We report measurements of the magnetic, transport, and thermal properties of the Heusler-type compound Fe₂VAl_{0.95}. We show that while stoichiometric Fe₂VAl is a nonmagnetic semimetal a 5% substitution on the Al site with the 3d elements Fe and V atoms leads to a ferromagnetic ground state with a Curie temperature $T_{\rm C}$ =33±3 K and a small ordered moment $\mu_{\rm s}$ =0.12 $\mu_{\rm B}$ /Fe in Fe₂VAl_{0.95}. The reduced value of the ratio $\mu_{\rm s}/\mu_{\rm p}$ =0.08, where $\mu_{\rm p}$ =1.4 $\mu_{\rm B}$ /Fe is the effective Curie-Weiss moment, together with the analysis of the magnetization data M(H,T), show magnetism is of itinerant nature. The specific heat shows an unusual temperature variation at low temperatures with an enhanced Sommerfeld coefficient, γ =12 mJ K⁻² mol⁻¹. The resistivity, $\rho(T)$, is metallic and follows a power law behavior ρ = ρ_0 + AT^n with $n\approx$ 1.5 below $T_{\rm C}$. With applying pressure, $T_{\rm C}$ decreases with the rate of $(1/T_{\rm C})(dT_{\rm C}/dP)$ =-0.061 GPa⁻¹. We conclude substitution on the Al site with Fe and V atoms results in itinerant ferromagnetism with a low carrier density.

I. INTRODUCTION

Weak ferromagnetic (or antiferromagnetic) transition metal and rare earth or actinide metallic compounds are intensively investigated, since novel ground states, such as heavy fermion behavior, non-Fermi-liquid states and unconventional superconductivity, may emerge at low temperatures. These exotic phases are located at the boundary of magnetically ordered states, and may be reached by tuning the ground state by chemical pressure (alloying), mechanical pressure and/or applying an external magnetic field. Heuslerand semi-Heusler-type of compounds composed of transition metals form an attractive materials family to investigate novel emerging phenomena, the more because these are candidates for half metallic states, in which the band electrons are fully spin polarized.^{1,2} In the magnetically ordered state of half metals, the exchange gap is quite large and the minority spin band is fully occupied. This might be of practical use in spin sensitive devices, which provides a second reason why Heusler-type compounds are investigated intensively. Since applications demand both a high spin polarization and stable ferromagnetism above room temperature, this is an exigent and challenging mission.

Although the concept of the half-metal comes truly from an itinerant electron picture, one can address the question how much local moment character strongly spin-polarized metals possess. ^{4,5} In fact, it is well known that in nearly and weak ferromagnetic itinerant electron systems, such as ZrZn₂ and MnSi, the conduction electrons are responsible for both the itinerant and localized electron nature (i.e., the Curie-Weiss behavior in magnetic susceptibility). For a few candidate materials only the low-temperature magnetic and thermal properties could be analyzed satisfactorily in the framework of itinerant electron magnetism. We mention the semi-Heusler-type ferromagnet NiMnSb (Ref. 4) and antifer-

romagnet CuMnSb,⁵ which were examined under magnetic field and high pressure.

In this paper we focus on the magnetic transition and the low-temperature properties of the Heusler-type ironvanadium compound, Fe₂VAl_{0.95}. Fe₂VAl and related alloys have attracted considerable attention^{6–11} since it was claimed that these 3d-electron systems with small carrier concentration, $n \approx 0.01$ per unit formula, exhibit a significant carrier mass enhancement and non-Fermi-liquid behavior. 6 Stoichiometric Fe₂VAl is nonmagnetic and related alloys, such as $Fe_{2+x}V_{1-x}Al$ and $Fe_2VAl_{1-\delta}$, exhibit ferromagnetic transitions. 7,10-14 Consequently, the samples at $x \approx 0$ and δ ≈ 0 are located at the brink of ferromagnetic order, close to the ferromagnetic quantum critical point, i.e., $T_{\rm C} \rightarrow 0.68$ Stimulated by these findings, theoretical work claimed Fe₂VAl is a nonmagnetic semimetal with the pseudogap at the Fermi level. 15-17 The considerable mass enhancement of the conduction carriers was attributed to excitonic correlations¹⁶ or spin fluctuations.¹⁷ However, subsequent specific heat, C(T), measurements in applied magnetic fields showed that the upturn in C/T at low temperatures results from a Schottky contribution of magnetic clusters in Fe₂VAl.⁸ The effects of off-stoichiometry have not been investigated quantitatively in the framework of nearly and weak ferromagnetism at $x \approx 0$ and $\delta \approx 0$ yet. Another interesting aspect of Fe₂VAl is its potential for application in thermoelectric devices, since off-stoichiometry and heattreatment procedures may results in an enhancement of the Seebeck coefficient. 6,11,12 In Fe_{2+x}V_{1-x}Al (Refs. 11 and 12) and $Fe_2VAl_{1-\delta}$, 12 the thermoelectric power is enhanced for $x \approx 0$ and $\delta \approx 0$: with a negative sign for x < 0 and $\delta > 0$, and positive sign for x>0 and $\delta<0$. In the case of stoichiometric Fe₂VAl the negative temperature coefficient in the electrical resistivity observed up to 1300 K and the constant value of the Hall coefficient at low temperatures^{6,7,12} suggest it is a low carrier-density semimetal with a pseudogap at the Fermi level.⁶ Antisite defects and magnetic nanoclusters induced by heat treatment and nominal off-stoichiometry bring about ferromagnetism^{7,10,13,18} and superparamagnetism.¹⁸ With increasing x in $Fe_{2+x}V_{1-x}Al$, the excess of Fe atoms occupy the nominal V site and, consequently, Fe₃Al (Fe₂FeAl) clusters are formed [notice bulk Fe₃Al is ferromagnetic with T_C =803 K (Refs. 6 and 13)]. The presence of antisite Fe atoms on the nominal V site in the FeV₂Al system brings about a simultaneous enhancement of the magnetization and resistivity at low temperatures. 7,9,10 This led to the claim that localized magnetic moments must be a crucial factor in the strong magnetic scattering of the conduction electrons responsible for the steep rise of the resistivity, the negative temperature coefficient of the resistivity, $d\rho/dT$ <0 and a giant magnetoresistance at x>0. Thus it is proposed that the steep rise of the electrical resistivity at lower temperature is not due to the energy gap but due to strong magnetic scattering. 7,9,10

