Received 22 August 2000; received in revised form 1 December 2000

Abstract

An endopeptidase from the fruits of *Melothria japonica* (Thunb.) Maxim. has been purified by DEAE-Sepharose chromatography and gel-filtration by a Sephacryl S-300. The enzyme has M_r of 61 kDa. The optimum pH of the enzyme was 8. The enzyme activity was inhibited by diisopropyl fluorophosphate and phenylmethanesulfonylfluoride, but not by EDTA. Casein was a poor substrate, but angiotensin I was cleaved by the enzyme within 30 min at four different sites. These results indicated that the enzyme was a serine oligopeptidase of broad substrate specificity. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Melothria japonica*; Cucurbitaceae; Fruits; Oligopeptidase; Plant peptidase

1. Introduction

Several fruits of the Cucurbitaceae species have large amounts of proteolytic enzymes within them. Among them, cucumisin [EC.3.4.21.25], a serine protease from the fruit of prince melons, has been well characterized (Kaneda and Tominaga, 1975; Yamagata et al., 1994; Uchikoba et al., 1995). Screening for proteolytic activity revealed that various fruits of the Cucurbitaceae had this activity in their juice, but as of yet there is no way of knowing whether or not the proteases are identical in content and specific activity.

Proteases having strong caseinolytic activity have been found in the fruits of Cucurbitaceae (Uchikoba et al., 1995; Arima et al., 2000); however, oligopeptidases from fruits of the Cucurbitaceae are unknown.

Here, we report that the peptidyl-*p*NA, Glt-Ala-Ala-Pro-Leu-*p*NA is hydrolyzed by the juice from the fruits of *Melothria japonica* (Thunb.) Maxim., called suzumeuri in Japan. However, the caseinolytic activity of the juice from the fruits was insignificant. The isolation of the general properties of the new peptidase from the fruits of *Melothria japonica* are described.

2. Results and discussion

The elution profile of the enzyme, using Glt-Ala-Ala-Pro-Leu-*p*NA as substrate, from a DEAE-Sepharose column is shown in Fig. 1. We term this activity *Melothria* peptidase. The fractions containing *Melthoria* peptidase were collected and then the enzyme was further purified by gel filtration of a Sephacryl S-300. From 100 g of the fruits of *Melthoria japonica*, 3.2 mg of the purified enzyme was obtained in a final yield of 11% (Table 1). The final preparation shown as a single band on the SDS-PAGE, having a M_r of 61 kDa (Fig. 2A), and the hydrolysis activity of Glt-Ala-Ala-Pro-Leu-*p*NA by the enzyme in the gel was detected at the same position as the band of purified *Melthoria* peptidase on SDS-PAGE (Fig. 2B).

Abbreviations: Boc, *t*-butyloxycarbonyl; Bz, benzoyl; DFP, diisopropyl fluorophosphate; Glt, glutaryl; MCA, 4-methy-coumaryl-7-amide; MIA, monoiodoacetic acid; PCMPS, *p*-chloromercuriphenylsulfonic acid; PMSF, phenylmethanesulfonylfluoride; *p*NA, *p*-nitroanilide; Pyr, pyroglutamyl-; SDS-PAGE, sodium dodecylsulfate polyacrylamide gel electrophoresis; STI, soybean trypsin inhibitor; Tos-Lys-CH_2Cl, *N*-Tosyl-L-lysine chloromethylketone

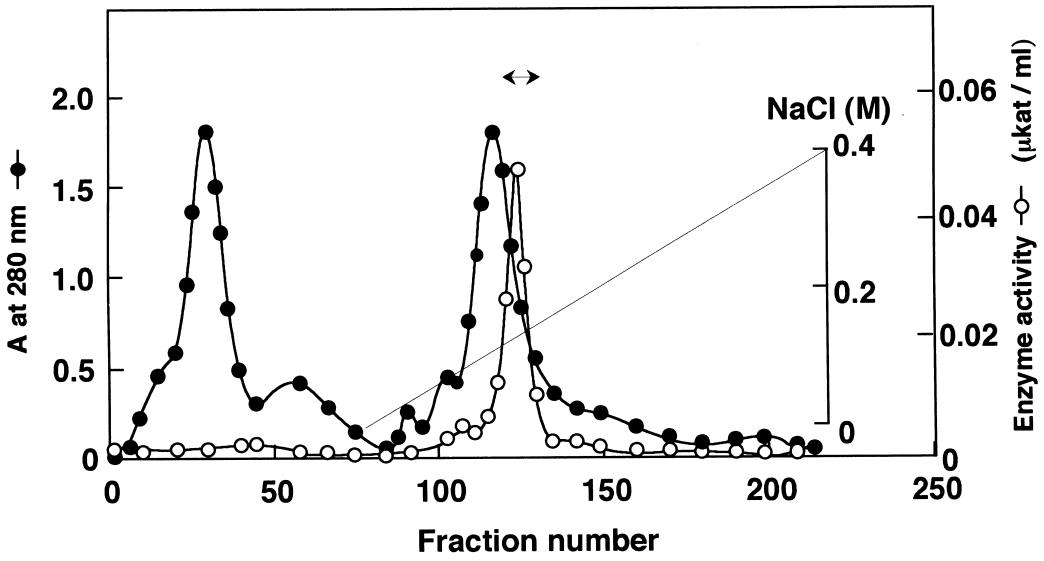

Fig. 1. Elution profile of *Melothria* peptidase from DEAE-Sepharose. Protein (*A* 280 nm) (closed circles), hydrolytic activity of Glt-Ala-Ala-Pro-Leu-*p*NA (open circles). The flow rate of the column was 72 ml/h and the fraction size is 8 ml. Double headed arrow shows fractions which were pooled.

Table 1
Purification of *Melothria* peptidase[a]

Purification step	Total protein (mg)	Total activity (μkat)	Specific activity (nkat/mg)	Recovery (%)	Purity (fold)
Juice	1130	5.62	4.98	100	1
DEAE-Sepharose	46	5.00	109	89	22
SephacrylS-300	3.2	0.594	186	11	37

[a] Peptidase was purified from 100 g of *Melothria japonica* fruits.

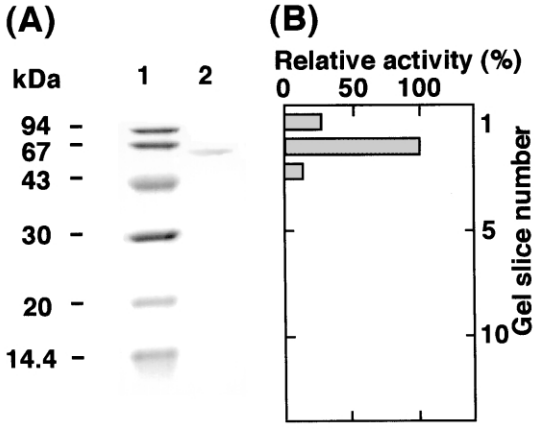

Fig. 2. SDS-PAGE and the activity assay in the gel of purified *Melothria* peptidase. (A) SDS-PAGE analysis. To avoid autolysis, the purified enzyme was inactivated by a treatment of 10 mM DFP. The iinactivated enzyme was subjected to a SDS-PAGE using the method of Laemmli (1970) in a 15% polyacrylamide gel. The gel was stained and Coomassie Brilliant Blue R-250. Lane 1, M_r markers, Lane 2, 10 μg of purified *Melothria* peptidase from Sephacryl S-300 gel-filtration. (B) The activity assay in the gel. Purified *Melothria* peptidase on a Sephacryl S-300 gel-filtration was subjected to SDS-PAGE and the acrylamide gel was cut in 3 mm slices. Each gel slice was incubated with 67 mMK, Na-Pi buffer, pH 7.5 containing 0.1 mM Glt-Ala-Ala-Pro-Leu-*p*NA at 30°. After 3 h the gel was taken out of the mixture, *A* 405 nm of the remaining solution was assayed in a Hitachi spectrophotometer U-1100.

The optimum pH for the hydrolysis of Glt-Ala-Ala-Pro-Leu-*p*NA was found to be pH8 (Fig. 3).

The enzyme (50 μl, 60 μg/ml) was incubated with 50 μl of 67 mM sodium, potassium-phosphate buffer, pH 7.5, containing various inhibitors at 37°. After 120 min, the remaining hydrolysis activity of Glt-Ala-Ala-Pro-Leu-*p*NA was measured (Table 2). The peptidase was completely inactivated by incubation with DFP, PMSF, and STI. The activity was strongly inhibited by phenylbutylamine. PCMPS, MIA, and pepstatin had a definite effect on the over-all activity, and EDTA caused no inhibition. These results indicated that the peptidase was a serine-type enzyme.

Angiotensin I was cleaved by *Melothria* peptidase within 30 min at four different sites (Arg^2-Val^3-, Tyr^4-Ile^5, Ile^5-His^6, and Phe^8-His^9) (Fig. 4). Among these cleavage sites, Arg^2-Val^3 was the most susceptible position for the enzyme. The cleavage rate of the position Arg^2-Val^3 by *Melthoria* peptidase was 0.3 nmol of the digestive product per min. The hydrolysis rates of other cleavage sites were less than 0.3 nmol of the digestive product per min. The cleaved sites, Tyr^4-Ile^5 and Phe^8-His^9, were identical to those of cucumisin. It seems that *Melthoria* peptidase has a broader substrate specifity than cucumisin. Casein was strongly hydrolyzed by cucumisin, but it was a poor substrate for *Melthoria* peptidase (data not shown). It seems that *Melthoria* peptidase belongs to oligopeptidase (Tsuru, 1998).

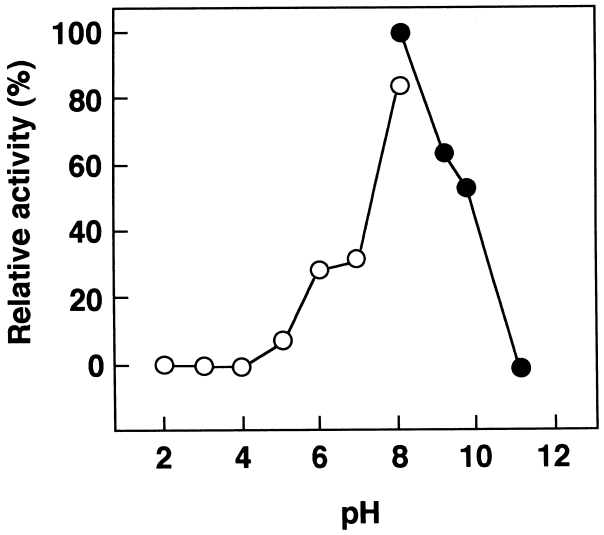

Fig. 3. The effect of pH on peptidase activity. Buffers: 0.2 M sodium phosphate-citric acid buffer (open circles, pH 2.0–8.0), 0.2 M glycine-NaOH buffer (closed circles, pH 8.0–11.0).

Table 2
Effect of various compounds on the enzyme activity of *Melothria* peptidase

Compounds	Concentration[a] (mM)	Class	Relative activity (%)

EDTA	2.0	Metallo	109

[a] Final concentration. These results are for a 120-min incubation of 37°C.

[b] Activity of a control with no addition was taken as 100%.

Glt-Ala-Ala-Pro-Leu-*p*NA appears to be more active as a substrate with *Melthoria* peptidase compared to a commercial peptidyl-*p*NA, such as Suc-Ala-Ala-Pro-Phe-*p*NA. Leu-*p*NA was not hydrolyzed by the enzyme. Several peptidyl-MCAs were slightly hydrolyzed by *Melthoria* peptidase as shown in Table 3. However, those hydrolytic activities of the enzyme were inferior to that of Glt-Ala-Ala-Pro-Leu-*p*NA. Hydrolytic activity of Bz-Arg-MCA by the enzyme was the highest among the peptide-MCAs tested, but the relative activity on Bz-Arg-MCA was only 4.58% of that on Glt-Ala-Ala-Pro-Leu-*p*NA. Among those peptide-MCAs, the acidic charged residue, such as Glu or Asp at the P_1 position (the amino acid residue of the carboxyl site of the cleavage bond), was not preferred by the enzyme. Substrate

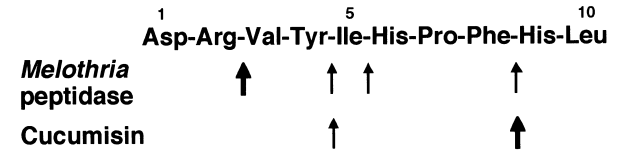

Fig. 4. Sites of human angiotensin I cleaved by *Melothria* peptidase or cucumisin (Uchikoba et al., 1995). The cleavage sites were predicted from the N-terminal sequence analysis of the digestion of angiotensin I. The thin arrows mark the cleavage sites with less than 10% recovery from the initial substrate (10 nmol), and the thick arrows indicate cleavage with more than a 10% recovery.

Table 3
Hydrolysis of peptidyl-(*p*NA/MCA) with *Melothria* peptidase

Substrates	Hydrolysis rate (nkat/ml)	Relative activity (%)

specifity studies indicate that the enzyme has a broad specifity at the P_1 position. Substrate specifity of *Melthoria* peptidase toward peptidyl-MCAs (or peptidyl-*p*NAs) was similar to that of *Euphorbia supina* protease (Arima et al., 2000).

The amino-terminal sequence of the first 10 residues of *Melthoria* peptidase was determined as shown in Fig. 5. The amino-terminal sequence of *Melthoria* peptidase was aligned with those of the eight plant serine proteases: that which is expressed in melon fruit (Yamagata et al., 1994); white gourd protease (Uchikoba et al., 1998); *Euphorbia supina* protease B (Armina et al., 2000); lily protease, induced in meiotic prophase (Kobayashi et al., 1994; Taylor et al., 1998); *Arabidopsis thaliana* protease, which are expressed in the precursor cells that are initiated upon auxin-induced lateral root formation (Neuteboom et al., 1999); ag12, which is expressed in the early stages of actinorhizal nodule formation in *Alnus glutinosa* (Ribeiro et al., 1995); and PR-P69 (also known as P69A) and P69B, a pathogen-induced in tomatoes (Tornero et al., 1996, 1997). Six out of 10 amino-terminal residues in *Melthoria* peptidase were identical to those of each protease of *E. supina*, *A. thaliana*, *A. glutinosa*, and P69B. The amino-terminal sequence, T-T-R/H-X-X-X-F/Y-L- was considered among the nine serine proteases shown in Fig. 5.

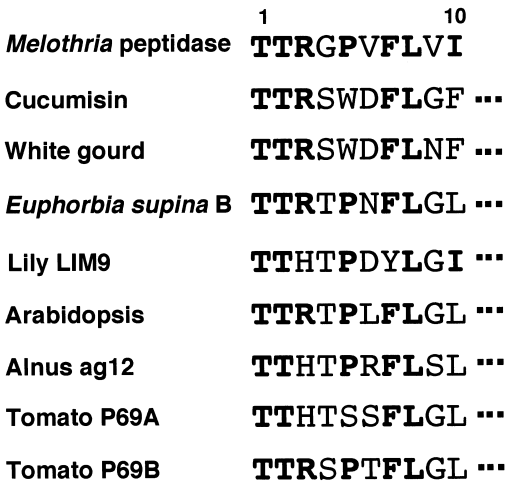

Fig. 5. Comparison of the N-terminal amino acid sequences of nine plant serine proteases. The proteases are *Melothria* peptidase in the present study. The bolds show identical amino acid residues to the sequence of *Melothria* peptidase.

Melthoria japonica is a plant of the Cucurbitaceae family. Cucumisin has already been isolated from the fruits of *Cucumis melov* var. Prince (Uchikoba et al., 1995). The M_r of *Melthoria* peptidase (61 kDa) was slightly smaller than that of cucumisin (67 kDa) (Uchikoba et al., 1995), and was similar to that of a serine protease (60 kDa) from spinach leaves (Aduccia et al., 1986).

3. Experimental

3.1. Material

Fruits of *Melthoria japonica* were collected in Kaseda City, Japan. DEAE-Sepharose was a product of Pharmacia. Tos-Lys-CH_2Cl was a product of Sigma. Peptidyl-MCAs and peptidyl-*p*NAs were purchased from the Peptide Institute. Other reagents were purchased from Wako Pure Chemical.

3.2. Enzymatic activity assay

Enzymatic hydrolysis of peptidyl-*p*NA, peptidyl-MCAs, and casein were performed by previously described methods (Uchikoba et al., 2000; Shimada et al., 2000; Kaneda et al., 1997). One unit of hydrolysis activity toward peptidyl-*p*NA was defined as the activity producing μkat (μmol of the products per s) under the stated conditions (pH 7.5, at 37°).

3.3. Enzyme purification

Melthoria peptidase was purified as follows. Unreipened fruits (100 g) of *Melthoria japonica* were homogenized with equal weights of buffer A (20 mM sodium, potassium-phosphate buffer, pH 7.5). After centrifugation (7000×*g*, 5 min), the supernatant was dialyzed against buffer A. After sitting over night at 7° the dialysate was placed on a column of DEAE-Sepharose (1.8×13 cm) equilibrated with buffer A. The enzyme was then eluted with 0.2 M sodium, potassium-phosphate buffer containing 0.4 M NaCl, pH 7.5. The active fractions were collected and concentrated with an Advantec-UHP-76 ultra filtering unit. The concentrated solution was put on a Sephacryl S-300 (1.8×46 cm) column equilibrated with 0.2 M sodium, potassium-phosphate buffer containing 0.1 M NaCl, pH 7.5. The active fraction was collected and kept at −20°.

3.4. Hydrolysis of angiotensin I

The peptide bonds of human angiotensin I cleaved by *Melothria* peptidase were determined by analyzing the newly formed N-terminal. Angiotensin I (10 nmol) was incubated at 37° with *Melthoria* peptidase (0.1 nmol) in buffer A, pH 7.5 (final volume, 20 μl). After 30 min, 0.1% TFA (10 μl) was added to the mixture and analyzed for the newly formed N-terminal using an Applied Biosystems Model 477A protein sequencer.

Acknowledgements

The authors thank Miss Y. Ouchida for her generous help in obtaining the fruits of *Melthoria japonica*.

Received in revised form 15 December 2000

Abstract

The incorporation of ^{13}C labelled glucose into trichocolein, deoxytomentellin, *trans*-phytol and stigmasterol has been studied in axenic cultures of the liverwort *Trichocolea tomentella*. Quantitative ^{13}C NMR spectroscopic analysis of the resulting labelling patterns showed that the isoprene units of the hemi- and monoterpenoid moieties and the diterpene phytol are derived from the methylerythritol phosphate pathway, whereas the isoprene units of stigmasterol are built up via the mevalonic acid pathway. These results indicate the involvement of both IPP biosynthetic pathways in different cellular compartments. A new, hydroperoxy geranyl phenyl ether derivative is also described. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Trichocolea tomentella*; Isopentenyl diphosphate; Mevalonic acid pathway; Methylerythritol phosphate pathway; Isoprenoids; Hemiterpene; Monoterpene; Phytol; Stigmasterol; ^{13}C-Labelling; Liverwort; Quantitative ^{13}C NMR spectroscopy

1. Introduction

Isoprenoids are the largest group of secondary metabolites with over 30,000 known compounds, including the steroids (Dictionary of Natural Products, 2000). Their common building block, the isoprene unit, is derived from isopentenyl diphosphate (IPP). In the past, the mevalonic acid (MVA) pathway has been accepted as the only biosynthetic route leading to IPP, which was believed to operate in all organisms. In contrast, the existence of the methylerythritol phosphate (MEP) pathway as an alternative route for IPP biosynthesis has only been known for a few years (Rohmer et al., 1993; Schwarz, 1994; for review, see Lichtenthaler et al., 1997a; Eisenreich et al., 1998; Lichtenthaler, 1999; Rohmer, 1999). So far, the reaction sequence of this pathway is established up to the formation of the cyclic diphosphate intermediate 2-*C*-methylerythritol 2,4-cyclodiphosphate (Rohmer et al., 1993; Sprenger et al., 1997; Lois et al., 1998; Takahashi et al., 1998; Rohdich et al., 1999; Herz et al., 2000; Lüttgen et al., 2000); the following steps to IPP are still uncharacterised.

The discovery of the methylerythritol phosphate (MEP) pathway has quite changed the general understanding of isoprenoid biosynthesis. Whereas vertebrates and archaebacteria appear to use only the mevalonate pathway to build isoprenoids, various eubacteria have been found to use either the mevalonate or the MEP pathway. Chlorophytes possess only the MEP pathway, whereas rhodophytes, chrysophytes, bryophytes and higher plants have been found to use the MVA pathway for the biosynthesis of steroids, and the MEP pathway for the formation of hemiterpenoids, monoterpenoids, carotenoids, phytol and other diterpenes (for review, see Lichtenthaler et al., 1997a; Eisenreich et al., 1998; Lichtenthaler 1999; Rohmer, 1999). The MVA pathway appears to be operative in the cytoplasm compartment of plant cells, whereas the MEP pathway seems to be located in the plastids. Segregation of the two pathways, however, is not necessarily complete, and exchange of metabolites between the two

pools has been observed in plants and plant cell cultures (Schwarz, 1994; Nabeta et al., 1995; Arigoni et al., 1997; Adam and Zapp, 1998; Piel et al., 1998; Adam et al., 1999). Despite a significant amount of recent research in this area, our knowledge on the contribution of both pathways to the biosynthesis of the different plant terpenoid classes is still limited.

In continuation of our previous studies on IPP biosynthesis in bryophytes (Thiel et al., 1997; Adam et al., 1998; Eisenreich et al., 1999), we have chosen the liverwort *Trichocolea tomentella* to determine the origin of the prenyl moieties of its major constituents, a series of isoprenyl phenyl ethers. Our previous work has shown that trichocolein (**1**), which contains a hemiterpene moiety, and deoxytomentellin (**2**), with a monoterpene moiety, can both be easily isolated in significant amounts from axenic cultures of *T. tomentella* making this liverwort an ideal candidate for biosynthetic study (Helminger and Becker, 1992). Until now, no information on the biosynthesis of these types of compounds has been available. In particular, study of the biosynthesis of a hemiterpene moiety is of great interest as presently only four reports are known: isoprene in several higher plants (Zeidler et al., 1997), the hemiterpene units in the furanocoumarins of *Apium graveolens* (Stanjek et al., 1999), in the hops bitter acid humulone in *Humulus lupulus* (Goese et al., 1999) and the prenylated flavonoid glabrol in *Glycyrrhiza glabra* (Asada et al., 2000).

Axenic cultures of liverworts are useful experimental systems for such biosynthetic studies (Adam et al., 1996; Adam and Croteau, 1998; Adam et al., 1998). Due to their small size, these cultures can be grown fully differentiated in vitro. As has been shown previously, these differentiated cultures maintain their capability of synthesising in type and content the whole range of isoprenoids in vitro, similar to natural conditions (Becker, 1994). Furthermore, labelled precursors can be administered to the plants via the culture medium, similar to cell culture systems. The simple morphology of liverwort tissue cultures supports the uptake of the respective compounds under physiological conditions, in contrast to cell cultures where the dedifferentiated status of the cells might have a drastic impact on many biochemical processes. Therefore, ^{13}C labelling experiments should give a realistic impression of the biosynthetic origin of isoprenyl phenyl ethers (**1**, **2**) in *T. tomentella* and allow biosynthetic comparisons to be made between the various classes of isoprenoids.

In this paper we describe the incorporation of [1-^{13}C]glucose into the terpenoid moieties of two isoprenyl phenyl ethers. The resulting labelling patterns are compared to that of the steroid stigmasterol (**3**) as a reference for mevalonate derived isoprenoids of the cytoplasm, and the diterpene *trans*-phytol (**4**) as marker compound for the plastidial MEP pathway.

2. Results and discussion

[1-^{13}C]Glucose was administered to aseptic cultures of *T. tomentella*. After a 20-fold fr. wt increase the plant material was harvested and the compounds were isolated with standard chromatographic procedures. Assignments of ^{13}C NMR signals of the purified compounds were obtained from the literature (Goad, 1995; Perry et al., 1996). Labelling patterns and absolute ^{13}C enrichments of the compounds were determined by quantitative ^{13}C NMR spectroscopy using Cr(III)-acetylacetonate as a relaxation reagent (Braun et al., 1996). The acetyl derivative of compound **3** was synthesised (**3a**) in order to introduce an internal ^{13}C reference with the natural ^{13}C abundance of 1.11%. In the case of nonderivatised compounds (**1**, **2**, **4**) the absolute ^{13}C enrichment has been calculated from the integrals of ^{13}C NMR signals on the basis of ^{13}C satellite analysis of the well separated proton signals in the respective ^{1}H NMR spectra (see Tables 1 and 3).

Trichocolein (**1**) and deoxytomentellin (**2**) both show only two labelled carbons per isoprene unit, with an average ^{13}C abundance of 5.25 ± 0.17 and 5.36 ± 0.04% respectively (Table 1). The labelling positions correspond to the alternative methylerythritol phosphate pathway (Fig. 1). The remaining carbon atoms of both the hemiterpene part (compound **1**) and the monoterpene part (compound **2**) also display an increased ^{13}C abundance with 2.64 ± 0.26 and 2.29 ± 0.22% respectively, compared to the expected natural abundance of

1.11%. This general background labelling might be explained by complex metabolic turnover of [1-^{13}C]glucose during the growth period, resulting in a statistical distribution of the labelled carbon atoms in various positions of intermediates of the carbohydrate metabolism (e.g. metabolism of glucose to carbon dioxide and subsequent assimilation via the Calvin cycle). The labelling of the phenyl ring is in accordance with the biogenetic scheme of the shikimate pathway, with direct formation of the substituted aromatic ring via 5-dehydroshikimic acid as for gallic acid (see Fig. 2) (Luckner, 1990). This can be concluded from the fact that the carboxyl carbon in both trichocolein and deoxytomentellin is unlabelled. In the case of formation of the C6–C1 skeleton by a side chain reduction of a phenyl propane unit (C6–C3), the carboxyl group would also bear a label. Labelling of the methyl groups (methoxy and methyl ester) is in agreement with the formation of C_1-groups via methionine/methyl dehydrofolic acid (Fig. 2) (Luckner, 1990).

The quantitative ^{13}C NMR analysis of stigmasterol acetate (**3a**) showed an enrichment pattern typical for the mevalonic acid pathway, with an average ^{13}C abundance of 4.20±0.29% (Table 2). The isolated com-

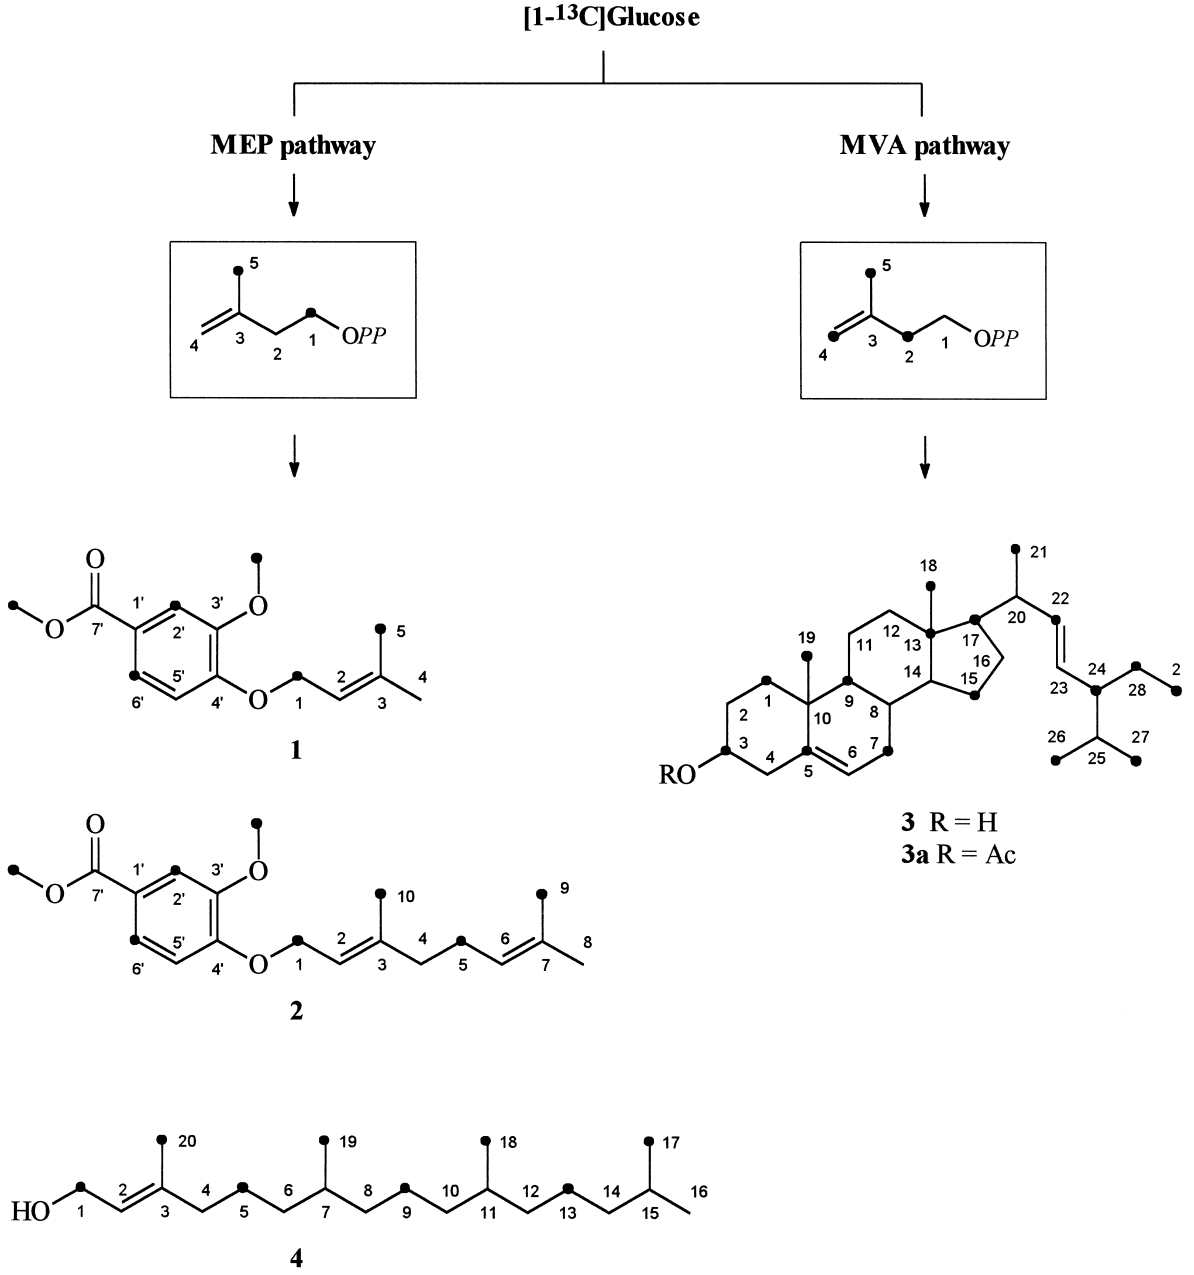

Fig. 1. Incorporation of [1-^{13}C]glucose into IPP via MVA pathway and MEP pathway and the resulting labelling patterns of compounds **1**, **2**, **3a** and **4**. *PP* = diphosphate residue, ● = ^{13}C labelled position.

pound also shows a ^{13}C enrichment (2.56±0.36%) of the unlabelled positions as already discussed for the hemi- and monoterpene moieties.

The labelling pattern of *trans*-phytol (**4**) from *T. tomentella* is in excellent agreement with that obtained from the liverworts *Ricciocarpos natans* and *Conocephalum conicum* (Adam et al., 1998), showing the formation of the isoprene units via the methylerythritol phosphate pathway (average ^{13}C abundance: 4.62±0.28%, Table 3). Again, an increased ^{13}C background labelling could be observed (2.86±0.04%, Table 3).

The average absolute ^{13}C abundances of all compounds are summarized in Table 4. These results demonstrate that both pathways of IPP biosynthesis

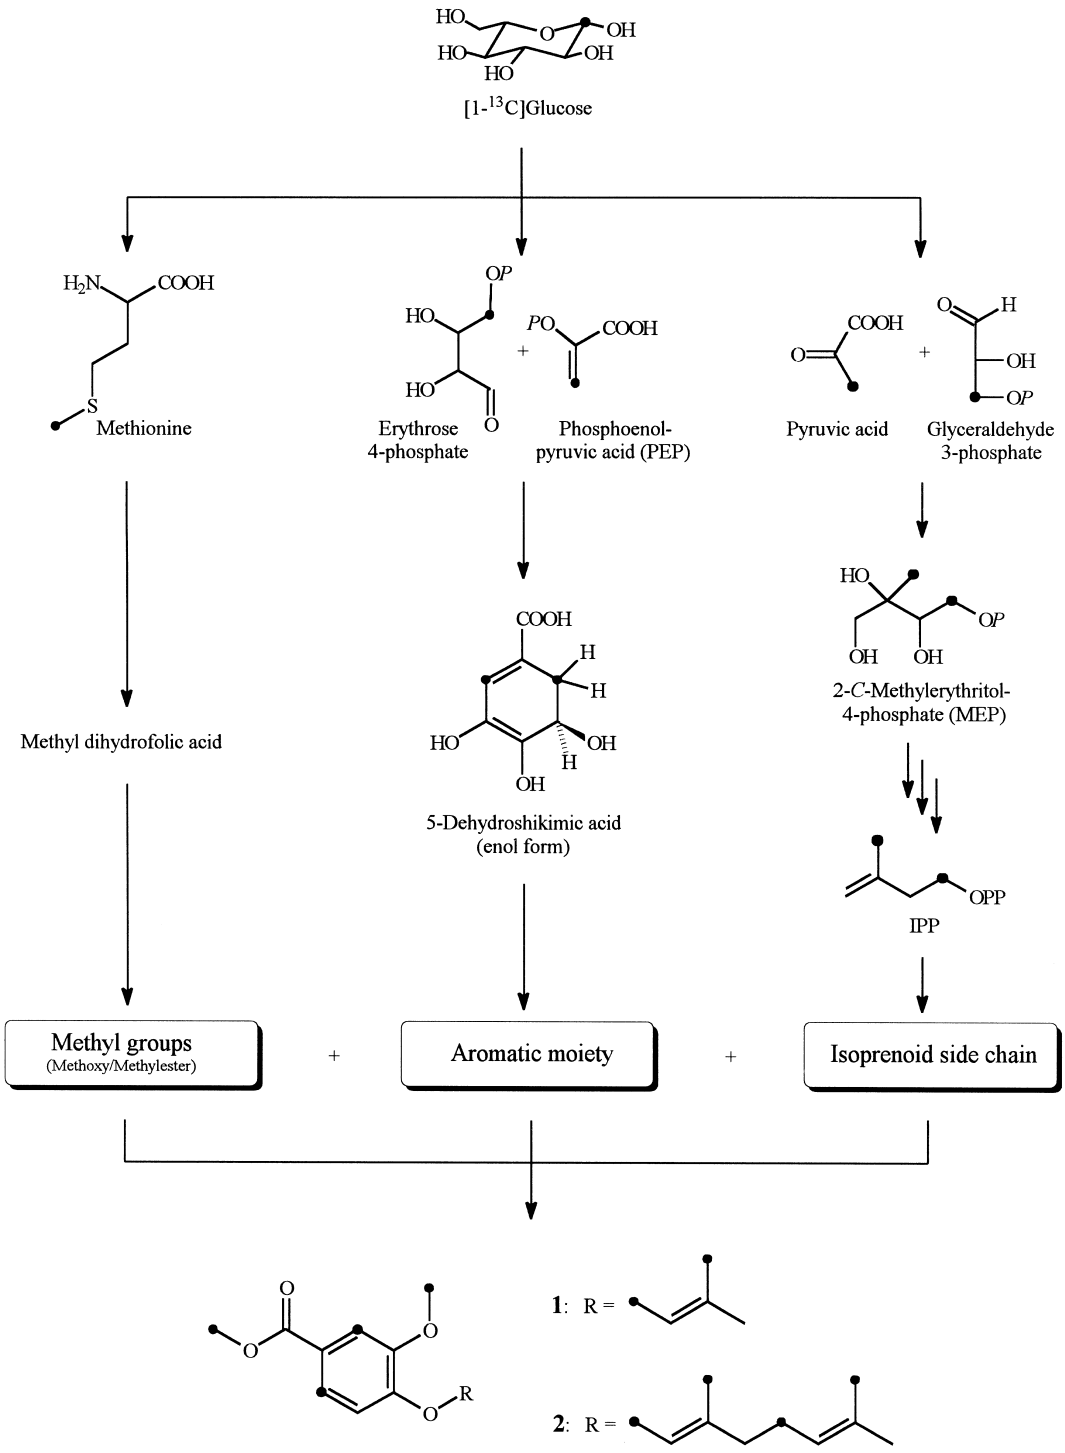

Fig. 2. Biosynthetic scheme for isoprenyl phenyl ethers showing incorporation of [1-^{13}C]glucose. Key: *P* = phosphate residue, *PP* = diphosphate residue, ● = ^{13}C labelled position.

operate in *T. tomentella*. The analysis of hemi-, mono- and diterpene units and sterols of *T. tomentella*, representing the basic terpenoid building blocks units C_5, C_{10} C_{15} (sterols = $2\times C_{15}$) and C_{20} gives a broad overview over the biosynthetic origin of isoprenoids of a single organism. The labelling patterns of all compounds investigated could be assigned to two groups formed independently from each other: firstly the sterols, formed via the mevalonic acid pathway, and secondly the hemi-, mono- and diterpenes, derived from the methylerythritol phosphate pathway.

In all compounds we observed a strict separation of the two pathway specific labelling patterns. A significant mixing of both IPP biosynthesis pathways in any of the isoprene units could not be deduced from the data. However, a minor incorporation of both IPP species in an isoprene unit could not be excluded, since the respective labelling could have been masked by the variation of the ^{13}C abundance data.

These facts agree with our earlier findings from the liverworts *R. natans* and *C. conicum* (Adam et al., 1998) and confirm that at least two well separated types of cellular compartments exist in liverworts, with different IPP biosynthesis machineries and prenyltransferase sets creating either C_{15} units, or C_5, C_{10} and C_{20} skeletons. These results are in agreement with the current hypothesis of the localization of the biosynthesis of the different terpenoid classes, assuming that mevalonic acid and sterol formation are located in the cytoplasm while the methylerythritol phosphate pathway and the biosynthesis of monoterpenes and diterpenes are segregated in plastids (Lichtenthaler, et al. 1997b; Rohdich et al., 1999).

Isohydroperoxytomentellin (**5**) (Fig. 3) is a previously unreported hydroperoxy compound which was isolated from unlabelled *T. tomentella* plant material during the course of this work. Mass spectrometry (DCIMS) showed a parent ion $[M+H]^+$ of 365.2, equating to a molecular formula of $C_{19}H_{24}O_7$. Both the ^1H and ^{13}C NMR spectra showed the substitution of the phenyl ring to be identical to that of the other isoprenyl ethers (**1**, and **2**), and very similar in structure to the related isoprenyl ether tomentellin (Perry et al., 1996). In contrast to tomentellin, the side chain differed in the position of one double bond (appearing as an exo-methylene group, δ_H 5.41, 5.19, both *s*), and the presence of an exchangeable proton signal at δ_H 10.75, suggesting either an alcoholic or peroxy proton. The structure of

Fig. 3. Isohydroperoxytomentellin (**5**).

the prenyl side chain was established from DEPT, COSY, HSQC and HMBC NMR data. The assignment of the signal at δ_H 10.75 to a hydroperoxy group was supported by the literature data of a monoterpene with a similar substructure, kobusimin A, isolated from both *Magnolia kobus* (Iida et al., 1982) and *Schistostephium crataegifolium* (Bohlmann et al., 1983).

3. Experimental

3.1. Spectroscopy and spectrometry

NMR Spectra were recorded in $CDCl_3$ (^1H NMR (500 MHz), ^{13}C NMR (125 MHz)) relative to $CDCl_3$ at δ_H 7.24; δ_C 77.0. ^{13}C Multiplicities were determined using the DEPT pulse sequence. 2D Spectra were recorded as COSY, HSQC and HMBC experiments. Quantitative ^{13}C NMR measurements were recorded with the inverse gated decoupling pulse sequence in the presence of 0.1 M $Cr(acac)_3$ (Braun et al., 1996). For integration, the signal-to-noise ratio of the ^{13}C-signals was at least 40:1. Direct chemical ionisation mass spectra (DCIMS) were recorded at 120 eV, using methane as carrier gas.

3.2. Plant material

An axenic culture of *T. tomentella* was obtained from the Collection of Autotrophic Organisms, Department of Hydrobotany, Institute of Botany, Czech Academy of Sciences, Trebon, Czech Republic. Growth characteristics and chemical composition of this culture have been intensively studied (Helminger and Becker, 1992). The liverwort was grown in 250 ml Erlenmeyer flasks under continuous incandescent light (60 μmol photons m^{-2} s^{-1} photosynthetically active radiation) at 22°C in 75 ml of modified Gamborg B5 liquid medium (Gamborg et al., 1968) containing 10 g/l glucose.

3.3. Labelling procedure

In feeding experiments 20% of the glucose was substituted by [1-^{13}C]glucose. Cultures were grown for 3 months.

3.4. Extraction, isolation and derivatisation

The extraction and isolation scheme followed standard procedures of our group (Adam et al., 1998). All isoprenyl phenyl ethers, with the exception of compound **5**, were identified by previously published NMR data (Perry et al., 1996). Dried ^{13}C labelled plant material (24.71 g) was ground and extracted in a soxhlet apparatus using CH_2Cl_2 (1.5 l) After removal of the solvent, the crude extract (1.62 g) was chromatographed on silica gel (vacuum liquid chromatography, VLC) employing a *n*-hexane–EtOAc gradient. The VLC fraction containing crude trichocolein (**1**) and deoxytomentellin (**2**) (198.3 mg, 7–8% EtOAc) was further purified via HPLC (250×4 mm, Si 60 Lichrospher Merck, 5 μm, *n*-hexane–EtOAc, 93:7), yielding 143.5 mg of **1** and 21.0 mg of **2**. The sterol containing VLC fractions (28,4 mg, 10–12%EtOAc) were purified by HPLC (250×4 mm, Si 60 Lichrospher, Merck, *n*-hexane–EtOAc 90:10) yielding 7.8 mg of the sterol mixture (campesterol/sitosterol/stigmasterol, ratio 1:2:4) This was acetylated overnight at room temperature (acetic anhydride/pyridine/toluene, 1:1:2, by vol.) and further purified by HPLC using an Ag^+ coated ion exchange column (Van Beek and Subrtova, 1995) (200×4 mm, Nucleosil 5 SA, Macherey and Nagel, 5 μm, *n*-hexane–*tert*-butyl methyl ether, 92:8), yielding 2.5 mg of acetylated stigmasterol (**3a**). The chlorophyll-containing fractions were combined and saponified by reaction overnight at room temperature with 6% (*w*/*v*) KOH in methanol. Following hydrolysis, the mixture was extracted 5× with CH_2Cl_2. After removal of the solvent, the mixture was separated by VLC on silica gel *n*-hexane–EtOAc (3.8% EtOAc) yielding 23.6 mg of *trans*-phytol (**4**).

3.5. Isohydroperoxytomentellin (**5**)

Compound **5** was isolated from unlabelled plant material that was extracted by methods described above. Separation of a VLC fraction (9% EtOAc, 51.4 mg) of the crude extract via HPLC (250×4 mm, Si 60 Lichrospher, Merck, *n*-hexane–EtOAc, 80:20) yielded 4.3 mg of (**5**) as a colourless oil: TLC (*n*-hexane–EtOAc, 80:20), $R_f = 0.11$, UV, purple with anisaldehyde/H_2SO_4. ^{1}H NMR data: δ_H 1.91 (3H, *br s*, H-8); 2.16 (3H, *br s*, H-9); 3.32 (1H, *d*, $J = 17$ Hz, H-4); 3.51 (1H, *d*, $J = 17$ Hz, H-4); 3.86 (3H, *s*, 3′OCH_3); 3.86 (3H, *s*, 7′OCH_3); 4.20 (1H, *d*, $J = 4$ Hz, H-1), 4.20 (1H, *d*, $J = 6$ Hz, H-1); 4.80 (1H, br *t*, $J = 5.5$ Hz, H-2); 5.19 (1H, *s*, H-10); 5.41 (1H, *s*, H-10); 6.14 (1H, *m* (allylic), H-6); 6.88 (1H, *dd*, $J = 2$; 8 Hz, H-5′); 7.51 (1H, *d*, $J = 2$ Hz, H-2′); 7.61 (1H, *dd*, $J = 2$; 8 Hz, H-6′), 10.75 (1H, *s*, HOO-). ^{13}C NMR data: δ_C 21.2 (*q*, C-9), 28.0 (*q*, C-8), 47.8 (*t*, C-4), 52.0 (*q*, 3′OCH_3), 56.0 (*q*, 7′OCH_3), 68.9 (*t*, C-1), 86.6 (*d*, C-2), 112.5 (*d*, C-5′), 112.7 (*d*, C-2′), 121.6 (*t*, C-10), 123.1 (*d*, C-6), 123.4 (*d*, C-6′), 123.5 (*s*, C-1′), 8.9 (*s*, C-3), 149.1 (*s*, C-3′), 151.9 (*s*, C-4′), 159.0 (*s*, C-7), 166.8 (*s*, C-7′), 200.3 (*s*, C-5); DCIMS (methane, probe) 120 eV *m*/*z* (rel. int.) $[M+H]^+$ 365.2 (0.55).

Abstract

The contents of 13 hydrolysable tannins in the leaves of white birch (*Betula pubescens* L.) trees were analysed at twelve stages throughout the growing season. All individual galloylglucoses, from 1-*O*-galloyl-β-D-glucopyranose to 1,2,3,4,6-penta-*O*-galloyl-β-D-glucopyranose, accumulated in young leaves, while ellagitannins showed significantly variable seasonal trends. The major ellagitannin during the whole growing season was pedunculagin, while 2,3-(*S*)-HHDP-glucopyranose, the end product of the proposed ellagitannin pathway, accumulated in mature leaves. Relationships between the characteristics of seasonal variation in the contents of individual ellagitannins and their chemical structures were used to unravel the biogenesis of ellagitannins in birch leaves. Evidence of degradation of ellagitannins through hydrolysis during leaf growth and development is presented and implications for herbivory are discussed. © 2001 Elsevier Science Ltd. 1. Introduction

Tannins form a large group of polyphenolic plant constituents that differ from most other natural phenolic compounds in their ability to precipitate proteins from solutions (Niehaus and Gross, 1997). The protein precipitation capacity of tannins has been suggested as an important factor reducing the suitability of plants for herbivores (Feeny, 1970; Hagerman and Robbins, 1987; Appel and Schultz, 1994). However, along with other measures of biological activities of tannins, this capacity varies depending on the chemical structure of the compound (Feldman and Sahasrabudhe, 1999; Feldman et al., 1999; Kilkowski and Gross, 1999). Thus the total content of tannins as such cannot serve as a measure of the biological activity of a plant sample. This holds true especially if seasonal variations in the contents of individual active and non-active tannins display different patterns even when their pooled content remains the same.

The tannins of terrestrial plants can be divided into two major structural groups: hydrolysable tannins (HTs) and proanthocyanidins (condensed tannins). HTs are characterised by a central polyol moiety (most often β-D-glucose) which is esterified with gallic acid (gallotannins, GTs) or hexahydroxydiphenic acid (ellagitannins, ETs). When the glucose core is esterified with five or fewer galloyl groups, the resulting compounds are defined as GT precursors or simple galloylglucoses (GGs), not GTs. The biogenesis of GGs has been shown to start with 1-*O*-galloyl-β-D-glucose as the first metabolite and to proceed by a series of consecutive and position-specific galloylation steps leading to 1,2,3,4,6-penta-*O*-galloyl-β-D-glucose (reviewed by Gross, 1999). In contrast to GGs, the biosynthetic pathway for the formation of ETs has not yet been determined, although it is generally assumed that all ETs are derived from 1,2,3,4,6-penta-*O*-galloyl-β-D-glucose by a stepwise, enzyme mediated oxidative coupling pathway (Helm et al., 1997).

Rapidly growing tree leaves display drastic seasonal changes in physical and biochemical characteristics, as has been shown in a number of studies (Feeny, 1970; Haukioja et al., 1978; Hatano et al., 1986; Baldwin et al., 1987; Makkar et al., 1991; Nurmi et al., 1996; Ossipov

PII: S0031-9422(00)00502-1

et al., 1997; Kause et al., 1999). Most of these studies, however, measured the total contents of tannin groups, such as GTs or proanthocyanidins. Only in a few cases have individual HTs been quantified during the growing season (Hatano et al., 1986; Ossipov et al., 1997). Even then the numbers of individual HTs or sampling dates have been quite limited, thus preventing the determination, e.g. of ellagitannin pathways. Nevertheless, the high content of total GTs has been shown to reduce the suitability of birch leaves for larvae of the geometrid moth *Epirrita autumnata* (Kause et al., 1999; Ossipov et al., 2000).

Recently, using the sensitive and selective method of negative ion HPLC–ESI-MS, we have identified fourteen GGs and twenty ETs in birch (*Betula pubescens* L.) leaves (Salminen et al., 1999). In the present study the main HTs were isolated and purified, and the results of HPLC–ESI-MS identification were confirmed with ^{1}H and ^{13}C NMR spectroscopy. The contents of thirteen HTs were analysed 12 times during the growing season, using HPLC–ESI-MS with ion trace analysis. Relationships between the characteristics of seasonal variation in the contents of individual HTs and their chemical structures were used to unravel the biogenesis of ellagitannins in birch leaves. The results obtained will presumably contribute to an understanding of the great variability in the suitability of birch leaves for herbivores in different stages of leaf development (Kause et al., 1999).

2. Results

2.1. Identification of hydrolysable tannins

Birch leaf HTs have been earlier identified with chromatographic, UV spectral and mass spectrometric methods (Salminen et al., 1999). The structures of the main HTs were now confirmed by ^{1}H and ^{13}C NMR techniques as 1-*O*-galloyl-β-D-glucose (**1**) (Saijo et al., 1990), 1,6-di-*O*-galloyl-β-D-glucose (**2**) (Saijo et al., 1990), 1,2,6-tri-*O*-galloyl-β-D-glucose (**3**) (Haddock et al., 1982a), 1,2,3,6-tetra-*O*-galloyl-β-D-glucose (**4**) (Haddock et al., 1982a), 1,2,3,4,6-penta-*O*-galloyl-β-D-glucose (**5**) (Saijo et al., 1990; Haddock et al., 1982a), casuarictin (**6**) (Gupta et al., 1982), tellimagrandin I (**7**) (Wilkins and Bohm, 1976), pedunculagin (**8**) (Feldman and Smith, 1996; Lee et al., 1992) and 2,3-(*S*)-HHDP-glucose (**9**) (Lee et al., 1992). Tellimagrandin II (**10**) and isostrictinin (**11**) were identified on the basis of UV and mass spectra (Salminen et al., 1999) and retention times (Hatano et al., 1986; Okuda et al., 1982).

It has been proposed that the metabolic pathway of ETs includes, in addition to **6**, another galloyl-bis-HHDP-glucose isomer, namely potentillin (**12**) (Haddock et al., 1982b; Haslam, 1992). Haddock et al. (1982b) also reported the difficulty of separating **6** and **12** by chromatographic methods. We found birch leaves to contain two major isomers of galloyl-bis-HHDP-glucose that elute closely in HPLC (R_ts 19.8 and 20.2). The earlier eluted isomer was identified as **6** by NMR (see above), and thus the later one must have been **12**.

The identity of 1,2,3-tri-*O*-galloyl-4,6-(*S*)-HHDP-α-D-glucose (**13**) was proposed on the basis of UV and mass spectra (Salminen et al., 1999) and of seasonal changes in its content relative to its β-1-galloylated isomer, **10**. Likewise, the chirality of the HHDP moieties located at the 2,3- or 4,6-positions of the glucose core of natural ellagitannins has been reported to be invariably in the (*S*)-series (Feldman and Smith, 1996; Khanbabaee and Lötzerich, 1998).

2.2. Seasonal trends in the content of hydrolysable tannins

Seasonal variations in the contents of birch leaf galloylglucoses are shown in Fig. 1. The maximum level was found in the youngest leaves. During leaf maturation the contents of all individual GGs per unit leaf weight decreased rapidly. However, their amounts per leaf increased, with a maximum between 28 May (**1**) and 7 June (**5**) (data not shown). This implies that the synthesis of GGs continued during the time when their content per unit leaf weight decreased due to dilution of GGs into the increasing leaf mass (Koricheva, 1999). Interestingly, after the short shoot leaves had reached their final size (after 5 July), clear increases were observed in the contents of all GGs except **1** (see Fig. 1).

In contrast to GGs, the contents of individual ETs showed variable seasonal trends (see Fig. 2a–d). This was especially obvious after excluding the rapid increase in leaf biomass during May and early June from the data by calculating the amounts of ETs per leaf (see Fig. 2e–h). For instance, while the contents of **6** and **8** seemed to remain at almost stable levels between 20 May and 7 June (Fig. 2b and c), their actual amounts per leaf increased significantly (Fig. 2f and g).

The order of individual ETs within the proposed ET pathway (Fig. 3) was determined from the relationships between the seasonal variation in the contents of individual ETs and their chemical structures. Plotting pairs of structurally or biogenetically related ETs showed that in the early stages of the growing season the balance was in favour of the predecessor, while during leaf maturation the balance switched towards the successor metabolite (for examples see Fig. 2).

Such ETs as **6**, **10** and **12** disappeared totally from the leaves of four birch trees already at 6 September, while the main patterns of HT variation were the same in all experimental trees. There were, however, large differences in the levels of individual HTs between individual

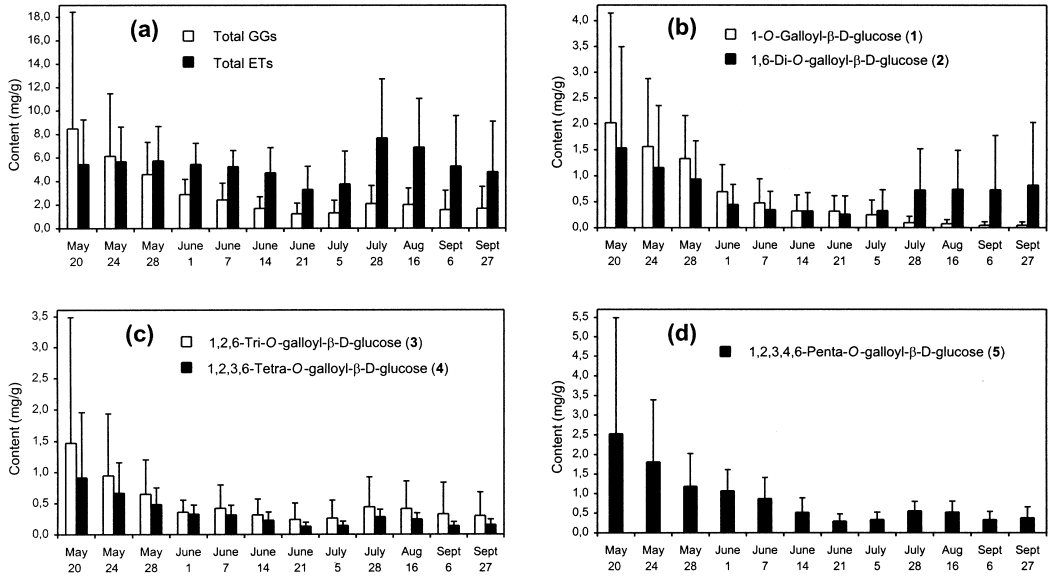

Fig. 1. Seasonal variation in the contents of hydrolysable tannins in leaves of white birch. (a) Total galloylglucoses and total ellagitannins; (b–d) individual galloylglucoses. Each bar on the graph represents the mean value of 10 trees. Vertical lines show standard deviations.

trees, as can be seen from the relatively large standard deviation bars in Figs. 1 and 2.

3. Discussion

Our results show that the contents of individual birch leaf HTs follow distinct seasonal patterns. This variation in the contents of individual GGs was consistent with previous studies (Nurmi et al., 1996; Ossipov et al., 1997); the patterns of variation of individual ETs, on the other hand, were now determined for the first time. These results allow us to describe the biosynthetic pathways of the main GGs, and in particular ETs, in birch leaves.

1-*O*-Galloyl-β-D-glucose has been shown to be the first metabolite in the biogenesis of GGs, being formed from UDP-glucose and gallic acid (Gross, 1982). This same phenomenon was confirmed in our birch data: **1** was one of the major GGs in young leaves, representing more than 24% of the total content of GGs. Several studies have also suggested that **1** acts as a principal galloyl donor for a series of consecutive and position-specific galloylation steps leading to **5**, the specificity of galloylations being usually 1-galloyl > 6-galloyl > 2-galloyl > 3-galloyl ⩾ 4-galloyl (reviewed by Gross, 1999). The biosynthesis of the second metabolite, **2**, requires two molecules of **1**. The first molecule acts as a galloyl donor and the second as an acceptor. Thus the increase in the content of **2** would mean a clear decrease in the content of **1**, especially if the rate of biosynthesis of **1** is simultaneously low. This was found to occur in mature leaves, after 5 July, as **2** became the major GG while **1** vanished almost totally (see Fig. 1b). The position-specificity of galloylations was proved to function in birch leaves as well; the other main GGs were identified as **3**, **4** and **5**.

In our study the final product of GG biosynthesis was **5**, as indicated by the absence of hexagalloylglucoses even in trace amounts. The metabolism of **5** in birch leaves thus mainly relates to the biosynthesis of ETs and not to transformation into hexagalloylglucose or other higher galloylated GTs. This specificity of birch leaves could be the result of the lack of enzymes that catalyse the formation of GTs from **5** (Hofmann and Gross, 1990; Niemetz and Gross, 1998, 1999).

Denzel and Gross (1991) found that **5** inhibited the activity of sumac leaf galloyltransferase, which in turn activated the transfer of 1-galloyl from **2** to the 2-position of the same compound. A similar feedback inhibition may take place in the transfer of 1-galloyl from **1** as well. Accordingly, when the content of **5** declines in birch leaves, for example in the process of its active utilisation, this inhibition would diminish. This would be followed by a simultaneous decrease in the content of **1** and by an increase in the content of **2** and all the biosynthetically subsequent HTs, as was found in our study (see Figs. 1 and 2, after 5 July). The function of **2** as a galloyl donor in birch leaves is unlikely, since it would also have meant an increase in the content of 6-*O*-galloyl-β-D-glucose as the deacylated by-product; this was not observed (data not shown).

According to Yoshida et al. (1992) there is a direct position-specific dependence on the ease of cleavability of different galloyl as well as HHDP groups through hydrolysis: 1-galloyl > 2-galloyl > 3-galloyl ⩾ 6- and 4-galloyl, 4,6-HHDP > 2,3-HHDP. The only galloyl group observed to be hydrolysed during this study was

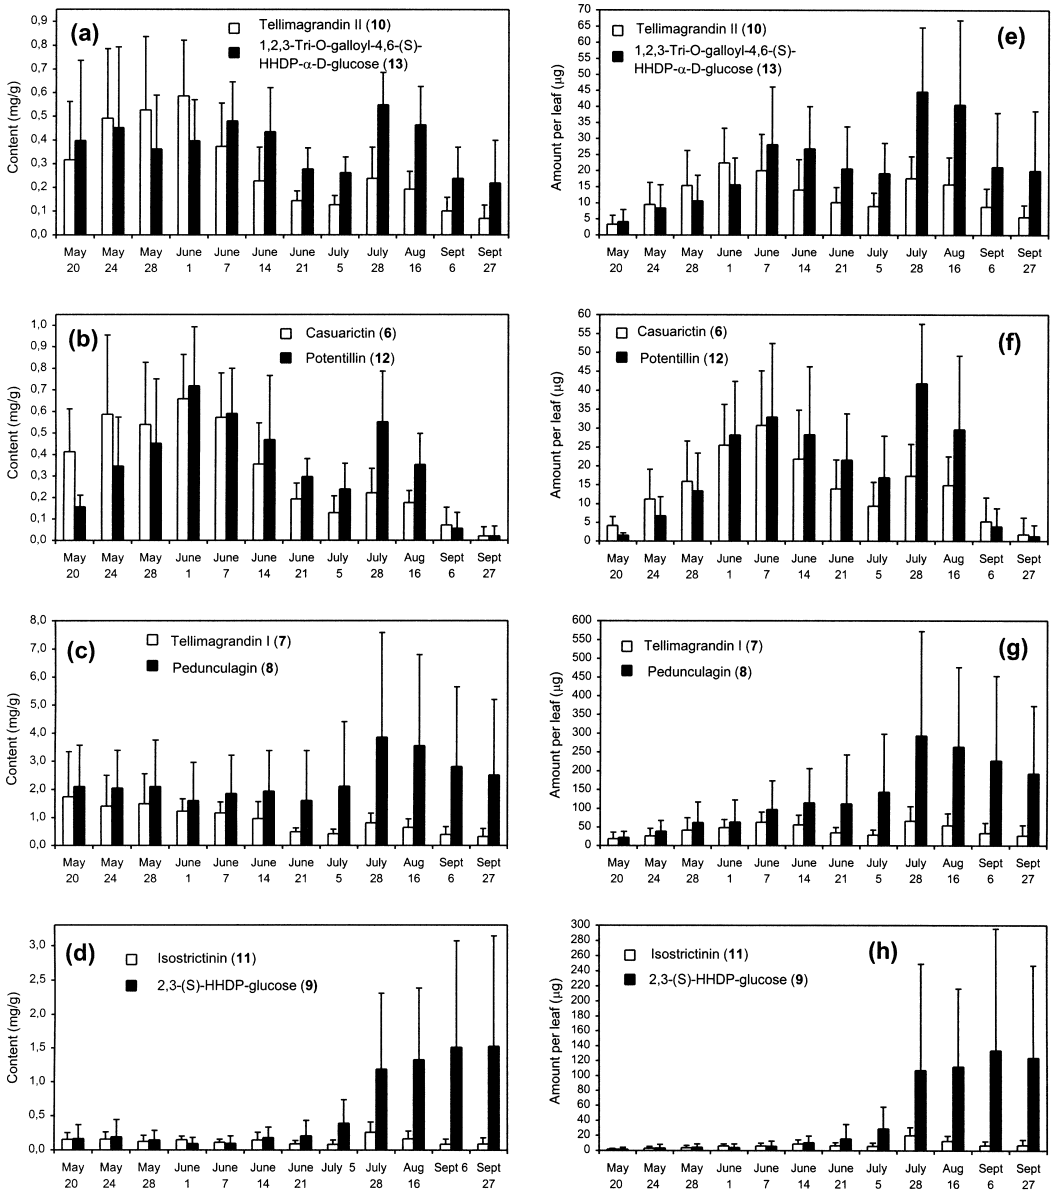

Fig. 2. Variation in contents (a–d) and amounts per leaf (e–h) of individual ellagitannins during leaf development. Each bar on the graph represents the mean value of 10 trees. Vertical lines show standard deviations.

the 1-galloyl of ETs. This indicates that for instance in **7** the oxidative coupling between 2- and 3-galloyls to yield **8** is preferred compared to the hydrolysis of 2-galloyl. This hydrolysis would have yielded 3-*O*-galloyl-4,6-HHDP-glucose, which has an ungalloylated anomeric centre, thus producing two peaks in HPLC; this, however, was not observed. The more rapid cleavability of 4,6-HHDP compared to 2,3-coupled was confirmed, since 8 h hydrolysis of **8** in 100°C water yielded **9** and ellagic acid. It is interesting that while the 2,3-HHDP group of **8** is less prone to hydrolysis than the 4,6-HHDP, it is also more difficult to incorporate into the glucose core than the 4,6-HHDP in chemical syntheses of **8** (Feldman and Smith, 1996). The delayed degradation of **8**, resulting in higher amounts of **9** in mature leaves only (see Fig. 2), could be due to the younger leaves having higher contents of certain GGs that inhibited the activity of ET degrading enzymes (Daniel et al., 1991).

In addition to hydrolysis, polymerisation and insolubilisation have also been suggested to decrease the content of ellagitannins (Scalbert et al., 1988; Peng et al., 1991; Klumpers et al., 1994; Viriot et al., 1994). According to Hatano et al. (1992), the intermolecular oxidative coupling producing oligomeric ETs in plants does not depend on a simple self-association of constituent monomeric tannins. Rather, it is controlled regiospecifically by enzymatic systems that vary among plant species. Presumably such enzymes were not present in our experimental trees, as polymerisation of

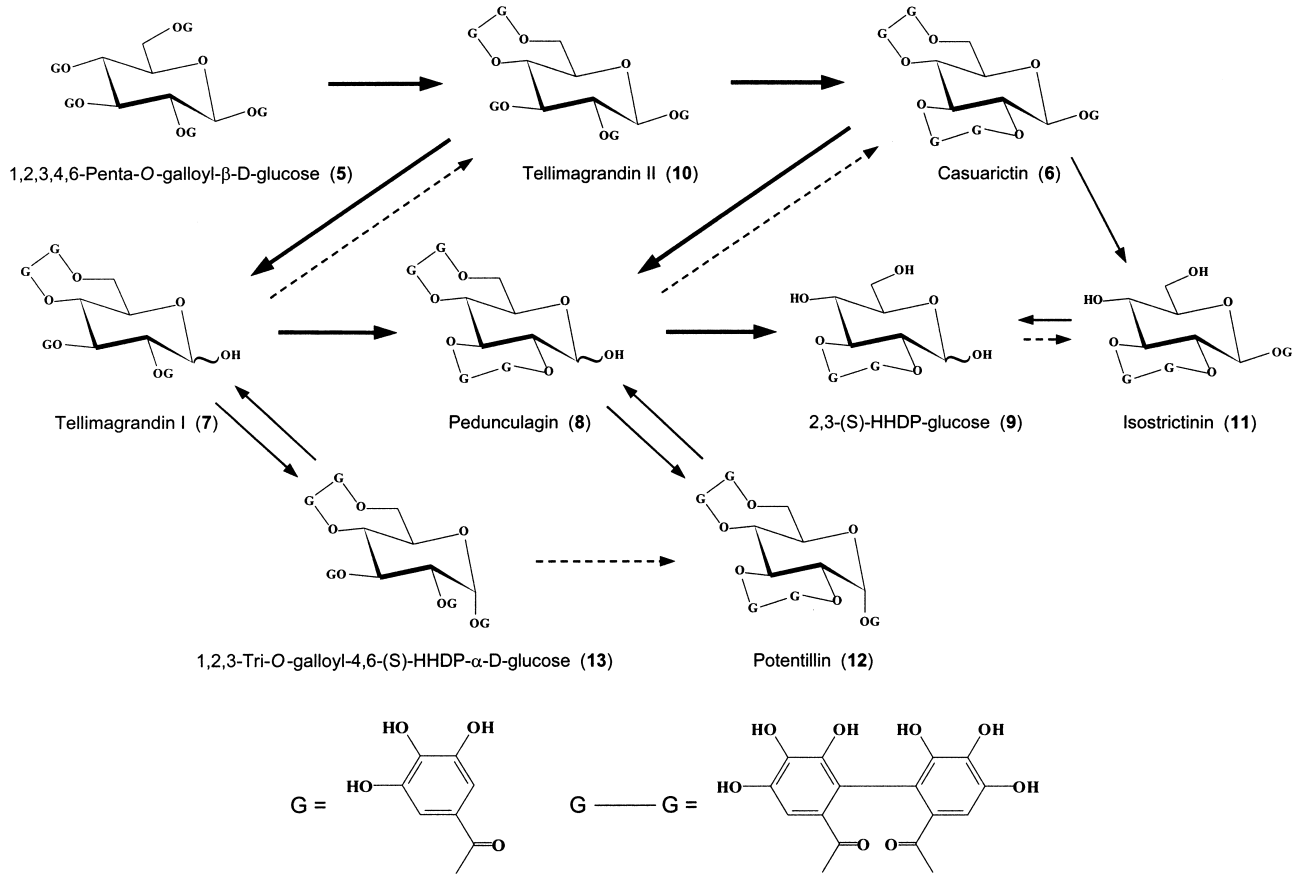

Fig. 3. Proposed biosynthetic pathway for formation of ellagitannins in the leaves of *Betula pubescens*.

birch leaf ellagitannins, for instance to dimers, was not observed. The amount of insoluble ETs, on the other hand, has been shown to increase during birch leaf growth and development (Salminen et al., unpublished work). One explanation for the almost total disappearance of **6** and **12** in autumn leaves could have been the opening of their glucose ring and the formation of C-glycosidic ETs such as vescalagin and castalagin, the main ETs for instance of oak wood (Helm et al., 1997; Puech et al., 1999). However, such ring opening is not characteristic of birch leaf ETs as neither vescalagin or castalagin, nor their degradation products vescalin or castalin were detected in any stage of leaf development.

In the ecological literature, foliar tannins are traditionally viewed as precipitators of leaf proteins, which by this means increase the herbivore resistance of plants (Feeny, 1970). The formation of only monomeric ETs from **5**, instead of highly galloylated GTs, suggests other functions for birch leaf hydrolysable tannins in addition to protein precipitation. Indeed, the accumulation of **9** in mature birch leaves is indirect proof of the existence and accumulation of ellagic acid, a proposed insect growth inhibitor (Klocke et al., 1986), in those same leaves as well. According to this view, HTs could play a dual role in plant-herbivore interactions, not only by a direct astringency-dependent deterrence of herbivorous insects, but also indirectly through their degradation products (Niehaus and Gross, 1997).

To sum up, we urge the need for studies in which individual HTs, including ETs, are considered as determinants of the changing suitabilities of birch leaves for herbivores (Kause et al., 1999). Such detailed studies will make it possible to determine whether these structurally diverse tannins, with possibly diverse biological activities, are truly effective defences against herbivores. In the words of Haslam (1988): "If tannins are so generalised in their action as supposed, it is very difficult to rationalise this generality with the very structural diversity found among the plethora of plant polyphenols — particularly those of the hydrolysable tannin class based on gallic acid and its derivatives."

4. Experimental

4.1. Plant material

Short shoot leaves of 10 29- to 33-year-old white birches (*Betula pubescens* L.) of known seed origin were sampled in the Botanical Garden of the University of Turku (SW Finland) 12 times during the growing season of 1999. All short shoot leaves in a tree are

produced in the spring flush; thus the age of sampled leaves grew monotonously with the season. The first samples were collected when the leaves had just opened from the bud, while the last leaves sampled were senescent and about to fall. Since the major changes in the content of birch leaf HTs have been reported to take place in young leaves (Baldwin et al., 1987; Nurmi et al., 1996; Ossipov et al., 1997) the sampling interval varied from four days in the early spring to three weeks in the autumn. Samples of 10–15 leaves per tree were collected between 9 and 10 a.m. haphazardly from branches located 2–5 m above the ground. The leaves were clipped from the petioles and placed in sealed plastic vials, which were enclosed in an insulated box filled with ice and transported immediately to a laboratory freezer. Voucher specimens have been deposited at TUR under the following accession codes: TUR 360093 and TUR 360103.

4.2. Sample preparation

The freeze-dried birch leaves (300 mg dry wt) were extracted three times with 70% aq. Me_2CO. After removal of Me_2CO at room temp., the aq. extract was freeze-dried and dissolved in 6 ml water. These aq. samples were filtered through 0.45 μm PTFE filters and kept frozen at −20°C until analysed with HPLC–ESI-MS.

4.3. Isolation and purification of hydrolysable tannins

A large number of freeze-dried white birch leaves (1.8 kg dry wt) were extracted with 70% aq. Me_2CO (containing 0.1% ascorbic acid to prevent oxidation) and fractionated on a Sephadex LH-20 column (40×2.5 cm i.d.) into seven fractions (fr 1–7), as previously described (Salminen et al., 1999). Individual HTs in the resulting fractions were purified further by chromatography on a Merck LiChroprep RP-18 column (44×3.7 cm i.d., 40–63 μm) using different gradients of CH_3CN in 1% aq. HCO_2H. This purification resulted in **1** (fr 1, 88 mg), **2** (fr 3, 48 mg), **3** (fr 5, 33 mg), **4** (fr 6, 39 mg), **5** (fr 7, 45 mg), **6** (frs 5 and 6, 23 mg), **7** (fr 5, 66 mg), **8** (fr 4, 35 mg) and **9** (fr 1, 19 mg).

4.4. Equipment and chromatographic conditions

4.4.1. HPLC–ESI-MS

HPLC–ESI-MS analysis of birch leaf extracts was performed using a Perkin-Elmer Sciex API 365 triple quadrupole mass spectrometer (Sciex, Toronto, Canada). This instrument is equipped with an ion-spray (pneumatically assisted electrospray) interface and a Macintosh data system. The HPLC system consists of two Perkin-Elmer Series 200 micro pumps (Perkin-Elmer, Norwalk, CT, USA) connected to a Series 200 autosampler. The eluate passes through a Merck Superspher 100 RP-18 column (75×4 mm i.d., 4 μm), and the UV trace is recorded with a 785A UV/VIS detector at 280 nm. After UV detection, part of the eluate was split off and introduced into the ESI-MS system.

Chromatographic and ESI-MS conditions were as described in a previous paper (Salminen et al., 1999).

4.4.2. ^1H and ^{13}C NMR

The ^1H and ^{13}C NMR spectra were recorded on a Jeol Lambda 400 MHz series spectrometer and a Brüker routine AM-200 NMR spectrometer, respectively. The spectra were run at ambient temperature in Me_2CO-d_6 (in some measurements a few drops of D_2O were added to enhance the solubility of the analyte). Chemical shifts were measured in relation to the solvent peak and converted to the TMS scale by adding 2.05 ppm (^1H NMR) and 29.92 ppm (^{13}C NMR).

4.5. Quantification of hydrolysable tannins

HTs of birch leaves were separated and quantified with HPLC–ESI-MS using ion trace analysis of deprotonated molecules ($[M–H]^-$) (Salminen et al., 1999). The mass selectivity of this method allows the quantitative analysis of HTs even though many of them are co-eluting in HPLC with other phenolic compounds present in birch leaf extracts. Calibration curves for quantification were prepared with known concentrations of **1**, **2**, **3**, **4**, **5** and **8**. The contents of **6**, **7**, **9** and **12** were calculated as **8** equivalents; **10** and **13** as **5** equivalents; and **11** as **3** equivalent mg/g in dry wt basis. Differences in the ionisation of HTs between individual runs were standardised by monitoring the ionisation of chlorogenic acid as an internal standard.

The R_ts and values of deprotonated molecules used for the quantification of tannins were as follows: **9**, 1.6 and 2.8 min (anomeric mixture), *m*/*z* 481; **1**, 5.0 min, *m*/*z* 331; **8**, 9.5 and 12.4 min (anomeric mixture), *m*/*z* 783; **7**, 14.0 and 16.8 min (anomeric mixture), *m*/*z* 785; **2**, 15.0 min, *m*/*z* 483; **11**, 15.6 min, *m*/*z* 633; **3**, 18.0 min, *m*/*z* 635; **6**, 19.8 min, *m*/*z* 935; **12**, 20.2 min, *m*/*z* 935; **10**, 21.1 min, *m*/*z* 937; **4**, 21.8 min, *m*/*z* 787; **13**, 23.6 min, *m*/*z* 937; **5**, 24.3 min, *m*/*z* 939.

Received 18 September 2000; received in revised form 4 December 2000

Abstract

The siliques and seeds of *Arabidopsis thaliana* accumulate a series of glucosinolates containing an alkyl side chain of varying length with a terminal benzoate ester function. The biosynthesis of these unusual nitrogen- and sulfur-containing natural products was investigated by feeding isotopically-labeled precursors to detached flowering stems. Glucosinolates were extracted, purified and analyzed by tandem mass spectrometry. Phenylalanine and benzoic acid were incorporated into the benzoate ester function, and methionine and acetate were incorporated into the aliphatic portion of the side chain in a position-specific manner. The labeling patterns observed were consistent with the chain extension of methionine by a three-step elongation cycle which begins with the condensation of acetyl-CoA with a 2-oxo acid derived from methionine and ends with an oxidative decarboxylation forming a new 2-oxo acid with an additional methylene group. Incorporation of desulfo-4-methylthiobutyl glucosinolate into 4-benzoyloxybutyl glucosinolate suggested chain-extended methionine derivatives are first converted to their corresponding methylthioalkyl glucosinolates with further side chain modification occurring later. Transformation of the methylthiol function to a hydroxyl group is followed by esterification with benzoic acid. The siliques appear to possess the complete machinery for carrying out all of the reactions in the biosyntheis of these complex glucosinolates. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Glucosinolates are sulfur containing secondary metabolites found mainly in members of the Brassicaceae, the mustard family (Underhill, 1980; Poulton and Møller, 1993; Halkier, 1999), where they play an important role in plant–herbivore and plant–pathogen interactions (Van Etten and Tookey, 1979; Chew, 1988). Their biological activities are often due to hydrolysis products released by the action of myrosinase (a β-thioglucoside glucohydrolase, EC 3.2.3.1), an enzyme stored separately from glucosinolates in the intact plant. All glucosinolates share a basic skeleton comprised of a β-thioglucose moiety, a sulfonated oxime and a side chain (Halkier, 1999) (Fig. 1). The great structural diversity of this class results from their variable side-chains (Brown and Mora, 1997; Fahey et al., 2001), which are all believed to be derived from a small group of common amino acids and their chain elongated derivatives (Underhill, 1980; Wallsgrove and Bennett, 1995).

The biosynthesis of the common glucosinolate skeleton is in large part understood, and many of the enzymes involved have been well-characterized (Halkier and Du, 1997; Halkier, 1999). The parent amino acid is first oxidized to an aldoxime (Fig. 1), catalyzed in most if not all cases by cytochrome P450 monooxygenases (Hull et al., 2000; Wittstock and Halkier, 2000). Then, a thiol group is added, probably as a result of conjugation with cysteine (Halkier, unpublished results), followed by C–S cleavage (Kiddle et al., 1999) to produce a thiohydroximate. Finally, transfer of glucose and sulfate moieties completes the basic skeleton.

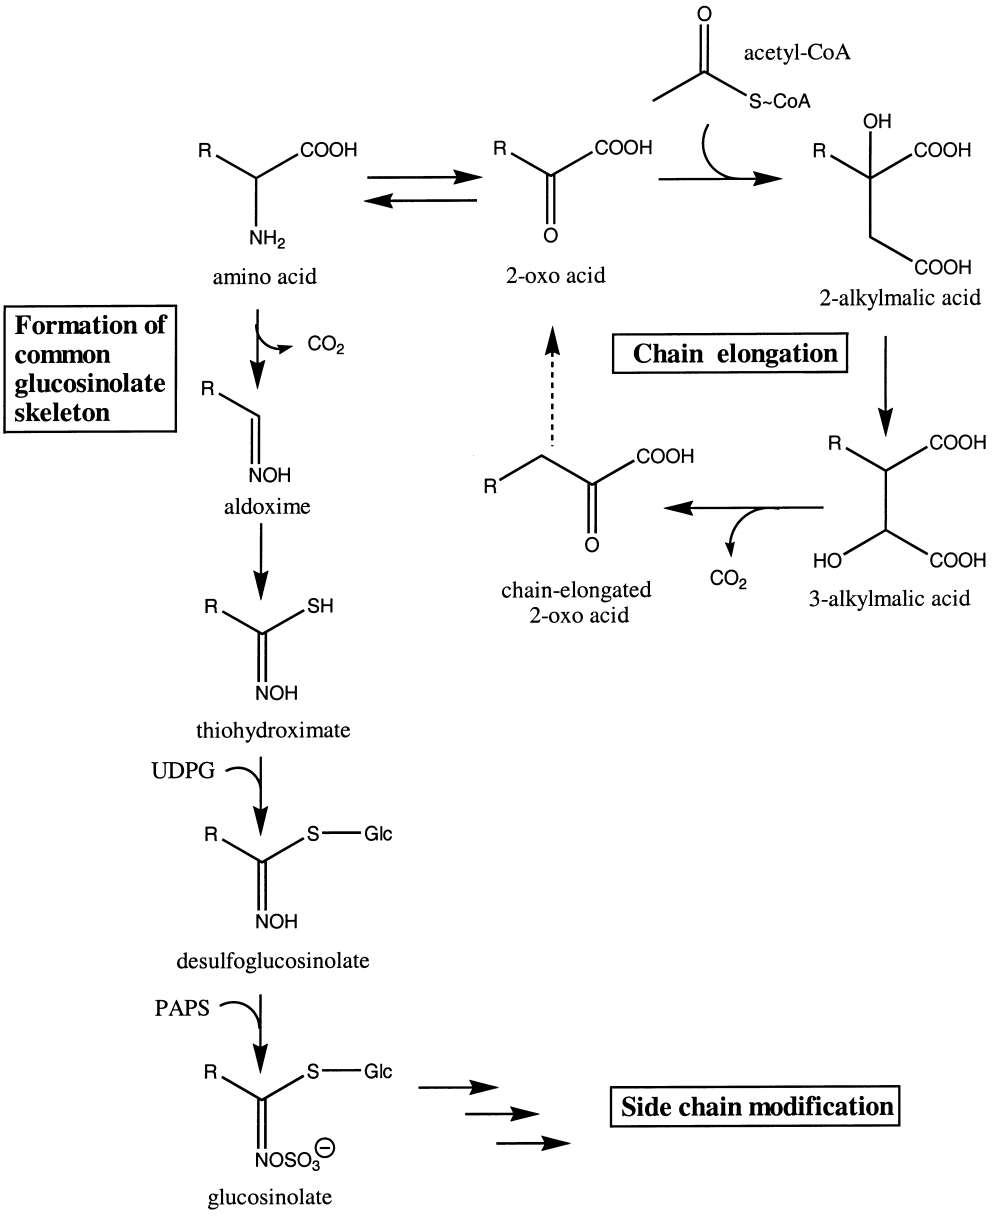

Fig. 1. Outline of glucosinolate biosynthesis showing the conversion of amino acids to the basic glucosinolate skeleton via a 4-step pathway. Prior to entering this pathway, amino acids such as methionine and phenylalanine can undergo one or more rounds of chain elongation. Additional side chain modifications can occur following the pathway. R indicates the variable side chain.

Much less is known about the biogenetic sequences responsible for side chain elongation and modification. In vivo metabolic studies, carried out in the 1960s using radio-labeled precursors (summarized in Underhill, 1980; Wallsgrove and Bennett, 1995), provided evidence for side chain elongation by deamination of the parent amino acid followed by a 3-step elongation cycle. Recent experiments with stable isotope labels have confirmed this pathway for the glucosinolates derived from elongated methionine derivatives in *Eruca sativa* (Graser et al., 2000). In the first step (Fig. 1), the 2-oxo acid formed by deamination condenses with acetyl CoA to form a 2-malic acid derivative which has been detected (Chapple et al., 1988). Then, isomerization to a 3-malic acid derivative followed by oxidative decarboxylation leads to the formation of a 2-oxo acid extended by one methylene group. Similar three-step elongations of 2-oxo acids are known in the citric acid cycle and in leucine biosynthesis (Bryan, 1980). Once extended, a 2-oxo acid can undergo additional cycles of chain elongation to form longer homologues with as many as six additional methylene groups in *Arabidopsis thaliana*, before being transaminated and entering the main pathway of glucosinolate biosynthesis. (Poulton and Møller, 1993; Wallsgrove and Bennett, 1995). In addition to elongation, the side chains of glucosinolates can be modified by thiol

oxidation, hydroxylation, esterification and other transformations. However, little information is available about the biosynthetic conversions involved.

The seeds and siliques of *A. thaliana* accumulate a series of benzoic acid glucosinolate esters of which 3-benzoyloxypropyl glucosinolate (3-BZO) and 4-benzoyloxybutyl glucosinolate (4-BZO) are the major compounds (Hogge et al., 1988). These unusual non-polar glucosinolates may be uniquely adapted for storage in the low-water environment of the seed. The benzoyloxy function may also have significance in altering susceptibility to cleavage by myrosinase. Given the co-occurrence of these substances with a series of methylthioalkyl and methylsulfinylalkyl glucosinolates, it may be postulated that the alkyl portion of the side chain is derived from the chain elongation of methionine, with one cycle of chain elongation required for 3-BZO and two cycles for 4-BZO. Following the loss of the methylthiol (or methylsulfinyl) function and its replacement by a hydroxyl function, ester formation can occur. The benzoic acid residue itself can be expected to arise from phenylalanine *via* cinnamic acid (Lee et al., 1995), but it is unclear if benzoylation and the other side chain modifications occur before or after formation of the common glucosinolate skeleton. Here we report the results of a series of experiments to study the formation of 3-BZO and 4-BZO in the siliques of *A. thaliana*. Isotopically-labeled precursors were fed in vivo, and the glucosinolate products isolated, purified and analyzed by tandem mass spectrometry. In addition to determining the precursors of each portion of the side chain, we investigated whether the steps in side chain modification precede or follow the other steps in the formation of glucosinolates.

2. Results and discussion

2.1. Incorporation of methionine, acetate, phenylalanine and benzoic acid

The biosynthesis of benzoic acid glucosinolate esters in *A. thaliana* siliques was investigated by feeding a variety of precursors to flowering stems. Glucosinolates were isolated in their desulfonated forms and analyzed by atmospheric pressure chemical ionization mass spectrometry from a 1:1 mixture of acetonitrile and water. Fig. 3 shows the molecular ion regions of the spectra of desulfo-4-benzoyloxybutyl glucosinolate (desulfo-4-BZO) isolated after feeding different precursors. The desulfo-4-BZO from an unfed control plant (Fig. 3a) gave a molecular species ($[M+H]^+$) at m/z 416 (100%) and two significant (>5% relative intensity) higher mass peaks at m/z 417 (30±0.3%, mean and standard error from five measurements) and 418 (8.5±0.1%). Administration with [2-^{13}C]acetate gave rise to desulfo-4-BZO with a mass spectrum (Fig. 3b) showing increases in the relative intensities of both m/z 417 (40.1±0.7%) and 418 (22.5±0.3%), demonstrating the incorporation of label from both one and two acetate units, respectively (Fig. 2). Fig. 3c shows the spectrum of desulfo-4-BZO following administration of [U-^{13}C]methionine. An intense ion at m/z 419 (42.8±0.8%) indicated the presence of three ^{13}C atoms and, therefore, the incorporation of only 3 of the 5 carbon atoms of methionine (Fig. 2). Application of either [$^2H_5$]phenylalanine or [$^2H_5$]benzoic acid to *A. thaliana* resulted in incorporation of all five ^{2}H atoms (m/z 421 = 6.4±0.1% from [$^2H_5$]Phe treatment, Fig. 3d; m/z 421 = 5.5±0.2% from [$^2H_5$]benzoic acid treatment). A similar pattern of results was observed for desulfo-3-BZO; however, only one acetate unit was incorporated after [2-^{13}C]acetate feeding (Fig.1).

To locate the sites of label within the molecule, tandem mass spectrometry, using low energy collision induced dissociation (CID), was carried out with the ions listed above. Fig. 4a shows the CID spectrum of m/z 416 ($[M+H]^+$) of unlabelled desulfo-4-BZO. Two major fragment ions are visible at m/z 254 and m/z 132, and their presence can be rationalized by the scheme shown in Fig. 5. First, loss of the glucopyran ring, by a proposed six-membered pericyclic mechanism can generate the ion at m/z 254, which can in turn undergo a second pericyclic fragmentation to give m/z 132 by loss of benzoic acid. Thus, the glucosinolate molecule fragmented conveniently into three parts: the sugar moiety, the benzoate group, and the aliphatic chain with N and S atoms attached. The CID spectrum of m/z 419 (Fig. 4b), from [$^{13}C_3$]-desulfo-4-BZO formed following [U-^{13}C]methionine treatment (see also Fig. 3c), showed ions at m/z 257 and 135, in contrast to m/z 254 and 132 in the native 4-BZO, unambiguously locating the three ^{13}C atoms on the aliphatic chain. On the other hand, fragmentation of $[M+H]^+$ from [$^2H_5$]-desulfo-4-BZO (m/z 421) formed following incorporation of either [$^2H_5$]phenylalanine or [$^2H_5$]benzoic acid gave product ions at m/z 259 and 132 (Fig. 4c). This result can only be explained by the presence of deuterium labeling on the benzoate group of the glucosinolate (Fig. 5). Therefore, it can be concluded that three of the five C atoms of 4-BZO arise from methionine, while the benzoate group is derived from phenylalanine (Fig. 2). Similar results were observed for 3-BZO.

From the mass spectrum of desulfo-4-BZO obtained following administration with [2-^{13}C]acetate (Fig. 3b), it appeared that the remaining two carbon atoms in the aliphatic chain of 4-BZO originated from the C-2 carbon atoms of two acetate residues (Fig. 2). Tandem MS experiments required to confirm this finding were less straightforward than those employed for the species obtained from the administration of methionine, phenylalanine or benzoic acid. The major difficulty was the small mass shift associated with incorporation of one or two ^{13}C atoms, and the consequent overlap of product

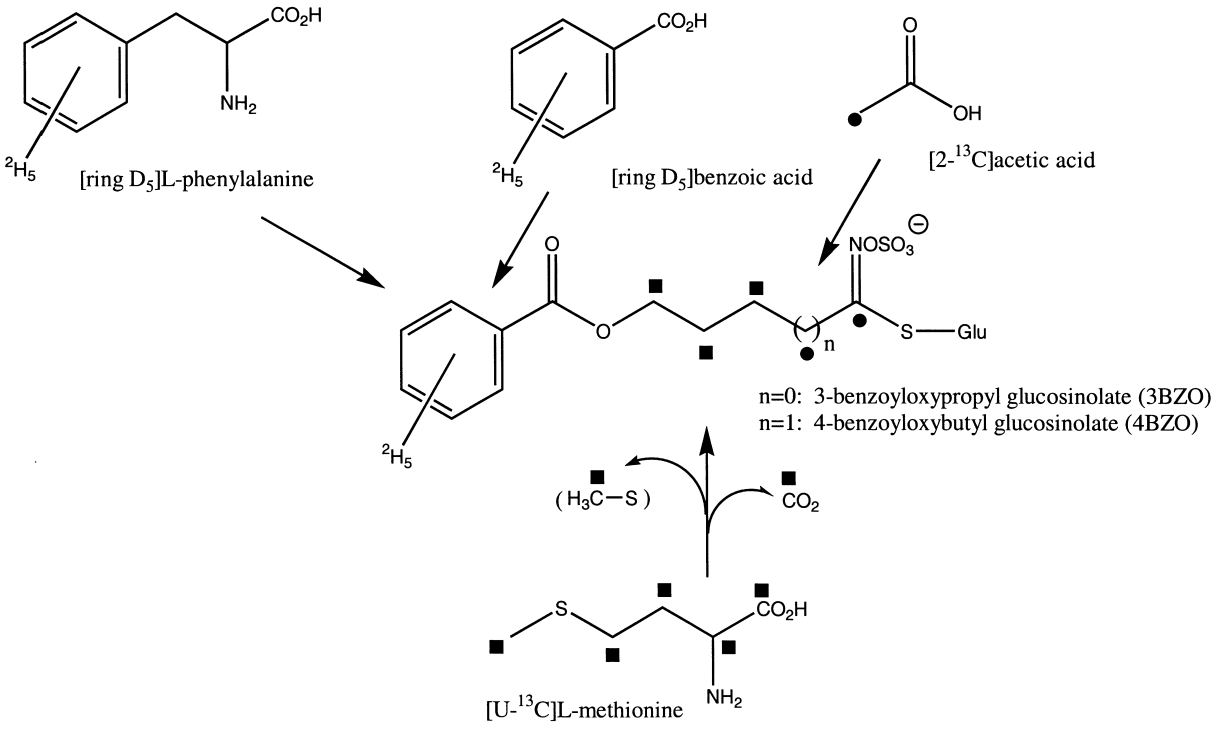

Fig. 2. In vivo labeling patterns of [$^2H_5$]L-phenylalanine, [$^2H_5$]benzoic acid, [U-^{13}C]L-methionine and [2-^{13}C]acetate incorporated into 3-benzoyloxypropyl- and 4-benzoyloxybutyl glucosinolate in siliques of *Arabidopsis thaliana*. Results show that phenylalanine and benzoic acid were incorporated into the benzoate ester function, while methionine and acetate were incorporated into the aliphatic portion of the glucosinolate side chain according to the chain elongation sequence proposed.

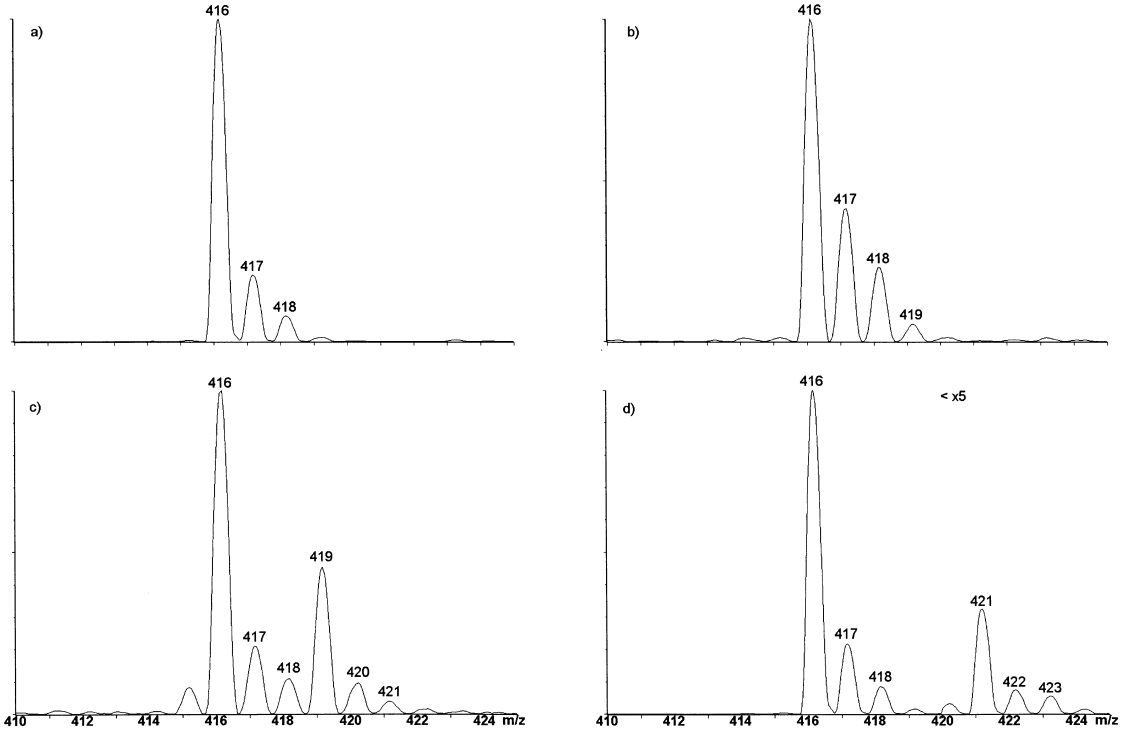

Fig. 3. The molecular ion region of the mass spectra of 4-BZO isolated from *Arabidopsis thaliana* siliques after administration of (b) [2-^{13}C]acetate, (c) [U-^{13}C]methionine, and (d) [$^2H_5$]phenylalanine or [$^2H_5$]benzoic acid. Panel (a) is the 4-BZO spectrum from unlabeled control plants. 'x5' in panel (d) indicates five-fold enhancement of signal intensity in the above region m/z 420.

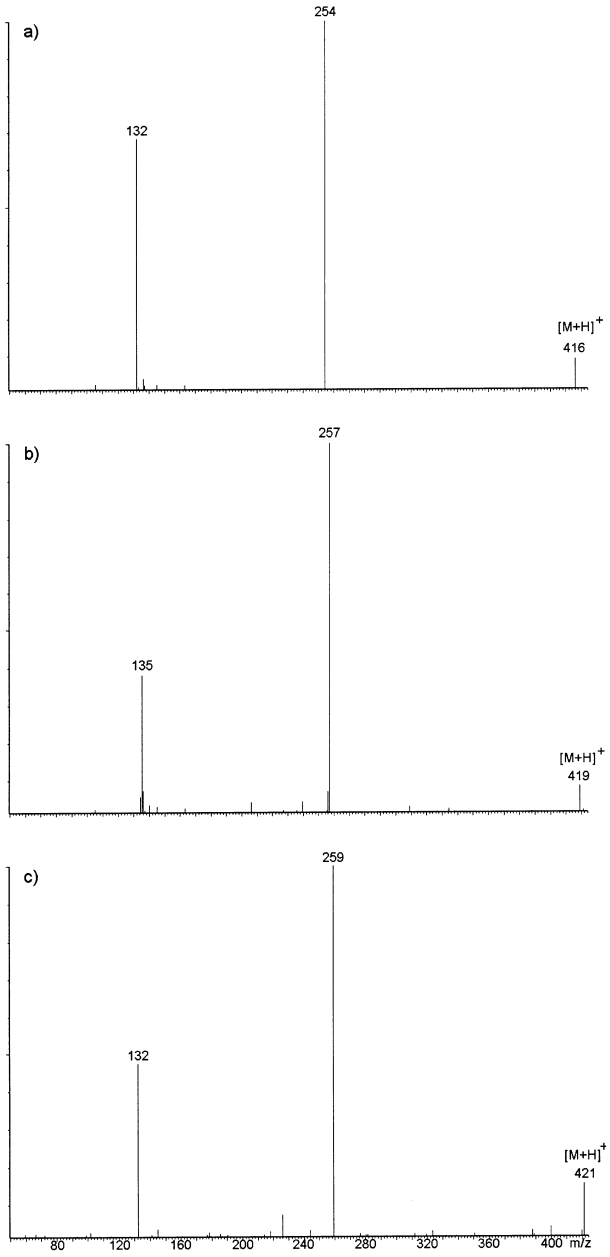

Fig. 4. Collision induced dissociation-product ion mass spectra for (a) $[M+H]^+$ of unlabeled 4-BZO, (b) $[M+H]^+$ of 4-BZO isolated from plants fed [U-^{13}C]methionine, and (c) $[M+H]^+$ of 4-BZO isolated from plants fed [$^2H_5$]phenylalanine or [$^2H_5$]benzoic acid.

$[M+H]^+$ ions (m/z 417 and 418) with those resulting from natural isotopic abundance in the unlabeled glucosinolate ($[M+H+1]^+ = m/z$ 417 and $[M+H+2]^+ = m/z$ 418). However, comparison of the CID spectra of m/z 417 and 418 from unlabeled desulfo-4-BZO with those obtained after [2-^{13}C]acetate incorporation did allow differentiation of natural isotopic abundance from specific precursor labeling. Fig. 6a shows the fragmentation pattern of $[M+H+1]^+$ (m/z 417) for the unlabelled glucosinolate, where 417 is largely due to the presence of a natural atom of ^{13}C somewhere in the molecule.

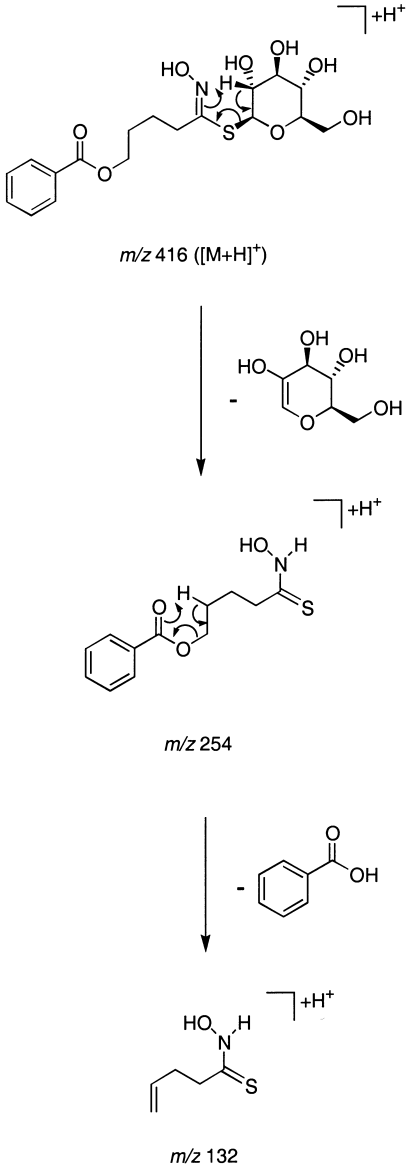

Fig. 5. Proposed mass spectral fragmentation of protonated 4-BZO under low energy CID conditions.

Fragmentation of m/z 417 gives m/z 255 and 254 with the ion at m/z 255 retaining ^{13}C, whereas m/z 254 arises from loss of the isotope during fragmentation (see Fig. 5). A similar effect is seen with m/z 132/133; however, here the ion retaining ^{13}C is relatively small — an observation consistent with the near random nature of isotope positioning caused by natural abundance. Fig. 6c shows the fragmentation pattern of $[M+H+1]^+$ (m/z 417) for desulfo-4-BZO labeled with ^{13}C from [2-^{13}C]acetate. In contrast to the spectrum obtained from the unlabeled compound, the m/z 133 ion is larger than that at m/z 132, indicating higher enrichment of one ^{13}C atom in the fragment. Since the m/z 132/133 ions originate from the glucosinolate aliphatic side-chain (Fig. 5), it is possible to conclude that the C-2 carbon of acetate is incorporated into this portion of the glucosinolate

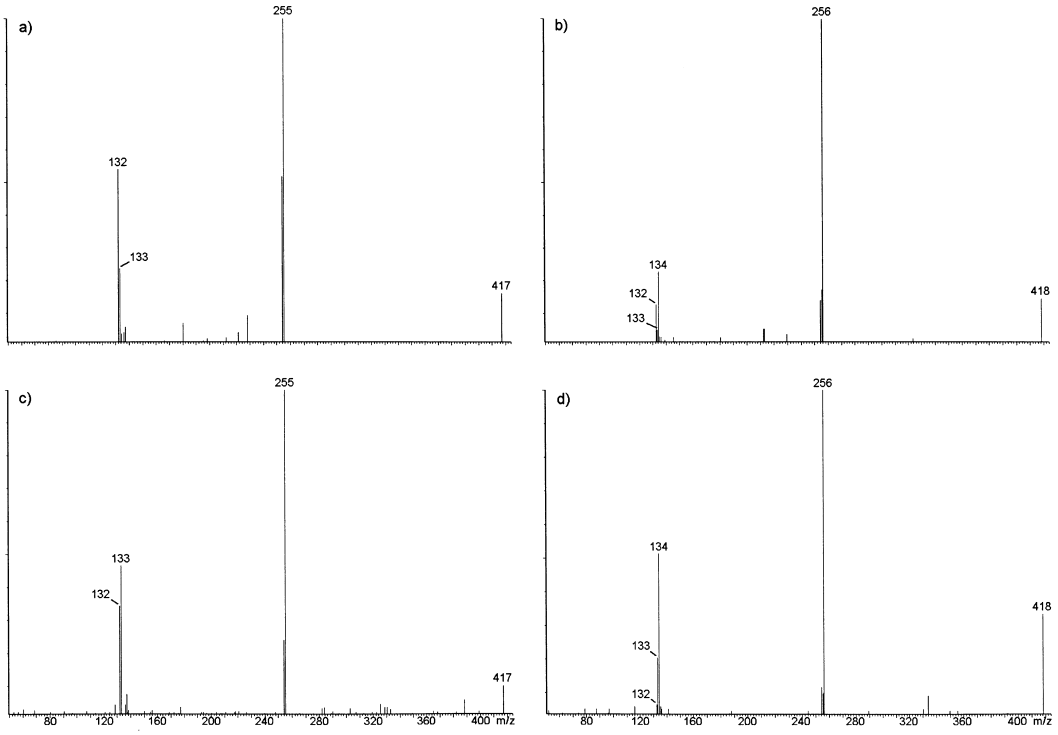

Fig. 6. Collision induced dissociation-product ion mass spectra of (a) $[M+H+1]^+$ from unlabeled 4-BZO, (b) $[M+H+2]^+$ from unlabeled 4-BZO, (c) $[M+H+1]^+$ from 4-BZO isolated from plants fed [2-^{13}C]acetate, and (d) $[M+H+2]^+$ from 4-BZO isolated from plants fed [2-^{13}C]acetate.

molecule. Examination of the CID spectrum of $[M+H+2]^+$ (m/z 418, Fig. 6b) for unlabeled desulfo-4-BZO shows that the +2 mass shift is largely retained in both major fragment ions (seen at m/z 256 and 134). This phenomenon results from the relatively high natural abundance of ^{34}S (4.4%), which contributes considerably to m/z 418, and from the fact that the sulfur atom is not lost during this fragmentation. However, Fig. 6d shows that the $[M+H+2]^+$ product ion spectrum from desulfo-4-BZO following [2-^{13}C]acetate treatment is different from the natural abundance spectrum. The ratio of m/z 134:132 in the spectrum from [2-^{13}C]acetate fed plants is 17:1, while the same ratio in the spectrum of unlabeled plants is only 2:1. Thus, there is a substantial enrichment of two ^{13}C atoms in the aliphatic side-chain fragment following treatment with labeled acetate, demonstrating that the aliphatic portion of the 4-BZO side-chain is formed from methionine elongated by two carbon atoms arising from the C-2 position of acetate. This result is consistent with the operation of the three-step chain elongation sequence proposed previously (Fig. 1) (Graser et al., 2000). During the biosynthesis of 4-BZO, an entire acetate residue is incorporated during each of the two rounds of chain elongation. However, the COOH group (C-1) of the first acetate residue is lost as CO_2 during the second round of elongation, and the COOH group of the second residue is lost during the conversion of the elongated methionine into the basic glucosinolate skeleton.

2.2. Incorporation of [1,2-^{14}C]desulfo-4-methylthiobutyl glucosinolate

The results described above account for the origin of all carbon atoms in the side-chains of 3-BZO and 4-BZO. However, they do not provide information about the sequence of biosynthetic steps in the formation of these benzoyloxyalkyl glucosinolates. In theory, many of the modifications of the side chain could occur either before or after the formation of the common skeleton. However, given the co-occurrence of 3-BZO and 4-BZO in *A. thaliana* siliques along with 3-OH-propyl- and 4-OH-butyl glucosinolates (Hogge et al., 1988), it is logical to assume that hydroxyalkyl glucosinolates are direct precursors of benzoyloxyalkyl glucosinolates, and that ester formation occurs after formation of the common skeleton (Kjaer and Christiansen, 1961). Related pairs of hydroxyalkyl- and benzoyloxyalkyl glucosinolates are also found in other plants (Daxenbichler et al., 1980).

To explore the sequence of side chain modifications in *A. thaliana*, a sample of [1,2-^{14}C]desulfo-4-methylthiobutyl glucosinolate was synthesized *in planta* by administering [2-^{14}C]acetate to detached *Eruca sativa* leaves. When this substance was administered to siliques of *A. thaliana*, radioactivity was detected in three other glucosinolates, 4-methylsufinyl-, 4-hydroxybutyl- and 4-benzoyloxybutyl glucosinolate with a specific incorporation of 2–3% (Table 1). All other glucosinolates in the tissue, including

Table 1
Incorporation of radioactivity into different glucosinolates of *A. thaliana* after siliques were fed with [1,2-^{14}C]desulfo-4-methylthiobutyl glucosinolate (4-MTB). All other glucosinolates including 3-benzoyloxypropyl (3-BZO), 7-methylthioheptyl, 7-methylsulfinyl, 8-methylthiooctyl, 8-methylsulfinyloctyl, indol-3-ylmethyl showed activities in the range of the background (0.48 Bq)

Glucosinolates	Radioactivity (Bq)	Spec. activity (GBq/mol)	Spec. incorporation (%)
4-Methylthiobutyl (4-MTB)	16.2	0.065	2.5
4-Methylsulfinylbutyl	2.35	0.07	2.7
4-Hydroxybutyl	1.6	0.08	3.3
4-Benzoyloxybutyl (4-BZO)	4.88	0.05	1.9

other chain elongated methionine derivatives were not labeled above the background. These results support a conversion of 4-methylthiobutyl glucosinolate (4-MTB) to 4-BZO via 4-methylsulfinylbutyl glucosinolate and 4-hydroxybutyl glucosinolate (Fig. 7). It has been previously suggested that 4-MTB is likely to be oxidized to 4-methylsulfinylbutyl glucosinolate, either enzymatically or spontaneously (Graham and Stanley, 1972). Next, loss of the sulfinylmethyl group and replacement by a terminal hydroxyl function (Haughn et al., 1991; McGrath et al., 1994) allows condensation with an activated benzoic acid intermediate (benzoyl-CoA, benzoyloxyglucose), to yield the benzoyloxyalkyl glucosinolates. Regardless of the exact sequence of intermediates, all of these transformations clearly occur after the formation of the common glucosinolate skeleton.

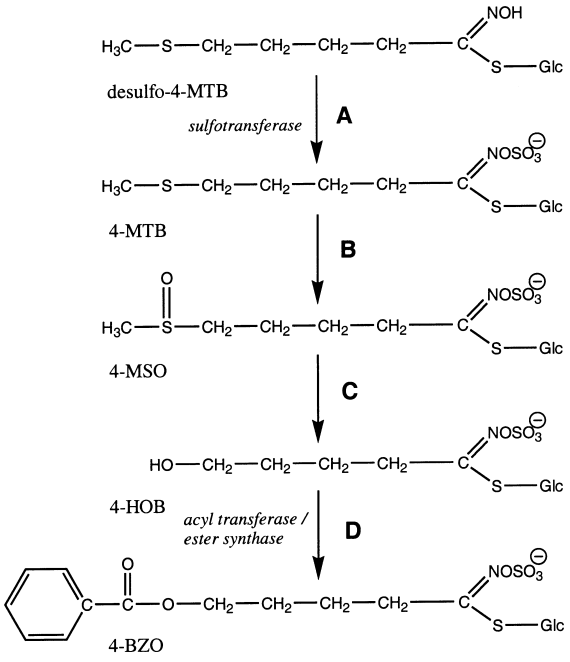

Fig. 7. Postulated intermediates in the final steps of 4-benzoyloxybutyl glucosinolate biosynthesis. The side chain of 4-methylthiobutyl glucosinolate (4-MTB) is modified by: (A) Oxidation of the thiol group to a sulfinyl, (B) replacement of the methylsulfinyl function by a hydroxyl group, and (C) condensation with activated benzoic acid to form 4-BZO.

The incorporation of desulfo-4-MTB into intact (sulfonated) glucosinolates suggests that *A. thaliana* possesses a sulfotransferase activity accessible to administered desulfonated glucosinolates. The sulfotransferases of glucosinolate biosynthesis have been previously characterized (Glendening and Poulton, 1988, 1990), and an incorporation of desulfoglucosinolates into intact glucosinolates has also been shown in other plant species (e.g. Chisholm and Matsuo, 1972). These findings raise the possibility that desulfoglucosinolates are a natural glucosinolate transport form in plants (Brudenell et al., 1999). When plants are damaged, intact glucosinolates are cleaved by myrosinase releasing toxic hydrolysis products. Hence, it may be advantageous for plants to transport glucosinolates in a form that is not susceptible to myrosinase activity (Lori et al., 1996).

2.3. Presence of biosynthetic pathway of 3 BZO and 4 BZO in A. thaliana siliques

Benzoyloxyalkyl glucosinolates in *A. thaliana* are only known to accumulate in the siliques and seeds (Hogge et al., 1988). To investigate the site of biosynthesis in this species, detached siliques were administered [U-^{14}C]phenylalanine and [2-^{14}C]acetate. For both precursors, analysis of the resulting 3-BZO and 4-BZO by liquid scintillation counting after HPLC separation showed substantial radioactivity in both glucosinolates after either precursor was administered (data not shown). Thus, the siliques themselves appear to contain the complete enzymatic apparatus for *de novo* biosynthesis of benzoyloxyalkyl glucosinolates. Indeed, previous workers have identified the silique walls as a major site for the formation of various types of glucosinolates (Lein, 1972; Du and Halkier, 1998). Nevertheless, at least part of the benzoyloxyalkyl pool in the seeds could arise from glucosinolates imported from other organs, whose side chains have been secondarily modified.

3. Conclusion

Our results have clarified the biosynthetic origin of the benzoyloxyalkyl glucosinolates of *A. thaliana*. Three discrete stages can be identified. First, methionine is extended by addition of 1,2 or more methylene residues via a three-step chain-elongation sequence involving the condensation of a 2-oxo acid with acetyl-CoA, as shown for the glucosinolates of *Eruca sativa* (Graser et al., 2000). Second, elongated amino acids derived from methionine

are converted into glucosinolates with methythioalkyl side chains. Third, the methylthioalkyl side chains are transformed to the corresponding hydroxylalkyl chains and then condensed with an activated benzoic acid species. While most of the reactions of the second stage (amino acids to glucosinolates) are now well understood (Halkier, 1999), much less is known about the enzymology or mechanism of the steps of the first and third stages (chain extension and modification). Detailed studies of some of these reactions are now in progress in our laboratory.

4. Experimental

4.1. Chemicals

[2-^{13}C]Acetic acid (>99%) and [ring-$^{2}H_5$]benzoic acid were purchased from Aldrich, [U-^{13}C]L-methionine (>97%) and [ring-$^{2}H_5$]L-phenylalanine (>98%) from Cambridge Isotope Laboratories, Inc. and [^{15}N]L-methionine (>99%) from Campro Scientific. All other reagents were from Sigma-Aldrich Chemical Co. unless otherwise stated.

4.2. Plant material

Seeds of *Arabidopsis thaliana* L. (ecotype Columbia), obtained from Lehle Seeds (Round Rock, Texas, USA), were sown in ordinary potting soil and raised in a controlled environment chamber with a day/night cycle of 16/8 h and 22°C/18°C. Illumination was with high-pressure sodium lamps (100% light intensity = 880 μmol m^{-2} s^{-1}) according to the following 16 h light program: 5 h with 50% illumination, 6 h with 75% illumination and 5 h with 50% illumination. Plants were watered every four days and fertilized once a week with 15:11:13, N:P:K (Osmocote, Scotts Europe).

4.3. Administration of basic precursors

Flowering stems of *A. thaliana* (12–20 cm long) were excised, by cutting just above the leaf rosette with a razor blade, and transferred into a 15 ml Falcon tube with 10 ml tracer solution. The incubations were performed for 5 days, under the growing conditions described above, using one of the following solutions: 5 mM [ring-$^{2}H_5$]phenylalanine with 3 mM L-methionine; 5 mM [ring-$^{2}H_5$]benzoic acid with 3 mM L-methionine; 5 mM [U-^{13}C]L-methionine; and 10 mM [2-^{13}C]acetic acid with 3 mM L-methionine and 3 mM L-phenylalanine. Unlabeled amino acids were fed together with labeled precursors to increase the rate of glucosinolate biosynthesis. All solutions were prepared in sterilized water containing sucrose (5%). Each precursor was fed to one tube containing 10–15 flowering stems. Additional tracer solution was added during the incubation as necessary. No microbial contamination of the incubation solutions were evident during the course of incubation.

4.4. Administration of desulfo-4-methylthiobutyl glucosinolate

[1,2-^{14}C]Desulfo-4-methylthiobutyl glucosinolate was prepared by feeding *Eruca sativa* with [2-^{14}C]acetate as described in Graser et al. (2000). [2-^{14}C]Acetate (8.8 TBq/mol) was administered to 120 expanding leaves of *E. sativa*. After leaves were incubated under standard growing conditions for 72 h, [1,2-^{14}C]4-MTB was isolated and purified as described below. One flowering stem was fed with [1,2-^{14}C]4-MTB (2.6 GBq/mol) in a volume of 12 ml water as described for the amino acid experiments. Siliques were harvested shortly before ripening.

4.5. Glucosinolate extraction

Extracts were made using methods adapted from previously published protocols (Thies, 1979; Graser et al., 2000). Fresh siliques were immersed in boiling, deionized water (5 ml per g sample) containing 100 μl 0.3 M $Pb(OAc)_2$–0.3 M $Ba(OAc)_2$ solution for 15 min. After 30 min gentle shaking at room temperature, samples were centrifuged at 4000 *g* for 10 min and the supernatant fraction loaded onto a small (100 mg) column of DEAE Sephadex A25. The column was rinsed with 67% (aqueous) MeOH and deionized water and, after capping, was treated with 50 μl sulfatase solution (prepared as described below) in 1 ml 20 mM NaOAc, pH 5.5, and left to stand overnight. The resulting desulfoglucosinolates were eluted from the column with 2×0.8 ml 60% (aqueous) MeOH, and the combined eluent was evaporated to dryness with nitrogen at 45°C. For HPLC analysis samples were redissolved in water. Unlabeled 3-BZO and 4-BZO were extracted from untreated siliques (5 g) of *A. thaliana* for use as standards.

Sulfatase for glucosinolate extraction (Thies, 1979) was prepared by dissolving 700 mg aryl sulfatase (Sigma type H-1 from *Helix pomatia*) in 30 ml deionized water and mixing with 30 ml absolute ethanol. After centrifugation at 5000 *g* for 20 min, the supernatant was mixed with 90 ml additional absolute ethanol and centrifuged again at 4000 *g* for 15 min. The pellet from this second centrifugation was dissolved in 25 ml deionized water and divided into 1 ml aliquots for storage at −20°C.

4.6. Desulfoglucosinolate purification and analysis

For APCI-MS analysis, desulfated 3-BZO and 4-BZO were purified by semi-preparative HPLC on a Hewlett Packard HP 1100 Series system with autosampler, column oven and diode-array detector. The procedure employed a C-18, fully-endcapped, reversed phase col-

umn (Hypersil ODS, 250×10 mm i.d., 5 μm particle size, Chrompack, Frankfurt, Germany) operated at 4.3 ml min^{-1} and 25°C, and eluted with a gradient (solvent A: H_2O, solvent B: MeCN) of 0–6% B (7 min), 6–24% B (30 min) and 24–32% B (8 min), followed by a cleaning cycle (32–92% B in 1 min, 5 min hold, 92–0% in 2 min, holding at 0 for 4 minutes to equilibrate). The eluent was monitored at 229 nm. Quantitation was achieved by addition of an internal standard (allyl glucosinolate, 0.5 μmol) during extraction with peak areas adjusted using response factors (Graser et al., 2000).

For radioactivity measurements, analytical HPLC was performed with a C-18 reversed phase column (LiChrospher RP-18, 250×4.6 mm i.d., 5 μm particle size, Chrompack) operated at 1 ml min^{-1} and 25°C. Elution was accomplished with a gradient (solvent A: H_2O, solvent B: MeCN) of 1.5–4% B (6 min), 4–18% B (7 min), 18–28% B (4 min), and 28–53% B (5 min), followed by a cleaning cycle (53–93% B in 2 min, 5 min hold, 93–1.5% B in 3 min, 2 min hold). Elution was monitored at 229 nm and the radioactivity of the collected fractions was quantified by liquid scintillation counting in 5 ml Lipoluma cocktail (Packard Bioscience, Groningen, The Netherlands) using a Packard Tricarb 2300TR liquid scintillation counter (^{14}C efficiency = 96.2%). Both analytical and semi-preparative HPLC systems were equipped with a C-18 LiChrospher (75×4.6 mm i.d., 5 μm particle size, Chrompack) reverse phase guard column.

4.7. APCI-MS analysis of 4-benzoyloxybutyl glucosinolate

Mass spectrometry was performed on a Quattro II (Micromass Ltd, Altrincham, UK) tandem quadrupole mass spectrometer (geometry quadrupole-hexapole-quadrupole) equipped with an atmospheric pressure chemical ionization (APCI) source. The corona pin was operated at 3.5 kV and the sample cone at 16 V. A mixture of acetonitrile and water (1:1) was used as the solvent, at a flow rate of 0.5 ml min^{-1}. Vaporization was achieved with a nitrogen sheath gas (300 l h^{-1}) and drying gas (150 l h^{-1}) at 400°C. Standard mass spectra were measured using the first quadrupole analyzer only, employing a narrow scan range of m/z 395–410 for 3-BZO and m/z 410–425 for 4-BZO and a scan time of 0.5 s. Product ion mass spectra were recorded by setting the first quadrupole to transmit the parent ion of interest and scanning the second quadrupole from m/z 50 to 425. Argon was used as the collision gas at 2×10^{-3} mbar, and a collision energy of 10 eV was employed to achieve fragmentation. Purified desulfoglucosinolates (typically 10–50 μg) were dissolved in water (0.3 ml) and aliquots (10 μl) injected directly into the APCI solvent flow using a loop injection valve (Rheodyne, CA, USA). If required, the solutions were diluted to ensure a similar detector response for each sample. For standard MS measurements, each sample was injected five times and average ion intensities calculated from peak areas.

Abstract

The biosynthesis of chelidonic acid was studied in cell suspension cultures of *Leucojum aestivum*. Cell cultures were supplied with [U-$^{13}C_6$]glucose, [1-^{13}C]glucose or [U-$^{13}C_5$]ribose/ribulose in standard medium containing unlabeled glucose. ^{13}C labeling patterns of amino acids obtained by hydrolysis of biomass were determined by NMR spectroscopy and compared to the labeling pattern of chelidonic acid. The data document the incorporation of a contiguous 4-carbon fragment derived from the pentose phosphate pool into chelidonic acid. This suggests a biosynthetic pathway involving the condensation of phosphoenolpyruvate with a pentose phosphate followed by dehydration, dehydrogenation, ring closure and decarboxylation conducive to the loss of C-5 of the pentose precursor. © 2001 Elsevier Science Ltd. 1. Introduction

The γ-pyrones, chelidonic acid (**1**) and meconic acid (**2**) (Fig. 1), are found in various alkaloid producing plants where they are supposed to serve as counterions for the storage of positively charged alkaloids in the vacuolar compartment (Ramstadt, 1953). Moreover, in *Cassia mimosoides* potassium chelidonate was claimed to serve as a leaf-closing factor (Ueda et al., 1998).

The biosynthesis of chelidonic acid is poorly understood. On the basis of radioisotope studies, a three-carbon unit and a four-carbon unit produced from the photosynthetic reduction cycle were proposed as building blocks of the γ-pyrone (Malcolm and Gear, 1971). More specifically, the shikimate precursor, 2-keto-3-deoxyarabinoheptulosonate 7-phosphate (DAHP, **5**) obtained by condensation of phosphoenolpyruvate (**3**) and erythrose 4-phosphate (**4**) has been suggested as an intermediate of chelidonic acid biosynthesis (Fig. 2).

We decided to perform incorporation experiments with *Leucojum aestivum* cultivated cells using mixtures of various ^{13}C-labeled carbohydrates with an excess of unlabeled glucose as precursors. The metabolic breakdown of ^{13}C-labeled carbohydrates yields labeled fragments which can be subsequently combined at random with fragments derived from unlabeled glucose by anabolic reactions of intermediary metabolism. ^{13}C-Labeled fragments from the precursor carbohydrate will be diverted to virtually all plant cell metabolites, and the individual metabolic products will be complex mixtures of different isotopomers reflecting their random assembly from ^{13}C-labeled and unlabeled glucose catabolites. In other words, the resulting metabolites derived from the glucose precursor are isotopomer mixtures reflecting their biosynthetic history.

The isotopomer composition of intermediary metabolites can be determined via analysis of biosynthetic amino acids which are easily obtained by hydrolysis of plant cell mass. The isotopomer composition of each biosynthetic amino acid can be determined quantitatively by NMR spectroscopy. By a systematic comparison

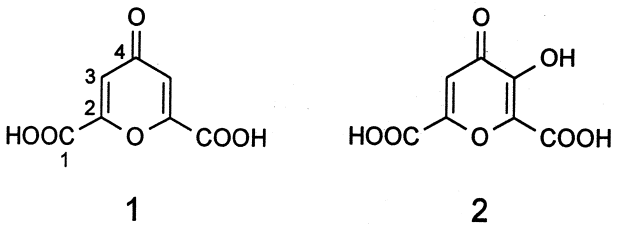

Fig. 1. Structure of chelidonic acid (**1**) and meconic acid (**2**).

between the labeling patterns of many primary metabolites with that of the secondary metabolite under study, the biosynthetic building blocks of the latter can be determined, even in the absence of a biosynthetic working hypothesis (for reviews, see Bacher et al., 1999; Eisenreich and Bacher, in press). Using this retrobiosynthetic approach, we here report that the carbon skeleton of chelidonic acid is assembled from one molecule each of a pentose and phosphoenolpyruvate.

2. Results

The analysis of chelidonic acid biosynthesis is complicated by the inherent symmetry of the molecule under study. The problem can be illustrated using the hypothetical pathway via DAHP as proposed by Malcolm and Gear (1971). In terms of this hypothesis, carbon atoms 1 and 7 of DAHP (**5**) would contribute isotope labels to the symmetry related carboxylic groups of chelidonic acid (**1**); since the NMR signals of the two carboxylic groups are degenerate due to the molecular symmetry, it would be impossible to discriminate between the label contributions by C-1 of phosphoenolpyruvate (**3**) and C-4 of erythrose 4-phosphate (**4**), respectively (Fig. 2).

These difficulties may be one of the reasons for the murky state of information on the biosynthesis of chelidonic acid. We decided to reanalyze this problem using the retrobiosynthetic method based on comparisons between labeling patterns of secondary and primary metabolites (for reviews, see Bacher et al., 1999; Eisenreich and Bacher, 2001). For this purpose, we performed incorporation experiments with various carbohydrates carrying single or multiple ^{13}C labels.

A cell culture of *L. aestivum* was incubated for 30 days in mineral salts medium containing 4 g of [U-$^{13}C_6$]glucose and 26 g of unlabeled glucose per litre (Table 1). The cell mass was harvested, and chelidonic acid was extracted and purified as described in Experimental. Subsequent to the extraction of chelidonic acid, the biomass was subjected to acid hydrolysis, and amino acids were isolated by chromatographic procedures. The ^{13}C labeling patterns of chelidonic acid and amino acids were then established by NMR spectroscopy as described under methods (Eisenreich and Bacher, 2001).

The catabolism of [U-$^{13}C_6$]glucose generates multiply ^{13}C-labeled fragments that can subsequently be combined in a stochastic manner with unlabeled fragments (derived from unlabeled glucose) by anabolic reactions. Further modification of the isotope distribution pattern is possible by passage through metabolic cycles such as the pentose phosphate cycle. Every specific metabolite is therefore a mixture of different isotopomers, and its NMR signals appear as complex multiplets resulting from the contributions of the ^{13}C–^{13}C coupling patterns of each respective isotopomer (Table 2). As an example, Fig. 3(a) shows the ^{13}C signature of C-3 of chelidonic acid. The central signal marked by b represents molecules carrying a single ^{13}C atom (isotopomer b, Fig. 4) that may have been formed from natural abundance glucose; alternatively, a single ^{13}C could have been contributed from the labeled glucose, but only after extensive fragmentation and reassembly.

The coupling satellites represent [1,2,3,4-$^{13}C_4$]-**1** (isotopomer k), [2,3,4-$^{13}C_3$]-**1** (isotopomer h), [2,3-$^{13}C_2$]-**1** (isotopomer f), and [3,4-$^{13}C_2$]-**1** (isotopomer e) (Fig. 4).

Table 1
Isotope incorporation experiments with cell cultures of *Leucojum aestivum*. The precursors were added as a bolus at the beginning of the growth phase

Experiment	^{13}C-Labeled precursor	Unlabeled carbohydrates
1	22 mM [U-$^{13}C_6$]glucose	145 mM glucose
2	55 mM [1-^{13}C]glucose	110 mM glucose
3	9 mM [U-$^{13}C_5$]ribose/ribulose	27 mM ribose, 156 mM glucose
4	0.2 mM [2-^{13}C]sedoheptulose	165 mM glucose

Table 2
NMR data of chelidonic acid in D_2O

Position	Chemical shift [ppm]		^{13}C–^{13}C coupling constants[a]	Isotope shifts[b]
	^{1}H	^{13}C	Hz	ppb
1		163.62	79.8 (2), 3.5 (4), 5.0 (3)	+19 (2)
2		157.31	79.5 (1), 71.1 (3)	−32 (1), −20 (3)
3	6.99	117.34	54.8 (4), 71.2 (2), 5.1 (1)	−16 (4), −25 (2), +4 (1)
4		184.13	54.8 (3), 3.4 (1)	−7 (3)

[a] Coupled atoms are given in parentheses.
[b] ^{13}C atoms causing isotope shifts to the chemical shift of the respective index atom are given in parentheses.

Due to heavy isotope chemical shift effects (Table 2), the respective centers of the satellite signals are offset to high field.

The molar fraction of each respective isotopomer in the sample can be obtained from the signal integrals as described in Experimental (Table 3). The salient feature of the labeling pattern is the occurrence, albeit at low level, of [1,2,3,4-$^{13}C_4$]chelidonic acid (isotopomer k, Fig. 4) containing four contiguous ^{13}C atoms incorporated en bloc from the proffered glucose.

The labeling patterns of representative amino acids isolated from biomass are shown in Fig. 5. In order to save space, the different isotopomers observed are all superimposed in one respective structure. The bars indicate the groups of adjacent ^{13}C atoms of each respective multiple-labeled isotopomer. The abundance of each isotopomer is shown by the width of the bars as well as by the numerical subscripts.

The labeling patterns are qualitatively similar to those found with numerous other plant cell cultures supplied with a mixture of [U-$^{13}C_6$]glucose and natural abundance glucose (Eichinger et al., 1999a,b; Goese et al., 1999; Werner et al., 1997). However, it should be noted that fragments with four respectively five contiguous carbon atoms occur only in the ring systems of aromatic amino acids and in histidine. This reflects the origin of these respective amino acids from erythrose 4-phosphate respectively ribose 5-phosphate. In the other amino acids, no contiguous blocks exceeding three ^{13}C atoms were found (Fig. 5).

In summary, these observations support the hypothesis that the detected $^{13}C_4$-carbon block in chelidonic acid has been introduced via a carbohydrate precursor that remains to be identified more accurately.

As described in detail previously, the isotopomer compositions of central metabolites can be determined retrobiosynthetically from the observed labeling patterns in amino acids (Bacher et al., 1999). Thus, the labeling pattern of ribose 5-phosphate (**7**) can be reconstructed from that of histidine (**6**). Moreover, tyrosine (**8**) reflects the labeling patterns of phosphoenolpyruvate (**3**) and erythrose 4-phosphate (**4**, Fig. 6). Using the reconstructed labelling patterns of central metabolites it is now possible to predict the labelling pattern of biosynthetic chelidonic acid via hypothetical biosynthetic pathways.

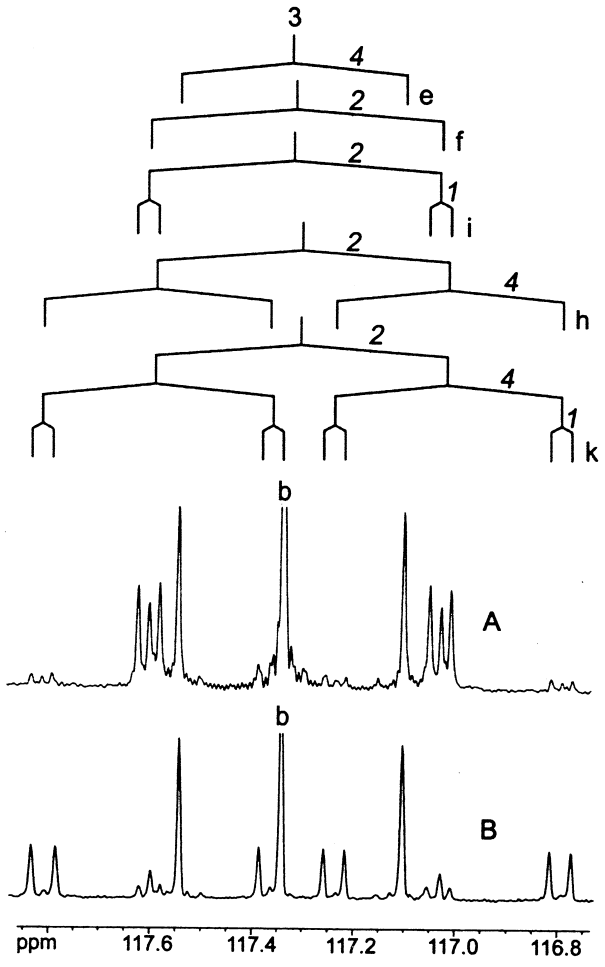

Fig. 3. ^{13}C NMR signal of C-3 of chelidonic acid obtained from the experiment with (a) [U-$^{13}C_6$]glucose and (b) [U-$^{13}C_5$]ribose/ribulose. ^{13}C coupling patterns are indicated. Numbers in italics indicate carbon atoms ^{13}C coupled to C-3. Letters denote isotopomers shown in Fig. 4.

Two hypothetical pathways for the assembly of chelidonic acid from carbohydrates are shown in Fig. 7. Pathway A involves a condensation of erythrose 4 phosphate (**4**) with phosphoenol-pyruvate (**3**) via the shikimate pathway intermediate, 2-keto-3-deoxyar-

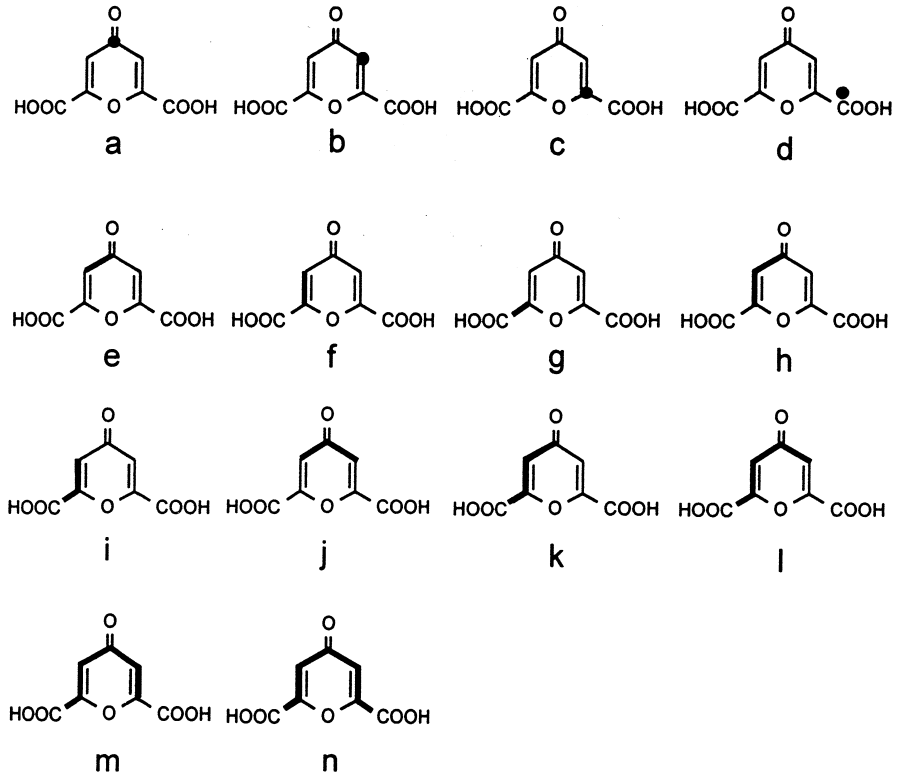

Fig. 4. ^{13}C Labelled isotopomers of chelidonic acid (a–n). Filled circles indicate ^{13}C atoms in single labelled isotopomers. Bold bars indicate adjacent ^{13}C atoms in multiple labelled isotopomers.

abinoheptulosonate 7-phosphate (**5**, DAHP). Pathway B similarly involves the condensation of a pentose 5-phosphate (**7**) with phosphoenolpyruvate (**3**) and subsequent loss of one carbon atom. The hypothetical pathway A via DAHP has been proposed earlier by Malcolm and Gear (1971) (see Fig. 2).

The labeling patterns expected for the formation of chelidonic acid via pathways A and B can be predicted quantitatively from the labeling patterns for phosphoenolpyruvate, erythrose 4-phosphate and ribose 5-phosphate extracted from the experimentally observed labeling patterns of tyrosine and histidine (Fig. 6). Due to the inherent symmetry of chelidonic acid, pairs of carbon atoms are homotopic. As a result, the isotopomer pattern present in the homotopic parts of the molecule cannot be distinguished by NMR spectroscopy and the "folded" pattern shown in the box is detected. The highest degree of similarity is found between prediction B and the experimental labeling pattern [Fig. 7(c)] but the evidence is far from conclusive. Therefore, an additional experiment was performed with [1-^{13}C]glucose as precursor. The data were processed in the same way as in the previous experiment.

The prediction of chelidonic acid labeling from [1-^{13}C]glucose via pathways A and B is summarized in Fig. 8. The agreement between the prediction B and the observed labeling pattern of chelidonic acid [Fig. 8(c)] is excellent. On the other hand, the experimental data differ substantially from the prediction via pathway A.

The data suggested that a further confirmation might be obtained using a universally ^{13}C labeled pentose rather than a hexose as precursor. On the other hand, it was unknown whether cultured plant cells metabolize exogenous pentoses.

An experiment with a [U-$^{13}C_5$]ribose/ribulose mixture was performed as summarized in Table 1. Natural abundance glucose as well as ribose were added together with the ^{13}C-labeled pentose mixture. The NMR signal of C-3 of chelidonic acid is shown in Fig. 3(b). Qualitatively, the spectrum shows the same satellite pattern

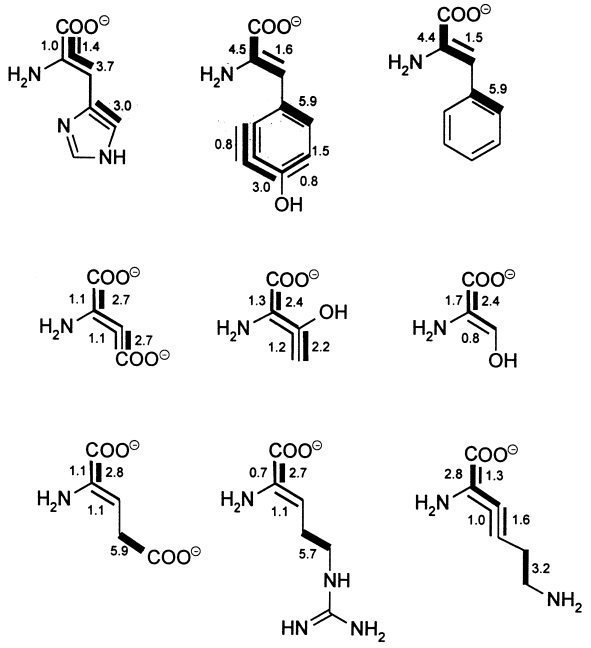

Fig. 5. Incorporation of [U-$^{13}C_6$]glucose diluted with unlabelled glucose into *Leucojum aestivum*. ^{13}C labelling patterns of amino acids obtained from cellular protein. Bold bars indicate multiple ^{13}C labelled isotopomers. The numbers indicate molar fractions of respective isotopomers.

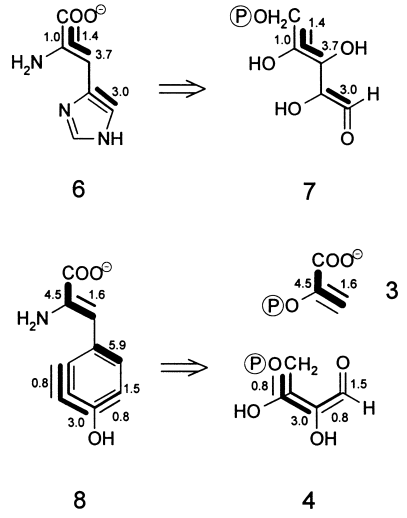

Fig. 6. Incorporation of [U-$^{13}C_6$]glucose diluted with unlabelled glucose into *Leucojum aestivum*. Reconstruction of the labelling patterns of ribose 5-phosphate (**7**), phosphoenolpyruvate (**3**), and erythrose 4-phosphate (**4**) from the detected labelling patterns of histidine (**6**) and tyrosine (**8**), respectively. For further details, see Fig. 5.

obtained from the experiment with [U-$^{13}C_6$]glucose. However, the relative intensity of the various satellite groups is different; most notably, the [$^{13}C_4$]-isotopomer has become the dominant species (Table 3). No [$^{13}C_5$]-isotopomer could be detected.

The data show that ribose and/or ribulose can serve as precursor in cultured plant cells with unexpected efficacy. Amino acid labelling patterns from the experiment with ribose/ribulose are shown in Fig. 9. As described above, the labelling pattern of ribose 5-phosphate and phosphoenolpyruvate was extracted from that of histidine and tyrosine/phenylalanine, respectively.

Starting from these data the labelling pattern of chelidonic acid was predicted again, as shown in Fig. 10. The isotopomers are correctly predicted by the hypothetical pathway via incorporation of an intact pentose with subsequent loss of the terminal carbon atom. However, the absolute abundance of isotopomers with multiple ^{13}C labels is not correct as predicted. The reason for this is at present not known. It could be caused by the localization of histidine biosynthesis and chelidonic acid biosynthesis in different compartments. It could also be influenced by the fact that a mixture of totally ^{13}C-labeled ribose and ribulose has been used as exogenous precursor. Nothing is known as yet about the metabolic utilization of ribulose. Thus, the quantitative outcome of the labeling experiment with the pentose/pentulose mixture could also be related to dynamic aspects of pentose vs. pentulose utilization.

3. Discussion

The elucidation of the biosynthesis of chelidonic acid is substantially hampered by the inherent symmetry of the molecule. The data reported in this paper confirm that, even in such a situation, biosynthetic hypotheses can be analysed by a retrobiosynthetic approach.

The use of cell cultures provides substantial advantages for biosynthetic experiments by comparison with whole plants or plant tissues, such as an unlimited time frame and the ease of application of nutrients and precursors. However, for a long time, plant cell cultures had been assumed to be very limited with regard to the set of compounds that could be used as isotope-labelled exogenous precursors. The general feeling was that very few, if any, exogenous compounds beside sucrose could be absorbed and utilized efficiently.

We have found that ribose is an excellent precursor for plant cell studies. By comparison with glucose as a precursor, ribose has the potential to contribute fragments containing more than three contiguous ^{13}C atoms via the pentose phosphate cycle. Glucose, on the other hand, is predominantly metabolized via glycolysis in plant cell cultures, thus generating primarily 3 carbon fragments.

On the basis of our results, DAHP can be ruled out as a precursor of chelidonic acid. Moreover, sedoheptulose also appears very unlikely as a precursor. The generation of sedoheptulose 7-phosphate specifically carrying a 4-carbon block supplied from [U-$^{13}C_5$]ribose/ribulose could be explained by the pentose phosphate cycle via the intermediate formation of [U-$^{13}C_4$]erythrose 4-phosphate.

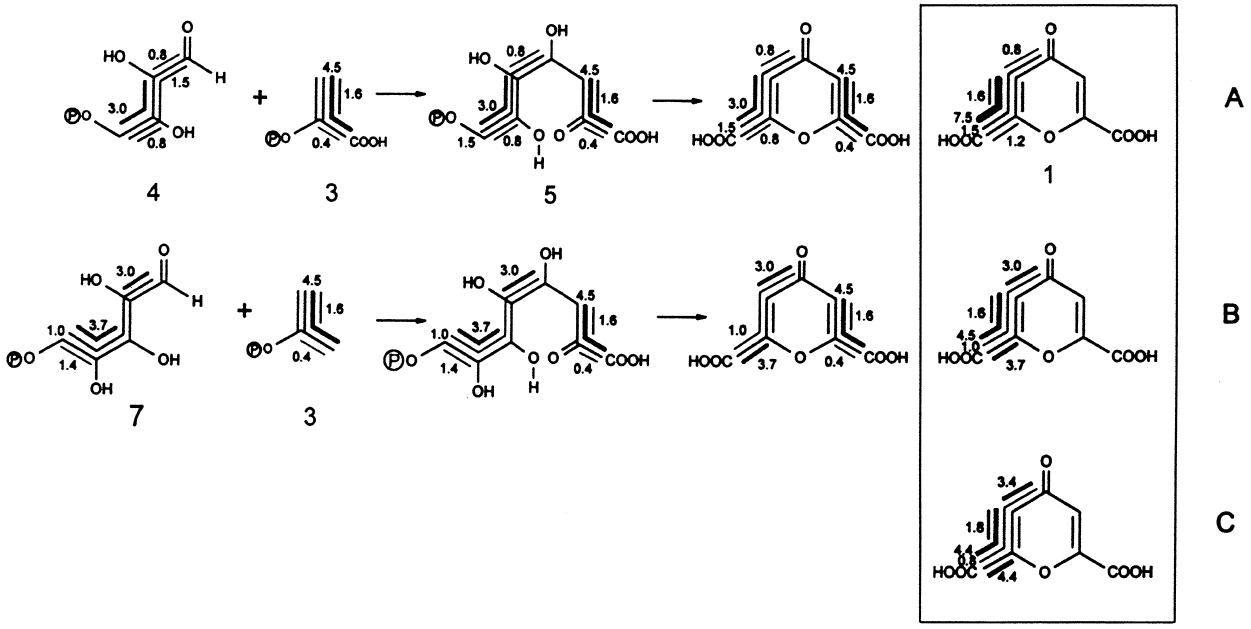

Fig. 7. ^{13}C Labelling patterns of chelidonic acid from the experiment with [U-$^{13}C_6$]glucose. (a) Prediction via a biosynthetic pathway starting from erythrose 4-phosphate (**4**) and phosphoenolpyruvate (**3**); (b) prediction via ribose 5-phosphate (**7**) and phosphoenolpyruvate (**3**); (c) observed. For further details, see Fig. 5 and text.

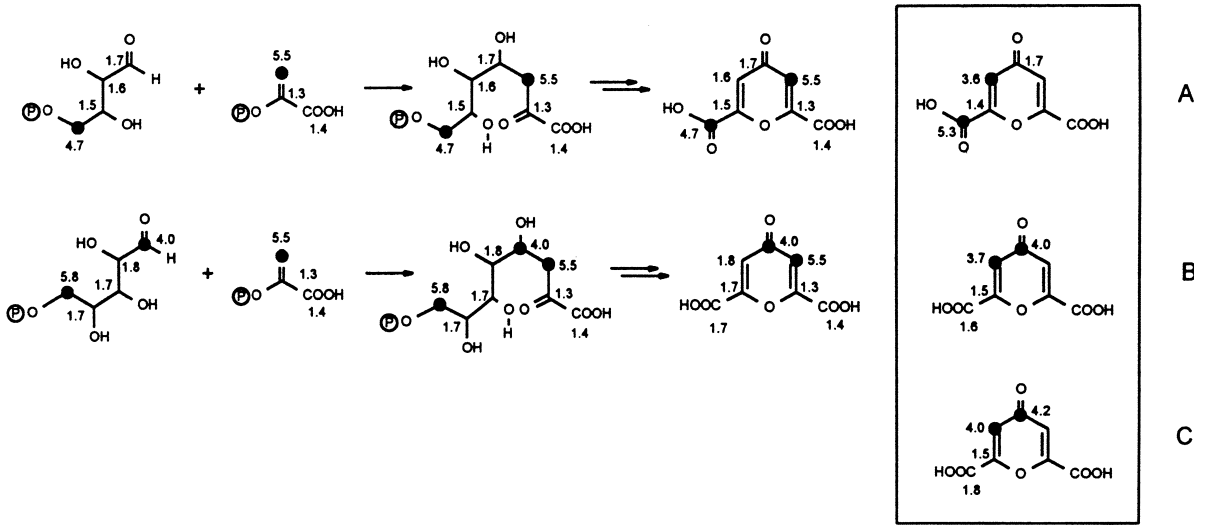

Fig. 8. ^{13}C Labelling patterns of chelidonic acid from the experiment with [1-^{13}C]glucose. (a) Prediction via erythrose 4-phosphate and phosphoenolpyruvate; (b) prediction via ribose 5-phosphate and phosphoenolpyruvate; (c) observed. Filled circles indicate significantly ^{13}C enriched atoms (> 3% ^{13}C abundance). Numbers indicate ^{13}C abundances. For more details, see Fig. 7 and text.

However, sedoheptulose could also be obtained directly from a pentose phosphate resulting in the formation of $^{13}C_5$-chelidonic acid. We have no evidence whatsoever for the presence of a chelidonic acid isotopomer with five contiguous ^{13}C atoms from either [U-$^{13}C_5$]ribose/ribulose or [U-$^{13}C_6$]glucose. Confirming this hypothesis, ^{13}C labelled sedoheptulose could not be incorporated into chelidonic acid (Table 4).

On the other hand, the data support the assembly of the chelidonic acid carbon skeleton from a pentose or pentose phosphate and phosphoenolpyruvate via a hypothetical mechanism summarized in Fig. 11. The proposed condensation between a pentose phosphate and phosphoenolpyruvate is analogous to the well-documented formation of DAHP from erythrose phosphate and phosphoenolpyruvate in the shikimate pathway of aromatic acid biosynthesis. The terminal carbon atom of the pentose precursor could then be removed via dephosphorylation, dehydrogenation and oxidative decarboxylation. Ring closure could occur by hemiacetal formation followed by two dehydrogenation steps. The order of events is hypothetical and additional

studies are necessary in order to elucidate the details of chelidonic acid biosynthesis.

4. Experimental

4.1. Materials

[U-$^{13}C_6$]glucose (99% ^{13}C) and [1-^{13}C]glucose (99% ^{13}C) were obtained from Omicron (South Bend, Indiana).

4.2. Synthesis of [U-$^{13}C_5$]ribose/ribulose

[U-$^{13}C_5$]ribose/ribulose was synthesized enzymatically from [U-$^{13}C_6$]glucose. The reaction mixture contained 100 mM Tris hydrochloride, pH 7.8, 6 mM dithiothreitol, 60 mM $MgCl_2$, 1 g of [U-$^{13}C_6$]glucose, 3 mM ATP, 75 mM phosphoenolpyruvate, 200 mM 2-oxoglutarate, 200 mM ammonium acetate, 5 mM $NADP^+$, 250 U of hexokinase, 250 U of glucose 6-phosphate dehydrogenase, 100 U of 6-phosphogluconate dehydrogenase, 250 U of pyruvate kinase and 250 U of glutamate dehydrogenase in a total volume of 90 ml. The mixture was incubated at 37°C. The pH of the solution was kept at 7.8 by addition of 3 M potassium hydroxide, and the progress of the reaction was monitored by ^{13}C NMR spectroscopy. After 5 h, the glucose had been completely converted into ribulose 5-phosphate. Thirty millilitres of 1 M barium chloride was added, and the white precipitate was removed by centrifugation. The supernatant was diluted with 600 ml of ethanol. The mixture was stirred overnight at 4°C. The white precipitate was collected by centrifugation and dried in vacuo over $CaCl_2$ at 4°C.

