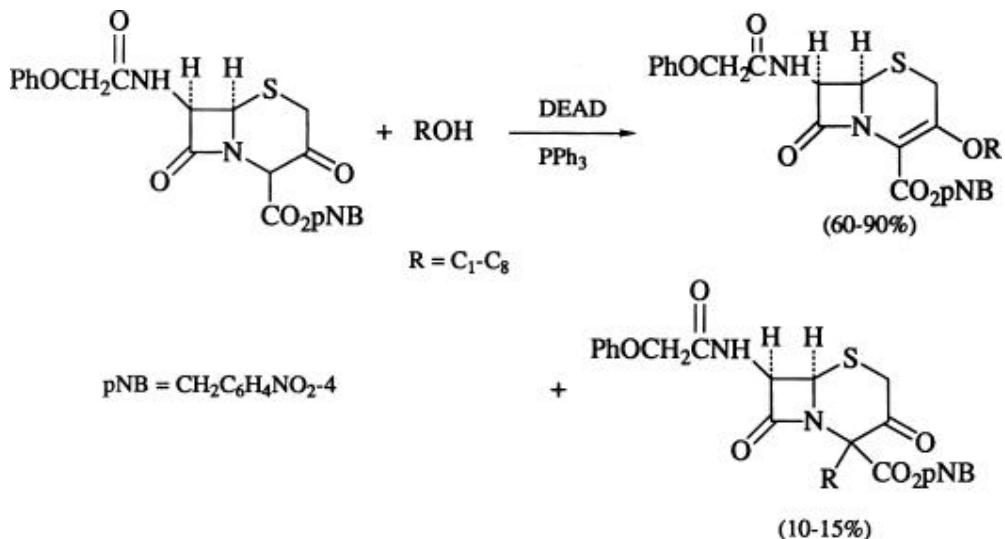

Generally, the Mitsunobu reaction is not successful when tertiary alcohols are used. However, coupling of phenols with several acetylenic tertiary alcohols proceeds in 35–55% yields. [4b,c](#) Since the stereochemistry of the reactions was not determined, the coupling mechanism is not known.

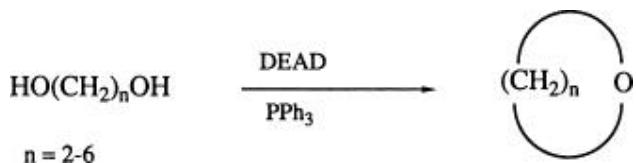

3.1.1.3.2. Enol Ethers

Enol ethers are prepared by reaction of β -ketoesters with alcohols. ([169-171](#)) Further discussion of the factors affecting C-vs. O-alkylation of these compounds is found in the section on ambident alkylations.

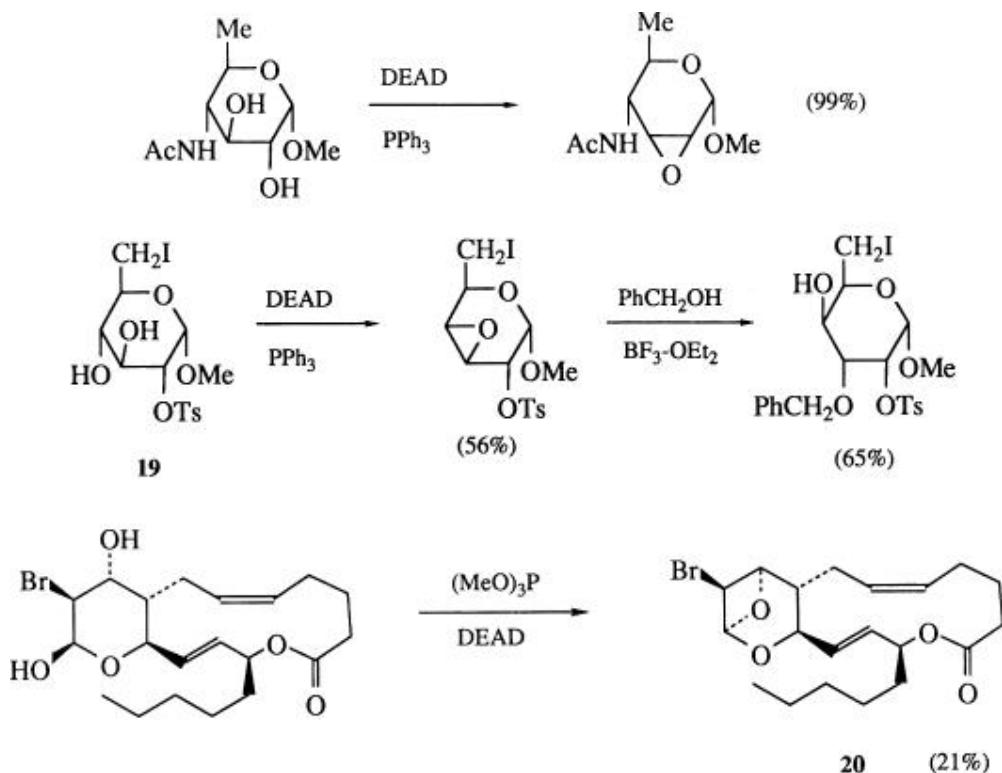

3.1.1.3.3. Dialkyl Ethers

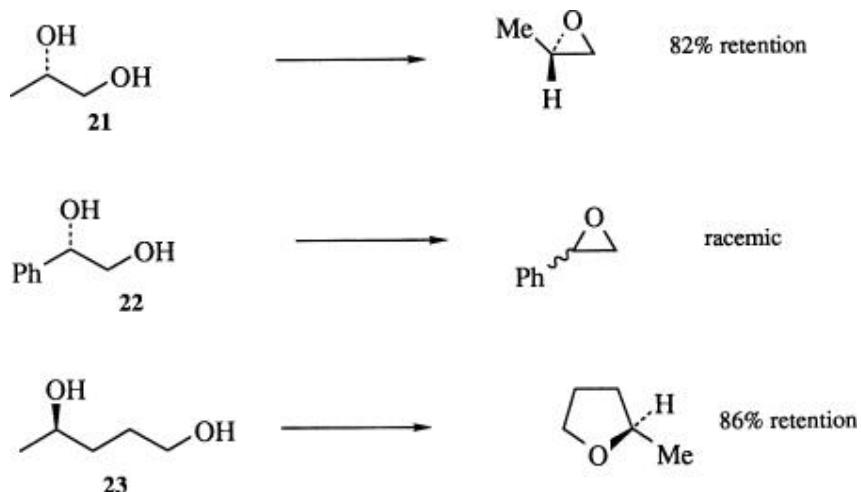

Intermolecular coupling of alcohols with DEAD/triphenylphosphine usually does not occur. Exceptions include the formation of **18** and the use of mercuric bromide to catalyze ether formation between sugars and cyclohexanol. (**172**, **173**) However, intramolecular coupling to make 3-to 7-membered cyclic ethers is a common and high-yield reaction. (**174**) Formation

of epoxides from *trans* 1,2-diols in sugars often occurs stereoselectively, with only one of the two hydroxy groups being activated and replaced because of steric effects. (**175-178**) Formation of epoxide can be used to invert both hydroxy groups of pyranoside **19**. (**179**) Formation of oxetane **20** is a key

step in the synthesis of thromboxane A₂. (180) Epoxidation of chiral diols **21–23** using triphenylphosphine/DEAD, triphenylphosphine/carbon tetrachloride, or diethoxytriphenylphosphine results primarily in retention of configuration in **21** and **23** and racemization in **22**. (181) An explanation of these results is

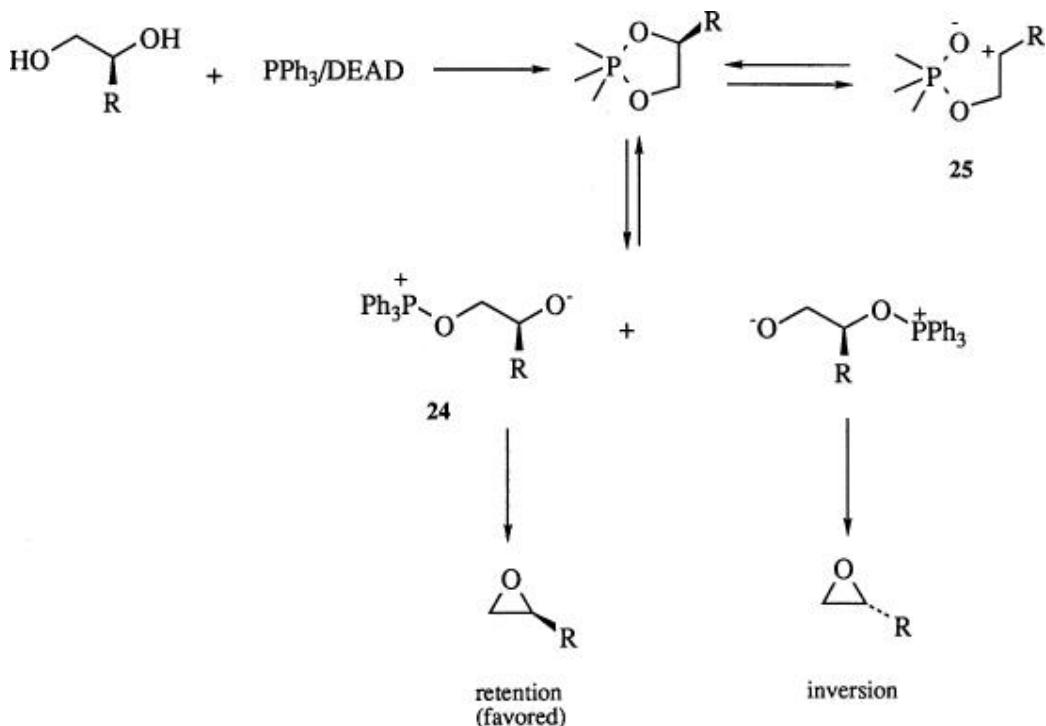

shown in **Scheme 1**. It is postulated that the phosphorane and betaines are in equilibrium. For steric reasons, epoxide formation from collapse of betaine **24** is favored, resulting in retention of configuration. Racemized product may be

due to racemization of the phosphorane via the stabilized carbocation **25**.

(181)

Scheme 1.

The regioselectivity for epoxide formation of 1,2-diols is opposite to that for ester formation (p. 343). Identical phosphorane intermediates are postulated in both cases. For esterification in the presence of a carboxylic acid, the phosphorane must open to give the secondary oxyphosphonium salt to account for the observed findings. In the absence of acid the phosphorane opens to give the primary oxyphosphonium zwitterion, which leads to epoxide formation with retention of configuration.

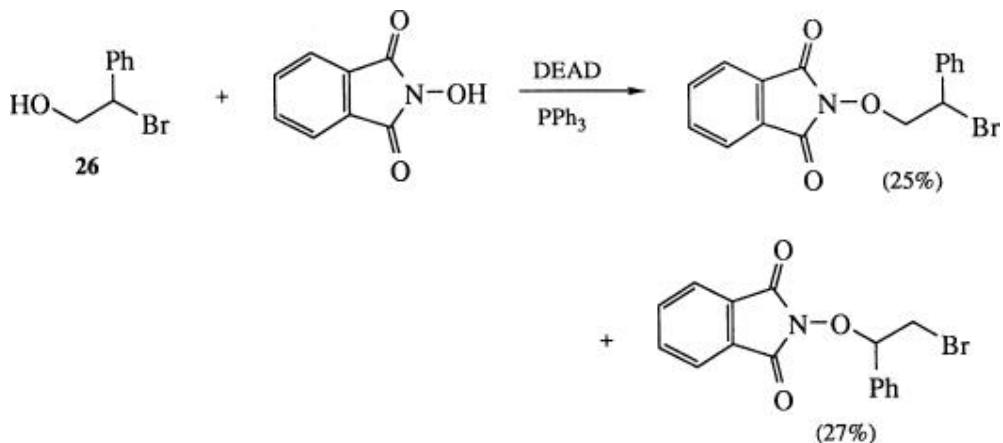

3.1.1.4. Other Oxygen Nucleophiles

Alcohols are converted to tosylates of inverted configuration using lithium tosylate or zinc tosylate and triphenylphosphine/DEAD in yields up to 94%.

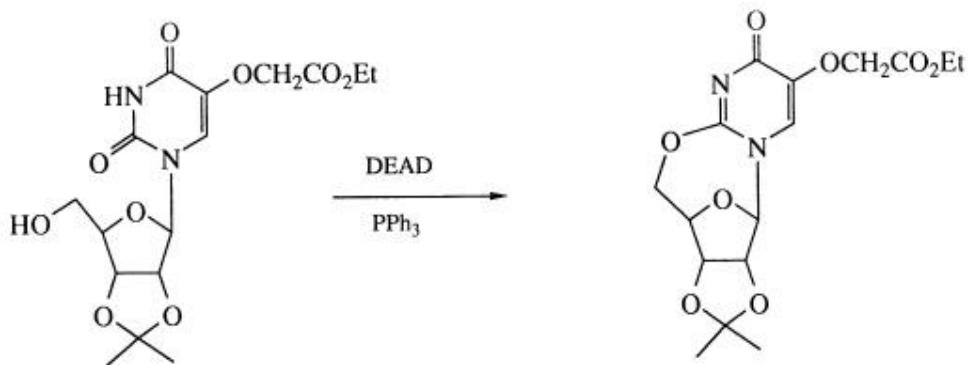

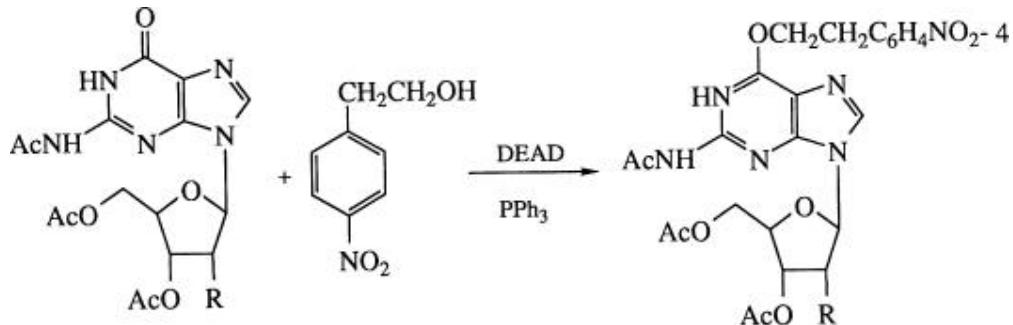

(140, 182) *N*-Hydroxyphthalimide reacts with alcohols and

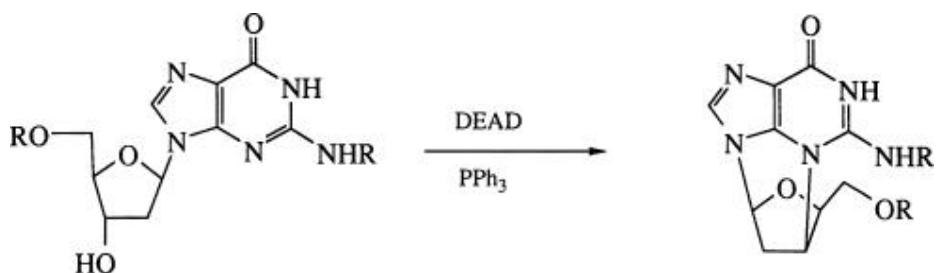

DEAD/triphenylphosphine to form phthalimidoxy derivatives. (183, 184)

Bromohydrin **26** forms equal amounts of the expected $\text{S}_{\text{N}}2$ product and that arising from a phenonium ion ($\text{S}_{\text{N}}1$) rearrangement. (185)

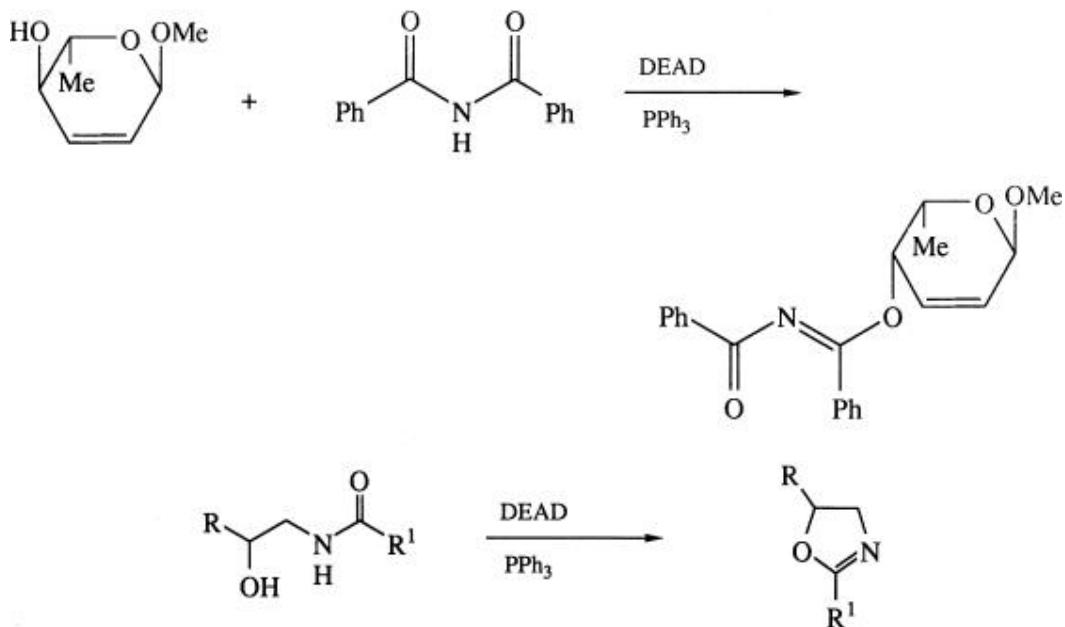

Ethanol, (186) 4-nitrophenethanol, (187-189) and 3,4-dimethoxybenzyl alcohol (190) react at oxygen of the amide functionality in guanosine nucleotides. In contrast, thymidine and uridine nucleotides alkylate on nitrogen with 4-nitrophenethanol, (191) while inosine gives a 2:1 mixture of O- vs. N-alkylation. (192) If the nucleotides have unprotected hydroxy groups, then intramolecular reactions

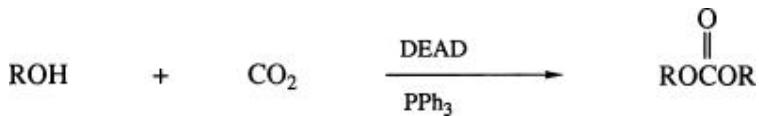

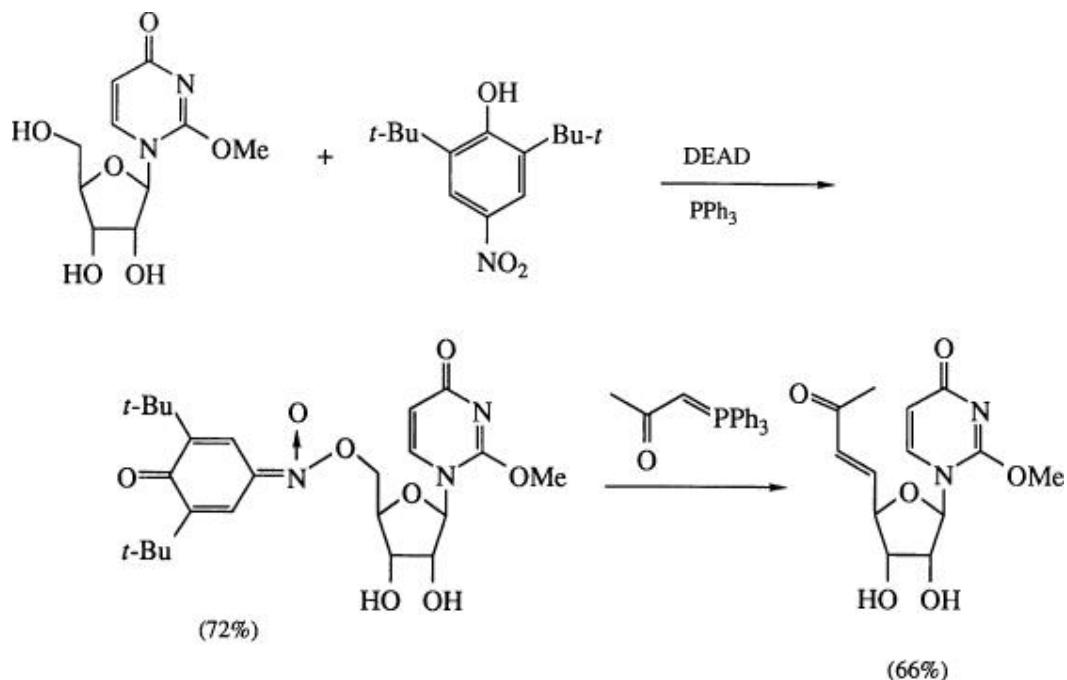

occur. (193, 194) While cyclic imides such as succinimide and phthalimide react at nitrogen, acyclic imides react at oxygen. (195) Hydroxyamides react intramolecularly to form 2-oxazolines. (196) Phosphinic acids (197) and phosphonates (198) form esters with alcohols using DEAD/triphenylphosphine.

