THE FIRST SPARK SPECTRUM OF PLATINUM

By A. G. SHENSTONE, *Princeton University*

(Communicated by R. H. Fowler, F.R.S.—Received 25 March 1938)

[Plate 6]

In 1929, Dr J. J. Livingood and myself attempted unsuccessfully to analyse the first spark spectrum of platinum. That failure was chiefly due to the lack of adequate observations in the Schumann region. The spectrum should, of course, be similar to Ni II and Pd II, both of which were previously analysed in the laboratory, but in the third long period the excitation energies have increased to such a point that the chief lines of the transition $5d^86s - 5d^86p$ are mainly below $\lambda 2000$. Their observation requires a vacuum spectrograph, which we did not have at that time.

OBSERVATIONS

Down to the limit of transmission of air, the spectra of the arc and spark were photographed with the 21 ft. grating, and the wave-lengths were measured against iron standards. It was found necessary to use graphite electrodes for the arc, because of the fact that it is very difficult, if not impossible, to run an arc between pure platinum rods. One is much more apt to get a glow discharge in which the cathode is hot, the anode cold and the spectrum that of air. In the Schumann region also, arc-spark observations were the chief source of the data. A modification of the method described by Selwyn (1929) was used, and excellent spectra were obtained down to the fluorite limit at $\lambda 1240$. The modification ensures an image of the source at the slit and makes the elimination of oxygen from the flowing nitrogen much more complete. The arc in pure nitrogen runs at 10–15 V higher potential than it does in air, and produces the second spark spectrum of some elements with considerable intensity. A diagram of the attachment is shown in fig. 1. The spectrograph is of conventional type employing a glass grating of 2 m. radius and 30,000 lines per inch. The spectrum can be photographed from $\lambda 500$ to $\lambda 2250$. Hilger Schumann plates and Ilford Q plates were used, the latter being practically perfect for the longer wave-lengths.

In order further to extend the observations, photographs of the hollow-cathode (Schuler tube) discharge were also taken. This proved to be relatively simple to do because we had already developed the technique for iron, one of the most difficult materials to excite in such a manner. The cathode was a thin-walled tube of graphite suspended by tungsten wires in a 2 l. pyrex flask. The platinum melted and gave a brilliant spectrum at about 1.5 kVA on the tube, the currents being from 1.5 to 2 amp.

and the voltage from 1000 to 750 depending on the gas pressure used. The production of a stable discharge at such powers was made possible by the use of a 6 kVA rectifier excited by constant current instead of by constant potential. This eliminates the

