# New synthesis routes for energetic materials using dinitrogen pentoxide

BY R. W. MILLAR<sup>1</sup>, M. E. COLCLOUGH<sup>1</sup>, P. GOLDING<sup>2</sup>, P. J. HONEY<sup>1</sup>, N. C. PAUL<sup>1</sup>, A. J. SANDERSON<sup>1</sup> AND M. J. STEWART<sup>1</sup>

<sup>1</sup>Defence Research Agency (Military Division), R.A.R.D.E., Fort Halstead, Sevenoaks, Kent TN14 7BP, U.K.

<sup>2</sup>Ministry of Defence (Procurement Executive), A.W.E., Aldermaston, Berkshire RG7 4PR, U.K.

The harsh and unselective nature of conventional nitrating agents, based on nitric-sulphuric acid mixtures or pure nitric acid, has led to the development of new nitration methodologies based on dinitrogen pentoxide ( $N_2O_5$ ) that overcome many of the drawbacks of conventional media, especially when dealing with sensitive substrates.

Two principal nitration systems have been developed: (i)  $N_2O_5$  in pure nitric acid, and (ii)  $N_2O_5$  in organic solvents, mainly chlorinated hydrocarbons. The former system possesses strength similar to mixed acid ( $HNO_3-H_2SO_4$ ) systems and is therefore potent, but displays advantages such as ease of generation of the nitration reagent by electrolysis and compatibility with nitramine products, facilitating the synthesis of nitramine explosives as well as certain aromatic nitro compounds.

The second system (N<sub>2</sub>O<sub>5</sub>/organic solvent) encompasses a much wider range of nitrations, and with suitable choice of substrate permits the generation of polynitrated species directly without the formation of acidic by-products, an important environmental consideration. These conditions are also compatible with sensitive substrates, particularly those possessing strained-ring heterocyclic skeletons; thus the nitration of such compounds with N<sub>2</sub>O<sub>5</sub> permits precursors for energetic polymers (e.g. polyNIMMO) to be prepared by selective nitration. Likewise, nitrated derivatives of suitably functionalized elastomeric pre-polymers (e.g. NHTPB) can also be manufactured; both of the latter category of compound find important application as energetic binders for novel explosive and propellant compositions, notably low-vulnerability (LOVA) propellant charges.

#### 1. Introduction

The majority of energetic materials (explosives, propellants, etc.) are organic compounds which derive their energy from the nitro group,  $-\mathrm{NO}_2$ . These nitro compounds encompass a wide variety of materials of greatly differing physical and chemical properties which can be small (i.e. low molecular weight) molecules or macromolecules, in other words polymers. The nitro substituents can be classified according to the nature of the atom to which they are attached: carbon, nitrogen or oxygen. Hence energetic materials are frequently described as being C-nitro 1 (or simply 'nitro', e.g. trinitrotoluene), N-nitro 2 (or 'nitramine', e.g. HMX), or O-nitro 3 (or 'nitrate ester', e.g. PETN), according to which functionality they contain (Urbanski 1967, 1984).

All of these functionalities are introduced into precursor or substrate molecules by a process called nitration (Schofield 1980; Olah  $et\ al.$  1989), which classically has used either pure nitric acid or nitric–sulphuric acid mixtures. The aim of this work is to show how a novel nitrating agent, dinitrogen pentoxide or  $N_2O_5$  can complement or even replace some of these classical procedures.

# 2. Nitration potential of $N_2O_5$ and its applications to energetic materials synthesis

 $\rm N_2O_5$  is an agent capable of introducing nitro groups into substrate molecules (Addison & Logan 1973; Fisher 1990), in other words a nitrating agent, and, although it had been prepared as early as 1849 (Deville 1849), it was largely neglected as a nitrating agent until the 1920s, when the first systematic study of this type was undertaken (Haines & Adkins 1925). Presumably this neglect was a result of the difficulty in obtaining the reagent in a pure form as well as problems in storage resulting from its poor thermal stability (Addison & Logan 1973), aspects which will be covered in more detail presently. The current resurgence of interest within this research group has demonstrated the versatility of  $\rm N_2O_5$ , which can be used to generate all three classes of energetic grouping from suitable precursors in clean, specific and frequently high-yielding reactions.