The white solid was dissolved in 150 ml of water. Ba^{++} was precipitated by the addition of 0.4 M Na_2SO_4 solution. The precipitate of $BaSO_4$ was removed by centrifugation. To the supernatant, $MgCl_2$ and $ZnSO_4$ were added to a final concentration of 10 and 1 mM, respectively. Phosphoriboisomerase (250 U) and alkaline phosphatase (1000 U) were added, and the mixture was incubated for 4 h at 37°C. The pH was kept at 7.8 by addition of 3 M potassium hydroxide. Aliquots of the mixture were monitored by ^{13}C NMR at intervals. The reaction was terminated after 4 h. Dowex 1X8 (OH^- form, 94 g) and Dowex 50WX8 (H^+ form, 70 g) was added, and the suspension was shaken for 15 h and then filtered. The filtrate was lyophilized.

4.3. Synthesis of [2-^{13}C]sedoheptulose (by a modified procedure from Wolfrom et al., 1952)

A solution containing 3 g of ribose in 10 ml of water was cooled to 4 °C. A cold solution of 1.31 g of K^{13}CN in 10 ml of distilled water was added, and the mixture was stirred at 4°C for 24 h. The reaction mixture was then boiled under reflux for 8 h. The solution was cooled, passed through a column of Amberlite IR-120 (Ca^{++}-form), and concentrated under reduced pressure. The solution (25 ml) was kept at 4°C for crystallization. Calcium[1-^{13}C]-D-altronate was collected as white crystals in 49% yield (1.8 g).

Calcium[1-^{13}C]altronate (1.6 g) was dissolved in 100 ml of hot water and applied to a column of Dowex 1X4 (Cd^{++}-form). The column was developed with 300 ml of water. The eluate was concentrated under reduced pressure. The residue was repeatedly suspended in 50 ml of benzene and concentrated under reduced pressure. Crystalline cadmium [1-^{13}C]D-altronate (1.6 g) was suspended in 30 ml of acetic acid anhydride. Dry HCl gas was passed slowly through the agitated slurry at 10°C for 15–20 min and at 50°C for 1 h. The reaction mixture was then stirred at room temperature for 16 h. The solution was concentrated under reduced pressure. Water (100 ml) was added, and the suspension was stirred at room temperature for 30 min. The mixture was extracted with CH_2Cl_2. The organic phase was washed with water and dried over Na_2SO_4. Removal of solvent under reduced pressure yielded [1-^{13}C]pentaacetyl-D-altronic acid as a colorless oil (2.6 g; 85%). ^{1}H NMR ($CDCl_3$, 360 MHz): δ, 5.69 (^{1}H, *d*, 2-H, $J = 8.0$ Hz), 5.36 (^{1}H, *dd*, $J1 = 8.0$ Hz, $J2 = 2.8$ Hz, 3-H), 5.22 (^{2}H, *dd*, $J1 = 8.0$ Hz, $J2 = 2.4$ Hz), 4.40 (^{1}H, *dd*, $J1 = 10.0$ Hz, $J2 = 2.8$ Hz), 4.20 (^{1}H, *dd*, $J1 = 8$ Hz, $J2 = 10$ Hz). ^{13}C NMR ($CDCl_3$, 96 MHz): δ, 172 (1-C*); 170.77; 170.20; 169.40; 168.10; 168.08; 70.03; 69.60; 69.10; 68.70; 61.61; 20.76; 20.51; 20.77

[1-^{13}C]Pentaacetyl-D-altronic acid (406 mg) was dissolved in 20 ml of toluene. Freshly distilled $SOCl_2$ (5 ml) was added, and the solution was heated under reflux for 2 h. The reaction mixture was concentrated under reduced pressure to yield [1-^{13}C]pentaacetyl-D-altronic chloride as a colorless oil which was dissolved in 50 ml of diethylether containing 500 mg of diazomethane. The solution was stirred at room temperature for 3 h. After removal of the solvent, the residue was dissolved in 10 ml of acetic acid containing 20 mg of Cu(II)acetate. The mixture was heated under reflux for 30 min. The acetic acid was then removed under vacuum, and the

oily residue was purified by chromatography (Silica gel; 200–300 mesh, gradient of ethyl acetate/hexane). Hexaacetyl-sedoheptulose (258 mg, 56%) was obtained as an oil. ^{1}H NMR ($CDCl_3$, 360 MHz) δ, 2.038 (3H, *s*); 2.031 (3H, 3); 2.060 (3H, *s*); 2.107 (3H, *s*); 2.118 (3H, *s*); 2.197 (3H, *s*); 4.210 (1H, *dd*, *J*1 = 12.24 Hz, *J*2 = 4.20 Hz), 4.340 (1H, *dd*, *J*1 = 12.24 Hz, *J*2 = 3.96 Hz), 4.670 (1H, *dd*, *J*1 = 3.96 Hz, *J*2 = 17 Hz), 4.920 (1H, *dd*, *J*1 = 3.96 Hz, *J*2 = 17.0 Hz), 5.226 (1H, *p*, *J* = 3.50 Hz), 5.365 (1H, *dd*, *J*1 = 3.50 Hz, *J*2 = 8.8 Hz); 5.460 (1H, *dd*, *J*1 = 2.00 Hz, *J*2 = 4.20 Hz); 5.645 (1H, *dd*, *J*1 = 8.80 Hz, *J*2 = 2.00 Hz). ^{13}C NMR ($CDCl_3$, 96 MHz): δ, 197.8 (2-C*); 170.5; 169.9; 169.6; 169.1; 168.2; 168.0; 74.25; 69.70; 68.57; 66.83; 66.33; 61.33; 20.29; 20.34; 20.47; 20.53; 20.63; 20.72.

[2-^{13}C]Hexaacetyl sedoheptulose (100 mg) was dissolved in 15 ml of methanol. Two-hundred milligrams of sodium methoxylate was added, and the solution was stirred at 4°C for 16 h. The reaction mixture was then kept at 4°C for 2 days. Methanol was removed under vacuum. The oily residue was dissolved in 4 ml of water. The solution was applied to a column of Dowex 1X4 (H^+-form). The elute was concentrated and purified by paper chromatography (Whatman paper No. 4) using pyridine–*n*-butanol–H_2O (2:5:1.8, v/v) as mobile phase. Sedoheptulose was visualized with $AgNO_3$/NaOH reagent and orcinol spray. [2-^{13}C]Sedoheptulose (28 mg, 62% yield) was obtained by elution with water.

4.4. Plant cell cultures

A cell suspension culture of *L. aestivum* cells growing in LS medium (pH 6.0) was gradually adapted to growth with glucose as carbon source over a period of 2 months. Cell suspensions were incubated on a gyratory shaker (130 rpm) at 22°C in continuous light. Doubling of cell mass required 4 weeks under these conditions.

4.5. Labeling experiments

Cells of *L. aestivum* (19 g) grown on D-glucose (natural ^{13}C abundance) as carbon source were transferred into a 250 ml Erlenmeyer flasks containing 75 ml of autoclaved LS medium (Linsmaier and Skoog, 1965) without sugar. ^{13}C-Labeled precursors were diluted with unlabeled nutrients in 6 ml of water, filter-sterilized and added (Table 1). After 1 month, the cell culture was transferred into 250 ml of the same medium (Table 1). The cell suspension was harvested by suction and was washed with a small amount of water.

4.6. Isolation of chelidonic acid

Wet *L. aestivum* cell mass (20 g) was macerated in 150 ml of hot water. The crude extract was centrifuged at 13,000 rpm for 30 min. The supernatant was applied to a column of Dowex 1X4 (12 × 1.1 cm, 200–400 mesh, H^+-form). The column was washed with 150 ml of water and developed with 150 ml of 2 M HCl. The eluate was concentrated under reduced pressure. The residue was purified by paper chromatography (Whatman paper No. 3) using 30% aqueous 2-propanol as mobile phase. Chelidonic acid was visualized with 5% aqueous KOH (R_f = 0.5, yellow band). The band of chelidonic acid was eluted with water. The eluate was concentrated under reduced pressure, and the crude product was recrystallized from ethanol. Typically, 10 mg of chelidonic acid were obtained from 20 g of *L. aestivum* cells (wet weight).

4.7. Isolation of amino acids

Amino acids were isolated from cell mass as described elsewhere (Eisenreich et al., 1991).

4.8. NMR spectroscopy

^{1}H and ^{13}C NMR spectra were recorded at 500.13 and 125.76 MHz, respectively, with a Bruker DRX500 spectrometer. Chelidonic acid was measured in D_2O; tyrosine, tryptophan and aspartic acid were measured in 0.1 M NaOD; other amino acids were measured in 0.1 M DCl.

4.9. Determination of ^{13}C enrichment

^{13}C Enrichments for all carbon atoms of biosynthetic me-tabolites were determined by quantitative NMR spectroscopy as described earlier (Eisenreich and Bacher, 2001). NMR signal assignments for chelidonic acid were based on two-dimensional HMQC, HMBC, and INADEQUATE experiments.

Equilibrium between basic nitrogen compounds in lupin seeds with differentiated alkaloid content

Tadeusz Aniszewski [a,*], Danuta Ciesiołka [b], Krzysztof Gulewicz [b]

[a] *Laboratory of Applied Botany, Department of Biology, University of Joensuu, PO Box 111, 80101 Joensuu, Finland*
[b] *Laboratory of Phytochemistry, Institute of Bioorganic Chemistry, Polish Academy of Sciences, 61-704 Poznań, Poland*

Received 27 July 2000; received in revised form 4 December 2000

Abstract

The results of studies on the content of the nitrogen basic compounds, viz. quinolizidine alkaloids, biogenic polyamines and basic amino acids in lupin seeds are presented. The investigations concerned three lupin species (*Lupinus angustifolius* L., *Lupinus albus* L. and *Lupinus luteus* L.) and 10 bitter and sweet cultivated varieties. Content of quinolizidine alkaloids in *L. angustifolius* ranged from 11.4 to 19.6 μg mg^{-1} dw (bitter cultivars), from 0.18 to 0.47 μg mg^{-1} dw (sweet), in *L. albus* from 0.58 μg mg^{-1} dw (sweet) to 29.6 μg mg^{-1} dw (bitter) and in *L. luteus* from 0.59 (sweet) to 14.7 μg mg^{-1} dw (bitter). Total biogenic polyamine content ranged in *L. angustifolius* from 2773.9 to 3180.2 pmol mg^{-1} dw (bitter) and from 315.0 to 599.0 pmol mg^{-1} dw (sweet), in *L. albus* from 432.6 pmol mg^{-1} dw (sweet) to 1832.0 pmol mg^{-1} dw (bitter) and in *L. luteus* from 506.9 pmol mg^{-1} dw (sweet) to 2091.8 pmol mg^{-1} dw (bitter). Total basic amino acids varied in *L. angustifolius* from 1034.3 to 1704.6 pmol mg^{-1} dw (bitter) and from 1761.9 to 2101.9 pmol mg^{-1} dw (sweet), in *L. albus* from 696.9 pmol mg^{-1} dw (bitter) to 1269.2 pmol mg^{-1} dw (sweet) and in *L. luteus* from 927.6 pmol mg^{-1} dw (bitter) to 1598.3 pmol mg^{-1} dw (sweet). We found a close dependence between alkaloid content and level of biogenic polyamines and basic amino acids in all three lupin species tested. All bitter lupin seeds also contain high level of biogenic polyamines but a low content of basic amino acids. The reverse relationship in sweet lupin seeds was found. The findings demonstrate that lupin nitrogen basic compounds are in steady equilibrium and that change of content in one compound leads to corresponding change in the content of another. © 2001 Elsevier Science Ltd. Keywords: *Lupinus angustifolius*; *Lupinus albus*; *Lupinus luteus*; Leguminosae; Lupins; Basic nitrogen compounds; Basic amino acids; Biogenic polyamines; Quinolizidine alkaloids

1. Introduction

Nitrogen basic compounds constitute an integral part of all plants. They include protein amino acids, such as arg, lys, his, and non protein amino acids, such as orn, its homologues (α-,β-diaminopropylic acid, α-,γ-diaminobuturic acid), α-*N*- and δ-*N*-acyl derivatives and 5-hydroxyarginine, homoarginine and lathirine and 6-*N*-acyl lysine and 5-hydroxylysine derivatives. Most of the non protein amino acids occur in numerous genera of *Lathyrus*, *Vicia* and others. They are condensed nitrogen reserves and show strong lathyrogenic properties (Fowden, 1970, 1974). Nitrogen basic compounds also include metabolic products of amino acids, i.e. biogenic amines and alkaloids. Biogenic amines are positively charged cellular components, which makes it hard to elucidate their possible cellular functions besides a straight forward cation effect (Villanueva et al., 1978; Friedman and Oshima, 1989). Di- and polyamines — put, cad, spd and spm are metabolic products of basic amino acids and are characterized by an unpleasant smell and toxic properties. This toxicity is manifested as nephotoxicity, hypothermia and sedation (Janne et al., 1978). The quinolizidine alkaloids (QAs) occurring in lupins are lys metabolic products. One of the di-amines, cad, is also a precursor of QAs in the alkaloid biosynthesis pathway. Basic amino acids (BAAs), biogenic polyamines (BPAs) and QAs are nitrogen reserves in plants. These reserves also play a very important physiological role (Wink, 1993; Aniszewski, 1994, 1995; El Ghachtouli et al., 1995; Tarenghi and Martin-Tanguy, 1995; Wang et al., 2000).

Abbreviations: agm, agmatine; arg, arginine; BAAs, basic amino acids; BPAs, biogenic polyamines; cad, cadaverine; dw, dry weight; his, histidine; lup, lupanine; lys, lysine; put, putrescine; QAs, quinolizidine alkaloids; orn, ornithine; spd, spermidine; spm, spermine.

Previous studies have been concerned with BAAs and QAs as these compounds have been considered as very important from the viewpoint of the potential use of lupins (Aniszewski, 1993a,b; Saito et al., 1993; Chango et al., 1993; Muzquiz et al., 1994; Aniszewski, 1998). In contrast, BPAs of lupins have not previously been studied although the effect of polyamines on animal cell growth, cell differentiation and their regulatory role in plants have been suggested (Bachrach et al., 1989; Hölttä and Sistonen, 1989; Galston and Sawhney, 1990). The question of the possible dependence of different nitrogen basic compounds in lupins has not been studied either, although it would seem to be very important from both the physiological and chemical points of view. The lack of empirical results on the relationship between nitrogen basic compounds in lupins was a strong motivation for us to set up the present experiments. The main aim of our work was to determine the correlation between the content of nitrogen basic compounds in 10 lupin cultivars from 3 lupin species (*Lupinus angustifolius* L., *Lupinus albus* L. and *Lupinus luteus* L.). The choice of the lupin as a test plant was not accidental. Lupin species are characterised by amounts of alkaloids ranging from 0.0000% to 4.0% of dry matter (Aniszewski, 1993a; Christiansen et al., 1999), various amino acids (Aniszewski, 1993b) and, probably varying amounts of polyamines. We addressed two basic questions in this study: (1) do changes in the amount of QAs affect changes in amount of BPAs and BAAs? and (2) what is the basic mechanism of this potential dependence between QAs, BPAs and BAAs in lupins?

2. Results

The compounds detected were products of the lys metabolic pathway and of the arg metabolic pathway. Cad and QAs are from the lys metabolic pathway and BPA from the arg metabolic pathway (Fig. 1).

The content of QAs clearly varied between and within species, according to the breeding quality of the cultivars. Table 1 shows the content of QAs in the three lupin species tested. *L. angustifolius* was represented by three bitter and three sweet cultivars. The content of QAs in these cultivars ranged from 0.18 in Emir to 19.6 μg mg^{-1} dw in Mirela. The mean total content of QAs in the bitter cultivars was about 40 times higher than in the sweet cultivars. *L. albus* and *L. luteus* was represented by one

Table 1
Content of quinolizidine alkaloids (QAs) in lupin species tested

Species	Cultivars	Alkaloid content (μg mg^{-1} dw)	±S.D.	Mean total QA content in cultivar group (μg mg^{-1} dw)
Lupinus angustifolius	Mirela	19.6	0.29	
	Ernani	12.3	0.205	
	Trebatsch	11.4	0.205	
	Bitter cultivar (mean)			14.4
	Emir	0.18	0.0032	
	Ernani 1	0.43	0.00795	
	Topless	0.47	0.0067	
	Sweet cultivar (mean)			0.36
Lupinus albus	Bac	29.6	0.53	
	Bitter cultivar (mean)			29.6
	WTD	0.58	0.00105	
	Sweet cultivar (mean)			0.58
Lupinus luteus	Milfontes	14.7	0.24	
	Bitter cultivar (mean)			14.7
	Parys	0.59	0.009	
	Sweet cultivar			0.59

bitter and one sweet cultivar. In the case of *L. albus* the bitter cultivar contained about 50 times more QAs than the sweet one. The content of QAs in bitter *L. luteus* was about 25 times higher than in the sweet cultivar.

The content of BPAs clearly varied between and within species, according to the breeding quality of the cultivars (Table 2). As we can see, the bitter cultivars contained considerably more BPAs than the sweet varieties. The ratio of mean total BPAs in the three bitter cultivars tested to mean total BPAs in the three sweet ones was about 6.0 in the case of *L. angustifolius* L. For *L. albus* and *L. luteus* this ratio was about 4.2 and 4.1, respectively. It is noteworthy that agm and cad was not found in either the sweet or bitter cultivars tested: Bac (*L. albus*) and Milfontes (*L. luteus*). Also put was found only in 4 (2 bitter and 2 sweet) cultivars. In the case of *L. albus* we did not find put in either the bitter or sweet cultivar.

Content of BAAs varied between species and cultivars (Table 3). The results showed that the sweet lupin cultivars contained clearly higher amounts of BAAs in comparison to the bitter ones. For example, the ratio of mean total BAAs in sweet to bitter cultivars was 1.48, 1.83 and 1.72 in *L. angustifolius*, *L. albus* and *L. luteus*, respectively. Among the tested amino acids arg had its highest content in sweet cultivars, especially in the case of *L. angustifolius*.

The difference between bitter and sweet cultivars is very clear in the case of BPAs and BAAs (Tables 2 and 3). It is also evident that all the bitter cultivars of the three lupin species tested contained considerably more BPAs (average 2.4 times) than BAAs. Inversely, in the sweet varieties there were substantially more BAAs (average 3.3 times) than BPAs. The ratio of BPAs corresponding to 1 μg of QAs in sweet to bitter cultivars was 6.62; 12.50 and 6.29 for *L. angustifolius*, *L. albus* and *L. luteus*, respectively. In the case of BAAs this ratio is 59.21, 93.12 and 42.93, respectively.

3. Discussion

The results show that there is a different distribution of free BAAs, lys and arg, and their metabolites in lupin plants. All these compounds are a source of nitrogen and play a very important role in the primary (BAAs) and secondary metabolism (QAs, BPAs). Lys is a basic amino acid synthesed by pyruvate and aspartate (Azevedo et al., 1997). The biosynthesis of orn and arg involves glutamate transformation. Of course, the origin of 2-ketoglutarate for glutamate synthesis continues to be debated (Gálvez et al, 1999; Lancien et al., 2000). However, glutamine and glutamate are considered to be compounds of crucial importance, since they are donors for the biosynthesis of major N-containing compounds, including amino acids, nucleotides, chlorophylls, polyamines, and alkaloids (Ireland and Lea, 1999). Glutamate is a donor for the biosynthesis of both orn and arg. To understand the role of lys, orn and arg in lupin metabolism means taking into account these amino acids as resources for secondary metabolism. As presented in the results, lys is a source for QAs synthesis via cad, which is one of the

[b] Not detected.

BPAs, but from a different pathway than that of the other polyamines studied. Arg and orn are a source of BPA synthesis. QAs are compounds specific only to lupin species whereas BPAs are compounds generally found in plants and animals. Functionally, both these groups of compounds are similar. QAs have a defensive role in lupin and allelopathic functions in relation to biocenosis (Wink, 1993; Aniszewski, 1994, 1995; Wang et al., 2000). BPAs perform a significant control function in plant cell pH and in maintaining balance between anions and cations as well as allelopathic functions in relation to the abiotic and biotic environment (Altman and Levin, 1993; Walters and Mackintosh, 1997). The similarities in the functions of BPAs, QAs and BPAs in lupin plants suggest that the content of one compound is dependent on the content of the others.

The results show that QAs are present in considerable amounts in bitter lupins and small amounts in sweet lupins. Bitter lupins are more primitive and sweet lupins are bred to reduce alkaloid content. It is known that the synthesis of QAs occurs in chloroplasts, from which QAs are transported to the other organs (Wink and Hartmann, 1980). Suzuki et al. (1996) reported that two acyltransferases for QA biosynthesis were not located in chloroplasts, where de novo synthesis of QA skeleton is assumed to take place. The enzyme activity was associated with the mitochondrial fractions and localized in the matrix, as judged from the marker enzyme assay. However, the ECTase activity was not associated with the mitochondrial fractions (Suzuki et al., 1996). Nonetheless, the intracellular transport of QAs is a very important process. In this process ATP energy is used (Barłóg, 1999) and the transportation of assimilates and nitrogen compounds in the phloem takes place (Nalborczyk, 1993). Seed alkaloid content is a result of the balance between synthesis processes in the vegetative organs and the accumulation processes in the seeds (Barłóg, 1999). The synthesis of QAs and their transportation to the seeds is more effective in bitter than in sweet lupins. Rich-alkaloid lupins also contain a high level of free BPAs, which form in the metabolic pathways of arg. We found that the content of total BPAs in the bitter cultivars of three lupin species ranged from 1832.0 pmol mg^{-1}dw in cv. Bac (*L. albus*) to 3180.2 pmol mg^{-1}dw in cv. Mirela (*L. angustifolius* L.). It is known that intracellular polyamine concentrations vary throughout the cell cycle, and polyamine synthesis is a very early event in cell proliferation (Morgan, 1998). On the other hand, it is also known that adequate intracellular levels of BPAs are necessary for the optimal growth and replication of all living organisms, including plants. Bitter lupins grow in stress conditions generally better than sweet lupins (Aniszewski, 1993a). Possibly the high content of BPAs in bitter lupins influences this

Table 3
Content of basic amino acids (BAA) in lupin species tested[a]

[a] Abbreviations: orn, ornithine; lys, lysine; arg, arginine.

better growth. BPAs influence the transcriptional and translational stages of protein synthesis, interact with nucleic acids, stabilize membranes and alter intracellular free calcium. Fruit-ripening and flower-setting processes in plants are modulated by polyamines (Morgan, 1998). On the other hand, the transport mechanisms of BPAs and the means by which polyamine uptake is induced are not clear. Our results show that a high content of QAs and BPAs accompanies a low content of free BAAs. The content of BAAs in bitter cultivars ranged from 696.9 pmol mg^{-1} dw in cv. Bac to 1704.6 pmol mg^{-1} dw in cv. Trebatsch. The low content of free BAAs in bitter cultivars is probably due to their incorporation into the synthesis of QAs (lys) and BPAs (arg and orn).

In contrast to bitter lupins, sweet cultivars show a reverse relationship between the nitrogen basic compounds. The breeding of sweet cultivars from bitter varieties results in a decrease in the content of QAs and BPAs, which is parallelled by an increase in the content of BAAs. This might suggest that the metabolism of lys and arg into QAs and BPAs respectively is very limited (Tables 1–3). This would eventually lead to the observed accumulation of BAAs in the pool of free amino acids in seeds. We are aware that Saito et al. (1993) suggested that the suppressed step for the formation of QAs in sweet plants is neither the various steps prior to the formation of cadaverine nor the specific reactions after the formation of cyclic QAs but is the ring closure reaction from cad to the initial bicyclic and tetracyclic QAs. The concentration of lys does not change in bitter and sweet plants, because protein-amino acid biosynthesis is strictly regulated in the plant cell (Saito et al., 1993). The content of BAAs in sweet cultivars tested by us ranged from 1267.2 pmol mg^{-1} dw in cv. WTD to 2101.9 pmol mg^{-1} dw in cv. Emir, while the content of BPAs was of the order 315–599 pmol mg^{-1} dw of seeds. On the other hand, the greater availability of BAAs might also result in facilitated biosynthesis of lys- and arg-containing proteins. Such a mechanism would explain the higher content of lys and arg in the population of seed protein in sweet cultivars of lupin.

It is worth noticing that the choice of lupin material used in this study was limited to the availability of different varieties of lupins, mainly bitter cultivars (in Poland the bitter variety of *L. luteus* is no longer cultivated and only 1 bitter variety Bac of *L. albus* is grown). Hence, in the case of these species, we tested only 1 bitter and 1 sweet cultivar. In spite of this, the results obtained for these two species shows a similar relationship and are highly compatible with those for *L. angustifolius*.

The data collected so far indicate that a decrease in the content of one group of compounds (QAs and PAs) is parallelled by an increase in the content of BAAs, and vice versa.

4. Experimental

4.1. Plant experimental material

The seeds of three lupin species (*Lupinus angustifolius* L., *Lupinus albus* L. and *Lupinus luteus* L.) were used in the determination of basic nitrogen compounds. These species were represented in the experimental study by two groups of cultivars. One group of cultivars was formed by low-alkaloid cultivars, also known in the literature as "sweet" cultivars and the second group by high-alkaloid cultivars, known as "bitter" cultivars (Aniszewski 1993b). Bitter cultivars are close to native varieties of lupins and sweet cultivars are bred varieties of lupins. Both *L. angustifolius* cv. Emir (sweet) and *L. albus* cv. Bac (bitter) were obtained for research by courtesy of Dr. Stanisław Stawiński of the Przebędowo Breeding Station of the Institute of Plant Breeding and Acclimatization located near Poznań. By courtesy of Dr. Jan Nijaki of the Plant Breeding Station in Wiatrowo near Poznań the following lupin cultivars were obtained for research: *L. angustifolius* cv. Ernani (bitter), *L. angustifolius* cv. Trebatsch (bitter), *L. angustifolius* cv. Topless (sweet), *L. angustifolius* cv. Ernani 1 (sweet), *L. albus* cv. WTD (sweet) and *L. luteus* cv. Parys (sweet). *L. luteus* cv. Milfontes (bitter) was obtained for research by courtesy of Dr Joao Neves Martins of the Agricultural University of Lisbon in Portugal. All seeds were harvested in 1998.

4.2. Analysis of metabolic pathways

The metabolic pathways of his, lys and arg were studied before the present experiments were set up (Nicholson, 1997). The pathways of QAs and BPAs were also analyzed, and on the basis of this analysis their route was constructed.

4.3. QAs analysis procedure

Two grams of lupin seed flour with 100 ml 80% methanol was sonicated by 30 min on a Sonorex Super AK 103H bath. Next, the mixture was filtrated on a Büchner funnel and the lupin flour was washed with methanol to an end volume of 100 ml. In the case of the analysis of bitter lupin varieties 10 ml water was added to 5 ml of extract. After removal of methanol the solution was also adjusted with water to 15 ml. In the case of the analysis of sweet lupin varieties 25 ml of extract was evaporated for removal of methanol and the solution was also adjusted with water to 15 ml.

Fifteen millilitres of alkaloid solution was applied on a column (2×0.8 cm) SCX (Strong Cation Exchanger), Alltech, USA. Before applying the alkaloids the column was activated by 5 ml of methanol and 5 ml of water. After applying the alkaloid sample the column was washed with 5 ml of water, 5 ml of methanol and 2.5 ml of water. The alkaloids were washed with 12 ml of 6% ammonia. The alkaloids were then extracted three times in 12 ml of chloroform. The chloroform was evaporated to dryness under a vacuum. Then 10 μl of caffeine (1 mg/ml) as an internal standard was added and dryed. After drying 40 μl methyl chloride was added to the sample. One microlitre of sample was applied on the GC–MS column.

GC–MS analyses were carried out with a Hewlett Packard gas chromatograph (Model 5890) with a mass selective detector (Model 5971A), equipped with DB-5 fused silica capilary column (30 m×0.25 mm i.d.; J&W, Folsom, CA, USA). The carrier gas was helium at a flow rate of 1 ml/min and the column temperature was programmed from 200°C (held for 2 min) at a rate of 5°C/min to 300°C, which was held for 12 min. The injector temperature was 250°C and the injections were performed in the split (1:20) mode (Stobiecki et al., 1997). Each analysis was done in four replications.

4.4. Free BAAs analysis

One gram of lupin fluor with 20 ml of 0.1% trifluoroacetic acid (TFA) was mixed and extracted for 3.5 h at room temperature. Then the sample was centrifuged at 3000 rpm 20 min on a Janetzky K70. The supernatant was evaporated to dryness. The residue was solved in 10 ml water and applied on a column (3×0.8 cm) with Dowex 50WX8 (H^+). The column was washed in 10 ml of metanol and then 5 ml of water. The amino acids were eluted with 15 ml 7 N of ammonia. The alkaline solution was shaken three times with 15 ml of chloroform to remove the alkaloids. The ammonia layer was than evaporated to dryness. To each sample 50 μl (3 mg/ml) DL-γ-amino-butyric acid (S.A.F. Hoffmann La Roche, Switzerland) was added as an internal standard. The samples were dried in a vacuum overnight. The dried amino acid samples were derivatized with isobutyl alcohol for esterification of carboxyl group. Esterification was performed in 3 N HCl solution in isobutanol at temperature of 100°C for 15 min. Acetylation of amino groups was done in a 300 μl mixture of methylene chloride and trifluoracetic acid anhydride 2:1 (v/v) at a temperature of 110°C for 5 min. After cooling, 1 μl of the reaction mixture was injected onto a GS-MS column. The carrier gas was helium at a flow rate of 1 ml/min and the column temperature was programmed from 100°C (held for 2 min) at a rate of 5°C/min, and at a rate 10°C/min, to 300°C which was held for 2 min. The injector temperature was 250° C and injections were done in the split mode. The analyses were performed in four replications.

4.5. Analysis of BPAs

The extraction of polyamines and their determination on the basis of TLC chromatography were adapted according to the method described by Flores and Galston

(1982), Friedman et al. (1986) as follows: lupin seeds were freezed in liquid nitrogen after which they were ground 2×15 s in a mill. Two hundred milligrams of lupin flour were scaled and mixed with 2 ml of 5% $HClO_4$ and extracted for 1 h in an ice bath. The sample was then centrifuged at 3000 rpm 20 min on a Janetzky K70. The supernatant was received and centrifuged again (supernatant is stable for about 6 months at −20°C). Dansylation of the polyamines obtained was done as follows: 200 μl of polyamine extract at $HClO_4$ was mixed with 400 μl of dansyl chloride (5 mg/ml) in acetone, prepared fresh. After that 200 μl of saturated Na_2CO_3 was added. The mixture was briefly vortexed and incubated in darkness overnight. Excess dansyl chloride was removed by reaction with 100 μl (100 mg/ml) of added proline and incubation in darkness for 30 min at room temperature. The dansylpolyamines were then extracted in 0.5 ml benzene for 1 min. Benzene fractions were stored in glass vials (stable for 1 month at −20°C). The standards (spm, spd, put, cad, agm) were dansylated in the same way. Twenty nanomol of standard were used for each reaction. Samples were put on DC-Plastikfolien Kieselgel (20×20 cm) plates in amounts of 30, 40, 50 and 60 μl. TLC was developed for about 1 h with either of two solvent systems: chloroform:triethylamine (25:2 v/v) or cyclohexane:ethylacetate (5:4 v/v). After TLC, the dansylpolyamine bands were scraped and eluted in 2 ml ethylacetate. The polyamines were quantified with a F-2000 Fluorescence Spectrometer, Hitachi (exitation at 350 nm and emission at 495 nm).

4.6. Reagents and standards

Reagents and standards used in the determination were DL-ornithine (Sigma), DL-citrulline (Sigma), agmatine (Sigma), spermine ×4 HCl (Sigma), spermidine ×3 HCl (Sigma), putrescine (Sigma), caffeine (Sigma), L-arginine (Aldrich), lysine (Aldrich), DL-γ-amino-butiric acid (S.A.F. Hoffmann La Roche, Switzerland). Four alkaloids used as standard were isolated and purificated from lupin seeds in the Institute of Bioorganic Chemistry of the Polish Academy of Sciences in Poznań. The purity of lupanine was 97.1%, 13-hydroxylupanine, 95.1%, angustifoline, 95.3% and sparteine, 96.4%.

4.7. Recovery tests

Recovery tests for QAs, BAAs and BPAs were done. Lup was used in recovery tests for QAs, lys for BAAs and put for BPAs. When the lup was passed thorough the experimental procedure, recovery was 96.0%. When the lup was mixed with seed flour and passed through the experimental procedure, recovery was 95.2%. The respective recoveries for lys were 95.1 and 94.7% and for put 93.7 and 93.2%. The recoveries were high and proved that analytical methods worked well.

Received 26 April 2000; received in revised form 3 November 2000

Abstract

From the rootstock of *Scabiosa columbaria* L. loganin and sweroside were isolated. Sweroside showed moderate antibacterial activity. Pure sweroside was converted to the sweroside aglycone 1-acetoxy derivative (DABCO/Ac_2O) after hydrolysis of the glucose unit. X-ray crystallography of the monoacetate showed unambiguously that it had been transformed to a new seco-iridoid having the novel *trans* diaxial configuration for the protons on C-1, C-9 and C-5. The mechanism for the rearrangement is discussed. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Scabiosa columbaria*; Dipsaceae; Loganin; Sweroside; Rearrangement; Sweroside aglycone-1-acetate

1. Introduction

Scabiosa columbaria L. is a perennial herb, which grows to a meter in height, flowers in midsummer, and has a large woody rootstock in the form of a tuber. Traditionally root decoctions are used for sterility. Ointments made from the charred tubers are also applied to venereal sores (Hutchings, 1996). Chemically almost nothing is known about the plant although the glycoside scabiosin has been isolated from it (Watt and Breyer-Brandwijk, 1962).

We started investigating the plant because it grows profusely in many parts of South Africa, and, despite its frequent use by the Zulu people, the chemistry of its constituents is almost unknown (Van Wyk, 1997).

2. Results and discussion

2.1. Isolation of loganin and sweroside

It was immediately clear from the preliminary examination of the extracts ($CHCl_3$)/EtOH) that *Scabiosa columbaria* contained several iridoids, mostly in the form of their glycosides. Fractionation of the extract yielded pure loganin **1a**. This compound was first isolated from the fruits of *Strychnos nux vomica* (Dunstan and Short, 1883). The full structure, stereochemistry and biosynthesis was only elucidated some 86 years later (Battersby and Hall, 1969).

Also present in the extract we found the seco-iridoid sweroside **2a** (Inouye et al., 1970) and this is the first isolation from the family Dipsaceae. It was accompanied by a complex mixture of other iridoids, all possessing an aldehyde functionality. This latter mixture and sweroside, **2a**, showed only moderate antibacterial activity when tested against a selection of gram-positive and gram-negative bacteria.

2.2. Rearrangement of sweroside on acetylation and X-ray analysis of the resultant product

Iridoids and seco-iridoids all possess the labile acetal moiety and are frequently subjected to varying degrees of acid or base treatment during work-up or subsequent manipulation. In this connection Bianco (1994) has published a review article which deals specifically with acid hydrolysis and the subsequent rearrangements which can occur.

We report here on the rearrangement which sweroside aglycone **2b** undergoes during acetylation in the presence

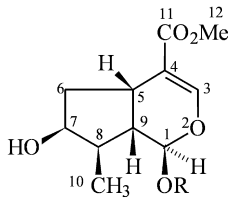
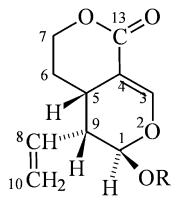
PII: S0031-9422(00)00460-X

of the base diazabicyclooctane (DABCO). (DABCO is easier to remove at the end of the reaction than pyridine). The reaction afforded the highly crystalline 1-acetoxy sweroside aglycone, a new compound with novel stereochemistry. This seco-iridoid **3**, has the protons at C-1, C-9 and C-5 in the axial orientation, giving rise to an all *trans*-configuration at these three carbon atoms. This stands in contrast to the "normal" 1,9-*trans*-9,5-*cis* arrangement found in iridoids and seco-iridoids in which the protons on C-1, C-9 and C-5 assume *eq.eq*. and *ax* orientations respectively. Since **3** was obtained as colourless orthorhombic crystals, amenable to X-ray analysis, the relative stereochemistry could be established with certainty (Fig. 1). Comparison with the extensive published NMR data (Ma et al., 1994) confirmed the view that "our" parent sweroside indeed had the accepted 1,9-*trans*-9,5-*cis* stereochemistry. Subsequent formation of **3**, with its 1,9-*trans*-9,5-*trans*-configuration was, therefore, attainable only if rearrangement had occurred during acetylation.

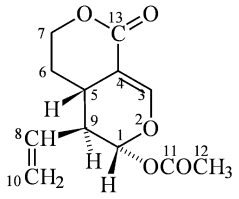
The seco-iridoid decentapicrin A, a compound for which X-ray data was available is shown in (**4**) (Van der Sluis and Labadie, 1981; Kojic-Prodic et al. 1985). This compound is identical in all respects to sweroside and differs only in the nature of the glycoside at C-1. A comparison of the magnitude of the coupling constants $J_{1,9}$ and $J_{5,9}$ respectively for **4** and **3** shows clearly a H-1/H-9 (*trans* di*equatorial*), H-5/H-9 (*cis axial*, *equatorial*) stereochemistry for **4**, compared with a *trans diaxial*, *trans diaxial*, arrangement for the same proton on **3**.



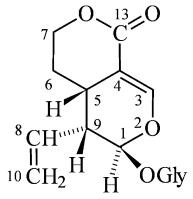
1a R = Glucose (Loganin)
1b R = H (aglucone)
1c R = $COCH_3$



2a R = glucose (sweroside)
2b R = H (aglucone)



3



Decentapicrin **4**

We were reassured that the proposed rearrangement occurs *during* the acetylation procedure, and not earlier, by showing that the sweroside aglycone (**2b**) had a stereochemistry unchanged from that of the parent sweroside (**2a**). A comparison of ^{1}H NMR spectral data for sweroside (**2a**), sweroside aglycone (**2b**) (see Section 3), and the rearranged acetate (**3**) (Table 1) confirms the

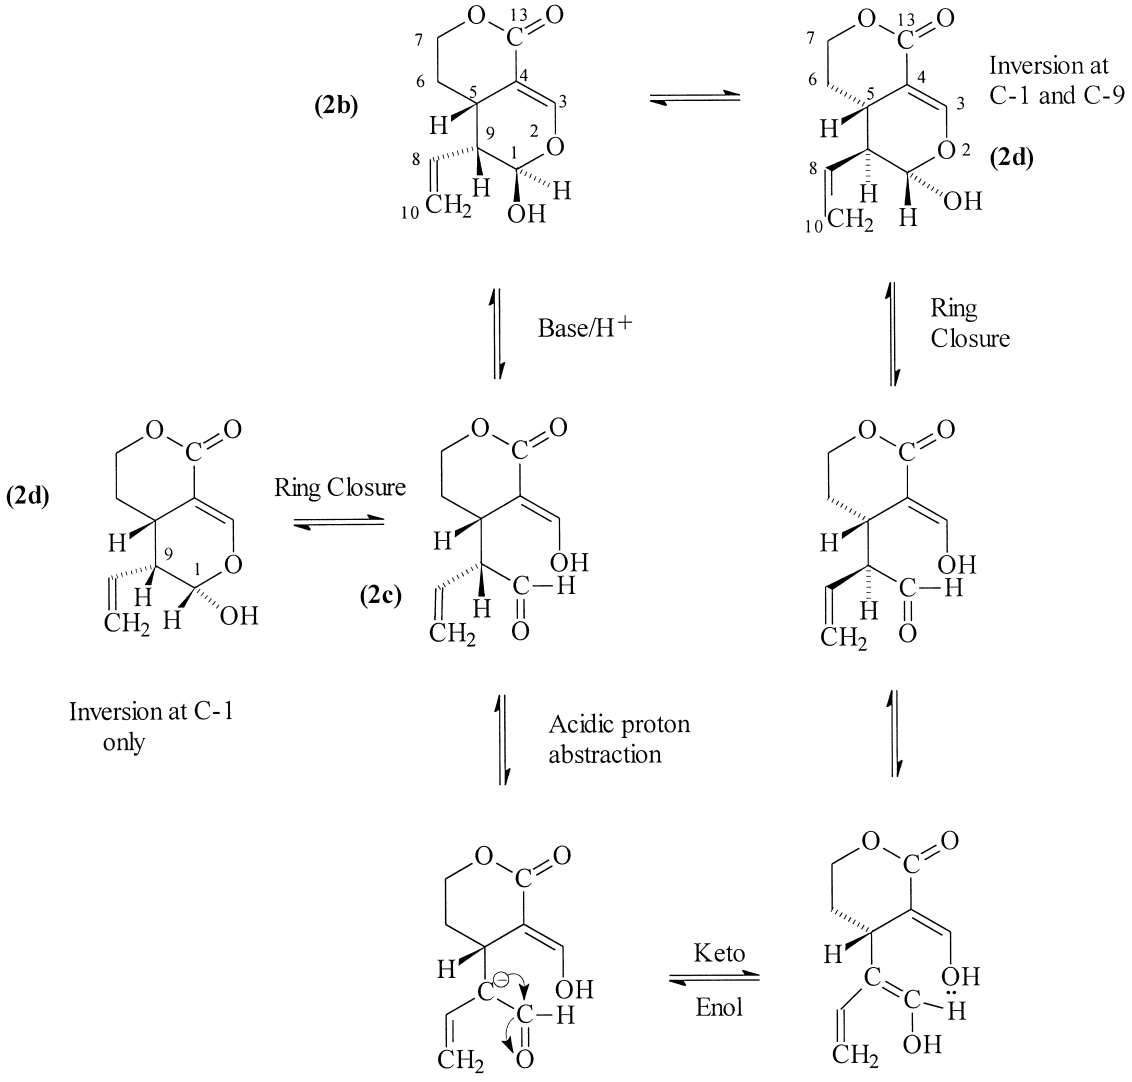
stereochemistry shown for (**2a**), (**2b**) and **3**. There is no doubt that the aglycone still retains the 1,9 *trans* d*ieq*. arrangement prior to acetylation. It is suggested that the rearrangement during acetylation proceeds as shown in Scheme 1.

1. The aglycone of sweroside, **2b**, under influence of the base (DABCO) ring opens to generate **2c**.
2. In a final step, prior to attachment of the acetyl moiety, **2c** loses an acidic proton at C-9, undergoes keto-enol tautomerism and ring-closes to **2d** (and also presumably the isomer of opposite configuration).

We suggest that a series of products, all in equilibrium with one another, are formed. On acetylation, and quite fortuitously, one of these products, **3**, crystallised out from the reaction mixture in reasonable yield. The product was amenable to X-ray and NMR analysis.



Scheme 1. Mechanism of inversion at C-1 and C-9.

Since acetylation usually occurs in the presence of pyridine (rather than DABCO/Ac_2O) the reaction on sweroside aglucone was also carried with this reagent. To our pleasant surprise the rearranged all *trans* sweroside **3** was obtained in 73% yield.

2.3. Rearrangement in the NMR tube

In order to study the effect of DABCO on sweroside aglycone **2b** (with intact stereochemistry at C-1, C-9 and C-5) the compound was dissolved in $CDCl_3$ in an NMR tube and DABCO only added. Progress of the reaction was monitored over 10 h. Small changes in the NMR spectrum were apparent within minutes. The H-1 signal disappeared rapidly, and after 40 min several new peaks appeared in the region δ 6.5–9.55. The most significant of these was a doublet at δ 9.4. ($J = 3.82$ Hz). This peak gradually increased in amplitude and after 4.5 h a further peak was visible at δ 9.87. Both peaks are presumed to be aldehyde peaks and their presence is regarded as evidence that ring opening occurs (Scheme 1). The effect is in line with earlier proposals (Bianco, 1994).

2.4. Iridoids with an *all*-trans ring fusion in nature

The first naturally-occurring iridoid of the above nature was reported by Foderaro et al. (1992). These iridoids are rare and the authors make the observation that "there are no known instances of epimerisation at C-5 among the hundreds of iridoid isolations". In a subsequent report Foderaro and Stermitz (1992) present detailed spectral data to support their finding. They record a $J_{1,9}$ coupling constant of 9.9 Hz for the compound (5dH)-6-*epi*dihydrocornin. The X-ray structure of a suitable derivative revealed clearly the all *trans* diaxial nature of the protons on C-1, C-9 and C-5.

The seco-iridoid **3**, produced synthetically, thus joins a small group of naturally-occurring iridoid compounds with distinctive stereochemical features and hopefully will alert other researchers to stereochemical changes which can occur during manipulation of iridoids.

2.5. Attempts to ring-open loganin with DABCO

Loganin aglycone **1b** (from β-glucosidase hydrolysis of loganin) was subjected to the same acetylation conditions of DABCO/acetic anhydride as described for sweroside aglycone. No rearrangement occurred and the 1-acetoxy derivative was isolated in good yield and high purity. The ^{1}H NMR spectrum differs very little from that of the parent aglucone apart from H-1 which showed the anticipated downfield shift from δ 4.98 to δ 6.07. The $J_{1,9}$ coupling constant is 3.5 Hz and in loganin itself it is 4.5 Hz (Boros and Stermitz, 1990). In this instance it is possible that the iridoid skeleton (as in loganin) is less susceptible to ring opening and subsequent rearrangement than the seco-iridoid system as in sweroside aglucone.

2.6. Biological activity tests

Since aq. root decoctions of Scabiosa columbaria find a traditional use in the treatment of venereal sores (Hutchings, 1996), some of the isolated components (sweroside, loganin and a semi-purified mixture) were tested for antibacterial activity. At concentrations of 0.001–0.50 mg/ml none of the compounds showed any activity. At a conc. of 1.0 mg/ml (minimum inhibitory concentration, MIC), sweroside and the "mixture" were active against *Bacillus cereus*, *B. pumulus*, *B. subtilis*, *Micrococcus kristinae*, *Staphylococcus aureus* (gram positive) and *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aerugenosa*, *Enterobacter cloacae* (gram negative). Neither inhibited the growth of Serratia marcescence. These activities can be regarded as "moderate" only.

3. Experimental

3.1. General

^{1}H and ^{13}C NMR spectra were recorded on Varian-200 and Varian-500 spectrometers. High resolution mass spectra were recorded on a Kratos MS 80 RF double-focussing magnetic sector instrument at 70 eV. For optical rotations a Perkin Elmer 241 digital polarimeter was used.

3.2. Plant material

Scabiosa columbaria (rootstock) was collected in an open field in the Hayfields area of Pietermaritzburg during January 1999. It was identified by Dr Trevor Edwards, Curator of the Bews Herbarium at the University of Natal. A voucher specimen (SED No. 6) of the whole plant has been deposited in the Herbarium.

3.3. Extraction and isolation

Freshly-collected tubers (850 g) were milled and extracted with 95% EtOH–$CHCl_3$ (1:1) for 6 days at RT. The solution was filtered and the lower phase separated off and concentrated (16 g). A portion of this material (9 g) was fractionated on a dry silica gel (Merck Silica Gel 9385) column using CH_2Cl_2–MeOH (100: 0→85: 15) as eluent. Three fractions were collected: fraction (i) afforded loganin aglycone (**1b**) (35 mg) after purification on the chromatron [CH_2Cl_2–Et_2O(1: 1)]; fraction (ii) gave loganin (**1a**) (70 gm) following separation on the chromatotron [CH_2Cl_2–MeOH (93: 7)]; fraction (iii) gave a crude mixture

(726 mg) which on separation as above [CH_2Cl_2–MeOH (90:10→85:15)] afforded impure sweroside (**2a**) (140 mg) and a mixture of other compounds unidentified as yet (280 mg). Further separation on the chromatotron [CH_2Cl_2–MeOH (93:7→90:10)] gave pure sweroside (**2a**) (77 mg).

3.4. Studies on loganin

The properties of loganin (above, mp 220°C) were identical in all aspects (NMR, mass spectra) to values published in the literature (Boros and Stermitz, 1990). The optical rotation, $[\alpha]_D^{25} = -62.4°$ ($c = 0.0004$, MeOH), is somewhat lower than the literature value of −82.8°C (El-Naggar and Beal, 1980).

Loganin (**1a**) (230 mg) was suspended in water pH 6.8 (5 ml) and β-glucosidase (30 mg) added. The solution was stirred at 37°C for 5 h, then exhaustively extracted with ether to give impure loganin aglucone. The latter was purified on the chromatotron [(CH_2Cl_2–Et_2O (5:4)] to give pure loganin aglucone (**1b**) (98 mg), oil. ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 1.15$ (3H, *d*, $J = 6.6$ Hz, Me), 1.53 (1H, *m*, H-6a), 2.30 (1H, *m*, H-6b), 1.95 (1H, *m*, H-8), 1.95 (1H, *m*, H-9), 3.17 (1H, *m*, H-5), 3.72 (3H, s, CO_2Me), 4.13 (1H, *m*, H-7), 4.98 (1H, *d*, $J = 4.9$ Hz, H-1), 7.41 (1H, *d*, $J = 1.3$ Hz, H-3). ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = 13.3$ (C-10), 31.5 (C-5), 41.4 (C-6), 42.0 (C-8), 46.2 (C-9), 51.4 (OMe), 74.5 (C-7), 95.6 (C-1), 115.5 (C-4), 151.7 (C-3), 168.2 (C-11).

Loganin aglycone-1-monoacetate **1(c)**. Loganin aglycone (43 mg) was treated with DABCO (6 mg) and shaken to dissolve in THF (2.5 ml). Ac_2O (0.2 ml) was added and the solution stirred at RT overnight. Removal of solvent, followed by separation on a small column (silica gel) eluted with $CHCl_3$, followed by CH_2Cl_2–Et_2O (7:3) gave a pure oil, (35.4 mg). EI–MS *m*/*z* (rel. int.): 270 (M^+, 2.1), 210 (M-OAc, 19), 192 (M–OAc–H_2O, 22), 150 (21), 139 (100), 125 (24), 97 (19). δ H NMR (200 MHz, $CDCl_3$): $\delta = 1.15$ (3H, *d*, $J = 6.8$ Hz, Me), 1.80 (1H, *m*, H-6a), 2.11 (3H, *s*, OCOMe), 2.20 (2H, *m*, H-8, H-9), 2.32 (1H, *m*, H-6b), 3.18 (1H, *m*, H-5), 3.73 (3H, *s*, CO_2Me), 4.14 (1H, *m*, H-7), 6.07 (1H, *d*, $J = 3.5$ Hz, H-1), 7.32 (1H, *d*, $J = 0.8$ Hz, H-3).

3.5. Studies on sweroside *2a* and its derivatives

Pure sweroside (**2a**) crystals softened at 82°C and melted (decomp.) at 120°C, (lit. Ma et al., 1994, 106–109°C), $[\alpha]_D^{25} = -164.6°$ ($c = 0.005$, MeOH), (lit. Ma et al., 1994, −157.6°). The ^{1}H NMR spectrum in CD_3OD was identical to that recorded by Ma et al. (1994).

Sweroside (**2a**) (280 mg) was hydrolysed as described for loganin and afforded the aglycone (**2b**) (after separation on a column) (73 mg) as an unstable oil. ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 1.52$ (1H, *m*, H-6a), 1.96 (1H, *m*, H-6b), 2.02–2.11 (1H, *m*, H-9), 2.70 (1H, sym. *m*, H-5), 4.32 (1H, *m*, H-7a), 4.48 (1H, *m*, H-7b), 5.21–5.28 (2H, *m*, H-10), 5.44 (1H, broadened s, H-1), 5.73 (1H, *ddd*, $J = 17.3$, 10.3, 9.2 Hz, H-8), 7.63 (1H, *d*, $J = 2.1$ Hz, H-3). ^{13}C NMR (125 Hz, $CDCl_3$): $\delta = 26.7$ (C-6), 28.5 (C-5), 46.9 (C-9), 68.5 (C-7), 94.4 (C-1), 104.8 (C-4), 119.8 (C-10), 134.7 (C-8), 153.6 (C-3), 166.3 (COO-). EI–MS *m*/*z* (rel int.): 120 (.5), 85 (62), 83 (100).

3.6. Sweroside aglucone-1-acetate (*3*)

Sweroside aglucone (**2b**) (above, 45 mg) was treated with DABCO (6.2 mg), THF (2.5 ml) and acetic anhydride as detailed for loganin aglycone to give the 1-acetory derivative (**3**) (31 mg), mp 112–113°C, (obtained only after several recrystallisations from 95% EtOH), $[\alpha]_D^{20} = +36.4°$ ($c = 0.112$, $CHCl_3$); IR (KBr): $\nu_{(mu)}$: 3160, 1765, 1701, 1618, 1404, 1284, 1201, 1189, 1060. EI–MS *m*/*z* (rel int.): 238 (M^+, 2.4), 196 (1.4). 178 (2.6), 160 (8.5), 127 (100), 112 (2.5), 97 (8.8). ^{1}H and ^{13}C NMR (500 and 125 MHz, $CDCl_3$) are collected in Table 1.

For the X-ray study on (**3**) diffraction data were collected on a Nonius CAD 4 diffractometer with graphite monochromated MoK radiation. The unit cell parameters were determined by a least squares fit. The structure was resolved by direct methods. Further details for 1-acetoxy sweroside aglucone (**3**) are: $C_{12}H_{14}O_5$. Final *R* value 0.0470, colourless orthorhombic crystals, cell parameters (A°) $a = 7.9637$ (7), $b = 10.2678$ (8), $c = 29.326$ (2), crystal dimensions (mm) $0.58 \times 0.46 \times 0.35$, space group $P2_12_12_1$, V(A°^{3}) 2398.0(3), $Z = 8$. (Fig. 1).

The dihedral angles H-1/C-1–C-9/H-9 and H-5/C-5–C-9/H-9 were 177.9 and 174.5° respectively, in good accord with the stereochemistry predicted by the ^{1}H NMR data.

Received 30 August 2000; received in revised form 13 November 2000

Abstract

Bioassays with lipophilic crude extracts of four Fijian *Aglaia* species against *Spodoptera littoralis* displayed strong insecticidal activity for *A. basiphylla* and *A. gracilis*, whereas *A. archboldiana* and *A. vitiensis* did not have any significant effects. The insect toxicity of *A. basiphylla* was caused by the well known benzofuran flavaglines rocaglamide, desmethylrocaglamide and aglafoline. In contrast, *A. gracilis* contained four related pyrimidinone derivatives in the root and stem bark, including two new congeners named marikarin and 3′-hydroxymarikarin. Moreover, two new putrescine bisamides, secoodorine and secopiriferine, a new benzopyran flavagline, desacetylaglain A, and a new norsesquiterpene were isolated from the leaves together with three known bisamides and 3-hydroxy-5,7,4′-trimethoxyflavone. The structures of the new compounds were elucidated by spectroscopic methods. Comparative feeding assays within the active pyrimidinone flavaglines showed that the free hydroxy group in aromatic ring A of marikarin diminishes insecticidal activity. © 2001 Elsevier Science Ltd. Keywords: *Aglaia archboldiana*; *A. basiphylla*; *A. gracilis*; *A. vitiensis*; Meliaceae; Cyclopenta[*b*]benzofurans; Cyclopenta[*bc*]benzopyrans; Flavaglines; Bisamides; Flavonol; Norsesquiterpene; Diterpene; Triterpene; Insect toxicity; *Spodoptera littoralis*

1. Introduction

In the last decade the genus *Aglaia* of the family Meliaceae has attracted considerable attention as a possible new source for unique natural products for integrated pest management. In contrast to other genera of the family the very high insecticidal activity of many different species cannot be attributed to the accumulation of nortriterpenoid limonoids, like e.g. azadirachtin, but to the formation of flavonol-cinnamate derived cyclopenta[*b*]benzofurans (Janprasert et al., 1993; Satasook et al., 1994; Nugroho et al., 1997, 1999; Brader et al., 1998). This has been confirmed in our laboratory by a preliminary survey of 30 different *Aglaia* species. Together with biogenetically related but less active cyclopenta[*bc*]benzopyrans and benzo[*b*]oxepines they represent a distinct class of natural compounds named flavaglines (Brader et al., 1998; Bacher et al., 1999). At present flavagline-producing species are known mainly from Indonesia, Sri Lanka, Thailand, and Vietnam, covering mainly the western range of the geographical extent of the genus (Pannell, 1992), whereas only one report is known from the eastern part, across the Wallace's line. In this case the well known flavagline rocaglaol (Ishibashi et al., 1993) was isolated from an Australian collection of *A. tomentosa* Teijsm. & Binn. (syn.: *A. ferruginea* C. T. White & Francis) (Mulholland and Naidoo, 1998), which is regarded as a complex species also widely distributed in the western range (Pannell, 1992; Hopkins et al., 1998).

In order to contribute to a better understanding of the different biogenetic capacities of *Aglaia* species as well as to provide an eco-geographical interpretation of the varying occurrence of the highly active flavaglines, we now compared different HPLC profiles and insecticidal activities of four Fijian *Aglaia* species, representing far eastern and endemic representatives of the genus. Using freshly hatched larvae of the polyphagous cotton leaf worm *Spodoptera littoralis* (Lepidoptera, Noctuidae), the lipophilic crude extracts of *A. gracilis* A. C. Smith and *A. basiphylla* A. Gray exhibited high insect toxicity, whereas those of *A. archboldiana* A. C. Smith and

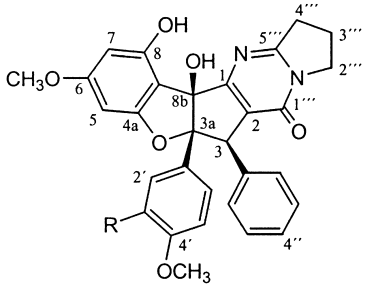
A. vitiensis A. C. Smith had no significant effects. Accordingly, an accumulation of flavaglines could only be detected in the first two species by HPLC–UV-diode array analyses. In *A. basiphylla* the insecticidal properties could be attributed to the well known flavaglines rocaglamide (**1**) (King et al., 1982), desmethylrocaglamide (**2**) (Ishibashi et al., 1993), and aglafoline (=methyl rocaglate) (**3**) (Ko et al., 1992; Ishibashi et al., 1993), whereas *A. gracilis* clearly deviated by a more complex chemical profile. Besides the known aglafoline (**3**), aglaiastatin (=aglaroxin D) (**4**) (Ohse et al., 1996; Molleyres and Kumar, 1996), and its dehydroderivative (**5**) (Kokpol et al., 1994), the root and stem bark additionally accumulate the two new cyclopenta[*b*]benzofurans **6** and **7**. Compared to the 43 already known benzofuran flavaglines, the two new compounds are characterized by a different substitution pattern in aromatic ring A, containing one methoxy and one hydroxy group in *meta*-position. Therefore, the new trivial names marikarin (**6**) and 3′-hydroxymarikarin (**7**) were introduced in appreciation of Mr. Marika Tuiwawa from the University of the South Pacific, Fiji, for all his help in collecting plants.

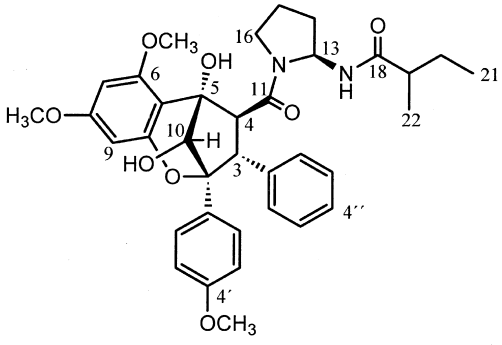
In accordance to our previous papers (Brader et al., 1998; Greger et al., 2000), the active cyclopenta[*b*]benzofurans (**3**–**7**) of *A. gracilis* mostly accumulate in the root and stem bark and are accompanied by large amounts of the secodammarane triterpene shoreic acid (**8**), previously described for other *Aglaia* species (Cui et al., 1997; Mohamad et al., 1999a,b). Moreover, from the roots the already known diterpene 13-hydroxy-7-oxolabda-8, 14-diene (**9**) (Wu and Lin, 1997) was also isolated and identified. In contrast, the HPLC profile of the leaves deviated by the dominating bisamides piriferine (**10**) (Saifah et al., 1988), odorine (**11**) (Shiengthong et al., 1979), and pyramidatine (**12**) (Saifah et al., 1993) together with the new putrescine derivatives secopiriferine (**13**) and secoodorine (**14**). Beyond that, the known 3-hydroxy-5,7,4′-trimethoxyflavon (**16**) and a series of cyclopenta[*bc*]benzopyrans also contribute to the characteristic HPLC profile of the leaves. However, from the latter series only the structure of the new desacetylaglain A (**15**) could unambiguously be identified in the present paper because of scarce plant material. In addition, small amounts of a new norsesquiterpene (**17**) could also be obtained for structure elucidation. In the present paper we report the isolation and structure elucidation of the new derivatives as well as the insecticidal activities of the new benzofuran flavaglines against *S. littoralis*.

2. Results and discussion

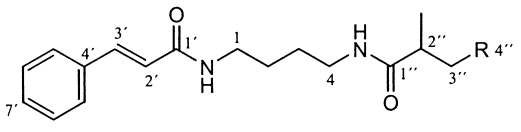
Methanolic crude extracts of leaves and root bark of three different individuals of *A. gracilis* (HG682-684) with nearly identical HPLC profiles were pooled together and the different organs separately analyzed by preparative MPLC linked with UV detection. Altogether fifteen compounds could be isolated, five of which were shown to be cyclopenta[*b*]benzofurans (**3**–**7**) accumulated in the root and stem bark. Based on their spectral



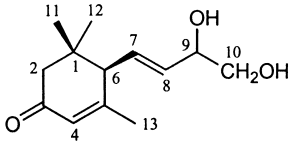
6 R = H marikarin
7 R = OH 3′-hydroxymarikarin



15 desacetylaglain A (H3-β, H-4α, 13*S*)



13 R = H secopiriferine
14 R = CH_3 secoodorine



17 9,10-dihydroxy-4,7-megastigmadien-3-one

characteristics and on comparison with already published data, compounds **3**–**5** were readily identified as the well-known derivatives aglafoline (**3**), aglaiastatin (**4**), and its dehydroderivative (**5**).

The new compounds marikarin (**6**) and 3′-hydroxymarikarin (**7**) belong, like **4** and **5**, to a group of benzofuran flavaglines characterized by a pyrimidinone unit. Their inconspicuous UV spectra showed small maxima at 273 nm (MeOH) for **6**, and 279 nm for **7**, and their IR spectra were characterized by strong signals at 1600–1678 cm^{-1} and 1146 cm^{-1} ($CHCl_3$). High resolution MS data of **6** resulted in the molecular formula $C_{30}H_{26}N_2O_6$ and the ^1H and ^{13}C NMR spectra were very similar to a pyrimidinone flavagline which has previously been isolated from *A. odorata* (Kokpol et al., 1994; Ohse et al., 1996) and *A. duppereana* (Nugroho et al., 1997). However, in the NMR spectra of marikarin (**6**) one methoxy resonance was missing and the MS showed a mass which was less by one CH_2 unit. On the other hand, the ^{13}C NMR data, including the quaternary resonances, proved the same oxygenation pattern of the flavagline skeleton in comparison with the 6,8,4′-trimethoxylated derivative from the literature cited above. Obviously compound **6** carries a phenolic hydroxy group at one of the positions 6, 8, or 4′. The methoxy groups at C-6 and C-4′ were still present in compound **6** which was confirmed by differential NOE measurements showing the effects 6-OCH_3 ↔ 5-H, 6-OCH_3 ↔ 7-H, and 4′-OCH_3 ↔ 3′/5′-H. Thus, the unsubstituted hydroxy group is positioned at C-8. Extensive 2D NMR measurements, especially long range shift correlation (HMBC), supported the structure of **6** and allowed to assign all ^1H and ^{13}C NMR resonances. 3′-Hydroxymarikarin (**7**) differed from **6** by a different substitution pattern of the phenyl ring attached at position 3a. In the ^1H NMR spectrum of compound **6** this ring showed the typical pattern of a *para* substituted benzene. In compound **7** however, the symmetry of the ring substitution got lost due to a further substituent in *meta* position resulting in the typical ^1H NMR resonance system of three aromatic protons with their typical *ortho* and *meta* coupling constants. The high resolution MS derived molecular formula $C_{30}H_{26}N_2O_7$ showed that an additional oxygenation took place with respect to compound **6**. The ^1H coupling pattern allowed the conclusion that the newly introduced oxygen is attached at C-3′. This was also supported by the ^{13}C chemical shift changes as a consequence of the additional oxygenation of this ring. The positions 3′ for the OH substituent and 4′ for OCH_3 were finally confirmed by the strong differential NOE from 4′-OCH_3 to 5′-H. The assignments of the absolute configurations at C-3, C-3a, and C-8b were based on the optical rotation of $[\alpha]_D^{20} = -45^\circ$ for **6** and -53° for **7** ($CHCl_3$), which agreed perfectly with a value of -50.1° for the closely related dehydroaglaiastatin (**5**). The latter was correlated via CD measurements with synthetic (-)-rocaglamide (see Nugroho et al., 1997).

Besides the dominating bisamides piriferine (**10**), odorine (**11**), and pyramidatine (**12**), already known from different *Aglaia* species, the leaf extract of *A. gracilis* additionally accumulated two hitherto undescribed derivatives, secopiriferine (**13**) and secoodorine (**14**). The prominent and broad maxima at 274 nm (MeOH) in the UV-spectra as well as the typical IR bands at 3441–3443 cm^{-1} ($CHCl_3$) for >NH stretching and dominating signals at 1627–1665 and 1517–1518 cm^{-1} for the >N–C=O/C=C stretching region showed immediately that they belong to the group of bisamides characteristic for *Aglaia* species. This was also confirmed by two broad NH resonances in the ^1H and two characteristic CO singlets in the ^{13}C NMR spectra of both compounds (Brader et al., 1998; Greger et al., 2000). The acid parts of **13** were cinnamic acid and a simple aliphatic isobutyric acid as in piriferine (**10**), however, unlike to piriferine the bifunctional amine part was not a cyclic 2-aminopyrrolidine, but an open chain putrescine. The NMR data for the acid moieties were very similar to piriferine (Saifah et al., 1988, 1993), the amine moiety showed the characteristic resonances for the four methylene groups of putrescine (Saifah et al, 1993; Brader et al., 1998; Greger et al., 2000). Secoodorine (**14**) was very similar to secopiriferine (**13**) with the only difference, that there was a 2-methylbutanoic acid component instead of isobutyric acid. The corresponding bisamide with a cyclic amine component is the widespread odorine. The NMR data of secoodorine (**14**) could be assigned by comparison with Purushothaman et al. (1979) and Shiengthong et al. (1979) for the acid moieties, and Saifah et al. (1993), Brader et al. (1998), and Greger et al. (2000), for the putrescine part. High resolution MS agreed with the molecular formulas $C_{17}H_{24}N_2O_2$ for **13**, and $C_{18}H_{26}N_2O_2$ for **14**. The 100% peaks in the EI mass spectra of both compounds were at m/z = 131 which was characteristic for the very stable cinnamoyl ion (Shiengthong et al., 1979). The absolute configuration at C-2″ in secoodorine (**14**), $[\alpha]_D^{20} = +11^\circ$ ($CHCl_3$), was not determined. However, in epi-odorine (= roxburghilin) it was determined as (*S*) by hydrolysis to (+)-2-methylbutanoic acid (Purushothaman et al., 1979).

The ^1H and ^{13}C NMR data of the cyclopenta[*bc*] benzopyran flavagline **15** were almost identical with those of aglain A (Dumontet et al., 1996). The only difference is the lack of the 10-OAc group which is changed to an unsubstituted OH group in **15**, thus named desacetylaglain A. Based on comparative HPLC of the crude extract and the corresponding CC and TLC fractions it became evident that **15** seems to be at least partly the result of a conversion during TLC separation from a compound with higher retention time and the same UV spectrum. Most probably it represents the hydolysis

product of aglain A. The relative stereochemistries at C-3, C-4, C-10, and the stereochemically labile N-acetale center C-13 can be derived from NOESY data (Dumontet et al., 1996; Brader et al., 1998). The crosspeaks 3-H ↔ 10-H proved the H-3β position and an *endo* arrangement between 3-H and 10-H, the NOE contact 4-H → 2″/6″-H indicated a H-4α position, whereas the crosspeaks 4-H ↔ 13-H were only possible for the 13*S* configuration (Dumontet et al., 1996) (see Section 3 for the complete NOESY data). The absolute configuration of the 2-methylbutanoic acid moiety (C-19) was not determined (compare discussion of compound **14**). However, the stereochemical presentation of formula **15** followed biogenetic considerations linking the known cyclopenta[*b*]benzofurans with the closely related cyclopenta[*bc*]benzopyrans (Bacher et al., 1999; Nugroho et al., 1999).

According to MS and NMR data, compound **17** was a new norsesquiterpene of the 4,7-megastigmadien-3-one type with additional hydroxy groups at positions 9 and 10 in the side chain ($C_{13}H_{20}O_3$). An analoguous 9-hydroxy compound, lacking the terminal C-10 oxygenation, was described for *Nicotiana tabacum* L. (Solanaceae) (Aasen et al., 1973) and *Teucrium heterophyllum* L'Her. (Lamiaceae) (Fraga et al., 1995). Corresponding glycosides of the latter have also been isolated from raspberry fruit (*Rubus idaeus* L., Rosaceae) (Pabst et al., 1992) and from the seeds of *Trifolium alexandrinum* L. (Fabaceae) (Mohamed et al., 1999a,b). Comparison of ^1H and ^{13}C NMR spectra of **17** with the data of these related compounds and additional 2D NMR measurements proved clearly the postulated structure. The absolute configuration at C-6 followed from the positive sign of the optical rotation $[\alpha]_D^{20} = +145^\circ$, which is due to the cyclic enone chromophore dominating the chiroptical properties (CD and $[\alpha]_D$) in the long wave length region (compare Pabst et al., 1992; Mohamed et al., 1999a,b). The absolute configuration of the peripheric asymmetric center C-9 was not determined.

Based on the present data, the biogenetic capacity towards flavagline formation of *Aglaia* species from the eastern part of their geographical range (Pannell, 1992) did not show significant differences to those of the western part, across the Wallace's line: the biologically very active benzofuran derivatives also accumulated mainly in the stem and root bark, whereas the ineffective benzopyrans were preferably found in the leaves together with bisamides (see Brader et al., 1998; Greger et al., 2000). Moreover, the accumulation of the triterpene shoreic acid (**8**) represents a further common character of the roots (e.g. Cui et al., 1997; Mohamad et al., 1999a,b). Since there are only very few reports on the occurrence of sesquiterpenes and diterpenes in *Aglaia* species, nothing can be said about the chemosystematic significance of compound **9** and **17** in the roots or leaves, respectively. Of special biogenetic interest, however, was the isolation of 3-hydroxy-5,7,4′-trimethoxyflavon (**16**) from the leaves which showed the same substitution of aromatic rings A and B as the co-occurring flavaglines. Hence it is most likely, that the characteristic substitution patterns of flavaglines were already formed on the stage of the flavonol precursor, which was later linked to a cinnamic acid moiety (Dumontet et al., 1996; Bacher et al., 1999; Nugroho et al. 1999). This co-occurrence of the same substitution pattern of aromatic rings A and B in flavonols and flavaglines was also reported for other *Aglaia* species, e.g. in an Indonesian provenance of *A. odorata*, where a disubstituted B-ring could be observed in both types of compounds (Nugroho et al., 1999). Furthermore, the co-occurrence of the pyrrolidine derived bisamides piriferine (**10**) and odorine (**11**) together with the corresponding open-chain putrescine derivatives secopiriferine (**13**) and secoodorine (**14**) also suggested close biogenetic connections. Like in the recently reported sulphur containing bisamides of *A. leptantha* (Greger et al., 2000), the putrescine derivatives may be regarded as biosynthetic precursors of the corresponding pyrrolidine derived bisamides.

The well-known insect toxicity of benzofuran flavaglines was confirmed by chronic feeding bioassays with freshly hatched larvae of *S. littoralis*. Insufficient quantities of 3′-hydroxymarikarin (**7**) precluded a bioassay. As shown in Table 1, the free hydroxy group in aromatic ring A of the new pyrimidinone derivative marikarin (**6**) led to a decrease of insecticidal activity, compared to the co-occurring pyrimidinones **4** and **5**.

Table 1
Insecticidal and growth inhibitory activities of pyrimidinone-type flavaglines and azadirachtin against neonate larvae of *Spodoptera littoralis*[a]

Compound	LC_{50} (95% FL[b]) ppm	EC_{50} (95% FL[b]) ppm
Marikarin (**6**)	12.2 (9.8–15.4)	0.69 (0.37–0.99)
Aglaiastatin (**4**)	1.2 (0.7–2.3)	0.09 (0.07–0.11)
Dehydroaglaiastatin (**5**)	1.7 (1.6–1.9)	0.19 (0.15–0.23)
Azadirachtin[c]	8.2 (6.6–11.6)	0.04 (0.02–0.07)
Azadirachtin[d]	0.6 (0.3–1.7)	n.m.[e]

[a] Assays were conducted with neonate larvae of *S. littoralis* ($n = 20$ for each treatment) that were forced to feed on artificial diet spiked with 8 different concentrations of the test compounds (0.025–25 ppm). After 5 days, survival and weight of the surviving larvae were determined and compared to controls that had been exposed to diet treated with solvent (MeOH) only. From the dose-response curves LC_{50} and EC_{50} values were calculated by probit-log analysis. In the case of azadirachtin, the surviving larvae were weighed after 5 days of exposure to obtain the EC_{50} value and then transferred to fresh untreated diet and reassessed after another 6 days. The survival rate of larvae after 11 days was again recorded and the LC_{50} value determined.

[b] Fiducial limits.

[c] Results after 5-day exposure.

[d] Results after 11-day exposure.

[e] Not measured.

After 5 days of exposure, aglaiastatin (**4**), characterized by a N–H group, displayed the highest toxicity with a LC_{50} value of 1.2 ppm. This value was clearly lower than that of the positive control azadirachtin of 8.2 ppm. Whereas the LC_{50} and EC_{50} values of **4** and **5** were comparable with those already published, the LC_{50} value of azadirachtin, purchased from Roth (Karlsruhe, Germany), clearly deviated (Nugroho et al., 1997). In order to clarify these discrepancies a reinvestigation was carried out using different times of exposure. As already described previously, azadirachtin is a very potent, but at low concentrations a rather slowly acting toxin displaying the highest activity during the molting process of the larvae (Rembold, 1995). The rather high LC_{50} value of 6.1 ppm previously published by Brader et al. (1998), was determined after a 5-day exposure where strong growth retarding effects of azadirachtin towards the first instar larvae may have delayed the transition to the next larval stage. After a 11-day exposure, however, the toxic effects clearly increased with a LC_{50} value of 0.6 ppm, probably due to the fact that all larvae entered the next molting process (see Table 1). Hence, it appears obvious that the time of exposure plays a prominent role in the determination of insecticidal activities and might also explain the different values reported in the literature.

3. Experimental

3.1. General

NMR: Bruker, AM 400 WB and AC 250. MS: Finnigan MAT 900 S. IR: Perkin-Elmer 16PC FT-IR. UV: Hewlett-Packard, 8452A Diode Array Spectrophotometer. Optical rotation: Perkin Elmer Polarimeter 241. HPLC: Hewlett-Packard 1090 II, UV diode array detection at 230 nm, column 250 × 4 mm, Hypersil BDS C-18, 5 μm, mobile phase MeOH (gradient 60–100%) in aqueous buffer (0.015 M *o*-phosphoric acid, 0.0015 M tetrabutylammonium hydroxide, pH 3), flow rate 1 ml/mm.

3.2. Plant material

Leaves, stem, and root bark from different individuals of four Fijian *Aglaia* species were collected separately: (a) *A. gracilis* from northwest Viti Levu, Lautoka, Mt.Evans, near Abaca, three individuals (HG 682-684); (b) *A. basiphylla* from east Viti Levu, Wailoku, near Suva, three individuals (HG 673-674, HG 692); (c) *A. vitiensis* from south Viti Levu, near Narukunimbua, three individuals (HG 732-734), and from east Viti Levu, Wailoku, near Suva, one individual (HG 735); (d) *A. archboldiana* from south Viti Levu, near Narukunimbua, three individuals (HG 693-695), and from north Viti Levu, near Nandarivatu, two individuals (HG 696-697). Voucher specimens are deposited at the Herbarium of the Institute of Botany, University of Vienna (WU).

3.3. Extraction and isolation

Dried leaves, stem and root bark of *A. archboldiana*, *A. basiphylla*, *A. gracilis*, and *A. vitiensis* were ground separately and extracted with MeOH at room temp. for 3 days, filtered and conc. The aqueous residues were extracted with $CHCl_3$ and the concentrated $CHCl_3$ fractions were used as lipophilic crude extracts for comparative HPLC analyses and preliminary bioassays. From three individuals of A. *gracilis* (HG 682-684) the $CHCl_3$ fractions from dried leaves (72 g) and roots (17 g) were combined separately, evapd to dryness under reduced pressure, and roughly sepd by column chromatography (Merck silica gel 60, 35–70 mesh) with hexane, EtOAc and MeOH. From the leaf extract (2500 mg) the combined fractions eluted with 100% EtOAc (530 mg) were further sepd by prep MPLC (400 × 38 mm column, Merck LiChroprep Si 60, 25–40 μm, UV detection, 254 nm) starting with 50% EtOAc in hexane to yield a fraction (16 mg) which led to 4.5 mg pure flavonol **16** by crystallization in MeOH. MPLC fraction with 70% EtOAc in hexane afforded a mixture (260 mg) which was sepd by cyclic MPLC to give 70 mg odorine (**11**), 75 mg piriferine (**10**), 10 mg pyramidatine (**12**), 2 mg norsesquiterpene (**17**) and a mixture (8.5 mg) which was further sepd by prep TLC (Merck silica gel 60, F_{254};CH_2Cl_2:EtOAc:MeOH = 70:25:5) to give 4.5 mg desacetylaglain A (**15**). Another MPLC fraction with 70% EtOAc led (i) to another mixture (15 mg), from which 2.5 mg aglaiastatin (**4**) was sepd by prep TLC, and (ii) to secopiriferine (**13**) and secoodorine (**14**) which were also purified by prep TLC to give 10 mg **13** and 16 mg **14**. In addition to the CC fractions with 100% EtOAc, those with 50%EtOAc in MeOH (210 mg) gave again 24 mg odorine (**11**), 28 mg piriferine (**10**), 3 mg secopiriferine (**13**), 5 mg secoodorine (**14**) and 6 mg flavagline (**5**). From the root extract (1400 mg) the combined CC fractions with 30% EtOAc in hexane (200 mg) were further sepd by prep MPLC with 15% EtOAc in hexane to give the impure labdanoid diterpene **9** (30 mg), which was purified by prep TLC (CH_2Cl_2: EtOAc:MeOH = 70:29:1) to yield 13 mg pure compound. Combined CC fractions eluted with 50% EtOAc in hexane and 100% EtOAc (500 mg) were further sepd by prep. MPLC starting with 30% EtOAc in hexane to yield 120 mg shoreic acid (**8**), and 32 mg impure aglafoline (**3**). With 50% EtOAc in hexane 42 mg impure **6**, 7 mg impure **7**, and 8 mg impure **3** were obtained, which all were further sepd by prep TLC (CH_2Cl_2:EtOAc:MeOH = 70:25:5) to give pure compounds: 18 mg aglafoline (**3**), 5 mg dehydroaglaiastatin (**5**), 4.5 mg marikarin

(**6**), 3.5 mg aglaiastatin (**4**) and 1 mg 3′-hydroxymarikarin (**7**).

3.10. Insect bioassays

Chronic feeding bioassays were carried out with freshly hatched larvae ($n = 20$) of the polyphagous pest insect *S. littoralis* (Noctuidae, Lepidoptera). The larvae were from a laboratory colony reared on artificial diet under controlled conditions at 26°C as described previously (Srivastava and Proksch, 1991). The test insects were kept on artificial diet spiked with 8 different concentrations of the test compounds (0.025–25 ppm) which were applicated with MeOH. After 5 days (moist chamber, darkness, 26°C) the survival rate and the larval growth of the surviving larvae were monitored in comparison to controls that had been exposed to diet treated with solvent only. LC_{50} and EC_{50} values were calculated by probit-log analysis (Table 1). Commercial azadirachtin (> 96%) purchased from Roth (Karlsruhe, Germany) was used as a positive control. In case of azadirachtin, the larvae were weighed after a 5-day exposure (for calculation of the EC_{50} value), transferred to an untreated fresh diet and reassessed after another 6 days. After 11 days the number of surviving larvae was recorded again and the LC_{50} value calculated.

Acknowledgements

The authors thank Mr. Marika Tuiwawa, curator from South Pacific Regional Herbarium, Institute of Applied Science, University of the South Pacific, Suva, Fiji, for his valuable help in collecting plants. Dr. Caroline M. Pannell from the Department of Plant Sciences, University of Oxford, gave valuable taxonomic advice. This work was supported by the Austrian National Committee for the Intergovernmental Program "Man and Biosphere" and the Fonds zur Förderung der wissenschaftlichen Forschung in Österreich (proj. no. 12385-CHE).

Institute of Chemistry, A. Gostauto 9, LT-2600, Vilnius, Lithuania

Received 25 April 2000; received in revised form 14 November 2000

Abstract

The plants of wild *Origanum vulgare* L. ssp. *vulgare* were collected in 10 localities of Vilnius district (Lithuania) in 1995–1999. The main constituents of the essential oils from 8 localities were β-ocimene (14.9–21.6%), germacrene D (10.0–16.2), β-caryophyllene (10.8–15.7%) and sabinene (6.6–14.2%). The essential oils from two localities contained only three above compounds as major components: germacrene D, β-ocimene and sabinene or β-caryophyllene, β–ocimene and germacrene D. Three chemotypes of essential oils were identified. The main chemotype was β-ocimene–germacrene D–β-caryophyllene. The terpenic hydrocarbons made up 52.8–80.6% of the essential oils. The 42 identified components made up 85.6–98.0% of the essential oil. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Origanum vulgare* L. ssp. *vulgare*; *Labiatae*; Essential oils; Chemotypes; β-Ocimene–germacrene D–β-caryophyllene chemotype

1. Introduction

Origanum vulgare is the only species of the *Origanum* genus growing wild in Lithuania (Natkevicaite-Ivanauskiene, 1976). *Origanum vulgare* L. ssp. *vulgare* is widely spread in all the country. Another subspecies, *Origanum vulgare* L. ssp. *puberula* Beck, is rare and was found only in one locality near Trakai.

The composition of essential oils of *O. vulgare* L. ssp. *vulgare* was carefully analysed in Italy (Melegari et al., 1995) and France (Chalchat and Pasquier, 1998) (Table 1). The seeds from 4 localities were studied in Italy and four chemotypes of essential oils were identified. The seeds of 70 clones cultivated in France were collected from different sources in France and other European countries (Chalchat and Pasquier, 1998). Chalchat and Pasquier (1998) classified the essential oils into six groups: sabinene, germacrene D, germacrene D–β-caryophyllene, *cis*-sabinene hydrate, terpinen-4-ol and monoterpene hydrocarbons. Only one terpinen-4-ol chemotype was found in both countries (Table 1, No. 3 and 9). The major three constituents (terpinen-4-ol, β-caryophyllene and γ-terpinene) of the above essential oils were the same. Data in Table 1 demonstrate that *O. vulgare* L. ssp. *vulgare* plants may synthesize at least nine chemotypes of essential oil.

The other subspecies of *O. vulgare* L. form several different chemotypes based on essential oil. The thymol and carvacrol chemotypes were identified in *O. vulgare* L. ssp. *hirtum* (Melegari et al., 1995; Sivropoulou et al., 1996; Kokkini et al., 1997; Bocchini et al., 1998; Skoula et al., 1999). The composition of essential oil depended on collection season (Kokkini et al., 1997). Bocchini et al. (1998) showed that plants with white and pink flowers have different pathways of monoterpene biosynthesis.

The carvacrol chemotype of essential oil is characteristic for *O. vulgare* L. ssp. *glandulosum* (Melegari et al., 1995). The thymol (Melegari et al., 1995) and sabinene–germacrene D (Leto et al., 1994) chemotypes were synthesized by *O. vulgare* L. ssp. *gracile*.

The *O. vulgare* L. ssp. *virens* plants produced germacrene D–sabinene or γ-terpinene (Chalchat and Pasquier, 1999), linalool–δ-elemene (Alves-Pereira and Fernandes-Ferreira, 1998), linalool (–β-caryophyllene), linalool–α-terpineol, linalool–terpinen–4-ol, terpineol–linalool, terpineol (–carvacrol) (Melegari et al., 1995) chemotypes of essential oils.

The main constituents of the essential oil *O. vulgare* L. ssp. *viride* growing wild in Iran were linalyl acetate, β-caryophyllene and sabinene (Afsharypuor et al., 1997), but carvacrol, γ-terpinene, *p*-cymene were characteristic for plants cultivated in Kishenev botanical garden (Bodrug et al., 1990). The carvacrol and germacrene D chemotypes were found in cultivated *O. vulgare* L. (without subspecies characterization) from Finland (Nykanen

[a] Numbers 1–4 were cultivated in Italy; 5–10 were cloned in France. Origin of seeds: 1, USA; 2, Budakalasz; 3, Liegi; 4, Spagna; 5–10, France and other European countries.

and Lebensen, 1986). The thymol chemotype of essential oil of *O. vulgare* L. was determined in Sicily (Baratta et al., 1998). The major components of *O. vulgare* L. from north India were linalool and myrcene (Kaul et al., 1996).

The other subspecies *O. vulgare* L. synthesize some more chemotypes (carvacrol, linalool, α-terpineol, linalyl acetate–β-caryophyllene) in comparison with *O. vulgare* L. ssp. *vulgare* (Table 1) (Melegari et al., 1995; Chalchat and Pasquier, 1998).

The other species of the *Origanum* genus mainly formed the same chemotypes as *O. vulgare* L. The main constituents of the essential oil of *O. laevigatum* Boiss. were bicyclogermacrene, germacrene D and β-caryophyllene (Tucker and Maciarelle, 1992; Baser et al., 1996) and that of *O. husnucan-baserii*–borneol and *trans*-sabinene hydrate (Baser et al., 1998). The bicyclogermacrene type has not been found in investigated *O. vulgare* L. species.

This paper presents the composition of the essential oils of *O. vulgare* L. ssp. *vulgare* grown wild in various localities of Vilnius district (Lithuania).

2. Results and discussion

The essential oils from *Origanum vulgare* L. ssp. *vulgare* plants collected in 8 localities of Vilnius district contained β-ocimene as the main constituent (Table 2 and Table 4 (H)). β-Ocimene exists in two forms — *cis* (*Z*) and *trans* (*E*). The ratio of isomers depends on location. Higher quantities of *trans*- rather than *cis*-β-ocimene were found in 5 localities (B, C, D, F, G). The plants with a relative high percentage of β-ocimene in essential oil were collected in ecologically clean places (in the forests far from the town and industrial objects). The four major constituents (β-ocimene, germacrene D, β-caryophyllene, sabinene) of essential oils were the same in all 11 samples from 8 localities (Tables 2–4). The basic composition of the essential oils under study (Tables 2 and 4) was the same as that of the plants *O. vulgare* L. ssp. *vulgare* cultivated in France and attributed by the investigators Chalchat and Pasquier (1998), to terpene hydrocarbons group (Table 1, No. 10). The essential oils under study contained lower percentage of *p*-cymene (0–2.5%) (Tables 2 and 4), than in the plants cultivated in France (0.7–17.2%) (Table 1, No. 10) (Chalchat and Pasquier, 1998). The plants in Vilnius district showed higher percentages sabinene, germacrene D and β-caryophyllene than those in France (Tables 1, 2 and 4).

The quantities of β-ocimene, germacrene D and β-caryophyllene exceeded 10% in all essential oils presented in Table 2. The amount of sesquiterpene hydrocarbons, germacrene D and β-caryophyllene, depended on growing location (Table 2, compare samples of 1999) and seasonal conditions (A locality: samples A, A1, A2). The samples of plants with as main component germacrene D and β-caryophyllene of essential oils were collected in ecologically polluted places (near the city and roads). The composition of the essential oils in locality D is associated with the colour of flowers (Table 2) as it was earlier noticed for plants of *O. vulgare* L. ssp. *hirtum* (Bocchini et al., 1998). The essential oil of plants with violet-pink flowers contained more β-ocimene than germacrene D or β-caryophyllene, while plants with pink flowers contained approximately the same quantities of

Sabinene	IV	IV	IV	IV	IV	IV	IV	III	IV	III–IV	IV

[a] The growing localities as in Table 2.

all three main constituents (Table 2, samples D1 and D2). The quantities of the first and second major components of the essential oil in samples from A–H and K localities were similar (Tables 2 and 4).

The largest difference was found in plants from locality J collected in 1999 (Table 4, J3). The amount of the first major constituent germacrene D exceeded~ 2.5 fold that of the second major compound, β-ocimene. The third main constituent was sabinene. The plants from locality J showed low percentages of β-caryophyllene in comparison with plants presented in Table 2. The essential oils from the above localities may be attributed to germacrene D–β-ocimene–sabinene chemotype (Table 4, J1, J2 and J3). The plants from locality K accumulated proportionally higher amounts of β-caryophyllene, and lower amounts of sabinene. The essential oils of K was of β-caryophyllene–β-ocimene–germacrene D chemotype (Table 4, K1, K2). The composition of essential oils

[a] The plants collected at full flowering in the localities: Sapiegine II in 1999 (H); Rokantiskes vicinity (J1, 1997; J2, 1998; J3, 1999); Sapiegine I (K1, 1997; K2, 1998, K3, 1999).

of plants collected in 1999 different from those collected in 1997 and 1998 (Table 4). The increase of germacrene D relative amount in 1999 was noticed not only in localities K, but in A and J (Tables 2 and 4), too. This phenomenon may be caused by the very warm spring and summer of 1999. It is known that some plants in Italy that synthesize mainly monoterpenic compounds in spring, produce sesquiterpenes in summer (Giner et al., 1993).

Of the 42 compounds identified in the essential oils, 38 are given in Tables 2 and 4. Apart from the above components α-cadinene (0.1–0.2%) and 3-octanone (0.1–0.2%) were found in samples B, C and D1, and borneol — in C and F. 32 compounds from Tables 2 and 4 were earlier identified in *Origanum vulgare* L. ssp. *vulgare* in Italy (Melegari et al., 1995) and France (Chalchat and Rasquier, 1998). Borneol, β-gurjunene, *allo*-aromadendrene, β-bisabolene and α-cadinene (Tables 2 and 4) were found in the essential oils of other subspecies of *O. vulgare* L. (Leto et al., 1994; Sivropoulou et al., 1996; Baratta et al., 1998; Bocchini et al., 1998). Bicyclogermacrene (Tucker and Maciarelle, 1992; Baser et al., 1996) and β-elemene (Baser et al., 1998) were identified in the essential oils of other species of *Origanum* genus.

Myrcene, 1,8-cineole + β-phellandrene, γ-humulene, bicyclogermacrene, α-farnesene + β-bisabolene, δ-cadinene, germacrene-D-4-ol + spathulenol made up more than 1% in all 17 samples of essential oils and caryophyllene oxide in 16 samples. The relative quantity of some constituents varied in wide interval (Tables 2 and 4). The amount of 9 constituents did not exceed 1%.

Mono- and sesquiterpene hydrocarbons made up 52.8–80.6% of essential oils (Tables 2 and 4). The major constituents of all investigated essential oils were hydrocarbons. All essential oils under study according

to Ietswaart's classification (Skoula et al., 1999) may be attributed to acyclic- and sesquiterpene-rich subspecies of *Origanum vulgare* L. The essential oil of 8 localities from 10 may be named as β-ocimene–germacrene D–β-caryophyllene chemotype (Tables 2–4; A–H).

3. Experimental

The aerial parts (~35 cm) of plants (0.2–1.0 kg) growing wild in 10 localities of Vilnius district (indicated here by alphabetic symbols, A–K) were collected in August 1995 (A sample), 1997 (J, K samples), 1998 (J, K) and 1999. A, B, and C localities are near Silenai, D-G–in Rastinenai vicinity, H–in Sapiegine II, J–in Rokantiskes and K–in Sapiegine I.

Voucher specimens have been deposited in the Herbarium of the Institute of Botany, Vilnius, Lithuania (numbers: A-61114, B-61115, C-61116, D-61117, E-61118, F-61119, G-61120, K-61121, H-61122 and J-61123).

All samples were collected at full flowering except A1, which was collected at the beginning of flowering stage. The ration of stems/leaves/flowers is approximately the same in all samples. The plants were dried at room temperature (20–25°C). The essential oils were prepared by hydrodistilation of 20–100 g of air-dried plants.

The analyses of the essential oils were carried out by GC and GC–MS. The HP 5890II chromatograph equipped with FID and capillary column HP-FFAP (30 m × 0.25 mm) was used for quantitative analysis. The GC oven temperature was set at 70°C for 10 min and then programmed from 70 to 210°C at a rate of 3°C min^{-1}, using He as the carrier gas (0.7 ml min^{-1}). Injector and detector temperatures were 200 and 250°C, respectively. Analyses by GC–MS were performed, using a chromatograph interfaced to a HP 5971 mass spectrometer (ionization voltage 70 eV) and equipped with capillary column CP-Sil 8 CB (50 m×0.32 mm). The oven temperature was held at 50°C for 2 min, then programmed from 50 to 180°C at a rate 3°C min^{-1}, held for 1 min, then programmed from 180 to 250°C at rate 20 °C min^{-1}, and isothermal at 250°C for 2 min, using He as the carrier gas (2.0 ml min^{-1}). Injector and detector temperatures −250°C.

The percentage composition of the essential oils was computed from GC peak areas without correction factors. Qualitative analysis was based on a comparison of retention times and indexes on both columns and mass spectra with corresponding data in the literature (Adams, 1995; Chung et al., 1993) and computer mass spectra libraries (Wiley and NBS 54K).

Received 21 March 2000; received in revised form 3 November 2000

Abstract

The results of the essential oil composition confirm that there are differences between populations within the same subspecies (*Satureja montana* ssp. *montana*), between the subspecies (*Satureja montana* ssp. *montana* and *Satureja montana* ssp. *pisidica*) and the species (*Satureja montana* and *S. kitaibelii*). The essential oil composition of *S. montana* ssp. *montana* is more related to the *Satureja montana* ssp. *pisidica* than *S. kitaibelii* which separates as a whole species. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Satureja montana* ssp. *montana*; *S. montana* ssp. *pisidica*; *S. kitaibelii*; *Lamiaceae*; Chemotaxonomy; Essential oils

1. Introduction

The genus *Satureja* L. embraces over 30 species whose center of distribution is located in the eastern part of the Mediterranean (Silic, 1979). These are annual or perennial semi-bushy aromatic plants that inhabit the arid, sunny, stony and rocky habitats.

The genus *Satureja* belongs to the family *Lamiaceae*, sub-family *Nepetoideae,* and the tribe *Mentheae* (Cantino et al., 1992). One of the diagnostic characteristics of the sub-family *Nepetoideae* is that its representatives contain more than 0.5% of essential oil (El-Gazzar and Watson, 1970). The essential oils have certain biological functions such as physiological function (in plant metabolism) and ecological function (in interactions of the plants with their environment) (Jancic et al., 1995). The essential oils are also significant for an explanation of phylogenetic relations.

The species *Satureja montana* L. is confusing from the taxonomic and, therefore, chorological point of view. Its high variability is evident, even within a single population polymorphism, and especially in populations coming from distant habitats. The variability is reflected in morphologic characteristics such as the form and size of the calyx and corolla, calycal dents, size, form and color of the nutlets, and particularly in the form, size and pubescence of the leaves and in a more or less pronounced pubescence of the stems (Silic, 1979). The taxa *S. montana* contains numerous subspecies.

Satureja kitaibelii Wierzb. ex Heuff. has been shown by the older authors as a member of one of the infraspecies systematic categories within an extremely polymorphic species *S. montana* (Briquet, 1893; Hayek, 1931; Stojanov and Stefanov, 1948; Ball and Getliffe, 1972; Diklic, 1974). Silic (1979) thinks that the pronounced morphologic differences and clearly separated area, in regard to the related taxons, confirm the view of those authors that consider *S. kitaibelii* as a separate species (Ravarut, 1961).

The essential oil composition of the species S. *montana* and *S. kitaibelii* is very variable. According to some authors the dominant components in the oil of *S. montana* are caryophyllene and geraniol (Sevarda et al., 1986), and according to others it is carvacrol (Palic and Gasic, 1993; Kustrak et al., 1996). The dominant components in the oil of *S. kitaibelii* are ρ-cymene, geraniol and β-elemene (Sevarda et al., 1989; Palic and Gasic, 1993; Chalchat et al., 1999).

The aim of the work is investigating the essential oil composition variability on different levels: within a

population, between populations of the same subspecies (two populations of *S. montana* ssp. *montana*), between the subspecies (S. *montana* ssp. *montana* and *S. montana* ssp. *pisidica*) and between the species *S. montana* and *S. kitaibelii*. The results could aid in solving the position of these taxons whose place within the clasification system is unclear.

2. Results and discussion

The composition and content of essential oils in the aerial parts of the plants of the studied populations are given in Table 2. Monoterpene hydrocarbons and their derivatives dominate in the chemical composition of essential oils of the studied populations. The sesquiterpene compounds are present in small quantities.

In the population *S. montana* ssp. *montana* from Beli Rzav gorge in the essental oil of the 33% of plants the acyclic monoterpene alcohol linalool is found as the dominating component, while in 43% of individuals it was aromatic monoterpene, ρ-cymene. In 10% of plants the essential oil is dominated by bicyclic alcohol of bornan class, borneol, while in 13% of individuals dominates bicyclic alcohol of thujanic class, trans-sabinen hydrate.

The population of *S. montana* ssp. *montana* from the surroundings of Zvornik is characterized by the presence of the same components in essential oils, except β-caryophyllene, as the previous population (from the gorge of the river Beli Rzav). Linalool as a dominant component was detected in the essential oils of 23% of individuals, ρ-cimene also in 23%, *trans*-sabinen hydrate in 27% and borneole in 3% of individuals. In this population 23% of the plants are dominated by phenol of the menthane class (ρ-cymen-8-ol).

According to the presence and quantity of dominant compounds, the essential oil composition of the investigated populations of *S. montana* ssp. *montana* differs from the results published earlier (Sevarda et al., 1986; Kustrak et al., 1996).

In 33% of the plants of *S. montana* ssp. *pisidica* from the mountain Galicica dominates linalool, in 37% of individuals ρ-cymene, in 3% borneole and in 27% — monoterpene phenol of the menthane class — carvacrol. These results agree with those from previous investigations of *S. montana* ssp. *pisidica* (Palic and Gasic, 1993).

In the essential oils of the plants of population *S. kitaibelii* coming from the gorge of the river Jelasnica, 14 components were identified (Table 2). The compounds which are absent in the essential oils with regard to the essential oils from populations of the species *S. montana* are: β-pinene, α-terpinene, z-(β)-ocymene and carvacrol. In 27% of the plants the dominant component in essential oils is monoterpene of the menthane class — limonene, in 63% is ρ-cymene and in 10% the dominant component is *trans*-sabinene hydrate. ρ-Cymene as the dominant component of the essential oil of the species *S. kitaibelii* had been also determined in earlier investigations (Sevarda et al., 1989; Palic and Gasic, 1993; Chalchat et al., 1999).

The principal component analysis was done on the basis of the quantitative content of 19 analyzed compounds in 120 individuals (Fig. 2). The PCA revealed that the first three axes represent 47.5% of total information. The first axe explains the most variabilities (22.7%) and possesses the highest biological significance, since it is capable to clearly separates the species *S. montana* ssp. *pisidica* from the species *S. kitaibelii* according to the limonene, α-pinene and camphene percentages (Fig. 2). By comparing the studied populations (based on the qualitative and quantitative composition of essential oils) a conclusion could be made that the most similar populations are the ones of *S. montana* ssp. *montana*.

The essential oil of *S. montana* ssp. *pisidica* differs from the essential oil of *S. montana* ssp. *montana* from the gorge of the river Beli Rzav and the surroundings of Zvornik in domination of carvacrol which in other populations is found in irrelevant quantities (Table 2). The small quantity of *trans*-sabinene hydrate and domination of carvacrol in the essential oils of some individuals could be a "reason plus" to differentiate it from the subspecies *montana*.

In the plants of *S. kitaibelii,* linalool appears in small quantities, while in the essential oils of some individuals there is a clear domination of limonene (Fig. 2). The *S. kitaibelii* population is specific for not having some compounds such as z-(β)-ocymene, α-terpinene, β-pinene and carvacrol (Table 2). The qualitative difference in the composition of essential oils in *S. kitaibelii* (absence of some compounds) might be a result of a specific genetic

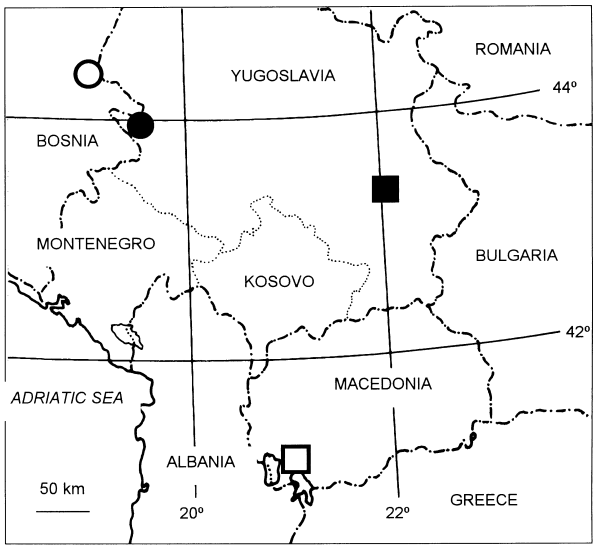

Fig. 1. Location of the analyzed populations. ○, *Satureja montana* ssp. *montana*; Beli Rzav; ●, *Satureja montana* ssp. *montana*; Zvornik; □, *Satureja montana* ssp. *pisidica*; Galicica; ■, *Satureja kitaibelii*, Jelasnica.

basis of this species. Since there are clear morphologic and chorologic differences, including even the pronounced chemical differences, it is to be accepted that the view of the authors that this taxon classify into a separate species *S. kitaibelii* (Ravarut, 1961; Silic, 1979).

The multivariate analysis reveals that *S. montana* ssp. *montana* represents a heterogeneous group while *S. montana* ssp. *pisidica* and *S. kitaibelii* are clearly separated between themselves. Cluster analysis using three methods (UPGMA, single linkage and complete linkage) revealed that essential oil composition of *S. montana* ssp. *montana* is more related to the one of *S. montana* ssp. *pisidica* than of *S. kitaibelii* (Fig. 3).

Our results contribute to the better knowledge of the chemotaxonomic structure of this polymorphic genus from the central part of the Balkan peninsula — and particularly the specificity of the species *S. kitaibelii*.

3. Experimental

3.1. Plant material

The plant material was collected from the following localities: *S. montana* ssp. *pisidica* (Wettst.) Silic from the

mountain Galicica — the south-western Macedonia; *S. montana* ssp. *montana* from the surroundings of Zvornik and the gorge of the river Beli Rzav — western Serbia; *S. kitaibelii* Wierzb. ex Heuff. from the gorge of the river Jelasnica — eastern Serbia (Fig. 1). Basic characteristics of the mentioned localities are given in Table 1. From each locality 30 plants were collected, picked in the period of blooming.

3.2. Steam distillation

The dried aerial part of each individual was submitted to the steam distillation with simultaneous extraction of the distillate by methylene-chloride (CH_2Cl_2), which enabled the separation of the essential oil. For this procedure the Likens–Nickerson apparatus was used (Maarse and Belz, 1981).

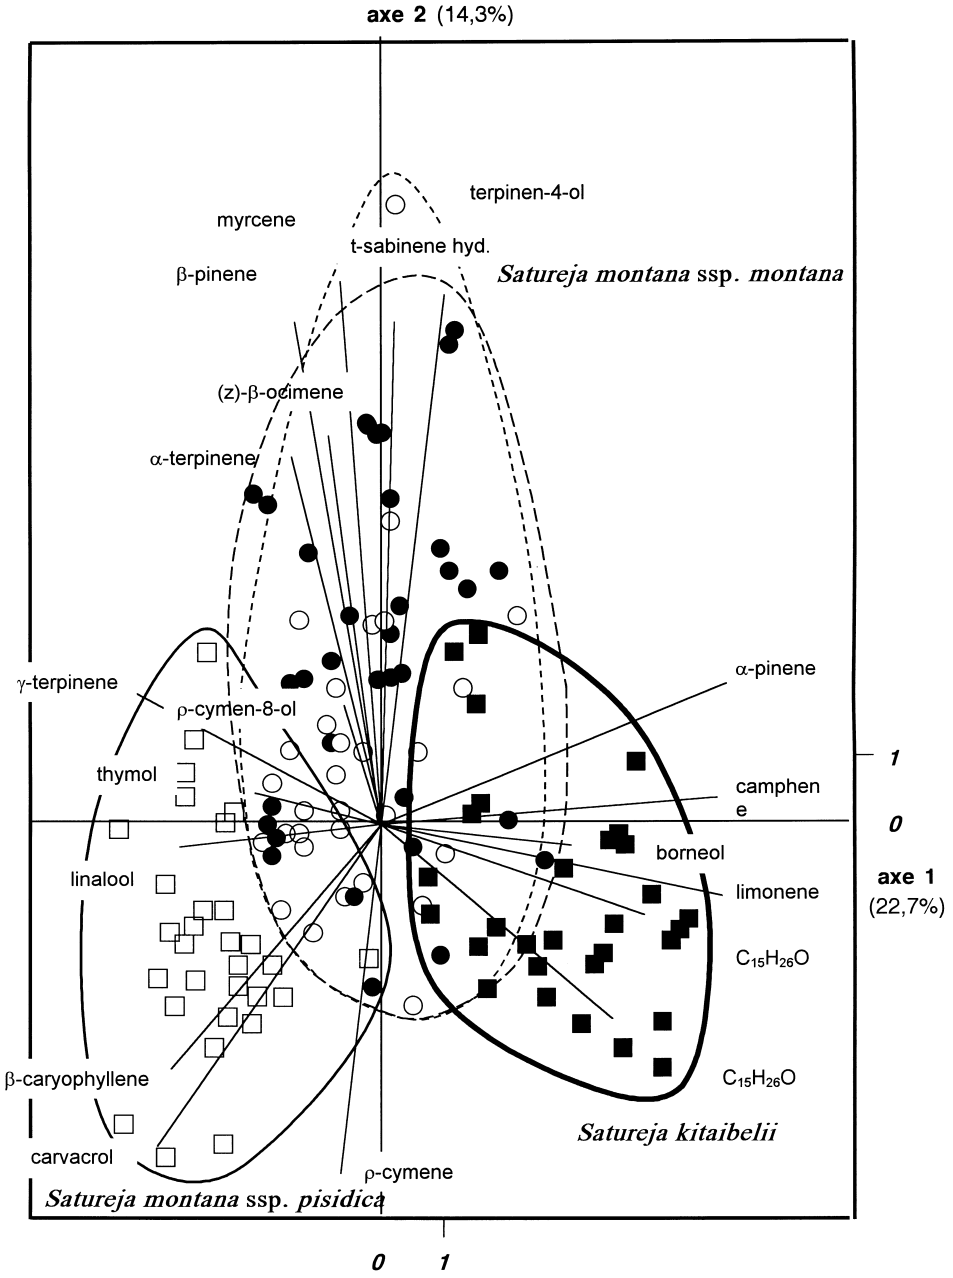

Fig. 2. PCA — graphical review of observations grouped in characters and individuals in the plan of the first two axes. ○, *Satureja montana* ssp. *montana*; Beli Rzav; ●, *Satureja montana* ssp. *montana*; Zvornik; □, *Satureja montana* ssp. *pisidica*; Galicica; ■, *Satureja kitaibelii*, Jelasnica. The space containing all the individuals of one populations is approximately bordered with a line.

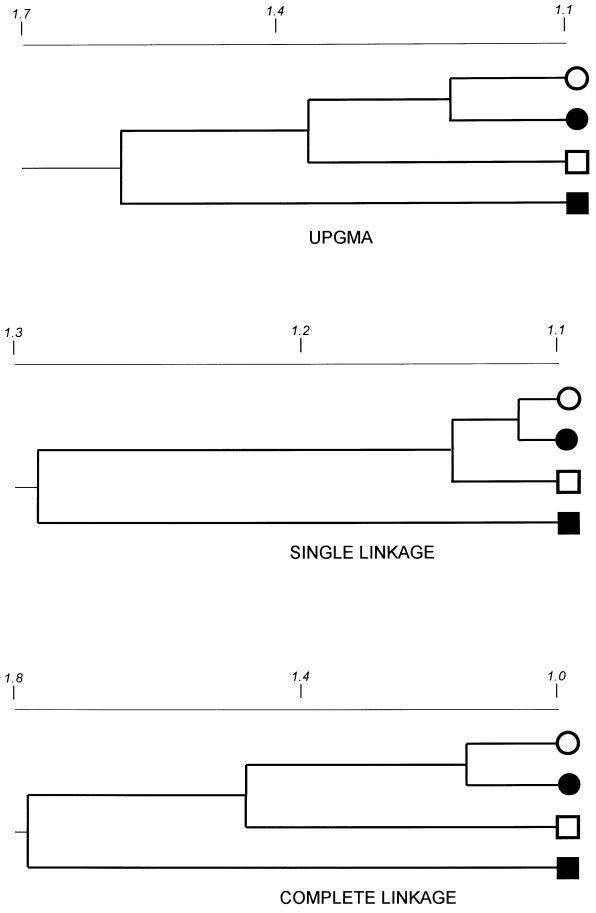

Fig. 3. Cluster analyses of *Satureja montana* and *Satureja kitaibelii* based on population means of essential oils. ○, *Satureja montana* ssp. *montana*; Beli Rzav; ●, *Satureja montana* ssp. *montana*; Zvornik; □, *Satureja montana* ssp. *pisidica*; Galicica; ■, *Satureja kitaibelii*, Jelasnica.

3.2.1. Combined GC–MS

The qualitative and quantitative analysis of the essential oils were done by GC and GC/MS under the following conditions: Analytical GC-A Varian model 3400 gas chromatograph equipped with a split/splitless injector (250°C), and a 30 m×0.32 mm DB-Wax silica capillary column and FID (300°C), were used for GC and GC/MS masurements. The column was temperature programmed from 50°C (3 min) to 200°C at 10°C/min; carrier gas 3 ml H_2/min. Peak areas were calculated electronically by a Varian DS-604 data station. GC/MS — the gas chromatograph was connected via an open split interface, and a fused silica capillary (at 250°C) to the ion source of a Finnigan MAT 8230 mass spectrometer, equipped with a PDP 11/74 computer. Working conditions: carrier gas 2 ml He/min; other GC conditions as above. MS: ion source (electron impact), 170°C, 70 eV. Constituents were identified by co-injection with authentic compounds, and by comparison of their mass spectra to those from the MS library (Wiley, 1984) taking into account the relative retention times.

3.3. Statistical analysis

In data processing, the multivariatiate statistic analysis was applied (De Lagarde, 1983). The principal component analysis (PCA) was used as a statistical method capable to suggest the structure of the set and analysis of the variables in relation to the studied characteristics. In total, 19 characteristics (chemical compounds) were analyzed in 120 individuals.

The program Statgraphics 5.0 (Statistical Graphics Corporation, USA, 1991) was used. Agglomerative cluster analyses on population means for all essential oils used the UPGMA (unweighted pair-group method, arithmetic average), single-link and complete-link clustering methods of the SAHN procedure of the NTSYS-pc computer program (Rohlf, 1990).

Acknowledgements

Our special thanks go to Dr. Bruno Fady for his useful comments and suggestions, and to Danica Bajic, Institute of Chemistry, Technology and Metallurgy from Belgrade for the GC analysis.

Abstract

Chemical investigation of dichloromethane and petrol extracts from the roots of *D. hatschbachii* A. M. G. Azevedo furnished thirteen compounds from which five are described for the first time and their structures were determined to be 3-(4′-hydroxyphenyl)-5-methoxy-6-(3,3-dimethylallyl)-2″,2″-dimethylchromene-(5″,6″:8,7)-3-(propyl-2-one)-4H-1-benzo-2,3-dihydropyran-2,4-dione; 6,4′-dihydroxy-3-(3,3-dimethylallyl)-2″,2″-dimethylchromene (5″,6″:5,4)-2-methoxy deoxybenzoin; 6,4′-dihydroxy-3-(3,3-dimethylallyl)-2″,2″-dimethylchromene (5″,6″:5,4)-2-methoxy-8-(propyl-2-one) deoxybenzoin; 6-(3,3-dimethylallyl)-2″,2″-dimethylchromene (5″,6″:4,5)-4′-hydroxy-3-methoxy stilbene and 3,5-dimethoxy-4′-hydroxy-4-(3,3-dimethylallyl) stilbene by spectral analysis (UV, IR, MS and 1D- and 2D- NMR experiments). The root extracts and some isolated compounds were bioactive, as revealed by bioautography and brine shrimp lethality assays. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

The genus *Deguelia* Aubl. belongs to the family Leguminosae, subfamily Papilionoideae, tribe Millettieae (Geesink, 1984; Tozzi, 1989, 1994, 1998). In this tribe are included some tropical trees and lianas, mainly of the genera *Lonchocarpus* Kunth, *Derris* Lour. and *Millettia* Wight. & Arn., in which the definition of natural groupings remains problematic. Since these genera were established, their circumscription and infrageneric classification have been modified by several authors. Geesink (1984), in his study of the Millettieae based on cladistic analyses, proposed many changes. Thus he elevated some sections to the generic level, as *Derris* sect. *Paraderris* Miq., and reinstated the genera *Brachypterum* (Wight & Arn.) Benth., *Deguelia* and *Philenoptera* A. Richard. In this sense, *Derris*, *Lonchocarpus* and *Millettia* received a more restricted treatment. This taxonomic analysis has been adopted with some modifications (Tozzi, 1989, 1992, 1994, 1995, 1998). Accordingly the generic delimitation of *Deguelia* now comprises those species previously belonging to *Lonchocarpus* subg. *Phacelanthus* Pittier (= *Lonchocarpus* ser. *Fasciculati* Benth.) and American *Derris* and *Millettia*. Analogously *Lonchocarpus* has been defined by Geesink's (1984) concept, enlarged by the inclusion of some species with panicles that should be classified in the genus *Philenoptera*. *Deguelia* and *Lonchocarpus* species can be recognized by the habit, the inflorescence structure and morphological characters of the flowers and fruits.

Deguelia comprises 20 species, which are found in tropical South America. Based on analysis of their morphological characters, two sections were recognized for *Deguelia*. *Deguelia* sect. *Multiovulis* A.M.G. Azevedo comprises five species and *Deguelia* Aubl. sect. *Deguelia* has the 15 remaining species. It has been suggested that flavonoid profiles might help to elucidate the problematic differentiation of the genera of the tribe Millettieae and their phylogenetic relationship (Gomes et al., 1981; Gottlieb et al., 1981; Gottlieb, 1982). The "potentiality of

PII: S0031-9422(00)00509-4

flavonoid characters to aid in taxonomic revision'' has been recently recognized (Harborne, 2000).

Chemical reports about flavonoid composition have been published for 35 species of *Derris* or *Lonchocarpus*, from which eight species are now included in *Deguelia*.

The flavonoid profiles furnished by some *Deguelia* species (Table 1) consist mainly of isoflavonoids. Among *Deguelia* isoflavonoids, a high incidence of rotenoids is found in *Deguelia* sect. *Deguelia* species while 4-hydroxy-3-phenylcoumarins predominate in *Deguelia* sect. *Multiovulis* species.

It is well known that many isoflavonoids have antimicrobial and insecticidal activities (Dewick, 1988), which can be respectively evaluated through bioautography (Saxena et al., 1995) and brine shrimp lethality assays (McLaughlin et al., 1995).

Deguelia hatschbachii A.M.G.Azevedo is a new species native to Brazil that was recently classified in *Deguelia* sect. *Multiovulis*.

We have undertaken a phytochemical study of roots extracts of *Deguelia hatschbachii* in order to evaluate whether its flavonoid profile can be used to complement morphological data in studies of taxonomy and phylogeny.

2. Results and discussion

Petrol and dichloromethane extracts of *D. hatschbachii* roots were submitted to chromatographic analysis (column, TLC and prep. TLC), allowing the isolation of ten flavonoids **(1, 2a–b, 3a–b, 4a–b, 5–7)**, two stilbenes **8,9** and lupeol **10**. Flavonoids **5–7** and stilbenes **8–9** are new compounds (Fig. 1).

Scandenin **(1)** (Garcia et al., 1986), robustic acid **(2a)** (Khalid and Waterman, 1983; Donnelly et al., 1995), robustic acid methyl ether **(2b)** (East et al., 1969; Olivares et al., 1982); 4′,5- dihydroxy-6-(3,3-dimethylallyl)-7-methoxy flavanone **(3a)** (Mahmoud and Waterman, 1985), lupinifolin **(3b)** (Mahidol et al., 1997), osajin **(4a)** (Delle Monache, et al., 1994), scandinone **(4b)** (Sekine et al., 1999) and lupeol **(10)** (Wenkert et al., 1978; Lehn and Ourisson, 1962; Budzikiewicz et al., 1963) were characterized by comparison of the respective spectral data with literature values.

Compound **5** was a new flavonoid. Its HREIMS showed a molecular ion $[M]^+$ of *m*/*z* 490.1989, corresponding to $C_{29}H_{30}O_7$ (required M^+ 490.1991). The ^1H and ^{13}C NMR spectral data indicated that A and B rings are similar to those in scandenin **1** (Tables 2 and 3). However, the ^1H NMR spectrum showed two sets of one-proton doublets at δ 3.87 ($J = 18.1$ Hz) and 3.53 ($J = 18.1$ Hz) assignable to diastereotopic methylene hydrogens, while a singlet at δ 2.20 (3H) was compatible with the expected resonance for an acetyl or acetate methyl group. It should be mentioned that the two sets of one-proton double doublets at δ 3.27 ($J = 13.9$ and 7.2 Hz) and 3.21 ($J = 13.9$ and 7.2 Hz) assignable to the methylene hydrogens of 3,3-dimethylallyl group is also evidence that **5** is chiral, which was further confirmed by optical rotation measurements. On the other hand, a signal corresponding to the hydrogen of the hydroxyl at C-4 of scandenin **1** was not observed, while the ^{13}C NMR spectrum showed typical carbonyl signals at δ 205.9, 187.6 and 169.1, respectively, corresponding to an alkyl ketone; an α,β- unsaturated ketone and a phenyl acetate groups, which was reinforced by the presence of strong absorptions at ν_{max} 1704, 1682 and 1770 cm^{-1} in the IR spectrum. The DEPT spectrum showed six CH_3, two CH_2, seven CH and fourteen quaternary carbons. The carbon signal at δ 61.4 was assigned to C-3. The EIMS showed a peak of *m*/*z* 300 (38%) corresponding to a fragment furnished by retro-Diels Alder cleavage of C-ring such as was previously observed for scandenin **1**. However, instead of a peak of *m*/*z* 134 representing the B-ring fragment, there was a fragment of *m*/*z* 190 (5%) suggesting that in compound **5** the corresponding fragment is 56 a.m.u. higher and must be attached to C-3. According to the NMR spectra discussed above, it is a propyl-2-one group and C-3 is chiral. These findings were further confirmed by extensive 2D- NMR experiments as well from the enhancements observed in the NOE difference spectrum (Fig. 2). In the HMBC spectrum, $^3J_{C\text{-}H}$ correlations between methylene hydrogens of propyl-2-one group with C-1′, C-2 and C-4 carbons as well as those observed between C-3 and H-2′, H-6′ hydrogens are especially illustrative concerning C-ring constitution. Based on MS/MS experiments selecting the ions of *m*/*z* 475 [285 (100%)], *m*/*z* 300 [285 (100%), 269 (5%), 257 (54%), 245 (25%)], *m*/*z* 257 [242 (20%)] and *m*/*z* 190 [147 (100%), 119 (48%)] we can suggest a fragmentation pathway for this compound (Fig. 3).

Compound **5** represents the first example of a 4-hydroxy-3-phenylcoumarin derivative where the corresponding β-keto ester tautomer is fixed by the presence of a substitute on C-3.

In the ^1H and ^{13}C NMR spectra of compound **6,** typical signals of a 3,3-dimethylallyl group, a dimethylchromene ring, an aromatic methoxyl group and a *para*-substituted aromatic ring were observed (Tables 2 and 3). In addition, singlets at δ 13.20 (1H) and 4.32 (2H), in the ^1H NMR spectrum, correspond to the absorptions of a hydrogen bonded hydroxyl and α-methylene hydrogens of a deoxybenzoin derivative (Kiuchi et al., 1990), which was confirmed by the presence of a carbonyl carbon signal at δ 203.6 and a methylene carbon signal at δ 47.6 in the ^{13}C NMR spectrum. Other signals in the ^{13}C NMR spectrum were compatible and DEPT (90° and 135°) experiments showed the presence of five CH_3, two CH_2, seven CH and eleven quaternary carbons. While these data lead to three structural possibilities [**6** (Fig. 1); **6a** and **6b** (Fig. 4)], the NOE difference spectral data

[a] a,b, Interchangeable values.

(Fig. 2) correspond to structure **6**. The EIMS displayed a molecular ion $[M]^+$ of m/z 408 (3%) suggesting the molecular formula $C_{25}H_{28}O_5$. The base peak of m/z 69 (100%) and those of m/z 301 (32%) and m/z 107 (15%), respectively, correspond to an isoprenyl cation as well as a fragment resulting from C_7-C_8 bond cleavage (Fig. 5). UV (λ_{max} 266 nm) and IR (ν_{max} 1700.1 cm^{-1}) spectral data were also in agreement with structure **6**.

Compound **6** was detected in the dichloromethane extract by HPLC, indicating that it is not an artifact produced from hydrolysis followed by decarboxylation of scandenin **1**, during the isolation process. Moreover we found that scandenin **1** remained unchanged after it was left in an alcoholic solution of potassium hydroxide under reflux (Uma Rani and Darbarwar, 1987). These results lead us to suggest that scandenin **1** is the biogenetic precursor of compound **6**.

Compound **7** showed a molecular ion $[M]^+$ of m/z 464 (16%), in the EIMS, suggesting the molecular formula $C_{28}H_{32}O_6$. This time, the base peak (m/z 301) corresponds to the fragment including ring A, originating from C_7–C_8 bond cleavage (Fig. 5). The presence of a 3,3-dimethylallyl group, a dimethylchromene ring, an aromatic methoxyl group and a *para*-substituted aromatic ring were deduced from their NMR spectral data (Tables 2 and 3), which were closely related to those of compound **6**. However, instead of a resonance for the hydrogens of a methylene group, three double doublets at δ 5.34 (J = 10.5, 4.0 Hz), 3.50 (J = 17.8, 10.5 Hz) and 2.57 (J = 17.8, 4.0 Hz) assignable to an ABX system were observed, while a singlet at δ 2.12 (3H) indicated the presence of an acetyl or acetate methyl group. In addition, the ^{13}C NMR spectrum showed two carbonyl signals at δ 207.6 and 204.4, respectively, corresponding to an alkyl ketone and an α,β-unsaturated ketone. In the ^1H NMR spectrum, the presence of the two sets of one-proton double doublets at δ 3.16 (J = 14.5, 7.0 Hz) and 3.03 (J = 14.5, 7.0 Hz), assignable to the methylene hydrogens of a 3,3-dimethylallyl group, also indicated that **7** is chiral. The ^{13}C NMR spectrum (Table 3) is totally compatible, showing signals for the presence of six CH_3, two CH_2, eight CH and twelve quaternary carbons, confirmed by DEPT (90° and 135°) experiments. These data are compatible with three structures [**7** (Fig. 1); **7a** and **7b** (Fig. 4)]; the CycleNOE experiments lead us to structure **7** (Fig. 2).

By analogy to compound **6**, we suggest that compound **7** is biogenetically derived from compound **5**; the natural occurrence of deoxybenzoin derivatives is rarely found.

The HREIMS for compound **8,** showed a molecular ion $[M]^+$ of m/z 376.2039 consistent with the molecular formula $C_{25}H_{28}O_3$ (376.2038). In the ^1H NMR spectrum, two one-proton doublets at δ 7.15 (J = 16.6 Hz) and 6.84 (J = 16.6 Hz) were observed, these being typical of olefinic hydrogens in *trans*-stilbenes; an AA′BB′ system at δ 7.32 (2H, *d*, J = 8.6 Hz) and 6.75 (2H, *d*, J = 8.6 Hz) was also noted this being ascribed to hydrogens of a *para*-substituted aromatic ring. The spectrum also showed signals corresponding to the presence of a 3,3-dimethylallyl group, a dimethylchromene ring, an aromatic methoxyl group and an aromatic hydrogen (Table 2). The ^{13}C NMR spectrum and DEPT (90° and 135°) experiments showed the presence of nine quaternary carbons, ten CH, one CH_2 and three CH_3 groups (Table 3). These data are compatible with four structural possibilities [**8** (Fig. 1); **8a**, **8b** and **8c** (Fig. 6)] by taking into account the oxidation pattern of A-ring originating from stilbene biosynthesis (Norin, 1989).

Structure **8b** can be eliminated because in the NOE difference spectrum, irradiation of methylene hydrogens at δ 3.34 (H-7′) caused an enhancement of H-3″ (δ 5.50; 0.9%), H-8′ (δ 5.06; 3.4%), H-10′ (δ 1.75; 5.1%) and H-7 (δ 6.84; 7.9%) signals. In the ^{13}C NMR spectrum, the signal for the methoxyl group was at δ55.6, and since that *ortho*-disubstituted methoxyl groups absorb around δ 60.0 (Agrawal, 1989), structure **8a** does not fit. In the ^1H NMR spectrum, the signal at δ 6.59 (1H) is not in agreement with H-4 such as in **8c**, because in lonchocarpene (Kaouadji, 1988; Kaouadji et al., 1986) the H-2

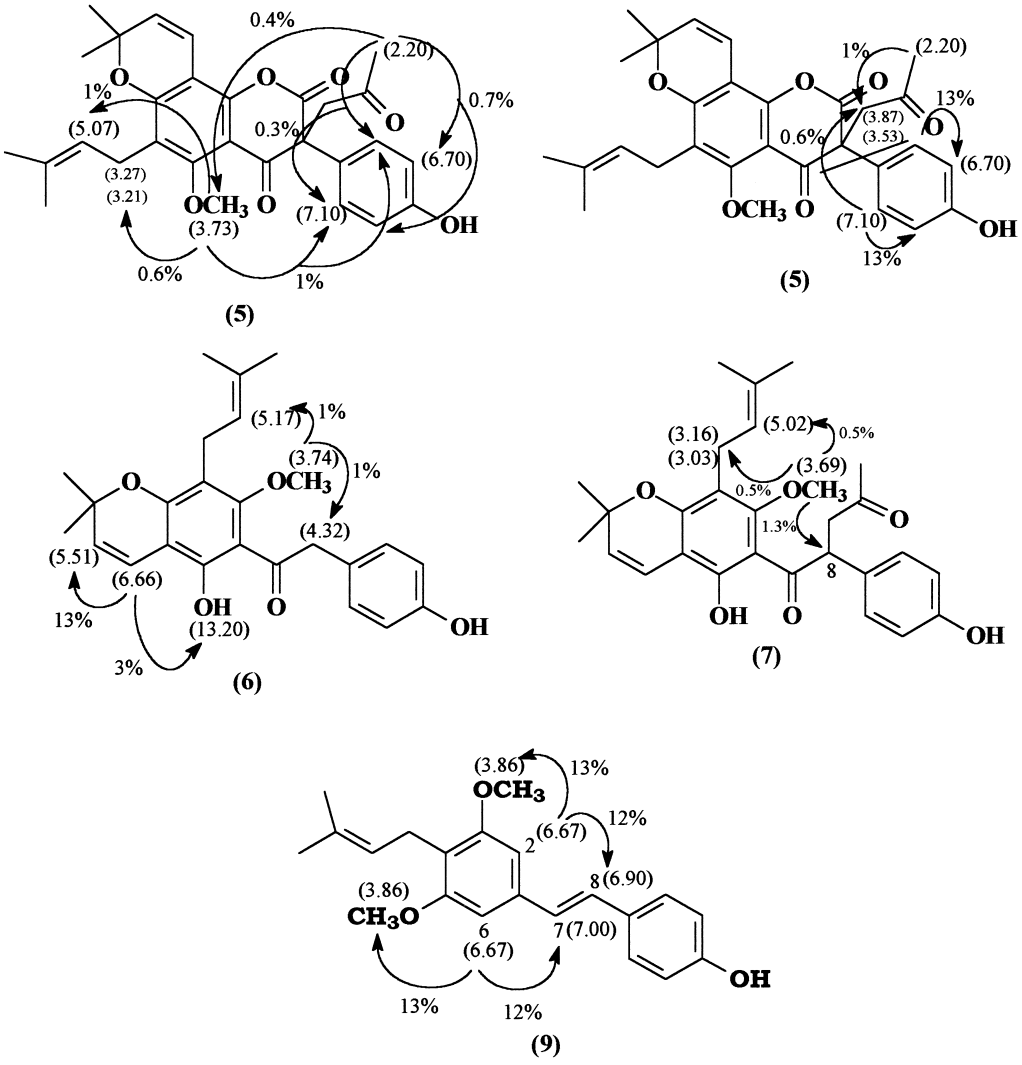

Fig. 2. NOE effects observed for some compounds isolated from *Deguelia hatschbachii*.

and H-4 signals resonate at δ 6.63 and 6.37, respectively. The main peaks observed in the EIMS represent the molecular ion $[M]^+$ of *m/z* 376 (21%) and loss of methyl radical of *m/z* 361 (100%). UV (λ_{max} 330 nm) and IR (ν_{max} 959.6 cm^{-1}) spectral data were also in agreement.

The HREIMS for compound **9,** showed a molecular ion $[M]^+$ of *m/z* 324.1725 consistent with the molecular formula $C_{21}H_{24}O_3$ (324.1725). The ^1H NMR spectrum (Table 2) showed a pair of doublets corresponding to a chain of a *trans*-stilbene derivative and an AA′BB′ system as observed for compound **8**. In addition, the spectrum showed typical resonances for a 3,3-dimethylallyl group and two singlets assigned to two equivalent aromatic hydrogens and two equivalent methoxyl groups. These findings indicate structure **9**, which was supported by NOE difference spectral data (Fig. 2). The ^{13}C NMR spectrum (Table 3) is also compatible with this proposition, where the presence of four CH_3, one CH_2 and nine CH groups, and seven quaternary carbons was confirmed by DEPT (90° and 135°) experiments. The EIMS showed a molecular ion $[M]^+$ of *m/z* 324 (100%) and the peaks of *m/z* 309 (93%) and *m/z* 269 (10%) presumably originated from the loss of -CH_3 and -C_4H_7 radicals, respectively. The UV (λ_{max} 325 nm) and IR (ν_{max} 958 cm^{-1}) spectral data were also compatible with this assignment.

Although eight flavonoids were identified by HPLC analysis in the dichloromethane extract, only five were quantified, because the peaks corresponding to compounds **2b** and **5** coeluted and compound **6** had decomposed. Quantitative analysis showed that lupinifolin **3b** and scandenin **1** are the most abundant compounds in petrol and dichloromethane extracts (Table 4).

Thus the flavonoids of *D. hatschbachii* mainly consist of isoflavonoids, as observed for the *Deguelia* species previously investigated.

The occurrence of 4-hydroxy-3-phenylcoumarins in *D. hatschbachii* reinforces its inclusion in *Deguelia* sect. *Multiovulis*. That is, these data support the use of flavonoid characters in studies of taxonomy.

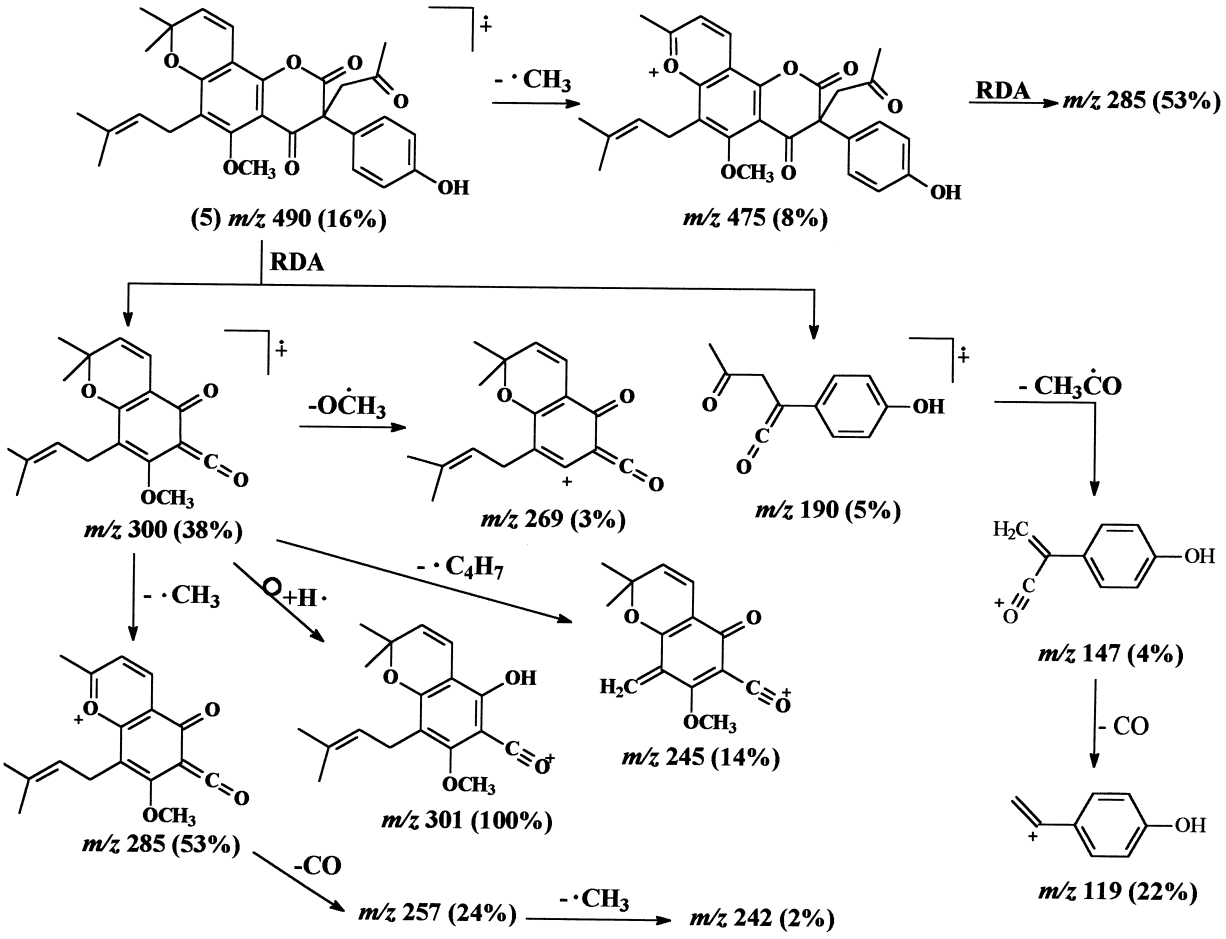

Fig. 3. Fragmentation pathway of compound **5**, based on MS/MS experiment.

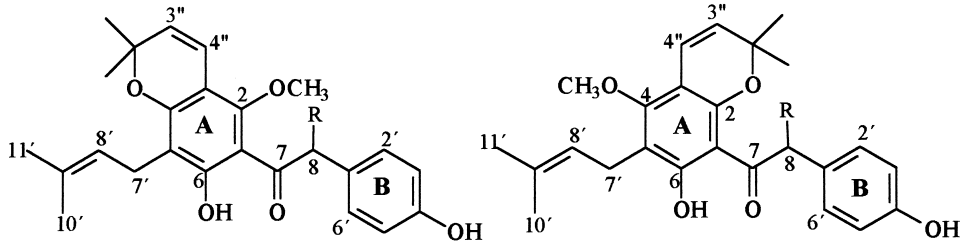

Fig. 4. Structural alternatives for compounds **6** and **7**.

Bioautography was performed according to Saxena et al. (1995) with some modification (Magalhães et al., 1998). Table 5 shows the results obtained with six *bacteria* and nine *fungi*. The dichloromethane extract and **1** showed activity against *Bacillus subtilis* and *Staphylococcus aureus* while **3a**, **3b** and **9** were active only against *Bacillus subtilis*. None of the flavonoids were active against the fungi, but the methanol extract showed activity against *Cladosporium cladosporioides*. A brine shrimp lethality assay was performed according to McLaughlin et al. (1995). As shown in Table 6, all tested samples displayed high toxicity with LC_{50} values

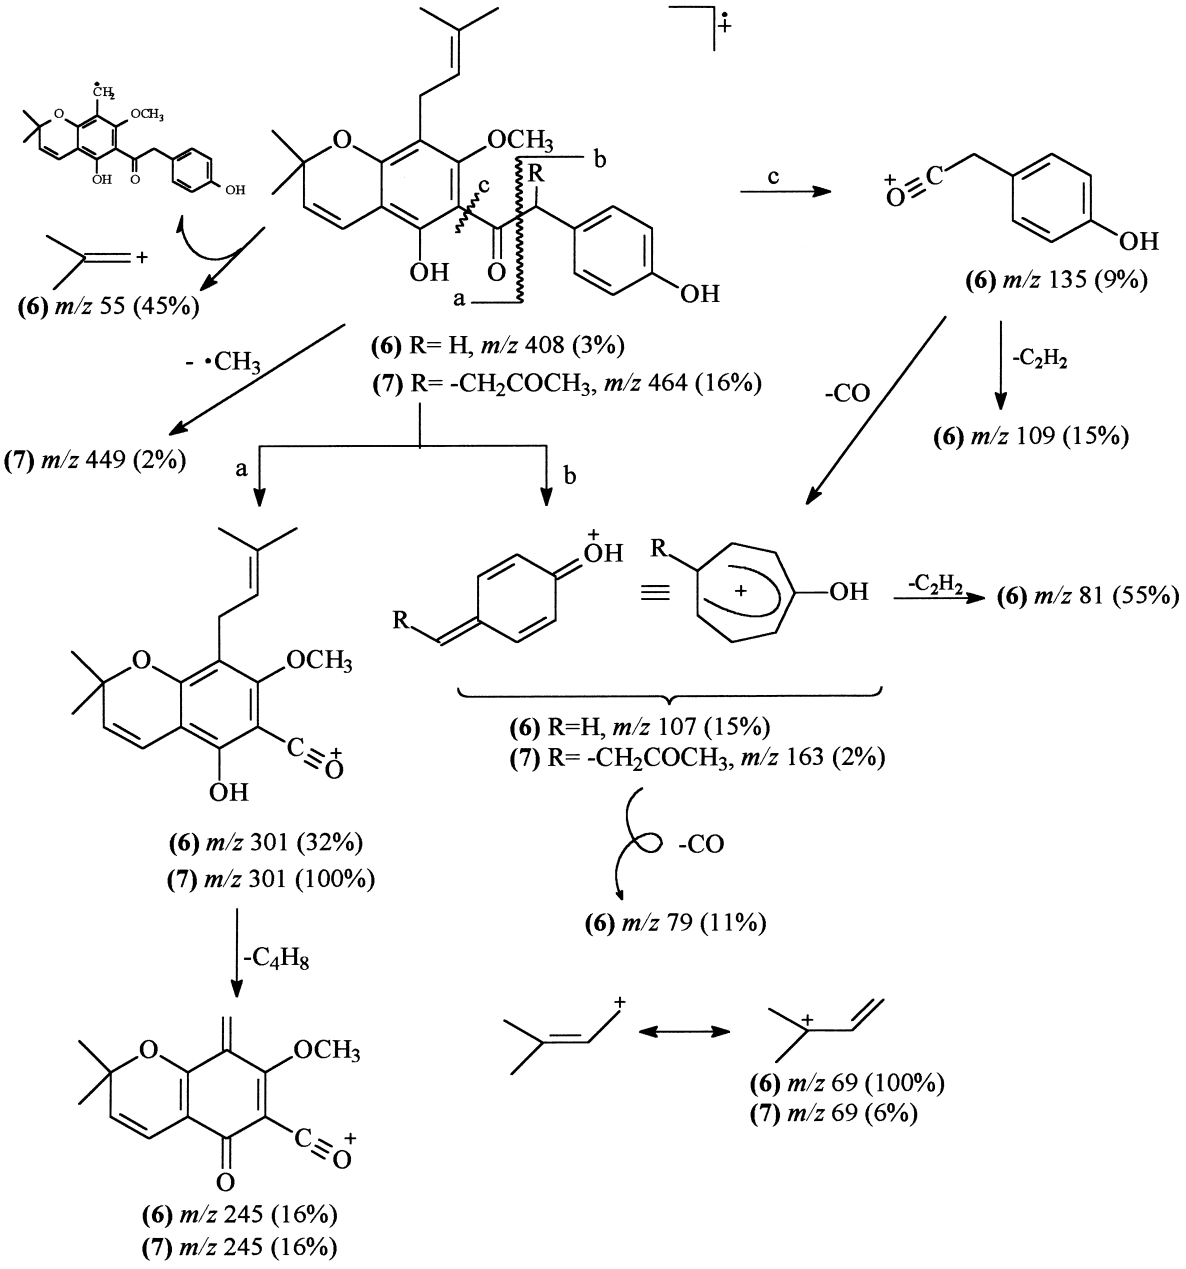

Fig. 5. Fragmentation pathway of compounds **6** and **7**.

being very low. It is important to bear in mind that even the known compounds (**1**, **2a**, **2b**, **3a**, **3b** and **4b**) have not been submitted to any biological assays before.

3. Experimental

UV: $CHCl_3$ or MeOH. IR: film or KBr. ^1H NMR in $CDCl_3$, at 7 or 11 tesla instruments with TMS as int. standard. EIMS 70 eV, direct probe. HREIMS and MS/MS experiments were performed using a VG Auto Spec-Fisions Instrument by using electron ionization technique at 70 eV (linked scan at 8 keV collisions with Helium). HPLC: Reversed-phase HPLC analyses were performed on a C-18 Nova Pak column, by using a variable wavelength UV and diode-array detection. Identification of the peaks in the chromatograms was carried out by co-injection with eight flavonoids previously isolated from the extracts of *D. hatschbachii* roots and further purified by preparative HPLC. Each standard compound was dissolved in acetonitrile and purified by semi-preparative HPLC (Waters) system, consisting of an universal liquid chromatograph injector, a model 484 variable-wavelength detector (adjusted to 240 nm), a model 740 data module and a model 600E system controller and pump, with a Regis ODS, 5 μm,

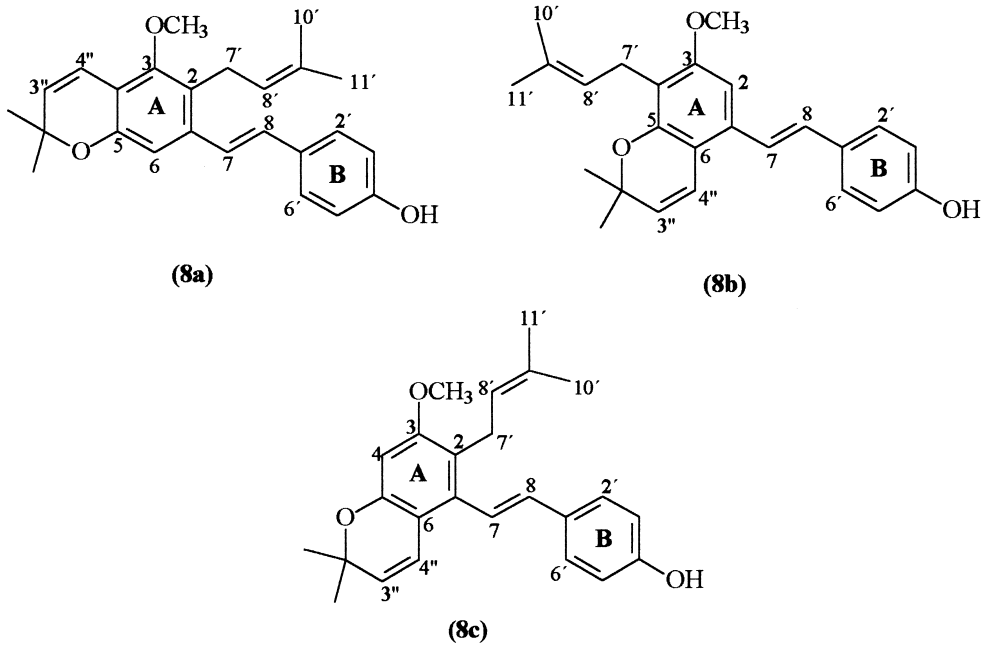

Fig. 6. Structural alternatives for compound **8**.

Table 4
Flavonoid content of extracts of *Deguelia hatschbachii* roots

Contents (mg/g of roots)		
Extract		
Flavonoids	Petrol	Dichloromethane
1	nd[b]	12.37
2a	nd	0.57
2b	nd	nq[a]
3a	0.64	2.90
3b	1.27	12.03
4b	nd	0.46

6	nd	nq

[a] nq = not quantified.
[b] nd = not detected.

250×10 mm i.d. column, and a CH_3CN-H_2O gradient of 20–100% CH_3CN in 45 min at a flow rate of 2.0 ml min^{-1}.

3.1. Quantitative analysis

Light petroleum and dichloromethane root extracts from *D. hatschbachii* were dissolved in acetonitrile. An aliquot (2 μl) of each extract was analyzed by a Hewlett Packard model 1090, series II/M HPLC with a Waters Nova-pak 3 μm column, with a CH_3CN–H_2O gradient of 20–100% CH_3CN in 45 min at a flow rate of 0.8 ml min^{-1}, with the column at ambient temperature. Detection was with a HP photodiode array. The identification of each peak in the corresponding chromatograms was achieved by comparison of retention times, t_R, and UV spectra with those obtained for the standards, as well as by coinjection with the corresponding standard. The retention times are given in minutes as **1** scandenin (27.7), **2a** robustic acid (24.3), **2b** methyl robustate (28.2), **3a** (26.2), **3b** lupinifolin (31.3), **4b** scandinone (30.9), **5** (27.3) and **6** (32.5).

3.2. Calibration curves

Standard solutions were prepared by serial dilutions of the isolated compounds in acetonitrile. Calibration curves were obtained by plotting the integrated peak areas at the maximum UV absorption for each compound versus concentration by performing linear regression analysis. Quantification was made by external calibration with correlation coefficients of 0.999 for each analysed compound.

3.3. Plant material

Roots of *Deguelia hatschbachii* were collected at UNICAMP campus next to the Economy Institute, in March 1994. Voucher specimens have been deposited at the herbarium (uec 95-38) of Campinas State University, Campinas-SP, Brazil.

3.4. Extraction and isolation

Dried roots (97.7 g) of *D. hatschbachii* were successively extracted with petrol (30–60°C), CH_2Cl_2 and MeOH for 50 hr in a Soxhlet apparatus. After solvent evaporation, the petrol extract gave a viscous yellow oil (1.7 g), while the dichloromethane extract gave a brown

Compound **1**	4.31
Compound **3a**	0.0004
Compound **3b**	13.01
Control (H_2O)	> 1000

solid (4.2 g) and the methanol extract (4.1 g) gave a brown gum. An aliquot of the dichloromethane extract (3.0 g) was applied to a silica gel column (120 g) eluted first with dichloromethane. The eluent polarity was gradually increased by addition of EtOAc and MeOH to furnish 342 fractions of 200 ml each which were reduced to 82 groups after TLC analysis. Most of the compounds were found in six groups ranging from fractions 4 to 66. A sample of each was further fractionated by successive prep. TLC (silica gel). Flavonoids were visualized under UV light ($\lambda = 254$ and 366 nm) and recovered from TLC plates by extraction with mixtures of CH_2Cl_2 and MeOH to furnish compounds **1** (12.4 mg), **2a** (4.1 mg), **2b** (5.7 mg), **3a** (20.0 mg), **3b** (20.1 mg), **4a** (2.0 mg), **4b** (4.0 mg), **5** (7.7 mg), **6** (2.9 mg), **7** (2.0 mg), **8** (21.4 mg) and **9** (4.8 mg). Analogously a part of the petrol extract (1.5 g) furnished compounds **3a** (3.2 mg), **3b** (8.2 mg), **8** (10.2 mg), **9** (5.0 mg) and **10** (7.4 mg),

Abstract

Peppermint (*Mentha×piperita* L.) essential oil and main components were assessed for their ability to interfere with plant respiratory functions. Tests were conducted on both root segments and mitochondria isolated by etiolated seedlings of cucumber (*Cucumis sativus* L.). Total essential oil inhibited 50% of root and mitochondrial respiration (IC_{50}) when used at 324 and 593 ppm, respectively. (+)-Pulegone was the most toxic compound, with a 0.08 and 0.12 mM IC_{50} for root and mitochondrial respiration, respectively. (−)-Menthone, followed (+)-pulegone in its inhibitory action (IC_{50} values of 1.11 and 2.30 mM for root and mitochondrial respiration respectively), whereas (−)-menthol was the less inhibitory compound (IC_{50} values of 1.85 and 3.80 mM respectively). A positive correlation was found for (+)-pulegone, (−)-menthone and (−)-menthol between water solubility and respiratory inhibition. The uncoupling agent, carbonyl-cyanide-*m*-chlorophenyl-hydrazone (CCCP), lowered (−)-menthol and (−)-menthone inhibition and annulled (+)-pulegone inhibition of mitochondrial respiration, whereas salicyl-hydroxamic acid (SHAM) 2-hydroxybenzohydroxamic acid, the alternative oxidase (AO) inhibitor, increased (−)-menthone inhibition and annulled both (+)-pulegone and (−)-menthol inhibitory activity. The possible interaction of (+)-pulegone and (−)-menthol with AO and the mechanism of action of (+)-pulegone, (−)-menthone and (−)-menthol on mitochondrial respiration are discussed. © 2001 Elsevier Science Ltd. 1. Introduction

Higher plants synthesize a great variety of terpenoids, which can be involved in allelophatic interactions. Monoterpenoids are the major components of some essential oils and have been recognized as main allelochemicals in higher plants: they have toxic effects on seed germination (Robinson, 1983; Rice, 1984), growth of some bacterial strains (Knobloch et al., 1989; Economou and Nahrstedt, 1991), development and growth of some insects (Lee et al., 1999), and growth of pathogenic fungi (Adam et al., 1998).

