(Received 9 July 2008; revised manuscript received 25 October 2008; published 8 December 2008)

We present here temperature-dependent Raman, x-ray diffraction, and specific heat studies between room temperature and 12 K on single crystals of spin-ice pyrochlore compound $Dy_2Ti_2O_7$ and its nonmagnetic analog $Lu_2Ti_2O_7$. Raman data show a "new" band not predicted by factor group analysis of Raman-active modes for the pyrochlore structure in $Dy_2Ti_2O_7$, appearing below a temperature of T_c =110 K with a concomitant contraction of the cubic unit cell volume as determined from the powder x-ray diffraction analysis. Low-temperature Raman experiments on O^{18} -isotope substituted $Dy_2Ti_2O_7$ confirm the phonon origin of the new mode. These findings, absent in $Lu_2Ti_2O_7$, suggest that the room-temperature cubic lattice of the pyrochlore $Dy_2Ti_2O_7$ undergoes a "subtle" structural transformation near T_c . We find anomalous *redshift* of some of the phonon modes in both the $Dy_2Ti_2O_7$ and the $Lu_2Ti_2O_7$ as the temperature decreases, which is attributed to strong phonon-phonon anharmonic interactions.

I. INTRODUCTION

Geometrically frustrated magnetic systems are those where spins cannot simultaneously minimize all their pairwise exchange energies because of geometrical reasons and hence cannot find a unique ground state. 1,2 In a real system, however, any small perturbation to these interactions can favor a particular ground state thus lifting the macroscopic degeneracy. The perturbation can be in the form of single-ion anisotropy, next or higher neighbor interactions, thermal or quantum fluctuations, dipolar interactions, lattice deformations, or externally applied stimuli such as pressure or magnetic field. The pyrochlore structure (space group $Fd\overline{3}m$), with stoichiometry $A_2B_2O_7$, is a typical example of geometrically frustrated magnets in three dimensions. In this structure, A^{3+} and B^{4+} ions form distinct interpenetrating networks of corner-sharing tetrahedra, displaced from each other by half the unit cell dimension. If either A or B ion has a magnetic moment, strong geometrical frustration results, which in the presence of one or more perturbative terms gives rise to various interesting ground states. Such is the case for the family of insulating rare-earth titanates $(R_2 \text{Ti}_2 \text{O}_7; R = \text{trivalent rare-earth ion})$, which show a wide diversity in their magnetic behavior (for a recent review on these pyrochlores, see Ref. 3) from a Néel ordered state in Er₂Ti₂O₇ (Ref. 4) to a spin-liquid state in Tb₂Ti₂O₇ (Ref. 5) and spin-ice states Dy₂Ti₂O₇ (Ref. 8) and Ho₂Ti₂O₇. In the spin-ice ground state, two spins on an elementary tetrahedron point in and the remaining two point out, an arrangement that is analogous to protons ordering in ordinary water ice. Consequently, the ground state degeneracy and hence the "zeropoint" entropy of a spin ice is shown⁸ to be very close to what Pauling⁷ estimated for the water ice nearly 50 years ago. Since spins can easily be manipulated by external stimuli, such as magnetic field, 9,10 studying spin ice is of considerable importance even from the point of view of understanding the properties of ordinary water ice. For these reasons, the spin ices $Dy_2Ti_2O_7$ and $Ho_2Ti_2O_7$ have attracted considerable recent attention. Besides these two canonical spin ices, other examples of spin-ice or spin-ice-like ground states include $Ho_2Sn_2O_7$ (Ref. 11) and $Tb_2Sn_2O_7$ (Ref. 12) members in the analogous stannate series, and, $Nd_2Mo_2O_7$ (Ref. 13) and $Sm_2Mo_2O_7$ (Ref. 14) in the molybdate pyrochlore series.

Spin-ice state in Dy₂Ti₂O₇ and Ho₂Ti₂O₇ emerges at very low temperatures when the dipolar interactions between the large Ising-type Dy³⁺(Ho³⁺) spins overwhelm the nearneighbor antiferromagnetic exchange, and therefore, a majority of studies on these pyrochlores, until recently, were limited to the liquid helium or lower-temperature range. Recently, vibrational properties of some titanate pyrochlores (including the spin-ice Dy₂Ti₂O₇) have been studied using infrared reflectivity¹⁵ and Raman spectroscopy^{16,17} up to room temperature. In the work by Maczka et al. 17 on $R_2 \text{Ti}_2 \text{O}_7$ (R=Er, Gd, and Dy), Raman studies of $\text{Gd}_2 \text{Ti}_2 \text{O}_7$ and Er₂Ti₂O₇ were carried out to determine the temperature dependence of Raman mode frequencies and linewidths. These authors, however, could not follow the temperature dependence of Raman modes in Dy₂Ti₂O₇. These studies have shown that mode frequencies of a few phonons decrease upon cooling, a behavior not often observed in solids and hence termed as "anomalous." This anomalous behavior has been qualitatively attributed by Bi et al. 15 to strong spinphonon coupling in Dy₂Ti₂O₇ for a few modes. Since the strength of exchange interaction is relatively much weaker for titanate pyrochlores [ranging between ~19 K in $Tb_2Ti_2O_7$ (Refs. 18 and 19) and ~ 25 K in $Sm_2Ti_2O_7$ (Ref. 20)], and there is no long-range spin order in Dy₂Ti₂O₇ as well as in Gd₂Ti₂O₇ and Er₂Ti₂O₇ down to very low temperatures,³ this qualitative explanation of the anomalous temperature dependence in terms of spin-phonon coupling has been questioned.¹⁷ Another explanation of this anomalous behavior in terms of a coupling between phonons and crystal field excitations can also be ruled out because Gd₂Ti₂O₇ also exhibits comparable phonon anomalies even though in Gd³⁺ ion no crystal field effect is expected due to spherical symmetry of the 4f charge cloud. It is suggested in Ref. 17 that the anomalous temperature dependence could arise from anharmonic interactions. In order to understand the anomalous temperature dependence of phonon modes, we have done detailed Raman studies on single crystals of Dy₂Ti₂O₇ and its nonmagnetic analog Lu₂Ti₂O₇ over a temperature range of 12 to 300 K. A quantitative comparison of the phonons of these two pyrochlores is done to understand the role of spin-phonon coupling in giving rise to the anomalous phonon behaviors. Most interestingly, we show here that an equally anomalous phonon behavior is present for the nonmagnetic Lu₂Ti₂O₇ as well. Another important outcome of our study is the observation of a "new" mode near 300 cm⁻¹ in the Raman spectra of Dy₂Ti₂O₇ recorded below T=110 K. Recently, Lummen et al. 16 also made a similar observation, who tentatively assigned the new mode to the first excited crystal-field level of Dy3+. By performing Raman spectroscopic experiments on an O¹⁸-isotope enriched crystal of Dy₂Ti₂O₇, we show here that the new mode is actually a phonon mode not expected from the factor group analysis of Raman active modes for the space group $Fd\overline{3}m$ of the pyrochlore structure. We also show that the emergence of new mode is corroborated by an abrupt change in the temperature dependence of the lattice constant by powder x-ray diffraction studies. These findings, absent in Lu₂Ti₂O₇, suggest a possible lattice symmetry lowering in Dy₂Ti₂O₇ below 110 K.

