A Pd⁰ complex is spontaneously generated from Pd(OAc)₂ and a bidentate phosphine such as dppp (1,3-bis(diphenylphosphino)propane). dppp is the reducing agent and is oxidized to the hemioxide dppp(O). The intramolecular reduction step is reversible. A stable Pd⁰ complex is quantitatively formed in the presence of 2 equiv of dppp, water, and a base (NEt₃). The oxidative addition of PhI gives a cationic complex, PhPd(dppp)(dppp(O))⁺, in which dppp(O) behaves as a monodentate ligand. PhPd(OAc)(dppp) is formed in the presence of added AcO⁻. The oxidative addition of PhI is an intricate reaction whose kinetics has been investigated only in the presence of added AcO⁻. It involves reactive dimeric or/and monomeric Pd⁰ complexes ligated by AcO⁻ whose relative reactivity is a function of the PhI concentration.

Introduction

It has been established that a Pd⁰ complex is spontaneously formed from Pd(OAc)₂ and monodentate phosphine ligands by an irreversible intramolecular reduction of a Pd^{II} complex by the phosphine (Scheme 1).¹ Phosphine oxide is formed in the reduction process.

Scheme 1. Mechanism of the Formation of Pd⁰ from Pd(OAc)₂ and PPh₃

Overall reaction

At least 3 equiv of PPh₃ are required to get a stable anionic 16-electron complex, Pd⁰(PPh₃)₂(OAc)⁻ (eq 2), in which one acetate of the Pd(OAc)₂ precursor remains ligated to the Pd⁰ center.² Pd⁰(PPh₃)₂(OAc)⁻ is the reactive species in oxidative addition of phenyl iodide (eq 3), which yields the unexpected PhPd(OAc)(PPh₃)₂ complex.^{1,2} The latter is the reactive species in Heck reactions, establishing the important role played by the acetate ions delivered by the catalytic precursor (Scheme 2).^{2,3}

Addition of bidentate bisphosphine ligands to Pd(OAc)₂ also provides efficient catalytic precursors for

a Pd⁰ complex, Pd⁰(Binap)₂, from Pd(OAc)₂ associated with 3 equiv of Binap (2,2'-bis(diphenylphosphino)-1,1'-binaphthyl) has been reported by Hayashi and Osawa.⁸ Binap has been identified as the chemical reducer, which is oxidized to the hemioxide Binap(O). In this case, the formation of the Pd⁰ complex is significantly accelerated by addition of water.

We report here mechanistic investigations on the mechanism of formation of Pd⁰ complexes from Pd(OAc)₂ and *n* equiv (*n* = 1–3) of dppp (1,3-bis(diphenylphosphino)propane, PPh₂(CH₂)₃PPh₂)⁷ as a prototype of chelating bisphosphines and on their reactivity in oxidative addition. In contrast to PPh₃, which is oxidized to (O)PPh₃ (Scheme 1), an insignificant poor ligand that does not play any role in catalytic reactions, the situation is expected to be much more complicated in the case of bidentate ligands. Indeed, the mono-oxidation of PPh₂(CH₂)₃PPh₂ provides a hemioxide ligand, PPh₂(CH₂)₃PPh₂(O) (named dppp(O) in the following), which still remains a monodentate phosphine ligand able to coordinate palladium complexes.

Results and Discussion

Evidence for the Formation of Palladium(0) Complexes from Pd(OAc)₂ and dppp in DMF. Pd(OAc)₂ + 1 equiv of dppp. Addition of 1 equiv of dppp to Pd(OAc)₂ in DMF (containing *n*Bu₄NBF₄, 0.3 M) results in the formation of a yellow-orange solution, which exhibited a reduction peak at *E*^p = -1.47 V vs SCE.⁹ The complex formed in solution was relatively stable at room temperature, as attested by its constant reduction peak current intensity (the current intensity is proportional to the electroactive species concentration). The complex exhibited a broad ³¹P NMR singlet at 11.0 ppm ($\Delta\nu_{1/2}$ = 30 Hz), which was assigned to Pd(OAc)₂(dppp) (eq 4).¹⁰ No oxidation peak was detected when the cyclic voltammetry was performed directly in oxidation, suggesting that either no Pd⁰ complex was spontaneously formed from Pd(OAc)₂(dppp) or that a Pd⁰ complex is formed but via a slow and endergonic equilibrium (eq 5 in Scheme 3), at a very low concentration, preventing any detection by cyclic voltammetry or ³¹P NMR spectroscopy.

The equilibrium (eq 5) could be shifted toward its right-hand side, either by water addition¹¹ (Scheme 3)

Scheme 3. Tentative Mechanism for the Formation of Pd⁰ from Pd(OAc)₂ and 1 equiv of dppp

or by reaction of PhI in an oxidative addition. Addition of water in large excess did not induce any formation of a Pd⁰ complex, which could have been detected in cyclic voltammetry. The ³¹P NMR singlet of Pd(OAc)₂(dppp) was not affected by the presence of water or PhI added in excess (10 equiv). No new signal appeared, which could have characterized a (phenyl)palladium(II) complex formed by oxidative addition of PhI to a Pd⁰ complex. The formation of a Pd⁰ complex is then thermodynamically not favored.