Carbonates are prepared from alcohols and CO₂ using DEAD/triphenylphosphine. (199) 2,6-Di-*tert*-butyl-4-nitrophenol reacts with the primary hydroxy

group of nucleosides to form aci-nitro esters using triphenylphosphine/DEAD. The aci-nitro esters react with Wittig reagents to form olefins, serving as masked aldehydes. (200) Aryl and alkyl carboxylic acids are converted to

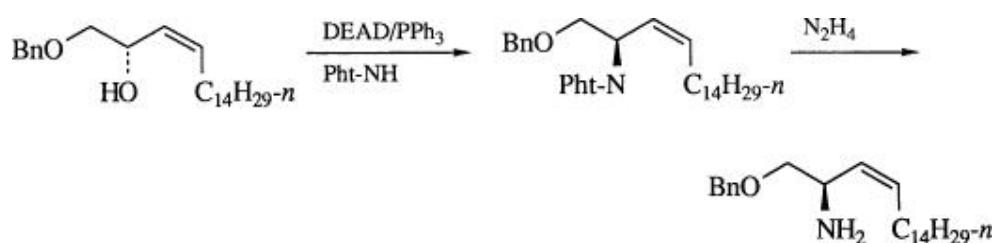

anhydrides in 60–96% yields using triphenylphosphine/DEAD in tetrahydrofuran. (201)

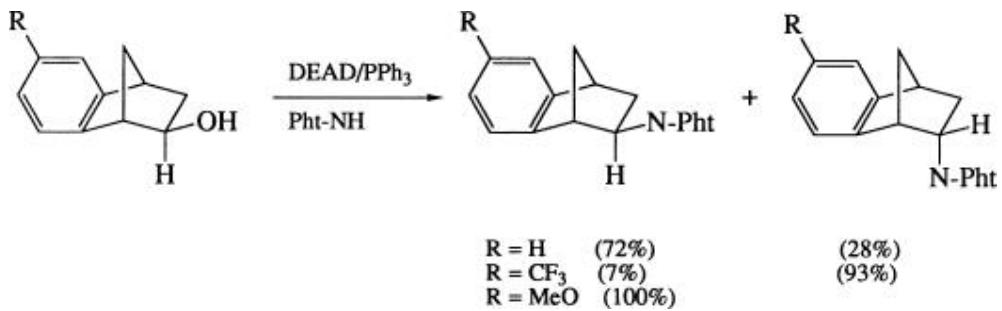

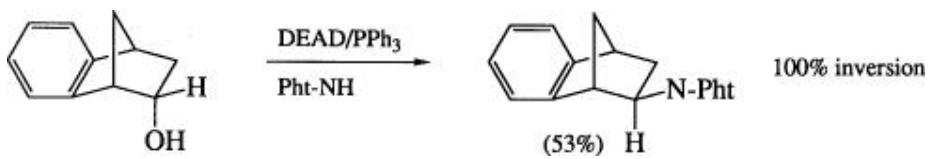

3.2. Carbon–Nitrogen Bond Formation

3.2.1.1. Cyclic Imides

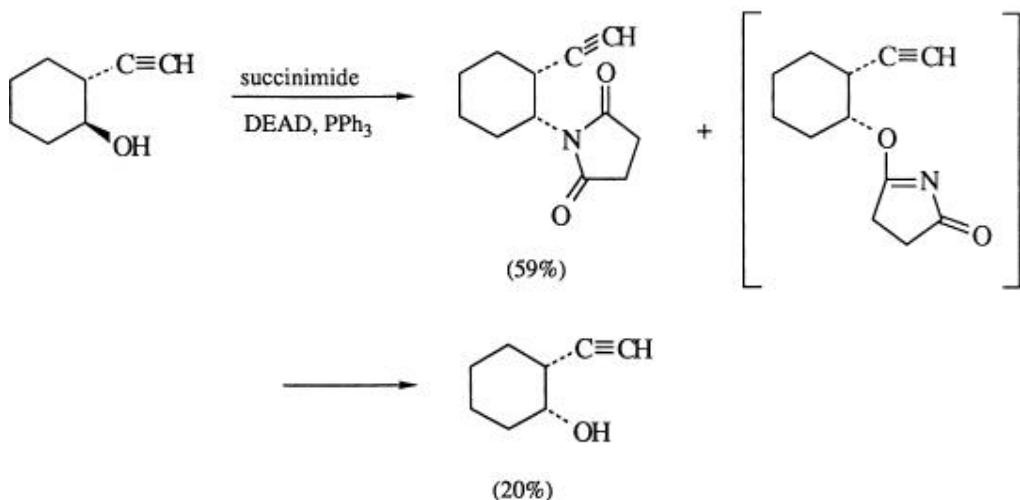

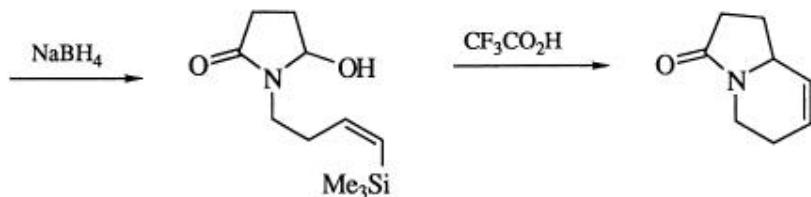

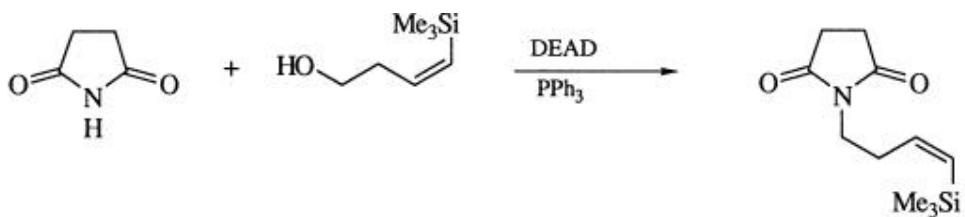

Conversion of alcohols into inverted amines is accomplished by coupling a secondary alcohol with phthalimide using DEAD/triphenylphosphine followed by hydrazinolysis of the phthalimido product to the amine. (202) *endo*-Benzonorbornen-2-yl alcohols react to form *exo* phthalimido

derivatives, but *exo* alcohols give mixtures of *endo* and *exo* products by a phenyl-assisted S_N1 process. Substitution of a trifluoromethyl group into the phenyl ring reduces the amount of S_N1 character, (203) while a 4-methoxy group results in complete retention. (204) Coupling of alcohols with other cyclic

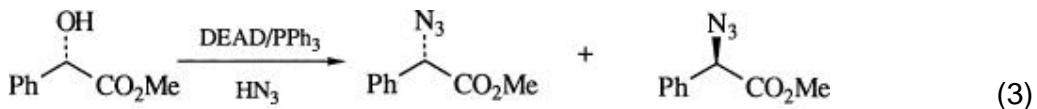

imides, including glutarimide, succinimide, hydantoin, and oxazolidinedione, is used to make substrates for *N*-acyliminium cyclizations. (205) There is one example of competitive O-alkylation, leading to an inverted alcohol. (206)

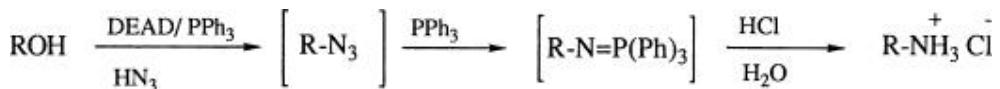

3.2.1.2. Azides

Alcohols are converted into azides using hydrazoic acid, zinc azide, or diphenylphosphoryl azide as nucleophile, generally in benzene or toluene solvent. Secondary alcohols are inverted except when steric hindrance leads to retention (207) or when the presence of an acidic hydrogen leads to racemization (Eq. 3). (208) A convenient one-pot preparation of amines from

1 : 1

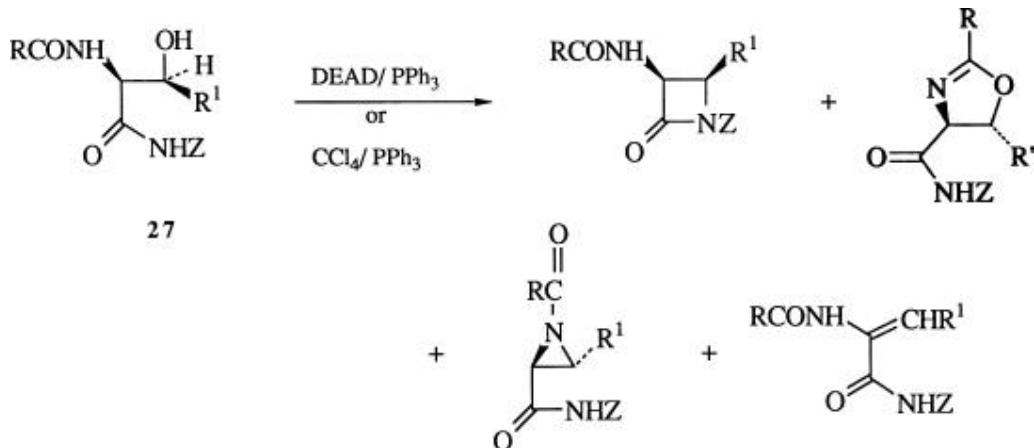

alcohols employs the Mitsunobu reaction to make the azide followed by an in situ Staudinger reaction with triphenylphosphine to produce an imino-phosphorane, which is hydrolyzed to the amine during aqueous workup. (208) Overall isolated yields range from 35 to 85%.

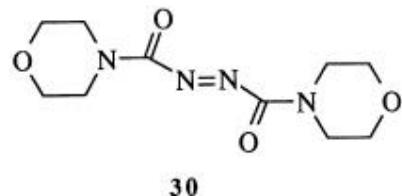

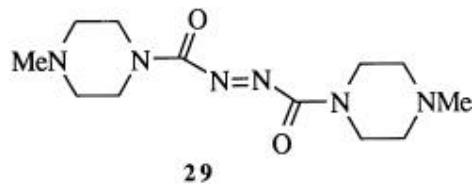

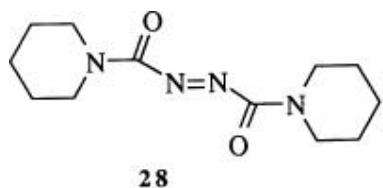

3.2.1.3. Lactam Formation

β -Lactams are formed by intramolecular dehydration of β -hydroxycarboxamide derivatives. (209-211) Side reactions include elimination and formation of oxazolines and aziridines. Oxazoline and aziridine formation can be prevented by using carbonate, (209-211) oxazolin-2-oyl, (212, 213) or phthalimide (212, 214, 215) protecting groups for the side-chain amino group. Yields of β -lactams are 80–90% for hydroxamate precursors ($Z = \text{benzyloxy}$) (209-211) and 70–80% for anilide precursors ($Z = 4\text{-tolyl}$). (214, 215)

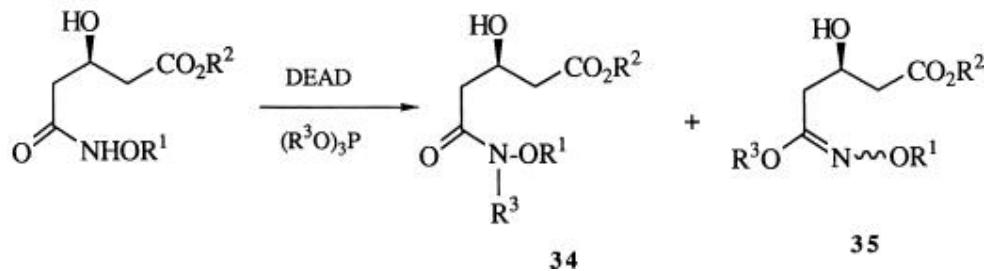

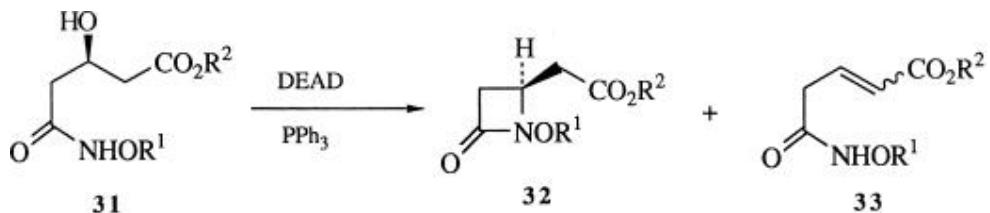

Cyclization of **27** ($Z = 4\text{-tolyl}$, $R = \text{H}$, $R' = \text{benzyloxy}$)

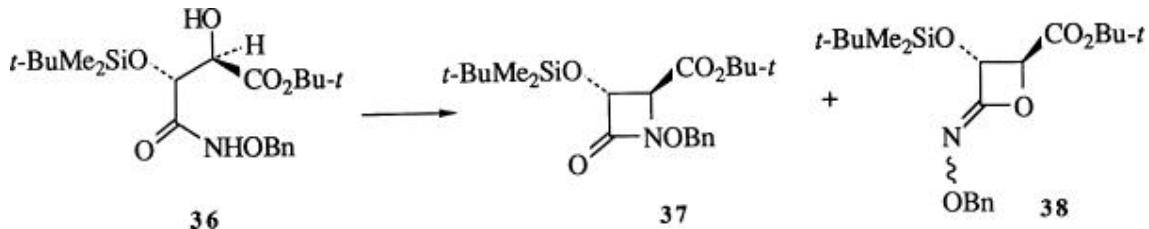

using DEAD and a variety of phosphines gives only small changes in yield of β -lactam: triphenylphosphine (74%), tri-*n*-butylphosphine (68%), triethyl phosphite (79%), and tris(dimethyl-amino)phosphine (67%). (215) Replacing DEAD with azo reagents **28–30** gives no β -lactam formation with triphenylphosphine, but 47–57% yields with tri-*n*-butylphosphine. (215) Cyclization of **31** with DEAD/triphenylphosphine gives 22% β -lactam **32** and 78% elimination product **33**. (216) The olefin

is also the major product with triphenylphosphine/carbon tetrachloride/triethylamine, triphenylphosphine dibromide, and triphenylphosphine dichloride. β -Lactam yields of 50–70% are achievable when triphenyl phosphite, phenoxydiphenylphosphine, or diphenoxypyhenylphosphine are used along with DEAD. Use of trimethyl phosphite and triisopropyl phosphite with DEAD results in mixtures of *N*- and *O*-alkylation (**34** and **35**). (216) Cyclization

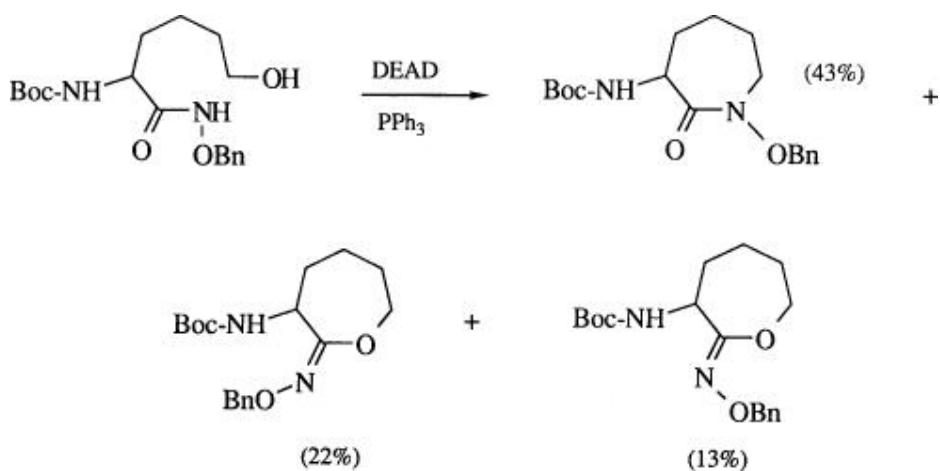

of amide **36** results in some competitive *O*-alkylation, depending on the azodicarboxylate. (217) With diisopropyl azodicarboxylate, 40% of **37** and no **38** are obtained. Diethyl azodicarboxylate gives 22% **37** and 5.5% **38**, while dimethyl azodicarboxylate gives 14% each of **37** and **38**.

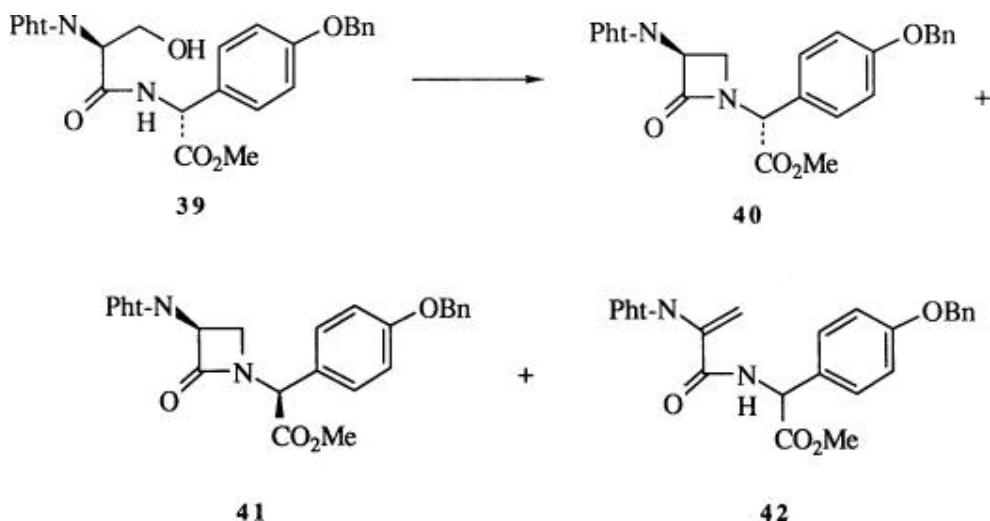

Competitive *N*- and *O*-alkylation also occurs in the cyclization to the 7-membered lactam. (218)

Cyclization of amide **39** using 5.0 equivalents of triphenylphosphine/DEAD in tetrahydrofuran affords a thermodynamic mixture of diastereomers **40** and **41** (2:1 ratio) along with 2% elimination product **42**. (219) Unreacted **39** isolated from a reaction mixture is not epimerized, indicating that epimerization occurs in the intermediate oxyphosphonium salt or in the product β -lactam. Treating pure **40** with 2.5 equivalents of DEAD/triphenylphosphine