Al poor $\text{Fe}_2\text{VAl}_{1-\delta}$ ($\delta > 0$), seems to undergo a ferromagnetic transition and shows metallic conduction below room temperature. The $\text{Fe}_2\text{VAl}_{1-\delta}$ system at $\delta > 0$ yields the opportunity to examine quantitatively not only the magnetic but also the transport and thermal properties within the framework of itinerant electron ferromagnetism, as established for intermetallic compounds, such MnSi and ZrZn_2 . In this paper we report a comprehensive study of the low temperature bulk properties of $\text{Fe}_2\text{VAl}_{0.95}$, notably magnetization, electrical resistivity, and specific-heat measurements. Whereas, as pointed out above, the magnetism in $\text{Fe}_{2+x}\text{V}_{1-x}\text{Al}$ is considered to be due to magnetic clusters having a semilocalized nature, our results on $\text{Fe}_2\text{VAl}_{0.95}$ show it is a weak ferromagnet, with a bulk magnetic transition at $T_C=33$ K and a low carrier concentration $n \approx 0.06$.

II. EXPERIMENTAL

Polycrystalline samples of Fe₂VAl_{0.95}, Fe₂VAl, and Fe₂VAl_{1.05} were prepared by arc melting the proper amounts of elements into the nominal chemical composition. The samples were subjected to a heat treatment at 1000 °C for 15 h for homogenization purposes, and next annealed at 400 °C for 15 h. For all samples the crystal structure was identified as the Heusler-type. No secondary phases were detected in the powder x-ray diffraction (XRD) profiles. Since after annealing the grain size (i.e., the individual crystallite size) in the polycrystalline samples is quite large (>several hundredths μ m), we expect that the volume fraction of impurity phases located at the grain boundaries is quite low. The samples we report on in this work are the same as those previously characterized by XRD, scanning electron microscope (SEM), and energy dispersive x-ray spectroscopy (EDS).⁷

dc-magnetization, four-probe ac electrical resistivity and specific-heat measurements down to T=2 K were carried out using a conventional superconducting quantum interference device magnetometer and a physical property measurement system (Quantum Design), respectively. Resistivity measurements down to T=0.23 K were carried out in a 3 He refrigerator (Heliox VL, Oxford Instruments) with a sensitive

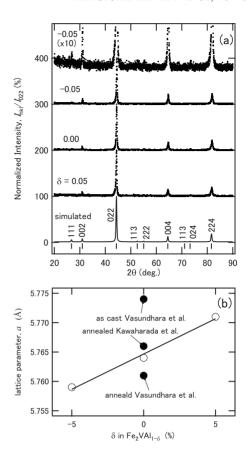

FIG. 1. (a) X-ray diffraction patterns of $Fe_2VAl_{1-\delta}$ at $\delta=-0.05,0.00,0.05$ and a simulated one for Fe_2VAl with the Heusler structure. The top XRD pattern of $\delta=-0.05$ is magnified ten times vertically. Ticks and numbers being along the simulated pattern indicate the position of the Bragg reflections and corresponding Miller indices, respectively, for the Heusler structure. (b) Lattice parameters obtained in this work as a function of δ (open circle). Solid line is a guide for eyes. Solid circles at $\delta=0$ represent reported values in Refs. 18 and 20.

LR700 (Linear Research) ac resistance bridge at the Van der Waals-Zeeman Institute of the University of Amsterdam. In the high-pressure measurement, a handmade measurement system specialized for high-pressure measurement with a glass Dewar vessel was used. To generate high pressure a hybrid clamp cell made from nonmagnetic NiCrAl and CuBe alloys was used. The sample was mounted on a specially designed plug and put inside a Teflon cell with the pressure-transmitting medium Daphne 7373 (Idemitsu).