Plants from the genus *Mentha* are a natural and important source of monoterpenoids used in food, pharmaceutical, and cosmetic industries (Hendriks, 1998). Peppermint, along with cornmint (*Mentha arvensis* var. *piperascens*) and spearmint (*Mentha spicata*), is one of the most economically important essential oil crops, with a world production exceeding 2000 metric tons per year (Deans and Waterman, 1993). The main monoterpenes in peppermint are menthol and menthone, followed by good percentages of menthyl acetate, limonene, 1,8-cineole and low percentages of pulegone (Maffei and Sacco, 1987).

Several pharmacological and biological effects have been associated with these oil components. In particular: menthol is a known antifungal and antimicrobial agent (Morris et al., 1979) and larvae repellent (Kelsey et al., 1984). It has been found to interact at the cell level with cytosolic Ca^{2+}, probably through an intracellular Ca^{2+} store release (Takeuchi et al., 1994) and Ca^{2+} channel blocking (Taylor et al., 1985; Hills and

Aaroson, 1992). Menthone is a growth inhibitor (Slama, 1978), whereas pulegone, a potent abortifacient, is metabolized by hepatic microsomal mono-oxygenases to a series of hepatotoxins that cause liver cancer (Nelson, 1995) and is involved in many reported cases of intoxication in humans and animals (Bakerink et al., 1996). Furthermore, pulegone is considered one of the most powerful allelochemicals and has been demonstrated to be about twice as toxic as HCN (Asplund, 1968,1969; Fisher, 1986,1991).

The effect of allelopathic compounds on mitochondrial respiration may be an important mechanism of action through which allelochemicals control growth of several weed species. Rasmussen and co-workers (1992) found that the hydroquinonic compound, sorgoleone, a major component in the exudate of grain *Sorghum bicolor* roots is a potent inhibitor of both soybean and corn mitochondrial respiration. Juglone (5-hydroxy-1,4-naphthoquinone), the main allelochemical isolated from the black walnut (*Juglans nigra* L.), exerts an opposite effect by stimulating oxygen uptake in mitochondria of *Glycine max* (Hejl et al., 1993). The inhibition of growth and spore formation of some plant pathogenic fungi by essential oil applications has been shown to be correlated with their respiration-inhibitory activity (Inouye et al., 1998).

Considering the extended application of mint oil and the possible future applications of natural compounds, such as essential oils in crop pest and weed control, we aimed to determine whether peppermint essential oil may affect oxygen uptake in plants. As a study system we used cucumber seedlings for their easiness of handling, uniform germination and growth and for the quick response they give to allelopathic agents (Maffei et al., 1999a).

2. Results and discussion

The oil chemical composition of peppermint plants used in this study was characterized by the presence of the monoterpene oxygenated compounds (−)-menthol (44.99%), (−)-menthone (20.78%), (+)-menthofuran (4.32%), (+)-menthyl acetate (4.07%) and (+)-pulegone (0.80%), along with good percentages of the monoterpene oxide 1,8-cineole (6.53%) and the olefin (−)-limonene (2.57%). Minor mono- and sesquiterpenes as reported earlier (Maffei and Sacco, 1987) made the remainder.

2.1. Root respiration

Peppermint essential oil prompted a significant inhibition of cucumber root respiration, for concentrations higher than 60 mg/l (Fig. 1). The amount of essential oil needed to obtain a 50% inhibition (IC_{50}) was 324 mg/l ($R=0.99$). This observation is in accordance with literature data on the inhibition of seed germination after exposure to volatile terpenes, which disrupt cell membranes and lead to cytological alterations with a reduction of biochemical activity of mitochondria and other organelles (Fisher, 1991).

A greater inhibitory effect was observed when roots were exposed to increasing concentrations of (−)-menthone [$IC_{50}=169.07$ mg/l, 1.11 mM, correlation coefficient (R) $=0.99$] and (−)-menthol ($IC_{50}=287.91$ mg/l, 1.85 mM, $R=0.96$). A slight stimulation of root oxygen uptake was registered for total essential oil, (−)-menthone and (−)-menthol concentrations ranging from 10 to 50 mg/l. On the contrary, (+)-pulegone inhibited oxygen uptake at all tested concentrations, with a 11.20 mg/l IC_{50} (0.075 mM, $R=0.99$). These results indicate that (+)-pulegone is a strong inhibitor of root respiration, being able to inhibit root respiration almost 29 times more than total essential oil, 15 times more than (−)-menthone and almost 26 times more than (−)-menthol. Usually, unsaturated monoterpene hydrocarbons require high concentrations (>2 mM) to cause 50% inhibition of germination (IC_{50}), whereas higher phytotoxic effects are observed from cyclic alcohols to cyclic ketones (<0.1 mM IC_{50}) (Reynolds, 1987). The greater toxicity of monoterpene ketones with respect to alcohols has been demonstrated in several cell systems (Reynolds, 1987; Fisher, 1991) and in rat liver tissues the exocyclic double bond of pulegone is responsible for its well known hepatotoxic effects (McClanahan et al., 1989). Inhibition of root respiration caused by (+)-pulegone is in accordance with the well known toxic properties already tested for this molecule (Thomassen et al., 1990; Nelson et al., 1992; Franzios et al., 1997) as well as its effect on plasma alkaline phosphatase (Molck et al., 1998).

Assuming that root respiratory rate inhibition (50%) by single peppermint oil components was additive and dependent on the relative percentage of each component in the total oil, from regression lines of Fig. 1 and considering the oil composition as stated above, it is possible to extrapolate that (−)-menthol contributed to the 43% of the overall oil inhibition, whereas (−)-menthone and (+)-pulegone to the 33 and 24% respectively.

2.2. Mitochondrial respiration

The effect of peppermint essential oil and oil components on mitochondrial respiration is shown in Fig. 2. The amount of total essential oil (595.03 mg/l, $R=0.99$) and (−)-menthol (592.91 mg/l, 3.80 mM, $R=0.95$) able to inhibit mitochondrial respiration by 50% were statistically the same. We still registered an increase in oxygen uptake for concentrations of total essential oil as high as 75 mg/l and for (−)-menthol applications up to 260 mg/l. Despite its lower IC_{50} (351.38 mg/l, 2.30 mM,

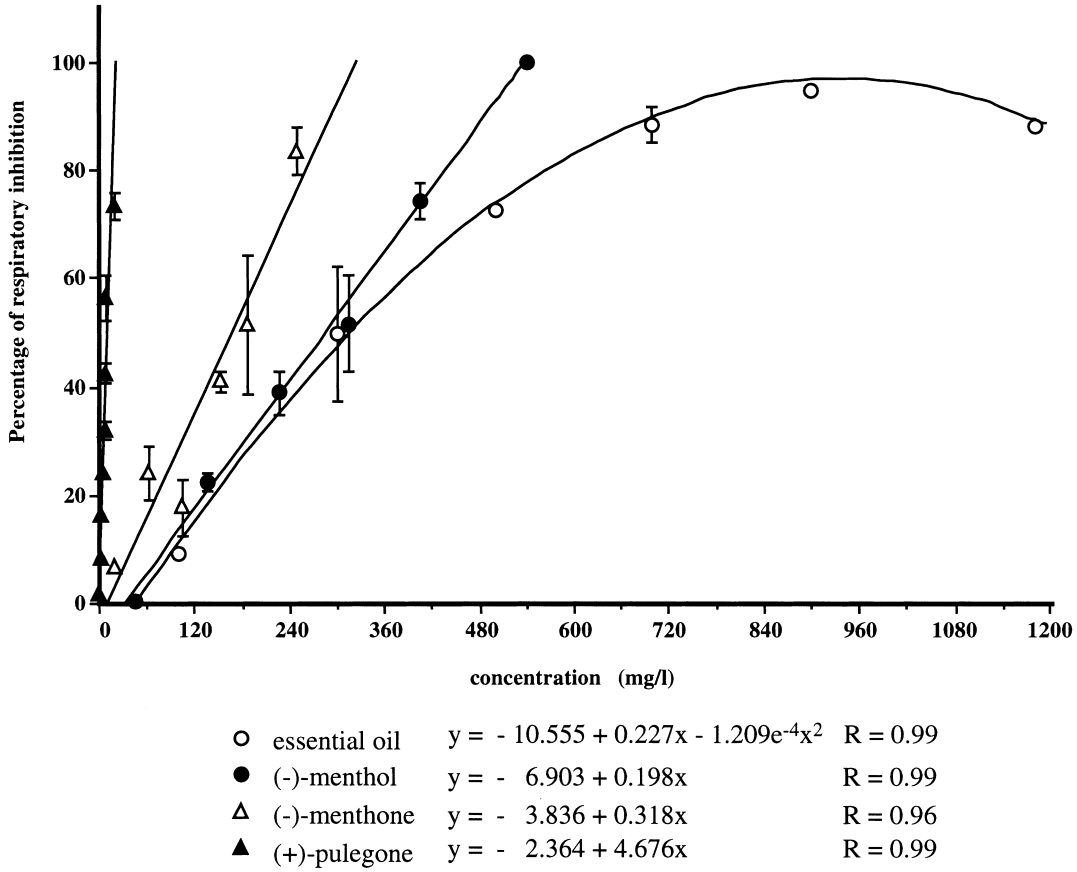

Fig. 1. Percentage of respiratory inhibition as a function of concentration of total essential oil, (−)-menthol, (−)-menthone and (+)-pulegone in cucumber (*Cucumis sativus*) roots. Bars indicate standard deviation.

$R=0.93$) also (−)-menthone resulted stimulatory at low concentrations. As in the root, (+)-pulegone IC_{50} (18.43 mg/l, 0.12 mM, $R=0.99$) was found to be the lowest. Washing of mitochondria in buffered solutions, with consequent recovery of full respiratory activity (data not shown) annulled the effect of total essential oil, (−)-menthol, (−)-menthone and (+)-pulegone applications. Our results showed that (+)-pulegone is a powerful inhibitor of mitochondria respiration, being effective in a range of concentrations equal or below other reported allelochemicals (Moreland and Novitzky, 1987). The complete recovery of respiration after washing of mitochondria indicates that membrane interactions could be the initial site of action of such molecules, as demonstrated in previous studies on ultrastructural alterations caused by several monoterpenes on plant cells and organelles (Muller, 1986). This could also explain why monoterpenes are usually sequestered in specialized glandular structures and kept away from cell membranes and living cytoplasm, in order to prevent plant tissues from autotoxicity.

The plot of IC_{50} against the water solubility (WS, expressed in ppm) (Fischer, 1991) of (−)-menthol, (−)-menthone and (+)-pulegone (Fig. 3) showed a negative significant correlation, with decreasing IC_{50} values with increasing water solubility, and a greater inhibition of roots with respect to purified mitochondria for (−)-menthone and (−)-menthol applications. In peppermint oil, there is an increasing trend in the inhibition of root and mitochondrial respiration that follows the order: alcohols [(−)-menthol], saturated ketones [(−)-menthone], unsaturated ketones [(+)-pulegone]. This trend parallels the capability of these compounds to solubilize in water. These data are in agreement with previous investigations done on antimicrobial activity (Knobloch et al.,1989), toxicity in plant cell cultures (Brown et al., 1987) and inhibition of tissue respiration (Fisher, 1986,1991).

Injection of the oxidative phosphorylation uncoupler CCCP (5 μM) in the purified mitochondrial fraction prompted a 26% (± 4.2) increase of the oxygen consumption rate (117 nmol O_2 h^{-1} μg $protein^{-1}$), which indicated the uncoupling of the electron transport system from ATP production. When CCCP was followed by total essential oil, a significant increase in the IC_{50} value (1032.33 mg/l) was observed with respect to CCCP untreated mitochondria and the same was for menthol (758.21 mg/l, 4.86 mM) and menthone (1558.47, 10.19 mM) (Fig. 4). (+)-Pulegone lost all its inhibitory action

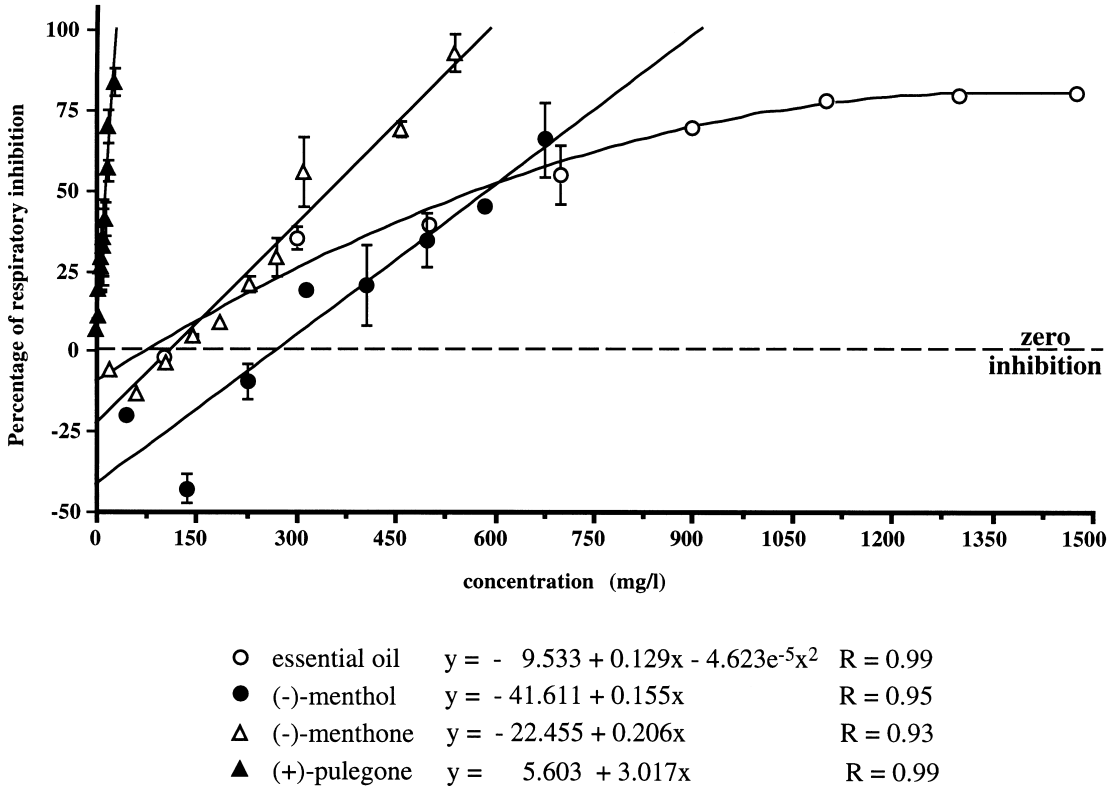

Fig. 2. Percentage of respiratory inhibition as a function of concentration of total essential oil, (−)-menthol, (−)-menthone and (+)-pulegone in cucumber (*Cucumis sativus*) mitochondria purified from root extracts. Bars indicate standard deviation.

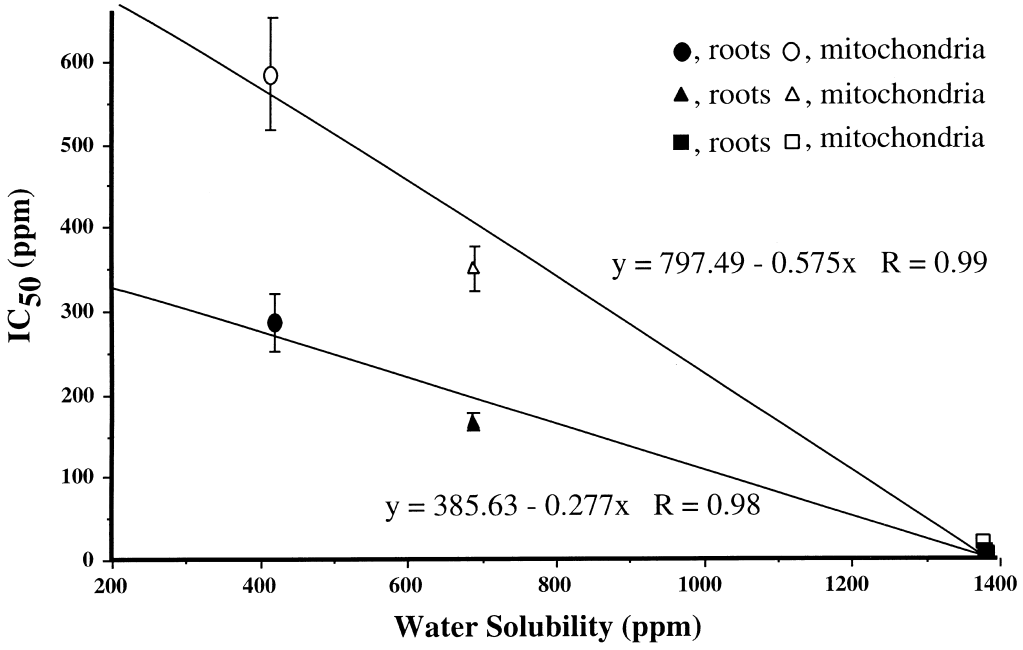

Fig. 3. Plot of the concentration of (−)-menthol, (−)-menthone and (+)-pulegone able to cause 50% of inhibition of respiration (IC_{50}) against their water solubility (Fisher, 1991). A positive correlation was found between respiratory inhibition and water solubility of compounds. Bars indicate standard deviation.

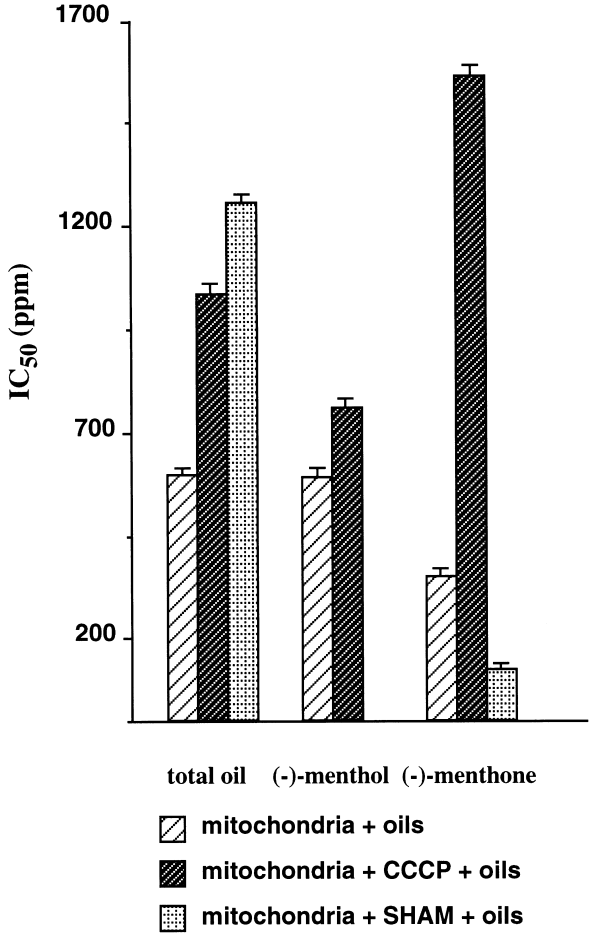

Fig. 4. Respiratory IC_{50} (ppm) in purified mitochondria preparations and after mitochondria incubation with the uncoupler CCCP (total essential oil, (−)-menthol and (−)-menthone) and the alternative oxidase (AO) inhibitor SHAM (total essential oil and (−)-menthone). Columns represent oil and components concentration (ppm) enough to inhibit mitochondrial respiration by 50%. Bars indicate standard deviation.

by dropping above zero inhibition at a concentration of 9.72 mg/l (Fig. 5). Spectrophotometric analyses indicated complete lack of interaction between CCCP and total essential oil and oil components (data not shown).

The protonophor CCCP, dissipating the membrane potential and catalyzing the movement of protons through the inner mitochondrial membrane (Daie et al., 1987; Felle, 1988), reduced the inhibitory action of peppermint oil, menthol and menthone. A CCCP-mediated pH increase in the intermembrane mitochondrial space could lower the ability of terpenoids to inhibit oxygen consumption, by rendering their possible site of action more polar. Meanwhile, the ability of CCCP to totally circumvent inhibition of state 3 rate by pulegone suggests a specific action of pulegone on cucumber mitochondrial functions.

Plant cells possess an alternative oxidation (AO) pathway that diverts the electron flow from ubiquinone to complex III. The electron flow is used to reduce oxygen to water with the production of heat. One of the specific inhibitors of the AO pathway is SHAM. The use of SHAM in control cucumber mitochondrial fractions caused a 24% (± 2.0) decrease in the oxygen uptake rate (99 nmol O_2 h^{-1} μg $protein^{-1}$). When peppermint essential oil was added to SHAM treated mitochondria, a consistent and significant IC_{50} increase was observed (1253.11 mg/l) (Fig. 4) with respect to inhibition observed in mitochondria without the use of SHAM. On the contrary, menthone showed a significantly decreased IC_{50} (125.39 mg/l, 0.82 mM) (Fig. 4) when compared to both SHAM untreated and treated mitochondria (351.38 mg/l) and significant lower IC_{50} values with respect to root respiration (169.07 mg/l, 1.11 mM) (Fig. 1). After treatment with SHAM, menthol and pulegone showed no inhibitory activity, by stimulating respiration for concentrations higher than 299.41 and 9.65 mg/l, respectively (Fig. 5). Even in this case spectrophotometric analyses indicate complete lack of interaction between SHAM and essential oil and oil components (data not shown).

When cucumber mitochondria are treated with SHAM (AO inhibitor), oxygen consumption by AO can be excluded (Vanlerberghe and McIntosh, 1997). The effect of SHAM on pulegone and menthol activity indicates that these two monoterpenes exert maximum inhibition of oxygen consumption when AO is active. The absence of interference between menthol, pulegone and SHAM supports these data. Partitioning of electrons through complex IV varies linearly with the degree of ubiquinone reduction and AO is not active until the level of reduced ubiquinone reaches a high threshold level (Dry et al., 1989). The increased menthone inhibition in the presence of SHAM could indicate a possible specific action on electron transfer chain from complex II (succinate dehydrogenase) to complex IV (cytochrome oxidase). On the other hand, the complete absence of inhibition by pulegone and menthol in the presence of SHAM indicates that these two monoterpenes might act on transfer of electrons from ubiquinone to complex III, thus triggering AO activity. Considering that AO accounts for 24% of cucumber respiration, an eventual diversion to AO would eventually reduce the total oxygen consumption by about 76%.

In conclusion, the mechanism by which peppermint essential oil and some of its oil components affect cucumber respiration is still unknown (Fisher, 1986, 1991). The greater inhibition shown when cucumber roots were exposed to terpenoids with respect to isolated mitochondria led us suggest that it is probably due to terpenoid interaction with cell walls and plasma membranes. This would trigger the initiation of a series of physiological responses via intracellular transduction pathways (Kombrink and Somssich, 1995). Besides, terpenes may interact by altering ion permeability and fluxes across the plasma membrane and possibly diverting oxygen toward

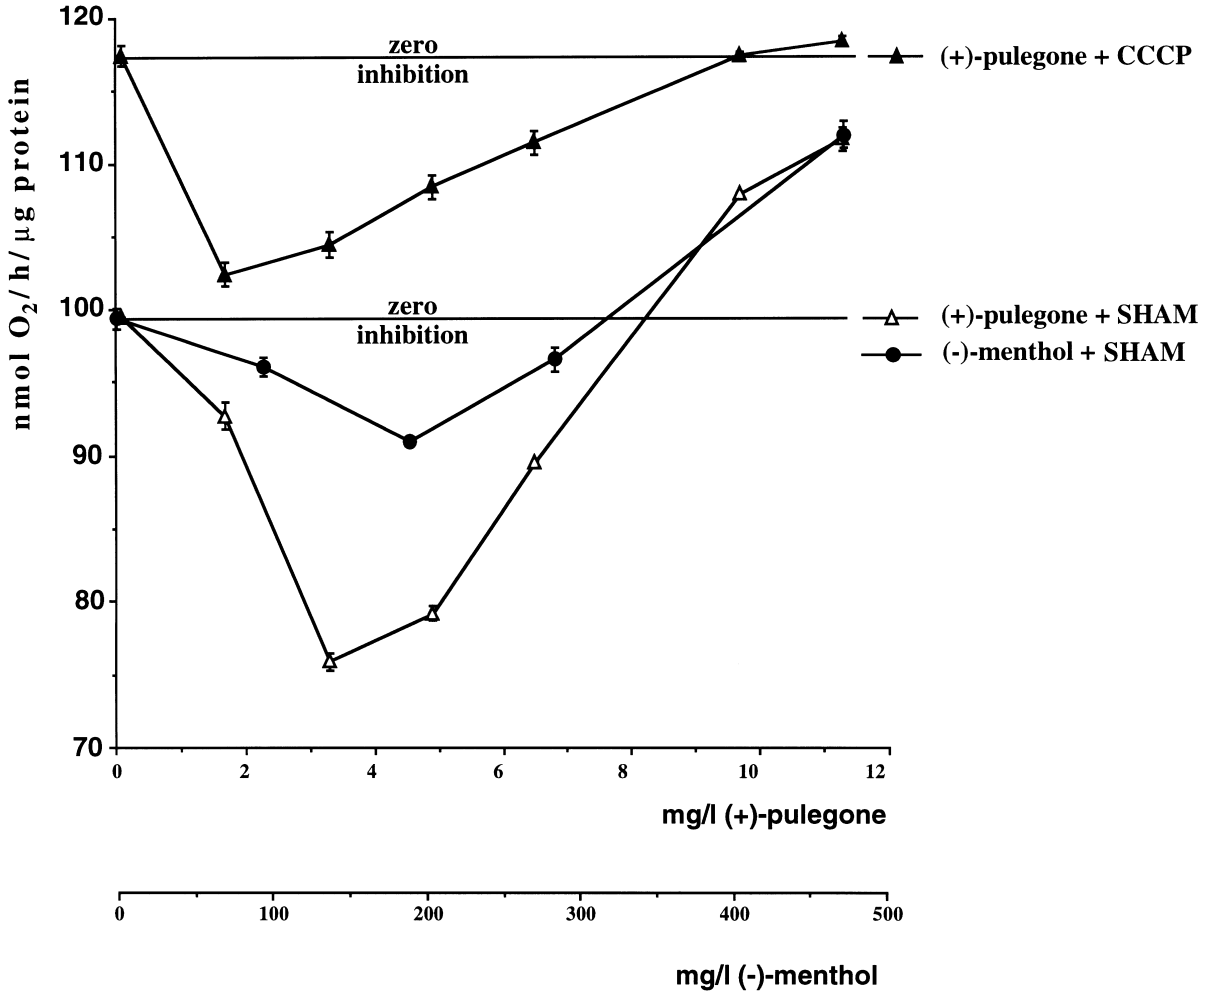

Fig. 5. Oxygen consumption in the presence of (+)-pulegone after treatment with CCCP and SHAM and in the presence of (−)-menthol after treatment with SHAM. Bars indicate standard deviation.

oxidative burst, as observed in some plant cell systems after elicitor treatments (Nürnberger et al., 1994).

3. Experimental

3.1. Plant material

Cucumber (*Cucumis sativus* L. var. "Piccolo di Parigi") seeds were grown as previously described (Maffei et al., 1999a). Peppermint (*Mentha×piperita* L.) plants are currently grown in experimental plots of the Botanical Garden of the University of Torino, and were distilled when in full bloom.

3.2. Essential oil distillation and chemicals

Peppermint oil was steam distilled by using a modified Clevenger apparatus. Distillation, GC analyses and compound identification were performed as reported elsewhere (Maffei et al., 1999b). (−)-Menthol, (−)-menthone and (+)-pulegone (purity >99%) were purchased from Sigma-Aldrich (Milan, Italy).

3.3. Mitochondria purification

Mitochondria isolation and purification were carried out at 4°C according to the protocol reported by Randall and Miernyk (1990) modified as follows. Roots from five day-old cucumber seedlings were harvested and homogenized in a solution (1:2 w/v) containing 0.3 M mannitol, 50 mM MOPS [3-(*N*-morpholino)-propanesulfonic acid] pH 7.2, 1 mM EDTA (ethylene diamine tetra acetic acid), 0.2% (w/v) defatted BSA (bovine serum albumine), 0.5% PVP-40 (polyvinylpyrrolidone), 2 mM L-cysteine and 10 mM 2-mercaptoethanol. The following procedures of mitochondria isolation, washing and purification were the same of Randall and

Miernyk (1990) with the exception for the use of 20 mM MOPS instead of TES in media in which mitochondria were resuspended and loaded on the Percoll density gradient, before centrifugation at 58.500×*g* (SW 41Ti rotor). All Percoll solutions contained 0.25 M sucrose, 10 mM MOPS pH 7.2, 0.1% defatted BSA (Randall and Miernyk, 1990).

Mitochondria, collected at the interface between 47 and 26% Percoll, were re-suspended and stored at 4°C overnight. Fixation and inclusion in resins for transmission electron microscopy were used for checking the purity of the mitochondrial fraction.

3.4. Oxygen consumption in root segments and mitochondrial preparations

Oxygen uptake was measured polarographically at 25°C with a Clark-type electrode (YSI Model 5300). A known amount of five-day-old root segments of 7 mm length were assayed in a 5 ml MES–NaOH 5 mM pH 6.00 solution. Mitochondrial respiration was measured in 2.5 ml respiration medium containing 0.25 M sucrose, 10 mM potassium phosphate buffer, 5 mM $MgCl_2$, 10 mM MOPS pH 7.4, with a known amount of mitochondrial protein. Protein content was measured according to Bradford (1976) and adjusted to 0.3–0.5 mg for each experiment. The integrity of mitochondria was verified using both HCN as respiratory chain inhibitor and the uncoupling agent CCCP (carbonyl-cyanide-*m*-chlorophenyl-hydrazone) (5 μM). Respiratory control and ADP:O ratios were calculated for each mitochondrial isolation as described by Estabrook (1967).

During mitochondrial experimentation, a constant state 3 respiratory rate, as defined by Chance and Williams (1955), with 10 mM succinate as respiration substrate was achieved before injection of the essential oils into the reaction chamber; the ADP:O ratio for succinate was 1.6. Total essential oil, (−)-menthol, (−)-menthone and (+)-pulegone, dissolved in methanol (= 0.4%), were tested in the range from 0 to 1500 ppm on both root segments and mitochondria. Methanol was present in both treated and control root/mitochondria preparations.

Essential oil effects on mitochondrial oxygen uptake was tested also after the treatment with the oxidative phosphorilation uncoupler CCCP (5 μM) and with the alternative oxidase inhibitor salicyl-hydroxamic acid (SHAM) supplied at 2 mM. Data are expressed as percentages of inhibition or stimulation of control respiration rate (state 3); IC_{50} values correspond to the concentration required to inhibit oxygen uptake by 50%.

3.5. Statistics

At least five replicates were performed for each experiment. The data obtained were analyzed by standard ANOVA using Systat 5.2 software for Macintosh. Significant differences are intended at $P < 0.05$. Linear and second-degree polynomial regressions were also calculated.

Received 14 June 2000; received in revised form 6 November 2000

Abstract

The antifungal activity of *Chrysanthemum coronarium* was evaluated against 12 agricultural pathogens. Flowerhead oil was active both in contact and headspace in vitro assays producing hyphal growth inhibition, although there was less activity on faster growing fungi. The main compounds identified in the oil were camphor (29.2%), α-pinene (14.8%), β-pinene (9.5%) and lyratyl acetate (9.8%). The blue color of the oil was due to the presence of chamazulene (0.5%). © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Chrysanthemum coronarium*; Asteraceae; Garland chrysanthemum; Antifungal activity; Essential oil composition; Camphor; α-Pinene; β-Pinene; Lyratyl acetate

1. Introduction

The Anthemidae tribe of the family Asteraceae includes medicinal species of the genera *Artemisia, Achillea, Chamaemelum, Chamomilla* and *Tanacetum*. The volatile components of their essential oils exhibit strong odours and many of them have been used as flavourings. In addition, the oils of *Tanacetum* species are reported to possess antibacterial activity (Gören et al., 1990). Essential oils contain monoterpenoids, sesquiterpenoids and other non-terpenoid compounds. Some of them have been reported to exhibit a wide range of biological activities (Picman, 1986).

Many species within the genera *Pyrethrum* and *Chrysanthemum* have been transferred to the genus *Tanacetum*, including small pyrethrum [*T. cinerariifolium* (Trevir.) vis.] which is used for insecticide production. Only two species of *Chrysanthemum* (*C. coronarium* L. and *C. segetum* L.) are widely distributed in the Mediterranean, western Africa and Asia (Trehane, 1995). *C. coronarium* var. *coronarium* is an ornamental and can be found as a common weed, while *C. coronarium* var. *spatiosum*, is used as a Chinese vegetable (chop-suey). Green leaves and stems of *C. segetum* L. are also consumed as vegetables (Sánchez-Monge, 1991).

Flowerheads of *C. coronarium*, are typically bicolored white and yellow, or only yellow, and have been used as chamomile adulterants (Garg and Sastry, 1996). In Japan the leaves are used for suppression of fishy odours in prepared foods (Kasahara and Nishibori, 1995).

The chemical composition of *C. coronarium* leaves has been studied by other authors: polyacetylenic compounds have been isolated from the aerial parts and insect antijuvenile hormone activity has been detected for some of them (Bowers and Aregullin, 1987; Sanz et al., 1990). From flowerheads of *C. coronarium*, sesquiterpene lactones (cumambrin and dihydrocumambrin) have been isolated (El-Masry et al., 1984).

In recent years, there has been a clear tendency towards the utilization of alternative methods for pest and disease control in agriculture, that are less damaging to the environment and human health. Research on natural products including plant extracts which might substitute for agrochemicals or contribute to the development of new agents (Addor, 1995) for pest control is extremely important. Essential oils have properties as

PII: S0031-9422(00)00461-1

fungicidal agents (Knobloch et al., 1987; Bishop and Thornton, 1996).

In this paper, we report the results of several bioassays to test activity of the essential oil of flowerheads of garland chrysanthemum (*C. coronarium*) by contact or by vapours against a panel of agricultural fungal pathogens. The chemical composition of this oil was also studied for the first time.

2. Results and discussion

The result of GC/MS analysis of the oil is summarized in Table 1. The main compounds identified were camphor (29.2%), α- and β-pinene (14.8 and 9.5%, respectively) and lyratyl acetate (9.8%). Significant amounts of camphene (5.2%), 2,7,7-trimethylbicyclo-[3.1.1]hept-2-en-6-ol acetate (3.8%), *p*-menthatriene (3.4%), germacrene D (2.7%) and α-phellandrene (2.6%) were also detected. Chamazulene, which gave the blue color to the oil, was present (0.5%).

To the best of our knowledge, this is the first report of the chemical composition of flowerheads of *C. coronarium*. Nevertheless, some compounds have been previously identified (Kameoka et al., 1975) from the leaf oil of *C. coronarium* L. var. *spatiosum*, although only α- and β-pinene and camphene were found in both cases.

The flowerhead oil of *C. coronarium* was active both in contact and on exposure to the headspace volatiles, since they both significantly reduced the growth of fungi in comparison with the control (although some exceptions are shown in Table 3). It should be mentioned, though, that results from the agar diffusion plate assay might also include some effects of the oil vapours besides the contact action.

Table 1
Chemical composition of the essential oil of flowerheads of *Chrysanthemum coronarium*

Component	Percentage (%)
α-Pinene	14.8
Camphene	5.2
α-Phellandrene	2.6
β-Pinene	9.5
4 Methylenecyclohexene	Trace
Limonene	0.7
β-Ocimene	0.3
Camphor	29.2
2,7,7-Trimethylbicyclo-[3.1.1]hept-2-en-6-ol acetate	3.8
Bornyl acetate	0.9
Lyratyl acetate	9.8
β-Caryophyllene	1.1
Germacrene D	2.7
p-Mentha-1,3,8-triene	3.4
Chamazulene	0.5
Total	84.5

In Table 2, the results indicate the growth of *Alternaria* sp., *Aspergillus flavus* and *Pythium ultimum* were highly reduced (>80%) when measured at the third day. Although no clear differences in activity could be observed for many fungi, the more resistant species were *Mycocentrospora acerina* and *Penicillium digitatum*.

In the volatile assay (Table 3), differences were obtained depending on species, e.g. *Fusarium moniliforme* was less affected than *P. ultimum*. The activity in the vapor phase was different for rapid growing species like *Botrytis cinerea* or *Sclerotinia sclerotiorum*, in which it changed from high inhibition (>70%) at day 3

to covering all the dish at day 6, than for others like *Fusarium* sp. and *M. acerina* whose growth was further reduced over time (see Table 3). In general, growth inhibition percentages were high, with variations depending on the day of observation and the test species. The activity of *C. coronarium* oil is clear, Bishop and Thornton (1996) reported similar results for *Monarda citriodora* L. essential oil when using a dose ten times higher (100 μl).

In our experiments, the volatile activity found was significant but less persistent for fast growing species such as *S. sclerotiorum*, *R. solani* and *B. cinerea* (Table 3). An interesting observation from the bioassays was that *B. cinerea, P. digitatum* and *S. sclerotiorum* decreased spore production in the presence of oil (either by contact or from the headspace volatiles). Other authors have associated secondary metabolites with spore production (Dionigi et al., 1992); sporulation of *Streptomyces tendae* was inhibited by geosmin production (derived from a sesquiterpene precursor).

Tanacetum species contain similar compounds in their essential oils although α- and β-pinene are found in very low quantities in comparison with *C. coronarium*. *T. parthenium* (L.) Bernth is characterized by a high camphor (44%) and *trans*-chrysanthemyl acetate (23%) content. *T. vulgare* L. (Hendriks et al., 1990) contains also lyratyl acetate, thujone and germacrene (depending on chemotype). Mosquito repellent activity of these oils was proved but without identification of the active principles (De Pooter et al., 1989). Camphor and bornyl acetate (Schearer, 1984) were identified as some of the more active (repellent to potato beetles) of the mixture of products present in the oil of tansy (*T. vulgare*). Probably some of the compounds present in low amounts also contribute to these effects.

The blue color of the oils was attributed to the presence of chamazulene which is known to be produced during the steam distillation. Other members of Asteraceae such as *Chamomilla, Stevia, Artemisia* and *Achillea* also give azulenic compounds (Kaneko et al., 1971; Sacco et al., 1983; Acosta et al., 1989; Román et al., 1990; Abad et al., 1995). For example, chamazulene is being used in large quantities in the pharmaceutical and cosmetic industries.

3. Experimental

3.1. Fungal species

The fungi were obtained from the culture collection at Liverpool John Moores University (School of Biological and Earth Sciences). Cultures of each of the fungi were maintained on potato dextrose agar (PDA), slants stored at 5°C. The fungal species used in the experiments were: *Alternaria* sp. (As), *Alternaria brassicola* (Ab), *Aspergillus flavus* (Af), *Botrytis cinerea* (Bc), *Fusarium moniliforme* (Fm), *Fusarium solani* (Fs), *Mycocentrospora acerina* (Ma), *Penicillium digitatum* (Pd), *Pythium ultimum* (Pu), *Rhizoctonia solani* (Rs), *Sclerotinia sclerotiorum* (Ss) and *Serpula lacrymans* (Sl).

3.2. Essential oils

Essential oil of bicoloured flowerheads of *Chrysanthemum coronarium* L. was obtained by hydrodistillation using a Clevenger-type apparatus. Material was obtained from plants grown in an experimental plot (Torreblanca Exp. Stat., Campo de Cartagena) in Murcia (Spain). Plants were sown in autumn (26 October 1995) and samples were harvested in April. Voucher specimens (no. 207) were deposited in the Centro de Investigación y Desarrollo Agroalimentario (Murcia, Spain) Herbarium (CIDAHERB). Before distillation the flowerheads were freeze dried. The yield of oil was about 0.1%(v/w) and it had a blue color and a disagreeble smell.

3.3. Contact assay

PDA plates were prepared using 9 cm glass Petri dishes containing Twenty microlitres of PDA. A 1 cm disc of agar was removed from the centre of the Plates. Twenty microlitres of water (control) or undiluted oil was pipetted into the wells. Two 5 mm diam. discs of the test species were cut from the periphery of less than 1 week old cultures on PDA plates and placed mycelial surface down on opposite edges of the test plates against the sides of the dishes. The plates were incubated in the dark at 20°C. After 3 and 6 days of inoculation, extension of hyphae towards the central well was measured from the inner edge of the inoculum discs to the leading edges of colonies at a point nearest the well. Mean growth measurements were calculated from 10 replicates of each of the fungal species.

3.4. Volatile assay

PDA plates were prepared using 8.2 cm plastic Petri dishes containing 20 ml of PDA. A 5 mm diam. disc of the test species was cut from the periphery of the actively growing culture of the PDA plates and placed mycelial surface down on the centre of the dish. The Petri dishes were placed with the lid upside down. A 10 μl aliquot of water (control) or undiluted oil was pipetted on the lid without agar. The plates were incubated in the dark at 20°C. Mean growth measurements were calculated from 10 replicates of each fungal species.

3.5. Chemical analyses

The oil was analysed by GC/MS. Operating conditions were 240°C for the injection temperature and the

oven was initially at 70°C and was then gradually increased at a rate of 4°C/min up to 220°C and held for 120 s. The Supelcowax 10 capillary column (30 m × 0.25 mm) was used. For chamazulene identification, a SE-54 capillary column (25 m × 0.25 mm) was operated at similar conditions but the oven temperature was increased to 220°C and held for 1 h. Mass spectra were recorded with a 5970 HP Mass Selective detector, the electron impact source operating at 70 eV and 240°C. Identifications were made by retention indices and direct comparison with authentic standards.

3.6. Statistics

Growth inhibition of the treatment against the control was measured by percentage, using the formula (C-T/C) × 100 where C is hyphal extension (mm) of controls and T is hyphal extension (mm) of oil treated plates. A *t*-test was also computed for statistical significance of the results in the contact and volatile assays.

Received 8 March 2000; received in revised form 20 November 2000

Abstract

Along with three known drimanes, polygodial, 1-β-(*p*-methoxycinnamoyl) polygodial and mukaadial, the sesquiterpene drimane named drimanial was isolated from the bark of *Drimys winteri* (Winteraceae). Its structure was elucidated based on spectroscopic evidence. Drimanial exhibited antinociceptive action against acetic acid induced pain, being about 3-fold less active than polygodial. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Drimys winteri*; Winteraceae; Antinociception; Sesquiterpene drimane; Drimanial

1. Introduction

Drimys winteri (J.R. Forst and G. Forst) is a plant used in the folk medicine of many countries, including Brazil, to treat several ailments, such as inflammatory and dolorous processes (Houghton and Manby, 1985). Phytochemical studies have demonstrated that this plant contains mainly sesquiterpenes of the drimane type (Cruz and Silva, 1973; Sierra et al., 1986; Brown, 1994; Cechinel Filho et al., 1998), and flavonoids (Cruz and Silva, 1973; Williams and Harvey, 1982; Reyes et al., 1990; Torres et al., 1992; Cechinel Filho et al., 1998). These drimanes have attracted particular interest because of their antifeedant, plant growth regulation, cytotoxic, antimicrobial and insecticidal properties (Jansen and Groot, 1991).

In previous studies, we showed that the hydroalcoholic extract obtained from *D. winteri* bark exhibits anti-asthmatic, anti-allergic, anti-inflammatory and antinociceptive effects (El Sayah et al., 1997; Tratsk et al., 1997; Mendes et al., 1998). These effects were related, at least partially, to the presence of polygodial (**1**), a sesquiterpene drimane, which is the main component of the plant (Cechinel Filho et al., 1998; El Sayah et al., 1998; Mendes et al., 1998; Andre et al., 1999; Mendes et al., 2000; El Sayah et al., 2000)

In the present study, we have investigated other components present in the *D. winteri* bark and isolated a new compound named drimanial (**2**), together with polygodial (**1**), 1-β-(*p*-methoxycinnamoyl) polygodial (**3**) and mukaadial (**4**). The preliminary antinociceptive effect of drimanial was analyzed against acetic acid induced pain in mice.

2. Results and discussion

Drimanial **2** ($C_{25}H_{30}O_6$) displays a ^{1}H NMR spectrum with signals for two aldehydes (δ 9.36, *s* and δ 9.78, *d*, $J = 3.3$ Hz), one olefinic proton (δ 7.04), three methyl singlets (δ 1.06, 1.17 and 1.23) and a *p*-methoxycinnamoyl residue (δ 3.86, *s*, OMe; δ 7.64 and 6.99, *d*, $J = 8.9$ Hz, 2 H each; δ 7.60 and 6.25, *d*, $J = 16$ Hz). The complete assignment of ^{1}H, ^{13}C NMR parameters for **2** are reported in Table 1 and are the result of one and two bond HETCOR experiments (Table 2). Comparison of

the ^{13}C NMR spectral data with those of 1-β-(*p*-methoxycinnamoyl) polygodial **3**, $C_{25}H_{30}O_5$ (Table 1), there was an additional oxygen present in drimanial in position 5. The paramagnetic shift of the signals due to C-4, C-6 and C-10 (α effect), and the diamagnetic shift observed for the signals to C-3, C-7 and C-9 (βeffect) support this assignment. The correctness of the assigned structure for drimanial (**2**) and of the NMR spectral parameters was further supported by the long-range connectivity reported in Table 2. In particular, in the long range NMR spectrum, the resonance at δ 78.1 assigned to C-5 shows a cross peak with Me-13; conversely, in the

[b] Maximal inhibition, MI.
[c] Data from Cechinel Filho et al., 1998.
[d] Data from Vaz et al., 1996.

INEPT experiments, the selective irradiation of each methyl signal (δ 1.23, δ 1.17 and δ 1.06) gave a response, inter alia, to the quaternary oxygenated carbon. Finally, the difference NOE spectra (Fig. 1) indicated that H-9, H-1, Me-13 and OH-5 are on the same side of the molecule, establishing the stereochemistry of **2** (Vichnewski et al., 1986).

Polygodial **1** and mukaadial **4** were identified by comparison of the spectral data with that reported in the literature (Brown, 1994; Mashimbye et al., 1999). However, mukaadial is reported for the first time in this genus. No reports were found on the ^{13}C NMR for 1-β-(*p*-methoxy cinnamoyl) polygodial **3** (Ferreto et al., 1988). Thus, the ^{13}C NMR spectral data for **3** are presented in Table 1 in this paper.

The in vivo pharmacological studies revealed that drimanial (**2**) produced a dose-related and almost complete inhibition of abdominal constrictions elicited by acetic acid. At the ID_{50} level, drimanial exhibited the same potency as 1-β-(*p*-methoxycinnamoyl) polygodial but it was about 3-fold less potent than polygodial in antagonizing acetic acid-induce nociception. However, drimanial was about 11- to 12-fold more potent than the positive control drugs aspirin and acetaminophen (Table 3).

In conclusion, results of the current study and those previously reported by our group indicated that a mixture of at least 3 sesquiterpenes, identified as being polygodial, 1-β-(*p*-methoxycinnamoyl) polygodial and drimanial, seem to be the main constituents present in the bark of the plant *Drymis winteri*, being responsible for the remarkable antinociceptive, anti-inflammatory and anti-allergic actions reported by the crude extract of this plant (Tratsk et al., 1997; Mendes et al., 1998, 2000). Considering the relatively higher concentrations of polygodial and to a lesser extenct, drimanial in the bark of *D. winteri*, it can be suggested that the 2 sesquiterpenes are the most relevant active compounds and responsible for the major pharmacological action of the plant.

3. Experimental

3.1. General experimental procedures

Optical rotations were recorded on a polarimeter Schmidt + Haensch Polartronic E Eloptron. IR spectra were recorded on FTIR 16 PC Perkin-Elmer aparatus (KBr film). ^1H (300 MHz) and ^{13}C (75.5 MHz) NMR were determined on a Varian Gemini 300 Spectrometer in acetone-d_6 with TMS as internal standard. MS were recorded on a Shimadzu-14 spectrometer in the electron impact mode (EI–MS) at 70 eV. Elemental analysis was determined in elemental CHN Perkin-Elmer 2400. CC: silica gel 60 (230–400 mesh); TLC: silica gel plates F_{254} (0.25 mm in thickness).

3.2. Plant material

Drimys winteri (Winteraceae) was collected in Bom Retiro (State of Santa Catarina, Brazil) in January 1994 and identified by Professor Leila da Graça Amaral (Department of Botany, Universidade Federal de Santa Catarina). A voucher specimen was deposited in the Herbarium Flor (UFSC) under number 26313.

3.3. Isolation

Air-dried powdered bark (1.5 kg) was extracted at room temperature with $CHCl_3$ for 7 days. Solvent was removed (in vacuo) to obtain the $CHCl_3$ extract (27 g). The extract was roughly fractionated by silica gel CC, eluting with *n*-hexane, EtOAc, MeOH mixtures of increasing polarity. Extended purification of the fraction eluted with hexane–EtOAc 9:1 yielded polygodial **1** (2.53 g). In a similar manner, the fraction eluted with hexane–EtOAc 8:2 gave mukaadial **4** (17 mg), hexane–EtOAc 6:3 gave 1-β-(*p*-methoxycinnamoyl) polygodial **3** (25 mg), and that eluted with hexane–EtOAc 1:1 afforded drimanial **2** (362 mg).

3.4. Acetic acid-induced abdominal constriction

Non-fasted male Swiss mice (25–35 g), housed at 22±2°C under a 12-h light/12 h-dark cycle and with access to food and water ad libitum, were acclimatised to the laboratory for at least 1 h before testing and were used throughout the experiments. The abdominal constrictions resulting from intraperitoneal injection of acetic acid (0.6%), consisting of a contraction of the abdominal muscle together with a stretching of hind limbs, was carried out according to the procedure described previously (Vaz et al. 1996; Mendes et al., 1998). Animals (6 to 8 per group) were treated with different doses of drimanial (2.3–23.5 μmol/kg, i.p.) or with vehicle (Tween 80 plus 0.9% NaCl solution) used to dilute the sesquiterpene (10 ml/kg, i.p.), 30 min prior to injection of acetic acid. Antinociceptive activity was expressed as the reduction in the number of abdominal constrictions, i.e. the difference between the control animals (vehicle pre-treated mice) and the mice pre-treated with drimanial.

3.5. Statistical analysis

Results are presented as mean±S.E.M., except the ID_{50} values (i.e. the dose of drugs reducing the nociceptive response by 50% relative to control value), which are reported as geometric means accompanied by their respective 95% confidence limits. The ID_{50} values were determined by linear regression from individual experiments using linear regression Graph Pad software (Graph Pad Software, San Diego, CA). The statistical significance between groups was performed by ANOVA followed by Dunnett's multiple comparison test. P values less than 0.05 ($P<0.05$) were considered as indicative of significance.

3.6. Drimanial 2

Amorphous powder. Mp 95–97°, $[\alpha]_D^{25}+43.2°$ ($CHCl_3$; c 0.926), IR ν_{max} cm^{-1}; 3482, 2928, 2854, 2732, 1710, 1682, 1632 and 1602. ^1H NMR (300 MHz, acetone-d_6) and ^{13}C NMR (75.5 MHz, acetone-d_6) in Table 1. IEMS: m/z (rel. int.) 426 [M^+] (1.2), 398 (0.5), 380 (0.5), 202 (7.6), 178 (25), 161 (100), 145 (12), 133 (13.6), 118 (7.6), 91 (6.5), 77 (7.6). Elemental analysis results, found: C, 70.25; H, 7.15. $C_{25}H_{30}O_6$ requires: C, 70.40; H, 7.09%.

Received 5 March 1999; received in revised form 6 November 2000

Abstract

Four sesquiterpenoids were isolated from *Petasites japonicus* (Siebold and Zucc.) Maxim. ssp. *giganteus* (F. Schmidt ex Trautv.) Kitam. (Compositae, Japanese name: Akitabuki) as allelochemicals. Their structures were elucidated on the basis of spectroscopic methods and their allelopathic effects were assessed. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Petasites japonicus* ssp. *giganteus* Kitam; Compositae; Rhizomes; Eremophilane derivatives; Allelopathy

1. Introduction

Petasites japonicus (Siebold & Zucc.) Maxim. ssp. *giganteus* (F. Schmidt ex Trautv.) Kitam is mainly distributed in the eastern area of Hokkaido, Japan. *P. japonicus* ssp. *giganteus* appears early in secondary succession and extends by rapid vegetative propagation via rhizomes. It is sometimes observed in forests where *P. japonicus* ssp. *giganteus* dominates in a place where trees are lacking and the vegetation beneath the plant is poor. These observations suggest that *P. japonicus* ssp. *giganteus* is allelopathic. In this investigation, we isolated four sesquiterpenoids from rhizomes of *P. japonicus* ssp. *giganteus* and determined their allelopathic effects on seed germination and seedling growth of lettuce (*Lactuca sativa* L.). Two were novel nor-eremophilane derivatives (**1, 3**), one was a novel dinor-eremophilane derivative (**2**), and the other was eremophilenolide (**4**). Although many reports about isolation of eremophilane derivatives from *Compositae* species have been published (Novoton et al., 1963; Sugama et al., 1985; Yaoita et al., 1996; Tori et al., 1997; Zhao et al., 1997), only a few have reported either nor- (Yaoita et al., 1994) or dinor-eremophilane derivatives (Yaoita et al., 1996).

2. Results and discussion

2.1. Allelopathic effects of *P. japonicus* ssp. *giganteus* rhizomes

Allelopathic effects of *P. japonicus* ssp. *giganteus* rhizomes were determined by seed germination and seedling growth test of lettuce with milled powder of freeze-dried rhizomes of *P. japonicus* ssp. *giganteus*. The results showed that *P. japonicus* ssp. *giganteus* had an inhibitory effect on the seedling growth of lettuce (Fig. 1).

Extracts from freeze-dried rhizomes of *P. japonicus* ssp. *giganteus* were divided into four fractions based on their solubilities in organic solvents, i.e. *n*-hexane, ethyl acetate, ethyl alcohol and water extracts, respectively. The effects of each fraction were estimated at 67 ppm, using the same method as used for the rhizome powder (Fig. 1). It was found that all of fractions, except for ethyl alcohol soluble fraction, had a significant inhibitory effect on lettuce seedling growth ($P < 0.01$, *t*-test), and that the *n*-hexane and water soluble fractions had a higher inhibitory effect than ethyl acetate soluble fraction. The *n*-hexane fraction was selected for further study.

2.2. Isolation and elucidation of allelochemicals

The *n*-hexane extract of fresh rhizomes of *P. japonicus* ssp. *giganteus* was subjected to a combination of silica

gel CC, prep. TLC and prep.HPLC to afford compounds **1–4**. Their structures were shown in Fig. 2.

Compound **1**, $C_{14}H_{20}O_2$, was isolated as a yellow oil. The molecular formula was determined to be $C_{14}H_{20}O_2$ by FD and HRMS. The ^{1}H (Table 1) and ^{13}CNMR spectra (Table 2) showed signals due to a tertiary methyl group [δ_H1.19 (3H, *s*, H-13) δ_C20.1 (C-13)], a secondary methyl group [δ_H0.96 (3H, *d*, H-14) δ_C16.0 (C-14)], an olefin group [δ_H7.5 (1H, *s*, H-6) δ_C166.7 (C-6), 137.0 (C-7)], and two carbonyl groups [δ_C197.8 (C-8), 198.6 (C-11)]. In the ^{1}H–^{1}H COSY spectrum, correlations between H-1 and H-2, H-2 and H-3, H-3 and H-4, H-1 and H-10, H-10 and H-9, and H-4 and H-14 were observed. The HMBC correlations of H-1, H-6, H-9 and H-10 to C-5 supported the structure of A ring. The HMBC correlations between H-9 and C-8, H-6 and C-11, and H-6 and C-7 determined the structure of B ring, and the correlation between H-14 and C-5 established the position of the tertiary methyl group. Furthermore, the HMBC correlations of H-12, H-6 to C-11 and between H-12 and C-7 were observed, suggesting the presence of an acetyl group (H-12, C-11, C-12) at C-7. The stereostructure of **1** was determined by analysis of the NOESY spectrum. The NOEs between H-10 and H-13 indicated a *cis*-junction of the A/B rings. From the NOEs between H-9α and H-2α, H-9α and H-4, and H-6 and H-14, it was implied that rings A and B should be in the chair type.

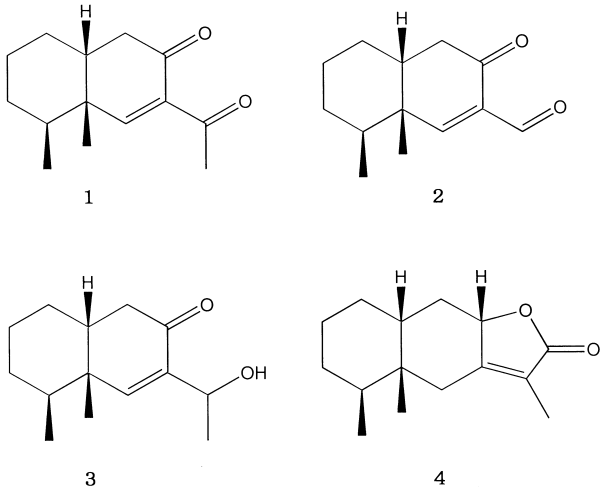

Fig. 2. Structures of compounds **1–4**.

Compound **2**, $C_{13}H_{18}O_2$, was isolated as a colorless oil. The molecular formula was determined to be $C_{13}H_{18}O_2$ by FD and HRMS, and by analysis of the DEPT spectrum. The molecular formula suggested that **2** had one less methyl group than **1**, which was also supported by the DEPT spectrum, in which the signals of only two methyl groups [δ_C20.9 (C-12), 16.1 (C-13) appeared. In the ^{1}H (Table 1) and ^{13}C NMR spectra (Table 2), signals due to a carbonyl group [δ_C199 (C-8)] and an aldehyde group [δ_H9.58 (1H, *s*, H-11), δ_C, 201.3 (C-11)] were observed. These facts suggested that the acetyl group at C-7 of **1** was replaced by an aldehyde group. The other signals in the ^{1}H and ^{13}C NMR spectra were very similar to those of **1**, indicating that both compounds had the same skeleton. This was supported by analysis of the ^{1}H–^{1}H COSY and HMBC spectra.

Compound **3**, $C_{14}H_{22}O_2$, was isolated as an yellow oil. The molecular formula was determined to be $C_{14}H_{22}O_2$ by FD and HRMS, and by analysis of the DEPT spectrum. The fragment ion peak at m/z 204 $[M\text{-}H_2O]^+$ in the EIMS spectrum indicated the presence of an alcohol OH group, supported by signals due to a hydroxyl-bearing methine group [δ_H 4.57 (1H, *dq*, H-11), δ_C66.9 (C-11)] in the ^{1}H (Table 1) and ^{13}C NMR spectra (Table 2). In the ^{1}H and ^{13}CNMR spectra, a signal due to just one carbonyl group [δ_C201.9 (C-8)] was observed. This fact indicated that one of the carbonyl groups of **2** (C-8 or C-11) was replaced by a secondary hydroxyl group. The presence of a hydroxyl group at C-11 was suggested by the ^{1}H–^{1}H correlation between H-11 and H-12. The ^{1}H and ^{13}CNMR, ^{1}H–^{1}H COSY and HMBC spectra suggested that **3** had the same skeleton as **1** and **2**.

Compound **4**, $C_{15}H_{24}O_2$, was identified as eremophilenolide by comparing the ^{1}H and ^{13}C NMR spectral data with those reported by Sugama et al (1985). The structure assignment was supported by ^{1}H–^{1}H COSY and HMBC spectra. In the report of Sugama et al. (1985), **4** was produced by converting 6β-hydroxyeremophilenolide isolated from the young flower stalks of *P.japonicus* according to the method of Naya et al. (1978), so it was not isolated from this species directly. However the isolation of eremophilenolide from *P. officinalis* Moench. was reported by Novotony et al. (1963), but this is the first report of its isolation from *P. japonicus* ssp. *giganteus*.

2.3. Allelopathic effects of isolated compounds

Allelopathic effects of isolated compounds were determined at 100, 300 and 500 ppm (Fig. 3). Although the inhibitory effects of all four compounds on hypocotyl growth increased with increasing concentration, the influence on radicle growth varied. Compounds **1** and **3,** to a lesser extent, promoted radicle growth (Fig. 3b), while partially inhibiting hypocotyl growth (Fig. 3a). Compound **1** significantly promoted radicle growth at each concentration, and the promotion rates did not differ among the concentrations examined ($P > 0.05$, *t*-test). Compounds **2** and **4** partially inhibited the growth of both the hypocotyl and radicle, and the inhibitory effects increased proportionally with their increased concentrations. Both compounds **2** and **4** inhibited the hypocotyl more strongly than that of the radicle at each concentration. Compound **2** showed the strongest

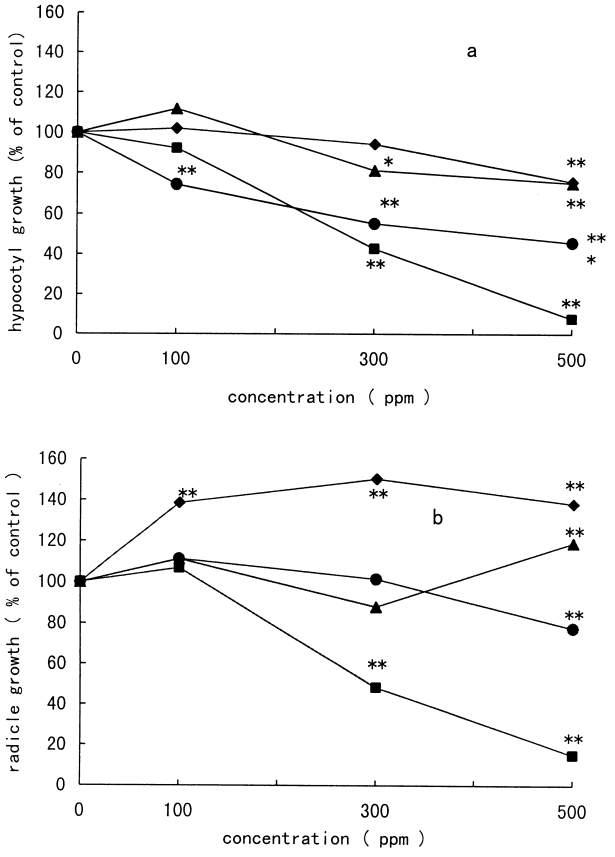

Fig. 3. Effects of isolated compounds on hypocotyl (a) and radicle (b) growth of lettuce. ◆; compound 1, ■; compound **2**, ▲; compound **3**, ●; compound **4**. *,**; *t*-test significantly different from the control at 0.05 and 0.01 level, respectively.

inhibition on both hypocotyl and radicle growth among the four compounds at 300 and 500 ppm. That is compound **2** had a much greater effect than compounds **1** or **3**, even though compounds **1–3** have similar, except for the functional group adapting to C-7. In order to examine any relationship between structure and activity, a more detailed study of this inhibition is required; this in turn add to our knowledge of the allelopathic effects of other eremophilane derivatives.

Compound **2** was the most potent inhibitor among the four compounds examined, but it did no account for the entire activity, *n*-hexane extented. This suggests the existence of other allelochemicals which are either even more effective than those compounds reported here, or the inhibitory effects are enhanced via interaction of allelochemicals. (Li et al., 1993). We thus investigated interactions of phenolic compounds as allelochemicals, and found that combinations of two phenolic compounds showed an additive inhibition effect on seed germination and seedling growth of lettuce. In the future, we will identify whether other allelochemicals are also present, and if their effects are enhanced when in combination with each other.

3. Experimental

3.1. General methods

^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX-500 FTNMR spectrometer. Chemical shifts are reported in δ units relative to TMS as an internal standard with $CDCl_3$ as solvent. EIMS were obtained at 70 eV with a direct inlet system. CC used Wakogel C-200, whereas prep. TLC utilized on Kieselgel 60 PF254. Prep. HPLC was carried out using a JASCO 880-PU (column, ODS, Wakosil-II 5C18HG, flow rate, 5.0 ml/min, temperature of column, 35°C, detector, JASCO 875-UV).

3.2. Plant material

Rhizomes of *P. japonicus* ssp. *giganteus* were collected in July 1997, in Ashoro-cho, Hokkaido, Japan.

3.3. Bioassay

Germination and seedling growth tests of lettuce (*Lactuca sativa* L.) were carried out on a silica gel support. For bioassays, rhizome powder (0.3 g) was added to a Petri dish containing silica gel (0.3 g) and distilled water (5 ml, containing 100 ppm (w/v) Tween 80). Lettuce seeds (50) were next placed onto the Petri dish and incubated at 20°C, 17 lux for 5 days.

To test either isolated compounds or fractions soluble in organic solvents, specified amounts of a sample were dissolved in either $CHCl_3$ (0.3 ml) or ethyl alcohol (0.3 ml) and the solution was added to silica gel (1.0 g). When isolated compounds were tested, the same amount of $CHCl_3$ was added as a control. The silica gel was left in a draft chamber for 24 h to remove organic solvents by volatilization and added to 5 cm Petri dish. Distilled water (2 ml) containing 100 ppm (w/v) Tween 80 was poured into the Petri dish and left overnight to allow the sample to dissolve completely. To test water soluble fraction, a sample was dissolved in distilled water (2 ml), and the solution was poured into a Petri dish containing silica gel (1 g). 30 seeds were placed in each dish and incubated under the same conditions as described above. The concentration of either compounds or fractions were calculated over the weight of distilled water plus silica gel (w/w).

Numbers of germinated seeds were counted every 24 h and the lengths of hypocotyls and radicles were measured on the 5th day and compared to those of the controls. Each test was repeated 3 times.

3.4. Extraction and isolation

Fresh rhizomes of *P. japonicus* ssp. *giganteus* (800 g) were extracted with *n*-hexane for 2 weeks at room temperature. The filtered extract was concentrated under

reduced pressure. The extract (4.2 g) was subjected to silica gel column chromatography using a *n*-hexane-EtOAc gradient to afford 19 fractions (Fr.1–19). Fr.13 (377 mg) was purified by prep.TLC (*n*-hexane:EtOAc = 4:1) and further by prep.HPLC using CH_3CN-H_2O gradient (1:1–3:1) to give 1 (13.6 mg). Fr.14 (676 mg) was applied to a silica gel column using an *n*-hexane-EtOAc (10:1), 9 fractions (14A–14I) were obtained. 14E (114 mg) was purified by prep. HPLC using CH_3CN-H_2O gradient (1:1–3:1) following CC using benzene-acetone (20:1) to give **2** (11.7 mg). 14I (99.4 mg) was pure **3**. Fr.17 (544 mg) was separated into 4 fractions (17A–17D) by prep.HPLC using a CH_3CN-H_2O gradient (1:1–3:1). 17A contained **1**. 17B mainly contained **4** and its further recrystallization with *n*-hexane-EtOAc gave pure crystalline **4** (10 mg).

Received 12 September 2000; received in revised form 27 November 2000

Abstract

We present cuticular wax chemical profiles for the leaves and stems of *Arabidopsis* wildtype Landsberg *erecta* and eleven isogenic *eceriferum* mutants: *cer5*, *cer10* to *cer15*, and *cer17* to *cer20*. These *cer* mutants have wax profiles that are different from those of wildtype in chemical chain length distribution, amount per chemical class, and/or total wax load. Analyses of detailed leaf and stem wax profiles for these *cer* mutants have allowed us to place some of these mutants at specific steps in wax production. The *cer13* gene is predicted to affect release of the 30 carbon fatty acid from the elongation complex or the reduction of C30 fatty acid to C30 aldehyde. The *CER19* gene product is predicted to be involved in C28 to C30 fatty acyl-CoA elongation. The *CER20* gene is predicted to affect the oxidation of C29 alkane to C29 secondary alcohol. Several predicted gene products affect only stem specific steps in the wax pathway. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Arabidopsis thaliana is a powerful model plant system for dissecting genetic components in cuticular wax production. In previous studies, 20 distinct wax loci of *A. thaliana*, designated *eceriferum* or *cer* were identified using a visual screen for altered stem surface glaucousness (Koornneef et al., 1989). Detailed wax chemical profiles of leaves and stems from nine of these *cer* mutant loci, *cer1* to *cer4*, *cer6* to *cer9*, and *cer16* were used to predict the role of *CER* gene function in the *A. thaliana* wax formation pathway (Jenks et al., 1995).

In this report, detailed analyses of leaf and stem cuticular wax of an additional 11 *cer* mutant loci are presented. Previous studies reported the amount of major wax classes on stems of these 11 *cer* mutants and some chemical chain length data for seven of these mutants (Hannoufa et al., 1993; McNevin et al., 1993; Lemieux et al., 1994). However, leaf wax, stem wax loads, and amount of stem wax constituents by chain length relative to plant area were not examined. Our detailed leaf and stem analyses of *cer5*, *cer10* to *cer15*, and *cer17* to *cer20* have allowed us to place some of these mutations at specific blocks in the *A. thaliana* wax enzymatic pathway, and for three loci to predict gene function. Detailed analysis of *cer* mutants is essential to the continued development of an accurate pathway for wax production.

2. Results and discussion

2.1. Cuticular wax load

The total wax load for the leaves and stems of wildtype, *cer5*, *cer10* to *cer15*, and *cer17* to *cer20* are presented in Table 1. Placement of these mutants on the genetic map confirms that each represents a distinct locus (Rashotte and Feldmann, unpublished results). The wax loads of the mutant tissues are significantly lower than the wildtype except for the stems of *cer15* and *cer17* and the leaves of *cer5, cer10*, and *cer11* (Table 1). While the total load is not significantly different for every mutant, the waxes of both the leaves and stems for all mutants are significantly altered in two

[a] All values are presented in μg dm^{-2} for three replicates: total load represents the average total amount of hexane soluble surface wax constituents (excluding triterpenoids and unknowns) in μg dm^{-2} for three replicate surface areas ± standard error.

or more chemical classes (Table 1). In general, the *cer* mutants displayed no correlation between reductions of wax load on the leaves vs. the stems, suggesting organ specific patterns.

2.2. *cer* Mutant cuticular waxes

The major chemical constituents of cuticular wax found in the leaf and stem of Arabidopsis are presented for all 11 *cer* mutants compared to their wildtype background in Figs. 1–4. These figures show detailed wax chemical profiles of these mutants as absolute values of μg dm^{-2} as has previously been presented for other Arabidopsis *cer* mutants and ecotypes (Jenks et al., 1995, 1996; Rashotte et al., 1997).

The wildtype background, Landsberg-erecta, has a leaf cuticular profile very similar to the previously examined Ws background (Jenks et al., 1996). Both wildtype backgrounds are almost entirely composed of alkanes and primary alcohols in the leaf, with C29 and C31 as the predominate alkanes and C26 and C28 as the predominate primary alcohols (Fig. 1). The differences in the 11 *cer* mutant leaf profiles in this paper in comparison to the wildtype appear mainly due to changes in the overall amounts or the chain-length distribution within the alkanes and primary alcohols (Figs. 1 and 2). Additionally, the stem cuticular profile of the wildtype is very similar to previously examined wildtype backgrounds (Jenks et al., 1996; Rashotte et al., 1997). Wildtype Arabidopsis stem profiles show a diversity of major chemical constituents as well as an increased overall load in comparison to leaf profiles. The most abundant wax chemical components in the stem are the C29 alkane, C29 ketone and C29 secondary alcohol, while the C28 fatty acid, the C30 aldehyde and the C28 primary alcohol are the most predominate components within their respective classes (Fig. 3). The change in the amount of these components or their predominance within a chemical class is found within each of the 11 *cer* mutants presented in Figs. 3 and 4.

The leaves of *cer5* have reduced primary alcohol and ester levels, 45 and 49% of wildtype levels, respectively (Fig. 1). The reduction in primary alcohols is mostly due to the greatly reduced levels of C26 and C28 constituents. In contrast to the leaf profile, the *cer5* stem profile has reduced levels in all chemical classes except primary alcohols and esters (Fig. 3). The C30 aldehyde and the C29 alkane levels are the most dramatically reduced. While the C29 ketone and C29 secondary alcohols levels are also reduced compared to wildtype levels, they are still at higher levels that the usually predominate C29 alkane (Fig. 1 and Table 1).

The leaves and stems of *cer10* show a slight skewing of chemical components toward longer chain lengths

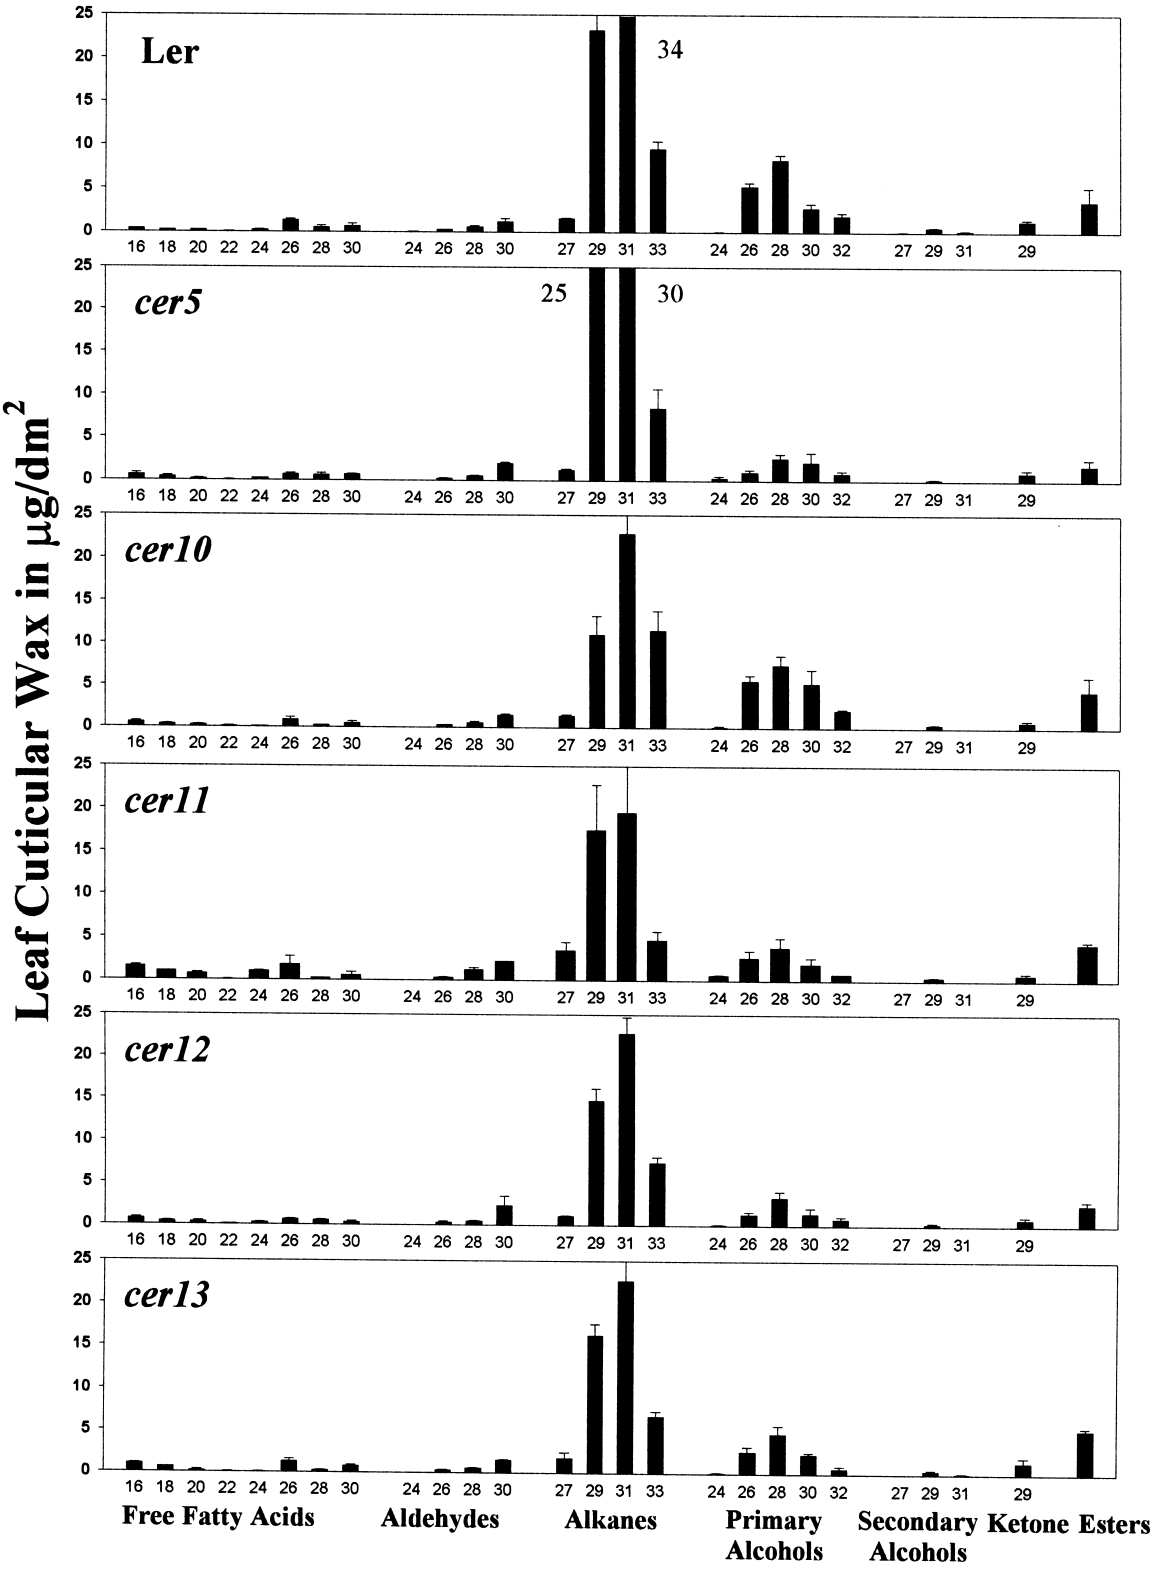

Fig. 1. Cuticular wax profiles of *A. thaliana* Wildtype and *cer* Mutants. Each bar shows the amount of a specific wax constituent, labeled on the X-axis by a wax class and a carbon unit length of that constituent. The ketone represents a 29 carbon length ketone. All measurements are in µg/dm^2 and are presented as and average of three replicates ± standard error. Bars that reach the top of the graph have additional numbers adjacent to them, indicating the actual wax amount, which is off the Y-axis. Fig. 1 shows leaf wax profiles of *cer5*, *10*, *11*, *12*, and *13* along with the wildtype Ler (Landsberg-erecta).

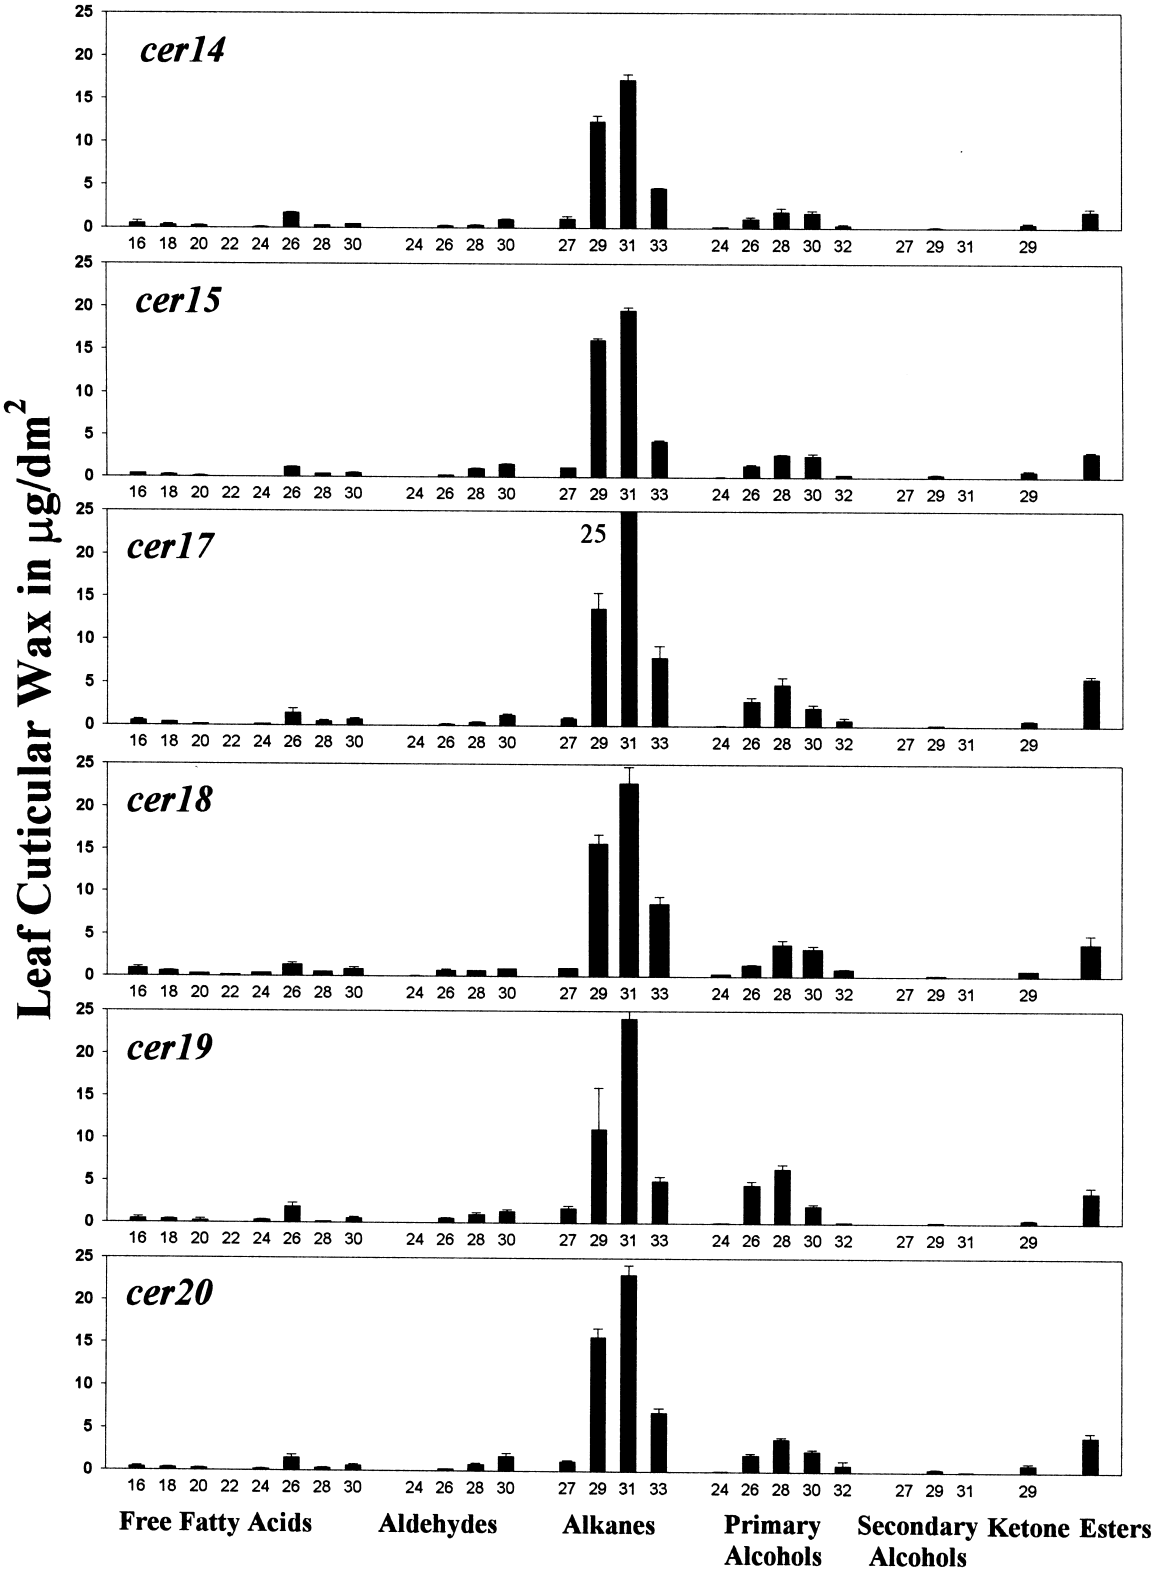

Fig. 2. Cuticular wax profiles of *A. thaliana* Wildtype and *cer* Mutants. Each bar shows the amount of a specific wax constituent, labeled on the X-axis by a wax class and a carbon unit length of that constituent. The ketone represents a 29 carbon length ketone. All measurements are in μg/dm^2 and are presented as and average of three replicates ± standard error. Bars that reach the top of the graph have additional numbers adjacent to them, indicating the actual wax amount, which is off the Y-axis. Fig. 2 shows leaf wax profiles of *cer14*, *15*, *17*, *18*, *19*, and *20*.

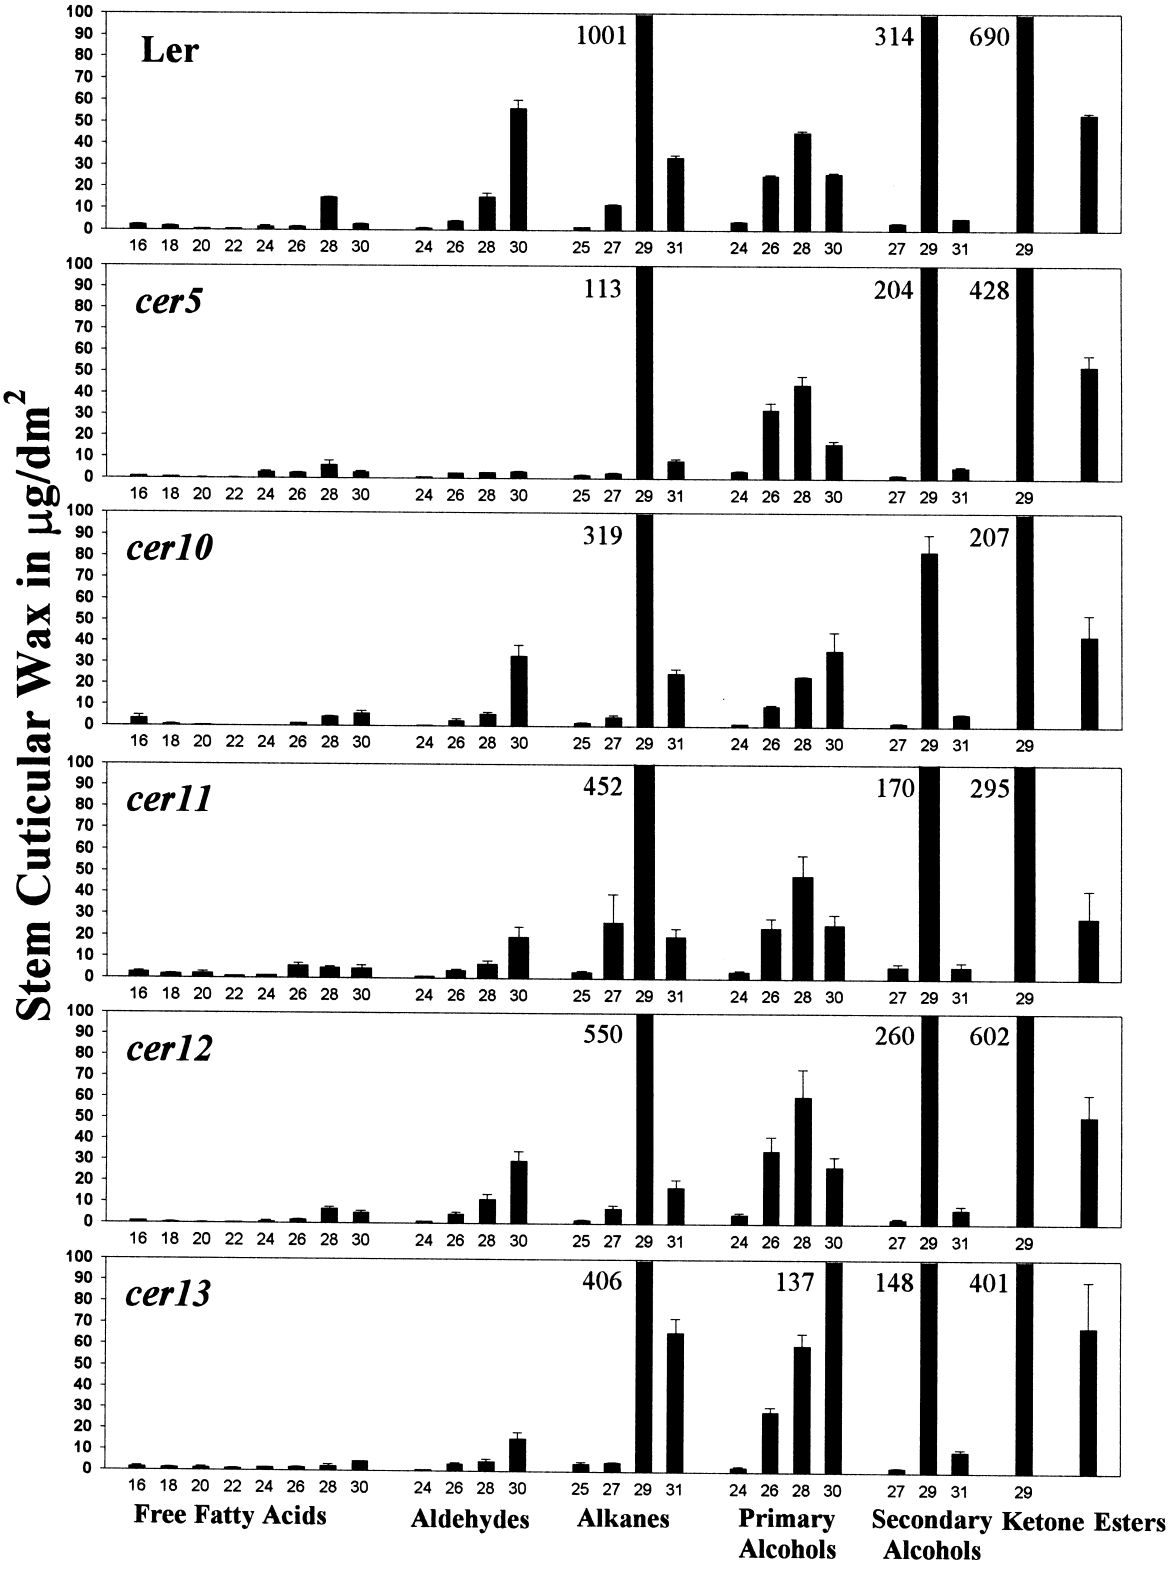

Fig. 3. Cuticular wax profiles of *A. thaliana* Wildtype and *cer* Mutants. Each bar shows the amount of a specific wax constituent, labeled on the X-axis by a wax class and a carbon unit length of that constituent. The ketone represents a 29 carbon length ketone. All measurements are in μg/dm^2 and are presented as and average of three replicates ± standard error. Bars that reach the top of the graph have additional numbers adjacent to them, indicating the actual wax amount, which is off the Y-axis. Fig. 3 shows stem wax profiles of the mutants *cer5*, *10*, *11*, *12*, and *13* along with Ler.

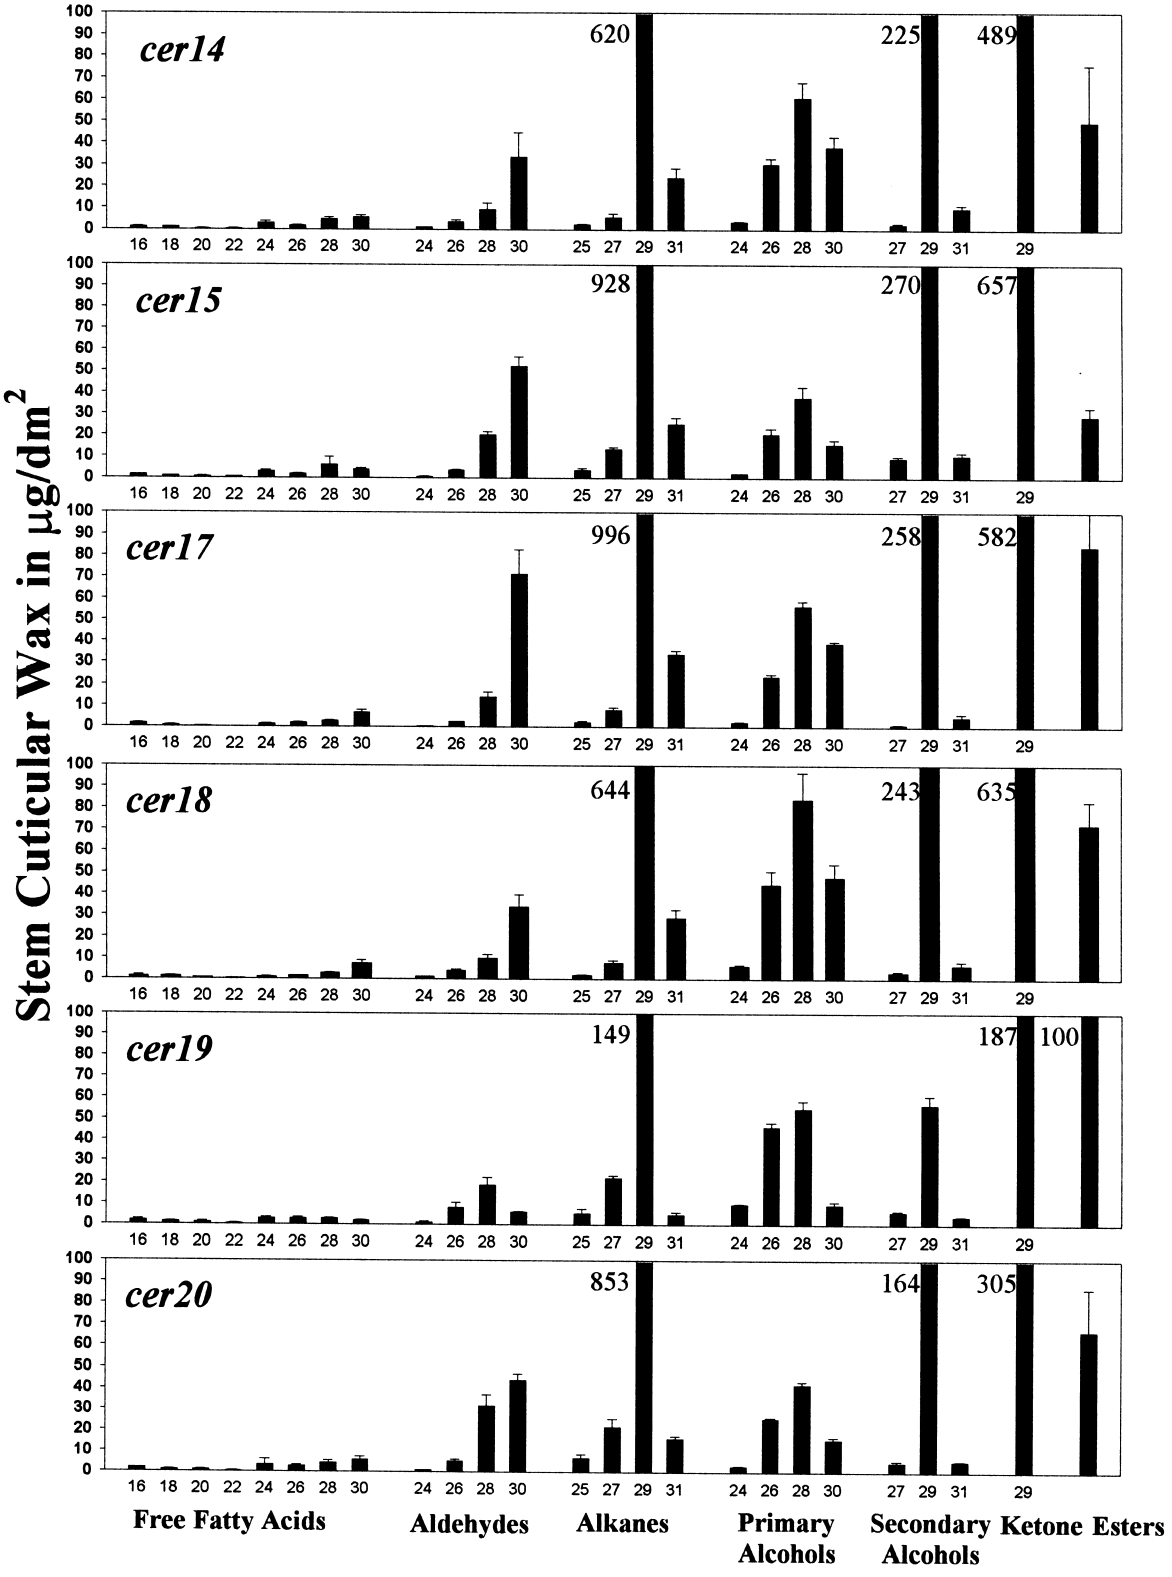

Fig. 4. Cuticular wax profiles of *A. thaliana* Wildtype and *cer* Mutants. Each bar shows the amount of a specific wax constituent, labeled on the X-axis by a wax class and a carbon unit length of that constituent. The ketone represents a 29 carbon length ketone. All measurements are in µg/dm^2 and are presented as and average of three replicates ± standard error. Bars that reach the top of the graph have additional numbers adjacent to them, indicating the actual wax amount, which is off the Y-axis. Fig. 4 shows stem wax profiles of *cer14*, *15*, *17*, *18*, *19*, and *20*.

(Figs. 1 and 3). In the leaves this skewing is due to the reduction of C29 alkane and the increase of C30 primary alcohol. The stems show a similar pattern having reduced C29 components and increased C30 primary alcohol levels.

The leaves of both *cer11* and *cer12* have a reduction in alkane and primary alcohol levels with little or no change in profile distribution (Fig. 1). The stems of *cer11* show about a 50% reduction in C29 components and C30 aldehyde with little to no reduction in primary alcohol levels or distribution. *cer12* also shows a major reduction in C29 alkane levels, although there is little change in other wax components (Fig. 3).

The leaves of *cer13* show a general reduction in wax load, with no change in wax profile (Fig. 1). In contrast, *cer13* stems show major reductions in all C29 components and major increases in the C31 alkane and C30 primary alcohol levels (Fig. 3). This has the effect of skewing the chain length distribution of *cer13* longer than wildtype.

The leaves of *cer14* and *cer15* have similar major reductions in alkane and primary alcohol levels that do not effect profile distribution (Fig. 2). The stems of *cer14* and *cer15*, however, are quite different. *cer14* stems show a reduction in C29 alkane, secondary alcohol and ketone levels, while other components are mostly unaffected (Fig. 4). In contrast, *cer15* stems have minor reductions in primary alcohol and esters.

The leaves of *cer17* leaves have reductions in C29 and C31 alkanes as well as C26 and C28 primary alcohols (Fig. 2). The stems of *cer17* have minor reductions in overall load with little effect on profile distribution (Fig. 4).

The leaves of *cer18* have a general load reduction, with little change from the wildtype wax profile (Fig. 2). The *cer18* stems have specific reductions in C29 alkane and C29 secondary alcohol levels, while primary alcohol levels show a general increase although maintaining the wildtype primary alcohol profile (Fig. 4).

The leaves of *cer19* have greatly reduced alkane levels, in addition to minor reductions in primary alcohol levels (Fig. 2). Stems show a different alteration in wax levels than leaves. All wax components greater than 29-carbon length are dramatically reduced compared to wildtype levels, while esters levels are greatly increased (Fig. 4).

The leaves of *cer20* have a general reduction in wax levels with little change in profile distribution (Fig. 2). *cer20* stem wax is primarily effected by reductions in C29 secondary alcohol and C29 ketone levels, with most other components remaining unaffected (Fig. 4).

2.3. Prediction of CER gene function

The detailed chemical analyses of leaf and stem wax chemistry of the *cer* mutants presented in Figs. 1–4 along with previous biochemical-genetic studies of *A. thaliana* have allowed us to make predictions about the altered gene functions in the mutants examined here (Hannoufa et al., 1993; McNevin et al., 1993; Lemieux et al., 1994; Jenks et al., 1995: and Rashotte and Feldmann, unpublished results). We have been able to predict the function of three *CER* genes and have placed blocks corresponding to the mutant genes on a wax enzymatic pathway (Fig. 5).

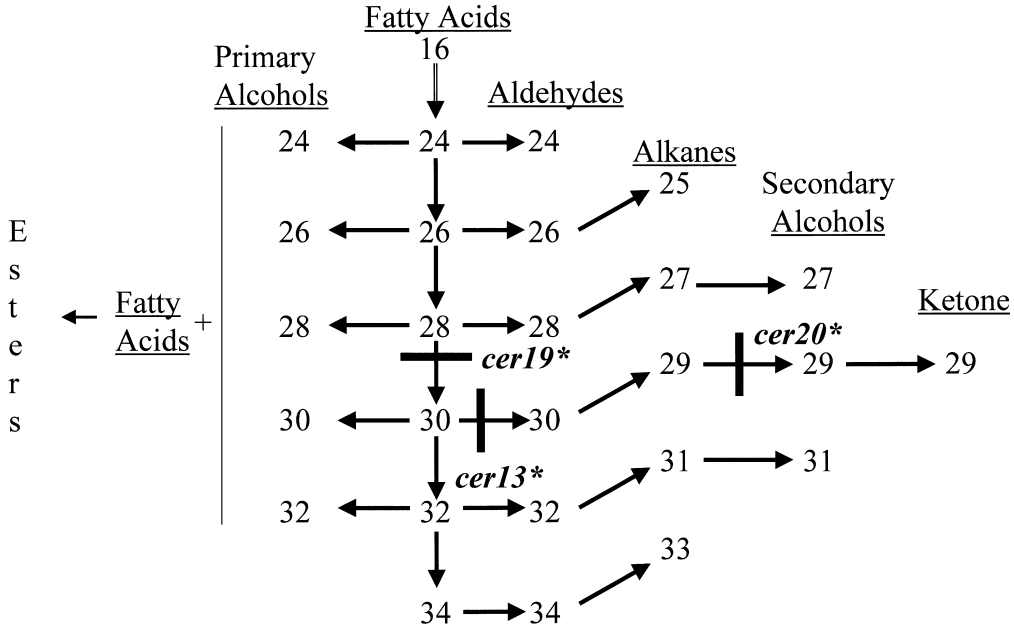

Fig. 5. Cuticular wax formation pathway in *A. thaliana*. A single lined arrow indicates single steps in this pathway, while a double lined arrow indicates multiple steps. Mutational blocks at specific steps of this pathway are indicated by a thick line across an arrow and are labeled by the mutation(s) that are proposed to block there. * Stem specific mutational block.

The *cer13* mutant stem has increased amounts of longer chain length components for both primary alcohols and alkanes compared to wildtype, and resembles the *cer3* and *cer7* mutants [Fig. 3 and Jenks et al. (1995)]. We propose that the *CER13* gene product is involved in C30 fatty acid to C30 aldehyde reduction. A block or mutation in the C30 fatty acid reductase should cause a build-up of C30 fatty acid, which could either be reduced directly to C30 primary alcohol or further elongated to C32 fatty acid. This C32 fatty acid would subsequently be reduced to C32 aldehyde and decarbonylated to C31 alkane (Fig. 5). In *cer13* stems there was a decrease of C30 aldehyde and subsequent C29 components, along with an increase of both C30 primary alcohol and C31 alkane components supporting this hypothesis (Fig. 1). However, we cannot rule out the possibility that this mutant could also have defects in a C30 fatty acid elongase release mechanism which only contributes fatty acids to the alkane flux of the pathway as had previously been suggested for *cer3* and *cer7* (Jenks et al., 1995). Additionally, because our pathway modification eliminates aldehydes as intermediates in the reduction of fatty acids to primary alcohols, the hypothesis of a fatty acid to aldehyde reduction block for *cer3* and *cer7* similar to that for *cer13* seems likely as well (Rashotte and Feldmann, unpublished results). It may be that more than one gene product is needed for the conversion of C30 fatty acid to C30 aldehyde in *A. thaliana*, since the *cer13* mutation does not cause a complete loss of C30 aldehyde or subsequently derived pathway products (Fig. 1). One possible candidate would be the *CER10* gene, since there is a similar trend of increased longer chain length components in the leaf and stem of the *cer10* mutant. These trends are, however, minor when examined as a percent of the total mutant wax load and thus the function of *CER10* must remain speculative.

Cer19 has dramatically reduced levels of wax constituents derived from any 30 carbon or longer acyl-CoA precursors in the stems, as observed in fatty acid, aldehyde, alkane, and primary alcohol classes (Fig. 4). Coenzyme A (CoA) activated fatty acyl chains, which are progressively elongated through condensation by two-carbon units, constitute the backbone of the wax enzymatic pathway from which all other wax components are formed (Lemieux et al., 1994). Thus, a defect in a specific step of fatty acid elongation should have greatly reduced levels of all wax components of chain lengths greater than the defective step. Therefore, *CER19* is predicted to be a gene directly involved in the C28 fatty acyl-CoA elongation step in the wax enzymatic pathway in the stem (Fig. 5). Although the leaves of *cer19* also have reduced amounts of components greater than C30, there is a reduction of components less than C30 with no obvious increase of C28 or C27 components as in the stem (Figs. 2 and 4). Thus, we hypothesize the *CER19* gene product is stem specific. Other mutants, such as the *gl3* mutation in *Z. mays* (Bianchi et al., 1985) and the *gl2* and *gl5* mutations of *Brassica oleracea* (Macey and Barber, 1970) have similar wax profiles.

Stem ester loads were higher on *cer19* than any other *cer* mutants [Jenks et al. (1995) and Figs. 3 and 4]. Interestingly, stem ester levels were also high on the *cer2* and *cer9* mutants of *Arabidopsis* that, like *cer19*, appear to have defects in fatty acid elongation (Jenks et al., 1995). It is possible that increased flow of C28 and shorter fatty acids to similar chain length primary alcohols allowed for greater amounts of esters to be produced. A putative transacylase with specificity for shorter chain length fatty acids and primary alcohols is thought to synthesize very long chain esters (Kolattukudy, 1967; 1996). The relative increase of primary alcohols in *cer19* and also in the *cer2* and *cer9* putative elongation mutants may result in increased ester levels, because the pools of short chain fatty acid and primary alcohol substrates for esterification were increased (Table 1 and Jenks et al., 1995).

The *cer20* stem appears to be blocked in the conversion of C29 alkane to C29 secondary alcohol (Fig. 4). The conversion of alkanes to secondary alcohols is putatively carried out by an oxidation of the 14th or 15th carbon in C29 alkane (Lemieux et al., 1994). A block in this specific oxidation step should result in higher C29 alkane levels, relative to the total load of the mutant, and reductions of C29 secondary alcohol and C29 ketone levels (Fig. 5). *cer20* is the only *cer* mutant that has increased levels of C29 alkane and reduced levels of both C29 secondary alcohol and C29 ketone, as a percent of its total wax load (Figs. 3 and 4 and Jenks et al., 1995). Interestingly, while the largest change in constituent levels relative to the total load of this mutant is between the levels of C29 alkane to C29 secondary alcohol (12.4% reduction), there is also a reduction between levels of C29 secondary alcohol to C29 ketone (Fig. 4). It is possible that the gene product of *CER20* is directly involved in the enzymatic oxidation of C29 alkane to C29 secondary alcohol or indirectly involved with oxidation events for both the oxidation of C29 alkane to C29 secondary alcohol and C29 secondary alcohol to C29 ketone.

The other *cer* mutants, *cer5, 10, 11, 12, 14, 15, 17,* and *18*, have distinct leaf and stem wax differences from the wildtype (Figs. 1–4). However, we were unable to place these mutants at specific steps in the wax pathway or predict their gene function. It is possible the gene products disrupted in these mutants are involved in wax functions other than biosynthesis, such as transport, regulation, or development. Cloning of the genes in the wax pathway as well as double mutant analyses may help confirm the role of each locus in cuticular wax formation.

3. Experimental

3.1. General experimental procedures

3.1.1. Cuticular wax analysis

The hexane soluble surface lipids (designated cuticular wax or wax) were bulk extracted from leaves and stems of 25 day old plants by immersing tissues in hexane for 30 s. Derivatization, gas chromatography, mass spectrometry, quantification of identified wax constituents, and measurement of surface area were performed according to (Jenks et al., 1995: Rashotte et al., 1997) as modified from McNevin et al. (1993). Three replicates were conducted for each wax profile and the data is presented as an average ± standard error in μg dm^{-2}.

3.1.2. Plant material

Arabidopsis thaliana ecotype Landsberg *erecta* (Ler) along with chemical- and radiation-induced *cer* mutants from (Koornneef et al., 1989) were used for wax analyses. Plants were grown in a controlled environmental chamber (CONVIRON, Winnipeg, Manitoba) at 22°C with a 16 hour photoperiod (~240 μmol min^{-2} s^{-1}; approximately 75% RH) and at 18°C in the dark. The *cer21* mutant was not used in our analyses because the uniqueness of the locus could not be confirmed (Hannoufa et al., 1993; Rashotte and Feldmann, unpublished results).

3.1.3. Chemicals identified as wax constituents on Arabidopsis

Hexadecanoic, octadecanoic, eicosanoic, docosanoic, tetracosanoic, hexacosanoic, octacosanoic, triacontanoic acids as C16, C18, C20, C22, C24, C26, C28, and C30 free fatty acids; *n*-pentacosane, *n*-heptacosane, *n*-nonacosane, *n*-hentriacosane, *n*-tritriacontane as C25, C27, C29, C31, and C33 alkanes; 1-tetracosanol, 1-hexacosanol, 1-octacosanol, 1-triacontanol, 1-dotriacontanol as C24, C26, C28, C30, and C32 primary alcohols; tetracosanal, hexacosanal, octacosanal, triacontanal as C24, C26, C28, and C30 aldehydes; 13- and 14-heptacosanol, 14- and 15-nonacosanol, 15- and 16-hentriacontanol as C27, C29, and C31 secondary alcohols; and 15-nonacosanone as C29 ketone.

Received 16 June 2000; received in revised form 13 November 2000

Abstract

The investigation of an Argentine collection of *Enydra anagallis* afforded sesquiterpene lactones of the melampolide type two of which were previously known. Their structures were elucidated by spectroscopic methods. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Enydra*; Compositae; Heliantheae; Sesquiterpene lactones; Melampolides

1. Introduction

The genus *Enydra* (Asteraceae, tribe Heliantheae) was placed by Stuessy (1977) in the subtribe Ecliptinae and then by Robinson (1981) in the subtribe Enhydrinae. Karis sampled many genera of Heliantheae in his morphological cladistic analysis and placed *Enydra* in the subtribe Melampodiinae (Bremer, 1994). It is one of the few genera of wet or aquatic habitats in the Compositae. The genus was originally described by Loureiro (1790) as *Enydra* but later it was spelled as "*Enhydra*" (De Candolle, 1836) taking in account the etymology of the word (from Greek, enhydra: in water).

From numerous species of *Tetragonotheca*, *Sigesbeckia*, *Acanthospermum*, *Melampodium*, *Lecocarpus*, and *Smallanthus*, all included in the subtribe Melampodiinae (Bremer, 1994), many diterpenoids and melampolide type sesquiterpenoids were isolated (Quijano et al., 1979; Barua et al., 1980; Saleh et al., 1980; Bohlmann et al., 1981, 1984a; Castro et al., 1989; Zdero et al., 1991; Macías and Fischer, 1992; Macías et al., 1993; Inoue et al., 1995; Quijano et al., 1997). Phytochemical studies of *E. fluctuans*, the only species of the genus previously investigated, have led to the isolation of several sesquiterpene lactones of melampolide type (Ali et al., 1972; Bohlmann et al., 1982a,b; Krishnaswamy and Ramh, 1995). *E. fluctuans* is used in Indian medicine in treatment of nervous ailments, skin diseases and has been employed as laxative (Chopra, 1956), anti-inflammatory, anti-bilious and demulcent (Kirtikar and Basu, 1933; Sastri, 1952).

From *E. anagallis*, the only species of this genus growing in Argentina, we now report the isolation of eight melampolides (**1**–**8**). Compounds **2**, **3** and **5**–**8** are described for the first time in this paper, and their structures were elucidated by extensive highfield NMR studies, standard ^{1}H–^{1}H COSY, HMQC and NOE experiments.

2. Results and discussion

Compound **1** was a gum with IR absorptions at 1760, 1735 and 1710 cm^{-1} which accounts for an α-methylene γ-lactone, a saturated ester and an α,β-unsaturated ester respectively. ^{1}H NMR data (Table 1) strongly suggested the presence of a 6,12-melampolide skeleton with two acyloxy side chains located at C-8 and C-9. An extensive NMR study, including ^{1}H, ^{13}C and NOE experiments, allowed us to assigne compound 1 the structure of uvedalin previously isolated from *Polymnia uvedalia* (Herz and Bhat, 1970) and *Smallanthus sonchifolius* (Inoue et al., 1995). Relative stereochemistry was supported by NOE experiments.

Compounds **2**–**5** showed ^{1}H and ^{13}C NMR data almost identical to those of the previously described for the 6,12-melampolide skeleton of compound **1**, even the signals for the C-14 methyl ester group and the C-9

7	H	8	H	H

acetate group. Close similarity in chemical shifts, coupling patterns and coupling constants led us to assume identical skeletal features for all of them. Differences were found in the side chains located at C-8. The ^{1}H NMR spectrum of **2** showed a three-proton singlet at δ 1.37 and a two proton AB system centered at δ 3.60 (J = 11.2 Hz), while the ^{13}C NMR spectrum displayed two signals at δ 56.9 (*s*) and δ 50.5 (*t*) for tetra- and disubstituted carbons bearing oxygen. The mentioned signals suggested a 2,3-dihydroxy-2-methylpropanoyloxy side chain at C-8 (Abegaz et al., 1994). This was further confirmed by diagnostic MS peaks. The MS spectrum showed the base peak at m/z 272 [M-HOAc-HOCOC(-CH_3)(OH)CH_2 (OH)]$^+$, a strong peak at m/z 213 (60%) due to the loss of 2,3-dihydroxy-2-methylpropionic acid, acetic acid and -(CO)OCH_3 group from the molecular ion and a small peak at m/z 240 related to the loss of 2,3-dihydroxy-2-methylpropionic acid, acetic acid and methanol from the molecular ion.

Compound **3** had a molecular formula $C_{22}H_{26}O_8$ (molecular ion peak at m/z 418.1630) and the ^{1}H NMR spectral parameters were nearly identical to those of the 6,12-melampolide **1**. ^{1}H NMR signals associated with the side chain were one vinyl proton broad singlet at δ 6.02, one vinyl proton triplet at δ 5.57 (J = 1.6 Hz) and a three- proton broad singlet at δ 1.93 (vinyl methyl protons). These values as well as the ^{13}C NMR signals at δ 126.6 (CH_2), δ 135.4 (C) and δ 16.9 (CH_3) suggested the presence of a methacrylate side chain (Rustaiyan et al., 1991; Abegaz et al., 1994). The structure of compound **3** was further supported by the mass spectral pattern with peaks at m/z 272 [(M-HOAc–HOCOC(CH_3)=CH_2)]$^+$, m/z 213 due to the loss of methacrylic acid, acid acetic and -(CO)OCH_3 from the molecular ion and m/z 240 due to the loss of methacrylic acid, acetic acid and methanol from the molecular ion as well as by a base peak at m/z 69 [C_4H_5O]$^+$ (Walachy and Fischer, 1981).

Compound **4**, $C_{22}H_{26}O_9$ (molecular peak at m/z 434.1576) showed ^{1}H NMR spectral data nearly identical to those of compound **3** being the signals of the side chain the most noticeable difference. These ^{1}H NMR data, including coupling constants, were in good agreement with the compound named 19-hydroxy-15-desoxy-orientalide previously isolated from *Clibadium pittierii* (Tamayo-Castillo et al., 1988).

The mass spectrum of compound **5** showed the [M]$^+$ at m/z 448.1739 which agreed with the molecular formula $C_{23}H_{28}O_9$. The features of the ^{1}H and ^{13}C NMR spectra suggested, as in the previously described compounds a 6,12-melampolide skeleton bearing methyl ester at C-14 and an acetate group at C-9. The main differences were observed in the signals of the side chain located at C-8. The ^{1}H NMR spectrum showed a three- proton doublet at δ 1.79 (J=1.2 Hz); a two-proton doublet at δ 4.34 (J= 5.6 Hz) and a one-proton triple doublet at δ 6.79 (J=6.0 and 1.6 Hz). Both doublets at δ 1.79 and 4.34 collapsed into singlets when the signal at δ 6.79 was irradiated. The ^{13}C NMR spectrum exhibited signals for two olefinic carbons at δ 127.6 (*d*) and δ 141.6 (*s*) and a methylene group at δ 59.7 (*t*) linked to oxygen, probably a hydroxyl group (IR absorption at 3473 cm^{-1}). This results, together with the presence of peaks at m/z 272 [M-HOAc–HOCO–C(CH_3)=CH–CH_2OH]$^+$, 99 [C_5H_7 O_2]$^+$ and 71 [C_4H_7 O]$^+$ in the mass spectrum led us to the conclusion that the side chain group must be 4-hydroxy-3-methyl-2-butenoyl (Bohlmann et al., 1982a, 1984b; El-Masry et al., 1985; Hernández et al., 1994), 4-hydroxy-2-methyl-3-butenoyl

(Bohlmann et al., 1982b; Öksuz and Ayyildiz, 1986) or 2-hydroxymethyl-2-butenoyl (Herz et al., 1984; El-Masry et al., 1985; Rustaiyan et al., 1991). The stereochemistry of the side chain double bond was deduced by NOE experiments. Saturation of the H-4′ signal led to an increment in intensity of the H-5′ and H-3′ signals, however, saturating the H-3′ signal only caused an increment of the H-4′signal intensity. Therefore the side chain in 5 must be a 4′-hydroxytiglate and not a 4′-hydroxyangelate.

The ^{1}H NMR spectra of compounds **6** and **7** showed the spectral pattern observed in compounds described above (Tables 1 and 2). However, the signal corresponding to the C-9 acetate group was not present. Instead, a higher field signal assigned to H-9 was observed suggesting a hydroxyl group situated at this position. In compound **6** this signal appeared at δ 4.00 as a triplet ($J=10$ Hz) coupling with H-8 (δ 6.27) and with the signal at δ 2.75 which was assigned to the proton of hydroxyl group. The signals corresponding to the acyloxy side chain located at C-8 were very similar to that compound **3** (Tables 1 and 2) so compound **6** was the 9-deacyl-derivative of compound **3**. The exact mass measurement of the $[M]^+$ at m/z 376.1522, provides the molecular formula $C_{20}H_{24}O_7$ and confirms this assignment.

In compound **7** the H-9 signal at δ 4.00 (*t*, *J ca* 9.0 Hz) and a signal at δ 2.80 (*d*, $J=9.6$ Hz) ascribable to the hydroxyl proton suggested again the structure of a 9-deacyl derivative. The nature of the acyloxy side chain at C-8 was evident from the ^{1}H NMR data: a one-proton multiplet overlapped with the H-1 signal at δ 6.84, and two three-proton signals, a broad singlet at δ 1.83 and a broad doublet at δ 1.80 ($J=7.2$ Hz) typical of a tiglic ester moiety (Lazari et al., 1998; Spring et al., 1999). Tiglate was clear also by the signals at δ 166.9 (C), 127.8 (C), 138.8 (CH), 14.5 and 12.8 (two CH_3) in the ^{13}C NMR spectrum. The side chain double bond configuration was confirmed by NOE experiments. The exact mass measurement of the $[M]^+$ at m/z 390.1675 provides a molecular formula $C_{21}H_{26}O_7$ and the mass peaks at m/z 290 $[M\text{-}HOCO\text{–}C(CH_3)=CH(CH_3)]^+$ and m/z 83 confirmed the nature of the ester side chain.

The ^{1}H NMR spectrum of compound **8** showed all the signals corresponding to a 6,12-melampolide skeleton. However two characteristics in the spectrum of compound **8** with respect to all other compounds previously described were obvious: absence of signals due to the lack of any side chain and a dramatic highfield shift of the signal for H-8 from *ca* δ 6.30 to δ 4.69. The molecular peak of compound **8** at m/z 309.1354 $[M+H]^+$ indicative for a molecular formula $C_{16}H_{20}O_6$, together with a large OH band in the IR spectrum at 3425 cm^{-1} and the sixteen peaks present in the ^{13}C NMR spectrum allow us to propose the structure of compound **8**.

3. Experimental

3.1. General

NMR: 400 MHz (^{1}H) and 75.4 MHz (^{13}C) in $CDCl_3$. NOE measurements were carried out by the one-dimensional difference method. Optical rotations at 20°. Low

and high-resolution MS measured with a Fisons Instruments VG Autospec, GC 8000 (70 eV). For separation of mixtures Waters and Konik equipments were used. Columns: (A) Beckman Ultrasphere C 8 (5 μm, 10 mm i.d.×250 mm) and (B) Phenomenex Ultemex C 18 (5 μm, 10 mm i.d.×250 mm). Retention times were measured from the solvent peak.

3.2. Plant material

Aerial parts and roots of *Enydra anagallis* Gadner were collected at the flowering stage in December 1993 in wet places of the riverside of Rio Romano, Monteros, Tucumán province, Argentine (a voucher specimen, LIL No 595793 is deposited in the herbarium de la Fundación Miguel Lillo, Tucumán, Argentina).

3.3. Extraction and isolation

Flowers, leaves and roots (350 g) were extracted with $CHCl_3$ (2×3 l) at rt for 4 days with shaking to give 11.5 g of residue (yield 3.2%) which was suspended in 100 ml of EtOH at 55°C, diluted with 75 ml of H_2O and extracted successively with hexane (2×150 ml) and $CHCl_3$ (2×150 ml). The second $CHCl_3$ extract was evapd under red. pres. to give 1.9 g of residue which was chromatographed on Si gel (57 g, 70–230 Mesh) with $CHCl_3$ and increasing amounts of EtOAc (0–100%) and finally MeOH; 82 fractions of 10 ml each being collected. Fractions containing sesquiterpene lactones (IR band at 1765 cm^{-1}) were further purified. Frs. 1-14 (383 mg) were eluted with $CHCl_3$ and increasing amounts of EtOAc (0–5%) and combined (383 mg). They were defatted with MeOH and, after filtration and evapn of solvent, the residue was processed by HPLC (Column B, MeOH–H_2O 2:1, 2 ml min^{-1}) to give compounds **6** (40 mg, R_t 6 min), **1** (78 mg, R_t 10 min) and **3** (52 mg, R_t 17 min). Frs. 15-29 (eluted with $CHCl_3$-EtOAc 95:5) were combined (509 mg) and processed by HPLC (Column B, MeOH–H_2O 4:3, 1.5 ml min^{-1}) to give four fractions which showed to be mixtures by TLC analysis. Rechromatography by HPLC (Column A, MeOH–H_2O 1:1, 1.7 ml min^{-1}) afforded compounds **6** (93 mg, R_t 19 min), **7** (8 mg, R_t 29 min) and **1** (5 mg, R_t 31 min). Fr 30-51 eluted with a $CHCl_3$-EtOAc gradient (9:1→8:2) and combined (375 mg). A portion (200 mg) was processed by HPLC (Column B, MeOH–H_2O 4:3,1.3 ml min^{-1}) to give compound **2** (22 mg, R_t 30 min). Frs 52-65 eluted with a $CHCl_3$–EtOAc gradient (3:1→1:2) and combined (183 mg). HPLC (Column B, MeOH–H_2O 6:5, 1.5 ml min^{-1}) gave compound **4** (37 mg, R_t 21 min) and a mixture (R_t 22-23 min) which was further processed by HPLC (Column A, MeOH–H_2O 6:5, 2 ml min^{-1}) to give a new portion of **4** (3 mg, R_t 22 min) and **5** (3 mg, R_t 27 min). Frs 66-82 were eluted with EtOAc and finally MeOH. They were combined (280 mg) and chromatographed by HPLC (Column B, MeOH–H_2O 1:1, 1.2 ml min^{-1}) to give compound **8** (46.8 mg, R_t 8 min).

ent-Pimarane derivatives from *Dysoxylum hainanense*

Xiao-Dong Luo *, Shao-Hua Wu, Yun-Bao Ma, Da-Gang Wu

Laboratory of Phytochemistry, Kunming Institute of Botany, The Chinese Academy of Sciences, Kunming 650204 Yunnan, People's Republic of China

Received 4 May 2000; received in revised form 2 October 2000

Abstract

Four *ent*-pimarene diterpenoids, *ent*-18-acetoxy-8(14)-pimarene-15*S*,16-diol, *ent*-18-acetoxy-16-hydroxy-8(14)-pimaren-15-one, *ent*-16,18-dihydroxy-8(14)-pimaren-15-one and *ent*-19-nor-4,16,18-trihydroxy-8(14)-pimaren-15-one, together with three known damarane triterpenoids, richenoic acid, eichlerianic acid and shoreic acid were isolated from the bark of *Dysoxylum hainanense* Merr. Their structures were elucidated on the basis of spectroscopic techniques. The absolute configurations of four diterpenoids were assigned as *ent*-pimarene type by chemical transformation and by co-occurrence in the plant as well as by negative optical rotations for four compounds. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Dysoxylum hainanense; Meliaceae; *ent*-Pimarene diterpenoids

1. Introduction

The genus *Dysoxylum*, comprising about 200 species grows naturally in India and southeast Asia. Fourteen of them are distributed in China. About 10 species of this genus have been found in the Yunnan province and *D. hainanense* Merr. is distributed in the Guangxi, Hainan, and Xishuangbanna County, Yunnan provinces (Yunnan Institute of Botany, 1977). While diterpenoids have been isolated from this genus (Onan et al., 1985; Aladesanmi and Adewunmi, 1990), the chemical constituents of this species have not been reported previously. As a continuing study on chemical constituents from Meliaceae plants (Luo et al., 1999), we examined the EtOH extract of the bark of *D. hainanense*. Four new diterpenoids, together with three known damarane triterpenoids, richenoic acid, eichlerianic acid and shoreic acid (Aalbersberg and Singh, 1991) were obtained. This paper describes the isolation and structural elucidation of these compounds.

2. Results and discussion

Compound **1** was assigned the molecular formula of $C_{22}H_{36}O_4$ by negative-ion HRFABMS. The IR spectrum showed absorption bands at 3318 cm^{-1} (–OH), 1714 cm^{-1} (C=O) and 1622 cm^{-1} (olefinic linkage). The ^1H NMR spectrum exhibited signals for an olefinic proton (δ_H 5.19, s), three upfield tertiary (δ_H 0.94, 0.84, 0.77) and downfield (δ_H 2.03) methyl singlets. The EIMS spectrum exhibited a strong fragment peak at m/z 303 (the loss of $-CHOHCH_2OH$ from the molecular ion peak). In addition, the ^{13}C and DEPT NMR spectra displayed the presence of nine methylenes, two of which were oxymethylenes, three methines, one of which was oxygenated, three quaternary carbons, two olefinic carbons (δ_C 127.3, 139.7), and an acetate group. All these data suggested that **1** was either a pimarene or isopimarene diterpenoid having a 1,2-dihydroxyethyl side chain and a double bond between C-8 and C-14 (Cambie et al., 1975; Jakupovic et al., 1987; Tsichritzis and Jakupovic, 1990). This was confirmed by analysis of the HMBC spectrum, with long range coupling for H-14 (δ_H 5.19, *s*) to C-13 (δ_C 36.6, *s*), H-15 (δ_H 3.40, *dd*, $J = 9.1$, 2.1 Hz) to C-16 (δ_C 62.7, *t*), and H-15 to C-13.

The chemical shift value (δ_C 139.7) of the olefinic carbon (C-8) suggested a pimar-8(14)-ene skeleton and not its C-13 epimer (about 136 ppm) (Cambie et al., 1975) for compound **1**. The ^{13}C NMR spectrum of **1** showed a resonance at δ_C 79.4, almost identical with the value of 15*R* (i.e. *ent*-15*S*), but very different from that reported for the 15*S* epimer (Wenkert et al., 1979) which also provided proof of the stereochemistry at C-15. Comparison of the chemical shift of the other oxymethylene (δ_C 73.0)

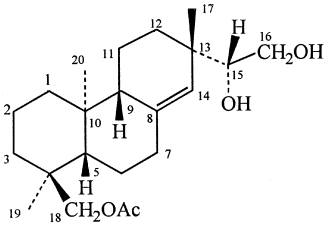
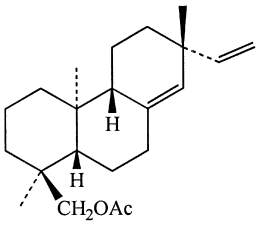
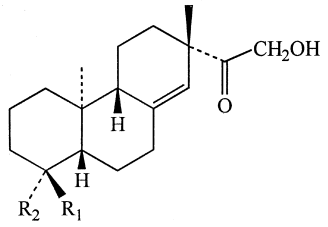
in **1** with that of 18-hydroxy (about 72 ppm) and 19-hydroxy (about 65ppm) diterpenic substances (Jakupovic et al., 1987) suggested that an acetoxyl or a hydroxyl group was connected at C-18 rather than at C-19 in compound **1**. The assumption was further supported by NOE interactions between H-18 [3.83 (1H, *d*, 10.9), 3.61 (1H, *d*, 10.9)] and H-5 [δ_H 1.30 (m)], and δ_H 0.77 (H-20) and 0.84 (H-19) in the ROESY spectrum. In the HMBC spectrum, cross-peaks between oxymethylene protons (H-18) to δ_C 17.9 (*q*, C-19), 37.9 (*s*, C-4), and 171.2 (*s*, OAc) confirmed an acetoxyl attached to C-18.



1



1a



2. $R_1 = CH_2OAc$, $R_2 = CH_3$

3. $R_1 = CH_2OH$, $R_2 = CH_3$

4. $R_1 = CH_2OH$, $R_2 = OH$

In order to establish the absolute configuration of compound **1**, a chemical transformation was performed according to the literature (Hiyama and Nozaki, 1973). Compound **1** was converted to **1a** whose optical rotation {$[\alpha]_D^{23}$ −82.3° (*c* 0.15, $CHCl_3$)} was similar in magnitude, but of opposite sign to that of pimarinol ($[\alpha]_D^{22}$ −94°) (Erdtman and Westfelt, 1963). The optical rotation value of **1a** was the same sign and similar in magnitude to those of (−)-pimara-8(14),15-diene ($[\alpha]_D$ −90°) and its derivatives (Hanson and White, 1970). Hence **1a** was determined to be an *ent*-pimarene type rather than a pimarene type. Thus, **1** was elucidated as *ent*-18-acetoxy-8(14)-pimarene-15*S*,16-diol.

Because of the co-occurrence in the plant as well as the negative optical rotations for all four compounds, compounds **2**–**4** were also regarded as *ent*-pimarenes.

Compound **2** was analyzed for $C_{22}H_{34}O_4$ by negative-ion HRFABMS. The ^{13}C and ^1H NMR spectral data of **2** and **1** were similar. The main difference was that a ketonic carbonyl group was present in the ^{13}C NMR spectrum of **2**, instead of the oxymethine in **1**. The ketonic carbonyl group was assigned to be C-15 since the proton signal for the H-15 was missing in that of **2**. A singlet peak appearing at δ_H 4.30 (2H, s) in the ^1H NMR spectrum of **2** was attributed to H-16 which was free from coupling with the neighboring proton. Compound **2** was regarded as the 15-oxo derivative of **1**. Therefore, **2** was deduced to be *ent*-18-acetoxy-16-hydroxy-8(14)-pimaren-15-one.

Compound **3** possessed the molecular formula $C_{20}H_{32}O_3$ as revealed by negative-ion HRFABMS and analysis of its ^{13}C NMR spectra. The NMR spectral data of **3** were very similar to those of **2** except for the absence of the acetyl data in **3**, which was consistent with its molecular formula comprising twenty carbons. The chemical shift value of H-18 shifted upfield to δ_H 3.36, 3.07 (each 1H) in the ^1H NMR spectrum of **3**, which suggested that **3** was the 18-deacetylated derivative of **2**. Thus **3** was elucidated as *ent*-16,18-dihydroxy-8(14)-pimaren-15-one.

The high resolution negative-ion FABMS spectrum of compound **4** indicated a molecular formula of $C_{19}H_{30}O_4$. Comparison of the ^1H and ^{13}C NMR spectral data of **4** with those of **3** revealed that there were two tertiary methyl groups present in **4** instead of three in **3**. Taking the similar spectral data and molecular formula ($C_{19}H_{30}O_4$) into account, compound **4** was an *ent*-norpimaren-15-one bearing a double bond between C-8 and C-14.

The HMBC spectrum showed correlations from δ_H 3.40 (2H, *d*, 10.8, H-18) to δ_C 73.7 (*s*, C-4), and 35.8 (*t*, C-3), which suggested that the methyl group attached to C-4 (C-19) was lost and replaced by a hydroxyl in **4**. The remainder of the structure was identical to that of **3** based on comparing the ^1H and ^{13}C NMR spectral data of two compounds, and detailed analysis of the HMBC and ROESY spectra of **4**. So compound **4** was determined to be *ent*-19-nor-4,16,18-trihydroxy-8(14)-pimaren-15-one.

Three known damarane triterpenoids, richenoic acid, eichlerianic acid and shoreic acid were identified by direct comparison of their spectral data with authentic samples (Aalbersberg and Singh, 1991).

3. Experimental

3.1. General

Mps: uncorr.; IR: KBr; ^1H, ^{13}C and 2D NMR spectra were recorded on a Brüker AM-400 and a DRX-500 NMR spectrometer with TMS as an internal standard. Chemical shift values were reported in δ (ppm) and coupling constants in Hz; FAB and EIMS data were recorded on a VG Autospec-3000 spectrometer; EIMS: 70 eV

3.2. Plant material

The bark of *D. hainanense* Merr. was collected from Xishuangbanna, Yunnan province, PR China, in December 1996. The plant was identified by Professor Tao, G.-D., Xishuangbanna Botany Garden, Academia Sinica. A voucher specimen (No. 7188) was deposited in the herbarium of Taxonomy Department, Kunming Institute of Botany, Academia Sinica, Kunming, PR China.

3.3. Extraction and isolation

Dried and powdered bark (4.2 kg) of *D. hainanense* was extracted three times with EtOH under reflux conditions, the extracts were combined and solvent was evaporated in vacuo. The resulting residue was suspended in H_2O and partitioned with EtOAc. The EtOAc layer was concentrated in vacuo to give a residue (72 g), which was subjected to column chromatography (silica gel), using $CHCl_3$–Me_2CO (from $CHCl_3$ to $CHCl_3$–Me_2CO 1:1) as eluent. Fractions were combined on the basis of their TLC profiles. Fractions 1–6 were further purified on silica gel CC with petroleum ether-EtOAc (from 5:1 to 1:1) as eluent and finally on reversed-phase C_{18} silica gel CC, eluted with CH_3OH–H_2O (3:1-3:2) to yield **1** (118 mg), **2** (66 mg), **3** (106 mg), **4** (27 mg), and three known damarane triterpenoids, richenoic acid, eichlerianic acid and shoreic acid.

3.4. ent-18-Acetoxy-8(14)-pimarene-15S,16-diol (1)

Viscous oil; $[\alpha]_D^{26}$ −3.5° (*c* 0.50, CH_3OH); EIMS *m/z* (70 eV): 364 $[M]^+$ (1.4), 303 (88), 289 (37), 243 (73), 229 (25), 213 (8), 181 (10), 161 (21), 147 (29), 135 (95), 121 (100), 107 (81), 95 (86), 81 (84), 69 (45); negative-ion HRFABMS *m/z*: 363.2500 $[M\text{-}1]^-$ (calc. for $C_{22}H_{35}O_4$, 363.2535); IR (KBr) ν_{max} cm^{-1}: 3418, 2931, 2870, 1714, 1622, 1469, 1381, 1240, 1036, 947; ^1H NMR ($CDCl_3$, 400 MHz): δ 5.19 (1H, *s*, H-14), 3.83 (1H, *d*, *J* = 10.9 Hz, H-18a), 3.61 (1H, *d*, *J* = 10.9 Hz, H-18b), 3.70 (1H, *brd*, *J* = 10.6 Hz, H-16a), 3.48 (1H, *J* = 11.0, 9.1 Hz, H-16b), 3.40 (1H, *dd*, *J* = 9.1, 2.1 Hz, H-15), 2.03 (3H, *s*, OAc), 0.94 (3H, *s*, H-17), 0.84 (3H, *s*, H-19), 0.77 (3H, *s*, H-20); for ^{13}C NMR spectral data: see Table 1.

3.5. Preparation of ent-18-acetoxyl-pimara-8(14),15-diene (1a)

Compound **1** (22 mg), ethyl orthoformate (100 mg), and benzoic acid (3 mg) were mixed and heated at 90–100°C for 2 h. After concentration in vacuo, benzoic acid (5 mg) was added and the mixture was heated at 175–180°C for 1.5 h. After cooling, CH_2Cl_2 (2 ml) was added, and the solution was washed with saturated Na_2CO_3. The CH_2Cl_2 fraction was concentrated and purified by CC on silica gel with CH_2Cl_2 as eluent to give **1a** (5 mg) (yield 25). Viscous oil; $[\alpha]_D^{23}$ −82.3° (*c* 0.15, $CHCl_3$); EIMS *m/z* (70eV): 330 $[M]^+$ (78), 316 (64), 301 (45), 270 (32), 257 (87), 241 (33), 225 (66), 211 (34), 181 (44), 149 (61), 135 (91), 121 (100), 105 (78), 55 (87); ^1H NMR ($CDCl_3$, 400 MHz): δ 5.75 (1H, *dd*, *J* = 17.6, 10.5 Hz, H-15), 5.20 (1H, *s*, H-14), 4.89 (1H, *dd*, *J* = 17.6, 1.0 Hz, H-16a), 4.86 (*dd*, *J* = 10.5, 2.2 Hz, H-16b), 3.84 (1H, *d*, *J* = 10.9 Hz, H-18a), 3.63 (1H, *d*, *J* = 10.9 Hz, H-18b), 2.04 (3H, *s*, OAc), 1.02 (3H, *s*, H-17), 0.85 (3H, *s*, H-19), 0.81 (3H, *s*, H-20).

Abstract

The methanol extract of the dried aerial parts of *Prangos tschimganica* afforded seven monoterpenoids and four γ-pyrone derivatives. Their structures were established on the basis of chemical and spectroscopic evidence. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Prangos tschimganica*; Umbelliferae; Monoterpenoids; γ-Pyrone derivatives

1. Introduction

Prangos tschimganica, which belongs to the family of the Umbelliferae, is indigenous to Central Asia. This plant has been used in traditional drugs for treatment of leukoplakia in Uzbekistan. Earlier reports described that coumarins and monoterpenes were abundant in the Umbelliferae (Lemmich and Havelund, 1978; Harkar et al., 1984), and previous phytochemical investigations of this plant led to the identification of several coumarins (Kuznetsova and Belenovskaya, 1966; Abyshev, 1980). Recently, coumarin derivatives isolated from the seeds of *Ammi majus* Linn (umbelliferae) have been used in the clinical treatment of various leukoplakic disorders in Japan (Takashima et al., 1988). The precise mechanism of the therapeutic effect of *P. tschimganica*, however, was not completely understood. In order to determine which of the components present in this plant were responsible for such diverse activites, we started work on the isolation of the constituents of *P. tschimganica*. We report here on the isolation and structural elucidation of 20 compounds (**1**–**20**), including seven new monoterpenoids (**1**–**7**) and four γ-pyrone derivatives (**10**–**13**) from the aerial parts of this plant collected in Uzbekistan.

2. Results and discussion

The ethyl acetate and *n*-BuOH soluble parts of the methanol extract of *P. tschimganica* were separated by a combination of silica gel and Toyo pearl column chromatographies as well as by normal and reversed-phase HPLC, to give 20 compounds.

Compound **1** had the molecular formula $C_{16}H_{24}O_6$ as established from its HR FABMS (*m*/*z* 311.1515), and its IR spectrum showed the presence of hydroxy groups (3360 cm^{-1}) and an aromatic ring (1643, 1618 cm^{-1}). The UV spectrum also showed the presence of an aromatic moiety with maxima at 220 nm. The ^1H NMR spectrum of **1** suggested the presence of three methyl groups [δ_H 2.29, 2.26, 2.19 (each 3H, *s*)] connected to an aromatic ring, two AB type aromatic protons [δ_H 7.09, 6.93 (each 1H, *d*, $J = 7.5$ Hz)] and a pair of methylene protons [δ_H 4.93, 4.63 (each 1H, *d*, $J = 11.3$ Hz)] bearing an oxygen function and a sugar moiety (Table 1 and Experimental section). The ^{13}C NMR spectrum of **1** showed 16 carbon signals which could be resolved by DEPT experiment into three methyls, two methines and four quaternary carbons, as well as an additional two methylenes and five methines attached to an oxygen

PII: S0031-9422(00)00407-6

function, respectively (Table 2). Additionally, the hexose was identified as β-glucopyranose from the chemical shifts. From this information, compound **1** was assumed to be a 1, 2, 3, 4-tetrasubstitude benzene derivative. In the HMBC spectrum of **1**, the proton signal at δ_H 4.93 (H-7a) was correlated with the carbon signals at δ_C 134.5 (C-1), 137.3 (C-2) and 128.6 (C-6) (Fig. 2). From this observation, a connection of C-7 the methylene carbon to C-1 was inferred. The proton signals at δ_H 4.93 (H-7a) and 4.63 (H-7b) were correlated with the carbon signal at δ_C 103.3 (C-1 of glc), detected in the HMBC spectrum. Furthermore, an NOESY experiment showed a correlation of H-7 with H-6 and H-8, H-5 with H-10 (Fig. 2). From these observations, the structure of **1** was deduced as 2, 3, 4-trimethylbenzylalcohol-*O*-β-D-glucopyranoside.

The HR FABMS spectrum of **2** showed a peak due to $[M+H]^+$ at *m/z* 329.1608, which agreed with the molecular formula of **2** as $C_{16}H_{25}O_7$. The UV and IR spectra of **2** indicated the existence of a conjugated carbonyl carbon (240 nm and 1731 cm^{-1}). The ^1H NMR spectrum of **2** revealed the presence of three methyls [δ_H

[a] Signal assignments were based on HSQC and DEPT experiments.
[b] Measured in CD_3OD.
[c] Measured in $CDCl_3$.

1.89, 1.29, 1.28 (each 3H, *s*)], two methines [δ_H 6.75, 6.54 (each 1H, *s*)], a methylene [δ_H 4.72, 4.44 (each 1H, *d*, $J=15.9$ Hz)] bearing an oxygen function and sugar moiety. The ^{13}C NMR spectrum of **2** showed conjugated diene carbonyl carbon signals at δ_C 189.6 (C-4), 166.8 (C-2), 156.7 (C-6), 133.6 (C-5) and 121.6 (C-3), in addition to three methyls, a quaternary carbon, as well as an additional methylene attached to an oxygen atom and β-glucose carbons (Table 2). From the above results, **2** was assumed to be monoterpene glucoside from the carbon number and the presence of three methyl groups. The ^1H NMR spectral data (Table 1) of **2** was similar to that of compound **3** (Bohlmann and Zdero, 1969), except for the presence of an additional β-glucopyranosyl moiety. This linkage of methylene (C-7) and anomeric carbon (C-1 of glc) was established by HMBC spectrum, in which a cross peak between the signal at δ_H 4.38 (1H, *d*, $J=7.7$ Hz, H-1 of glc) and the carbon signal at δ_C 67.7 (C-7) was observed. Therefore, **2** was determined to be 1,1,5-trimethyl-2-hydroxymethyl-(2,5)-cyclohexadien-(4)-one-*O*-β-D-glucopyranoside. The aglycone of **3** was synthesized from the 1,1,5-trimethyl-2-hydroxymethyl-(2,5)-cyclohexadiene-(4)-one by treatment with sodium borohydride (Bohlmann and Zdero, 1969). This is the first time that **3** has been isolated from a natural source.

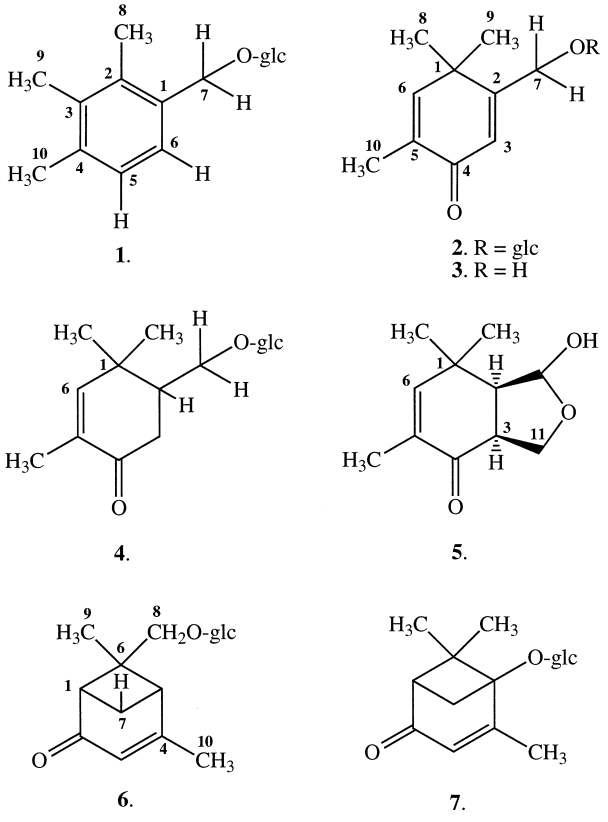

Fig. 1. Structures of compounds isolated from *P. tschimganica*.

Compound **4**, $C_{16}H_{26}O_7$, showed the presence of hydroxyl and ketone groups (3393 and 1732 cm^{-1}) in the IR spectrum and the conjugated ketone group (235 nm) in the UV spectrum. The ^1H NMR spectrum revealed the presence of three methyls [δ_H 1.71, 1.22, 1.04 (each 3H, *s*)], a pair of methylene [δ_H 2.69, 2.41 (each 1H, *dd*, $J=4.4$, 16.0 and 12.5, 16.0 Hz)], a methine [δ_H 6.46 (1H, *s*)] attached to a double bond, a methine [δ_H 2.21 (1H, *m*)] and a pair of methylene [δ_H 4.15, 3.42 (each 1H, *dd* and *t*, $J=4.1$, 9.6 and 9.6 Hz)] groups bearing an oxygen function. The ^{13}C NMR spectrum of **4** was similar to that of **2** expect for the signal at δ_C 203.7 (C-4), 45.6 (C-2) and 38.9 (C-3) (Table 2). From the $^1H^1H$ COSY experiment, the presence of a partial structure [$-CH_2(3)-CH(2)-CH_2(7)-$] was suggested. In the HMBC spectrum of **4**, correlations of δ_H 1.22 (H_3-9) and 1.04 (H_3-8) with δ_C 45.6 (C-2) and 158.6 (C-6); δ_H 2.21 (H-2) with δ_C 203.7 (C-4); δ_H 1.71 (H_3-10) with δ_C 158.6 (C-6) and 203.7 (C-4); δ_H 4.24 (H-1 of glc) with δ_C 72.0 (C-7) were detected. From these observations, the structure of **4** was deduced to be a 2,3 dihydro derivative of **2**. The relative stereochemistry of **4** was determined from the NOESY spectrum. The proton signal at δ_H 2.21 (Hb-2) was correlated with the proton signal at δ_H 1.22 (H_3-9), whereas that the proton signal at δ_H 2.41 (Ha-3) was correlated with the proton signal at δ_H 1.04 (H_3-8). From these correlations, the hydroxymethyl group could be assignment to be equatorial. The coupling constants ($J=4.4$ and 16.0 Hz) of the

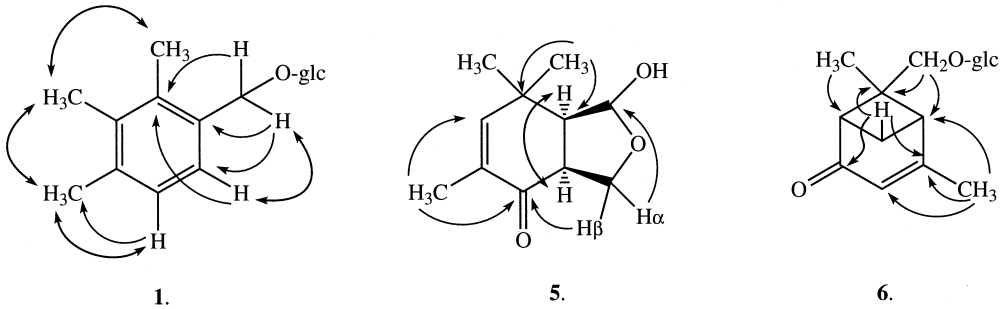

Fig. 2. Long range ^1H, ^{13}C NMR correlations and NOE calculations observed by HMBC, NOESY for **1**, **5** and **6**. ^1H, ^{13}C long correlation →; NOESY correlation ↔.

proton signal at δ_H 2.69 (Hb-3) also supported the above conclusion. Therefore, the structure of **4** was elucidated to be 1,1,5-trimethyl-2-hydroxymethyl-5-cyclohexene-4-one-7-*O*-β-D-glucopyranoside.