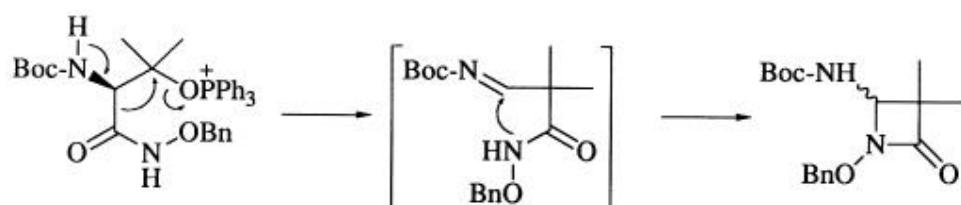

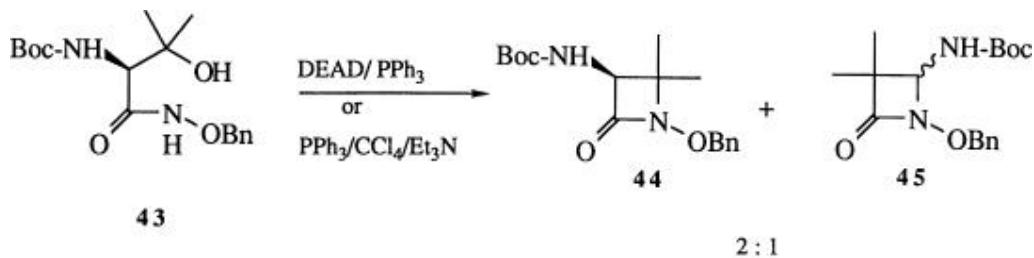

in tetrahydrofuran results in a reestablishment of the 2:1 diastereomeric mixture in 15 minutes, indicating that the DEAD-triphenylphosphine adduct is a sufficiently strong base to epimerize the product β -lactam. Decreasing the amounts of DEAD and triphenylphosphine has no effect on the diastereomeric ratio of **40** to **41**, which are at thermodynamic equilibrium, but increases the elimination product **42**: 7% at 2.5 equivalents, 12% at 1.8 equivalents, 16% at 1.5 equivalents, and 23% at 1.0 equivalent. When triphenylphosphine is

replaced with triethyl phosphite, the reaction is slower and less epimerization takes place. With 2.5 equivalents of DEAD/triethyl phosphite, the ratio of **40:41** is 6.8:1, while with 1.0 equivalent the ratio is >50:1. ¹H NMR analysis indicates that epimerization is taking place in the oxyphosphonium ion intermediate. (168, 219)

β -Lactam formation occurs with tertiary alcohol **43** but gives a mixture of isomeric products **44** and **45**. **4a** Labeling experiments suggest that **45** arises via an intramolecular 1,2-acyl migration–cyclization process. (220)

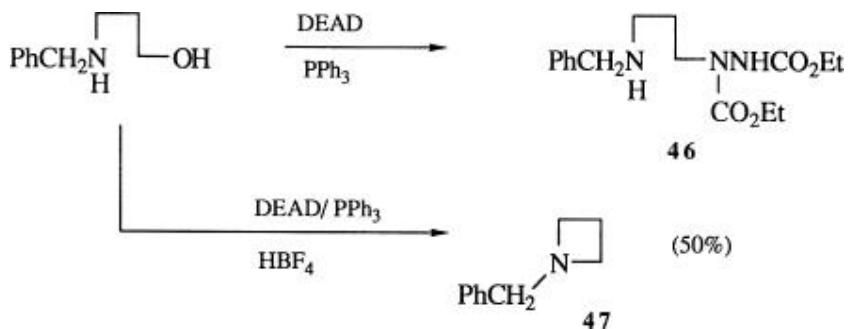

3.2.1.4. Other Carbon–Nitrogen Bond-Forming Intramolecular Cyclizations
Aziridines, (221) azetidines, (222, 223) pyrrolidines, (224, 225) and piperidines (222) are formed by intramolecular reactions of ω -aminoalcohols with

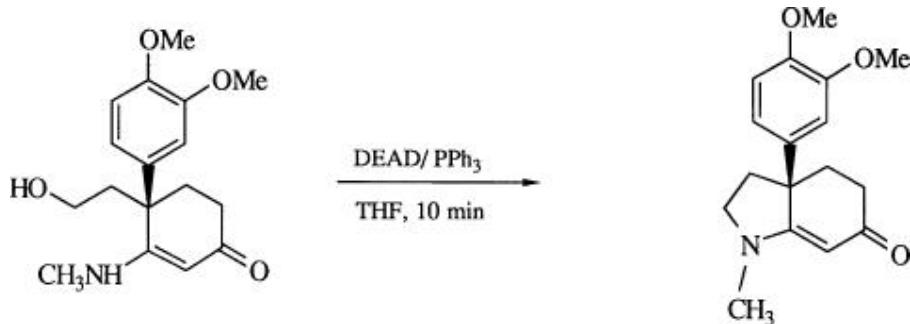

DEAD/triphenylphosphine.

High yields of aziridines are obtained from 2-aminoethanol derivatives provided that the amine is secondary and one of the carbon atoms is substituted. (221)

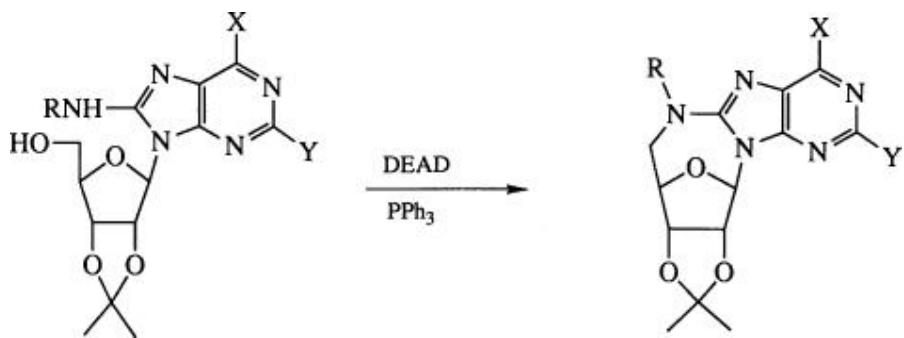

Reaction of 3-(*N*-benzylamino)-1-propanol with DEAD/triphenylphosphine results in formation of the DEAD adduct **46**. (222) The desired azetidine **47** is obtained by using an acid to protonate the hydrazide anion, preventing

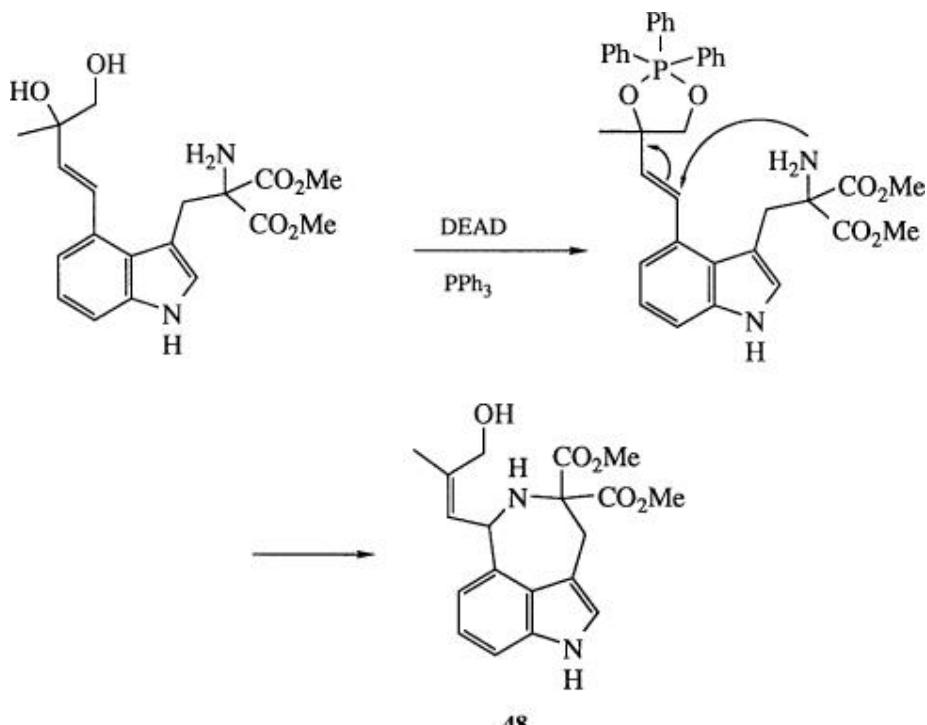

its reaction. The pyrrolidine moiety of mesembrine is constructed by an intramolecular Mitsunobu reaction. (224) Nitrogen-bridged cyclonucleosides with

a 7-membered ring are prepared in high yields with DEAD/triphenylphosphine. (226) An intramolecular $\text{S}_{\text{N}}2'$ reaction provides the 7-membered heterocycle

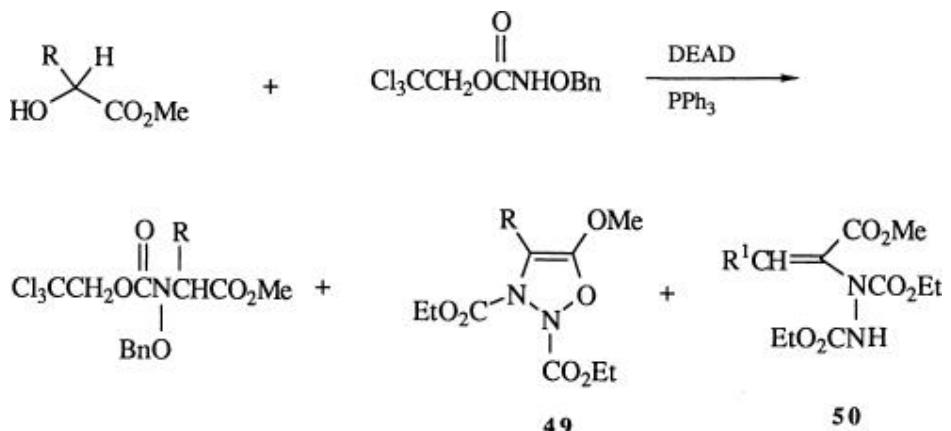

48. (227) Activation of the tertiary alcohol is made possible by initial activation of the primary hydroxy group followed by ring closure to the phosphorane, which is observed by ³¹P NMR.

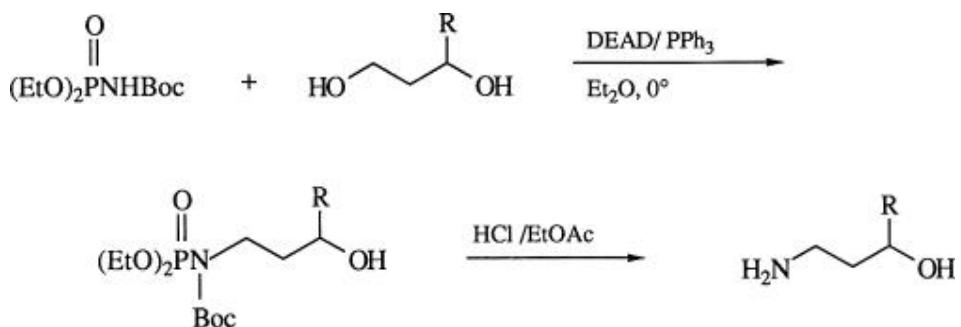

3.2.1.5. Other Intermolecular Carbon–Nitrogen Bond-Forming Reactions

Protected hydroxylamines react with α -hydroxycarbonyl compounds to form protected aminoacid esters in 20–82% yields, plus adducts **49** and **50** in 10–50% yields arising from reaction of the α -hydroxycarbonyl compound with

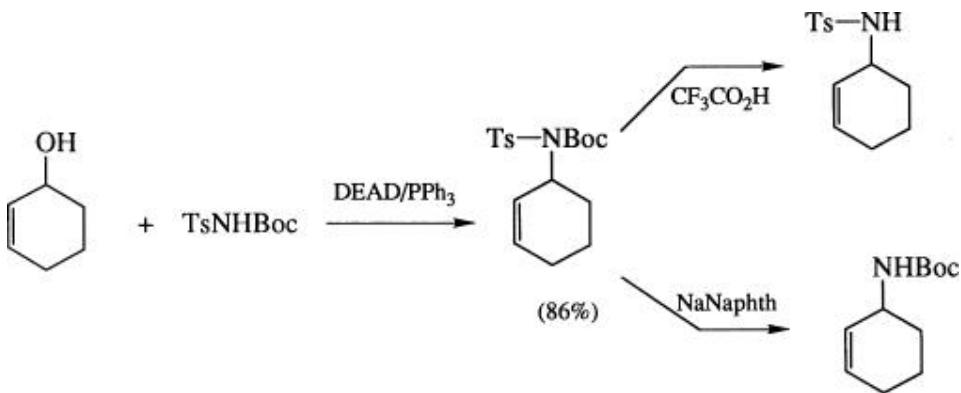

DEAD. (228) Phosphoramides condense with alcohols, and the resulting *N*-alkylated products can be cleaved to form amines. [229,230a](#)

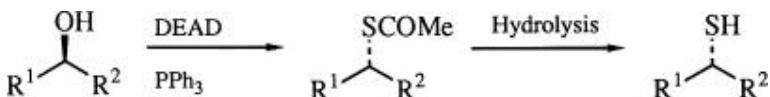

N-Alkyl- and *N*-acylsulfonamides react with alcohols in the presence of DEAD/triphenylphosphine to give alkylated sulfonamide products. The Boc or tosyl groups can be selectively removed to give the monoselectively protected amines. [230b](#)

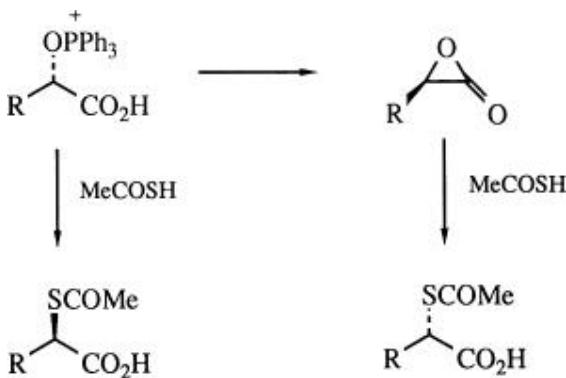

3.3. Carbon–Sulfur Bond Formation

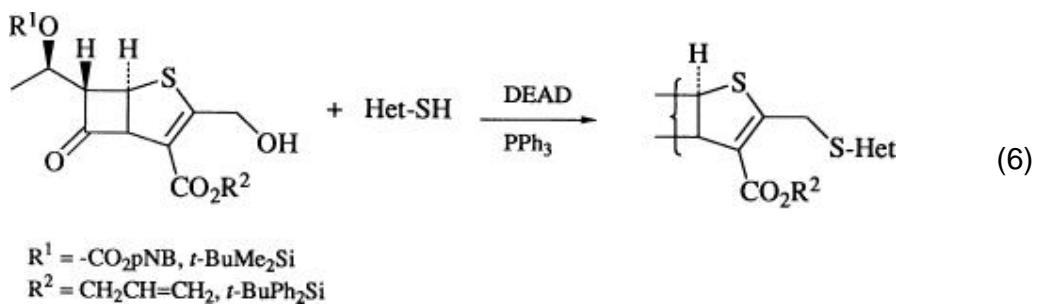

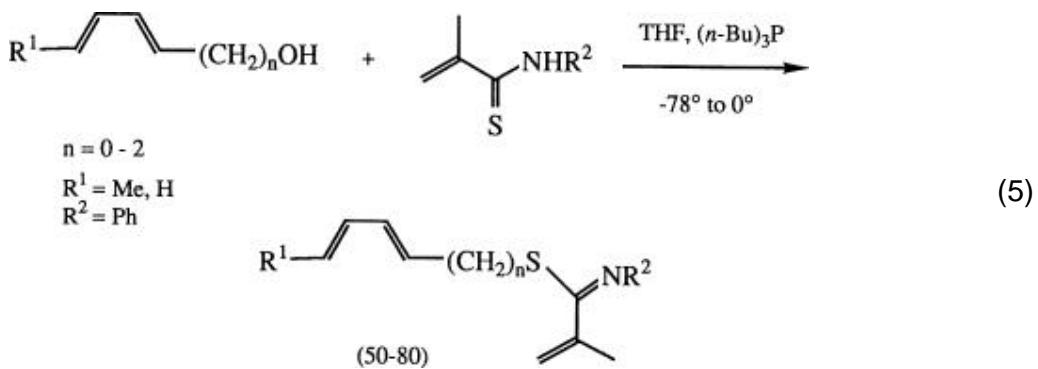

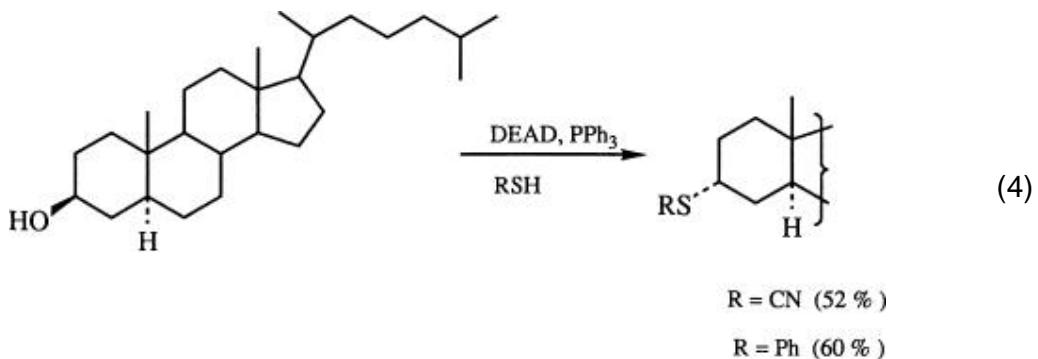

Alcohols can be converted into thiols by reaction of the alcohol with triphenylphosphine, DEAD, and thiolacetic acid to form a thiol ester, followed by saponification or reduction of the thiol ester to the thiol. (231-244) Important to the success of this reaction is preformation of the DEAD-triphenylphosphine

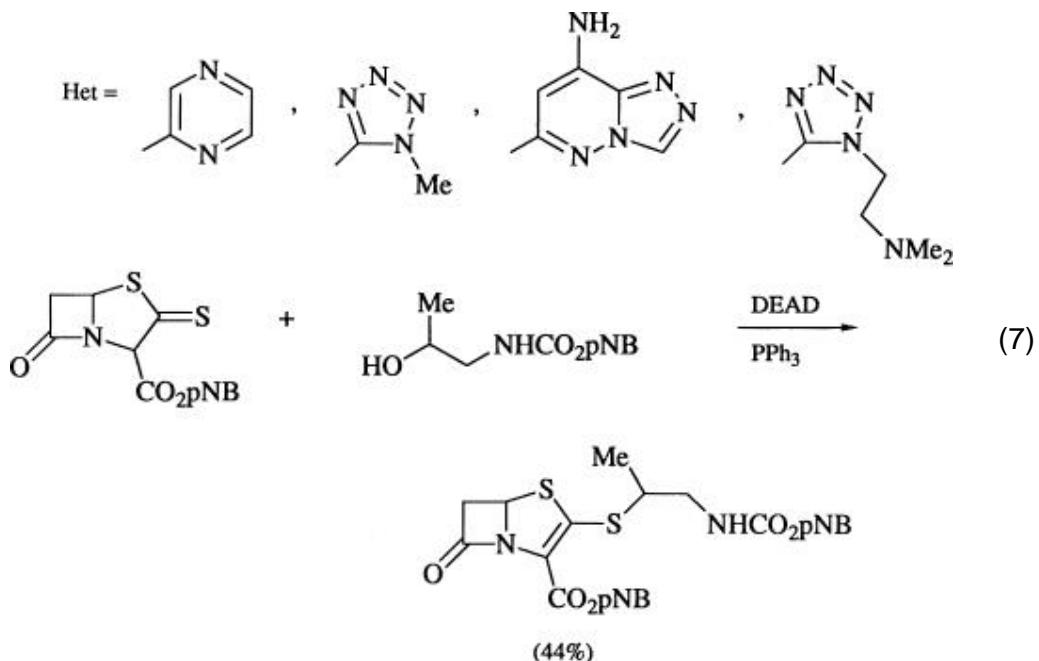

adduct at 0° before addition of the thiolacetic acid and the alcohol, which prevents nucleophilic addition of the thioacid to DEAD. (231) While complete inversion occurs with optically pure 2-octanol, (231) 3- β -cholestanol, (231) ethyllactate, (232) methyl phenylacetate, (232) and diethyl malate, (232) significant racemization occurs with ethyl mandelate (69% ee), (232) mandelic acid (85% ee), (233) lactic acid (68% ee), (233) and 2-hydroxy-3-phenylpropionic acid (52% ee). (233) In the last three, involvement of an α -lactone intermediate appears to be the cause of racemization. (233) Other nucleophiles used to form carbon–sulfur bonds