At higher temperature (48 °C), the solution progressively turned to dark brown with formation of black palladium, which could not be characterized either by cyclic voltammetry or by ³¹P NMR. The reduction peak of Pd(OAc)₂(dppp) progressively disappeared, suggesting that a Pd⁰ complex was progressively formed but was too unstable¹² because of a lack of coordinating ligand, excluding thus any fine kinetic investigation.

Pd(OAc)₂ + 2 equiv of dppp. The situation changed dramatically when 2 equiv of dppp was added to Pd(OAc)₂ (2 mM) in DMF. Indeed, at room temperature, the reduction peak current intensity of Pd(OAc)₂(dppp) at *E*^p = -1.51 V vs SCE (*R*₁ in Figure 1a) decreased with time, while an oxidation peak *O*₁ at *E*^p = -0.41 V was observed (Figure 1b) whose oxidation peak current intensity increased as a function of time. This oxidation peak disappeared in the presence of PhI; consequently it characterizes a Pd⁰ complex. The formation of the Pd⁰ complex was also monitored by ³¹P NMR spectroscopy. The magnitude of the signal of Pd(OAc)₂(dppp) at 11.0 ppm decreased with time, while a new singlet was detected at 4.20 ppm and assigned to a Pd⁰ complex, which disappeared in the presence of PhI. Two other signals were also detected at 29.6 and -17.0 ppm and assigned to the hemioxide PPh₂(CH₂)₃PPh₂(O) by comparison with an authentic sample of dppp after oxidation by dioxygen. The former signal characterizes the phosphine oxide O=PPh₂-, the latter the phosphine -PPh₂ of dppp(O).

This establishes that (i) a stable Pd⁰ complex is formed at room temperature from Pd(OAc)₂(dppp), in the presence of 2 equiv of dppp per Pd(OAc)₂, and (ii) dppp is the reducing agent. The ³¹P NMR singlet of Pd(OAc)₂(dppp) disappeared completely only after ad-

(12) As observed by Kollar et al, a mixture of Pd(OAc)₂ and 1 equiv of dppp gave rise to an undefined Pd⁰ complex. Reactions were then conducted from mixtures of Pd(OAc)₂, 1 equiv of dppp, and 1 or 2 equiv of PPh₃, leading to competition between dppp and PPh₃ for the reduction of the Pd^{II} center. Scheme 4. Mechanism of the Formation of Pd⁰ from Pd(OAc)₂ and 2 equiv of dppp in DMF

Figure 1. Cyclic voltammetry performed in DMF (containing *n*Bu₄NBF₄, 0.3 M) at a steady gold disk electrode (0.5 mm diameter in a and 2 mm diameter in b; scan rate 0.2 V s⁻¹) at 20 °C. (a) Pd(OAc)₂ (2 mM) and dppp (4 mM): reduction of Pd(OAc)₂(dppp). (b) Oxidation of the Pd⁰ complex generated from Pd(OAc)₂ (2 mM) and dppp (4 mM), 120 s after mixing.

dition of water, indicative of an equilibrated reaction shifted to completion by water (as observed by Osawa and Hayashi in the case of Binap⁸), a phenomenon that was not observed when only 1 equiv of dppp was added to Pd(OAc)₂ (vide supra). The stability of the Pd⁰ complex was improved in the presence of a base such as NEt₃, as observed for PPh₃.² This was interpreted as a stabilization of the anionic complex Pd⁰(PPh₃)₂(OAc)⁻ vis à vis its decomposition to the unstable Pd⁰(PPh₃)₂ by the protons (formed concomitantly with the Pd⁰ complex, Scheme 1) prone to react with the ligated acetate to form acetic acid.³ By analogy, one deduces that the Pd⁰ complex formed from Pd(OAc)₂ and 2 equiv of dppp is also an anionic Pd⁰ complex ligated by one acetate, which is stabilized in the presence of a base (eq 6). Moreover, in ³¹P NMR, it appears as a singlet, indicative of two equivalent ³¹P.

Therefore, a tentative overall reaction can then be expressed as in eq 7, at this preliminary stage in the study.

To take into account the important role of the second dppp ligand as well as the noninfluence of water on the rate of formation of a Pd⁰ complex in the presence of only 1 equiv of dppp, a mechanism is proposed (Scheme 4), which differs from the tentative mechanism proposed earlier in Scheme 3.

In the presence of an extra dppp, a fast reversible ligand substitution occurs on the Pd⁰ complex **2**, formed in the slow intramolecular reduction step (**1** → **2**). The overall reaction goes to completion by hydrolysis of the released phosphonium salt, which produces the hemi-oxide dppp(O) (Scheme 4).