Nitration reactions, of any of the types mentioned here, are believed to proceed via the nitronium ion,  $NO_2^+$ , and we can immediately subdivide the nitrating ability of  $N_2O_5$  according to the medium used. On the one hand 100% nitric acid, with high nitronium ion concentration on account of the high degree of dissociation of  $N_2O_5$  arising from the high polarity of the solvent (Ingold & Miller 1950; Odokienko *et al.* 1978). On the other the organic solvents, typically chlorinated hydrocarbons (e.g.  $CH_2Cl_2$  or freons), where a low nitronium ion concentration is found owing to the essentially undissociated nature of  $N_2O_5$  in this environment (Chedin 1935).

Thus, the first medium provides a potent, unselective nitration system akin to mixed acid but with some advantages over the classical system, while the second enables gentler conditions to be achieved, which are essentially non-acidic and hence useful for nitrating acid-sensitive substrates or for performing selective nitrations. To show instances of reactions where the various types of energetic groups may be introduced, and how these correlate with the two types of nitrating system, the examples shown here (table 1) are illustrative. Thus, the harsher nitric acid system is more suitable for aromatic nitrations or nitrolyses to yield nitramines from their N-acyl precursors (although, under suitable conditions, these transformations can sometimes also be effected in appropriate organic solvent media), while on the other hand, the organic media, particularly chlorinated hydrocarbons or freons, are essential to enable the ring cleavage or selective nitration reactions to be carried out. With some substrates possessing both strained rings and labile groups, the reaction can be 'fine-tuned' to enable selective nitration of these compounds to be attained: this important aspect of  $N_2O_5$  chemistry will be covered in more detail later (§6). It should be emphasized that, although reaction in the first two categories can sometimes be effected under organic solvent conditions as well, the latter two categories require exclusively organic solvent conditions, also preferably free from adventitious acid in certain cases.

Before giving details of the preparation of  $N_2O_5$  and further examples of how these nitration systems may be used to synthesise specific energetic compounds,

PHILOSOPHICAL THE TRANSACTIONS COL

New synthesis routes for energetic materials

Table 1. Summary of  $N_2O_5$  nitrations (Key: A = nitric acid system, O = organic solvent system.)

reaction type	conditions A/O	examples	product name	
aromatic nitration			(C-)nitro compound	
nitrolysis	A(O)	$R_2N$ — $COCH_3$ — $R_2N$ — $NO_2$	nitramine

selective nitration	0	$ \begin{array}{c} \text{H}_3\text{C} & \text{CH}_2\text{OH} \\ \text{O} \end{array} $	nitrate ester derivative of strained-ring compound	

applications to which these four basic reaction types, two in nitric acid medium and two in organic solvent medium, may be put are now discussed and are detailed below (table 2).

To date, the formation of polymer precursors, either by selective nitration forming energetic monomers (e.g. 3-hydroxymethyl-3-methyloxetane nitrate, NIMMO 53,  $\S 6$ ), or by nitration of pre-formed polymers (e.g. nitrated hydroxy-terminated polybutadiene, NHTPB 52,  $\S 6$ ), has made the greatest impact, simply because of the dearth of energetic polymers suitable for binder applications; each of these examples will be covered in more detail later.  $N_2O_5$  nitration chemistry, however, can also furnish a wide variety of products of interest to the energetic materials community: energetic plasticizers for propellants and polymer bonded explosives (PBX), crystalline high explosives with intermediate melting points suitable for high performance melt cast explosives, and thermally stable high explosives for specialist applications. The applicability of the various types of nitration reactions in each field are indicated in table 2.

# 3. Preparation of $N_2O_5$

Two main routes are currently in use for the preparation of  $N_2O_5$ , both in our laboratories and industrially:

$$(a) \quad 2 \text{HNO}_3 \xrightarrow[-2e^-]{\text{N}_2\text{O}_4} \text{N}_2\text{O}_5 + \text{H}_2\text{O}\,; \qquad \text{(b)} \quad \text{N}_2\text{O}_4 \xrightarrow{\quad \text{O}_3 \quad} \text{N}_2\text{O}_5.$$
 cell membrane

The first, by electrolysis of nitric acid in the presence of  $N_2O_4$ , is based on a process developed in the Lawrence Livermore National Laboratory (Harrar & Pearson 1983) and subsequently developed in this country. This generates a solution of  $N_2O_5$ 

#### R. W. Millar and others

Compound types: a nitrate esters/nitroaromatics; b nitramines/nitramine-nitrates; c nitramines/nitroaromatics; d nitrate esters (nitramines).

of some 15–20% (mass/vol.) strength in anhydrous nitric acid. Rates of production of several kilograms per day are currently available and scale-up to higher production levels poses no serious technical problems (Bagg *et al.* 1991); the electrolytic cell employed is shown in figure 1.  $N_2O_5$  generated in this way finds application mainly in the first two types of nitration reaction: aromatic nitration and especially nitrolysis to generate HMX (see §4).