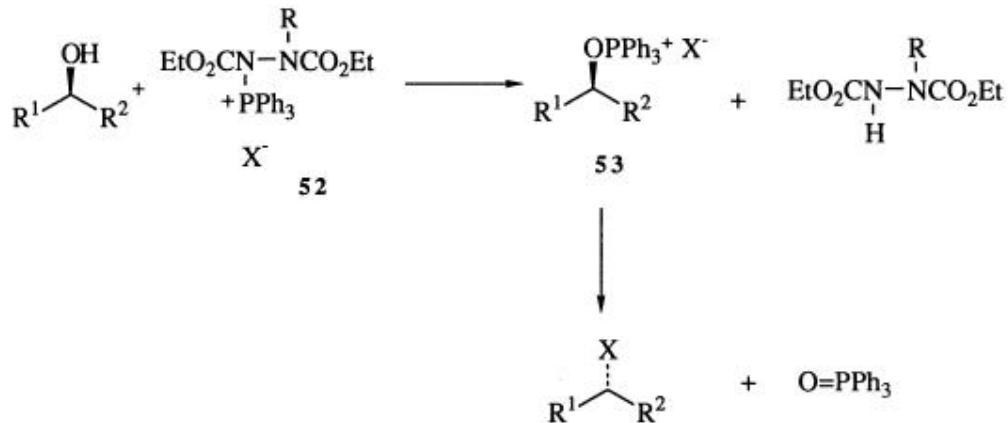

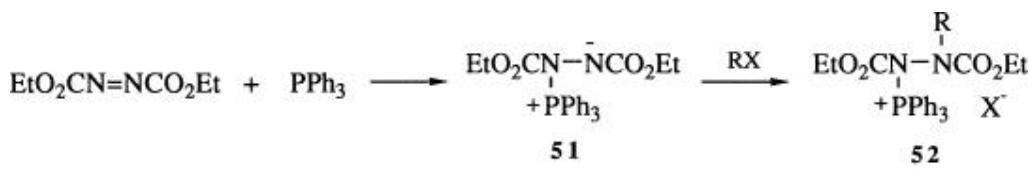

include thiocyanate (Eq. 4), (245) thiophenol (Eq. 4), (244-247) thioamides (Eq. 5), (248, 249) thioureas, (250) zinc *N*, *N*-dimethyldithiocarbamate, (251) alkyl thiols, (252) heterocyclic thiols (Eq. 6), (253, 254) and dithioesters (Eq. 7). (255)

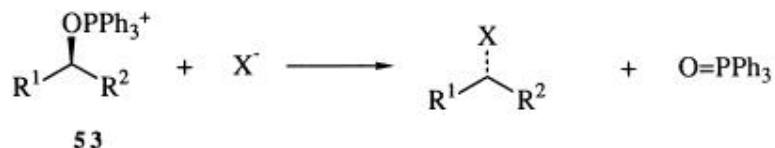

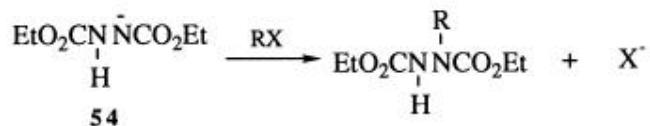

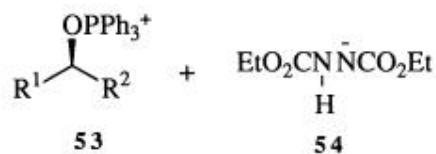

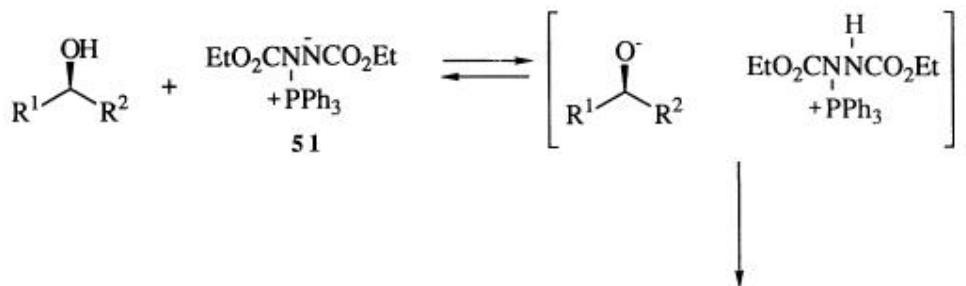

3.4. Carbon–Halogen Bond Formation

Alcohols are converted into halides using DEAD/triphenylphosphine along with an alkyl or acyl halide. (245) Two possible reaction pathways are shown. In

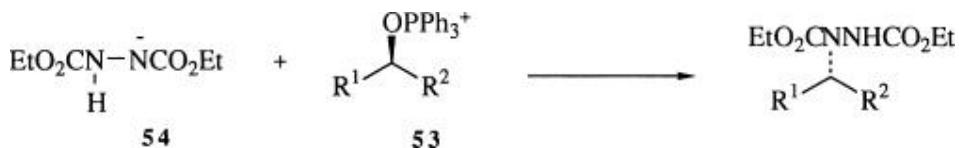

MECHANISM II

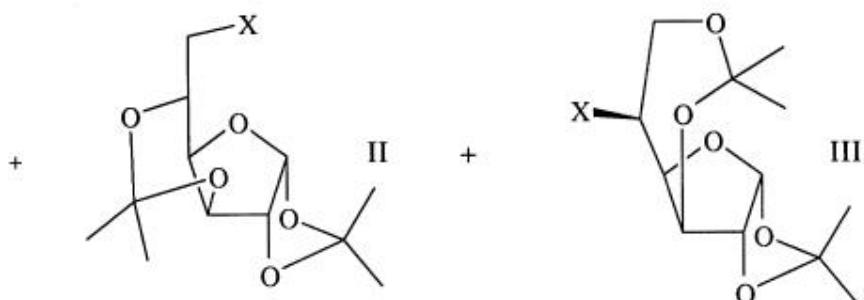

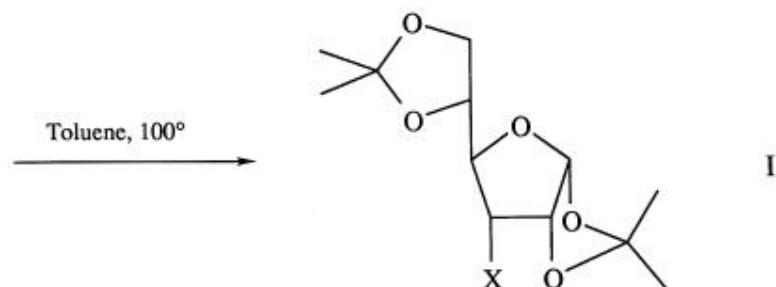

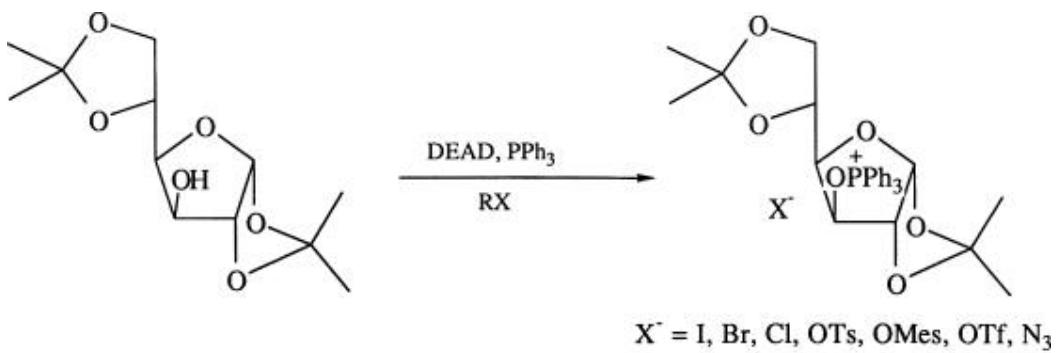

the first pathway the zwitterionic intermediate **51** is alkylated to form the azaphosphonium intermediate **52** with the halide counterion. The transfer of phosphorus occurs from **52** to the alcohol to form the oxyphosphonium

intermediate **53**, with X^- perhaps serving as a basic catalyst. S_N2 reaction of **53** with X^- produces the inverted halide. The second pathway differs in that phosphorus transfer occurs from the zwitterionic intermediate **51** to form the oxyphosphonium intermediate **53** and hydrazine anion **54**. The hydrazine anion is then alkylated with RX to generate X^- , which reacts with oxyphosphonium intermediate **53** to produce the inverted halide. In the latter mechanism an expected competing side reaction would be reaction of **53** and **54**, a commonly observed reaction when no acid or alkylating agent is present. (256)

The lack of this as a competing side reaction in the absence of acid is one piece of evidence to disfavor the second mechanism. Intermediate phosphoranes, which have been shown to form with hindered alcohols in the absence of acid, may also play a role. (12-16)

The intermediate oxyphosphonium salts from several hindered carbohydrates have been isolated and characterized. (10, 257) Heating the oxyphosphonium salt in toluene results in S_N2 displacement for $X^- = I$, but rearrangements

	X	I	II	III
I	70%	0%	0%	
Br	7%	35%	11%	
Cl	5%	55%	27%	

when $\text{X}^- = \text{Br}^-, \text{Cl}^-$ because of attack of X^- on the isopropylidene protecting group.

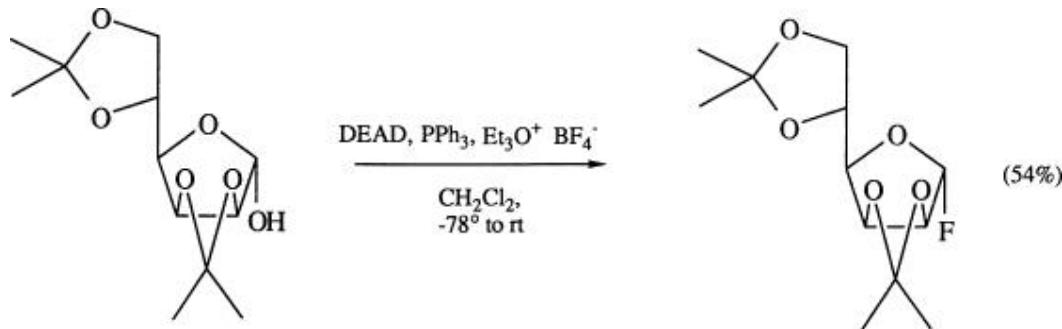

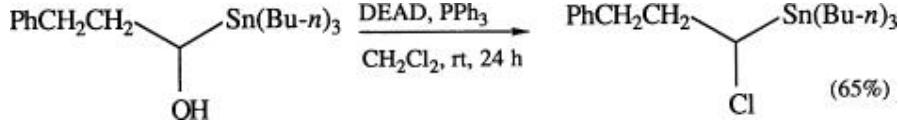

Besides alkylating or acylating agents, several other sources of halide ion can be used in conjunction with DEAD/triphenylphosphine. The halide may be

supplied by an ammonium salt such as pyridinium hydrochloride or hydrobromide, methoxyamine hydrochloride, or 2-amino-5-bromothiazole hydrobromide. (258) In these cases the zwitterionic intermediate **51** is protonated by HX to liberate X⁻ for the reaction. The mildness of this procedure is demonstrated by formation of the penam **55** in 85% yield when no other method was successful. (258) The source of halide may also be methylene chloride

as solvent (259) or methylene bromide in benzene solution. (260)

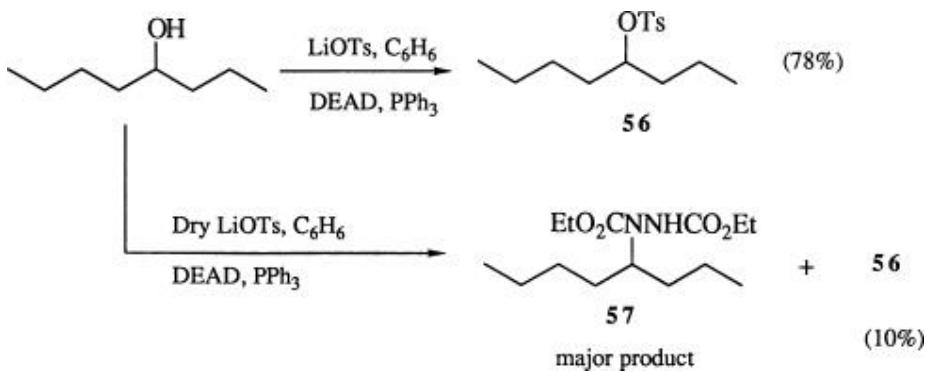

Triethyloxonium tetrafluoroborate is used as a source of fluoride. In the one example reported,

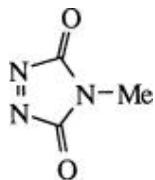

retention of configuration occurred. (261)

Primary and secondary alcohols react with triphenylphosphine, DEAD, and zinc halides to produce alkyl halides in 66–90% yields. (251, 262) Formation of 2-phenethyl chloride from the corresponding alcohol with no elimination indicates the mildness of the procedure. (262) Lithium halides, including F, Cl, Br, and I, or also lithium cyanide, react with alcohols in the presence of triphenylphosphine/DEAD to give the corresponding halides or nitrile in

50–96% yields. (263) Water (or HX) may play a role in these reactions. In the reaction of 4-octanol with lithium tosylate, triphenylphosphine, and DEAD, a 78% yield of the expected tosylate **56** was formed. However, when the lithium tosylate was rigorously dried, only 10% of **56** was formed, and the major product was the DEAD addition product **57**. (182) Optically active secondary

alcohols are converted to inverted iodides and bromides in 65–91% yields using MeX, triphenylphosphine, or tri-*n*-butylphosphine, with the DEAD substitute 4-methyl-1,2,4-triazolidine-3,5-dione (**58**). (264)

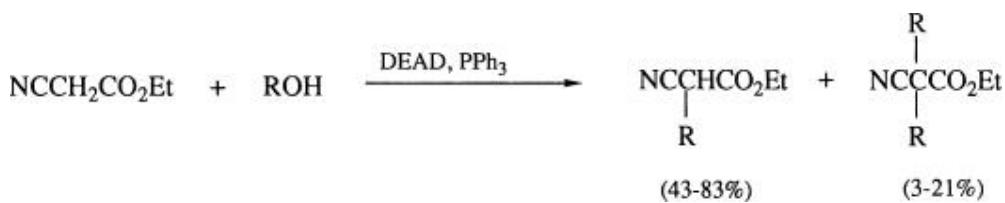

58

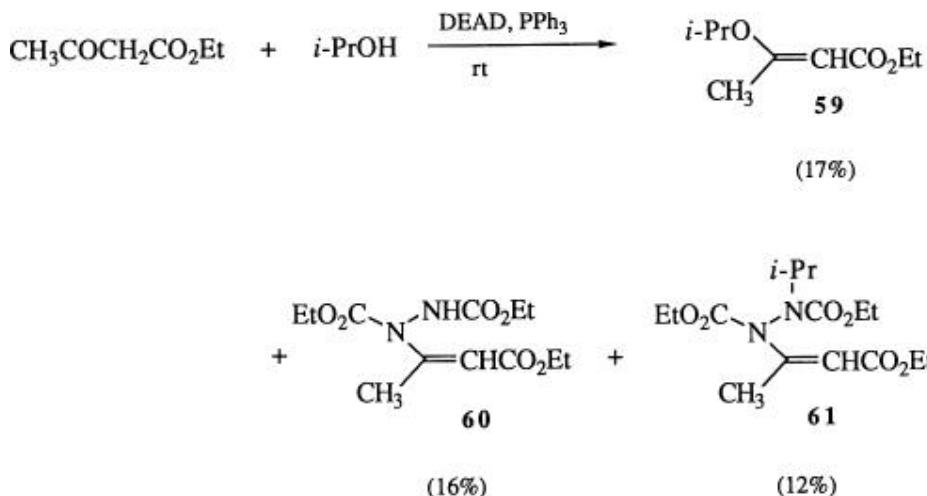

3.5. Carbon–Carbon Bond Formation

Use of the Mitsunobu reaction to form carbon–carbon bonds is limited to compounds having highly acidic C — H bonds, such as β -diketones, (265) β -ketoesters, (265) α -cyanothioesters, (266) and α -cyanoesters. (265) β -Diesters are not acidic enough to undergo reaction. (265)

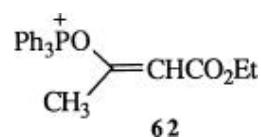

Alkylation of ethyl cyanoacetate occurs in 43–83% yields with primary and secondary alcohols provided the DEAD–triphenylphosphine adduct is preformed. Dialkylation occurs to the extent of 3–21%. (265) Reaction of ethyl acetoacetate

with 2-propanol and the preformed DEAD-triphenylphosphine adduct at room temperature gives 17% O-alkylated product **59** plus the DEAD addition products **60** and **61**. No C-alkylation occurs. Reducing the temperature to -10° to -20° increases the yield of **59** to 35%. (265) Compounds **60**

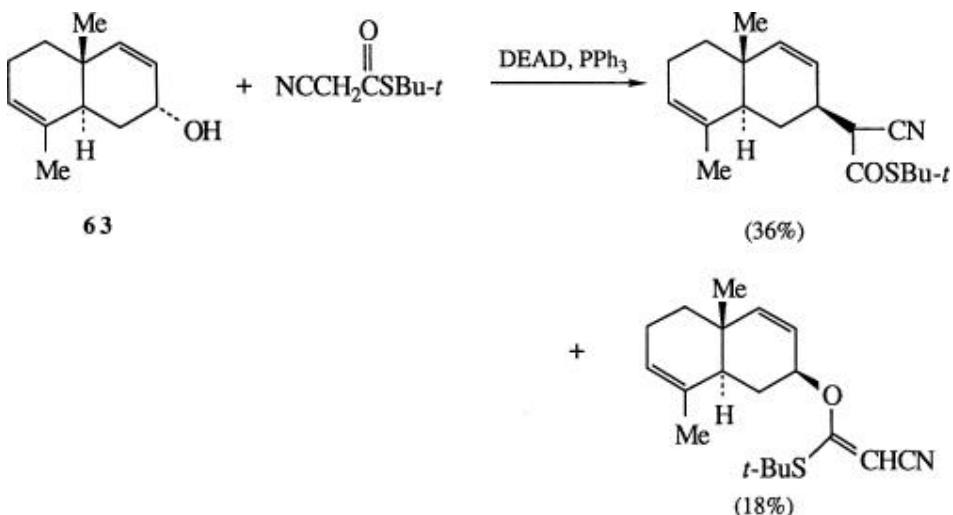

and **61** may be formed from the oxyphosphonium ion **62**. In the absence of an alcohol, **60** is formed in 68% yield. (265) Methyl acetoacetate undergoes

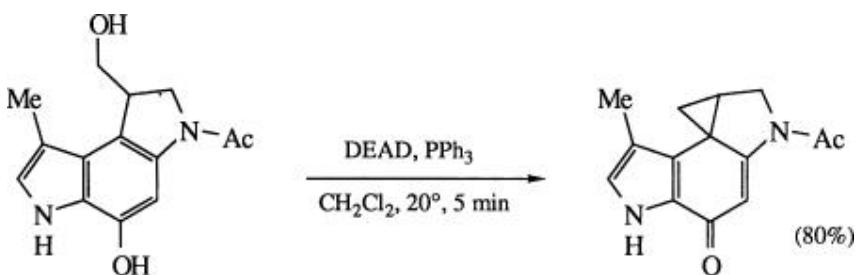

reaction with optically active 2-octanol at -30° giving an O/C alkylation ratio of 90/10 with 15% racemization. (267) Alkylation with 1-phenyl-1-ethanol gives a 55/45 C/O ratio with 5% racemization. (267) The C/O ratio is 40/60 with 1-(4-nitrophenyl)-1-ethanol with <10% racemization; the overall yield of alkylated products is 24%. (268, 269)

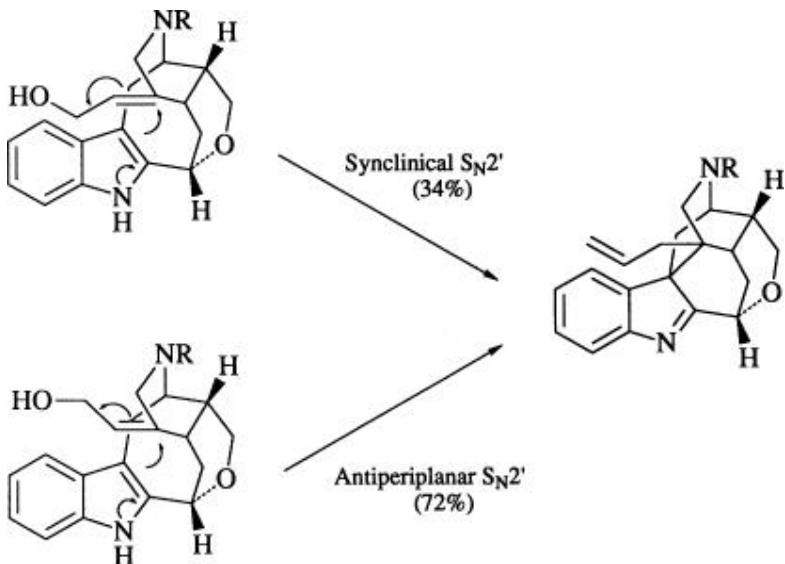

Alkylation of 1,3-cyclohexanedione with 2-propanol in the presence of DEAD/triphenylphosphine gives exclusively O-alkylation in 81% yield. (265) Alcohol **63** undergoes reaction with (*S*)-*tert*-butyl cyanothiolacetate to provide a 2:1 mixture of C/O products in overall 54% yield. (266) Intramolecular formation

of a fused cyclopropane ring via a Mitsunobu reaction is a key step in the syntheses of the antitumor antibiotic CC-1065 and related compounds.
[270–273a](#)