Compound **5**, showed the presence of an hydroxyl (3464 cm^{-1}) functionality in the IR spectrum and an α, β-unsaturated carbonyl carbon in the UV spectrum (234 nm). The EI mass spectrum gave a peak at *m/z* 196.1086 ($C_{11}H_{16}O_3$), suggesting that the degree of unsaturation in **5** was 4. The ^1H NMR spectrum of **5** displayed the presence of three methyl protons [δ_H 1.77, 1.26 and 1.25 (each 3H, *s*)], a pair of methylene protons [δ_H 4.37 and 4.11 (each 1H, *d*, $J=8.3$ and *dd*, $J=5.0$, 8.3 Hz)] bearing an oxygen function, two methine proton [δ_H 2.99 and 2.39, each 1H, *t*, $J=5.0$ and 4.7 Hz)], a methine proton (δ_H 5.32 1H, *d*, $J=4.7$ Hz) attached to the oxygen function, and one aromatic proton (δ_H 6.49, 1H, *s*) (Table 1). The ^{13}C NMR spectrum of **5** revealed that the 11 carbon signals included three methyl, three methine and three quaternary carbons, as well as an additional methine carbon (δ_C 100.5) and a methylene carbon (δ_C 71.4) connected to the oxygen function, respectively. From the ^1H ^1H COSY spectrum of **5**, the presence of partial structure [−CH(O−)−CH−CH−CH_2(O−)] was deduced. On the basis of correlations of the HMBC spectrum of **5**, the proton signals at δ_H 4.37 (H-11) was correlated with the carbon signal at δ_C 100.5 (C-7); δ_H 1.25 (H_3-8) with δ_C 57.4 (C-2); δ_H 2.99 (H-3) and 4.11 (Hb-11) with δ_C 198.5 (C-4); δ_H 1.77 (H_3-10) with δ_C 198.5 (C-4). These facts clearly indicated that **5** had the same basic skeleton as **4**. The correlation of δ_H 2.39 (H-2) with 2.99 (H-3) (Fig. 2) in the NOESY spectrum confirmed that the relative configuration of C-2 and C-3 was in a *cis* orientation. Hence, the structure of tschimganical A (**5**) was determined as shown (Fig. 1).

The molecular formula of **6** was determined to be $C_{16}H_{24}O_7$ on the basis of the FABMS and ^{13}C NMR spectral data (Table 2). Its IR spectrum showed absorption bands due to hydroxyl (3422 cm^{-1}) groups, and the UV spectrum suggested the presence of an α, β-unsaturated carbonyl carbon with a maxima at 252 nm. The ^1H NMR spectrum of **6** (Table 1) exhibited two tertiary methyl groups, two methine and methylene groups, as well as a methine attached to a double bond and a methylene bearing oxygen functionality, signals due to a sugar moiety was also noted. From the $^1H^1H$ COSY spectrum, the partial structure [−CH(1)−CH_2(C-7)−CH(C-5)−] was deduced. The structure of **6** was assumed to be a verbenone type tricyclic monoterpene, which was supported by HMBC correlations between; the proton signal at δ_H 2.92 (H-7b) with the quaternary carbon δ_C 174.0 (C-4), the carbonyl carbon δ_C 206.3 (C-2) and the carbon δ_C 58.4 (C-6); the proton signal at δ_H 4.29 (H-8a) with the carbon signals at δ_C 58.4 (C-6), 55.2 (C-1) and 47.5 (C-5); the proton signal at δ_H 2.09 (H_3-10) with δ_C 122.2 (C-3) and 47.5 (C-5) (Fig. 2). The location of the β-D-glucopyranose was also determined as follows; the proton signal at δ_H 4.29 (H-8a) was correlated with δ_C 104.4 (C-1 of glc). Thus, the structure of **6** was assigned as shown (Fig. 1).

The HR FABMS of **7** gave same molecular formula of $C_{16}H_{24}O_7$ as that of **6**. Its ^1H and ^{13}C NMR spectral data were very similar to that for **6**, except for the presence of two methyls and a methylene and a methine in **6** and three methyls and one quaternary carbon in **7**. Its 2D NMR spectra suggested that both compounds **6** and **7** have same skeleton, except for the connecting position of the glucose moiety. In the HMBC spectrum of **7**, the correlation of δ_H 4.56 (H-1 of glc) with δ_C 84.6 (C-5), suggested the structure of **7** as shown (Fig. 1).

Compound **10** exhibited a quasi-molecular ion peak at *m/z* 463 in the negative FAB MS giving the molecular formula as $C_{22}H_{24}O_{11}$ in combination with ^{13}C NMR spectral analysis. The UV and IR spectra of **10** indicated the presence of hydroxyl groups (3382 cm^{-1}) and a conjugated double bond (326 and 246 nm). The ^1H and ^{13}C NMR spectral data of **10** were very similar to that of **9** except for the presence of signals assignable to the feruloyl moiety. In the HMBC spectrum of **10**, the correlations of δ_H 4.81 (H-1 of glc) and 4.43 (H_2-6 of glc) with δ_C 143.4 (C-3) and 168.9 (C-1 of feruloyl) (Table 3). From these results, the connectivities of the glucose and feruloyl groups were determined as shown

Table 3
^{13}C NMR spectral data for compounds **8**–**12** amd **13**

[a] Measured in CD_3OD.
[b] Measured in $CDCl_3$.
[c] Additional signals: 168.9 (C-1′), 115.3 (C-2′), 147.1 (C-3′), 127.1 (C-4′), 111.8 (C-5′), 149.5 (C-6′), 150.8 (C-7′), 116.6 (C-8′), 124.6 (C-9′), 56.9 (OCH_3).
[d] Additional signals: 168.2 (C-1′), 116.5 (C-2′), 146.1 (C-3′), 128.4 (C-4′), 116.1 (C-5′), 148.7 (C-6′), 150.6 (C-7′), 117.6 (C-8′), 127.4 (C-9′), 56.8 (OCH_3).
[e] Additional signals: 174.8 (C-1′), 44.6 (C-2′), 27.3 (C-3′), 23.1 (C-4′ and C-5′).
[f] Additional signals: 168.9 (C-1′), 115.3 (C-2′), 147.2 (C-3′), 128.2 (C-4′), 116.6 (C-5′), 146.9 (C-6′), 149.7 (C-7′), 114.9 (C-8′), 123.6 (C-9′).

(Fig. 3). Hence, **10** was determined to be 3-hydroxyl-2-methyl-4-*H*-pyran-4-one-3-*O*-(6-)-β-D-glucopyranoside.

The NMR spectral data of **11** were similar to those of **10**, and its HR FABMS gave the same molecular formula of $C_{22}H_{24}O_{11}$ as that of **10**. In the ^{1}H NMR spectral data for **11** and **10**, the evident differences between them were the signals due to the double bond [**11**: δ_H 6.85 and 5.76 (each 1H, *d*, $J=12.9$ Hz), **10**: δ_H 7.56 and 6.30 (each 1H, *d*, $J=15.0$ Hz)] of the feruloyl group. From the coupling constant of the double bond protons, its geometry of **11** was determined to be *cis*. That evidence was supported by the NOESY spectrum, in which a cross-peak between δ_H 6.85 and 5.76 was observed. From these results, the structure of **11** was determined to be 3-hydroxyl-2-methyl-4-*H*-pyran-4-one-3-*O*-(6-*O*-*cis*-feruloyl)-β-D-glucopyranoside (Fig. 3).

The ^{1}H and ^{13}C NMR spectral data of **12** and **13** were very similar to those of **9** except for the appearance of the signals due to the isovaleryl and caffeoyl moieties, respectively, suggesting that **12** and **13** have the same γ-pyrone glucoside moiety. The positions of both functions were established by correlations of the HMBC spectrum between the carbonyl carbon and proton signal of H_2-6 in the glucose moiety. Thus, **12** and **13** were shown to be 3-hydroxyl-2-methyl-4-*H*-pyran-4-one-3-*O*-(6-*O*-isovaleryl)-β-D-glucopyranoside and 3-hydroxyl-2-methyl-4-*H*-pyran-4-one-3-*O*-(6-*O*-caffeoyl)-β-D-glucopyranoside respectively (Fig. 3).

The following known compounds were identified by comparison with the literature data: 1,1,5-trimethyl-2-formyl-4-methoxyl-(2,5)-cyclohexadiene (**14**) and 1,1,5-trimethyl-2-formyl-6-methoxyl-(2,4)-cyclohexadiene (**15**) (Lemmich and Pedersen, 1971), (+)-spathulenol (**16**) and globulol (**17**) (Bohlmann and Robinson, 1983a,b), 1β, 6α-dihydroxyeudesm-4(15)-ene (**18**) (Bohlmann and Robinson, 1983a,b), (−)-caryophyllene β-oxide (**19**) (Fukuyama and Kodama, 1992), maltol (**8**) and maltol-β-D-glucopyranoside (**9**) (Tanaka et al., 1986), xanthotoxin (**20**) (Grande et al., 1986). The trade name of xanthotoxin was called methoxalen, which has been used in clinical treatment of various leukoplakic diseases in Japan (Takashima et al., 1988).

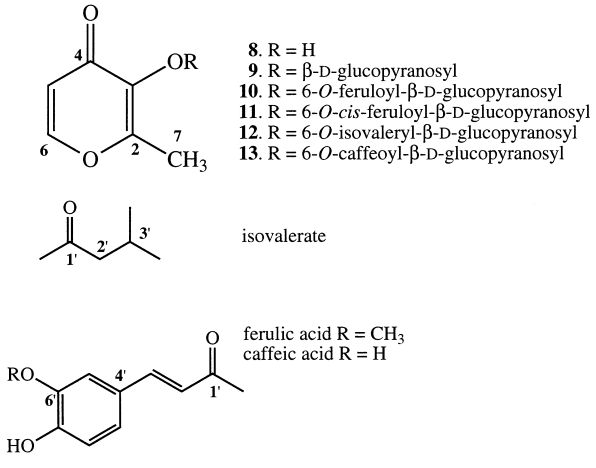

Fig. 3. Structures of compounds isolated from *P. tschimganica*.

3. Experimental

3.1. General

^{1}H NMR: 400 MHz with TMS as int. stand; ^{13}C NMR: 100 MHz; CC: silica gel 60 (Merck), Sephadex LH-20 (Pharmacia) and Toyo pearl HW-40 (TOSOH); HPLC: GPC H-2002 (SHODEX), ODS: D-ODS-5 (YMC).

3.2. Plant material

The aerial parts of *Prangos tschimganica* were collected in June 1998 from Uzbekistan. Herbarium specimens were deposited in the herbarium of Institute of Botany, Academy of Sciences, Uzbekistan. This plant was identified by Dr. Olimjon K. Kodzhimatov.

3.3. Extraction and fractionation

The MeOH extracts (357 g) of the dried aerial parts of *P. tschimganica* (1.9 kg) were partitioned between EtOAc and H_2O. The EtOAc layer was concentrated to give a residue (80 g), which was subjected to silica gel column chromatography, this being eluted with solvents of increasing polarity (*n*-hexane-AcOEt) to give 21 frs (frs 1–21). Fr. 12 (1.2 g) was applied to a Toyo pearl column, eluted with $CHCl_3$–MeOH (2:1) to give 7 frs (12.1–12.7). Fr. 12. 4 (345 mg) was purified by GPC (MeOH) to give compound **5** (1 mg). Fr. 15 (3.2 g) was subjected to on Toyo pearl chromatography, with $CHCl_3$–MeOH (2:1) as eluted to give 7 frs (15.1–15.7). Fr. 15. 4 (824 mg) was separated by using GPC ($CHCl_3$) to yield compound **3** (48 mg). Fr. 20 (8.8 g) was applied to a silica gel column, this being eluted with $CHCl_3$–MeOH (9:1 to 7:3), to give 10 frs (fr. 20.1–20.10). Then, fr. 20. 6 was isolated by HPLC (ODS, MeOH–H_2O, 9:1), giving compound **12** (3 mg). The water layer was partittioned between *n*-BuOH and H_2O to give the *n*-BuOH soluble part (44 g). The *n*-BuOH layer was applied to a silica gel column, eluted with $CHCl_3$–MeOH (8:2 to 1:1). Twelve fractions were obtained. Fr. 2 (2.2 g) was subjected to silica gel column chromatography and eluted with $CHCl_3$–MeOH (9:1), to give 7 frs (fr. 2.1–2.7). Fr. 2.4 and 2.5 were purified by GPC (MeOH), and gave compounds **1** (18 mg), and a mixture (74 mg) of compounds **10** and **11**; this mixture was again purified by HPLC (ODS, MeOH–H_2O, 8:2), and gave pure compounds **10** (63 mg) and **11** (10 mg). Fr. 3 (3.8 g) was subjected to silica gel column chromatography, and eluted with $CHCl_3$–MeOH (8:2), to afford 4

fractions (3.1–3.4). The mixture of fr. 3.3 and fr. 3.4 was separated by GPC (MeOH), and gave a further 10 frs (fr. 3.3.1–3.3.10), compounds **2** (54 mg), **4** (7 mg), **6** (6 mg) and **7** (6 mg) were obtained after the purification of fr. 3.3.3 (226 mg) using HPLC (ODS, MeOH–H_2O, 4:6). Fr. 4 (3.4 g) was applied to a Toyo pearl column, eluted with $CHCl_3$–MeOH (2:1), to gave 4 frs (fr. 4.1–4.4). The mixture of fr. 4.2 and 4.3 was subjected to silica gel column chromatography and eluted with $CHCl_3$–MeOH (8:2), to give 6 frs (fr. 4.2.1–4.2.6).compound **13** (15 mg) was obtained after the purification of fr. 4.2.1 using GPC (MeOH).

*3.3.1. 2,3,4-Trimethylbenzyl alcohol-O-β-D-glucopyrano-side (**1**)*

White amorphous powder, $[\alpha]_D^{25}$ −35.6 (*c* 1.1, MeOH); IR ν_{max}^{KBr} cm^{-1}: 3360, 2951, 1643, 1618, 1476, 1089, 1063; UV λ_{max}^{MeOH} nm (log ε): 220 (4.2); HR FABMS: *m/z* 311.1515 $[M\text{-}H]^-$, calcd. for $C_{16}H_{23}O_6$, 311.1495; ^1H NMR spectral data (CD_3OD) δ: 4.30 (1H, *d, J* = 7.7 Hz, H-1 of glc), 3.90 (1H, *dd, J* = 1.9, 11.9 Hz, H-6 of glc), 3.68 (1H, *dd, J* = 5.6, 11.9 Hz, H-6 of glc), 3.40–3.30 (3H, *m*, H-3∼5 of glc), 3.25 (1H, *t, J* = 7.7 Hz, H-2 of glc); ^{13}C NMR spectral data: Table 2.

*3.3.2. 1,1,5-Trimethyl-2-hydroxymethyl-(2,5)-cyclohexadien-(4)-one-O-β-D-glucopyranoside (**2**)*

Clear oil, $[\alpha]_D^{25}$ −45.6 (*c* 1.0, MeOH); IR ν_{max}^{KBr} cm^{-1}: 3387, 1731, 1668, 1624, 1450, 1373, 1165, 1077; UV λ_{max}^{MeOH} nm (log ε): 240 (4.3); HR FABMS: *m/z* 329.1608 $[M+H]^+$, calcd. for $C_{16}H_{25}O_7$, 329.1600; ^1H NMR spectral data (CD_3OD) δ: 4.38 (1H, *d, J* = 7.7 Hz), 3.89 (1H, *d, J* = 11.8 Hz, H-6 of glc), 3.68 (1H, *br d, J* = 11.8 Hz, H-6 of glc), 3.35–3.27 (4H, *m*, H-2∼5 of glc); ^{13}C NMR spectral data: Table 2.

*3.3.3. 1,1,5-Trimethyl-2-hydroxymethyl-(2,5)-cyclohexadien-(4)-one (**3**)*

Pale yellow oil, IR ν_{max}^{KBr} cm^{-1}: 3416, 1730, 1669, 1625, 1452, 1373, 1100; UV λ_{max}^{MeOH} nm (log ε): 234 (4.2); EI MS: *m*/z 166.0968 $[M]^+$, calcd. for $C_{10}H_{14}O_2$, 166.0994; ^1H NMR spectral data ($CDCl_3$) δ: 6.52 (1H, *s*, H-6), 6.45 (1H, *s*, H-3), 4.40 (2H, *s*, H-7), 1.87 (3H, *s*, H-10), 1.24 (6H, *s*, H-8 and H-9); ^{13}C NMR spectral data: Table 2.

*3.3.4. 1,1,5-Trimethyl-2-hydroxymethyl-(5)-cyclohexene-(4)-one-O-β-D-glucopyranoside (**4**)*

Clear oil, $[\alpha]_D^{25}$ −24.6 (*c* 0.7, MeOH); IR ν_{max}^{KBr} cm^{-1}: 3393, 1732, 1668, 1450, 1368, 1163, 1078; UV λ_{max}^{MeOH} nm (log ε): 235 (4.2); HR FABMS: *m/z* 353.1544 $[M+Na]^+$, calcd. for $C_{16}H_{26}O_7Na$, 353.1576; ^1H NMR spectral data (CD_3OD) δ: 6.46 (1H, *s*, H-6), 4.24 (1H, *d, J* = 7.8 Hz, H-1 of glc), 4.15 (1H, *dd, J* = 4.1, 9.6 Hz, H-7), 3.87 (1H, *d, J* = 10.7 Hz, H-6 of glc), 3.67 (1H, *dd, J* = 4.8, 10.7 Hz), 3.42 (1H, *t, J* = 9.6 Hz, H-7), 3.37–3.26 (3H, *m*, H-3, 4 and 5 of glc), 3.18 (1H, *t, J* = 7.8 Hz, H-2 of glc), 2.69 (1H, *dd, J* = 4.4, 16.0 Hz, H-3), 2.41 (1H, *dd, J* = 12.5, 16.0 Hz, H-3), 2.21 (1H, *m*, H-2), 1.71 (3H, *s*, H-10), 1.22 (3H, *s*, H_3-9), 1.04 (3H, *s*, H_3-8); ^{13}C NMR spectral data: Table 2.

*3.3.5. Tschimganical A (**5**)*

Clear oil, $[\alpha]_D^{25}$ +4.0 (*c* 0.1, $CHCl_3$); IR ν_{max}^{KBr} cm^{-1}: 3464, 1667, 1601, 1521, 1473, 1213, 1016; UV λ_{max}^{MeOH} nm (log ε): 234 (4.3); EI MS: *m/z* 196.1086 $[M]^+$, calcd. for $C_{11}H_{16}O_3$, 196.1099; ^1H and ^{13}C NMR spectral data: Tables 1 and 2.

*3.3.6. Vervenone-8-O-β-D-glucopyranoside (**6**)*

Clear oil, $[\alpha]_D^{25}$ +3.5 (*c* 0.6, MeOH); IR ν_{max}^{KBr} cm^{-1}: 3422, 1673, 1653,1077; UV λ_{max}^{MeOH} nm (log ε): 252 (4.2). HR FABMS: *m/z* 351.1435 $[M+Na]^+$, calcd. for $C_{16}H_{24}O_7Na$, 351.1420; ^1H NMR spectral data (CD_3OD) δ: 4.33 (1H, *d, J* = 7.7 Hz, H-1 of glc), 3.85 (1H, *d, J* = 11.5 Hz, H-6 of glc), 3.68 (1H, *dd, J* = 3.7, 11.5 Hz, H-6 of glc), 3.35–3.27 (3H, *m*, H-3, 4 and 5 of glc), 3.21 (1H, *t, J* = 7.6 Hz, H-2 of glc); ^{13}C NMR spectral data: Table 2.

3.3.7. Vervenone-5-O-β-D-glucopyranoside (7)

Clear oil, $[\alpha]_D^{25}$ +1.8 (*c* 0.5, MeOH); IR ν_{max}^{KBr} cm^{-1}: 3421, 1670, 1650,1078; UV λ_{max}^{MeOH} nm (log ε): 253 (4.2); HR FABMS: *m/z* 351.1426 $[M+Na]^+$, calcd. for $C_{16}H_{24}O_7Na$, 351.1420; ^1H NMR (CD_3OD) δ: 5.67 (1H, *s*, H-3), 4.56 (1H, *d, J* = 7.5 Hz, H-1 of glc), 3.85 (1H, *d, J* = 11.9 Hz, H-6 of glc), 3.68 (1H, *dd, J* = 5.3, 11.9 Hz, H-6 of glc), 3.35–3.27 (3H, *m*, H-3, 4 and 5 of glc), 3.21 (1H, *t, J* = 7.6 Hz, H-2 of glc), 3.16 (1H, *dd, J* = 2.3, 9.3 Hz, H-7), 2.55 (1H, *dd, J* = 2.3, 6.8 Hz, H-1), 2.47 (1H, *d, J* = 9.3 Hz, H-7), 2.06 (3H, *s*, H_3-10), 1.46 (3H, *s*, H_3-8), 1.04 (3H, *s*, H_3-9). ^{13}C NMR: Table 2.

*3.3.8. 3-Hydroxyl-2-methyl-4-H-pyran-4-one-3-O-(6-O-feruloyl)-β-D-glucopyranoside (**10**)*

Pale yellow oil, $[\alpha]_D^{25}$−75.0 (*c* 1.2, MeOH); IR ν_{max}^{KBr} cm^{-1}: 3382, 1706, 1644, 1515, 1430, 1255, 1176, 1065; UV λ_{max}^{MeOH} nm (log ε): 326 (4.6), 300 (4.5), 246 (4.6); HR FABMS: *m/z* 463.1238 $[M\text{-}H]^-$, calcd. for $C_{22}H_{23}O_{11}$, 463.1240; ^1H NMR spectral data (CD_3OD) δ: 7.81 (1H, *d, J* = 4.9 Hz, H-6), 7.56 (1H, *d, J* = 15.0 Hz, H-3′), 7.15 (1H, *br s*, H-5′), 7.03 (1H, *d, J* = 7.2 Hz, H-9′), 6.80 (1H, *d, J* = 7.2 Hz, H-8′), 6.35 (1H, *d, J* = 4.9 Hz, H-5), 6.30 (1H, *d, J* = 15.0 Hz, H-2′), 4.81 (1H, *d, J* = 7.6 Hz, H-1 of glc), 4.43 (2H, *m*, H_2-6 of glc), 3.89 (3H, *s*, OCH_3), 3.49–3.38 (4H, *m*, H2∼5 of glc), 2.34 (3H, *s*, H_3-7); ^{13}C NMR spectral data: Table 3.

*3.3.9. 3-Hydroxyl-2-methyl-4-H-pyran-4-one-3-O-(6-O-cis-feruloyl)-β-D-glucopyranoside (**11**)*

Pale yellow oil, $[\alpha]_D^{25}$ −62.0 (*c* 0.7, MeOH); IR ν_{max}^{KBr} cm^{-1}: 3406, 1723, 1644, 1515, 1431, 1254, 1196, 1068;

UV λ_{max}^{MeOH} nm (log ε): 326 (4.6), 299 (4.5), 247 (4.6); HR FABMS: *m/z* 463.1243 [M-H]$^-$, calcd. for $C_{22}H_{23}O_{11}$, 463.1240; ^{1}H NMR spectral data (CD_3OD) δ: 7.92 (1H, *d, J* = 5.5 Hz, H-6), 6.89 (1H, *br s*, H-5′), 7.13 (1H, *d, J* = 7.9 Hz, H-9′), 6.85 (1H, *d, J* = 12.9 Hz, H-3′), 6.82 (1H, *d, J* = 7.9 Hz, H-5′), 6.76 (1H, *d, J* = 7.9 Hz, H-8′), 6.41 (1H, *d, J* = 5.5 Hz, H-5), 5.76 (1H, *d, J* = 12.9 Hz, H-2′), 4.80 (1H, *d, J* = 7.6 Hz, H-1 of glc), 4.48 (1H, *d, J* = 10 Hz, H_2-6 of glc), 4.36 (1H, *dd, J* = 6.0 and 10.0 Hz, H_2-6 of glc), 3.89 (3H, *s*, OCH_3), 3.45–3.35 (4H, *m*, H2∼5 of glc), 2.34 (3H, *s*, H_3-7); ^{13}C NMR spectral data: Table 3.

*3.3.10. 3-Hydroxyl-2-methyl-4-H-pyran-4-one-3-O-(6-O-isovaleryl)-β-D-glucopyranoside (**12**)*

Clear oil, $[\alpha]_D^{25}$ −19.2 (*c* 0.5, MeOH); IR ν_{max}^{KBr} cm^{-1}: 3397, 1733, 1648, 1436, 1254, 1195, 1067; UV λ_{max}^{MeOH} nm (log ε): 256 (4.7); HR FABMS: *m/z* 395.1342 [M + Na]$^+$, calcd. for $C_{17}H_{24}O_7Na$, 395.1318; ^{1}H NMR spectral data (CD_3OD) δ: 8.00 (1H, *d, J* = 5.6 Hz, H-6), 6.43 (1H, *d, J* = 5.6 Hz, H-5), 4.85 (1H, *d, J* = 7.7 Hz, H-1 of glc), 4.42 (1H, *d, J* = 12.0 Hz, H_2-6 of glc), 4.17 (1H, *dd, J* = 6.1, 12.0 Hz, H_2-6 of glc), 3.30–3.22 (4H, *m*, H-2∼5 of glc), 2.38 (3H, *s*, H_3-7), 2.16 (2H, *d*, *J* = 7.5 Hz, H-2′), 2.04 (1H, *m*, H-3′), 0.93 (6H, *d*, *J* = 7.3 Hz, H_3-4′ and -5′); ^{13}C NMR spectral data: Table 3.

*3.3.11. 3-Hydroxyl-2-methyl-4-H-pyran-4-one-3-O-(6-O-caffeoyl)-β-D-glucopyranoside (**13**)*

Pale yellow oil, $[\alpha]_D^{25}$−57.0 (*c* 1.0, MeOH); IR ν_{max}^{KBr} cm^{-1}: 3266, 1723, 1644, 1515, 1455, 1254, 1196, 1066; UV λ_{max}^{MeOH} nm (log ε): 329 (4.6), 301 (4.5), 250 (4.6); HR FABMS: *m/z* 449.1075 [M-H]$^-$, calcd. for $C_{21}H_{21}O_{11}$, 449.1084; ^{1}H NMR spectral data (CD_3OD) δ: 7.91 (1H, *d, J* = 4.9 Hz, H-6), 7.49 (1H, *d, J* = 15.8 Hz, H-3′), 7.08 (1H, *s*, H-5′), 6.92 (1H, *d, J* = 7.3 Hz, H-8′), 6.79 (1H, *d, J* = 7.3 Hz, H-9′), 6.37 (1H, *d, J* = 4.9 Hz, H-5), 6.21 (1H, *d, J* = 15.8 Hz, H-2′), 4.81 (1H, *d, J* = 7.6 Hz, H-1 of glc), 4.43 (2H, *m*, H_2-6 of glc), 3.49–3.38 (4H, *m*, H2∼5 of glc), 2.34 (3H, *s*, H_3-7); ^{13}C NMR spectral data: Table 3.

Book reviews

Root Methods: A Handbook
Edited By A. L. Smit, A. G. Bengough, C. Engels, M. van Noordwijk, S. Pellerin and S. C. van de Geijn, Springer Press, Berlin Heidelberg, 2000, 587 pp. 108 figs., DM 198. ISBN 3-540-66728-8

Roots play a vital role in plant architecture as well as in water and nutrient supply for plant growth. Yet our understanding on root physiology and biochemistry is still poor. This is primarily due to methodological reasons. Work on roots is tedious and time-consuming and there is a need for new methods. The most recent developments in root research has particularly been supported by new developments in computing hardware and software. Thus it seems timely to publish a modern handbook on root methods such as the present one. *Root Methods* is a comprehensive review on modern and revised older methods for plant root research, describing methods used in the field and in the laboratory. The book covers various interactions of plant roots with soil emphasizing root dynamics and distribution. Besides methods of root observations, a survey of the application of isotope techniques in root physiology is given.

In the preface of the book A. L. Smit emphasizes that "not only sophisticated methods (image analysis, CT scans etc.) are described, but also time-saving quick and (hopefully not too) dirty tricks to quantify root growth and root distribution in the soil profile". The following chapters of the book were written by leading experts on the respective subjects. The first chapter on "Root Characteristics: Why and What to Measure", written by D. Atkinson, explains the importance of roots in ecology and crop production. The questions are asked "Why do particular plant species grow in the places they do?" "What root parameters need to be measured?" and "What is the functional, physiological, or ecological significance of a particular morphological assessment?" This introductory chapter provides a background to the later chapters discussing methods of the different aspects of root research. These chapters are on "Anatomy and Histology of Roots and Root-Soil Boundary" (E. de Neergarrd et al.), "Control and Measurement of the Physical Environment" (W.R. Whalley et al.), "Modelling Root System Growth and Architecture" (L. Pagès et al.), "Sampling Strategies, Scaling and Statistics" (A.G. Bengough et al.), "Auger Sampling, Ingrowth Cores and Pinboard Methods" (M. do Rosário G. Oliveira et al.), "Trench Profile Techniques and Core Break Methods" (M. van Noordwijk et al.), "Root Observations and Measurements at (Transparent) Interfaces with Soil" (A.L. Smit et al.), "The Measurement and Analysis of Fine Root Longevity" (J.E. Hooker et al.), "Root Image Analysis and Interpretation" (R. Richner et al.), "Computer-Assisted Tomography" (S. Asseng et al.), "Isotope Techniques" (I.J. Bingham et al.), "Assessing the Ability of Roots for Nutrient Acquisition" (Ch. Engels et al.), "Water Uptake" (J.E. Fernández et al.), "Modelling Water and Nutrient Uptake" (P. de Willigen et al.) and finally a chapter entitled "Plant Anchorage" (A.R. Ennos and S. Pellerin). The book ends with a list of suppliers (companies, addresses, items) and a extensive subject index.

Root Methods gives a broad overview of available methods of root-specific research, emphasizing root interactions with their physicochemical environment and it is indeed a Handbook for direct use in laboratories and in the field. The reader will miss, however, comprehensive coverage of methods of studying biotic (pathogenic and symbiotic) interactions, especially associations that occur between roots and soil microorganisms. Some short paragraphs on mycorrhizas are insufficient for readers interested in mutualistic root-fungus interactions. Nevertheless the book should be available in libraries of institutes and universities. It can be recommended to any scientist interested in plant metabolism, physiologists and biochemists as well as agricultural engineers. It should also attract graduate students in plant biology and will be of great help for those starting their scientific work in root metabolism.

ChemOffice Ultra 2000
CambridgeSoft, c/o CHEM Research GmbH, Frankfurt, DM 3,290

ChemOffice is the most popular chemical software package containing three applications: *ChemDraw Ultra* (chemical structure drawing), *Chem3D Ultra* (molecular modeling and analysis) and *ChemFinder Ultra* (searching and information integration). The program has been sold and installed more than 100,000 times. Each of the *ChemOffice* applications can be used as a single program, however, an automatic data exchange is possible.

ChemDraw is a well-known standard program for drawing chemical structures. It creates high quality chemical publishing materials and has also become the preferred drawing tool for chemical information querying. It is probably the most powerful chemical software on the market. After a long development over many years, this software is now easy to learn and comfortable in daily use. Chemists can search by structure and substructure, using automatic reaction mapping and specifying atom and bond properties. Using structure cleanup and chemical intelligence gives accurate drawings, chemically correct structures and reaction diagrams from rough drawings where bond angles and length might be wrong. (Some problems, however, can arise by correcting complex structures.)

ChemDraw Ultra adds *ChemNMR* that predicts ^{13}C and ^{1}H NMR shifts and displays their line spectra from *ChemDraw* structures. The line spectra are inserted as graphical objects which are moveable within the *ChemDraw* document. And *Name = Struct* generates a *ChemDraw* structure by typing in systematic chemical names — and vice versa — for most substances. It also allows to automatically insert the name of a structure. Beilstein's AutoNom 2.1 program is included to generate IUPAC-standard names from *ChemDraw* structures.

The *Chem3D Ultra* software converts *ChemDraw* structures into 3D models. It uses molecular mechanics to find low energy conformations to visualize molecular surface properties and calculate partial charges. Besides small molecules, there are basic functions to depict also proteins and other macromolecular structures. The *MOPAC Pro* component adds advanced functionality such as computing properties and advanced energy minimizations.

The third software, *Chemfinder Ultra*, is a chemically intelligent database search engine, giving access to chemical information for tens of thousand of compounds using the *ChemDraw Plugin*. You are able to create structure query to search on-line databases. You can search by names, CAS numbers, formulas, molecular weights or boiling and melting points. The program enables you to integrate *ChemDraw* documents in the Web or to visualize 3D molecules in the Web.

I can strongly recommend *ChemOffice Ultra 2000* to researchers and students giving them an invaluable tool to solve their problems in the field of chemistry. The program is easy to use and reliable. (The handbooks are also useful!)

Editorial comment

Phytochemistry in the genomics and post-genomics eras☆,[1]

In this guest editorial we interview Dr Richard A Dixon, President of the Phytochemical Society of North America (2000–2001), on his thoughts about the future of phytochemistry now that whole plant genomes are becoming available. Rick is Director of the Plant Biology Division at the Samuel Roberts Noble Foundation in Ardmore, Oklahoma, and is a member of the Editorial Board. He has already aired these views on the future of phytochemistry in two thought-provoking articles in the PSNA Newsletter, which we felt, with permission, deserved to reach a wider audience through *Phytochemistry*. We have taken the liberty to re-edit these in the form of an interview, but acknowledge that the contents are more or less an abridged version of the articles in the PSNA Newsletter. We reproduce his views.

How do you feel phytochemistry as a discipline stands at the present time and where will it go in the future?

Before starting to think about where phytochemistry is going in the future, let us first consider the past achievements of some scientists who can clearly be classified as phytochemists based on the dedication to them of special issues of the journal Phytochemistry. These include some of the founding members of the society and the journal. Eric Conn, Tom Mabry, Neil Towers, Jeffrey Harborne and Clarence Ryan have all made major contributions to phytochemistry, and have trained many of the new generation of phytochemists. The important point is that, together, their work encompasses a variety of subdisciplines, including chemotaxonomy, ethnobotany, pharmacognosy, ecological biochemistry, enzymology, metabolic biochemistry, and molecular biology. Each has taken an individual approach to understanding the chemical processes that make plants such a rich source of molecular diversity. Understanding this chemical diversity at the level of simply cataloging molecules was never the be all and end all of phytochemistry, but a first step towards utilizing plant natural products to benefit humankind by exploitation of their activities as, for example, medicines or plant protectants.

However, the discipline of phytochemistry is entering a new era with the coming of the third millennium. During the last 30 years or more, phytochemistry has taken something of a back seat to other branches of plant science, such as developmental biology and physiology, that have somehow appeared to be more glamorous. Over the last 10 years, the rapidly developing "discipline" of plant molecular biology, with its associated "spinning off" of the field of agricultural biotechnology, has tended to further obscure the purpose and potential impact of phytochemistry. This is particularly so for young scientists who have been attracted by the demonstrable power of molecular biology away from more traditional chemical training. It is, therefore, somewhat ironic that the new developments in molecular biology are now driving renewed interest in phytochemistry.

If that is so, how can phytochemistry be integrated with these other disciplines?

In the past, successful molecular biology labs working on plant natural product pathways would require at least one lab member to be familiar with the chemistry of the favorite class of compound worked on by that particular group. Few molecular labs would have the chemical expertise to work on a broad range of natural product classes, or indeed feel a need to do so. That is now changing. Genomics has fundamentally altered the way in which we view plant biology. The pre-genomics reductionist view ("I work on this pathway") is being superceded by a new ability to take a global view of cellular processes. The complete genome sequence of *Arabidopsis* is now available, to be soon followed by that of rice. Large-scale sequencing programs are rapidly documenting the expressed genes in many other species, including wheat, soybean, *Medicago truncatula* (as a model for alfalfa, Fig. 1) and banana. The big question is what all these genes do, and the science that addresses this

question has been termed functional genomics. Many companies and institutes engaged in large scale functional genomics programs are beginning to see the relative paucity of graduates trained in chemistry and biochemistry (read phytochemistry in the case of plant genomics programs) as a major limitation to future progress.

There are several ways of addressing plant gene function on a large scale, but, for most genes, these approaches ultimately lead to some kind of biochemical analysis. In one approach, an attempt is made to sequence all expressed genes, from a range of developmentally or environmentally selected cDNA libraries (Newman et al., 1994). Expressed sequence tags (ESTs) are compared to sequences in existing gene databases, from which function can sometimes be inferred (but always with caution!). If the function is not apparent, analysis of gene expression profiles using microarray technology (''DNA chips'') might give clues as to function based on the developmental or environmental control pattern of the candidate genes (Kehoe et al., 1999). However, if a gene becomes a candidate for a particular function, it is usually necessary to confirm that function by expressing the gene in some heterologous expression system, such as *E. coli*, yeast, or insect cells. Plants themselves are also becoming vehicles for rapid functional identification of cloned genes, since the development of high throughput transformation systems for some species. Availability of substrates (possibly labeled, and with the correct stereochemistry, of course!) and a specific assay method are then essential. They always were, but the point now is that the speed with which EST programs may lead to candidate genes for plant natural product biosynthesis makes the biochemical assay of enzyme activities the potential rate limiting step.

How can we accelerate the rate at which we can understand biosynthesis and modification of natural products?

Alternative approaches to functional genomics further expand the scale of experiments. Thus, several strategies now exist for creating DNA-tagged mutants in which genes may be randomly up-regulated or down-regulated (Azpiroz-Leehan and Feldmann, 1997; Weigel et al., 2000), and the independent transgenic lines may then be directly screened for biochemical phenotype by phytochemical analysis. Such an approach, that has been termed ''phytochemical biopanning'' in cases where genes are up-regulated, requires the establishment of high throughput metabolic profiling for analysis of gene function, since many thousands of lines may have to be screened before establishing a ''hit'' on a particular gene or pathway of interest. Phytochemical analysis therefore becomes an essential analytical tool for gene discovery. The only difference from classical metabolite analyses carried out in labs throughout the world is one of scale (tens of thousands of samples rather than hundreds) with the need for an attendant increase in speed via automation. The currently applied techniques for metabolic profiling are well familiar to phytochemists- liquid or gas chromatography coupled to light absorption, fluorescence or mass detection. Significant opportunities exist for developing improved techniques for metabolic profiling, particularly in the area of nanoscale separations and their automation, and in more efficient mass detection methods, such as Fourier transformation ion cyclotron MS.

For phytochemists with an interest in computer science, a major challenge will be to assemble databases of metabolic profiles that will be able to communicate with gene sequence, protein profile and gene expression databases. This new field of ''metabolomics'' or ''metanomics'' will facilitate a far greater understanding of how gene expression regulates the metabolic phenotype of the cell than has been hitherto possible (Trethewey et al., 1999).

Can you, therefore, foresee the acquisition of this knowledge giving rise to new and innovative science?

The term ''structural genomics'' was initially applied to large-scale studies of genome structure and organization, but is now also used to describe how the primary sequence of amino acids in a protein relates to the function of that protein. Currently, the core of structural genomics is protein structure determination, primarily by X-ray crystallography, and the design of computer programs to predict protein fold structures for new proteins based on their amino acid sequences and structural principles derived from those proteins whose 3-dimensional structures have been determined (Skolnick and Fetrow, 2000). Plant natural product pathways are a unique source of information for the structural biologist in view of the almost endless catalytic diversity encountered in the various pathway enzymes, but based on a finite number of reaction types. Plants are combinatorial chemists par excellence, and understanding the principles that relate enzyme structure to function will speed up the gene discovery process for enzymes of plant natural product pathways. It will also open up possibilities for the rational design of new enzymes to generate novel biologically active natural products (Ferrer et al., 1999). The chemical diversity that is currently explored by analyzing natural products from new plants collected in diverse habitats throughout the world may soon be generated in vitro by site-directed mutagenesis or shuffling of gene sequences derived from well understood classes of plant natural product biosynthetic enzymes. Phytochemistry will have the same goals as before, but a different source of chemical diversity with which to work.

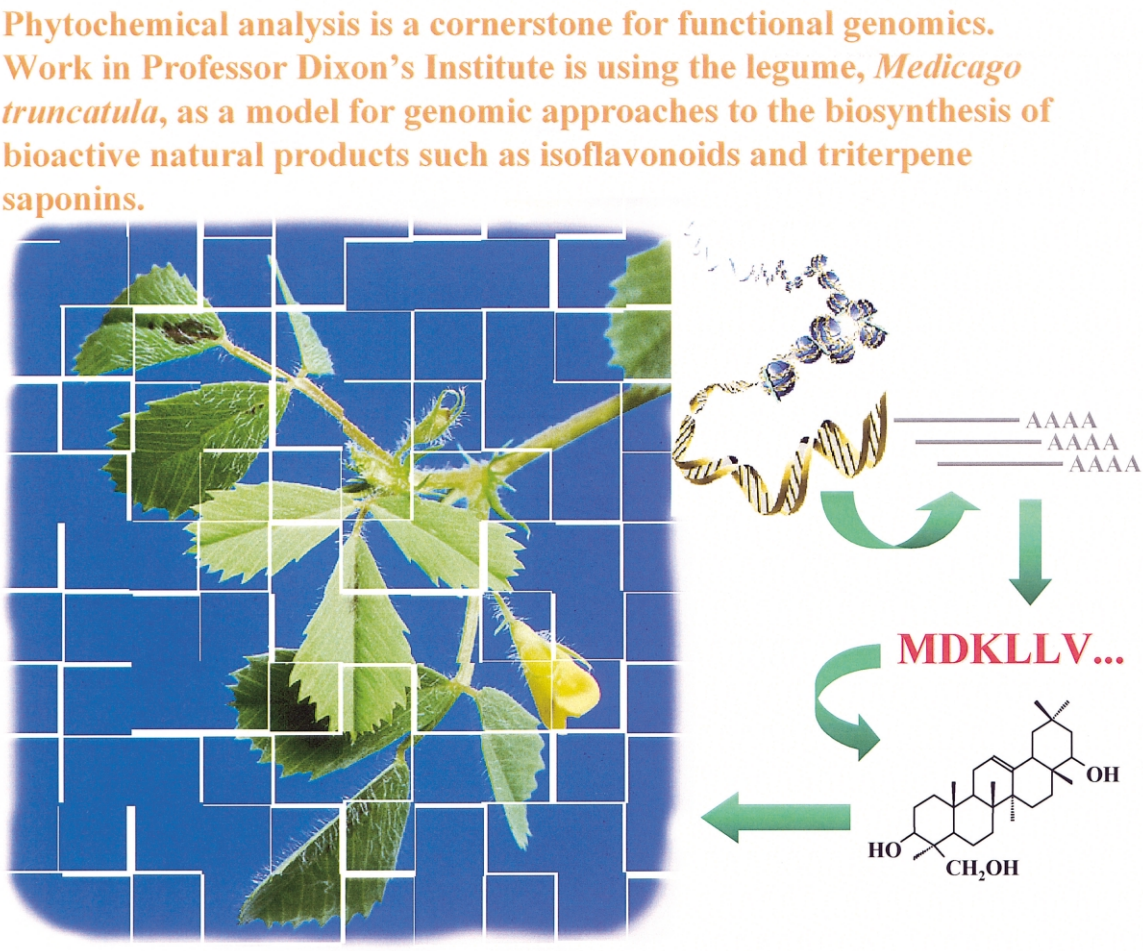

Fig. 1. Professor Dixon's Institute is using the legume, *Medicago truncatula*, as a model for genomic approaches to the biosynthesis of bioactive natural products such as isoflavonoids and triterpene saponins,

Do you see any new radical alterations in our perceptions and basic understanding of natural products biosynthesis arising as a result?

Structural biology will play an increasing role in the "post-genomics era" after the completion of the major plant genome sequencing initiatives. However, even when the biochemical functions of all the genes in the plant are known, there is still a major challenge, namely understanding how metabolic networks function within the cell (Huang, 2000). This understanding is necessary for full realization of the potential of metabolic pathway engineering. It is becoming increasingly clear that the enzymes of primary and secondary metabolic pathways, and signal transduction components such as protein kinase cascades, are somehow localized in loosely associated complexes, even if operationally soluble according to classical biochemical criteria. Understanding the subcellular organization of plant metabolism will require the development of new technologies, at the interface of phytochemistry and cell biology, to localize metabolites and their enzymes within the cell, and integration with computational methods for modeling of pathway flux through organized enzyme complexes.

In a recent *Phytochemistry* editorial comment by Mark Plotkin, who posed the ethnobotanist view, he considered the lack of trained phytochemists to be real in the west. How do you view the situation and how do we move forward?

I hope I will not offend any of my colleagues by stating that it is usually easier to train a chemist or biochemist to become a molecular biologist than it is to train someone whose background is in molecular biology or genetics to become a good biochemist or phytochemist. Those enzymes and small molecules all seem to have different properties, and there don't seem to be any expensive kits to help solve the problems! Phytochemists should therefore be in increasing demand as we move into the genomics and post-genomics eras. It is therefore of critical importance for our field that young scientists with an interest in plant chemistry become familiar with

the new fields of functional and structural genomics. They should not, however, forego a rigorous training in all aspects of plant chemistry. The older ones among us should also be looking for new opportunities to apply our knowledge of plant chemistry and biochemistry in the context of the new advances in plant science. I hope the readership of *Phytochemistry* will realize the enormous opportunity we all now face, and become increasingly involved in multidisciplinary studies that will ultimately tell us exactly how plants elaborate the fascinating chemical structures that many have spent their careers elucidating.

Inhibition of polygalacturonase from *Verticillium dahliae* by a polygalacturonase inhibiting protein from cotton

Jacinda T. James, Ian A. Dubery *

Department of Chemistry and Biochemistry, Rand Afrikaans University, PO Box 524, Auckland Park, 2006, South Africa

Received 26 April 2000; received in revised form 20 July 2000

Abstract

An extracellular endo-polygalacturonase (PGase) [E.C. 3.2.1.15] was isolated from 18-day-old culture filtrates of *Verticillium dahliae* and partially purified using gel permeation chromatography. The band responsible for PGase activity was electrophoretically characterized as having a molecular mass of approximately 29 500 and an isoelectric point of 5.4. Kinetic studies indicate a K_m of 3.3 mg ml^{-1} and V_{max} of 0.85 μmol reducing units min^{-1} ml^{-1} with polygalacturonic acid as substrate. Polygalacturonase inhibitor protein (PGIP) in cotton seedlings was induced by 5 mM salicylic acid and immunochemical analysis indicated high levels in the hypocotyl tissues. PGIP was purified from roots and stems using affinity chromatography with endo-PGase from *Aspergillus niger* as an immobilised ligand. The purified PGIP contained monomeric and dimeric molecules with molecular masses of 34 and 66 kDa respectively. Purified cotton PGIP inhibited endo-polygalacturonase from *A. niger* in a non-competitive or mixed manner with an inhibition constant, K_I of 15 nM. The isolated *V. dahliae* PGase was, however, inhibited in a positive cooperative manner, indicative of allosteric interactions between the enzyme and the inhibitor protein. In addition to reducing the reaction rate, decreased substrate affinity may contribute to the accumulation of elicitor-active oligouronides. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Gossypium hirsutum*; Malvaceae; Cotton; *Verticillium dahliae*; Polygalacturonase; Polygalacturonase inhibiting protein

1. Introduction

Verticillium dahliae is a destructive soil-borne fungal pathogen that causes vascular wilt diseases on more than 160 plant species including important crop plants such as cotton, tomatoes and potatoes. *V. dahliae* penetrates the host through the roots and spreads systemically through the xylem, leading to the appearance of wilt symptoms (Daayf et al., 1995).

The plant cell wall plays a complex role in resistance by presenting a physical barrier to the infecting pathogen. Polysaccharides capable of regulating gene expression and defense responses, as well as enzymes and proteins involved in host defense mechanisms, are localized in the cell wall (Karr and Albersheim, 1970). The importance of polygalacturonases (PGases) in fungal pathogenesis is now well established for certain plants (Karr and Albersheim, 1970; Jones et al., 1972). Research on fungal endopolygalacturonases has demonstrated that these enzymes release elicitor-active oligogalacturonide fragments from the plant cell wall rather than being elicitors of defense themselves.

Polygalacturonase inhibiting proteins (PGIPs) have been found to be present in the cell wall of most dicotyledonous plants, and are specific, reversible, saturable, high-affinity ''receptors'' for fungal, but not plant endopolygalacturonases (Cervone et al., 1989, 1990). PGIPs are structurally related to several resistance gene products and belong to a super-family of leucine-rich repeat proteins specialized for recognition of non-self molecules and rejection of pathogens (Jones and Jones, 1997). The receptor-like leucine-rich molecular structure of the PGIP protein provides a molecular basis for the proposed role of PGIP as a secreted receptor component of the cell-surface signaling system involved in recognition events between plant and fungi (De Lorenzo et al., 1993; Jones and Jones, 1997). Although PGIPs, which have a broad specificity against fungal endo-PGase (Cervone et al., 1990), can reduce the activity of

PII: S0031-9422(01)00024-3

these enzymes in vitro (Cervone et al., 1987); PGIPs from different plants inhibit PGase from a single fungal species to different extents (Yao et al., 1995). Furthermore, the inhibition of PGases by PGIPs can be highly specific (Leckie et al., 1999). Different isoforms of PGIP from a single plant source can differentially inhibit PGases from several fungal species or PGase isozymes from a single fungal pathogen. The possibility exists that different PGIP members encode PGIPs with distinct regulation and specificity (Desiderio et al., 1997).

Formation of the endo-PGase-PGIP complex in vitro results in an alteration of the balance between the release of elicitor-active oligosaccharides and the depolymerisation of the active oligogalacturonides into inactive molecules, thus favouring the accumulation of elicitor active molecules at the site of infection and the resulting activation of the defense responses of the host (Cervone et al., 1989; Bergmann et al., 1994). This intriguing concept of plant-derived elicitors for activating pathogen defense is very likely to function in many plant-pathogen interactions. In this cotton:*V. dahliae* study we have characterized PGIP from the host and extracellular PGase from the pathogen and report on the kinetics of interaction between the inhibitor protein and its ligand.

2. Results and discussion

2.1. Polygalacturonase purification and characterization

PGase (E.C. 3.2.1.15) was isolated from 18-day-old cultures. The maximum PGase levels were determined by the agarose diffusion assay (Dingle et al., 1953) and correlated to a growth curve. Mycelial growth peaked at days 14–15, decreasing thereafter. Maximum PGase production was obtained from day 17 to 20 when the glucose in the medium was consumed and growth conditions became limiting.

The main fraction of *V. dahliae* PGase activity was partially purified by means of $(NH_4)_2SO_4$ precipitation and chromatography on a Sepharose Cl-6B gel filtration column (Fig. 1) with a yield of 4.1%. In addition to the main peak of PGase activity, several smaller activity peaks of higher molecular mass, possible aggregates, were observed. The purification procedure is summarized in Table 1. The final specific activity of the preparation varied between 100 and 200 U mg^{-1}.

Although it is known that PGase play a central role in pathogenesis (Cervone et al., 1986), the amount of information on it's structure and function is minimal, due to the technical difficulties in preparing suitable quantities of homogenous PGase. Most of the physiological studies involving PGase have been performed with preparations containing contaminating proteins or enzymes.

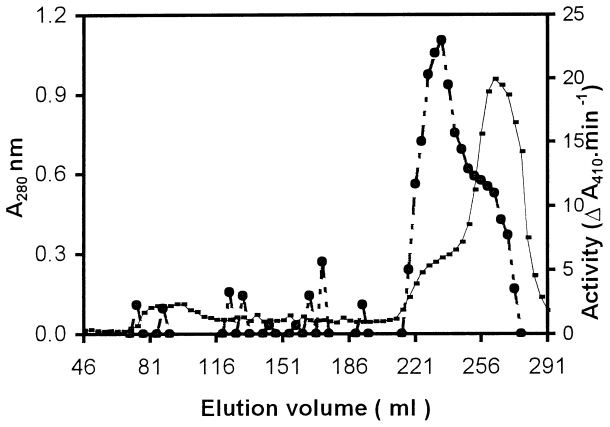

Fig. 1. Elution profile of a Sepharose Cl-6B gel filtration column to purify PGase from *Verticillium dahliae*. The $(NH_4)_2SO_4$ precipitate fraction was loaded onto the column (60×2.5 cm) at a flow rate of 20 ml h^{-1}, eluted with dH_2O and 3.5 ml samples were collected. The fractions were monitored spectrophotometrically at 280 nm (■). PGase activity (-●-), is expressed as $\Delta A_{410}.10^{-4}$ min^{-1} ml^{-1}.

Table 1
Purification of extracellular endo-polygalacturonase from *Verticillium dahliae* culture filtrates

Purification step	Protein concentration (μg ml^{-1})	Vol. (ml)	Total protein (mg)	Yield (%)
Culture filtrate[a]	57.1	1350	77.1	100
$(NH_4)_2SO_4$ precipitation[a]	3020	10	30.2	39.2
Sepharose Cl-6B column	104.8	43	4.5	5.8
Post-column concentration	145.6	23	3.4	4.1

[a] Final specific activity varied between 100 and 200 U mg^{-1}. Activity could not be reproducibly assayed in crude extracts.

The apparent molecular mass determined by means of SDS–PAGE (Fig. 2) for *V. dahliae* PGase was approximately 29.5 kDa which correlated with the value of 31 kDa calculated by gel filtration. Molecular mass values, ranging from 32 to 37 kDa seems to be a characteristic property among endo-PGases from different fungi (Cervone et al., 1986). Using native IEF-gels, the pI value determined for partially purified PGase from *V. dahliae* was 5.4 (Fig. 3). Polygalacturonases from different fungal sources exhibit a great variability of isozymatic forms, distinguishable by their isoelectric points. Apart from structural and functional differences more information is needed on the regulation of PGases to fully understand their biological significance.

2.2. PGIP induction and purification

A variation in the distribution of PGIP throughout the plant has been reported (Salvi et al., 1990), and a study was done to determine the occurrence of PGIP in the different plant organs of cotton seedlings.

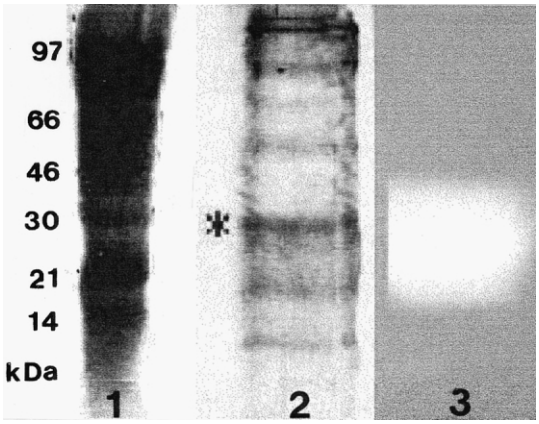

Fig. 2. SDS–PAGE analysis of the Sepharose Cl-6B-purified PGase from *Verticillium dahliae*. Proteins, stained with silver, are indicated in lane 2. Activity staining of the renatured enzyme, indicated with an asterix, on an agarose overlay gel is shown in lane 3. Standard M_r markers are indicated in lane 1.

Immunochemical detection of PGIP levels in crude *Gossypium hirsutum* L. homogenates by Western blot analyses, using a primary antibody against a conserved, surface exposed peptide from bean PGIP, indicated that the highest amount of PGIP was induced in the hypocotyls and to a lesser extend in the first leaves (Fig. 4). The prominent band detected by the antibody in hypocotyls had a M_r of 34 kDa that corresponds with the value reported for deglycosylated PGIP (Stotz et al., 1994, Yao et al., 1995). The results also show a reaction with other proteins present in the crude extract. Bergmann et al. (1994) reported the same for *Phaseolus vulgaris* L. homogenates and attributed the cross-reaction to antibodies interacting with carbohydrate moieties.

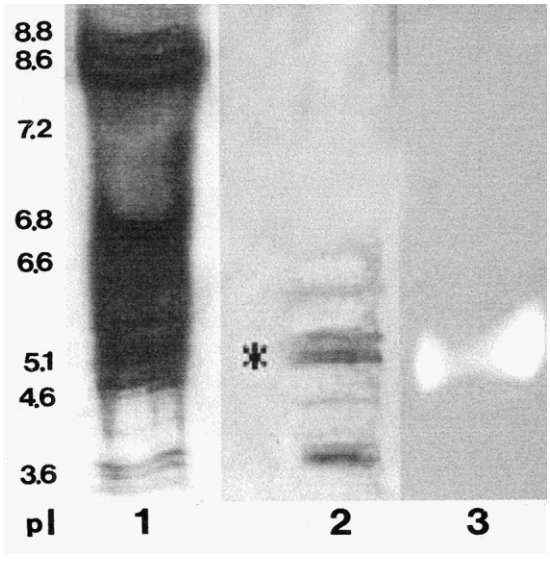

Fig. 3. PAGIEF analysis of the Sepharose Cl-6B–purified PGase from *Verticillium dahliae*. Proteins were stained with silver (lane 2). Activity staining of the enzyme, indicated with an asterix, on an agarose overlay gel is shown in lane 3. Standard pI markers are indicated in lane 1.

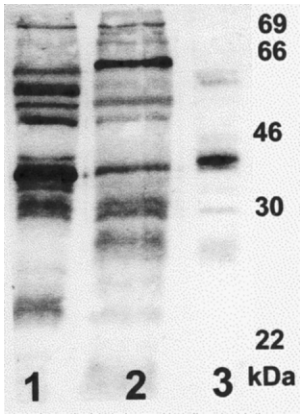

Fig. 4. Tissue specific distribution of PGIP in cotton seedlings. Western blot analysis of immunoreactive proteins present in crude extracts of the hypocotyls (roots and stems, lane 1) and first leaves (lane 2) of cotton seedlings following separation by 12.5% PAGE. Shown in lane 3 is affinity purified PGIP from bean pods, used as a positive control. Molecular mass markers are indicated at right.

The root and stem tissues of infected plants play an important role in the defense mechanisms to *Verticillium* wilt (Lahkim and Nachmias, 1995). PGIP was isolated from cotton hypocotyls by means of $(NH_4)_2SO_4$ precipitation and affinity chromatography on an *Aspergillus niger* endo-PGase-Sepharose column as indicated in Fig. 5 (Cervone et al., 1987). PGIP is an inducible protein and mRNA transcripts accumulate in response to wounding, elicitors and fungal infection (Devoto et al., 1997). It is known that endogenous levels of salicylic acid increase both locally and systematically as a consequence of pathogen attack and that the application of salicylic acid can induce defense responses and resistance towards pathogens (Yalpani et al., 1991). Following the procedure of Bergmann et al. (1994), who reported that the treatment of bean seedlings with salicylic acid resulted in an increase in steady-state levels of PGIP, cotton seedlings were sprayed with 5 mM salicylic acid at 24 h intervals over a time period of 72 h in order to induce maximal amounts of PGIP. The kinetics of induction of PGIP in cotton was not investigated; however, the yield of salicylic acid induced PGIP was approximately 1.0 μg protein per g tissue (Table 2)

Table 2
Purification of polygalacturonase inhibitor protein, PGIP, from hypocotyls of cotton, *Gossypium hirsutum,* cv, OR_{19} seedlings

Purification step	Protein concentration (μg ml^{-1})	Vol. (ml)	Total protein (mg)	Yield (%)
Crude preparation[a]	180.9	233	42.3	100
$(NH_4)_2SO_4$ precipitation[a]	335.6	6	2	4.8
Dialysis	238.1	10	2.38	5.6
Endo-PGase affinity column	9.52	21	0.2	0.5

[a] Activity could not be determined in the crude extracts.

compared to barely detectable levels in noninduced seedlings. PGIP purified from bean hypocotyls was used as a control and produced the same elution pattern as for cotton PGIP (Fig. 5).

2.3. Electrophoretic analyses of cotton PGIP

Purified cotton PGIP was characterized by means of SDS–PAGE and Western blot analyses. One prominent band was detected by SDS–PAGE analysis corresponding to apparent molecular masses of 66 kDa (Fig. 6A).

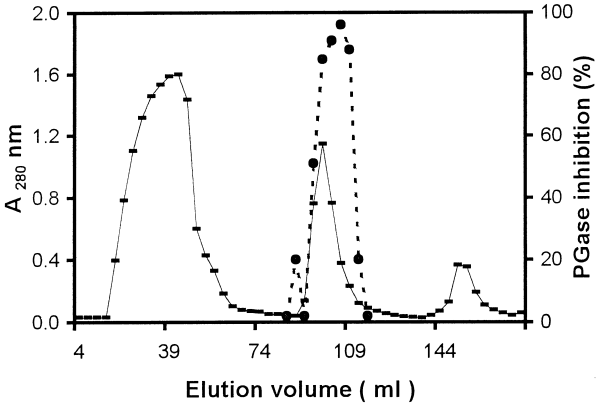

Fig. 5. Elution profile of extracts from cotton roots and stems, induced with 5 mM salicylic acid, on an endo-PGase affinity column (13×1.5 cm). The post-dialysis PGIP fraction (13 ml) was applied to the column with 20 mM NaOAc pH 5.0 and the PGIP fraction was desorbed at 60 ml h^{-1} with phosphate buffered saline, pH 7.3. Fractions were monitored spectrophotometrically at A_{280} (-■-). The PGIP peak (-●-) was identified by the inhibition of *A. niger* polygalacturonase, using the reducing sugar assay. The third peak was obtained with 0.1 M sodium borate buffer, pH 8.0, used to wash and desorb bound phenolics from the column.

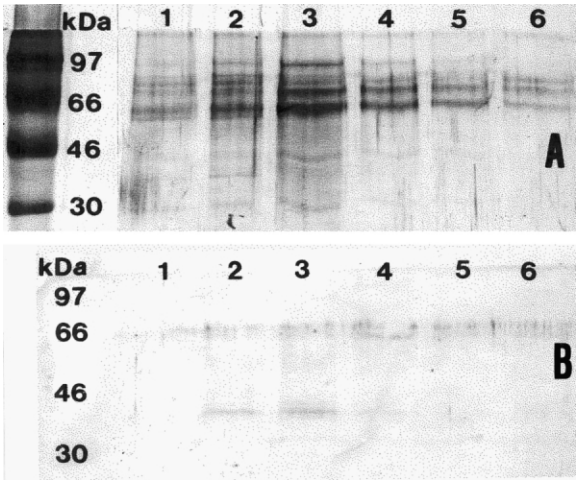

Fig. 6. Electrophoretic and immuno-blot analysis of the protein fractions desorbed from the endo-PGase affinity column. SDS–PAGE followed by silver staining, was performed on 12.5% gels on the PGIP fractions eluted from the colum (part A, lanes 1–6) with subsequent Western blot analysis of these fractions (part B of the figure). The M_rs are indicated on the left.

This band was also observed in the Western blot (Fig. 6B), together with the 34 kDa band observed in crude extracts. Yao et al. (1995) reported a 34 kDa polypeptide for apple PGIP and suggested that differential glycosylation accounted for the observed heterogeneity in molecular mass. Molecular masses of 34–45 kDa have been reported for PGIPs from several sources (Cervone et al., 1987; Bergmann et al., 1994; Stotz et al., 1994) as well as higher molecular weight forms (91 kDa, Abu-Goukh et al., 1983). It is possible that cotton PGIP exists as a dimer, binding covalently to negatively charged pectin in the cell wall or to each other through non-specific interactions. Cross-linking during the purification procedure due to reaction with bifunctional terpene aldehydes such as gossypol, could also lead to dimerization (Mahoney and Chan, 1985).

2.4. Inhibition of the PGase from Verticillium dahliae by cotton PGIP

An agarose diffusion assay showed that purified cotton PGIP inhibited the PGase purified from *V. dahliae* culture filtrates to various degrees when added in different ratios to the reaction mixture (results not shown). A molar ratio of 1(PGase) : 4(PGIP) reduced the activity to near zero but since the inhibition is reversible, a high concentration of PGIP would be needed to completely inhibit the PGase. The inhibition was confirmed with native-PAGE gels and subsequent overlays in the absence and presence of cotton PGIP (overlay gels not shown).

2.5. Kinetic analysis of inhibition

PGase from *V. dahliae,* diluted to a concentration of 30 ng ml^{-1} in a 400 μl reaction volume, producing a linear response over 30 mins ($\Delta A_{410} = 9.3\times10^{-3}$ min^{-1}), was used for kinetic studies. The ΔA_{410} min^{-1} was calculated for the inhibited and uninhibited assay and the percentage of inhibition was determined. An inhibition value of 50% was obtained with 7.5 ng ml^{-1} of purified cotton PGIP, and the activity was reduced to 30% at 9.5 ng ml^{-1}, indicating that cotton PGIP is an effective inhibitor of PGase from *V. dahliae*. The inhibition of reaction rate by increasing concentrations of purified cotton PGIP was measured at different concentrations of polygalacturonic acid (PGA). Increasing concentrations of PGIP lead to the progressive inhibition of PGase activity (Fig. 7A).

Kinetic studies of PGIPs revealed that some inhibit fungal PGases by a competitive type of inhibition whereas others are non-competitive, however this difference might depend on the source of the PGase rather than the source of the PGIP (Jones and Jones, 1997). Mixed or non-competitive inhibition was displayed between cotton PGIP and PGase from *A. niger*, with a K_m of 3.3 mg ml^{-1}, a V_{max} of 1.07 μm reducing sugar

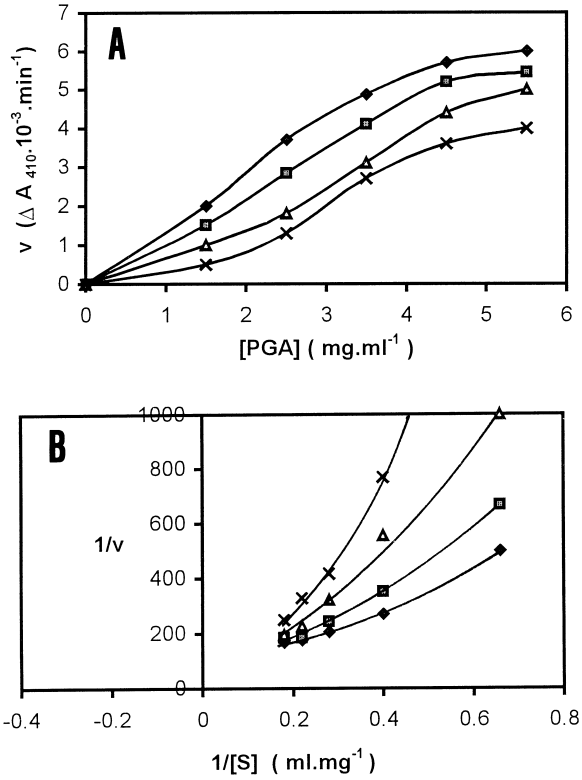

Fig. 7. Inhibition of purified PGase from *V. dahliae* by cotton PGIP at fixed enzyme concentration (30 ng ml^{-1}) and varying inhibitor concentrations: ◆, the uninhibited assay; assay with 2.4 ng ml^{-1} PGIP ■; 4.8 ng ml^{-1} PGIP ▲, and 7.2 ng ml^{-1} PGIP, X. A: Michaelis–Menten plot of PGase activity with different concentrations of PGA together with three different concentrations of PGIP. B: Lineweaver–Burk plot showing the positive allosteric inhibition with several inhibitor concentrations. v = Enzyme activity; S = substrate concentration.

equivalents produced min^{-1} ml^{-1} and a K_i of 15 nM (Fig. 8). Non-competitive inhibition is an indication of the inhibitor binding to a site on the PGase molecule different from the active site. Using a mutagenesis approach, Caprari et al. (1996), was able to confirm that the PGIP does not bind to the active site of the PGase from *Fusarium moniliforme*.

Lineweaver–Burk analysis of the data was performed to determine the type of inhibition displayed between PGase from *V. dahliae* and PGIP from cotton (Fig. 7A and B). V_{max} for the uninhibited treatment was estimated as 0.85 μmol reducing sugar equivalents produced min^{-1} ml^{-1} with a K_m of 3.3 mg ml^{-1}. The graphs obtained are not typical Michaelis–Menten curves and the sigmoidal pattern obtained indicates a positive allosteric interaction between PGase, PGIP and the PGA substrate, suggesting that the reaction rate is reduced at low substrate concentrations but not necessarily at others. Co-operative allosteric interactions occur when the binding of one ligand at a specific site is influenced by the binding of another ligand, modulator or effector at a different (allosteric) site on the protein (Palmer, 1995). Previously, no allosteric inhibition of a fungal PGase by a PGIP have been reported in the few cases where the kinetics of inhibition have been described.

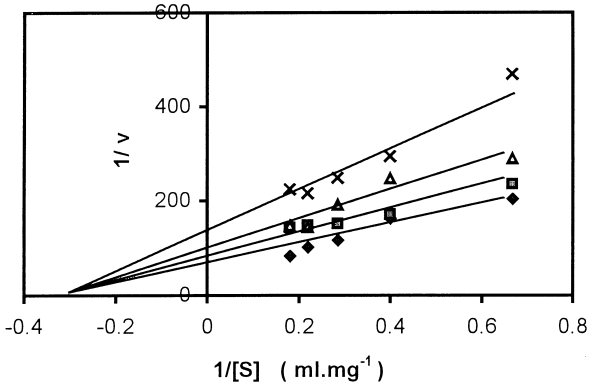

Fig. 8. Inhibition of PGase from *Aspergillus niger* by cotton PGIP at fixed enzyme concentration (100 ng ml^{-1}) and varying inhibitor concentrations (0–7.2 ng ml^{-1}). The Lineweaver–Burk plot shows the non-competitive inhibition with several inhibitor concentrations: 2.4 ng ml^{-1} (■), 4.8 ng ml^{-1} (▲) and 7.2 ng ml^{-1} (X). The uninhibited assay is denoted by ◆. v = Enzyme activity; S = substrate concentration.

The results obtained indicate that the PGase from *V. dahliae* is a "K"-series enzyme, where the presence of the modifier (in this case PGIP), results in a change in K_m but not in the apparent V_{max} for the substrate. If the binding characteristics alone are affected, V_{max} will usually remain unchanged, so the inhibition pattern could be regarded as non-competitive or mixed inhibition. As PGIP does not bind directly to the active site of the enzyme, it could be possible that binding induces a conformational change in the enzyme, resulting in a lower substrate affinity. The sigmoidal binding of a modifier or inhibitor can amplify the regulatory effect (Palmer, 1995), thus reducing the activity of the PGase. This would delay the rapid degradation of PGA to inactive monomers and result in the generation of elicitor-active oligogalacturonides with a higher degree of polymerization. These results are in support of the model proposed for the PGIP:endo PGase interaction (De Lorenzo et al., 1993) where the formation of the enzyme-inhibitor complex in vitro, results in an alteration of the balance between the release of elicitor-active oligosaccharides and the depolymerisation of the active oligogalacturonides into inactive molecules, thereby favouring the accumulation of elicitor active molecules at the site of infection and the resulting activation of the defense responses of the host.

3. Experimental

3.1. Plant material and fungal isolate

Seeds of *Verticillium* resistant cotton cultivar OR_{19} (obtained from the Agriculture Research Council's Institute for Tobacco and Cotton, Rustenburg, South

Africa) were germinated and maintained at 30°C. Roots and stems of 3-week-old plants were used in all experiments. A pathogenic isolate of *V. dahliae* was obtained from infected *Acala*$_{1517/70}$ cotton stems (Meyer et al., 1994).

3.2. Polygalacturonase purification and characterization

Fungal mycelia were cultivated in liquid culture in the dark at 25°C for 18 days, in 1 l flasks, containing 500 ml of medium (Nachmias et al., 1982). A growth curve was determined over a period of 21 days. The extracts were screened by means of an agarose diffusion assay (Dingle et al., 1953) to determine maximum PGase production (Section 3.8).

Culture filtrates harvested on day 18 were used for purification of PGase. Following centrifugation at 15 000×*g*, proteins present in the the clear supernatant (1350 ml) was precipitated at 90% $(NH_4)_2SO_4$ saturation for a minimum of 1 h. The precipitate was collected by centrifugation at 15 000×*g* for 20 min and dissolved in dH_2O. The sample was fractionated using gel permeation chromatography on Sepharose CL-6B (2.5×60 cm) with dH_2O as eluant (Meyer et al., 1994) at a flow rate of 20 ml h^{-1}. The fractions obtained after gel filtration that exhibited PGase activity were combined and concentrated in a dialysis bag against glycerol to stabilize the enzyme for storage at 4°C.

PGase from *V. dahliae* was characterized by native PAGE, agarose overlay gels (Kanellis et al., 1991), SDS–PAGE (Laemmli, 1970) and IEF gels (Robertson et al., 1987). The M_r was determined using analytical gel filtration with a Sepharose CL-6B column (2.5×60 cm) using 0.1 M NaPi buffer, pH 8.0 as eluting buffer (Andrews, 1970). V_0 and V_t were determined with blue dextran and DNP-alanine respectively to calibrate the column, together with a set of calibration proteins from 14 to 158 kDa.

3.3. Enzyme staining in gels

Enzyme activity of endo-PGases present in the culture filtrates and crude extract were screened by means of an agarose diffusion assay (Dingle et al., 1953).

Following PAGE, the gels were incubated in 0.1 M NaOAc, pH 5.0 for 10 min. Agarose gels (2×85×100 mm) were poured onto Gelbond® film (FMC Bioproducts). The agarose soln. contained 0.8% agarose (w/v), 100 mM HOAc (pH 5.0) and 1 mg ml^{-1} PGA (w/v). Following incubation, the overlay gels were stained in 0.005% ruthenium red for 2 h and destained in dH_2O until clear bands were evident (Kanellis et al., 1991).

In order to determine activity following SDS–PAGE, gels were washed twice for 15 min in 0.1 M NaOAc, pH 4.5 containing 0.05 mg ml^{-1} BSA and 0.1% Triton-X100 at room temperature. The enzyme was allowed to renature at 4°C overnight in 0.1 mM NaOAc, pH 4.5 containing 0.05 mg ml^{-1} BSA and 0.02% β-mercaptoethanol. Gels were then washed for 10 min in 20 mM NaOAc, pH 4.5 and enzyme activity localized as described above. The band of activity was compared to the SDS-gel to determine the molecular weight of PGase from *V. dahliae*.

3.4. Enzyme activity determinations

A reducing sugar assay for the determination of released galacturonic oligomers was used with the colour reagent p-hydroxybenzoic acid hydrazide (Kombrink et al., 1988). PGase, either the positive control *Aspergillus niger* PGase, 100 ng ml^{-1}, or purified PGase from *Verticillium dahliae,* 30 ng ml^{-1}, was added as a 200 μl aliquot to 200 μl autoclaved PGA (2.5 mg ml^{-1}) in 20 mM NaOAc buffer, pH 5.0. PGase activity was assessed over time (0–60 min) to determine the linear range. Duplicate samples were taken at 4 different time intervals (0, 10, 20 and 30 min). Activity was expressed as ΔA_{410} min^{-1} ml^{-1} or converted to arbitrary units, one unit being equivalent to the release of 1.0 μmol galacturonic acid units min^{-1} ml^{-1} at pH 5.0.

3.5. Induction and purification of PGIP

PGIP in cotton seedlings was chemically induced with salicylic acid. Seedlings were sprayed with 5 mM sodium salicylate, pH 7.0 for 72 h. Distilled water was used as a control. The extraction procedure of Salvi et al. (1990) was carried out at 4°C with slight modifications. Plant material (hypocotyls, 200 g) was homogenized for 2 min in cold 20 mM NaOAc, pH 5.0 containing 500 mM NaCl (1:2 m/v). Proteinase inhibitor, PMSF (0.1%), was added prior to homogenization. The suspension was vacuum filtered through a number 1 sinter glass funnel and the filtrate centrifuged at 12 000×*g* for 20 min. The proteins in the supernatant were precipitated for 1 h with $(NH_4)_2SO_4$ at a final saturation of 90%, followed by centrifugation 12 000×*g* for 20 min to collect the precipitate. The precipitate was resuspended in a small volume of 20 mM NaOAc, pH 5.5 and dialyzed with at least 4 changes of the same buffer in a dialysis membrane with a molecular cut-off value of 12–14 kDa. The suspension was centrifuged at 12 000×*g* for 20 min and the PGIP purified further by affinity chromatography on an endo-PGase affinity column as described by Cervone et al. (1987). PGIP activity was measured using the PGase assay described above. One unit was defined as the amount of inhibitor required to reduce the activity of one unit of enzyme by 50%

3.6. Electrophoretic analyses

Protein concentration was determined according to Bradford (1976) or the bicinchoninic acid protein assay from Pierce (Rockford, IL). Purified preparations were

analysed by native PAGE, agarose overlay gels (Kanellis et al., 1991) and IEF gels (Robertson et al., 1987). SDS-electrophoresis was carried out according to Laemmli (1970); gels were stained with either Coomassie R250 or silver (Bristow, 1990).

3.7. Western blot analyses

Blotting was performed overnight at 4°C and 36 V using PVDF-Plus membranes and 25 mM Tris (pH 8.2), 192 mM glycine, 20% (v/v) methanol and 0.1% (w/v) SDS as transfer buffer. The primary antibody was raised in rabbits against a synthetic peptide, A-L-L-Q-I-K-K-D-L-G-N-P-Y, located near the N-terminus of bean PGIP and coupled to Keyhole Limpet Haemocyanin (Bergmann et al., 1994). Goat anti-rabbit IgG, conjugated to alkaline phosphatase was used as secondary antibody at a dilution of 1:1000 with nitro blue tetrazolium chloride/5-bromo-4-chloro-3-indolyl phosphate as substrate (Berger et al., 2000).

3.8. Inhibition studies

The agarose diffusion assay (Dingle et al., 1953) for PGase activity was performed to test for the presence of PGIP. The assay medium consisted of 100 mM citrate and 200 mM NaPi (pH 5.3) to which final concentrations of 1% agarose, 0.5% ammonium oxalate and 0.1 mg l^{-1} PGA were added. The assay was carried out with the addition of 50 μl culture medium supernatant into each well and overnight incubation at 30°C. Activity zones were visualized by staining the background with 0.05% ruthenium red.

For enzyme assays and kinetic studies the reducing sugar assay as described in Section 3.4 was used. Enzyme was added to different concentrations of cotton PGIP (0–7.2 ng ml^{-1}) to determine the degree of inhibition. PGIP preparations were mixed with PGase and incubated for 10 min prior to the addition of the PGA substrate. Substrate concentrations were varied between 1.5 and 5.5 mg ml^{-1} to determine the type of inhibition. Duplicate samples were taken at 0, 10, 20 and 30 min and analyzed for galacturonic acid.

Cell-wall proteins from Sitka spruce xylem are selectively insolubilised during formation of dehydrogenation polymers of coniferyl alcohol

Gordon J. McDougall *

Received 13 September 2000; received in revised form 5 January 2001

Abstract

Extracts from the lignifying xylem of Sitka spruce that were enriched in cell-wall-associated glycoproteins contained peroxidase and oxidase activity and readily formed lignin-like water-insoluble dehydrogenation polymers (DHPs) from coniferyl alcohol (CA) when supplied with H_2O_2. During the formation of DHPs, the abundance of a number of polypeptides in the extracts was diminished. However, these polypeptides were also diminished in control reactions that contained H_2O_2 but lacked CA. Polypeptides could be recovered from the DHPs by heating in SDS-PAGE sample buffer but no insolubilised polypeptides could be recovered from the $+H_2O_2$ reactions. Although most of the DHP-bound polypeptides were easily removed by pre-washing the DHPs, two polypeptides at 125 and 52 kDa remained tightly bound to the DHPs. The abundance of the two DHP-bound polypeptides mirrored the diminution of 120 and 46 kDa polypeptides in the extracts. The N-terminal protein sequences of the 125 and 52 kDa DHP-bound polypeptides were essentially identical to the sequences obtained from the 120 and 46 kDa polypeptides from the extracts, which confirmed that the DHP-bound polypeptides were derived from these soluble polypeptides. The 125-kDa DHP-bound polypeptide yielded an N-terminal protein sequence that was identical to a laccase-type oxidase previously identified in similar extracts from lignifying Sitka xylem. The N-terminal protein sequence of the 46-kDa polypeptide was homologous with a subset of plant peroxidases. The DHPs had tightly bound peroxidase and oxidase activity, which suggested that these polypeptides were active in their insolubilised state. The mechanism and selectivity of insolubilisation of these enzymes is discussed. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Insoluble dehydrogenation polymers (DHPs) produced from monolignols by the action of peroxidase and H_2O_2 are, in effect, synthetic lignins (Monties, 1989) and have been used to predict the structure (Freudenberg and Neish, 1968) and model the behaviour (Adler, 1977) of natural lignins.

It has been noted that peroxidases used to catalyse the formation of DHPs in vitro become tightly associated with the DHPs and retain activity (Evans and Himmelsbach, 1991). The nature of this association is not understood. In this paper, I describe the selective insolubilisation of cell-wall-associated glycoproteins from the lignifying xylem of Sitka spruce during the peroxidase-catalysed dehydrogenation of coniferyl alcohol.

2. Results and discussion

As noted in previous studies (McDougall, 1997; Richardson et al., 1997; Deighton and McDougall, 1998), high salt and ConA bound extracts from the lignifying xylem of Sitka spruce had appreciable oxidase and peroxidase activity (Table 1). The ConA bound extract, which was enriched in cell-wall-associated glycoproteins (McDougall, 1997), represented a 5.8-fold and 3.7-fold enrichment in oxidase and peroxidase activity over the

high salt extract with recoveries of 58 and 41%, respectively. The ConA bound extract readily formed insoluble dehydrogenation polymers (DHPs) from coniferyl alcohol when supplied with H_2O_2.

Four polypeptides (of apparent Mrs of 120, 69, 62 and 46 kDa) were consistently diminished in abundance after the formation of DHPs from CA and H_2O_2 (see Fig. 1, compare lanes a and c). The same polypeptides were also diminished by the addition of H_2O_2 alone (Fig. 1, lane b). These polypeptides may have been oxidatively cross-linked in a manner similar to the proline-rich and extensin-like polypeptides secreted from chickpea (Otte and Barz, 2000) and French bean cultures (Wojtaszek et al., 1997). These polypeptides were not diminished unless the H_2O_2 concentration was greater than 35 mM (Fig. 2) which is much higher than the conditions noted in these papers. This suggests that the diminution of these proteins occurred by a different mechanism. However, it is should be noted that the same polypeptides were diminished when DHPs were produced over longer (2–3 days) reaction times with lower H_2O_2 concentrations (results not shown). No insoluble polypeptides could be recovered in pellets from the + H_2O_2 control samples (Fig. 3, lane d), even if insoluble polymers, such as cellulose or pre-formed DHPs, were added as carriers after the reactions were completed.

Although other polypeptides were carried into the DHPs, they were removed by pre-washing in water. Only two polypeptides (of apparent Mrs of 125 and 52 kDa) were consistently recovered from the DHPs by boiling in SDS-sample buffer (Fig. 1, lane d; Fig. 3, lane e) after the stringent pre-washing procedure. The 125 and 52 kDa polypeptides remained bound to the DHPs after successive extractions in 250 mM sodium acetate pH 5.0, 250 mM Tris pH 8.5 and 1 M NaCl. Therefore, it is unlikely that these polypeptides were bound to charged groups, which, in any case, are rare in DHPs (Monties, 1989). As they were not extracted by 1 M NaCl containing 0.5% Triton X-100, it is unlikely that hydrophobic interactions were involved. On this point, it was also noted that the addition of pre-formed DHPs to incubations did not cause the diminution of any polypeptide (Fig. 4, lane d). These observations indicate that the diminished polypeptides did not adsorb to the surfaces of the insoluble polymers.

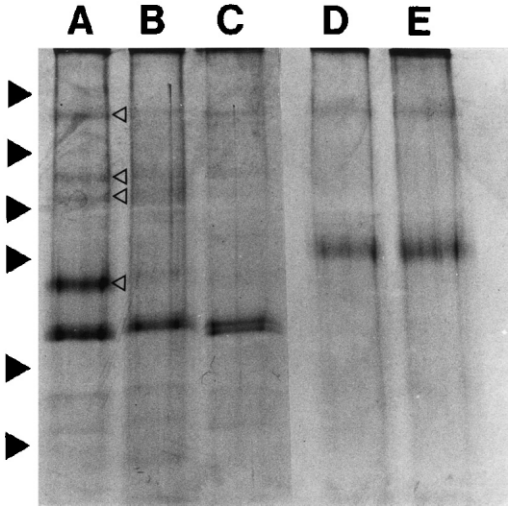

Fig. 1. Insolubilisation of xylem proteins and DHP formation. Lanes a–c contain the equivalent of 2 μg protein (based on the protein content of the original extracts) of the supernatants from the control reaction (a), + H_2O_2 reaction (b) and the + H_2O_2 + CA reaction. Lanes d and e are replicates and represent one-fifth of the DHP-bound sample. Closed triangles denote the migration of the molecular mass marker proteins at 175, 83, 62, 47.5, 32.5 and 25 kDa respectively. Open triangles mark the polypeptide bands discussed in the text.

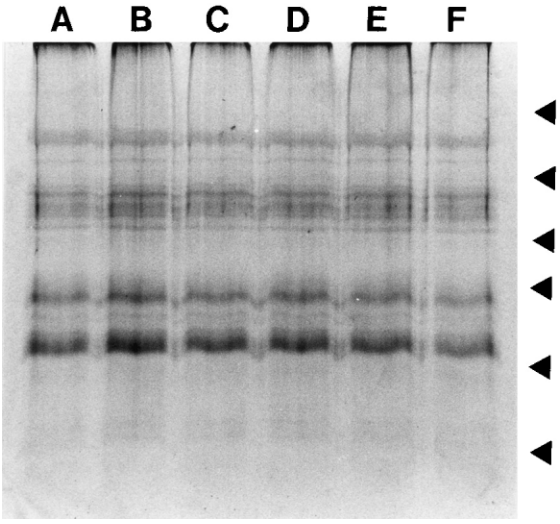

Fig. 2. Effect of H_2O_2 concentration on insolubilisation of xylem proteins. All lanes contain the equivalent of 2 μg protein (based on the protein content of the original extracts) of the supernatants from the various reactions. Lane a = control, lane b = 1 mM H_2O_2, lane c = 5 mM H_2O_2, lane d = 10 mM H_2O_2, lane e = 25 mM H_2O_2 and lane f = 35 mM H_2O_2. Closed triangles denote the migration of the molecular mass marker proteins at 175, 83, 62, 47.5, 32.5 and 25 kDa respectively.

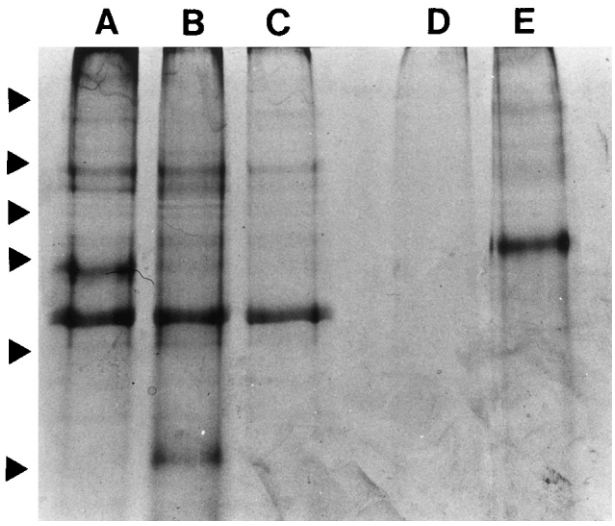

Fig. 3. Insolubilisation of xylem proteins and DHP formation. Lanes a–c contain the equivalent of 2.5 μg protein (based on the protein content of the original extracts) of the supernatants from the control reaction (a), $+H_2O_2$ reaction (b) and the $+H_2O_2+$CA reaction (c). Lane d contains half of the $+H_2O_2$ pellet sample and lane e contains one-fifth of the DHP-bound sample from the $+H_2O_2+$CA reaction. Closed triangles denote the migration of the molecular mass marker proteins at 175, 83, 62, 47.5, 32.5 and 25 kDa respectively.

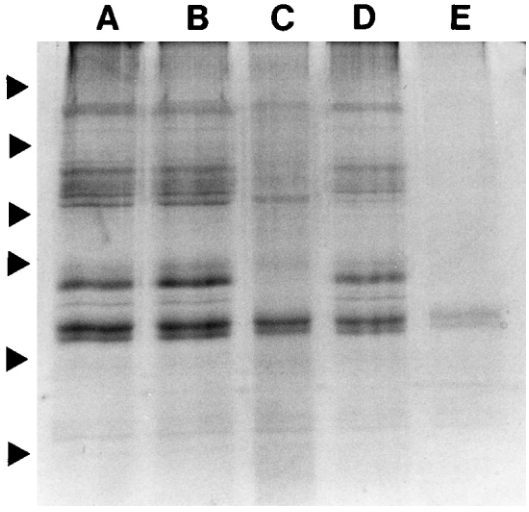

Fig. 4. Insolubilisation of xylem proteins and DHP formation. Lanes a–e contain the equivalent of 2.5 μg protein (based on the protein content of the original extracts) of the supernatants from the control reaction (a), the +CA reaction (b), $+H_2O_2$ reaction (c), the reaction containing pre-formed CA-DHPs (d) and the $+H_2O_2$ +CA reaction (e). Closed triangles denote the migration of the molecular mass marker proteins at 175, 83, 62, 47.5, 32.5 and 25 kDa respectively.

The abundance of the 125 and 52 kDa DHP-bound polypeptides with the DHPs appeared to mirror the diminution of the 120 and 46 kDa bands from the ConA bound extract (see Figs. 1 and 3). The 125 and 52 kDa DHP-bound polypeptides yielded N-terminal protein sequences that were essentially identical to the sequences obtained from the 120 and 46 kDa polypeptides (respectively) from the ConA bound extract (Table 2). This strongly suggests that the DHP-bound polypeptides were derived from these polypeptides. The sequence of the 125/120 kDa polypeptides was identical to a polypeptide previously identified in a study of cell-wall-associated glycoproteins that were more abundant in the developing xylem of compression wood than non-compression wood of Sitka spruce (McDougall, 2000). This sequence was identified as a laccase-type polyphenol oxidase (EC. 1.10.3.3) by its homology with a number of plant laccases (Table 2). The sequence had greatest homology with one of the four laccase genes from the developing xylem of *Liriodendron tulipifera*, Laccase 2–4 (65% identity and 85% similarity) (Lafayette et al., 1999) but it also had considerable homology to an *Arabidopsis* EST for a putative laccase (T9I4.21) and a laccase (Poplar-110) from poplar xylem (Ranocha et al., 1999). In addition, the amino-terminal sequence of the Sitka protein could be aligned exactly with the amino-terminal residues predicted (Nielsen et al., 1997) or observed for these proteins. Moreover, the 125/120-kDa polypeptide had homology (53% identity) with an EST sequence from the developing xylem of Loblolly pine (*Pinus taeda*) which, in turn, had considerable homology to other plant laccase genes over its full sequence (Allona et al., 1998).

The 52/46kDa polypeptide was homologous, particularly in the residues 6 to 15, with the amino-terminal sequences of peroxidases (EC. 1. 11.1.7) from *Arabidopsis*, *Vigna angularis*, *Glycine max*, *Oryza sativa* and an EST clone from *Pinus taeda* (Table 1). This sequence was also similar to a polypeptide of apparent M_r 48 kDa (QDDEPPXXKE) that was more abundant in extracts of cell-wall-associated glycoproteins from the developing xylem of compression wood of Sitka spruce than non-compression wood (McDougall, 2000).

After the multi-step washing procedure, the insoluble DHPs retained oxidase and peroxidase activity at approximately 10 and 3% respectively of the total activities of the extract (results not shown). It was not possible to judge whether the peroxidase or oxidase activities of the supernatants were reduced after the formation of the DHPs. CA (and its oxidation products) remained in the supernatants even after desalting on PD-10 columns (results not shown) and were oxidised in preference to ABTS (Richardson et al., 1997). However, peroxidase activity was readily detected in the supernatant samples after non-denaturing SDS-PAGE and staining with *o*-dianisidine/H_2O_2 (Fig. 5). The predominant peroxidase activity in all samples was centred on 36 kDa (Fig. 5, lanes a–d).

The mechanism of insolubilisation of the laccase and peroxidase enzymes is unclear but it is possible that the enzymes became attached to the DHPs as they catalysed their formation. The insolubilisation of peroxidases that catalyse the formation of DHPs has been reported

[a] Each sequence begins at the predicted or observed N-terminal residue. Codes for ESTs are given in parentheses. Potential N-glycosylation sequons are underlined.

[b] ID denotes identity.

[c] S denotes similarity.

[d] N denotes number of residues compared.

[e] The blank cycle at residue 17 of the 120/5-kDa polypeptide was preceded and followed by good quality cycle peaks and coincides with an asparagine residue in a potential *N*-glycosylation consensus sequon (i.e. N-X-S/T where X can be any amino acid residue except P; see Hubbard and Ivatt, 1981) in all the other sequences. Therefore, this blank cycle was most likely to be due to a glycosylated asparagine residue as the hydrophilic glycosylated-Asn-anilinothiazolinone (ATZ) derivative formed during Edmann degradation is not recovered.

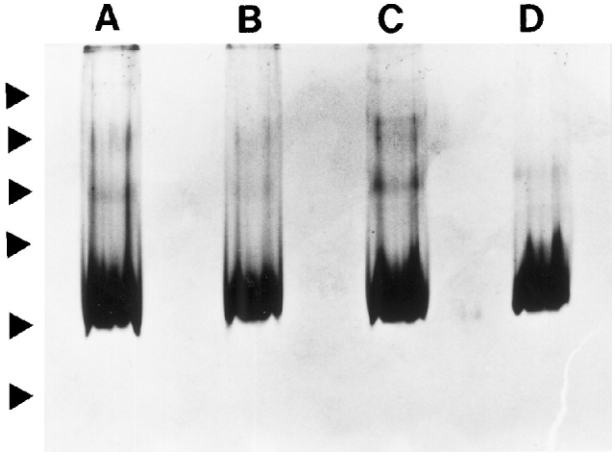

Fig. 5. Peroxidase activities of supernatant samples after separation by ND SDS–PAGE. Equivalent volumes of supernatants were separated by ND SDS–PAGE then stained for peroxidase activity using *o*-dianisidine/H_2O_2. Lane a = control reaction, lane b = + CA reaction, lane c = + H_2O_2 reaction and lane d = + H_2O_2 + CA reaction. Closed triangles denote the migration of the molecular mass marker proteins at 175, 83, 62, 47.5, 32.5 and 25 kDa respectively.

(Evans and Himmelsbach, 1991) and oxidase activity in similar extracts of Sitka xylem can oxidise and polymerise CA to water-insoluble DHPs (Deighton et al., 1999). Considering that the DHP-bound polypeptides have higher apparent M_rs than their putative precursors (125 and 52 kDa versus 120 and 46 kDa), these polypeptides may have been covalently modified during the formation of DHPs, presumably by the addition of CA groups. Testing this hypothesis would require the purification and comparison of the soluble and DHP-bound polypeptides. It has been suggested that peroxidases become covalently attached to lignin, whilst catalysing its polymerisation, through linkages between tyrosine residues and the growing lignin polymer (Evans and Himmelsbach, 1991; McDougall, 1993a). Indeed, there is evidence that tyrosine residues enhance the incorporation of synthetic proteins into DHPs during the peroxidase-catalysed polymerisation of CA (McDougall, 1996). It has also been suggested that the near-invariant tyrosine residue, found close to the N-terminal of plant peroxidases, was particularly well situated to be involved in such a linkage (McDougall, 1993b). However, the N-terminal protein sequences of both the DHP-bound peroxidase and laccase-type oxidase contained tyrosine residues in their expected positions. This suggests that these tyrosine residues were available to the sequencing reactions and were not involved in cross-links.

The selective insolubilisation of the 46 kDa peroxidase into the DHPs is intriguing, as it was a minor component of the peroxidase profile of the supernatants as judged by ND SDS-PAGE (Fig. 5). However, the 46 kDa peroxidase may have a low affinity for the oxidation of *o*-dianisidine but a particular affinity for the oxidation and polymerisation of CA. It may have been predominantly responsible for the formation of the DHPs and, indeed, Zimmerlin et al. (1994) reported that a 46 kDa cationic cell-wall-associated peroxidase from French bean had high specificity for the oxidation of ferulic acid.

On the other hand, the 46 kDa peroxidase and the 120 kDa laccase may have structural motifs that lead to

their insolubilisation. Welinder et al. (1996) aligned the available N-terminal sequences of *Arabidopsis* peroxidases and identified 28 sub-groups. The peroxidases with the greatest homology to the Sitka 46 kDa sequence belong to a sub-group that has a longer N-terminal sequence before the near-invariant FY motif than other peroxidases. A cysteine-rich peptide motif has been identified that mediates the insolubilisation of proteins into cell walls (Domingo et al., 1999) and a novel peroxidase with structural protein-like properties from *Scutellaria* (Morimoto et al., 1999), which rapidly became insolubilised to the cell wall in the presence of H_2O_2, has been discovered. However, the sequences that are most homologous to the 46 kDa Sitka peroxidase and the 120 kDa Sitka laccase do not contain similar structural motifs.

Although the conditions for the formation of the DHPs (70 mM H_2O_2 and 10 mM CA) are unlikely to exist in vivo, the selective insolubilisation of oxidases and peroxidases into DHPs in vitro may have parallels in lignifying tissues. If peroxidases and oxidases became cross-linked to lignin whilst catalysing its deposition, this could explain the accumulation of tightly bound peroxidase (e.g. Fukuda and Komamine, 1982; Abeles and Biles, 1991; McDougall, 1992) and oxidase activities (McDougall et al., 1994; McDougall and Morrison, 1996; Richardson et al., 1997) in the cell walls of lignifying tissues. The attachment of these enzymes to lignin during its formation would immobilise these enzymes and may limit the extent of lignification in the wall (McDougall, 1993a,b).

3. Experimental

3.1. Plant material

Branches of Sitka spruce (*Picea sitchensis* (Bong) Carr.) were obtained from the Forest Research clone bank at Ledmore, Perth and Kinross, Scotland, in late May 1998. In the laboratory, the developing xylem was carefully scraped from the old wood then frozen. The scraped tissue contained only enlarging and differentiating xylem cells, which were confirmed as lignifying cells by acid phloroglucinol staining (Kneebone, 1962).

3.2. Extraction procedure

Tissue was thawed then placed in an excess of ice-cold homogenisation buffer [25 mM MOPS pH 7.0 containing 0.5% v/v polyvinylpolypyrrolidine (PVPP) and 0.5 mM phenylmethylsulphonyl fluoride (PMSF)], homogenised in a Waring blender then in an Ultra-Turrax disintegrator (Deighton and McDougall, 1998). The insoluble residue was re-homogenised in buffer that lacked PVP and PMSF. These filtrates were discarded and the entire procedure was repeated ×3. The insoluble crude cell walls were extracted with 25 mM MOPS pH 7.0 containing 200 mM $CaCl_2$ (ConA buffer) for 1 h on ice with stirring. The high salt extracts were applied to Concanavalin-A (ConA) Sepharose columns (8 ml bed volume) and the eluate discarded. After a five-column volume wash of ConA buffer, the ConA-bound extract, enriched in cell-wall-associated glycoproteins (McDougall, 1997), was eluted with ConA buffer containing 100 mM α-methyl mannoside.

3.3. Assays for protein content and oxidase activity

Protein content was measured by the dye-binding method (Bradford, 1976). Peroxidase activity was determined by measuring the oxidation of 2, 2′-azinobis (3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) at A_{420} (Sterjiades et al., 1992). Oxidase activity was determined by measuring the increase in A_{420} due to the formation of the oxidised chromophore of ABTS in 1 h (Deighton and McDougall, 1998).

3.4. Production of dehydrogenation polymers (DHPs) of coniferyl alcohol

Assays were based on the method of Tsutsumi et al. (1998) and contained the Sitka ConA-bound extract and final concentrations of 10 mM coniferyl alcohol (CA) in 100 mM NaOAc pH 5.0. Reactions were started by the addition of an aliquot of 0.882 M (1/10 stock) H_2O_2 (equivalent to 36 mM) then a further aliquot of H_2O_2 was added after 30 min to a final concentration of 70 mM. After 60 min incubation at 30°C, insoluble DHPs were precipitated by centrifugation (15 000 rpm, 5 min, 8°C) and the supernatants carefully removed. Equivalent aliquots of the supernatants were precipitated using 2.5-fold excess of cold (−20°C) acetone. Control assays that lacked CA, H_2O_2 or the ConA-bound extract were also run. No DHPs were formed in these controls but putative insoluble material was put through the same washing procedures.

The DHPs were resuspended in an excess of washing solution, mixed well then recovered by re-centrifugation. The multi-step washing procedure consisted of successive 3×2 ml washes of H_2O, 250 mM sodium acetate buffer pH 4.0, 250 mM Tris-HCl pH 8.5, 1 M NaCl, 1 M NaCl containing 0.5% Triton X-100 then H_2O. The washed DHPs were resuspended in SDS–PAGE sample buffer, boiled for 5 min then centrifuged prior to analysis by SDS–PAGE. Twenty-fold larger incubations were used to obtain sufficient material for the sequencing experiments.

Insoluble DHPs, formed under the same conditions from horseradish peroxidase (SIGMA product P-8250) and coniferyl alcohol, were dissolved in 1, 4-dioxane then re-precipitated by the addition of excess water. These purified DHPs contained no bound peroxidase or other proteins (apparent by SDS–PAGE and silver staining)

and they were used to judge the effect of added preformed DHPs on the supernatant proteins.

3.5. Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS–PAGE)

Extracts were precipitated with acetone and separated on 10% acrylamide gels as described before (Richardson et al., 1997). Gels were stained using the Bio-Rad silver-stain method.

3.6. N-terminal protein sequencing

This procedure has been described before (McDougall, 2000). Sequence similarities were determined by the "BLITZ" method against the non-redundant protein and DNA databases maintained by the European Bioinformatics Institute (at http://www2.ebi.ac.uk/bic_sw). The loblolly pine cDNA sequence analysis project jointly run by the University of Minnesota and North Carolina State University (at http://www.cbc.umn.edu.researchprojects) was also searched. Where required, the positions of N-terminal residues of protein sequences derived from DNA sequences were predicted using the SignalP programme (at http://www.cbs.dtu.dk/services/SignalP). The sequence retrieval system at ExPASy Geneva (at http://www.expasy.ch/srs5) was also used.

Acknowledgements

I thank Julie Duncan for technical help, Dr. Heather Ross for expert guidance on protein sequencing and Professor Howard Davies for his support. I thank Dr. Steve Lee of Forest Research for access to the Sitka spruce clone bank. SCRI receives Grant-in-Aid from the Scottish Executive Rural Affairs Department.

Biosynthesis of diaporthin and orthosporin by *Aspergillus ochraceus*

Jonathan P. Harris, Peter G. Mantle *

Biochemistry Department, Imperial College of Science, Technology and Medicine, London SW7 2AY, UK

Received 26 July 2000; received in revised form 19 December 2000

Abstract

Diaporthin and orthosporin were characterised from the fungus *Aspergillus ochraceus* D2306. Diaporthin was identified by high-resolution electron impact mass spectrometry and ^{1}H and ^{13}C NMR spectroscopy, from which new spectroscopic assignments were made. Orthosporin was also identified by mass spectrometry and both fungal metabolites are reported for the first time as co-metabolites and also as products of *A. ochraceus*. The methylation inhibitor ethionine affected production of both diaporthin and orthosporin in spite of no obvious methylation step in the biosynthesis of orthosporin, implying that extracellular orthosporin may arise by de-*O*-methylation of diaporthin. The biosynthetic origin of diaporthin was demonstrated by incorporation of [1-^{14}C]acetate and [methyl-^{14}C]methionine administered in early idiophase. © 2001 Elsevier Science Ltd. Keywords: Aspergillus ochraceus; Polyketides; Biosynthesis; Diaporthin; Orthosporin

1. Introduction

Diaporthin (Fig. 1, **1**) was first described by Bazzigher (1953), who showed that it could reproduce symptoms of the canker of Chestnut trees caused by *Endothia parasitica* (Murr.) And. Epidemics of this disease had almost destroyed Chestnut forests in North America. Diaporthin from *E. parasitica* was further characterised and was shown to inhibit the growth of several bacteria and yeasts (Boller et al., 1957). Diaporthin structure was further explored by Hardegger et al. (1966) by ^{1}H NMR spectroscopy of diaporthinic acid (both as a product of anaerobic hydrolysis of diaporthin and of chemical synthesis) and diaporthinic acid derivatives.

Independently, orthosporin (de-*O*-methyldiaporthin; Fig. 1, **2**) was isolated from the plant pathogenic fungus *Drechslera siccans*, which causes irregular brown spots on leaves of oats, and of both perennial and Italian ryegrass (Hallock et al., 1988); limited physico-chemical data was obtained. Orthosporin caused necrosis when applied in solution to leaves of maize, crabgrass, soya bean, barnyard grass and spiny amaranth, but not to leaves of perennial ryegrass. Ichihara et al. (1989) isolated orthosporin from cultures of *Rhynchosporium orthosporum*, which causes leaf scald on orchard grass and, by treatment with diazomethane, obtained diaporthin and extended assignment of its NMR spectroscopic data.

No biosynthetic studies have previously been performed on diaporthin and it has only been reported as a metabolite of plant pathogens. The present study arose from finding several polyketide metabolites other than the important mycotoxin ochratoxin A (Fig. 2, **3**) in fermentations of the saprophytic fungus *Aspergillus ochraceus* (Harris, 1996). This study was, therefore, in the context of competing demands on acetate by pathways of secondary metabolism.

2. Results and discussion

In submerged fermentation, the production of diaporthin closely followed biomass accumulation by *A. ochraceus* D2306 (Fig. 3), both reaching a maximum value at approximately 100 h. Thereafter, the concentration of diaporthin declined, possibly by metabolic recycling analogous to that for the pentaketide citrinin (Barber et al., 1988). In the fermentation broth, orthosporin was a minor component, typically about half of the concentration of diaporthin; data are not shown since the purity of the HPLC peak could not always be assured in samples taken later in the fermentation.

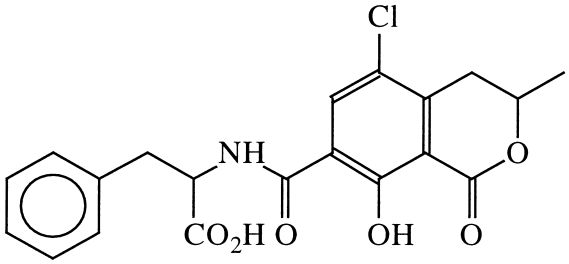
Fig. 1. Structures of diaporthin (**1**) and orthosporin (**2**).

The first biosynthetic experiment explored a range of precursor feeding times for [1-^{14}C]acetate and [methyl-^{14}C] methionine (Table 1) during the early stage of diaporthin accumulation and the consequent specific radioactivities of the diaporthin isolated at 168 h. Although measured during a phase of diaporthin decline, the highest specific activity from acetate was evident from feeding during mid-accumulation of diaporthin when most of the cellular replication had occurred. Measured radioactivity above background was in the range 120–730 dpm. This was more clearly evident concerning demonstration of



3

Fig. 2. Structure of ochratoxin A (**3**).

Table 1
The amount (μg) and specific radioactivity (dpm/μg) of [^{14}C]diaporthin recovered from *A. ochraceus* D2306 potato dextrose broth fermentations fed either [1-^{14}C]acetate (3.7 or 5 μCi) or [methyl-^{14}C]-methionine (2 μCi) at specified times

Experiment	Time (h)	Diaporthin amount (μg)	Specific radioactivity (dpm/μg)
1st [1-^{14}C]acetate feed	32	4	37
	50	9	60
	72	10	73
2nd [1-^{14}C]acetate feed	8	155	3
	22.5	63	35
	32	113	70
	50	52	93
[Methyl-^{14}C]methionine feed	32	6	20
	72	4	152

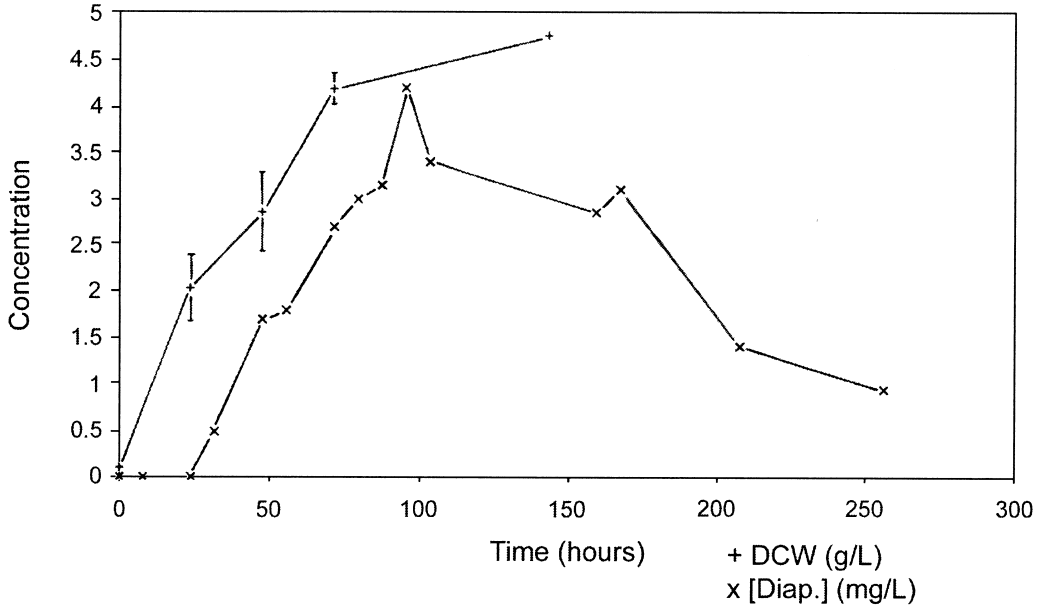


Fig. 3. Dry cell weight (DCW) and diaporthin concentration (Diap.) versus time for an *A. ochraceus* potato dextrose broth fermentation.

O-methylation of orthosporin (classified as a hexaketide by Turner, 1971) from [methyl-^{14}C]methionine, consistent with this probably being the last step in the biosynthesis of diaporthin.

A second experiment, using rather more radiolabelled acetate given over a wider range of early stages of fermentation and assessed with greater confidence (numerical values 465–7910 dpm) in the diaporthin isolated at 80 h, more clearly focused on the 50 h stage in giving the strongest evidence of acetate origin. This was in the context of the competing demands of primary and secondary metabolism on acetate.

Autoradiography of the TLC resolution of the diaporthin from these experiments showed a single radioactive area in each case, and combined eluates from these areas gave a typical mass spectrum for diaporthin.

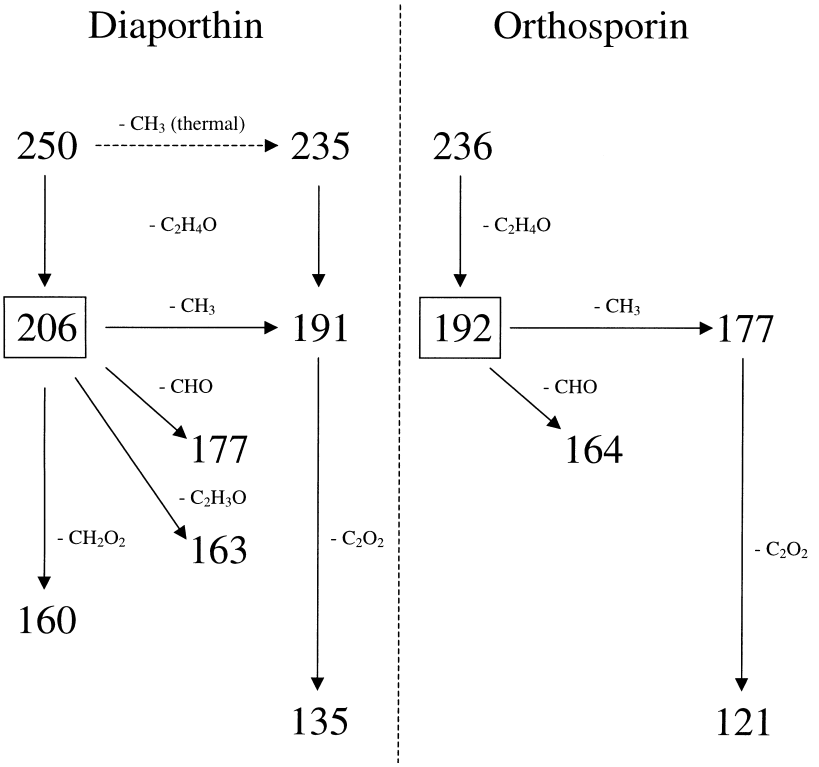
Table 2
The concentration of orthosporin and diaporthin 80 h post inoculation in *A. ochraceus* D2306 potato dextrose broth fermentations fed with 50 mg ethionine at specified times

Addition time (h)	Orthosporin (mg/l)	Diaporthin (mg/l)
32	0.3	0.5
50	0.9	1.4
56	0.9	1.8
72	1.4	2.9
Control	1.2	2.3

The methylation inhibitor ethionine had a marked effect on the yield of both diaporthin and orthosporin measured at 80 h, especially when added to fermentations at early stages in the accumulation of diaporthin (Table 2). In the assumption that diaporthin arises intracellularly by methylation of orthosporin, the influence of ethionine on the concentration of orthosporin in the fermentation broth might only occur if extracellular orthosporin arises through demethylation of diaporthin, analogous to the demethylation steps in the biosynthesis of opiate alkaloids (Mann, 1987).

Notably, neither orthosporin nor diaporthin were detected in similar fermentations of the five other *A. ochraceus* isolates tested.

New MS fragmentation data for diaporthin (Scheme 1) formed the basis for interpretation also of analogous HREIMS data for orthosporin to refine the schematic predictions of Hallock et al. (1988). The fully assigned ^{1}H NMR data for diaporthin was assisted by DEPT experiments, 500 MHz resolution of the signals for C9 protons, ^{1}H/^{1}H decoupling experiments and evidence that the aromatic protons at C5 and C7 are meta coupled. MS data for orthosporin conformed closely to that of Hallock et al. (1988).



Scheme 1. Interpretation of MS fragmentation of diaporthin according to linked scan (B/E) experiments and HREIMS data. Analogous fragmentations for orthosporin are matched according to HREIMS data.

3. Experimental

3.1. Aspergillus ochraceus isolates

The main study used an Australian isolate D2306 (Connole et al., 1981), also used in biochemical and toxicological studies (Tapia and Seawright, 1984; Mantle and Chow, 2000; Stander et al., 2000; Stoev et al., 2000) on account of its high ability to produce ochratoxin A. Occurrence of diaporthin was also tested in the classic ochratoxin-producing isolate NRRL 3174 (=ATCC 22947 as used by Madhyastha et al. (1990). Also three isolates from USA red and white beans marketed for food in the UK and which did not produce ochratoxin A were tested, as was one from Bulgarian wheat which produced only a trace of ochratoxin A (Mantle and McHugh, 1993).

3.2. Fungal culture

Isolates were grown to sporulate profusely on 20 g shredded wheat moistened with water (8 ml) in 500 ml Erlenmeyer flasks at 28 C for 3 weeks. The material was homogenised (Sorvall Omni-Mixer) in water to give spore inoculum for potato dextrose broth (Difco, 100 ml in 500 ml flasks, $2–4\times10^6$ spores ml^{-1}). Flasks were incubated at 28°C on a rotary shaker (200 rpm and 10 cm eccentric throw).

3.3. Measurement of fermentation dynamics

3.3.1. Biomass

At intervals 10 ml samples were taken from triplicate flasks for dry cell weight analysis. The broth was filtered through a pre-weighed sintered 10 ml syringe which was then freeze-dried to constant weight.

3.3.2. Diaporthin and orthosporin

The amounts of diaporthin and orthosporin were measured by extracting (as below) the broth of whole flasks at intervals. Solvent extract residues were dissolved in a standard volume of MeOH and 20 μl analysed by HPLC. The system used an isocratic mobile phase (H_2O: HOAc: acetonitrile, 59.5: 1: 39.5, v:v:v) at 1 ml min^{-1} through a Separon SGX C-18 column (150×5 mm, Kolona Chromatografika, Czechoslovakia) into a Hewlett Packard 1040 M diode array detector (monitoring wavelength 239 nm, Rt 3.5 min for diaporthin and 1.8 min for orthosporin) controlled by ChemStation software on an IBM 486 PC, calibrated for diaporthin quantification.

3.4. Isolation and characterisation of diaporthin and orthosporin

Twenty flasks of potato dextrose broth, incubated with *A. ochraceus* D2306 for 5 days, were filtered through sintered glass, the pH value adjusted to 3 (conc. HCl) and extracted with an equal volume of EtOAc. The organic phase was partitioned against 3% $NaHCO_3$ to remove acidic metabolites such as the ochratoxins, evaporated to dryness and the residue of neutral metabolites dissolved in MeOH for preparative HPLC. The first of two systems used an isocratic mobile phase of H_2O: HOAc: acetonitrile (59.5:1:39.5, v:v:v) at 5.6 ml min^{-1} through a Dynamax Macro C-18 column (30×2.5 cm) with UV absorbance detection at 239 nm (Pye Unicam PU4020). Fractions of enriched diaporthin (Rt 23 min) were concentrated and re-injected into the second system which differed only in the mobile phase (MeOH: H_2O, 70:30, v:v, Rt 15 mm). HREIMS of the isolated diaporthin (Micromass autospec Q, source temp. 210–220°C, electron energy 70 eV) was made, and linked scans (B/E) were performed on the four most abundant ions (m/z 250, 235, 206 and 191) using He as the collision gas in the first field-free region. NMR spectra of diaporthin in acetone-d_6 were obtained on a Bruker 500 MHz instrument.

A further 20 flask cultures incubated for 3 days were extracted for orthosporin, which was isolated for EIMS analysis by the protocol for diaporthin (Rt for orthosporin 14 and 13 min in the first and second HPLC systems, respectively).

The other *A. ochraceus* isolates described above were cultured similarly to determine whether they produced diaporthin and/or orthosporin.

3.5. Biosynthetic experiments

3.5.1. Experiment 1

[1-^{14}C] Sodium acetate (3.7 μCi) was added to a flask culture at 32, 50 or 72 h post-inoculation, whilst [methyl-^{14}C]methionine (2 μCi) was added to another flask at 32 or 72 h post-inoculation. Cultures were incubated until 168 h post-inoculation and then extracted.

3.5.2. Experiment 2

[1-^{14}C] Sodium acetate (5 μCi) was added to a flask at 8, 22.5, 32, or 50 h post-inoculation. Cultures were incubated until 80 h post-inoculation and then extracted.

A portion (10–25%) of each culture extract was analysed by HPLC, quantifying the diaporthin (peak purity indicated from diode array data) and collecting the corresponding eluate for scintillation counting. Ecolume scintillant (8 ml, ICN Biomedicals, California, USA) was mixed with the eluate, refrigerated overnight and counted three times for 1 min in an Intertechnique SL 30 liquid scintillation counter, when reproducible values were obtained. Specific radioactivities of the [^{14}C]diaporthin were calculated. Confirmation that radioactivity resided specifically in diaporthin was obtained by autoradiography (Fuji RX film for 4 weeks at −70°C) of 2-dimensional chromatograms (Polygram SW G/UV254

plates, 10×10 cm) developed first in xylene: MeOH: HOAc (90:5:5, v:v:v, R_f 0.33) and then in toluene: EtOAc: HCO_2H (5:4:1, v:v:v, R_f 0.64). Silica corresponding to the radiolabelled diaporthin was eluted with propan-2-ol and the eluate analysed by EIMS.

3.6. Methylation inhibition with ethionine

The methylation inhibitor ethionine (10 ml of a 5 mg ml^{-1} sterile solution) was added to a flask culture at 32, 50, 56 or 72 h post-inoculation. Sterile H_2O was added similarly to a control culture. Cultures were incubated until 80 h, when the broth was extracted and diaporthin and orthosporin quantified.

3.7. Diaporthin

^1H NMR (500 MHz, acetone-d_6): δ; 1.23 (3H, *d*, $J=6.3$ Hz, H-11), 2.57 (H, *dd*, $J=14.3$, 7.8 Hz, H_A-9), 2.62 (H, *dd*, $J=14.3$, 4.9 Hz, H_B-9), 3.90 (H, *s*, H-12), 4.16 (H, *m*, H-10), 6.45 (H, *d*, $J=2.3$ Hz, H-5), 6.48 (H, *s*, H-4), 6.53 (H, *d*, $J=2.4$ Hz, H-7). ^{13}C NMR (125.8 MHz, acetone-d_6): δ; 23.6 (C-11), 43.9 (C-9), 56.2 (C-12), 65.5 (C-10), 100.6 (C-8a), 100.9 (C-7), 101.9 (C-5), 106.5 (C-4), 140.8 (C-4a), 156.7 (C-3), 164.2 (C-8), 167.1 (C-6), 167.9 (C-1).

Abstract

To gain a better understanding of brassinosteroid biosynthesis, the levels of brassinosteroids and sterols related to brassinolide biosynthesis in *Arabidopsis*, pea, and tomato plants were quantified by gas chromatography-selected ion monitoring. In these plants, the late C-6 oxidation pathway was found to be the predominant pathway in the synthesis of castasterone. Furthermore, all these plant species had similar BR profiles, suggesting the presence of common biosynthetic control mechanisms. The especially high levels of 6-deoxocathasterone and 6-deoxocastasterone may indicate that their respective conversions to 6-deoxoteasterone and castasterone are regulated in planta and hence are important rate-limiting steps in brassinosteroid biosynthesis. Other possible rate-limiting reactions, including the conversion of campestanol to 6-deoxocathasteonre, are also discussed. Tomato differs from *Arabidopsis* and pea in that tomato contains 28-norcastasterone as a biologically active brassinosteroid, and that its putative precursors, cholesterol and its relatives are the major sterols. © 2001 Elsevier Science Ltd. 1. Introduction

Brassinosteroids (BRs) are steroidal hormones that regulate plant growth. Brassinolide is the most bioactive of all the naturally occurring BRs and is derived from castasterone, which, in turn, is synthesized via either the early C-6 oxidation or late C-6 oxidation pathways, as shown in Fig. 1 (Choi et al., 1997; Fujioka and Sakurai, 1997; Sakurai, 1999; Fujioka et al., 2000). Mutants defective in either BR biosynthesis or sensitivity were isolated from *Arabidopsis thaliana* L., garden pea (*Pisum sativum* L.) and tomato (*Lycopersicon esculentum* M.). These mutants have a characteristic dwarf phenotype (for reviews, see Yokota, 1997; Clouse and Feldmann, 1999) and have provided proof that BRs play a hormonal role in the growth and development of plants.

It is essential that the concentration of plant hormones is regulated to sustain normal plant growth. To maintain this hormone homeostasis there needs to be a balance of biosynthesis and metabolism or inactivation (Yokota, 1999). The aim of this work was to examine how BR biosynthesis is controlled in planta. To this end all BRs and sterols related to brassinolide biosynthesis in *Arabidopsis*, pea, and tomato were quantified by GC–SIM and the data obtained are discussed in the context of defining the possible control points on an assumption that the levels of intermediates should be elevated prior to the control biosynthetic steps. Furthermore, it is demonstrated that tomato shoots are rich in cholesterol and related 28-norsterols, which are the likely precursors

of 28-norcastasterone that has been identified as a bioactive BR by Yokota et al. (1997).

2. Results and discussion

In order to quantify all the biosynthetic precursors of brassinolide, it is necessary to know their precise chromatographic properties when using procedures such as charcoal chromatography, Sephadex LH-20 chromatography, silica gel chromatography, reversed-phase HPLC, and gas chromatography. We found that charcoal and Sephadex LH-20 can separate various BRs as a group (see Section 4). Elution profiles of BRs on silica gel column chromatography are shown in Table 1 and use of ethanol-free chloroform was found appropriate, as elution profiles were altered when commercial chloroform was used. Table 1 also summarizes the elution profiles of BRs in reversed-phase HPLC using water-acetonitrile gradients. Table 2 shows the retention times of BRs in GC, as well as mass spectrometric data obtained by GC–SIM. The levels of BRs in *Arabidopsis* seedlings, pea and tomato shoots are shown in Table 3. The quantitative data of campestanol and unsaponifiable bulk sterols in *Arabidopsis*, pea and tomato are shown in Table 4. The relevant GC–MS data are listed in Table 5.

The present work revealed that a higher concentration of the late C-6 oxidation pathway metabolites exist in all plants (Table 3). In contrast to the high levels of 6-deoxocathasterone in these tissues, no trace of cathasterone, a key intermediate in the early C-6 oxidation pathway could be detected. Some of the early C-6 oxidation pathway metabolites were detected at quite low levels in *Arabidopsis* and pea, but no trace was found in tomato. Thus, the late C-6 oxidation pathway is most likely the major biosynthetic route to castasterone in *Arabidopsis* and pea, while it is an exclusive route in tomato. Many higher plants including shoots of *Castanea crenata* (Arima et al., 1984), cultured cells of *Catharanthus roseus* (Choi et al., 1996) and pollen of *Cupressus arizonica* (Griffiths et al., 1995) contain 6-deoxoBRs at higher levels than 6-oxoBRs (for review, see Fujioka, 1999). Recently, Koka et al. (2000) revealed that 6-deoxoBRs are far more active than 6-oxoBRs in restoring the growth of the BR-deficient tomato mutant *dumpy*. Thus, it may be assumed that the late C-6 oxidation pathway is more prevalent and more important than the early C-6 oxidation pathway in many plants. Furthermore, the profiles of the late C-6 oxidation pathway metabolites were quite similar in *Arabidopsis*, pea and tomato (Table 3), suggesting the presence of common biosynthetic control mechanisms in each species. Tissues of the three species examined were all of different ages, suggesting that such biosynthetic control mechanisms is not transient but persistent through a considerably long growth period.

In these plant tissues, the most abundant BR is 6-deoxocastasterone (Table 3). The level of 6-deoxocastasterone is at least one order of magnitude higher than that of its metabolite castasterone, suggesting the conversion of 6-deoxocastasterone to castasterone is an important rate-limiting step. This reaction is catalyzed by the DWARF enzyme (Bishop et al., 1999). Thus, it is likely that the level or activity of DWARF protein is

[c] Identified based on the spectral data of Goad and Akihisa (1997).

strictly regulated. Over-expressing the tomato *Dwarf* gene reduces the level of 6-deoxocastasterone 50-fold suggesting that the *Dwarf* gene is transcriptionally regulated (Bishop et al., 1999). However, in mutants which have a defect in the perception or signaling of BRs, the level of castasterone is dramatically increased, as seen in the pea mutant *lka* (Nomura et al., 1997, 1999), the *Arabidopsis* mutant *bri1-4* (Noguchi et al., 1999a) and the tomato mutant *curl-3* (T. Yokota, T. Nomura and G.J. Bishop, unpublished results, 1999). Thus, suppression of the DWARF protein activity or level in normal plants may be ascribed to feedback control by a repressor that is regulated through perception or signaling of BRs. Similar mechanisms have been proposed for the biosynthesis of the plant hormone gibberellin A1 by analyzing gibberellin insensitive mutants of *Zea mays, Arabidopsis* and wheat which accumulate gibberellins (Hedden and Kamiya, 1997).

The second most abundant BR after 6-deoxocastasterone was 6-deoxocathasterone in all the plant tissues examined. The levels of its product, 6-deoxoteasterone is two to three orders of magnitude lower. Thus, C-23 hydroxylation of 6-deoxocathasterone to 6-deoxoteasterone appears also to be a rate-limiting step. In *Arabidopsis*, C-23 hydroxylation in both the late and early C-6 oxidation pathways may be catalyzed by a CPD protein named CYP 90A (Szekeres et al., 1996, Altmann, 1998; Clouse and Feldmann, 1999). Recently the tomato *DUMPY* gene was demonstrated to be likely involved in C-23 hydroxylation (Koka et al., 2000). The transcription of the *CPD* gene has been found to be suppressed by active BRs through a feedback mechanism (Mathur et al., 1998). This indicates that the synthesis of 6-deoxoteasterone is also an important control point in BR biosynthesis.

It was postulated that C-22 hydroxylation of 6-oxocampestanol to cathasterone serves as the rate-limiting reaction in Madagascar periwinkle (*Catharanthus roseus*) cells because the level of the latter is extremely low as compared with the former (Fujioka et al., 1995). Such a proposition was also applied to *Arabidopsis* in which the C-22 hydroxylation is catalyzed by DWF4 protein designated CYP90B (Choe et al., 1998). Our data showed that the levels of 6-deoxocathasterone are ca. one to five hundredths as compared with its precursor campestanol in *Arabidopsis* and pea and one hundredth in tomato (Tables 3 and 4). This indicates that C-22 hydroxylation may also be a reaction that controls the BR biosynthesis in the late C-6 oxidation pathway. No molecular evidence to confirm this proposition, however, has yet been obtained.

The synthesis of campestanol from campesterol comprises four reactions in which 5α-reduction is included (Fujioka et al., 1997; Noguchi et al., 1999b). All of the three intermediates seem to have a short lifetime because their abundance is generally quite low in plants (Takatsuto et al., 1999). Irrespectively, the ratios of campestanol relative to campesterol were found to be small, namely 1:52 in *Arabidopsis*, 1:13 in pea and 1:20 in tomato, suggesting that this pathway may also be the control point of BR synthesis. However, this seems not to be always the case, because the level of campestanol is often comparable to that of campesterol in higher plant tissue such as *M. periwinkle* cells (Fujioka et al., 1995) and wheat seeds (Takatsuto et al., 1999).

Although campesterol is a precursor of C_{28} BRs, it is not a major sterol in *Arabidopsis*, pea and tomato compared to many other plants (Yokota, 1999). Conversely, major sterols like sitosterol are usually not preferred precursors of BRs (Yokota, 1997, 1999; Takatsuto et al., 1999). However, tomato is unique in that 28-norcastasterone, a C_{27} BR, is a major biologically active BR (Table 3) and, in accord with this, the sum of cholesterol and related C_{27} precursors account for about 60% of the total sterol amount (Table 4). Such C_{27} precursors

detected include lathosterol (5α-cholest-7-en-3β-ol) and, tentatively, lophenol (4α-methyl-5α-cholest-7-en-3β-ol) together with two unknown sterols 1 and 2, the mass spectra of which are reminiscent of those being early precursors of cholesterol (Table 5). It should be noted that these sterols were undetectable by total ion current monitoring in *Arabidopsis* and pea. 28-Norcastasterone may be synthesized from cholestanol derived from cholesterol similarly to the biosynthesis of castasterone from campestanol (Fujioka and Sakurai, 1997; Sakurai, 1999). Although cholestanol was identified from tomato in this study (Table 4), other putative downstream intermediates have not yet been analyzed. Synthesis of authentic BRs to assist in the identification of the intermediates is now in progress.

3. Concluding remarks

The relative levels of BR intermediates provide some indication as to likely control points in the biosynthesis of BRs. Especially three reactions in the late C-6 oxidation pathway, from campestanol to 6-deoxocathasterone, from 6-deoxocathasterone to 6-teasterone and from 6-deoxocastasterone to castasterone seem to be universally controlled at least in dicotyledonous plant species. It is also intriguing to investigate on why there appear to be multiple rate-limiting steps in the BR biosynthesis pathway. To this end, metabolic studies will be required using radioactive labeled intermediates. In addition the cloned biosynthetic genes will enable the transcriptional regulation of the biosynthetic pathway to be studied and provide further information as to the potential control points.

4. Experimental

4.1. Plant materials

The following plant tissues were used for BR analysis: (1) whole plants ($n = 271{,}191$ g fr. wt) of 26-day-old *Arabidopsis* (cv. Landsberg) grown in a growth room at 23°C under continuous light; (2) shoots ($n = 204$, 427 g fr. wt) of 19-day-old pea (cv. Torsdag) grown in a greenhouse at 20°C under natural photoperiod; and (3) apical shoots ($n = 35$, 192 g fr. wt) of 60-day-old tomato (cv. Ailsa Craig) grown in cabinets as described by Bishop et al. (1999). For sterol analysis, 20-day-old *Arabidopsis* plants, 11-day-old pea shoots, and 60-day-old tomato apical shoots were harvested.

4.2. Bioassay

To monitor the biological activity of BRs, sample aliquots were assayed by the rice lamina inclination test (Yokota et al., 1996).

4.3. Extraction and purification of BRs

The MeOH extract of the harvested materials was spiked with $^2H_6$-labelled BRs as internal standards before reduction to an aq. residue. The aq. residue was partitioned between EtOAc and 0.5 M K_2HPO_4. The EtOAc phase was evaporated to dryness and partitioned between hexane and 80% MeOH. The 80% MeOH phase was evaporated to dryness and the residual solid was purified on a silica gel column (Wakogel C-300; Wako Pure Chemicals, Osaka, Japan) eluted with $CHCl_3$ containing 0, 8, and 10% MeOH in the case of *Arabidopsis*, with $CHCl_3$ containing 0, 1, 7, and 10% MeOH in the case of pea, and with $CHCl_3$ containing 0, 10, and 20% MeOH in the case of tomato. Immediately before use, $CHCl_3$ was washed with H_2O to remove EtOH used as a stabilizer, washed with saturated NaCl, dried over anhydrous Na_2SO_4 and distilled. Based on the biological activity of the eluates and the elution profiles of authentic BRs (Table 1), the 8% MeOH fraction of *Arabidopsis*, and the combined 1 and 7% MeOH fractions of pea were applied to a charcoal column (chromatography grade; Wako Pure Chemicals) which was eluted with MeOH–H_2O (6:4 and 8:2, v/v), MeOH, MeOH–$CHCl_3$ (9:1, 7:3, 5:5, 3:7, and 1:9, v/v) and $CHCl_3$. The MeOH–$CHCl_3$ (9:1–3:7) fractions from charcoal column chromatography of *Arabidopsis* and pea, and the 10% MeOH fraction of silica column chromatography of tomato were then applied to a Sephadex LH-20 column (bed volume, 500 ml; Pharmacia) using MeOH–$CHCl_3$ (4:1) as a mobile phase. Successive 10-ml fractions were collected. Fractions 36–40 were combined, dissolved in MeOH and passed through columns of diethylaminopropyl silica (Bondesil; Varian, Palo Alto, CA) and octadecyl silica (ODS-SS-1020-T; Senshu Science, Tokyo, Japan). Reversed-phase HPLC was carried out on a Senshu Pak ODS-3251-D column (250×8 mm i.d.; Senshu Science) eluted with the following acetonitrile-H_2O gradient at a flow rate of 2.5 ml min^{-1}: 0–20 min, 45% acetonitrile; 20–40 min, 45–100% acetonitrile; 40–60 min, 100% acetonitrile. Fractions were collected every min. The column oven temp. was maintained at 40°C. Based on bioassay and the HPLC R_ts of authentic BRs (Table 1), BR fractions were collected for analysis by GC–MS/SIM.

4.4. Extraction and purification of sterols

Plant materials were extracted with MeOH–$CHCl_3$ (4:1), evaporated to dryness and partitioned between EtOAc and 0.5 M K_2HPO_4. A portion equivalent to 100 mg fr. wt of the EtOAc-soluble phase was spiked with [$^2H_6$]campestanol as an internal standard, evaporated to dryness and saponified with 1 N KOH in MeOH at 90°C for 1.5 h. The hydrolysate was diluted with H_2O and extracted with hexane. The hexane phase

was washed with H_2O, evaporated to dryness, dissolved in $CHCl_3$ and passed through a short silica gel column. The eluate was subjected to GC–MS/SIM analysis.

4.5. GC–MS/SIM analysis of BRs

BRs except cathasterone and 6-deoxocathasterone were converted to monomethaneboronate (MB) or bismethaneboronate (BMB) by heating at 70°C for 30 min with pyridine that contains 2 mg ml^{-1} methaneboronic acid. Typhasterol, teasterone, 6-deoxotyphasterol, and 6-deoxoteasterone were further treated with *N*-methyl-*N*-trimethylsilyl-trifluoroacetamide (MSTFA) at room temp. for 5 min to give MB-TMSi derivatives. Cathasterone and 6-deoxocathasterone were converted to TMSi derivatives with MSTFA-pyridine (1:4) at 70°C for 30 min. GC-EI MS/SIM (70 eV) was carried out on a JMS AX 505W instrument (JEOL, Tokyo, Japan) fitted with a DB-1 column (0.25 mm i.d.×15 m; 0.25-μm film thickness; J & W Scientific, Folsom, CA). The carrier gas was He at a flow rate of 1 ml min^{-1}, the injection port temp. was 280°C, and samples were introduced by splitless injection. The column oven temp. was programmed at 170°C for 1.5 min, before being elevated to 280°C at 37°C min^{-1}, and then to 300°C at 1.5°C min^{-1}. Identification of BRs was verified when the relative intensities of the M^+ ion and two daughter ions for each molecule were consistent with those of the corresponding deuterated internal standards (Table 2). The contents of BRs were calculated from the peak area ratios of $^2H_6$ and $^2H_0$ M^+ ions or $^2H_6$ and $^2H_0$ fragment ions. No internal standard was available for 28-norcastasterone, so that its level was determined from a calibration curve constructed from the peak area ratios of the M^+ ions of 28-norcastasterone and [$^2H_6$]brassinolide BMB derivatives.

4.6. GC–MS/SIM analysis of sterols

Sterol samples were trimethylsilylated with MSTFA at room temperature for 5 min, and then subjected to GC–MS/SIM using the same conditions used for BR analysis except that the column was a HP-5 Trace Analysis (0.2 mm i.d.×12 m; 0.33-μm film thickness; Hewlett Packard, Palo Alto, CA). Identification of sterols was conducted by comparing their full-scan mass spectra with those of authentic specimens (Table 5). In case of lophenol, the mass spectral data published by Goad and Akihisa (1997) were used as reference. The levels of sterols were determined by GC–SIM using calibration curves constructed from the ratios of the M^+ peak areas of [$^2H_6$]campestanol–TMSi to those of authentic respective sterols. The levels of lophenol, lathosterol, unknown sterol 1, and unknown sterol 2 were calculated from their total ion current trace areas, relative to that of [$^2H_6$]campestanol–TMSi.

Abstract

[5-^{3}H, 1′-^{14}C, $^{13}C_6$, ^{12}C] Indole-3-acetic acid (IAA), was applied to the flavedo (epicarp) of intact orange fruits at different stages of development. After incubation in the dark, at 25°C, the tissue was extracted with MeOH and the partially purified extracts were analyzed by reversed phase HPLC-RC. Six major metabolite peaks were detected and subsequently analyzed by combined HPLC-frit-FAB–MS. The metabolite peak 6 contained oxindole-3-acetic acid (OxIAA), indole-3-acetyl-*N*-aspartic acid (IAAsp) and also indole-3-acetyl-*N*-glutamic acid (IAGlu). The nature of metabolite 5 remains unknown. Metabolites 3 and 4 were diastereomers of oxindole-3-acetyl-*N*-aspartic acid (OxIAAsp). Metabolite 2 was identified as dioxindole-3-acetic acid and metabolite 1 as a DiOxIAA linked in position three to a hexose, which is suggested to be 3-(-*O*-β-glucosyl) dioxindole-3-acetic acid (DiOxIAGlc). Identification work as well as feeding experiments with the [5-^{3}H]IAA labeled metabolites suggest that IAA is metabolized in flavedo tissue mainly through two pathways, namely IAA–OxIAA–DiOxIAA–DiOxIAGlc and IAA–IAAsp–OxIAAsp. The flavedo of citrus fruit has a high capacity for IAA catabolism until the beginning of fruit senescence, with the major route having DiOxIAGlc as end product. This capacity is operative even at high IAA concentrations and is accelerated by pretreatment with the synthetic auxins 2,4-D, NAA and the gibberellin GA_3. © 2001 Elsevier Science Ltd. 1. Introduction

The flavedo of citrus fruit (epicarp) is the outer colored part of the fruit ca 1 mm thick. In addition to the pigments that provide the characteristic color to the fruit, this tissue is rich in essential oils and constitutes the first barrier of defense against pathogens. Plant growth regulators (PGRs) have an important influence on the flavedo during fruit development, and the effect of endogenous and applied PGRs have attracted considerable attention of basic and applied research (Baldwin, 1993).

Several experimental evidences suggest that auxins are ripening inhibitors, which have to be inactivated for the advancement of the maturation process (Frenkel, 1975; Given et al., 1988; Cohen, 1996). The concentration of IAA, the most important natural auxin in plants, is very low in *Citrus unshiu* during growth, except 2–3 weeks after full bloom (Takahashi et al., 1975) and exogenous IAA application has not been reported to have major effects on citrus peel coloration (Goldshmidt, 1988). By contrast, application of synthetic auxins such as 2,4-D, 2,4,5-T and NAA, which are not as easily metabolized as IAA by plant tissues, delay aging and the loss of green color, reduce external decay and improve keeping quality in citrus fruit (Dezakos, 1983). Consequently, caution should be exercised when analyzing these observations. In fact, it has been demonstrated that most of the IAA applied to tomato pericarp is inactivated in less than 10 h (Catalá et al., 1992), which could not be enough time to cause the expected responses. In this line of evidence, the effect of exogenous IAA application has been controversial; for example, the role of IAA in promoting cell elongation in intact plants could not be demonstrated

until a continuous auxin infusion system was used (Romano et al., 1995).

How a plant controls its hormonal metabolism to regulate its developmental events continues to be of interest. This is particularly important in the case of IAA, where the levels of the hormone seem to be very strictly regulated (Kawaguchi and Syono, 1996). The level of IAA in plant tissue is the balance of the biosynthesis, transport and inactivation pathways. Indoleacetic acid is metabolized by conjugation to sugars and amino acids and by hydroxylation and/or oxidation at various positions of the indole ring (Normanly, 1997; Normanly and Bartel, 1999). Deactivation of the hormone through such mechanisms is likely to be an integral part of the homeostatic control of IAA levels. Hence, structural as well as quantitative analysis of IAA metabolites is crucial for the elucidation of regulatory points in the catabolism of the hormone. In the present study, we analyze the chemical structure and metabolism of the major metabolite compounds and propose the main routes for IAA inactivation in the flavedo of orange fruits.

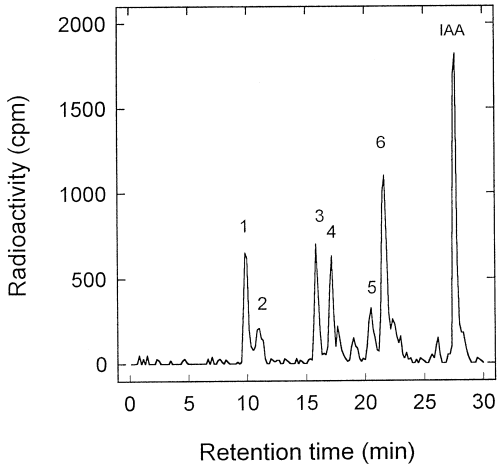

Fig. 1. Gradient elution reversed-phase HPLC-RC of an aliquot of a MeOH extract from orange flavedo tissue following application of 12.3 kBq [5-^{3}H]IAA (999 GBq mmol^{-1}) and incubation in the dark, at 25°C for 6 h. The identity of the metabolite peaks is: 1, DiOxIAGlc; 2, DiOxIAA; 3 and 4, diastereomers of OxIAAsp; 5, unidentified; 6, OxIAA and IAAsp.

2. Results

2.1. Decarboxylative/nondecarboxylative IAA metabolism

In a preliminary experiment we observed that crude extracts and excised discs of orange flavedo tissue had a high capacity to decarboxylate [1′-^{14}C]IAA but, when the labeled IAA was applied to the flavedo of intact fruits, decarboxylation could not be detected. These results suggest that IAA decarboxylation may be an artifact attributable to a wound induced increase in extracellular peroxidase activity and that the IAA fed to the flavedo is deactivated by nondecarboxylative mechanisms, in concordance with previous observations with tomato pericarp discs (Catalá et al., 1992, 1994). Gradient elution reversed phase HPLC-RC analysis of partially purified MeOH extracts of mature green orange flavedo tissue, fed with [5-^{3}H]IAA, showed 6 main metabolite peaks, all of which eluted before IAA and were designated in order of decreasing polarity from 1 to 6 (Fig. 1).

2.2. Identification of metabolite peak 1

The FAB spectrum of methylated metabolite 1 (Table 1a) contained $[M+H]^+$, m/z 384/390 (endogenous/[$^{13}C_6$] fragment), which corresponded to a methylated DiOxIAA-*O*-glucoside (3-(*O*-β-glucosyl)-2-indolone-3-HOAc). The fragment m/z 222/228 $[M+H\text{-}162]^+$

Table 1
Tabulated mass spectra of identified IAA metabolites[a]

Metabolite peak	Compound	$[MH]^+$	Other ions
(a) FAB spectra of methylated IAA metabolites			
1	DiOxIAGlc	384/390 (43/70)	222/228 (73/Bp), 206/212 (29/50), 205/211 (13/57), 204/210 (50/83), 146/152 (9/11)
2	DiOxIAA	228 (Bp)	212 (38), 211 (29), 210 (46), 152 (15)
3–4	OxIAAsp	341 (25)	204 (7), 180 (7), 162 (11), 152 (16), 102 (7)
6	IAAsp	325 (Bp)	162 (24), 136 (90), 102 (8)
6	IAGlu	339 (Bp)	136 (54)
(b) FAB spectra of methylated and acetylated IAA metabolites			
1	DiOXIAGlc	594/600 (11/7)	437/441 (7/13), 331 (Bp), 247/253 (9/13), 246/252 (10/19), 211 (4), 204/210 (6/12), 169 (21), 109 (12), 43 (9),

(c) Electron impact spectra of methylated and silylated IAA metabolites			
6	IAAAsp	396 (28)	208 (Bp), 136 (4), 73 (23)
6	IAGlu	410 (27)	208 (Bp), 135 (5), 73 (15)

[a] The intensity of non-labeled versus labeled peaks are presented in parentheses. Bp, base peak with relative intensity 100%.

corresponded to the loss of a Glc, leaving a protonated methylated DiOxIAA with further loss of H_2O from the methylated DiOxIAA, *m/z* 204/210 $[M\text{-}162\text{-}H_2O]^+$. Further, the oxidized indole appeared as a quinolonium ion, *m/z* 146/152. The loss of *m/z* 222/228 to *m/z* 204/210 $[m/z\ 222/228\text{-}H_2O]^+$, and not to $[m/z\ 222/228\text{-}O]^+$, was diagnostic for loss of an O in position 3 from a hydroxylated OxIAA. This was also confirmed by a quinolonium observed at *m/z* 146/152 since a OH, positioned elsewhere in the benzene ring, would have been retained in the quinolonium structure giving *m/z* 162/168, which was not present in the spectrum (Östin et al., 1995). Since the molecule was methylated in the carboxyl group and lacked specific fragments for N-linked sugars, the glucosylation must have occurred through the 3-positioned OH group (Östin et al., 1995).

The methylated and acetylated metabolite 1 (Table 1b) contained a $[M+H]^+$ at *m/z* 594/600, which corresponded to the incorporation of five acetyl groups. Four of these acetyl groups were incorporated into the Glc showing up in the fragment series *m/z* 331, 169, 109, 43. No double labeling of endogenous/fed [$^{13}C_6$]IAA was visible in these fragments, since the label was situated in the benzene ring of the oxidized indole. The relative intensities of this series of acetylated hexose peaks at *m/z* 169 > *m/z* 109 and the absence of a dominant *m/z* 211 excluded fructose and pointed at Glc, as deduced from spectra of acetylated sugars; however, galactose, lactose and mannose could not be excluded. The fifth acetyl group was linked to the N in the oxidized indole and the loss of Glc produced methylated/acetylated DiOxIAA with *m/z* 246/252; the quinolonium ion was present as *m/z* 146/152.

2.3. Identification of metabolite peak 2

The FAB spectrum of methylated metabolite 2 only contained peaks from the fed [$^{13}C_6$]IAA with a $[M+H]^+$ at *m/z* 228, corresponding to the methylated DiOxIAA characteristic fragmentation, $[M\text{–}H_2O]^+$, *m/z* 210, and the quinolonium ion, *m/z* 152 (Table 1a).

The protonated methylated/acetylated molecule of DiOxIAA was present as $[M+H]^+$, *m/z* 312. This corresponded to the incorporation of two acetyl groups, which were then sequentially lost as $[M\text{–}CH_3COOH]$, *m/z* 252 and $[MH\text{–}CH_3COO\text{–}CH_3CO]$, *m/z* 210 (Table 1b). The acetylation occurred through the OH groups in the 3 and N positions.

2.4. Identification of metabolite peaks 3 and 4

The metabolite peaks 3 and 4 were identified as stereoisomers of OxIAAsp as their methylated derivatives by LC–MS (Table 1a). The protonated molecule $[M+H]^+$, *m/z* 341, corresponded to the $^{13}C_6$-labeled compounds and no endogenous compounds were detected. The side chain with the methylated Asp gave the fragments *m/z* 204, *m/z* 162 and *m/z* 102. Loss of Asp retained the $^{13}C_6$ fragment *m/z* 180, with further quinolonium formation at *m/z* 152. The formation of the two stereoisomers, which rapidly isomerized into each other, were diagnostic of the oxindole (Plüss et al., 1989; Tuominen et al., 1994).