The second route, ozonation of  $N_2O_4$ , although known for some decades (Harris et al. 1967), was not, to our knowledge, developed into a viable large-scale synthetic process until the inception of work in our laboratories. The gas-phase reaction of ozone (as a 5–10 % mixture with oxygen) with  $N_2O_4$  generates essentially acid-free  $N_2O_5$  which is trapped as a solid and can be stored at low temperature for lengthy periods until required. Its dissolution in organic solvents, typically chlorinated hydrocarbons (e.g. dichloromethane) or freons, gives a mild nitrating agent useful in ring cleavage and selective nitrations. Currently around 1 to 1.5 kg per week can be made on our laboratory scale apparatus but there is no intrinsic limitation to scale-up, high output ozonizers being available commercially.

New synthesis routes for energetic materials

## 4. N<sub>2</sub>O<sub>5</sub>-Nitric-acid nitrations

Turning now to specific examples of reactions in each of the four above categories, the utility of  $N_2O_5$  nitrations in energetic materials chemistry is illustrated. First, aromatic nitrations: compounds 5 (2,4-dinitroethylbenzene, an energetic plasticizer ingredient), 7a (2,4-diamino-1,3,5-trinitrobenzene, explosive) and 7b (2,4,6-triamino-1,3,5-trinitrobenzene, explosive) are formed cleanly and in essentially quantitative yield.

$$\begin{array}{c|c} \operatorname{CH}_2\operatorname{CH}_3 & \operatorname{CH}_2\operatorname{CH}_3 \\ \hline NO_2 & \operatorname{NO}_2 \\ \hline & & & & & \\ \operatorname{NO}_2 & & & & \\ \hline & & & & & \\ \operatorname{NO}_2 & & & & \\ \hline & & & & & \\ \end{array}$$

Furthermore, polynitrofluorenes (e.g. 11), which are novel thermally stable explosives, have been made for the first time (Honey 1991). Interestingly, in this reaction  $N_2O_5$  effects the introduction of a gem-dinitro moiety.

A remarkable phenomenon has been discovered in  $N_2O_5$ -nitric-acid nitrations of aromatic substrates, namely an unexpected rate enhancement (figure 2) of up to 30 times at high  $N_2O_5$  concentration over that which would be expected from nitric-acid-sulphuric-acid systems of similar concentration (Moodie & Stephens 1987; Moodie *et al.* 1990, 1991). This feature gives  $N_2O_5$ -nitric acid solutions unique nitration potential which will be exploited in future studies.

R. W. Millar and others

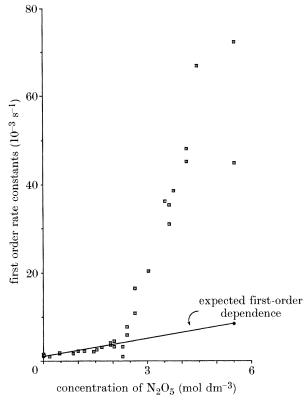

Figure 2. Rate profile for an aromatic nitration. The nitration of phenyltrimethyl ammonium perchlorate (PTMAP) by  $\rm N_2O_5/HNO_3$  shows an unexpected rate enhancement.

Nitrolysis reactions to form nitramines again offer improvements over existing methodology, largely due to the instability of these products in media containing sulphuric acid (Wright 1969). The route of greatest practical utility so far is, of course, the production of HMX (14) via DADN (13) (Siele *et al.* 1981), which is now being utilized in this country on pilot scale and is under development for production scale in the U.S.A.:

Phil. Trans. R. Soc. Lond. A (1992)

The reaction steps are (a) acetylation followed by mild nitration, (b) vigorous nitration by  $N_2O_5/HNO_3$ .

### 5. N<sub>2</sub>O<sub>5</sub>-Organic solvent nitrations

These types of reaction embrace two distinct but related areas of chemical synthesis, namely ring-cleavage reactions and selective nitrations, and each will be dealt with in turn.