As performed in earlier works of this group for PPh₃,¹ the rate of formation of the Pd⁰ complex from a solution of Pd(OAc)₂ (2 mM in DMF containing *n*Bu₄NBF₄, 0.3 M) and dppp (2 equiv) was monitored by amperometry at a rotating gold disk electrode polarized at -0.1 V, on the oxidation plateau wave of the Pd⁰ complex. The oxidation current intensity of the Pd⁰ complex (proportional to its concentration) was recorded as a function of time (Figure 2a): (i) at 48 °C to have reasonable reaction times, (ii) in the presence of water (20 equiv) to observe an overall irreversible reaction, and (iii) in the presence of NEt₃ (30 equiv) to avoid the decomposition of the generated Pd⁰ complex. The plot of ln[(*i*_{lim} - *i*)/*i*_{lim}] versus time was linear (Figure 2b), characteristic of a first reaction order in palladium: (*i*_{lim} - *i*)/*i*_{lim} = ([Pd⁰]_{lim} - [Pd⁰])/[Pd⁰]_{lim} with *i*_{lim} = oxidation current intensity at infinite time and *i* = oxidation current intensity at *t*. The rate constant *k* for the formation of the Pd⁰ complex **3** (Scheme 4, where the irreversible reaction **1** → **2** is rate determining) is then determined from the slope of the regression line (Figure 2b). ln((*i*_{lim} - *i*)/[Pd⁰]_{lim}) = -*kt* with *k* = 2.8 × 10⁻³ s⁻¹ at 48 °C. The formation of a Pd⁰ complex from Pd(OAc)₂ and 2 equiv of dppp is thus slightly slower than that from PPh₃ (*k* = 3.6 × 10⁻³ s⁻¹ at 48 °C).^{1b}

When only 1 equiv of dppp was considered, the reverse reaction **2** → **1** became preponderant so that no Pd⁰ complex was formed at room temperature. The reverse reaction **2** → **1** is in fact an *intramolecular* oxidative addition of a phosphonium salt to a Pd⁰ center (activation of the P-OAc bond in complex **2**), which was not observed when starting from Pd(OAc)(PPh₃)₂¹ because it would then be *intermolecular* (Scheme 1). This explains why the reduction step in the case of PPh₃ was irreversible (Scheme 1) and why no accelerating effect of water was observed.¹

Pd(OAc)₂ + 3 equiv of dppp. Addition of 3 equiv of dppp to Pd(OAc)₂ in DMF (containing *n*Bu₄NBF₄, 0.3 M) together with 30 equiv of NEt₃ and 1 equiv of H₂O results in the formation of a yellow-orange solution, which exhibited the reduction peak of Pd(OAc)₂(dppp). When the cyclic voltammetry was performed from time to time, the reduction current intensity decreased up

Figure 2. Kinetics of the formation of the Pd⁰ complex generated from Pd(OAc)₂ (2 mM) and dppp (4 mM), under conditions where the reaction is irreversible, i.e., in the presence of H₂O (40 mM) and NEt₃ (60 mM), monitored as a function of time at a rotating gold disk electrode (2 mm diameter, $\omega = 105 \text{ rad s}^{-1}$) polarized at -0.1 V . (a) Variation of $i/i_{\text{lim}} = [\text{Pd}^0]/[\text{Pd}^0]_{\text{lim}}$ with time (i_{lim} = oxidation current intensity at t). (b) (\blacklozenge): experimental variation of $\ln((i_{\text{lim}} - i)/i_{\text{lim}}) = \ln([\text{Pd}^0]_{\text{lim}} - [\text{Pd}^0])/[\text{Pd}^0]_{\text{lim}}$ with time; solid line: $\ln([\text{Pd}^0]_{\text{lim}} - [\text{Pd}^0])/[\text{Pd}^0]_{\text{lim}} = -kt$ with $k = 2.8 \times 10^{-3} \text{ s}^{-1}$ at 48°C .

to zero while the oxidation peak of a Pd⁰ complex at -0.41 V was observed, its oxidation peak current intensity increasing with time. However, this oxidation peak did not disappear after addition of PhI (30 equiv).

The formation of the Pd⁰ complex was monitored by ³¹P NMR spectroscopy. The magnitude of the singlet of Pd(OAc)₂(dppp) at 11.0 ppm decreased with time, while the singlet of the Pd⁰ complex at 4.2 ppm increased with time. dppp(O) was also detected on the spectrum by its two characteristic singlets (vide supra). As observed in cyclic voltammetry, the Pd⁰ complex did not react with PhI. This is consistent with the formation of the coordinately saturated 18-electron complex Pd⁰(dppp)₂ (eqs 8, 9), known to be nonreactive in oxidative additions of aryl halides.¹³

The rate of formation of Pd⁰(dppp)₂ determined at 48°C by the amperometry technique (vide supra) was similar to that of the Pd⁰ complex generated from Pd(OAc)₂ + 2 equiv of dppp. This confirms that the rate-determining step is indeed the reaction **1** → **2** (Scheme 4), followed by the fast ligand exchange by one or two dppp ligands according to the dppp excess.

