The Wannier-Bloch resonance states are metastable states of a quantum particle in a space-periodic potential plus a homogeneous field. Here we analyze the states of quantum particle in space- *and* time-periodic potential. In this case the dynamics of the classical counterpart of the quantum system is either quasiregular or chaotic depending on the driving frequency. It is shown that both the quasiregular and the chaotic motion can also support quantum resonances. The relevance of the obtained result to the problem of a crystal electron under simultaneous influence of dc and ac electric fields is briefly discussed. [S1063-651X(98)09010-2]

Probing of a quantum system with an electric field is widely used in experimental physics. If the system has a number of discrete levels (which are associated with classically bounded motion) followed by a continuous spectrum (associated with unbounded motion) then after applying an electric field the discrete energy states become metastable. The decay time of a metastable state is determined by the probability of tunneling through the potential barrier separating the regions of the classically bounded and unbounded motion. Examples are the states of a Rydberg atom or the vibrational state of a dipole molecule in a strong electric field.

The situation is more complicated if a particle should tunnel through *many* barriers to escape from the regions of bounded motion. A famous example of such a system is the states of an electron in a crystal lattice in an external homogeneous field, which are known as metastable Wannier-Bloch states and Wannier-Stark states [1]. Although the calculation of the decay time for these states is a difficult problem [2], the physics behind the phenomenon is the same—the resonances are supported by the regions of classically bounded motion. The question we address in this paper is, whether a quantum resonance state can be supported by something other than a bounded classical motion. To this end we introduce a model, which will be the subject of our study [3]:

$$H = p^2/2 + \cos(\omega t)\cos x + Fx \equiv H_0 + Fx. \tag{1}$$

In Eq. (1) the Hamiltonian H_0 corresponds to the so-called double resonance model, which can show a chaotic diffusion in x for some interval of the driving frequency ω [4]. The diffusive motion is neither bounded nor ballistic, so the answer to the question—if it can support resonances—is far from obvious.

It should be noted that the Hamiltonian (1) has an explicit periodic dependence on time and, therefore, the notion of energy states is substituted by the notion of quasienergy states. Below we discuss the metastable quasienergy states of the system for different values of the driving frequency. The only (however important) restriction we impose on ω is that the period $T_\omega = 2\pi/\omega$ should be rational to the Bloch period $T_B = \hbar/F$, i.e., $T_B/T_\omega = r/q$. This condition allows us to employ the formalism of quasimomentum [5], which essentially simplifies the problem. To calculate the metastable states we use the numerical method proposed in Ref. [6]. Using this method one finds the metastable Wannier-Bloch states by solving the eigenvalue problem for the system's evolution operator over the common period $T = qT_B = rT_\omega$:

$$U^{(k)}\chi_{l,k}(x) = \exp[-i\lambda_l(k)T/\hbar]\chi_{l,k}(x), \tag{2}$$

$$U^{(k)} = e^{-iqx}\widehat{\exp}\left\{-\frac{i}{\hbar}\int_0^T\left[\frac{(\hat{p}+\hbar k - Ft)^2}{2} + V(x,t)\right]dt\right\}. \tag{3}$$

In Eqs. (2) and (3) $\chi_{l,k}(x)$ is the space-periodic part of the metastable Wannier-Bloch state $\psi_{l,k}(x) = \exp(ikx)\chi_{l,k}(x)$ (l is the band index, k is the quasimomentum, $-1/2 < k < 1/2$), $U^{(k)}$ is one of the possible representations of the k-specific system evolution operator over the common period (the caret over the exponent sign denotes time ordering), and $V(x,t) = \cos(\omega t)\cos x$ for the case considered here. Expanding $\chi_{l,k}(x)$ in the Fourier series,

$$\chi_{l,k}(x) = \sum_{n=-\infty}^{\infty} c_n^{(l,k)}|n\rangle, \quad |n\rangle = (2\pi)^{-1/2}\exp(inx),$$