2.5. Identification of metabolite peaks 5 and 6

Metabolite 5 (Fig. 1) could not be identified in these experiments. The putative OxIAA and IAAsp comigrated in peak 6. In our study they were separated by TLC, after methylation, into two radiolabeled fractions corresponding to the retention time of the methylated OxIAA and IAAsp, respectively. The proportion of the two metabolites was 1:14 (OxIAA:IAAsp). However, the amount OxIAA obtained in this experiment was not enough to facilitate a complete identification. The identity of OxIAA was based on retention time in the two chromatographic systems, combined with the presence of DiOxIAA and DiOxIAGlc as products of the putative OxIAA in the feeding experiments (Table 2). The IAAsp peak was also found to contain IAGlu. IAAsp was identified in GC–MS as its methylated silylated derivative with its $^{13}C_6$-labeled molecular ion $[M]^+$, *m/z* 396, and formation of the silylated quinolinium ion, *m/z* 208, and quinolinium ion, *m/z* 136. The TMSi group was represented by *m/z* 73 (Table 1c). The LC–MS spectrum of the methylated IAAsp contained a $[M+H]^+$ at *m/z* 325 and a quinolinium ion at *m/z* 136, as well as the fragment *m/z* 162 and its immonium fragment 102 (Table 1a). IAGlu was identified by GC–MS as its methylated silylated derivative with its $^{13}C_6$-labeled molecular ion $[M]^+$, *m/z* 410, and formation of the silylated quinolinium ion, *m/z* 208, the TMSi group was represented by *m/z* 73 (Table 1c). The LC-MS spectrum of the methylated IAGlu contained a protonated molecule $[M+H]^+$ at *m/z* 339 and a quinolinium ion at *m/z* 136 (Table 1a).

2.6. Metabolism of the main IAA metabolites by orange flavedo

The results of these experiments are depicted in Table 2. When putative OxIAA was fed to the flavedo, two metabolite peaks with the same retention time as DiOxIAA and DiOxIAGlc, respectively, were obtained. Application of DiOxIAA to the tissue produced one metabolite peak with the same retention time as DiOxIAGlc, while feeding with the putative DiOxIAAGlc did not result in any further conversions. These results suggest the following metabolic sequence IAA–OxIAA–DiOxIAA–DiOxIAGlc. Metabolism of IAA has been reviewed by Bandurski et al. (1995), Normanly (1997) and Normanly and Bartel (1999). IAAsp and/or OxIAA appear to be the first committed step of non-decarboxylative

Table 2
Metabolism of the main orange flavedo IAA metabolites[a]

Metabolite fed	Incubation time. (h)	Percentage of radioativity in the extract

[a] Ten microlitres of a soln containing ca 12.5 kBq of the purified [5-^{3}H]IAA metabolite indicated in each case (figures in bold) were applied to the surface of the equatorial part of the peel. After incubation, the flavedo MeOH extracts were analyzed by HPLC-RC. Radioactivity associated with IAA metabolites expressed as % of total radioactivity in the extract ±S.D. ($n=3$).
[b] and [c] Are diastereomers of OxIAAsp, corresponding to metabolite peaks 3 and 4 (Fig. 1), respectively.

oxidation of IAA. The OxIAA/DiOxIAA oxidation pathway has been observed in several plant species including rice, corn, broad bean and *Arabidopsis*. One of the most established catabolic pathway has been described for *Zea mays*, where IAA is converted to OxIAA as the first step in a route leading to 7-Glc–OxIAA, which has been hypothesized to accumulate in the vacuoles. (Nonhebel et al., 1985). In the flavedo, we have shown that OxIAA is converted to DiOxIAGlc, following a novel catabolic pathway. The presence of a Glc in the indole ring as a major "end product" of the OxIAA pathway had only been reported previously in *Zea mays* by Nonhebel et al., 1985.

We have also shown that application of IAAsp to the flavedo produced two peaks identified as the two diastereomers of OxIAAsp and, when these diastereomers were fed separately, a similar profile was obtained showing both isomers, but no further metabolism could be detected, suggesting the metabolic sequence IAA–IAAsp–OxIAAsp. Metabolism of IAAsp to OxIAAsp has also been described in several plant species such as in cuttings (Plüss et al., 1989) and shoots (Tuominen et al., 1994) from *Populus*; in this latter case, OxIAAsp was converted to OxIAA and subsequently hydroxylated in the benzene ring. In *Dalbergia dolichopetala* (Östin et al., 1992) IAAsp has been proposed as an intermediate giving rise to both DiOxIAAsp and ring hydroxylated OxIAAsp derivative. Another pathway having IAAsp as an intermediate has been described in *Vicia faba* cotyledons (Tsurumi and Wada, 1985, 1986a,b) through the formation of DiOxIAAsp, having probably OxIAAsp as an intermediate which, in turn, is transformed into Glc–DiOxIAAsp and then transported to the roots. In tomato fruit the IAAsp pathway leads to OxIAAsp, linked to a diglucoside in the N position (Östin et al., 1995).

When the unidentified metabolite peak 5 was fed to the flavedo, only one major peak, with the same retention time as the metabolite fed, was obtained, suggesting that this is a catabolic end product or a non utilised storage form.

2.7. Effect of incubation time and maturity on [5-^{3}H]IAA metabolism

Table 3 shows the results of three representative moments in the study i.e. green, turning (start of change

Table 3
Effect of incubation time and maturity on the metabolism of [5-H]IAA by orange flavedo tissue[a]

Fruit maturity	Incubation time (h)	Percentage of radioativity in the extract						
		DiOxIA-Glc	DiOxIAA	OxIAAsp	OxIAAsp	Unidentified peak 5	IAAsp + OxIAA	IAA

[a] Ten microlitres of a soln containing 12.3 kBq [5-^{3}H]IAA, 999 GBq mmol^{-1} were applied. After incubation, the flavedo MeOH extracts were analyzed by HPLC-RC. Radioactivity associated with IAA metabolites expressed as % of radioactivity in the extract ±S.D. ($n=3$).

in peel color), and fully colored senescent fruit. In green and turning fruits, most of the [5-^{3}H]IAA taken up by the tissue was metabolized in less than 24 h, while, in orange colored senescent tissue, the metabolism was considerably slower. DiOxIAGlc accumulated to the greatest extent at the end of the incubation period, DiOxIAA accumulated from the beginning, but at a lower extent and peaked at 24 h of incubation. The two diastereomers of OxIAAsp soon reached maximum and equivalent concentrations, thereafter decreasing slowly. Metabolite 5, which was not identified, accumulated after 6–12 h incubation. Metabolite peak 6, identified as a mixture of IAAsp and OxIAA, accumulated rapidly during the first hours of incubation and then decreased, as they were further metabolised. In orange senescent fruit the degradation of IAA was much slower and higher levels of the metabolite peak 6 could be observed. This could probably be attributed to the accumulation of OxIAA, as a result of the decline of its metabolism to DiOxIAA and DiOxIAGlc. In green tissue, the most abundant metabolite after 48 h incubation was DiOxIAGlc. An estimation about the relative abundance of the metabolites formed in these experiments indicated that the route branching from OxIAA, in green and turning tissue, would account for 50–60% of IAA metabolism; the IAAsp route would take 15–25%, while metabolite 5 would account for 5–10% of total IAA metabolism. In senescent tissue the metabolism of IAA was strongly reduced and, after 48 h of incubation, 30% of the [5-^{3}H]IAA remained unmetabolized.

2.8. Effect of IAA concentration

When applying growth substances to plant tissues, the question always arises as to whether apparent metabolism actually represents detoxification of an abnormally large amount of exogenous compounds. Increasing IAA concentrations from 1.23 to 12.3 μM scarcely affected the pattern of IAA metabolism, while increasing the concentration to 123 μM resulted in an increase of unmetabolized IAA, a decrease in metabolites OxIAAsp, DiOxIAA, DiOxIAGlc, and a progressive accumulation of unidentified metabolite 5, OxIAA and IAAsp (Table 4). *Arabidopsis* fed with low concentrations of tritiated IAA (Östin et al., 1998) produced mainly OxIAA and much smaller proportions of the conjugates IAAsp and IAGlu. Increasing the concentration of the IAA fed induced a larger proportion of the amino acid conjugates formed. A similar shift in metabolism seems to be valid even for the orange flavedo tissue with DiOxIAGlc as the final product in the OxIAA pathway and OxIAAsp in the IAAsp pathway.

2.9. Effect of treatment with plant growth regulators

The effect of PGRs in plant tissues depends on a complex network of interactions. It has been speculated that one hormone may influence the stability and metabolism of a second one (Palni et al., 1988). In Table 5, it can be observed that pre-treatment with the synthetic auxins, 2,4-D, NAA and the giberellin GA_3 increased

Table 4
Effect of substrate concentration on [5-^{3}H]IAA metabolism of orange flavedo tissue[a]

Applied IAA (μM)	Incubation time (h)	Percentage of radioativity in the extract

[a] Fruits were submerged 30 min in a 1 mM soln of the hormone. Then, 10 μl of a soln containing 12.3 kBq [5-^{3}H]IAA (99 GBq mmol^{-1}) were applied. After incubation, the flavedo MeOH extracts were analyzed by HPLC-RC. Radioactivity associated to IAA metabolites expressed as % of total radioactivity in the extract ±S.D. ($n=3$).

IAA metabolism during the first 5 h of incubation. For longer periods, no changes could be observed because of the low levels of unmetabolized IAA remaining in the tissue.

3. Conclusions

Despite a number of papers dealing with IAA metabolism in different plant systems, only in a few cases a more comprehensive overview, particularly for non-decarboxylative catabolism, has been found in the last years (Kleczkowski and Schell 1995; Normanly, 1997). It is still of interest to extend these studies to a representative number of plant systems to know what is common and what is different among them. In fruits, only the tomato, a climacteric fruit characterized by an upsurge of respiration and ethylene production associated to ripening, catabolism has been comprehensively approached; in this case the IAAsp pathway leads to OxIAAsp, linked to a diglucoside in the N position (Östin et al., 1995). In our studies with oranges, first of this nature in non-climacteric fruits, the OxIAA pathway is predominant for IAA inactivation, leading to DiOxIAGlc according to a novel pathway. The presence of a Glc in the indole ring as a major "end product" of the OxIAA pathway has only been reported previously in *Zea mays* by Nonhebel et al. (1985), with formation of 7-Glc-OxIAA. Glucosylation of

the indole ring is also a quite common "end product" of the OxIAAsp pathway in several plant systems, but only in *Vicia* seedlings has been shown that GlcDiOxIAAsp formed in the cotyledons is transported to the roots (Tsurumi and Wada, 1986b). By analogy, it could be suggested that these metabolites could be transported to other parts of the plant or engulfed by the vacuoles.

Despite their utility, feeding experiments are limited in several aspects, such as the difficulty to detect high turnover metabolites or the short timing of the experiments in relation to many physiological processes, which could conceal the fate of the so called "end products". The multiplicity and redundancy of reactions involved in the regulation of IAA levels are serious obstacles to the knowledge of the mechanisms involved in IAA homeostasis. Identification of the enzymes involved in IAA metabolism, and isolation of the corresponding genes, coupled to the introduction of *Arabidopsis*, a model system with outstanding possibilities, has improved considerably, in the last years, our knowledge of auxin biology (Leyser, 1997; Normanly and Bartel, 1999). While biosynthesis, transport and conjugation have received extensive attention, degradation has been largely ignored. Recently, Östin et al., 1998, have studied several aspects of IAA metabolism, in *Arabidopsis*, in order to devise novel and relevant screens with which to identify mutants of IAA metabolism. Hopefully, in a near future, application of biochemical and genetic approaches to *Arabidopsis* defective mutants in IAA catabolism will allow a more comprehensive understanding of IAA homeostasis and the extension of this knowledge to other plant systems.

4. Experimental

4.1. Plant material

Orange fruits (*Citrus sinensis* L., cv. Washington Navel), grown in an orchard close to Valencia (Spain) were picked at different stages of development as indicated in the text.

4.2. Isotopically labeled substrates

[5-^{3}H]IAA, 999 GBq mmol^{-1}; [1′-^{14}C]IAA, 2.04 GBq mmol^{-1} and [$^{13}C_6$]IAA, or a mixture of them, were used. When required, the concentration was adjusted with [^{12}C]IAA.

4.3. Incubation conditions

Orange fruits were washed with H_2O, surface sterilized with a 0.2% NaOCl soln and rinsed with sterile H_2O. Ten microlitres of [5-^{3}H, 1′-^{14}C, $^{13}C_6$, ^{12}C]IAA, or a mixture of them, dissolved in citrate Pi buffer 50 mM, pH 4.5, were placed on the equatorial part of the fruit in a circle of 10 mm diameter. Fruits were incubated in the dark, at 25°C, in a 25 l vacuum desiccator through which 300 ml min^{-1} of air was circulated. At specified intervals, peel discs of 15 mm diameter were taken out with a cork borer and the flavedo was excised with a razor blade and frozen at −80°C until analysis. For metabolic studies, except when otherwise indicated, 10 μl of a soln containing 12.3 kBq [5-^{3}H]IAA (999 GBq mmol^{-1}) was applied. To obtain [$^{13}C_6$ and 5-^{3}H]IAA metabolites for identification by mass spectrometry and for re-application studies, respectively, large scale incubations were carried out with mature green fruits. Ten microlitres of 40 μM [$^{13}C_6$]IAA containing 24.5 kBq of [5-^{3}H]IAA as a tracer in the first case and 10 μl of a soln 37 μM IAA containing 377 kBq [5-^{3}H]IAA, in the second, were applied to each fruit.

4.4. Extraction and purification

For metabolic studies, flavedo discs were homogenized in 80% MeOH, 100 mg l^{-1} BHT, (4 ml g^{-1} fr. wt) and extracted for 1 h, in the dark, at 4°C, with constant shaking, centrifuged 10 min at 3000 *g* and the pellet re-extracted with MeOH (2 ml g^{-1}). The combined supernatants were reduced to the aq. phase, adjusted to pH 3 with 1 M HCl, and passed through a C_{18} cartridge. IAA metabolites were then eluted with 5 ml of MeOH, 0.1 M HOAc. The dried eluate was dissolved in 10% MeOH, 0.1 M HOAc, and filtered through a 45 μm membrane before HPLC-RC.

To obtain IAA metabolites for feeding experiments and MS identification, the extraction was performed in groups of 20 discs, as described previously. The MeOH extracts were reduced to the aq. phase, in a rotary evaporator under vacuum. Ten millilitres of 50 mM Pi buffer, pH 8, were added, and the extract was run through a 30×10 mm i.d. PVP column and then eluted with 12 ml of the same buffer. The eluent, adjusted to pH 3 with 1 M HCl, was run through a C_{18} cartridge, which was eluted with 5 ml of MeOH, 0.1 M HOAc. The MeOH eluate was reduced to dryness in vacuum and dissolved in 10% MeOH, 0.1 M HOAc, before reversed phase HPLC.

4.5. Elution by HPLC

For metabolic studies reversed-phase HPLC was carried out using a 150 x 3.9 mm i.d. 5 μm C_{18} column. The column was eluted at a flow rate of 1 ml min^{-1} with a 30 min linear gradient of 10–50% MeOH in 0.1 M HOAc. The eluate was directed to a radioactivity monitor, fitted with a 500 μl flow cell operating in homogenous mode. The scintillant to eluate ratio was 3:1 (v/v).

To obtain IAA labeled metabolites for mass spectrometric identification and for feeding experiments the same HPLC conditions were used, except that a fraction collector substituted the radioactivity monitor. Aliquots

of the fractions were analyzed for radioactivity by liquid scintillation counting, and those corresponding to individual metabolite peaks were combined and reduced to dryness in Speed Vac. In order to improve the purity of the metabolite peaks and to avoid cross contamination, for feeding experiments with [5-^{3}H]IAA metabolites, a second purification step by reversed phase HPLC in isocratic mode was performed. Each fraction was resuspended in 10% MeOH, 0.1 M HOAc and resolved, in 12.5% MeOH (fractions 1 and 2), 15%, (fractions 3, 4 and 5) and 20% (fraction 6).

4.6. Derivatisation and further purification for mass spectrometric identification

To improve separation and sensitivity in the LC–MS, free carboxylic acids were methylated in the HPLC-purified fractions. The samples were soulibilized with a droplet of 1% HOAc and diluted with 100 μl MeOH. Thereafter 900 μl of Et_2O and 100 μl TMSi–CH_2N_2 were added and the mixture was incubated at room temp. overnight. The methylated fractions were further purified by TLC (Kieselgel 60 F_{254}, 10×5 cm; Merck), and the plates were eluted with butanone-EtOAc–EtOH–H_2O (3:5:1:1). Transversal 1 cm sections were scraped, suspended in MeOH, and the radioactive fractions were further purified by HPLC, in a system consisting of two Beckman 110B solvent delivery modules with a Beckman Model 420 controller. The column, 100×80 mm (i.d.), was packed with 4 μm C18 ODS. The radioactivity detector was an heterogeneous flow cell packed with Ce-activated Li glass scintillant. Radioactive fractions were collected, divided into two aliquots for GC–MS and for LC–MS, respectively and dried in Speed Vac. The aliquot analyzed by GC–MS was previously dissolved in 25 μl acetonitrile and silylated by adding 25 μl of bis (TMSi)-trifluoroacetamide with 1% (v/v) trimethylchlorosilane, heated in a sealed vial at 70°C for 15 min and, finally, reduced to dryness and re-dissolved in acetonitrile. The other aliquot was dissolved in LC–MS eluent, prior to analysis by LC–MS.

4.7. Analysis by GC–MS and LC–MS

GC-MS was performed using a Hewlett-Packard 5890 gas chromatograph linked to a Jeol JMS SX 102 mass spectrometer. Samples were injected, splitless, at 280°C, onto a 25 m×0.25 mm methyl silicone fused silica column with a film thickness of 0.25 μm. The carrier gas was He. The column temp. was programmed to rise 20°C min^{-1} from 70 to 280°C and then held at this temp. until elution of the sample. Ions were generated with 70 eV, with an ionisation current of 300 μA, the acceleration voltage being 10 kV, and positive ion mass spectra were obtained at a rate of 1 s per scan for a mass range of m/z 25–800.

The capillary HPLC frit-FAB MS system used for the identification of the metabolites has been described (Östin et al., 1992). For the initial HPLC separation a 300×0.32 mm capillary column packed with ODS, 5 μm was used. The ion source temp. was 50°C and ions were generated with a beam of 5 kV Xe atoms at an emission current of 20 mA. The acceleration voltage was 10 kV. Positive ion mass spectra were obtained at a rate of 5 s per scan for m/z 50–800. The spectra were background subtracted and the data were processed by a JEOL-MD7000 data system.

4.8. Metabolism of the main IAA metabolites by orange flavedo

The main [5-^{3}H] metabolites, purified as indicated previously, were applied individually (ca 12.5 kBq each) to mature-green orange fruits and, after incubation, the tissue was extracted and analyzed by HPLC-RC.

4.9. Effect of incubation time and maturity on [5-^{3}H]IAA metabolism

A time course study of the metabolism of [5-^{3}H]IAA by orange flavedo tissue was conducted from the end of September, with young small immature green fruits, until the end of December, with fully colored senescent oranges, at one or two week intervals. Ten microlitres of a 50 mM citrate buffer pH 4.5, containing 12.3 kBq [5-^{3}H]IAA, were applied to the fruit. After incubation, flavedo discs were excised, extracted with MeOH, and the partially purified extracts were analyzed by HPLC-RC, as indicated previously.

4.10. Effect of treatment with plant growth regulators

Fruits were submerged for 1/2 h in 1 mM 2,4-D, NAA and GA_3 respectively. Then, fruits were blotted dry and 10 μl of a 50 mM citrate buffer pH 4.5, containing 12.3 kBq [5-^{3}H]IAA, were applied to the fruit. After incubation, flavedo discs were excised, extracted with MeOH, and the partially purified extracts were analyzed by HPLC-RC, as indicated previously.

Received 28 August 2000; received in revised form 30 January 2001

Abstract

An investigation was carried out on the uptake and speciation of Al species in Al tolerant Chinese cabbage (*Brassica rapa* L. ssp. *pekinensis*). Plants were exposed to 10 μg cm^{-3} of Al in the chemical forms of Al^{3+}, Al-citrate and Al-malate in a time span from 1 up to 24 h. In each experiment the nutrient solution and stem sap were analysed by a combination of FPLC–ICP–AES and ES–MS–MS techniques. Speciation analysis enabled determination of particular chemical forms of Al present in the nutrient solution or in stem sap. The results indicate that Al^{3+} added to the nutrient solution remained as Al^{3+} in the solution during the experiments, but in the roots transformation to Al-malate occurred. Al was transported from roots to the upper parts of the plant as Al-malate (70%) and Al^{3+} (30%). Al-citrate or Al-malate added to the nutrient solution were transferred to the upper parts of the plant without transformation of their chemical forms. © 2001 Elsevier Science Ltd. 1. Introduction

Al toxicity is a well-known limiting factor in plants growing in acid soils. However, some plants are able to tolerate even phytotoxic concentrations of Al. They have evolved special tolerance mechanisms, among which external and internal tolerance mechanisms (Taylor, 1988, 1991) are mostly reported. It was presumed that low molecular weight organic acids are involved in both tolerance mechanisms (Bartlett and Riego, 1972; Hue et al., 1986; Jones, 1998). The detoxification of Al proceeds through complexation reactions either outside or inside the roots. Numerous studies of these mechanisms were based on the determination of low molecular weight organic acids. Pellet et al. (1995) demonstrated that Al exposure triggered a stimulation of citrate release in Al-tolerant maize. Citric acid exudation into the rhizosphere also appears to be one of the mechanisms of Al-tolerance in snapbeans (Miyasaka et al., 1991), in *Cassia tora* L. (Ma et al., 1997b) and in tropical maize (Jorge and Arruda, 1997). The study of Ma et al. (1997a) indicated that the formation of an Al-citrate complex in the cells of *Hydrangea macrophylla* leaves is responsible for the internal detoxification of Al. Zheng et al. (1998) and Ma et al. (1997c, 1998) proved that internal and external Al-detoxification mechanisms contribute to high Al resistance in buckwheat, since excretion of oxalic acid from the roots and accumulation of Al in the form of Al-oxalate in the leaves appears as a response to Al stress. Similarly Ma and Miyasaka (1998) demonstrated that the roots of Taro exuded oxalic acid under elevated concentrations of Al. Delhaize et al. (1993b) and Ryan et al. (1995) reported that addition of Al to the nutrient solution stimulated excretion of malic and succinic acid from roots of wheat seedlings. de la Fuente et al. (1997) reduced the Al inhibition of root growth by over-expression of the bacterial citrate synthase gene in transgenic tobacco. In addition, a supplement of organic acids to the nutrient solution containing Al has been shown to protect root growth and reduce Al toxicity in many crops (Ownby and Popham, 1989; Delhaize et al., 1993b; Ginting et al., 1998). In order to explain Al-tolerance mechanisms, the uptake, the kinetics of Al uptake and the spatial distribution of Al in Al-tolerant and Al-sensitive plants were investigated (Zhang and Taylor, 1989; Ryan et al., 1993; Delhaize et al., 1993a; Lazof et al.,

PII: S0031-9422(01)00055-3

1994). These studies were based on the determination of total Al.

Al toxicity greatly depends on the chemical species of the element. For better understanding of Al uptake and its translocation into the upper parts of plants, it is essential to identify the Al species formed in the nutrient solution after exposure, and in the stem sap. There are only a few analytical methods available for identification and quantification of monomeric aqua- and hydroxy- Al species (Mitrovič et al., 1996) and low molecular weight Al (LMW-Al) complexes (Michalas et al., 1992; van Hees et al., 1996; Ma et al., 1997a, 1998; Bantan et al., 1998a,b, 1999a,b). Fast protein liquid chromatography (FPLC) in combination with optical atomic spectrometric methods and electrospray tandem mass spectrometry (ES–MS–MS), provides a powerful tool for the speciation of LMW-Al species in plants (Bantan et al., 1999a,b). By combining the proposed analytical techniques the quantitative determination of various LMW-Al species is possible.

In the present study the uptake and speciation of different Al species in the Chinese cabbage (*Brassica rapa* L. ssp. *pekinensis*) was examined, focusing on the identification and quantification of Al forms present in the nutrient solution and stem sap.

2. Results

2.1. Determination of various Al species in synthetic solutions

In order to examine the behaviour of different positively and negatively charged Al species at pH 4.2, synthetic working solutions of Al^{3+}, Al-citrate, Al-malate (10 μg Al cm^{-3}) were injected on the Mono Q or Mono S columns. Typical chromatograms are presented in Fig. 1. These data indicate that the positively charged Al^{3+} was quantitatively eluted on the Mono S column from 3.5 to 4.5 min (Mitrovič et al., 1996). On the Mono Q column Al^{3+} was strongly adsorbed and did not disturb further separations (Bantan et al., 1998b). Negatively charged Al-citrate was quantitatively eluted from 2.5 to 3.0 min on the Mono Q column. On the Mono S column it was eluted with the solvent front (Bantan et al., 1998a). At pH 4.2 Al-malate exists as a mixture of positively and negatively charged complexes. The portion of Al-malate that corresponds to negatively charged complexes (65%) was separated on the Mono Q column from 2.0 to 3.0 min, and the remaining positively charged species were strongly adsorbed on the column. On the Mono S column 65% of negatively charged Al-malate was eluted with the solvent front, while positively charged Al species (35%) were separated from 3.0 to 4.0 min (Bantan et al., 1999a). Speciation of Al-phosphate was also investigated on the Mono Q or Mono S columns. This species is difficult to study because of precipitation of Al-phosphate. At ppm concentration levels the colloidal solution of Al-phosphate above the precipitate was strongly adsorbed on the Mono S and Mono Q columns (Bantan et al., 1999b).

The fractions that contained Al were also identified by ES–MS–MS. The corresponding spectra are presented in Fig. 2. In the mass spectrum of separated Al-citrate synthetic solution (A) a peak with m/z 191 corresponded to deprotonated citric acid. The other peaks with masses m/z 124, 125, 142, 147 and 188 resulted from the eluent of the chromatographic run (NH_4NO_3). The peak m/z 191 was selected for chemically induced dissociation (CID) and after the fragmentation, daughter ions with masses m/z 111, 87 and 85 resulted. In the mass spectrum of separated Al-malate synthetic solution (B), the peak with m/z 133 represented deprotonated malic acid. It was selected as a parent ion for CID and in the MS/MS spectrum peaks with m/z 114.6, 70.3, 72.3 and 88.5 appeared.

2.2. Determination of various Al species in the nutrient solution

In order to test the stability and to determine the chemical forms of Al added to the nutrient solution, speciation of the growth media was performed by FPLC–ICP–AES and ES–MS–MS techniques immediately after the addition of particular Al species, and after 24 h. It is evident from Fig. 3, that in the nutrient solution at pH of 4.2, the Al species added were not transformed. Al^{3+} added to the nutrient solution was separated quantitatively on a Mono S column from 3.5 to 5 min [Fig. 3(A)]. Al-citrate added to the nutrient solution was eluted quantitatively from 2.5 to 3.0 min on a Mono Q column [Fig. 3(B)]. Al-malate added to the nutrient media was eluted as negatively charged complex on a Mono Q column (65%) and a positively charged complex on a Mono S column (35%) [Fig. 3(C) and (D)]. ES–MS–MS analyses of fractions after the chromatographic separations, which contained Al, confirmed the presence of Al^{3+}, Al-citrate or Al-malate. The same results were obtained immediately after the addition of Al species to the nutrient solution, and after 24 h.

2.3. The uptake of Al^{3+}

Aluminium concentrations applied in the experiments did not result in the appearance of phytotoxicity symptoms in the cabbage. When the plants were transferred to the nutrient solution with or without Al, no significant difference in the root growth was observed during one month of the exposure.

For determination of Al species initially present in the stem sap (control), plants were transferred to fresh nutrient solution without Al. After that stem sap was collected and analysed for total Al and its species. The

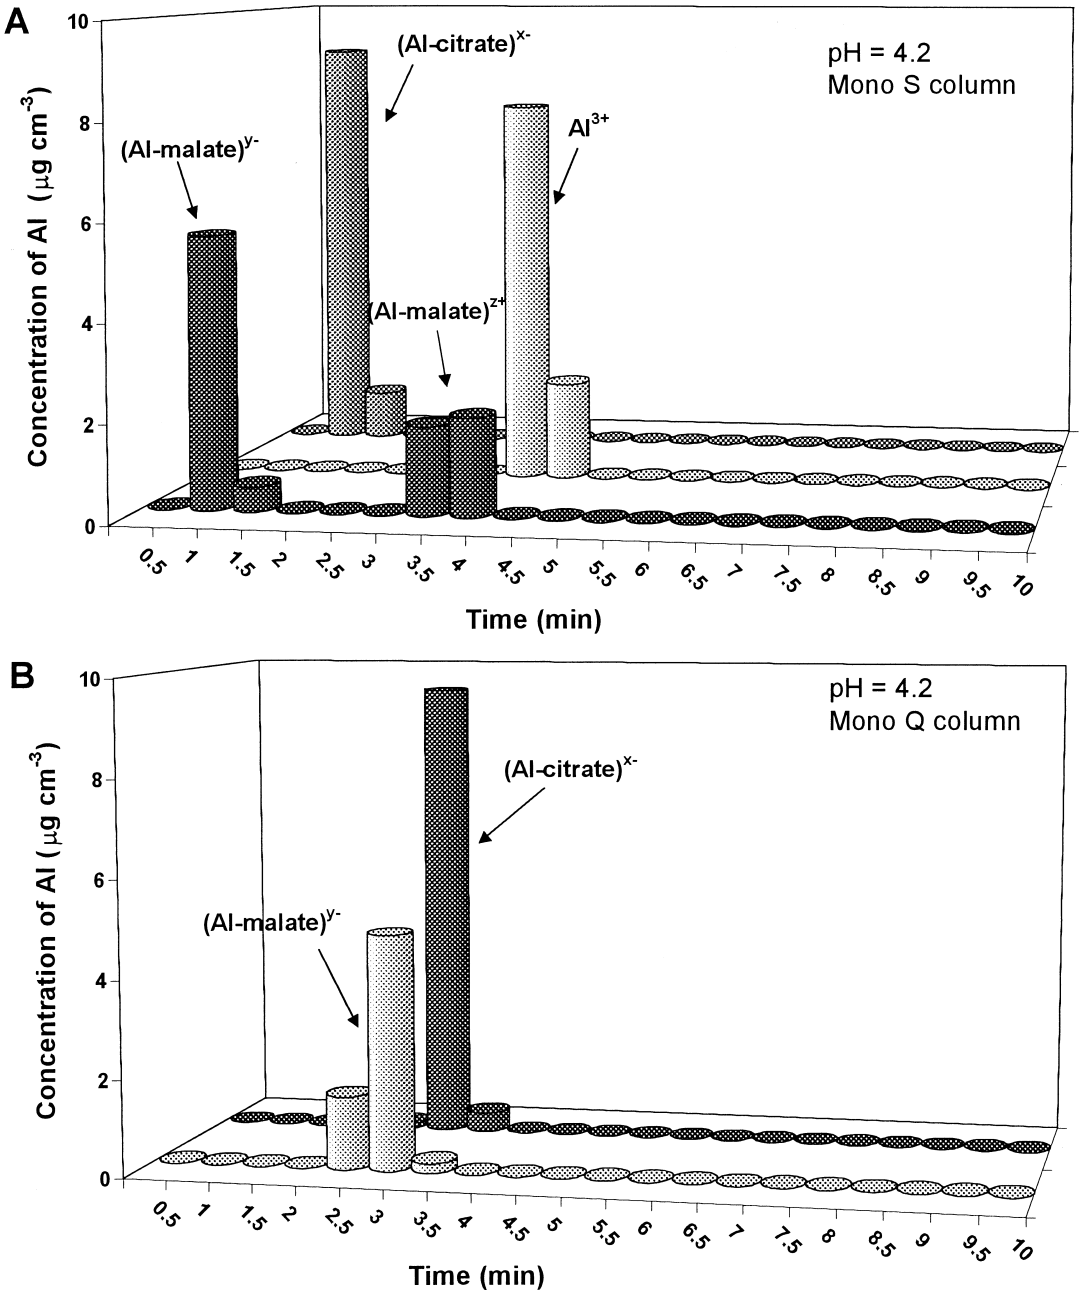

Fig. 1. Typical distribution of Al^{3+}, Al-citrate and Al-malate at pH 4.2 on a cation exchange Mono S column (A) and on an anion exchange Mono Q column (B) using ICP–AES detection. Data represent a mean of three samples with the relative standard deviation of ±5%.

total Al concentration was found to be 0.048±0.002 μg cm^{-3}. Speciation on a Mono Q column with ICP–AES and ES–MS detection indicated that Al was eluted from 2.0 to 3.0 min at the retention time typical for Al-malate. ES–MS spectra confirmed the presence of a peak with m/z 133. These data demonstrated that the Al species initially present in stem sap corresponded quantitatively to Al-malate. The concentration of this Al species was negligible in comparison to the 10 μg cm^{-3} (0.37 mM) Al used in the plant experiments.

In order to study the uptake and speciation of Al^{3+}, the plants were kept in the nutrient solution containing 10 μg cm^{-3} Al^{3+} for various time periods. The nutrient solution and the stem sap were analysed in each experiment. The results are given in Tables 1 and 2 and represent the average of two successive determinations per sample. It can be seen from Table 1 that the total concentration of Al in the nutrient solution decreased with time. It was 50% lower after 1 h of the exposure and at the limit of detection after 7 h. Analysis by FPLC–ICP–

AES indicated (Table 1) that Al^{3+} in the nutrient solution did not change its chemical form in the course of the experiment. It was quantitatively eluted as Al^{3+} on the Mono S column from 3.5 to 4.5 min, while on the Mono Q column it was strongly retained by the resin. Additional mass spectrometric analysis (Fig. 4) demonstrated that the concentration of known LMW organic acids in the nutrient solution was below the limit of detection, since characteristic peaks with m/z 191 (citrate), 173 (aconitate), 149 (tartrate), 133 (malate), 195 (gluconate) were not present in the mass spectrum. Two intensive peaks with m/z 210 and 226 appeared in the mass spectrum of the nutrient solution (Fig. 4), but we were not able to identify them.

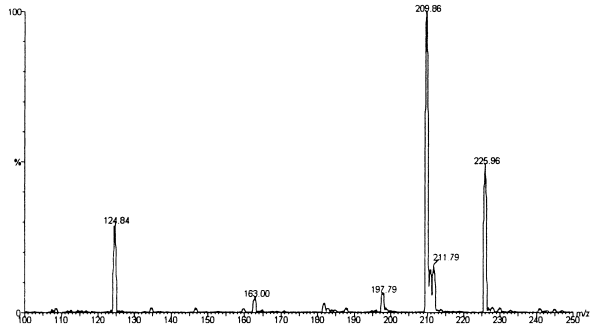

Fig. 4. ES–MS spectra of nutrient solution sampled after 1 h of exposure of cabbage to Al^{3+}.

Analysis of stem sap indicated (Table 2) that after 1 h of exposure only 1.75 μg cm^{-3} of Al was present in the sap, and that its concentration decreased with time to 0.2 μg cm^{-3} of Al after 24 h. The FPLC separations indicated that on a Mono Q column Al was eluted from 2.0 to 3.0 min. The same portion of Al was eluted with the solvent front on a Mono S column. On the basis of the retention times on the two columns it could be presumed that this species corresponds to Al-malate. The mass spectra resulted in a small peak with m/z 133, which in MS–MS analysis was fragmented to peaks with m/z 114.6, 70.3, 72.3 and 88.5 (Fig. 5). Additional peaks present in the Fig. 5 (m/z 142 and 147) corresponded to the eluent of the chromatographic run. This confirmed the presence of Al-malate. The remaining 30% of the total Al in stem sap (Table 2) was separated from 3.5 to 4.5 min on a Mono S column and corresponded to unchanged Al^{3+}. These experiments demonstrated that Al^{3+}, which was added to the nutrient solution, was mainly transformed to Al-malate.

In order to examine Al accumulation in the plant, root and leaf saps were analysed after 4 h of exposure. It

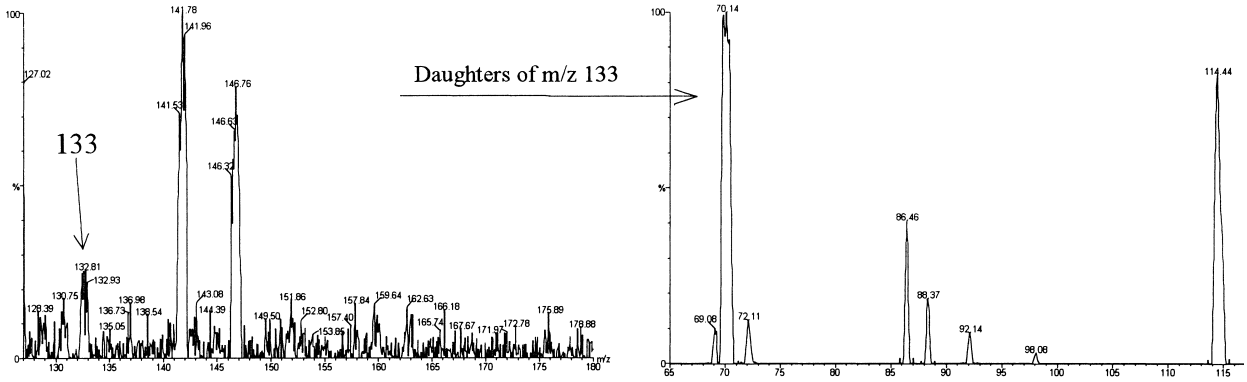

Fig. 5. ES–MS spectrum and corresponding MS–MS spectrum of m/z 133 for eluted fraction from 2 to 2.5 min on a Mono Q column for stem sap sampled after 1 h of exposure to Al^{3+}.

was found that 27 μg cm^{-3} of Al was present in the roots and 0.6 μg cm^{-3} was present in the leaves.

2.4. Uptake of Al-malate and Al-citrate

In order to test the response of Chinese cabbage to other Al species, Al-citrate or Al-malate were added to the nutrient solution. The nutrient solution and the stem sap were analysed by FPLC–ICP–AES and ES–MS–MS techniques 4 h after exposure. The results are presented in Table 3. In both experiments the total concentration of Al in the stem sap was approximately 8 μg cm^{-3}. Al-Citrate present in the nutrient solution was transferred to the stem sap and was quantitatively eluted from 2.5 to 3.5 min on a Mono Q column. On the Mono S column it was eluted with the solvent front (Table 3). In the mass spectra a peak with a m/z 191 was observed and MS–MS analysis confirmed that it corresponded to Al-citrate. Similarly, Al-malate that was transferred to the stem sap did not change its form. It was eluted as negatively charged species from 2.0 to 3.0 min on the Mono Q column (60%). The same portion was eluted with the solvent front on the Mono S column and the residual 40% as a positively charged species from 3.0–4.0 min (Table 3). The MS and MS/MS analysis confirmed the presence of Al-malate. The experimental data proved that neither Al-citrate nor Al-malate changed their chemical forms in the stem sap.

Analysis of the nutrient solution indicated that in both experiments the total concentration of Al 4 h after exposure was approximately 12 μg cm^{-3}. FPLC–ICP–AES (Table 3) in combination with ES–MS–MS analysis demonstrated that Al-citrate or Al-malate, which were added to the nutrient solution, were the only species present at the end of the experiments. Mass analysis confirmed that no other LMW acids were exuded in the course of the experiments.

The same experiments were carried out employing 1 and 7 h of exposure to Al-citrate or Al-malate. At the end of these experiments the total concentration of Al was found to be 12 μg cm^{-3} in the nutrient solution and 8 μg cm^{-3} in stem sap. FPLC–ICP–AES and ES–MS–MS confirmed the presence of the same Al species as in the 4 h exposure experiments.

Table 3
Separation of Al species in the stem sap or in the nutrient solution by FPLC–ICP–AES method after 4 h of exposure of the cabbage plant to 10 μg cm^{-3} Al-citrate or Al-malate in a half stength Hoagland nutrient solution

2.5. Discussion

Nutrient solution contains various ions that are possible chelators of Al. To minimize problems related with Al speciation, precipitation and polymerization, many authors (Ryan et al., 1995; Pellet et al., 1995; Ma et al., 1997b; Zheng et al., 1998) used a simple $CaCl_2$ solution treated with or without Al. Such experiments may lead to plant stress due to the lack of essential nutrients. Lazof et al. (1994) added Al to a nutrient solution and calculated the activity of free Al^{3+} by a computer program. Regarding speciation calculations on Al distribution the reliability of the calculations is a direct function of the thermodynamic data used (Berthon, 1996). A rigorous selection, or, better determination under appropriate conditions (pH, ionic strength) of stability and solubility product constants is thus required for all the complexes possibly formed between the reactants included in the model (Berthon, 1996). The latter aspect is particularly important in the case of Al, because of the difficulties in studying its complexes. In the computer speciation of Al the complexity of the nutrient solution (other cations present and their stability constants with ligands available, ionic strength of the nutrient solution) is usually not taken into consideration. Additionally, cations that are present in the nutrient solution are already in the equilibrium with available ligands. Therefore, the kinetic parameters should be taken into consideration in the calculations as well. Keeping all this difficulties in mind may help in understanding how speciation data may sometimes be so controversial.

In our investigation the concentrations of different Al species added to the nutrient solution were measured experimentally. It was evidently proven that Al was not complexed by phosphate or EDTA present in the nutrient solution, although they are strong chelators of Al^{3+}. If Al was complexed, these species would be identified and quantified with the analytical techniques applied. Al-phosphate would precipitate and the colloidal particles would be adsorbed on the resin of both columns (Bantan et al., 1999b). If the negatively charged Al-EDTA complex was formed, it would be eluted from 1.0 to 2.0 min on the Mono Q column (Bantan et al., 1998b) and with a solvent front on a Mono S column. The formation of $Al(SO_4)^+$ complex is not favourable, because the pH of the nutrient solution was 4.2 (Mitrovič et al., 1996). These observations can be explained by the fact that other cations present in the nutrient solution (Fe, Ca and Mg) compete for the available ligands. So, the concentrations of free phosphate and EDTA were not sufficient for complexation of Al. Besides, the pH of the nutrient solution was very low (4.2) and the formation of Al complexes at this pH is not favourable.

When Al-citrate or Al-malate were added to the nutrient solution their chemical forms did not change, since citrate and malate are strong chelators of Al. These observations enabled us to use the same nutrient solution for plant growth and for the Al treatment experiments, so that the possibility of plant stress caused by lack of essential nutrients was eliminated.

Most researchers studied the response of plants to Al stress by measuring the exudation of organic acids into the nutrient solution or its synthesis in the roots. However, Ma et al. (1997a, 1998) recently focussed on the identification of the form of Al present in Al accumulator plants by NMR spectroscopy. They suggested that internal detoxification of Al was achieved by formation of Al-citrate (Ma et al., 1997a) or Al-oxalate (Ma et al., 1998) in plant leaves. In our investigation the species, which were transported from roots to the leaves were identified and quantified. It is evident from the speciation analysis of the stem sap that 70% of Al was in the form of Al-malate and 30% in the form of Al^{3+}. The determination of total concentration of Al in root sap and in leaves sap confirmed that Al was partially accumulated in the roots. It was presumed that 30% of Al was immobilised in the apoplasts of roots and did not enter the cytoplasm. This presumption was based also on the data of total concentrations of Al in stem sap Al, which decreased with the time of exposure. If Al entered the cytoplasm it would be probably transformed to the Al-malate complex and transported in the upper parts of the plant. The total concentration of Al species in the stem sap would be consequently much higher during the course of the experiments. Additionally, the concentration of Al^{3+} in the nutrient solution (Table 1) was rapidly decreased. Eight hours after the exposure the concentration of Al in the nutrient solution was almost negligible. According to these data the rate of Al uptake was much higher than the rate of water uptake. Al was most likely immobilised in the root cell wall, rather than taken up in the cytoplasm. Nevertheless, further experiments are necessary to confirm this prediction.

In order to test the response of the cabbage to other Al species, Al-citrate or Al-malate were added to the nutrient solution. These experiments were performed in order to determine if the form of Al in the nutrient solution is important in the uptake patterns. The total concentration of Al in the nutrient solution 1 up to 7 h after the exposure was slightly higher than at the beginning of the experiment. It could be therefore concluded that both Al species were taken up into the plant roots at a slightly slower rate than water/nutrient solution. Since the volume of the nutrient solution was reduced, the Al species in the nutrient solution was concentrated. The total concentration of Al in the stem sap was constant (8 $\mu g\ cm^{-3}$) during the course of the experiments and was much higher than in the stem sap of the cabbage exposed to Al^{3+}. Speciation analysis of the stem sap indicated that Al-citrate or Al-malate did not change their chemical forms.

The results presented in this work demonstrated that the form of Al species has an important role in the uptake and transport mechanisms in Chinese cabbage. Al-citrate and Al-malate were taken up without being transformed. Al^{3+} was probably immobilised on the root cell wall. Only a small portion of Al entered the cells, where it was partially transformed to Al-malate and transported to the upper parts of the plant.

2.6. Experimental

2.6.1. Plant cultivation

Seeds of Chinese cabbage (*Brassica rapa* L. ssp. *pekinensis* (Lour.) Hanelt) were sown in the soil in pots. When the plantlets were about 10 cm tall, with an average of four leaves, they were carefully removed from the soil and the roots and stem were washed with water. The plants were transferred to one-half strength aerated Hoagland nutrient solution (pH 4.8) containing 2.6 mM KNO_3, 2.5 mM $Ca(NO_3)_2{\cdot}4H_2O$, 1 mM $MgSO_4{\cdot}7H_2O$, 0.5 mM KH_2PO_4, 0.054 mM $FeCl_3{\cdot}4H_2O + 0.06$ mM EDTA, 0.023 mM H_3BO_3, 4.57 μM $MnCl_2{\cdot}4H_2O$, 0.366 μM $ZnCl_2$, 0.146 μM $CuCl_2{\cdot}2H_2O$, 0.042 μM $H_2MoO_4{\cdot}4H_2O$. The cabbage was grown at 23°C, with 13-h/11-h day/night cycles and at 40 Wm^{-2} light intensity for 3 weeks. After that period the height of the plants was about 15 cm with an average of seven leaves, while the roots were approximately 10 cm long. These plants were used during the course of the experiments.

2.6.2. Preparation of Al solutions

A stock Al^{3+} solution (500 μg Al cm^{-3}) was prepared in a 100 cm^3 calibration flask by dissolving 0.694 g of $Al(NO_3)_3{\cdot}9H_2O$ (Riedel-de Haën) in doubly distilled water.

Stock Al-citrate and Al-malate solutions (500 μg Al cm^{-3}) were prepared in 100 cm^3 calibration flasks by dissolving 0.694 g of $Al(NO_3)_3{\cdot}9H_2O$ in water, followed by addition of either 3.5 g of citric acid or 2.5 g of malic acid. The Al:ligand molar ratio was 1:10, which was adequate for the formation of LMW-Al complexes (Bantan et al., 1999a).

Synthetic working solutions of Al^{3+}, Al-citrate and Al-malate (10 μg Al cm^{-3}) were prepared from Al stock solutions in imidazole-HCl buffer adjusted to pH 4.2, and were used for the study of the behaviour of these Al species on both FPLC columns. A synthetic working solution of Al-phosphate (pH = 4.2, 10 μg cm^{-3}) was made by mixing appropriate amounts of stock Al^{3+} solution and 2 mol dm^{-3} H_3PO_4 in an imidazole-HCl buffer (10:1 PO_4^{3-} to Al molar ratio).

2.6.3. Preparation of nutrient solutions containing various Al species

An appropriate amount of Al^{3+}, Al-citrate or Al-malate stock solution (500 μg Al cm^{-3}) was added to the nutrient solution, so that the final concentration of Al was 10 μg cm^{-3}. The pH of the nutrient solution after addition of the Al^{3+} stock solution was reduced from 4.8 to 4.2. When the stock solutions of Al-citrate or Al-malate were added to the nutrient media, the pH dropped to 2.5 and was adjusted to 4.2 by careful addition of 0.5 mol dm^{-3} NaOH.

In order to determine the Al chemical species present in the nutrient solution at pH 4.2 and to test their stability, analysis of the growth media by FPLC–ICP–AES technique were carried out immediately after the addition of Al^{3+}, Al-citrate or Al-malate, and after 1 day.

2.6.4. Treatment of plants with various Al species

In order to investigate the uptake and speciation of various Al species, each plant was placed in aerated growth vessel and exposed to the 50 cm^3 of half strength Hoagland nutrient solution containing Al^{3+}, Al-citrate or Al-malate (10 μg cm^{-3} Al). Plants were kept in the growth media containing particular Al species for 1, 4, 7, 14 and 24 h. At the end of each experiment the plant was taken from the nutrient solution, the stem washed with doubly distilled water and cut with stainless steel knife. The roots with the remaining stem were then returned to the same nutrient solution and the plant stem was held above the surface of the nutrient media. 0.5 to 1 cm^3 of the stem sap was collected with a plastic syringe from the stem cutting. It took about 30 min to collect approximately 1 cm^3 of stem sap. In the stem sap the total Al and Al species were determined. The nutrient solution used in the course of the experiments was analysed as well. Each experiment was performed with three replicate plants.

2.6.5. Determination of Al

The total Al in nutrient solution and in the fractions after chromatographic separation was determined by inductively coupled plasma-atomic emission spectrometry (ICP–AES) on a Perkin-Elmer (Norwalk, CT, USA) Plasma 40 emission spectrometer at 396.152 nm (Bantan et al., 1998b). Total Al in stem sap was determined by electrothermal atomic absorption spectrometry (ETAAS) on a Hitachi (Hitachi, Tokyo, Japan) Z-8270 polarised Zeeman atomic absorption spectrophotometer at 309.3 nm. Prior to analysis the stem sap was diluted 1:100 with water and analysed under the optimal measurement conditions (Bantan et al., 1998a).

In order to determine the total concentration of Al in roots or in plant leaves, the biological specimens were carefully washed with doubly distilled water and dried at room temperature. The samples were cut into small pieces with a stainless steal knife and frozen with liquid nitrogen. Then the samples were equilibrated to room temperature and squeezed with a stainless steal squeezer. The plant sap from roots or leaves was collected in polyethylene cups and analysed by ETAAS under the optimal measurement conditions (Bantan et al., 1998a).

2.6.6. Determination of Al species in nutrient solution and stem sap

A Merck-Hitachi (Darmstadt, Germany) 6200 gradient high-pressure pump, equipped with a Rheodyne (Cotati, CA, USA) Model 7161 injector was used in the chromatographic separations. Separation of negatively charged LMW organic Al complexes was performed on a Mono Q strong anion exchange fast protein liquid chromatography (FPLC) column (Pharmacia, Uppsala, Sweden). Stem sap or nutrient solution (0.2 cm^3) was injected onto the column and an aqueous-(0–100% 4 mol dm^{-3} NH_4NO_3) linear gradient elution was applied for 10 min at a flow rate of 1 cm^3 min^{-1}. Eluate was collected in 0.5 cm^3 fractions and diluted with 0.5 cm^3 of yttrium (Y) standard solution, so that the internal standard concentration was 10.0 μg Y cm^{-3}. The concentration of Al was determined "off line" by the ICP–AES technique at optimum measurement conditions (Mitrovič et al., 1996; Bantan et al., 1999a). Positively charged monomeric aqua- and hydroxy-Al species (Mitroviæ et al., 1996) and positively charged LMW-Al organic complexes (Bantan et al., 1999a) were separated on a Mono S strong cation exchange FPLC column (Pharmacia, Uppsala, Sweden) applying aqueous-(0–100% 8 mol dm^{-3} NH_4NO_3) linear gradient elution for 10 min. All other chromatographic parameters and the detection of separated Al species were the same as for the Mono Q FPLC column.

For the identification of the LMW Al binding ligands, the fractions were diluted 1:10 with water and analysed by the electrospray tandem mass spectrometry (ES–MS–MS, Micromass Quatro LC tandem quadrupole mass spectrometer UK Ltd. Manchester, UK) technique, employing a Z spray ion source as described previously (Bantan et al., 1999b).

Received 29 September 2000; received in revised form 1 December 2000

Abstract

The biotransformation of (*R*)-(+)- and (*S*)-(−)-limonene by fungi was investigated. More than 60 fungal cultures were screened for their ability to bioconvert the substrate, using solid phase microextraction as the monitoring technique. After screening, the best fungal strains were selected for further study and were grown as sporulated surface cultures in conical flasks and as submerged liquid cultures. It was found that (+)- and (−)-limonene were converted by *Penicillium digitatum* to α-terpineol (main metabolite), *cis*- and *trans*-*p*-menth-2-en-1-ol, neodihydrocarveol and limonene oxide (minor metabolites) using liquid cultures. The bioconversion of (*R*)-(+)- and (*S*)-(−)-limonene by *Corynespora cassiicola* yielded (1*S*,2*S*,4*R*)- and (1*R*,2*R*,4*S*)-limonene-1,2-diol respectively. The bioconversions by liquid cultures were also monitored by solid phase microextraction as a function of time. The optimum conversion of limonene to α-terpineol by *Penicillium digitatum* was obtained after 8 hours (yield up to 100%). Since an important pH-decrease was noticed in some liquid broths, the stability of limonene under acidic conditions was investigated. No acid catalysed conversion products were recovered after 8 days from control flasks at pH 3.5 containing limonene. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Much work has been done on the biotransformation of the inexpensive hydrocarbon monoterpene limonene (Bowen, 1975), which is, besides α-pinene, the most widely distributed terpene in nature (Krasnobajew, 1984). The (+)-isomer is present in citrus peel oils at a concentration of over 90%; a low concentration of the (−)-isomer is found in oils from the *Mentha* species and conifers (Bauer et al., 1990). The microbial conversion of limonene is very well documented, the first data date back to the sixties. A soil pseudomonad was isolated by an enrichment culture technique on limonene as the sole source of carbon (Dhavalikar and Bhattacharyya, 1966) and was able to convert the substrate to a large number of neutral and acidic products. Another group isolated a *Pseudomonas incognita* by an enrichment technique on the monoterpene alcohol linalool (Madyastha et al., 1977). The metabolism of limonene by this bacterium was investigated (Rama Devi and Bhattacharyya, 1977). After fermentation the medium yielded as the main product a crystallic acid, perillic acid, together with unmetabolised limonene and some oxygenated compounds, such as dihydrocarvone, carvone and carveol. The biotransformation of limonene by another *Pseudomonas* strain, *P. gladioli* was also reported (Cadwallader et al., 1989; Cadwallader and Braddock, 1992). Major conversion products from (+)-limonene were (+)-α-terpineol and (+)-perillic acid. This was the first time that the microbial conversion of limonene to α-terpineol was reported. α-Terpineol is widely distributed in nature and is one of the most commonly used perfume chemicals (Fenaroli, 1975). The first data on fungal bioconversion of limonene date back to the late sixties. A *Cladosporium* sp. designated as T_7 was isolated on limonene and was able to convert the substrate to *trans*-limonene-1,2-diol (Mukherjee et al., 1973). Another

PII: S0031-9422(00)00499-4

Cladosporium, designated T_{12}, converted limonene into α-terpineol (Kraidman et al., 1969).

Fungi, isolated from rotting orange rind, were also found to be able to convert limonene to α-terpineol (Mattison et al., 1971). Bowen (1975) isolated two common citrus moulds, *Penicillium italicum* and *P. digitatum*, responsible for the postharvest diseases of citrus fruits. Fermentation of *P. italicum* on limonene yielded *cis*- and *trans*-carveol (26%) as main products, together with (+)-carvone (6%) and minor metabolites. Conversion by *P. digitatum* yielded the same products in lower yields. The bioconversion of limonene by *Aspergillus niger* has also been described (Rama Devi and Bhattacharyya, 1978). This fungus was able to carry out three types of oxygenative rearrangements. More recently, a Japanese group studied the biotransformation of limonene and related compounds (1-methylcyclohexene and cyclohexene) by *Aspergillus cellulosae* M-77 (Noma et al., 1992). (+)-Limonene was mainly converted to (+)-isopiperitenone (19%), (+)-limonene-1,2-*trans*-diol (21%), (+)-*cis*-carveol (5%) and (+)-perillyl alcohol (12%). The production of isopiperitenone from limonene was published for the first time.

The production of glycols from limonene and other terpenes with a 1-menthene skeleton was reported (Abraham et al., 1984). The most appropriate strains were *Corynespora cassiicola* and *Diplodia gossypina*. The same group (Abraham et al., 1985) also investigated the biotransformation of (*R*)-limonene to (*R*)-α-terpineol by the fungus *Penicillium digitatum*. An extensive overview on the microbial transformations of terpenoids with a 1-*p*-menthene skeleton was published by this group (Abraham et al., 1986). One of the most recent publications in this area reported the bioconversion of limonene to α-terpineol by immobilised *P. digitatum* (Tan and Day, 1998a) and studied the effect of organic cosolvents on the bioconversion of (*R*)-(+)-limonene to (*R*)-(+)-α-terpineol (Tan and Day, 1998b). In all these examples submerged liquid cultures were used. The bioconversion of limonene by fungal spores has not been published to date.

This paper reports the biotransformation of (*R*)-(+)-(**1**) and (*S*)-(−)-limonene (**19**) by sporulated surface cultures and liquid cultures of fungi and the use of solid phase microextraction (SPME) for fast screening.

2. Results and discussion

2.1. Screening of sporulated surface cultures by fungi by SPME

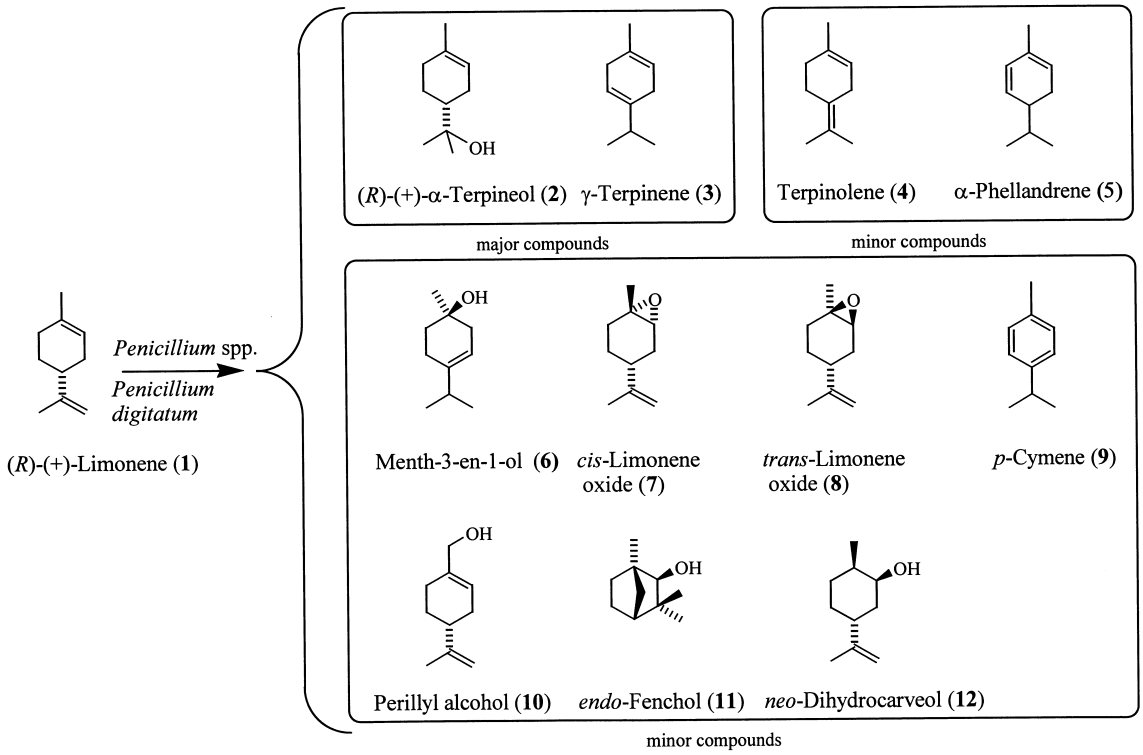
More than 60 fungal strains, grown as sporulated surface cultures, were screened for their ability to bioconvert the substrate (*R*)-(+)-limonene (**1**), using solid phase microextraction (SPME) as the monitoring technique. Therefore, a method was developed to cultivate sporulated surface cultures of the fungi in small vials, and the SPME-parameters were optimised. Different SPME-fibers, extraction times and temperatures were compared. Extraction of volatiles (limonene and metabolites) was done by headspace SPME. It was found that the best SPME fiber for extraction of limonene and its metabolites was 50/30 μm divinylbenzene/carboxen on polydimethylsiloxane. The optimum adsorption time was 30 min. The best extraction temperature was room temperature, but because of temperature fluctuation, a constant adsorption temperature of 25°C was chosen as optimum. A desorption temperature of 250°C and desorption time of 2 min was sufficient to desorb all volatiles into the gaschromatographic inlet.

The most interesting conversion of (*R*)-(+)-limonene (**1**) was the formation of (*R*)-(+)-α-terpineol (**2**) by various *Penicillium* species. Other metabolites recovered were γ-terpinene (**3**), terpinolene (**4**), α-phellandrene (**5**), *endo*-fenchol (**11**), menth-3-en-1-ol (**6**), *p*-cymene (**9**), *neo*-dihydrocarveol (**12**), *cis*-limonene oxide (**7**), *trans*-limonene oxide (**8**) and perillyl alcohol (**10**) (see Scheme 1). The most interesting strains were *P. digitatum* (both isolated (CMC) and obtained, DSM 62840) and *Corynespora cassiicola* DSM 62475.

2.2. Biotransformation of (R)-(+)-limonene by sporulated surface cultures

After screening, the best fungal strains were selected for further study and were grown as sporulated surface cultures in conical flasks. The biotransformation was monitored by dynamic headspace, steam distillation solvent extraction and liquid/liquid extraction.

In a first experiment, the bioconversion of (*R*)-(+)-limonene (**1**) by two strains was compared, namely *Penicillium digitatum* (CMC), selected as interesting strain, based on the SPME screening results, and *Aspergillus niger* (AND), since *A. niger* has been used successfully in many bioconversion reactions (Rama Devi and Bhattacharrya, 1978; Arfmann et al., 1987, 1988; Demyttenaere and Willemen, 1998; Demyttenaere and De Kimpe, 2000; Demyttenaere et al., 2000). To 10-day old sporulated surface cultures, 100 μl of a 20% limonene in EtOH solution was sprayed. Two more substrate additions took place after 15 and 17 days respectively. It was found that *Aspergillus niger* was not able to convert limonene, whereas *Penicillium digitatum* produced (*R*)-(+)-α-terpineol (**2**) from limonene with low yields (0.7–1.4%). In a second experiment, the bioconversion of (*R*)-(+)-limonene (**1**) by two strains of *Penicillium digitatum*, namely strain CLE and strain PDD was compared in duplicate. The first substrate addition (125 μl of a 20% limonene in EtOH solution) was performed after 7 days. Two more substrate

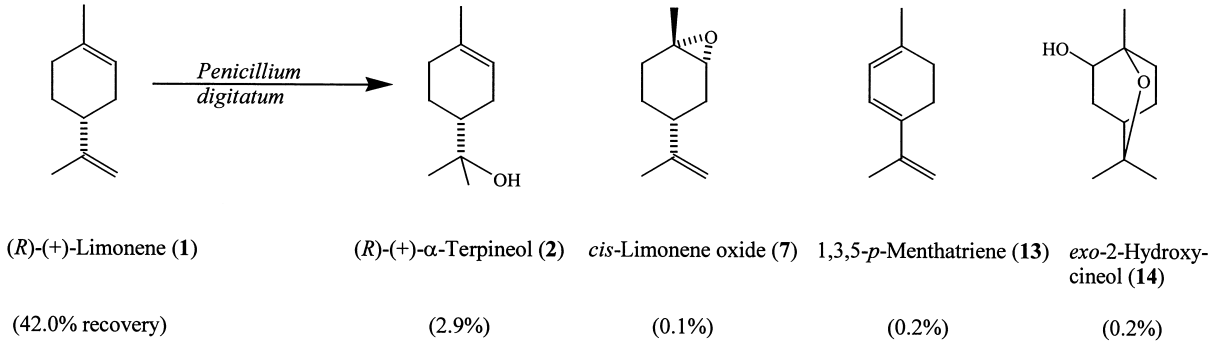


Scheme 1. Biotransformation of (*R*)-(+)-limonene by sporulated surface cultures of fungi — monitoring by SPME.

additions took place after 12 and 14 days resp. From the headspace extracts of the surface cultures, it could be seen that up to 44% of the substrate (*R*)-limonene (**1**) was recovered unchanged. The yield of conversion to (*R*)-α-terpineol (**2**) was 1.1 and 1.3% for the two *P. digitatum* cultures of strain CLE resp. and 2.7 and 2.9% for the two cultures of strain PDD resp. Minor metabolites were 1,3,5-*p*-menthatriene (**13**) (0.2–0.6%), *cis*-limonene oxide (**7**) (0.1–0.2%) and *exo*-2-hydroxycineol (**14**) (0.1–0.2%) (see Scheme 2).

It is important to note that the pH of the surface cultures dropped to pH 3 after the cultures were subjected to steam distillation/solvent extraction. Therefore, a control experiment was run to check the degradation of limonene in sterile agar medium and MEA-medium, acidified to pH 3.5 (at lower pH, the agar did not solidify), during headspace sampling and steam distillation/solvent extraction. The substrate (*R*)-limonene happened to be very stable: only small traces (0.14%) of β-myrcene were recovered from the steam distillate. No acid catalysed conversion products from limonene were recovered from the headspace extracts.

It can be concluded that sporulated surface cultures of *P. digitatum* are able to convert the substrate (*R*)-(+)-limonene (**1**) to (*R*)-α-terpineol (**2**). Since the very high volatility of the substrate, limonene, a high amount of substrate loss due to evaporation during headspace extraction was noticed, resulting in high substrate recovery. Therefore, when dynamic headspace sampling is compared with headspace SPME-sampling, the latter



Scheme 2. Bioconversion of (*R*)-(+)-limonene by sporulated surface cultures of *Penicillium digitatum*.

method is more sensitive and efficient for fast screening.

2.3. Bioconversion of (R)-(+)- and (S)-(−)-limonene by liquid cultures

In a first experiment the bioconversion of (*R*)-(+)-limonene by submerged liquid cultures was studied, comparing five fungal strains, namely *Corynespora cassiicola* (marked COC), *Aspergillus niger* (marked AND) and three different strains of *Penicillium digitatum* (marked CLE, CMC and PDD respectively). All strains were cultivated in duplicate, except strain CLE. As a control, the stability of the precursor was checked in acidified broth (pH 3.5) that was not inoculated but kept under sterile conditions.

Over a period of 8 days, 3×25 μl of (*R*)-(+)-limonene (each time 125 μl of a 20% solution of limonene in EtOH) was added to cultures of 50 ml each. The first substrate addition was performed after 46 h of cultivation, the second after 5 days and the third after 7 days. Samples were taken 24 h after the first substrate addition, and 22.5 h after the second and third substrate addition, respectively. *Corynespora cassiicola* was able to transform the substrate to (1*S*,2*S*,4*R*)-limonene-1,2-diol (**15**) with a final yield of 46.9–60.6%. This biotransformation confirms previously published literature data (Abraham et al., 1986). All *P. digitatum* cultures converted (*R*)-(+)-limonene (**1**) to (*R*)-(+)-α-terpineol (**2**) with an initial yield up to 45.7% (after 24 h). These results are in agreement with literature data (Abraham et al., 1985). *Aspergillus niger*, however, was not able to convert the substrate. The substrate recovery was very low, namely 0.0% from the two *C. cassiicola* cultures and 0.11–0.14% from the *A. niger* cultures. From the control flasks, no acid catalysed conversion products were recovered. This means that all products recovered from the culture media are bioconversion metabolites and that all the substrate was either metabolised or evaporated.

The substrate recovery and yields of biotransformation products obtained from limonene by the *Penicillium digitatum* cultures are displayed in Table 1.

It is important to note that the conversion of (*R*)-(+)-limonene to (*R*)-(+)-α-terpineol by *P. digitatum* took place during the first part of the experiment (first 24-h period). The conversion of (*R*)-limonene (**1**) to (1*S*,2*S*,4*R*)-limonene-1,2-diol (**15**) by *C. cassiicola* on the other hand was slow. The highest yield was obtained at the end of the experiment (after 5 days of conversion). The final pH of the *C. cassiicola* culture media was neutral, whilst the culture media of *P. digitatum* were slightly basic (pH 8.5) at the end of the experiment.

In a second experiment the bioconversion of (*R*)-(+)-limonene (**1**) and (*S*)-(−)-limonene (**19**) by submerged liquid cultures was studied, comparing two fungal strains, namely *Corynespora cassiicola* (COC) and *Penicillium digitatum* (PDD). Also the difference between high (3×50 μl limonene per 50-ml culture) and low (3×25 μl limonene per 50-ml culture) precursor addition was compared (only for the conversion of (*R*)-limonene to limonene-1,2-diol by *C. cassiicola*). The first substrate addition took place after 42 h of cultivation, the second after 50 h cultivation and the third after 66 h cultivation. Samples were taken 8 h after the first substrate addition, 16 h after the second substrate addition and 8 and 24 h, respectively, after the third substrate addition.

The percentage of substrate recovery and the yields of the bioconversion products are listed in Table 2 (bioconversion of (*R*)-limonene) and Table 3 (bioconversion of (*S*)-limonene).

Again it was noticed that the bioconversion of both (*R*)-(+)- and (*S*)-(−)-limonene to (*R*)-(+)- and (*S*)-(−)-α-terpineol, respectively, by *P. digitatum* was fast (67.2% yield of (+)-α-terpineol after 8 h when 50 μl substrate was administered to a 50-ml culture), whilst the conversion to limonene-1,2-diol by *C. cassiicola* was a slow process (max. yield only obtained after 3 substrate additions, i.e. at the end of the experiment (5 days)). No difference was observed between high (3×50 μl) and low (3×25 μl) substrate addition in the conversion of limonene to limonene-1,2-diol by *C. cassiicola*. Substrate recovery was very low, especially for the cultures of *C. cassiicola* (< 1%). When control experiments were run with 50 μl of (*R*)-limonene dissolved in 50 ml of sterile culture broth in the presence of 0.5% EtOH, it was shown that the concentration of limonene dropped to half of its original concentration after less than one hour and that all limonene was evaporated after six hours.

The bioconversion of (*R*)-(+)- and (*S*)-(−)-limonene by *C. cassiicola* and *P. digitatum* is given schematically in Schemes 3 and 4.

2.4. Monitoring of the bioconversion of limonene by liquid cultures during time course

2.4.1. Monitoring of the bioconversion by liquid cultures in conical flasks by liquid extraction

The bioconversion of (*R*)-(+)-limonene by two *Penicillium digitatum* (CMC and PDD) strains and one *Corynespora cassiicola* strain grown as liquid cultures in conical flasks was monitored during time course by liquid extraction with Et_2O. To the pregrown cultures of 50 ml, one substrate addition of 250 μl of a 20%-solution of (*R*)-limonene in EtOH (i.e. 50 μl limonene) was performed. At time $t = 0$ min, 30 min and consequently every 90 min until 480 min, a 5-ml sample was taken from each culture and extracted with E_2O. From the results displayed in Fig. 1 it can be seen that the maximum yield for the bioconversion of (*R*)-limonene to (*R*)-α-terpineol was obtained after 8 hours (almost

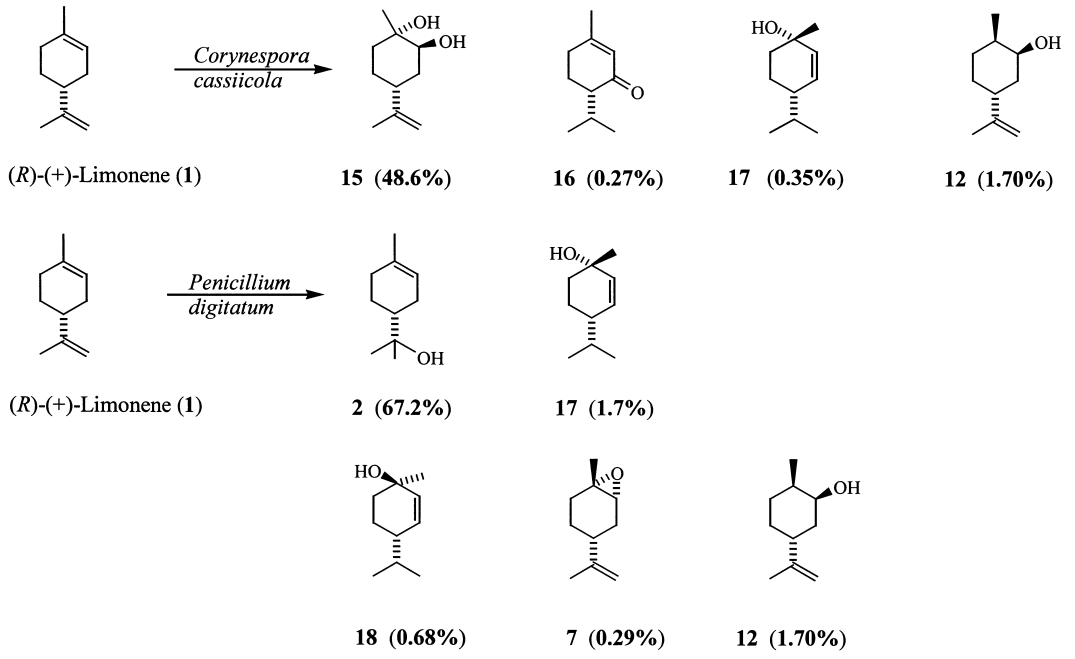
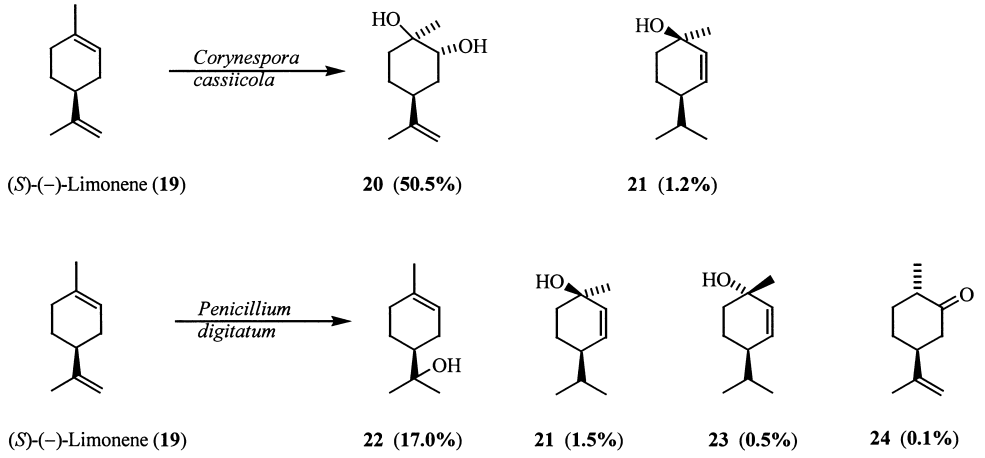
100% yield for strain CMC and approx. 75% yield for strain PDD). The conversion of (*R*)-limonene to limonene-1,2-diol by *C. cassiicola* however was only approx. 12% after 8 h, suggesting that this conversion is very slow.

2.4.2. Monitoring of the bioconversion by liquid cultures in SPME-vials by SPME

The bioconversion of (*R*)-(+)-limonene by two strains of *Penicillium digitatum* (CMC and PDD), grown as liquid cultures in small SPME-vials, was monitored by SPME. From 50-ml pregrown cultures of 48 h, 15 ml culture was transferred into 40-ml SPME vials and stirred (800 rpm). To each culture 10 μl of a 10%-solution of (*R*)-limonene in EtOH (i.e. 1 μl of limonene) was added. At time $t = 0$ min and consequently every 90 min until 540 min, the cultures were sampled by liquid SPME. The conversion was monitored by plotting the peak area of (*R*)-limonene and (*R*)-α-terpineol of the chromatograms as a function of time (see Fig. 2). From this graph, it can be concluded that SPME is a very powerful technique to monitor the



Scheme 3. Biotransformation of (*R*)-(+)-limonene by liquid cultures of *Penicillium digitatum* and *Corynespora cassiicola* — for the names of the molecular structures, see Table 2.

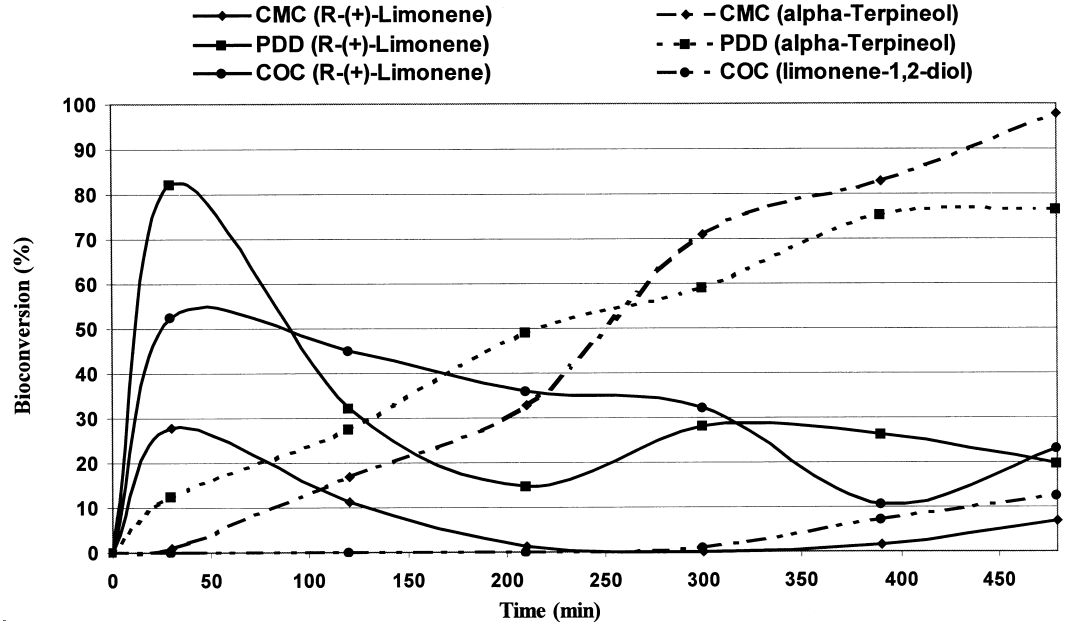


Scheme 4. Biotransformation of (*S*)-(−)-limonene by liquid cultures of *Penicillium digitatum* and *Corynespora cassiicola* — for the names of the molecular structures, see Table 3.

bioconversion of limonene by fungi as a function of time. However, since peak areas and not concentrations are plotted, no conversion yields can be calculated from SPME-extractions. It is clear that all (*R*)-limonene is either consumed or evaporated after 300 min and a maximum conversion is obtained after 360 min.

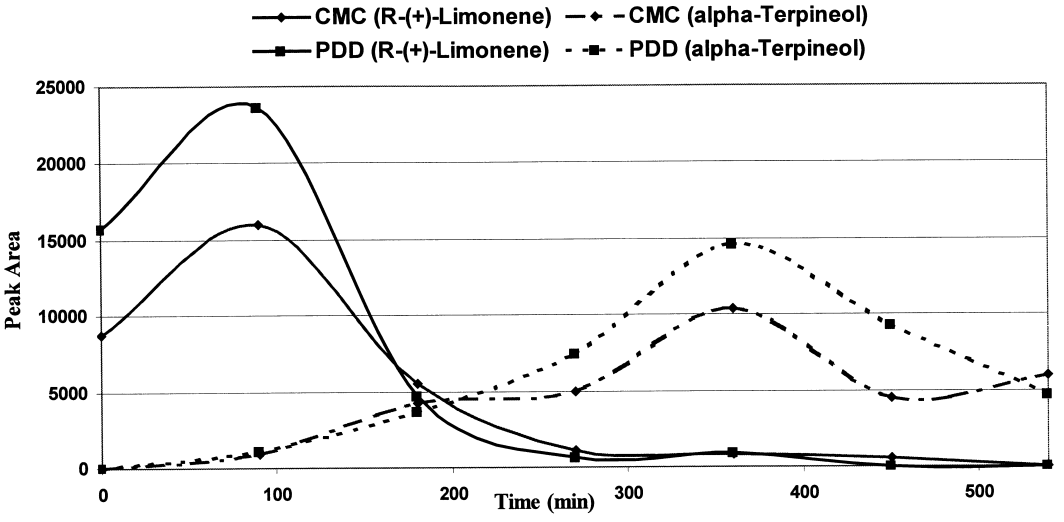
2.4.3. Monitoring of the bioconversion by spore suspensions in SPME-vials by SPME

The bioconversion of (*R*)-(+)-limonene by spore suspensions in the course of time was monitored by SPME. Two strains of *Penicillium digitatum* were compared (CMC and PDD). For this experiment, spore suspensions were prepared by harvesting spores from Petri dish cultures with a physiological solution (0.85% NaCl) containing 0.5% Tween 80. The spore suspensions thus obtained contained approx. 1×10^8 spores/ml. A control experiment was also run, consisting of pure water. To each spore suspension and to the water control, 10 μl of a 10%-solution of (*R*)-limonene in EtOH (i.e. 1 μl of limonene) was added. At time $t=0$ min and consequently every 90 min until 450 min, the suspensions were sampled by liquid SPME. The conversion was monitored by plotting the peak area of (*R*)-limonene and (*R*)-α-terpineol of the chromatograms as a function of time (see Fig. 3). It can be concluded that



CMC = *Penicillium digitatum* isolated from spoiled mandarin – PDD = *Penicillium digitatum* DSM 62840
COC = *Corynespora cassiicola* DSM 62475

Fig. 1. Monitoring bioconversion of (*R*)-limonene by liquid fungal cultures in conical flasks by liquid extraction.



CMC = *Penicillium digitatum* isolated from spoiled mandarin – PDD = *Penicillium digitatum* DSM 62840

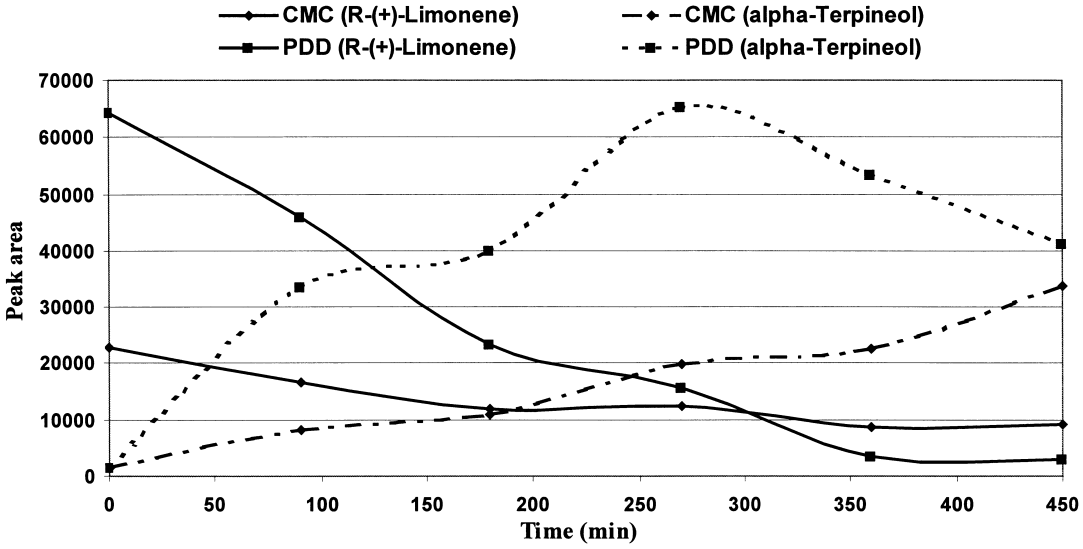
Fig. 2. Monitoring bioconversion of (*R*)-limonene by liquid cultures in small SPME vials by SPME.

the optimum conversion yield of spores of strain PDD was higher and appeared earlier (after 270 min) than the strain CMC (optimum later than 450 min). Since no conversion products were noticed in the control, it can be concluded that spores of *Penicillium digitatum* were able to convert (*R*)-(+)-limonene to (*R*)-(+)-α-terpineol and that SPME is a suitable screening technique for monitoring the biotranformation capacity of fungal spores.

3. Experimental

3.1. Microorganisms and cultivation

More than 60 fungal strains were used in this study. They belonged to the following species: *Penicillium digitatum*, *P. italicum*, *P. roquefortii*, *P. chrysogenum*, *P. lividum*, *Aspergillus niger*, *Aspergillus versicolor*, *Botryodiplodia malorum*, *Rhizopus oryzae*, *Beauveria*



CMC = *Penicillium digitatum* isolated from spoiled mandarin – PDD = *Penicillium digitatum* DSM 62840

Fig. 3. Monitoring bioconversion of (*R*)-limonene by spore suspensions in small SPME vials by SPME.

bassiana, *Cunninghamella elegans*, *C. blakesleeana*, *Hyphozima roseoniger*, *Corynespora cassiicola*, *Chaetomium cochliodes* and *Mortierella* sp. The fungi were either isolated from spoiled fruit or contaminated media, or obtained from DSM (Deutsche Sammlung von Mikroorganismen). After screening experiments, some fungal strains were selected for further study and marked as follows: CMC (*Penicillium digitatum* isolated from spoiled mandarin), CLE (*Penicillium digitatum* Saccardo isolated from spoiled tangerine and assigned ATCC 201167), PDD (*Penicillium digitatum* DSM 62840), COC (*Corynespora cassiicola* DSM 62475), AND (*Aspergillus niger* DSM 821). The cultures were cultivated and conserved by periodic replications (every 2 weeks) on malt extract agar (MEA: malt extract 2%, bacteriological peptone 0.1%, glucose 2% and agar 2%–pH 5.4).

3.2. Screening of sporulated surface cultures by fungi by SPME

The fungi were cultivated as small sporulated surface cultures in 40-ml SPME-vials (Supelco Inc., Bellafonte, USA) (Demyttenaere and De Kimpe, 2000; Demyttenaere et al., 2000). Therefore, the vials were filled with 10 ml medium (MEA), autoclaved, and inoculated with fresh spores. The vials were covered with cotton wool and the cultures were incubated at 30°C during 24 h and at room temp during 48 h, after which complete sporulation had taken place. To each sporulated surface culture, 5 μl of a solution of (*R*)-(+)-limonene (puriss., >99%, FLUKA) in EtOH (10%) was sprayed. The vials were covered with PTFE-Silicone Septa and Open Top Phenolic Closures (Supelco) and stored at room temperature until the start of the headspace SPME-extraction. During extraction, the SPME fibers were exposed to the headspace of the cultures for 5, 15 or 30 min at 25°C.

To select the best sampling parameters, 40-ml SPME-vials were filled with 10 ml agar medium (2% agar/water) to which 5 μl of the same solution of limonene in EtOH (10%) or solutions containing limonene and α-terpineol in different ratios were sprayed. Different SPME fibers were used, namely 100 μm polydimethylsiloxane (PDMS), 50/30 μm divinylbenzene/carboxen on polydimethylsiloxane, 65 μm carbowax/divinylbenzene (CWDB) and 85 μm polyacrylate (PA) (Supelco Inc., Bellafonte, USA). Different sampling times (5, 15, 30 and 60 min) and temperatures (10, 20, 30, 40, 50°C and room temperature) were compared.

3.3. Biotransformation of (*R*)-(+)-limonene by sporulated surface cultures

For the experiments with sporulated surface cultures, 500-ml conical flasks were used, filled with 100 ml MEA-medium and inoculated with 0.5 ml of freshly obtained spore suspensions. For the first experiment, spore suspensions of *Penicillium digitatum* (CMC) containing 1.8×10^8 spores/ml and *Aspergillus niger* (AND) containing 4.5×10^8 spores/ml were used as inoculum. For the second experiment with sporulated surface cultures, spore suspensions of *Penicillium digitatum* (CLE) containing 1.5×10^8 spores/ml and *P. digitatum* (PDD) containing 9.9×10^7 spores/ml (as counted with a Malassez cell) were used to inoculate the medium. After inoculation, the cultures were incubated at 30°C for 24 h and at room temp during the rest of the experiment. Substrate addition was carried out by spraying a

solution of (*R*)-(+)-limonene in EtOH (20%) onto the sporulated surface cultures. The biotransformation was monitored by dynamic headspace, steam distillation solvent extraction and liquid/liquid extraction as described earlier (Demyttenaere and Willemen, 1998). Control experiments with acidified (pH 3.5) sterile agar medium and MEA-medium without fungi were also performed as described previously (Demyttenaere and De Pooter, 1998).

3.4. Bioconversion by liquid cultures

The biotransformation by submerged liquid cultures was run during 5–8 days with various strains of *Penicillium digitatum*, *Aspergillus niger* and *Corynespora cassiicola*. The fungi were cultivated in 250-ml conical flasks, filled with 50 ml liquid medium (YMPG: yeast extract 0.5%, malt extract 1%, bacteriological peptone 0.5%, glucose 1%–pH 6.1) as described earlier (Demyttenaere and Willemen, 1998). Inoculation was done with 0.5 ml of freshly obtained spore suspensions containing 1.7×10^8 spores/ml (AND), 9.7×10^7 spores/ml (CMC), 9.9×10^7 spores/ml (PDD) and 1.5×10^8 spores/ml (CLE) as counted with a Malassez cell. The test substrate ((*R*)-(+)- or (*S*)-(−)-limonene) was added as a 20% (v/v) solution in absolute EtOH (125 or 250 μl of this solution were added to the cultures). At different time intervals, 5-ml samples were taken and extracted with Et_2O. This experiment was also run with control flasks, which contained sterile YMPG-broth which was acidified to pH 3.5 by addition of acetic acid but no inoculation was executed.

3.5. Chemical compounds

The substrates used for the biotransformation experiments were (*R*)-(+)- and (*S*)-(−)-limonene (puriss. ⩾ 99%, Fluka, Belgium). As reference compounds α-terpineol (98%, Janssen Chimica, Belgium) and (1*S*,2*S*,4*R*)-limonene-1,2-diol (kindly supplied by Dr. Mariët van der Werf, TNO-Voeding, Department of Applied Microbiology and Gene Technology, Zeist, The Netherlands) were used.

3.6. Preparative separation and identification of metabolites

For the isolation of the bioconversion product (1*S*,2*S*,4*R*)-limonene-1,2-diol, combined extracts were concentrated under a gentle N_2-flow and injected in a Delsi Intersmat IGC 120 ML gas chromatograph equipped with a 3 m packed column (5% SE-30, Chromosorb W-AW 60–80, 6 mm o.d.) and a Thermal Conductivity Detector (TCD). The carrier gas was H_2 (1 bar). The fraction was collected and the metabolite was identified by ^1H and ^{13}C NMR (JEOL JNM-EX270, 270 MHz). The melting point was measured by a Büchi 535 apparatus and the IR-spectrum was obtained with a Nicolet Impact 410 spectrometer.

3.7. Analysis of the samples with GC and GC–MS

GC- and GC–MS-analyses were performed as described earlier (Demyttenaere and Willemen, 1998). For the analysis of the SPME-extracts, a HP 6890 GC Plus coupled with a HP 5973 MSD (Mass Selective Detector-Quadrupole type), equipped with a CIS-4 PTV (Programmed Temperature Vaporisation) Injector (Gerstel), and a HP5-MS capillary column (30 m×0.25 mm i.d.; coating thickness 0.25 μm) was used. Working conditions were: injector 250°, transfer line to MSD 250°, oven temperature: start 40°C, hold 2 min; programmed from 40 to 150°C at 5°C min^{-1}, from 150 to 170°C at 10°C min^{-1} and from 170 to 250°C at 30°C min^{-1}, hold 2 min; carrier gas (He) 1.2 ml min^{-1}; split 1/10; ionisation: EI 70 eV; acquisition parameters: scanned *m*/*z*: 40–180 (5–20 min), 40–250 (> 20 min).

Substances were identified by comparison of their mass spectra and retention indexes (Kováts Indexes) with those of reference substances (where possible) and by comparison with the NIST Mass Spectral Library (Version 1.6d, 1998).

For elucidation of the chirality of the metabolite limonene-1,2-diol, the sample was analysed by chiral GC using a 25 m column (0.33 mm i.d.) with a permethylated CYDEX-B stationary phase (SGE) (coating thickness 0.25 μm) and it was co-injected with an authentic sample of (1*S*,2*S*,4*R*)-limonene-1,2-diol.

3.8. (1S,2S,4R)-Limonene-1,2-diol

Yellow solid. Mp 53.9°C. ^1H NMR (270 MHz, $CDCl_3$): δ 1.18–1.97 (7H, *m*); 1.27 (3H, *s*); 1.73 (3H, *s*); 2.22–2.27 (1H, *m*); 3.50 (2H, *s*); 4.73 (2H, *s*). ^{13}C NMR (68 MHz, $CDCl_3$): δ 21.0 (*q*); 26.1 (*t*); 26.6 (*q*); 33.6 (*t*); 33.9 (*t*); 37.4 (*d*); 71.3 (*s*); 73.8 (*d*); 108.9 (*t*); 149.3 (*s*). Abstract

Root exudates released into soil have important functions in mobilizing metal micronutrients and for causing selective enrichment of plant beneficial soil micro-organisms that colonize the rhizosphere. Analysis of plant root exudates typically has involved chromatographic methods that rely on a priori knowledge of which compounds might be present. In the research reported here, the combination of multinuclear and 2-D NMR with GC–MS and high-resolution MS provided de novo identification of a number of components directly in crude root exudates of different plant types. This approach was applied to examine the role of exudate metal ion ligands (MIL) in the acquisition of Cd and transition metals by barley and wheat. The exudation of mugineic acids and malate was enhanced by Fe deficiency, which in turn led to an increase in the tissue content of Cu, Mn, and Zn. The presence of elevated Cd maintained at a free activity pCd of 8.8 ($10^{-8.8}$ M), resulted in reduced phytosiderophore production by Fe deficient plants. The buffer morpholinoethane sulfonate (MES), which is commonly used in chelator-buffering nutrient solutions, was detected in the root exudate mixture, suggesting uptake and re-secretion of this compound by the roots. The ability to detect this compound in complex mixtures containing organic acids, amino acids, and other substances suggests that the analytical methods used here provide an unbiased method for simultaneous detection of all major components contained in root exudates. © 2001 Elsevier Science Ltd. 1. Introduction

Plant root exudates can constitute up to 30–40% of the plant's photosynthetic productivity (Samtsevich, 1965; Oades, 1978; Sauerbeck et al., 1981; Whipps, 1990). They are known to play important roles in a number of rhizospheric processes, including nutrient (e.g. Fe and Zn) acquisition (Romheld, 1991; Zhang et al., 1991; Hopkins et al., 1998), plant-microbe associations (e.g. *Rhizobium* symbiosis with leguminous roots) (Janczarek et al., 1997; Scheidemann and Wetzel, 1997), regulation of plant growth (Einhellig et al., 1993), and determination of microbial community structure in the plant rhizosphere (Grayston et al., 1995; Yang and Crowley, 2000). It is also expected that root exudate components interact with both organic and inorganic contaminants to regulate their bioavailability and transport in the soil environment. Moreover, root exudation may be an important mediator in altering the species composition of the rhizosphere microflora that function in nutrient transformations, decomposition

and mineralization of organic substances, and formation of soil organic matter, all of which are related to soil quality (Hodge and Millard, 1998). This latter aspect is particularly in need of clarification, in view of the ever-increasing threat of global environmental change and soil pollution caused by anthropogenic activity. However, the relationship between changes in exudate composition and microbial community structure and function in soils is poorly understood. The lack of comprehensive knowledge of exudate chemistry has been a major barrier to such mechanistic understanding.

The slow progress in exudate characterization can be largely attributed to the lack of analytical approaches that are comprehensive, require neither sample fractionation nor a priori knowledge, and that are capable of rigorous structure identification. Using a combination

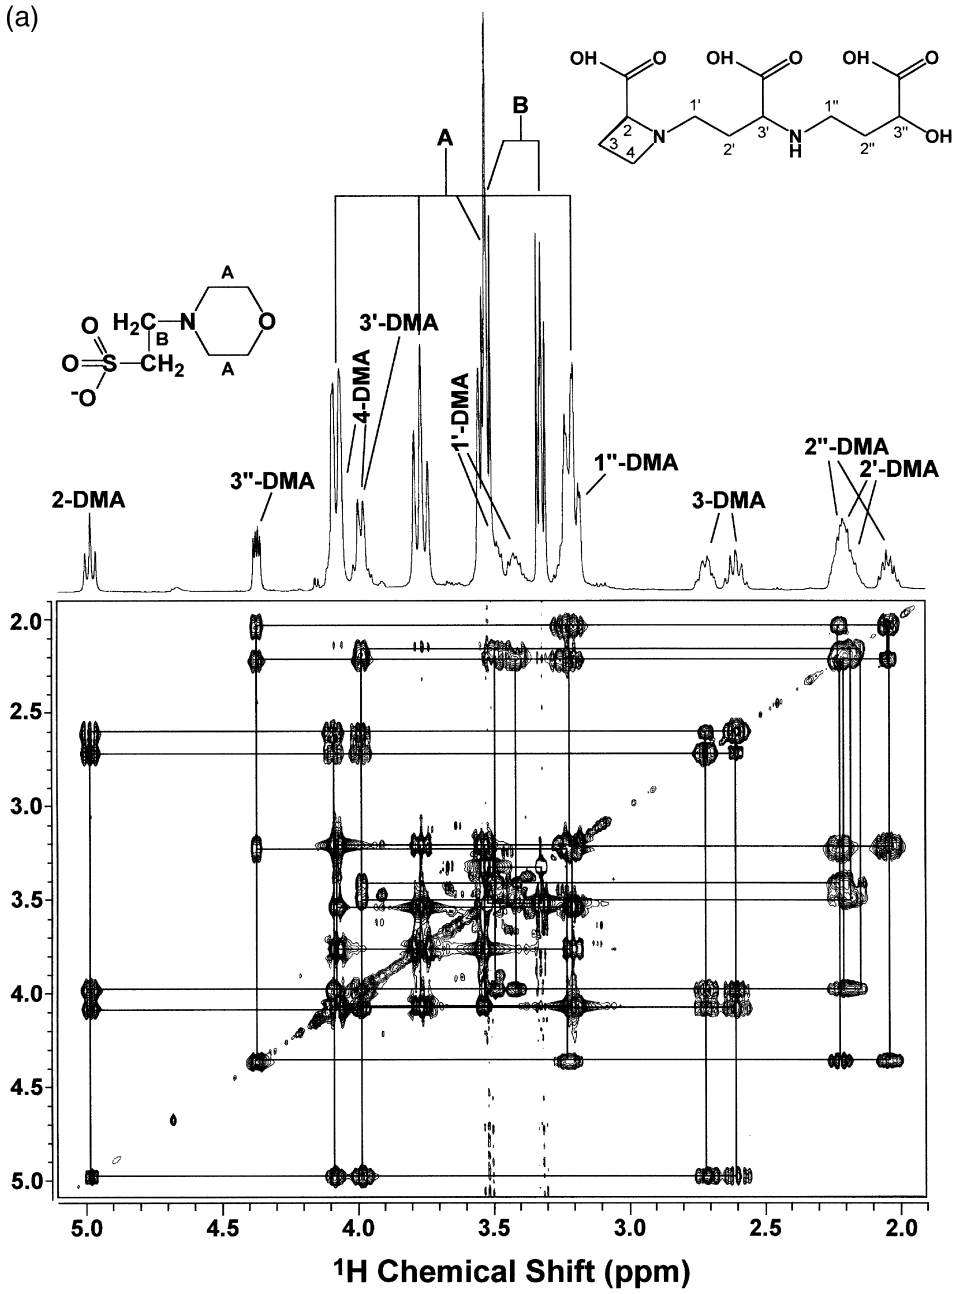

Fig. 1. (a) 2-D ^{1}H TOCSY, (b) ^{1}H–^{13}C HSQC, and (c) ^{1}H–^{13}C HMBC spectra of crude AgCS wheat exudate. The TOCSY spectrum was acquired with 2.5 s interpulse delay, 5 kHz spectral width in both dimensions, 8.2 kHz B1 field strength, 47.3 ms mixing time, and 0.41 and 0.072 s acquisition time in F2 and F1, respectively. The HSQC spectrum was obtained with 2.5 s interpulse delay, 5 kHz spectral width in F2 and 25 kHz in F1, and 0.147 and 0.022 s acquisition time in F2 and F1, respectively. The HMBC spectrum was recorded with the same parameters as the HSQC spectrum except for 0.499 s acquisition time in F2. DMA: 2′-deoxymugineic acid (right structure); C_A, C_B: A and B carbons of morpholinoethane sulfonate (MES, left structure), respectively. The pH of the exudate sample was 2.5.

of multi-nuclear and 2-D NMR with GC–MS, we have previously demonstrated a comprehensive determination of barley root exudates (Fan et al., 1997b) based on known spectroscopic databases (Fan, 1996) and literature information on phytosiderophores (Ma and Nomoto, 1993).

However, for totally unknown compounds or those not represented in the databases, the above approach is not always sufficient to deduce the complete structure(s). To supply the necessary information, we have now added high-resolution mass spectrometry to the previous methods to obtain molecular formula information. This greatly facilitated the determination of the complete structures of various exudate components not in the databases. We also demonstrated that root exudate profiles were highly dependent on plant species and genotypes of the same species as well as growth conditions. Moreover, we observed a significant attenuating effect of Cd treatment on root exudate profiles and yet an enhancement of transition metal uptake for both barley and wheat plants.

2. Results and discussion

2.1. Exudate analysis

Roots exudates of wheat, barley, and rice plants were analyzed by a combination of NMR and GC–MS methods as described previously (Fan et al., 1997b). Using this approach, comprehensive profiles of the components were obtained directly from crude exudates without sample fractionation. Illustrated in Fig. 1 are results of 2-D ^{1}H total correlation spectroscopy (TOCSY), ^{1}H–^{13}C heteronuclear single quantum coherence spectroscopy (HSQC), and ^{1}H–^{13}C heteronuclear multiple bond correlation spectroscopy (HMBC) for the root exudate of the wheat amphiploid (AgCS) under the low Fe-high Cd (↓Fe-↑Cd) treatment. From ^{1}H TOCSY analysis, covalent correlations between pairs of protons that are up to 4 bonds apart were traced, while the HSQC and HMBC experiments revealed carbon coupling to its directly attached protons and to protons 2-4 bonds away, respectively. Two dominant components

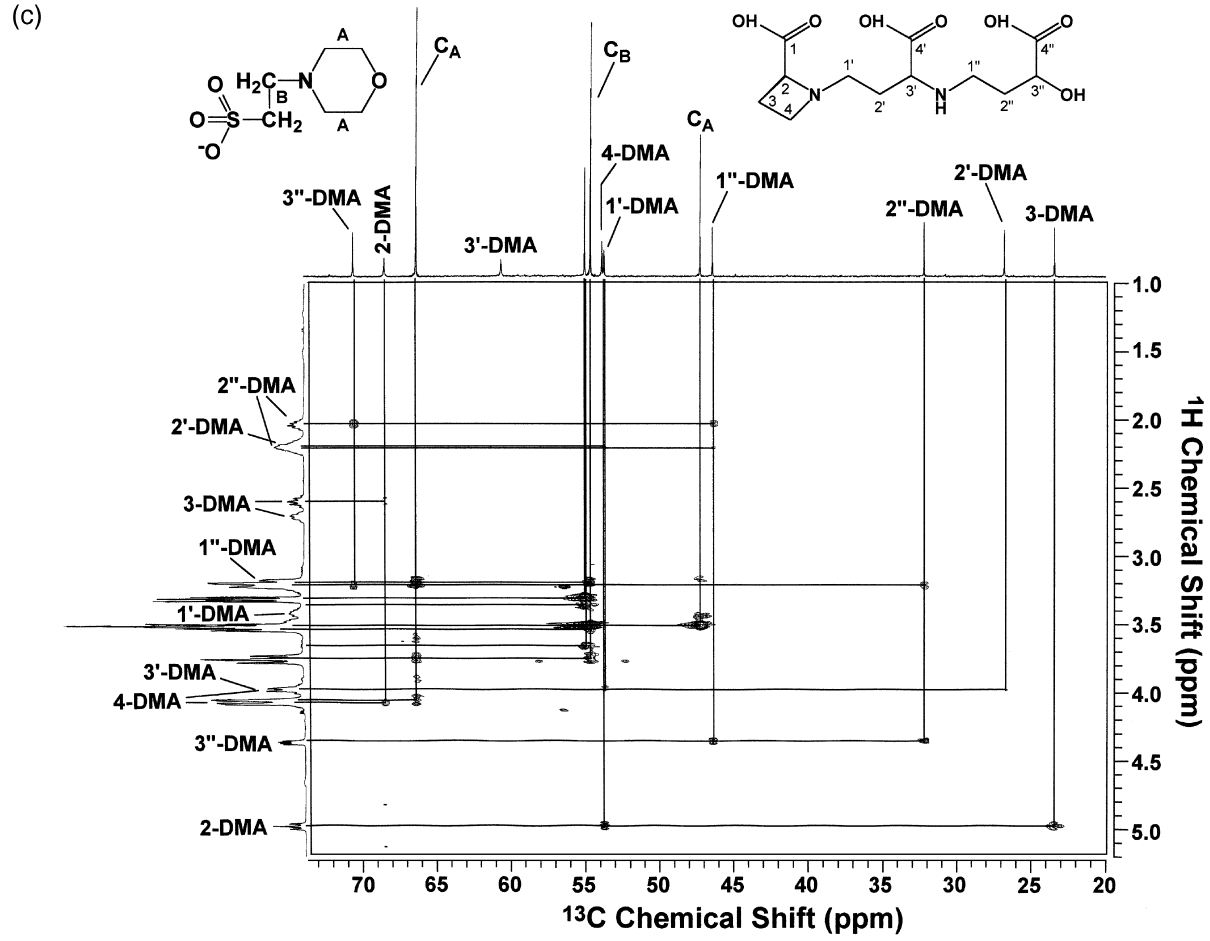

Fig. 1 (*continued*).

of the AgCS exudate were identified from these spectra, i.e. 2′-deoxymugineic acid (2′-DMA) and MES (the buffer included in the plant growth medium but not during exudate collection). The phytosiderophore, 2′-DMA, has been reported in common wheat (*Triticum aestivum* L.) root exudates (Murakami et al., 1989), but its exudation by the AgCS hybrid has not been characterized previously. As for MES, it is thought to be an impermeant buffer (but see below) and is not expected to be present in root exudates.

2′-DMA was assigned based on the ^{1}H and ^{13}C chemical shifts, proton covalent (scalar) connectivity acquired from the TOCSY spectrum (Fig. 1A), the proton to carbon covalent connectivity obtained from the HSQC (Fig. 1B) and HMBC spectra (Fig. 1C), as well as molecular ion data acquired from electrospray MS (ES–MS). All proton connectivities expected for 2′-DMA (H-2 to H-3 to H-4, H-1′ to H-2′ to H-3′, and H-1″ to H-2″ to H-3″) were present in Fig. 1A, so were the one-bond carbon to proton correlations in Fig. 1B. In addition, scalar correlations were evident in the HMBC spectrum (Fig. 1C) for the three carboxylate carbons to their closest protons (C-1 to H-2, C-4′ to H-3′, and C-4″ to H-3″) and between protonated carbons and their neighboring protons that are 2 (e.g. C-2″ to H-3″), 3 (e.g. C-1″ to H-3″), and 4 bonds (e.g. C-1′ to H-4) apart. Moreover, two mass ions (m/z 304 and 326) were evident in the full scan ES-MS spectrum (Fig. 2) of the same exudate, which corresponded to the molecular ion (M) and M + Na of 2′-DMA. Taken together, these NMR and MS data provided unequivocal identification of 2′-DMA in crude AgCS root exudates.

The presence of MES was deduced from the NMR [Fig. 1(a)–(c)], ES-MS (Fig. 2), and high-resolution fast atom bombardment (FAB) mass spectral data (data not shown). As shown in Fig. 2, the ES-MS spectrum of the crude AgCS exudate was abundant in the mass ions of 196, 218, and 413, in addition to 304 and 326. The *m*/*z* 218 and 413 ions were related to the *m*/*z* 196 ion based on their daughter ion patterns (data not shown), and could correspond to the Na adduct of the 196 monomer and dimer, respectively. From the FAB data of *m*/*z* 196, a molecular formula of $C_6H_{14}O_4NS$ was inferred with a mass error of 5.8 ppm. This information greatly assisted NMR in deducing the MES structure as described below.

The ^{1}H TOCSY data [Fig. 1(a)] revealed two sets of –CH_2–CH_2– groups with one set (A) having nonequivalent and the other (B) equivalent geminal protons. The integrated area of set A resonances was roughly twice that of set B resonances. In accordance with the molecular formula, set A protons should have originated from two chemically equivalent –CH_2–CH_2– groups while set B protons were derived from one –CH_2–CH_2– group. These three –CH_2–CH_2– groups accounted for all six of the carbons allowed in the molecular formula. In addition, the chemical shifts of both set A and B protons indicated that they were neighboring to heteroatoms such as N, O, or S. No other carbons including those from the carboxylates were present in the structure based on the analysis of 1-D ^{13}C NMR and 2-D HMBC [Fig. 1(c) and data not shown], which is consistent with the molecular formula. Moreover, no exchangeable (primary or secondary) amines were present based on the ^{1}H TOCSY spectrum recorded in H_2O instead of D_2O (data not shown), suggesting that the N is in a tertiary amine. A quarternary amine was ruled out based on the required number (14) of protons in the molecular formula. Altogether, the above structural clues allowed the MES structure to be deduced ab initio. Further proof for this assignment was obtained from the ^{1}H NMR analysis of the MES standard (data not shown), which matched exactly with that acquired from the AgCS exudate. Thus, using the combined NMR and MS approach, molecular structures of exudate components were identified from crude exudates without the need for a priori knowledge or any sample fractionation.

Using a similar approach, the exudate profile for the Chinese spring wheat (CS, a parent of AgCS) was examined. An example analysis of the CS exudates by TOCSY is shown in Fig. 3. Assigned components included Ile, Leu, Val, lactate (lac), Ala, acetate, 2′-DMA (peaks 1–9), malate, citrate, glycinebetaine (GB), Gly, α- and β-glucose (Glc), and α-trehalose (see Fan, 1996 for NMR parameters for these compounds). Except for the sugars, these assignments were verified by the ^{1}H–^{13}C HSQC analysis (data not shown) and in part by the GC–MS analysis of the same exudate (see below). In addition to components yielding sharp resonances, there were those whose cross-peaks were relatively broad (indicated by arrows). The identities of these components are currently unknown, although they are likely to be of macromolecular origin (e.g. proteins), as indicated by their chemical shifts and broad peak widths. A polypeptide that appears to be related to Al resistance has been reported in wheat root exudates (Basu et al., 1999)

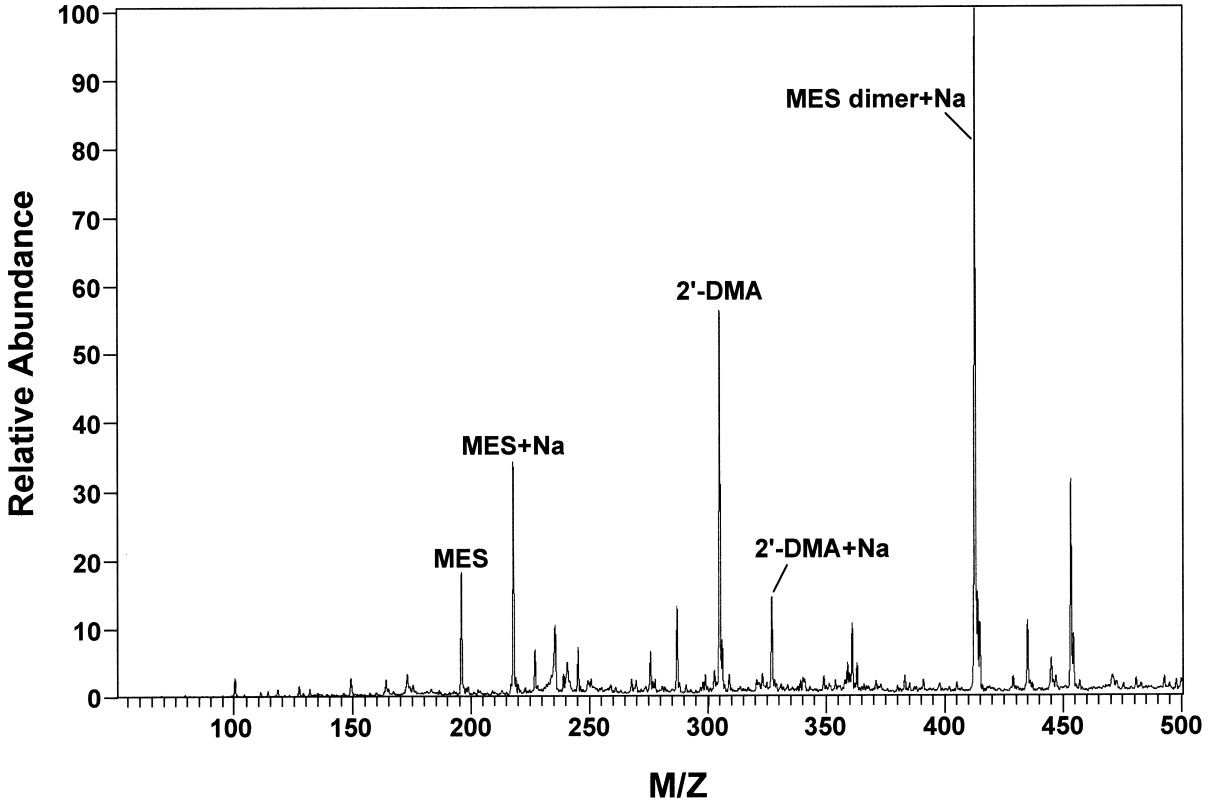

Fig. 2. Full scan electrospray mass spectrum of crude AgCS wheat exudate. The ES–MS spectrum was acquired in 50% methanol plus 1% formic acid from a LC-Q mass spectrometer.

2.2. Comparison of root exudate profiles from different plant species, genotypes, and growth conditions

Altogether, the above NMR spectroscopic analysis provided comprehensive profiles of exudate components (both known and unknown to our database) excreted by barley, wheat, and rice plants, as illustrated in Fig. 4. By comparing these ^{1}H NMR spectra, it is clear that exudate profiles varied with plant species and genotypes as well as treatment conditions. For example, the barley exudate differed from wheat exudates (CS and AgCS), most notably in the dominant mugineic acids present (3-*epi*-OHMA + MA for barley and 2′-DMA for wheat). A significant difference in the relative quantity of GB, Ala, γ-aminobutyrate (GAB), Gly, Glu, and acetate was also noted, although the difference in acetate may be complicated by a differential loss through volatilization during the freeze-drying process. The rice exudate profile was different again from those of barley and wheat, in that except for Gly, the amino acids and mugineic

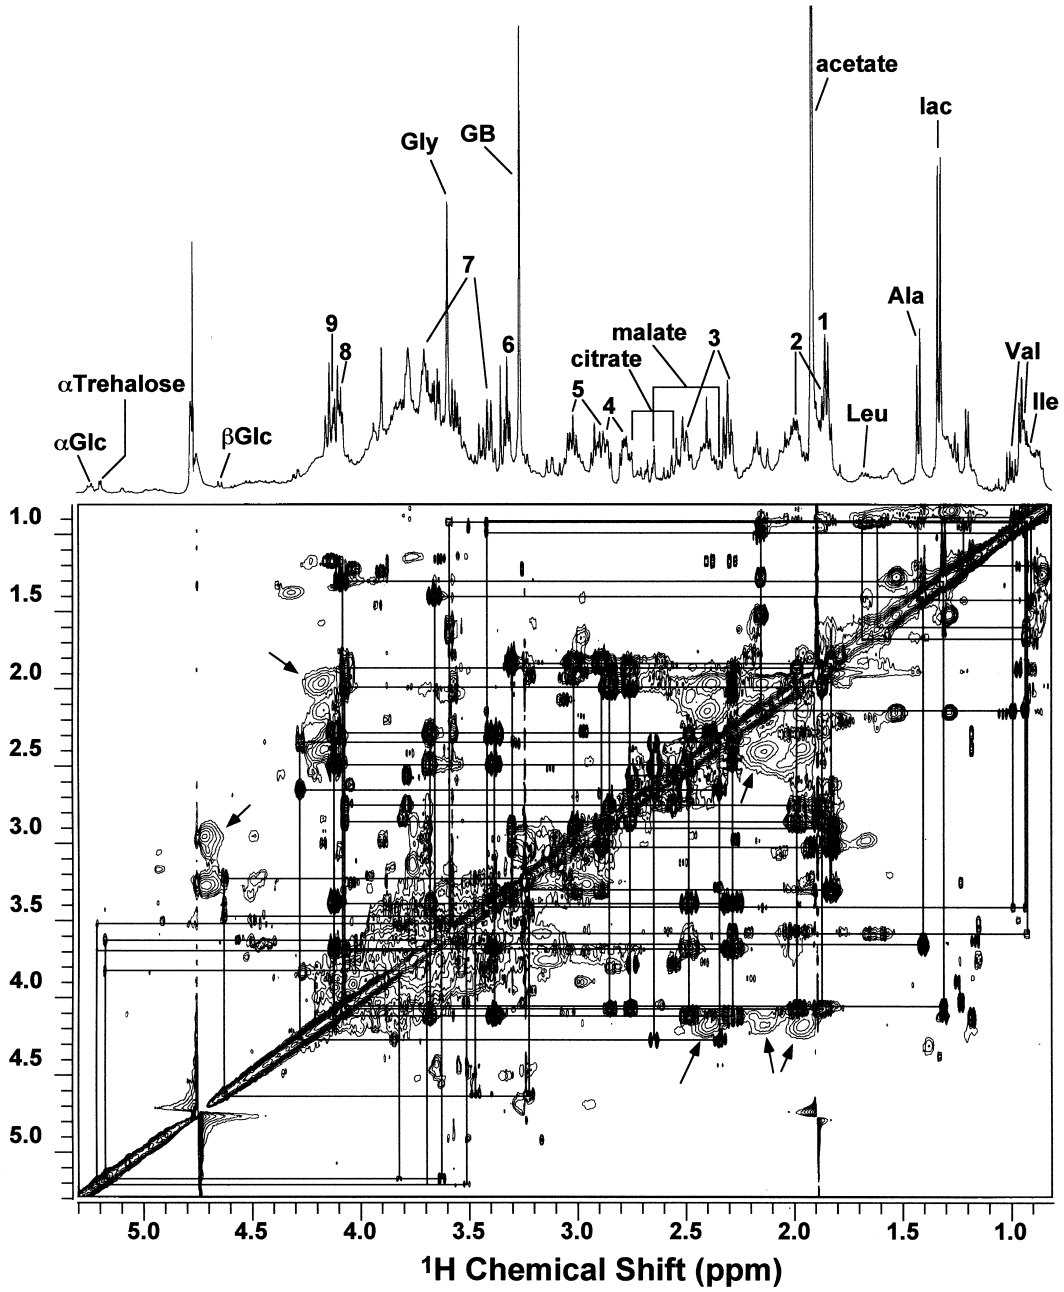

Fig. 3. 2-D ^{1}H TOCSY spectrum of Chinese Spring wheat root exudate. The TOCSY spectrum was acquired using 1.5 s interpulse delay, 5 KHz spectral width in both dimensions, 8.54 kHz B1 field strength, 47.3 ms mixing time, and 0.41 s and 0.051 s acquisition time in F2 and F1, respectively. Peaks 1-9: H-2′, H-2″, H-3, H-1″, H-1′, H-3′, H-4, H-3″, and H-2 of 2′-DMA, respectively; lac: lactate, GB: glycinebetaine, α,β-Glc: α,β-glucose. The pH of the exudate sample was 7.5.

acids were present only at very low concentration. In addition, an unknown polyol component was abundant in the rice exudate but absent in barley or wheat exudates.

Except for the exudation of 2′-DMA, the two wheat genotypes (CS vs. AgCS) exhibited rather different exudate profiles (Fig. 4). The AgCS exudate was dominated by the medium buffer MES and contained relatively little amino and organic acids, while the CS exudate was abundant in both amino and organic acids. In addition, unknown component(s) represented by a group of resonances from 1.1 to 1.6 ppm in the AgCS exudate were absent in the CS exudate. The difference in the MES content was presumably a result of the different treatment conditions, with MES included in the AgCS but absent in CS growth media. However, it is unlikely that the abundance of MES in the AgCS exudate was purely a result of contamination from the growth medium. This is because extensive rinsing of roots was performed before exudate collection. Moreover, an identical MES treatment was used to culture barley, yet MES was much less abundant in the barley exudate (Fig. 4). Instead, it is plausible that MES was taken up by AgCS roots and then excreted along with other exudate components. The possible effects of MES on the physiology of plants grown in buffered hydroponic media are unknown, but this finding suggests that this question should be studied in more detail for experimental protocols that use MES and other buffers to maintain the pH of plant growth media.

The same exudates from Fig. 4 were also analyzed by GC–MS and the results are shown in Table 1, along with those from the NMR spectroscopic analysis. The GC–MS analysis not only confirmed many of the NMR assigned components described above, but also provided absolute quantification of these components plus those that were below NMR detection limits. At the same time, the NMR analysis (with the aid of GC–MS analysis) provided absolute quantification for components (e.g. mugineic acids) that were not readily analyzed by GC–MS. Thus, the two approaches complemented each other in providing richer information than that achievable by each method alone.

In terms of total amounts of identified exudate components on a per gram root weight basis, the wheat hybrid AgCS ranked the highest (although a major portion was attributed to MES), followed by barley, wheat CS, and rice. It is also notable that many quantitative

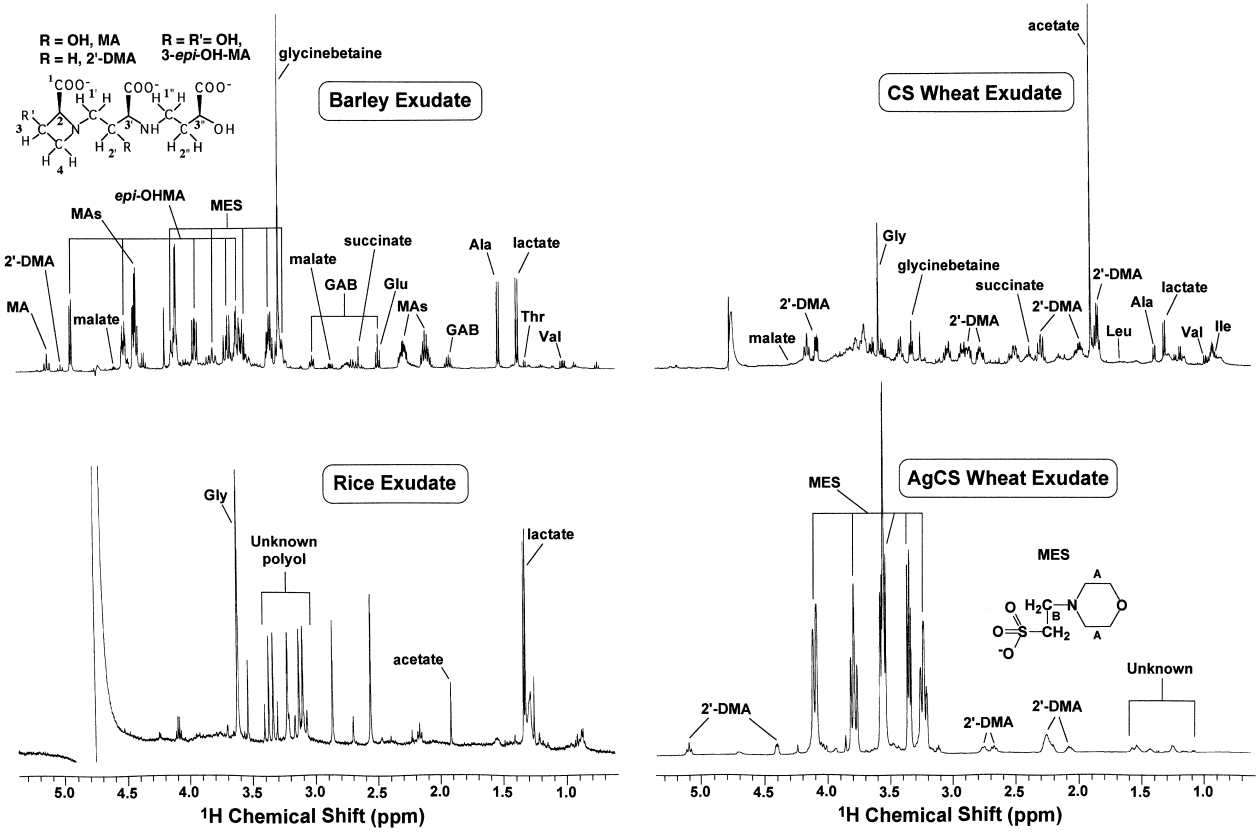

Fig. 4. 1-D ^{1}H NMR spectra of barley, wheat (CS and AgCS), and rice root exudates. The 1-D spectra were acquired using 2 s acquisition time, 2 (rice) or 5 s (the rest) interpulse delay, 5000 Hz spectral width, and 512 (rice) or 128 (the rest) transients. The abbreviations are as those in Figs. 1 and 5. The pH values of barley and AgCS root exudates were 2.2 and 2.5, respectively while those of rice and CS root exudates were 7.5.

differences in the exudate components of the four plant types were evident from the GC–MS profiles, which is consistent with the NMR characterization. Moreover, the abundance of the mugineic acid phytosiderophores in barley and wheat exudates was noted. In contrast, the exudation of these phytosiderophores by Fe-deficient rice roots was not apparent, which may be related to the NMR detection limit plus a much lower capacity of rice roots in excreting these compounds (Kawai et al., 1988). This lower capacity for mugineic acid exudation by rice roots has been correlated with their reduced ability to tolerate Fe deficiency (Marschner et al., 1986; Kawai et al., 1988; Mori et al., 1991).

2.3. Effect of combined Cd and Fe deficiency treatment on root exudate profiles of barley and wheat plants

Utilizing the above approach, we examined the chemical profiles of both barley and AgCS wheat exudates collected under a combination of Cd and Fe deficiency treatments. The effects of these treatments on plant growth, metal uptake, total Fe-mobilizing capacity, and other physiological parameters have been reported elsewhere (Shenker et al., submitted to Journal of Environmental Quality, JEQ). Here, we compared the effect of these treatments on root metal content with that on exudate composition, as shown in Figs. 5 and 6, for barley and wheat, respectively. Although many more exudate components have been analyzed (see Fig. 4), the comparison is illustrated for abundant metal ion ligands (MIL), since they are more likely to influence metal mobilization and uptake by plant roots. The stability constants of these MIL with different metal ions vary considerably, and their actual ability to mobilize various metal ions will depend on the pH and ionic composition of the soil solution, as well as kinetic factors involved in the dissolution of soil minerals.

Table 1
GC–MS and NMR quantification of wheat and barley root exudates under low Fe plus Cd treatment

	μmol/g root dry wt.

Total	32.63	20.19	234.55	5.46

[a] Quantified by GC–MS except for 3-*epi*-OHMA, 2′-DMA. MA, GB, MES, and acetate, which were analyzed by NMR using existing lactate as an internal standard.

[b] AgCs quantified by NMR with the addition of 1 mM Ala as an internal standard.

[c] ND, not detected; –, not determined.

Under Fe deficient conditions (↓Fe-↓Cd and ↓Fe-↑Cd), the increased exudation of the 3-*epi*-OHMA, MA, 2′-DMA, and malate in barley (Fig. 5 and Table 2) and 2′-DMA in wheat exudates (Fig. 6) was evident, as compared to Fe sufficient conditions (↑Fe-↑Cd and ↑Fe-↓Cd). This increase was in turn related to the elevated production of Fe mobilizing substances (FeMS) by barley (data not shown) and wheat (Fig. 6) under Fe deficiency. These results are consistent with the role of these MIL in Fe acquisition. The exudation of other abundant MIL (i.e. lactate, Ala, GAB, and GB for barley; MES for wheat) did not exhibit a clear response to Fe deficiency (Figs. 5, 6 and Table 2), which suggests that they are not specifically involved in Fe acquisition. However, these MIL may still function generally in chelating Fe for uptake.

Accompanying the increased exudation of the phytosiderophores was the elevated content of Zn and Cu in barley roots (Fig. 5), Cu in wheat roots (Fig. 6) as well as Zn, Cu, and Mn in both shoots (Shenker et al., 2000). This finding suggests that the MAs may be important in the acquisition of Zn, Cu, and Mn, in addition to Fe. It is also noteworthy that the exudation pattern of malate was similar to that of the MAs by barley roots (Fig. 5). This result could be accounted by the exudation of malate and MAs via a common anion channel. However, other abundant anions in root tissues including citrate and malate (unpublished results) did not exhibit such exudation pattern, which argues against a systemic leakage through such a channel. In fact, citrate was not exuded by barley or wheat roots to any significant extent (data not shown). Regardless of the exudation mechanism(s), it is possible that the exuded malate could serve a similar role as MAs in mediating the observed accumulation of transition metals in barley and wheat tissues.

As for Cd acquisition, there was no statistically significant correlation of the above MIL to the Cd content

of roots (Figs. 5 and 6) or shoots (data not shown) of barley and wheat. This result suggests that Cd acquisition may involve a mechanism different from that of transition metal acquisition. It is also interesting to note that there appeared to be a weak correlation between MES concentration in wheat exudates and root Cd content (Fig. 6). It is possible that the presence of MES may interact with Cd to affect the latter uptake into wheat. Cd accumulation could weaken membrane integrity or increase membrane permeability via lipid peroxidation (Stohs and Bagchi, 1995; Goyer, 1997), which allows Cd-bound MES to enter into root cells

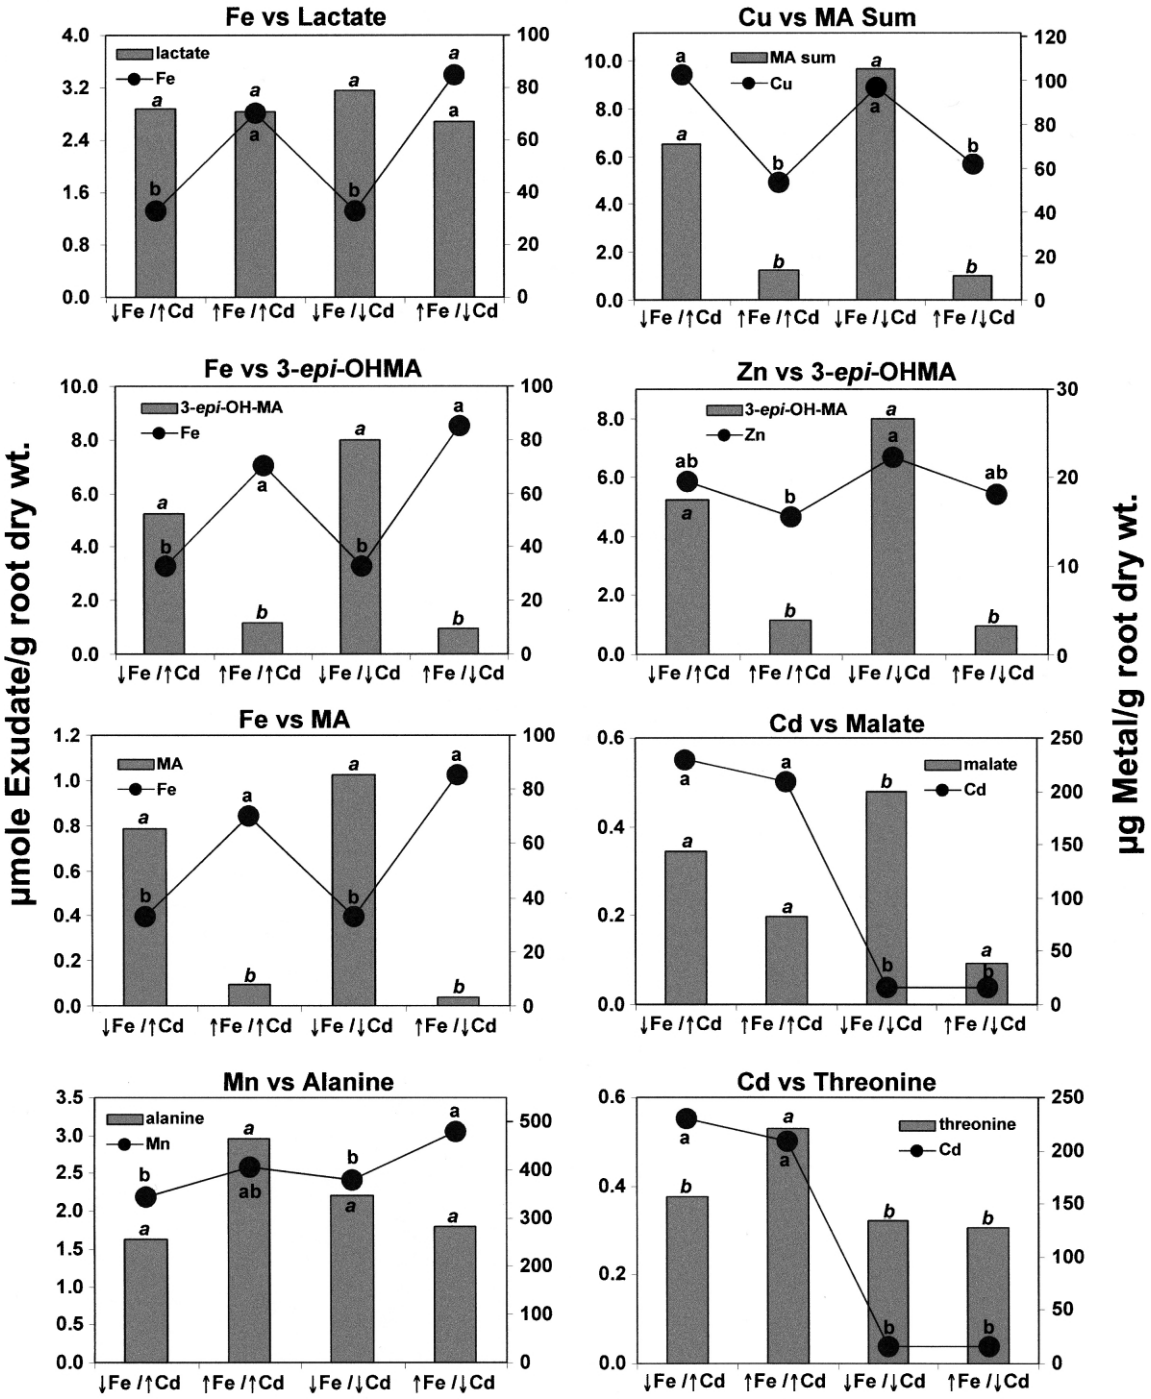

Fig. 5. Relation of barley root exudate components to root metal contents. The root exudate components were analyzed as described in Materials and Methods while the root metal content was acquired from Shenker et al. (2000). 3-*epi*-OHMA, 3-*epi*-hydroxymugineic acid; 2′-DMA, 2′-deoxymugineic acid; MA Sum, 3-*epi*-OHMA + 2′-DMA + MA. Two-way ANOVA test or Duncan's multiple range analysis of variance from the GLM statistical package of SAS was performed on the data. Different letters (italicized letters for exudate components and normal letters for root metal content) indicate statistical difference at a $P < 0.05$ significance level.

and later to be released to the collection solution down the concentration gradient. This hypothesis is consistent with the higher Cd uptake and MES release by AgCS wheat roots than by barley roots (cf. Figs. 5 and 6; Table 1). For barley, the exudation of Ser, Thr, and Glu appeared to be related to the high Cd treatment under Fe sufficient conditions (Fig. 5 and Table 2). It is possible that these MIL may be involved in Cd acquisition.

In conclusion, the combination of multinuclear and 2-D NMR with GC–MS and high-resolution MS provided de novo identification of a number of components directly in crude root exudates of different plant types. This approach was applied to examine the role of exudate MIL in the acquisition of Cd and transition metals by barley and wheat. The results suggest that enhanced exudation of mugineic acids and malate may be involved in transition metal but not Cd acquisition. Therefore, the acquisition mechanism appears to differ between the essential and toxic pollutant metals.

3. Experimental

3.1. Plant growth

The plant varieties used were Barley (*Hordeum vulgare* L., cv. CM-72), wheat (*Triticum aestivum* L., cv. AgCS, a hybrid of Chinese spring wheat and *Lophopyrum*. sp) supplied by Dr. J. Dvorak (Rommel and Jenkins, 1959), Chinese spring wheat (CS, a parent of AgCS), and rice (*Oryza sativa*, L., cv M201). Barley and AgCS wheat seedlings (eight per treatment) were grown for 22 days in nutrient solutions containing $CdCl_2$ buffered by an excess of EDTA and HEDTA (Fan et al., 1997b; Shenker et al., 2000) to produce Fe-sufficient (pFe = 17.2) and deficient (pFe = 18.2–18.4) conditions in combination with free Cd activity (pCd) of 8.8 or 10.0. Other free metal activities were pZn = 10.1, pCu = 13.5; and pMn = 7.3 (for complete plant growth protocol refer to Shenker et al., 2000). The four treatments

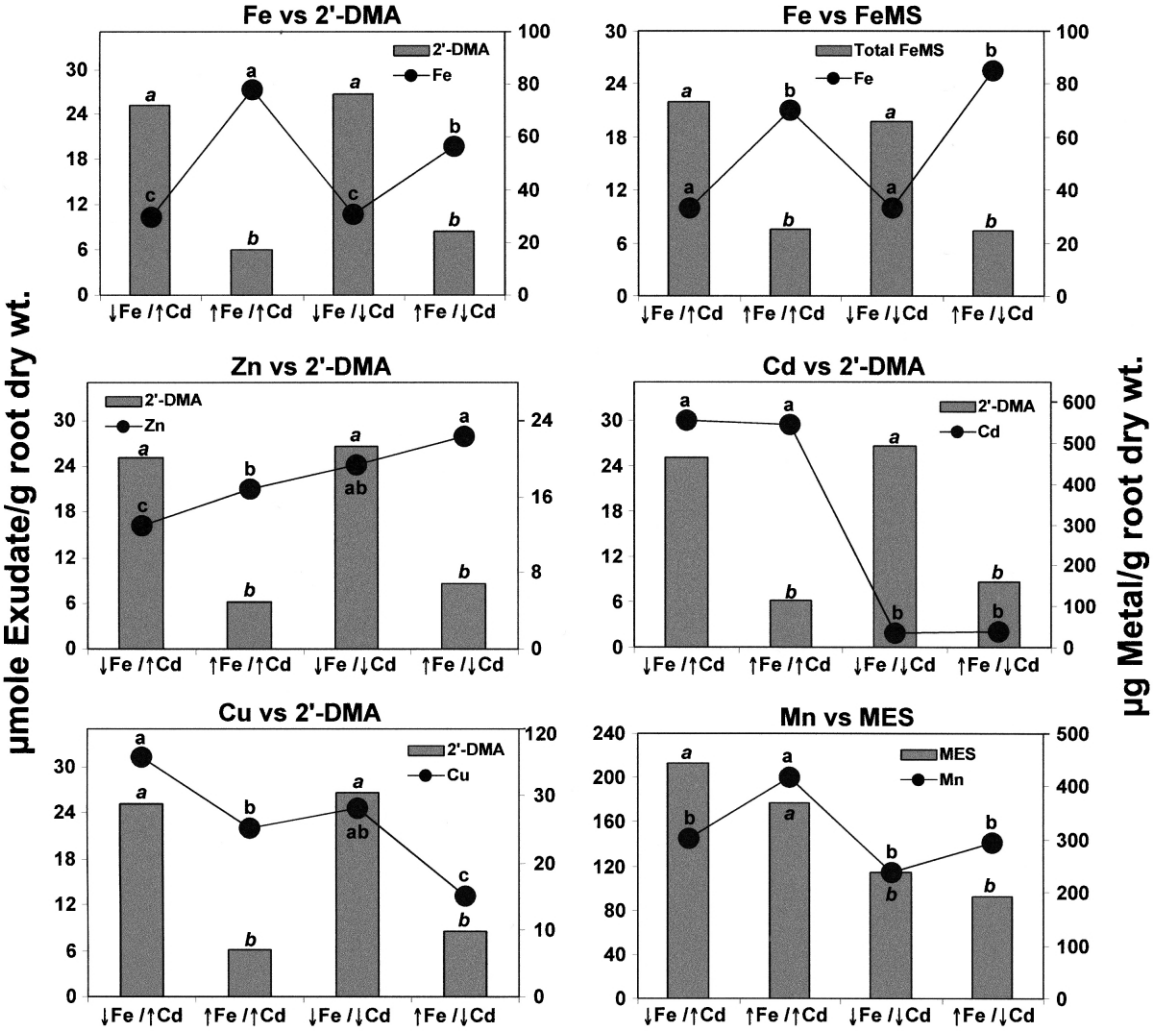

Fig. 6. Relation of wheat root exudate components to root metal contents. The root exudate components were analyzed as described in Materials and Methods while the root metal content and concentration of Fe mobilizing substance (FeMS) were acquired from Shenker et al. (2000). 2′-DMA, 2′-deoxymugineic acid; MES, morpholinoethane sulfonate. Statistical analysis was performed as in Fig. 5.

are designated as: (1) low Fe/high Cd (↓Fe-↑Cd); (2) high Fe/high Cd (↑Fe-↑Cd); (3) low Fe/low Cd (↓Fe-↓Cd); and (4) high Fe/low Cd (↑Fe-↓Cd). Morpholinoethane sulfonate (MES) at 2 mM was also included to buffer the pH of the nutrient solution at 6.2±0.2. Chinese spring (CS) wheat and rice (cv. M201) seedlings (four per treatment) were grown similarly for a month except that the nutrient solution employed was half-strength modified Hoagland solution (Epstein, 1972) containing full-strength (50 μM) Fe(III)-EDTA, 25 μM EDTA, and 10 μM $CdSO_4$ in the absence of MES (Fan et al., 2000). The calculated pMs in this nutrient solution were pFe = 17.6, pMn = 7.3, pCu = 12.8, pZn = 9.9, pNi = 12.1, and pCd = 8.9 (Shenker et al., 2000). The pH of the growth media was maintained at 6.0±0.3 by daily titration with 0.1 M HCl or KOH while the nutrient solution was renewed frequently to avoid nutrient depletion.

3.2. Root exudate collection

Roots were soaked in 1 mM $Ca(NO_3)_2$ for 10–20 min and rinsed extensively with doubly deionized (DD) H_2O to remove organic and inorganic constituents of the nutrient solution, including metabolites, exudates, chelates, mineral elements, and buffer ions before exudate collection. Root exudates were collected 2–3 times each in 150–200 ml DDH_2O during peak diurnal release of phytosiderophores (2–4 h after light onset) of the last 3–6 growth days. The collected solutions were immediately filtered through glass microfiber filters (GF/C, Whatman, Maidstone, England) to exclude root fragments and much of the microbial population, pooled, and lyophilized for storage. Prior to NMR studies, the exudates were resuspended in sterile water, filter sterilized, and passed through Chelex 100 resin (BioRad, Hercules, CA) to remove paramagnetic ions, as described previously (Fan et al., 1997b).

3.3. NMR analysis

The Chelex 100-treated exudates of barley and AgCS were acidified to pH 2, lyophilized, and redissolved in D_2O, whereas the CS and rice exudates were not acidified (pH values ranging from 7.0 to 7.8). NMR spectra were recorded at 25°C on a Varian (Palo Alto, CA) 11.75 Tesla UnityPlus (all ^1H experiments) and a Bruker AM-400 spectrometer (1-D ^{13}C analysis). The following 2-D ^1H experiments were conducted: ^1H total correlation (TOCSY), double-quantum filtered correlation (DQF-COSY), ^1H–^{13}C heteronuclear single quantum coherence (HSQC), and ^1H-^{13}C heteronuclear multiple bond correlation (HMBC). Selected samples were dissolved in DD H_2O containing 10% D_2O + 0.9 M HCl

for Watergate TOCSY measurement (Piotto et al., 1992) at 5°C which optimized the detection of exchangeable protons (Fan et al., 1997a). Detailed acquisition parameters are described in respective figure legends. The 1-D NMR spectra were apodized using an exponential function yielding 0.5-2 Hz line broadening, and zerofilled to 64 or 128 K points before Fourier transformation. The 2-D NMR data were zerofilled or linear-predicted to 8×2 K points and apodized with a mild Gaussian function before 2-D Fourier transformation.

3.4. Mass spectrometry

Nanospray mass spectra were acquired on an LCQ "classic" quadrupole ion trap mass spectrometer (ThermoQuest, Austin, TX) equipped with a nanospray source (Protana, Odense, Denmark) operated at a spray voltage of 800 V and a capillary temperature of 150°C. Lyophilized root exudates were dissolved in 50% methanol, 1% formic acid and 2 μl transferred to an Econo12 nanospray needle (New Objective Inc, Cambridge, MA). MS^2 and MS^3 analyses were performed at a collision energy of 30% and an isolation width of 4 Da.

Accurate mass of exudate components were measured on a Finnigan 2001 Newstar FT/MS system (ThermoQuest, Madison WI) at 3 .0 Tesla. The spectrometer was externally calibrated with PMMA 640. The lyophilized sample was delivered to the mass spectrometer by flow injection at 5 ml / min using a syringe pump (Cole Palmer, Vernon Hills, IL) to an Analytica, API external source operating at a capillary voltage of 5.5 kV.

3.5. GC–MS analysis

All exudates were acidified in 0.1 N HCl before an aliquot was lyophilized and derivatized with *N*-methyl-*N*-[*tert*-butyldimethylsilyl]trifluoroacetamide (MTBSTFA) before analysis on a Varian 3300 gas chromatograph interfaced to a Finnegan ITD 806 mass spectrometer (Fan et al., 1997b).

3.6. Exudate quantification

All components of exudate collection solutions were quantified by their GC–MS response as compared to that of the standard with known concentration, except for the mugineic acids (MAs), glycinebetaine (GB), acetate, and MES (see Fig. 4). The latter were quantified from their ^1H NMR responses by comparison with the methyl resonance of alanine at 1.47 ppm (either endogenous or added) after corrected for signal saturation and number of protons. The concentration of the endogenous Ala was determined from GC–MS analysis (Fan et al., 1997b). In addition, the FeMS data were adapted from Shenker et al. (2000), which were acquired using the Cu–CAS (chrome azurol S) colorimetric assay (Shenker et al., 1995). This assay measured the total capacity of Fe mobilization in crude exudates.

Received 11 August 2000; received in revised form 4 December 2000

Abstract

From the bark of *Pinus strobus* infected with pinewood nematode, *Bursaphelenchus xylophilus,* a stilbenoid 3-*O*-methyldihydropinosylvin and a flavanone (2*S*)-pinocembrin were isolated as active principles of inducibly produced antifungal compounds. The structures of the compounds were determined on the basis of spectroscopic analyses. Close investigations of spectroscopic analyses led to the complete assignment of ^{13}C NMR and ^{1}H NMR chemical shifts for the former compound and to the determination of the stereochemistry of the latter compound from *P. strobus* to be 2*S*. Furthermore, the distribution and time course accumulation of the identified compounds were investigated. The former compound was demonstrated to be nematocidal and the concentrations of the compound in the inoculated branches were sufficient enough to inactivate the pinewood nematode within one week after inoculation. © 2001 Elsevier Science Ltd. 1. Introduction

When plants are challenged by microbial invasion, many of them produce phytoalexins (Harborne, 1999) to ward off microbes. Phytoalexins are defined (Paxton, 1981) as "low molecular weight, antimicrobial compounds that are both synthesized and accumulated in plants after exposure to microorganisms". During our survey of chemical defense responses of pine species which are resistant to the pinewood nematode *Bursaphelenchus xylophilus,* which causes pine wilt disease (Kiyohara and Tokushige, 1971), *Pinus strobus* was demonstrated to accumulate antifungal compounds against *Cladosporium herbarum* in its xylem and those compounds were identified as pinosylvin, pinosylvin monomethylether, pinobanksin, and pinocembrin (Yamada and Ito, 1993a). However, there were two unidentified compounds in the pine bark after infection by the nematode. Here we report the isolation and structural determination of the unidentified compounds based on spectroscopic analyses. We also report the distribution and time course accumulation of isolated antifungal compounds in the bark and wood of nematode-infected *P. strobus* together with the inhibitory effects of one of the isolated compounds on the nematode. The possible roles of these compounds in the defense mechanisms of pine are also discussed.

2. Results and discussion

An antifungal compound **1** in the bark of *P. strobus* was isolated as a clear oil. A comparison of UV, EIMS, HREIMS, and ^{1}H NMR spectra with previously reported spectra (Takasugi et al., 1987; Suga et al., 1993) showed that the structure of compound **1** could be a 3-*O*-methyldihydropinosylvin. This compound was previously reported as a heartwood constituent of *P. armandii* (Fang et al., 1988) without any data and as that of *P. albicaulis* (Lindström and Westfelt, 1967) with only the melting point. Lindstedt and Misiorny (1951) used paper chromatography to determine the presence of compound **1** together with pinosylvin and 3-*O*-methylpinosylvin in the heartwood of *P. strobus*. However, they did not detect compound **1** in the bark of the plant. These results suggest that compound **1** is inducibly produced in the bark or transferred to the bark from the

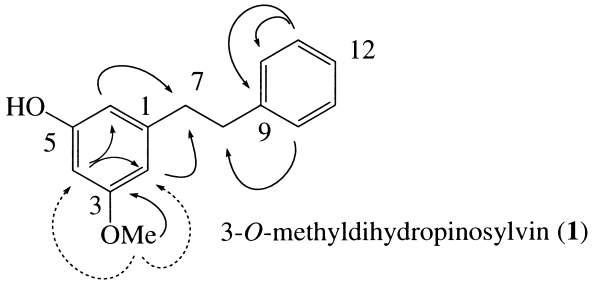
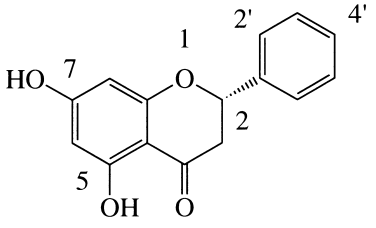
xylem as a response to nematode infection. As there had not yet been a complete assignment of ^{1}H NMR and ^{13}C NMR spectral data for this compound, close investigation using 2D NMR (COSY, HSQC, HMBC, and NOESY) and DEPT analyses on the compound were conducted. Fifteen carbon signals which were assigned to 12 aromatic carbons (8 methines, 4 quaternary carbons), 2 methylene carbons, and a methoxyl carbon were obtained by DEPT analysis. Diagnostically significant C–H long-range correlations found in HMBC and NOESY are given in Fig. 1. A proton at δ 6.20 ppm which showed a C–H long-range correlation with an aliphatic methine at δ 2.76 ppm were assignable to H–2 or H–6. Moreover, because this proton showed an NOE with a methoxyl group at δ 3.68 ppm, it was assigned to H-2. This key assignment allowed us to complete the remaining assignments. Finally, the complete assignment of ^{1}H NMR and ^{13}C NMR chemical shifts was determined as shown in the experimental section.