Complex Formed in the Oxidative Addition of PhI to the Pd⁰ Complex Generated in Situ from Pd(OAc)₂ and 2 equiv of dppp in DMF. Addition of

Scheme 5. Oxidative Addition of PhI to the Pd⁰ Complex Generated from Pd(OAc)₂ and 2 equiv dppp in DMF

PhI to the Pd⁰ complex formed quantitatively in a solution of Pd(OAc)₂ with 2 equiv of dppp in the presence of NEt₃ (3 equiv) in DMF gave a (phenyl)palladium(II) complex. The signal of the Pd⁰ complex at 4.20 ppm was no longer observed as well as the signal at -17.0 ppm characteristic of the nonoxidized PPh₂ moiety of the hemioxide dppp(O). The ³¹P NMR spectrum of the (phenyl)palladium(II) complex revealed a complex structure involving three different ³¹P ligated to the Pd^{II} center: 15.0 ppm (dd, $J_{\text{PPtrans}} = 359 \text{ Hz}$, $J_{\text{PPcis}} = 34 \text{ Hz}$, PPh₂ of dppp(O) cis to Ph), 7.9 ppm (dd, $J_{\text{PPtrans}} = 359 \text{ Hz}$, $J_{\text{PPcis}} = 51 \text{ Hz}$, P of dppp cis to Ph), -3.1 ppm (dd, $J_{\text{PPcis}} = 34$ and 51 Hz , P of dppp trans to Ph). An additional singlet at 29.7 ppm characterizes the P=O moiety of the mono-ligated dppp(O). This gives evidence for a structure of complex **4** (Scheme 5) in which the Pd^{II} is bis-ligated by one dppp and mono-ligated by the hemioxide dppp(O) (formed concomitantly with the Pd⁰ complex) acting thus as a monodentate ligand.

The rationalization given above (Scheme 5) requires that the 16-electron four-ligated complex **4**, PhPd(dppp)-(dppp(O))⁺, is a cationic complex. Its ionic character was confirmed by conductivity measurements. The initial conductivity due to the ionic character of the Pd⁰ complex (2 mM in DMF) formed in eq 7 increased from 5.4 to 39 μS after addition of PhI (10 equiv).¹⁴ The presence of released I⁻ was confirmed by cyclic voltammetry. One oxidation peak was indeed detected at $+0.45 \text{ V}$ vs SCE and readily assigned to the oxidation of free I⁻, by comparison with that of an authentic sample of *n*Bu₄NI. The structure of a related complex, *p*-CN-C₆H₄-Pd(dppp)(dppp(O))⁺, very similar to complex **4**, has been observed by Hallberg and Larhed,¹⁶ based on electrospray mass spectroscopy during a Heck reaction from *p*-CN-C₆H₄OTf with Pd(OAc)₂/dppp as the catalytic precursor. The value $M = 1048$ implies the mono-complexation of dppp(O), as evidenced in the present work by different approaches.

In contrast to PPh₃, for which PhPd(OAc)(PPh₃)₂ was formed in the oxidative addition of PhI (Scheme 2),¹⁻³ PhPd(OAc)(dppp) was not formed. It was however produced quantitatively after addition of *n*Bu₄NOAc in excess (10 equiv) (eq 10) and identified by its ³¹P NMR spectrum—two doublets at -3.7 ppm ($J_{\text{PP}} = 48 \text{ Hz}$) and

(14) The conductivity increase is compatible with that observed for cationic arylpalladium(II) complexes.¹⁵

(15) Jutand, A.; Mosleh, A. *Organometallics* **1995**, *14*, 1810.

(16) Hallberg, A.; Larhed, M. Personal communication at the Post-OMCOS-10 Symposium, Paris, July 1999.

(13) (a) Fitton, P.; Rick, E. A. *J. Organomet. Chem.* **1971**, *28*, 287. (b) Amatore, C.; Broecker, G.; Jutand, A.; Khalil, F. *J. Am. Chem. Soc.* **1997**, *119*, 5176.

19.4 ppm ($J_{\text{PP}} = 48$ Hz)—similar to the one reported in the literature.¹⁷

The addition of *n*Bu₄NI in excess (10 equiv) resulted in the formation of PhPdI(dppp) (eq 11), identified by comparison of its ³¹P NMR spectrum with that of an authentic sample (two doublets at -8.6 ppm ($J_{\text{PP}} = 53$ Hz) and 12.4 ppm ($J_{\text{PP}} = 53$ Hz)).^{13b} However this reaction was considerably slower than that of AcO⁻ ions.

Consequently the structure of the (aryl)Pd^{II}(dppp) complex formed in the oxidative addition of a Pd⁰ complex generated from Pd(OAc)₂/2dppp strongly depends on the aryl derivative considered: (i) four-ligated cationic ArPd(dppp)(dppp(O))⁺ complexes are formed when starting from aryl triflates;¹⁶ (ii) cationic ArPd(dppp)(dppp(O))⁺ complexes are formed in the very first catalytic cycles when starting from aryl iodides and then neutral ArPdI(dppp) complexes produced by reaction of I⁻ released in the catalytic reaction; (iii) ArPd(OAc)(dppp) complexes are formed in the presence of excess acetate ions (often used as a base in Heck reactions)⁵ whatever the aryl iodides/triflates derivatives. We must also take into account that all these complexes might be involved in equilibrium, as we previously established for ArPdI(PPh₃)₂, ArPd(OAc)(PPh₃)₂, and ArPd(PPh₃)₂⁺.¹⁸ It is worthwhile to note that, in DMF, complexes ligated by three phosphines, ArPd(PPh₃)₃⁺, have never been detected in appreciable amount even in the presence of PPh₃ in large excess,¹⁵ whereas ArPd(dppp)(dppp(O))⁺ complexes are formed due to less steric hindrance of dppp when compared to PPh₃.