we reduce the problem to diagonalizing of the matrix $U^{(k)}_{n,n'} = \langle n|U^{(k)}|n'\rangle$. In the numerical calculation the matrix $U^{(k)}_{n,n'}$ is truncated to the size $N \times N$. We note that the infinite matrix $U^{(k)}_{n,n'}$ is unitary, but the truncated ($n, n' \leq N$) matrix is *not* unitary and, therefore, the eigenvalues $\lambda_l(k)$ are complex. The key point of the method is that the eigenvectors of the truncated matrix $U^{(k)}_{n,n'}$ converge to the metastable Wannier-Bloch states when the dimension N increases [6].

We begin with the case of a large driving frequency $\omega \gg \omega_{cr}$ when the dynamics of the system H_0 is quasiregular [see Fig. 1(a)]. (The critical value ω_{cr} of the driving frequency for a transition from quasiregular to chaotic dynamics can be estimated using Chirikov's nonlinear resonance overlap criteria, which corresponds to $\omega_{cr} \approx 1$ [7].) The force F is adjusted to satisfy the resonance condition $2\pi/\omega$

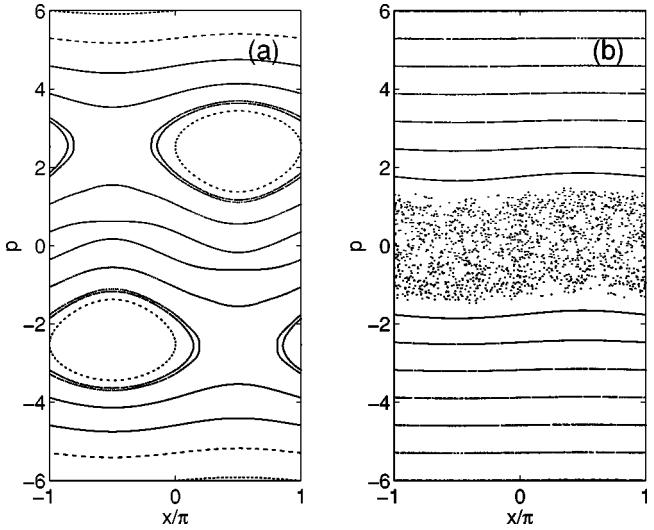

FIG. 1. Phase space portrait of the system (1) for $\omega \approx 2.51 > \omega_{\rm cr} \sim 1$ (a) and $\omega = 0.3 < \omega_{\rm cr}$ (b). 18 different trajectories $p(t_n)$, $x(t_n)_{\rm mod:2\pi}$, $t_n = nT + T/4$ are plotted in each case.

$=\hbar/F \equiv T$ and $\hbar = 0.5$ is used throughout the paper. For $\omega \gg \omega_{\rm cr}$ the dynamics of the system (1) can be approximately described by the effective Hamiltonian

$$H^{(+,-)} = \frac{p^2}{2} + \frac{1}{2}\cos(x \mp \omega t) + Fx, \tag{4}$$

where the plus and minus sign refers to the upper and lower half planes of phase space. By substituting $x' = x \mp \omega t$ the Hamiltonian (4) is transformed to the time-independent Hamiltonian $H' = p^2/2 + 0.5\cos x' + Fx'$ and the known results for Wannier states can be used. Namely, let ϵ_l to be the spectrum of the Wannier-Bloch states [we remind the reader that the energy bands of the Wannier-Bloch states are degenerate, i.e., $\epsilon_l(k) = \epsilon_l$], then the quasienergy spectrum of the system (4) has the form

$$\mathrm{Re}[\lambda_l(k)] = \frac{\hbar}{T}\left\{\left(\frac{\omega^2}{2} + \mathrm{Re}[\epsilon_l]\right)\frac{T}{\hbar} \mp 2\pi k\right\}_{\rm mod:2\pi},$$

$$\mathrm{Im}[\lambda_l(k)] = \mathrm{Im}[\epsilon_l]. \tag{5}$$

The term $2\pi k$ in Eq. (5) has a simple physical meaning. In fact, similar to the case of a time-independent potential, we can construct from the extended Bloch-like functions $\psi_{l,k}(x)$ a set of localized states $\Psi_{l,m}(x) = \int dk \exp(i2\pi mk)\psi_{l,k}(x)$. Then the presence of the term $2\pi k$ denotes that the localized state $\Psi_{l,m}(x)$ moves one lattice period to the right or left per period of the driving frequency.