III. RESULTS AND DISCUSSION

A. Crystallographic

X-ray diffraction patterns of Fe₂VAl_{1- δ} at δ =-0.05, 0, and 0.05 are apparently identified to be of the single phase Heusler-type (Cu₂MnAl) structure in the space group $Fm\overline{3}m$. A as shown in Fig. 1(a), no impurity phases were detected, except for small amounts of Al and Al oxide inclusions indicated by SEM and EDS measurements.⁷ Therefore, we expect, the actual Al composition, δ , is slightly smaller than the

nominal one. Figure 1(b) shows the δ dependence of lattice constant, a, estimated in this work with those reported in previous works^{18,20} for comparison. The lattice constant at δ =0 measured in this work corresponds well with those for annealed samples. The linear dependence of a versus δ supported that the excess Fe and V atoms occupy the Al site for δ >0 and the excess Al atom locates at the Fe and/or V site(s) for δ <0, since Al has smaller ionic radius than those of Fe and V.

As shown below (see Sec. III C), the resistivity versus temperature curve obtained for δ =0.05 is quite similar to those reported by Nishino *et al.* ¹² Rounded maxima in the resistivity were observed at $T_{\text{max}}^{\text{low}}$ =40 K and $T_{\text{max}}^{\text{high}}$ =250 K in a sample with composition (Fe_{2/3}V_{1/3})_{75.7}Al_{24.3}, ¹² which corresponds to δ =0.035 in the notation Fe₂VAl_{1- δ} used here. The maximum at T=40 K in the resistivity for $\delta=0.035$ locates the Curie temperature slightly lower than $T_{\text{max}}^{\text{low}} = 50 \text{ K}$ of δ =0.05 observed in this work [Fig. 5(a)]. Following the argument of the effect of off-stoichiometry based on the rigid band model^{12,21} which is consistent with the Al content variations of the sign in Seebeck and Hall coefficients,^{7,12} we are convinced that the excess Fe and V atoms in Fe₂VAl_{1-\delta} occupy the Al site for $\delta > 0$, and vice-versa. Actually, it was shown recently by comprehensive magnetic and transport studies in the vicinity of $\delta \approx 0$ that not only the Curie point, $T_{\rm C}$, but also the saturation moment, $\mu_{\rm s}$, shows a continuous variation as a function of δ .²²

B. Magnetization

In Fig. 2(a) we show the magnetization of $Fe_2VAl_{0.95}$ as a function of magnetic field, M(H), measured at various fixed temperatures. A spontaneous moment appears in the temperature range T=30-40 K, which indicates ferromagnetic order [see Fig. 4(a)]. In Fig. 2(b) we have traced the temperature variation in the magnetic susceptibility, $\chi(T)$, measured in a field of 20 kOe. As indicated by the straight line in the plot of $1/\chi(T)$ versus T the susceptibility follows a Curie-Weiss law, $\chi(T) = C/(T-\theta)$, for T > 100 K, from which we extract the Curie constant C=0.243 emu K/g and a Curie-Weiss temperature θ =51 K. By using C $=N\mu_{\rm p}^2\mu_{\rm B}^2/3k_{\rm B}$, an effective magnetic moment $\mu_{\rm p}=1.4\mu_{\rm B}/{\rm Fe}$ is obtained, where N, $\mu_{\rm B}$, and $k_{\rm B}$ are the number of magnetic (Fe) atoms, the Bohr magneton and Boltzmann's constant, respectively. This value of $\mu_{\rm p}$ is considerably larger than that of heat-treated Fe₂VAl $(\mu_p \sim 0.2 \mu_B/\text{Fe})$.²³ The saturation moment at T=2 K is $\mu_s=0.12 \mu_B/\text{Fe}$, which is much smaller than the paramagnetic moment, $\mu_{\rm p} = 1.4 \mu_{\rm B}/{\rm Fe}$. The small value of the ratio $\mu_s/\mu_p=0.083$ corroborates the itinerant electron nature of ferromagnetism in Fe₂VAl_{0.95}. It is noteworthy that an Al-site substitution of only 5% (δ =0.05) modifies the magnetic properties strongly: the appearance of a spontaneous moment and low magnetic transition temperature and a strong enhancement of the paramagnetic moment. We stress that these changes cannot be due to an impurity phase, like for instance $Fe_{1-x}V_x(x=1/3)$, for which the estimated values of $\mu_{\rm p}$ and $\mu_{\rm s}$ are one order of magnitude larger than those observed and T_C is above room temperature.²⁴ In contrast with the observations concerning magnetism in an-

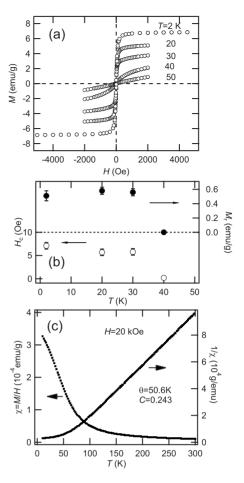

FIG. 2. (a) Magnetization versus field (M-H) of Fe₂VAl_{0.95} at fixed temperatures as indicated. (b) Coersive force, H_c , and remanent magnetization, M_r , as a function of temperature. (c) Magnetic susceptibility, $\chi(T)=M/H$, and reciprocal susceptibility, $1/\chi(T)$, as a function of temperature measured in a fixed field H=20 kOe. The susceptibility is expressed in units per gram.