The second antifungal compound, **2**, in the bark was obtained as a clear oil. The ^{1}H NMR spectrum of **2** was identical with pinocembrin (Kuroyanagi et al., 1983), and the assignment of ^{13}C NMR chemical shifts based on 2D NMR (COSY, HSQC, and HMBC) of **2** was identical with that based on the 1D long-range C–H coupling and deuterium isotope effects from hydroxyl groups to ^{13}C chemical shifts (Jung and McLaughlin, 1990). In a EIMS of pinocembrin-3-*d* (**3**), a base ion *m/z* 258 $[M]^{+}$ (100) and fragment ions *m/z* 181 (60) and *m/z* 152 (52), which were assigned as an A–C ring fragment and an A ring fragment, respectively, were observed. The CD spectra of this compound showed a positive absorption around 310–325 nm and a negative absorption around 285 nm. These findings indicate for the first time that the absolute configuration at C-2 of pinocembrin from *P. strobus* to be *S* (Miyaichi et al., 1987). Although the presence of compound **2** in the heartwood and sapwood of *P. strobus* had been shown, the presence of compound **2** in the bark of the plant had not yet been detected using paper chromatography (Lindstedt and Misiorny, 1951) and may be inducibly produced in the bark or transferred to the bark from the xylem as a response to nematode infection.



3-*O*-methyldihydropinosylvin (**1**)

Fig. 1. Arrows show the diagnostically significant C–H correlation found in HMBC (⟶) and NOE (⇢).



pinocembrin (**2**)

We also investigated the distribution and time course accumulation of these compounds in the bark and the wood of nematode-infected *P. strobus* using GC. Branches of the *P. strobus* were divided into three portions based on distance from the site of infection to determine the distribution of the compounds. Fig. 2 shows the time course accumulation of compound **1** in the bark and the wood and that of compound **2** in the bark of inoculated and non-inoculated branches. Compound **1** accumulated in the bark of all portions (A, B, and C) one week after infection. However, no accumulation of compound **1** was found in the bark of the non-inoculated control. In the case of the wood, which was found to consist only of sapwood by microscopic analysis, compound **1** accumulated in portion C of the inoculated branches. However, the amount was only about one-third of that found in bark one week after inoculation. In portions A and B of the wood of inoculated branches, only a trace accumulation of compound **1** was detected. On the other hand, no accumulation of compound **1** was found in the wood of any portions of the non-inoculated branches. These findings concerning the accumulation of compound **1** in the wood were similar to those regarding the accumulation of 3-*O*-methylpinosylvin, pinobanksin, and pinocembrin in wood of nematode-infected *P. strobus* branches (Yamada and Ito, 1993a). These compounds also accumulated only in portion C of the inoculated branches. When the nematode *B. xylophilus* was inoculated to the branches of susceptible pine trees *P. thunbergii,* most of them were located in the resin canals of cortex and were hardly found in the xylem three days after inoculation (Mamiya, 1985). Therefore, the difference in the accumulation pattern of compound (**1**) in the bark and the wood of *P. strobus* might be related to the amounts of nematodes which might locate in those tissues of the plant in the same manner as in *P. thunbergii*. It is often considered that there is a close association between the age of sapwood and the formation of heartwood, which contains a high amount of secondary metabolites (Hillis, 1987). The age of portion C, which was adjacent to a stem, could be sufficient to produce secondary metabolites in relatively higher amounts than that accumulated

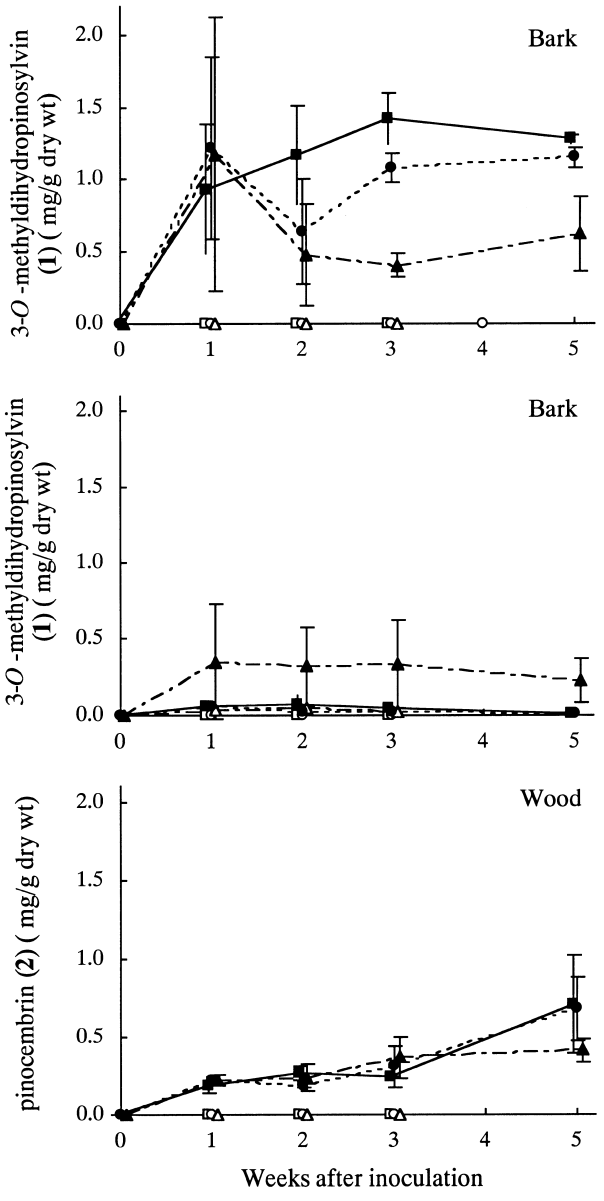


Fig. 2. Distribution and time course accumulation of inducibly produced compounds in the bark and in the wood of *Pinus strobus* branches after inoculation with *Bursaphelenchus xylophilus*. Inoculated and control branches were divided into three portions based on distance from the infection site (A: 6–11 cm, B: 16–21 cm and C: 26–31 cm). The infection site is 31 cm away from the stem and portion C is adjacent to the stem. 3-*O*-methyldihydropinosylvin (**1**) in the bark (upper) and in the wood (middle) and pinocembrin (**2**) in the bark (lower). Vertical bars show standard deviations of three replicates. ——□——, portion A in noninoculated branches; – – ○ – –, portion B in non-inoculated branches; —— △ ——, portion C in non-inoculated branches; ——■——, portion A in inoculated branches; – – ● – – portion B in inoculated branches; —— ▲ —— portion C in inoculated branches.

in portions A and B. The accumulation pattern of compound **2** in the bark of inoculated branches was different from that found for compound **1** in the bark and wood and also different from that found for compound **2** in the wood (Yamada and Ito, 1993a). Compound **2** gradually accumulated in all portions of the bark of nematode-inoculated branches. However, it did not accumulate in any portions of non-inoculated branches. It is supposed that these secondary metabolites in heartwoods and in plants tissues under certain stresses such as mechanical injury or fungal infection are produced in situ from transport and/or storage metabolites, such as carbohydrates and/or lipids by living parenchyma cells (Hart, 1981; Hillis, 1987). 3-*O*-Methyldihydropinosylvin (**1**) and pinocembrin (**2**) could also be produced in situ at portions A, B and C of the bark and the wood of inoculated branches. In addition, it is difficult to hypothesize that these compounds were transferred to the bark from the wood where the accumulation level of these compounds was lower than that in the bark (compound **1** was almost absent in portions A and B of the wood). Therefore, it could be concluded that the biosynthetic pathway of *3-O*-methyldihydropinosylvin (**1**) and pinocembrin (**2**) in both bark and wood were activated in the respective portions by the infection stress of *B. xylophilus,* which can move in tissues of *P. strobus* (Tamura et al., 1988; Yamada and Ito, 1993b). It may be possible that these compounds were derived from glucosides of respective compounds by the hydrolyzing activity of β-glucosidase which was released from invading microbes into infected tissue, as in the case of Sitka spruce (Woodward and Pearce, 1988). This possibility could be unlikely, since the glucosides of 3-*O*-methyldihydropinosylvin (**1**) and pinocembrin (**2**) have not been reported from *P. strobus* thus far.

Compound **1**, which was obtained by catalytic hydrogenation of 3-*O*-methylpinosylvin, was reported to have strong nematocidal activity (Ali et al., 1992; Suga et al., 1993). This fact helps us to understand the chemical defense mechanisms of *P. strobus* against microbial invasion. Because compound **1** accumulated in the bark and the wood of nematode infected branches was not only antifungal but also nematocidal against *B. xylophilus,* it is possible to assume that, as a phytoalexin, compound **1** can protect *P. strobus* from invasion of those organisms. However, the role of the induced compound **1** in nature remains unclear. The nematocidal and nematode-immobilizing activities of compound **1** are not distinguishable in the present study from those of previous reports. Hence, we investigated the nematocidal and nematode-immobilizing activity of compound **1** on *B. xylophilus*. These activities were measured by comparing the ratio of nematodes, which did not move in medium containing compound **1**, with the ratio of nematodes, which were not recovered from an immobilized state within one or three days after transferring then into compound **1**-free medium (see experimental). Nematodes were completely killed in 250 ppm soin. of compound **1** (Table 1). About half of the nematodes were immobilized in a 100 ppm soln. of compound **1** (0 days). Among the

immobilized nematodes, ca. half did not recover by 1 and 3 days after transferring them into compound **1**-free medium; they were considered to have been killed by the nematocidal activity of compound **1**. Soln. with conc. of less than 50 ppm did not affect the mobility of the nematodes. A significant difference was not observed between one-day- and two-day-treatments with compound **1** before transferring nematodes into compound **1**-free medium. These results indicate that within one week after nematode infection, the conc. of 3-*O*-methyldihydropinosylvin was sufficient (ca. 1000 ppm in the bark and ca. 400 ppm in the wood) to completely inhibit nematode activity in the bark of inoculated branches and in the wood adjacent to the stems of the inoculated branches. In our previous studies, a rapid dispersion of nematode was not inhibited in *P. strobus* branches within one week after infection (Yamada and Ito, 1993b; Tamura et al., 1988). However, the reproduction of the nematode was thereafter inhibited. This phenomenon can be explained by the time delay of the accumulation of inhibitory compounds that occurs after the infection. In addition to the above results, nematocidal compounds pinosylvin and pinosylvin monomethylether (Suga et al., 1993) also accumulated in the wood of inoculated branches (Yamada and Ito, 1993a). The amount of the latter compound was also sufficient to completely inhibit nematode activity. These inhibitory compounds found in the bark and wood from *B. xylophilus-infected* branches of *P. strobus* play important roles in the chemical resistance of the plant against pine wood nematodes. Some phytoalexins which were initially found as antibiotic principles in plant–microbe interactions were known to be also induced by nematodes and showed nematostatic and nematocidal activities (Veech, 1982). Therefore, nematodes could be included among the "microorganisms" referred to in the definition of phytoalexins in the report of by Paxton (1981).

3. Experimental

3.1. General

Analytical TLC was carried out using Merck pre-coated silica gel 60 plates (F254; layer thickness, 0.25 mm). Compounds on the TLC plates were detected under UV light (wavelength, 365 and 254 nm) and by visualization with Gibbs reagent (Tahara et al., 1984). ElMS spectrometry was conducted on a JEOL JMS-DX303 HF instrument (direct inlet system, 70 eV ionization potential). ^{1}H NMR (500 MHz) and ^{13}C NMR (125 MHz) spectra were determined on a JEOL alpha 500; TMS was used as an internal standard. Data are described in δ ppm. Capillary GC was carried out on a CBP-1 (1: 25 m, i.d.: 0.22 mm, film thickness: 0.25 μm; carrier gas: N_2 1 ml/mm; column temp. prog.: 150–270° C at 4°C/min; injector temp.: 270°C) coupled to a Shimadzu GC-9AM using an FID detector set at 270°C. Low resolution GC–MS were recorded by an HP5790 coupled to an HP5890 equipped with an HP-i fused silica capillary column (1: 25 m, i.d.: 0.2 mm, film thickness: 0.11 μm; carrier gas: He 1 ml/min; column temp. prog.,: 120–210°C at 3°C/min; injector temp.: 260°C.

3.2. Plant material and inoculation of nematode

These procedures have been described previously (Yamada and Ito, 1993a,b). Briefly, the procedure progressed as follows: five thousand *B. xylophilus* were inoculated to cut-wound sites on branches on seven-year-old *P. strobus* trees. The branches were at 120–140 cm height from the ground and the age of them at portion C, which was adjacent to a stem, was 3–4 years old. The inoculation sites were 31 cm away from the stems. Sterile water was used for the control experiment. After a set number of weeks, bark and wood in three portions A–C (A, 6–11 cm; B, 16–21 cm and C, 26–31 cm from the inoculation site) of the branches were separated.

The bark and wood were both extracted with EtOH and the extracts were used as samples for the GC analysis. The entire procedure was replicated three times. A portion of the bark extract was used as the source of the antifungal compounds.

3.3. Extraction and isolation

EtOH extraction of *B. xylophilus-infected* bark tissue of *P. strobus* (9.7 g) afforded 1.53 g of crude extract (Yamada and Ito, l993a) which was subjected to silica gel chromatography and fractionated into 31 fractions (10 ml each) using *n*-hexane-Me_2CO (10:1) as an eluting solvent. A spot showing quenching and navy blue against Gibbs reagent on TLC (R_f 0.33; *n*-hexane Me_2CO 7:3) in fractions 12–15 exhibited antifungal activity against *C. herbarum* (isolate OCh-1) on TLC

bioautography (Oku et al., 1979). The active principle in these fractions was isolated by HPLC [R_t 18.59 mm, column: Prepsil ODS 10×250 mm with a guard column 10×50 mm (GL science Co.), solvent: 50% aq. soln. of CH_3CN, flow rate 5 ml/min, detection: UV 254 nm]. Finally 6.3 mg of a clear paste of compound **1** was obtained. A spot showing quenching, being dark under 365 nm UV light, and appeared sky blue against Gibbs reagent on TLC (R_f 0.31; hexane–acetone 7:3) was detected in fractions 21–30. This spot also exhibited antifungal activity against *C. herbarum*. The active principle in these fractions was isolated by HPLC (R_t 11.87 mm, in the same conditions applied for compound **1**). Finally, 1.2 mg of clear paste of compound **2** was obtained.

3.4. GC analysis

EtOH extract from each tissue samples was analyzed by GC after trimethylsilylation as follows: 20 μl from 4 ml of EtOH soln. of the bark (1 g dry wt) extract and 20 μl of 1-naphthol (1 mg/ml in Me_2CO) as the internal standard were mixed and concd. under red. press. then TMSI-H (GL Sciences Inc.) and BSA (GL Sciences Inc.) — 20 μl each — were added and heated at 109°C for ca. 10 s. One microlitre of the sample was used for the capillary GC analysis. The R_t of the TMSi derivative of compound **1** was 18.1 mm. The peak of the TMSi derivative of compound **1** in crude extract was confirmed by a comparison of the fragmentation pattern with those of an TMSi-derivative of isolated compound **1**. The analytical conditions used for compound **2** have been reported previously (Yamada and Ito, 1993a,b).

3.5. Physicochemical properties

3.5.1. 3-O-Methyldihydropinosylvin (*1*)

Gibbs test: (+), navy blue. UV, HREIMS, ElMS, and ^{1}H NMR spectral data were in good agreement with literature values (Takasugi et al., 1987; Suga et al., 1993). The following data are presented for the assignment of chemical shift values. ^{1}H NMR (500 MHz, CD_3OD): δ2.76 (2H, *dd, J*=9.3, 6.0 Hz, H-7), 2.85 (2H, *dd, J*=9.3, 6.0 Hz, H-8), 3.68 (3H, *s,* OMe), 6.16 (1H, *t, J*=2.1 Hz, H-4), 6.20 (1H, *br.t, J*=1.8 Hz, H-2), 6.22 (1H, *br.t, J*=2.0 Hz, H-6), 7.14 (3H, *m,* H-10, H-12, H-14), 7.22 (2H, t, *J*=7.5 Hz, H-11, H-13). ^{13}C NMR 6(125 MHz, CD_3OD): 38.9 (C-8, -CH_2-), 39.3 (C-7, -CH_2-), *55.5* (OMe), 99.9 (C-4), 106.5 (C-2), 109.0 (C-6), 126.8 (C-12), 129.3 (C-11, C-13), 129.5 (C-10, C-14), 143.1 (C-9), 145.1 (C-1), 159.4 (C-5), 162.2 (C-3).

3.5.2. (2S)-Pinocembrin (*2*)

Gibbs test: (+), sky blue. ^{1}H NMR and ^{13}C NMR data were in good agreement with literature values (Kuroyanagi et al., 1983; Jung and McLaughlin, 1990).

3.5.3. (2S)-Pinocembrin-3-d_2

This (ca. 0.5 mg) was obtained by dissolving compound **2** in MeOH-d_6 for one month. UVλ_{max}^{MeOH} nm: 321 sh 290. CD (in MeOH, rel. int.): $[\theta]_{326}$ +0.25, $[\theta]_{3llsh}$ +0.20 $[\theta]_{286}$ −1.00, $[\theta]_{220}$ +1.47. EIMS *m/z* (rel. int.): 259 $[MH]^+$ (41), 258 $[M]^+$ (100), 257 (59), 256 (16), 182 (23), 181 (60), 180 (17), 154 (17), 153 (37), 152 (52), 149 (12), 124 (21), 106 (14), 105 (12). HREIMS: $[M]^+$ 258.0921 ($C_{15}H_{10}D_2O_4$ requires 258.0861).^{1}H NMR (500 MHz, Me_2CO-d_6): δ 5.57 (1H, *s,* H-2), 5.97 (1H, *br. s,* H-6), 6.00 (1H, *br. s,* H-8), 7.40 (1H, *dd*-like, *J*=7.5, 1.5 Hz, H-4′), 7.45 (2H, *dd*-like, *J*=*7.5,* 7.2 Hz, H-3′ and H-5′), 7.57 (2H, *dd*-like, *J*=7.6, 1.5 Hz, H-2′ and H-6′). 9.66 (*s,* C-7-OH), 12.16 (*s,* C-5-OH).

3.6. Bioassay

Sterilized pine wood nematodes (Tamura and Mamiya, 1973) [isolate: S-10 (Kiyohara, 1989)] were incubated on a mycelial mat of *Botrytis cinerea* on potato dextrose agar, and were extracted with a Baerman funnel apparatus (Southey, 1986). EtOH-H_2O (1:49) soln. (0.5 ml) of 3-*O*-methyldihydropinosylvin in conc. ranging from 0 to 500 ppm was added to 4 ml glass vials. A soln. without 3-*O*-methyldihydropinosylvin was used as a control. Incubated nematodes (ca. 1000 nematodes of all stages in 0.5 ml of H_2O) were then added to each vial (final conc. ranged from 0 to 250 ppm). All test vials were maintained in the dark at 25°C. After 1 or 2 days of the exposure to the compound soln., moving and immobilized nematodes were counted under a microscope and the ratio of them (R_1) against entire nematodes was calculated. Then the entire nematodes were transferred into H_2O in vials. One and 3 days after transfer, immobilized nematodes were counted again and the ratio of the immobilized nematodes (R_2) was calculated. The immobilized nematodes at this stage were judged as dead. The difference of the two ratios (R_1-R_2) shows the ratio of nematodes which were recovered from immobilized state by the effect of the compound.

Received 16 November 2000; received in revised form 29 December 2000

Abstract

Snails (*Helix aspersa* L.) were fed filter paper treated with the potato glycoalkaloids, α-solanine and α-chaconine, singly or together. In pure form, both glycoalkaloids deterred feeding, with chaconine being the more active compound. In combination, authentic solanine and chaconine interacted synergistically in their inhibition of feeding. The antifeedant activities of methanolic extracts of tuber peel of the potato varieties Majestic and Sharpe's Express presented via filter paper discs did not differ significantly from those of authentic glycoalkaloid solutions of comparable concentration and ratio. In contrast, feeding inhibition by diluted tuber peel extracts of the variety Homeguard was greater than that elicited by comparable authentic glycoalkaloid solutions suggesting additional inhibitory compound(s) in the peel of this variety. Comparison of data from peel extracts of all three potato varieties and authentic glycoalkaloids indicated that the level of feeding inhibition by the extracts was, at least in part, a consequence of a synergism between solanine and chaconine. © 2001 Elsevier Science Ltd. 1. Introduction

The principal potato glycoalkaloids α-solanine and α-chaconine are biologically interesting and economically important compounds (Friedman and McDonald, 1997). They are toxic to a wide range of organisms and are generally considered to be defensive allelochemicals (Roddick, 1996; Friedman and McDonald, 1997). Membrane disruption is arguably the most important mechanism by which glycoalkaloids compromise the structural and functional integrity of cells/tissues of other organisms and, in this respect, chaconine is invariably more damaging than solanine. In addition, it is now well established that synergism between these two glycoalkaloids significantly enhances the membrane-disruptive activity of potato glycoalkaloid mixtures. This interaction was first conclusively demonstrated using synthetic lipid membrane vesicles (liposomes) (Roddick and Rijnenberg, 1987), but has subsequently been confirmed in various membrane/living systems (Table 1). Synergisms also occur between other similarly 'paired' glycoalkaloids of other *Solanum* species with a common aglycone and a solatriose or chacotriose carbohydrate moiety (Roddick et al., 1990, 2001). In contrast, solanine and chaconine are equally effective in inhibiting the neurotransmission enzyme acetylcholinesterase and do not synergise in this action (Roddick, 1989).

One of the main ways in which plant allelochemical action is manifest is through feeding deterrence. Preingestive antifeedant effects of glycoalkaloids are probably due to the bitter/burning taste sensations they impart (Sinden et al., 1976; Zitnak and Filadelfi, 1985). Both taste tests with pure glycoalkaloids (Zitnak and Filadelfi, 1985) and electrophysiological studies of insect galeal and tarsal chemosensilla (Mitchell and Harrison, 1985) showed chaconine to be the more potent of the potato glycoalkaloids, but whether a synergism occurs between solanine and chaconine in antifeedant activity is not known. This question acquires added interest from the facts that (i) taste perception, an integral component of feeding, relies on both membrane integrity and neurotransmitory enzymes, and (ii) potato glycoalkaloids synergise in disruption of membranes but not in inhibition of acetylcholinesterase.

The aim of this study was to determine whether solanine and chaconine, singly and in combination, are capable of deterring feeding activity, using as the test organism the snail, *Helix aspersa*. In contrast to slugs such as *Deroceras reticulatum* which is a serious pest of potato and apparently shows some tolerance of potato glycoalkaloids (Johnston et al., 1989; Johnston and Pearce, 1994), snails are highly susceptible to *Solanum* glycoalkaloids (Alzérreca and Hart, 1982; Marston and Hostettmann, 1984). However, no major investigation of the effects of potato glycoalkaloids on snails has been conducted; a single report exists of solanine lacking molluscicidal activity (see Marston and Hostettmann, 1984). The present study also compared the antifeedant activity of potato peel extracts from three potato varieties and equivalent (in concentration) authentic glycoalkaloid solutions to determine whether compounds in peel other than glycoalkaloids also influence feeding and/or modulate the effects of glycoalkaloids.

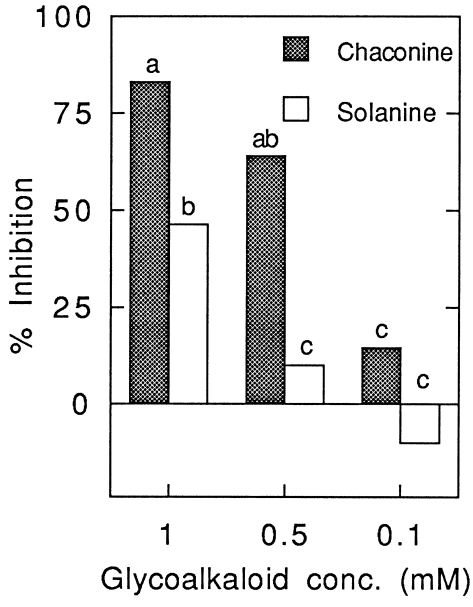

Fig. 1. Effects of authentic solanine and chaconine on feeding by *Helix aspersa*. Snails were presented with two filter paper discs presoaked with methanolic solutions of authentic solanine or chaconine. Control discs were treated with methanol only. After evaporation of the alcohol, snails were left to eat for 48 h at 15°C. Feeding was assessed by measuring the dry weight of the remaining discs. Values are means of six replicates. Treatments marked with different letters (a, b or c) are significantly different from each another at $P \leqslant 0.05$.

2. Results

Both solanine and chaconine caused appreciable feeding inhibition at 1.0 mM (Fig. 1), although solanine was only about half as effective as chaconine. At 0.5 mM chaconine still caused 65% inhibition, but solanine was inactive. Neither compound caused significant inhibition of feeding at 0.1 mM.

To assess the antifeedant effects of solanine/chaconine mixtures, snails were presented with filter paper treated with either authentic solanine or chaconine or a combination of the two compounds, at a range of concentrations (and ratios) determined by the data in Fig. 1. The highest concentration of glycoalkaloid used was 0.4 mM, at which feeding inhibition was unlikely to be greater than 65% thus making it possible to observe any interactive effects between solanine and chaconine, whether antagonistic, additive or synergistic. As shown in Fig. 2, chaconine caused significant inhibition of feeding at 0.2 mM and above and values were consistent with those in Fig. 1 but, unexpectedly, solanine was inhibitory at 0.4 mM, but not below this.

The combinations of solanine and chaconine tested all had a total glycoalkaloid strength of 0.4 mM (Fig. 2). Each of the three combinations containing both glycoalkaloids produced a synergistic inhibition of snail feeding (Fig. 2). Individually, neither 0.3 mM solanine nor 0.1 mM chaconine altered feeding significantly,

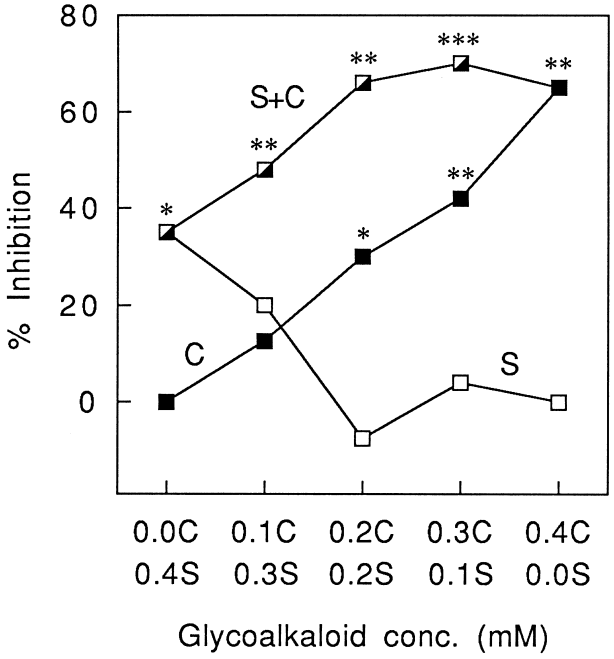

Fig. 2. Antifeedant effects of authentic solanine and chaconine in *Helix aspersa* when supplied singly and in combination. Snails were presented with two filter paper discs pre-soaked with methanolic solutions of authentic solanine or chaconine. Control discs were treated with methanol only. After evaporation of the alcohol, snails were left to eat for 48 h at 15°C. Feeding was assessed by measuring the dry weight of the remaining discs. Values are means of six replicates. *, **, *** = significantly different from control at $P \leqslant 0.05$, 0.01 and 0.001 respectively. S = solanine; C = chaconine.

whereas in combination feeding was reduced by ca 50%. The combination of 0.2 mM chaconine and 0.2 mM solanine (which individually elicited ca 30 and 0% inhibition respectively), produced more than 60% inhibition. Similarly, inhibition by the combination of 0.3 mM chaconine (ca 40% inhibition) and 0.1 mM solanine (zero inhibition) was nearly 70%.

Following glycoalkaloid analyses of methanol extracts of peel of three potato varieties, Majestic, Sharpe's Express and Homeguard (Table 2), equivalent methanolic solutions of authentic solanine and chaconine (in terms of concentration and ratio) were prepared for comparison of antifeedant activity. Majestic and Sharpe's Express peel contained roughly comparable levels of chaconine and solanine, but those in Homeguard were approximately 25% less. In Majestic and Sharpe's Express, all peel extracts and authentic mixtures produced virtually identical inhibition (Fig. 3). Dilution by one-half did not alter the level of inhibition in any treatment whereas dilution to one-tenth strength essentially eliminated inhibition in both authentic mixtures and peel extract (Fig. 3). In Homeguard, there was not the same consistency between the effects of peel extracts and authentic glycoalkaloid mixtures. The full-strength extract and the authentic mixture again produced virtually identical inhibition (Fig. 3), but at one-half dilution the activity of the authentic mixture was substantially less whereas that of the peel extract was not significantly different from the full-strength extract (Fig. 3). Dilution to one-tenth nullified inhibition by the authentic glycoalkaloid mixture, but did not affect the peel extract activity (Fig. 3).

Table 2
Glycoalkaloid concentrations in methanolic tuber peel extracts of the three potato varieties tested for antifeedant activity on *Helix aspersa*[b]

Variety	Glycoalkaloid conc. (mM)		C:S ratio
	Chaconine[a]	Solanine	
Sharpe's Express	0.44	0.18	2.44
Majestic	0.39	0.13	3.00
Homeguard	0.30	0.10	3.00

[a] Values are means of six replicates.
[b] Authentic glycoalkaloid solutions were prepared with identical strengths of solanine and chaconine.

3. Discussion

The finding that chaconine is a more powerful inhibitor of feeding by *H. aspersa* than solanine concurs with comparisons of the activity of these glycoalkaloids in many other test systems from synthetic and cell membranes (Roddick et al., 1988; Roddick and Rijnenberg, 1986; Tschesche and Wulff, 1964), through micro-organisms and simple animals (McKee, 1959; Allen and Feldmesser, 1971; Sinden et al., 1973; Thorne et al., 1985; Fewell and Roddick, 1993), to insects (Mitchell and Harrison, 1985) and mammals (Sharma et al., 1979). The synergism demonstrated here in antifeedant activity also extends the range of test systems/activities that exhibit this interaction (Table 1) to those which have behavioural implications. It is thus probable that a synergistic interaction between solanine and chaconine contributes to many of the other adverse effects elicited by potato glycoalkaloids (including illness/toxicity in humans), although the experimental evidence is still awaited.

The differential antifeedant activity of solanine and chaconine and the synergism between them suggest that their inhibition of feeding by *H. aspersa* is more likely mediated through effects on the membranes of chemoreceptor cells than via impairment of enzymes involved in nervous signal transduction. Sensory cell function can be impaired by changing membrane potential/trans-membrane ion transport and glycoalkaloids are indeed known to alter these parameters (Blankemeyer et al., 1992, 1995) and to synergise in this action (Gee et al., 1996).

Alternatively, it is possible that membrane damage per se does not occur, but that the synergism between solanine and chaconine extends to their organoleptic properties. Consistent with this possibility is that chaconine is more bitter/burning (by 4× and 2× respectively) than solanine (Zitnak and Filadelfi, 1985). On

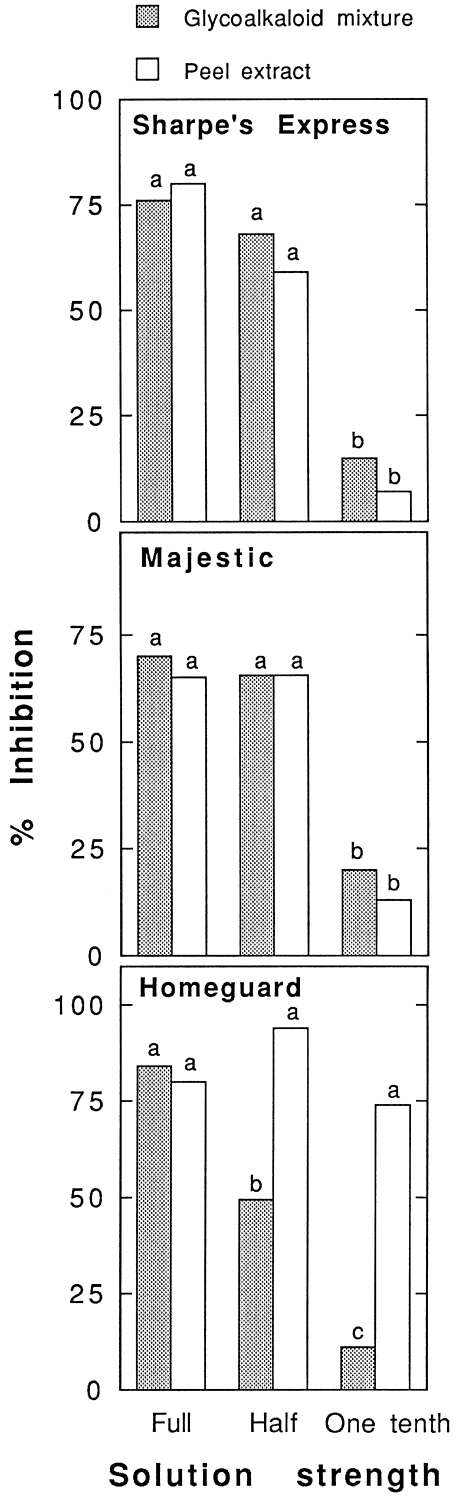

Fig. 3. Comparison of the antifeedant effects in *Helix aspersa* of methanolic extracts of tuber peel from three potato varieties and equivalent strength mixtures of authentic solanine and chaconine. Snails were presented with two filter paper discs pre-soaked with methanolic solutions of solanine or chaconine, or methanolic extracts of peel. Control discs were treated with methanol only. After evaporation of the alcohol, snails were left to eat for 48 h at 15°C. Feeding was assessed by measuring the dry weight of the remaining discs. Values are means of six replicates. Treatments marked with different letters (a, b or c) are significantly different from each another at $P \leqslant 0.05$.

the other hand, comparative taste tests (by humans) on bland potato tissue enhanced with solanine and with an equal concentration of a 3:1 mixture of chaconine:solanine yielded no evidence of a synergism between the glycoalkaloids (Sinden et al., 1976). However, comparison of the levels of glycoalkaloids that inhibit feeding in snails with those causing adverse taste sensations in humans is not only hindered by the use of different experimental systems, but of questionable validity in view of the taxonomic distance between humans and snails, compounded by the biochemical/physiological/behavioural distance between taste and feeding activity. The possibility has not escaped us that feeding activity in the snails may also have been adversely influenced by the blandness of the filter paper diet and the lack of choice/variety in the diet (Speiser and Rowell-Rahier, 1993).

The finding that feeding inhibition caused by full-strength peel extracts of Sharpe's Express and Majestic and equivalent authentic glycoalkaloid mixtures (Fig. 3) was of a similar order to that by chaconine alone (Fig. 2) at approximately the same strength (0.4 mM — Table 2, solanine is inactive at all concentrations in extracts) may have been due to deterrence by 0.4 mM chaconine alone being nearly maximal, thus masking any synergism. The declining apparency of a synergism with the increasing strength of the glycoalkaloid solution is well known from other studies (Roddick et al., 1990; Fewell and Roddick, 1993). That it may explain this observation is supported by the half-strength peel extracts and authentic mixtures causing about twice the effect of 0.2 mM chaconine alone (i.e. demonstrating the synergism). The observation that the full-strength peel extract of Homeguard (and the equivalent authentic glycoalkaloid mixture) caused similar inhibiton to full-strength Sharpe's Express and Majestic peel extracts (and authentic mixtures) even though glycoalkaloid levels were ~25% lower could be attributed to manifestation of the synergism at the lower chaconine concentration. Although in Homeguard, inhibition by the half-strength authentic mixture is less than by the full-strength mixture, this still represents a marked synergism when compared with inhibition by 0.15 mM chaconine (Fig. 2).

Of considerable interest is that Homeguard peel extracts diluted to one-half or one-tenth strength showed no reduction in feeding inhibiton and were more inhibitory than could be explained by their glycoalkaloid content alone. This could suggest that a factor(s) other than glycoalkaloids contributes to feeding inhibition by this variety of potato. Sinden et al. (1976) found that authentic potato glycoalkaloids did not produce as intense taste sensations as equivalent levels in natural tissues, although the differences were not as marked as reported here. Potatoes are known to elaborate other secondary compounds which affect feeding, e.g phenolics, terpenoids and protease inhibitors (Johnston and Pearce, 1994) and a number of inorganic and organic

compounds are known to be able to suppress or enhance glycoalkaloid activity (see Roddick and Leonard, 1999). In addition, the presence of small, unidentified late-eluting peaks in the glycoalkaloid extracts raises the question of whether glycoalkaloids other than solanine and chaconine may have been present which were inhibitory in their own right and/or capable of synergising with each other and/or with solanine and chaconine. Knowledge of the anti-feedant activity (and indeed the biological activity) of glycoalkaloids is restricted to only a few (~5) major compounds found in important food plants; for all other glycoalkaloids, including the minor compounds, no such information exists.

4. Experimental

4.1. Potato material

Certified seed tubers of the maincrop potato variety Majestic and the two early varieties, Homeguard and Sharpe's Express, were planted 30 cm apart in single rows in the experimental plot of the School of Biological Sciences, University of Exeter. Each trench was 15–20 cm wide and deep and was partially filled with manure before planting. Plants were watered twice weekly. Tubers were harvested by hand and stored in paper sacks at 15° and 40% relative humidity.

4.2. Glycoalkaloids

Pure (98%) solanine and chaconine used in feeding studies were prepared and supplied by Dr. A. Fewell (Fewell, 1993). Analysis of tuber peel glycoalkaloids was as described by Smith (1997). This involved extraction into MeOH and clean-up using a C18 SPE column (Anachem, UK) according to the method of Carman et al. (1986). Qualitative and quantitative analyses of glycoalkaloids were based on the HPLC method of Bushway and Storch (1982). The column was a carbohydrate analysis column (Waters Associates, USA) with an amino pre-column; mobile phase was tetrahydrofuran:water:acetonitrile (53:17:30); flow rate 1 ml/min; detector wavelength 215 nm. The identity of extracted glycoalkaloids was confirmed by their retention times on HPLC relative to authentic samples, and by electrospray MS.

4.3. Source and maintenance of snails

Snails (*Helix aspersa* L.) were gathered locally and housed in a lidded glass tank (40×60×40 cm) the bottom of which was lined with gravel. The tank was moistened periodically by sprinkling with distilled water and a constant supply of fresh lettuce leaves provided as food. Tanks were kept in a room at an ambient temperature of approximately 15°C with natural illumination.

4.4. Feeding experiments

Feeding experiments were conducted in lidded plastic propagating trays (22×17×20 cm) the base of which was lined with moist paper towelling. Perforated cling-film was placed over the towelling to prevent the snails from feeding on the towelling. Preliminary experiments established that snails will readily consume dry filter paper discs. Glycoalkaloids were applied to Whatman GP1 5.5 cm diameter filter papers in 0.25 ml MeOH (the minimum volume required to wet the entire surface). The MeOH was allowed to evaporate (ca 5 min) before the snails were introduced into the propagating tray. For experiments involving tuber extracts, MeOH peel extracts were prepared from single tubers of each of the three varieties and their solanine and chaconine content measured (Smith, 1997). The MeOH extracts were then applied to filter papers, as above. MeOH extracts were employed in preference to expressed sap since the latter would contain enzymes that would (a) produce polyphenolic compounds that may have adversely effected snail feeding behaviour, and (b) hydrolyse the glycoalkaloids (Bergenstråhle et al., 1992). MeOH extracts were, therefore, considered to provide a closer approximation of the state in which glycoalkaloids and other intracellular components exist in vivo, although it was appreciated that other factors such as pH would not operate in such extracts.

Snails were starved at 18°C for 24 h prior to each experiment, after which three were placed centrally in each of 6 propagating trays together with 2 discs of control or treated filter paper and left to feed under natural illumination at 15°C for 48 h. Only snails weighing between 6 and 8 g were used in experiments. Feeding activity was quantified by determining the amount of filter paper (dried to constant weight) remaining in control and glycoalkaloid treatments.

4.5. Replication and statistical analysis

All treatments in all experiments were replicated six times. Experiments involving glycoalkaloid-containing peel extracts and equivalent authentic solutions were carried out on two separate occasions. All data were analysed by ANOVA and *t*-tests, where appropriate after sin transformation.

Acknowledgements

We thank Dr. Alison Fewell for a supply of pure solanine and chaconine, Mr. James Kingdon and Mrs Anna Leonard (School of Biological Sciences, University of Exeter) for growing the potatoes and technical assistance, respectively, and Dr. Stephen Lock (Campden and Chorleywood Food Research Association) for electrospray

MS analyses of glycoalkaloids. DBS gratefully acknowledges receipt of a BBSRC CASE studentship in conjunction with the Campden and Chorleywood Food Research Association.

Received 29 May 2000; received in revised form 28 November 2000

Abstract

The composition of the previously unknown essential oils of *Stachys* subsect. Swainsonianeae (Labiatae) are investigated by GC–MS analyses. The group includes the taxa *Stachys ionica*, *St. spruneri*, *St. swainsonii* ssp. *swainsonii*, *St. swainsonii* ssp. *argolica*, *St. swainsonii* ssp. *melangavica* and *St. swainsonii* ssp. *scyronica*, all endemic to Greece. Eighteen populations were analyzed, and more than two hundred components were identified. Statistical analyses of oil components separated *St. ionica*, due to its high amount of (*E*)-nerolidol, high amount of α-cadinol and low amount of (+)-(*E*)-caryophyllene. The rest of the taxa forms a coherent group where (+)-(*E*)-caryophyllene, δ-cadinene and partly β-elemene, (+)-caryophyllene oxide and (+)-limonene predominate but each of them never exceeds 20% of the total. Essential oil composition reflects current taxonomy and phytogeography of the group with a somewhat isolated position for *St. ionica*. Similarities in morphology and essential oil composition of the *St. swainsonii* group and *St. spruneri* may be the result of extensive gene flow in the past. Evidence from volatile oil compounds that may attribute to *St. swainsonii* ssp. *melangavica* a hybrid origin from crosses between *St. spruneri* and *St. swainsonii* ssp. *swainsonii*/*scyronica* group is scarce. © 2001 Elsevier Science Ltd. Keywords: *Stachys* subsect. Swainsonianeae; *Stachys ionica*; *Stachys spruneri*; *Stachys swainsonii*; Labiatae; Chemotaxonomy; Volatile constituents; Intraspecific variability; Hybridization; Statistics

1. Introduction

The subcosmopolitan genus *Stachys* L. comprises more than 270 species (Mabberley, 1997) and is justifiably considered as one of the largest genera of the Labiatae. In the Old World area there are two main centres of diversity for the genus, as assessed by the number and distribution of the species. One is confined to S and E Anatolia, Caucasia, NW Iran and N Iraq, and the other to the Balkan Peninsula (Bhattacharjee, 1980). Greece is certainly an area particularly rich in taxa. More than 50 species and subspecies are distributed in the mainland and/or the islands (Greuter et al., 1986); a significant proportion of them are considered endemic. *Stachys* sect. Swainsoniana Bhattacharjee subsect. Swainsonianeae Bhattacharjee is confined to Greece and includes seven perennial, suffruticose taxa of narrow distribution, particular habitat preference, and the same chromosome number of $2n=34$. Among them, the vulnerable *St. euboica* Rech. fil. is localized to the SE part of Evvia island (Constantinidis, 1995), and its subsectional placement appears problematic: although originally described as an ally of *St. mollisima* Willd., it was not placed together with it in subsect. Decumbentes by Bhattacharjee (1980) but in subsect. Swainsonianeae. Because of its taxonomic uncertainty, this species will be studied together with members of subsect. Decumbentes in a forthcoming paper. *St. ionica* Halácsy, wholly confined to the islands of the Ionian sea, is a good example of insular differentiantion; its populations do not reach adjacent west Greek mainland. *St. spruneri* Boiss. is distributed in SE Sterea Ellas, mostly in Attiki. Its populations in certain areas grow sympatrically or parapatrically with the last and more diverse species, *St. swainsonii* Bentham. This last species has been further divided into four subspecies (Phitos and Damboldt, 1969; Persson, 1981) all narrow endemic chasmophytes which, according to morphological and palaeogeographical evidence, presumably represent relicts of formally more widespread species complexes.

In spite of the large size of *Stachys*, the composition of volatile compounds is known in only a small number of species. These include *St. balansae* Boiss. (Cakir et al., 1997) and *St. obliqua* Waldst. and Kit. (Harmandar et al., 1997), two species of sect. *Eriostomum*; *St. palustris* L. (Maly, 1985) and *St. sylvatica* L. (Maly, 1985; Lawrence, 1992) of sect. *Stachys*; *St. candida* Bory and Chaub. and *St. chrysantha* Boiss. (Skaltsa et al., 1999) of sect. *Candida*; *St. annua* L. (Maly, 1988) and *St. recta* L. (Maly, 1985; Cakir et al., 1997) of sect. *Olisia*; *St. corsica* Pers. (Pélissier et al., 1999) of sect. *Corsica*; *St. glutinosa* L. (Mariotti et al., 1997) of sect. *Aucheriana*; *St. lavandulifolia* Vahl (Sezik and Basaran, 1986; Ghannadi and Alemdoost, 1996) of sect. *Zietenia*; *St. aegyptiaca* Pers. (Halim et al., 1991) and *St. inflata* (Sajjadi, 1996) of sect. *Ambleia*; and *St. betonica* Benth. [= *St. officinalis* (L.) Trevisan] (Maly, 1985) of sect. *Betonica*.

The present study aims at investigating the volatile compounds, previously unknown, of all members of *Stachys* subsect. Swainsonianeae, with the exception of *St. euboica* (see above). Intraspecific variability is also examined by processing more than one population per taxon (Table 1). The results are compared with the biology and taxonomy of the taxa, to extract evidence of possible chemotaxonomic significance. Eighteen populations of the following six taxa were examined: *Stachys ionica*, *St. spruneri*, *St. swainsonii* ssp. *argolica* (Boiss.) Phitos and Damboldt, *St. swainsonii* ssp. *melangavica* D. Persson, *St. swainsonii* ssp. *scyronica* (Boiss.) Phitos and Damboldt and *St. swainsonii* ssp. *swainsonii*.

2. Results and discussion

All the investigated *Stachys* taxa contain essential oils that range from 0.16 to 0.38% based on dry wt (Table 2). The highest oil contents were found in *St. ionica* (0.36–0.38%) and *St. spruneri* (0.29–0.31%). In the other four taxa, the oil content was between 0.16 and 0.23%. As it is shown in the analytical Table 2, all the essential oils are complex mixtures of more than one hundred constituents in each investigated case, with contributions of main products never exceeding 20% of the total. Among them the sesquiterpenes consist the main portion in all studied taxa, while a population of *St. spruneri* (spr-1) has a high content in monoterpene hydrocarbons (41.4%) as well. Apart from a population of *St. swainsonii* ssp. *argolica* (arg-2) which has a significant aldehyde fraction (15.9%), and relatively high terpene esters content (7.3%), all other populations have a much lower level of such compounds ($<4.1\%$). Generally, all taxa have rather low amounts of phenylpropanoids, and fatty acids and aliphatic esters, with the exception of swa-2. The use of a chiral column allowed the determination of enantiomers in several main

Table 1

[a] Kovats index on HP-5 column.

compounds. In most cases only one isomer is present in the essential oil, the other being absent or present in trace amounts.

The main constituents of the essential oils in *Stachys* subsect. Swainsonianeae are (+)-α-pinene (8.0% in spr-1), (+)-limonene (17.3% in spr-1 and 8.6% in spr-3), (+)-β-linalool (8.2% in arg-2), α-copaene (9.4% in mel-2), (+)-(*E*)-caryophyllene (relatively high values in several populations), α-cadinol (high percentages in *St. ionica*), (*E*)-nerolidol (high amounts in *St. ionica*) and α-sinensal (10.5% in ion-1). A quick glance at the other investigated representatives of various *Stachys* sections

reveals two significant indications. First, that there is a wide range of principal compounds in the oils of *Stachys* species studied so far, as, e.g. germacrene D in *St. obliqua* (Harmandar et al., 1997), a member of section *Eriostomum* and carvacryl acetate in *St. corsica* (Pélissier et al., 1999), a member of section *Corsica*. Both constituents are unknown, or present in small quantities in the members of *Stachys* subsect. Swainsonianeae. Thus, chemical variation of volatile compounds may be promising as chemotaxonomically important for the whole genus. Second, two investigated members of *St.* sect. *Candida* (*St. candida* and *St. chrysantha*; Skaltsa et al., 1999), most closely related to sect. *Swainsoniana,* share relatively high values of (*E*)-caryophyllene and α-cadinol with the studied taxa. To what extent composition of volatile oils reflects taxonomic or phylogenetic relationships in *Stachys* is unknown at present, since many of its ca 270 members remain to be investigated. However, chemistry of volatile compounds has been proved particularly helpful in assessing taxonomic relationships of several genera in Labiatae (Stahl-Biskup, 1991; Kokkini, 1992; Skoula et al., 1999; Sanz et al., 2000).

To evaluate whether the identified constituents may be useful in reflecting taxonomic relationships in *Stachys* subsect. Swainsonianeae all the components of Table 2 that exceed 1% of total oil contribution in at least one *Stachys* population (marked in bold in Table 2) were subject to principal component analysis (PCA) and cluster analysis (CA). In the absence of information about shape of the groupings and/or statistical distribution of values, Euclidean distance combined with unweighted pair group average linking were used for CA (Dunlop et al., 1997). The resulted dendrogram appears in Fig. 2. In PCA (Fig. 1), horizontal axis accounts for ca. 38% of the variation while vertical axis for a further 15%.

As it is evident from both statistical analyses, the three populations of *St. ionica* clearly stand out forming a separate group in PCA or a deep dichotomy in CA. Thus, chemically speaking, *St. ionica* appears to be the most differentiated species, with metabolic pathways leading to compounds in its essential oil not significantly shared with the rest of the species. Indeed, useful chemotaxonomic markers for *St. ionica* include its high content in (*E*)-nerolidol (>14% in all populations, <0.7% in all other taxa), relatively high amounts of α-cadinol (>8.8%, generally <3.5% in other taxa except an anomalous high value in scy-1), and low amounts of (+)-(*E*)-caryophyllene (<1.2%, usually >4.7% in other taxa except scy-1). Thus, compared to the rest of the species in the subsection, *St. ionica* appears to have the most distinguishable chemotype. Chemical differentiation is correlated to the distribution of the species, which is confined to the Ionian islands and is, therefore, well-isolated from the rest of the group. Such a pattern of distribution does not currently permit gene exchange between *St. ionica* and the rest of the taxa in subsect. Swainsonianeae. Further, chemical differentiation of essential oil appears to be the result of genetic differentiation enhanced by spatial isolation. Crossing experiments between all taxa of subsection Swainsonianeae performed by Persson (1981) and subsequent estimation of pollen stainability in F_1 generation indicated mean percentages of functional

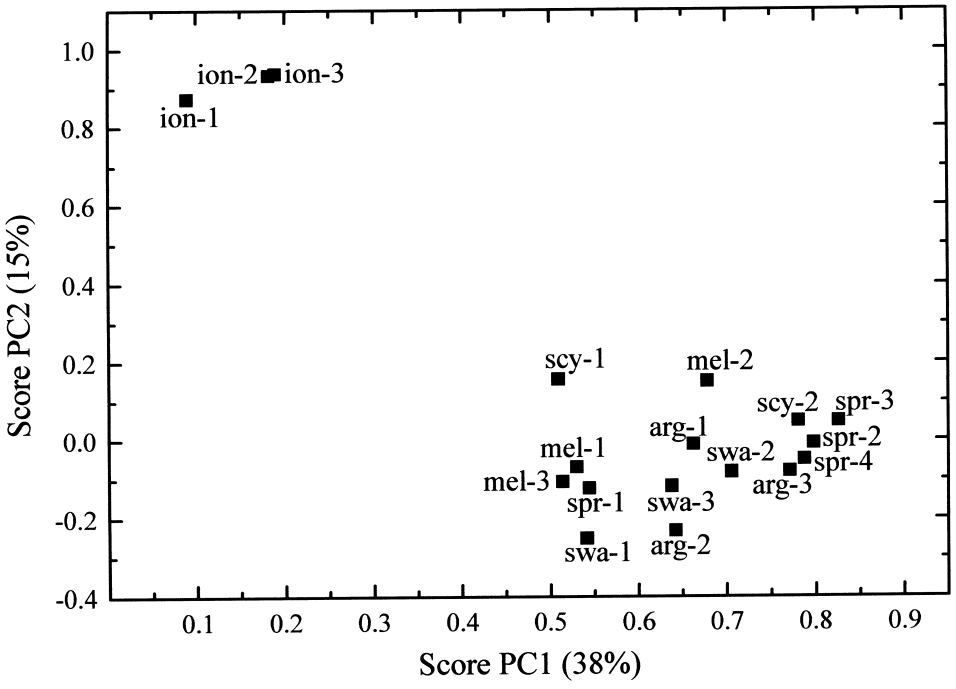

Fig. 1. Principal component analysis (PCA) of main volatile constituents in *Stachys* subsect. Swainsonianeae. For abbreviations of taxa see Table 1.

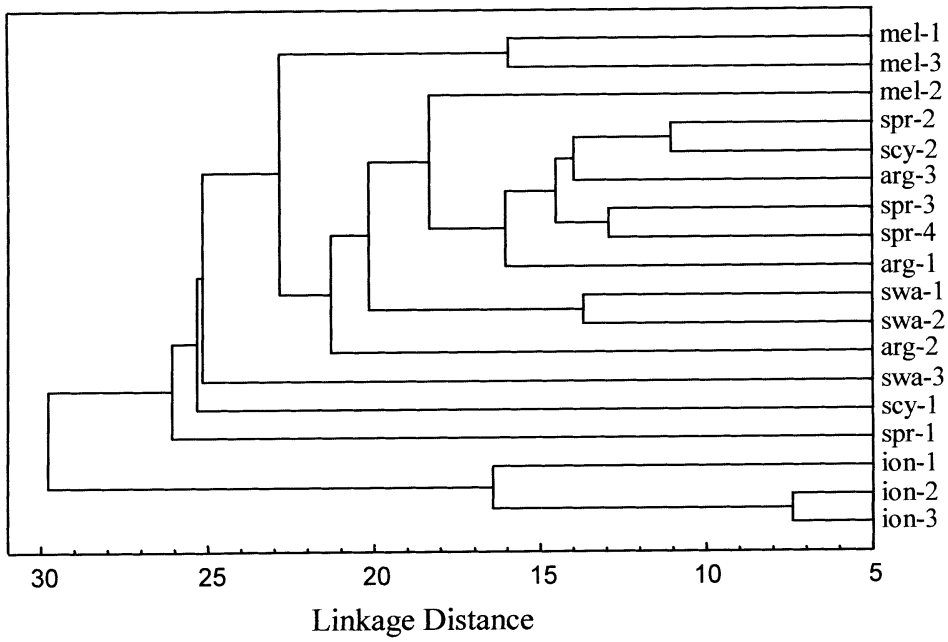

Fig. 2. Dendogram resulted from cluster analysis (CA) of main volatile constituents in *Stachys* subsect. Swainsonianeae. For abbreviations of taxa see Table 1.

pollen between 40 and 59% in all crossings between *St. ionica* and any of the *St. swainsonii* subspecies as opposite to functional pollen between 60 and 79% in all crossings among *St. swainsonii* subspecies.

The role that distance may play in the composition of essential oils within *St. ionica* is effectively presented in populations ion-2 and ion-3. These populations share a great resemblance in essential oil constituents and are grouped together in both PCA and CA. The populations originate from the same island, and are separated from each other by a few kilometers distance. Their pronounced chemical similarity can be attributed to either free gene flow (all members of *St.* sect. Swainsonianeae are pollinated by insects but are capable of inbreeding) or comparatively recent fragmentation of a previously more continuous population. Essential oil of ion-1 from Zakinthos is weakly differentiated, mainly by the relatively low amount of torreyol, lack of sclarene and relatively high levels of α-sinensal.

For the rest of the taxa, resolution provided by both statistical analyses is rather low. All four populations of *St. spruneri* are characterized by the high amounts of (+)-(*E*)-caryophyllene (>8.5%). Spr-1 deviates somewhat by the presence of relatively high amounts of (+)-α-pinene, (+)-limonene and α-selinene but its position is not highlighted by either PCA or CA. This particular population grows in the vicinity of two subspecies of *St. swainsonii* (ssp. *melangavica* and ssp. *scyronica*) but shows no morphological evidence of hybridization. The two populations of *St. spruneri* collected on the same mountain (spr-3 and spr-4) are not grouped together, as in the case of ion-2 and ion-3.

For the four subspecies of *St. swainsonii* main chemical constituents vary. Like *St. spruneri,* all share high proportions of (+)-(*E*)-caryophyllene (but this compound is unusually low in scy-1). Arg-2 is characterized by quite high levels of (+)-β-linalool and n-nonanal, while rather high levels of manoyl oxide are found in swa-3. The sesquiterpene β-elemene is higher than 8.3% in scy-1, mel-1 and mel-3. However, none of these populations is given any particular position in PCA or CA.

Lack or resolution in statistical processing within *St. spruneri* and *St. swainsonii* essential oils may be attributed to two important reasons. Firstly, all five taxa are taxonomically closely related and occasionally grow intermixed or parapatrically to each other. They can be experimentally crossed, and pollen stainability of F_1 generation ranges at quite high levels, mostly between 60 and 79% (Persson, 1981). Some populations of the Mt. Gerania area may even be attributed to hybrid swarms but have not been included in the present study to avoid masking chemical results of 'pure' taxa. Secondly, *St. spruneri* and all *St. swainsonii* members have probably been evolved rather recently, and speciation processes are still in progress. Facilitated by climatic fluctuations, extensive gene flow that occurred in the past (Persson, 1981) may have significantly contributed towards a shading of distinct secondary products that would characterize each taxon.

Based on morphological and experimental evidence, *St. swainsonii* ssp. *melangavica* was given an unusual origin by Persson (1981). This taxon may represent the stabilized hybridogenous result of ancient crossings between *St. spruneri, St. swainsonii* ssp. *swainsonii* and

St. swainsonii ssp. *scyronica*. This being true, the formation and establishment of ssp. *melangavica* may be attributed to homoploid hybridization coupled with spatial isolation and disappearance of certain ancestor populations. The composition of the essential oil of the three *St. swainsonii* ssp. *melangavica* populations examined compared to those of the three presumably parental taxa gives us, however, rather sparse data of intermediacy.

Mean values of caryophyllene oxide (both isomers) of *St. swainsonii* ssp. *melangavica* ($\bar{a}_1 = 1.2$) come closer to *St. spruneri* ($\bar{a}_2 = 2.1$) than to ssp. *swainsonii*/*scyronica* group ($\bar{a}_3 = 11.5$). The same happens to the mean limonene amounts. Viridiflorene seems to be absent in *St. spruneri*, while it exists in considerable amounts in ssp. *melangavica* ($\bar{a}_4 = 6.6$) and lower values in the ssp. *swainsonii*/*scyronica* group ($\bar{a}_5 = 3.1$). The percentage of β-elemene in mel-1 and mel-3 is high (18.8 and 10.8, respectively) compared to its presumed parental taxa, but the low percentage of mel-2 (0.7) is contrasting. Finally, the related germacrene D and germacrene-D-4-ol appear in mel-2 and mel-3 respectively, but not in any other examined population except a low amount of germacrene D in spr-2. In other compounds differentiation is either weak or random, and mostly provides no information. These results are less spectacular than those reported in e.g. hybrids of *Origanum* (Skoula et al., 1999), where the volatile fraction of *O. x intercedes* Rech. fil. was found intermediate between the parents, while *O. x minoanum* P.H. Davis had some constituents higher than in both parents; or in *Mentha x villoso-nervata* Opiz, with percentages of main compounds resembling one parent or the other, while the amount of germacrene D was considerably higher than in both parents (Gavalas et al., 1998). The reasons for rather weak indications of intermediacy in *St. swainsonii* ssp. *melangavica* volatile compounds should be attributed to the high similarity in composition of all essential oils of the *St. spruneri*/*swainsonii* group, and the rather pronounced interspecific variation observed.

3. Experimental

3.1. Plant material

All 18 members of *Stachys* subsect. Swainsonianeae were collected from natural populations growing on calcareous rocks or stony slopes. In *St. ionica* and *St. swainsonii* (less so in *St. spruneri*) it was observed that basal parts of stem may follow rock fissures and root, often in quite a distance from the parental plant. This vegetative propagation imposes the threat of collecting ramets in case that neighbouring populations are carelessly sampled. To avoid this, the distance that separates each of the populations in the present study was assured to be never less than 2 km. As intraspecific rather than intrapopulational variation was our concern, flowering shoots of at least 10 different individuals of each population were merged to constitute each sample. Details of the collection localities are presented in Table 1. To make our results comparable, only plants in similar stages of development were analyzed. Voucher specimens of each population were determined by Th. C. and deposited in the Herbarium of the Institute of Botany, University of Patras (UPA).

3.2. Analysis of volatile compounds

Fifty grams of air-dried plant material from each population were cut in small pieces, and the essential oils were obtained by steam distillation in 500 ml H_2O for 3 h (Hellenic Pharmacopoeia IV, 1989), in a modified Clevenger apparatus with a water-cooled oil receiver to reduce hydrodistillation over-heating artifacts. Although steam distillation is a rather harsh method to obtain oil samples, and presumably responsible for the production of artifacts, the same method was followed by several previous workers with *Stachys* (see introduction) and was adopted here to obtain comparative results. The oils taken in 2 ml of capillary GC grade *n*-pentane and dried over anhydrous sodium sulphate, were subsequently analyzed by GC–MS and stored at −20°C. The composition of the volatile constituents was established by GC–MS analyses. GC–MS analyses were performed on a Hewlett-Packard 5973-6890 system operating in EI mode (70 eV) equipped with a split/splitless injector (220°C), a split ratio 1/10, using three different columns: a fused silica HP-5 MS capillary column (30 m×0.25 mm (i.d.), film thickness: 0.25 μm); a HP-Innowax capillary column (30 m×0.25 mm (i.d.), film thickness: 0.50 μm) and a chiral Cydex B capillary column (50 m×0.22 mm (i.d.), film thickness: 0.25 μm). The temperature program for HP-5 MS column was from 60°C (5 min) to 280°C at a rate of 4°C/min; for HP-Innowax column from 60°C to 260°C at a rate of 3°C/min and for Cydex B column from 50 to 130°C (2 min) at a rate of 2°C/min and from 130 to 250°C at a rate of 4°C/min. Helium was used as a carrier gas at a flow rate of 0.8 ml/min. Injection volume of each sample was 2 μl. Retention indices for all compounds were determined according to the Van der Dool approach (Van den Dool and Kratz, 1963), using *n*-alkanes as standards. The identification of the components was based on comparison of their mass spectra with those of Wiley and NBS Libraries (Massada, 1976) and those described by Adams (1995), as well as by comparison of their retention indices with literature data (Davies, 1990; Adams, 1995; Bisio et al., 1998). In many cases, the essential oils were subject to co-chromatography with authentic compounds (Fluka, Sigma). The recognition of the optical isomers was made by comparison with authentic

samples and according to reported elution order for the particular column (Ravid et al., 1994, 1995; SGE Scientific Ltd data).

Abstract

The essential oils isolated from leaves of ten and from unripe berries of eight populations of *Laurus azorica* (Seub.) Franco, collected on five islands of the Azorean archipelago, were analysed by GC and GC–MS. All oil samples were dominated by their monoterpene fraction (60–94%), α-pinene (15–37%) and 1,8-cineole (12–31%) being the main components of the leaf oils, while *trans*-β-ocimene (27–45%) and α-pinene (12–22%) were the main components of the oils from the berries. The sesquiterpene fractions of the oils ranged from 3 to 17% and the main components were β-caryophyllene (traces — 8%) and β-elemene (traces—3%) both in the leaf and berry oils. Some phenylpropanoid components were also present, in total amounting to 17%, *trans*-cinnamyl acetate (215% of the leaf oils) being the main component of this fraction. Cluster analysis of the enantiomeric composition of α- and β-pinene in the oils from the leaves clearly showed two groups, one constituted by the two populations growing on the island S. Jorge, and the other constituted by the remaining populations. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Laurus azorica (Seub.) Franco (= *L. canariensis* Webb & Berth., non Willd.), most commonly known as ''loireiro'', ''loureiro'', or ''louro'', is an endemic species of the Azores, Madeira and the Canary islands. The tree is an important constituent of the laurel-juniper forest (cloud-zone forest) that, according to Sjögren (1984), occurs on all islands of the Azorean archipelago except on Graciosa, generally above 500 m, but occasionally down to 175 m and, on Pico, rarely above 1400 m. Pena and Cabral (1997) reported the presence of this species at Feiteira, Graciosa, which we confirmed recently (June 1999). The berries and the fixed oil extracted from them are used as an anti-infective skin preparation; the oil is applied externally as an anti-rheumatic and for wound-healing, and is taken orally for treatment of apoplexy; the fixed oil is also used for treating boils, as a hemostatic and for troubles of the respiratory system (Neves and Valente, 1992; Rivera and Obón, 1995). Recently, Candeias et al. (1999) suggested that the leaf essential oil has a moderate hepatoprotectant activity.

As part of a screening programme of the aromatic flora of Macaronesia, the present study deals with the analysis of the essential oils from *L. azorica* collected on five Azorean islands.

2. Results and discussion

2.1. Essential oil composition

2.1.1. Essential oil from the leaves

The essential oil samples isolated from the leaves were obtained in yields ranging from 0.3 to 0.7% (v/w). Fifty to fifty-five components were identified in each oil sample, amounting to 83–95% of the total oils (Table 1). The total percentages of the fraction of sesquiterpene hydrocarbons in the oils from the leaves collected in 1996 and 1997 (at Cabrito and Pico Rachado on Terceira and

at Santo António on S. Jorge) seem to show marked differences, as these values were 5–10 times higher for the leaves of July 1997 than for those of April 1996. The question whether these differences are due to seasonal variations or to the different year of collection cannot be answered at this moment.

All the oil samples were dominated by their monoterpene fraction (60–86%). α-Pinene (15–37%), 1,8-cineole (12–31%) and β-pinene (9–18%) were the main components. The oxygen-containing monoterpenes represented 21–42% of the total oils. The sesquiterpene fraction occurred in smaller amounts (3–17%), β-carbophyllene (traces — 8%) and β-elemene (traces — 3%) being the only sesquiterpenes that attained relative amounts larger than 3%. The essential oils contained also a phenylpropanoid fraction, amounting to 17%, *trans*-cinnamyl acetate (2–15%) being the main component. It may be noteworthy that in the oils isolated from the leaves collected in April 1996 at Cabrito (Terceira) and at S. António (S. Jorge), *trans*-cinnamyl acetate was the third major component of the total oil.

2.1.2. Essential oil from the berries

The essential oil samples isolated from the berries were obtained in yields ranging from 0.4 to 0.9% (v/w). Fifty to fifty-four components were identified in each oil sample, amounting to 89–98% of the total oils (Table 2). The composition of the essential oils showed almost no marked qualitative or quantitative differences.

All the oil samples were dominated by their monoterpene fraction (84–94%). *trans*-β-Ocimene (27–45%), α-pinene (12–22%), *cis*-β-ocimene (9–16%) and β-pinene

Table 2

[c] nd = Not detected.

(7–13%) were the major components. The oxygen-containing monoterpenes represented only 5–9% of the oils. The sesquiterpene fraction occurred in smaller amounts (3–8%) and all sesquiterpenes occurred in concentrations lower than 2%, except for β-carbophyllene (0.3–2%) and β-elemene (0.5–2%). The phenylpropanoid fraction, consisting only of *trans*-cinnamyl acetate, ranged from traces to 2%.

A literature search provided only one reference to a paper on the composition of the essential oil from the leaves of *L. azorica* (Hokwerda et al., 1982). No data were found on the oil from the berries of this species. In the steam distilled leaf oil of *L. azorica* grown in the Hortus Botanicus of the University of Groningen, Hokwerda et al. (1982) also found α-pinene (13%), 1,8-cineole (10%) and β-pinene (7%) as main components, but in smaller amounts than those found in the present study. Although the exact amounts for the components of the other fractions were not reported in that work, *allo*-aromadendrene (5–10%) was the main component among the sesquiterpenes, and cinnamyl acetate and elemicin (both 1–5%) were the major constituents of the phenylpropanoid group.

The well-known laurel oil is obtained from the leaves of *L. nobilis*, the only other species of this genus. Considering some of the more recent publications on the composition of the leaf oil of *L. nobilis* (Kutubidze and Kharebava, 1990; Kharebava, 1991; Baghdadi et al., 1992; Borges et al., 1992; Tucker et al., 1992; Biondi et al., 1993; Pino et al., 1993; Fiorini et al., 1997; Baratta et al., 1998), there are some noteworthy quantitative differences, regarding the main components, in comparison with the leaf oil of *L. azorica*. 1,8-Cineole, the major compound in laurel oil is the second main component in *L. azorica* leaf oil, whereas α- and β-pinene, two main components in *L. azorica* leaf oil, are present in smaller amounts in laurel oil; other main components in laurel oil, namely linalool, α-terpinyl acetate and

sabinene, are minor components of the leaf oils from *L. azorica* we analysed.

2.2. Enantiomeric composition of α- and β-pinene

Of the chiral compounds present in the monoterpene fraction of the essential oils, only α- and β-pinene were investigated for their enantiomeric ratio, due to the low concentrations of the other chiral monoterpenes in the oils, in most cases below 2%. In all oil samples (+)-α-pinene (74–91% in the leaf oils, 86–93% in the berry oils) and (−)-β-pinene (64–88% in the leaf oils, 83–94% in the berry oils) were the predominant enantiomers. The cluster analysis of the enantiomeric composition of α- and β-pinene in the oil samples isolated from the leaves and berries yielded one marked result: a clear separation of the leaf oils of the two populations of S. Jorge from the leaf oils of the rest of the populations collected at the other four islands (Fig. 1). The samples isolated from the leaves collected on the island S. Jorge (SAJ and EsJ) showed concentrations of (−)-α-pinene above 20% and of (+)-β-pinene above 29%, and those isolated from the leaves collected on the other four islands showed concentrations of (−)-α-pinene and (+)-β-pinene less than 14 and 20%, respectively.

Although the enantiomeric ratios of α- and β-pinene in the oils from the berries showed some variation, we did not observe a certain trend, *e.g.* related to location or island.

According to Kreis et al. (1990), the enantiomeric ratios of α- and β-pinene in the leaf oil of *L. nobilis* were 61% of (+)-α-pinene and 56% of (+)-β-pinene. These values are considerably different from those we observed for the leaf oil of *L. azorica*.

Our results suggest that there is a considerable homogeneity in the populations of *L. azorica* grown in the Azorean archipelago, at least in relation to their essential oils, despite of some differences concerning the enantiomeric composition.

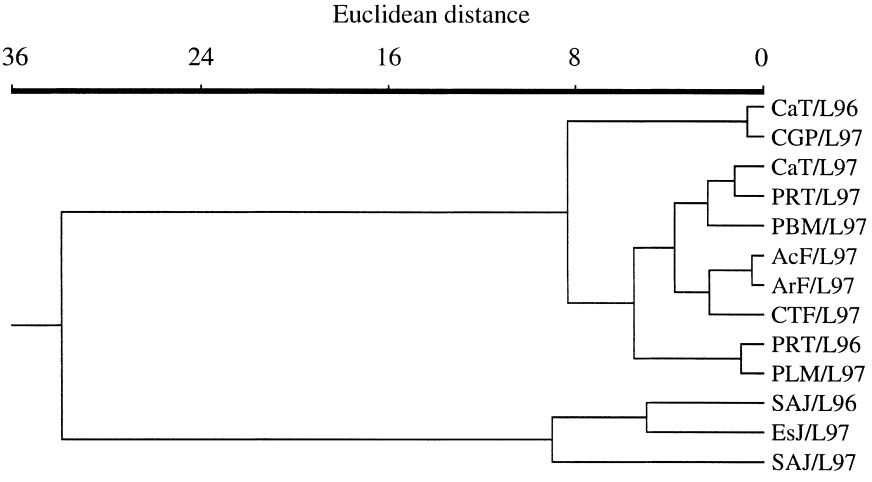
3. Experimental

3.1. Plant material

Collective samples of leaves and of unripe berries from *L. azorica* (Seub.) Franco were collected, in April 1996 and/or in July 1997, at Cabrito (530 m) and Pico Rachado (830 m) on Terceira, at Santo António (500 m) and Espigão (580 m) on S. Jorge, at Cabeço do Gato on Pico (300 m), at Pico Bartolomeu (890 m) and Pico Longo (500 m) on S. Miguel, and at Arrochela (700 m), Cabeço dos Trinta (800 m) and Areeiro (200 m) on Faial. A voucher specimen of the plant has been deposited in the Herbarium of the Museu, Laboratório e Jardim Botânico de Lisboa (no. LISU 165930).

3.2. Isolation procedure

The essential oil samples were isolated from deep-frozen (−20°C) material by distillation-extraction for 3



CaT – Cabrito, Terceira; CGP - Cabeço do Gato, Pico; PRT – Pico Rachado, Terceira; PBM – Pico Bartolomeu, S. Miguel; AcF - Arrochela, Faial; ArF - Areeiro, Faial; CTF – Cabeço dos Trinta, Faial; PLM - Pico Longo, S. Miguel; SAJ – Santo António, S. Jorge; EsJ - Espigão, S. Jorge.

L96 – Leaves collected in April 1996; L97 - Leaves collected in July 1997.

Fig.1. Dendrogram obtained by cluster analysis of the enantiomeric composition of α- and β-pinene in the essential oils from leaves of ten Azorean populations of *Laurus azorica*, based on Euclidean distance and using the unweighed pair-group method with arithmetic average (UPGMA).

h, using a Likens-Nickerson-type apparatus (Likens and Nickerson, 1964) with *n*-pentane as organic solvent, or by hydrodistillation for 3 h, using a Clevenger-type apparatus (Anonymous, 1996). The samples isolated by hydrodistillation were used to estimate the oil yields, and those isolated by distillation-extraction to determine their percentage composition, since the chance of artifact formation must be considered smaller when the latter isolation method is used.

3.3. Gas chromatography

GC analyses were performed using a twin FID instrument, a data handling system and a vapourizing injector port into which two columns of different polarities were installed: a DB-1 fused-silica column (30 m×0.25 mm i.d., film thickness 0.25 μm; J & W Scientific Inc.) and a DB-17HT fused-silica column (30 m×0.25 mm i.d., film thickness 0.15 μm; J & W Scientific Inc.). The oven temp. was programmed, 45–175°C, at 3°C min^{-1}, subsequently at 15°C min^{-1} up to 300°C, and then held isothermally for 10 min; injector and detector temps were 280 and 300°C, respectively; carrier gas, H_2 at 30 cm s^{-1}.

GC chiral analyses were performed using an FID instrument, a data handling system and a Cyclodex-B fused-silica column (30 m×0.25 mm i.d., film thickness 0.25 μm; J & W Scientific Inc.). The oven temp. was 75°C isothermal; injector and detector temps were 230 and 240°C, respectively; carrier gas, H_2 at 42 cm s^{-1}.

In the chiral analyses, authentic samples of α- and β-pinene enantiomers were used for comparison.

Samples were injected using the split-sampling technique with a ratio of 1:50. Percentage composition of the oils was computed using the normalization method from the GC peak areas without correction factors. Percentage data shown are mean values of two injections of each oil sample.

3.4. Gas chromatography-mass spectrometry

The GC–MS unit was equipped with a DB-1 fused-silica column (30 m×0.25 mm i.d., film thickness 0.25μm; J & W Scientific Inc.), and interfaced with an ion trap detector (ITD, software version 4.1). Oven temp. was as described above; transfer line temp., 280°C; ion trap temp., 220°C; carrier gas, He at 30 cm s^{-1}; split ratio, 1:40; ionization energy, 70 eV; ionization current, 60 μA; scan range, 40–300 μm; scan time, 1 s.

The identity of the components was assigned by comparison of their RIs, relative to C9–C17 *n*-alkanes, and MS with corresponding data of components of reference oils.

3.5. Cluster analysis

The percentage composition of the essential oil samples and the enantiomeric composition of α- and β-pinene in the oils were used to determine the relationship between the different populations of *L. azorica* by cluster analysis using the NTSYS software (Rohlf, 1992). Euclidean distance was selected as the measure of similarity, and the unweighed pair-group method with arithmetic average (UPGMA) was used for cluster definition.

Cyclolinopeptides F–I, cyclic peptides from linseed

Teruki Matsumoto, Akira Shishido, Hiroshi Morita, Hideji Itokawa, Koichi Takeya *

School of Pharmacy, Tokyo University of Pharmacy and Life Science, 1432-1 Horinouchi, Hachioji, Tokyo 192-0392, Japan

Received 5 July 2000; received in revised form 23 October 2000

Abstract

Four cyclic peptides, cyclolinopeptides F–I, were isolated from seeds of *Linum usitatissimum*. Their structures were elucidated by extensive 2D NMR spectroscopic methods and by chemical degradation. Further, their immunosuppressive activity is examined.
© 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Linum usitatissimum*; Linaceae; Cyclolinopeptide; Cyclic peptide; Immunosuppresive activity

1. Introduction

Cyclolinopeptide A (CLA), a cyclic nonapeptide, which exhibits various biological activities (Wieczorek et al., 1991; Naider et al., 1971; Brewster and Bovey, 1971; Tonelli, 1971; Blasio et al., 1989) has been isolated from linseed oil as one of the first isolated natural cyclic peptides (Kaufmann and Tobschirbel, 1959). In a previous paper, we reported on the separation, purification and structure elucidation of cyclolinopeptides B–E having cyclic nona- or octapetides, from the seeds of *Linum usitatissimum* (Morita et al., 1997, 1999). As part of our investigation on new biologically active cyclic peptides from higher plants (Itokawa et al., 1997), we focused our attention on the isolation of additional cyclic peptides from linseed. In this report, we describe both the isolation and structural elucidation of four new cyclic peptides, cyclolinopeptides F (**1**)–I (**4**) by extensive 2D NMR spectroscopic methods and their immunosuppressive activities against mouse splenocytes.

2. Results and discussion

Purification of the methanolic extract prepared from the linseed involving Diaion HP-20 column chromatography, using a H_2O–MeOH gradient system. The MeOH eluate was next applied to a silica gel column, this being followed by HPLC [ODS] to yield the four new cyclic peptides, cyclolinopetides F–I (CLF–CLI) in yields of 0.0008%, 0.0024%, 0.0002% and 0.00007%, respectively.

Cyclolinopeptides F (CLF) and G (CLG) were obtained as white powders. Their molecular formulae were shown to be $C_{55}H_{74}N_9O_{10}S_2$ and $C_{56}H_{76}N_9O_{10}S_2$, respectively by the quasi-molecular ion peak at m/z 1084.5018 $[M+H]^+$ and at m/z 1098.5138 $[M+H]^+$ in the HR-FABMS. Both IR spectra had absorption peaks which were attributed to amine, amide carbonyl and sulfoxide groups. Since the UV absorption maximum in the neighborhood of 280 nm suggested the presence of a tryptophan residue, the compounds were hydrolyzed with 6 N HCl containing 4% thioglycolic acid. HPLC analysis of each hydrolysate showed that CLF was a cyclic octapeptide consisting of two phenylalanines (Phe), two methionines (Met), proline (Pro), leucine (Leu), valine (Val) and tryptophan (Trp) per mol and CLG was a cyclic octapeptide consisting of two phenylalanines (Phe), two methionines (Met), proline (Pro), leucine (Leu), isoleucine (Ile) and tryptophan (Trp) per mol. However, both methionines in CLF and CLG were present as methionine sulfoxides, because each molecular formula had an additional two oxygen atoms, compared with the cyclic octapeptide presumed from above amino acid degradation and both had IR absorption bands (CLF: 1016 and CLG: 1015 cm^{-1}) indicating sulfoxide groups.

In the ^1H and ^{13}C NMR spectra (Tables 1 and 2), CLF and CLG had seven amide protons and eight amide carbonyl carbons, respectively, and thus were

obviously octapeptides. However, analysis of the NOE data and $2J_{H–C}$ and $3J_{H–C}$ correlations by HMBC did not permit elucidation of their amino acid sequences as shown in Figs. 1 and 3. Hence, CLF and CLG were chemically transformed to their corresponding linear derivatives (CLF′ and CLG′), i.e. by reduction of their methionine sulfoxide using thioglycolic acid and subsequent decomposition with cyanogen bromide. This gave the linear peptides, which displayed an absorption IR bands at 1775 cm^{-1} attributed to an homoserine lactone. Sequential analyses due to the HMBC correlations indicated by arrows in Figs. 2 and 4 showed that CLF′ and CLG′ were, respectively, the linear peptides Pro–Phe–Phe–Trp–Val–HomoSer Lactone and as Pro-Phe–Phe–Trp–Ile–HomoSer Lactone each additional dipeptide was assumed to be Leu[7] HomoSer lactone. ROE correlations of CLF were observed between the Mso[6] α-proton and the Leu[7] amide proton, and between the Mso[8] α-proton and the Pro[1] δ-proton, respectively. Also, ROE correlations of CLG were noted between the Mso[8] α-proton and Pro[1] δ-proton, and between the Ile[5] α-proton and the Mso[6] amide proton. Consequently, the structure of CLF was identified as *cyclo* (-Pro–Phe–Phe–Trp–Val–Mso–Leu–Mso-) and CLG as *cyclo* (-Pro–Phe–Phe–Trp–Ile–Mso–Leu–Mso-). The absolute stereochemistries of the component amino acids was

determined to be entirely in the L-configurations as evidenced by derivatization of the acid hydrolysate with Marfey's reagent (Marfey, 1984), followed by HPLC analyses.

Cyclolinopeptides H (CLH) and I (CLI) were isolated as white powders, and their molecular formulae were determined to be $C_{56}H_{76}N_9O_9S_2$ for CLH by HR-FABMS m/z 1082.5201 $[M+H]^+$ and $C_{55}H_{74}N_9O_9S_2$ for CLI by HR-FABMS m/z 1068.5110 $[M+H]^+$. HPLC of their acid hydrolysates showed that CLH was an octapeptide consisting of two Phe, two Met, Pro, Leu, Ile, Trp per mole and CLI was an octapeptide consisting of two Phe, two Met, Pro, Leu, Val, Trp per mole. Each amino acid was confirmed to be in the L-configuration using Marfey's method. The amino acid components of CLH and CLI were similar to those of CLG and CLF. However, the FAB mass spectra are 16 amu less than those of CLG and CLF. The facts suggested the presence of one methionine and one methionine sulfoxide in CLH and CLI instead of two methionine sulfoxides in CLG and CLF, respectively. According to the above speculation, reductive transformations of methionine sulfoxide in CLG and CLF by thioglycolic acid are demonstrated to give three compounds, respectively. One of them in CLG (or CLF) agreed completely with CLH (or CLI) in comparison of

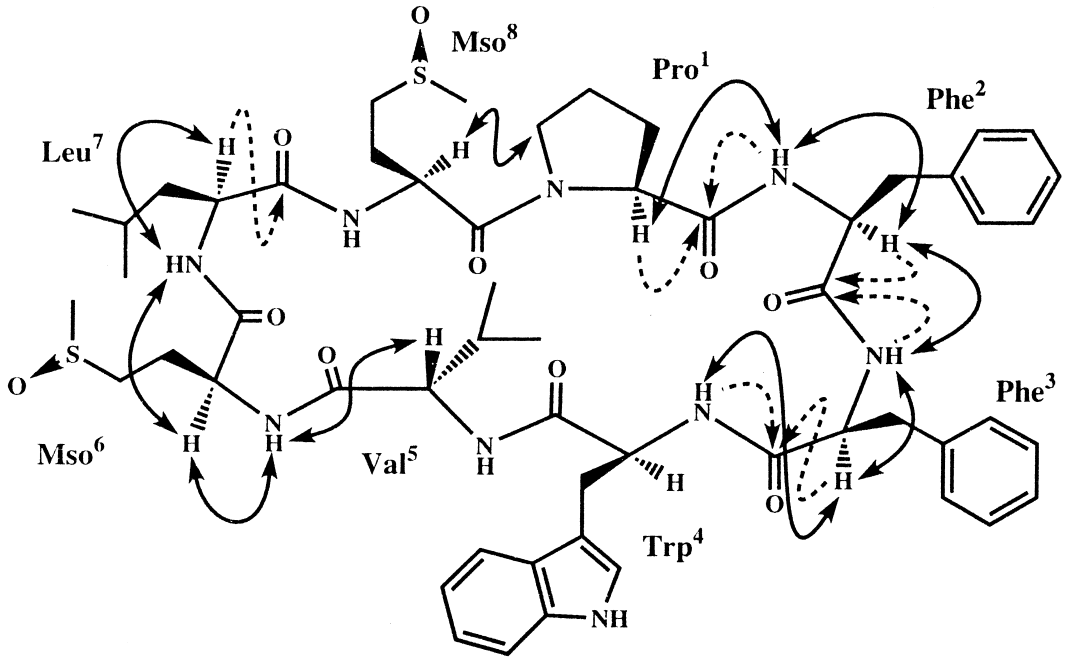

Fig. 1. Cyclolinopeptide F (**1**): dashed arrows show selected HMBC correlations and arrows show some selected NOE relationship.

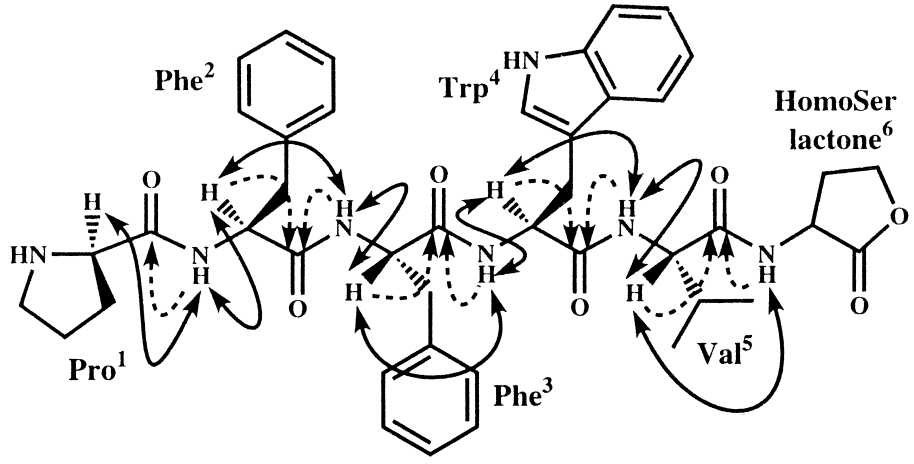

Fig. 2. Cyclolinopeptide F′: dashed arrows show HMBC correlations and arrows show some selected NOE relationship.

various physical and spectral data. Consequently, the sequence of amino acids in CLH (or CLI) is basically same to that in CLG (or CLF). The amino acid sequences of CLH and CLI were determined from ROE correlations as shown in Figs. 5 and 6. Consequently, the structures of CLH were identified as *cyclo* (-Pro–Phe–Phe–Trp–Ile-Mso–Leu–Met-) and CLI as *cyclo* (-Pro–Phe–Phe–Trp-Val–Met–Leu–Mso-).

CLB (*cyclo* (-Pro–Pro–Phe–Phe–Val–Ile–Met–Leu-Ile-)) showed an inhibitory effect on mitogen (concanavalin A) induced response of human peripheral-blood lymphocytes (IC_{50}: 44 ng/ml), which is comparable to that of cyclosporin A (Morita et al., 1997). Furthermore, CLA (*cyclo* (-Pro–Pro–Phe–Phe–Leu–Ile–Ile–Leu–Val-)), CLB and CLE (*cyclo* (-Pro–Leu–Phe–Ile–Mso–Leu–Val-Phe-)) possessing different amino acid sequences showed a moderate inhibitory effect of about the same potency on the mouse lymphocyte proliferation induced by Con. A (IC_{50}: CLA 2.5 μg/ml; CLB 39 μg/ml; CLE 43 μg/ml) (Morita et al., 1999). However, CLC (*cyclo* (-Pro–Pro–Phe–Phe-Val–Ile–Mso–Leu–Ile-)), CLD (*cyclo* (-Pro–Phe-Phe–Trp–Ile–Mso–Leu–Leu-)) and CLF–CLI (IC_{50}: >100 μg/ml, respectively) did not show any of the above activities. It is known that the biological activity of CLA is critically dependent on the sequence and conformation (Kessler et al., 1988). The conformational analyses and further conformation–biological activity relationship of CLA–CLI, are currently being investigated in our laboratories.

3. Experimental

3.1. General

Optical rotations were measured on a JASCO DIP-4 spectrometer and $[\alpha]_D$ values are given in 10^{-1} deg cm^2 g^{-1}. The IR and UV spectra were taken on JASCO FT/IR 620 and Hitachi 557 spectrometers, respectively, and the ^{1}H and ^{13}C NMR spectra were recorded on Brüker AM-500 spectrometers, with chemical shifts (δ) reported in ppm, the spectra were recorded at 320°. FABMS were taken with a VG Autospec spectrometer. HPLC was carried out using an Inertsil PREP-ODS column (20 mm i.d.×250 mm and 30 mm i.d.×250 mm, GL Science Inc.) packed with 10 μm ODS. TLC was conducted on precoated Kieselgel 60 F254 (Art. 5715; Merck) with spots detected by use of the Dragendorff reagent.

3.2. Plant material

Seeds (*Linum usitatissium*, Linaceae) were purchased from Nikka Oil Co., Japan and the oil was removed by manual pressing. The plant was identified by Professor Yutaka Sashida, director of the medicinal garden in Tokyo University of Pharmacy and Life Science. A voucher specimen is deposited in our Laboratory.

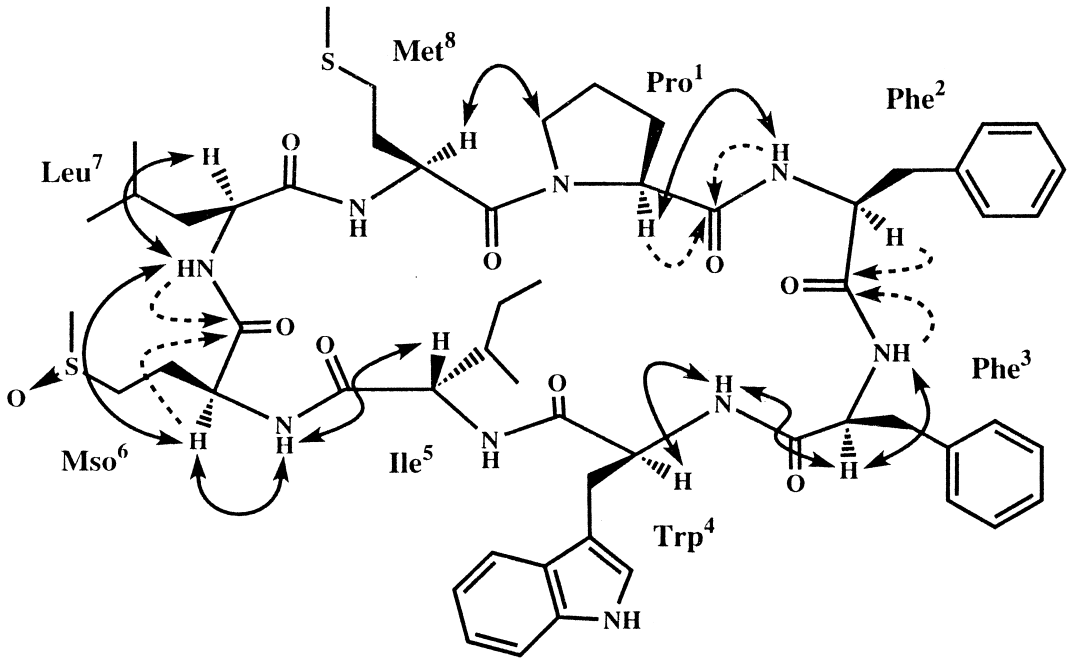

Fig. 5. Cyclolinopeptide H (**3**): dashed arrows show selected HMBC correlations and arrows show some selected NOE relationship.

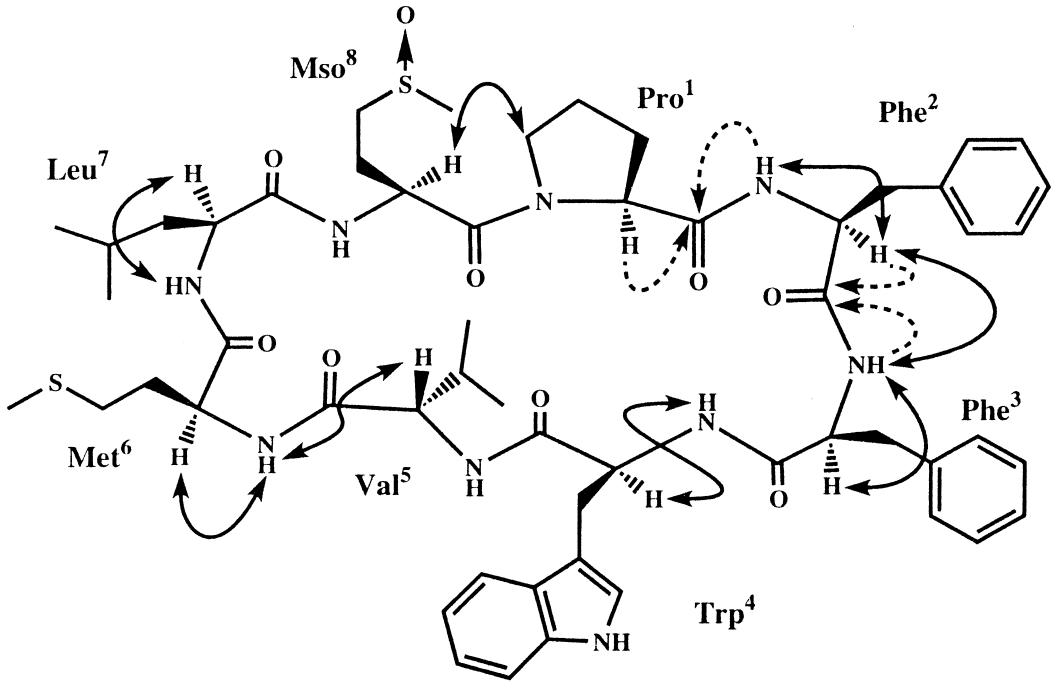

Fig. 6. Cyclolinopeptide I (**4**): dashed arrows show selected HMBC correlations and arrows show some selected NOE relationship.

3.3. Extraction and separation

Seeds (*L. usitatissium*, 30 kg) were manually pressed to remove oil by squeezing, these being extracted with hot MeOH three times to give a MeOH extract (4 kg). The latter was subjected to Diaion HP-20 column chromatography using a H_2O–MeOH gradient system (0:1–1:0), and the fraction eluted with 100% MeOH was further subjected to silica gel column chromatography using a $CHCl_3$–MeOH gradient system (1:0–0:1). A 15% MeOH fraction was subjected to ODS HPLC with 40–60% CH_3CN solvent system to give CLF (0.0008%), CLG (0.0024%), CLH (0.0002%) and CLI (0.00007%).

3.8. Absolute configuration of amino acid

A solution of each peptide (1 mg) in 6 N HCl was heated at 110°C for 24 h in a sealed tube. After removal of HCl by repeated evaporation in vacuo, the hydrolysate was dissolved in water and treated with 1-fluoro-2,4-dinitrophenyl-5-L-alanine amide (Marfey's reagent) and 1 M $NaHCO_3$ at 35°C for 1 h. After cooling, it was treated with 2 M HCl and then concentrated to dryness. This residue was subjected to HPLC, flow rate 1 ml/min, detection at 340 nm, solvent: 10–80% MeOH (80 min gradient added on 10 min to be eluted with 100% MeOH)/50 mM triethylamine phosphate (TEAP) buffer (pH 3.2). Retention time (min) of authentic amino acids were as follows: L-Pro (54.8), D-Pro (60.6), L-Met (63.9), D-Met (76.8), L-Val (66.8), D-Val (79.7), L-Trp (67.4), D-Trp (75.8), L-Phe (71.9), D-Phe (84.6), L-Ile (74.0), D-Ile (86.4), L-Leu (75.5), D-Leu (87.4), L-Msn (46.7), D-Msn (51.2), L-Mso (45.4), D-Mso (47.4).

3.9. Reaction of CLF and CLG with thioglycolic acid and cyanogen bromide

Solutions of CLF (18.9 mg) and CLG (21.1 mg) in 40% thioglycolic acid (1.0 ml) were individually heated at 50°C for 24 h, respectively. Each reaction mixture

was subjected to HP-20 column chromatography, then further purified by HPLC, to give two cyclic octapeptides consisting of one methionine sulfoxide and one methionine, and one cyclic octapeptide containing two methionine. The latter was treated with 100 M cyanogen bromide and 70% formic acid (1.0 ml) for 24 h at room temperature. The reaction mixture from CLF (or CLG) was lyophilized and purified by HPLC to give an acyclic homoserine lactonic product CLF′ (3.0 mg) (or CLG′ (5.5 mg)).

3.9.1. CLF′

3.10. Biological assay

The bio-assay method using mouse lymphocytes was as follows. After dislocation of cervical vertebrae of ICR mice aged 5–8 week*s*, the spleen was removed and mashed. Then, the cells were suspended in RPMI 1640 medium and passed through a stainless steel mesh. The single cell suspension was washed twice with the medium and finally suspended in RPMI 1640 medium containing 10% fetal calf serum, and 10 mg/ml kanamycin to give 3.5×10^6 cells/ml. 200 μl of this suspension was placed in each well of a microtiter plate with 96 flatbottom wells. Concanavalin A was added to each well to a final concentration of 2.5 μg/ml. Subsequently, 4 μl of serially diluted EtOH solution of test compound was added to a final concentration of 10–100 000 ng/ml. The plate was incubated for 3 days in 5% CO_2/95% air at 37°C. After termination of cell culture, 20 μl of 5 mM 1-methoxy PMS and 0.2 mM WST-1 (DOJINDO Laboratories) in phosphate buffered saline was added to every well and the plate was incubated again at 37°C in 5% CO_2/air for a 4 h. The plate was read on a microplate reader (Corona MT P-32, Corona Co., Japan) at 415 nm. A dose–response curve was plotted for each drug, and the concentration which gave 50% inhibition of cell growth (IC_{50}) was recorded.

Jesterone and hydroxy-jesterone antioomycete cyclohexenone epoxides from the endophytic fungus *Pestalotiopsis jesteri*

Jia Yao Li, Gary A. Strobel *

Department of Plant Sciences, Montana State University, Bozeman, MI, 59717, USA

Received 16 October 2000; received in revised form 8 December 2000

Abstract

Jesterone and hydroxy-jesterone are novel highly functionalized cyclohexenone epoxides isolated from a newly described endophytic fungal species — *Pestalotiopsis jesteri*. They were purified from cultures of the fungus by bioassay guided fractionation using *Pythium ultimum* as the indicator organism. Jesterone, in particular, displays selective antimycotic activity against the oomycetous fungi which are some of the most plant pathogenic of all disease causing fungi. The possible importance of these cyclohexenones to the biology of the endophytic fungus–host plant relationship is also discussed. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Rainforest; Endophyte; Oomycete; Cyclohexenone; Plant pathogen; Antimycotic

1. Introduction

Pestalotiopsis jesteri is a new endophytic fungus recently described from the Southern Highland Province of Papua New Guinea (Strobel et al., 2000). The fungus was isolated from the inner bark of small limbs of a *Fragraea bodenii* (locally termed an oak tree but belonging to the family, Gentianaceae) located at the singsing grounds of the Aluakambe village. Limbs from the top, middle and lower crown of the tree each yielded this peculiar fungal endophyte. This particular plant species is common to the forests of the tropical New Guinea Highlands. This region of the world was selected for study since nearly 70% of Papua New Guinea is covered with virtually undisturbed rainforests. Specifically, the Southern Highlands province receives between 80 and 100 cm of rainfall per year and this region of the world is virtually unexplored microbiologically. Under these moist conditions various plant pathogenic microorganisms (especially the oomycetes) normally thrive. Yet the forest seems to remain relatively healthy suggesting the presence of substances that are suppressive or lethal to oomycetes. Thus, our rationale to find novel antioomycetous compounds focuses on tropical regions of the world such as Papua New Guinea. In particular, we commonly search for unusual endophytic or epiphytic fungi or other microbes found associated with normally healthy appearing plants. These plants may survive the onslaught of plant pathogens in such environments because of the antimicrobial compounds being produced by endophytic or epiphytic microbes associated with them (Strobel et al., 1999). Thus, the focus of this report is to describe the isolation, and structural elucidation of two novel cyclohexenone epoxides being produced by two of the three isolates of the newly described endophytic fungus — *Pestalotiopsis jesteri*. In addition, we report that one of these cyclohexenone epoxides possesses impressive antimycotic activity against a suite of plant pathogenic oomycetes.

2. Results and discussion

Each of the isolates of *P. jesteri* used in this study was obtained from the top, middle and lower crown areas of a 20 m high oak tree (*Fragraea bodenii*) in the Southern Highlands provience of Papua New Guinea. These fungal isolates were obtained as endophytes from representative small limbs (0.5–1.0 cm in dia.) from one tree in the Aluakambe village. They were cultured and initially examined for activity against *P. ultimum* (a plant pathogenic oomycete). Only isolates from the lower and

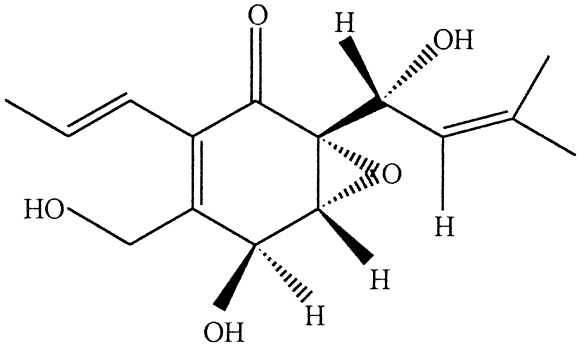
Jesterone (1)



Hydroxy-jesterone (2)

middle crown locations in the tree were biologically active. These isolates were selected for further study. After culturing, extracting and purification, the yield of a biologically active product was 20 mg/l. This product was ultimately shown to be homogeneous by TLC in solvents A and B and was termed — "**jesterone (1)".** The various fractions obtained during the purification procedures were consistently subjected to an agar plate bioassay system employing *P. ultimum* as the test organism. While some other fractions had some bioactivity, **(1)**, the primary fermentation product, obtained using the processes described, had the greatest bioactivity against the test organism.

However, in the process of purifying **(1)**, another fermentation product appeared. This compound also possessed antifungal activity, but to a lesser extent than **(1)**. The yield of this compound was about 120 mg/l. This compound was purified and also shown to be homogeneous by TLC and was structually related to **(1)**, it was termed — "**hydroxy-jesterone (2)".**

The names jesterone **(1)** and hydroxy-jesterone **(2)** have been selected for these compounds in reference to the biological source from which they arise, namely *Pestalotiopsis jesteri*. We originally named the source organism *P. jesteri* because the 3–4 appendages on each spore bear terminal spheroid structures making the spore appear as a jester's hat (Strobel et al., 2000).

Both **(1)** and **(2)** are liquids at room temperature possessing a slightly yellowish tinge. Electrospray mass spectrometry of **(1)** revealed an M + M (dimer) + Na^+ at 551 *m*/*z* yielding a mass of 264 for this compound. On the other hand, **(2)** showed an M + H^+ at 281 *m*/*z*, thus, a M_r of 280. By high resolution mass spectroscopy **(1)** yielded an observed molecular ion at 264.135338 (calculated M_r = 264.136572) with an empirical formula of $C_{15}H_{20}O_4$. In HRMS **(2)** yielded a M_r = 280.130447 (calculated M_r = 280.131074). Thus, the empirical formula of **(2)** is $C_{15}H_{20}O_5$.

The ^1H NMR spectrum of **(1)** showed 18 non-exchangeable protons including 3 olefinic protons and those with 3 methyl groups. Analyses of the ^{13}C NMR, DEPT and HSQC spectra of **(1)** allowed for the identification of 2 methylene carbons including 1 hydroxymethylene functionality, 2 methine carbons possessing oxygen substituents, 5 quaternary carbons including 3 olefinic, 1 carbonyl and 1 bearing an oxygen substituent. The IR spectrum showed a strong -OH absorption band at 3426 cm^{-1} and an α-β- unsaturated ketone band at 1678 cm^{-1}. The carbon skeleton of **(1)** was constructed from the COSY and HMBC spectra (Table 1, Fig. 1). The coupling constant of protons on carbons 2 and 3 (J = 16.11 Hz) indicated a *trans*-olefinic bond. On the other hand, The NOESY spectrum showed no NOE between individual protons on carbons 6, 9 and 10 indicating that the -OH on carbon 6 and the epoxy on carbons 7 and 8 are in a transconfiguration. This structural assignment was confirmed by observing NOE interactions between protons on carbons 7 and 9 and 10.

The NMR spectra of **(2)** were similar to **(1),** and they revealed that carbon 9 possesses a hydroxyl group. The structure of **(2)** was constructed from COSY, HMBC and NOESY experiments (Table 2). Based on all of the data

available the structures of both **(1)** and **(2)** can be assigned with some relative stereochemistry in place.

The newly isolated cyclohexenones **(1)** and **(2)** belong to a relatively rare class of oxygenated cyclohexanoids which occur in microbes as well as in higher plants (Muhlenfeld and Achenbach, 1988). These substances have a range of activities from antifungal, antitumor, phytotoxic, to enzyme inhibitory and phytotoxic. The latter case is illustrated by the discovery of the PT toxin from the fungus *Pestalotiopsis longiseta* and *P. theae,* which are pathogens of tea (Nagata et al., 1992). The PT toxin and its related compound, epipoxydon are cyclohexenone epoxides with structures markedly different than either **(1)** or **(2)**, but still have the cyclohexenone ring system. In addition, other phytotoxins in this same group of oxygenated cyclohexenones are phyllostine and phyllosinol (Sakamura et al., 1971). Although a number of cyclohexenones related to **(1)** and **(2)** have been reported in the chemical literature, until now, with the exception of ambuic acid, none have any indication of anti-oomycete activity (Li et al., 2001). However, activities against other fungi have been noted. For instance, eupenoxide is an antimycotic from *Eupenicillum* sp. (Duke and Rickards, 1984). It possesses a hydroxylated cyclohexene ring system with both an alkene (7-carbon) and hydroxy methylene side chain. On the other hand, panepoxydone, with a core epoxycyclohexenone structure comparable to jesterone/hydroxy-jesterone is an impressive inhibitor of NF-κB mediated signal transduction in COS-7 cells (Erkel et al., 1996).

Recently, ambuic acid has been isolated and its structure determined from many isolates of *Pestalotiopsis* spp. worldwide (Li et al., in press). It turns out that *Pestalotiopsis* spp. are some of the most commmon inhabitants, as endophytes, of many higher plants in the world's rainforests. Ambuic acid is also a highly functionalized cyclohexenone epoxide possessing some biological activity against certain plant pathogenic fungi including *P. ultimum* (Li et al., 2001). Because ambuic acid bears many structural features with **(1)** and **(2)**, it appears that they have a metabolic pathway in common. In addition, because such a wide variety of metabolites have been recently isolated from *Pestalotiopsis* spp., it would also appear that this group of fungi represents a potential "factory" of previously undiscovered, as well as important secondary fungal products including taxol (Strobel et al., 1996). Presently, the role of these compounds to the biology of the fungus, as it exists within plant tissues, is only a matter of conjecture. However, given the impressive biological activity of some of these molecules, especially as antifungal agents, their role may be to protect the very plants that they inhabit.

Both **(1)** and **(2)** are antimycotics. The minimum inhibitory concentrations (MIC) required to produce total inhibition of fungal growth after exposure to given concentrations of these compounds is reported (Table 3). These compounds have no inhibitory effect against the ascomycetous fungus *Sclerotina sclerotiorum* and the imperfect fungus *Geotrichum candidum*. However, the basidiomycetous fungus *Rhizoctonia solani* and the ascomycetous fungus *Pyricularia oryzae* were both sensitive to **(1)** but not **(2)** (Table 3). However, the most noticeable biological activty of either of these compounds was that of **(1)** on the oomyceteous fungi *Pythium ultimum, Aphanomyces* sp., *Phytophthora citrophthora, P. citrophthora* and *P. cinnamomi* (Table 3). These, relatively low MIC values for **(1)** against these important plant pathogenic fungi suggests that it may have commercial potential. On the other hand, (2) while having some activity against a few of the test fungi (some of the oomycetes), was relatively inactive against the majority of the fungi tested (Table 3).

We also note that *P. jesteri* behaves as many other fungi relative to secondary product formation. That is, after several serial transfers on the PDA (potato dextrose agar) medium and then placement into the MID medium the fungus did not produce **(1)**, however, **(2)** was still produced. Commonly, as has been shown with other fungi, this phenomenon may be related to the absence of critical plant metabolites that can affect the metabolism of a plant inhabiting fungus (Pinkerton and Strobel, 1975; Li et al., 1998). Usually, after one or more of these plant compounds are restored to the medium used to grow the fungus, the production of the fungal metabolite resumes. While this problem has been solved in other microbe-plant cases we have not solved it yet in the case of *P. jesteri*.

Representatives of the fungal genus *Pestalotiopsis* sp. are some the most commonly isolated endophytes of the higher plants of the world's rainforests (Li et al., 2001). The novel fungus *P. jesteri* was originally obtained from an oak species native to the Southern Highlands of Papua New Guinea. Although we had made vast collections of other plants in this area, the fungus was only obtained from this one tree species. It maybe that *P. jesteri* is host-selective. Another interesting biological aspect of *P jesteri* is that only certain isolates of it make **(1)** and **(2)**. Thus, while the association of these secondary products with this particular fungus does not always occur we can only speculate that they may play some role in the microbe-host plant relationship.

Table 3
Minimum inhibitory concentrations of jesterone and hydroxy-jesterone for a representative group of plant pathogenic fungi[a]

[a] Details of the testing procedures are given (see Experimental).

3. Experimental

3.1. General spectroscopic procedures

All NMR data were collected in a Bruker DRX-500 NMR with the sample dissolved in 0.5 ml of $CDCl_3$. Specific details and results on each NMR experiment performed are available from the authors.

Electrospray mass spectra of **1** and **2** were obtained on a home built instrument with the sample dissolved in methanol/water/acetic acid 50:50:1 by vol. Each sample was injected into the instrument with a flow rate of 2 μl per min. with a spray voltage of 2.2 kV via the loop injection method. High resolution EI mass spectrometry was performed on a VG 70E-HF double focusing mass spectrometer operating at a mass resolution of 1500.

The ultraviolet absorption spectra of **1** and **2** were obtained in a Beckman DU 50 spectrometer with the compounds dissolved in methanol.

3.2. Thin layer chromatography

Thin layer chromatography of fungal fermentation products was performed on Merck silica gel plates (0.25 mm thick) using solvent systems A = chloroform: methanol 10:1 v/v: and solvent system B = hexane: ethyl acetate 1:1 v/v. compounds were detected with the anisaldehyde/sulfuric acid reagent (Cardellina, 1991).

3.3. Jesterone **(1)** and hydroxy-jesterone **(2)** isolation

Jesterone was isolated from 3-week old still cultures of *P. jesteri* grown at 23°C in two 2 l flasks each containing 500 ml of MID medium (Strobel et al., 1996). After removal of the mycelium by filtration, the culture fluid was successively extracted twice with equal volumes of methylene chloride. After flash evaporation of the solvent, approximately 450–500 mg of residue remained. This residue was dissolved in 2 ml of methylene chloride and applied to a 3×30 cm column of silica gel. On to the column was placed 400 ml of a mixture of chloroform/methanol 10:1 v/v. Fractions of 10 ml were collected and nearly mid-way in the elution profile, a compound with an $R_F = 0.44$ in solvent A appeared. Each of the tubes containing this compound were pooled with a final yield of 50–60 mg of material. This residue was

again subjected to flash column silica chromatography on a comparable sized silica column on to which was placed a 400 ml mixture of hexane /ethyl acetate 2:1 v/v until a compound having the appropriate migration pattern in solvent A appeared.

Furthermore, another compound appeared in the elution profile of the first silica gel column. It, however, possessed a greater retention time on the flash column than jesterone and also had weaker activity against *P. ultimum*. The R_F of this compound in solvent A was 0.34 and in solvent B the R_F was 0.15. About 150 mg of this impure compound was collected and subjected to additional flash chromatograpy on a new silica column. On to it was placed 400 ml of a hexane and ethyl acetate mixture but at a ratio of 1:1 v/v, which allowed its elution at about 200 ml. The yield of this compound was about 120 mg/l. It was biologically active against the test fungus, but to a lesser extent. This compound was also shown to be homogeneous by TLC and was structually related to **(1)**.

3.4. Agar plate bioassay test

The agar plate bioassay test consisted of the placement of an aliquot (20 μl) of each column fraction on a potato dextrose agar (PD) plate. The solution was allowed to evaporate to dryness on the surface in a decontaminated (alcohol sprayed) laminar flow hood for 15–20 min. Subsequently, 1 mm plugs of PD agar containing a rapidly growing culture of *Pythium ultimum* were placed within 1 cm of the test residue previously deposited on the plate. After 2 days of incubation at 23°C, fungal colony inhibition could be assessed by virtue of its uneven growth, with little or no growth developing toward the dried residue possessing active antifungal compounds.

3.5. Minimum inhibitory concentration (MICs) tests

MIC (minimum inhibitory concentration) values for **1** and **2** were obtained using a standard plate bioassay test method that employs a microtitre plate containing various concentrations of the test compound and the fungus to be tested in PD broth. The test fungus to be observed is placed in the wells as a 1 mm dia agar plug obtained from a rapidly growing PDA plate supporting the growth of the test fungus. Each well, after 48 h at 23°C, was examined and the well showing no growth next to well having some growth was taken as the MIC value.

3.6. Jesterone (*1*)

Liquid (yellowish) at room temperature. UV λ max (methanol) (log ε): 216, 240 and 265 (3,193, 3,252 respectively) HRMS: found 264.135338 (M^+): calc. for $C_{15}H_{10}O_4 = 264.136572$. For ^1H and ^{13}C NMR spectral analysis, see Table 1.

3.7. Hydroxy-jesterone (*2*)

Liquid (yellowish) at room temperature. UV λ max (methanol) (log ε): 216, 240 and 265 (3.193, 3.252, and 3.243 respectively); HRMS: found 280.130447 (M^+); calc. for $C_{15}H_{20}O_5 = 280.131074$. For ^1H and ^{13}C NMR spectral analysis, see Table 2.

Acknowledgements

This work was supported by the Montana Agricultural Experiment Station. Help in acquiring the NMR spectroscopic data was provided by Dr. Scott Busse, and all mass spectral data were acquired by Dr. Joe Sears, both at the MSU Department of Chemistry.

This paper is dedicated to Professor W. Kraus on the occasion of his 70th birthday

Abstract

The extract of the floral parts of *Viguiera quinqueremis* afforded, in addition to known compounds, six new sesquiterpene lactones as well as a new myoinositol derivative. All compounds were detected in glandular trichomes which were collected micromechanically from the anther appendages and were analyzed by HPLC. Structure identification was performed by ^{1}H NMR measurements including LC NMR and LC MS experiments. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Viguiera quinqueremis*; Heliantheae; Asteraceae; Chemotaxonomy; Sesquiterpene lactones; Myoinositols

1. Introduction

Viguiera quinqueremis Blake is part of a group of approximately 14 species that Blake (1918) merged in the series *Bracteatae* of section *Paradosa*, the South American branch of the large and polyphyletic genus *Viguiera*. The taxa of *Bracteatae* are endemic to Brazil and Paraguay and so far relatively few attempts were made to establish their phytochemical patterns. Up to now, four heliangolides of the 1-keto-2,3-unsaturated-3,10-epoxy-type were identified from *V. oblongifolia* (Bohlmann et al., 1984; Tamayo-Castillo et al., 1990) and *V. robusta* (Da Costa et al., 1996), respectively, while *V. nervosa* was reported to lack sesquiterpene lactones (Tamayo-Castillo et al., 1990). *V. quinqueremis* is a perennial herb with sessile, mostly alternate and linear-oblong leaves. Microscopic studies of vegetative plant parts revealed the absence of glandular trichomes that are typical for the sequestration of sesquiterpene lactones, while numerous such glands were present on the anther appendages. It was the aim of the current study to identify the chemical constituents of these trichomes.

2. Results and discussion

HPLC analyses of extracts from glandular trichomes of anther appendages of *V. quinqueremis* plants from a population collected near Diamantina, State of Minas Gerais, Brazil, showed the presence of at least 15 peaks with UV-spectra and chromatographic behavior typical for sesquiterpene lactones. Comparison with retention times of reference compounds from our previous chemotaxonomic studies on Helianthinae (Spring and Buschmann, 1996) together with spectral data obtained by LC ^{1}H NMR and LC MS measurements led to the identification of the known heliangolides **1**–**6** (De Vivar et al., 1976; Ohno and Mabry, 1980; Delgado et al., 1982; Gao and Mabry, 1986) and **11**–**13** (Buschmann and Spring, 1995; Spring et al., 1982, 1989) (Fig. 1). Preparative HPLC was used to purify the remaining unidentified compounds for detailed spectroscopic measurements. The structures were elucidated by extensive MS and NMR studies, including ^{1}H–^{1}H COSY, HSQC and 2D-NOESY experiments. Low sample amounts prohibited the determination of the absolute configuration of the discussed compounds and the chemical formulae are given in analogy to known compounds.

^{1}H NMR and COSY spectra of compounds **7** and **8** (Table 1) were mostly similar to those of the niveusin A

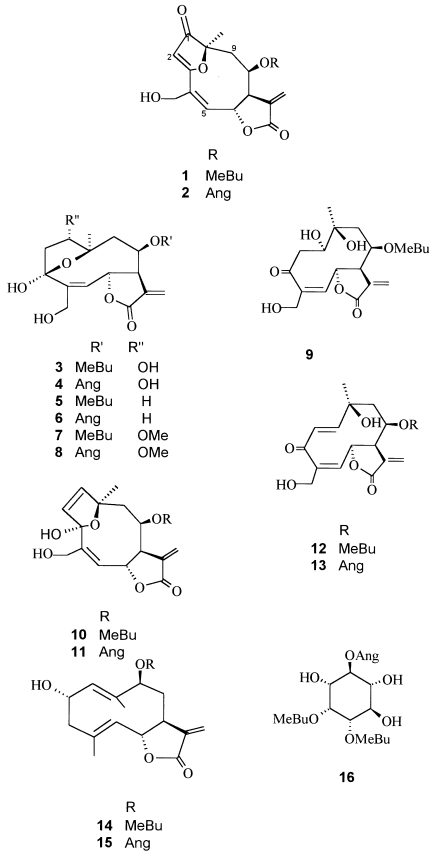

Fig. 1. Compounds isolated from *Viguiera quinqueremis*. The absolute configuration of the discussed compounds was not determined and the chemical formulae are given in analogy to known compounds.

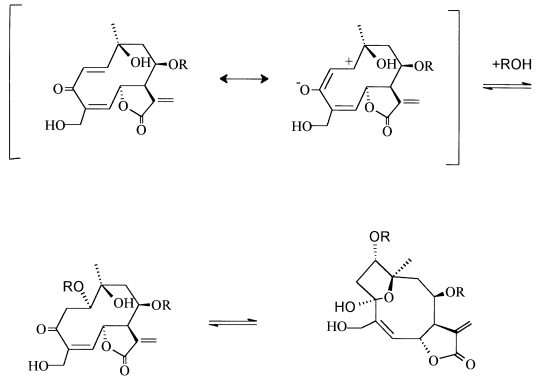

Scheme 1. Possible reaction of 1,2-unsaturated tifruticin type sesquiterpene lactones (e.g. **12**) with nucleophiles leading to 1-*O*-substitued derivatives (e.g. **9**) and to 3,10-epoxy-isomers (e.g. **3** and **7**) after spontaneous reaction from the keto alcohol to the hemiketal form.

derivatives **3** and **4**, respectively. However, the signal of the hydroxyl function at C-1 (e.g. δ 2.97 *d*, $J = 7.6$ Hz in **3**) was missing in the spectra of **7** and **8**. Instead, a signal at δ 3.42 (*s*, 3H), suggested the presence of a methoxy group at this position in both compounds. This was confirmed by APCI MS data of **7** and **8** which showed $m/z = 411$ $[M+H]^+$, indicative of $C_{21}H_{30}O_8$, and 409 $[M+H]^+$, indicative of $C_{21}H_{28}O_8$, respectively. The substitution of a hydroxyl by a methoxy group also explained the more lipophilic migration behavior of the two compounds in HPLC separations when compared with the hydroxylated derivatives **3** and **4**. This raised questions about their occurrence as natural constituents or as artifacts arising from addition of MeOH to the tifruticin precursors **12** and **13** when MeOH was used in the purification process (Scheme 1). Attempts were made to clarify this by extracting glandular trichomes and performing the subsequent HPLC separation using solvents with and without MeOH. CH_3CN extracts separated in 30% CH_3CN and in 50% MeOH, respectively, led to HPLC diagrams that clearly showed minor peaks with retention times and UV spectra typical of **7** and **8**. The same peaks in similar amounts appeared in samples extracted with MeOH. These results support the natural occurrence of the methoxy derivatives. On the other hand, current experiments (data not shown) with the tifruticins **12** and **13** purified from *Helianthus annuus* indicate that in these instances spontaneous methoxylation at C-1 occurs upon storage in MeOH over several weeks. It therefore cannot be ruled out that both ways of origin contributed to the existence of **7** and **8**.

The ^{1}H NMR and COSY spectra of compound **9** (Table 1) showed the characteristic signals of a 1,15-dihydroxy-4, 11(13)-unsaturated heliangolide with a methylbutyrate side chain. Since the protons at C-2 showed coupling with only one neighboring hydrogen (H-1), C-3 was assumed to be quaternary. A 3,10-epoxy-substitution was excluded due to the chemical shift of H-7 (δ 3.41 instead of ca. δ 4.1 as in niveusin-type compounds). This led to the assumption of a keto form at C-3, similar as in compound **12** and **13**. MS data (APCI) showed $m/z =$ 397 $[M+H]^+$ indicative of $C_{20}H_{28}O_8$, thus confirming the proposed structure of **9**. The relative stereochemistry of the substituents was deduced from 2D-NOESY experiments which showed effects between H-7/H-8, H-7/H-2b, H-6/H-9a and H15a,b/H-1. This indicated the β-orientation of the ester at C-8 and the α-position of the hydroxyl at C-1. Compound **9** therefore has to be regarded as the keto derivative of niveusin A methylbutyrate (**3**). The purification of this isomer in a stable form was unexpected to us, since similar changes in the constitution of niveusin B (**6**) and of niveusin C derivatives, previously observed during HPLC separation, led to NMR spectra (measured in $CDCl_3$) of only the hemiketal form which appears to be stabilized in aprotic solvents (Spring et al., 1991).

The ^{1}H NMR spectrum of compound **10** (Table 1) was identical with that of 1,2-anhydridoniveusin A (**11**) (Spring et al., 1989), except for the side chain signals which indicated the presence of a methylbutyrate instead of an angelate. The β-orientation of the side chain at C-8 was deduced from the NOE between H-7 and H-8. MS data (APCI) showed $m/z = 379$ $[M+H]^+$ indicative of $C_{20}H_{26}O_7$, thus confirming the suggested structure. The

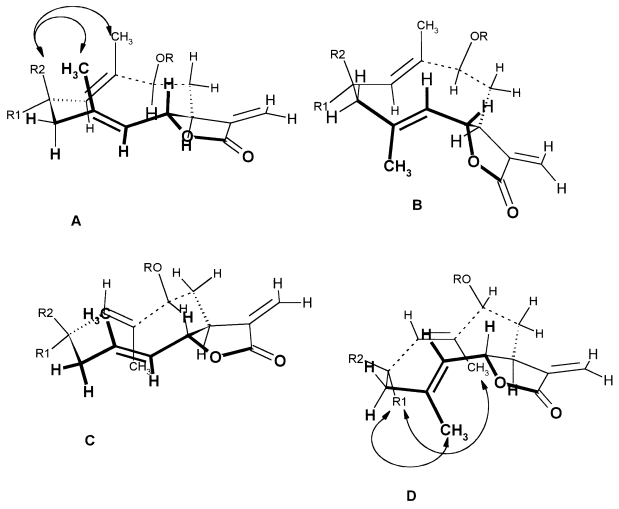
[b] Signal obscured.

signal of H-7 (δ 3.51 *m*) was upfield by ca. 0.5 ppm compared with the niveusin-type compounds **3**–**8**. According to the lowest conformation found by searching the conformational space with the GMMX option of PCMODEL, this is most likely due to inverse shift effects of the 3, 10-epoxy group and the 1,2-double bond with respect to H-7. These force field calculations (see Experimental) also support the ß-orientation of the side chain when comparing theoretical coupling constants with those experimentally determined (Table 1).

Coupling constants for H-7/13 (*J* = 3 and 3.5 Hz) of **14** (Table 1) indicated the presence of a 1(10), 4-*E*,*E*-germacradienolide. COSY experiments revealed the sequence of H-7 to H-9 and H-7 to H-5. The methylbutyrate side chain had to be attached to H-9 due to its chemical shift. H-1 (δ 5.03) was coupled to the H-14 methyl (δ 1.56 *bs*) and to a complex signal at δ 4.81 (*ddd*) which was consistent with the presence of a hydroxyl group at H-2. The suggested structure was confirmed by MS data (APCI) which showed $m/z = 349$ $[M+H]^+$ indicative of $C_{20}H_{28}O_5$. The relative stereochemistry at C-9 and C-2 was deduced from an NOE between H-7 and H-9 which indicated ß-orientation of the ester at C-9. On the other hand, NOEs between H-2 and both methyl groups (H-14 and H-15), and the absence of NOEs between H-2, H-7 and H-9 indicated that the C-2 hydroxyl was α-oriented. This was substantiated by force field calculations in the following manner: For either orientation (α or β hydroxyl) four principal conformational options exist with respect to the orientation of the methyl groups at C-4 and C-10 (Scheme 2). However, only the two conformations are likely to explain the observed NOEs of H-2, where both methyl groups are oriented opposite to the hydroxyl (Scheme 2: conformation A for α-hydroxyl and conformation D for β-hydroxyl). Considering the energetic



Scheme 2. Possible conformations of **14** with respect to the orientation of C-2 hydroxyl and the methyl groups at C-4 and C-10. 2α–OH: R1 = OH, R2 = H, R = methylbutyrate; 2β-OH: R1 = H, R2 = OH, R = methylbutyrate.

status (see Experimental) of the 8β-O-methylbutyrate derivative, the assumption of a 2β-hydroxyl leads to an equilibrium between all four previously described conformations (A–D). This would cause more NOEs than observed. On the other hand, for the 2α-hydroxyl, only one (A) out of these conformations has to be considered which fully explains the measured NOEs. Finally, the theoretically derived coupling constants of the 2α-hydroxyl form are in best agreement with those experimentally determined (see Table 1).

The ^{1}H NMR spectrum of **15** (Table 1) was identical with that of **14** in all parts, except for the side chain which showed the typical signals of an angelate. The proposed structure was confirmed by MS data (APCI) which showed $m/z = 347$ $[M+H]^+$ (consistent for $C_{20}H_{26}O_5$). HSQC spectra of compound **9**, **10** and **14** allowed the assignment of the proton bearing carbon signals (Table 2).

Compound **16** was isolated from the less polar fractions. The ^{1}H NMR data (Table 3) showed the presence of three side chains, one angelate and two methylbutyrates, but no signals typical of a sesquiterpene lactone skeleton. Instead, six protons with signals between δ 3.65 and 5.61 indicated the pattern of an inositol. The positions of the side chains were deduced from HMBC in combination with COSY spectra. The carbonyl carbon of the angelate residue showed coupling to a triplet at δ 5.18 (H-6) which was further coupled to the signals at δ 3.65 *t* (H-5) and δ 3.91 *dd* (H-1). The sequence of the remaining protons followed from COSY experiments and HMBC measurements indicated the connection of the two methylbutyrate residues through coupling with the protons at δ 5.61 *t* (H-2) and δ 4.88 *dd* (H-3), respectively. The relative stereochemistry of the substituents was deduced from coupling constants and supported by force field calculations (Table 3) leading to the suggested structure which was finally confirmed by MS data (APCI) which showed $m/z = 431$ $[M+H]^+$ indicative of $C_{21}H_{34}O_9$.

[a] n.o., signals not observed due to HSQC; sample amounts were insufficient for HMBC.

2.1. Chemotaxonomic aspects

Comparison of the sesquiterpene lactone pattern of *V. quinqueremis* with that of other members of its section revealed similarity in the overall dominance of heliangolides. However, the 1-keto-2,4-unsaturated budlein derivatives which were the exclusive constituents of *V. oblongifolia* (Bohlmann et al., 1984) and *V. robusta* (Da Costa et al., 1996) are only present to a minor extent in *V. quinqueremis*. The lack of sesquiterpene lactones reported from *V. nervosa* (Tamayo-Castillo et al., 1990) is most likely due to the low amount of glandular trichomes present in plant samples which were dominated by vegetative plant parts. Reexamination of the flowering parts of this species appears to be necessary. The isolation of a myoinisitol from glandular trichomes of *V. quinqueremis* is so far a unique feature of this taxon within the whole

genus. Within the Heliantheae, inositols have only been reported from *Hymenoxys texana* and *H. biennis* (Gao et al., 1990a,b; Spring et al.; 1994).

3. Experimental

3.1. Extraction of plant material

V. quinqueremis Blake was collected near Diamantina, along km 473–475 on BR-259 highway (S 18°25′, W 43°43′, altitude 1370 m), State of Minas Gerais, Brazil, in April 1998 by F.B. Da Costa and determined by J.N. Nakajima and E.E. Schilling (voucher specimens are deposited at the herbarium SPFR, Ribeirão Preto, SP under the collection number FBC No. 64). For HPLC (Hypersil ODS, 5 mμm; 4×250 mm; 30% MeCN, 1.3 ml/min or 50% MeOH, 1 ml/min; UV detection simultaneously at 225 and 265 nm or with diode array detection; dimethylphenol as int. standard). For screening of compounds and for solvent experiments with respect to the natural occurrence of compound **7** and **8**, glandular trichomes were collected mechanically from the anther appendages as previously described (Spring, 1991).

For isolation of compounds, air-dried flower heads (84 g) were extracted with CH_2Cl_2. The solvent was evaporated, the residue was redissolved in MeOH, diluted with water (1:1 v/v) and centrifuged in order to remove insoluble parts. The clear supernatant was applied to HPLC (conditions as given above) and compounds were separated in a gradient of aqueous MeOH (40–60% in 20 min, 1 ml/min). When necessary, 30% MeCN (1.3/per min) was used for repurification of fractions on the same type of column. Prior to preparative separation of specific compounds, an aliquot of the crude extract (equivalent to ca. 2 g plant material) was used for LC ^{1}H NMR and LC MS analysis which were carried out under identical HPLC conditions (MeOH gradient) in order to allow direct correlation of the obtained data. LC ^{1}H NMR spectra were measured on a Varian Unity *Inova*; 500 MHz, detector type 9050 equipped with a NMR flow cell of 60 μl detectable volume. Routine NMR experiments were carried out on 300 MHz Varian Unity *Inova*. LC MS experiments were performed on a Finnigan TSQ 700 under atmosphere pressure chemical ionization (APCI), positive mode. Calculations were done with PCMODEL, Ver. 7, Serena Software, Bloomington using the MMX force field. Conformational search was done with the GMMX option. Conformations are considered within a 3 Kcal limit from the lowest energy. Coupling constants are derived from the Altona equations which are implemented in the program. They are averaged over the Boltzmann distribution of their corresponding conformer.

HPLC retention times of compounds from *V. quinqueremis* in 50% MeOH (RRT_1) and in 30% MeCN (RRT_2) relative to dimethylphenol (retention time ca. 13 min in both solvents): **1**, 0.56/0.59; **2**, 0.53/0.56; **3**, 0.62/0.46; **4**, 0.57/0.42; **5**, 1.17/0.82; **6**, 1.12/0.79; **7**, 1.37/0.95; **8**, 1.25/0.90; **9**, 0.46/0.31; **10**, 0.60/0.54; **11**, 0.59/0.53; **12**, 0.72/0.60; **13**, 0.68/0.51; **14**, 1.96/1.63; **15**, 1.86/1.60; **16**, 1.60/1.48 (RRT_1/RRT_2).

3.1.1. 1α-Methoxy-3α,15-dihydroxy-3,10-epoxy-8β-O-methylbutanoyl-4,11(13)-germacradien, 6α,12-olide (7)

Benzopyran derivatives from *Mallotus apelta*

Tian-Ying An, Li-Hong Hu *, Xiao-Fang Cheng, Zhong-Liang Chen

National Center for Drug Screening, Shanghai Institute of Materia Medica, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, 200031, People's Republic of China

Received 17 July 2000; received in revised form 20 November 2000

Abstract

From the leaves of *Mallotus apelta*, seven benzopyran compounds were obtained and their structures were determined using spectroscopic methods. One showed moderate antibiotic activity against *Micrococcus lutens*. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Mallotus apelta*; Euphorbiaceae; Benzopyran; *Micrococcus lutens*

1. Introduction

Mallotus apelta Muell. Arg. (Euphorbiaceae), widely distributed plant in the south of China, is used in Chinese medicine for the treatment of chronic hepatitis (Jiangsu New Medical College, 1977). Some antibiotic triterpenoids and steroids have been reported to be isolated from its root (Shan and Feng, 1985). Our previous study on the root of this plant has shown the presence of five new diterpenoids (Cheng and Chen, 1999; Cheng et al., 1999) and one new alkaloid (Cheng et al., 1998), and further investigation of its leaves has resulted in the isolation of seven new benzopyran derivatives **1**–**7**. Compound **1** showed moderate inhibitory activity against *Micrococcus lutens*.

2. Results and discussion

Compound **1**, obtained as a yellow oil, showed an $[M]^+$ at *m*/*z* 3412.2609 in the HREIMS, which corresponded to $C_{22}H_{30}O_4$ (*calc*. 412.2614). The IR spectrum suggested the presence of an hydroxyl group (3434 cm^{-1}) and conjugated carbonyl groups (1716, 1602 cm^{-1}). The ^1H NMR and ^{13}C NMR spectral data (Table 1) revealed **1** had the same 4-hydroxy-2H-1-benzopyran-5,7(3H,6H)-dione skeleton as hariganetin, which was previously isolated from the fronds of *Wagneriopteris japonica* Loeve et Loeve (Wada et al., 1988). The ^1H NMR, ^{13}C NMR, ^1H–^1H COSY and HMQC spectra further revealed the presence of a chelated hydroxyl group (δ 15.99, *s*, OH-4), two methyls (δ 1.45, *d*, $J = 6.3$ Hz, H_3-11; δ 1.37, *s*, H_3-22), an isoprenyl side chain (δ 3.11, *m*, H_2-23; δ 5.08, *m*, H-24; δ 1.64, *s*, H_3-26 and δ 1.72, *s*, H_3-27) and a geranyl side chain (δ 2.64, *m*, H_2-12; δ 4.83, *m*, H-13; δ 1.84, *m*, H_2-15; δ 1.91, *m*, H_2-16; δ 5.00, *m*, H-17; δ 1.64, *s*, H_3-19; δ 1.56, *s*, H_3-20 and δ 1.53, *s*, H_3-21).

HMBC correlations (Fig. 1) between the methylene protons at δ 2.64 (H_2-12) and two carbonyl carbons at δ 201.2 (C-5) and δ 196.9 (C-7) and a quaternary carbon at δ 56.3 (C-6) established the geranyl side chain was at C-6. The observed HMBC crosspeaks between the methylene protons at δ 3.11 (H_2-23) and two olefinic carbons at δ 112.4 (C-8), δ 161.6 (C-9) and C-7 allowed the assignment of isoprenyl group at C-8. Correlations between the doublet methyl protons at δ 1.45 (H_3-11) and the oxygenated methine carbon at δ 71.4 (C-2) and the methylene carbon at δ 38.0 (C-3); the methyl protons at δ 1.37 (H_3-22) and C-5, C-6, and C-7, showed that the two methyl groups were connected with C-2 and C-6, respectively. The axial orientation of H-2 was deduced from its *J* coupling constant values with H_2-3 ($J_{2,3} = 4.3$, 9.6 Hz) (Lambert et al., 1987). The stereochemistry of the substitutents at C-6 and C-2 were not assigned. So compound **1** was determined to be 4-hydroxy-2,6-dimethyl-6-(3,7-dimethyl-2,6-octadienyl)-8-(3-methyl-2-butenyl)-2H-1-benzopyran-5,7(3H,6H)-

[a] Carbons that correlate with the proton resonance.

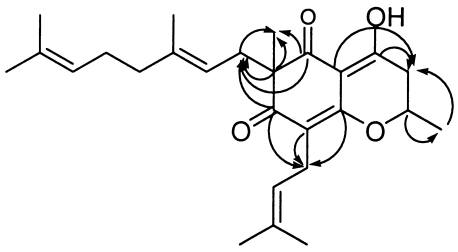

Fig. 1. Important HMBC interactions in compound **1**.

dione. These compounds which have the structure of β-hydroxyl carbonyl showed a pair of signals of two tautomers in acetone-d_6 in their ^{1}H NMR spectra (Anthonsen et al., 1971), while they only showed one tautomer signal in $CDCl_3$ (Wada et al., 1988).

Compound **2**, a yellow oil, has the molecular formula $C_{22}H_{30}O_4$, which was established by HREIMS (found. 358.2145; calc. 358.2144). Its UV and IR spectra were very similar to those of **1**. A comparison of the ^{1}H NMR and ^{13}C NMR spectra of **2** with those of **1** revealed that the only difference was that the isoprenyl side chain at C-8 in **1** was replaced by a methyl in **2**. Therefore, the structure of **2** was determined to be 4-hydroxy-2,6,8-trimethyl-6-(3,7-dimethyl-2,6-octadienyl)-2H-1-benzopyran-5,7(3H,6H)-dione, which was confirmed by analysis of its 2 D NMR spectra.

Compound **3**, *m*/*z* 412.2598, $C_{26}H_{36}O_4$, was obtained as a yellow oil. Its UV and IR spectra indicated it was also a benzopyran derivative. The NMR spectra data (Table 2) revealed that it had the same side chains as those in **1**, namely, a geranyl, an isoprenyl group and two methyls. The structure of **3** was determined by tracing the connectivities shown in the HMBC spectrum. Crosspeaks (Fig. 2) were observed between the methylene protons at δ 3.04 (H_2-12) and the oxygenated olefinic carbon at δ 164.7 (C-5), the quaternary olefinic carbon at δ 110.6 (C-6) and the carbonyl carbon at δ 195.6 (C-7). The chelated hydroxyl proton at δ 11.68 (5-OH) was correlated with C-10 (δ 104.4), C-9 (δ 186.3), C-6 and C-5. Moreover, the methyl at δ 1.40 (H_3-27) was correlated with C-7 and C-9; the methylene protons at δ 2.65 (H_2-17) were correlated with C-9 and the quarternary carbon at δ 53.0 (C-8). Thus, compound **3** was determined to be 5-hydroxy-2,8-dimethyl-6-(3-methyl-2-butenyl)-8-(3,7-dimethyl-2,6-octadienyl)-2H-1-benzopyran-4,7(3H, 8H)-dione.

[a] Carbons that correlate with the proton resonance.

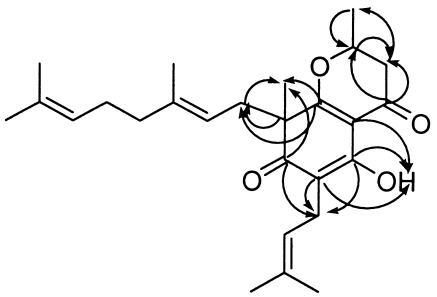

Fig. 2. Important HMBC interactions in compound **3**.

The HREIMS of **4** gave a m/z at 358.2151 for $[M]^+$, which was consistent with the molecular formula $C_{22}H_{30}O_4$. The UV, ^1H NMR and ^{13}C NMR spectra (Table 2) were very similar to those of **3**. A comparison of the ^1H NMR and ^{13}C NMR of **4** with those of **3** revealed that the isoprenyl side chain at C-6 in **3** was replaced by a methyl in **4**. So the structure of **4** was determined to be 5-hydroxy-2,8,6-trimethyl-8-(3,7-dimethyl-2,6-octadienyl)-2H-1-benzopyran-4,7(3H,8H)-dione.

Compound **5** was isolated as optically active pale yellow needles, $[\alpha]_D^{25}$ −92.8° (c 0.13, $CHCl_3$), mp 122–124°C, whose molecular formula $C_{16}H_{20}O_4$ was established from analysis of the HREIMS. The IR spectrum suggested the presence of hydroxyl groups (3240 cm^{-1}) and a conjugated carbonyl group (1635 cm^{-1}) and the UV spectrum gave λ_{max} at 244, 294, 350 nm. Its ^1H NMR and ^{13}C NMR spectra were closely similar to lespedezaflavanone G, isolated from *Lespedeza formosa* (Li et al., 1992), except that the 4-methoxyl-3-(3-methyl-2-butenyl) phenyl at C-2 was replaced by a methyl in compound **5**. So compound **5** was determined to be 2,3-dihydro-5,7-dihydroxy-2,6-dimethyl-8-(3-methyl-2-butenyl)-4H-1-benzopyran-4-one, which was confirmed by its HMBC spectrum.

Compound **6** was isolated as optically active pale yellow needles. Its HREIMS indicated a molecular formula of $C_{16}H_{20}O_4$ (m/z 276.1427). Comparison of the NMR spectral data of **6** with those of **5** revealed that they had the same skeleton and side chains. HMBC showed correlations between the methylene protons at δ 3.35 (H_2-12) and the carbons at δ 159.6 (C-5), δ 105.6 (C-6) and δ 161.9 (C-7); and the correlations between the methyl protons at δ 1.98 (H_3-17) and C-7, C-8 (δ 102.8) and C-9 (δ 158.3). So the isoprenyl group at C-6 and the methyl at C-8 were established. Therefore **6** was established to be 2,3-dihydro-5,7-dihydroxy-2,8-dimethyl-6-(3-methyl-2-butenyl)-4H-1-benzopyran-4-one.

The molecular formula of $C_{12}H_{14}O_4$ for **7** was established from its HREIMS. Its ^1H NMR and ^{13}C NMR spectra were closely similar to compound **5** except that the 3-methyl-2-butenyl side chain at C-8 was replaced by a methyl in compound **7**. So the structure of **7** was assigned to be 2,3-dihydro-5,7-dihydroxy-2,6,8-trimethyl-4H-1-benzopyran-4-one.

All compounds were tested for their antibiotic activity against *Staphylococcus aureus*, *Micrococcus lutens*, *Pseudomonas aeruginosa* and *Escherichia coli* (see Table 4). Only compound **1** showed moderate activity against *M. lutens* with a minimum inhibitory concentration (MIC) of 7.34 μg/ml. (Reference: Triclosan).

3. Experimental

3.1. General experimental procedures

The melting points were determined on a Yanaco melting point apparatus and were uncorrected. Optical rotations were recorded on a Perkin-Elmer 241 polarimeter using $CHCl_3$ as solvent. IR spectra were recorded on a Perkin-Elmer 599B spectrophotometer. UV spectra were measured on a Shimadzu UV-250 spectrophotometer. NMR spectra were recorded on a Brüker AM-400 and DRX-400 spectrophotometer. Mass spectra (EIMS and HREIMS) were taken on a MAT-711 instrument.

3.2. Plant material

The leaves of *M. apelta* were collected from Guilin, Guangxi of China, in August 1997. The plant was identified by comparing with voucher specimens, which were already deposited in the herbarium of the Guilin Institute of Medicinal Control. Guangxi, PR China (NO: 90007).

3.3. Extraction and isolation

The leaves of *M. apelta*. (2.0 kg) were extracted with petroleum ether (8 l × 3) at 20°C. Removal of the solvent under reduced pressure left an oily extract (32 g). Into this extract, 200 ml acetone was added, and, after the insoluble solid was filtered, the mother liquid was concentrated to a residue (25 g), which was subjected to Si gel chromatography, eluted with petroleum ether containing increasing amounts of EtOAc to yield 8 fractions. Fraction 2 (500 mg, eluted with petroleum ether-EtOAc, 10:1) was further purified on Si gel and eluted with petroleum ether-$CHCl_3$ (2:3) to afford two subfractions I and II. Subfraction I was then subjected to RP-18 column chromatography, eluted with Me_2CO–H_2O (3:1) to afford compound **1** (29.0 mg). Subfraction II was also subjected to RP-18 column chromatography, eluted with Me_2CO–H_2O (3:1) to afford compound **2** (21.0 mg). Fraction 4 (367 mg, eluted with petroleum ether–EtOAc, 10:1) was further purified using Si gel chromatography and eluted with petroleum ether–$CHCl_3$ (1:2) to give compounds **3** (14.0 mg) and **4** (20.0 mg). Fraction 5 (320 mg, eluted with petroleum ether–EtOAc, 5:1) was further purified on Si gel (petroleum ether-$CHCl_3$–Me_2CO, 5:1:1) to give a mixture which was finally purified on preparative TLC plates (petroleum ether-$CHCl_3$–Me_2CO, 5:1:1) to give compound **5** (6.4 mg) and **6** (5.6 mg). Fraction 6 (76 mg, eluted with petroleum ether–EtOAc, 5:1) was further purified on Sephadex LH-20 eluted with EtOH to obtained compound **7** (6.8 mg).

3.4. 4-Hydroxy-2,6-dimethyl-6-(3,7-dimethyl-2,6-octadienyl)-8-(3-methyl-2-butenyl)-2H-1-benzopyran-5,7(3H,6H)-dione (*1*)

Received 25 July 2000; received in revised form 8 December 2000

Abstract

Nemorosone, the major constituent of the floral resin of *Clusia rosea* was isolated after exhaustive chromatography. This compound was fully characterized as it is in the nature, without methylation as reported before. A keto–enol equilibrium was observed and both isomers were totally characterized by NMR spectroscopic techniques. The previously announced structure for methyl-nemorosone was corrected on the basis of application of chemical methylation, high field 2D NMR techniques and NOE difference spectroscopy experiments on the natural product. Our studies concluded that an interchange occurred in the assignment of the benzoyl moiety position with an isoprenyl group in that structure. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Clusia rosea*; Guttiferae; Copey; Polyisoprenylated benzophenone; Nemorosone

1. Introduction

Polyisoprenylated benzophenones with a bicyclo 3.3.1-nonane-2,4,9-trione system have been isolated from the Guttiferae family. Plukenetione E acetate **1** (Henry et al., 1999) (benzophenone type A),[1] clusianone **2** (Delle Monache et al., 1991) (benzophenone type B) and methyl-nemorosone **3** (De Oliveira et al., 1996) (benzophenone type C) show this bicyclic structure, but the relative position of the benzoyl group is different for these compounds (Fig. 1). Methyl-nemorosone **3**, 16-hydroxy-methyl-nemorosone and 7-epi-methyl-nemorosone were isolated from the methylated floral resins of *Clusia* species (including *Clusia rosea*) and they are the sole type C prenylated benzophenone described (De Oliveira et al., 1996, 1999). It is common to use diazomethane during the study of these floral resins to obtain the methylated derivatives of the natural products (De Oliveira et al., 1996, 1999). In this study without any previous treatment of the resin, we have examined the major constituent of the floral resin of *Clusia rosea*, a polyisoprenylated benzophenone, nemorosone **4** exists in its keto–enol equilibrium. The NMR spectroscopic studies of the tautomeric forms of nemorosone and the methyl derivatives obtained, revealed data which are inconsistent with the described structure of methyl-nemorosone **3**. This prompted us to reinvestigate the chemical structure.

2. Results and discussion

Floral resins of *Clusia rosea* were extracted with ethanol and a major compound was obtained using a combined method of crystallization and VLC (see Experimental). The molecular formula $C_{33}H_{42}O_4$, identical to clusianone, was deduced using MS, ^{13}C NMR and DEPT analyses. In the EIMS spectrum, peaks at m/z 105 and 69 showed the presence of an unsubstituted benzoyl group and isopentenyl moieties, respectively. Two tautomers were observed in the NMR spectroscopic experiments and their ^{13}C and ^{1}H NMR spectral data are given in Table 1.

The ^{1}H NMR spectrum indicated the presence of three isopentenyl groups and one enolic proton for each isomer. A bicyclo 3.3.1 nonane-2,4,9-trione system could be recognized by the ^{13}C NMR chemical shifts of C-1 (δ

Fig. 1. Related polyisoprenylated benzophenones with a [3.3.1] nonane-2,4,9-trione system.