II. EXPERIMENTAL TECHNIQUES

Stoichiometric amounts of Dy₂O₃/Lu₂O₃ (99.99%) and TiO₂ (99.99%) were mixed thoroughly and heated at 1200 °C for about 15 h. The resulting mixture was well ground and isostatically pressed into rods of about 8 cm long and 5 mm diameter. These rods were sintered at 1400 °C in air for about 72 h. This procedure was repeated until the compound Dy₂Ti₂O₇/Lu₂Ti₂O₇ was formed, as revealed by powder x-ray diffraction analysis, with no traces of any secondary phase. These rods were then subjected to single crystal growth by the floating-zone method in an infrared image furnace under flowing oxygen. X-ray diffraction, carried out on the powder obtained by crushing part of a single crystalline sample and energy dispersive x-ray analysis on a scanning electron microscope indicated a pure pyrochlore Dy₂Ti₂O₇/Lu₂Ti₂O₇ phase. The Läue back-reflection technique is used to orient the crystal along the principal crystallographic directions. To prepare the O¹⁸-isotope rich samples of Dy₂Ti₂O₇, thin crystal slices of Dy₂Ti₂O₇ (O¹⁶) were cut from their as-grown boule. The thickness was further reduced to less than 500 μ m by polishing the flat ends. Each crystal slice thus obtained was cut into two halves. While one half was annealed in oxygen atmosphere enriched with ¹⁸O₂ (95%) isotope at 950 °C for 7 days, the other half was

subjected to an identical heat treatment but under normal oxygen atmosphere. We found that the samples annealed under $^{18}O_2$ atmosphere gained nearly 2% in weight, while the weight of samples annealed under normal oxygen atmosphere remained unchanged, which indicates that a substantial isotopic exchange took place during the heat treatment.

Raman spectroscopic measurements on a (111) cut thin single-crystalline slice (0.5 mm thick and 3 mm in diameter, polished down to a roughness of almost 10 μ m) of Dy₂Ti₂O₇ and Lu₂Ti₂O₇ were performed at low temperatures in backscattering geometry, using 514.5 nm line of an Ar⁺ ion laser (Coherent Innova 300) with ~15 mW of power falling on the sample. Temperature scanning was done using a CTI-Cryogenics closed cycle refrigerator. Temperature was measured and controlled (with a maximum error of 0.5 K) using a calibrated Si-diode sensor and a CRYO-CON 34 temperature controller, respectively. The scattered light was collected by a lens and was analyzed using a computer controlled DILOR XY Raman spectrometer having three holographic gratings (1800 grooves/mm) coupled to a liquid nitrogen-cooled charged coupled device, CCD 3000 (Jobin Yvon-SPEX make) of pixel resolution 0.85 cm⁻¹. The instrumental broadening is about 5 cm⁻¹.

High-resolution x-ray diffraction measurements were performed between 10–300 K (with temperature accuracy better than 0.5 K) using a highly accurate two-axis diffractometer in a Bragg-Brentano geometry (focalization circle of 50 μ m) using the Cu- K_{β} line (λ =1.39223 Å) of a 18 kW rotating anode.

Specific heat of $Dy_2Ti_2O_7$ and $Lu_2Ti_2O_7$ was measured between 5 and 300 K using a Quantum Design physical property measurement system (PPMS). Thin single crystal slices (thickness $\sim 500~\mu m$) weighing about 10 mg each were mirror polished and mounted on the sample holder of PPMS. Addenda specific heat of the bare sample holder and a small amount of APIZONE N grease (to make thermal contact with the sample) was measured each time before loading the single crystals on the sample holder.

III. RESULTS

A. Raman spectrum of Dy₂Ti₂O₇ and Lu₂Ti₂O₇

The pyrochlore family belongs to the space group $Fd\overline{3}m(O_7^h)$ with an $A_2B_2O_6O'$ stoichiometry, where A^{3+} occupies the 16d and B^{4+} occupies the 16c positions and the oxygen atoms O and O' occupy the 48f and 8b sites, respectively. Factor group analysis for this family of structures suggests six Raman active modes $(A_{1g}+E_g+4F_{2g})$ and seven infrared active modes $(7F_{1u})$. Figure 1 (bottom panel) shows the Raman spectrum of $Dy_2Ti_2O_7$ at 12 K between wave number 50 and 1000 cm⁻¹ which is fitted with 14 Lorentzians, labeled M1 to M14. The assignment of various modes have been done following the previously reported results of Refs. 21 and 22 (see Table I for details). The six Raman active modes are labeled M3 (174 cm⁻¹, F_{2g}), M6 (312 cm⁻¹, F_{2g}), M7 (330 cm⁻¹, E_g), M8 (453 cm⁻¹, E_g), M9 (515 cm⁻¹, E_g), and M10 (563 cm⁻¹, E_g). The top panel of Fig. 1 shows the Raman spectrum of Lu₂Ti₂O₇ at 12

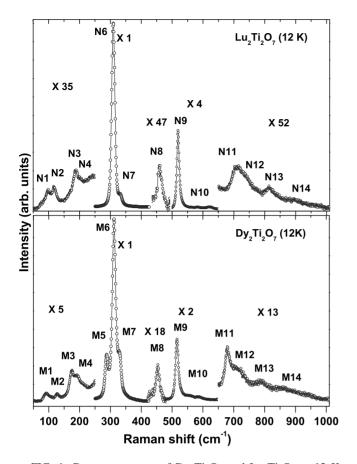

FIG. 1. Raman spectrum of $Dy_2Ti_2O_7$ and $Lu_2Ti_2O_7$ at 12 K. Open circles represent the experimental data. Raman intensity in the regions from 50–250, 425–475, 475–650, and 650–1010 cm⁻¹ are rescaled with respect to the region between 250–425 cm⁻¹ in order to view the weak modes clearly. The different modes labeled as M1(N1) to M14(N14) are assigned in the text (Table I).