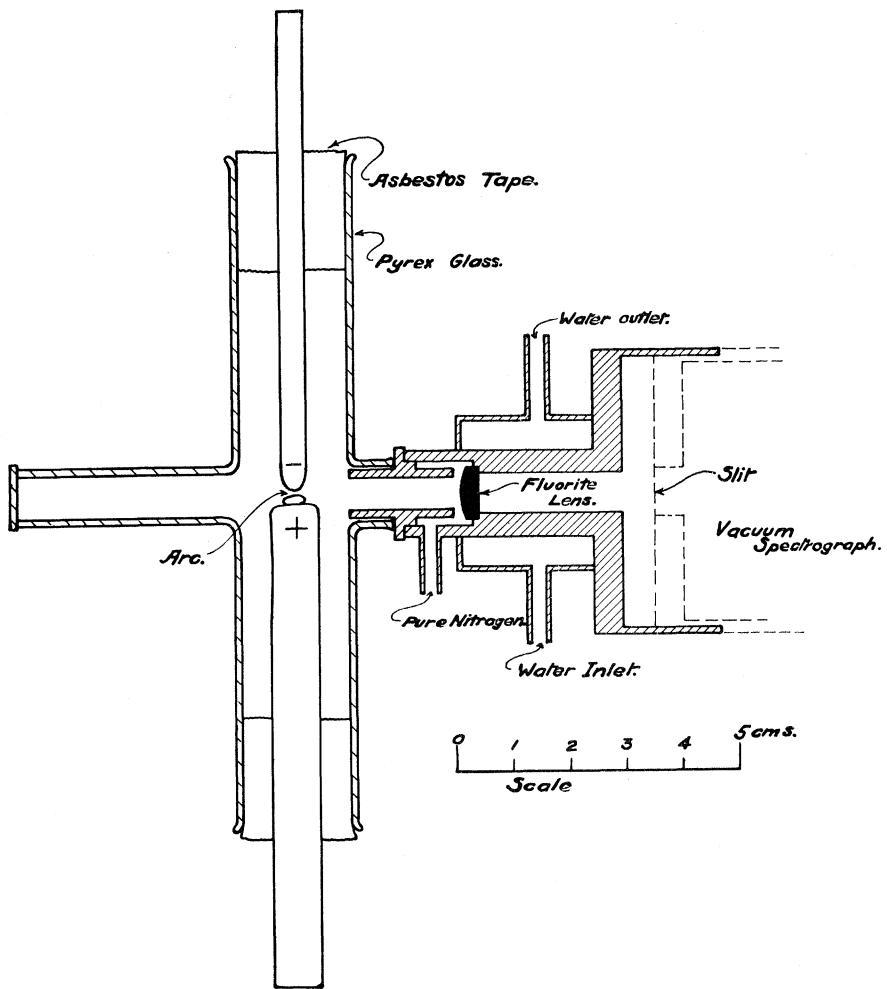

FIG. 1. Attachment for photographing spectra to $\lambda 1240$.

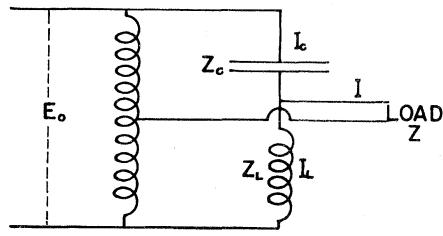

FIG. 2. Constant current circuit.

necessity for ballast resistances and allows the use of the full voltage of the rectifier on the tube itself. The constant-current circuit is quite simple and has been known for many years (Steinmetz). The principle is shown in fig. 2, and the theory is as follows. Our particular adaptation of the circuit will be described in detail elsewhere.

ON THE FIRST SPARK SPECTRUM OF PLATINUM

455

 E_0 = supply voltage. I_C, I_L, I = currents through condenser, inductance and load. Z_C, Z_L, Z = reactances of the condenser, inductance and load.

$$\frac{E_0}{2} = Z_C I_C + Z I,$$

$$\frac{E_0}{2} = Z_L I_L - Z I,$$

$$I_C = I + I_L.$$

Solving for I

$$I = \frac{E_0}{2} \frac{(Z_L - Z_C)}{Z_C Z_L + Z(Z_C + Z_L)}.$$

If the capacitative and inductive reactors are made so that $Z_C = -Z_L$, this expression reduces to

$$I = \frac{E_0}{Z_C},$$

or taking the absolute value

$$|I| = \frac{E_0}{X},$$

where

$$X = |Z_C| = |Z_L| = \frac{1}{2\pi\nu C} = 2\pi\nu L,$$

i.e. the current I is, in the ideal case, completely independent of the load. Any required variation of the current is produced by varying the applied voltage E_0 .

The constant-current circuit is an odd arrangement with which to work because one must reverse all one's usual actions. For instance, it is dangerous to open the circuit and perfectly safe to short-circuit it. This is of great advantage if the tube arcs, since the power then falls to nearly zero instead of rising. Although the rectifier is built to deliver 1500 V, an ordinary arc requiring 20–30 V with no ballast resistance can be run from it with perfect safety and extreme stability.

The lines in the Schumann region were measured initially against nitrogen and carbon lines (Boyce and Robinson 1936) and were afterwards corrected by the use of a number of platinum lines whose wave numbers could be calculated by use of the combination principle. The Schuler tube plates were standardized from copper lines produced by the introduction of a small quantity of copper into the cathode.

ANALYSIS

The arc spectrum of platinum is a ten-electron spectrum with low terms corresponding to the structures $5d^96s$, $5d^86s^2$, $5d^{10}$. From the relative positions of those three, it can be predicted that the lowest term of the first spark spectrum should be $5d^92D$, followed by $5d^86s^4F$ and higher still by $5d^76s^24F$. The lowest odd terms should be $5d^86p^4$ and $2D, F, G$.

The spectra of the elements of the third long period exhibit such large term differences that ordinary methods of breaking into the spectra are of little value, but there is an unusual method, which proved successful in this case. It is well known that a transition in the first spark spectrum of a metal from a middle level to a low level produces a line which is sharp and strong in the arc and only slightly broader in the spark, whereas a transition from a high to a middle level produces a line which appears in both arc and spark but is very broad in the spark and displaced about 2·5 wave numbers to longer wave-lengths. In the present case the strongest lines of those two classes should be $5d^96s\ ^4F_{4\frac{1}{2}} - 5d^96p\ ^4G_{5\frac{1}{2}}$ and $5d^96p\ ^4G_{5\frac{1}{2}} - 5d^97s\ ^4F_{4\frac{1}{2}}$. Since one can find from the analysed spectrum Au II the regions in which those two lines should occur, it was a very simple matter to pick them out, and so from their sum to obtain the important difference $5d^96s\ ^4F_{4\frac{1}{2}} - 5d^97s\ ^4F_{4\frac{1}{2}}$. The analysis then proceeded by the usual tedious method of building a square array by searching for known differences.