Carbon–carbon bond formation at the 3 position of the tricyclic indole shown below can be accomplished via an intramolecular S_N2' reaction by treatment with DEAD/triphenylphosphine/ NaH in THF. The *Z* isomer reacts faster than the *E* isomer and gives a better yield (72% vs. 34%), which is probably due to the antiperiplanar relationship between the 2,3-indole double bond and the developing vinyl group. [273b](#)

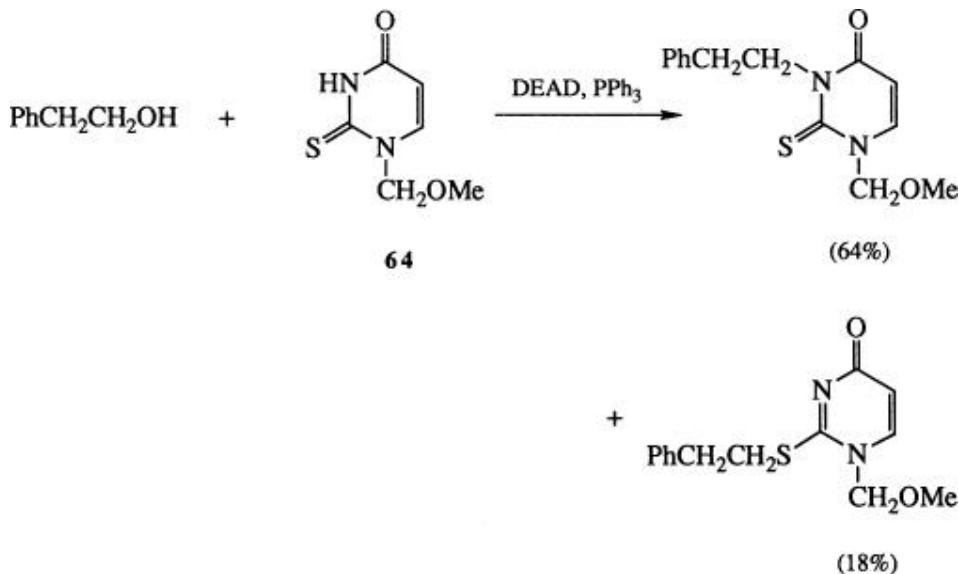

Nitriles are formed via reaction of alcohols with DEAD/triphenylphosphine and hydrogen cyanide. (245) Oleyl alcohol reacts with lithium cyanide/DEAD/triphenylphosphine to give the corresponding nitrile in 58% yield. (263)

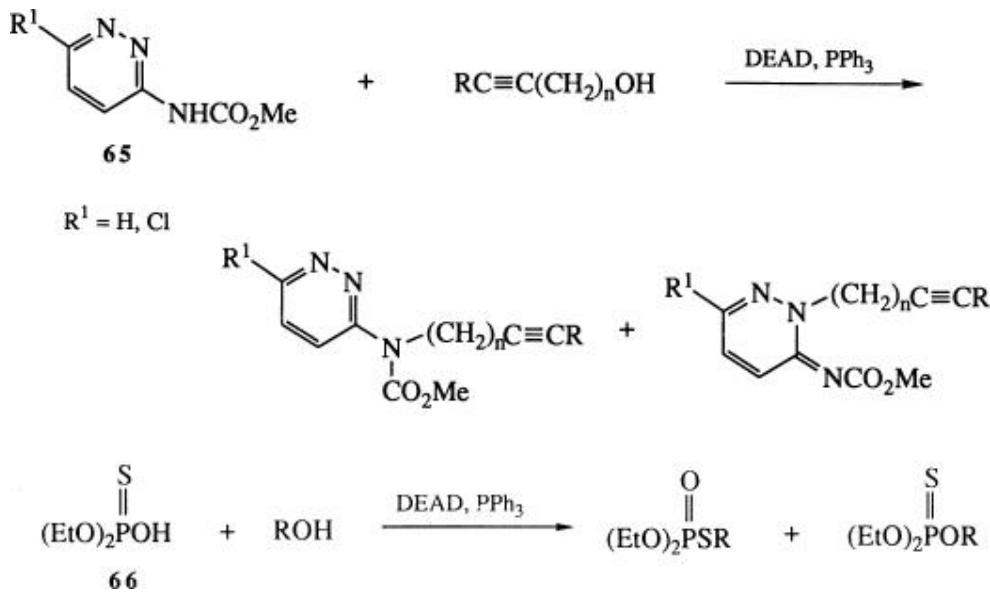

3.6. Ambident Nucleophiles

Ambident alkylations have been briefly discussed in previous sections, including *N*- vs. *O*-alkylation of hydroxamic acids, carboxamides, and nucleotide imides, and *C*- vs. *O*-alkylation of β -diketones and β -ketoesters. Further examples of ambident reactivity are described below.

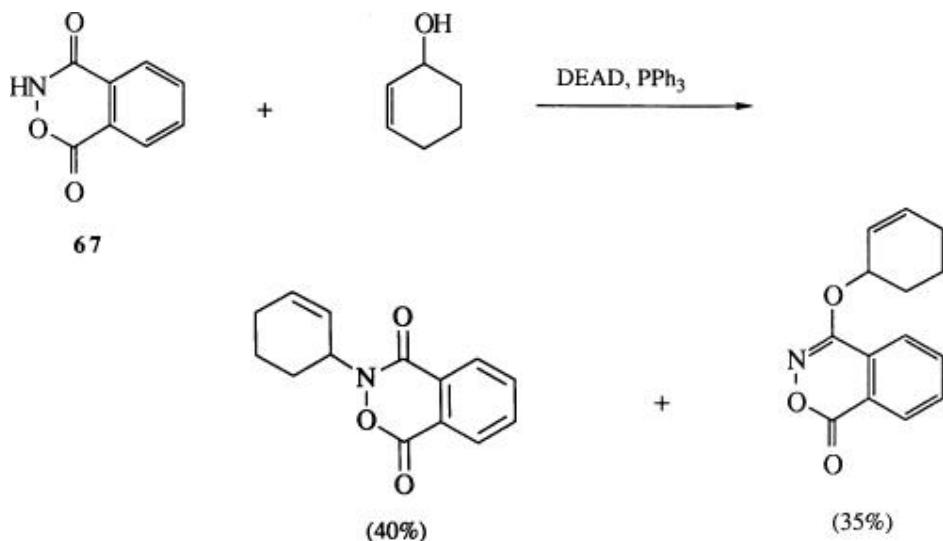

N-Alkylation predominates over *S*-alkylation in the reaction of thiouracil **64** with 2-phenylethanol. (250) Competitive *N*-alkylation of the diazenes **65** occurs

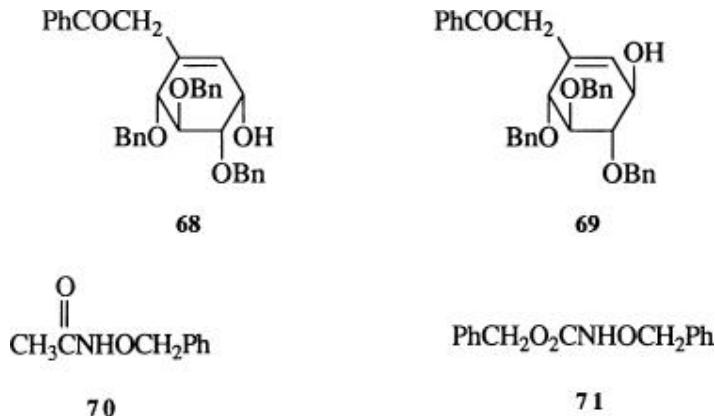

with product ratios ranging from 2:1 to 1:2 depending on the alcohol. (274) Both *O*- and *S*-alkylation occur in the Mitsunobu reaction of alcohols with phosphorothioic acid **66**. With primary alcohols the *S*-alkylated product is formed nearly exclusively, but with secondary alcohols nearly equal amounts of products are formed. (275) *N*,*O*-Phthaloylhydroxylamine (**67**) undergoes reaction with

2-cyclohexenol to give 40% *N*-alkylated product and 35% *O*-alkylated product. (89) Reaction of **68** with **67** gives 28% β *C*–*N* product and 33% β *C*–*O*

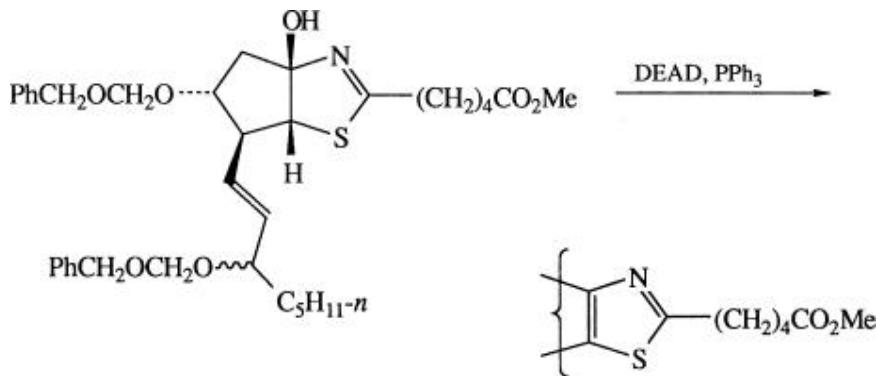

product. The anomer **69** undergoes reaction to give only α -C–O product in 58% yield. (89) Hydroxamate **70** reacts with a primary alcohol almost exclusively on oxygen, while hydroxamate **71** reacts primarily on nitrogen. (276)

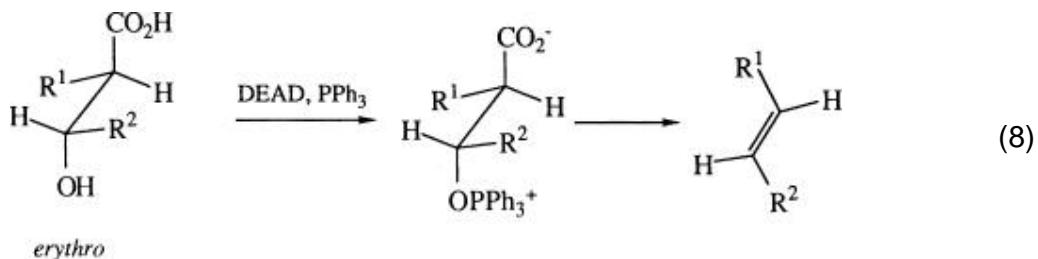

3.7. Dehydration to Form Alkenes

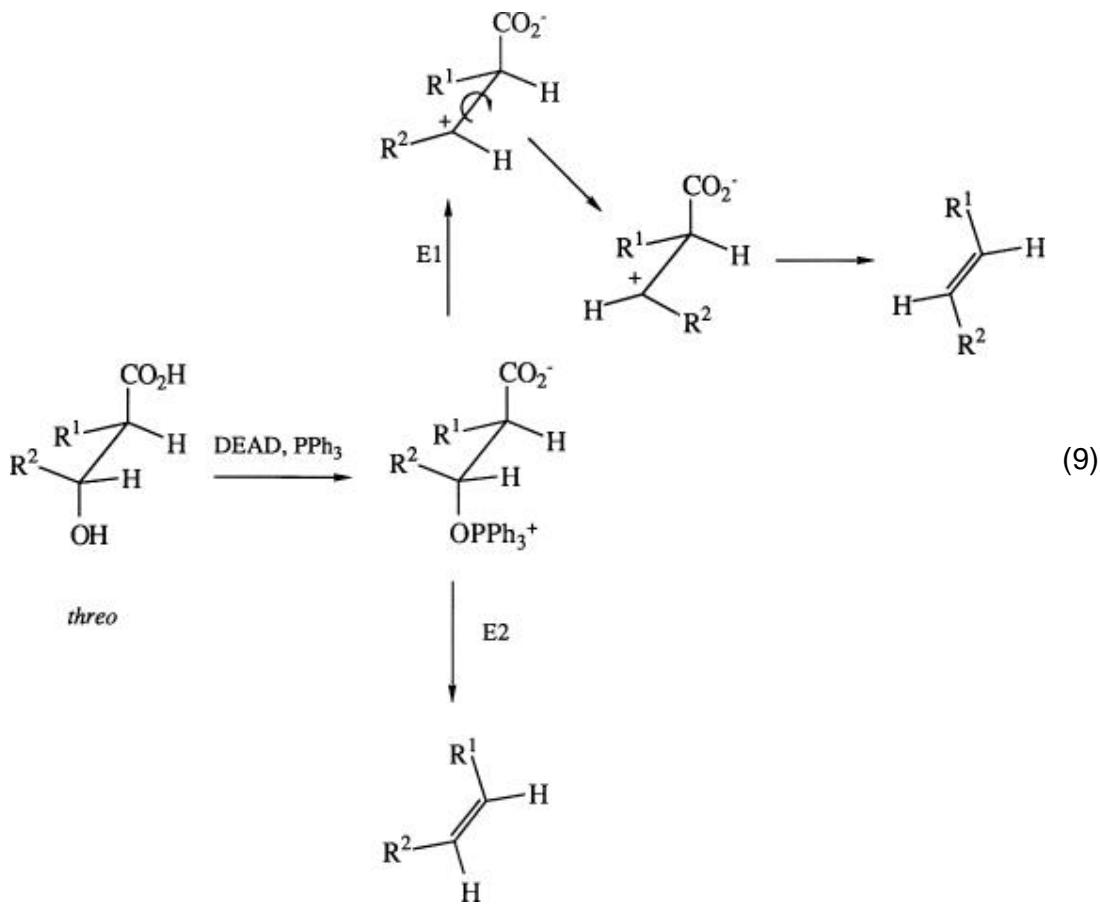

Addition of triphenylphosphine/DEAD to an alcohol in the absence of a nucleophile leads to formation of alkenes. (277-282) Alkenes can be major side

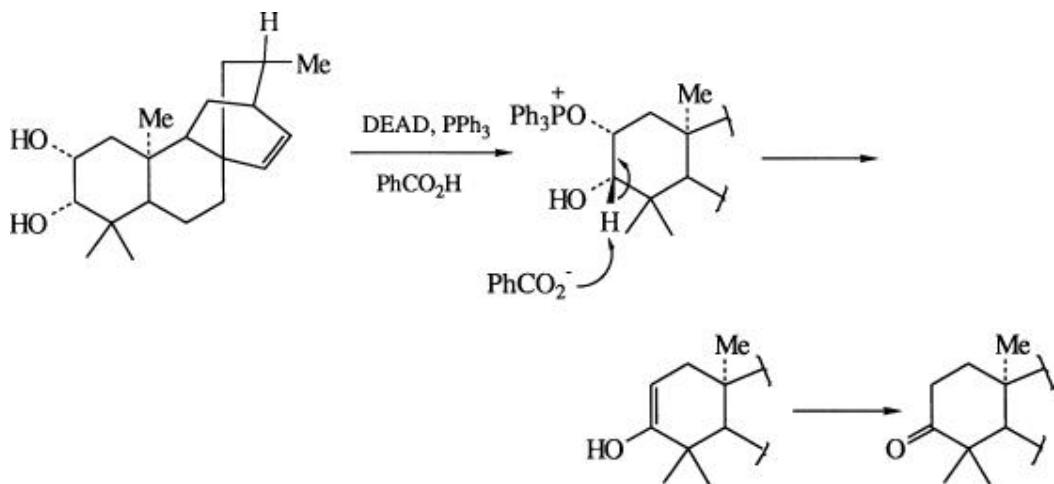

products in esterification reactions. Use of more acidic carboxylic acids (i.e., less basic carboxylic anions as nucleophiles) such as trifluoro- and dichloroacetic acids reduces the amount of elimination product. (7)

erythro-3-Hydroxycarboxylic acids undergo *anti* elimination to form *E* alkenes in 80–95% yields (Eq. 8). Under the same conditions, *threo*-3-hydroxycarboxylic acids form *Z* alkenes when R² is an alkyl group, but form *E* alkenes when R² is an electron-donating group such as 4-anisyl (Eq. 9). The latter is rationalized by invoking competitive E1 and E2 mechanisms, with

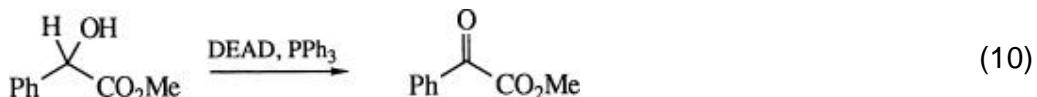

the E1 mechanism predominating when R² is electron donating. (283, 284)
 Hindered *cis*-1,2-diols eliminate to form enols which tautomerize to ketones. (285, 286)

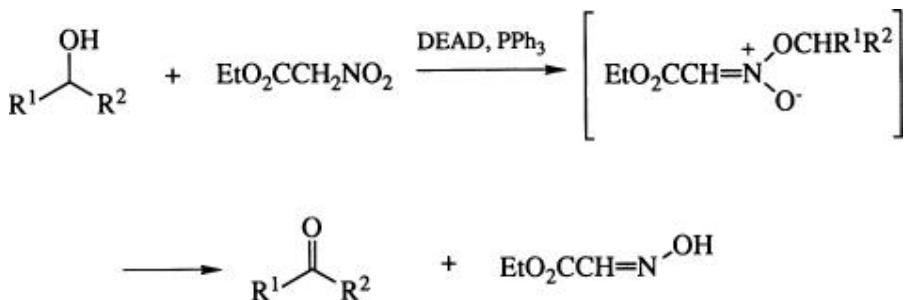

3.8. Other Reactions

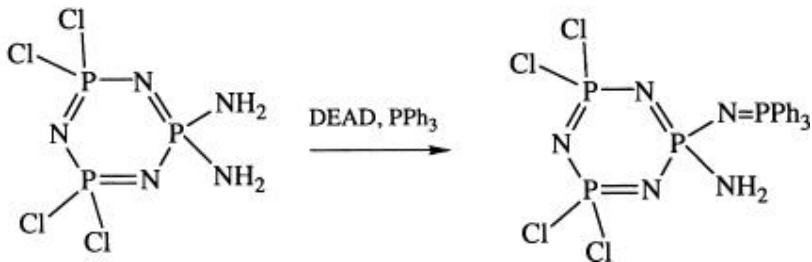

In isolated instances the outcome of the Mitsunobu reaction is alcohol oxidation rather than substitution. (228, 287, 288) With aromatic α -hydroxycarbonyl compounds, oxidation is the predominant reaction. (228) The highest yield of oxidation product occurs with a DEAD/triphenylphosphine ratio of 2:1 and with compounds of increasing α -H acidity (Eq. 10). Attempted condensation

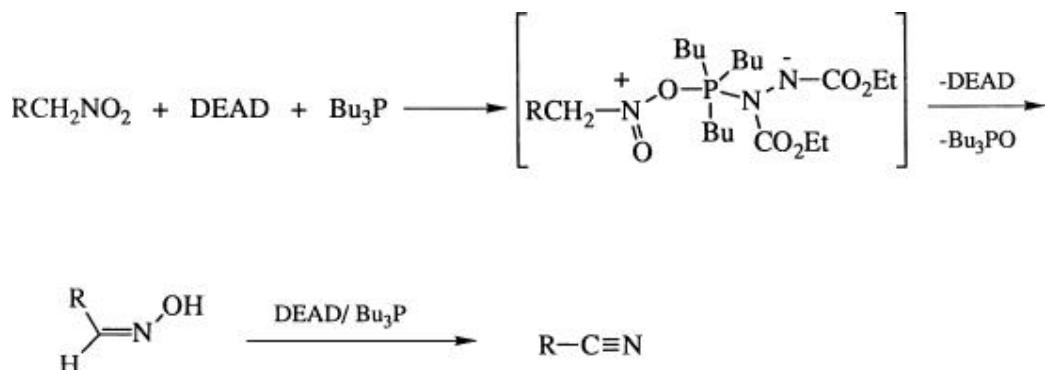

of ethyl nitroacetate with alcohols leads instead to oxidation of the alcohols to ketones or aldehydes, presumably arising from O-alkylation of the nitroacetate. (288)