Rate and Mechanism of the Oxidative Addition of PhI to the Pd⁰ Complex Generated in Situ from Pd(OAc)₂ and 2 equiv of dppp in DMF. The oxidative addition of PhI to the Pd⁰ complex generated in situ from Pd(OAc)₂ (2 mM in DMF) and 2 equiv of dppp, in the presence of NEt₃ (30 equiv) and H₂O (20 equiv), was monitored by amperometry, as performed previously for PPh₃.² The rotating electrode was polarized at -0.1 V, on the plateau of the oxidation wave of the Pd⁰ complex. The decay of the oxidation current intensity, proportional to the Pd⁰ concentration, was recorded versus time after addition of PhI (5 equiv) at 48 °C. The solution turned from orange-yellow to pale yellow. From the curve obtained in Figure 3a, one already observes that the decay of the Pd⁰ concentration does not obey a classical decreasing exponential curve, fitting with a reaction order of +1 for Pd⁰, as reported for Pd⁰(PPh₃)₂(OAc)⁻,² suggesting a more complicated mechanism for the oxidative addition. It is important to note that, under similar conditions, the Pd⁰ complex generated from Pd(OAc)₂ and 2 equiv of dppp is considerably less reactive with PhI (by a factor 300) than Pd⁰(PPh₃)₂(OAc)⁻ generated from Pd(OAc)₂ and 3 equiv of PPh₃.³

In a first approach, the influence of ions such as AcO⁻ or I⁻, which are released in the oxidative addition

(Scheme 5), has been investigated. They could indeed coordinate the Pd⁰ and consequently affect its reactivity in the course of the oxidative addition.^{2,3,19} No effect of I⁻ (5 equiv of *n*Bu₄NI added before PhI) was observed on the kinetics. However, the kinetics was affected by the presence of AcO⁻ ions. First of all, the oxidative addition was faster as soon as 1 equiv of *n*Bu₄NOAc was added before PhI. Second, the kinetics became well reproducible²⁰ in the presence of AcO⁻ with a kinetic curve still not compatible with an exponential decay (Figure 3b). This suggests that AcO⁻ ions, when in excess, may interfere in the oxidative addition process by changing the structure of the Pd⁰ complex initially produced from Pd(OAc)₂ and 2 equiv of dppp. When AcO⁻ ions (10 equiv) were added together with Pd(OAc)₂ and 2 equiv of dppp at 48 °C, the rate of formation of the Pd⁰ complex was faster but the resulting Pd⁰ complex was not so stable (the solution turned progressively to brown) and decomposed slowly within 75 min, after a variable induction period, thus exceeding the duration required for the investigated oxidative additions (20 min). The accelerating effect of AcO⁻ ions on the rate of formation of the Pd⁰ complex may be regarded as featuring an irreversible trapping of the intermediate complex **2** as complex **5** (eq 12), this reaction being faster than the reactions **2** → **1** or **2** → **3** in Scheme 4. At this level, we do not know whether the observed Pd⁰ decomposition is that of complex **5** or of a further complex.

When the AcO⁻ ions were added once the Pd⁰ complex has been formed quantitatively from Pd(OAc)₂ + 2 equiv dppp, the decomposition time of the resulting Pd⁰ was considerably longer than the time required for the oxidative addition. This latter procedure was therefore adopted for the detailed mechanistic investigation of the oxidative addition. PhI was added just after addition of AcO⁻ ions. The final complex formed in the oxidative addition was then PhPd(OAc)(dppp).

The kinetics of the oxidative addition of PhI (5 equiv) has been investigated as a function of the AcO⁻ concentration in the range 1–15 equiv. Figure 4 exhibits the plot of 1/*t*_{1/2} versus AcO⁻ concentration (*t*_{1/2} = half reaction time of the oxidative addition). The reaction is then first order in AcO⁻ at low AcO⁻ concentrations, while it becomes zero order at higher AcO⁻ concentrations (over 7 equiv of AcO⁻). The saturating effect suggests that AcO⁻ ions are involved in an equilibrium, which delivers the reactive Pd⁰ complex and which is completely shifted toward this reactive species as soon as 7 equiv of AcO⁻ are present.

Whatever the AcO⁻ concentration, at low PhI concentrations (less than 10 equiv) the reaction order in Pd⁰ is neither 1 nor 0 but 1/2, as shown by the linear

(20) The kinetics were not reproducible in the absence of added AcO⁻, probably because of the formation of aggregates.

Figure 3. Kinetics of the oxidative addition of PhI to the Pd⁰ complex generated from Pd(OAc)₂ (2 mM) and dpdp (4 mM) in the presence of H₂O (40 mM) and NEt₃ (60 mM), monitored as a function of time at a rotating gold disk electrode (2 mm diameter, $\omega = 105 \text{ rad s}^{-1}$) polarized at -0.1 V . 48 °C. (a) Variation of the oxidation current intensity i (proportional to the Pd⁰ concentration) with time in the presence of PhI (10 mM). (b) Same reaction in the presence of *n*Bu₄NOAc (30 mM) added to the Pd⁰ complex before PhI.