nealed Fe₂VAl (Ref. 18) and Fe₂V_{1-x}Cr_xAl,²⁵ the ferromagnetic transition in Fe₂VAl_{0.95} is also signaled: (i) in the temperature derivative of the resistivity, $(1/\rho)(d\rho/dT)$, shown in Fig. 5(b), (ii) by the temperature variation of the specific heat divided by temperature, C/T, showing a λ -peaklike shape [Fig. 9(b)], (iii) by the M^4 -M/H plot [Fig. 3(a)], and (iv) by the M^2 - $(T/T_C)^{4/3}$ plot [Fig. 4(a)]. Notably, the transition temperatures T_C =33±3 K determined by the different techniques agree within the uncertainty of 3 K. Correspondingly, both coercive force, H_c , and remanent magnetization, M_r , emerge around T_C [Fig. 2(b)].

As mentioned in Sec. I, it is interesting to examine whether magnetism in Fe₂VAl_{0.95} has an itinerant or localized character. In the latter case it is expected that the induced spin is localized at the 3d atoms (Fe or V) substituted on the Al site. In Figs. 3(a) and 3(b) we analyze the magnetization data around $T_{\rm C}$ in terms of M^4 -H/M and M^2 -H/M (Arrott) plots, respectively. For weak ferromagnetic systems the M^4 versus H/M curve at T= $T_{\rm C}$ is predicted to be linear with an intercept zero. ²⁶ Inspecting Fig. 2(a) we conclude $T_{\rm C}$ =33 K. Notice, in the Arrott plot the M^2 versus H/M curves all exhibit a strong curvature toward the H/M axis.

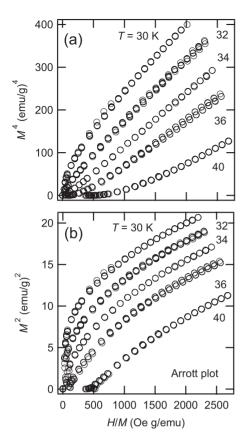

FIG. 3. Magnetization of $Fe_2VAl_{0.95}$ measured at fixed temperatures as indicated, plotted as (a) M^4 versus H/M and (b) M^2 versus H/M (Arrott plot).

This feature is quite similar to those found in prototypical itinerant ferromagnets, such as MnSi and Ni₃Al.²⁶ Thus the magnetization data provide strong evidence for itinerant ferromagnetism with $T_C=33$ K in $Fe_2VAl_{0.95}$. Based on the generalized Rhodes-Wohlfarth plot,²⁶ we obtain the characteristic temperature T_0 =895 K for Fe₂VAl_{0.95}. The ratio $T_{\rm C}/T_0$ is an important parameter as it characterizes the degree of localization or itineracy of the spin moment.¹⁹ For $T_{\rm C}/T_0 \ll 1$ the magnetic material has a strong itinerant character while at $T_{\rm C} \sim T_0$ local moment magnetism results. The estimated value $T_{\rm C}/T_0$ =0.038 is comparable to the values reported for MnSi (0.13), Ni₃Al (0.0116), ZrZn₂ (0.053), and Sc₃In (0.0097) which all exhibit weak ferromagnetism.²⁶ With help of T_0 , one may calculate the temperature dependence of the magnetization below $T_{\rm C}$. With decreasing $T_{\rm C}/T_0$ the M(T) curve deviates more and more from the mean-field behavior, $M = M(0)[1 - (T/T_C)^2]^{1/2}$, and has a tendency to follow $M = M(0)[1 - (T/T_C)^{4/3}]^{1/2}$. In fact, as shown in Fig. 4(b), $M^2(T)$ of Fe₂VAl_{0.95} obeys the $T^{4/3}$ dependence for a weak itinerant ferromagnet rather than the T^2 dependence of the mean-field model.²⁶ By using M(T)=M(0)[1] $-(T/T_{\rm C})^{4/3}$]^{1/2} the zero-temperature magnetization and Curie point are estimated to be M(0)=5.7 emu/g and $T_C=36$ K at H=200 Oe, respectively.

C. Electrical resistivity

In Fig. 5(a) we show the temperature dependence of the resistivity, $\rho(T)$. The resistivity, $\rho(T)$, exhibits rounded

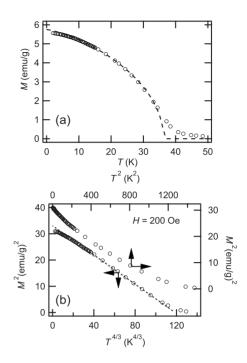

FIG. 4. (a) Magnetization in a field H=200 Oe as a function of temperature for T<50 K. (b) M^2 - $T^{4/3}$ and M^2 - T^2 plots measured in a field H=200 Oe. The dashed lines are calculated by using $M^2(T)$ = $M(0)[1-(T/T_C)^{4/3}]^{1/2}$ with M(0)=5.7 emu/g and T_C =36 K obtained by a least-square fit.

maxima at $T_{\rm max}^{\rm low} = 52\,$ K and $T_{\rm max}^{\rm high} = 260\,$ K. A comparison with ${\rm Fe_{2+x}V_{1-x}Al}$ at $x \approx 0$ (Refs. 7, 10, and 14) reveals that the resistivity above $T \sim 260\,$ K is dominated by scattering due to thermal excitations in the pseudogap. Below $T \sim 260\,$ K