^aOrigin of the mode has been discussed in the text.

K where all the modes are seen, except the mode M5. The six Raman active modes of $\text{Lu}_2\text{Ti}_2\text{O}_7$ appear at 188 cm⁻¹ (N3, F_{2g}), 313 cm⁻¹ (N6, F_{2g}), 336 cm⁻¹ (N7, E_g), 458 cm⁻¹ (N8, F_{2g}), 520 cm⁻¹ (N9, F_{2g}), and 609 cm⁻¹ (N10, F_{2g}). Some of the previous studies^{23–25} labeled the mode M9(N9) as $A_{1g}+F_{2g}$, and overlooked the weak mode near 450 cm⁻¹. We and Lummen *et al.* ¹⁶ have observed a mode near 450 cm⁻¹ in several of the pyrochlore titanates. This mode has sometimes been assigned to TiO₂ as an impurity phase in the pyrochlore sample. ²⁶ We rule out this possibility because a strong mode of TiO₂, near 610 cm⁻¹, is not seen in our single crystals. We have therefore assigned the 450 cm⁻¹ mode to F_{2g} phonon, as done in Refs. 21 and 22.

We now come to the origin of the additional modes M1(N1), M2(N2), M4(N4), M11(N11), M12(N12),M13(N13), and M14(N14), also observed in Refs. 17 and 24 and seen in both magnetic and nonmagnetic pyrochlores (Fig. 1). The modes labeled as M11 to M14 can be assigned to second-order Raman scattering.¹⁷ Since the modes M1, M2, and M4 are seen in both Dy₂Ti₂O₇ (magnetic) and Lu₂Ti₂O₇ (nonmagnetic), these cannot be assigned to crystalfield transitions of Dy³⁺ in Dy₂Ti₂O₇. We, therefore, assign these modes to infrared active or silent modes rendered Raman active due to a possible lowering of the local symmetry at some crystallographic sites, as suggested in Ref. 24. We have followed the evolution of the different modes with temperatures from 12 to 300 K for both Dy₂Ti₂O₇ and Lu₂Ti₂O₇ and the results are discussed below.

B. Evolution of Raman spectra with temperature

Raman spectra of Dy₂Ti₂O₇ have been recorded at several temperatures varying from 12 to 300 K. The maximum changes are seen in Raman bands M1-M7 in the spectral range of 50–400 cm⁻¹. We, therefore, show in Fig. 2 the Raman spectra at a few typical temperatures in this spectral range. The modes M1, M2, M3, and M4 are weak, their intensities are, therefore, rescaled as indicated in Fig. 2 with respect to the mode M6. It can be clearly seen that for T>110 K, the spectra in the 250–400 cm⁻¹ range can be fitted by two Lorentzians representing the two allowed Raman modes (M6 and M7). However, the spectra at T =110 K and below, indicate a new mode (termed as M5) marked by an arrow in the panels corresponding to T=110, 50 and 12 K in Fig. 2. The frequencies of the modes M1, M2, M3, M4, M5 (new mode), M6, M7, M9, M10, and M11 are plotted against temperature in Fig. 3. It can be seen that the modes M1, M3, M4, M9, M11, and the new mode M5 (which appears below 110 K) show large anomalous redshifts upon decreasing temperature. The mode M7 initially shows a blueshift and then a small redshift below 110 K. The mode M1 shows a small blueshift as temperature decreases below 110 K. However, the intense mode M6 and the modes M2 and M10 exhibit blueshift with decreasing temperature, a usual behavior seen in solids. The temperature dependence of the M3 and M9 modes shows an interesting trend, namely, the rate of softening $(\frac{\partial \omega}{\partial T})$ increases below 110 K.

Temperature dependence of some of the modes of non-magnetic Lu₂Ti₂O₇ is plotted in Fig. 4. It is clearly seen that

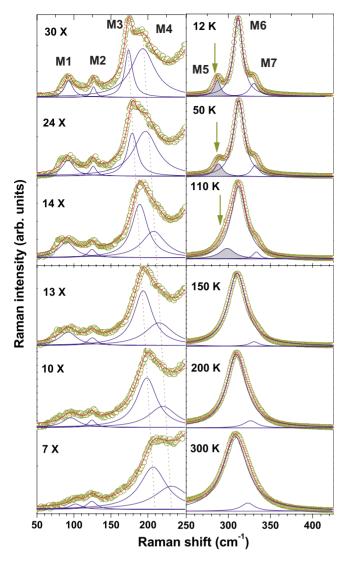

FIG. 2. (Color online) Raman spectra of $Dy_2Ti_2O_7$ at different temperatures. Solid lines are fit to the experimental data (open circles), as discussed in text. A new mode (M5) appears at 110 K which has been marked by arrows in panels corresponding to 100, 50, and 12 K. Raman intensity in the low frequency regions (50–250 cm⁻¹) has been rescaled.

phonon modes N1, N2, N3, N4, N6, N7, and N9 show anomalous temperature dependence, similar to the ones seen in $\mathrm{Dy_2Ti_2O_7}$ phonons.

C. Appearance of a new mode in Dy₂Ti₂O₇

In Fig. 2, it is clearly evident that a new mode (M5) emerges near $\omega \sim 300~{\rm cm^{-1}}$ below $T_c = 110~{\rm K}$ in Dy₂Ti₂O₇ whereas no new Raman mode has been seen in Lu₂Ti₂O₇ even at 12 K (Fig. 1) in the present study or in other titanate pyrochlores, such as Gd₂Ti₂O₇, ¹⁷ Er₂Ti₂O₇, ¹⁷ Ho₂Ti₂O₇, ¹⁶ and Sm₂Ti₂O₇ (Ref. 20) studied previously. At room temperature, the Raman spectrum of Dy₂Ti₂O₇ between 250 and 400 cm⁻¹ is satisfactorily fitted to a sum of two Lorentzian functions centered at 308 and 322 cm⁻¹, corresponding to the modes F_{2g} (M6) and E_g (M7), respectively (see Table I).