Figure 4. Kinetics of the oxidative addition of PhI to the Pd⁰ complex generated from Pd(OAc)₂ (2 mM) and dpdp (4 mM) in the presence of H₂O (40 mM) and NEt₃ (60 mM) monitored as a in Figure 3, at 48 °C. The kinetics is investigated in the presence of various amounts of AcO⁻ ions added as *n*Bu₄NOAc just before PhI (10 mM). Plot of $1/t_{1/2}$ ($t_{1/2}$ = half reaction time) vs AcO⁻ concentration (total concentration including the acetate released from AcOH when the reaction 7 is performed in the presence of NEt₃).

plot of $(i/i_0)^{1/2} = ([\text{Pd}^0]/[\text{Pd}^0]_0)^{1/2}$ versus time (Figure 5a) (i = oxidation current intensity of Pd⁰ at t ; i_0 = initial oxidation current intensity of Pd⁰), in agreement with the kinetic law given in eq 13.

$$d[\text{Pd}^0]/dt = -k_{\text{obs}}[\text{Pd}^0]^{1/2} \quad ([\text{Pd}^0]/[\text{Pd}^0]_0)^{1/2} = -k_{\text{obs}}t/2[\text{Pd}^0]_0^{1/2} + 1 = (i/i_0)^{1/2} \quad (13)$$

k_{obs} is then calculated from the slope (Figure 5a): $k_{\text{obs}} = 8.6 \times 10^{-5} \text{ M}^{1/2} \text{ s}^{-1}$ (vide infra).

At higher PhI concentrations (over 10 equiv) and whatever the AcO⁻ concentration, we observed a deviation from the reaction order of 1/2 (Figure 5b) at longer reaction times. This is consistent with the superposition

Figure 5. Kinetics of the oxidative addition of PhI to the Pd⁰ complex generated from Pd(OAc)₂ (2 mM) and dpdp (4 mM) in the presence of H₂O (40 mM) and NEt₃ (60 mM) monitored at a rotating disk electrode, as a in Figure 3b, at 48 °C. (a) *n*Bu₄NOAc (8 mM), PhI (10 mM); plot of $(i/i_0)^{1/2} = ([\text{Pd}^0]/[\text{Pd}^0]_0)^{1/2}$ vs time (i = oxidation current intensity of Pd⁰ at t ; i_0 = initial oxidation current intensity of Pd⁰). (b) *n*Bu₄NOAc (30 mM), PhI (160 mM); plot of $(i/i_0)^{1/2} = ([\text{Pd}^0]/[\text{Pd}^0]_0)^{1/2}$ vs time. (c) *n*Bu₄NOAc (30 mM), PhI (160 mM); (+): plot of i (i = oxidation current intensity of Pd⁰ at t) vs time. The solid line is the simulated theoretical curve using the kinetic law: $i = (i_0/C_0)\{(C_0/2 + k_{\text{obs}}/K_{\text{obs}})e^{-k_{\text{obs}}t/2} - k_{\text{obs}}/K_{\text{obs}}\}^2$ with $k_{\text{obs}} = 5.3 \times 10^{-5} \text{ M}^{1/2} \text{ s}^{-1}$, $K_{\text{obs}} = 2.1 \times 10^{-3} \text{ s}^{-1}$, and $C_0 = 2 \text{ mM}$.

of a second kinetics with a reaction order of +1 for Pd⁰, as established by comparison with a theoretical kinetic curve (Figure 5c, [PhI] = 160 mM, [Pd⁰]₀ = C₀ = 2 mM) simulated using the kinetic law of eq 14c, with $k_{\text{obs}} = 5.3 \times 10^{-5} \text{ M}^{1/2} \text{ s}^{-1}$ and $K_{\text{obs}} = 2.1 \times 10^{-3} \text{ s}^{-1}$.

$$d[\text{Pd}^0]/dt = -K_{\text{obs}}[\text{Pd}^0] - k_{\text{obs}}[\text{Pd}^0]^{1/2} \quad (14a)$$

$$[\text{Pd}^0] = \{([\text{Pd}^0]_0/2 + k_{\text{obs}}/K_{\text{obs}})e^{-K_{\text{obs}}t/2} - k_{\text{obs}}/K_{\text{obs}}\}^2 \quad (14b)$$

$$i = (i_0/C_0)\{(C_0/2 + k_{\text{obs}}/K_{\text{obs}})e^{-K_{\text{obs}}t/2} - k_{\text{obs}}/K_{\text{obs}}\}^2 \quad (14c)$$

According to this hypothesis, the oxidative addition proceeds by two parallel pathways, one with a reaction order of +1/2 in Pd⁰, the second one involving a reaction order of +1 in Pd⁰ showing up mostly at high PhI concentrations. This dual mechanism is operating whatever the AcO⁻ concentration. The reaction order in PhI was determined at high AcO⁻ concentrations (>7 equiv) when the kinetics did not depend on the AcO⁻ concentrations. The plots of k_{obs} and K_{obs} versus PhI concentration are reported in Figures 6a,b, respectively. When the reaction order in Pd⁰ is 1/2, the reaction order in

Figure 6. Kinetics of the oxidative addition of PhI (in the range 20–350 mM) to the Pd⁰ complex generated from Pd(OAc)₂ (2 mM) and dppp (4 mM) in the presence of H₂O (40 mM) and NEt₃ (60 mM) monitored at a rotating disk electrode, as in Figure 5c, at 48 °C. $v = k_{\text{obs}}[\text{Pd}^0] + k_{\text{obs}}[\text{Pd}^0]^{1/2}$. (a) Variation of k_{obs} vs PhI concentration. (b) Variation of k'_{obs} vs PhI concentration.