The ring cleavage reactions shown below constitute an entire family of novel reactions discovered by the Synthetic Chemistry Section at R.A.R.D.E. in the early 1980s (Golding *et al.* 1988*a,b*), and enable the preparation of multifarious nitrated compounds of high-energy content (viz. **16a**, **16b**, **17a**, **17b**), which are applicable in all fields of energetic materials technology except, perhaps, those areas requiring ultimate thermal stability.

$$\begin{array}{c} \text{CH}_2\text{O}_5\\ \text{halogenated}\\ \text{solvent} \\ \text{O to 10 °C} \\ \\ \textbf{15}\\ n=2 \text{ or 3} \\ \text{X} = \text{O or NR (R = alkyl, etc.)} \\ \end{array} \quad \begin{array}{c} \text{H}_2\text{O}_5\\ \text{halogenated}\\ \text{solvent} \\ \text{O}_2\text{NO} - (\text{CH}_2)_n - \text{X} - \text{NO}_2\\ \text{O}_2\text{NO} - (\text{CH}_2)_n - \text{X} - \text{NO}_2\\ \text{16a} \quad \text{X} = \text{O}, \ n = 2\\ \text{16b} \quad ,, \quad , \ n = 3\\ \text{17a} \quad \text{X} = \text{NR}, \ n = 2\\ \text{17b} \quad ,, \quad , \ n = 3 \\ \end{array}$$

The substrates (15) are strained-ring heterocycles with three- or four-membered rings containing either oxygen or nitrogen heteroatoms, making a total of four possible sets of reactions. It should be noted that these reactions possess a common feature, namely, the simultaneous introduction of two energetic groups, either similar (nitrate in the case of the oxygen heterocycles) or dissimilar (nitramine-nitrates in the case of the nitrogen heterocycles). Thus the reaction is a new type of nitration, namely an addition reaction, which features complete utilization of the nitrating agent, unlike the more usual substitutive nitration where, with  $N_2O_5$ , half of the nitrating agent would be wasted. These reactions are generally high yielding and encompass a wide range of compounds, the main limitation being that R is not equal to H or certain other groups for the nitrogen heterocycles (see below).

As a new nitration method, these reaction sequences possess in common several advantages over conventional nitration routes using mixed acids:

- (a) absence of waste acids for disposal;
- (b) simple product separation (evaporation of solvent often suffices);
- (c) ease of temperature control (reactions are essentially non-exothermic);
- (d) high selectivity in position of attack with polyfunctional substrates.

Yields are frequently high (80–98%) and product contamination from byproducts is correspondingly low. In addition, the first two features suggest important environmental advantages, since waste liquors from conventional nitrators require tedious post-reaction treatment to prevent pollution and indeed to avoid hazard, containing labile chemical constituents such as, for instance, acetyl nitrate. The  $\rm N_2O_5$ -strained-ring reactions, on the other hand, avoid these problems and exhibit

the further advantages mentioned above. The last feature (selectivity in position of attack) is of relevance primarily to energetic binder synthesis, but before turning to this topic the ring-cleavage nitration reactions will be surveyed.

Strained-ring oxygen heterocycles (15, X = O) with three-membered (epoxide, n = 2) or four-membered (oxetane, n = 3) rings are cleaved cleanly and in high yield to give the corresponding dinitrate esters 16a and 16b, 1,2- or 1,3-dinitrates according to the substrate. The reaction is quite general and fails to give yields exceeding ca. 70% in only a few cases, notably heavily substituted epoxides or oxetanes substituted at the 2-position; in the latter case oxidative cleavage reactions are believed to supervene. Reaction rates may be accelerated in certain cases by catalysis (e.g. addition of Lewis acids such as  $AlCl_3$ ).

Applications to the synthesis of energetic plasticizer compounds are shown above, giving rise to both known (nitroglycerine 19 or trimethylolethane trinitrate 21) and novel compounds (diglycerol tetranitrate 23 or erythritol tetranitrate 25). The reactions appear to be unaffected by even moderate amounts of nitric acid, formed either from atmospheric moisture or by reaction with other functionalities in the substrate molecule (e.g. in the cases of glycerol 18 or 3-hydroxymethyl-3-methyloxetane 20); in this respect these nitrations contrast sharply with the nitrogen heterocycle reactions, particularly those of the aziridines (see below).