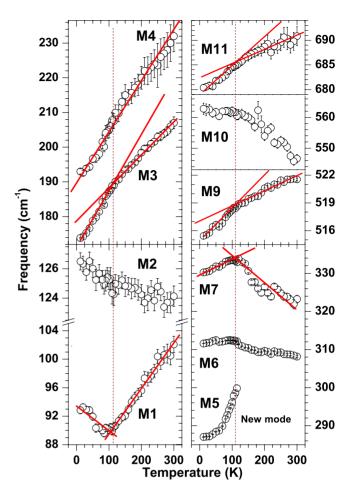

FIG. 3. (Color online) Temperature dependence of the different modes of $\mathrm{Dy_2Ti_2O_7}$. Solid lines are guides for the eyes. New mode (M5) appears below 110 K.

A similar fit worked equally well at lower temperatures down to about 115 K, as shown for T=200 and 150 K spectra in the lower panels of Fig. 2. However, for the spectrum recorded at T_c =110 K, it became necessary to include a third Lorentzian in order to capture an essential feature, which is the emergence of a new mode on the low-frequency side of the mode M6 (middle panel of Fig. 2). This mode gets further resolved and more pronounced as the sample temperature is lowered below T_c , as shown by arrows in the panels corresponding to 110, 50, and 12 K.

We note that Lummen *et al.*¹⁶ and Maczka *et al.*¹⁷ also see this new mode in their low-temperature Raman spectra of Dy₂Ti₂O₇. Lummen *et al.*¹⁶ tentatively assigned the new mode near 300 cm⁻¹ to the first excited CF level after the crystal-field splitting estimation due to Rosenkranz *et al.*²⁸ However, the crystal-field splittings of the lowest *J*-multiplet calculated by Jana *et al.*²⁷ differ considerably. Our results of the specific heat measurements on Dy₂Ti₂O₇ and Lu₂Ti₂O₇, discussed in the later part of this article, suggest that the energy gap between the ground and the first excited CF level is ~250 cm⁻¹ which is closer to Rosenkranz's estimation than Jana's calculations. Based on these observations, the assignment of the new mode as a CF mode (transition from ground state to the first excited CF level) by Lummen *et al.*¹⁶ looks attractive. However, this assignment of the new mode

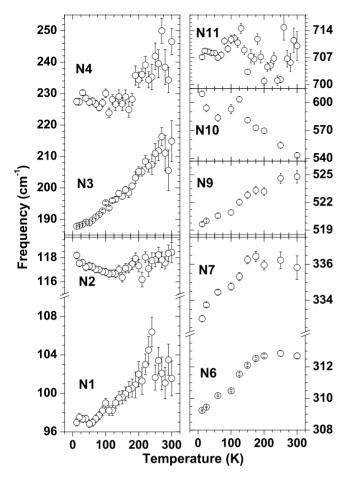

FIG. 4. Temperature dependence of the different modes of $Lu_2Ti_2O_7$.

to be the CF origin is not compatible with our low-temperature Raman experiments on single crystal of O^{18} -isotopic $Dy_2Ti_2O_7$. Since all the Raman active modes in pyrochlores involve O-ion vibrations only, replacement of O^{16} by O^{18} in $Dy_2Ti_2O_7$ will redshift all the phonon modes, whereas the positions of CF modes, if present, will remain unchanged. Our experimental results shown in Fig. 5 show a redshift of $\sim 4~\rm cm^{-1}$ of the new mode when O^{16} is replaced by O^{18} , thus suggesting the new mode to be a lattice vibration and not a CF transition. This assignment is further

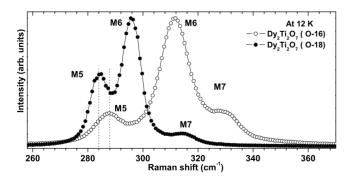

FIG. 5. Raman spectra of O¹⁶ (open circle) and O¹⁸ (closed circle) isotopic Dy₂Ti₂O₇ at 12 K in the range of 260–370 cm⁻¹. A change in frequencies is seen with a change in O-ion isotopic mass.

strengthened by the fact that the full width at half maxima (Γ) is less in O¹⁸ rich Dy₂Ti₂O₇ $(\Gamma=6.7 \text{ cm}^{-1})$ as compared to its value ($\Gamma = 9.1 \text{ cm}^{-1}$) in O^{16} rich $Dy_2Ti_2O_7$. This decrease in Γ is also seen for the M6 and M7 modes. It has been shown earlier that the phonon linewidth depends on isotopic mass as $\Gamma \propto M_{\rm isotope}^{-1}$. This, therefore, strongly suggests that the new mode M5 near 300 cm⁻¹ is of phonon origin. Another possibility is that the new mode (M5) becomes observable below 110 K when the linewidth of the mode M6 decreases. This explanation will not be consistent with our results on Lu₂Ti₂O₇: at 300 K the linewidth of the N6 mode in Lu₂Ti₂O₇ is similar to the corresponding M6 mode and no new mode is seen in Lu₂Ti₂O₇ at low temperatures. The appearance of the new mode (M5) is, therefore, attributed to a Raman inactive phonon mode becoming Raman active due to lowering of the site symmetries arising from local structural deformation below 110 K. Following the indication of a possible structural transition, we have performed x-ray diffraction experiments as a function of temperature and the results are discussed below.

D. Low temperature x-ray diffraction

In order to examine if the appearance of the new mode in Dy₂Ti₂O₇ at 110 K is related to a possible structural transition, we have recorded high accuracy powder x-ray diffraction patterns from room temperature down to 10 K. Inspection of the whole diffraction pattern recorded at 10 K did not show additional new peaks nor splitting or broadening of the existing Bragg peaks. However, as shown in Fig. 6, the temperature dependence of the lattice parameter a extracted from (004) and (333) Bragg reflections clearly displays a discontinuous change in the lattice parameter near 100 K, the temperature at which the new mode (M5) appears in our Raman data. In contrast, the temperature variation in the lattice parameter in its nonmagnetic analog Lu₂Ti₂O₇, plotted in Fig. 6 for comparison, is smooth as expected in the absence of a structural deformation. The solid lines in Fig. 6 are fit to the data by the relation $a(T) = a_0 \left[1 + \frac{be^{c/T}}{T(e^{c/T} - 1)^2}\right]$, where a_0 is the lattice constant at 0 K and b and c are fitting parameters.²⁹ For Dy₂Ti₂O₇ a_0 =10.116 Å, b=3.152 K, c=436.3 K and for $Lu_2Ti_2O_7$ they are 10.024 Å, 3.119 K, and 513.0 K, respectively.