Phosphazenes are prepared from reaction of DEAD/triphenylphosphine with carboxamides, sulfonamides, and phosphinamides. 289–292a

Treatment of primary nitro groups in dichloromethane with $\text{Sn}(\text{SPh})_4$, tributylphosphine, and DEAD affords the corresponding nitriles in a combined process of deoxygenation and dehydration. The same result can be obtained in a slower reaction using only tributylphosphine (2 equiv) and DEAD (1 equiv), the proposed mechanism of which is shown. 292b

4. Comparison with Other Methods

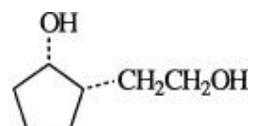

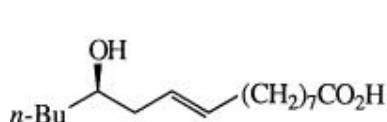

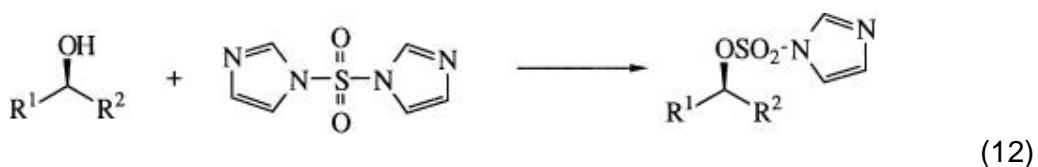

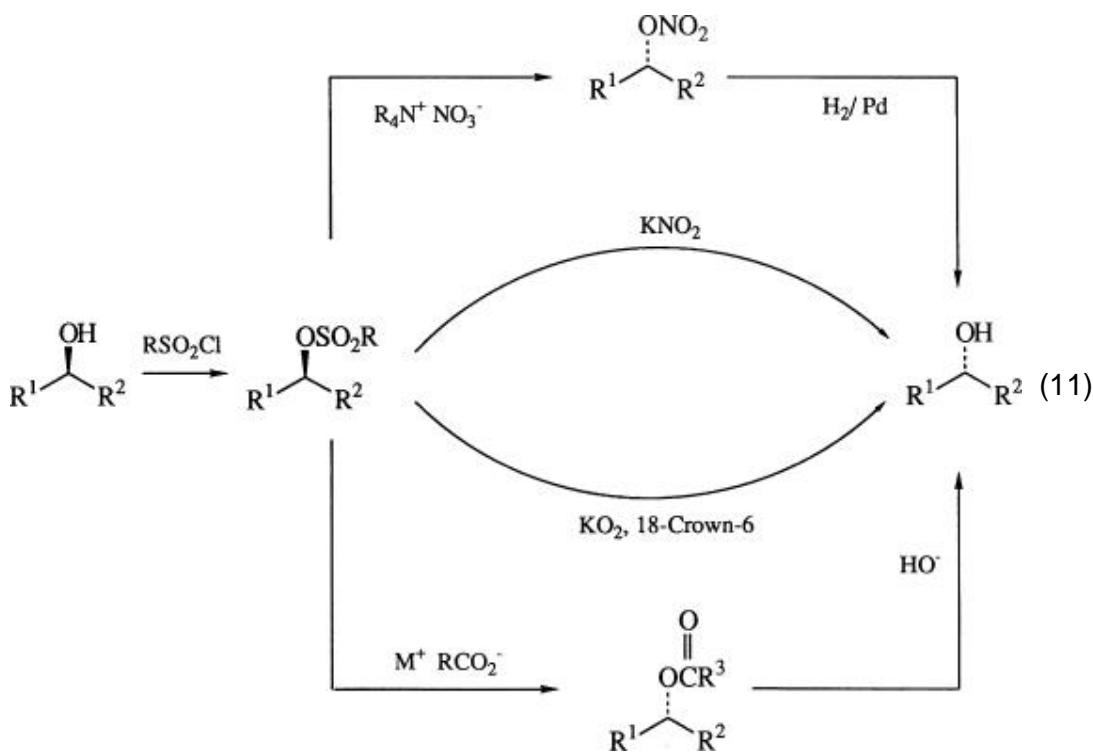

The manipulation of the alcohol functional group is a synthetic goal which has been approached by a wide variety of methods. Most of these methods rely on activation of the hydroxy group followed by displacement with an appropriate nucleophile. In the Mitsunobu reaction the alcohol activation is accomplished via an oxyphosphonium salt. In this section alternatives to the Mitsunobu reaction are discussed and compared in terms of yield, stereoselectivity, and ease of operation.

In general terms the advantages of the Mitsunobu method include the following: (1) generally good yields with high stereoselectivity (inversion); (2) experimental ease since the alcohol activation and displacement reactions take place in one pot, often at room temperature; (3) compatibility with a wide range of functional groups, as outlined in the Scope and Limitations section.

One of the major drawbacks of the Mitsunobu reaction is the difficulty of removing the redox byproducts triphenylphosphine oxide and di(ethoxycarbonyl)hydrazine. This becomes a major concern in large-scale applications where product purification by chromatography is not feasible.

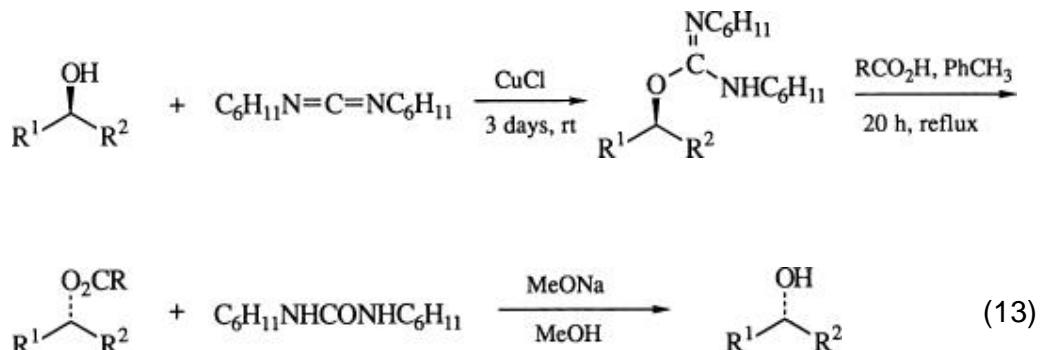

4.1. Inversion of Alcohols

Other than the Mitsunobu reaction, there are several methods for inverting alcohols. Four procedures involve formation of a sulfonate ester followed by: (1) displacement with a cesium, (293-297) potassium, (298, 299) or tetraalkylammonium carboxylate (300) followed by hydrolysis; (2) displacement with potassium superoxide; (301-303) (3) displacement with potassium nitrite; (304, 305) or (4) displacement with nitrate ion followed by reduction (306, 307) (Eq. 11). Similarly, imidazolyl sulfonates, prepared by reaction of the alcohol with *N,N'*-sulfuryldiimidazole, are displaced with inversion of configuration by benzoate (Eq. 12). (308-310) Some documented cases where the alternative methods give better results than the Mitsunobu reaction are described below. For inversion of the homoallylic alcohol (*R*)-ricinealaidic acid (72) the Mitsunobu reaction gives racemization, whereas mesylate formation, substitution with cesium propionate, and hydrolysis with lithium hydroxide give 51% inverted alcohol

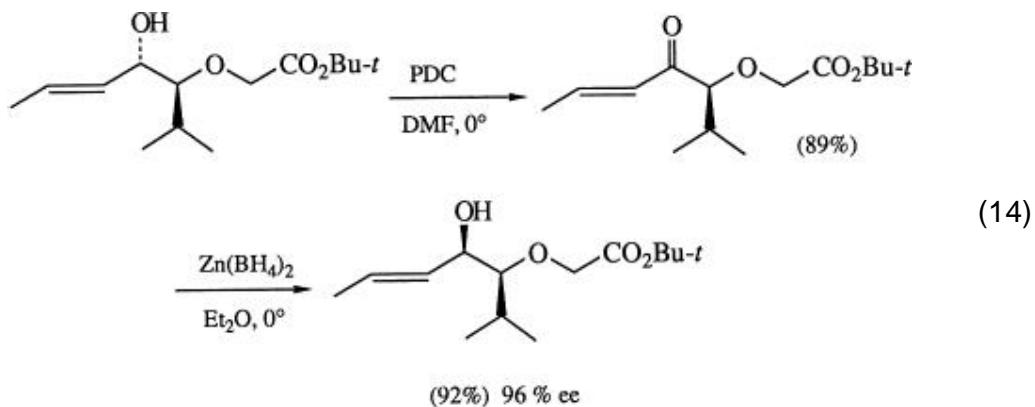

and 30% elimination product. (293) Mitsunobu reaction with 73 gives predominant formation of elimination product and cyclic ether, while mesylate formation followed by cesium acetate/18-crown-6 ether gives a 70% yield of inverted ester with only 5% elimination product. (295) Other examples include inversion of capnellene-8 α ,10 β -diol via the mesylate and potassium superoxide displacement, (303) inversion of 3 α -hydroxygibberellins using reaction of cesium acetate/18-crown-6 ether on the mesylate, (297) inversion

of a crinine precursor using mesylate formation followed by cesium acetate, (296) and inversion of a swainsonine precursor by making the trifluorosulfonate followed by reaction with potassium acetate/18-crown-6 ether. (299) Conversion of alcohols to isourea ethers followed by esterification and hydrolysis is a mild and simple Mitsunobu alternative (Eq. 13). (311) Overall yields range from 45 to

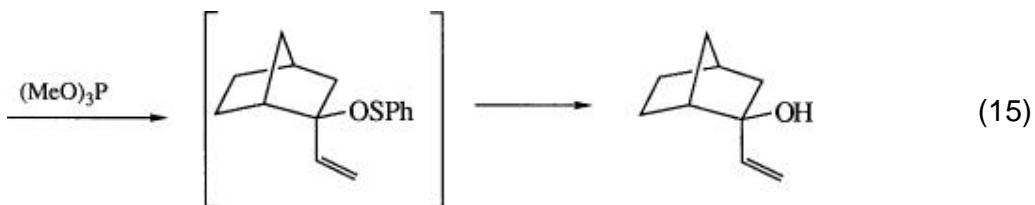

75%. The method is applicable to imide alkylations. (312) An attractive feature of this method is that the dicyclohexylurea byproduct is insoluble and easily removable by filtration.

When alcohol activation/displacement methods do not work, inversion by means of oxidation to a ketone and selective reduction is sometimes a viable alternative (Eq. 14). (313-316) Tertiary alcohols cannot be inverted using the

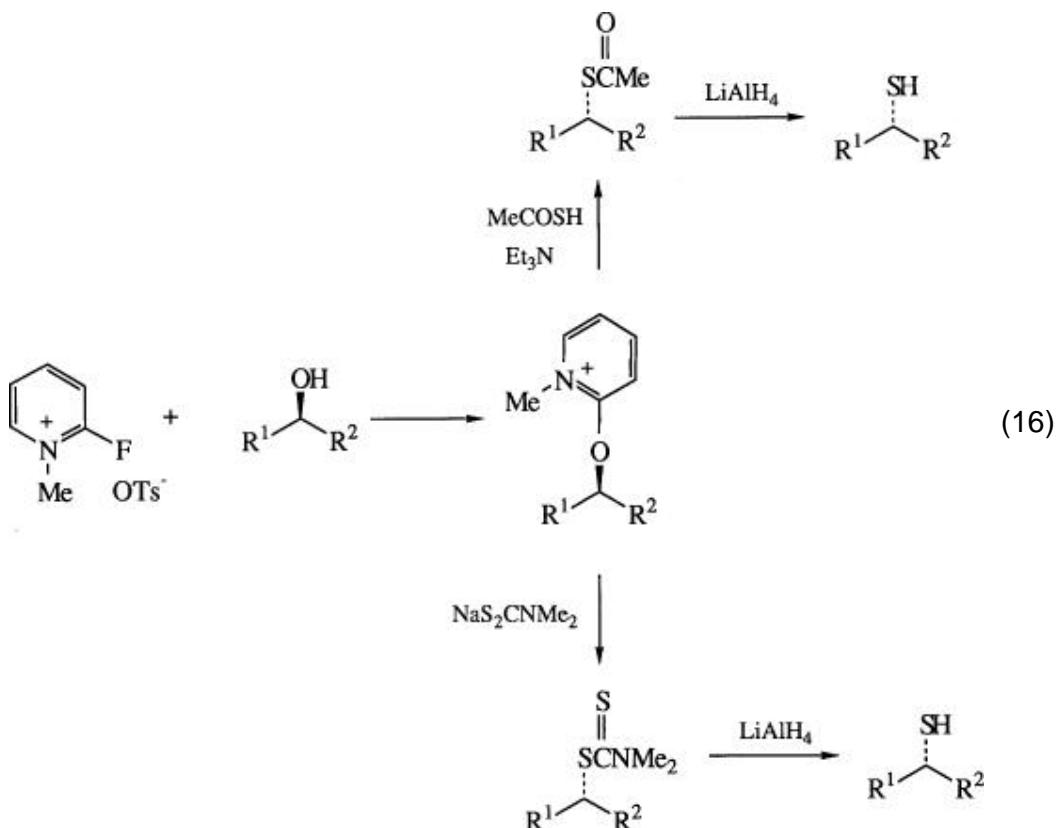

Mitsunobu method or other alcohol activation/displacement methods. As an alternative, tertiary vinyl alcohols are inverted by a [2,3] sulfoxide sigmatropic rearrangement (Eq. 15). (317, 318)

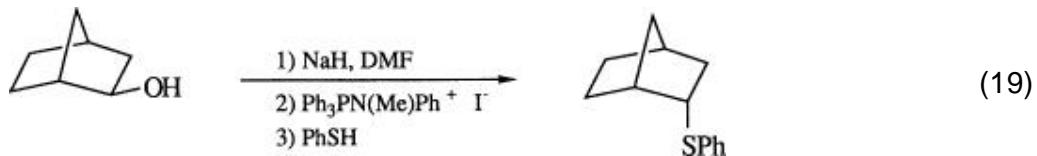

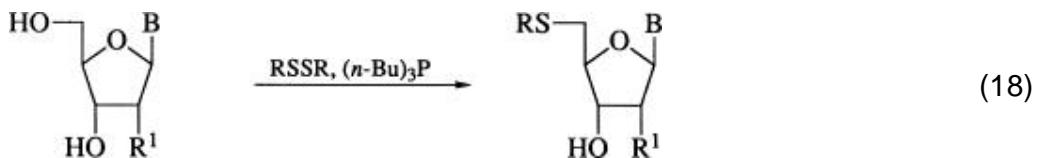

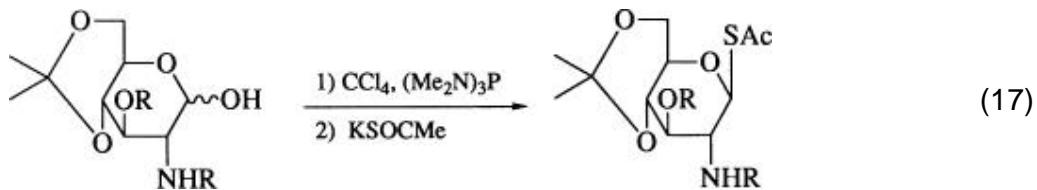

4.2. Carbon–Sulfur Bond Formation from Alcohols

Alternatives to the Mitsunobu reaction for preparing inverted thiols from alcohols include: (1) formation of a sulfonate ester, displacement with a cesium thiocarboxylate, followed by reduction or hydrolysis; (232) (2) formation of 2-alkoxypyridinium salts using 2-fluoro-1-methylpyridinium tosylate, displacement with thiolacetate (319) or sodium *N*, *N*-dimethylthiocarbamate, (320) and reduction (Eq. 16); (3) preparation of alkoxytris(dimethylamino)phosphonium hexafluorophosphate

salts followed by reaction with thiolate, thiocyanate, or thiolacetate (Eq. 17); (321-324) the byproducts are easy to remove since they are water soluble; (4) reaction of the alcohol with a disulfide and tri-*n*-butylphosphine (Eq. 18); (325) (5) reaction of the alcohol with tri-*n*-butylphosphine and an *N*-alkyl- or

N-arylthiosuccinimide; (326) clean inversion of configuration is demonstrated by formation of 3 α -(phenylthio)cholest-5-ene in 81% yield from cholesterol; and (6) activation of an alcohol using aminotriphenylphosphonium

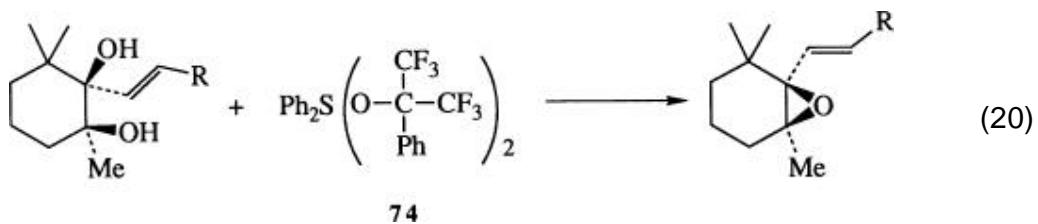

salts followed by displacement with a thiol (Eq. 19). (327) For carbon–sulfur bond formation from alcohols, the Mitsunobu reaction has found the most use in formation of inverted thiolacetates which are usually hydrolyzed or reduced to free thiols. The Mitsunobu and mesylate/cesium carboxylate procedures gave similar yields and enantioselectivities in a side-by-side comparison. (232) In the preparation of phenylthio compounds from primary or secondary alcohols the procedures using tri-*n*-butylphosphine with diaryl disulfides or *N*-(arylthio)succinimide have found the widest use. (328)

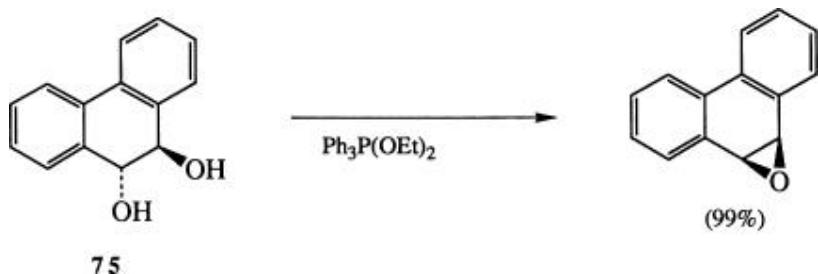

4.3. Carbon–Oxygen Bond Formation

As alternatives to the Mitsunobu reaction, cyclic ethers are prepared from diols by use of diethoxytriphenylphosphorane, (329, 330) pentaethoxyphosphorane, (330, 331) diaryldialkoxysulfuranes, (332, 333) and the reagent systems triphenylphosphine/carbon tetrachloride (334, 335) and tris(dimethylamino)phosphine/carbon tetrachloride. (336, 337) A comparative study of the cyclodehydration of chiral diols using triphenylphosphine/carbon tetrachloride/potassium carbonate, diethoxytriphenylphosphine, and triphenylphosphine/DEAD revealed that (*S*)-propane-1,2-diol and (*R*)-pentane-1,4-diol cyclize with retention of configuration while (*S*)-phenylethane-1,2-diol gives primarily racemic styrene oxide with all three reagent systems. (181)

Two noteworthy reactions are the following: The sulfurane **74** promotes the epoxidation of the highly hindered bis(tertiary) alcohol (Eq. 20). (333)
Diethoxytriphenylphosphine

converts the acidic and thermally sensitive diol **75** to the arene oxide in 99% yield, demonstrating the mildness of the reaction conditions. (329)

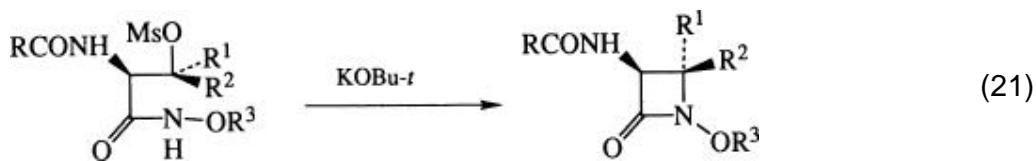

Aryl alkyl ethers are prepared from reaction of the alcohol with tris(dimethylamino) phosphine/carbon tetrachloride followed by reaction with phenols. (322)

4.4. Carbon–Nitrogen Bond Formation

Formation of azides from alcohols is accomplished using triphenylphosphine/carbon tetrachloride/lithium azide (338, 339) or tris(dimethylamino)phosphine/carbon tetrabromide/sodium azide. (321, 340) A comparison of reagents used in the preparation of 5' -azido-5' -deoxythymidine from thymidine indicates that triphenyl phosphine/carbon tetrabromide/lithium azide produces better yields (90%) than triphenyl phosphite/iodomethane/lithium azide (50% yield) or triphenylphosphine/DEAD/lithium azide (36–46% yields). (339)

Aziridines, azetidines, and pyrrolidines are prepared by action of triphenylphosphine dibromide (341-343) or triphenylphosphine/carbon tetrachloride/triethylamine (344, 345) on the appropriate aminoalkanols.