Finally, the possession of ring strain in these oxygen heterocycles has been shown to be a prerequisite for these reactions to proceed in high yield; substrates with five, six and seven membered rings, i.e. **26a**, **27a** and **28a** react sluggishly yielding

generally less than 5% of the corresponding dinitrates, unless other functionalities (particularly a second oxygen atom in the 3-position) are present:

New synthesis routes for energetic materials

However, in such cases (compounds 26b, 27b and 28b), products formed by competing reaction pathways are also found, e.g. formate-nitrates 31, as well as the expected hemiformal nitrates 30; the former are believed to originate from hydride abstraction, proceeding via stable dioxolenium cation intermediates (Golding et al. 1989).

With the nitrogen heterocycles (15, X = NR), the three-membered (aziridine, n=2) and four-membered (azetidine, n=3) compounds give rise to the corresponding nitramine-nitrate products 17a and 17b in many cases in good to excellent yields. As mentioned earlier, the aziridine reactions are particularly susceptible to acid resulting from either adventitious moisture or from hydroxylic species within the substrate molecule, and in such cases only low yields of the desired nitramine-nitrates are obtained (R. W. Millar, N. C. Paul and D. H. Richards, unpublished results), with homopolymerization of the aziridine supervening (Dermer & Ham 1969).

The products find application as melt-castable explosives or plasticizers; thus the explosive materials pentryl 33 and Tris-X 35 (Millar et al. 1992) feature a high oxygen balance and the latter is an entirely novel compound, inaccessible by other routes, illustrating the utility of N<sub>2</sub>O<sub>5</sub>-ring cleavage reactions.

Phil. Trans. R. Soc. Lond. A (1992)

R. W. Millar and others

Both of these products are highly energetic and show other favourable physical properties. These strained-ring/ $N_2O_5$  reactions can also yield energetic plasticizers, starting from nitrogen heterocycles: Bu-NENA 38, for instance, is a component of some LOVA propellant compositions, whereas nitrocarbamates such as 40 make excellent energetic plasticizers (Olsen *et al.* 1966).

Finally, the cleavage reactions of nitrogen heterocycles have been found to be not quite as general as those of the oxygen series, with the course of the reaction being affected by the nature of the exocyclic nitrogen substituent (R) as well as the ring size:

Phil. Trans. R. Soc. Lond. A (1992)

**48** R = H

37-76% **46** R =  $CON(CH_3)_2$ 49 47  $R = COC_2H_5$ 

New synthesis routes for energetic materials

Thus when R is hydrogen no nitramine-nitrates are obtained: aziridines such as 43 yield 1,2-dinitrates 45 by a rearrangement reaction with expulsion of N<sub>2</sub>O, while azetidine 48 gives the cyclic nitramine, N-nitroazetidine 49, by a substitutive nitration (Golding et al. 1991). The behaviour becomes more complex with other Nacyl substituents, some aziridines (e.g. the carbamyl compound 41) showing predominantly ring-opening behaviour giving nitramine-nitrate products (e.g. 44) whereas others (e.g. the propionyl compound 42) yield mixtures, indicating competing reaction pathways. The azetidines, on the other hand, tend toward deacylative nitration (nitrolysis), yielding N-nitroazetidine 49 with groups such as carbamyl (e.g. 46) or propionyl (47) (Golding et al. 1991). Such deacylations are, of course, well known in nitration chemistry (Smith 1966; Gilbert et al. 1975) and reflect the lower ring strain in azetidines which permits alternative reactions to occur.

### 6. Selective nitrations and energetic binders

Selective nitrations, as suggested earlier, are feasible in organic solvent medium and, owing to the mild nitrating power of N<sub>2</sub>O<sub>5</sub> under these conditions, it is possible to allow a nitration to proceed only partly to completion where two or more functional groups of widely differing lability are present in the same molecule. Such an approach, of course, would be quite impossible with conventional strongly acid media, e.g. nitric-sulphuric acid mixtures, whereas other known mild reagents, e.g. acetyl nitrate or tetranitromethane, are impractical on large scale on account of excessive hazard and expense.

Two approaches to energetic binder macromolecules by selective nitration chemistry using  $N_2O_5$  are illustrated by the following reactions: first, the epoxy groups in an epoxidised hydroxy-terminated polybutadiene 51 can be cleaved by  $N_2O_5$  while leaving the chain double bonds essentially intact to yield an energetic polybutadiene containing vicinal dinitrate groups.

$$\sim_{\text{CH}_2}\text{--}_{\text{CH}}\text{--}_{\text{CH}_2}\sim_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2}\text{--}_{\text{CH}_2$$

This material, known as NHTPB (nitrated hydroxy-terminated polybutadiene, 52) is currently undergoing scale-up and evaluation in collaboration with industry, since it is readily preparable on large scale from cheap precursors and shows desirable properties for binder applications (Stewart *et al.* 1990).