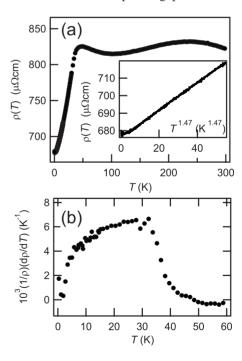

FIG. 5. (a) Resistivity $\rho(T)$ as a function of temperature at H =0. Inset: resistivity below $T_{\rm C}$ plotted as a function of $T^{1.47}$. (b) Temperature variation of $(1/\rho)(d\rho/dT)$. The slope change at T =33 K signals $T_{\rm C}$.

 $\rho(T)$ exhibits metallic behavior, with a low carrier number.⁷ On the other hand, the maximum at $T_{\text{max}}^{\text{low}} = 52$ K is caused by the para-to-ferromagnetic phase transition, as was also observed in the Fe-rich composition of $\text{Fe}_{2+x} \text{V}_{1-x} \text{Al.}^{7,10,14}$ In $\text{Fe}_2 \text{VAl}_{0.95} \rho(T)$ remains metallic down to $T \sim 1$ K, while in the case of $\text{Fe}_{2+x} \text{V}_{1-x} \text{Al}$, especially for $x \leq 0.05$, a semiconductor behavior is reported. The latter was corroborated by weak localization effects of the carriers in a random potential.⁹ As shown in Fig. 5(b), the sharp anomaly in $(1/\rho)(d\rho/dT)$ is indicative of a bulk ferromagnetic transition at T=33 K. In the ferromagnetic phase the resistivity follows a power law behavior $\rho(T) \sim T^n$ with $n \cong 3/2$ [see inset to Fig. 5(a)]. Notice, it was derived by the self-consistent renormalization (SCR) theory that the temperature dependence of ρ should follow a power law $\sim AT^2$ at $T < T_C$. 19

D. Magnetoresistance and low-temperature electrical resistivity

The itinerant ferromagnetic character of Fe₂VAl_{0.95} is also reflected in the transverse magnetoresistance (TMR), $\rho(H)$ $-\rho(0)]/\rho(0)$, especially around $T=T_{\rm C}$, as shown in Fig. 6(a). The TMR is negative below 100 K and has a minimum at a temperature slightly above $T_{\rm C}$. The TMR reaches a maximum size of -11% at T=43 K in H=80 kOe. The negative temperature coefficient between 50 K<T<100 K and the maximum in $\rho(T)$ slightly above $T_{\rm C}$ are wiped out above H=30 kOe, as shown in Fig. 6(a). According to a numerical calculation based on the SCR theory,²⁷ the negative magnetoresistance is due to the presence of spin fluctuations above $T_{\rm C}$ and, consequently, the maximum temperature in the TMR shifts toward higher temperature with increasing magnetic field. This field dependence of TMR is comparable with that in the itinerant ferromagnet Sc₃In $(T_C=5.3 \text{ K}).^{27,28}$ For T >100 K, the TMR is positive. These transport data differ from those in nonmagnetic $Fe_{1.98}V_{1.02}Al$, where $\rho(T)$ exhibits a rounded maximum around room temperature and the magnetoresistance is negative. Remarkably, the temperature dependence of the resistivity changes to $\rho = \rho_0 + AT^2$ below a certain temperature T^* , which increases magnetic field [Fig. 6(b)]. This feature is quite similar to that of non-Fermi-liquid systems, such as U₃Ni₃Sn₄ where the Fermi-liquid behavior is recovered under magnetic field or external pressure.²⁹

E. Pressure effects on resistivity

As mentioned above, crystallographic and chemical defects affect strongly on the magnetic grand state of Fe₂VAl and related alloys. Remarkably, lattice constant of Fe₂VAl reflects sensitively these structural deviations from the Heusler structure. Plausibly, Curie temperature, $T_{\rm C}$, is a function of not only carrier number but also the variation of lattice constant, $\Delta a/a$. To distinguish those effects on the ferromagnetic transition in Fe₂VAl_{0.95}, it is expected that resistivity measurement under high pressure provides crucial information. The lattice expansion, $\Delta a/a = 0.10\%$ at $\delta = 0.05$, can be compensated by applying an experimentally accessible pressure, $\Delta P = 3(\Delta a/a)_{\delta=0.05}/\kappa_V \sim 0.5$ GPa, where κ_V is volume compressibility estimated to be 6.81 \times 10⁻³ GPa⁻¹ for $\delta = 0.2^0$ As shown in the inset of Fig. 7,

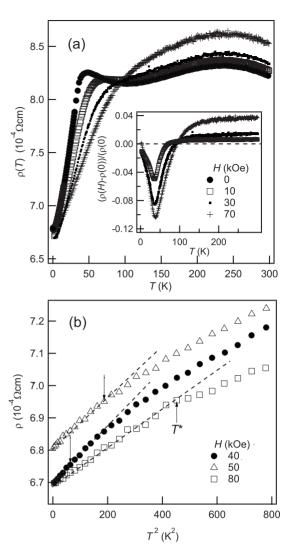

FIG. 6. (a) Resistivity versus temperature of Fe₂VAl_{0.95} in magnetic fields up to 70 kOe as indicated. Inset: Temperature dependence of the magnetoresistance $[\rho(H)-\rho(0)]/\rho(0)$ at H=10, 30, and 70 kOe. (b) Resistivity as a function of T^2 at H=40, 60, and 80 kOe. The T^2 behavior (dashed lines) is obeyed till a temperature T^* indicated by vertical arrows.