Scheme 6. Minimal Mechanism for the Oxidative Addition

PhI is 0 (k_{obs} is constant, Figure 6a). This means that the rate-determining step of the overall oxidative addition does not involve PhI but is a step in which a reactive monomeric Pd⁰ complex is formed from a dimer (order 1/2 in Pd⁰). When the reaction order in Pd⁰ is +1, the reaction order in PhI is not strictly +1 since the straight line for the variation of k'_{obs} does not intercept at the origin (Figure 6b); thus $k'_{\text{obs}} = a[\text{PhI}] + b$. On the basis of these experimental results, the simplest mechanism, which rationalizes all findings, is proposed in Scheme 6. A reactive dimeric Pd⁰ species A_2 leads to two successive equilibria involving a nonreactive monomeric Pd⁰ species A and another one A' , which reacts with PhI in parallel (Scheme 6).

Indeed, provided that the various rate constants are adequate, this mechanism displays all the experimentally observed features:

- At low PhI concentrations, $k_0[\text{PhI}] \ll k_1$ and the monomer A' is the only reactive species. The kinetic law for the disappearance of the dimer A_2 is then given by the eq 15a, after considering a fast equilibrium between A_2 and 2A and the steady-state approximation for A' .

$$v = 2k_3[\text{A}'][\text{PhI}] = 2k_2k_3[\text{A}][\text{PhI}]/(k_{-2} + k_3[\text{PhI}]) \quad (15a)$$

When $k_3[\text{PhI}] \gg k_{-2}$, one obtains eq 15b.

$$v = 2k_2[\text{A}] = 2k_2(k_1/k_{-1})^{1/2}[\text{A}_2]^{1/2} = k_{\text{obs}}[\text{A}_2]^{1/2} \quad (15b)$$

Scheme 7. Mechanism for the Oxidative Addition

This kinetic law is then in agreement with the experimental reaction order of 1/2 found for Pd⁰ and 0 for PhI with $k_{\text{obs}} = (5 \pm 1) \times 10^{-5} \text{ M}^{1/2} \text{ s}^{-1}$ (Figure 6a), a value compatible with that found above.

$$k_{\text{obs}} = 2k_2(k_1/k_{-1})^{1/2}, \text{ then } k_2(k_1/k_{-1})^{1/2} = (2.5 \pm 0.5) \times 10^{-5} \text{ M}^{1/2} \text{ s}^{-1}$$

- At higher PhI concentrations, $k_0[\text{PhI}] \gg k_1$ and the oxidative addition proceeds not only from A' but also from A_2 in competition with its dissociation (Scheme 6).

The kinetic law is then expressed as in eq 16a.

$$v = k_0[\text{A}_2][\text{PhI}] + 2k_3[\text{A}'][\text{PhI}] = k_0[\text{A}_2][\text{PhI}] + 2k_2k_3[\text{A}][\text{PhI}]/(k_{-2} + k_3[\text{PhI}]) \quad (16a)$$

With the same hypothesis as above: $k_3[\text{PhI}] \gg k_{-2}$, one gets eq 16b.

$$v = k_0[\text{A}_2][\text{PhI}] + 2k_2(k_1/k_{-1})^{1/2}[\text{A}_2]^{1/2} \quad (16b)$$

The kinetic law (eq 16b) is in agreement with the experimental reaction order of 1/2 for Pd⁰ and 0 for PhI found above in addition to an experimental reaction order of 1 found for Pd⁰. However, in the latter case, the reaction order is strictly 1 in PhI, which was not observed experimentally (see the variation of k'_{obs} in Figure 6b). This implies that the dimer A_2 should also disappear along a concurrent path being zero order in PhI. This may arise to give an inactive or active dimeric complex A_2^* (Scheme 7).

The corresponding kinetic law is then given in eq 17.

$$v = k_0[\text{A}_2][\text{PhI}] + k_4[\text{A}_2] + 2k_2(k_1/k_{-1})^{1/2}[\text{A}_2]^{1/2} = k'_{\text{obs}}[\text{A}_2] + k_{\text{obs}}[\text{A}_2]^{1/2} \quad (17)$$

$$k'_{\text{obs}} = k_0[\text{PhI}] + k_4 = a[\text{PhI}] + b \quad (\text{see eq 14a and Figure 6b})$$

From Figure 6b one deduces $k_0 = 6.5 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ and $k_4 = 1.1 \times 10^{-3} \text{ s}^{-1}$.