For large-scale preparation of β -lactams, cyclization of a β -mesylate is a viable alternative to the Mitsunobu cyclization since chromatographic separation of the redox byproducts is not required (Eq. 21). (346, 347)

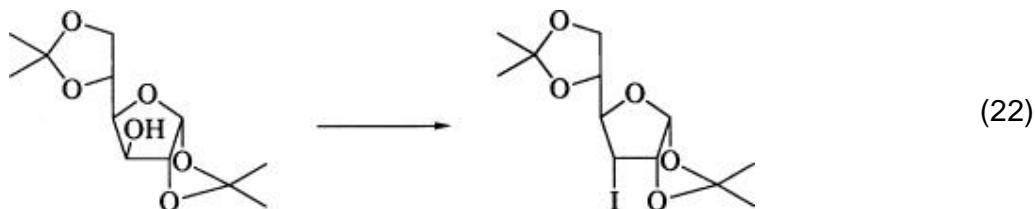

4.5. Formation of Carbon–Halogen Bonds

Other than the Mitsunobu reaction, alcohols are converted to halides by several methods. Many of these methods involve mechanisms similar to the Mitsunobu reaction in that an oxyphosphonium salt formed from the alcohol is then converted to the halide by an S_N2 displacement. These methods include the reagents triphenyl phosphite/iodomethane, triphenylphosphine/halogen adducts, triphenylphosphine/carbon tetrahalide, triphenylphosphine/2,4,5-triiodoimidazole, triphenylphosphine/*N*-halosuccinimide, and tris(dimethylamino) phosphine/carbon tetrachloride. A comprehensive review of these reagents was published in 1983. [6a](#)

Activation of the alcohol is also accomplished by formation of imidazolyl sulfonate, [\(308–310\)](#) trifluoromethanesulfonates, [348–349](#) imino esters, [\(350\)](#) chlorosulfates, [\(351\)](#) 2-alkoxybenzoxazolium salts, [\(352\)](#) and 2-alkoxybenzothiazolium salts, [\(353\)](#) followed by S_N2 displacement with halide.

Diacetone-D-glucose, having a hindered secondary hydroxy group, serves as a good example to compare the various reagents. The inverted iodide (Eq. 22) is prepared in moderate to good yields by nearly all the reagents, as shown

in Table A. By contrast, none of the methods give the inverted chlorides or bromides in appreciable yields. With the phosphonium reagents, rearrangement of the 5,6-isopropylidene groups or elimination are the major reaction pathways.

^aThe major reaction is rearrangement to 6-halide.

^bThe major side reaction is elimination.

4.6. Carbon–Carbon Bond Formation

C-Glycosides are synthesized by reaction of malonate anions with sugar hydroxy groups that have been activated as alkoxytris (dimethylamino)

phosphonium salts. (362) Alcohols are converted to nitriles using tris(dimethylamino)phosphine

/carbon tetrachloride/potassium cyanide (321, 363) or triphenylphosphine/carbon tetrachloride/potassium cyanide. (364, 365)

Alcohols activated as 1-ethyl-2-alkoxypyridinium salts react with Grignard reagents to form carbon–carbon bonds. (366)

5. Experimental Considerations

Although optimal conditions for the Mitsunobu reaction depend on the substrate alcohol and the nucleophile, a few generalities are outlined below.

5.1.1.1.1. Solvent

The majority of Mitsunobu reactions are carried out in tetrahydrofuran solution. However, several other solvents have been used with good results, including dioxane, (62, 178, 367) dichloromethane, (368-370) chloroform, 175–176 diethyl ether, (52, 54, 86, 96, 99, 371-373) dimethylformamide, (139, 176, 177, 374) toluene, (34, 35, 375, 376) benzene, (48, 49, 53, 90, 106, 111, 123, 128, 377-383) and hexamethylphosphoramide. (138, 384) The dipolar aprotic solvents have found use with carbohydrates that are insoluble in the typical nonpolar solvents.

5.1.1.1.2. Phosphine

Triphenylphosphine has been used in more than 90% of the reported Mitsunobu reactions. Tri-*n*-butylphosphine, (215, 248, 385, 386) substituted triarylphosphines, (7) tris(dimethylamino)phosphine, (215) trialkyl phosphites, (170, 180, 215, 219) triphenyl phosphite, (216) phenoxydiphenylphosphine, (216) and diphenoxypyphenylphosphine (216) have found limited use. Use of diphenyl(2-pyridyl)phosphine (387) and (4-dimethylamino)diphenylphosphine (197) facilitate product isolation since the resulting phosphine oxide is removed by aqueous acid washing. Use of polymeric triphenylphosphine eliminates the problem of phosphine oxide removal from the product. 388a

5.1.1.1.3. Azodicarboxylate

Diethyl and diisopropyl azodicarboxylates are used in most Mitsunobu applications and generally can be used interchangably. Dimethyl azodicarboxylate is used less often, but has the advantage that the byproduct hydrazine can be removed by aqueous extraction. (170) Polymer-supported alkyl azodicarboxylates can be used, and have the advantages of facilitating product purification and of being reusable. 388b Oxidants other than azodicarboxylates successfully employed in Mitsunobu reactions include 4-methyl-1,2,4-triazolidine-3,5-dione (58), (264) dibenzoyl peroxide, (133) dimethyl ketomalonate, (389) and 3-methylbenzothiazole-2-selone. (390)

5.1.1.1.4. Nucleophile

For inversions, typical carboxylic acid nucleophiles include benzoic acid, acetic acid, formic acid, 4-nitrobenzoic acid, and 3,5-dinitrobenzoic acid. The latter two are often used since the corresponding esters are generally crystalline compounds which can be readily purified. For compounds with acidic or basic labile functionalities such as β -lactams, formic acid or phenoxyacetic acid (28) are used since the corresponding esters are readily hydrolyzed. Mosher esters

are prepared using α -methoxy- α -(trifluoromethyl)phenylacetic acid. (126, 127, 391, 392)

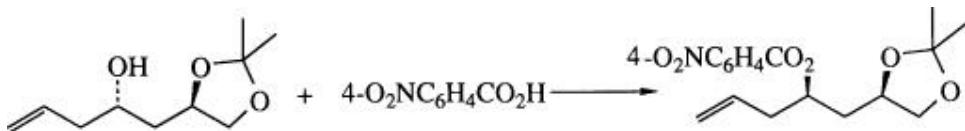

5.1.1.1.5. Temperature

Most Mitsunobu reactions are carried out between 0° and room temperature. More hindered secondary alcohols, such as those found in carbohydrates, often require temperatures of 70–100°. An initial temperature of –50° gives increased selectivity in the esterification of an anomeric center in carbohydrates. (50)

5.1.1.1.6. Order of Addition of Reagents

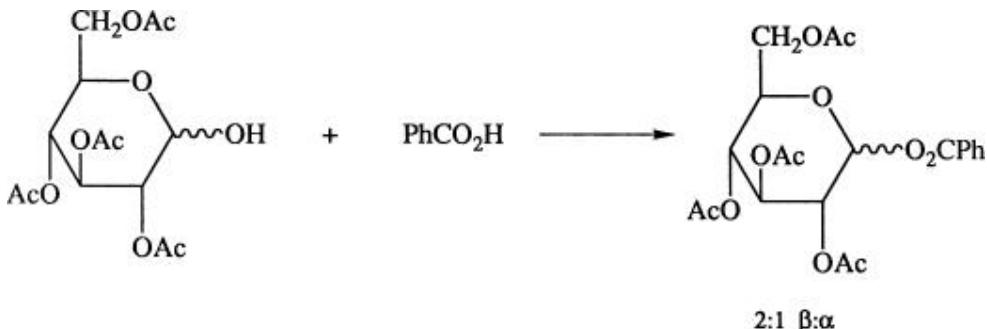

Typically, triphenylphosphine, the alcohol, and the nucleophile are dissolved in the solvent and DEAD is added dropwise to the solution. (5) Alternatively, DEAD and triphenylphosphine are reacted first to form the DEAD-triphenylphosphine adduct, followed by addition of the alcohol and the nucleophile. (50, 231) Since DEAD is a strong oxidant, Michael acceptor, and dienophile, it is important that no excess DEAD be present in the reaction. This is accomplished either by preforming the DEAD–triphenylphosphine adduct or by adding DEAD slowly to the reaction mixture so that the DEAD–triphenylphosphine adduct forms while keeping the DEAD concentration low. In tetrahydrofuran and dichloromethane solution, formation of the DEAD–triphenylphosphine adduct is fast, completing within minutes at –20°. (7)

6. Experimental Procedures

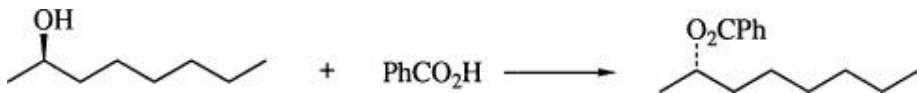

6.1.1.1. (4S)-2,2-Dimethyl-4-[(2R)-2-(4-nitrobenzoyloxy)pent-4-enyl]-1,3-dioxolane (Esterification with Inversion) (34)

To a stirred suspension of triphenylphosphine (5.41 g, 0.0206 mol) and 4-nitrobenzoic acid (3.45 g, 0.0206 mol) in toluene (60 mL) cooled to -30° was added a solution of (4S)-2,2-dimethyl-4-[(2S)-pent-4-enyl-2-ol]-1,3-dioxolane (3.2 g, 0.0172 mol) in toluene (10 mL). A solution of diethyl azodicarboxylate (3.3 mL, 0.0206 mol) in toluene (30 mL) was added dropwise over 15 minutes to the vigorously stirred mixture while the temperature was maintained at -30° . When the addition was complete the mixture was allowed to warm gradually to 0° over 1 hour whereupon saturated aqueous sodium bicarbonate (75 mL) was added. The aqueous phase was separated and extracted with ether (2×75 mL). The organic extracts were combined, dried, and concentrated. To the residue was added ether (25 mL) and hexane (75 mL) whereupon the bulk of the triphenylphosphine oxide was filtered off. Concentration of the residue gave a viscous oil which was purified by chromatography (ether–hexane 1:4) to give the 4-nitrobenzoate ester (5.23 g, 90%) as colorless needles from cold hexane, mp 28–30°; $[\alpha]_D^{21} = -44.8^\circ$ (c 2.5, CHCl₃); ν_{max} (CHCl₃) 1725, 1608, 1530, 1352, 1275, 920, 874, 840 cm⁻¹; ¹H NMR δ 8.1–8.4 (4H, m), 5.5–6.1 (1H, m), 5.35 (1H, m), 5.18 (1H, m), 5.05 (1H, m), 3.9–4.35 (1H, m), 4.0 (1H, dd, *J* = 6, 6 Hz), 3.55 (1H, dd, *J* = 5, 7.7 Hz), 2.05 (2H, m), and 1.32 and 1.38 (3H each, s); Anal. Calcd. for C₁₇H₂₁O₆N : C, 60.88; H, 6.31; N, 4.17. Found: C, 60.75; H, 6.35; N, 4.2

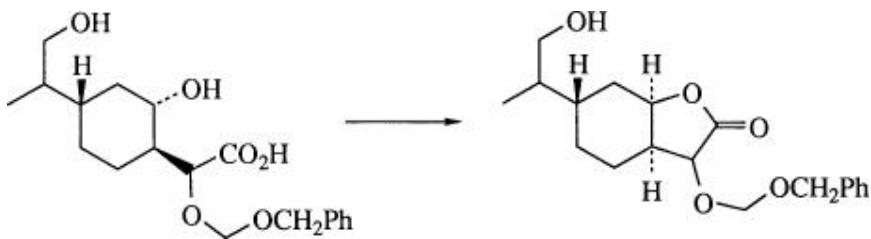

6.1.1.2. 2,3,4,6-Tetra-O-acetyl-1-O-benzoyl-D-glucose (Selective Esterification of an Anomeric Center) (50)

To a solution of triphenylphosphine (0.98 g, 3.7 mmol) in dry tetrahydrofuran (6 mL) at -50° , under an argon atmosphere, was added DIAD (0.74 mL, 3.7 mmol). The mixture was stirred at this temperature for 10 minutes, whereupon a thick yellow precipitate formed. The hemiacetal 2,3,4,6-tetra-O-acetyl-D-glucose (1.0 g, 2.9 mmol) was added and the stirring continued at -50° for a further 10 minutes before benzoic acid (0.46 g, 3.8 mmol) was added. The mixture was allowed to warm slowly to room temperature over a period of 2 hours, the solvent removed in vacuo, and the residue purified by flash chromatography (ethyl acetate/hexane 1:4) to furnish the title compound (1.04 g, 80%) as a 2:1 mixture of anomers. Crystallization from ether gave the pure β -anomer (mp 143–144°); $[\alpha]_D - 27.6^\circ$ (c 1.0, CHCl_3).

6.1.1.3. 2-(+)-Benzoyloxyoctane (Esterification using Polymer-Supported Triphenylphosphine) 388a

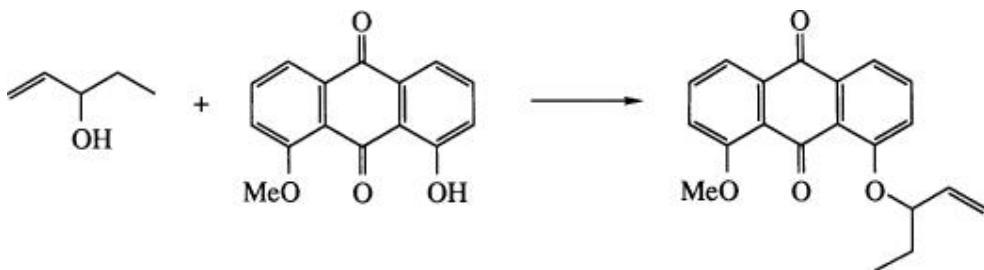

Benzoic acid (3.05 g, 2.5 mmol) and polymer-supported triphenylphosphine (1.5 g, 4.4 mmol contained P) were weighed into an oven-dried 50-mL flask. Dry tetrahydrofuran (10 mL) was then added under a nitrogen atmosphere, followed by 2-($-$)-octanol (3.25 g, 2.5 mmol) diluted with tetrahydrofuran (5 mL). The flask was cooled on a 25° water bath while DEAD (6.09 g, 3.5 mmol) was added by syringe over 2–3 minutes. The polymer darkened in appearance, but little yellow color from the DEAD reagent remained in solution. TLC indicated complete reaction within 10 minutes. The mixture was stirred 4 hours at ambient temperature and then filtered. The polymer was thoroughly washed with ether. Evaporation of the solvent afforded an oily white solid containing the ester and the sym-dicarbethoxyhydrazine. The mixture was transferred to and eluted from a shortpath silica column using 5–10% ether in hexane (the majority of the hydrazine product is insoluble in this solvent). Removal of solvent after chromatography gave the title compound in 65% yield.

6.1.1.4. (3a*S*,6*S*,7*aR*)-3-[Benzylxy]methoxy]hexahydro-6-(2-hydroxy-1-methylethyl)-2(3*H*)-benzofuranone (Lactonization of a Secondary Alcohol in the Presence of a Primary Alcohol) (150)

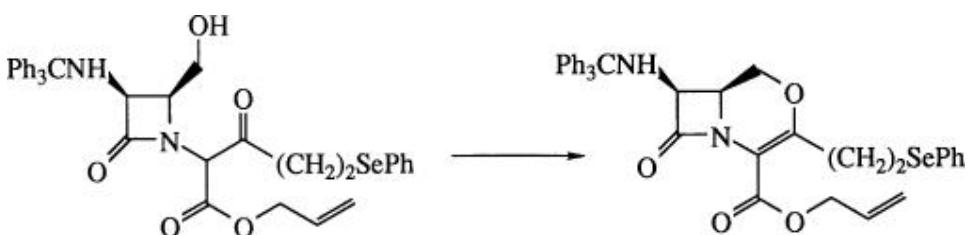

A magnetically stirred solution of tetrahydrofuran (310 mL) and triphenylphosphine (5.2 g, 19.8 mmol) at -20° under nitrogen was treated with diethyl azodicarboxylate (2.3 mL, 14.8 mmol) in tetrahydrofuran (10 mL). After 30 minutes at -20° , diastereomeric diols

(1*S*,2*S*,4*S*)-7-[(benzyloxy)methoxy]-2,9-dihydroxy-*p*-menthane-7-carboxylic acid (2.6 g, 7.39 mmol) in tetrahydrofuran (50 mL) were added via syringe pump over 4.5 hours while carefully maintaining the reaction temperature at -20° . The reaction mixture was quenched at -20° with saturated aqueous sodium chloride (100 mL) and 30% hydrogen peroxide. After dilution with ether (500 mL) the layers were separated and the aqueous layer was extracted with additional ether (3×200 mL). The combined organic layers were dried with magnesium sulfate and filtered, and the solvents were removed in vacuo. Flash chromatography (70/30 ethyl acetate/hexanes) afforded a mixture of epimeric lactones contaminated with diethyl hydrazodicarboxylate. Analytical samples were obtained by medium pressure liquid chromatography (75/25 ethyl acetate/hexanes) α -isomer: white crystals, mp 83–84°; IR (thin crystalline film) 3500, 2900, 1780, 1500, 1450, 1380, 1340, 1275, 1200, 1160, 1060, 1025, 960, 900, 855, 740, 695 cm^{-1} ; ^1H NMR (CDCl_3) δ 7.30 (s, 5H), 4.85 (AB_q , $J_{\text{AB}} = 8.0$ Hz, 2H), 4.85 (br m, 1H), 4.6 (s, 2H), 3.90 (br s, 1H), 3.55 (m, 2H), 2.20 (br d, 2H), 1.90–1.00 (m, 7H), 0.95 (d, $J = 6.6$ Hz, 3H); MS, m/e 335 ($M + H$, isobutane).

6.1.1.5. 1-Methoxy-8-O-(1-penten-3-yl)anthraquinone (Preparation of an Alkyl Aryl Ether) (393)

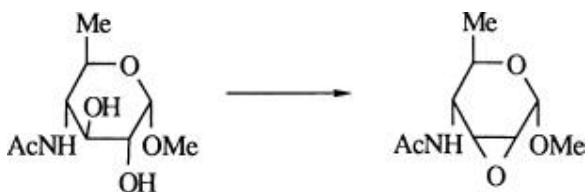

To a stirred solution of 1-hydroxy-8-methoxyanthraquinone (20 g, 78.7 mmol), triphenylphosphine (26 g, 95.9 mmol), and 1-penten-3-ol (12 mL, 10.1 g, 0.117 mol) in dry tetrahydrofuran (300 mL) at 0° was added dropwise from an addition funnel diethyl azodicarboxylate (20 mL, 20.12 g, 0.127 mol) dissolved in dry tetrahydrofuran (50 mL). After addition, the mixture was stirred at room temperature for 1 hour. Tetrahydrofuran was removed under reduced pressure to give a dark red syrup which was filtered through neutral alumina with dichloromethane and then chromatographed on silica gel (3:1 hexane/ethyl acetate) to provide the yellow ether (22.1 g, 87%); mp 97–98.5°; ¹H NMR (CDCl_3) δ 1.10 (t, 3H, $J = 7.4$ Hz), 1.98 (m, 2H), 4.01 (s, 3H), 4.68 (m, 1H), 7.28 (m, 2H), 7.59 (m, 2H), 7.81 (m, 2H). High resolution mass spectrum: Calcd. for $\text{C}_{20}\text{H}_{18}\text{O}_4$: 322.1204. Found: 322.1201.