 $T_{\rm max}^{\rm high}$ increases while $T_{\rm max}^{\rm low}$ decreases with pressure. The increment of $T_{\rm max}^{\rm high}$ with applying pressure can be responsible for that the pseudo gap locating at the Fermi level increases. On the other hand, the decrement of $T_{\rm max}^{\rm low}$ seems to be related to that of $T_{\rm C}$. Pressure dependence of $T_{\rm C}$ obtained from the temperature variation of $(1/\rho)(d\rho/dT)$ is shown in Figs. 8(a) and 8(b). With increasing pressure the anomalous point shifts toward lower temperature with the pressure coefficient of $(1/T_{\rm C})(dT_{\rm C}/dP)$ =-0.061 GPa⁻¹ [Fig. 8(b)], which corresponds well with $(1/T_{\rm max}^{\rm low})(dT_{\rm max}^{\rm low}/dP)$ =-0.074 GPa⁻¹. The volume effect on $T_{\rm C}$ is comparable with those for itinerant ferromagnets, such as Ni₃Al [~-0.10 GPa⁻¹ (Refs. 30 and 31)]. Therefore, the emergence of the ferromagnetism at δ >0 can results from mainly the carrier doping in Fe₂VAl_{1- δ} while the volume expansion seems to be a miner effect. At $T \ll T_{\rm C}$, it is noteworthy that ρ_0 increases with the pressure coefficient of $(1/\rho_0)(d\rho_0/dP)$ =0.038 GPa⁻¹ while the exponent of temperature, n, decreases from n=1.42 at 0.11 GPa to

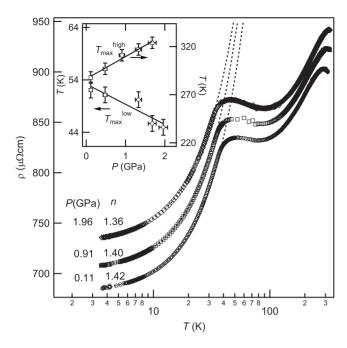

FIG. 7. Resistivity versus temperature of Fe₂VAl_{0.95} at various pressures. Dashed line shows a power low dependence of $\rho(T) \sim AT^n$. The exponent, n, was obtained by fitting $\rho(T)$ to $\rho(T) = \rho_0 + AT^n$ below 11 K. Applied pressure, P, and obtained exponent, n, are indicated on the respective $\rho(T)$ curve. Inset: pressure dependence of the maximum temperatures, $T_{\rm max}^{\rm low}$ and $T_{\rm max}^{\rm high}$. Solid lines are guides for the eyes.

1.36 at 1.96 GPa, which obtained in a temperature range of 3.5 < T < 11 K (Fig. 7).

F. Specific heat

In Fig. 9(a) we show the specific heat divided by temperature, C/T, as a function of T^2 measured on Fe₂VAl_{1- δ} samples with δ =-0.05, 0, and +0.05. A low-temperature upturn as present for Fe₂VAl_{1.05} and Fe₂VAl was also observed previously in Fe₂VAl (Refs. 6 and 8) and in Fe_{2-x}V_{1+x}Al.¹⁰ Remarkably, for Fe₂VAl_{0.95} C/T has a strong curvature toward the T^2 axis. Assuming that this curvature in C/T is due to a ferromagnetic spin-wave contribution, $C_{\rm sw} \sim a T^{3/2}$, we fitted the experimental curve at H=0 to $C/T = \gamma + a_{sw}T^{1/2+}$ $+\beta T^2$ below 20 K [fit not shown in Fig. 9(a)]. The fitting parameters are $\gamma=12.6$ mJ K⁻² mol⁻¹, $a_{\rm sw}=1.38$ mJ K^{-5/2} mol⁻¹, and $\beta=0.025$ mJ K⁻⁴ mol⁻¹. However, the presence of the spin-wave contribution in the lowtemperature specific heat is not supported by measurements in magnetic field. In field the curvature in C/T enhances significantly. At H=80 kOe our fitting procedure results in a larger value for a_{sw} , whereas the spin-wave contribution should be suppressed under magnetic field, as for instance in Ni (Ref. 32) and CeRu₂Ge₂.³³ This strongly suggests that the low-temperature variation in C(T)/T is not due to a ferromagnetic spin-wave contribution.