A survey of the literature for experiments on Dy₂Ti₂O₇ showing anomalous behavior near 110 K directed us to a report³⁰ on the nuclear gamma resonance of ¹⁶¹Dy³⁺ in Dy₂Ti₂O₇ by Mössbauer spectroscopy suggesting a change in the nuclear quadrupolar interaction with temperature. The total electric field gradient in the Dy³⁺ nuclei comes from the 4f orbitals of Dy³⁺ and the external charges around, in the lattice. As suggested in Ref. 30, there is no significant change in the lattice contribution with temperature but a dramatic change was seen in the electric-field gradient due to 4f orbitals with temperature that becomes almost zero at 110 K. We propose a possibility that when the electric field gradient at Dy^{3+} ions due to their 4f orbitals becomes negligibly small, the surrounding atoms in the lattice slightly readjust and move out of their regular Wyckoff positions thus deforming the local crystal symmetry without disturbing the

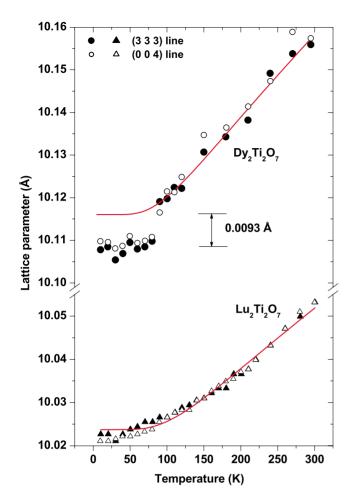

FIG. 6. (Color online) Variation in the lattice parameter of $Dy_2Ti_2O_7$ with temperature. An abrupt jump of the lattice parameter, indicative of a structural deformation, is seen near 100 K, a temperature where new mode appears in Raman spectrum. In comparison, the lattice parameter of nonmagnetic $Lu_2Ti_2O_7$ varies smoothly over the entire range of temperature. Solid lines are fit to the data as discussed in text.

average electric field gradient due to the surrounding ions in the lattice. There is a recent study on the temperature dependence of spin-relaxation time in Dy₂Ti₂O₇.³¹ Unfortunately, the data are taken only between 10 and 90 K and at 300 K. The data corresponding to 300 K do not agree with the value extrapolated from the Arrhenius behavior fitted to the data between 10 and 90 K. Later, experiments by Kitagawa *et al.*³² filled up the gap in the data in the range of 90–300 K. In Fig. 6 of Ref. 32, we can see a small jump near 100 K in the value of the spin relaxation time. It is, therefore, tempting to suggest that the discrepancy seen by Sutter *et al.*³¹ and Kitagawa *et al.*³² may be related to the structural deformation we observed at 110 K.

E. Specific heat

The specific heat of $\mathrm{Dy_2Ti_2O_7}$ (C_{DTO}) and $\mathrm{Lu_2Ti_2O_7}$ (C_{LTO}) single crystals in the temperature range T=5–300 K is shown in Fig. 7(a). Specific heat of both compounds shows a smooth monotonic decrease upon cooling below

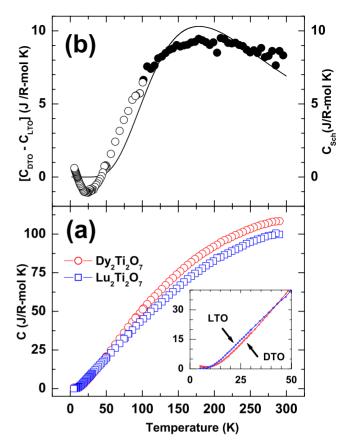

FIG. 7. (Color online) (a) Temperature dependence of specific heat (C) for the pyrochlores $\mathrm{Dy_2Ti_2O_7}$ (DTO) and $\mathrm{Lu_2Ti_2O_7}$ (LTO) in the temperature range 5–300 K. Inset: blown-up view of the low-temperature part of the main panel; (b) closed and open circles are data points corresponding to the difference $C_{\mathrm{DTO}} - C_{\mathrm{LTO}}$. The closed circles represent approximate Schottky contribution (C_{Sch}) in the specific heat of DTO above 100 K. The solid line is the calculated Schottky anomaly due to the first five higher lying crystal field doublets at 385, 503, 547, 679, and 956 K taken from Ref. 32.

room temperature. For Dy₂Ti₂O₇, a tendency toward increase in the specific heat values when cooled below 10 K is due to short-range magnetic correlations between the Dy³⁺ spins.⁸ In particular, no anomalous feature is seen in $C_{\rm DTO}$ around T=100 K, the temperature where the new mode first appears in the Raman spectrum. While the specific heat of nonmagnetic Lu₂Ti₂O₇ arises purely due to thermal lattice vibrations, the specific heat of Dy₂Ti₂O₇ has an additional Schottky contribution arising from thermal (de)population of higher lying CF split levels of Dy $^{3+}$ ions. Therefore, $C_{\rm DTO}$ above 10 K can be expressed as an algebraic sum of contributions due to Schottky term (C_{Sch}) and thermal lattice vibration term (C_{latt}) . Since $\text{Dy}_2\text{Ti}_2\text{O}_7$ is structurally analogous to $\text{Lu}_2\text{Ti}_2\text{O}_7$, albeit with a slightly smaller molecular weight, C_{latt} term in the specific heat of Dy₂Ti₂O₇ can be approximated by the measured specific heat of nonmagnetic Lu₂Ti₂O₇. However, as shown in the inset of Fig. 7(a), C_{LTO} in the range T=10-40 K exceeds $C_{\rm DTO}$ by values up to 1 J/R mol K (\sim 10% near T=25 K). We note that this difference remains largely negative even after rescaling $C_{\rm LTO}$ by a factor μ = $(M_{\rm DTO}/M_{\rm LTO})^n$ (for both n=1/2 and 3/2), where $M_{\rm DTO}$ and M_{LTO} are molecular weights of Dy₂Ti₂O₇ and Lu₂Ti₂O₇, re-