6.1.1.6. Allyl(6S,7S)-8-Oxo-3-[2-(phenylseleno)ethyl]-7-(tritylamino)-1-aza-4-oxa-bicyclo[4.2.0]oct-2-ene-2-carboxylate (Formation of a Cyclic Enol Ether) (394)

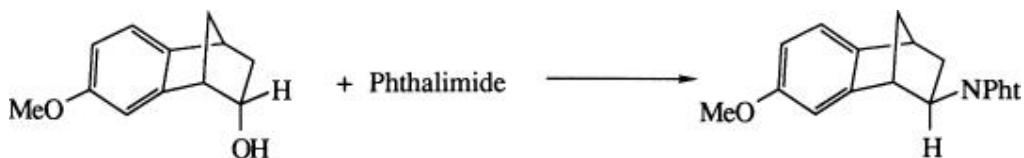

To a solution of allyl

2-[(3S,4S)-4-hydroxymethyl-2-oxo-3-tritylamino-1-azetidinyl]-3-oxo-5-phenylselenopentanoate (6.49 g, 9.73 mmol) and triphenylphosphine (2.68 g, 1.05 equiv) in dry tetrahydrofuran (270 mL) under argon was added diisopropyl azodicarboxylate (2.07 mL, 1.05 equiv). After 15 minutes the solvent was removed, and the residual oil was chromatographed to afford the O-2-isocephem (5.30 g, 73%) as white crystals (from ethyl acetate/hexane): mp 128–129°; IR (KBr) 1770, 1710, 1610 cm^{-1} ; ¹H NMR (CDCl_3) δ 2.71–3.35 (m, 8H), 4.56–4.97 (m, 3H), 5.20–5.42 (m, 2H), 5.83–6.00 (m, 1H), 7.19–7.49 (m, 20H).

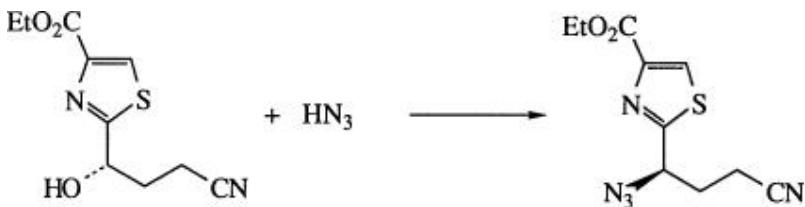

6.1.1.7. Methyl 4-Acetamido-2,3-anhydro-4,6-dideoxy- α -D-allopyranoside (Formation of an Epoxide) (175)

Triphenylphosphine (2.0 g) was added to a solution of methyl 4-acetamido-4,6-dideoxy- α -D-glucopyranoside (630 mg, 2.9 mmol) in ethanol-free chloroform (50 mL). After stirring 15 minutes, diethyl azodicarboxylate (1.3 g) was added dropwise. The mixture was stirred 4 hours at room temperature and then allowed to stand overnight. The solvent was removed and the residue subjected to column chromatography on silica gel (60 g). Balast compounds were eluted with benzene–ethanol (100:2); product was isolated in 99% yield (570 mg); mp 185–186° (from ethyl acetate); $[\alpha]_D + 205^\circ$ (CHCl_3). ^1H NMR (CDCl_3) δ 1.15 (3H, d, $J_{56} = 6.1$ Hz, H-6), 2.00 (3H, s, MeCON), 3.35 (dd, $J_{23} = 4.0$ Hz, H-3), 3.40 (3H, s, MeO), 3.50 (dd, $J_{12} = 3.2$ Hz, H-2), 3.59 (dq, $J_{45} = 9.5$ Hz, H-5), 4.15 (dt, $J_{34} = 1.8$ Hz, H-4), 4.86 (d, H-1), 6.24 (d, $J_{4-\text{NH}} = 9.0$ Hz, NH).

6.1.1.8. exo-2-Phthalimido-7-methoxybenzonorbornene (Phthalimide as a Nucleophile) (205)

A solution of *endo*-2-hydroxy-7-methoxybenzonorbornene (600 mg, 3.15 mmol), phthalimide (640 mg, 4.3 mmol), and triphenylphosphine (1.1 g, 4.2 mmol) in tetrahydrofuran (25 mL) was treated with diethyl azodicarboxylate (0.65 mL, 4.12 mmol). The reaction was stirred at room temperature under argon for 72 hours. Brine (30 mL) was added and the layers separated. The aqueous layer was washed with ether (4×20 mL). The combined organic pool was dried over sodium sulfate, filtered, and evaporated in vacuo to give 2.55 g of a viscous oil, which was purified by flash chromatography with dichloromethane as the eluant to give 850 mg (84%) of product as a white solid: mp 133–134°; ^1H NMR (CDCl_3) δ 7.85–7.55 (m, 4H, phthalimide ArH), 7.08 (d, 1H, $J = 8.0$ Hz, H-5), 6.88 (d, 1H, $J = 2.3$ Hz, H-8), 6.66 (dd, 1H, $J = 8.0$ and 2.3 Hz, H-6), 4.33–3.97 (m, 1H, CHN), 3.77 (s, 3H, OMe), 3.55–3.40 (m, 2H, bridgeheads), 2.88–2.45 (m, 2H, methylene), 2.10–1.45 (m, 2H, methylene); IR (KBr) 2970, 1709, 1612, 1478, 1466, 1370, 1354, 1331, 1289, 1246, 1233, 1128, 1089, 1030, 719, 662 cm^{-1} ; EIMS, m/e (rel. intensity) 319 (3.8, M^+), 146 (100), 131 (20.4), 115, (7.0), 103 (16.5), 77 (8.6).

**6.1.1.9. 4-Ethoxycarbonyl-2-(3'-cyano-1'-(R)-azidoprop-1'-yl)thiazole
(Formation of an Azide) (395)**

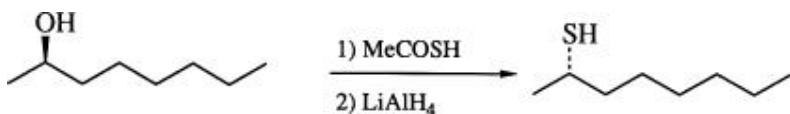

To a stirred solution of 4-ethoxycarbonyl-2-(3'-cyano-1'-(S)-hydroxyprop-1'-yl)thiazole (13.2 g, 55 mmol) and triphenylphosphine (15.9 g, 60.5 mmol) in toluene (225 mL) at room temperature were successively added a solution of hydrazoic acid in absolute toluene (110 mL, 60.5 mmol) and diethyl azodicarboxylate (10.5 g, 60.5 mmol) in absolute toluene (110 mL). The reaction was stirred at room temperature overnight and the solvent was removed in vacuo. The residue was treated with ethyl acetate/petroleum ether (1:1) to remove triphenylphosphine oxide. The filtrate was evaporated and the residue was first filtered on silica gel (ethyl acetate/petroleum ether, 1:1) followed by basic aluminum oxide (ethyl acetate/petroleum ether, 3:7) to give the product azide (13.1 g, 90%); mp 49–50°; $R_f = 0.57$ (ethyl acetate); $[\alpha]_D^{20} + 64.1^\circ$ (c 1.2, CH_2Cl_2); ee > 98%; ^1H NMR (CDCl_3) δ 1.43 (t, 3H, $J = 7$ Hz), 2.10–2.87 (m, 4H), 4.48 (q, 2H, $J = 7$ Hz), 5.15 (m, 1H), 8.35 (s, 1H); Anal. Calcd: for $\text{C}_{10}\text{H}_{11}\text{N}_5\text{O}_2\text{S}$: C, 45.27; H, 4.18; N, 26.40; S, 12.09. Found: C, 45.34; H, 4.24, N, 26.25; S, 11.90.

6.1.1.10. [(4S)-(Benzylloxycarbonyl)]-N-benzyloxy-2-azetidione (Formation of a β -Lactam) (396)

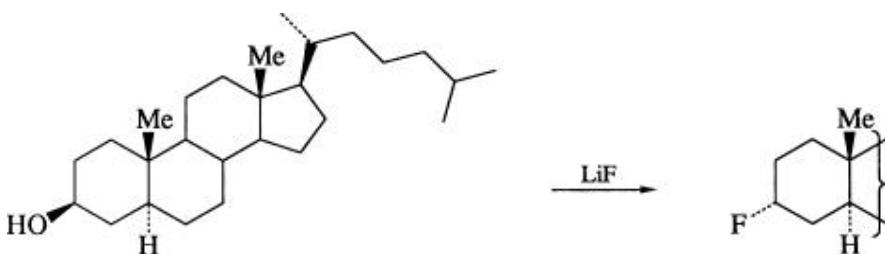

The monobenzyl hydroxamate of D-malic acid (2.64 g, 8.02 mmol) was dissolved in dry tetrahydrofuran (50 mL). Triphenylphosphine (2.0 g, 8 mmol) was added, followed by diethyl azodicarboxylate (1.26 mL). The solution was stirred at room temperature under a drying tube for 11 hours. The solution was then concentrated to 10 mL and chromatographed on a medium-pressure

apparatus with ethyl acetate-hexanes (1:4 then 1:1) on silica gel. Evaporation of the rich cut gave the product as an oil (2.4 g, 96%); $[\alpha]_D^{20} - 12.6^\circ$ (*c* 3.6, MeOH); IR (neat) 1745, 1780 cm^{-1} ; ^1H NMR δ 2.8 (m, 2H), 4.1 (m, 1H), 4.95 (s, 2H), 5.2 (s, 2H), 7.32 (s, 5H), 7.5 (s, 5H).

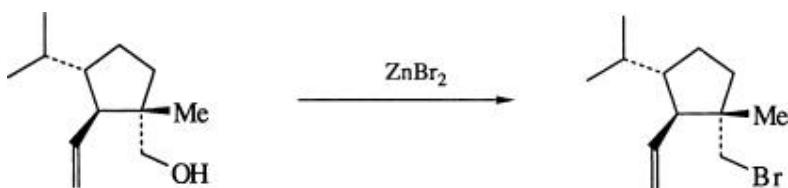

6.1.1.11. (2*S*)-(+)-Octanethiol (*Formation of a Thiol*) (231)

Diisopropyl azodicarboxylate (8.33 g, 40 mmol) was added to an efficiently stirred solution of triphenylphosphine (10.50 g, 40 mmol) in tetrahydrofuran (100 mL) at 0°. The mixture was stirred at 0° for 30 minutes, resulting in a white precipitate. (2*R*)-(-)-Octanol (2.60 g, 20 mmol) and thiolacetic acid (3.04 g, 40 mmol) in tetrahydrofuran (50 mL) were added dropwise over 10 minutes and the mixture was stirred for 1 hour at 0° and 1 hour at 22–25°. A clear yellow solution resulted. The solution was concentrated and then purified by column chromatography over silica gel (elution with hexanes–dichloromethane, 1:1) to give the desired octane thiolacetate (3.70 g, 98%). The thiolacetate (3.00 g, 15.95 mmol) was dissolved in anhydrous ether (25 mL) and added dropwise to a suspension of lithium aluminum hydride (0.61 g, 4.0 equiv) in ether (15 mL) under a nitrogen atmosphere. The reaction mixture was stirred at 22–25° for 0.5 hour and the excess lithium aluminum hydride was destroyed by the careful addition of 1 N hydrochloric acid solution (10 mL). The ether layer was separated and dried over sodium sulfate to give the thiol (2.37 g, 100%) as a clear oil. A purified sample was prepared by distillation (2.05 g, 88.6%), bp 65–70° (15 torr).

6.1.1.12. 3- α -Cholestanyl Fluoride (*Formation of a Carbon–Fluorine Bond*) (263)

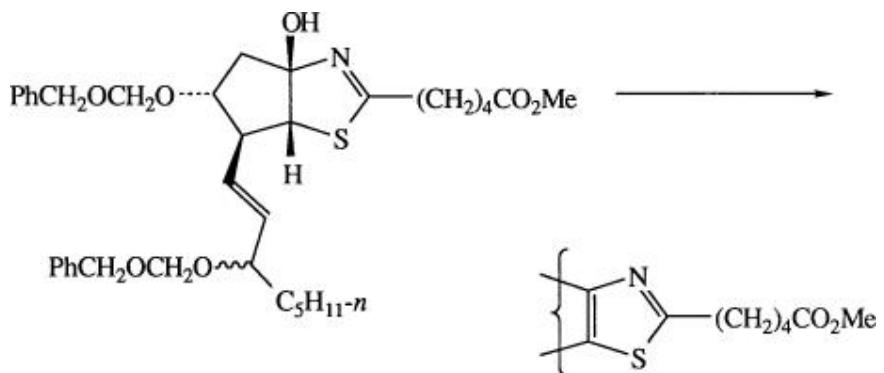

Diethyl azodicarboxylate (1.70 g, 9.8 mmol) was added dropwise with stirring to a 0° solution of triphenylphosphine (2.62 g, 10 mmol) in dry tetrahydrofuran under argon. After 20 minutes lithium fluoride (0.52 g, 20 mmol) was added to the nearly colorless solution followed by 3- β -cholestanol (0.388 g, 1.0 mmol) dissolved in a minimum volume of tetrahydrofuran. The mixture was aged at room temperature until the alcohol was consumed. Upon evaporation of solvent, the residue was poured into water and extracted with ether. The ether extracts were washed with brine, dried over sodium sulfate, and evaporated. Flash chromatography on silica afforded the fluoride in 51% yield.

6.1.1.13. (–)-1(S)-(Bromomethyl)-1-methyl-2 β -vinyl-3 α -isopropylcyclopentane (Formation of a Carbon-Bromine Bond using Zinc Bromide) (397)

A solution of 1(S)-(hydroxymethyl)-1-methyl-2 β -vinyl-3 α -isopropylcyclopentane (0.80 g, 4.4 mmol) and freshly recrystallized triphenylphosphine (3.45 g, 13.2 mmol) in anhydrous tetrahydrofuran (25 mL) was treated with a solution of zinc bromide (0.99 g, 4.4 mmol) in tetrahydrofuran (15 mL) followed by a solution of diethyl azodicarboxylate (2.1 mL, 13.3 mmol) in tetrahydrofuran (15 mL). After 15 minutes, the transparent orange solution became a slurry. The mixture was stirred at room temperature for 16 hours and filtered. Concentration of the filtrate in vacuo gave an orange residue that was purified by chromatography on silica gel (hexane elution) to give the product (0.98 g, 91%) as a colorless oil:

$[\alpha]_D^{23} = 13.98^\circ$ (c 2.9, CHCl_3); ^1H NMR (300 MHz, CDCl_3) δ 5.61 (ddd, $J = 17.1, 10.3, 9.4$ Hz, 1H), 5.05 (dd, $J = 10.3, 2.1$ Hz, 1H), 5.00 (dd, $J = 17.2, 2.1$ Hz, 1H), 3.38 (d, $J = 9.9$ Hz, 1H), 3.34 (d, $J = 9.9$ Hz, 1H), 2.13 (dd, $J = 9.6, 9.7$ Hz, 1H), 1.89–1.27 (series of m, 6H), 0.96 (s, 3H), 0.90 (d, $J = 6.8$ Hz, 3H), 0.83 (d, $J = 6.7$ Hz, 3H); ^{13}C NMR (75 MHz, CDCl_3) δ 139.4, 116.6, 54.9, 48.8, 46.5, 45.8, 37.0, 30.0, 24.2, 21.9, 20.7, 18.0; MS, m/z ($\text{M}^+ - \text{Br}$) Calcd. 165.1643, Obsd 165.1685.

6.1.1.14. Methyl

[(5a,6b)(1E,3R)]-5,6-Dihydro-5-[(phenylmethoxy)methoxy]-6-(3-[(phenylmethoxy)methoxy]-1-octenyl)-4H-cyclopentathiazole-2-pentanoate (Dehydration to Form an Alkene) (278) Methyl(3a*R*-(3a*α*,5*β*,6*a*,(1*E*,3*R*),
6*aα*))-3*a*,5,6,6*a*-tetrahydro-3*a*-hydroxy-5-[(phenylmethoxy)methoxy]-6-(3-[(phenylmethoxy)methoxy]-1-octenyl)-4*H*-cyclopentathiazole-2-pentanoate (0.60 g) was dissolved in dry tetrahydrofuran (10 mL). Diethyl azodicarboxylate (1.04 g, 6.0 mmol) was added and the solution was cooled to 0°, followed by addition of triphenylphosphine (1.60 g, 6.10 mmol). The reaction was aged for 20 hours, then the solvent was removed, and the residue was partitioned between ether (30 mL) and water (30 mL). The organic layer was separated, washed with brine, and dried. Evaporation gave a gum (3.1 g) which was purified by column chromatography (100 g of silica gel, 33% ethyl acetate/hexane) to give the thiazole (0.38 g, 67%) as a clear oil: IR (CHCl₃) 1730 cm⁻¹; ¹H NMR (300 MHz, CDCl₃) δ 0.88 (3H, t), 1.20–1.88 (12H, m), 2.37 (2H, t), 2.84 (1H, dd, *J* = 16.0, 4.8 Hz), 2.98 (2H, t), 3.15 (1H, dd, *J* = 16.0, 6.9 Hz), 3.68 (3H, s), 3.86 (1H, m), 4.07 (1H, m), 4.58 (1H, m), 4.50–488 (8H, m), 5.48 (1H, m), 5.76 (1H, m), 7.33 (10H, m); MS (Cl) m/e 622 (MH⁺), 484, 408, 364.

7. Tabular Survey

Mitsunobu reactions of alcohols to form carbon–oxygen, carbon–nitrogen, carbon–sulfur, and carbon–halogen bonds are grouped in Tables I–XX and follow the order of the discussion in the Scope and Limitations section.

Because of the large number of examples of ester formation, this category has been further broken down into six subcategories that relate to the general nature of the alcohol component: general secondary alcohols, general primary alcohols, alcohols contained in β -lactams, alcohols contained in steroids, alcohols contained in carbohydrates, and allylic alcohols.

Within each table, the compounds are listed according to increasing carbon number, and increasing hydrogen number within a given carbon number. Yields are given in parentheses; numbers not in parentheses are product ratios. A dash indicates that no yields or experimental conditions are given in the reference. Unless otherwise noted, triphenylphosphine and diethyl or diisopropyl azodicarboxylate were used in the reactions.

Some entries involve esterification of a structurally large alcohol with a comparably large acid to give a product that, even using a partial structure, is too large for the printed page. In such entries, the notation [RH] appears under the acid structure, and the product structure contains R in place of the acid. Likewise, when very large ethers are products, the notation [ROH] appears under the hydroxy compound, and the product contains RO in place of the hydroxy compound.

The literature has been reviewed from 1981 through June 1990. Examples of reactions prior to 1981 are found in the previous reviews of Castro [6a](#) and Mitsunobu. [\(5\)](#)

The following abbreviations are used in the tables:

Ac	acetyl
Bn	benzyl
Boc	<i>tert</i> -butoxycarbonyl
Bz	benzoyl
C ₅ H ₉	cyclopentyl
C ₆ H ₁₁	cyclohexyl
Cbz	carbobenzyloxy
ClAc	chloroacetyl
DEAD	diethyl azodicarboxylate

DIAD	diisopropyl azodicarboxylate
DMAD	dimethyl azodicarboxylate
DMF	<i>N,N</i> -dimethylformamide
DMTr	4,4¢-dimethoxytriphenylmethyl
Ether	diethyl ether
HMPA	hexamethylphosphoric triamide
MEM	methoxyethoxymethyl
Mes	mesityl
MOM	methoxymethyl
MTD	4-methyl-1,2,4-triazoline-2,5-dione
MTFPA	2-methoxy-2-(trifluoromethyl)phenylacetic acid
Pht	<i>o</i> -phthalyl, <i>o</i> -C ₆ H ₄ (CO) ₂
pNB	<i>p</i> -nitrobenzyl
rt	room temperature
SEM	(2-trimethylsilylethoxy)methyl
TES	triethylsilyl
THF	tetrahydrofuran
THP	tetrahydropyranyl
Ts	<i>p</i> -toluenesulfonyl

8. Acknowledgments

I wish to thank Dr. Edward Grabowski for serving as a catalyst for this chapter, and for his many helpful comments and discussions.