As indicated in Fig. 9(a), the difference in specific heat between δ =0 and -0.05 is quite small except in the low-temperature region where C/T showing an upturn. We fitted the high temperature specific heat, $C_{\rm HT}$, in the temperature

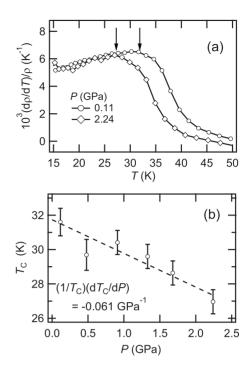

FIG. 8. (a) Temperature dependence of $(1/\rho)(d\rho/dT)$ at various pressures. Arrow indicates Curie point defined as the maximum point of $(1/\rho)(d\rho/dT)$. (b) Pressure variation in $T_{\rm C}$. Dashed line represents a fitting curve of $T_{\rm C}$ versus P obtained by the linear least-squares method.

range 8–30 K to $C_{\rm HT} = \gamma T + \beta T^3 + \eta T^5$ and estimated $\gamma = 3.10 \pm 0.02$ mJ mol $^{-1}$ K $^{-2}$, $\beta = 0.0265 \pm 0.0001$ mJ mol $^{-1}$ K $^{-4}$, and $\eta = (1.82 \pm 0.02) \times 10^{-5}$ mJ mol $^{-1}$ K $^{-6}$ for $\delta = -0.05$, and $\gamma = 2.19 \pm 0.02$ mJ mol $^{-1}$ K $^{-2}$, $\beta = 0.0283 \pm 0.0001$ mJ mol $^{-1}$ K $^{-4}$, and $\eta = (1.75 \pm 0.01) \times 10^{-5}$ mJ mol $^{-1}$ K $^{-6}$ for $\delta = 0$. These estimated parameters correspond well to those of Fe₂VAl obtained previously in the temperature range 8–25 K.

G. Comparison with paramagnetic Fe₂VAl in the specific heat

Contrasted to the case of δ =-0.05, C/T of δ =0.05 is enhanced obviously compared with that of $\delta=0$. Employing paramagnetic Fe₂VAl as a reference material in the specific compositional change in C(T), = $C(Fe_2VAl_{0.95})-C_{HT}(Fe_2VAl)$ is obtained as shown in Fig. 9(b). Obviously, at zero field a pronounced anomaly is present at $T \approx 34$ K, i.e., at the same temperature where $(1/\rho)(d\rho/dT)$ exhibits a maximum. This anomaly is superposed on the background which has a broad maximum around $T \sim 30$ K [see inset Fig. 9(b)]. The magnetic entropy is obtained by integrating $C_{\rm FM}/T$ versus T and is estimated at 0.7% of R ln 2, where R and $C_{\rm FM}$ are the gas constant and the ferromagnetic component in the specific heat, respectively. Such a small value is expected for a weak itinerant ferromagnet. 19 Below the phase transition point the $\Delta C/T$ curve decreases further with decreasing temperature. Below $T \sim 10$ K the specific heat can be expressed by the sum of linear ($\sim T$) and quadratic ($\sim T^2$) terms. The magnetic field wipes out the magnetic transition anomaly in $\Delta C/T$ and

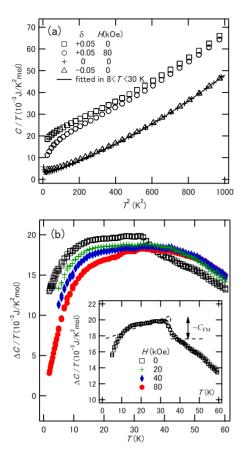

FIG. 9. (Color online) (a) Specific heat divided by temperature C/T plotted as a function of T^2 of Fe₂VAl_{0.95} (δ =+0.05), Fe₂VAl (δ =0), and Fe₂VAl_{1.05} (δ =-0.05) in zero and applied magnetic field. The solid line represents the fit results in the temperature region 8 K < T < 30 K (see text). (b) Temperature dependence of $\Delta C/T$ defined by $[C(\delta$ =+0.05)- $C(\delta$ =0)]/T at fields of 20, 40, and 80 kOe as indicated. Inset: expanded view of $\Delta C/T$ around the Curie temperature at zero field. The dashed line represents an idealized ferromagnetic contribution, $C_{\rm FM}$.

causes $\Delta C/T$ to decrease, as shown in Fig. 9(b). An anomalous T^2 temperature dependence in the specific heat was observed also in Pd₂MnIn,³⁴ GdCu,³⁵ CuMnSb,³⁶ and CeNiSn.³⁷ It seems to be due to a sharp density of state (DOS) shape around $E_{\rm F}$, such as the V-shape density of states with small residual component at the Fermi level, as observed in the Kondo insulator CeNiSn.³⁷ In CeNiSn, at lower temperature the temperature variation in the specific heat shows a deviation from the T-linear dependence, which can be fitted by the sum of a T linear and a T^2 terms.³⁸ Additionally, the band structure below $T_{\rm C}$ in Fe₂VAl_{0.95} is more complicated because the ferromagnetic ordering seems to modify considerably the DOS structure due to the exchange splitting, $\Delta_{\rm e}$, between the spin-up and spin-down bands, which increases effectively with applying external field below $T_{\rm C}$. In fact, the low-temperature specific heat $\Delta C \sim \gamma T + \delta T^2$ changes, that is, the ratio of γ/δ decreases upon application of a magnetic field [Fig. 9(b)].