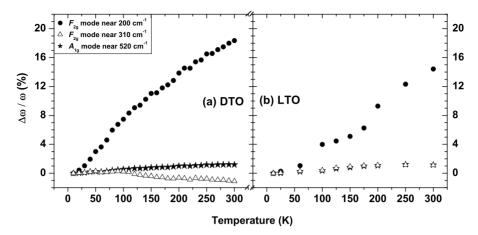

FIG. 8. Percentage change of frequencies $(\frac{\Delta\omega}{\omega}\%)$ of (a) Dy₂Ti₂O₇ and (b) Lu₂Ti₂O₇ phonons with temperature which thus indicates a similar amount of phonon softening in both the pyrochlores.

spectively. These observations suggest that the lattice specific heat of Dy₂Ti₂O₇ is smaller than the specific heat of nonmagnetic Lu₂Ti₂O₇, which is possibly due to the thermal lattice expansion behavior of these compounds shown in Fig. 6. While the lattice of Lu₂Ti₂O₇ expands continuously upon heating above 10 K, Dy₂Ti₂O₇ exhibits a relatively small lattice expansion at first until it expands steeply between 80 and 100 K and thereafter in a manner analogous to that of Lu₂Ti₂O₇. What transpire from the above discussion is that Lu₂Ti₂O₇ in not a useful lattice template for Dy₂Ti₂O₇ at low temperatures. However, above T=100 K the thermal expansion behavior and the degree of anharmonicity (vide infra) of the two compounds are in quantitative agreement, therefore, the specific heat of Lu₂Ti₂O₇ is used to approximate the lattice specific heat of Dy₂Ti₂O₇ in the temperature range 100 to 300 K. A rough estimate of the Schottky contribution in the specific heat of $Dy_2Ti_2O_7$ above T=100 K is obtained using $C_{\rm Sch}(=C_{\rm DTO}-C_{\rm LTO})$. $C_{\rm Sch}$ obtained using this procedure is shown in Fig. 7(b) by closed circles. It exhibits a broad maximum centered at T=175 K with a value of ~ 9 J/Dy mol K. For comparison, we calculated the Schottky specific heat using the crystal field levels scheme given in Ref. 32, estimated by rescaling the CF parameters of Ho₂Ti₂O₇ obtained by Rosenkraz et al.²⁸ using inelastic neutron-scattering data. The calculated Schottky anomaly exhibits a peak at roughly the same temperature as the experimentally derived C_{Sch} , with a value of about 10 J/R mol K at the peak temperature of 175 K. On the other hand, the calculated Schottky anomaly by Jana et al.²⁷ (shown in Fig. 2 of Ref. 27) exhibits a huge peak of 9.5 J/Dy mol K at a much lower temperature of T=65 K. Moreover, at still lower temperatures, where $C_{\rm DTO}$ is less than $C_{\rm LTO}$ and hence $C_{\rm Sch}$ is expected to be very small, the calculated $C_{\rm Sch}$ due to Jana et al. ranges from about 1 J/R mol K near T=20 K to 6.5 J/R mol K near T=40 K. Our specific heat data clearly favors the crystal-field levels scheme of Rosenkranz et al., while ruling out the validity of the crystal field scheme due to Jana et al.²⁷ From the position of maximum at 175 K in the experimentally derived $C_{\rm Sch}$, it is easy to appreciate that the first excited crystal-field split level of Dy³⁺ in Dy₂Ti₂O₇ lies well above room temperature as proposed by Rosenkranz et al.²⁸ In Fig. 7(b) the open circles represents the difference $C_{\rm DTO}-C_{\rm LTO}$ below T=100 K which disagree with the calculated $C_{\rm Sch}$ curve, because at low temperatures, use of Lu₂Ti₂O₇ as a lattice template slightly overestimates the $C_{\rm latt}$ of Dy₂Ti₂O₇ leading to even negative values of the difference $C_{\rm DTO}-C_{\rm LTO}$ below T=40 K as discussed above.

In short, the specific heat investigations of $\mathrm{Dy_2Ti_2O_7}$ and $\mathrm{Lu_2Ti_2O_7}$ clearly indicate that the position of first excited crystal-field split doublet is close to 350 K (240 cm⁻¹). These results favor the crystal field scheme for $\mathrm{Dy^{3+}}$ in $\mathrm{Dy_2Ti_2O_7}$ derived from the work of Rosenkranz *et al.* on $\mathrm{Ho_2Ti_2O_7}$, ²⁸ however, due to problems associated with correct determination of C_{Sch} at low temperatures, the validity of crystal field splitting due to Rosenkranz *et al.* could not be verified completely.

F. Anomalous redshift of phonons

For spin-ice $Dy_2Ti_2O_7$, as shown in Fig. 3, a large anomalous softening (redshift) of the modes M1, M3, M4, M9, and M11 is seen with decreasing temperature. The new mode (M5) that appears below 110 K also shows a considerable large amount of redshift with decreasing temperature. Interestingly, the phonon modes of the nonmagnetic $Lu_2Ti_2O_7$ also show large anomalous softening, as temperature decreases. As shown in Fig. 4, the phonons N1, N2, N3, N4, N6, N7, and N9 show redshifts, similar to the $Dy_2Ti_2O_7$ phonons. Temperature dependence of the strong F_{2g} modes (M3, N3, M6, and N6) and the A_{1g} mode (M9 and N9) of the two pyrochlores are compared in Fig. 8 which emphasizes that magnitude of phonon softening with decreasing temperature in both pyrochlores is comparable.

Temperature variation in a phonon mode (i) of frequency ω_i can be expressed as

$$\omega_i(T) = \omega_i(0) + (\Delta \omega_i)_{qh}(T) + (\Delta \omega_i)_{anh}(T) + (\Delta \omega_i)_{el-ph}(T) + (\Delta \omega_i)_{sp-ph}(T).$$
(1)

The first term corresponds to the phonon frequency at T = 0 K. The second term is a contribution to the phonon frequency due to a change in lattice constant with temperature

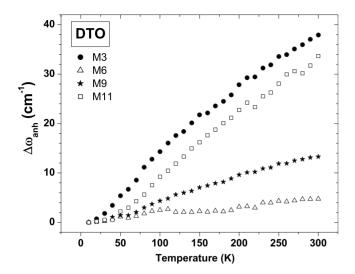

FIG. 9. The intrinsic anharmonic contribution $(\Delta\omega_{anh})$ to the change in frequency of $Dy_2Ti_2O_7$ phonons estimated from experimental data.

and is known as quasiharmonic contribution to the frequency change. The third term corresponds to the intrinsic anharmonic contribution to phonon frequency that comes from the real part of the self-energy of the phonon decaying into two phonons (cubic anharmonicity) or three phonons (quartic anharmonicity). The fourth term $(\Delta \omega_i)_{\text{el-ph}}$ is due to coupling of phonons with charge carriers within the system which is absent in insulating pyrochlore titanates. The last term, $(\Delta \omega_i)_{\text{sp-ph}}$, is the change in phonon frequency due to spin-phonon coupling arising from modulation of spin exchange integral by the lattice vibration.