Identification of levels is usually accomplished by a comparison of the intensities of the combinations and their Zeeman effects with the theoretical intensities and Zeeman effects for Russell-Saunders coupling. In the spectra of the heavy metals, these criteria normally break down because the coupling is more nearly $j-j$ than L-S. Pt II is no exception to this rule, so that the great majority of the levels can be given numbers only.

There is, however, sufficient evidence to assign Russell-Saunders names to a number of the low even levels. An examination of fig. 3 shows that the correlation of levels in Ni II, Pd II and Pt II is of the type to be expected. The separations of the components of $5d^96s\ ^4F$ and 2F increase rapidly with the atomic number, although the spread of the configuration shows only a small and irregular change. The parallelism of many of the connecting lines in fig. 3 is striking, and it has been used as evidence in identifying levels. Obvious exceptions are the two levels corresponding to $^4P_{2\frac{1}{2}}$ and $^2D_{2\frac{1}{2}}$. They have been pushed far down and up by the presence of $^2F_{2\frac{1}{2}}$ between them, which in turn is due to the rapid increase of the term separations with atomic number. The selection of 20093·0 as $6s^2\ ^4F_{4\frac{1}{2}}$ and 24475·7 as $6s\ ^2G_{4\frac{1}{2}}$ is based partly on the comparison with Ni II and Pd II and partly on the fact that that choice is more consistent with the observed intensities.

The relative positions of the structures nd^9 and $nd^8(n+1)s$ are very different in the three long periods. It might be expected that their difference would decrease as the value of n increases. This is not the case, the difference being in fact about 8000 in Ni II, 25,000 in Pd II and 5000 in Pt II. The 4d and 5s electrons in the second long period thus show much greater differences in binding energy than do the 3d and 4s of the first period or the 5d and 6s of the third period. No theoretical explanation of this fact has been given.

In Pt II the structure d^7s^2 appears. Its position in Ni II can be estimated from Zn II and Cu II to be about 35,000–40,000 wave numbers above d^8s . In Pd II it should be about 6000 wave numbers higher still.

ON THE FIRST SPARK SPECTRUM OF PLATINUM

457

In Tables I and II are given all the even and odd levels which have been fixed with reasonable certainty. Many more of doubtful reality were found, chiefly from the Schuler tube data. In agreement with the known characteristics of the Schuler tube discharge, the levels from about 93,000 to 99,000 are excited very strongly by neon and

quite weakly by helium. The energy of the neon ion (173,930 wave numbers) is capable of exciting the platinum atom to 95,376 wave numbers in the first ion starting from the lowest level of the atom (J. J. Livingood 1929). The presence of many metastable arc levels accounts for the additional energy observed. The levels between 80,000 and 90,000 are excited more strongly by helium than by neon, probably because of the helium resonance which falls about 81,300 in Pt II. The levels above 110,000 are excited by helium only.

The ionization limit can be calculated roughly from the levels $6s^4F_{4\frac{1}{2}}$ and $7s^4F_{4\frac{1}{2}}$. If the reasonably certain $8s^4F_{4\frac{1}{2}}$ level is accepted, a more accurate value can be calculated by means of a Ritz formula. This calculation gives 144,936 wave numbers for the difference $5d^86s^4F_{4\frac{1}{2}} - 5d^83F_4$, making the Rydberg series value 4·2% too high. The

ON THE FIRST SPARK SPECTRUM OF PLATINUM

459

similar calculation in Hg II gives 4%, an agreement which lends support to the identification of $8s^2 4F_{4\frac{1}{2}}$ (H. N. Russell 1927). The ionization potential is 18.47 V from $5d^9 2D_{2\frac{1}{2}}$ to $5d^8 3F_4$.

The line list (Table III) includes the following:

- (1) $\lambda 1976$ – 1242 , identified lines only.
- (2) $\lambda 1242$ – 4514 , all certain low transition lines and all identified high transition lines.

There have been omitted 136 unidentified diffuse lines and about 1000 other lines most of which are weak and observed only in the Schuler tube.

In fig. 4, Plate 6 are shown enlargements of typical platinum arc and spark spectra in the region $\lambda 1300$ – 2100 .