78.0 and 71.4), C-5 (δ 57.1 and 64.8), C-8 (δ 48.2 and 47.3), three conjugated ketonic carbonyls C-2, C-4 (δ 192.2, 195.0) and C-10 (193.2 and 193.1), two enolic carbons C-2 and C-4 (δ 168.2 and 170.9) and a carbonyl group at C-9 (δ 207.3 and 207.6). The bicyclo and isopentenyl groups were also identified by the HMBC experiments. HMBC connectivities enabled differentiation between the two isomers, (see Table 1).

The presence of the enolizable 1,3-diketone system for nemorosone generates a tautomeric pair **4a** and **4b** in a ratio ca. 2:1 in the NMR spectra (Fig. 2). The analysis of the tautomeric pair was essential to define the correct structure of nemorosone. In order to observe if the signals simplified, NMR spectra were obtained at $-55°$, but the ratio of the tautomeric mixture did not change, although the signals were better defined. After the analysis of the NMR spectra, only the methyl groups of the 3-methyl-2-butenyl substituents could not be assigned due to the splitting of the signals.

The presence of allylic methylenes at δ 3.14–3.38 indicated a 3-methyl-2-butenyl group on C-3 as is described for plukenetione D acetate, plukenetione E acetate **1** and methyl nemorosone **3** (De Oliveira et al., 1996; Henry et al., 1999; Grossman and Jacobs, 2000). The chemical shift of these protons can only be justified in that position, which led us to eliminate the possibility of a type B benzophenone for the analyzed compound. A benzoyl group at C-1 was suggested by the high chemical shift of this carbon (δ 78.0 and 71.4) in the observed tautomers. This characteristic was similar to plukenetiones and propolone A (De Oliveira et al., 1996; Cuesta-Rubio et al., 1999; Henry et al., 1999).

In order to define between a structure type A or C for the isolated benzophenone, nOe difference spectroscopy experiments were performed. Saturation at the frequency of the Me-33 gave positive increment at the aromatic protons signals (H-12 and H-16) of the benzoyl group and the protons of methylene-27. In the same way, irradiation of H-$6_{eq.}$ showed an interaction with methylene protons at C-22 and when the latter protons were irradiated, interactions with methylene protons at C-6 and Me-25 were observed. These results confirmed unequivocally structure **4** for nemorosone, a type A benzophenone.

The basic bicyclic ring system in **4** requires the phenyl ketone at C-1 and the isopentenyl chain at C-5 to be in an equatorial orientation. The ^{13}C chemical shift of Me-$33_{ax.}$ (δ 15.6) suggested an equatorial position for the isopentenyl group at C-7. The upfield shift of the C-$33_{ax.}$ signal results from steric compression of a gauche interaction between this carbon and the CH_2-22 of the equatorial isopentenyl group on C-7 (Wehrli et al., 1988; Günther, 1998). The coupling constant between H-$6_{ax.}$ and H-7 confirmed this observation and it was deduced by selective irradiation at the frequency of H-$6_{eq.}$ This decoupling simplified the H-$6_{ax.}$ signal to a doublet J = 12.6 Hz, which must be a diaxial H-$6_{ax.}$ and H-7 coupling constant. The coupling constants observed are similar to those reported for propolone A and guttiferone B in which the side chain on C-1, C-5 and C-7 have an equatorial orientation and a coupling constant

[a] * and †, these methyl groups could be interchanged between them. [‡] The chemical shift changes with the concentration.

of ca. 10 Hz was observed between H-7 and H-$6_{ax.}$ (Gustafson et al., 1992; Cuesta-Rubio et al., 1999). Therefore, the non-enolic part of the bicyclo structure must have a *pseudo*-chair conformation, with H-7 in an α-axial orientation and the isopentenyl group on C-7 in a β-equatorial orientation. All bicyclo 3.3.1 nonane derivatives with axial isopentenyl groups on C-7 that have been analyzed by HMBC experiments showed a higher ^{13}C chemical shift for C-33 (δ 22–23) than at observed for nemorosone, i.e.: plukenetiones D and E, guttiferone E, guttiferone F, 30-epi-cambogin and isoxanthochymol (Gustafson et al., 1992; Fuller et al., 1999; Henry et al., 1999; Grossman and Jacobs, 2000). In the case of the xanthochymol and cambogin structures which have an isopentenyl group in axial position at C-7 as confirmed by X-ray crystallography, we think that the NMR spectral assignment of the axially oriented methyl of the *gem*-dimethyl group, has been interchanged with that of a methyl belonging to an isopentenyl moiety.

Initially, the presence of nemorosone **4** in floral resins of *Clusia rosea* was deduced by mean of a derivative, methyl-nemorosone and structure **3** was proposed for this compound. The NOE and the HMBC experiments described by De Oliveira et al., (1996), are consistent with both their proposed structure for methyl-nemorosone **3** and with the methyl derivative **5b** generated from the methylation of tautomer **4b** of our proposal. In order to confirm this hypothesis, we proceeded to treat nemorosone with an ethereal solution of diazomethane. After usual workup, we isolated a product whose NMR spectrum showed that both methylated isomers **5a** and **5b** were present in a ratio 1:3. After comparison of the ^{1}H and ^{13}C NMR chemical shifts of the natural product and the methyl derivatives with other similar compounds previously

described, we propose that the correct structure for methyl-nemorosone must be **5b**. The NMR spectral data observed for one of the methylated isomers, produced after treatment of nemorosone with diazomethane, are exactly the same reported for the previously described methyl-nemorosone structure **3** (De Oliveira et al., 1996). Recently, the methyl derivative corresponding to the methylation of the tautomer **4a** has been isolated from the same floral resins (De Oliveira et al., 1999). The NMR spectral data of this product called nemorosone II, are in complete agreement with the NMR data observed for the other methyl isomer **5a** produced after treatment of the natural product nemorosone **4** with diazomethane.

The results lead us to postulate that all prenylated benzophenones with a bicyclo 3.3.1 nonane-2,4,9-trione system isolated heretofore, are derivatives of type A or B. Propolone A, isolated from propolis, is a derivative of nemorosone and plukenetiones are stereoisomers of Nemorosone (Cuesta-Rubio et al., 1999; Henry et al., 1999; Grossman and Jacobs, 2000). The reported structures for methyl-nemorosone **3** and 14-hydroxy-methyl nemorosone, the only described type C benzophenones, are not correct due to an interchange in the assignment of the benzoyl moiety position with an isoprenyl group (De Oliveira et al., 1996, 1999). The proposed structure for 7-epi-nemorosone is probably also incorrect, but further NMR measurements would be needed to confirm this.

From a biogenetic point of view, type A or B polyisoprenylated benzophenones could be biosynthesized from a common precursor **6**, by an opposite mechanism of cyclization over an activated moiety (i.e.: pyrophosphate) from the aromatic ring, could generate both types of benzophenones. This fact can also explain the absence of type C polyisoprenylated benzophenones (Fig. 3).

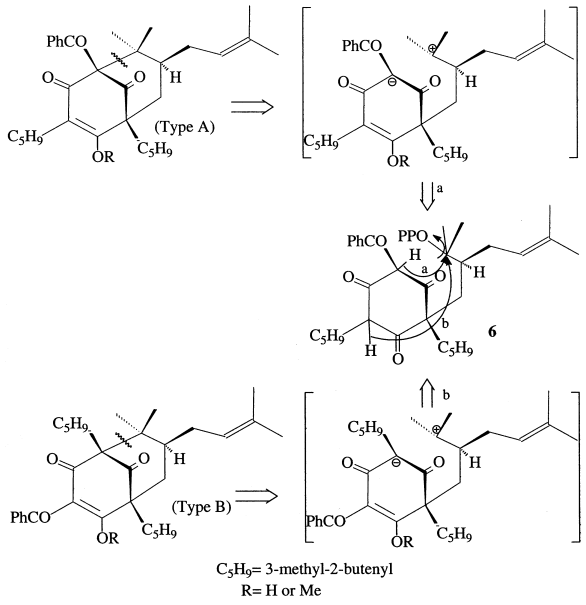

Fig. 3. Proposed biogenetic pathway for type A and B polyisoprenylated benzophenones.

3. Experimental

Flowers of *Clusia rosea* were collected in Habana (Cuba) in October 1999 and a voucher specimen (No. 705) was deposited in the Herbarium of the Instituto de Investigaciones Fundamentales de la Agricultura, Habana, Cuba. Melting points were uncorrected and determined using a Fisher-Johns apparatus. Optical rotation was measured in a Jacob DIP-360 polarimeter equipped with a sodium lamp (589 nm) and a 10 cm microcell. UV spectra was obtained with a Shimadzu U-160 spectrophotometer and IR spectra with a Nicolet Magna 750 spectrophotometer. EI–MS was obtained at 70 eV by direct inlet with a Jeol JMS-AX505HA. ^{1}H NMR (500 MHz) and ^{13}C NMR (125 MHz) spectra were recorded with a Varian Unity Plus 500 using TMS as internal standard, at a temperature of −55°. nOe difference spectroscopy experiments were measured in a sealed deoxygenated tube.

The floral resin of *Clusia rosea* (3.5 g) was removed with a palette knife and extracted immediately with ethanol. Nemorosone was crystallized from a mixture of EtOH–H_2O, yielding 510 mg of impure compound. The product was subject to a VLC (Targett et al., 1979) on silica gel with C_6H_{12}–EtOAc (3:1) in order to purify it to homogeneity.

Nemorosone **4**: $C_{33}H_{42}O_4$ mixture of tautomers **4a** (1-benzoyl-3,5,7-tri-(3-methyl-2-butenyl)-4-hydroxy-8-dimethyl-biciclo[3.3.1]-3-nonene-2,9-dione) and **4b** (1-benzoyl-3,5,7-tri-(3-methyl-2-butenyl)-2-hydroxy-8-dimethyl-biciclo[3.3.1]-2-nonene-4,9-dione). Received 16 August 2000; received in revised form 21 December 2000

Abstract

A more detailed phytochemical analysis of extracts of the aerial parts of *Spigelia anthelmia L.* (Loganiaceae) yielded 20 structurally related new compounds besides spiganthine and ryanodine. Structure elucidation was achieved mainly by spectroscopic methods. The compounds were tested on their cardiac and on their insect antifeedant activities. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Spigelia anthelmia*; Loganiaceae; Spiganthine; 20-Deoxyspiganthine; 8α-Hydroxyspiganthine; 20-Norspiganthine-5-carboxylic acid; Ryanodine; 10-*epi*-Ryanodine; 8,9-Dehydro-10-*epi*-ryanodine; 20-Hydroxyryanodine; Cardioactivity; Insect antifeedant activity

1. Introduction

Stimulated by the bioassay-monitored isolation of the cardioactive spiganthine from extracts of *Spigelia anthelmia* (Achenbach et al., 1995), we were interested in a more detailed phytochemical analysis of the plant. Major target of this investigation was the isolation of minor constituents, their structure elucidation and biological tests in order to gain structure–activity correlations.

2. Results and discussion

An extract from 2 kg dried aerial parts of *S. anthelmia* (''Urtinktur'' prepared with EtOH/water according to the prescription of the German Homoeopathic Pharmacopoeia) was diluted with water and repeatedly extracted with chloroform and then EtOAc followed by chromatography of the dried extracts on Sephadex LH 20® and silica gel, respectively. The separation procedures were monitored by the characteristic colour reaction of the spiganthine- and ryanodine-type compounds with anisaldehyde on TLC plates.

Further separation and isolation of pure constituents was achieved by HPLC on reversed phase silica gel. These procedures yielded constituents **1–17** from the $CHCl_3$-extracts and the more polar constituents **18–22** from the EtOAc-extracts (Table 1).

The spectroscopic investigations, and particularly FAB–MS (negative ions) revealed a number of differently oxygenated but structurally related C_{20}-structures with the common feature of a pentacyclic $C_{14}O$-skeleton carrying a pyrrolecarboxylic ester group, which is typical for spiganthine (Achenbach et al., 1995) and ryanodine (Wiesner et al., 1967).

In the ^1H NMR and ^{13}C NMR, all signals appeared well separated and — supported by the results of our earlier studies (Achenbach et al., 1995) — could easily be assigned to the individual positions. Correlation spectroscopy and NOE-measurements corroborated the assignments (Tables 2 and 3).

The structures of the spiganthine-type compounds **1–3** and **18** are easily recognized by a double doublet in the range of δ 3.23–3.86, which belongs to H-4 and causes a splitting of the typical low-field signal of H-3 at δ 5.6–5.8 (see Table 2).

15

The less polar compound **2** carried the methyl group CH_3-20 at C-5 instead of the hydroxymethyl in spiganthine (**1**). In comparison to **1**, the more polar **3** was additionally hydroxylated at C-8. The equatorial configuration of this hydroxyl resulted from the coupling constants of the neighbouring protons and from NOE studies. Within the spiganthine-group, **18** with a free carboxyl at C-5 represented the most polar compound. On treatment with diazomethane, **18** promptly formed the methyl ester.

Under hydrolytic conditions, **1** underwent saponification giving spiganthol (**23**) and 2-pyrrolecarboxylic acid; in addition, anhydrospiganthol (**24**) was formed.

These results were in accordance with the reaction of ryanodine under aqueous acidic conditions (Kelly et al., 1951).

In contrast to the spiganthines, constituents **4–17** and **19–22** exhibited "only" a singulet signal for H-3 at considerably lower field (δ 5.60–5.70 ppm), which indicated a hydroxy-substituted quarternary C-4. Further NMR-studies revealed **4** as ryanodine (Wiesner et al., 1967) and **19** as its 20-hydroxy derivative.

The remaining isolated constituents were mainly characterized by typical differences of the resonance signal of H-10: whereas this signal in **1–4**, **18** and **19** always appeared in the δ 3.69–3.80 ppm range as a doublet ($J\sim10$ Hz) indicating a *trans*-diaxial relationship, it was observed in all other compounds as a singulet, "broad" singulet or a doublet with only a small coupling constant of 1 Hz at δ 3.66–4.66 ppm. These spectral features suggested "loss" of the neighbouring H-9 and/or an equatorial position of H-10 (=10-*epi*-configuration). Consequently, NOE measurements were performed and corroborated an equatorial H-10 by the significant interaction observed between H-10 and CH_3-17 for constituents **5–17** and **20–22**. The results gave evidence that these compounds belong to the rare 10-*epi*-ryanodine series.

Table 1
Compounds isolated from the "Urtinktur" of *Spigelia anthelmia*

Compound class	Compound	Fraction	Content[a] ($\%\times10^{-3}$)
Spiganthines			
	Spiganthine (**1**)	$CHCl_3$	7.7

Further ^{1}H and ^{13}C NMR-studies revealed the structure of 9-hydroxy-10-*epi*-ryanodine (**5**) (NOE between CH_3-21 and H_{ax}-8) and of the hydroxylated 9-*epi*-10-*epi*-ryanodines **6, 7** and **20**, which carried the CH_3-21 methyl group in the axial position. Major argument for this configuration at C-9 comes from the observed NOE between CH_3-21 and H_{ax}-7.

The depicted stereochemistry at C-13 in **7** is also based on NOE-studies, which revealed strong effects from CH_3-17 to CH_2-18, from CH_3-19 to H-3, and from H-13 to H-14. With regard to the established absolute configuration of ryanodine, these NMR-observations confirmed the 13*S*-configuration for **7**.

Among the 10-*epi*-ryanodines, the common structural feature of constituents **8–11**, **21** and **22** was an unsaturation within the cyclohexane ring system. ^{1}H and ^{13}C NMR easily determined its $\Delta^{8,9}$-position and also recognized the presence and positions of additional hydroxyl groups. The configuration at the steric center C-13 in **9** and **21** was established as in **7**.

Catalytic hydrogenation of **11** saturated the double bond and simultaneously deoxygenated the allylic OH-group at C-21 to give 9-*epi*-10-*epi*-ryanodine in about 70% yield.

Treatment of **11** with 3-chloroperoxybenzoic acid (Waterhouse et al., 1987) produced, among others, the two expected stereoisomeric epoxides, one of which proved to be identical with the isolated constituent **17.** Assignment of structure **17** and its corresponding stereoisomer was deduced from characteristic coupling differences in the H-7/H-8 spin-system of their ^{1}H NMR: in **17**, H-8 appears as a doublet ($J_{7eq,8}\sim$6 Hz) with $J_{7ax,8}\sim$0 Hz, whereas in the stereoisomeric epoxide obtained only by epoxidation of **11** coupling constants of $J_{7ax,8}\sim J_{7eq,8}\sim$2 Hz were observed for H-8. On the basis of these data, the structure with the α-orientation of the oxirane ring has to be attributed to **17**.

This result was valuable for the structure elucidation of constituents **12–14** and **16**, which belonged to the α-series of epoxides with the only exemption of **13**.

A small amount of the epoxide **12** was subjected to a hydrolytic ring-opening reaction using oxalic acid. This reaction resulted in the —almost quantitative—conversion of **12** to an isomeric product identical with the isolated constituent **15**.

A very characteristic feature in the ^{13}C NMR of **15** was a pronounced downfield-shift of the resonance of the C-6 from δ 84.3 ppm (in **12** and all other hitherto mentioned constituents) to δ 96 ppm in **15**. Extensive NMR-studies established structure **15** and rationalized the in vitro conversion of **12** to **15**: protonation of the oxirane oxygen facilitates the nucleophilic attack of C-9 by the axial hydroxyl at C-6. This process might occur as a concerted reaction and brings about **15**.

The colour reaction with anisaldehyde/sulfuric acid was used as a spot test on TLC plates in the course of

[a] Similar values might be interchanged.

our isolation work: all isolated compounds gave this rather sensitive reaction, which, in addition, permitted a general distinction between ryanodines/*epi*-ryanodines and spiganthines, respectively. In contrast to the ryanodines/*epi*-ryanodines, which produced a yellow-ochre colour, the spiganthines gave a red-purple spot. Obviously, the colour reaction did not depend on the presence of the 2-pyrrolecarboxylic ester group, since compounds **23** and **24** also reacted positively.

Despite all the precautions taken during our isolation and structure elucidation work (avoidance of higher temperatures, storage under nitrogen at low temperatures, absence of acidic or alkaline media, no excessive light etc.) some of the isolated compounds might be artefacts or partly artefacts: 9-hydroxylated compounds might have been transferred into the corresponding 8,9-dehydro compounds (e.g. **5** or **6**→**8**; **7**→**9**). Proton catalyzed rearrangement during work-up might have converted **12** to **15**. Oxygenating enzymes might be responsible for the generation of some of the epoxides.

However, considering the amounts isolated of the individual constituents and the various distinct grades of hydroxylation we regard most of the described compounds original natural products.

Among these, only spiganthine, ryanodine and 9-hydroxy-10-*epi*-ryanodine (**5**) (Jefferies et al., 1992) are already known compounds, whereas the others represent new natural products.

3. Biological activities

Ryanodine and spiganthine are known for their cardiac (Jenden and Fairhurst, 1969; Penefsky, 1974; Vierling, 1988; Achenbach et al., 1995; Sutko et al., 1997) and insecticidal (Jefferies et al., 1992; González-Coloma et al., 1996, 1999) activities. The availability of quite a number of new substances with structural variations arouse the interest to start structure–activity studies.

3.1. Cardiac activity

These tests were carried out as described earlier (Achenbach et al., 1995). Each of the tested compounds induced a delay in the development of cardiac contractions in a similar way as spiganthine (**1**) and ryanodine (**4**) but with divergent potencies. Fig. 1 shows a representative experiment using **8**, a substance about equally potent as **1** and **4**.

The concentration-versus-activity relationships of 12 of the most effective compounds are presented in Fig. 2, and the corresponding EC_{50} values are compiled in Table 4, where they have been divided in roughly three groups: strong, medium and weak activity. The EC_{50} values of the other tested compounds (**3, 5, 14–18** and **20–22**) were 100–1000 times higher than the value of ryanodine (**4**).

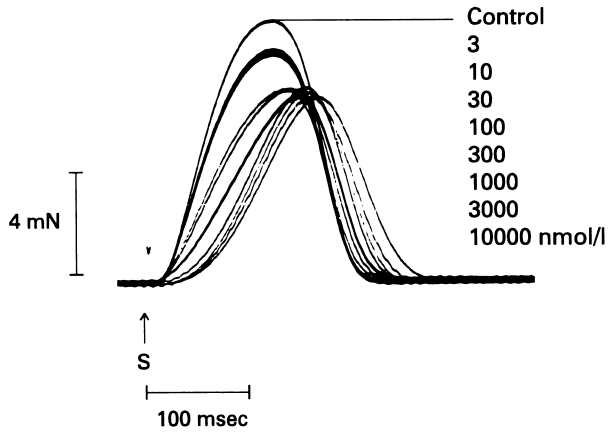

Fig. 1. Effect of 8,9-dehydro-10-*epi*-ryanodine (**8**) on the contraction of the guinea-pig papillary muscle. Increasing concentrations (nmol/l) of **8** caused a remarkable prolongation of the latency time between the stimulus (S) and the beginning of the contraction; additionally, the force of contraction (mN) decreases. (Stimulation frequency: 1 Hz). Ordinate: force in mN; abscissa: time in msec.

For the most active substances **1, 2, 4** and **8**, the following structure–activity relationships were revealed: omission of the hydroxy group from position C-4 (**4**→**2**) or C-20 (**1**→**2**) with an otherwise unchanged structure caused only slight attenuation of the biological activity; and transfer of the hydroxyl from C-4 to C-20 (**4**→**1**) did also not significantly influence the activity. Furthermore, compound **8**, which represents the least hydroxylated substance in the 8,9-dehydro-series, is similarly active as **4**, from which it structurally differs by unsaturation ($\Delta^{8,9}$) and epimerisation at C-10. But 10-epimerisation combined with 8,9-epoxidation (**4**→**12**, **13**) reduced the cardiac activity considerably to less than 10%, and the presence of the two hydroxy groups at C-4 and C-20 (**1**→**19** or **4**→**19**) led to an even more dramatic reduction of activity. These results suggested an essential influence of the polarity of ryanodine/spiganthine-type compounds for their cardiac activity.

As a general guide line we summarize our results: the already known compounds spiganthine (**1**) and ryanodine (**4**) exhibit highest cardiac activity, which is not much influenced by neither removal of their hydroxy group at C-4 or C-20 nor by introduction of an 8,9-double bond together with 10-epimerization. In contrast, 8,9-epoxidation and, particularly, introduction of additional hydroxy groups causes loss of cardiac activity.

3.2. Insect antifeedant and insecticidal activity

Major efforts have been invested to study the antifeedant and insecticidal potential of ryanodine (**4**) and structurally related compounds (Wiesner et al., 1967;

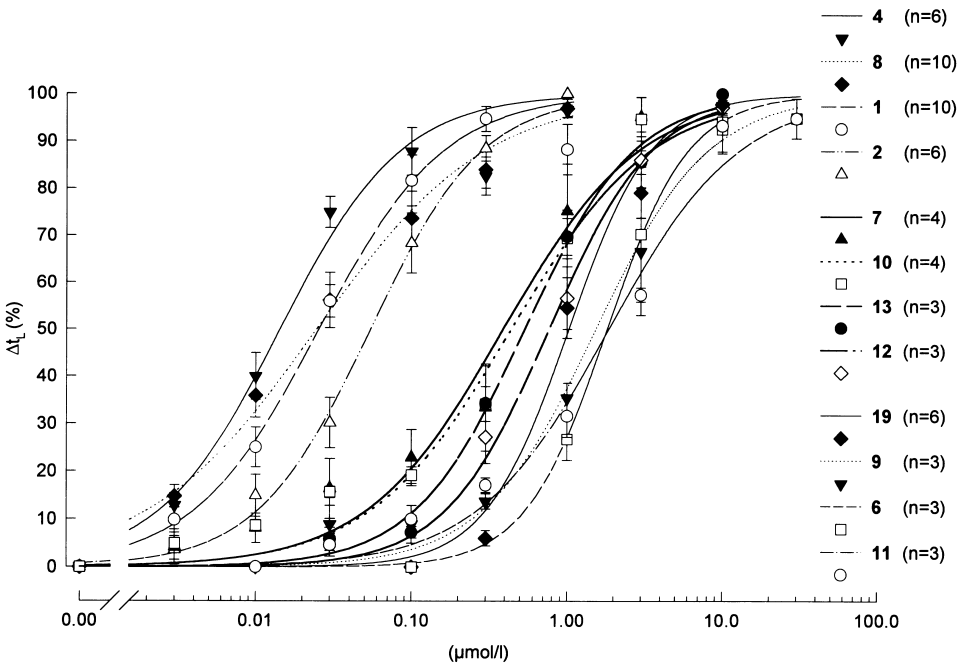

Fig. 2. Concentration–activity relationship of the 12 most active compounds isolated from *Spigelia anthelmia*. Ordinate: prolongation of the latency time (Δt_L) in % of the maximal prolongation of each muscle group. (Shown are mean values ± S.E.M.) Abscissa: concentration of the test compounds in μmol/l (logarithmic scale). The depicted curves were fitted to the mean values using a logistic function.

Table 4
EC_{50} values (nmol/l) of the most active compounds isolated from *Spigelia anthelmia* determined by fitting a logistic function to the mean values of the concentration–activity curves presented in Fig. 2

Substance	Number of experiments (*n*)	EC_{50} (nmol/l)
4	5	14
8	9	17
1	8	25
2	6	54
7	4	390
10	4	440
13	3	540
12	3	770
19	6	1100
9	3	1500
6	6	1800
11	3	1900

Waterhouse et al., 1987; Jefferies et al., 1992; González-Coloma et al., 1996). A newer investigation also included spiganthine (**1**) and a number of our isolated ryanodine derivatives in these studies. The results have been published very recently (González-Coloma et al., 1999) and demonstrated significant antifeedant activity against some test beetles for spiganthine, ryanodine, the β-epoxide **13** and, particularly, 9-hydroxy-10-*epi*-ryanodine (**5**). In addition, considerable insecticidal activities were observed for spiganthine, ryanodine, and the α-epoxide **12**. These effects were especially remarkable for **12** in the presence of piperonyl butoxide, an agent known as a synergist for the insecticidal action of ryanodine (Waterhouse et al., 1987), which might inhibit the biological decomposition of **12** (González-Coloma et al., 1999).

4. Experimental

4.1. General

TLC was done on ready-made plates using S-1 = $CHCl_3$:MeOH:H_2O (80:20:1). Detection: UV and anisaldehyde reagent (Stahl and Kaltenbach, 1961). Unless stated otherwise, IR were run as dry films on NaCl; [α]D, UV, and CD measurements in MeOH at 20°. ^1H NMR at 360 MHz and ^{13}C NMR at 90 MHz in CD_3OD with TMS as int. standard. MS were recorded by FABMS (negative ions) in glycerol (xenon, 8 kV). Sephadex® LH 20 was used for CC, Si gel 60 for MPLC (at ca 3 bar); HPLC was done on Nucleosil® RP18 with the solvent systems S-2 = MeOH:H_2O (43:57), S-3 = MeOH:H_2O (30:70) or S-4 = MeOH:H_2O (20:80).

4.2. Extraction and chromatography

The exctract of 2 kg dried aerial parts of *Spigelia anthelmia* (purchased from Müggenburg, Hamburg, Germany, batch-no. 2917) was prepared with 20 l EtOH:H_2O (86:14) according to the German Homoeopathic Pharmacopoeia. Evapn. yielded 260 g residue, which was diluted in 6 l MeOH:H_2O (1:3) and subsequently extracted with $CHCl_3$ (3×5 l) and EtOAc (3×3

l). Evapn of the solvents afforded 75 g $CHCl_3$-I, 1.8 g $CHCl_3$-II, 1.2 g $CHCl_3$-III, 8.2 g EtOAc-I, 2.3 g EtOAc-II and 1.2 g EtOAc-III. Repeated CC of $CHCl_3$-II, $CHCl_3$-III, and EtOAc-I was done on Sephadex LH 20 with MeOH followed by MPLC on Si gel using the solvent system $CHCl_3$:MeOH (from 95:5 to 8:2). Finally, HPLC with S-2 or S-3 yielded pure spiganthines/ryanodines as described in Table 1. The separation procedures were monitored by the characteristic colour reaction of these compounds with anisaldehyde reagent.

4.3. Spiganthine (*1*)

Crystals from $CHCl_3$:Me_2CO (3:1) (23 mg), mp 159°. TLC: R_f 0.46; anisaldehyde: red-purple. HPLC: R_t 35.0 min (S-2). [α]D +35° (*c* 0.5). CD λ_{max} nm (Θ): 205 (+5875), 225 (−4000), 245 (+570), 265 (−95), 280 (+275). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 492 $[M-H]^-$ (100), 381 $[M-111-H]^-$ (40). All other physicochemical properties were also identical with an authentic sample (Achenbach et al., 1995).

4.4. Hydrolysis of spiganthine (*1*)

A solution of 7.5 mg of **1** in 5 ml aqueous KOH (1%) was stirred for 90 min at 60°C. After neutralization with 2 n H_2SO_4, the aqueous phase was extracted with EtOAc, the organic extract evapd and the residue purified by CC on silica gel using S-1. This yielded compounds **23** (2.5 mg), **24** (2.5 mg) and 2-pyrrolecarboxylic acid (1 mg).

4.5. Spiganthol (*23*)

Amorphous. TLC: R_f 0.31; anisaldehyde: pink. ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 399 $[M-H]^-$ (80), 367 $[M-32-H]^-$ (90), 281 (100).

4.6. Anhydrospiganthol (*24*)

Amorphous. TLC: R_f 0.44; anisaldehyde: pink. ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 381 $[M-H]^-$ (100).

4.7. 2-Pyrrolecarboxylic acid

Amorphous. TLC: R_f 0.27; anisaldehyde: yellow. UV λ_{max} nm (log ε): 260 (3.54). ^{1}H NMR: δ 6.12 (1H, *dd*, J_1 = 4, J_2 = 2.5 Hz, H-4), 6.76 (1H, *dd*, J_1 = 4, J_2 = 1.5 Hz, H-3), 6.85 (1H, *dd*, J_1 = 2.5, J_2 = 1.5 Hz, H-5).

4.8. 20-Deoxyspiganthine (*2*)

Crystals from $CHCl_3$:Me_2CO (1:1) (1.5 mg), mp 144–147°. TLC: R_f 0.48; anisaldehyde: red-purple. HPLC: R_t 57.5 min (S-2). [α]D +12° (*c* 0.1). IR ν_{max} cm^{-1}: 3400, 2925, 1695. UV λ_{max} nm (log ε): 265 (3.88). CD λ_{max} nm (Θ): 205 (+2165), 225 (−2801), 295 (−515). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 476 $[M-H]^-$ (50), 365 $[M-111-H]^-$ (60), 281 (100).

4.9. 8α-Hydroxyspiganthine (*3*)

Crystals from $CHCl_3$:Me_2CO (3:1) (1 mg), mp 255–257°. TLC: R_f 0.24; anisaldehyde: red-purple. HPLC: R_t 17.5 min (S-2). [α]D +26° (*c* 0.1). IR ν_{max} cm^{-1}: 3410, 2930, 1700. UV λ_{max} nm (log ε): 265 (4.18). CD λ_{max} nm (Θ): 205 (+4170), 225 (−3650), 244 (+390), 265 (−576). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 508 $[M-H]^-$ (80), 397 $[M-111-H]^-$ (50), 281 (100).

4.10. 20-Norspiganthine-5-carboxylic acid (*18*)

Crystals from $CHCl_3$:MeOH (1:1) (20 mg), mp >300°. TLC: R_f 0.09; anisaldehyde: red-purple. HPLC: R_t 5.0 min (S-2), R_t 7.5 min (S-4). [α]D +15° (*c* 0.4). IR ν_{max}^{KBr} cm^{-1}: 3400, 2970, 1680. UV λ_{max} nm (log ε): 265 (4.11). CD λ_{max} nm (Θ): 205 (+55), 230 (−3170), 265 (+1995). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 506 $[M-H]^-$ (100).

4.11. Methyl ester of *18*

Compound **18** (7 mg) was dissolved in 1 ml MeOH and treated with 3 ml diazomethane/Et_2O at room temp. for 5 h. After evapn the residue was purified by HPLC on RP-18 using S-2 to obtain 1 mg of the methyl ester of **18** (amorphous). TLC: R_f 0.51; anisaldehyde: red-purple. HPLC: R_t 34.0 min (S-2). [α]D +18° (*c* 0.1). ^{1}H NMR: δ 0.78 (3H, *d*, *J* = 6.5 Hz, Me-19), 1.00 (3H, *d*, *J* = 6.5 Hz, Me-21), 1.14 (3H, *d*, *J* = 6.5 Hz, Me-18), 1.15–1.22 (1 H, *m*, H-7β), 1.36 (3H, *s*, Me-17), 1.45–1.56 2H, *m*, H-8β, H-8α), 1.74–1.87 (1H, *m*, H-9), 2.23 (1H, *ddd*, J_1 = 13, J_2 = 11, J_3 = 6 Hz, H-7α), 2.26–2.36 (1H, *m* , H-13) overlapped by 2.32 (1H, *d*, *J* = 13 Hz, H-14_B), 2.61 (1H, *d*, *J* = 14Hz, H-14_A), 3.10 (3H, *s*, CO_2Me), 3.75 (1H, *d*, *J* = 10, H-10), 3.94 (1H, *dd*, J_1 = 8,5 J_2 = 2 Hz, H-4), 5.76 (1H, *d*, *J* = 8.5 Hz, H-3), 6.19 (1H, *dd*, J_1 = 4, J_2 = 2.5 Hz, H-25), 6.72 (1H, *dd*, J_1 = 4, J_2 = 1.5 Hz, H-24), 6.99 (1H, *dd*, J_1 = 2.5, J_2 = 1.5 Hz, H-26). FABMS *m/z* (rel. int.): 520 $[M-H]^-$ (100).

4.12. Ryanodine (*4*)

Crystals from $CHCl_3$:Me_2CO (3:1) (8 mg), mp 180°. TLC: R_f 0.46; anisaldehyde: yellow-ochre. HPLC: R_t 57.5 min (S-2). [α]D +9° (c 0.7). IR ν_{max} cm^{-1}: 3305, 2930, 1695. UV λ_{max} nm (log ε): 265 (4.15). CD λ_{max} nm (Θ): 205 (+4495), 230 (−4915), 245 (−510), 260

(−2095). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 492 [M-H]$^-$ (100), 381 [M-111-H]$^-$ (70). All other physicochemical properties were also identical with an authentic sample purchased from Calbiochem® Biochemicals.

4.13. 20-Hydroxyryanodine (**19**)

Crystals from $CHCl_3$:MeOH (3:1) (19 mg), mp 188°. TLC: R_f 0.33; anisaldehyde: yellow-ochre. HPLC: R_t 18.5 min (S-2). [α]D +8° (*c* 1.0). IR ν_{max} cm^{-1}: 3305, 2955, 1695. UV λ_{max} nm (log ε): 265 (4.32). CD λ_{max} nm (Θ): 205 (+5815), 230 (−5040), 245 (−765), 265 (−2565). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 508 [M-H]$^-$ (100), 397 [M-111-H]$^-$ (40).

4.14. 9-Hydroxy-10-epi-ryanodine (**5**)

Crystals from $CHCl_3$:Me_2CO (3:1) (3.5 mg), mp 169°. TLC: R_f 0.51; anisaldehyde: yellow-ochre. HPLC: R_t 71.0 min (S-2). [α]D +2° (*c* 0.1). IR ν_{max} cm^{-1}: 3305, 2930, 1695. UV λ_{max} nm (log ε): 265 (4.06). CD λ_{max} nm (Θ): 205 (+6435), 230 (−7670), 245 (−460), 265 (−3200). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 508 [M-H]$^-$ (100), 397 [M-111-H]$^-$ (40).

4.15. 9-Hydroxy-9-epi-10-epi-ryanodine (**6**)

Crystals from $CHCl_3$:Me_2CO (3:1) (40 mg), mp 178°. TLC: R_f 0.40; anisaldehyde: yellow-ochre. HPLC: R_t 60.0 min (S-2). [α]D +11° (*c* 1.0). IR ν_{max}^{KBr} cm^{-1}: 3340, 2935, 1690. UV λ_{max} nm (log ε): 265 (4.33). CD λ_{max} nm (Θ): 205 (+4915), 230 (−5465), 245 (−325), 265 (−2415). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 508 [M-H]$^-$ (100), 397 [M-111-H]$^-$ (50).

4.16. (13S)-9,18-Dihydroxy-9-epi-10-epi-ryanodine (7)

Crystals from $CHCl_3$:Me_2CO (3:1) (3 mg), mp 190°. TLC: R_f 0.28; anisaldehyde: yellow-ochre. HPLC: R_t 24.0 min (S-2). [α]D +10° (*c* 0.35). IR ν_{max} cm^{-1}: 3305, 2925, 1695. UV λ_{max} nm (log ε): 265 (4.17). CD λ_{max} nm (Θ): 210 (+2025), 230 (−3940), 245 (−470), 270 (−4720). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 524 [M-H]$^-$ (100), 413 [M-111-H]$^-$ (90).

4.17. 9,20-Dihydroxy-9-epi-10-epi-ryanodine (**20**)

Crystals from $CHCl_3$:MeOH (3:1) (3 mg), mp 178°. TLC: R_f 0.28; anisaldehyde: yellow-ochre. HPLC: R_t 20.0 min (S-2). [α]D +4° (*c* 0.1). IR ν_{max} cm^{-1}: 3390, 2930, 1695. UV λ_{max} nm (log ε): 265 (4.26). CD λ_{max} nm (Θ): 205 (+5030), 230 (−3730), 245 (−410), 265 (−2350). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 524 [M-H]$^-$ (100), 413 [M-111-H]$^-$ (20).

4.18. 8,9-Dehydro-10-epi-ryanodine (**8**)

Crystals from $CHCl_3$:Me_2CO (1:1) (6 mg), mp 165. TLC: R_f 0.56; anisaldehyde: yellow-ochre. HPLC: R_t 62.0 min (S-2). [α]D +20 (*c* 0.1). IR ν_{max} cm^{-1}: 3365, 2930, 1700. UV λ_{max} nm (log ε): 265 (4.15). CD λ_{max} nm (Θ): 210 (+2205), 230 (−4370), 245 (−385), 265 (−1920). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 490 [M-H]$^-$ (100), 379 [M-111-H]$^-$ (40).

4.19. (13S)-8,9-Dehydro-18-hydroxy-10-epi-ryanodine (**9**)

Crystals from $CHCl_3$:Me_2CO (3:1) (6 mg), mp 168°. TLC: R_f 0.46; anisaldehyde: yellow-ochre. HPLC: R_t 26.0 min (S-2). [α]D +11° (*c* 0.2). IR ν_{max} cm^{-1}: 3390, 2920, 1695. UV λ_{max} nm (log ε): 265 (4.07). CD λ_{max} nm (Θ): 210 (−355), 230 (−3730), 245 (−445), 265 (−2375). ^{1}NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 506 [M-H]$^-$ (60), 395 [M-111-H]$^-$ (60), 281 (100).

4.20. 8,9-Dehydro-20-hydroxy-10-epi-ryanodine (**10**)

Crystals from $CHCl_3$:Me_2CO (3:1) (4.5 mg), mp 148°. TLC: R_f 0.40; anisaldehyde: yellow-ochre. HPLC: R_t 23.0 min (S-2). [α]D +14° (*c* 0.2). IR ν_{max} cm^{-1}: 3350, 2920, 1700. UV λ_{max} nm (log ε): 265 (4.18). CD λ_{max} nm (Θ): 210 (+1615), 230 (−2355), 245 (−355), 265 (−1680). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 506 [M-H]$^-$ (100), 395 [M-111-H]$^-$ (60).

4.21. 8,9-Dehydro-21-hydroxy-10-epi-ryanodine (**11**)

Crystals from $CHCl_3$:Me_2CO (3:1) (15 mg), mp 178°. TLC: R_f 0.35; anisaldehyde: yellow-ochre. HPLC: R_t 33.0 min (S-2). [α]D +25° (*c* 1.0). IR ν_{max} cm^{-1}: 3365, 2935, 1700. UV λ_{max} nm (log ε): 265 (4.71). CD λ_{max} nm (Θ): 205 (+3070), 230 (−4175), 245 (−165), 265 (−1565). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m/z* (rel. int.): 506 [M-H]$^-$ (100), 395 [M-111-H]$^-$ (50).

4.22. 9-Epi-10-epi-ryanodine from **11**

The solution of 4.5 mg **11** in 4 ml EtOH was stirred in the presence of palladium (10% on carbon) (25 mg) under hydrogen for 6 h at room temp. The reaction mixture was evapd and the residue purified by CC on silica gel using S-1 to obtain 3 mg of 9-*epi*-10-*epi*-ryanodine (amorphous). TLC: R_f 0.56; anisaldehyde:

yellow-ochre. [α]D +14° (*c* 0.3). UV λ_{max} nm (log ε): 265 (4.25). CD λ_{max} nm (Θ): 200 (+4760), 230 (−4040), 245 (−180), 255 (−595), 265 (+890). ^{1}H NMR: δ 0.74 (3H, *d*, *J* = 6.5 Hz, Me-19), 0.90 (3H, *s*, Me-20), 1.08 (3H, *d*, *J* = 6.5 Hz, Me-18), 1.14 (3H, *s*, Me-21), 1.27–1.43 (5H, *m*, H-7β, H-8α) including 1.34 (3H, *s*, Me-17), 1.89 (1H, *d*, *J* = 14 Hz, H-14$_B$), 1.95–2.08 (2H, *m*, H-9, H-8β), 2.11–2.28 (2H, *m*, H-7α, H-13), 2.58 (1H, *d*, *J* = 14 Hz, H-14$_A$), 3.78 (1H, *d*, *J* = 2.5 Hz, H-10), 5.65 (1H, *s*, H-3), 6.24 (1H, *dd*, J_1 = 4, J_2 = 2.5 Hz, H-25), 6.87 (1H, *dd*, J_1 = 4, J_2 = 1.5 Hz, H-24), 7.03 (1H, *dd*, J_1 = 2.5, J_2 = 1.5 Hz, H-26). FABMS *m*/*z* (rel. int.): 492 [M-H]$^-$ (100), 381 [M-111-H]$^-$ (90).

4.23. Epoxydation of **11**

Compound **11** (7 mg) was epoxydized with 3-chloroperoxybenzoic acid (20 mg) according to Waterhouse et al. (1987). Purification of the reaction mixture by CC on silica gel using S-1 and subsequent HPLC on RP-18 (S-2) yielded the two epoxydation products EP-1 (**17**) and EP-2 (*iso*-**17**).

4.24. EP-1

Amorphous (0.8 mg). TLC: R_f 0.30; anisaldehyde: yellow-ochre. [α]D +10° (*c* 0.05). All other physicochemical properties were also identical with the isolated natural compound **17**.

4.24.1. 8α,9α-Epoxy-21-hydroxy-10-epi-ryanodine (**17**) (=EP-1)

Crystals from $CHCl_3$:Me_2CO (3:1) (4 mg), mp 193°. TLC: R_f 0.30; anisaldehyde: yellow-ochre. HPLC: R_t 30.0 min (S-2). [α]D +13° (*c* 0.2). IR ν_{max} cm^{-1}: 3365, 2935, 1700. UV λ_{max} nm (log ε): 265 (4.14). CD λ_{max} nm (Θ): 205 (+4160), 230 (−4780), 245 (−290), 265 (−2060). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m*/*z* (rel. int.): 522 [M-H]$^-$ (100), 411 [M-111-H]$^-$ (50).

4.25. EP-2 (=8β,9β-Epoxy-21-hydroxy-10-epi-ryanodine)

Amorphous (1 mg). TLC: R_f 0.30; anisaldehyde: yellow-ochre. HPLC: R_t 36.0 min (S-2). [α]D +20° (*c* 0.05). ^{1}H NMR: δ 0.73 (3H, *d*, *J* = 6.5 Hz, Me-19), 0.93 (3H, *s*, Me-20), 1.09 (3H, *d*, *J* = 6.5 Hz, Me-18), 1.37 (3H, *s*, Me-17), 1.91 (1H, *d*, *J* = 14 Hz, H-14$_B$), 1.98 (1H, *dd*, J_1 = 15, J_2 = 2 Hz, H-7β), 2.17–2.28 (1H, *m*, H-13), 2.42 (1H, *dd*, J_1 = 15, J_2 = 2 Hz, H-7α), 2.64 (1H, *d*, *J* = 14 Hz, H-14$_A$), 3.55 (1H, *dd*, J_1 = J_2 = 2 Hz, H-8), 3.71 (2H, *s*, H-21$_A$, H-21$_B$), 4.29 (1H, *s*, H-10), 5.63 (1H, *s*, H-3), 6.24 (1H, *dd*, J_1 = 4, J_2 = 2.5 Hz, H-25), 6.86 (1H, *dd*, J_1 = 4, J_2 = 1.5 Hz, H-24), 7.03 (1H, *dd*, J_1 = 2.5, J_2 = 1.5 Hz, H-26). FABMS *m*/*z* (rel. int.): 522 [M-H]$^-$ (100), 411 [M-111-H]$^-$ (20).

4.26. (13S)-8,9-Dehydro-18,21-dihydroxy-10-epi-ryanodine (**21**)

Crystals from $CHCl_3$:MeOH (1:1) (1.5 mg), mp 162°. TLC: R_f 0.26; anisaldehyde: yellow-ochre. HPLC: R_t 14.5 min (S-2). [α]D +7° (*c* 0.2). IR ν_{max} cm^{-1}: 3390, 2930, 1695. UV λ_{max} nm (log ε): 265 (4.56). CD λ_{max} nm (Θ): 210 (+1450), 230 (−2580), 245 (±0), 265 (−1185). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m*/*z* (rel. int.): 522 [M-H]$^-$ (100), 411 [M-111-H]$^-$ (50).

4.27. 8,9-Dehydro-20,21-dihydroxy-10-epi-ryanodine (**22**)

Crystals from $CHCl_3$:MeOH (1:1) (4.5 mg), mp 173°. TLC: R_f 0.20; anisaldehyde: yellow-ochre. HPLC: R_t 16.0 min (S-2). [α]D +6° (*c* 0.2). IR ν_{max} cm^{-1}: 3365, 2930, 1695. UV λ_{max} nm (log ε): 265 (4.08). CD λ_{max} nm (Θ): 205 (+2275), 230 (−3630), 245 (−300), 265 (−1730). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m*/*z* (rel. int.): 522 [M-H]$^-$ (100), 411 [M-111-H]$^-$ (20).

4.28. 8α,9α-Epoxy-10-epi-ryanodine (**12**)

Crystals from $CHCl_3$:Me_2CO (3:1) (13.5 mg), mp 196°. TLC: R_f 0.54; anisaldehyde: yellow-ochre. HPLC: R_t 42.0 min (S-2). [α]D +13° (*c* 0.4). IR ν_{max} cm^{-1}: 3305, 2935, 1705. UV λ_{max} nm (log ε): 265 (4.11). CD λ_{max} nm (Θ): 205 (+5035), 230 (−4520), 245 (−410), 265 (−2455). ^{1}H NMR: Table 2. ^{13}C NMR: Table 3. FABMS *m*/*z* (rel. int.): 506 [M-H]$^-$ (100), 395 [M-H-111]$^-$ (30).

4.29. Acid-catalyzed isomerization of **12**

Aqueous oxalic acid (1%) (3 ml) was added to a solution of **12** (4 mg) in Me_2CO (3 ml) and stirred for 60 h at room temp. After evapn of the organic solvent, the aqueous residue was diluted with 5 ml H_2O and extracted with 3×10 ml EtOAc. Evapn and CC of the extract on silica gel using S-1 yielded 3.5 mg of the pure product. Crystals from $CHCl_3$:Me_2CO (3:1), mp 172°. TLC: R_f 0.38; anisaldehyde: yellow-ochre. HPLC: R_t 41.5 min (S-2). [α]D −10° (*c* 0.2). All spectroscopic data were also identical with those of genuine **15**.

4.30. 6-Deoxy-6β,9β-epoxy-8α-hydroxy-10-epi-ryanodine (**15**)

Crystals from $CHCl_3$:Me_2CO (3:1) (6 mg), mp 172°. TLC: R_f 0.38; anisaldehyde: yellow-ochre. HPLC: R_t 41.5 min (S-2). [α]D −8° (*c* 0.2). IR ν_{max} cm^{-1}: 3400, 2930, 1695. UV λ_{max} nm (log ε): 265 (3.93). CD λ_{max} nm (Θ): 205 (+1685), 230 (−3265), 245 (−400), 265 (−2400), 295 (+230). ^{1}H NMR: Table 2. ^{13}C NMR:

Table 3. FABMS m/z (rel. int.): 506 $[M\text{-}H]^-$ (80), 395 $[M\text{-}111\text{-}H]^-$ (60), 275 (100).

4.31. 8β,9β-Epoxy-10-epi-ryanodine (**13**)

Crystals from $CHCl_3$:Me_2CO (3:1) (4 mg), mp 212°. TLC: R_f 0.51; anisaldehyde: yellow-ochre. HPLC: R_t 50.0 min (S-2). $[\alpha]_D$ +7° (c 0.2). IR ν_{max} cm^{-1}: 3390, 2915, 1595. UV λ_{max} nm (log ε): 265 (4.03). CD λ_{max} nm (Θ): 205 (+1705), 230 (−3015), 245 (±0), 265 (−1245). ^1H NMR: Table 2. ^{13}C NMR: Table 3. FABMS m/z (rel. int.): 506 $[M\text{-}H]^-$ (100), 395 $[M\text{-}111\text{-}H]^-$ (10).

4.32. (13S)-8α,9α-Epoxy-18-hydroxy-10-epi-ryanodine (**14**)

Crystals from $CHCl_3$:Me_2CO (3:1) (3.5 mg), mp 200°. TLC: R_f 0.39; anisaldehyde: yellow-ochre. HPLC: R_t 17.0 min (S-2). $[\alpha]_D$ +7° (c 0.2). IR ν_{max} cm^{-1}: 3370, 2930, 1695. UV λ_{max} nm (log ε): 265 3.87). CD λ_{max} nm (Θ): 205 (+1015), 230 (−2365), 245 (−360), 265 (−1210). ^1H NMR: Table 2. ^{13}C NMR: Table 3. FABMS m/z (rel. int.): 522 $[M\text{-}H]^-$ (100), 411 $[M\text{-}111\text{-}H]^-$ (30).

4.33. 8α,9α-Epoxy-20-hydroxy-10-epi-ryanodine (**16**)

Crystals from $CHCl_3$:Me_2CO (3:1) (2 mg), mp 208°. TLC: R_f 0.37; anisaldehyde: yellow-ochre. HPLC: R_t 19.0 min (S-2). $[\alpha]_D$ +8° (c 0.1). IR ν_{max} cm^{-1}: 3365, 2930, 1700. UV λ_{max} nm (log ε): 265 (4.12). CD λ_{max} nm (Θ): 205 (+3730), 230 (−3530), 245 (−480), 265 (−2030).

4.34. Pharmacological experiments

Pharmacological tests were performed as described previously (Achenbach et al., 1995).

Received 11 September 2000; received in revised form 11 December 2000

Abstract

Five flavonoid glucuronides were obtained from the fruit of *Helicteres isora*, three of which were previously unknown compounds: isoscutellarein 4′-methyl ether 8-*O*-β-D-glucuronide 6″-*n*-butyl ester, isoscutellarein 4′-methyl ether 8-*O*-β-D-glucuronide 2″, 4″-disulfate and isoscutellarein 8-*O*-β-D-glucuronide 2″,4″-disulfate. The structures were determined on the basis of spectroscopy and hydrolysis experiments. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Helicteres isora*; Sterculiaceae; Jamu; Flavonoid glucuronide; Sulfate; Structural elucidation

1. Introduction

Helicteres isora L. (Sterculiaceae) is widely distributed from southern China, to India, Southeast Asia and Australia. The roots are used in the treatment of chronic nephritis and gastric ulcers in China. In Indonesia, the fruit of *H. isora* is referred to as "Ulet-Ulet" on Java island and is a raw material for production of "Jamu". It is used as an anthelmintic against tapeworm and in the treatment of gastrospasm. Chemical analyses of *H. isora* have detected the presence of cucurbitacins (Bean et al., 1985), flavonoids (Romesh and Yuvarajan, 1995), neolignans (Tezuka et al., 1999) and rosmarinic acid derivatives (Satake et al., 1999). In the present paper, we discuss the isolation and structural elucidation of five flavonoids including three new compounds (Fig. 1).

2. Results and discussion

A 70% methanol extract of the fruit of *H. isora* was fractionated by combination of MCI gel, SiO_2 gel, Sephadex LH-20 and RP-18 column chromatography to afford a series of flavonoids (**1**–**5**). Compounds **1**–**5**, positive on Mg–HCl and anthrone tests, were obtained as yellow amorphous powders, indicating them to be flavonoid glycosides.

Compound **1** was identical to isoscutellarein 4′-methyl ether 8-*O*-β-D-glucuronide. Its structure was confirmed by NMR and UV spectrum in addition to acid hydrolysis and enzymic hydrolysis. This compound was previously isolated from *Takakia lepidoziodes* (Markham and Porter, 1979) (Tables 1 and 2).

Compound **2** gave an $[M–H]^-$ at m/z 531.1581, which corresponded with the molecular formula of $C_{26}H_{28}O_{12}$ from the HR-negative-FAB-MS spectrum. The IR spectrum showed absorption bands assignable to an ester group (1738 cm^{-1}) and an alkyl group (2970 cm^{-1}). The ^{13}C NMR spectrum of **2** showed 24 carbon signals; 4 carbon units more than that of **1**. The ^1H NMR spectrum of **2** indicated a similar pattern to that of **1**, except for the signals corresponding to an *n*-butyl moiety. In the HMBC spectrum (Fig. 2), the methylene signals at δ 3.95 and 3.96 in the *n*-butyl moiety correlated with the carboxyl carbon signal at δ 168.94. Based on the above observation, the *n*-butyl group must be attached to glucuronic acid at the 6″-position as an ester linkage. Furthermore, the location of the glycosyl linkage was determined to be at C-8 from the HMBC spectrum; the

anomeric proton signal at δ 4.69 showed a long range correlation with an oxygenated quaternary carbon at δ 124.88, assignable to C-8 on the basis of the long rang correlation with 6-H (δ 6.11). Further correlation was observed between the methoxyl proton signal at δ 3.84 and oxygenated carbon signal at δ 162.08 assignable to C-4″. From these results, **2** was determined to be isoscutellarein 4′-methyl ether 8-*O*-β-D-glucuronide 6″-*n*-butyl ester. Compound **2** is not considered to be an artifact of isolation, as compound **1** could not be converted into compound **2** after stirring in an *n*-BuOH for 12 h at 70°C.

HR-negative-FAB-MS spectrum of **3** showed a molecular ion at m/z 555.0485 corresponding with the molecular formula of $C_{22}H_{19}O_{15}S$. The ^{1}H and ^{13}C NMR spectra of **3** were similar to those of **1**, except for the proton and carbon signals due to C-1″ and C-2″ of the glucuronic acid moiety. Acid hydrolysis of **3** yielded isoscutellarein 4′-methyl ether and D-glucuronic acid {$[\alpha]_D = +21.0^\circ$ (H_2O, $c = 0.58$)}, in addition to sulfate. The sulfate ion can be precipitated with barium chloride. However, **3** was not hydrolyzed with β-glucuronidase. This result confirmed that the sulfate group must be linked to the glucuronic acid moiety. The position of the sulfate group was determined by comparison of the ^{1}H and ^{13}C NMR spectra of **1** and **3**. In the NMR spectrum

of **3**, sulfation shifts (Gudej, 1991) were observed for 2″-H (+1.00 ppm) in ^{1}H resonance and for C-1″ (−5.34 ppm) and C-2″ (+4.85 ppm) in ^{13}C resonances as compared with those of **1**. These data indicated that the sulfate group must be linked to the C-2″ hydroxyl of the glucuronic acid unit. Furthermore, the location of the glycosyl linkage was determined to be at C-8 from the HMBC spectrum. Thus, the structure of **3** was characterized as isoscutellarein 4′-methyl ether 8-*O*-β-D-glucuronide 2″-sulfate. This compound was already isolated from the same genus plant, *Helicteres angustifolia* (Chen et al., 1994).

The UV spectrum of **4** resembled that of **1**, also indicating it to be the same aglycone. The ^{1}H- and ^{13}C NMR spectral data of **4** were almost identical to those of **3**, except for the signals in the aliphatic region. Acid hydrolysis of **4** yielded isoscutellarein 4′-methyl ether and D-glucuronic acid, in addition to sulfate ($BaCl_2$, ppt), whereas **4** was not hydrolyzed with β-glucuronidase. In the ^{13}C NMR spectrum of the sugar region, it was observed that the carbon signal at C-4″ appeared at a much lower magnetic field than that in **3**. Furthermore, in the ^{1}H NMR, the proton signals due to H-4″ and H-5″ appeared at δ 5.02 (*brd*, $J = 3.5$ Hz) and 4.49 (*brs*), respectively. From the downfield shifted signal at C-4″, the C-4″ position was assumed to be substituted with the second sulfate group. However, under these solvent conditions (DMSO-d_6), $J_{3'',4''}$ (3.5 Hz) and $J_{4'',5''}$ (< 1.0 Hz) based on equatorial coupling were observed, without indicating di-axial coupling [*J* value (7–10 Hz)] due to the chair form of glucuronic acid. This observation can be explained as follows (Fig. 3): the carboxyl and sulfate groups are less solvated in DMSO and exist in a free state. Thus, the preferred conformation is believed to be one in which both the carboxyl group and the sulfate group are axial because of a dipolar interaction between the two groups (Djerassi, 1960). This phenomenon was further suggested by the observation whereby the sugar ring was converted from a twist boat to a chair form when the solvent was changed to the polar protic solvent D_2O (data not shown). These data demonstrated that **4** was isoscutellarein 4′-methyl ether 8-*O*-β-D-glucuronide 2″,4″-disulfate.

The NMR spectra of **5** exhibited the same diagnostic signals for 8-*O*-β-D-glucuronide 2″,4″-disulfate as did **4**. Based on both the ^{13}C and ^{1}H NMR spectral data, the absence of the signal due to the methoxyl group was demonstrated. Furthermore, the UV spectrum of **5** in H_2O upon addition of NaOMe indicated the isoscutellarein-skeleton with a free 4′-hydroxyl. Therefore, **5** was concluded to be isoscutellarein 8-*O*-β-D-glucuronide 2″,4″-disulfate.

3. Experimental

3.1. General procedures and plant material

Optical rotations were measured using a Jasco DIP-1000 digital polarimeter. HR-FAB-MS were recorded on a JEOL JMS-BU 20 spectrometer. IR and UV spectra were measured on a Shimadzu FT-IR 8300 infrared spectrometer and a Hitachi U-3000 spectrometer, respectively. The NMR spectra were recorded in DMSO-d_6, on a

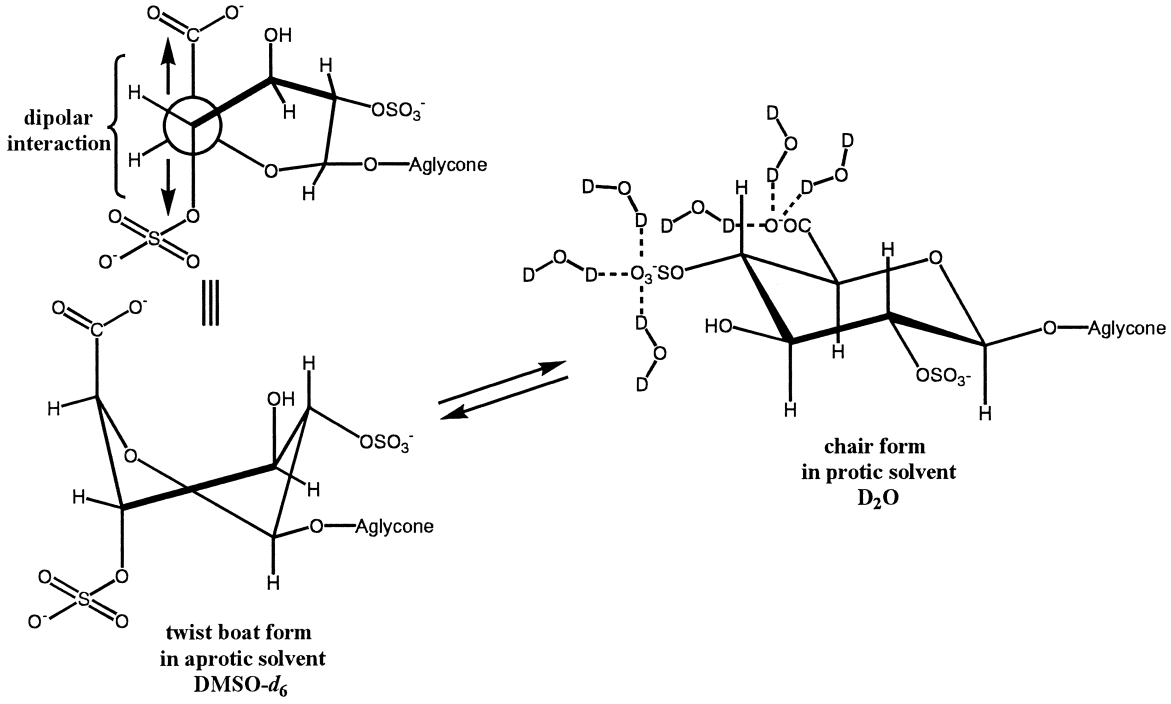

Fig. 3. Solvent effects in compounds **4** and **5**.

Bruker DPX-400 instrument. GC used a Shimadzu gas chromatograph model GC-17A (capillary column: DB-17, 30 m×0.32 mm, carrier gas: He, 1.73 ml/min, column temp.: 170°C). The fruit of *H. isora* was purchased from JAMU factory in Jakarta and the plant was identified by Dr. Asmanizar, University of Indonesia. The herbarium specimen has been deposited at the Botanical Museum of Kobe Gakuin University.

3.2. Extraction and isolation

The fruit of *H. isora* (4 kg) was initially extracted using hot MeOH (7 hr, 12 l×5) and further extracted using hot 70% MeOH (7 h, 12 l×3). Each solvent was removed under reduced pressure to yield a MeOH and a 70% MeOH extract. The 70% MeOH extract was suspended in a MeOH–H_2O (400:1200 ml) mixture and further extracted in successive steps using $CHCl_3$, AcOEt and *n*-BuOH (each 1600 ml×3). The *n*-BuOH extract was subjected to silica gel chromatography using a gradient of AcOEt, MeOH and H_2O system to give flavonoid-containing fractions. These fractions were subjected repeatedly to RP-18 column chromatography using MeOH–H_2O (1:7) and finally were purified by CC on Sephadex LH-20 using MeOH–H_2O (4:1) to give compounds **1** (15 mg) and **2** (10 mg). The H_2O extract was applied to MCI-gel using a gradient of MeOH and H_2O (1:4–4:1) to give flavonoid-containing fractions. These fractions were subjected repeatedly to RP-18 column chromatography using H_2O and finally were purified by CC on Sephadex LH-20 using MeOH–H_2O (1:1) to give compounds **3** (30 mg), **4** (100 mg) and **5** (10 mg).

3.3. Acid hydrolysis

Refluxing each compound (5 mg) for 4 h in 5% HCl yielded aglycone, D-glucuronic acid (identified by comparison with authentic sample, GC and $[\alpha]_D$) and sulfate (ppt. with $BaCl_2$).

Received 26 September 2000; received in revised form 20 December 2000

Abstract

Chlorinated bisbibenzyls of the bazzanin type are detected in crude bryophyte plant extracts of *Bazzania trilobata* from different locations using MALDI-TOF mass spectrometry. These results show that these chlorinated compounds are not artefacts of an incidental occurrence or of the sample preparation but are genuine and produced by the liverwort or an endosymbiotic metabolism. Further experiments were performed concerning the in vitro chlorination of the halogen free basic unit isoplagiochin C. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Liverworts; *Bazzania trilobata*; Chlorometabolites; MALDI-TOF-MS; Halogenation

1. Introduction

The number of halogenated natural products isolated from different living organisms has strongly increased during the last years (Naumann, 1993). Most of these metabolites with a broad structural diversity are found in marine organisms like algae and invertebrates (sponges, molluscs, worms) (Faulkner, 1992). Halometabolites from bacteria (e. g. chloramphenicol, chlortetracyclin) (van Pée, 1996) and fungi (e. g. griseofulvin) (Turner and Aldridge, 1983) exhibit high therapeutic significance. Halogenated compounds from higher plants are less numerous although they were detected in all plant divisions (ferns, lichen, flowering plants) (Neidleman and Geigert, 1986). Recently, chlorinated metabolites named bazzanin A **1** to bazzanin K **11** were isolated for the first time from mosses (bryophytes), in particular from the liverwort *Bazzania trilobata* (Martini et al., 1998). With the exception of the modified structure of **11** these compounds are obviously derived from isoplagiochin C **12** or isoplagiochin D **13**, two known bryophyte constituents (Hashimoto et al., 1996). Similar chlorometabolites were detected nearly at the same time in *Plagiochila sp*. (Anton et al., 1997) and *Lepidozia incurvata* (Schmidt, 1996) and very recently in *Herbertus sakuraii* and *Mastigophora diclados* (Hashimoto et al., 2000).

The bazzanins originally were isolated from crude moss extracts of *Bazzania trilobata* through multiple chromatographic separation steps in quantities of 2–23 mg; their structures have been elucidated based on extensive NMR spectral evidence and by usual mass spectrometry (EI–MS, CI–MS, DCI–MS) (Martini et al., 1998). It is always a point of discussion whether halometabolites detected in any living organisms are genuine (Neidleman and Geigert, 1986). So it is well accepted that the halogenated compounds isolated from marine invertebrates in many cases originate from incorporation of algae food. For plant materials exo- or even endosymbiontic fungi could be producers of halometabolites — especially when very small amounts are detected (Sakai et al., 1988). Halogen containing compounds even may be an artefact of isolation procedures especially in the case of halohydrins (Hashimoto et al., 1989). We searched for a rapid screening method for bazzanins in *Bazzania trilobata* from different locations with minimal sample pre-treatment to exclude artificial formation of these chlorometabolites.

2. Results and discussion

MALDI mass spectrometry has been shown to be a robust technique tolerating considerable salt loads and permitting the analysis of even complex mixtures because of the soft ionisation (Goheen et al., 1997). Its use for the analysis of low molecular weight compounds

PII: S0031-9422(01)00010-3

is quite rare because of possible matrix interferences (Krishnamurthy et al., 1996). The analysis of chlorinated organic compounds in a complex biological matrix has not been reported before to our knowledge. Chlorinated compounds and their degree of chlorination can be identified because of the characteristic isotope patterns.

The plant material from the original detection of chlorinated compounds was collected in Weißkirchen, Saarland, Germany. The plant samples analysed in this paper originate from Rinnthal, Rheinland-Pfalz, Germany and Lautzkirchen, Saarland, Germany. The air-dried and powdered plant material was extracted with methanol and subjected directly to MALDI mass spectroscopy. A pre-extraction with ether to remove the non-polar fraction proved to be not necessary. To achieve a further purification the methanol extract was distributed between ethyl acetate and water and the ethyl acetate soluble fraction was chromatographed on Sephadex LH-20. The last fraction was finally obtained as a powder and gave the best results in the MALDI-TOF detection. Because of their polar and aromatic structures the bazzanins absorb laser light directly and their detection does not need any additional matrix.

Containing one to six halogen atoms the bazzanins should give very specific molecular-weight distributions in mass spectra according to the isotope pattern calculation. The MALDI-MS spectra of all analysed fractions of both plant samples resulted in peak patterns being in significant accordance to the molecular formulas of bazzanins (Table 1 and Fig. 3) showing the characteristic intensity distribution (for an example see Fig. 4). We found no substantial differences between the plant samples from Rinnthal and Lautzkirchen. The chlorinated bisbibenzyls were detected in purified samples as well as in the crude methanolic extract.

These results show that the bazzanins are genuine substances from *Bazzania trilobata* which are not produced during the sample preparation and do not occur incidentally. This novel detection of chlorinated organic compounds in the complex biological matrix of a crude plant extract should be a suitable instrument for further phytochemical studies.

The biogenesis of the bazzanins is a point of discussion. Haloperoxidases are enzymes which catalyse the incorporation of halogen atoms into organic molecules in the presence of a halide and hydrogen peroxide and

which are thought to be involved in the biosynthesis of most halometabolites (Neidleman and Geigert, 1986; Hohaus et al., 1997). Numerous in vitro reactions are described for the commercially available chloroperoxidase (CPO, EC 1.11.1.10) from *Caldariomyces fumago* (Franssen, 1994). We subjected a synthetic sample of isoplagiochin C **12** (Eicher et al., 1998) to a chemoenzymatic transformation with KCl/H_2O_2 in the presence of CPO in a buffered aqueous medium (Speicher, 2000) and the crude reaction mixture was also analysed using MALDI-MS (see Fig. 2). The in vitro chlorination of isoplagiochin C **12** resulted in the incorporation of 1–5 chlorine atoms. The MALDI mass spectra of the crude reaction mixture were in good agreement with the spectra from the natural sources. In this experiment the addition of an enzyme solution is essential to achieve chlorination.

3. Experimental

3.1. Plant material

The plant materials of the liverwort *Bazzania trilobata* (L.) S. F. Gray (family: Lepidoziaceae) were collected in Weißkirchen, Saarland, Germany in March 1994 (Martini et al., 1998), Rinnthal, Rheinland-Pfalz, Germany during June 1999 and Lautzkirchen, Saarland, Germany

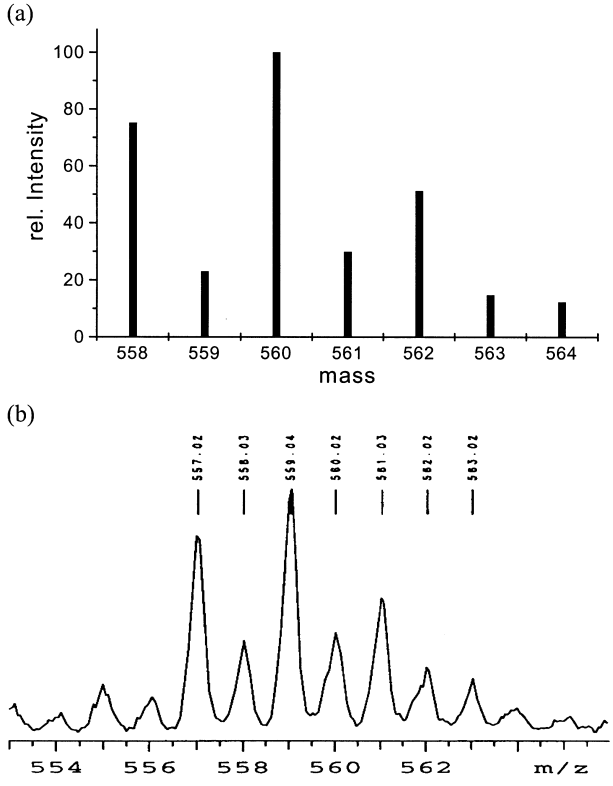

Fig. 4. (a) Calculated (Sheffield ChemPuter: http://www.shef.ac.uk/chemistry/chemputer) and (b) measured (in negative mode as $(M\text{-}H)^-$ions) peak pattern of bazzanins E, F **5**,**6** ($C_{28}H_{18}Cl_4O_4$).

during December 1999 and identified by Prof. Dr. R. Mues (Institut für Botanik der Universität des Saarlandes, Saarbrücken, Germany). Voucher specimens are deposited in the herbarium SAAR, Saarbrücken.

3.2. Extraction and analysis

Air dried and powdered plant materials (60 g) were extracted with diethyl ether (250 ml) in a Soxhlet apparatus to remove the non polar compounds (this part was omitted in a control experiment), followed by an exhaustive percolation with methanol (1000 ml) in a glass column (8×50 cm). The evaporated methanolic extract was distributed between ethyl acetate (250 ml) and water (250 ml). The organic layer was evaporated in vacuo and the resulting ethyl acetate phase (ca. 0.60 g) chromatographed on Sephadex LH-20 (4×60 cm, Amersham Pharmacia Biotech, Uppsala) using methanol–diethylether (4:1) as eluent to yield three main fractions. After solvent removal fractions 1 (0.35 g) and 2 (0.10 g) were green-brown viscous oils whereas fraction 3 (0.10 g) was obtained as an ochreous powder. Solvents with a high grade purity were used for isolation and purification procedures.

3.3. In vitro halogenation of isoplagiochin C **12**

126.6 mg (0.30 mmol) of isoplagiochin C **12** (pre-dissolved in 1 ml ethanol) were added to a solution of 3.00 mmol potassium chloride in 120 ml 0.1 M potassium phosphate buffer (pH 3.0). The temperature of the mixture was kept constant to 30–35°C and 6.0 mmol H_2O_2 (30% in H_2O) as well as 1000 units of the chloroperoxidase (EC 1.11.1.10 from *Caldariomyces fumago* obtained from Fluka as suspension in 0.1 M sodium phosphate pH 4.0, 1717 U/mg, 8 mg protein/ml) were added in ten portions each during 10 h. After five portions an additional amount of the halide (3.00 mmol) was added. The mixture was extracted with ethyl acetate, dried ($MgSO_4$) and concentrated.

3.4. Mass spectrometry

The MALDI-TOF measurements were performed using a Bruker Reflex III MALDI-TOF mass spectrometer equipped with a delayed extraction system facility using a N_2-Laser (337 nm) with a single pulse duration of 3 ns and 10^7–10^8 W/cm^2 irradiation.

The sample preparation for MALDI-TOF analysis was performed by dissolving the oily or powdered samples in methanol at concentrations of about 1 mg/ml. One microliter of the solutions were spotted on the metal target plate and dried at room temperature. MALDI-TOF mass spectra were recorded in reflectron mode with negative acceleration voltage without matrix.

Received 13 November 2000; received in revised form 2 January 2001

Abstract

The sesquiterpenoid constituents of the essential oils from the liverworts *Frullania tamarisci*, *Frullania fragilifolia* and of the angiosperm *Valeriana officinalis* were investigated. Tamariscene, a compound with a new sesquiterpene skeleton, valerena-4,7(11)-diene and five new pacifigorgiadienes, namely pacifigorgia-1,10-diene, pacifigorgia-1(6),10-diene, pacifigorgia-1(9),10-diene, pacifigorgia-2,10-diene, and pacifigorgia-2(10),11-diene were isolated and identified. Structure elucidation was carried out by NMR spectroscopy and chemical correlations to establish absolute configurations. Compounds present in both the essential oils of the *Frullania species* and *Valeriana officinalis* were enantiomeric to each other. A plausible biogenetic relationship between the pacifigorgiane, valerenane and tamariscane skeletons is postulated. Pacifigorgia-6,11-diene, not yet detected in nature, was generated by dehydration and rearrangement of natural (−)-tamariscol. © 2001 Elsevier Science Ltd. All rights reserved.

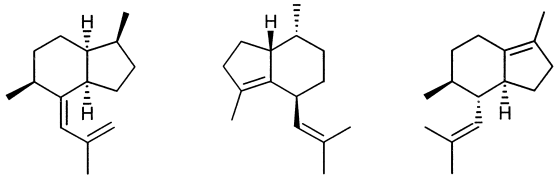
Keywords: *Frullania tamarisci*; *F. fragilifolia*; *Valeriana officinalis*; Hepaticae; Essential oil; Structure elucidation; Pacifigorgiane; Tamariscane; Valerenane; Sesquiterpene

1. Introduction

The leafy liverworts *Frullania tamarisci* and *F. fragilifolia* (Tayl.) of the order Jungermanniales and the medicinal plant *Valeriana officinalis* L. were investigated and showed a striking chemical relationship concerning their volatile constituents. Essential oil samples were obtained by hydrodistillation and analysed by gas chromatography–mass spectrometry (GC–MS). Individual components, including a number of new sesquiterpene hydrocarbons, were isolated by liquid chromatography and preparative GC and investigated by NMR (^{1}H, ^{13}C, ^{1}H–^{1}H–COSY, HMQC, HMBC, NOESY). The absolute configuration of the new compounds was derived by dehydration of the related natural alcohols, polarimetric measurements, total hydrogenation and enantioselective gas chromatography using cyclodextrin as stationary phases.

2. Results and discussion

The following sesquiterpenoids in the order of their elution from a capillary column with polydimethylsiloxane were identified as constituents of the essential oil of *F. fragilifolia*: (−)-tamariscene (**1**), α-copaene, (−)-pacifigorgia-1(9),10-diene (**2**), β-elemene, (−)-pacifigorgia-1,10-diene (**3**), (−)-pacifigorgia-1(6),10-diene (**4**), (−)-pacifigorgia-2,10-diene (**5**), 11-bourbonene (Warmers et al., 1998), (+)-pacifigorgia-2(10),11-diene (**6**), selina-5,11-diene, α-humulene, γ-muurolene, bicyclogermacrene and (+)-germacrene A.



6 **7** **8**

In the essential oil of *F. tamarisci* in addition to **1–4** and **6** the following sesquiterpenoids were identified: α-copaene, (−)-β-elemene, 11-bourbonene, γ-gurjunene, selina-4,11-diene, eremophilene, (+)-germacrene A, β-

bazzanene, (−)-tamariscol (**9**) (Connolly et al., 1984; Tori et al., 1991), globulol, rosifoliol, ledol and T-cadinol.

In the essential oil of *Valeriana officinalis* (Valerianaceae) the following sesquiterpenoids were identified: (+/−)-δ-elemene, (+)-**1**, α-ylangene, α-copaene, (+)-**2**, β-elemene, (+)-**4**, β-caryophyllene, γ-elemene, (−)-valerena-4,7(11)-diene (**7**), alloaromadendrene, 2-*epi*-*trans*-β-caryophyllene, germacrene D, bicyclogermacrene, δ-cadinene, (−)-pacifigorgiol (**10**) (Bos et al., 1986), germacrene B, spathulenol, alismol and valerianol.

All known compounds were identified by mass spectrometry in conjunction with their gas chromatographic retention indices by comparison with a spectral library established under identical experimental conditions (Joulain and König, 1998). Main components of the sesquiterpenoids present in the essential oils were **1** in *F. fragilifolia* with 11% relative to all compounds detected in the essential oil, **9** with 56% in *F. tamarisci*, and γ-elemene with 11% in *V. officinalis*. All other components ranged between trace amounts and 3% of all constituents of the essential oil.

The new sesquiterpene hydrocarbon tamariscene (**1**) was the major constituent of *F. fragilifolia*. The mass spectrum exhibits a molecular ion signal at *m/z* 204 and an elemental composition of $C_{15}H_{24}$. The proton NMR spectrum shows the presence of two doublets for methyl groups ($\delta = 1.01$, 1.03) and one methyl singlet with a downfield shift ($\delta = 1.74$) indicating that the methyl group is attached to a double bond. An exocyclic methylene group must be present due to two singlets at $\delta = 4.71$ and 4.89. As the ^{13}C NMR reveals only one downfield shifted quaternary carbon ($\delta = 144.66$) the methyl group must be attached to the same carbon as the exocyclic methylene group. Thus, an isopropylidene group is established and therefore the main structure must be postulated to be tricyclic with one double bond. In the ^{13}C NMR three primary carbon atoms ($\delta = 19.16$, 21.29, 24.37), five secondary carbons ($\delta = 29.04$, 30.32, 30.41, 35.53, 109.50), five tertiary ($\delta = 28.93$, 30.06, 33.55, 44.64, 50.19) and two quaternary carbons ($\delta = 34.15$, 144.66) are found. It is remarkable that the two protons appearing at $\delta = 0.54$ (H-4a) and 0.72 (H-5a), respectively, belong to methylene groups (C-4: $\delta = 29.04$; C-5: $\delta = 30.32$) as derived from the ^1H-^{13}C-COSY spectrum. The connectivity of the different groups was established through ^1H–^1H–COSY and HMBC experiments: The methyl group H-15 ($\delta = 1.03$; 19.16) couples to one proton of the multiplet at $\delta = 1.44$–1.55 (H-7, H-9a) in the COSY spectrum and to the multiplet at $\delta = 1.13$–1.26 (H-6/H-8a) in the HMBC spectrum. Proton H-5a couples to the multiplets $\delta = 1.66$–1.76 (H-5b/H-8b), 1.33–1.41 (H-4b) and 1.13–1.26 (H-6/H-8a), which indicates that the methylene groups are located between the tertiary carbons C-3 ($\delta = 28.93$) and C-6 ($\delta = 50.19$). As the methyl group H-14 ($\delta = 1.01$; 21.29) exclusively couples to the methine proton H-3, this connection is established also. The doublet signal with the integral of one proton at $\delta = 0.95$ is assigned to the methine proton H-10 because its carbon ($\delta = 33.55$) couples to the doublet of doublets at $\delta = 1.07$ (H-2), as well as to the signals at $\delta = 1.76$–1.86 (H-3), 1.74 (H-13) and 1.44–1.55 (H-7/H-9a) and to the signal at $\delta = 1.58$–1.66 (H-9b) in the HMBC. In the ^1H–^1H–COSY spectrum only couplings from H-10 to the signals at $\delta = 4.71$ (H-12a) and to H-13 are observed. The quaternary carbon C-1 ($\delta = 34.15$) couples to H-10, H-6/H-8a, H-7/H-9a, H-9b, H-12a ($\delta = 4.71$) in the HMBC experiment. As proton H-9b shows cross peaks with H-7/H-9a and H-6/H-8a and the other proton of this methylene group H-9a (located in the multiplet with H-7) couples with H-5b/H-8b, H-9b and H-6/H-8a the methylene groups H-8a,b and H-9a,b must be adjacent. As C-7 couples not only to H-15, as known from the ^1H–^1H–COSY spectrum, but also to H-6/H-8a, H-7/H-9a, H-5a, H-9b and H-5b/H-8b, the HMBC spectrum proves that this molecule has a tricyclo[5.3.0.$0^{1,3}$]decane backbone.

The relative configuration was derived from the NOE experiment: H-10 shows a correlation with H-4_{ax} and H-6 as well as with the methylene group H-13. Proton H-6 itself interacts with methylene group H-15. H-4_{ax} gives a NOE signal indicating the proximity of methylene group H-14. From this, a *cis*-configuration for all substituents and *exo*-orientation of the isopropylidene group can be concluded.

The mass spectrum of pacifigorgia-1(6),10-diene (**4**) shows a molecular ion signal at *m/z* 204. From this the elemental composition of $C_{15}H_{24}$ is derived. In the ^1H-NMR spectrum four methyl groups can be detected. Two of the methyl groups represented by singlets at $\delta = 1.65$ and 1.71 (H-12, H-13) are attached to a quaternary olefinic carbon and the other two (H-14 and H-15) exhibit doublet signals in the aliphatic region ($\delta = 0.83$, 0.95) and are thus bonded to tertiary carbons. As the ^{13}C NMR spectrum shows four downfield shifted signals two double bonds must be present in this bicyclic compound. Four primary carbon atoms ($\delta = 18.15$, 18.35, 19.55, 26.04), four secondary carbons ($\delta = 23.56$, 27.51, 31.77, 33.02), four tertiary ($\delta = 32.92$, 39.86, 41.74, 124.40) and three quaternary carbons ($\delta = 131.50$, 137.23, 137.71) are found in the ^{13}C NMR. As both downfield shifted methyl groups (H-12 and H-13) show cross peaks in the ^1H–^1H–COSY spectrum with the olefinic proton H-10 at $\delta = 4.88$, an isobutylene group is evident. H-10 couples to H-2 ($\delta = 2.82$) which in turn couples to H-3/H-5a ($\delta = 1.73$–1.87), the proton next to the methyl group H-14, which is indicated through a cross peak in the ^1H–^1H–COSY spectrum. The methylene groups H-4 ($\delta = 1.36$–1.52; 27.51) and H-5 (5a: 1 H absorbing in the multiplet $\delta = 1.73$–1.87; 5b: 1 H in multiplet $\delta = 1.93$–2.10; 23.56) must follow in that order because H-4 couples to H-3/H5a ($\delta = 1.73$–1.87) and H-5b/H-8b/H-9a ($\delta = 1.93$-2.10). Furthermore, the

coupling between the proton H-7 ($\delta = 2.47$–2.57) to the methyl group H-15 ($\delta = 0.95$) and to the methylene group H-8a,b is indicated by cross peaks with the multiplets of H-8a ($\delta = 1.23$–1.31) and H-5b/H-8b/H-9a ($\delta = 1.93$–2.10). The methylene group H-8a,b in turn couples to the multiplets at $\delta = 1.93$–2.10 (H-5b, H-8b, H-9a) and 2.16–2.25 (H-9b), thus establishing the second ring separated by a double bond from the six-membered ring. From the HMBC it becomes clear that C-6 ($\delta = 137.7$) is bonded to C-7 ($\delta = 41.74$) and C-5 ($\delta = 23.56$) because it shows a coupling to H-15, H-8a and H-4a,b as well as to the multiplet H-5b/H-8b/H-9a. In the six-membered ring the connectivity is established through the couplings of C-2 ($\delta = 39.86$) to H-14, H-12, H-13 and H-4a,b on one hand and of C-4 ($\delta = 27.51$) to H-14, H-3/H-5a on the other hand. Carbon C-1 ($\delta = 137.23$) gives only poor couplings to H-8a and to the multiplet H-5b/H-8b/H-9a. With these data the pacifigorgiane skeleton is evident with the double bonds in 1(6) and 10 position. The observed NOE shows close correlation between H-10 and H-14, but not with H-3, which is only possible when the olefinic proton H-10 is turned towards the ring and the isobutylene group is *cis* to the methyl group H-14. As dehydration of the alcohol (−)-pacifigorgiol (**10**) with known absolute configuration (Martin, 1983) yielded the identical compound **4** in the product mixture, it was evident that all substituents are in *cis*-orientation.

The same techniques were applied to identify the structures of the pacifigorgiadienes **2**, **3**, **5**, **6** and the rearrangement product pacifigorgia-6,11-diene (**8**). The data of the 2-dimensional NMR experiments for **2**, **6** and **8** are given in Tables 1–3.

The absolute configuration of (+)-tamariscene (**1**) was established through the dehydration reaction of (−)-pacifigorgiol (**10**), which was isolated from the essential oil of *V. officinalis*. As illustrated in Fig. 1, path b, (+)-**2** and (+)-**4** were obtained in ca. 1:10 ratio. The same products, this time in ca. 1:1 ratio, were formed in the rearrangement reaction (Fig. 1, path a) of (+)-tamariscene by storage of a sample of this compound in chloroform at 8° C for 21 days. The identity of the products was proved by enantioselective GC and by GC–MS.

It is remarkable that in the dehydration reaction (Fig. 1, path b) the *cis* elimination, which would lead to (+)-**3** does not occur even though the conjugated, disubstituted diene should be thermodynamically favoured. When (−)-tamariscol (**9**) is submitted to dehydration with prolonged reaction time (Fig. 2) the elimination reaction leading to (−)-pacifigorgia-1,10-diene (**3**) and (−)-pacifigorgia-2,10-diene (**5**) is indeed taking place. Comparison of the dehydration products (−)-**3** and (−)-**5** and the earlier isolated authentic compounds by enantioselective GC led to the absolute configuration.

The structure of (−)-valerena-4(7),11-diene (**7**) was established by NMR investigation (Table 4). The relative configuration was assigned from the results of NOE experiments, the absolute configuration is assumed to be

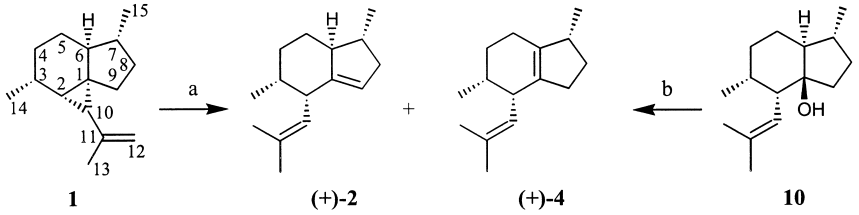

Fig. 1. Correlation reactions between tamariscene (**1**) and pacifigorgiol (**10**). Rearrangement conditions: (a) $CHCl_3$, 8°C, 21 days dehydration conditions: (b) pyridine, $SOCl_2$, 0°C, 3 min.

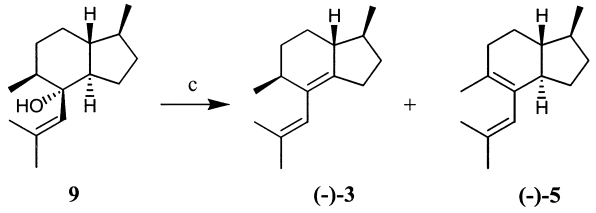

Fig. 2. Correlation reaction between tamariscol (**9**) and the pacifigorgiadienes (**3**) and (**5**). Dehydratisation conditions: (c) pyridine, $SOCl_2$, 0°C, 3 h.

identical to known oxygenated constituents of *V. officinalis*, with the same skeleton. The same applies to **6**, where the relative configuration was established through NOE experiments, but hydrogenation reactions could not reveal the absolute configuration by comparison with other pacifigorgianes as the rings are *cis*-fused.

For the rearrangement product (+)-pacifigorgia-6,10-diene (**8**) as obtained from (−)-tamariscol (**9**), only the relative configuration can be assigned (NOE) as the chiral centre at C-7 is eliminated and it is not known if the other two chiral centres at C-2 and C-3 are affected by the rearrangement reaction.

H-15	H-3a,b	H-3a,b, H-6

The co-occurrence of valerenanes and pacifigorgianes in *Valeriana officinalis* and the presence of tamariscene led to the assumption, that tamariscanes may be a common precursor for both valerenanes and pacifigorgianes. This is schematically rationalized in Fig. 3.

3. Experimental

3.1. General experimental procedures

GC: Orion Micromat 412 double column instrument with 25 m fused silica capillaries with polysiloxane CPSil-5 and polysiloxane CPSil-19 (Chrompack); Carlo Erba Fractovap 2150, 4160 gas chromatographs with 25 m fused silica capillaries with heptakis(2,6-di-*O*-methyl-3-*O*-pentyl)-β-cyclodextrin or heptakis(6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin in OV 1701 (50%, w/w), split injection; split ratio approx. 1:30; FID; carrier gas 0.5 bar H_2; injector and detector temperatures were 200 and 250°C, respectively. Preparative GC (Hard and König, 1994): Modified Varian 1400 and 2800 instruments, equipped with a stainless steel column (1.85 m×4.3 mm) with 10% polydimethylsiloxane SE-30 on Chromosorb W-HP; and Silcosteel® (Amchro) column (1.95 m×5.3 mm) with heptakis(6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin dissolved in polysiloxane SE-52 (1:1, w/w) on Chromosorb W-HP; FID; helium as carrier gas at a flow rate of 240 ml/min; injector and detector temperatures were 200 and 250°C, respectively. GC–MS measurements (EI, 70 eV) were carried out with a Hewlett Packard HP 5890 gas chromatograph coupled to a VG Analytical 70-250S mass spectrometer. Ion source temperature: 200°C. NMR-spectroscopy: NMR measurements were carried out with a Bruker WM 400 or a Bruker WM 500 instrument using TMS as internal standard. Polarimetry: measurements were carried out with a polarimeter 341 (Perkin Elmer) at 589 nm at 20°C. Due to very small amounts of isolated compounds only the sense of optical rotation is given to avoid inaccuracies. Dehydration of **9** was carried out by addition of thionylchloride to a solution of the

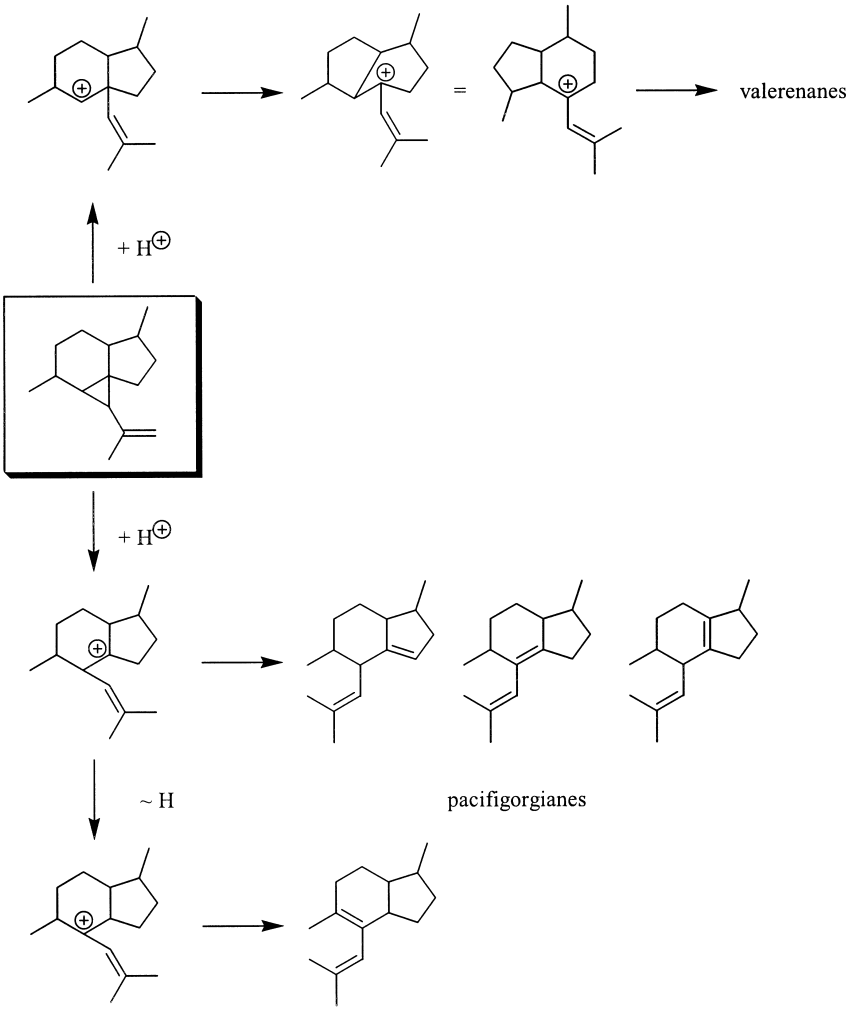

Fig. 3. Possible biogenetic relationship between tamariscene, pacifigorgianes and valerenanes.

alcohol in pyridine at 0°C. After 3 h of stirring water was added and the workup was performed with aq. $NaHCO_3$ solution and hexane extraction. For the dehydration of **10** the reaction was quenched after 3 min.

Hydrogenation was executed by bubbling hydrogen gas through the sample dissolved in hexane and addition of palladium/charcoal for 1 min and additional stirring of the reaction mixture under slight positive hydrogen pressure for 30 min.

Rearrangement reaction of (+)-**1** was performed in chloroform over a period of 21 days at 8°C.

3.2. Plant material and essential oils

Frullania fragilifolia (Tayl.) was collected at the Hinanger Wasserfall (Sonthofen, Allgäu, Germany) in November 1997 at 850 m alt. *Frullania tamarisci* was collected in Wintergreen (Virginia, USA) in May 1997 and at Loekeberg, Sweden, in September 1995. The essential oils of the liverworts were obtained by hydrodistillation (2 h) of aqueous homogenates of the fresh and green liverworts using ca. 1 ml of *n*-hexane as collection solvent. The oil of *Valeriana officinalis* (Europäisches Baldrianöl, Ref.: 971651, 14.08.97) was obtained from Paul Kaders GmbH, Hamburg, Germany.

3.3. Isolation of single constituents of essential oils

The isolation was carried out using column chromatography (silica gel 60 (Merck), eluent: *n*-pentane, −20°C) and preparative GC.

3.4. Tamariscene (*1*)

(−)-(1*R*,2*S*,3*R*,4*S*,7*R*,8*S*)-4,8-dimethyl-2-(1′-methylethylene)-tricyclo[5.3.0.0^{1,3}]decane, colourless oil; RI_{CPSil5}: 1355; sense of optical rotation (benzene): negative for enantiomer isolated from *Frullania fragilifolia* and *F. tamarisci*; positive for enantiomer isolated from *Valeriana officinalis*; ^{1}H NMR (400.1 MHz, C_6D_6): δ 0.54 (1H, *m*, H-4a), 0.72 (1H, *m*, H-5a), 0.95 (1H, *d*, H-10, $J=6.1$ Hz), 1.01 (3H, *d*, CH_3-3, $J=6.6$ Hz), 1.03 (3H, *d*, CH_3-7, $J=6.6$ Hz), 1.07 (1H, *dd*, H-2, $J=5.6$; 5,6 Hz), 1.13–1.26 (2H, *m*, H-6, H-8a), 1.33–1.41 (1H, *m*, H-4b), 1.44–1.55 (2H, *m*, H-7, H-9a), 1.58–1.66 (1H, *m*, H-9b), 1.66–1.76 (2H, *m*, H-5b, H-8b), 1.74 (3H, *s*, CH_3-11), 1.76–1.86 (1H, *m*, H-3), 4.71 (1H, *s*, H-12a), 4.89 (1H, *s*, H-12b); ^{13}C NMR (100.6 MHz, C_6D_6): $\delta=19.16$ (*q*, C-15), 21.29 (*q*, C-14), 24.37 (*q*, C-13), 28.93 (*d*, C-3), 29.04 (*t*, C-4), 30.06 (*d*, C-2), 30.32 (*t*, C-5), 30.41 (*t*, C-9), 33.55 (*d*, C-10), 34.15 (*s*, C-1), 35.53 (*t*, C-8), 44.64 (*d*, C-7), 50.19 (*d*, C-6), 109.50 (*t*, C-12), 144.66 (*s*, C-11); MS (EI, 70 eV), *m*/*z* (rel. int.): 204 $[M]^+$(26), 162 (23), 161 (21), 147 (48), 133 (30), 119 (24), 109 (25), 108 (40), 107 (38), 105 (55), 95 (30), 94 (36), 93 (85), 91 (55), 81 (40), 79 (53), 77 (35), 67 (36), 55(56), 53 (32), 43 (16), 42 (22), 41 (100), 39 (50).

Book reviews

The Wealth of India, First Supplement, Volume 1: A–Ci
Edited by R. Kochhar, National Institute of Science Communication, CSIR, New Delhi, India, 2000. 283 pp. ISBN 81-7236-208-0.

Historically, the first comprehensive dictionary of the economic products of the Indian subcontinent was prepared by a Scotsman, George Watt (1851–1931) and was published between 1889 and 1893. This was eventually superceded by the *Wealth of India* produced by the Indian Commonwealth Service, which appeared in 11 volumes from 1948 to 1976. What is presented here is the first of five volumes, which are intended to update the major work and to cover the literature from 1985 to 1992. The main plant entries in this first supplement include *Acacia*, *Arachis*, *Artemisia*, *Brassica*, *Camellia*, *Catharanthus* and *Citrus*. There are, of course, animal entries as well on bees, camels and civet cats. In general, older botanical names are retained, so that the pyrethrum plant, now properly referred to as *Tanacetum cinerariifolium*, appears in this volume as *Chrysanthemum*.

Since the agricultural, medicinal and industrial exploitation of the Indian flora depends on their phytochemistry, phytochemical information is very much to the fore. Results published in *Phytochemistry* appear on almost every page. There is a useful listing of the acetogenins isolated from *Annona* spp. with details of m.p., molecular formulae, source and biological activity. The medicinal uses of plants dominate in many entries. I was surprised that *Atropa acuminata*, a plant I have worked on myself, is treated here as being synonymous with *A. belladonna*, when our published work on the alkaloids and phenolics favour recognition as a distinct species in its own right. Incidentally, it is interesting to see that the product atropine which was formerly imported into India, is now harvested from *A. acuminata* plantations and exported to several countries.

I was concerned generally that the various entries failed to alert the reader to the toxic effects of some of the plant products. Thus, abrin, the protein of *Abrus precatorius* seed, is well known to be extremely poisonous. And yet it is stated that the seeds may be utilised for human consumption after (unspecified) processing and may also be used to treat prostate and breast cancer. I suspect that any medicinal uses applied to *Abrus* seed extracts have to be carefully monitored. The article on Neem (*Azadirachta*) was interesting in that in India the medicinal and cosmetic uses seem to be more important than the pesticidal value.

This volume is attractively produced and contains a workmanlike index. Although principally intended as a contribution to economic botany and the medicinal plant literature, it will be of interest and value to a wide audience of scientists.

African Traditional Medicine
H.D Neuwinger, Medpharm Scientific Publishers, Stuttgart, 589 pp., + 46 pp. supplement, hardcover. ISBN 3-88763-086-6. Price DM/sFr 198.

The African flora provides a rich source of drugs that have been used in traditional medicine. Reports on this use have been published in several books, some reviewed journals and quite often in quite unknown and obscure publications. Therefore, it had been quite difficult for scientists interested in a particular African plant to find out whether this plant had been used in traditional African medicine. As traditional medical application can give a hint to the active principles present in a plant, this information can be quite valuable.

Hans Dieter Neuwinger, who has already written important scholarly works on "African ethnobotany: Poisons and drugs" (1996) and "Afrikanische Arznei-

pflanzen und Jagdgifte'' (1994, 1998), has again drawn our attention to African medicinal plants. He has screened the available literature (books, journal articles in English, French, German) for papers on African traditional medicine. The result is a reference source covering 5400 African plant species and 16,300 medicinal applications.

The book is organised in short monographs of the 5400 plant species which have been ordered alphabetically. Each monograph lists particular medicinal applications such as ''headache, cough, narcotic effects, cardiac pains, anthelmintic, aphrodisiac or purgative'' followed by the plant organ used and a reference. These monographs are a treasure trove for information on African medicines which could lead to more detailed studies on ingredients and active principles. A supplement provides a key to plants used for particular medical applications.

The author is certainly right in his warning: ''Let's say it right away: this book is purely a reference book, not one to be read for entertainment. It documents in the form of a dictionary our knowledge of African plants with their immeasurable richness in variety of species and their use in traditional medicine.'' For a non-botanists it might be difficult to identify a particular plant (whose scientific name can be ambiguous because of synonyms) as no family names are provided. Also, the list of references appears to be small in comparison to the wealth of information provided. In addition, no information is given on active ingredients or mode of actions. However, more expanded information can be found in ''African ethnobotany'' or ''Afrikanische Arzneipflanzen und Jagdgifte 1994, 1998), of the same author.

In conclusion, *African Traditional Medicine* is a true reference book which should not me missed by phytochemists, pharmacologists or ethnopharmacologists interested in African ethnobotany.

Molecules of Interest

The latest hype on Hyp-*O*-glycosylation codes

Marcia Jane Kieliszewski *

Department of Chemistry and Biochemistry, Ohio University, Athens, OH 45701, USA

Received 30 November 2000; received in revised form 13 January 2001

Abstract

Contemporary glycobiology reflects the intense interest in glycoproteins and their biological roles. Addition of saccharides by *N*- or *O*-glycosylation is precise rather than random and forms a uniquely interactive molecular surface. We designate these well conserved glycomotifs as glycomodules to emphasize their functional significance. Thus, elucidation of the glycosylation codes that determine saccharide addition is a significant goal. The focus here is on the Hyp *O*-glycosylation of cell wall proteins. This involves two consecutive posttranslational modifications, proline hydroxylation and glycosylation. Peptide sequence rather than conformation seems to determine these modifications. Hyp glycosylation occurs in two distinct modes: Hyp arabinosylation and Hyp galactosylation. The Hyp contiguity hypothesis predicts arabinosylation of contiguous Hyp residues and galactosylation of clustered non-contiguous Hyp. Elucidation of Hyp glycosylation codes involves the design and expression of putative glycomotifs as simple repetitive peptides. Thus, repetitive $(Ser\text{-}Hyp)_n$ directed Hyp galactosylation resulting in the exclusive addition of arabinogalactan polysaccharide to all the non-contiguous Hyp residues, and a new AGP. Another repetitive peptide from gum arabic glycoprotein, containing both contiguous and non-contiguous Hyp, directed both modes of Hyp glycosylation. Furthermore, expression of the $(Ser\text{-}Hyp_x)_n$ series confirmed the arabinosylation of contiguous Hyp. Thus, the Hyp contiguity hypothesis is a useful predictive tool in the functional genomics toolbox. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Hydroxyproline-rich glycoprotein; Arabinogalactan-protein; Extensin; Glycosylation; Cell walls

1. Introduction

Glycobiology is currently of intense interest because biologists now know that carbohydrate is much more than a dietary filler. Carbohydrate addition to proteins confers new properties that contribute to biological function. This glycosylation is not random. It is not uniform. It is not readily deduced from genome readouts. It is the most common posttranslational modification and involves more than 50% of eukaryotic proteins (Apweiler et al., 1999). As a multipurpose tool, it yields a dazzling array of designer products to suit the function planned. So, what determines it?

Protein glycosylation involves the enzymic transfer of specific sugars to specific amino acid residues of a protein. While Table 1 shows that a surprising number of amino acids are potential sugar acceptors, they fall into two major categories: *N*- and *O*-glycosylation. Thus asparagine residues are involved in *N*-glycosylation while *O*-glycosylation involves the hydroxyamino acids, mainly serine and threonine, occasionally tyrosine, and, specific to plants, hydroxyproline. Recent advances in identifying Hyp glycosylation motifs and the elucidation of Hyp glycosylation codes are the focus of this review.

2. *N*- And *O*-glycosylation motifs

N- and *O*-glycosylation differ in virtually all aspects: biosynthetic strategy, donor sugars, glycosylation site sequence motifs and chemical stability of the sugar-amino acid "glycopeptide" linkage. Although both types of glycosylation construct complex sugar sequences (oligosaccharides or repetitive polysaccharides) by "strict order" stepwise addition (Staudacher and Marz, 1998), the sugars and linkages differ. *N*-glycosylation involves mannose addition to a chitobiose core followed by the block transfer of a preformed oligosaccharide from its dolichol lipid carrier to the polypeptide (Sturm, 1995). In contrast *O*-glycosylation is generally viewed as

sequential transfer of single sugar residues from their sugar nucleotides to the polypeptide. This includes neutral sugars, amino sugars and uronic acids, but not mannose. However, there are exceptions: Yeast transfers dolichol-activated mannose to Ser or Thr residues of secretory proteins in the ER (Strahl-Bolsinger et al., 1999). In plants lipid-linked acidic arabinosyl oligosaccharides are transferred to HRGP acceptors (Bolwell, 1986). One intermediate contained about 15 sugar residues and a galactose reducing end (Hayashi and Maclachlan, 1984). This implies the block transfer of lipid-linked oligosaccharide modules as building blocks of AGP polysaccharides and a possible paradigm for pre-assembly of other complex modular polysaccharides.

The genome does not explicitly encode glycosylation sites as ''glycocodons'' but implicitly as codes within a code. These glycosylation codes include the classic *N*-glycosylation motif Asn-Xaa-Thr/Ser, the clustered Ser/Thr *O*-glycosylation sites of animal mucins and the serine consensus sequences that act as substrate for the xylosyltransferase that initiates the attachment of glycosaminoglycans to the core proteins of animal proteoglycans (Brinkmann et al., 1997).

3. Localization of hydroxylation and glycosylation

Glycosylation codes depend on another code, the N-terminal signal sequence, to target the polypeptide to the ER/Golgi for posttranslational processing. Additional codes, or targeting signals determine final destinations. These include retention by the ER/Golgi, or further transfer to protein storage bodies, central vacuole, or plasma membrane. The major ''default'' secretory pathway exiles HRGPs to the exterior, where they appear as components of sticky stigma adhesives, root-cap slime lubricants and wound-induced gummosis exudates. HRGPs also participate in the extracellular matrix as major components of the plasma membrane glycocalyx (GPI-anchored AGPs; Serpe and Nothnagel, 1999) and crosslinked cell wall networks (extensins) while the role of the repetitive proline-rich proteins (PRPs) is less clear (Frueauf et al., 2000).

As Hyp-glycosylation forms the interactive molecular surface of most HRGPs, carbohydrate must be a major determinant of function. It is therefore of considerable interest to elucidate the rules that direct the addition of saccharide sidechains to the extended Hyp-rich polypeptide template that determines their spatial orientation.

The glycosylation profile of an HRGP results from two consecutive posttranslational modifications: The first occurs in the ER (Wojtaszek et al., 1999) and involves hydroxylation of some, but not all proline residues by prolyl hydroxylases. The second occurs in the Golgi and involves glycosylation of some, but not all hydroxyproline residues by glycosyltransferases. Thus prolyl hydroxylases, glycosyltransferases and the HRGP polypeptide itself are the primary determinants of HRGP glycosylation.

If prolyl hydroxylases and glycosyltransferases are the primary enzymic determinants of HRGP glycosylation patterns what features of the macromolecular substrate do these enzymes recognize?

4. The Hyp contiguity hypothesis

Plant prolyl hydroxylase hydroxylates peptidyl proline but the substrate specificity is not well defined, although poly-L-proline is an excellent substrate (Tanaka et al, 1980). In aqueous solution this occurs as a characteristic three-residue per turn extended helix, designated polyproline II. Initially this suggested recognition of conformation rather than sequence. However, subsequent work, including CD spectroscopy, shows that Hyp residues and glycosylated Hyp occur in sequences lacking a

polyproline II conformation (Kieliszewski and Lamport, 1994). This implies that plant prolyl hydroxylase, like animal prolyl hydroxylase, is primarily directed by the amino acid sequence of the substrate. However, peptide motifs hydroxylated by plants differ from those hydroxylated by animals (Myllyharju and Kivirikko, 1999); for example, plants do not hydroxylate transgenic collagen (Ruggiero et al., 2000).

Two modes of Hyp glycosylation characterize the HRGPs, namely, arabinosylation and galactosylation. Arabinosylation predominates in the extensins and PRPs; on alkaline hydrolysis they yield Hyp-arabinosides. Galactosylation gives rise to the arabinogalactan polysaccharides of arabinogalactan-proteins; on alkaline hydrolysis AGPs yield Hyp-polysaccharides. What structural differences might account for this difference in glycosylation? A preponderance of highly conserved peptide motifs containing contiguous Hyp residues in the extensins and clustered non-contiguous Hyp residues in the arabinogalactan proteins suggested a simple glycosylation code and the concept of functional glycomodules (Table 2). Thus, the Hyp contiguity hypothesis, as originally formulated (Kieliszewski and Lamport, 1994), predicted arabinosylation of contiguous Hyp residues and galactosylation of clustered, non-contiguous Hyp residues. We designate these evolutionarily conserved glycomotifs as glycomodules to emphasize their likely functional significance (Shpak et al., 1999) although it remains to be fully elucidated. Thus, further refinement and verification of the Hyp contiguity hypothesis will help to identify glycomodules from HRGP gene sequences and thus contribute to the functional and structural modeling of the plant extracellular matrix.

5. Experimental testing of the Hyp contiguity hypothesis

Rigorous testing of the Hyp contiguity hypothesis demands an initial identification of glycosylated Hyp-rich motifs by direct methods. There are two approaches, degradative and biosynthetic. The first depends on degrading an isolated HRGP to yield identifiable glycopeptides; the second depends on the biosynthesis of identifiable glycopeptides through the genetic engineering of endogenous test substrates. Both approaches depend on characterizing the products based on the very different chemical reactivities of peptide bonds and glycosidic linkages towards aqueous acid, aqueous alkali, and anhydrous hydrogen fluoride. The following summarizes the salient points:

Both peptides and glycosides are acid-labile, especially arabinofuranosides which cleave at pH 1. However, peptides and glycosides exhibit markedly different labilities to alkali. While peptides undergo base-catalyzed hydrolysis, glycosidic linkages are stable with the significant exception of *O*-seryl- or *O*-threonyl-linked sugars that are cleaved in mild alkali due to elimination (not hydrolysis) of the sugar from the β-carbon. Thus, glycosylated serine and threonine cannot be directly isolated and quantified, but must be inferred indirectly. On the other hand the Hyp-*O*-glycosidic linkage is to the γ-carbon and is base-stable. Complete alkaline hydrolysis of the polypeptide releases intact Hyp glycosides: Hyp arabinosides from extensins, Hyp arabinosides and Hyp polysaccharides from AGPs, and Hyp hetero-oligosaccharides from cell walls of the Chlorophycean algae (Lamport, 1980). Further chromatographic separation yields a quantitative Hyp glycoside profile that indicates the number of Hyp glycosylation sites in an HRGP and the relative abundance of each species, but not their position.

Finally, there is the stability of the peptide bond in anhydrous hydrogen fluoride (HF) in contrast to the rapid HF-solvolysis of glycosidic linkages (Mort and Lamport, 1977). Removal of the *O*-glycosides from various HRGP polypeptides enabled both direct and indirect peptide sequence analysis, hence identification of putative Hyp glycosylation motifs whose number should tally with the Hyp glycoside profile. But assigning the appropriate Hyp arabinoside or Hyp polysaccharide to each glycomotif based on the Hyp contiguity hypothesis requires independent verification.

Defining the position of each Hyp-glycoside in an isolated HRGP is difficult. In theory a "brute force" approach based on enzymic or partial alkaline hydrolysis of the glycoprotein should yield unique glycopeptides that define the glycosylation motifs. However, there are limitations to that approach when dealing with highly glycosylated macromolecules that are difficult to purify and not available in bulk (i.e. tens to hundreds of milligrams). While this degradative approach is feasible for the PRPs (Kieliszewski et al., 1995), it is difficult for extensins and extremely difficult for AGPs.

An alternative strategy uses a biosynthetic approach that exploits the highly repetitive character of HRGPs. Indeed, the PRPs and extensins frequently contain only two major repeat motifs while AGPs exhibit a more cryptic periodicity consisting of simple motifs largely defined by carefully spaced Hyp residues. Therefore, we considered the possibility of presenting the cells with a range of simple repetitive test motifs as candidates for hydroxylation and glycosylation.

Table 2
HRGP glycomodules

Repetitive peptide motif	Hydroxyproline oligosaccharide
$(Xaa^{a})_{1–3}$-Hyp-$(Xaa)_{1–3}$-Hyp	Arabinogalactan polysaccharide
Xaa-Hyp-Hyp	Ara_{1-3} addition mainly to first Hyp
Xaa-Hyp-Hyp-Hyp-Hyp	Ara_{3-4} addition to Hyp residues

[a] Xaa is commonly Ser, Ala, Thr, but not Hyp.

Earlier work had demonstrated the feasibility of a genetic engineering approach based on ligation of small overlapping oligonucleotides for the construction of synthetic genes and the expression of repetitive proteins in bacteria (McGrath et al., 1990). Therefore, we explored the extension of this technique to the elucidation of posttranslational codes in plants. This meant designing simple repetitive polypeptides to encode putative glycosylation motifs, generally only one or two of a kind in each construct to avoid ambiguity. Addition of an appropriate N-terminal signal peptide targeted these polypeptides into the ER/Golgi secretory pathway. Further addition of a C-terminal green fluorescent protein (GFP) reporter facilitated separation of these new HRGPs from others lacking GFP, and in amounts sufficient for biochemical characterization: Hyp-glycoside profiles, sugar and amino acid analyses, circular dichroism, NMR, and so on.

Our first designs tested the hypothesis that clustered non-contiguous Hyp motifs direct the addition of arabinogalactan-polysaccharide to AGPs. Thus a synthetic gene encoding (Ser-Pro) repeats gave rise to a fusion glycoprotein which was an arabinogalactan-protein (Shpak et al., 1999). Repetitive Ser-Pro was an excellent substrate for tobacco prolyl hydroxylase, and the non-contiguous Hyp directed polysaccharide addition exclusively to all the Hyp residues, creating a new AGP.

Another synthetic gene encoding a variant of the *Acacia senegal* 19-residue gum arabic glycoprotein consensus sequence contained motifs for polysaccharide addition to Hyp (Ser-Hyp-Ser-Hyp-Thr-Hyp) and for Hyp arabinosylation (contiguous Hyp blocks). Thus, expression of the repetitive gum arabic glycoprotein consensus sequence in *Nicotiana tabacum* directed arabinosides to some Hyp residues and polysaccharide to others consistent with known Hyp glycoside profiles for native gum arabic glycoprotein (Shpak et al., 1999).

These results established the feasibility of the approach and make it possible to move on and ask more detailed questions about the glycosylation and molecular design of HRGPs. For example, what defines "clusters of non-contiguous Hyp"- how much separation is required to confer non-glycosylated status on a lone Hyp residue? Which intervening amino acids confer non-glycosylated status? Does that explain the absence of Hyp-polysaccharide from the non-contiguous Hyp motif, Tyr-Thr-Hyp-Ser-Hyp-Lys-Pro-Hyp, of the moncocot extensin THRGP? Do flanking residues modify the glycosylation code? Does the polysaccharide vary according to the motif? Does it vary from species to species or even within a species, for example by undergoing processing in different tissues?

To date we know that in tobacco cultures repetitive $(SP)_n$ and $(AP)_n$ give very similar glycosylated products (L. Tan and M. Kieliszewski, unpublished data), indicating that within a species and particular tissue type, arabinogalactan polysaccharide attached to non-contiguous Hyp is probably identical both in size, composition, and frequency of attachment. Comparison between species is instructive. The similarity between the compositions of Hyp-polysaccharides isolated from *Acacia senegal* GAGP and transgenic *Nicotiana tabacum* "GAGP" confirms Akiyama's observation: "The structure and the sugar compositions of the carbohydrate portions of the tobacco AGP are quite similar to the *A. senegal* gum, suggesting that they are closely related to each other" (Akiyama and Kato, 1981). Such similarity in polysaccharide structure between two widely separated families, *Leguminosae* and *Solanaceae*, argues for a global Hyp glycosylation code, at least in higher plants. It also implies a certain elegant simplicity where an AGP peptide template directs the number and arrangement of identical polysaccharide substituents, which are tailored to the tissue by the expression of respective glycosyl transferases, and which might undergo further modification or processing of the polysaccharide sidechains (Cheung et al., 1995).

Most recently we tested the contiguous Hyp, $(SP_x)_n$ series of expression products: $(Ser\text{-}Hyp_2)_n$, $(Ser\text{-}Hyp_3)_n$ and $(Ser\text{-}Hyp_4)_n$ (Shpak and Kieliszewski, unpublished data). They confirm that arabinosylation of contiguous Hyp begins with dipeptidyl Hyp, at least in tobacco. However, increasing the Hyp contiguity increased both the number of Hyp residues arabinosylated in the glycomotif and the size of the added arabinooligosaccharide. Surprisingly however, the putative $(Ser\text{-}Hyp_3)_n$ product contained a mixture of Hyp-glycosides including Hyp-polysaccharide, rather than the expected uniform arabinosylation. This apparently anomalous addition of polysaccharide was due to incomplete hydroxylation of $(Ser\text{-}Pro_3)_n$ resulting in a mixture of contiguous and non-contiguous Hyp residues. The virtual absence of $Ser\text{-}Pro_3$ motifs in *Nicotiana* (compared with other species like *Acacia* and *Arabidopsis*) suggests that tobacco prolyl hydroxylase has a low affinity for an unusual substrate. This emphasizes that the specificity of multiple prolyl hydroxylases underpins the glycosylation framework of HRGPs.

These results with synthetic genes were consistent with the Hyp contiguity hypothesis and encouraged us to extend the genetic engineering approach to naturally occurring HRGPs, particularly the "difficult-to-purify" AGPs notoriously present as mixtures (Serpe and Nothnagel, 1999). Could we isolate a pure GFP-AGP fusion glycoprotein free from other AGPs? And would its glycosylation profile conform to that predicted by the Hyp contiguity hypothesis? We chose LeAGP1 in view of its outstanding interest as the major AGP of tomato, the likely occurrence of a homolog in tobacco, and the availability of the LeAGP1 gene (Gao et al., 1999). As predicted, LeAGP1 containing EGFP was significantly more hydrophobic than other endogenous AGPs thus permitting purification of LeAGP1, the first AGP purified to homogeneity. The experimentally determined

Hyp glycoside profile agreed with that predicted from the Hyp contiguity hypothesis (Z.D. Zhao, A. Showalter and M. Kieliszewski, unpublished data).

6. Conclusion

To conclude we suggest that relating the structure and function of extracellular matrix macromolecules is not as difficult as once feared. It is now possible to make cautious predictions about HRGP structure starting from the primary sequence, and perhaps even genomic sequences. The clear distinction between Hyp arabinoside motifs of extensins and Hyp polysaccharide motifs of AGPs suggests a molecular architecture built of small functional units or glycomodules. In "mix and match" mode an appropriate blend of glycomodules results in HRGPs tailored to the tissue. Thus, in the cell wall the rigidity and tensile properties of extensin depend on stabilization of the HRGP polypeptide by the arabinosylated Ser-Hyp_4 glycomodule. On the other hand, at the surface of the plasma membrane the Hyp-arabinogalactan polysaccharides of GPI-anchored AGPs act as a hydrophilic buffer retaining water through the mobility of their 1,6-linked oligosaccharide sidechains.

Review

Phytoecdysteroids: biological aspects

Laurence Dinan*

Department of Biological Sciences, University of Exeter, Hatherly Laboratories, Prince of Wales Road, Exeter, Devon, EX4 4PS, UK

Received 30 November 2000; received in revised form 8 February 2001

Abstract

Phytoecdysteroids are a family of about 200 plant steroids related in structure to the invertebrate steroid hormone 20-hydroxyecdysone. Typically, they are C_{27}, C_{28} or C_{29} compounds possessing a 14α-hydroxy-7-en-6-one chromophore and A/B-*cis* ring fusion (5β-H). In the present review, the distribution, biosynthesis, biological significance and potential applications of phytoecdysteroids are summarised. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Phytoecdysteroid; Distribution; Biological activity; Biosynthesis; 20-Hydroxyecdysone

1. Introduction

Ecdysteroids were first recognised as steroidal hormones controlling moulting and metamorphosis in insects. Today, it is realised that these steroids are present at all stages of insect development, regulating many biochemical and physiological processes: in newly-laid eggs, during embryonic and postembryonic developments and in adult insects, regulating aspects of development, metamorphosis, reproduction and diapause. Ecdysteroids are the steroid hormones of all classes of arthropods and probably of other invertebrates too (see Koolman, 1989, for reviews). Analogues of ecdysteroids (phytoecdysteroids) also occur in a certain proportion of plant species. Their function in plants is still conjectural, but it is believed that they provide some degree of protection against non-adapted phytophagous insects and/or soil nematodes (Bergamasco and Horn, 1983; Kubo and Hanke, 1986). The first ecdysteroid, ecdysone (E), was isolated by Butenandt and Karlson (1954) from silkworm pupae and its structure was finally elucidated in 1965 by means of X-ray crystallography (Huber and Hoppe, 1965). Subsequently, 20-hydroxyecdysone (Fig. 1; 20E; see Lafont et al., 1993, for standardised abbreviations for ecdysteroids) was identified from a number of arthropod sources and this compound is now generally recognised as the major biologically active ecdysteroid in most invertebrate systems, although this

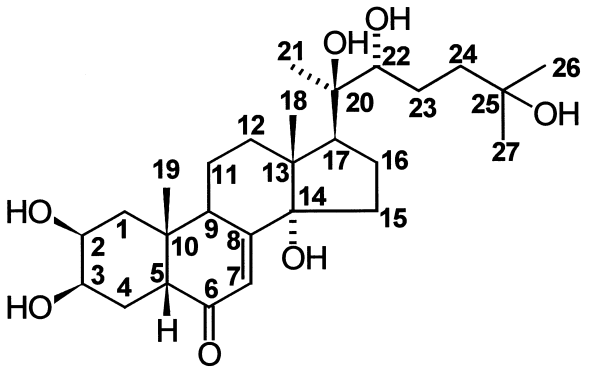

Fig. 1. Structure of a typical ecdysteroid (20-hydroxyecdysone), showing the numbering of the carbon atoms.

does not exclude the possibility that other ecdysteroids may be active in certain types of invertebrate or at specific stages of development. The first isolations of ecdysteroids from plant sources were a rather remarkable coincidence. While investigating the chemical constituents of the leaves of *Podocarpus nakaii* for antitumour agents, Nakanishi et al. (1966) isolated three polyhydroxylated steroids (ponasterones A, B and C). At almost the same time, Takemoto's group isolated 20E and inokosterone from the roots of *Achyranthes fauriei* (Takemoto et al., 1967). Likewise, 20E was found in the wood of *Podocarpus elatus* (Galbraith and Horn, 1966), the rhizomes of *Polypodium vulgare* (Heinrich and Hoffmeister, 1967) and in dry pinnae of *Pteridinium aquilinum* (Kaplanis et al., 1967). These early reports stimulated further research and it soon became apparent that ecdysteroids were rather widespread in plants (reviewed in Hikino and Hikino, 1970; Horn, 1971; Nakanishi, 1971, 1992; Prakash and Ghosal, 1979; Hetru and Horn, 1980; Abubakirov, 1982; Bergamasco and Horn, 1983; Horn and Bergamasco, 1985; Kubo and Hanke, 1986; Lafont and Horn, 1989; Camps, 1991; Lafont and Wilson, 1996). Since the discovery of ecdysteroid analogues in plants, it has been convenient to designate these as phytoecdysteroids to differentiate them from those isolated from insects, crustaceans and other animal sources (zooecdysteroids). However, this division must be regarded as non-exclusive, since many ecdysteroids (e.g. E, 20E, makisterone A, ajugasterone C) are present in both animals and plants. This review will consider the distribution of ecdysteroids in the plant world, their structural diversity, biosynthesis, possible functions and also their potential agrochemical and medicinal applications. Emphasis will be placed on the more recent literature. The reader is referred to the excellent reviews listed above for earlier literature.

2. Distribution of ecdysteroids in the plant world

Phytoecdysteroids (PEs) have been reported to occur in over 100 terrestrial plant families representing ferns, gymnosperms and angiosperms. They are found in both

annuals and perennials. The ecdysteroid-like compound 14α-hydroxypinnasterol (like 20E, but having unsaturation at C-4 and a 3α-hydroxyl function, yet lacking a 25-hydroxyl group) and related compounds have been also characterized from the red marine alga *Laurencia pinnata* (Fukuzawa et al., 1986). In both an early survey of Japanese plants (Imai et al., 1969) and a recent survey of more widely-distributed plant species (Dinan, 1995a), it was found that 5–6% of the tested species were positive for ecdysteroids. The occurrence of PEs in plants does not seem, at first sight, to reflect any precise evolutionary trend, but appears rather random. However, recent studies focussing on significant numbers of species in specific families indicate that the occurrence of ecdysteroids can be related to phylogenetic position (Dinan et al., 1998; Savchenko et al., 1998; Zibareva, 2000). For example, within the genus *Chenopodium*, ecdysteroids appear to be absent from all members of the subgenus *Ambrosia* and present in most (but not all) members of the subgenus *Chenopodium* (Dinan et al., 1998). This study focussing on the Chenopodiaceae revealed the need to study a significant number of related species before the taxonomic patterns became discernable. Since less than 2% of the world's flora has been investigated for the presence of ecdysteroids, it is not surprising that the distribution of ecdysteroid-containing species has appeared random to most investigators. However, it can be stated with some certainty that even in families which have been previously regarded as devoid of phytoecdysteroids, representatives can be found which are ecdysteroid-positive provided that enough species are screened (e.g. Gramineae and Solanaceae; Dinan, 1995a; Savchenko et al., 2000). There does not appear to be a correlation between the frequency of positive species in a family and the levels of ecdysteroids found. For example, certain species in the genera *Leuzea* (*Rhaponticum*) and *Serratula* contain large amounts of ecdysteroids (Volodin et al., 1993), but overall the frequency of ecdysteroid-containing species in the Compositae is rather low (Sarker et al., 1997; Dinan et al., unpublished). In most ecdysteroid-containing species, levels are typically 0.1% or less of the dry weight. However, as indicated above, levels attain much higher levels in certain organs of particular species: e.g. 3.2% in the stem of *Diploclisia glaucescens* (Bandara et al., 1989). Ecdysteroid patterns may be complex. 20E seems to be the most abundant PE. It is usually accompanied by one or two other major ecdysteroids (e.g. *Rhagodia baccata*; Dinan et al., 1999b) and a plethora of other minor PEs (e.g. *Silene otites*; Báthori et al., 1999). The other major PEs are normally related to 20E by one biochemical change (e.g. 5β-hydroxylation generating polypodine B or 24β-methyl substitution generating makisterone A). The composition of the main and minor constituents of a species is often changed during the course of development (summarised in Lafont et al., 1991), and, moreover, their contents vary in the different parts, or even between plants at the same stage of development (e.g. *Limnanthes douglasii*: Sarker et al., 1997). There seems to be no general rule as to where the largest concentrations of PEs are located: fruits, flowers, bark, rhizomes, roots or seeds. Indeed, the concentration and chemical nature of the PEs may vary, and often changes, with the plant part, according to season, the habitat, vegetation period, and developmental stage (Dinan, 1992a,b; Grebenok and Adler, 1991). However, evidence is gradually accumulating that ecdysteroid concentrations are highest in tissues which are most important for the survival of the plant or, in the case of annuals, of the species into the next generation. Although it is by no means conclusive, these variations in ecdysteroid levels and profiles during development and between organs/plants can be most readily reconciled with a role in phytophagous predator deterrence, rather than the other suggested functions for PEs (see below). In theory, the profile of ecdysteroids (especially the cocktail of minor ecdysteroids) could be used as a chemical fingerprint for chemotaxonomic purposes. The variations in levels and profiles of ecdysteroids during development complicate this application of PEs. However, seed extracts do appear to have value in this regard (Zibareva, 1997; Dinan et al., 1998, 2000). Various chromatographic procedures applicable for the separation of PEs were recently reviewed (Lafont et al., 1994).

3. Structural diversity

A compilation of known ecdysteroid structures up to 1995 has been published (Lafont and Wilson, 1996). Structural diversity among (phyto)ecdysteroids has been previously reviewed (Hetru and Horn, 1980; Lafont and Horn, 1989; Lafont et al., 1991; Lafont, 1997,1998). In the following discussion, references are cited for PEs which appeared in the literature after 1995; for compounds first published prior to this, the reader is referred to The Ecdysone Handbook (Lafont and Wilson, 1996). Most PEs possess a cholest-7-en-6-one carbon skeleton (C_{27}), derived biosynthetically from cholesterol. Some phytoecdysteroids are derived from phytosterols and thus possess a C_{28} or C_{29} skeleton, with an alkyl group at C-24. In all naturally occurring PEs, the methyl groups at C-10 and C-13 have a β-configuration. The B/C- and C/D-ring junctions are always *trans*. The A/B-ring junction is normally *cis* (5β-H), and only rarely *trans* (5α-H). Most ecdysteroids possess a hydroxyl group in the 14α-position. The 14α-hydroxy-7-en-6-one chromophore results in a characteristic ultra-violet absorption with λ_{max} at 242 nm in methanol. Although variation in the steroid ring structure is not substantial, significant variation lies in the number, position and

orientation of the hydroxyl groups and the conjugating moieties linked through these. The commonly hydroxylated sites are the 2β-, 3β-, 14α-, 20*R*- and 22*R*- positions, which together give rise to the highly biologically active ponasterone A (25-deoxy-20-hydroxyecdysone). Hydroxyl groups may be present at the 1α- (e.g. integristerone A), 1β- (e.g. 1-*epi*-integristerone A; Sarker et al., 1998a), 2α- (e.g. paristerone), 3α- (e.g. 3-*epi*-2-deoxyecdysone), 5α- (e.g. 5α-polypodine B), 5β- (e.g. polypodine B), 9- (e.g. viperidinone), 11α- (e.g. turkesterone), 12β- (e.g. 22-dehydro-12-hydroxycyasterone; Calcagno et al., 1995) 19- (e.g. sogdisterone), 21- (e.g. 22-deoxy-20,21-dihydroxyecdysone; Dinan et al., 1999b), 22*S*- (e.g. 22-*epi*-20-hydroxyecdysone) 24*S*- (e.g. pteroserone), 24*R*- (e.g. 24-*epi*-pterosterone), 25- (e.g. 20-hydroxyecdysone), 26*R*/*S*- (e.g. inokosterone), 28- (e.g. makisterone D) and/or 29- (e.g. amarasterone B) positions, but rarely at C-23 (gerardiasterone [Báthori et al., 1998], 23-hydroxycyasterone, rapisterone). 21-Hydroxyecdysteroids have only recently been detected (Báthori et al., 1999; Dinan et al., 1999a,b). The hydroxyl group(s) may also be involved in glycosidic (galactoside [e.g. Baltayev, 1998; Sadikov et al., 2000], glucoside, xyloside), ester [acetate, benzoate, cinnamate, 3-*p*-coumarate, crotonate [2-deoxy-20-hydroxyecdysone 3-crotonate; Báthori et al., 1997] 3-hydroxybutanoate [venustone], pyrrole 2-carboxylate [canescensterone], sulphate), ether (methoxy; e.g. polypodoaurein) and/or isopropylidene (2,3- or 20,22-monoacetonide) bond formation resulting in a wide variety of ecdysteroid conjugates.

In keto-ecdysteroids, an oxo-group may be located at the 2- (e.g. 2-dehydro-3-*epi*-20-hydroxyecdysone; Sarker et al., 1998b), 3- (e.g. silenosterone), 12- (e.g. ajugalactone), 17- (e.g. rubrosterone), 20- (e.g. poststerone) or 22- (e.g. 22-oxo-cyasterone) position, in addition to the characteristic one at C-6. The ecdysteroid-related compound calonysterone has an unusual structure to ring-B (6-hydroxy-5,8-dien-7-one; Canonica et al., 1973) and its chemical formation from 20E has been reported (Suksamrarn et al., 1994). Olefinic bonds have been so far reported at 4- (e.g. 14α-hydroxypinnasterol), 8- (e.g. praemixisterone), 9(11)- (e.g. kaladasterone), 12- (e.g. stachysterone A), 14- (e.g. podecdysone B), 24- (e.g. stachysterone C), 25- (e.g. ajugasterone B or decumbesterone A [Takasaki et al., 1999]) and/or the 24(28)- (e.g. 24(28)-dehydromakisterone A) positions in unsaturated PEs. In some of these compounds the conjugated system of the chromophoric group is extended with the result that, in the UV-spectrum, the λ_{max} is shifted to longer wavelength (e.g dacryhainansterone, which is a 7,9-dien-6-one, absorbs maximally at 298 nm in methanol). A few ecdysteroid analogues have been isolated which lack unsaturation at C-7 (cheilanthones A and B, 7,8-dihydroajugasterone C and tenuifoliosides A and B).

When a one- or two-carbon alkyl group is present at C-24, resulting in a C_{28} (e.g. makisterone A [24*R*] or 24-*epi*-makisterone A [24*S*]) or a C_{29} (e.g. makisterone C) carbon skeleton, such extention of the C_{27} skeleton provides a basis for the classification of these compounds into C_{28}, C_{29} or C_{30} (if a 4-methyl group is also present; e.g carpesterol) PEs. The alkyl group may be unsaturated (methenyl [e.g. 24(28)-dehydromakisterone A] or ethenyl) or hydroxylated at C-24[1] (e.g. makisterone D) or C-24[2] (e.g. amarasterone B), or a combination of these (e.g. 24(24[1])[*Z*]-dehydroamarasterone B; Baltayev et al., 1997). Rapisterone C is currently unique in possessing a 23-alkyl (ethyl) group (Baltaev, 1992). Carpesterol and 14α-hydroxycarpesterol possess a 4-methyl group (Kusano et al., 1975) and, in stachysterone A, the methyl group usually located at C-13 is translocated to C-14 (Imai et al., 1970). Further oxidation of a primary hydroxyl group, resulting in a carboxylic acid, has been detected in ecdysteroids isolated from invertebrate sources (e.g. at C-26 to yield ecdysonoic acid). Ecdysteroids with free carboxyl groups have not yet been isolated from plant sources. However, several PEs possess a lactone ring in the side-chain, where a carboxyl at C-24 (sidisterone), C-26 (e.g. [29-nor]cyasterone), or C-29 (carthamosterone) forms an internal ester with a hydroxyl at C-20 (sidisterone), C-22 (e.g. ajugalactone), C-25 (carthamosterone), C-28 (e.g. [29-nor]cyasterone) or C-29 (e.g. repansterone; Calcagno et al., 1996). A furan ring may be generated in some cases by cyclization of a parent C_{27} skeletal side-chain through dehydration of C-22 and C-25 hydroxyls (e.g. ajugasterone D and stachysterone D). PEs lacking either a complete or a partial side-chain, possessing a C_{19} (e.g. rubrosterone), C_{21} (e.g. poststerone) or C_{24} (e.g. sidisterone) parent skeleton, have been characterized from several plants and are regarded as ecdysteroid metabolites because of their low biological activities (in insect systems: e.g. Dinan et al., 1999a).

If one considers combinations of the known individual structural modifications of PEs, this suggests that there are over 1000 possible structures which might occur in nature, of which ca. 250 permutations have been identified so far, leaving many more which could be detected in the future. It should be mentioned that most of the structural modifications are found only in minor ecdysteroids and the available biological evidence suggests that most of these modifications result in compounds which are less active than 20E (Dinan et al., 1999a). Many of the modifications found in PEs are also found in other classes of plant triterpenoids (brassinosteroids, cucurbitacins, withanolides etc.). This raises the possibility that enzymes of the later stages of the biosynthetic pathways may lack specificity and be common to plants producing these different classes of secondary compounds; if each pathway has a distinct early intermediate, this would permit the generation of many diverse analogues in each class without massive genetic redundancy of hydroxylases etc.

A number of ecdysteroids (mycoecdysteroids) with unusual structural features (16-hydroxy, 24-hydroxy or 22,23-epoxide) have been isolated from the mushrooms *Paxillus atrotomentosus* and *Tapinella panuoides* (Vokác et al., 1998a,b). Several unusual ecdysteroids have been isolated from *Polyporus umbellatus* (polyporusterones A–G; Ohsawa et al., 1992) and *Polyporus versicolor* (Valisolalao et al., 1983). Further, 3β,14α,17α,20,24,25-hexahydroxy-5α-ergosta-7,22-dien-6-one has been isolated from *Lasiosphaera nipponica* (Takaishi et al., 1992). However, it is currently unclear if the ecdysteroids are biosynthesised by the fungi themselves or taken up from the substratum and modified.

4. Phytoecdysteroid production in vitro

The occurrence of ecdysteroids in callus cultures was first described for seedling callus tissues from several *Achyranthes* species (Hikino et al., 1971) and *Trianthema portulacastrum* (Ravishankar and Metha, 1979). PEs have also been isolated from the culture filtrates of *Ajuga turkestanica* (Lev et al., 1990), *A. reptans* var. *atropurpurea* (Matsumoto and Tanaka, 1991), *Pteridium aquilinum* (McMorris and Voeller, 1971) and *Serratula tinctoria* (Corio-Costet et al., 1996). 20E was produced at a two- to six-fold higher level by cell and callus cultures of *Ajuga turkestanica* than the level found in root and aerial parts (Camps et al., 1990). Similarly, suspension cultures of *Pteridium aquilinum* produced higher concentrations of ecdysteroids (especially ponA) than found in the wild plant. Unfortunately, the growth rate of the cultures was very slow (Vanek et al., 1990), but a strategy could be developed for the culture to be used as a source of these compounds (Svatoš and Macek, 1994). Hairy root cultures of *A. reptans* var. *atropurpurea* transformed with *Agrobacterium rhizogens* produced four phytoecdysteroids (20E, 29-norcyasterone, cyasterone and isocyasterone), which were present in the methanol extract of the roots (Matsumoto and Tanaka, 1991). In vitro culture studies of root and shoot tissue of *A. reptans* revealed that the roots produced PEs when cultured isolated from the rest of the plant, whereas the PEs were not detected in shoots cultured in the absence of root tissue. These results reveal that the ecdysteroids in *A. reptans* are biosynthesised in the roots (Tomás et al., 1992; 1993). Ecdysteroid concentrations were higher in cultures supplemented with hormone than in basal medium and increased during the growing period. The C_{28}/C_{29} ecdysteroid ratio was very high and different from those observed in in vivo and in vitro whole plant cultures. A comparison of sterol and ecdysteroid profiles of plant and cell culture of *Serratula tinctoria* suggested that roots are the organs containing the highest quantities of PEs (Corio-Costet et al., 1993). Callus cultures of *S. coronata* produce 20E, inokosterone and E together with unidentified ecdysteroids in variable proportions and at levels which are lower than those in wild plants but higher than those in plants grown in vitro (Anufrieva et al., 1998).

5. Biosynthesis

Our understanding of the biosynthetic pathway(s) for ecdysteroids in plants is limited. In part, this was a consequence of the lack of convenient study systems, a situation which is beginning to change with the application of amenable in vitro systems, such as hairy root cultures or cell suspension cultures. In view of the potential applications of PEs in crop protection (see below) it is surprising that more emphasis has not been placed on the elucidation of the biosynthetic pathway(s) for PEs, since modification of PE levels/profiles through genetic engineering is heavily dependent on prior knowledge of the biosynthetic pathway(s) and their regulation. Current knowledge of the biosynthetic pathways for ecdysteroids has been recently reviewed (Warren and Hetru, 1990; Grieneisen, 1994; Rees, 1995; Lafont, 1997), but the emphasis has inevitably been on synthesis in invertebrates, for which somewhat more is known. Only the review by Adler and Grebenok (1995) deals specifically with the biosynthesis of PEs. The presence of PEs in various plant parts at very different concentrations does not allow any conclusion to be drawn about the tissue or organ in which these compounds are primarily produced (rather than accumulated). Recent studies have demonstrated that active biosynthesis of PEs takes place in developing tissues (Grebenok and Adler, 1991,1993), and these compounds are transported to other organs (Ripa et al., 1990; Grebenok and Adler, 1991; Tomás et al., 1993). Plants (unlike insects) are capable of biosynthesising PEs from mevalonic acid. In many cases, the biosynthesis of PEs has been demonstrated to proceed *via* cholesterol and/or lathosterol (Adler and Grebenok, 1995). In insects, it has been suggested that 7-dehydrocholesterol is an intermediate in the ecdysteroid pathway (Grieneisen et al., 1991). In relation to this in plants, it has been shown by application of [4-^{14}C, 7α-$^{3}H_1$] and [4-^{14}C, 7β-$^{3}H_1$] cholesterols to *Taxus baccata* and *Polypodium vulgare* that the *cis* 7β- and 8β-hydrogens of cholesterol are removed during the biosynthesis of E and 20E (Cook et al., 1973). From other studies involving specifically-labelled cholesterols, the location of the radiolabel in biosynthesised 20E indicated that hydrogen migration occurred from the 3α- and 4β-positions to C-4 and C-5, respectively, whereas the 4α-hydrogen was retained at C-4. According to these results, the formation of the A/B *cis*-ring junction might be best explained by concomitant 1,2-Wagner–Meerwein hydride migrations from the 4β- to the 5β- and from the 3α- to the 4α-position with the implicit displacement of the 4α-hydrogen of cholesterol

to the 4β-position in the ecdysteroid (Davies et al., 1980). Despite these studies, the early stages in the biosynthesis of PEs from cholesterol still remained to be fully understood (Adler and Grebenok, 1995). Incubation of radiolabelled [2-^{14}C]mevalonic acid, [4-^{14}C]cholesterol and [23,24-^{3}H]ecdysone in *Zea mays* led to the formation of radiolabelled E and 20E conjugates, which were hydrolysable with an acid phosphatase preparation (Devarenne et al., 1995). A recent report indicates that (poly)phosphorylated ecdysteroid conjugates are also formed in spinach, where they may be involved in the down-regulation of ecdysteroid biosynthesis (Grebenok et al., 1994). In the only study on the enzymology of ecdysteroid synthesis in plants, it was shown that hydroxylation of ecdysone at the C-20 position to form 20E is a cytochrome P_{450}-dependent reaction occurring predominantly in the microsomal fraction in spinach leaves (Grebenok et al., 1996).

As mentioned above, several new experimental systems have been identified which show considerable promise for the elucidation of the biosynthetic pathway for ecdysteroids. In vitro cultures of *Polypodium vulgare* prothalli revealed that labelled mevalonate and cholesterol were incorporated into all identified PEs (Reixach et al., 1996). In hairy root cultures of *Serratula tinctoria*, radiolabelled [^{3}H]cholesterol and [^{14}C]mevalonic acid provide an efficient incorporation into PEs (Delbecque et al., 1995).

As far as the biosynthesis of PEs in *Ajuga reptans* is concerned, recent studies have concerned in vitro cultures of non-transformed (Tomás et al., 1993) and transformed (Matsumoto and Tanaka, 1991) roots. In non-transformed root cultures, 6 phytoecdysteroids (20E, ajugalactone, 29-norcyasterone, 29-norsengosterone, cyasterone and sengosterone) were found to accumulate in the root cultures in proportions which varied with the culture conditions and which were different to the proportions found in whole plants from the wild or in vitro whole plant cultures. The authors conclude that two major biosynthetic pathways, side-chain dealkylation ($C_{29}\rightarrow C_{28}$, but not $C_{29}\rightarrow C_{27}$) and 5β-hydroxylation, are operating leading to two series of related $C_{29}/C_{28}/C_{27}$ compounds, namely cyasterone/29-norcyasterone/20-hydroxyecdysone (5β-H) and sengosterone/ 29-norsengosterone/5,20-dihydroxyecdysone (5β-OH), although the levels of the C_{27} ecdysteroids were very low ($< 5\%$), such that 5,20-dihydroxyecdysone could not be quantified in the in vitro root cultures. Ajugalactone was viewed as a dead-end product in the biosynthesis. The extent to which both 5β-hydroxylation and dealkylation are operational is very dependent on the culture conditions, and this goes a long way to explaining the highly variable ecdysteroid profiles found in *A. reptans* samples.

In an elegant series of papers (summarised in Fujimoto et al., 2000), ^{13}C- and deuterium-labelled precursors have been fed to ecdysteroid-producing hairy roots of *A. reptans* var. *atropurpurea* and ^{13}C and ^{2}H NMR was used to identify the enriched positions in the biosynthesised ecdysteroids. In these hairy-root cultures, a much simpler ecdysteroid profile was found (mainly 20E, with lesser amounts of 29-norcyasterone and cyasterone). 20E could be labelled from both [^{13}C]cholesterol and [^{13}C]acetate, whereas 29-norcyasterone (C_{28}) and cyasterone (C_{29}) were only labelled from [^{13}C]acetate (Nagakari et al., 1994a), indicating that the last two are generated from an appropriate phytosterol (also supported by the lack of labelling at C-28 and C-29 after application of [^{13}C]acetate, indicating that C-28 and C-29 derive from S-adenosyl methionine; Yagi et al., 1996). Recently, clerosterol has been shown to be a precursor phytosterol of the C_{28} and C_{29} ecdysteroids (Nomura et al., 2000). The conversion of cholesterol to 20E in this system has been more closely studied; the retention of label, without migration, from [3α-^{2}H]-, [4α-^{2}H]- and [4β-^{2}H]-cholesterols and [3α-^{2}H]- and [5-^{2}H]3β-hydroxy-5β-cholest-7-en-6-ones are all compatible with 3β-hydroxy-5β-cholest-7-en-6-one being an intermediate in the biosynthesis of 20E. Further [5-^{2}H]3β-hydroxy-5α-cholest-7-en-6-one was not converted to 20E (Nagakari et al., 1994b). These results are in contrast to those described above for *Polypodium vulgare* (Davies et al., 1980), which demonstrated migration of the hydrogens at C-3 and C-4 and indicated the involvement of a 3-oxo-4-ene intermediate. Application of [6-^{2}H]cholesterol to *A. reptans* hairy roots revealed that 6-H largely migrates to become the 5β-H (compatible with the intermediacy of a 5α,6α-epoxide), but one-third of the 5β-H derives from another source, indicating that the route(s) to the A/B *cis*-ring junction are more complex (Fujimoto et al., 1997). This hairy root system has also been used to investigate the stereochemistry of hydroxylation at C-25 during 20E formation, which was found to proceed with a mixture of retention and inversion of configuration (Nakagawa et al., 1997). Hydroxylation at C-2 proceeds with retention of configuration (Nomura and Fujimoto, 2000), as had previously been found in the insect *Schistocerca gregaria* (Greenwood et al., 1984). *Ajuga* hairy roots convert 3β-hydroxy-5β-cholestan-6-one and 2β,3β-dihydroxy-5β-cholestan-6-one to 20E, demonstrating that the 7-ene can be introduced at a later stage in the biosynthetic pathway and that 7-dehydrocholesterol is not an obligatory intermediate (Hyodo and Fujimoto, 2000). This finding is compatible with the detection of 7,8-dihydroecdysteroids in other plant species (e.g. Pomilio et al., 1996).

6. Biological significance of phytoecdysteroids to plants

The importance of the ecdysteroids in the life-cycle of plants has not been fully elucidated. There are two main

hypotheses. The first is that PEs have a hormonal role within the plant, but there is very little hard evidence in support of this hypothesis and quite a lot against it (reviewed in Dinan, 1998). Alternatively, it has long been recognised that PEs possess insect moulting hormone activity and they could participate in the defence of plants against non-adapted phytophagous invertebrates. This is supported by the fact that the major PE present in most ecdysteroid-containing plants is 20E, which is also the major ecdysteroid in insects. Deterrent effects of 20E on non-adapted insect species are observed at 2–25 ppm (Blackford and Dinan, 1997b, and references cited therein), which is well within the concentration range found in ecdysteroid-containing plants. The biological activity of some PEs has been tested in a wide variety of insect bioassays (reviewed in Bergamasco and Horn, 1980; Cymborowski, 1989; Dinan, 1989). Almost all PEs demonstrate quantifiable ecdysteroid activity (Dinan et al., 1999a). They have also been shown to affect insect growth and reproduction when added to natural or artificial diets, which would otherwise support optimum growth and reproduction (Melé et al., 1992; Sláma et al., 1993; Tanaka and Takeda, 1993; Blackford and Dinan, 1997b; Mondy et al., 1997). Investigation of the consequences of ingestion of dietary PEs is appropriate for an understanding of the ecological or physiological phenomena involved in plant–insect interactions. The activity of a PE depends on its affinity for, and the effective concentration at, the target site (normally assumed to be the ecdysteroid receptor complex), and, if it is ingested, its potency depends also on the amount ingested, the ability to cross the gut wall and the consequences of the metabolism. A number of researchers have suggested the possibility of allelochemical properties of PEs as hormonal disruptors and toxins for insects and other invertebrates (Robbins et al., 1970; Kubo et al., 1983; Arnault and Sláma, 1986; Camps and Coll, 1993; Savolainen et al., 1995; Mondy et al., 1997). It has also been demonstrated that ecdysteroids possess antifeedant activity against certain species of insects and that some species possess taste receptors which respond to ecdysteroids (Ma, 1969; Tanaka et al., 1994; Descoins and Marion-Poll, 1999). However, there are several highly polyphagous insect species which develop normally on diets containing very high concentrations (400 ppm) of 20E (Robbins et al., 1968; Kubo et al, 1987; Robinson et al., 1987; Tanaka and Naya, 1995; Blackford et al., 1996; Blackford and Dinan, 1997a,c). Hence, PEs can be considered as a chemical defence against certain, but not all, herbivorous insects (Lafont and Horn, 1989).