The lattice contribution $(\Delta \omega_i)_{qh}(T)$ to the phonon energy accounts for an expansion or contraction of the lattice leading to a change in the harmonic force constant without changing the phonon population. This change in frequency of a mode i can thus be approximately related to the change in volume using the Grüneisen parameter $\gamma_i = -\frac{\partial \ln \omega_i}{\partial \ln V} = \frac{B_0}{\omega_i} \frac{\partial \omega_i}{\partial P}$, where B_0 is the bulk modulus. Taking T = 12 K as the reference temperature (the lowest temperature in our measurements), $\frac{\omega_i(T) - \omega_i(12 \text{ K})}{\omega_i(12 \text{ K})} = -\gamma_i \frac{V_i(T) - V_i(12 \text{ K})}{V_{12 \text{ K}}}$. To order to account for this quasiharmonic contribution, we have taken the measured values of the Grüneisen parameters from our high pressure Raman and x-ray experiments on Dy₂Ti₂O₇ at room temperature³³ and the values are $\gamma(M3)=2.2$, $\gamma(M6)=1.7$, $\gamma(M9)=0.9$, and $\gamma(M11)=2.2$. The volume of the unit cell at different temperatures has been taken from the temperature dependence of the lattice parameters shown in Fig. 6. The quasiharmonic contribution is subtracted from the experimental frequencies to obtain the change in frequency $(\Delta \omega)$ solely due to intrinsic anharmonic effects $[(\Delta \omega_i)_{anh}(T)]$ and to the spin-phonon coupling $[(\Delta \omega_i)_{\text{sp-ph}}(T)]$. This is shown for the modes M3, M6, M9, and M11 in Fig. 9.

The effect of spin-phonon coupling on the phonon frequency may be accounted for using 15,34,35 ($\Delta \omega_i$)_{sp-ph}(T) = $\lambda \langle \mathbf{S_i} \mathbf{S_j} \rangle$, where $\langle \mathbf{S_i} \mathbf{S_j} \rangle$ is the spin correlation function and λ is the spin-phonon coupling coefficient. In the temperature-dependent infrared studies of Dy₂Ti₂O₇ in Ref. 15 the phonon anomalies have been attributed to the spin-phonon cou-

pling. Our quantitative measurements of the phonon frequency for various modes in the spin-ice $\mathrm{Dy_2Ti_2O_7}$ [Fig. 8(a)] and the nonmagnetic $\mathrm{Lu_2Ti_2O_7}$ [Fig. 8(b)] clearly show that the magnitude of phonon softening is comparable in both pyrochlores. Since $\mathrm{Lu_2Ti_2O_7}$ is a nonmagnetic pyrochlore, there is no contribution from $(\Delta\omega_i)_{\mathrm{sp-ph}}(T)$ which thus rules out this mechanism for explaining the phonon anomalies in $\mathrm{Dy_2Ti_2O_7}$. Therefore, the change in frequency $(\Delta\omega)$ (as shown in Fig. 9) is solely due to intrinsic anharmonic effects $[(\Delta\omega_i)_{\mathrm{anh}}(T)]$.

The anharmonic effects become considerable when the system temperature increases and a phonon decay into two or three phonons due to cubic or quartic anharmonic interactions. We recall that in the language of quantum many-body theory of phonons in insulating solids without isotopic mass disorder are described as quasiparticles with a complex self-energy $\Sigma = \Delta + i\Delta'$ originating from anharmonic phonon-phonon interactions. The complex self-energy is specific to each phonon and depends on frequency and temperature. The observed frequency $\omega_i(T)$ and damping parameter γ_i exhibit a temperature dependence, $^{36-38}$

 $\omega_i^2 = \omega_i^2(0) + 2\omega_i(0)\Delta(\omega_i, T),$

i.e.,

$$\omega_i \approx \omega_i(0) \left[1 + \frac{\Delta}{\omega_i(0)} \right],$$
 (2)

and

$$\omega_i \gamma_i = 2\omega_i(0) \Delta'(\omega_i, T), \tag{3}$$

where $\omega_i(0)$ is the temperature-independent *i*th mode frequency in the harmonic approximation. Since the highest temperature in our experiment is 300 K, much smaller than the Debye temperature of the titanate pyrochlores (~500 K), it is sufficient to consider only the contribution of cubic anharmonicity. Considering only the simplest decay channels, as was done by Klemens,³⁹ phonon of frequency $\omega(\vec{q} \sim \vec{0})$ decays into two phonons $\omega_1(\vec{q}_1)$ and $\omega_2(\vec{q}_2)$ keeping the phonon energy and momentum conserved, i.e., $\omega_i(0) = \omega_1 + \omega_2$ and $\vec{0} = \vec{q}_1 + \vec{q}_2$, then,

$$\Delta_i(\omega_i, T) = \Delta_i^A [1 + 2\overline{n}(\omega_i(0)/2)], \tag{4}$$

where \overline{n} is the Bose-Einstein mean occupation number of the ith state. The self-energy parameter Δ_i^A can be positive or negative. Most often, the value of Δ_i^A is negative, i.e., the observed mode frequency decreases with increasing temperature, which is the "regular" behavior. However, in the case of phonons termed "anomalous" the sign of Δ_i^A has to be positive, which is most likely the case for the titanate pyrochlores. Beside the titanate pyrochlores, other examples of anomalous phonons include B_{1g} Raman-active phonon in SnO_2 , 36 B_{1g} Raman-active phonons in $Pr_{1.85}Ce_{0.15}CuO_4$ (see Fig. 7 of Ref. 40), and infrared-active TO_3 and LO_4 phonons in spinels $MgAl_2O_4$ (see Fig. 3 of Ref. 41) and, the one which is most relevant to the present study, $F_{2g}(1)$, $F_{2g}(2)$, and E_g Raman-active modes of β -pyrochlore KOs_2O_6 . Here, the phonon anomaly has been found not only for the $F_{2g}(1)$ mode involving potassium, but also for the two oxy-