The saturating effect of acetate ions on the kinetics of the oxidative addition, observed at high AcO⁻ and low PhI concentrations (Figure 4), implies that the AcO⁻ ions are involved in an equilibrium, which produces the Pd⁰ dimer A_2 with a reaction order of +1 for AcO⁻ (Figure 4). This equilibrium would be completely shifted toward the dimer A_2 as soon as 7 equiv of AcO⁻ are added to the solution, in which a Pd⁰ complex has been formed spontaneously from Pd(OAc)₂ and 2 equiv of dppp. The complex A_2 is then the major Pd⁰ species. This suggests that the Pd⁰ complex, formed from Pd(OAc)₂ and 2 equiv of dppp, is not Pd⁰(dppp)(OAc)⁻ (**3**) as tentatively proposed in Scheme 4, but probably a dimer A_2^0 formed from Pd⁰(dppp)(OAc)⁻, due to the bidentate character of dppp (Scheme 8). The dimer A_2^0 ,

Scheme 8. Mechanism for the Oxidative Addition of PhI to the Pd⁰ Complex Generated from Pd(OAc)₂ and 2 equiv of dppp in the Presence of AcO⁻ Ions^a

^aFor more clarity, the two Ph ligands of the P atoms have been omitted.

with two 16-electron Pd⁰ centers, can be coordinated to extra AcO⁻ to form a new Pd⁰ dimer, **A**₂. This dissociates into a nonreactive 18-electron complex **A**. The cleavage of the a P–Pd bond is then required to produce a reactive 16-electron Pd⁰ complex, **A'** (Scheme 8). At high PhI concentration, the dimer **A**₂ is found to be reactive, although each Pd⁰ center has 18 electrons. It probably reacts after an equilibrated cleavage of one P–Pd bond without any modification of the kinetic law. *k*₀ would then be the apparent rate constant of the overall reaction, i.e. fast equilibrated cleavage of one P–Pd bond (equilibrium constant *K*₀) followed by a slow oxidative addition of PhI (rate constant *k*₀) with *k*₀ = *K*₀*k*₀.

We are conscious that none of the proposed structures for complex **3**, **A**₂⁰, and **A**₂ could be characterized. We only know the ³¹P NMR shift of the Pd⁰ complex formed from Pd(OAc)₂/2dppp in the absence of extra AcO⁻ at 4.2 ppm, which is assigned to complex **A**₂⁰. However, the proposed structures for complexes **A**₂, **A**, and **A'** are consistent with the experimental kinetic results and kinetic laws. So we use them here only as a chemical rationale of the complex mechanistic sequence, which has been fully characterized kinetically (Scheme 7). We do not propose any structure for **A**₂^{*}, although there might be an identity between **A**₂^{*} and **A**₂⁰.

Conclusion

As for monodentate phosphine, a Pd⁰ complex is spontaneously formed from Pd(OAc)₂ and a bidentate phosphine such as dppp. dppp is the reducing agent and is oxidized to the hemioxide dppp(O). In contrast to PPh₃, the intramolecular reduction step is reversible. Consequently, a stable Pd⁰ complex is quantitatively formed in the presence of 2 equiv of dppp, water, and a base (NEt₃), which stabilized the Pd⁰ complex vis à vis

its decomposition by protons, generated by the hydrolysis of a phosphonium salt (Scheme 4). In the presence of 3 equiv of dppp, a nonreactive Pd⁰(dppp)₂ complex is generated. The oxidative addition with PhI gives a cationic complex PhPd(dppp)(dppp(O))⁺ (in which dppp(O) behaves as a monodentate ligand) or PhPd(OAc)(dppp) in the presence of added AcO⁻. The oxidative addition of PhI is an intricate reaction whose kinetics could be fully investigated only in the presence of added AcO⁻. Its involves reactive dimeric or/and monomeric Pd⁰ complexes ligated by AcO⁻, whose respective reactivity is a function of the PhI concentration (Scheme 8). The complexity of the oxidative addition pathways when performed with a dppp ligand compared to that with a PPh₃ ligand stems from the bidentate character of the dppp ligand which favors dimeric structures.

Experimental Section

General Remarks. ³¹P NMR spectra were recorded on a Bruker spectrometer (101 MHz) in DMF containing 10% of acetone *d*₆. Cyclic voltammetry was performed with a home-made potentiostat and a waveform generator Tacussel GSP4. The cyclic voltammograms were recorded on a Nicolet 301 oscilloscope. Conductivities were measured on a Tacussel CDM210 conductimeter (cell constant = 1 cm⁻¹).

Chemicals. DMF was distilled from calcium hydride under vacuum and kept under argon. Pd(OAc)₂, dppp, PhI, *n*Bu₄NI, and *n*Bu₄NOAc were commercial.

Electrochemical Setup and Electrochemical Procedure for Voltammetry. Experiments were carried out in a three-electrode thermostated cell connected to a Schlenk line. The counter electrode was a platinum wire of ca. 1 cm² apparent surface area. The reference was a saturated calomel electrode (Tacussel) separated from the solution by a bridge filled with 3 mL of DMF containing *n*Bu₄NBF₄ (0.3 M). DMF (12 mL) containing *n*Bu₄NBF₄ (0.3 M) was introduced into the

cell followed by 5.4 mg (0.024 mmol) of $\text{Pd}(\text{OAc})_2$ and then 1–3 equiv of dppp. Cyclic voltammetry was performed at a steady gold disk electrode (0.5 mm or 2 mm diameter) at a scan rate of 0.2 V s^{-1} . Kinetic measurements for the Pd^0 formation and its reactivity with PhI were performed at a rotating gold disk electrode (2 mm diameter, $\omega = 105 \text{ rad s}^{-1}$) polarized at -0.1 vs SCE.