In view of the above, the spectrum of the system (1) for large ω should be a symmetric net of parallel lines with positive and negative slopes. The numerical result confirms this prediction (see Fig. 2). We also note that that the spectrum, independent of the value of the driving frequency, possesses the approximate symmetries $\langle \lambda_l(-k)\rangle = \langle \lambda_l(k)\rangle$ and $\langle \lambda_l(k+1/2)\rangle = \langle \lambda_l(k) + \hbar\omega/2\rangle$ (here angular brackets stand for a set of eigenvalues for given k). These symmetries are a consequence of the exact symmetries of the evolution operator (3) under the transformations $t \to -t$ (accomplished by complex conjugation) and $x \to x + \pi$, $t \to t + T/2$. The numerical results depicted in Fig. 2 shows that for $\omega > \omega_{\rm cr}$ the Hamiltonian (1) supports metastable states. This is actually not surprising, because in the frame moving with the velocity $\pm\omega$ the classical trajectory undergoes a bounded oscillation. The main deviation from the case of the ''running wave'' Hamiltonian (4) is that now the bands ϵ_l in Eq. (5) gain a finite width, which is well seen in the large scale figure of the imaginary part of the quasienergy.

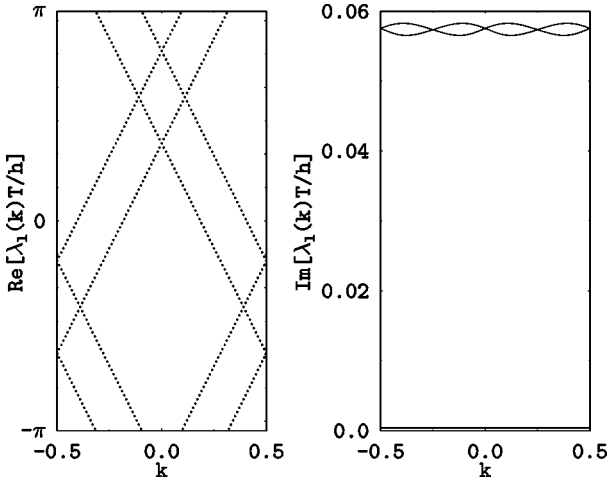

FIG. 2. Real and imaginary parts of the quasienergies corresponding to first four metastable Wannier-Bloch states of the system (1). The value of the driving frequency is $\omega \approx 2.51$ (scaled Planck constant $\hbar = 0.5$, $F = \hbar\omega/2\pi = 0.2$).

We proceed with the case $\omega < \omega_{\rm cr}$ [see Fig. 1(b)]. In this case the phase space of the classical counterpart of the system (1) for $F = 0$ consists of two components—a chaotic component in the form of a strip along the x-axis, and a regular component surrounding the chaotic region [8]. Since the chaotic and regular components are separated by an invariant curve, a trajectory with an initial condition belonging to the chaotic component stays there forever. For $F \neq 0$ the invariant curve does not exist and a particle always escapes from the chaotic strip to the region of the unbounded regular