gen modes $F_{2g}(2)$ and E_g , arising from highly anharmonic vibrations of oxygen ions. We have discussed the relevance of this to the present case in the next paragraph. It has been argued that the sign of Δ_i^A is negative or positive depending on whether the restricted two-phonon density of states $\widetilde{D}(\omega)$ (integrated over all decay channels $\omega_i \rightarrow \omega_1 + \omega_2$ and $\vec{0} = \vec{q}_1 + \vec{q}_2$) has a maximum at a frequency higher or lower than the phonon frequency. It will be very interesting to obtain $\widetilde{D}(\omega)$ for $\mathrm{Dy}_2\mathrm{Ti}_2\mathrm{O}_7$ from *ab initio* lattice dynamical calculations to explain the anomalous temperature dependence quantitatively.

We wish to speculate why the phonon-phonon anharmonic interactions are strong in the titanate pyrochlores. The most anomalous phonon is the F_{2g} mode near 200 cm⁻¹, which is related to O' sublattice vibration. We recall that the 8b site in the pyrochlore structure is occupied by O' ions. However, the 8a sites are vacant. The presence of unoccupied 8a sites can result in large vibrational amplitude of O' ions and hence make F_{2g} mode at 200 cm⁻¹ most anomalous. In order to test the validity of our assumption, we did a very rough comparison of the displacement parameter $\langle u^2 \rangle$ of oxygen ions in β -pyrochlore KOs₂O₆ taken from the singlecrystal x-ray analysis of Ref. 43 with that in the pyrochlore Tb₂Ti₂O₇ for which $\langle u^2 \rangle$, obtained from neutron diffraction data, is available between 4.5 and 600 K.44 We find that the ratio of square root of vibrational amplitude of oxygen to the bond length d_{A-O} (A=K or Tb), for the two compounds, has nearly the same magnitude (\sim 3%). Further, O ion at 48fsites are also slightly displaced from their ideal position $\frac{3}{8}a$ to $(\frac{3}{8}-x)a$, where a is the lattice parameter.⁴⁵ This will make the vibrational amplitude of O ion at 48f sites larger, and hence the A_{1g} mode at 519 cm⁻¹ will also be more anharmonic than usual but less than the 200 cm⁻¹ F_{2p} mode involving O' ion.

IV. SUMMARY AND CONCLUSION

In summary, the Raman light scattering properties of the spin ice Dy₂Ti₂O₇ and its nonmagnetic analog Lu₂Ti₂O₇ have been studied in detail between T=12 and 300 K. Our observations are as follows: (1) In Dy₂Ti₂O₇ crystal a new mode not predicted by factor group analysis of Raman-active modes for the pyrochlore lattice emerges upon cooling the sample below T=110 K. Raman data from O^{18} -isotopic Dy₂Ti₂O₇ strongly indicate the phononic nature of this mode. On the other hand, in Lu₂Ti₂O₇, no new mode appears in the whole temperature range studied; (2) the slope $(\frac{d\omega}{dT})$ for the modes M1 and M7 shows a distinct change of sign at T=110 K, (3) a large anomalous softening of some of the phonons with decreasing temperature is seen in both $Dy_2Ti_2O_7$ and $Lu_2Ti_2O_7$; (4) at the same temperature, the cubic lattice parameter of Dy₂Ti₂O₇ changes abruptly by about 0.1%, while the lattice parameter of nonmagnetic Lu₂Ti₂O₇ varies smoothly over the entire temperature range of our investigations.

The appearance of a new (phonon) mode in the Raman spectra is indicative of symmetry lowering in Dy₂Ti₂O₇ below T=110 K. However, the powder x-ray diffraction peaks of Dy₂Ti₂O₇ do not show any splitting or emergence of new Bragg peak at least down to about $T=10\,$ K. Thus, within the experimental limits of our powder x-ray diffraction experiments, the symmetry lowering in Dy₂Ti₂O₇, if any, could not be detected. It should be recalled that all six Raman active phonon modes in the pyrochlore lattice are due to vibrations of the oxygen ions alone, rare-earth and titanium ions being located at the center of inversion. Since oxygen ion has a very low x-ray scattering cross section, a "subtle" change in the anionic sublattice may go unnoticed in x-ray powder diffraction experiments. We, therefore, propose that a subtle structural deformation occurs in the anionic sublattice of $Dy_2Ti_2O_7$ near $T_c=110$ K, giving rise to a new phonon mode in the Raman spectra below this temperature. A similar situation has recently been noted by Knee et al. 46 for the pyrochlore superconductor Cd₂Re₂O₇ which exhibits a nontrivial structural deformation involving a small deformation in the ReO₆ octahedral lattice, at 200 K, giving rise to some additional low frequency Raman modes.

Finally, our study of the nonmagnetic analog $Lu_2Ti_2O_7$ which shows an anomalous softening of phonons of comparable magnitude as that in $Dy_2Ti_2O_7$ suggests that spin-phonon coupling is not responsible for the anomalous temperature dependence of phonons in these and other members of the rare-earth titanate pyrochlore series. We rather propose that strong phonon-phonon anharmonic interaction can lead to these anomalous phonons.

To conclude, Raman spectroscopy data, in conjunction with x-ray diffraction studies of the spin-ice Dy₂Ti₂O₇ and of its nonmagnetic analog Lu₂Ti₂O₇ are reported over a largely unexplored temperature window, between 10 and 300 K. Our data reveal a subtle structural deformation of the Dy₂Ti₂O₇ lattice at 110 K. We show that anomalous phonon softening is a generic feature of rare-earth titanate pyrochlores which is not limited to the magnetic members of this family, thereby ruling out the spin-phonon coupling in these pyrochlores which was earlier proposed¹⁵ to be responsible for the anomalous phonon behavior. We propose that this behavior is due to unusually strong phonon anharmonicity in these pyrochlores. We believe that our experimental results will motivate further studies on the spin ice Dy₂Ti₂O₇ in order to understand the nature of the phase transition near 110 K and its possible consequences on the spin ice models.