TABLE III. Pt II

All important lines to $\lambda 1242$. Identified lines only, shorter than $\lambda 1242$

SUMMARY

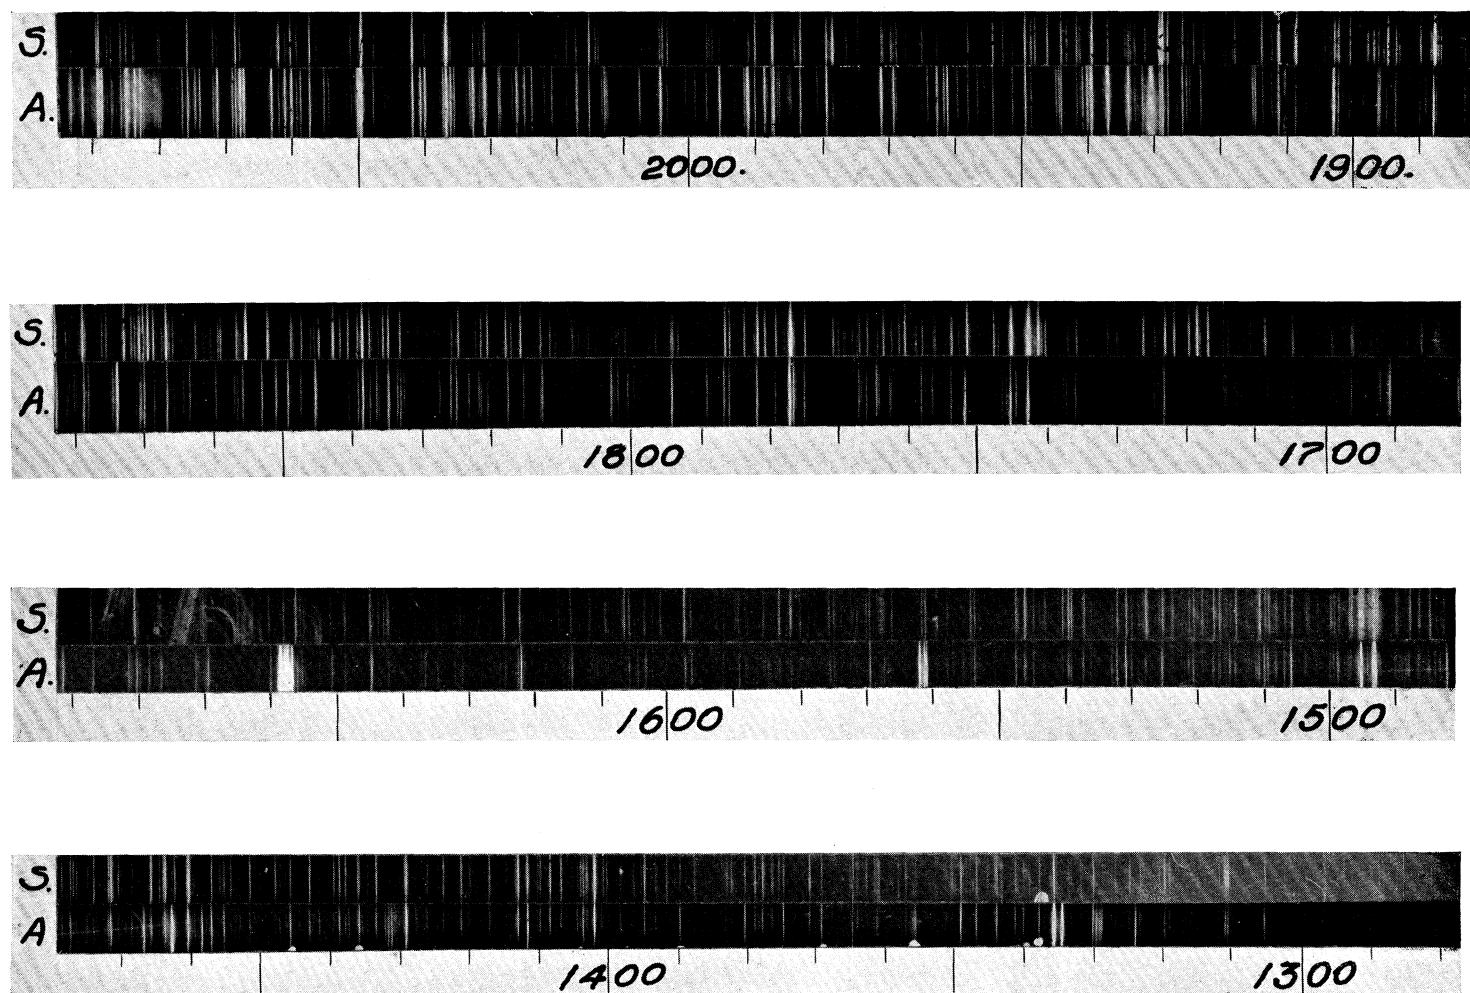

The paper reports observations on the spectrum Pt II and classifies a large number of levels. A list of lines is also given including:

- (i) All identified lines between $\lambda 976$ and 1242.
- (ii) All certain low-transition lines and all identified high-transition lines between $\lambda 1242$ and 4514.