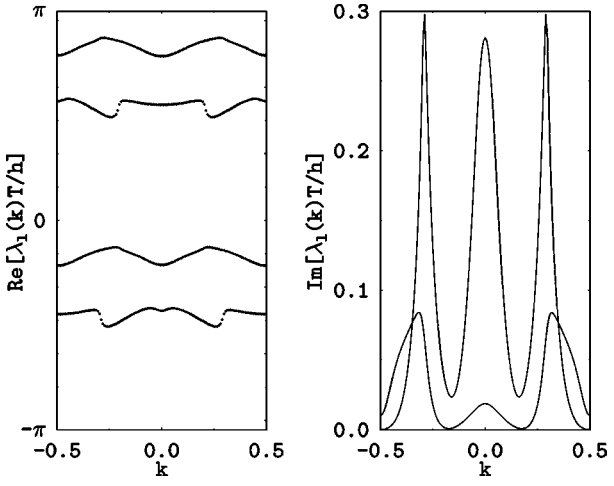

FIG. 3. Same as Fig. 2 but for $\omega = 0.3 < \omega_{\rm cr}$, $F = \hbar\omega/2\pi \approx 0.02$. (The imaginary part is shown only for two upper bands. For lower bands the curves should be shifted by one-half of the Brillouin zone.)

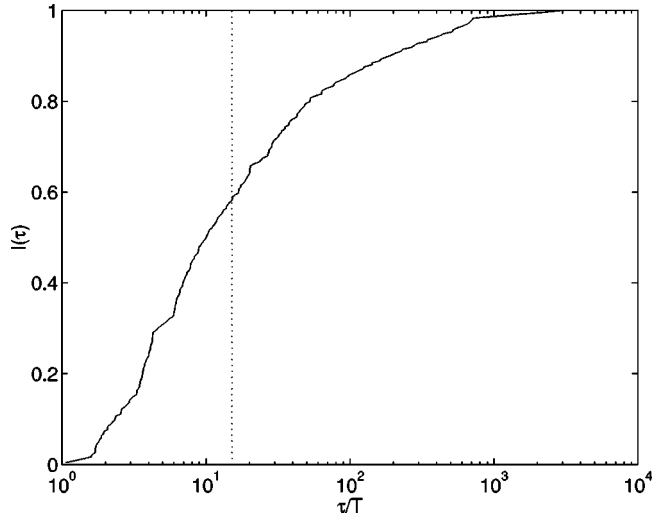

FIG. 4. Integrated distribution function for the decay times $\tau_{\mathrm{qu}}=\hbar/2\,\mathrm{Im}[\lambda_l(k)]$ of the quantum metastable states for the parameters of Fig. 3. The vertical line shows the value of the classical decay time $\tau_{\mathrm{cl}}=15.2\ T$.

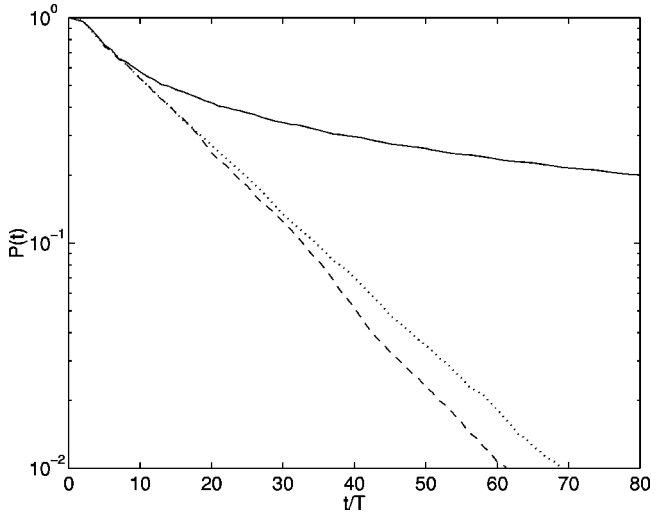

FIG. 5. Probability for a classical and quantum particle to stay within the chaotic component $|p|<1.8$ ($\omega=0.3$, $F\approx 0.02$). Dotted line: classical result, solid line: quantum result provided the condition $T_B=T_\omega$ ($\hbar=0.5$), dashed line: ''incommensurate'' case ($\hbar=0.5109531$). In the quantum case the curves were obtained by simulating wave packet dynamics with minimal uncertainty packet centered at $x=0$, $p=0$ as an initial condition.

motion. However, the escape time can be very large. The numerical simulation of the classical dynamics of the system (1) gives an exponential distribution for the escape time $P(t)\sim\exp(-t/\tau_{\mathrm{cl}})$ (see Fig. 5, dotted line), where τ_{cl} tends to infinity as F tends to zero. This result gives us a hint that in the quantum case the Hamiltonian (1) could also support metastable states.