The second approach involves the generation of energetic monomers by selective nitration: candidate molecules such as 3-hydroxymethyl-3-methyloxetane **20** and glycidol **18** have been found to be susceptible to nitration on the hydroxyl function while leaving the strained ring unchanged and essentially quantitative yields in the nitration step have been achieved under suitable conditions (Stewart *et al.* 1990; Bagg *et al.* 1991):

The nitrated strained-ring monomers, 3-hydroxymethyl-3-methyloxetane nitrate 53 and glycidyl nitrate 54, are then polymerized cationically to their respective polymers resulting in materials with the desired molecular weight range and suitable hydroxyl functionality, enabling subsequent cross-linking to a polyurethane rubber to be carried out:

The resulting energetic rubbers constitute a significant new class of energetic materials with wide application in propellant and explosive technology, notably enabling viable high-performance low-vulnerability propellant formulations to be manufactured for the first time (Debenham *et al.* 1991), and such materials are undergoing scale-up to tonnage levels in collaboration with industry.

#### 7. Conclusions

 $\rm N_2O_5$  nitrations are versatile and have much to offer the energetic materials chemist/technologist. It has been established that two essentially different but

Phil. Trans. R. Soc. Lond. A (1992)

complementary systems are available: (a)  $N_2O_5$  in nitric acid; and (b)  $N_2O_5$  in organic solvents. The former system, now available on pilot plant scale, can effect nitrations of the aromatic and nitrolysis type, useful for generating (C-) nitro and nitramine products respectively. It is a potent nitration system which has already shown advantage over mixed acid systems, particularly in the preparation of nitramines such as HMX.

New synthesis routes for energetic materials

The  $N_2O_5$  organic solvent system, on the other hand, although a milder nitration medium can nevertheless effect nitration of a wide variety of substrates, in particular the selective nitration of polyfunctional substrates and also nitration of polymers such as epoxidized HTPB. These products are of great importance industrially and have demonstrated that the future of  $N_2O_5$  in the field of energetic materials chemistry is assured.

#### Discussion

- F. Volk (Fraunhofer Institute, F.R.G.). You produced interesting polymeric nitrate esters. I would be interested in the thermal stability of these nitrate esters. Do you have any results of long-term ageing tests?
- R. W. MILLAR. We have found polyNIMMO to possess good thermal stability in the vacuum stability test, with figures (for the uncured material) of around 1 cm³/40 h/5 g polymer at 100 °C being typical (up to 2.5 cm³ is acceptable). Notably, it is significantly more stable than liquid nitrate esters such as nitroglycerine. The only long-term ageing results available relate to accelerated ageing tests of polyNIMMO cured with Desmodur N100 and stabilized with 2-nitrodiphenylamine (1%): this material displayed a reduced rate of nitrate ester breakdown (compared with unstabilized material) and chain scission of the polymer backbone was greatly retarded, demonstrating that its stability is comparable with that of binders currently used in propellant compositions.
- B. J. Thomson (Health and Safety Executive, U.K.). Conventional batch nitration reactions feature highly among the incidents occurring in batch processes because of their strongly exothermic nature; so the low exothermicity of  $N_2O_5$  nitrations can be viewed as a step towards minimizing the risk associated with nitration. But conventional batch nitration mixtures can also be detonable in their own right, when examined by conventional tests, such as the BAM U.N. 50/60 Tube Test. What are the detonability or explosive characteristics of the  $N_2O_5$  nitration systems, particularly the  $N_2O_5/organic$  solvent systems?
- R. W. MILLAR. First, to clear up a possible misconception, only  $N_2O_5$ -ring opening nitrations show by exothermicity;  $N_2O_5$ -hydroxyl group reactions are strongly exothermic, and to overcome this potential problem we use flow reactor technology.

This also greatly reduces the bulk medium risk since very little energetic material is present in the flow reactor zone at any given time.

Concerning the question of detonability of  $\rm N_2O_5$ -organic solvent mixtures, particularly for large-scale batch reactions, in these circumstances we keep the  $\rm N_2O_5$  concentration down to around 10 mass/vol. % since this is considered by our hazards section to be outside the detonable range of concentrations.