Next, let us discuss quantitatively the comparison between the magnetic moment, μ_p , and carrier concentration, n, modified by the off-stoichiometry in Fe₂VAl_{0.95}. As shown

in Fig. 6(b), the resistivity follows a quadratic temperature dependence below $T=T^*$, with T^* increasing with magnetic field. The larger value of the coefficient of the T^2 term, A= 10^{-7} – 10^{-6} Ω cm/K², estimated in Fe₂VAl_{0.95} reminds one of the mass enhancement in the stoichiometric samples.^{6,8} To compare with the Kadowaki-Woods law, we should consider the small carrier concentration, n, in Fe₂VAl and related alloys.^{7,10} In the Fermi-liquid theory, A/γ^2 is proportional to $1/k_{\rm F}^4$, where γ and $k_{\rm F}$ are the Sommerfeld constant in the specific heat and the Fermi wave vector, respectively.³⁹ Compared with heavy fermion systems with $n \approx 1$ (per rare earth or actinide element), it is expected that A/γ^2 is enhanced by a factor of $1/n^{4/3}$ =2300-360 in the case of Fe₂VAl since n=0.003-0.012. In this estimate, we assumed $k_{\rm F} \sim n^{1/3}$ given by the Drude model (the free electron model).⁴⁰ Therefore, A/γ^2 can be a measure of n, or in other words, the Fermi surface volume. In Fe₂VAl_{0.95}, A/γ^2 is 2 $\times 10^{-3}$ Ω cm K⁻²/(JK⁻² mol⁻¹)² being a factor of 40 larger than that established as the Kadowaki-Woods ratio ~1 $\times 10^{-5} \ \Omega \ \text{cm K}^{-2}/(\text{JK}^{-2} \ \text{mol}^{-1})^2$. Therefore, $n \sim 40^{-3/4}$ =0.063 per unit formula in Fe₂VAl_{0.95}. This value of n is one order of magnitude larger than in Fe₂VAl (Ref. 7) and seems to be consistent with the value of the Hall coefficient of $\text{Fe}_2\text{VAl}_{0.95}$. 7,12 The observed value $\gamma \approx 12 \text{ mJ mol}^{-1} \text{ K}^{-2}$ at H=0 is rather large when we consider the carrier concentration, $n \approx 0.06$, and the value of normal metals, γ ≈ 1 mJ mol⁻¹ K⁻². Consequently, the enhancement factor m^*/m_e is ~30, where m_e is the bare electron mass. Compared with the values $\gamma \approx 1.5-2.2$ mJ mol⁻¹ K⁻² and n =0.003-0.012 (Ref. 7) in nonmagnetic Fe₂VAl, this large enhancement of γ in ferromagnet Fe₂VAl_{0.95} is surprising because Fe₂VAl is located closer to the magnetic quantum critical point, $T_{\rm C} \rightarrow 0$,6 where the magnetic fluctuations should be more strongly enhanced. As C/T below T_C has an anomalous temperature and magnetic field dependence, we speculate that the enhancement mechanism of γ distinctly differs from the electron-electron correlation mechanism realized in the heavy fermion systems. Stoichiometric Fe₂VAl is located at the vicinity of a ferromagnetic threshold composition, δ_c . However, not only the Curie temperature, T_c , but also the paramagnetic moment, $\mu_{\rm p}$, which is strongly dependent on the number of conduction carriers 7,22,23 seem to disappear at $\delta = \delta_c$ in $\text{Fe}_2 \text{VAl}_{1-\delta}$. In contrast, heavy fermion systems show only the magnetic transition temperature, $T_{\rm M}$, going to zero while keeping a magnetic moment which has both a localized and an itinerant nature. In other words, the paramagnetic moment does not vanish around the critical point in heavy fermion systems.

IV. SUMMARY

Magnetic, transport, and specific-heat measurements have been carried out on the Heusler-type compound Fe₂VAl_{0.95}. The data reveal a ferromagnetic transition takes place at $T_{\rm C}$ = 33 K with the characteristics of an itinerant electron ferromagnet. With applying pressure, $T_{\rm C}$ decreases with the pressure coefficient of $(1/T_{\rm C})(dT_{\rm C}/dP)$ =-0.061 GPa⁻¹. The Sommerfeld coefficient in the specific heat is enhanced, γ ≈ 12 mJ mol⁻¹ K⁻², compared to 3 mJ mol⁻¹ K⁻² in

 ${\rm Fe_2VAl_{1.05}}$ and 2 mJ mol⁻¹ K⁻² in stoichiometric Fe₂VAl. The temperature dependence of resistivity deviates from the characteristics of a Fermi liquid, AT^2 , while under magnetic field the quadratic temperature dependence, $\rho(T) \sim T^2$, appears below a certain temperature, T^* , which increases with increasing magnetic field. At lower temperature the temperature variation in the specific heat shows a deviation from the T-linear dependence, especially, under magnetic field, which can be fitted by the sum of a T-linear and a T^2 terms. While the magnetism has a typical characteristics of a weak itinerant ferromagnet, the deviations from the Fermi-liquid characteristics.

acteristics are quite different from those (i.e., non-Fermiliquid behavior) in a heavy fermion system and a nearly or a weak itinerant ferromagnet.