Figure 3 shows the real and imaginary parts of $\lambda_l(k)$ for four most stable quasienergy bands. It is seen that the imaginary part is small, thus, the Hamiltonian (1) does support metastable states. Moreover, we have found the decay time $\tau_{\mathrm{qu}}=\hbar/2\,\mathrm{Im}[\lambda_l(k)]$ of the quantum metastable state to be surprisingly large in comparison with the classical decay time τ_{cl}. Figure 4 shows the integrated distribution function $I(\tau_{\mathrm{qu}})$ for the decay times τ_{qu} of the quantum states $\psi_{l,k}(x)$ irrespectively to band index and quasimomentum in semilogarithmic scale. It is seen that τ_{qu} can exceed τ_{cl} by several orders of magnitude. Thus we encounter a quantum stabilization phenomenon (see Fig. 5, solid line). We would like to stress that the quantum stabilization discussed is a kind of quantum interference phenomenon, sensitive to the commensurability condition $T_B/T_\omega=r/q$. In the incommensurate case the stabilization is absent [9].

In conclusion, the main result of the paper is the demonstration of the fact that the chaotic unbounded motion is able to support long-lived resonances in the quantum case. This result was obtained for the model system (1), which we chose because of its relative simplicity. A more common system corresponds to the Hamiltonian

$$H=p^2/2+\cos x+Fx+\varepsilon x\cos(\omega t) \tag{6}$$

(a model of a crystal electron subject to dc and ac electric field). Using the Kramers-Hennerberger transformation $p'=p+(\varepsilon/\omega)\sin(\omega t)$, $x'=x-(\varepsilon/\omega^2)\cos(\omega t)$ it is easy to show that the system (6) is equivalent to a Hamiltonian

$$H=\frac{p^2}{2}+\cos\left[x+\frac{\varepsilon}{\omega^2}\cos(\omega t)\right]+Fx, \tag{7}$$

which also generates chaotic dynamics for $\varepsilon>\varepsilon_{\mathrm{cr}}(\omega)$ (see [10], for example). Thus the obtained result is also valid for the system (6) in the regime of developed chaos. A detailed discussion of the metastable state of the latter system is planned to be a subject of a forthcoming paper [11].

[5] A general proof, that translation over a time period (which defines the quasienergy) commutes with translation over a space period (which defines the quasimomentum) provided the commensurability condition $T_B/T_\omega = r/q$, is given in the paper by J. Zak, Phys. Rev. Lett. **71**, 2623 (1993).

[6] M. Glück, A. R. Kolovsky, H. J. Korsch, and N. Moiseyev, Eur. Phys. J. D (to be published). The idea behind the numerical method is that the truncating procedure automatically satisfies the nonhermitian resonance boundary condition (zero amplitude of ''incoming wave'') for the eigenvalue problem (2).

[7] See, e.g., A. J. Lichtenberg and M. A. Lieberman, *Regular and Chaotic Dynamics* (Springer, Berlin, 1983).

[8] Depending on the value of ω, there can also appear additional regular components embedded in the chaotic region. For the chosen value $\omega = 0.3$ the chaotic component is uniform, however.

[9] Recently we have explained this effect by showing a formal analogy between the eigenvalue problem (2) and a scattering problem with q open channels [M. Glück, A. R. Kolovsky, and H. J. Korsch (unpublished)].