As already mentioned, 20E is generally accompanied in plants by one or two other major ecdysteroids and several other minor ecdysteroids. The relative contribution of the various major and minor ecdysteroids to a potential defensive role of PE is a moot point at present. It has been suggested that the minor PEs provide evolutionary flexibility to respond to predation if and when the major compounds are no longer effective; mutation results in plants with altered ecdysteroid profiles and new major ecdysteroids which are effective in deterring the predators (Jones and Firn, 1991; Alison et al., 1997).

Recently, it has been demonstrated that ecdysteroid accumulation in spinach is inducible by mechanical (Schmelz et al., 1998) or insect (Schmelz et al., 1999) damage to roots. Evidence was further provided for the involvement of jasmonates in the induction of de novo ecdysteroid synthesis. Also, short- and long-term labelling of 20E from [2-^{14}C]mevalonic acid in spinach demonstrate that ecdysteroids are metabolically stable in this species, which fits much better with a role in plant defence, rather than a phytohormonal role (Schmelz et al., 2000).

Definitive assessment of the contribution of PEs to the deterrence of invertebrate predators must await the comparison of the susceptibility of genetic lines of the same plant species which differ in their ecdysteroid levels and/or profiles (Dinan, 1998).

7. Structure–activity studies

It is often presumed that most, if not all, ecdysteroid responses are mediated by intracellular ecdysteroid receptor complexes, of which the two main components (the *EcR* and *USP* proteins) belong to the nuclear receptor superfamily (Yao et al., 1993), and which modify the activity of specific gene sets. However, it should be mentioned that evidence is accumulating that ecdysteroids may also have non-genomic effects (reviewed in Tomaschko, 1999). Consequently, SAR studies can be strongly influenced by the invertebrate species used, its stage of development and the format of the bioassay in addition to the more usual problems common to all bioassays (purity of the test compound, penetration, sequestration, metabolism etc.). PEs have been tested in a variety of insect bioassays, and found to exhibit moulting hormone activity. From both in vitro (Cherbas et al., 1980) and a variety of in vivo assays (mainly the dipteran *Calliphora* and *Musca* pupariation bioassays; Cymborowski, 1989; Dinan, 1989) the following structural requirements for high activity were deduced (Bergamasco and Horn, 1980): (a) a *cis* A/B ring junction; (b) a 7-en-6-one group; (c) a complete sterol side-chain having a 22*R* oxygen function, and containing, in some cases, additional alkyl groups at the 24α-position; (d) an oxygen function generally in the form of a 3β-OH group; and (e) additional OH groups at C-14α and C-2β, and, in many cases, also at C-20 and C-25. More recently, a systematic study on 20E conjugates (fatty acid/benzoic acid mono, di- and tri-esters, glucoside and glucosidic esters) for ecdysteroid activity in common assays on *Sarcophaga* (Diptera) and *Galleria*

(Lepidoptera) revealed that the 2-acetyl derivative and the 25-benzoate derivatives of 20E retain a significant amount of activity, but di- and tri-esters, as well as all glucosidic derivatives of 20E, were much less or virtually inactive relative to 20E (Píš et al., 1991; Sláma et al., 1993). PEs having an 11α-OH group bind with about the same affinity to the *Chironomus tentans* (Diptera) ecdysteroid receptor as the corresponding compound lacking this OH group. For these compounds, the potency to elicit a hormonal response corresponds with the affinity for the ecdysteroid receptor, as detected by induction of acetycholinesterase enzyme for cell differentiation (Spindler-Barth et al., 1997). However, the results of in vivo studies reveal that there may be a wide variation in the susceptibility of different insects to a particular ecdysteroid analogue, and an equally wide variation in the response of a single insect species to different molecular structures (Robbins et al., 1970; Sláma et al., 1993). In view of this, an extensive study involving the quantitative assessment of a large number of HPLC-purified ecdysteroids in a uniform assay system (the *Drosophila melanogaster* B_{II} bioassay; Clément et al., 1993) has recently been undertaken (Harmatha and Dinan, 1997; Dinan et al., 1999a). Structure-activity relationships were analysed by Comparative Molecular Field Analysis (CoMFA) to generate two models with good predictive capabilities. Further, it was possible to propose a pharmacophore hypothesis for ligand interaction with the ecdysteroid receptor (Fig. 2), in which binding is the result of incremental contributions of a number of molecular features (heteroatoms at C-2, C-3, C-20 and C-22, a large dipole at C-6 and a moderately bulky hydrophobic group, located beyond C-22) at the angles and distances approximating to those present in 20E. Each of these features contributes to the binding affinity, but there is no absolute requirement for any one of them. In comparison to the previous empirically derived SAR conclusions (summarised above), it is now clear that the *cis*-A/B-ring junction, the Δ^7-double bond, the 6-keto group, the full 8-carbon side-chain and each of the hydroxyls listed above is not essential for activity, although absence of both parts of the 7-en-6-one moiety do seem to remove all activity. Also, it is clear that the consequences of the addition/removal of individual structural features is not always additive; e.g. the consequences of presence/absence of hydroxyl groups at C-5 or C-25 depend on the structural features present in other parts of the molecule. It remains to be seen if a completely different structural scaffold bearing several or all of the six pharmacophore elements would retain activity, but the models from which the pharmacophore hypothesis was derived are being successfully used to predict the activity of novel ecdysteroids prior to their chemical synthesis (Hormann et al., unpublished results). Biological activity data obtained for phytoecdysteroids have also contributed significantly to two other modelling studies of ligand binding to the ecdysteroid receptor. Wurtz et al. (2000) have used homology modelling and docking to generate virtual models for 20E and bisacylhydrazine interaction with the ligand binding domain. Ravi et al. (unpublished) have applied 4D-QSAR techniques to the same dataset which was used for CoMFA modelling (Dinan et al., 1999a,b). There is generally good agreement between the CoMFA and 4D-QSAR models, but the 4D-QSAR additionally permits the prediction of which functional groups on the ecdysteroid are involved in hydrogen-bonding to the receptor.

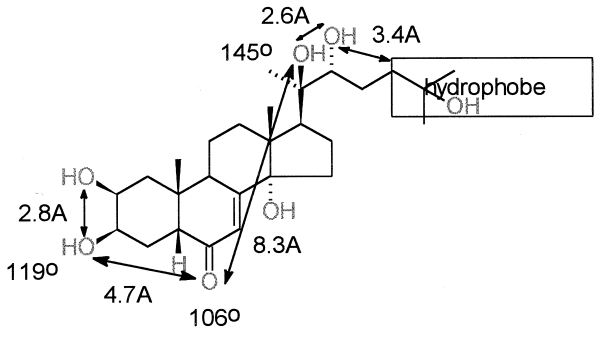

Fig. 2. Pharmacophore hypothesis for ecdysteroid binding to the *Drosophila melanogaster* ecdysteroid receptor (redrawn from Dinan et al., 1999a,b).

8. Applications of phytoecdysteroids

Since the discovery of large amounts of ecdysteroids in plants (relative to the much lower concentrations found in most animal sources), PEs have been purified for use in biochemical and physiological experiments in invertebrate systems. In fact, it is fair to say that our knowledge of the role of ecdysteroids in insect endocrinology would be much poorer if it had not been for the availability of ecdysteroids (especially 20E, E and ponA) from plant sources. In recent years, however, new areas of potential applications have been identified. These fall into two broad categories; agricultural and biomedical. Of necessity, the discussion which follows is more speculative than in the preceeding sections.

8.1. Agricultural applications

8.1.1. Improvement of silk yields

Feeding of exogenous ecdysteroids to larvae of the silkworm, *Bombyx mori*, at certain stages of development has been shown to enhance synchronous development of the larvae and, when co-administered with a juvenile hormone analogue, to elevate significantly the yield of silk obtainable from the cocoon (Chou and Lu, 1980; Ninagi and Maruyama, 1996). Such treatments have considerable potential to improve the efficiency of

silkworm rearing by Asian farmers, especially since the hormonal treatments could be based on extracts of appropriate indigenous plant species.

8.1.2. Design of more specific invertebrate pest control agents

Identification of compounds which specifically interfere with the mode of action of ecdysteroids in invertebrates is a very attractive and promising way of controlling pest species while reducing the effects on other animal groups and lowering the environmental burden. The effectiveness of such a strategy has recently been demonstrated by the identification of non-steroidal bisacylhydrazines as agonists of the ecdysteroid receptor complex and the development of two of the compounds as selective and successful insect control agents (Dhadialla et al., 1998). The ecdysteroids themselves have very limited application in the control of pests, since they do not possess the required properties for successful pesticides; they are too polar, too chemically complicated and too metabolically and environmentally unstable (Dinan, 1989). However, they can contribute significantly as lead compounds. In this sense, the vast diversity of ecdysteroid analogues found in plants provides a natural resource for structure-activity studies (see previous section). This was realised some time ago (Cherbas et al., 1980), but the more restricted availability of ecdysteroid analogues in very pure form, the requirement for larger amounts of each analogue and, most importantly, the complexity of the available bioassay systems then available, restricted the possibilities of this approach at that time. However, the methodological and technical advances of recent years, permitting rapid purification and identification of analogues, extensive QSAR and computerised molecular modelling, will ultimately permit the recognition of further simple, non-steroidal molecules which fit the pharmacophore hypothesis and may lead to novel insecticides. Such approaches can be extended to the taste receptors of insects to identify ecdysteroid analogues (steroidal or non-steroidal) which are potent antifeedants.

8.1.3. Modification of ecdysteroid levels in crop species

An alternative approach to crop protection based on ecdysteroids is to modify ecdysteroid levels and/or profiles in crop plants (most of which do not contain ecdysteroids) to enhance protection against invertebrate predators. This is based on the assumption that ecdysteroids contribute significantly to the protection of the plants which contain them, at least against non-adapted predators. There is increasing evidence that this is true, but the situation is complicated by the knowledge that there are certain polyphagous insect pests which are unaffected by diets containing very high concentrations of ecdysteroids (reviewed in Dinan, 1998). However, these tolerant species appear to detoxify the ingested ecdysteroids in specific ways (commonly by acylation with long-chain fatty acids at C-22; Robinson et al., 1987; Kubo et al., 1987; Blackford et al., 1997; Blackford and Dinan, 1997a) and it seems feasible that plants could be generated which contain ecdysteroid analogues which do not permit the ready biochemical detoxification by predators (e.g. by generating high levels of 22-deoxy ecdysteroids which retain activity on ingestion because they are not a substrate for the detoxification enzymes; Connat et al., 1983). The very broad, but uneven, distribution of ecdysteroid-containing species in the plant world leads most researchers in this area to believe that most, if not all, plants retain the genetic capacity to produce ecdysteroids, but that the biosynthetic pathway is not expressed in most species. If this is true, modification of the activity of genes which regulate ecdysteroid biosynthesis (either through a traditional selection approach, genetic modification or application of appropriate elicitors) could generate crop plants with elevated ecdysteroid levels. Thus, ecdysteroids have potential for the GM or non-GM protection of crop species. The apparent non-toxicity of ecdysteroids to mammals (see below) makes this potentially very attractive, as it may not be necessary to incorporate tissue- or temporally-specific accumulation of ecdysteroids into the system.

8.2. Biomedical applications

8.2.1. Effects of ecdysteroids on vertebrates

The reader is referred to two excellent reviews (Simon and Koolman, 1989; Sláma and Lafont, 1995) which summarise the disparate literature on this aspect. The wide-spread occurrence of ecdysteroids in invertebrates and plants suggests that man's consumption of these steroidal compounds may not be insignificant. Spinach, for example, contains ca. 50 μg/g f.w. (Dinan, 1995b). Although no thorough toxicological study appears to have been performed for any ecdysteroid, there is evidence that the acute toxicity of these compounds to mammals is extremely low (Ogawa et al., 1974; Kosar et al., 1997). On the contrary, there is some evidence that they may even be beneficial under certain circumstances (Hikino and Takemoto, 1972; Kuzmenko et al., 1997; Wu et al., 1998; Trenin and Volodin, 1999). They appear to be mildly anabolic (Koudela et al., 1995; Sláma et al., 1996), supposedly without the adverse side-effects associated with vertebrate steroids or their analogues (Syrov, 1984); rumour suggests that some athletes and sportsmen of various nations have taken advantage of this since the mid-1980s. 20E has significant spermicidal activity (Bandara et al., 1989) and influences the sexual activity of male rats (Mirzaev and Syrov, 1992). Other pharmacological effects have also been ascribed to ecdysteroids or to extracts of ecdysteroid-containing plants. A number of preparations and tonics with reported roborant, adaptogenic and antidepressive

effects are based on the plant *Leuzea carthamoides* which possesses very high levels of ecdysteroids, mainly 20E (Sláma and Lafont, 1995). A number of reports suggest that ecdysteroids may be effective in the control of diabetes (Yoshida et al., 1971; Uchiyama and Yoshida, 1974; Najmutdinova and Saatov, 1999). Recent studies (Badal'yants et al., 1996; Prymak et al., 1996) have shown that derivatives of PEs exhibit a hepatoprotective action which was related to their effect on liver chromatin and their ability to prevent negative shifts of phospholipid metabolism. Three ecdysteroids from *Ajuga decumbens* (cyasterone, polypodine B and decumbesterone A) have been reported to be potential cancer chemopreventative agents (Takasaki et al., 1999). Thorough clinical trials are required to substantiate and confirm all the above findings.

8.2.2. Gene switches

There is considerable interest in gene replacement therapies to correct inborn errors. However, such introduced genes require the correct temporal expression to be fully effective. Thus, systems are being sought which allow these genes to be switched on and off by the availability of an appropriate elicitor. One transgenic system which is receiving attention is the ecdysteroid/ecdysteroid receptor complex (Sawicki et al., 1998; Morgan et al., 1999; Albanese et al., 2000; Lüers et al., 2000), since the ecdysteroid receptor is not a natural component of vertebrate cells, ecdysteroids are believed to be non-toxic to vertebrates and ecdysteroids do not appear to activate vertebrate steroid hormone receptors, even at very high concentrations. A number of permutations using either all of the *EcR* protein or the ligand-binding part fused to the DNA-binding domain of another member of the nuclear receptor superfamily are being considered. In insects, *EcR* naturally forms a heterodimer with *USP*. The homologue of *USP* in verbrates is the retinoid X receptor, *RXR*. When expressed in vertebrate systems, *EcR* will partner *RXR*. However, the ecdysteroid binding specificity is considerably altered, such that 20E is largely ineffective at inducing reporter gene activity, while the rare phytoecdysteroid muristerone A is much more effective, but only at high concentrations (1–10 μM, whereas 100-fold lower concentrations are effective with *EcR*/*USP* heterodimers). Ponasterone A is also effective, but concentrations (1–10 μM) are required which are 1000-fold greater than those required in insect systems. The non-steroidal bisacylhydrazines (which also have very low mammalian toxicity) are being considered as alternative ligands (Suhr et al., 1998). Gene switches based on ecdysteroid systems are also being developed for plants (Jepson et al., 1998; Martinez et al., 1999a,b). While these developments are highly interesting, it is clear that they will have to undergo considerable refinement before commercially or medically viable systems are available.

8.2.3. Antimicrobial agents

The antimicrobial activity of *Asparagus dumosus* against several fungal and bacterial species was ascribed to the presence of 20E (Ahmad et al., 1996).

9. Concluding remarks

PEs are attracting renewed attention because of their specific effects on invertebrate development (potential in invertebrate pest control) and their varied benign pharmacological actions on mammals (biomedical applications and gene switches). In the past three decades, several thousand species of plants have been surveyed for the presence of PEs and the structures of over 200 PEs have been deduced. The most frequently encountered PE is 20E, the principal physiological inducer of moulting and metamorphosis in arthropods. It is currently not clear what the biological significance of this extensive structural variety among PEs is, but the numerous structural analogues provide an excellent natural resource for biochemical and physiological structure-activity studies. Studies on the distribution of PEs within the plant kingdom are still fragmentary, but it is becoming apparent that ecdysteroid-containing species are to be found grouped together in particular genera or tribes within families. Continuation of the search for new plant sources of PEs will provide a better understanding about their distribution in plants, their possible chemotaxonomic and ecological implications, and furnish further analogues for structure-activity relationship studies. Potential medical, pharmacological and agricultural applications of PEs are beginning to be recognised and implemented and these will provide further impetus to investigate the fundamental aspects of PE research, such as elucidation of the biosynthetic pathway, which have been rather neglected.

Acknowledgements

Research in Exeter was supported by the Biotechnology and Biological Sciences Research Council of the UK, EU-INTAS (Contract 96-1291) and Rohm & Haas Co. (Spring House, PA, USA). I thank Pauline Bourne for reading and commenting on the manuscript.

[b]*Department of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, The Ohio State University, Columbus, OH, 43210, USA*

Received 26 October 2000; received in revised form 3 January 2001

Abstract

The whole cells and the chloroperoxidase enzyme of *Caldariomyces fumago* were capable of halogenating the flavanones, naringenin and hesperetin, at C-6 and C-8 in the presence of either Cl^- or Br^-. However, they did not act on other test flavones. The biohalogenated products of naringenin and hesperetin were isolated and found to be identical to those obtained from chemical reactions using molecular halogen and hypohalous acid. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Caldariomyces fumago*; Chloroperoxidase; Enzymatic halogenation; Flavanones; Flavones

1. Introduction

The use of microbial enzymes for the transformation of organic compounds has been employed as a powerful method in metabolism studies and in modern synthetic organic chemistry for decades (Smith and Rosazza, 1975; Faber, 1992). One of the enzymatic reactions that has been widely studied is a chloroperoxidase-catalyzed halogenation (Franssen, 1994). Chloroperoxidase from *Caldariomyces fumago* (CPO; EC 1.11.1.10) is a well-known enzyme, capable of halogenating a great variety of organic compounds such as β-ketoacids (Shaw and Hager, 1959), cyclic β-diketones (Hager et al., 1966), steroids (Levine et al., 1968), alkenes (Yamada et al., 1985), activated aromatic compounds (Wannstedt et al., 1990), and heterocylcic compounds (Franssen et al., 1987). The reaction mechanism of CPO involves the formation of a halogenium ion (X^+) or hypohalous acid (HOX) as an intermediate which can effect electrophilic substitution with electron-rich substrates (Yamada et al., 1985; Libby et al., 1992).

The enzymatic halogenation of several flavanones and flavones having electron-donating groups was investigated in this study. Flavonoids are very common as secondary metabolites found in nature with a great variety of structural forms and biological activities (Harborne, 1988). The vast literature related to flavonoid biotransformations is primarily concerned with oxidation, methylation and glucosidation (Ibrahim and Abul-Hajj, 1990a,b; Ibrahim et al., 1997). One study was found on the microbial chlorination of the isoflavone genistein by *Streptomyces griseus* and *S. plicatus* (Anyanwutaku et al., 1992). There are no previous reports on the chloroperoxidase-catalyzed halogenation of flavonoid compounds. Therefore, we examined the use of whole cells and CPO of *C. fumago* to brominate and chlorinate various flavanones and flavones. The enzymatic study was also compared with chemical halogenation using molecular halogen and hypohalous acid.

2. Results and discussion

The enzymatic bromination and chlorination of flavanones and flavones using *C. fumago* whole cells and CPO gave the results shown in Table 1. With Br^- and Cl^- present as halides, both *C. fumago* and CPO catalyzed the halogenation of the flavanones, naringenin and hesperetin, but were inactive toward the test flavones. The metabolic products were isolated and identified on the basis of NMR and mass spectral analyses. Mass spectra of halogenated compounds showed typical characteristics of isotope peak, suggesting a number of halogen atoms present in each metabolite.

Table 1
Reaction products from various flavanones and flavones by chloroperoxidase-catalyzed reaction

Substrate	Halide	Product	Yield (%)	
			C. fumago whole cells	$CPO/H_2O_2/X^-$
Flavone, flavonol,	Br^-	–	–	–
7-Hydroxyflavone,	Cl^-	–	–	–
5,7-Dihydroxyflavone,		–	–	–
Quercetin, 6-chloroflavone		–	–	–
Naringenin	Br^-	6,8-Dibromonaringenin (**1**)	2.4	9.3
		8-Bromonaringenin (**2**)	1.8	7.8
	Cl^-	6,8-Dichloronaringenin (**3**)	21	2.8
		6-Chloronaringenin (**4**)	7.6	1.9
Hesperetin	Br^-	6,8-Dibromohesperetin (**5**)	Not tested	8.3
		8-Bromohesperetin (**6**)	Not tested	2.2
	Cl^-	6,8-Dichlorohesperetin (**7**)	3.0	Trace
		6-Chlorohesperetin (**8**)	1.7	1.0

The biobrominations of naringenin and hesperetin gave 6,8-dibromonaringenin (**1**), 8-bromonaringenin (**2**), 6,8-dibromohesperetin (**5**), and 8-bromohesperetin (**6**), respectively. The mass spectral analysis indicated the presence of two bromine atoms in **1** and **5** and one bromine atom in **2** and **6**. The ^1H NMR spectra of brominated compounds were similar to those of naringenin and hesperetin, except for the disappearance of two proton signals in **1** and **5** and one proton signal in **2** and **6** at the H-6 and/or H-8 regions (Tables 2 and 3). These data clearly supported that **1** and **5** were dibrominated products having two bromine atoms at positions 6 and 8. The position of the bromine atoms in **2** and **6** were identified by analysis of the ^{13}C NMR spectra. Relative to naringenin and hesperetin, the ^{13}C NMR spectra of **2** and **6** showed a new quaternary carbon signal around 88 ppm, while one of the two methine carbon peaks in the 96 ppm region disappeared (Table 4). This suggested that the bromine atom might be at either C-6 or C-8. HMBC data of **2** showed that the hydroxyl proton at 12.15 ppm (OH-5) had long range couplings to the methine carbon at 96.30 ppm, and two quaternary carbons at 102.97 and 162.97 ppm corresponding to C-6, C-4a, and C-5, respectively. The methine proton at 6.14 ppm (H-6) showed long range couplings with signals at 88.41 (C-8), 102.97 (C-4a), and 162.97 (C-5 and C-7) ppm. In addition, compounds **2** and **6** gave similar ^{13}C NMR spectral patterns and the carbon signals at C-7 and C-8a of **2** and **6** were shifted upfield by 4.5 ppm compared to those of naringenin and hesperetin. These results indicated that the bromine atom in **2** and **6** must be at C-8.

The enzymatic chlorinations of naringenin and hesperetin also gave four metabolic products, 6,8-dichloronaringenin (**3**), 6-chloronaringenin (**4**), 6,8-dichlorohesperetin (**7**) and 6-chlorohesperetin (**8**). The mass and ^1H NMR spectral analyses of **3** and **7** established the presence of two chlorine atoms at positions 6 and 8. The mass and ^1H NMR spectra of **4** and **8** indicated one chlorine atom at either position 6 or 8 (Tables 2 and 3). The ^{13}C NMR

[c] Assignments could be reversed.

spectra of **4** and **8** showed a quaternary carbon and a methine carbon signals in the C-6 and C-8 regions at lower field compared to those of their precursors (Table 4). The structural assignment of **4** as 6-chloronaringenin was supported by a COLOC experiment. The hydroxy proton at δ 12.74 (OH-5) had long range couplings to the quaternary signals at 101.02, 103.52, and 160.33 ppm thus corresponding to C-6, C-4a, and C-5, respectively. Since the ^{13}C NMR spectral pattern of **8** was similar to that of **4,** the chlorine atom in **8** was placed at C-6. This was supported by the appearance of carbon signals at C-5 and C-7 of **4** and **8** at higher field by about 5 ppm compared to those of naringenin and hesperetin.

It was noted that, when the CPO enzyme was employed to halogenate naringenin and hesperetin, brominated products were obtained in better yields than chlorinated ones (Table 1). This was explainable since the halogenation of CPO is electrophilic and the reactivity of halogenium ions increases in the following order: Cl^+, Br^+ and I^+ (Yamada et al., 1985). However, when *C. fumago* whole cells were used, yields of chlorinated metabolites were higher. This might be due to the weak growth of *C. fumago* in the medium containing KBr. Overall, the halogenated products were obtained in low yields together with starting material. The halogenation of the substrates may proceed in competition with the halogenation of CPO itself at tyrosine residues until the enzyme is no longer active (Wannstedt et al., 1990). Furthermore, since the enzymatic reactions were carried out in suspension, the uptake of the substrates for biotransformation may be poor.

6-chlorohesperetin (**8**); R = Me, R' = OH, X = Cl, X' = H

The flavone-type compounds, flavone, flavonol, 7-hydroxyflavone, 5,7-dihydroxyflavone, quercetin, and 6-chloroflavone, were not suitable as substrates of CPO. The aromatic rings of these compounds possessing a strongly conjugated system were quite stable, and were thus inert to the enzymatic reaction. The relevant flavanones were reactive since the conjugation in the flavanone system was disrupted by removing the 2,3-double bond. The biomimetic reactions of naringenin and hesperetin with chemical halogenating agents were examined. Their reaction products were identical to those obtained from the enzymatic reactions. The halogenations of naringenin and hesperetin are electrophilic and occurred at the C-6 and C-8 positions on the A-rings. With the two hydroxy groups at C-5 and C-7, the A-rings of naringenin and hesperetin are considerably more nucleophilic and hence reactive towards electrophilic halogenating species than their B-rings.

3. Experimental

3.1. General experimental procedures

^{1}H NMR spectra were recorded on an IBM AF-270 and a JNM-A500 spectrometer. ^{13}C NMR spectra were recorded on an IBM AF-270 at 67.9 MHz, a JNM-A500 and a Bruker AM-500 at 125 MHz. $(CD_3)_2CO$ was used as solvent. MS was performed using a VG 70 250S mass spectrometer and HP 5989B MS engine at 70 eV. FTIR spectra were obtained using a Magna-IR^{TM} spectrometer 750, using KBr plates. Optical rotations were measured with a Perkin Elmer 241 photoelectric polarimeter.

Chemicals, all test samples, flavone, flavonol, 7-hydroxyflavone, 5,7-dihydroxyflavone, quercetin, 6-chloroflavone, naringenin, and hesperetin, were obtained from Sigma. Bromine and CPO were also purchased from Sigma. Sodium hypochlorite was obtained from Carlo. Other chemicals used were reagent grade.

3.2. Micro-organism

Caldariomyces fumago ATCC 11925 was obtained from the American Type Culture Collection. Live cultures were maintained by subculturing on suitable slants at room temperature or storage at 4°C in tightly capped culture tubes.

3.3. Enzymatic halogenation of flavanones and flavones by C. fumago whole cells

A two-stage fermentation technique was employed. Stage I and stage II cultures were prepared by the following method. The surface growth from *C. fumago* slants on mycophil agar (BBL) was suspended in 5 ml volumes of normal saline solution. One milliliter of the suspension was transferred into 100 ml of stage I medium in 500 ml erlenmeyer flasks. The stage I cultures were incubated at ambient temperature (20°C) on a rotary shaker at 250 rpm for 48–72 h. Approximately 10 ml volumes of the actively growing stage I cultures were transferred to 100 ml of fresh medium in 500 ml erlenmeyer flasks. All fermentation experiments were carried out in a Czapek-yeast- KCl or Czapek-yeast-KBr medium, consisting of glucose, 30 g; $NaNO_3$, 3.0 g; K_2SO_4, 1.0 g; $MgSO_4$, 0.5 g; KCl or KBr, 0.5 g; $(Fe)_2(SO_4)_3$, 0.01 g; yeast extract, 3.3 g in 1 l H_2O. Media were sterilized by autoclaving at 121°C, 15 lb/in^2 for 15 min.

For initial screening experiments, 10 mg of each sample as a solution in DMF (50 mg/ml) was added and suspended into each flask of 24 h stage II cultures. The culture was further incubated and monitored. Ten milliliters of the cultures were sampled daily and extracted

with 10 ml of $CHCl_3$, twice. The extracts were concentrated to dryness and redissolved in 0.25 ml of 95% EtOH. The solutions were subjected to silica gel TLC and developed with toluene-Me_2CO (10:1) and/or CH_3Cl-MeOH (40:1). TLC plates exposed to UV light and Fast Blue BB spray reagent were analyzed. Control cultures of organism without substrate and controls consisting of substrate in medium without organism were performed along with sample cultures.

Preparative scale fermentations were conducted on 150–190 mg of substrates, using a two-stage shaken culture fermentation as described above. The stage II cultures with substrate were incubated for 24–48 h before being harvested. The whole culture broths were exhaustively extracted twice with an equal volume of $CHCl_3$. The $CHCl_3$ extracts were dried over Na_2SO_4, evaporated and purified.

3.4. Enzymatic halogenation of flavanones and flavones by CPO (Sigma)

The reaction conditions were modified from the method described by Yamada et al. (1985). For initial screening, the enzymatic reaction mixture contained 10 ml of 0.1 M potassium phosphate buffer (pH 2.75), 100 μmol of KBr or KCl, 25–50 units of CPO, and 20 μmol of a substrate. All substrates were insoluble in water, and had to be first dissolved in 70 μl of warm EtOH, then poured and suspended in the reaction mixture. The reaction was initiated by slowly adding 100 μmol of H_2O_2 and continued for 60 min at room temperature with constant stirring. The control test was performed without the enzyme. The reaction was monitored by TLC as above.

Preparative scale halogenation was conducted on 0.8 mmol of substrates. Each substrate was dissolved in 3 ml of warm EtOH, then poured into the reaction mixture. The reaction mixture consisted of 400 ml of 0.1 M potassium phosphate buffer (pH 2.75), 4 mmol of KBr or KCl, and 1000 units of CPO. H_2O_2 (4 mmol) was then slowly added. After 60 min, the reaction mixture was extracted with $CHCl_3$ (200 ml×3). The extracts were concentrated to dryness and followed by a series of chromatographic methods for the isolation of the halogenated products.

3.5. Isolation procedures

3.5.1. Halogenated products 1–4 of naringenin formed by C. fumago whole cells

From the microbial bromination of naringenin (180 mg) with *C. fumago* in Czapek-yeast-KBr, the dried $CHCl_3$ extract was subjected to silica gel PF_{254} chromatography using toluene–Me_2CO (10:1) as eluant. Naringenin (58 mg) was recovered. Flavonoid-containing fractions (18 mg) were subjected to prep. TLC using a silica gel 60 F_{254} plate at 0.25 mm thickness. The chromatogram was developed three times, using toluene–Me_2CO (10:1) for the first development, then, $CHCl_3$–MeOH (40:1) for the last two. The plate was visualized under UV light at 254 nm. Two major bands were observed. The compound from each band was extracted from silica gel using Me_2CO. 6,8-Dibromonaringenin (**1**) (4.3 mg) and 8-bromonaringenin (**2**) (3.2 mg) were isolated.

The microbial chlorination of naringenin (190 mg) was performed with *C. fumago* in Czapek-yeast-KCl. The dried $CHCl_3$ extract was applied to a silica gel PF_{254} column with toluene–Me_2CO (12:1) giving 6,8-dichloronaringenin (**3**) (40 mg) and 6-chloronaringenin (**4**) (14.5 mg).

3.5.2. Halogenated products 1–4 of naringenin formed by CPO (Sigma)

Each preparative scale bromination and chlorination was conducted on 217 mg of naringenin according to the method described above. The dried extract of each reaction mixture was subjected to silica gel 60 GF_{254} column chromatography with toluene–Me_2CO (12:1) as eluant. 6,8-Dibromonaringenin (**1**) (20.2 mg), 8-bromonaringenin (**2**) (16.9 mg), and naringenin (126 mg) were isolated from the dried extract of the enzymatic bromination. 6,8-Dichloronaringenin (**3**) (6 mg), 6-chloronaringenin (**4**) (4.2 mg), and naringenin (135 mg) were isolated from the dried extract of the enzymatic chlorination mixture.

*3.5.3. Halogenated products **5**–**8** of hesperetin formed by CPO (Sigma)*

Preparative scale bromination and chlorination were performed on 240 mg and 120 mg of hesperetin, respectively, according to the method described above. The dried extract of each reaction mixture was chromatographed over silica gel 60 GF_{254} with toluene–Me_2CO (15:1). 6,8-Dibromohesperetin (**5**) (20 mg), 8-bromohesperetin (**6**) (5.1 mg), and hesperetin (120.8 mg) were isolated from the dried extract of the enzymatic bromination mixture. 6-Chlorohesperetin (**8**) (1.2 mg) and hesperetin (82 mg) were isolated from the dried extract of the enzymatic chlorination mixture. Trace amounts of 6,8-dichlorohesperetin (**7**) were observed on a silica gel TLC plate.

*3.5.4. Chlorinated products **7** and **8** of hesperetin formed by C. fumago whole cells*

One hundred and ninety milligrams of hesperetin were biotransformed with *C. fumago* in Czapek-yeast-KCl. The dried $CHCl_3$ extract was chromatographed over silica gel 60 (230–400 mesh) with toluene–Me_2CO (12:1). Hesperetin (64 mg) was recovered. Prep. TLC of flavonoid-containing fractions (23 mg) was performed on a silica gel 60 F_{254} plate at 0.25 mm thickness using $CHCl_3$:MeOH (40:1). Two metabolic products, 6,8-dichlorohesperetin (**7**) (5.7 mg) and 6-chlorohesperetin (**8**) (3.2 mg), were isolated.

*3.5.4.1. 6,8-Dibromohesperetin (**5**).* An amorphous powder; $[\alpha]_D^{20}$ 0° (MeOH; c 0.1); λ_{max}^{MeOH} nm (log ε): 230 (4.1), 332 (4.0); ν_{max} (KBr) cm^{-1}: 3410 (OH), 1635 (>C=O); ^1H NMR cf. 3.6. Chemical reaction with molecular halogen and hypohalous acid

3.6.1. Chemical bromination of naringenin

The biomimetic reaction of naringenin with bromine was examined under conditions similar to the chloroperoxidase reaction. The reaction mixture consisted of 7.8 ml of 1 M phosphate buffer (pH 2.75), 1.5 mmol of H_2O_2, 0.76 mmol of KBr, 20 ml of H_2O, and 10 ml of EtOH–Me_2CO (1:1). Naringenin (100 mg; 0.37 mmol) dissolved in 4.0 ml of EtOH–Me_2CO (1:1) was added to the reaction mixture and thoroughly mixed. Bromine solution (0.76 mmol of Br_2 in 400 μl of EtOH) was then slowly added at room temperature with mild stirring. After 45 min, the reaction mixture was extracted with $CHCl_3$ (25 ml×2). The combined extract was dried over Na_2SO_4 and evaporated to dryness. The residue was subjected to silica gel GF_{254} chromatography with toluene–Me_2CO (12:1) as eluant to give 6,8-dibromonaringenin (**1**) (26 mg) and 8-bromonaringenin (**2**) (17.0 mg).

3.6.2. Chemical bromination of hesperetin

Hesperetin (200 mg; 0.66 mmol) was dissolved in 8.0 ml of EtOH–Me_2CO (1:1), then poured into the reaction mixture. The reaction mixture contained 14 ml of 1 M phosphate buffer (pH 2.75), 2.6 mmol of H_2O_2, 1.3 mmol of KBr, 40 ml of H_2O, and 20 ml of EtOH-Me_2CO (1:1). The reaction was started by slowly adding bromine solution (1.3 mmol of Br_2 in 700 μl of EtOH). After 45 min, the reaction mixture was extracted with $CHCl_3$ (45 ml×2). The combined extract was dried over Na_2SO_4 and evaporated to dryness. The residue was applied to silica gel GF_{254} with toluene–Me_2CO (15:1) as eluant to afford 6,8-dibromohesperetin (**5**) (23.8 mg) and 8-bromonaringenin (**6**) (26.0 mg).

3.6.3. Chemical chlorination of naringenin

The reaction mixture consisted of 14 ml of 1 M phosphate buffer (pH 2.75), 40 ml of H_2O, 20 ml of EtOH–Me_2CO (1:1), and 200 mg of naringenin dissolved in 8.0 ml of EtOH–Me_2CO (1:1). To the reaction mixture was added dropwise 3.75 ml of sodium hypochlorite solution, then, 3.75 ml of HOAc. After stirring the mixture for 1 h at room temperature, the mixture was extracted with $CHCl_3$ (45 ml×2). The combined extract was dried over Na_2SO_4 and evaporated to dryness. The residue was subjected to silica gel GF_{254} chromatography with toluene–Me_2CO (12:1) as eluant. 6-Chloronaringenin (**4**) (6 mg) was isolated. Trace amounts of 6,8-dichloronaringenin (**3**) were observed by silica gel TLC plate.

3.6.4. Chemical chlorination of hesperetin

The biomimetic chlorination of hesperetin (200 mg) was performed under similar conditions as above. The dried residue was applied to silica gel GF_{254} with toluene-

Me_2CO (15:1) as eluant, yielding 6-chlorohesperetin (**8**) (9 mg). Trace amounts of 6,8-dichlorohesperetin (**7**) were observed by silica gel TLC plate.

Abstract

Five isoforms of β-galactosidase (EC 3.2.1.23), designated as β-galactosidases I–V, were isolated from five-day-old mung bean (*Vigna radiata*) seedlings. β-Galactosidases II and III were purified to electrophoretic homogeneity by a procedure involving acid precipitation, ammonium sulfate fractionation, chromatography on diethylaminoethyl-cellulose (DEAE-Cellulose) and con A-Sepharose, and chromatofocusing. β-Galactosidases I, II and III have the same molecular mass of 87 kDa, comprising two non-identical subunits with molecular masses of 38 and 48 kDa, while β-galactosidases IV and V have molecular masses of 45 and 73 kDa, respectively. All the enzymes were active against *p*-nitrophenyl-β-D-galactoside, and to a lesser extent, *p*-nitrophenyl-α-L-arabinoside and *p*-nitrophenyl-β-D-fucoside. The enzymes were inhibited by D-galactono-1,4-lactone, D-galactose, Hg^{2+}, Ag^{+} and sodium dodecyl sulfate (SDS). β-Galactosidases I, II and III were shown to be competitively inhibited by either D-galactono-1, 4-lactone or D-galactose. Isoforms I, II and III have a common optimal pH of 3.6, while isoforms IV and V have pH optima at 3.8 and 4.0, respectively. Isoelectric points of isoforms I, II and III were 7.7, 7.5 and 7.3, respectively. Double immunodiffusion analysis indicated that β-galactosidases I, II, III and V are immunologically similar to each other, while β-galactosidase IV shares partially identical antigenic determinants with the other four isoforms. The purified β-galactosidases II and III were capable of releasing D-galactose residue from the hemicellulose fraction isolated from mung bean seeds. © 2001 Elsevier Science Ltd. 1. Introduction

β-Galactosidase (EC 3.2.1.23) is widely distributed in plant tissues. The enzyme has been implicated in a number of biological processes including plant growth and fruit ripening. One characteristic of fruit ripening and softening is the mobilization of cell wall components. The release of monomeric galactose from cell walls of ripening fruits has been described with apple, tomato, melon, avocado, kiwifruit and mango (Bartley, 1976; Pressey, 1983; Ranwala et al., 1992; Deveau et al., 1993; Ross et al., 1993; Ali et al., 1995). Molecular approaches were also used to unravel the role of β-galactosidases in fruit development and ripening. Ross et al. (1994) isolated a cDNA clone encoding an apple β-galactosidase. Northern blot analysis showed accumulation of a transcript homologous to the cDNA clone during fruit ripening. A cDNA clone, a member of the β-galactosidase gene family, was isolated from a cDNA library of tomato fruit. This cDNA showed ripening-related gene expression in normal fruits, with lower levels apparent in the non-softening mutants (Carey et al., 1995). Another cDNA, corresponding to β-galactosidase II of tomato, was also cloned. Northern blot analysis revealed that the β-galactosidase II gene transcript was detectable at the breaker stage of ripeness, maximum at the turning stage, and present at decreasing levels during the later stages of normal tomato fruit ripening (Smith et al., 1998).

The correlation of β-galactosidases with plant growth and development has also been investigated. This included the isolation and characterization of β-galactosidases from cowpea, nasturtium, radish, mung bean, barley, carrot, rice shoots and lupins (Biswas, 1987; Edwards et al., 1985, 1988; Sekimata et al., 1989; Kundu et al., 1990; Giannakouros et al., 1991; Konno and Katoh, 1992; Konno and Tsumuki, 1993; Buckeridge and Reid, 1994).

We have found that the activities of some glycosidases in germinating mung bean seeds increased to a high level between days 4–6. β-*N*-Acetylglucosaminidase, β-galactosidase and α-mannosidase showed the highest specific activity. The increase of β-galactosidase activity during seed germination was also reported in plants such as pinto beans (Agrawal and Bahl, 1968), castor beans (Harley and Beevers, 1985), nasturtium (Edwards et al., 1988), barley (Giannakouros et al., 1991) and lupin (Buckeridge and Reid, 1994). The increase of β-galactosidase activity during the germination of barley seeds seems to be very moderate when compared with the many-fold increase in the activity of the same enzyme observed in the seeds of dicotyledon plants (Giannakouros et al., 1991). Thus, the developmental regulation of plant β-galactosidase during germination and growth has become evident. However, much less is known about the mechanism underlying this regulation. We investigated the structure and function of mung bean β-galactosidase as a first step towards studying its gene expression and regulation. This paper deals with the purification and characterization of five isoforms of β-galactosidase, and the activity of the two purified isoforms, II and III, of the enzyme towards cell wall polysaccharides of mung bean seeds. Separation by two-dimensional electrophoresis, followed by Western blot analysis of the two purified isoforms, II and III, as well as the immunological relationship of the five isoforms are also described.

2. Results

2.1. Purification

Acid precipitation removed a large portion of the contaminating proteins (about 65% of total proteins) in the cell-free extract, resulting in a 2.6-fold purification (Table 1). With the purification procedure shown in Scheme 1, five β-galactosidases, I–V, were isolated as summarized in Table 1 and Fig. 1. β-Galactosidases I, II and III, which did not bind to either DEAE-cellulose or Con A-Sepharose, were purified by chromatofocusing. β-Galactosidases II and III were purified to electrophoretic homogeneity after repeating chromatofocusing twice, and whereas a faint contaminating band ran ahead of β-galactosidase I in a non-denaturing gel (Fig. 2), it did not indicate the actual molecular weights. The β-galactosidase IV, retained on the DEAE-cellulose (Fig. 1A) and Con A-Sepharose columns (Fig. 1C), was eluted in sequence from the columns. The eluted β-galactosidase IV was shown to be still contaminated with many proteins in a non-denaturing gel (data not shown). Thus, β-galactosidase V, which bound to Con A-Sepharose (Fig. 1B), was purified with this column. The purified isoform V contained approximately equal amounts of a contaminating protein that moved slightly faster than the enzyme in a non-denaturing gel (data not shown). The overall recovery of the five β-galactosidase isoforms was about 34%.

2.2. Characteristics of β-galactosidases

The molecular masses of β-galactosidases I, II, III, IV and V, estimated from their elution volumes from Sephacryl S-200, were 87, 87, 87, 73 and 45 kDa, respectively (data not shown). However, β-galactosidases I, II and III showed mobilities corresponding to 300–400 kDa in a non-denaturing gel (Fig. 2). A possible explanation for this discrepancy is that, firstly, the enzyme with isoelectric points in the range 7.3–7.7 might form aggregates during their concentration in the stacking gel (pH 6.8). Secondly, these isoforms are likely to be glycoproteins in nature, because they bound to a Con A column when NaCl was eliminated from the elution buffer. SDS–PAGE of β-galactosidases I, II and III showed that each form consisted of two non-identical subunits

Table 1
Purification of β-galactosidases from five-day-old mung bean seedlings[a]

Step	Total protein (mg)	Total activity (units)	Specific activity (units/mg protein)	Purification (fold)	Yield (%)
Cell-free extract	11,206.0	645.5	0.0576	1.0	100
Acid precipitation	3946.3	580.2	0.15	2.6	89.9

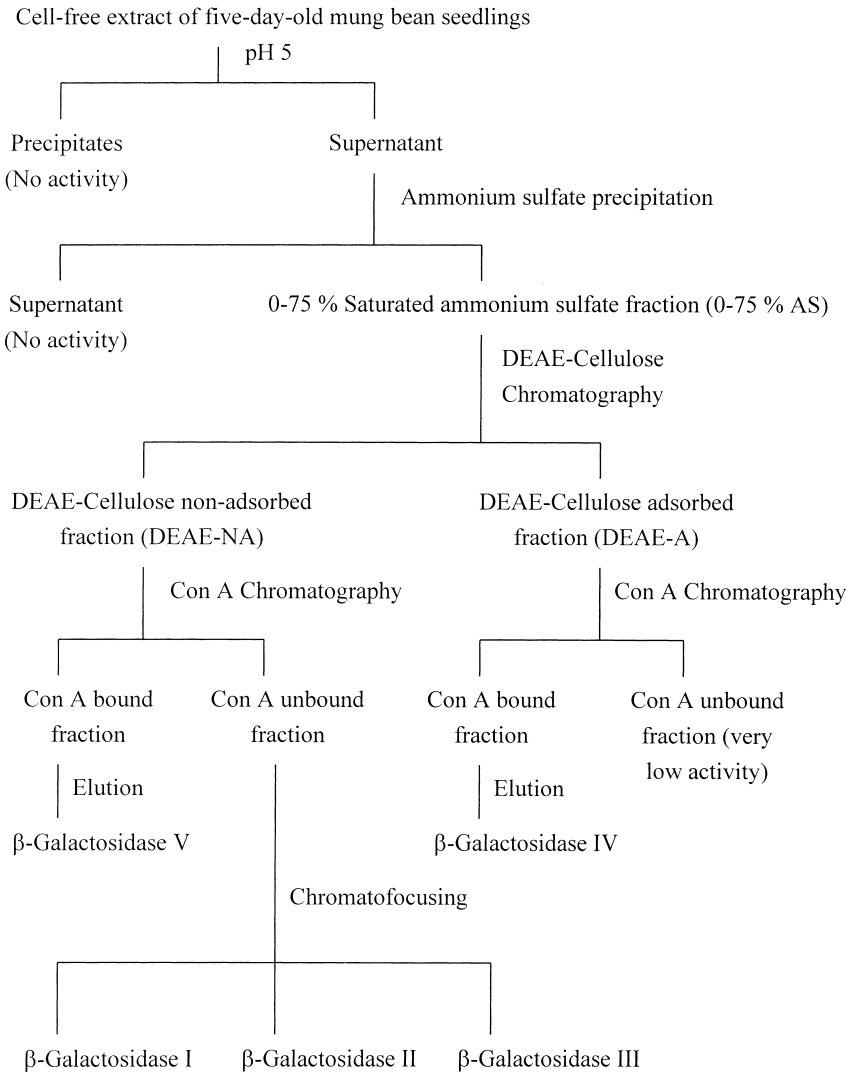
Chromatofocusing					
I	0.48	19.1	39.79	691	2.96
II	0.51	48.7	95.49	1657	7.54
III	0.58	55.5	95.69	1661	8.59

[a] A total of 4.1 kg of mung bean seedlings was used for the purification. Roman numerals I–V stand for β-galactosidases I–V, respectively.



Scheme 1.

with molecular masses of 38 and 48 kDa (Fig. 3). Since the SDS–PAGE provided only a rough estimation of molecular mass, these two figures (38 and 48 kDa) were more accurately determined by running these two subunits through 0.1% SDS polyacrylamide gradient gel (10–20%) along with molecular weight standard proteins (data not shown). Two proteins bands, approximately 22 and 30 kDa, were also observed in β-galactosidase I and were probably due to contaminating proteins in the enzyme preparation (Fig. 3).

Effects of sugars and sugar derivatives on β-galactosidases I, II and III are shown in Table 2. D-Galacto-1,4-lactone was the most potent inhibitor followed by D-galactose and lactose. D-Galacto-1, 4-lactone at 12.5 mM almost completely inhibited the three isoforms (97.7–98.3% inhibition). The three isoforms were 71–72% inhibited by 50 mM D-Galactose, 26–28% inhibited by 50 mM lactose and slightly inhibited by 12.5 mM D-glucono-δ-lactone. D-Arabinose and D-fucose at 50 mM had no effect on the three enzymes. A kinetic analysis indicated that D-galactono-1, 4-lactone and D-galactose acted as competitive inhibitors. K_i values for these two competitive inhibitors were determined by replots of data taken from double reciprocal plots. D-Galacto-1, 4-lactone has K_i values of 0.13, 0.085 and 0.17 mM for isoforms I, II and III, respectively, while D-galactose has K_i values of 11.4, 15 and 13 mM for I, II and III, respectively. The three isoforms have a common optimal pH of 3.6. Isoforms IV and V have pH optima at 4.0 and 3.8, respectively (Fig. 4). Isoforms I, II and III have temperature optima around 50–53°C (Fig. 5) and isoelectric points of 7.7, 7.5 and 7.3, respectively. All of the isoforms were stable from pH 4.0 to 8.0. Effects of metallic ions, EDTA, and SDS on β-galactosidase activities are shown in Table 3. Ag^+, Hg^{2+} and SDS at 1 mM strongly inhibited the activities of isoforms I, II and III. The cell-free extract was active against 12 *p*-nitrophenyl glycosides tested. After purification, isoforms II and III retained the activities of β-galactosidase, β-D-fucosidase and α-L-arabinosidase, but were essentially devoid of activity

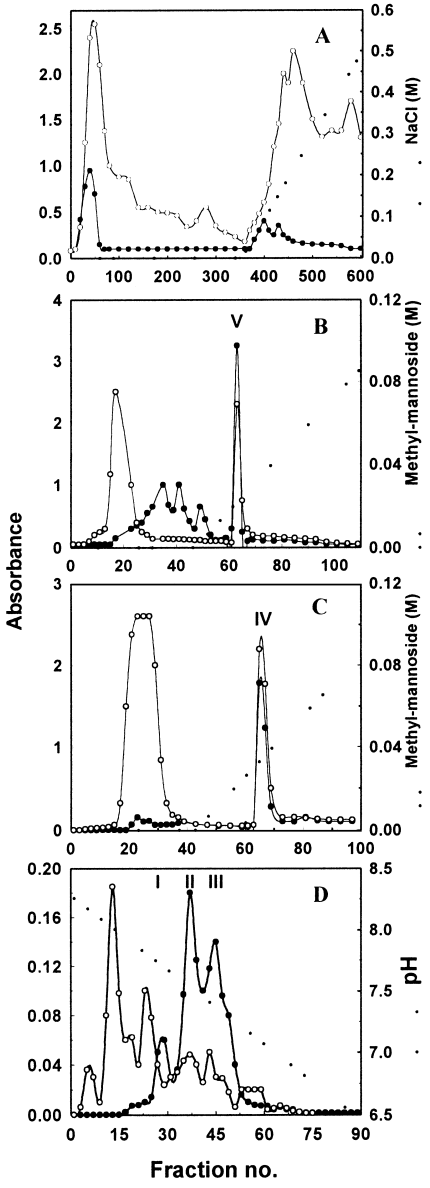


Fig. 1. Elution profiles of β-galactosidases on DEAE-cellulose columns (A), Con A-Sepharose columns (B, C) and chromatofocusing (D). The ammonium sulfate precipitated enzyme sample was applied to a DEAE-cellulose column (A). The DEAE-cellulose non-adsorbed fraction containing β-galactosidases I, II, III and V, and the adsorbed fraction (β-galactosidase IV), were then purified by Con A-Sepharose chromatography (B, C). The Con A-Sepharose adsorbed fraction is called β-galactosidase V. The non-adsorbed fraction containing β-galactosidases I, II and III was further purified by chromatofocusing. Experimental details are given in the Experimental section. Protein is expressed as absorbance at 280 nm (○) and β-galactosidase activity as absorbance at 420 nm (●).

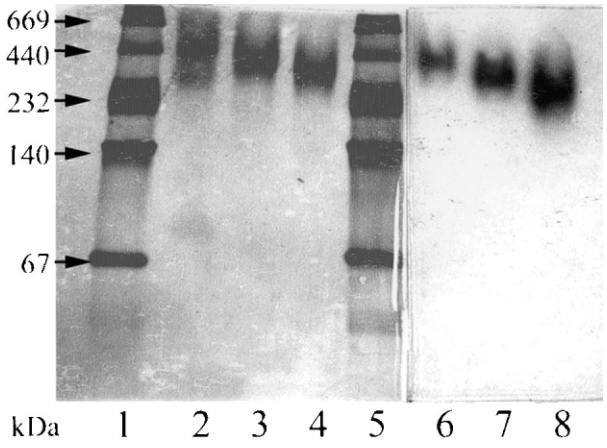

Fig. 2. The electrophoretic pattern of purified β-galactosidases I, II and III. After electrophoresis of the native enzymes (ca 5 μg protein each), the left half of the gel (lanes 1–5) was stained with silver nitrate, and the right half (lanes 6–8), with activity staining. Lanes 1 and 5, molecular mass markers from top: thyroglobulin (669 kDa), ferritin (440 kDa), catalase (232 kDa), lactate dehydrogenase (140 kDa) and bovine serum albumin (67 kDa); lanes 2 and 6, β-galactosidase I; lanes 3 and 7, β-galactosidase II; lanes 4 and 8, β-galactosidase III.

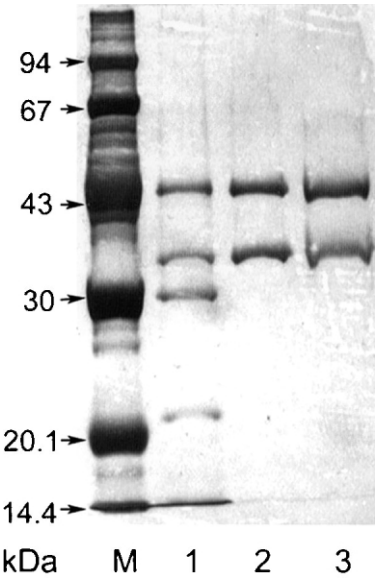

Fig. 3. SDS–PAGE of purified β-galactosidases I, II and III. Molecular mass markers from top: phosphorylase b (94 kDa), bovine serum albumin (67 kDa), ovalbumin (43 kDa), carbonic anhydrase (30 kDa), trypsin inhibitor (20.1 kDa) and α-lactalbumin (14,4 kDa). The numbers 1, 2 and 3 stand for β-galactosidases I, II and III, respectively. The gel was stained with silver nitrate.

towards the nine other *p*-nitrophenyl glycosides (less than 5%) (Table 4). Ratios of the activities of β-D-galactosidase, β-D-fucosidase and α-L-arabinosidase exhibited by isoforms II and III are 100, 35.7, 32.7% and 100, 31.2, 24.6%, respectively. Plant β-galactosidases with multiple glycosidase activities have been described (Conchie et al., 1968; Kiss et al., 1981; Simos and Georgatsos, 1988). Since β-galactosidases II and III were purified to apparent homogeneity, cross-contamination from other glycosidases seems unlikely. Therefore, it is reasonable to suggest that the three glycosidase activities mentioned above reside in a single molecular species of β-galactosidases II and III.

Table 2
Effects of sugars and sugar derivatives on β-galactosidase activities[a]

	β-Galase activity (nkatals)		
	I	II	III
No inhibitor	3.76×10^{-2} (100%)	3.87×10^{-2} (100%)	4.41×10^{-2} (100%)
D-Galactono-1,4-lactone (12.5 mM)	8.35×10^{-4} (2.2%)	6.68×10^{-4} (1.7%)	1.0×10^{-3} (2.3%)
D-Glucono-δ-lactone (12.5 mM)	3.46×10^{-2} (92%)	3.44×10^{-2} (89%)	3.74×10^{-2} (85%)
D (+) Arabinose (50 mM)	3.72×10^{-2} (99%)	3.67×10^{-2} (95%)	4.28×10^{-2} (97%)
D (+) Fucose (50 mM)	3.64×10^{-2} (97%)	3.64×10^{-2} (94%)	4.19×10^{-2} (95%)
D (+) Galactose (50 mM)	1.05×10^{-2} (28%)	1.12×10^{-2} (29%)	1.24×10^{-2} (28%)
Lactose (50 mM)	2.71×10^{-2} (72%)	2.87×10^{-2} (74%)	3.22×10^{-2} (73%)

[a] Sugars and sugar derivatives at a final concentration of 12.5 or 50 mM were pre-incubated with appropriate amount of enzyme in 50 mM sodium citrate buffer (pH 3.6) at 37°C for 10 min. PNP-β-D-galactopyranoside was then added to the mixture to assay the enzyme activity.

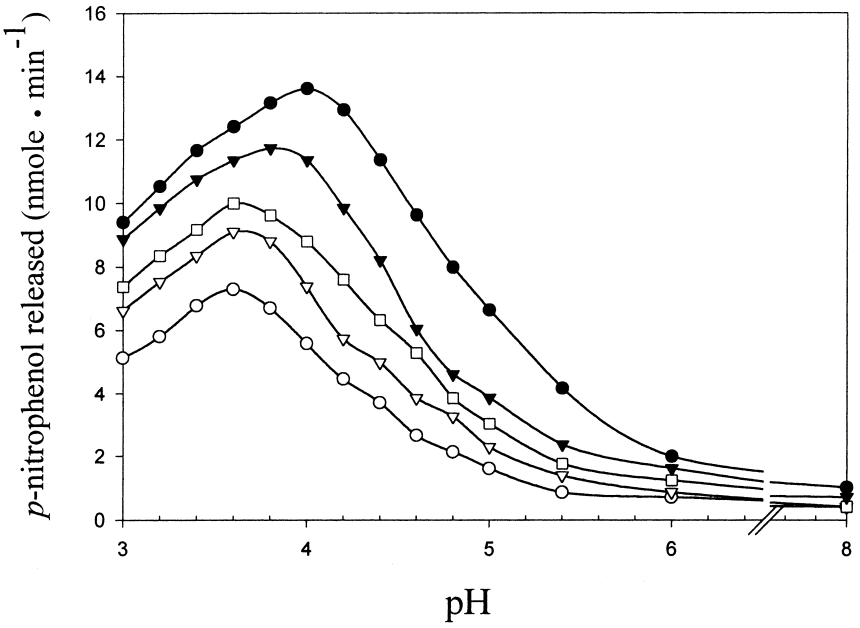

Fig. 4. Effect of pH on the purified β-galactosidases. McIIValine buffer (pH 3–6) and Na-phosphate buffer (pH 7–8) were used. The purified β-galactosidases I (○), II (▽), III (□), IV (●) and V (▼) were assayed at various pH by the method given in Experimental.

2.3. Immunochemical study

In order to investigate immunological relationships of the five isoforms of mung bean β-galactosidase, antisera were raised against the purified β-galactosidases II and III. Ouchterlony double immunodiffusion analysis indicated that all five β-galactosidase isoforms cross-reacted with anti β-galactosidase II antiserum (antiserum II) (Fig. 6A). The same result was obtained when anti β-galactosidase III antiserum (antiserum III), instead of antiserum II, was used (Fig. 6B). A spur was shown between the purified β-galactosidase IV and either β-galactosidase III or V. These results suggest that β-galactosidases I, II, III and V are immunologically similar to each other, while β-galactosidase IV shares partially identical antigenic determinants with the other four isoforms. In the purification of these β-galactosidases, isoform IV was the only β-galactosidase bound to the DEAE-cellulose column equilibrated at a pH of 7.2 (Fig. 1A). The charge difference on the surface of isoform IV may in part account for its different immunological properties as compared with the other four isoforms.

Purified isoforms II and III were separated with two-dimensional electrophoresis using the method of O'Farrell (1975) and probed with antiserum II or III. The 2-D electrophoresis gel of isoform II is shown in Fig. 5. Similar results were obtained with isoform III. The results indicated that both isoforms II and III consisted of two groups of polypeptides with molecular masses of 38 and 48 kDa, the former containing at least six polypeptides and the latter four. The results are in accord with the finding that β-galactosidases II and III consist of two non-identical subunits (Fig. 3). The results also suggest that β-galactosidases in mung bean may be encoded by a multiple gene family. The β-galactosidases purified from cotyledons of mung bean

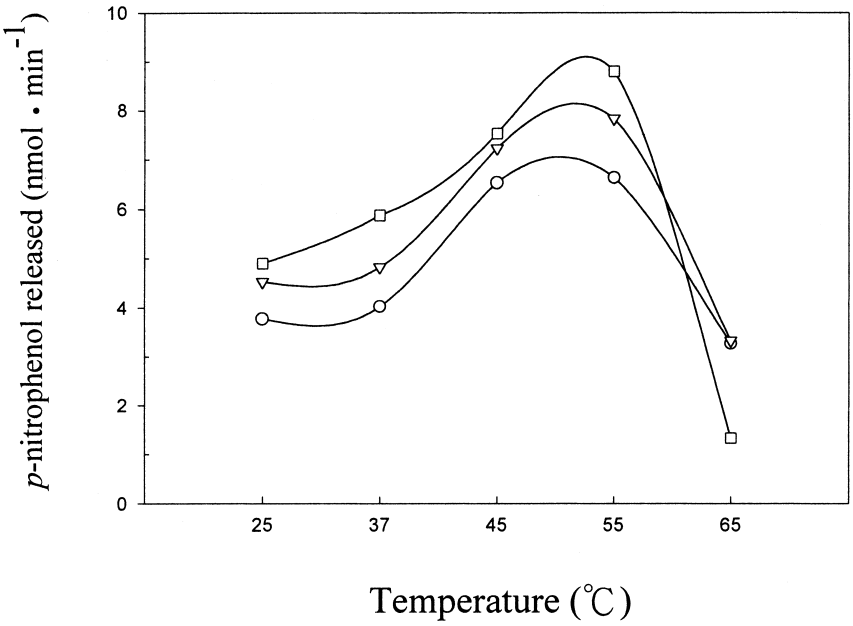

Fig. 5. Temperature optima of β-galactosidases I, II and III. Enzyme activities of the purified β-galactosidases I (○), II (▽) and III (□) were assayed at various temperatures by the method given in the Experimental.

Lactose	103.7±9.0	92,785.2±8032.7	159,585.2±3089.5

[a] Experimental conditions are given in Experimental. Enzyme activity is expressed as μmol of D-galactose liberated per min per mg protein. The data are expressed as mean ± S.D. from three determinations.

were previously shown to be homodimers (Kundu et al., 1990). A question arises whether the 38 kDa subunit is the degradation product of the 48 kDa subunit. To clarify this point, cell-free extracts of the 5-day-old germinated mung bean seeds, the supernatant fraction of acid (pH 5.0) precipitated fraction and 0–70% saturated ammonium sulfate of the cell-free extract were separated by SDS–PAGE and subjected to Western blot analysis. The results showed that all three samples exhibited two polypeptides with molecular masses corresponding to 38 and 48 kDa, which cross-reacted with antiserum II (data not shown).

2.4. Degradation of cell wall polysaccharides by β-galactosidases II and III

β-Galactosidase activity was determined during the course of mung bean germination. The enzyme activity increased from day 1 after imbibition in the dark, approached a high level around day 5 and remained about the same until day 9 (data not shown). To understand whether β-galactosidases II and III potentially participate in the mobilization of cell wall polysaccharides, the two purified enzymes and cell-free extract were examined for their hydrolytic activity towards cell wall polysaccharides isolated from mung bean seeds.

The results indicated that both β-galactosidases II and III were capable of releasing monomeric galactose from the cell wall polysaccharides in vitro (Table 5). Rates of galactose liberation by β-galactosidase II were high with 4 and 24% KOH soluble hemicellulose as substrates, and moderate with xyloglucan, hot water soluble and oxalate soluble pectins. While exhibiting high activity towards 24 and 4% KOH soluble hemicellulose and xyloglucan similar to β-galactosidase II, β-galactosidase III showed relatively lower activity on hot water soluble and oxalate soluble pectin. The cell-free extract exhibited higher activity on 24 and 4% KOH soluble hemicellulose than the other cell wall polysaccharides. The release of monomeric D-galactose from 4 or 24% KOH soluble hemicellulose by purified β-galactosidase II amounted to 2.5–2.6 μg after prolonged incubation for more than 6 h. This is approximately equivalent to 3.3–3.5% of total polysaccharides (75 μg) in the reaction mixture. Purified β-galactosidase III gave similar results (data not shown). Both enzymes also have high activity against lactose (Table 5). Thus, purified β-galactosidases II and III were capable of efficiently releasing D-galactose residue from the hemicellulose fraction in vitro.

3. Discussion

In this report, we have isolated and characterized five isoforms of β-galactosidase from etiolated mung bean seedlings. β-Galactosidases II and III were purified to electrophoretic homogeneity, while I, IV and V were partially purified. Optimal pH (3.6–4.0) and temperature (50–53°C), isoelectric points (7.3–7.7) and molecular mass (87, 87, 87, 73, 45 kDa) of these enzymes were comparable with those of other plant β-galactosidases previously described (Li et al., 1975; Biswas, 1987; Edwards et al., 1988; Kundu et al., 1990), with the exception that the β-galactosidase isolated from mature seeds of mung bean had molecular masses of 162 kDa (Dey, 1984).

The results of SDS–PAGE (Fig. 3) and two-dimensional electrophoresis (Fig. 5) indicate that β-galactosidases II and III are composed of two non-identical subunits (38 and 48 kDa). Fig. 7 also shows that the 38 and 48 kDa

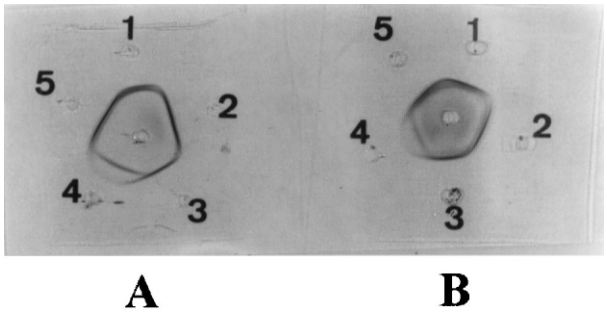

Fig. 6. Double immunodiffusion analysis of β-galactosidases I–V. Panel A: centre well, anti β-galactosidase II antiserum; wells 1–5, the purified β-galactosidases I–V, respectively. Panel B: centre well, anti β-galactosidase III antiserum; wells 1–5, the same as panel A.

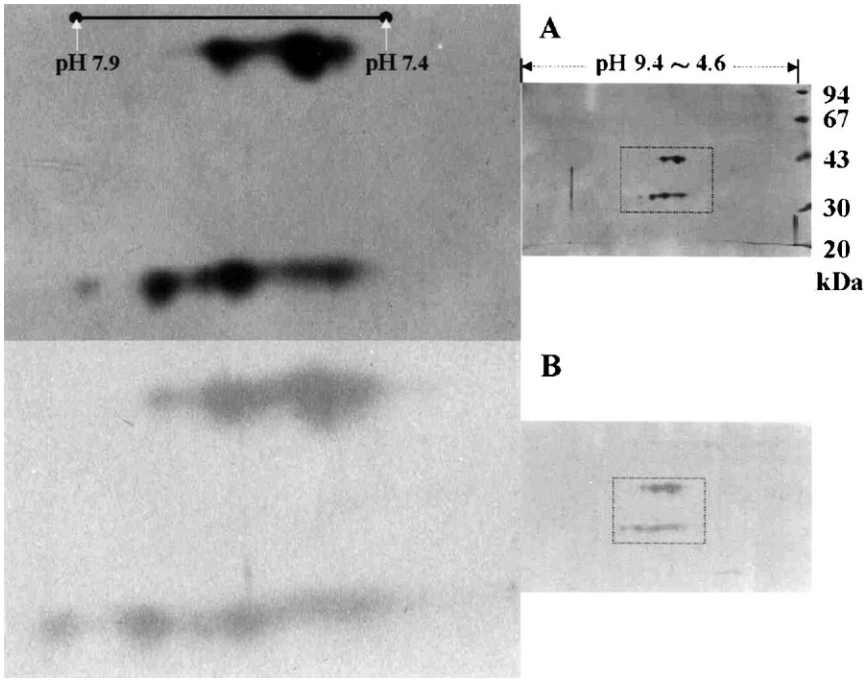

Fig. 7. Two-dimensional gel electrophoresis of β-galactosidase II. A, silver staining; B, Western blotting. The areas marked with dotted lines are enlarged at left.

subunits were further separated into six and four polypeptides, respectively, which differed only in isoelectric point values. These results, together with the previous reports (Simos et al., 1989; Giannakouros et al., 1991), suggest that the multiplicity of plant β-galactosidases was at least in part due to different isoelectric point values.

It has been suggested that β-galactosidases play a vital role in plant growth and development, the β-galactosidases described here, which are capable of efficiently hydrolysing the hemicellulose fractions of mung bean seeds (Table 5), are apparently similar to a number of broad specificity β-galactosidases found in cotyledons and germinated seeds. The mung bean β-galactosidases are developmentally regulated as suggested by the finding that the activity of the β-galactosidases rapidly increased to a high level between day 4 and day 6 of germination. Our results, together with the previous findings (Edwards et al., 1985; Konno and Tsumuki, 1993), suggest that a number of β-galactosidases differing in substrate specificities are synthesized or activated to mobilize, or modify cell wall components during seed germination and plant growth, and that the temporal expression of the β-galactosidase genes are subjected to developmental regulation.

4. Experimental

4.1. Plant material and enzyme source

Mung bean seeds (*Vigna radiata* VC 3890 Sel No. 5) were submerged in distilled water at 25°C for 2 h and surface-sterilized with 0.5% hydrogen peroxide, thoroughly washed with H_2O and germinated in the dark at 28°C. Five-day-old germinated seeds were thoroughly washed with ice-cold H_2O and homogenized with Polytron (Kinematica) in 50 mM Tris–HCl (pH 7.2) containing 10 mM 2-mercaptoethanol and 1 mM EDTA. Unless otherwise indicated, all steps and the purification procedure were conducted at 5°C. The resultant slurry was squeezed through three layers of cheesecloth, phenyl methylsulphonyl fluoride (PMSF) was added at a final concentration of 1 mM, and centrifuged at 12,800×*g* for 30 min. The supernatant was dialysed against the same buffer solution containing 1 mM PMSF. The dialysed enzyme solution was referred to as cell-free extract.

4.2. Enzyme purification

The overall procedure for the purification of mung bean β-galactosidases is shown in Scheme 1. The cell-free extract was adjusted to a pH of 5.0 to precipitate large amounts of contaminating proteins, while retaining most of the β-galactosidase activity in the supernatant. Solid ammonium sulfate was added to the supernatant to obtain a 0–75% saturated ammonium sulfate fraction, which contained most of the β-galactosidase activity. The 0–75% saturated ammonium sulfate fraction was applied to a DE-52 column. Both DEAE-cellulose adsorbed (DEAE-A) and non-adsorbed (DEAE-NA) fractions were shown to contain β-galactosidase activity. These two fractions, therefore, were further subjected to Con A affinity column chromatography. After

Con A chromatography, almost all of the β-galactosidase activity in the DEAE-A was recovered in the Con A bound fraction. The β-galactosidase eluted from this column is named β-galactosidase IV. On the other hand, β-galactosidase activity in the DEAE-NA was separated into Con A bound and Con A unbound fractions. The former was eluted as a single protein peak that is called β-galactosidase. The latter was further separated into three activity peaks by chromatofocusing. These three isoforms were called β-galactosidases I, II and III, based on the order of their emergence from the column. β-Galactosidases II and III were purified to apparent homogeneity by repeated chromatofocusing on the same column. The experimental conditions for each purification step are described as follows.

The cell-free extract was adjusted to pH 5.0 with 3.5 M acetic acid, allowed to stand at 5°C for 2 h, and the precipitates were removed by centrifugation. Solid ammonium sulfate was added to the supernatant until 75% saturation was reached. The sample obtained from 75% saturated ammonium sulfate precipitation was redissolved in a small volume of 10 mM Tris–HCl (pH 7.2) containing 10 mM 2-mercaptoethanol (Buffer A), dialysed overnight against the same buffer solution and applied to a DEAE-cellulose (DE-52, Whatman) column (4.4×15 cm) previously equilibrated with Buffer A. The column was washed with 10 volume of Buffer A and eluted with a linear gradient (2 l total volume) of 0–0.5 M NaCl in 10 mM Tris–HCl (pH 7.2) containing 10 mM 2-mercaptoethanol. Fractions of 8 ml each were collected at a flow rate of 2 ml/min. Active fractions were pooled and concentrated using an Amicon ultrafiltration device (Ya 1000 membrane). This sample was called the DEAE-cellulose adsorbed fraction (DEAE-A). The column washing solution that still had β-galactosidase activity was concentrated and referred to as the DEAE-cellulose non-adsorbed fraction (DEAE-NA).

For purification of the DEAE-NA, Con A-Sepharose column (2.6×10 cm) was equilibrated with 20 mM Tris–HCl buffer (pH 7.2) containing 0.3 M NaCl, 1 mM $CaCl_2$ and 1 mM $MnCl_2$ (Con A affinity buffer). The DEAE-NA were pooled, concentrated with the Amicon ultrafiltration device, and dialysed against the Con A affinity buffer. The non-dialysable solution was placed on the Con A-Sepharose column. After washing with the Con A affinity buffer, the column was eluted with a linear gradient (250 ml total volume) of 0–0.2 M α-methylmannoside in 20 mM Tris–HCl (pH 7.2) containing 0.3 M NaCl. Fractions of 6 ml were collected. It was found that the effluent and washing showed β-galactosidase activity that had not bound to Con A-Sepharose under the chromatographic conditions used. The fractions exhibiting β-galactosidase activity in the effluent and washing were pooled and designated as a Con A-Sepharose non-adsorbed fraction that was shown to contain β-galactosidases I, II and III. β-Galactosidase V bound on Con A-Sepharose was eluted from the column.

The DEAE-A was also purified with the Con A-Sepharose column. The procedure was essentially as described above except that the column was equilibrated with 20 mM Tris–HCl (pH 7.2) containing 1 M NaCl. There was no detectable β-galactosidase activity in the washing solution and effluent. The protein peak that coincidentally came off the column with β-galactosidase activity after elution was referred to as β-galactosidase IV.

The Con A-Sepharose non-adsorbed fraction containing β-galactosidases I, II and III was concentrated to 3–4 ml and purified by chromatofocusing according to the instruction manual of Pharmacia. Polybuffer Exchanger PBE 94 (Pharmacia) column (1.0×15 cm) was equilibrated with 25 mM Tris–HCl (pH 8.3). Polybuffer 96 (Pharmacia) was diluted 13-fold with deionized water and adjusted to pH 6.8 with 6 M HCl (eluent). Eighteen milliliters of the eluent was introduced to the column to create a pH gradient from 6.8 (top) to 8.3 (bottom). The concentrated enzyme solution was dialysed against the eluent and placed on the column. β-Galactosidases I, II and III were eluted in this order from the column with 90 ml of the eluent. In order to obtain homogeneous enzyme, chromatofocusing was conducted twice more for each β-galactosidase peak.

4.3. Enzyme assays

β-Galactosidase activity was determined by measuring the release of *p*-nitrophenol from *p*-nitrophenyl (PNP)-β-D-galactopyranoside according to the method of Agrawal and Bahl (1968). The reaction mixture contained, in a final volume of 0.5 ml, 50 mM sodium citrate buffer (pH 3.6), 5 mM substrate, and varying amounts of enzyme. The reactions were carried out at 37°C for 10 min. Liberated *p*-nitrophenol was measured spectrophotometrically at 420 nm after stopping the reaction with the addition of 0.7 ml of 0.2 M sodium carbonate. Absorbance (A_{420}) was proportional to the amount of enzyme in the reaction mixture under the assay conditions. The absorbance, A_{420}, was also linear with time within the amounts of enzyme used. One unit of β-galactosidase is defined as the amount that hydrolyses 1 μmol of PNP-β-D-galactopyranoside per min at pH 3.6 and 37°C. One katal is defined as the amount of β-galactosidase that hydrolyses 1 mol of PNP-β-D-galactopyranoside per second under the same condition. Other glycosidase activities were determined by the use of the respective PNP-glycoside. The reaction conditions were essentially the same as those described above.

Release of D-galactose from cell wall polysaccharides was determined using β-D-galactose dehydrogenase (Sigma) (Kurz and Wallenfels, 1974). Protein concentration was determined by the methods of Bradford (1976) using bovine serum albumin as a standard.

4.4. Preparation of cell walls

Cell walls of mung bean seeds were prepared according to the method described by Jarvis et al. (1981). Mung bean seeds were homogenized in ice-cold H_2O (5 l/kg) containing 5 g/l sodium deoxycholate and 10 g/l *n*-octanol in a Waring blender. The homogenate was filtered through three layers of cheesecloth and washed on a 120-mesh sieve with ice-cold H_2O (4 l/kg). The crude cell walls were suspended in distilled water (650 ml/kg), homogenized for 2 min with Polytron (Kinematica) and washed with distilled water (8 l/kg). The homogenization and sieving was repeated until no more starch grains were released. Lipids were removed by stirring with 800 ml/kg chloroform–methanol (1:1/v:v), and the cell walls removed by filtration and freeze-dried.

4.5. Cell wall fractionation

The dry cell walls were sequentially extracted with hot water, 0.25% ammonium oxalate-oxalic acid, 4% KOH and 24% KOH by the method of Kato and Matsuda (1976). Xyloglucan was prepared from mung bean seeds according to the procedure previously described (Edwards et al., 1985).

4.6. Degradation of cell wall polysaccharides

Each of the two pectic fractions (hot water and oxalate soluble fractions), the two hemicellulosic fractions (4% KOH and 24% KOH soluble fractions), and xyloglucan obtained above was dissolved in 0.2 M sodium citrate buffer (pH 3.6) at a final concentration of 1.5 mg/ml and used as substrate for purified β-galactosidases II and III, and the cell-free extract. The reaction mixture contained, in a final volume of 0.83 ml, 75 μg substrate and an appropriate amount of enzyme or cell-free extract. The reaction mixture was incubated at 37°C and aliquots were taken at various intervals for determination of D-galactose with galactose dehydrogenase (Kurz and Wallenfels, 1974).

4.7. Preparation of antisera

Purified β-galactosidases II and III, which are homogeneous on disc polyacrylamide gel electrophoresis, were used as the antigens. Two rabbits were injected subcutaneously four times with 150–180 μg each of β-galactosidases II and III emulsified with Freund's complete adjuvant. Intervals between injections were 2–3 weeks. The rabbits were killed one month after the final injection. The blood clots were centrifuged and the clear serum lyophilized and stored at −70°C.

4.8. Immunological methods

Ouchterlony double immunodiffusion was performed at room temperature in a 2% agarose gel as previously described (Ouchterlony and Nilsson 1973). Western blot analysis was performed according to the method of Burnette (1981) with some modification.

4.9. Electrophoresis

Purified β-galactosidases were analysed by electrophoresis in non-denaturing conditions using 4% acrylamide stacking gel and 5–20% acrylamide gradient separating gel (Hames, 1981), SDS–PAGE (Laemmli, 1970) and two-dimensional electrophoresis (O'Farrell, 1975). Proteins were stained with 0.2% (w/v) Coomassie Brilliant Blue R-250 or silver nitrate (Blum et al., 1987). Activity staining of β-galactosidase was performed according to the method described by Spielman and Mowshowitz (1982) using 6-bromo-2-naphthy-β-D-galactoside (Sigma) as a substrate.

4.10. Enzyme characterization

The molecular mass of the native β-galactosidases were determined by gel filtration on a Sephacryl S-200 column (1.6×90 cm). The column was calibrated with Blue Dextran and standard proteins (ribonuclease A, chymotrypsinogen A, ovalbumin, albumin, aldolase, catalase, ferritin, and thyroglobulin) (Sigma). The molecular mass of the denatured enzymes was estimated by SDS–PAGE. The pH optima of the purified enzymes against PNP-β-D-galactopyranoside was determined in McII-Valine buffer covering a pH range of 3–6 and Na-phosphate buffer covering a pH range of 7–8. The isoelectric point of the purified enzyme was estimated from the elution profile of chromatofocusing. In the inhibition study of β-galactosidase activity by sugars, sugar derivatives, metallic ions and SDS, β-galactosidase was preincubated for 10 min at 37°C with each compound or metallic ion at a concentration of 1 mM (for metallic ion and SDS) or 12.5 mM (for sugar and sugar derivatives), then assayed as normal. In order to understand the mechanism of inhibition of β-galactosidase, either by D-galactono-(1→4)-lactone or by D-galactose, β-galactosidase activity was assayed in the presence of varying concentrations of the inhibitor. The data were analysed with a double reciprocal plot.

Biosynthesis of 2-aminobenzaldehyde in flowers of *Robinia pseudoacacia* and *Philadelphus coronarius*

Peter Spiteller, Wolfgang Steglich *

Department Chemie der Ludwig-Maximilians-Universität, Butenandtstraße 5-13 (Hauß F), D-81377 München, Germany

Received 29 November 2000; received in revised form 18 January 2001

Abstract

Feeding experiments with ^{13}C- and fluorine-labelled precursors were performed to reveal the biosynthesis of 2-aminobenzaldehyde in flowers of *Robinia pseudoacacia* and *Philadelphus coronarius*. The results are in agreement with the transformation of anthranilic acid to indole followed by oxidative ring opening and hydrolysis of the resulting *N*-formyl-2-aminobenzaldehyde. This route differs from that observed in *Hebeloma saccharioliens* (Basidiomycetes) in which anthranilic acid is directly reduced to 2-aminobenzaldehyde. © 2001 Elsevier Science Ltd. 1. Introduction

2-Aminobenzaldehyde is an essential flavour component of many flowers (Joulain, 1987; Tollsten and Bergström, 1988; Surburg et al., 1990; Brunke et al., 1997; Kaiser, 1997) and has been detected in honey (Ichimura, 1994). 2-Aminobenzaldehyde is also present in the mushroom *Hebeloma saccharioliens* (Wood et al., 1992) where it is formed by reduction of anthranilic acid (von Nussbaum et al., 1997).

In bacteria (Uchida et al., 1953) and plants (Nair and Vaidyanathan, 1964; Divakar et al., 1979; Pundir et al., 1984; Kunapuli and Vaidyanathan, 1991) 2-aminobenzaldehyde (**3**) is considered to be derived from indole (**1**) by a dioxygenase-catalyzed cleavage of the pyrrole ring and hydrolysis of the resulting *N*-formyl-2-aminobenzaldehyde (**2**) (Scheme 1). This pathway, however, has not yet been confirmed by labelling experiments.

2-Aminobenzaldehyde is also responsible for the sweet fragrance of blossoms from *Robinia pseudoacacia* L. and *Philadelphus coronarius* L. (Joulain, 1987). In order to study the biosynthesis of this compound we applied several ^{13}C- and fluorine-labelled precursors to flowers of both species and followed their metabolism. Fluorine labels can be detected by mass spectrometry with high sensitivity as was demonstrated in our studies with *Hebeloma saccharioliens* (von Nussbaum et al., 1997).

2. Results and discussion

R. pseudoacacia and *P. coronarius* were harvested by cutting flowering twigs at their lower end. Feeding experiments were performed by dipping the stems into a water/DMSO solution of the labelled compound. After 2 days the flowers were extracted with diethyl ether. The extract was carefully concentrated and then distilled into a vial cooled to −78°C. The distillate was diluted with diethyl ether and injected into the GC–MS combination. The results of the feeding experiments are given in Table 1.

2-Amino-4-fluorobenzaldehyde, 2-amino-5-fluorobenzaldehyde and 2-amino-6-fluoro-benzaldehyde were obtained in good yield after feeding flowers of *P. coronarius* with 4-, 5- or 6-fluoroanthranilic acid, respectively. Importantly, no incorporation of ^{13}C was detectable in 2-aminobenzaldehyde after application of 2-amino[*carboxy*-^{13}C]benzoic acid. These results exclude a direct conversion of anthranilic acid into 2-aminobenzaldehyde and

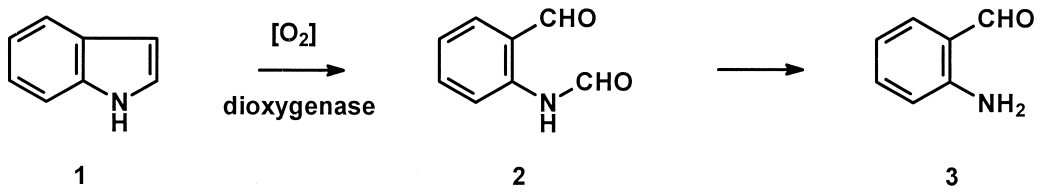


Scheme 1. Biosynthesis of 2-aminobenzaldehyde in plants.

Table 1
Feeding experiments with *Philadelphus coronarius*[a]

Precursor fed to *P. coronarius*	Product	R_i (product)	Incorporation rate in%[b]
2-Amino-4-fluorobenzoic acid	6-Fluoroindole	1331	14
	2-Amino-4-fluorobenzaldehyde	1218	12
2-Amino-5-fluorobenzoic acid	5-Fluoroindole	1344	35
	2-Amino-5-fluorobenzaldehyde	1224	6
2-Amino-6-fluorobenzoic acid	4-Fluoroindole	1365	5
	2-Amino-6-fluorobenzaldehyde	1218	8
5-Fluoroindole	2-Amino-5-fluorobenzaldehyde	1224	27
6-Fluoroindole	2-Amino-4-fluorobenzaldehyde	1218	32
5-Chloroindole	2-Amino-5-chlorobenzaldehyde	–	0

[a] Nearly identical incorporation rates were obtained by feeding 2-amino-5-fluorobenzoic acid, 2-amino-[*carboxy*-^{13}C]benzoic acid, and 5-fluoroindole to *Robinia pseudoacacia*.

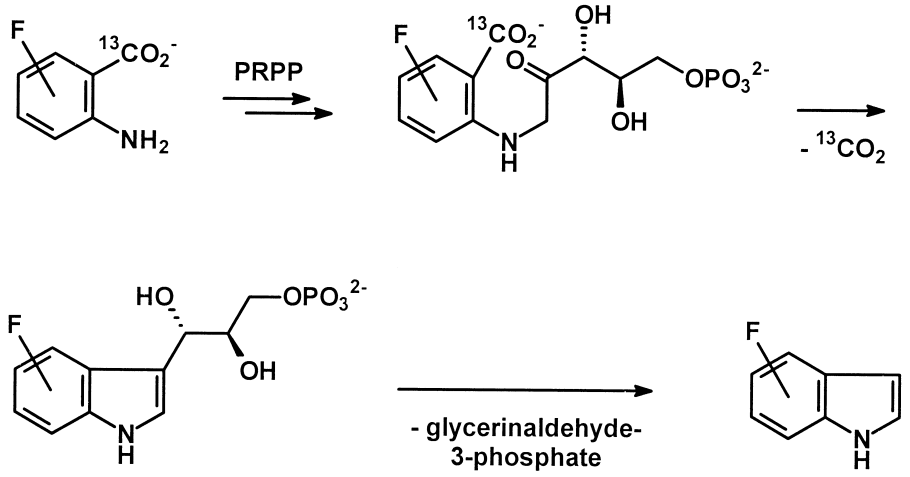
[b] In the GC–MS experiments the ratio of the ion current of the molecular ion $m/z = 139$ (labelled compound) is given in % in relation to the sum of the ion current of the molecular ions $m/z = 121$ and 139 (unlabelled and labelled compounds).

are in accordance with the well known indole (tryptophan) pathway (Umbarger, 1978; Miles, 1991; Stryer, 1999), whereby the ^{13}C-carboxyl group of anthranilic acid is lost as $^{13}CO_2$ (Scheme 2).

The role of indole as an intermediate was confirmed by feeding flowers of *P. coronarius* with 5-, respectively 6-fluoroindole. As expected 2-amino-5-fluorobenzaldehyde, respectively 2-amino-4-fluorobenzaldehyde were formed in good yields (Table 1).

This proves that in flowers of *P. coronarius* 2-aminobenzaldehyde is generated by conversion of anthranilic acid to indole followed by oxidative cleavage of the pyrrole ring and not by direct reduction of anthranilic acid as in the fungus *Hebeloma sacchariolens*. Remarkably, each of the six enzymes involved in the "indole pathway" tolerates a fluorine label at least in position 4, 5 or 6 of 2-aminobenzoic acid. On the other hand, 5-chloroindole is not incorporated, showing the limits of halogen labelling. When 2-amino-6-fluoroanthranilic acid was fed to flowers of *P. coronarius*, the production of 2-amino-6-fluorobenzaldehyde was higher than that of the intermediate 4-fluoroindole. Probably, 4-fluoroindole is a better substrate for the dioxygenase than indole itself.

Comparable incorporation rates were obtained by applying 2-amino-4-fluorobenzoic acid, 2-amino-5-fluorobenzoic acid, 2-amino[*carboxy*-^{13}C]benzoic acid and 5-fluoroindole to flowers of *Robinia pseudoacacia*.



Scheme 2. Conversion of 2-aminobenzoic acids to indoles in plants (PRPP = 5′-phosphoribosyl-1-pyrophosphate).

3. Experimental

3.1. General

Gas chromatography–mass spectrometry (GC–MS) was performed on a Finnigan MAT 90 double focussing mass spectrometer, equipped with an EI ion source operating at 70 eV. For GC–MS, a Varian GC 3400 gas chromatograph with a fused silica DB-5ms capillary column (30 m×0.25 mm, coated with a 0.25 μm layer of liquid phase) and helium as a carrier gas (flow rate: 1.5 ml/min; split ratio: 1:30) was used for sample separation. The injector temperature was kept at 300°C, injection volumes were 0.2–0.4 μl of a 1–2% (m/v) solution. Temperature programme: 2 min isothermal at 50°C, then 10 K/min up to 300°C, finally 10 min isothermal at 300°C. Retention indices R_i (Kováts, 1958) were determined by co-injection of a 0.2 μl sample of a standard mixture of saturated straight chain alkanes (C_{10}–C_{36}).

3.2. Plant material

Flowers of *R. pseudoacacia* and *P. coronarius* were collected in München in May 1998, 1999 and 2000.

3.3. Feeding experiments

Two hundred and fifty milligrams of the precursor were dissolved in 200 ml water containing 1 ml DMSO. In the case of 2-amino[*carboxy*-^{13}C]benzoic acid only 100 mg were used. Flowering twigs (200–400 g) from *P. coronarius* or *R. pseudoacacia* were dipped with their stems into these solutions. Two days later, the flowers were collected and kept at −20°C until processing.

3.4. Preparation of GC–MS-samples

The flowers were extracted twice with 150 ml diethyl ether and the combined extracts dried over Na_2SO_4. After careful removal of the solvent, the residue (~ 0.1 ml) was distilled at 50°C (0.01 mbar) into a vial cooled to −78°C. The distillate was then diluted with 50 μl diethyl ether and injected in 1–3 μl portions into the GC–MS.

3.5. Mass spectral data and retention indices

2-Aminobenzaldehyde: $R_i = 1221$; GC–MS: *m*/*z* (rel. int.): 121 (67), 93 (100), 92 (28), 76 (12), 66 (44), 65 (37). 2-Amino-4-fluorobenzaldehyde: $R_i = 1218$; GC–MS: *m*/*z* (rel. int.): 139 (59), 124 (11), 111 (100), 84 (39), 83 (38). 2-Amino-5-fluorobenzaldehyde: $R_i = 1224$. 2-Amino-6-fluorobenzaldehyde: $R_i = 1218$. Indole: $R_i = 1303$; GC–MS: *m*/*z* (rel. int.): 117 (100), 90 (49), 89 (30). 4-Fluoroindole: $R_i = 1365$; GC–MS: *m*/*z* (rel. int.): 135 (100), 108 (51), 107 (38). 5-Fluoroindole: $R_i = 1344$. 6-Fluoroindole: $R_i = 1331$.

Abstract

Transformed roots were obtained after the inoculation of sterile root discs of *Panax ginseng* C.A. Meyer with *Agrobacterium rhizogenes* A4. The established hairy root lines displayed three morphological phenotypes when cultured on hormone-free liquid Schenk and Hildebrandt medium. Most of the cultures showed the characteristic traits of hairy roots (HR-M), while others were either callus-like (C-M) or thin (T-M) without branching. The growth rate of the transformed root lines was always higher than that of untransformed roots, showing that the genetic changes caused by the *A. rhizogenes* transformation conditioned a higher biomass formation. When considering the different transformed root phenotypes, we can observe that the highest ginsenoside production was achieved by HR-M root lines, closely followed by C-M ones, whereas the lowest yield was reached by T-M root phenotype. The study of the integration of the TL-DNA and TR-DNA fragments of the pRiA4 in the root genome showed that the *aux1* gene was always detected in HR-M and C-M root phenotypes which presented the highest biomass and ginsenoside productions. This fact suggests a significant role of *aux* genes in the morphology of *Panax ginseng* transformed roots. The ginsenoside pattern of transformed roots varied according to their morphology, although the ginsenoside contents of the Rg group was always higher than that of the Rb group. From our results, we can infer the potential of some root phenotypes of *Panax ginseng* hairy root cultures for an improved ginsenoside production. © 2001 Published by Elsevier Science Ltd. 1. Introduction

Panax ginseng roots have been widely used in Chinese traditional medicine since ancient times owing to their stimulating and tonic properties. The pharmacological activities of ginseng or its crude extracts are based on the presence of a mixture of triterpenic saponins referred to as ginsenosides. The two major groups of ginsenosides are the Rb and Rg groups, which have 20 (S) protopanaxadiol and 20 (S) protopanaxatriol, respectively, as the sapogenines. Rb group includes the ginsenosides Rb1, Rb2, Rc and Rd, while Rg group includes the Re, Rf and Rg1 ones as the main compounds. Among all these ginsenosides, Rb1 and Rg1 are the most effective compounds (Tanaka and Kasai, 1984).

Ginsenosides accumulate in the root of the plant, but the agricultural production of roots is expensive. Therefore, the production of ginsenosides, by means of different biotechnological alternatives has been extensively studied by a number of researchers, using callus tissues (Furuya et al., 1983a; Odnevall et al., 1989; Asaka et al., 1993; Mathur et al., 1994), cell suspensions (Furuya et al., 1983b; Mathur et al., 1994) and root cultures (Yoshikawa and Furuya, 1987); nevertheless, the productivity obtained so far has been low because of the low growth rates of cultures. The induction and establishment of hairy roots after the infection of *Panax ginseng* rhizomes with *Agrobacterium rhizogenes* has been successfully performed (Yoshikawa and Furuya, 1987; Ko et al., 1989; Inomata et al., 1993; Bulgakov et al., 1998; Washida et al., 1998). These roots grow more rapidly and produce higher levels of saponins than the ordinary cultured roots obtained by hormonal control.

Hairy root formation is a consequence of the integration of the T-DNA of Ri-plasmid of *Agrobacterium*

rhizogenes A4 into the plant genome. In the case of agropine type strains (such as *A. rhizogenes* A4), two T-DNA fragments (TL-DNA and TR-DNA) are separately transferred into the plant material (Huffmann et al., 1984; Jouanin, 1984). The integration of the TL-DNA into the plant genome is essential for developing transformed roots; three genes of this fragment, known as *rol*A, *rol*B and *rol*C are responsible for the full hairy root syndrome (Carderelli et al., 1987; Palazón et al., 1997, 1998a). Although the TR-DNA is not essential for hairy root formation, it has been shown that the *aux1* genes harboured in this T-DNA segment provide to the transformed cells with an additional source of auxin. Recently, we have found that *aux* genes play a significant role in the morphology and alkaloid production of transformed roots of *Datura metel* and *Duboisia hybrid* (Moyano et al., 1999).

In this work, we report the establishment of three different phenotypes of *Panax ginseng* C.V. Meyer transformed roots in which the role of the TL-DNA and TR-DNA fragments of the pRiA4 on the root morphology is considered. At the same time, the relationship between the different root phenotypes and their capacity to produce biomass and ginsenosides is also studied.

2. Results

2.1. Study of growth and ginsenoside productivity

Root discs developed both callus tissues and roots 4–8 weeks after infection with *A. rhizogenes* A4. At the same time, numerous roots began to emerge from the surface of these callus pieces. Sixty five per cent of the inoculated root discs developed roots either directly from them or through callus formation.

These hairy root lines showed 3 different morphologycal phenotypes: 50% presented the characteristic traits of hairy roots described by Carderelli et al. (1987) with primary roots with extensive lateral branching and a profusion of root hairs (HR-M); 35% showed callus-like appearance with very thick primary roots and several secondary roots (C-M), and 15% were rather long and thin without branching points, tending to become brown except for newly developing yellowish parts (T-M) (Fig. 1). These three root phenotypes were maintained stable over successive subcultures for 2 years.

Hairy root lines started to grow without any lag phase (data not shown) and growth pattern varied according to observed phenotypes. When considering the growth rate

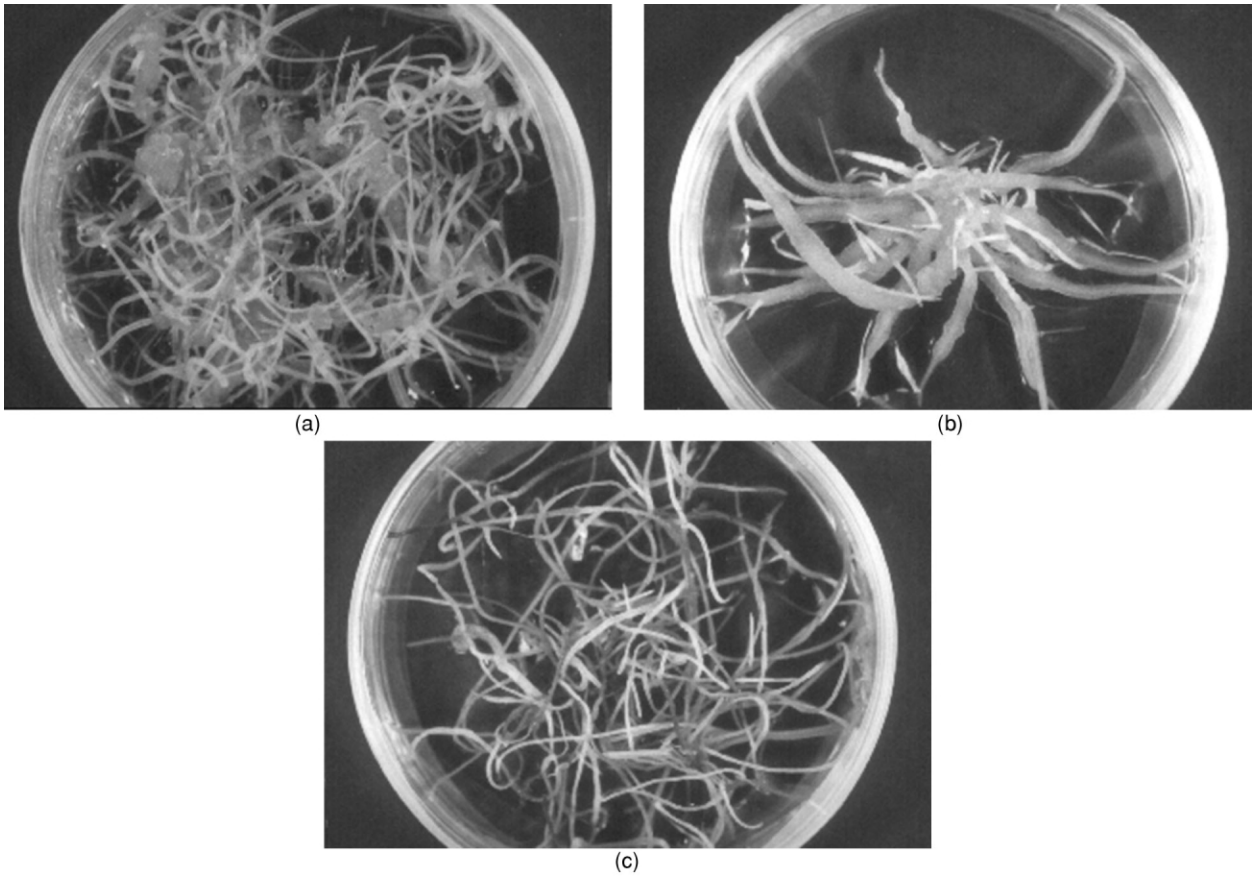

Fig. 1. Four week old *Panax* ginseng hairy root cultures on SH solid medium, showing three different phenotypes. (a) Roots with the characteristic traits of hairy roots (HR-M). (b) Roots with callus-like morphology (C-M). (c) Roots with thin morphology (T-M).

average of the transformed root lines studied (Fig. 2), it was possible to observe that the C-M and HR-M root lines achieved the highest values; the growth rate (final fresh weight/fresh inoculum weight) obtained after 4 weeks of culture, by C-M, HR-M and T-M roots was 7.9, 7.1 and 3.2, respectilvely, while in control roots it was 1.5. From these results we can infer that the genetic changes caused by the *A. rhizogenes* transformation conditioned a higher capacity for the biomass formation affecting branching, as shown in cucumber (Amselem and Tepfer, 1992), *Catharanthus roseus* (Palazón et al., 1998b) and in *Duboisia*, *Datura* and tobacco transformed root cultures (Moyano et al., 1999). At the same time, as described by Rhodes et al. (1990), the growth rate of transformed roots depends, to a large extent, on linear extension, on the formation of a large number of new growing points as lateral branches and on a secondary increase in root diameter as the root cells undergo cell expansion and differentiation.

Four ginsenosides (Rb1, Rb2, Rc, Rd) of Rb group and three (Re, Rf and Rg1) of Rg group were extracted and quantified from the root lines studied. HR-M root lines achieved the highest total ginsenoside level (5.4 mg/gDW) followed by C-M (4.8 mg/gDW) and control roots (4.5 mg/gDW). Roots with thin morphology produced less than half of the ginsenoside production achieved by the HR phenotype (Table 1 and Fig. 2).

In the three root phenotypes considered, as well as in the untransformed roots, the RbT/RgT ratio was lower than 1, indicating that the production of Rg group ginsenosides was always higher than that of the Rb group (Table 1). Similar results were obtained by Bulgakov et al. (1998) with *P. ginseng* transgenic roots for the *rol*C gene of *A. rhizogenes*. As indicated by Ko et al. (1989) and Inomata et al. (1993), the maximum production of the different ginsenosides occurs at different growth stages. Maximum levels of Rb1 are usually found in the early growth stages, while maximum amounts of Rg1 appear later; these facts could explain the ginsenoside patterns of transformed root cultures after 4 weeks of growth.

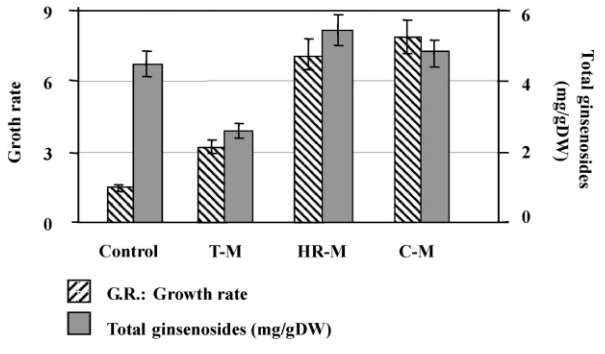

Fig. 2. Growth rate (final fresh weight/inoculum fresh weight) and ginsenoside contents (mg/g DW) of the different root phenotypes. Roots were cultured for 4 weeks in hormone-free SH liquid medium. In all cases the inoculum fresh weight was 0.5±0.05 g. Each value was the mean of five replicates of each one of the 15 root lines considered, belonging to each respective phenotype studied.

Table 1
Ginsenoside contents (expressed as percentage of DW) of the different hairy root phenotypes studied. Roots were cultured for 4 weeks in hormone-free SH liquid medium. In all cases the inoculum fresh weight was 0.5±0.05 g. Each value is the mean of five replicates of each one of the 15 root lines considered, belonging to each respective phenotype studied. Total ginsenoside contents is expressed as mg ginsenosides/gDW

Ginsenosides	Control	T-M	HR-M	C-M
Rb1	11.3	8.0	14.8	21.2
Rb2	2.8	5.3	4.8	3.5
Rc	0.5	4.1	4.5	3.7
Rd	0.1	2.6	7.6	3.6
Re	68.3	57.7	40.1	38.1
Rf	2.0	5.6	2.1	2.0
Rg1	15.0	16.8	28.5	27.9
RbT	14.7	20.0	29.1	31.9
RgT	85.3	80.0	70.8	68.1
Total (mg/gDW)	4.55	2.58	5.44	4.84
RbT/RgT	0.17	0.25	0.41	0.47

The ginsenoside pattern also varied depending on the root phenotypes. The main ginsenoside found in T-M, HR-M and C-M root lines was the Re ginsenoside followed by the Rg1 one (Table 1). Whereas in T-M roots the Re and Rg1 represented 57.7 and 16.8%, respectively, of the total ginsenoside contents, in HR-M and C-M root lines, the Re constituted 40.1 and 38.1%, and the ginsenoside Rg1, represented 28.5 and 27.9%, respectively of the total. As it is known (Gubar et al., 1997), the Re ginsenoside is formed after the addition of two rhamnose residues to the Rg1. These results suggest a higher activity of enzymes involved in the incorporation of rhamnose to the Rg1 compound in the T-M root phenotype than on the other phenotypes studied. The main ginsenoside of the Rb group in T-M, HR-M and C-M root lines was the Rb1, which represented 8, 14.8 and 21.2% of the total ginsenosides determined. Because the Rd ginsenoside represented at most 2.6% of the total, and from it Rb1, Rb2 and Rc are formed by the action of different enzymes involved in the addition of sugar residues, our results suggest that the activity of these enzymes was high and dependent on the root phenotypes studied. But in order to clarify the ginsenoside metabolism, further assays are requested.

The control roots presented a different ginsenoside pattern from that achieved by HR-M and C-M roots, but more similar to that of T-M roots. The Re, Rg1 and Rb1 constituted 68, 15 and 11.3% of the total ginsenoside contents.

When considering the ginsenoside yield of the *P. ginseng* transformed root cultures after 4 weeks of growth (Fig. 3), we can observe that the highest yield was achieved by HR-M root lines (72.9 mg/l), followed by

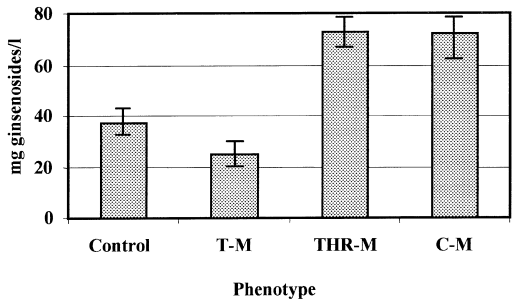

Fig. 3. Ginsenoside yield, expressed as mg total ginsenosides/l, in the different *Panax ginseng* hairy root phenotypes studied. Roots were cultured for 4 weeks in hormone-free SH liquid medium. In all cases the inoculum fresh weight was 0.5±0.05 g. Each value is the mean of five replicates of each one of the 15 root lines considered, belonging to each respective phenotype studied.

the C-M ones (71.6 mg/l). The lowest ginsenoside yield of the transformed root phenotypes studied corresponded to the T-M roots (24.8 mg/l), which also presented low ginsenoside contents and a limited growth. The ginsenoside production of untransformed roots (36.8 mg/l), was always lower than that obtained by HR-M and C-M root lines studied.

As it is known, the ginsenoside yield of the cultures not only depends on the accumulation of these compounds but also on the biomass formation. In our case, although the ginsenoside contents of HR and C root phenotypes were only 1.2 and 1.1 times higher than that achieved by control, in both cases their productivity was twice as high as that of the controls. These results show that in our *P. ginseng* transformed root cultures, the capacity to produce and accumulate ginsenosides is associated with biomass formation because the highest productivity was achieved by the root phenotypes with the highest growth rate.

From our results we can infer that the transformed nature of *P. ginseng* roots conditioned an important increase of biomass and productivity, especially in roots displaying the full hairy root morphology, corroborating the suitability of transformed root cultures for an improved secondary metabolite production.

2.2. Study of the fragments of Agrobacterium T-DNA integrated into the transformed root genome

The presence of the *rolC* gene of the TL-DNA of the pRiA4 as well as that of the *aux1*, *ags* and *mas1* genes of the TR-DNA has been studied in the three different transformed root phenotypes established. The transformed nature of the all selected root lines of each morphology was confirmed by the presence of the *rolC* gene in the plant genome. The products of *aux* genes are involved in the additional route for indole acetic acid in transformed cells (Nilsson and Olsson, 1997), whereas *ags* and *mas1* genes code the enzymes responsible for agropine and manopine biosyntheses, respectively. 100% of the root lines displaying callus-like (C-M) or hairy root morphology (HR-M) but only 25–45% of root lines showing a thin structure (T-M) presented this gene in their genome. Previously, we reported that in *D. metel*, *Duboisia* and tobacco transformed roots, the presence of *aux1* gene in the plant genome conditioned the callus-like morphology (Moyano et al., 1999). We could observe that 100% of roots displaying this structure included this gene in their genome, whereas only 25–60% of roots with typical hairy root morphology presented this gene in their cells. From our results obtained in *P. ginseng* transformed roots, we can infer that the *aux1* gene is related to root morphology, especially to lateral branching development, since thin roots did not form secondary root, whereas C-M and HR-M roots presented a very high degree of secondary root formation. In our case, the additional source of auxin induced by *aux1* gene in the root genomes, was not the only factor responsible for the disorganization of root tissues (Jung et al., 1995), since roots displaying the full hairy root morphology also harboured the *aux1* gene in their genome.

The presence of the opines agropine and manopine and the genes which codify for enzymes involved in their formation, *ags* and *mas1* genes in the root genomes was also studied (Table 2). The results obtained show that 25% of thin root lines, 75% of hairy roots and 100% of callus-like ones included the *ags* gene in their genome whereas *mas1* gene was present in 100% of HR and C roots but only in 50% of thin root lines. When considering the presence of both opines, agropine and manopine, in the selected root lines it can be seen that the root lines with thin morphology did not include these compounds in their cells, but that they were present in all root lines with callus-like structure. On the other hand in the HR-M root lines studied, it was possible to observe that roots which lacked the *ags* gene did not include agropine in their composition and manopine was hardly detected. When studying the relationship between the presence of opines in the transformed root phenotypes established with their ginsenoside production it is possible to

Table 2
PCR study of the presence of different fragments of *Agrobacterium rhizogenes* T-DNA inserted in the genome of the transformed root phenotypes. Percentage of transformed root lines of each phenotype studied in which the presence of opines was detected

Root morphology	Genes				Opines	
	rolC	*aux1*	*ags*	*mas1*	Agropine	Manopine
HR-M	100%	100%	75%	100%	75%	100%
C-M	100%	100%	100%	100%	100%	100%
T-M	100%	25–45%	25%	50%	0%	50%

observe that the less productive root lines (T-M ones) also lacked the *ags* and *mas1* genes and consequently the capacity to produce opines. Nevertheless, further studies are needed in order to know the effect of the presence of the genes responsible for the opine biosynthesis in ginsenoside production.

Taking all these results together, we can observe that the transformed root phenotypes, which presented the highest growth rate (HR-M and C-M phenotypes) were also those with the highest ginsenoside production. At the same time, together with the *rol* genes of the TL-DNA segment of *A. rhizogenes*, 100% of root lines belonging to these two phenotypes harboured the *aux1* gene of the TR-DNA fragment. On the contrary, the phenotype with very slow growth and ginsenoside production (T-M) never included this gene in its genome, although the *rol* genes were always present. From these results we can infer that *aux1* gene, although not essential for the root formation, plays an important role in the root morphology by increasing lateral branching resulting in higher biomass and ginsenoside production. Our results also show that in *P. ginseng*, the capacity of transformed roots to produce opines does not interfere with the ginsenoside production. To our knowledge, this is the first report that a relationship between growth and ginsenoside production, and the presence of different genes of the TL-DNA and TR-DNA of the Ri plasmid of *A. rhizogenes* has been shown in *P. ginseng* hairy root cultures.

3. Materials and methods

3.1. Induction and culture of hairy roots

Transformed roots of *Panax ginseng* C.A. Meyer were induced from 4-year-old rhizomes after infection with *Agrobacterium rhizogenes* A4 strain. Sterilized root discs were wounded with a sterile needle loaded with *A.rhizogenes* suspension grown in liquid YEB medium (Vervliet et al., 1975) for 24 h at 28±2°C on a rotary shaker at 100 rpm. The inoculated root discs were placed on Schenk-Hildebrandt's medium (SH) (Schenk and Hildebrandt, 1972) containing 3% (w/v) sucrose, 0.1% (w/v) myo-inositol and 0.27% (w/v) Phytagel (Sigma) at 26°C. The medium was adjusted to pH 7.0 before autoclaving. After 2 days of cocultivation the explants were transferred to the fresh medium containing cefotaxime (500 mg/l) in order to eliminate the bacteria. After cultivation for one or two months, roots started to appear at the infection sites and, in order to obtain the root lines, single roots were picked off and placed onto new media together with cefotaxime, until the bacteria were eliminated. Hairy roots with no bacterial contamination were cultured on hormone-free SH solid medium, already described, in the dark at 26°C. After 6 months of subculturing the roots every two weeks on fresh solid medium, the root lines were transferred to SH liquid medium and kept in a rotary shaker at 100 rpm, 26°C in the dark. Subcultures were performed every two weeks in fresh medium. Untransformed roots (control roots) were obtained from sterile rhizome discs cultured in Murashige and Skoog (MS) medium (Murashige and Skoog, 1962) supplemented with 3% (w/v) sucrose, 0.01% (w/v) myo-inositol, 2 mg/l indole butyric acid, 0.1 mg/l kinetin and 0.27% (w/v) Phytagel (Sigma) at 26°C in darkness. Roots 2–3 cm long were transferred separately to the same medium used for hairy roots and subcultured every 2–3 weeks.

In order to study the capacity of hairy roots to produce biomass and ginsenosides, from 80 hairy root lines established, 15 relatively quickly growing root lines showing each phenotype considered were selected and cultured for 4 weeks in the above mentioned medium and conditions. Biomass formation was expressed as growth rate (final fresh weight/inoculum fresh weight); the inocula fresh weight (0.5±0.05 g) were cultured in 100 ml Erlenmeyer flasks containing 10 ml of SH liquid medium.

3.2. PCR analysis

Total DNA was isolated from hairy roots by using "genomic Prep ™ Cells and Tissue DNA isolation Kit" (Pharmacia Biotech). PCR analyses were performed using the pre-formulated, predispensed single dose reaction beads "Ready to Go™" (Pharmacia Biotech). The complete mixture contained 200 ng of total DNA, 12.5 pmol/μl of each oligonucleotide primer, 200 μM dNTPs, 1.5 units Taq polymerase, and buffer supplied by the enzyme manufacturer (1/10 V) in a total volume of 25 μl. The oligonucleotide primers used that would anneal to *rol*C gene of the TL-DNA of pRi of *A. rhizogenes* A4, produced a DNA fragment of 534 bp.

3.3. Opine analyses

Opine analyses were performed by High Voltage Paper Electrophoresis according to a modification of the method indicated by Petit et al. (1983), as described in Moyano et al. (1999).

3.4. Extraction and analysis of ginsenosides

Extraction of ginsenosides was based on the method described by Samukawa et al. (1995). Freeze-dried powdered samples (50 mg) were washed in petroleum ether (3×8 ml) and centrifuged at 33,520 *g* for 10 min. The pellet was extracted and sonicated for 15 min with 15 ml of 70% methanol and centrifuged again at 33,520 *g* for 10 min. After evaporating the methanolic extract to dryness and dissolving it in 10 ml of acetonitrile: water (80:20), 20 μl of the ginsenoside extract was loaded onto a Hewlett-Packard Lichrospher® 100 Diol (5 μm) column

(250×4 mm) connected to a Pharmacia LKB HPLC system. The solvent mixture of acetonitrile-water (4.5:1 v/v, pH 2.5 with H_3PO_4) was eluted at a flow rate of 0.8 ml/min and ginsenosides were detected at 202 nm. The peak areas corresponding to ginsenosides from the samples, with the same retention time as authentic ginsenosides (Rf, Rg1, Rd, Re, Rc, Rb2, Rb1), were integrated by comparison with an external standard calibration curve. Ginsenosides Rb1, Rb2, Rc, Rd, Re, Rf and Rg1 (99.8%) were purchased from Karl Roth (Germany).

Ginsenoside contents of the analyzed samples were expressed as mg ginsenosides/g DW (dry weight). The total ginsenoside productivity, after 4 weeks of culture, of transformed roots was indicated as mg of total ginsenosides per liter of culture medium as described by Jouhikainen et al. (1999).

Received 13 November 2000; received in revised form 18 January 2001

Abstract

The ring expansion of 3-hydroxyindolin-2-one to 2-hydroxy-1,4-benzoxazin-3-one (HBOA) was investigated by labelling experiments. Action of the cytochrome P450 enzyme BX4 from maize on 3-hydroxyindolin-2-one under an $^{18}O_2$ atmosphere induced production of 2-hydroxy-1,4-benzoxazin-3-one in which the ring oxygen — but not the 2-hydroxy group of HBOA — is labelled. A mechanism for this transformation is proposed. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Zea mays*; Gramineae; Biosynthesis; Ring expansion; Mono-oxygenase; P450; HBOA; BX4

1. Introduction

The cyclic hydroxamic acids DIBOA (2,4-dihydroxy-1,4-benzoxazin-3-one) and DIMBOA (2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one) are important enhancers of the sustainability of grasses (Gramineae) against insects and micro-organisms (Niemeyer, 1988; Sicker et al., 2000).

Investigations on the biosynthesis of DIBOA and DIMBOA in maize revealed the involvement of several P450 enzymes (Frey et al., 1997). Their corresponding genes have been cloned (Frey et al., 1995) and heterologously expressed in yeast. The general course of the biosynthesis from indole has been established (Frey et al., 1997) and the kinetic parameters for each reaction step have been determined (Glawischnig et al., 1999). BX4, an enzyme of the CYP71C subfamily, catalyses the oxidative ring expansion of 3-hydroxy-indolin-2-one to 2-hydroxy-1,4-benzoxazin-3-one (HBOA), a reaction, whose mechanism remained obscure (Frey et al., 1997). In this paper we demonstrate that the action of $^{18}O_2$ on 3-hydroxyindolin-2-one (**1**) in the presence of BX4 leads to labelling of the ring oxygen atom in HBOA in accordance with the mechanism proposed in Scheme 2.

2. Results and discussion

BX4 was expressed heterologously in the yeast strain WAT11 (Frey et al., 1997; Glawischnig et al., 1999). Microsomes were isolated from galactose induced yeast cells (Pompon et al., 1996). 3-Hydroxyindolin-2-one (**2**) was incubated with these microsomes under an atmosphere of $^{18}O_2$, and the reaction product HBOA was isolated. The labelled HBOA and the unlabelled HBOA, respectively, were subjected to trimethylsilylation in order to allow further purification by GC and identification by MS (Woodward et al., 1979). The GC of the unlabelled compound exhibits two main peaks. One with a molecular ion at m/z 237 corresponds to *O*-trimethylsilyl-HBOA, the second at m/z 309 to the *O,N*-bistrimethylsilyl derivative (Woodward et al., 1979). The spectra of the products prepared under an $^{18}O_2$ atmosphere indicated the incorporation of one labelled oxygen atom by a shift of two mass units for the corresponding molecular ions. The position of the label can be deduced from the fragmentation pattern of *O*-trimethylsilyl-HBOA (m/z 239) given in Scheme 1. Most indicative are two fragment ions at m/z 210 and 121 that are formed from the molecular ion by loss of $H^{16}CO$ or

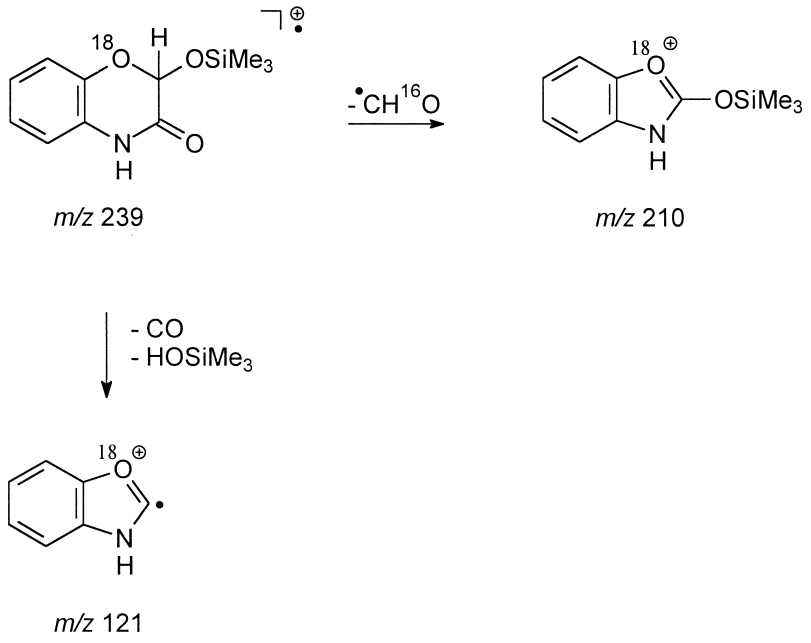
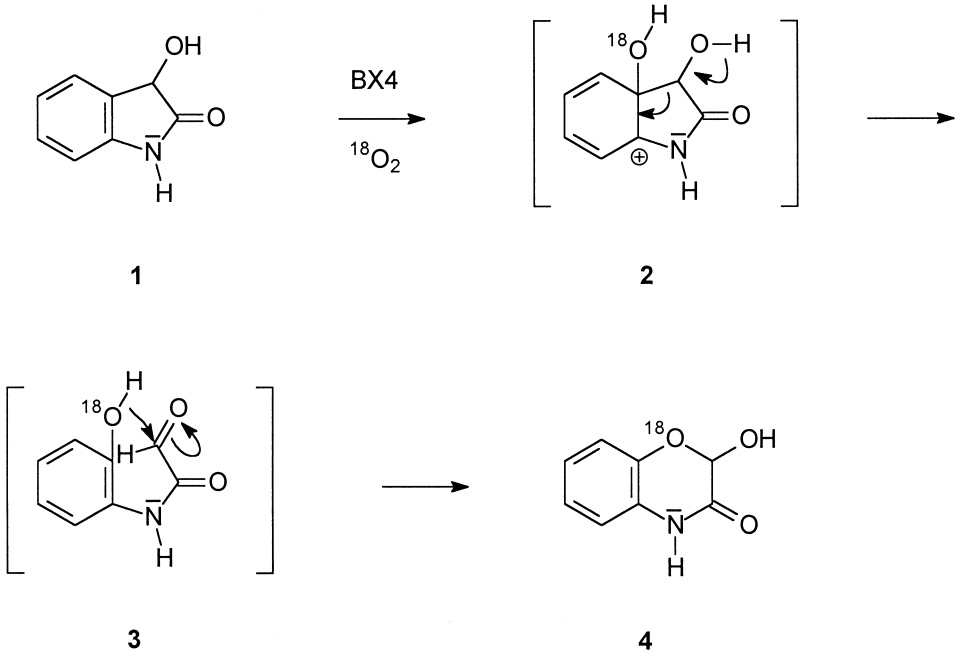


Scheme 1. Generation of the ions *m/z* 210 and 121 in the MS of ^{18}O-labelled *O*-trimethylsilyl-HBOA (*m/z* 239).



Scheme 2. Ring expansion of 3-hydroxyindolin-2-one (**1**) catalyzed by BX4 under an $^{18}O_2$-atmosphere.

$C^{16}O$ and $H^{16}OSiMe_3$, respectively. Since the ion *m/z* 121 still retains the ^{18}O-label, the labelled oxygen in HBOA has to be placed at ring position 1.

Cytochrome P450 enzymes (Sono et al., 1996) are known to catalyze arene epoxidation and aromatic hydroxylation by molecular oxygen. These biochemical transformations are involved in a great variety of oxidative biosynthetic pathways in plants (Halkier, 1996; Schuler, 1996). In the case of 3-hydroxyindolin-2-one (**1**) the oxidative ring expansion to 2-hydroxy-1,4-benzoxazinone (**4**) by BX4 and molecular oxygen can be explained by the mechanism given in Scheme 2. Attack of an electrophilic oxygen species at C-3a of the indole system should lead to a delocalized cation **2** (Newcomb and

Toy, 2000) or its protonated epoxide equivalent, which then fragments under rearomatization to yield the phenolic aldehyde **3**. In the last step, 2-hydroxy-1,4-benzoxazin-3-one (**4**) is formed by intramolecular addition of the phenolic ^{18}OH group to the aldehyde function. This mechanism is in accordance with the outcome of the labelling experiment.

3. Experimental

3.1. General

Gas chromatography/mass spectrometry (GC–MS) was performed on a Finnigan MAT 90 double focussing mass spectrometer, equipped with an EI ion source operating at 70 eV. For GC–MS, a Varian GC 3400 gas chromatograph with a fused silica DB-5ms capillary column (30 m × 0.25 mm, coated with a 0.25 μm layer of liquid phase) and helium as carrier gas was used for sample separation (flow rate: 1.5 ml/min; split ratio: 1:30). The injector temperature was kept at 300°C, injection volumes were 0.2–0.4 μl of a 1–2% (m/v) solution. Temperature programme: 2 min isothermal at 50°C, then 10 K/min up to 300°C, finally 10 min isothermal at 300°C. Retention indices R_i (Kováts, 1958) were determined by co-injection of a 0.2 μl sample of a standard mixture of saturated straight chain alkanes (C_{10}–C_{36}).

3.2. Labelling experiment

3-Hydroxyindolin-2-one was synthesized from isatin by reduction in a yeast cell culture (Frey et al., 1997). BX4 was expressed heterologously in the yeast strain WAT11 as described (Frey et al., 1997). Microsomes were isolated from galactose induced yeast cells (Pompon et al., 1996) and the concentration of microsomal protein was determined. Microsomes (18 mg microsomal protein) were suspended in 5 ml of sodium phosphate buffer (40 mM, pH 7.5), containing dithiothreitol (1.4 mM) and glycerol (6%) and kept at 0°C. NADPH and 3-hydroxyindolin-2-one were added (0.7 and 0.19 mM final concentration, respectively). The reaction vessel was flushed with nitrogen before $^{18}O_2$ (Cambridge Isotope) was applied. After 2 h at 25°C, the reaction was stopped by addition of MeOH (1.5 ml) and acidified to pH 2 with HOAc (1 M, 0.4 ml). The suspension was centrifuged (15 min, 4800 rpm) and the supernatant was extracted (3×) with EtOAc (3 ml). After evaporation of the solvent, the residue was dissolved in MeOH. The labelled HBOA was purified by HPLC [90% H_2O, 10% HOAc, 6 ml/min, detection at 254 nm using a Merck Lichrosphere RP-18 column (10 × 250 mm), R_t: 15 min]. HBOA was trimethylsilylated with 10 μl BSTFA [bis(trimethylsilyl)trifluoroacetamide] (65°C, 30 min) (Stalling et al., 1968). Unlabelled HBOA as reference compound was also subjected to trimethylsilylation prior to the GC–MS investigation.

3.3. Mass spectral data

Unlabelled *O*-trimethylsilyl-HBOA: R_i 1741; GC–MS *m/z* (rel. int.): 237 $[M]^+$ (76), 222 (58), 209 $[M\text{-}CO]^+$ (19), 208 (59), 194 (60), 166 (41), 150 (20), 135 (12), 119 (45), 75 (78), 73 (100), 65 (8), 45 (18); unlabelled *N,O*-bistrimethylsilyl-HBOA: R_i 1634; GC–MS *m/z* (rel. int.): 309 $[M]^+$ (45), 294 (19), 280 (6), 266 (18), 250 (2), 237 (8), 220 (10), 208 (13), 192 (20), 179 (9), 176 (15), 165 (16), 164 (15), 147 (50), 119 (5), 103 (11), 91 (3), 75 (25), 73 (100), 59 (4), 45 (13); ^{18}O-labelled *O*-trimethylsilyl-HBOA: R_i 1741; GC–MS *m/z* (rel. int.): 239 $[M]^+$ (65), 224 (59), 211 $[M\text{-}CO]^+$ (25), 210 (78), 196 (47), 183 (3), 180 (4), 178 (3), 168 (38), 152 (21), 137 (9), 135 (6), 121 (42), 97 (3), 91 (4), 75 (98), 73 (100), 65 (6), 45 (15);^{18}O-labelled *N,O*-bistrimethylsilyl-HBOA: R_i 1634; GC–MS *m/z* (rel. int.): 311 $[M]^+$ (100), 296 (27), 282 (12), 268 (23), 252 (2), 239 (8), 222 (16), 210 (19), 194 (22), 191 (18), 181 (8), 178 (9), 167 (13), 166 (11), 147 (65), 121 (3), 103 (5), 91 (2), 77 (3), 75 (21), 73 (100), 59 (2), 45 (13).

Received 28 September 2000; received in revised form 26 January 2001

Dedicated to Dr. Earle V. Roberts in celebration of his service of over 30 years to the Chemistry Department, University of the West Indies, Mona Campus

Abstract

Squamulosone (aromadendr-1(10)-en-9-one), isolated in large quantity from the plant *Hyptis verticillata* Jacq. (Labiatae), was incubated with the fungus *Curvularia lunata* ATCC 12017 in two different growth media. Six metabolites were isolated from each medium, with five of the products being common to both fermentations. All seven metabolites are novel. The insecticidal activity of these aromadendranes was evaluated against the sweet potato weevil *Cylas formicarius elegantulus*. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Curvularia lunata* ATCC 12017; Squamulosone; Biotransformation; Hydroxylation; *Hyptis verticillata*; Aromadendrane; Cadinane; Sesquiterpene

1. Introduction

Hyptis verticillata Jacq., a member of the Labiatae family of plants, has been traditionally used in the treatment of eczema, psoriasis, scabies, athlete's foot, rheumatoid arthritis and cold-related problems (Stanley, 1928; Ayensu, 1981; Morton, 1981). Previous investigations of this plant have led to the isolation of several compounds including lignans, flavonoids, triterpenes and a sesquiterpene (cadina-4,10(15)-dien-3-one), some of which possess interesting biological activities (German, 1971; Okuda et al., 1982, 1984; Tsuchiya et al., 1985; Klopman and Buyukbingol, 1988; Wang et al., 1989; Yasukawa et al., 1989; Broomhead and Dewick, 1990; Novelo et al., 1993; Kuhnt et al., 1994, 1995; Porter et al., 1995).

We now report the isolation of two further sesquiterpenes: squamulosone (aromadendr-1(10)-en-9-one) (**1**) and cadin-4-en-1β-ol (**9**). Squamulosone (**1**), first isolated from *Phebalium squamulosum* Vent. (Rutacaceae), was rigorously characterised by chemical means (Batey et al., 1971). Its enantiomer, millecrone B, was later isolated from the South African nudibranch *Leminda millecra* (Pika and Faulkner, 1994). Cadin-4-en-1β-ol (**9**) was first identified from a *Streptomyces* sp. (Gerber, 1971). This is, however, the first reported isolation of these compounds from *H. verticillata*.

In our ongoing programme to examine the metabolism of terpenes by fungi (Hanson et al., 1994b; Buchanan and Reese, 2000), compound **1** was fed to *Curvularia lunata* ATCC 12017 (synonyms: IMI 61535, CBS 215.54, NRRL 2380) using two different media: potato dextrose broth (PDB) and a beef extract medium (BEM). Six metabolites were isolated from each fermentation with five of the products being common to both fermentations. All analogues produced were novel. *C. lunata* is well known for its efficient 11β-hydroxylation of steroids (Lin and Smith, 1970a, 1970b; Ohlson et al., 1980; Sonomoto et al., 1983; Holland and Riemland, 1985; Mazumder et al., 1985; Chen and Wey, 1990), but it has also been used to transform a number of terpenes (Azerad, 2000) including *R*-(+)-pulegone (Ismaili-Alaoui et al., 1992), (*R*)-hydrophenanthrenone (Hammoumi et al., 1993), a number of 1,6-difunctionalised eudesmanes (Garcia-Granados et al., 1991), and an

aromadendrane (de Lima et al., 1999). Previously, a number of aromadendranes have been incubated with fungi including *Cephalosporium aphidicola* (Hanson et al., 1994a), *Glomerella cingulata* (Miyazawa et al., 1994, 1995), *Mucor plumbeus* (Guillermo et al., 1997), *Beauveria densa* and *B. bassiana* (de Lima et al., 1999), and also with a limited number of bacteria (Abraham et al., 1992). However, this is the first report of the incubation of squamulosone with a microorganism and also the first record of hydroxylation on the cyclopentane ring of the aromadendrane skeleton by any microorganism.

2. Results and discussion

Reinvestigation of the dichloromethane extract of *H. verticillata* has led to the isolation of the aromadendrane **1** in a significant (0.06%) yield. The IR and UV spectra of **1** revealed the presence of an α,β-unsaturated carbonyl, while the ^{13}C and DEPT NMR spectra indicated a molecular formula of $C_{15}H_{22}O$. The compound was thus a tricyclic terpene. The ^{1}H NMR spectrum contained two highly shielded protons resonating at 0.71 and 0.82 ppm, that were indicative of a cyclopropane ring. A comparison of the ^{1}H and ^{13}C NMR data with the literature (Batey et al., 1971; Pika and Faulkner, 1994) indicated that **1** was aromadendr-1(10)-en-9-one: either squamulosone or its enantiomer millecrone B. The laevorotatory nature of **1**, however, confirmed the structure of this compound as that of squamulosone.

The second sesquiterpene isolated was obtained as a mixture with cadina-4,10(15)-dien-3-one, a major compound of the dichloromethane extract (Porter et al., 1995). The mixture was subjected to reduction using lithium aluminium hydride in the presence of lanthanum chloride. This produced the more polar 3α-hydroxycadina-4,10(15)-diene (Neef et al., 1982) and thus enabled the isolation of cadin-4-en-1β-ol (epicubenol) (**9**) as an oil that was identified by spectral studies and comparative analyses with literature values (Gerber, 1971).

Squamulosone (aromadendr-1(10)-en-9-one) (**1**) was incubated with *C. lunata* to yield seven analogues that were identified as 2α-hydroxyaromadendr-1(10)-en-9-one (**2**), 2β-hydroxyaromadendr-1(10)-en-9-one (**3**), 13-hydroxyaromadendr-1(10)-en-9-one (**4**), 14-hydroxyaroma dendr-1(10)-en-9-one (**5**), 2β,13-dihydroxyaromadendr-1(10)-en-9-one (**6**), 13,14-dihydroxyaromadendr-1(10)-en -9-one (**7**) and 10α-hydroxy-1,2-epoxyaromadendran-9-one (**8**).

The IR spectrum of **2** highlighted the presence of a hydroxyl group and this was seen to be borne by a methine resonating at 74.8 ppm in the ^{13}C NMR spectrum. The downfield shift of ~10 ppm for C-3 and the the upfield shift of 5.1 ppm for C-4 justified the placement of the new hydroxyl at C-2. Additionally, data from the HR(EI)MS confirmed the molecular formula to be $C_{15}H_{22}O_2$ (*m*/*z* 234.1610). This formula was also applicable to **3**, ($[M]^+ = 234.1617$), which was found to be a C-2 epimer of **2**. The stereochemistry of the new function in **2** followed from the large coupling constant of 14.6 Hz for H-2. Analogue **3**, having a much reduced coupling constant ($J = 5.1$ Hz) and a slightly higher resonance value (δ 4.92) when compared with **2**, therefore, possessed a β stereochemistry for the hydroxyl.

In isomer **4**, the disappearance of the methyl singlet at δ 1.07 in the ^{1}H NMR spectrum of the substrate occurred simultaneously with the appearance of two doublets at δ 3.33 and 3.42 ($J = 11.1$ Hz). These signals were assigned to the diastereotopic protons on the now hydroxylated C-13. This was supported by the appearance of a methylene resonance at δ 72.0 in the ^{13}C NMR spectrum and was confirmed by the HR(EI)MS data (*m*/*z* 234.1615, $C_{15}H_{22}O_2$).

Similar observations were made for analogue **5** where a large downfield shift of the vinylic methyl protons of the substrate from 1.78 to 4.31 ppm was seen. The relatively low value of the oxygen-bearing methylene at δ 61.1, which was a direct result of the anisotropic effect of the carbon–carbon double bond on the primary alcohol, reinforced the positioning of the new hydroxyl function on C-14.

Data from the HR(EI)MS of **6** suggested a molecular formula of $C_{15}H_{22}O_3$ ($[M]^+ = 250.1569$) and this indicated the presence of two additional hydroxyl groups. The two new oxygen-bearing carbons observed in the ^{13}C NMR were present as a methine (δ 74.2) and a methylene (δ 71.9) and were assigned to C-2 and C-13, respectively. Comparison of the chemical shifts within the cyclopentane and cyclopropane rings with those observed for **3** and **4** supported hydroxyl insertion at the sites proposed. Again, the low value for the coupling constant of the H-2 proton (d, $J = 4.7$) proved useful in fixing the stereochemistry of the C-2 hydroxyl as β.

The second dihydroxylated product, **7**, lacked the H-13 and H-14 methyl singlets (δ 1.07 and 1.78) present in the ^{1}H NMR spectrum of the fed substrate. A comparison of the carbon resonance values of this metabolite with both **4** and **5** verified **7** as 13,14-dihydroxyaromadendr-1(10)-en-9-one.

Derivative **8** possessed a molecular formula of $C_{15}H_{22}O_3$ ($[M]^+ = 250.1561$) and inherently had five degrees of unsaturation. With the carbonyl remaining intact (δ 208.3), the additional ring was evidently derived from an epoxide function (1107 cm^{-1}) within the structure. 2D NMR data aided correct placement of the groups on the skeleton and were particularly useful in assigning stereochemistries. Analogue **8** is thought to proceed firstly through the 1,10-epoxy derivative which is then hydroxylated at C-2. This epoxide then rearranges to relieve the increased strain induced by the rigid ring

systems and the sp^2 hybridised carbon of the carbonyl. The more stable 10α-hydroxy-1,2-epoxide is thus formed. As in previous studies, where methyl groups on the cyclopropane ring of aromadendranes were hydroxylated by fungal mono-oxygenases, it was observed that the cyclopropane ring remained intact (Azerad, 2000).

Squamulosone (**1**) was found to possess insecticidal activity against *Cylas formicarius elegantulus* (the sweet potato weevil), a major pest of the sweet potato, *Ipomoea* sp. (Buchanan and Reese, 2000). Thus we were prompted to compare the toxicity of **1** with that of its biotransformed analogues (Table 2). Epoxide **8** was not isolated in quantities sufficient for bioassay. Squamulosone (**1**) was an effective insecticide after 48 h at a concentration of 60 μg per insect, surpassed only by its 13-hydroxy derivative (**4**). All metabolites effected high mortalities after 72 h. It would appear that the insertion of a hydroxyl group at C-13 increases the toxicity of the terpene, however, the opposite is seen when this substituent is placed at C-2 or-14.

In summary sesquiterpenes **1** and **9** have been isolated for the first time from aerial parts of *H. verticillata*. Terpene **1** has been transformed by *C. lunata* to seven novel metabolites. Hydroxylation occurred on the C-13 methyl group and at the C-2 and-14 allylic positions. The aromadendranes **1**–**7** were found to possess insecticidal activity.

3. Experimental

^1H and ^{13}C NMR spectra were generated in deuterated chloroform at 200 and 50 MHz, respectively, using a Bruker AC200 instrument. 2D NMR data were also generated in deuterated chloroform at 500 and 125 MHz, respectively, using a Varian Unity 500 NMR spectrometer. Tetramethylsilane (TMS) was used as the internal standard. ^{13}C NMR assignments for the aromadendranes are listed in Table 1. Melting points were determined on a Thomas–Hoover capillary melting point apparatus. Infrared data were acquired on a Perkin Elmer FTIR Paragon 1000 instrument using KBr disks. The UV spectra were determined on a Hewlett Packard HP 8452A spectrophotometer. Optical rotations were acquired on a Perkin Elmer 241 polarimeter. High-resolution electron impact mass spectrometry (HREIMS) was performed on a VG 70-250S instrument at an ionising voltage of 70 eV. Column chromatography was performed with Kieselgel silica (40–63 μm). Compounds on TLC plates were visualised by the use of the ammonium phosphomolybdate/sulfuric acid spray reagent followed by heating at 120°C. *Curvularia lunata* ATCC 12047 was obtained from the American Type Culture Collection, Rockville, MD, USA. Petrol refers to the petroleum fraction boiling between 60 and 80°C.

4. Extraction and isolation

Hyptis verticillata plant material was collected in St Andrew, Jamaica. A voucher specimen was deposited in

the Botany Herbarium, UWI (accession number No. 33483). The green leaves and stems (17.61 kg) were chopped and extracted twice with CH_2Cl_2 (47 l) at room temperature. The extracts were pooled and concentrated in vacuo to produce a dark green gum (145.5 g). The crude gum was chromatographed on silica gel using 3% EtOAc in petrol to give eight major fractions (A–H). The moderately non-polar fraction B (42.3 g) was subjected to further purification by column chromatography using 1% EtOAc in petrol. This led to the isolation of a (99:1) (w/w) mixture of cadina-4,10(15)-dien-3-one and cadin-4-en-1β-ol (**9**) (6.3 g) and aromadendr-1(10)-en-9-one (**1**) (10.3 g).

4.1. Aromadendr-1(10)-en-9-one (*1*)

Needles from acetone, mp 50–51°C, $[\alpha]_D^{25}$:−202° ($c=1.43$, $CHCl_3$) [lit. mp 45–46°C, $[\alpha]_D$:−234° ($c=1.2$, $CHCl_3$) (Batey et al., 1971)]; IR ν_{max} 2954, 2871, 1639 (C=O), 1468, 1315 cm^{-1}; UV (MeOH) λ_{max} (log ε) 254 (3.81); ^1H NMR: δ 0.71 (1H, *ddd*, $J=5.2$, 9.5, 11.8 Hz, H-7), 0.82 (1H, *dd*, $J=9.5$, 11.1 Hz, H-6), 1.04 (3H, *d*, $J=6.5$ Hz, H-15), 1.07 (3H, *s*, H-13), 1.18 (3H, *s*, H-12), 1.42 (1H, *m*, $\frac{w}{2}=26.7$ Hz, H-3), 1.78 (3H, *bs*, H-14), 1.87 (1H, *m*, $\frac{w}{2}=18.7$ Hz, H-3), 2.21 (1H, *m*, $\frac{w}{2}=24.0$ Hz, H-4), 2.34 (1H, *m*, $\frac{w}{2}=22.3$ Hz, H-2), 2.35 (1H, *dd*, $J=11.8$, 14.8 Hz, H-8), 2.62 (1H, *bt*, $J=11.0$ Hz, H-5), 2.67 (1H, *bdd*, $J=8.2$, 18.0 Hz, H-2), 2.81 (1H, *dd*, $J=5.2$, 14.8 Hz, H-8).

4.2. Cadin-4-en-1β-ol (*9*)

A mixture of cadina-4,10(15)-dien-3-one and cadin-4-en-1β-ol (**9**) (2.00 g) was dissolved in dry THF (50 ml). Lanthanum chloride (2.22 g, 9.13 mmol) was added and the suspension was stirred at room temperature (15 min). Lithium aluminium hydride (1.39 g, 36.52 mmol) was added and the mixture was stirred for another 10 min (until effervescence ceased). The mixture was neutralised with dilute hydrochloric acid and extracted with Et_2O (100 ml×3). The organic layer was dried with magnesium sulfate and concentrated in vacuo to afford a solid which was chromatographed on silica gel with 3% EtOAc in petrol. This gave 3α-hydroxycadina-4,10(15)-diene (1.35 g, 6.14 mmol) as needles from petrol-acetone, mp 115–117°C, $[\alpha]_D^{25}$ −107° ($CHCl_3$ 0.15) [lit. mp 116–117°C, $[\alpha]_D^{25}$ −107° ($CHCl_3$ 0.15) (Buchanan and Reese, 2000)]; IR (KBr) ν_{max} cm^{-1} 3402 (OH), 1652 (C=C); ^1H NMR δ 0.74 (3H, *d*, $J=7.60$ Hz, H-14), 0.90 (3H, *d*, $J=7.60$ Hz, H-13), 1.78 (3H, *d*, $J=0.80$ Hz, H-11), 4.25 (1H, *bm*, $\frac{w}{2}=19.10$ Hz, H-3), 4.57 (1H, *d*, $J=0.85$ Hz, H-15), 4.70 (1H, *d*, $J=0.85$ Hz, H-15), 5.60 (1H, *d*, $J=0.85$ Hz, H-5); ^{13}C NMR δ 15.0 (C-13), 19.3 (C-11), 21.4 (C-14), 26.3 (C-12), 26.4 (C-8), 35.9 (C-9), 36.2 (C-2), 43.6 (C-6), 45.4 (C-7), 46.3 (C-1), 71.0 (C-3), 103.7 (C-15),125.7 (C-5), 136.8 (C-4), 151.6 (C-10).

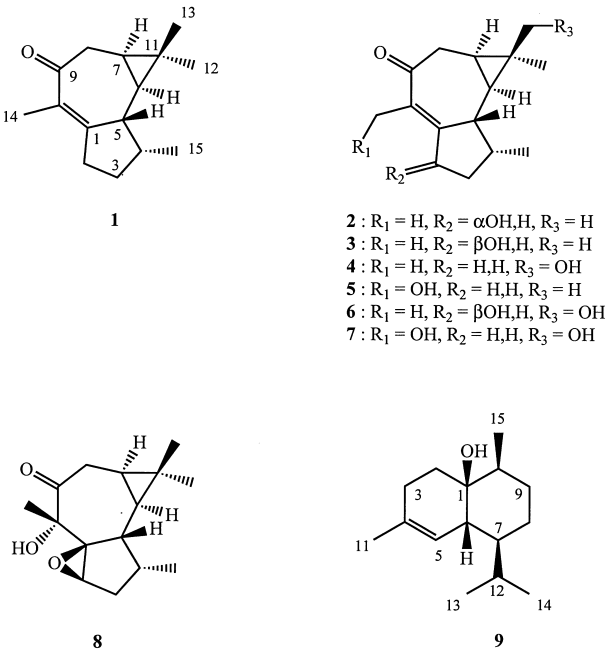

Fig. 1. Aromadendrane and cadinane sesquiterpenes.

Also eluting in 3% EtOAc in petrol was cadin-4-en-1β-ol (**9**) (23 mg), as a gum, $[\alpha]_D^{25}$: 100° ($c=0.3$, $CHCl_3$) [lit. oil, $[\alpha]_D^{25}$: −96° ($CHCl_3$) (Gerber, 1971)]; IR (KBr) ν_{max} cm^{-1} 3425, 1456, 1386, 1074, 1026; ^1H NMR δ 0.84 (3H, *s*, H-14), 0.90 (3H, *s*, H-13), 1.02 (3H, *d*, $J=7.5$ Hz, H-15), 1.14 (1H, *septet*, $J=4.8$ Hz, H-7), 1.32 (2H, *t*, $J=4.7$ Hz, H-8), 1.38 (1H, *m*, $\frac{w}{2}=17.7$ Hz, H-2α), 1.52 (2H, *m*, $\frac{w}{2}=17.5$ Hz, H-9), 1.69 (3H, *s*, H-11), 1.80 (1H, *m*, $\frac{w}{2}=16.7$ Hz, H-10), 1.99 (1H, *d*, $J=2.5$ Hz, H-3β), 2.01 (1H, *m*, $\frac{w}{2}=5.4$ Hz, H-12), 2.07 (1H, *m*, $\frac{w}{2}=15.0$ Hz, H-6), 2.13 (1H, *s*, H-2β), 2.15 (1H, *s*, H-3α), 5.37 (1H, *d*, $J=5.0$ Hz, H-5); ^{13}C NMR: δ 14.0 (C-15), 16.8 (C-14), 18.9 (C-8), 21.8 (C-13), 23.4 (C-11), 27.2 (C-12), 27.8 (C-3), 28.5 (C-9), 31.3 (C-2), 37.2 (C-10), 41.8 (C-6), 49.1 (C-7), 72.3 (C-1), 123.4 (C-5), 133.4 (C-4).

5. Feeding protocol

The fungus was maintained on potato dextrose agar (PDA) slants. PDB was comprised of potato dextrose broth (24 g l^{-1}) (Chen and Wey, 1990). BEM was composed of peptone (1 g l^{-1}), yeast extract (1 g l^{-1}), beef extract (1 g l^{-1}) and glucose (5 g l^{-1}) (Garcia-Granados et al., 1991). One 14 day old slant was used to inoculate four 500 ml conical flasks each containing 125 ml of liquid medium. The flasks were incubated at 200 rpm at 27°C. An EtOAc solution (2 ml) containing 10% of the total mass of the substrate was fed 24 h after inoculation. The remaining 20, 30 and 40% portions of the substrate were fed at 36, 48 and 60 h after inoculation, respectively. The fermentation was allowed to proceed for a further 10 days. The pH was measured and the

mycelium was filtered from the broth. Broth extraction utilised EtOAc (3×500 ml). The mycelium was homogenised in EtOAc. The extracts were dried with sodium sulfate, concentrated in vacuo, and analysed by thin-layer chromatography.

6. Incubation of aromadendr-1(10)-en-9-one (1)

Squamulosone (**1**) (1 g) was fed to *C. lunata* in 20 flasks of each medium as outlined above. The fungus was harvested 10 days after the final feed to give broth extracts (0.578 and 0.683 g) and mycelial extracts (0.922 and 0.762 g) from PDB and BEM, respectively. The pH at the end of each fermentation was 6.5. Analysis of both extracts by TLC indicated the presence of biotransformed compounds. The broth and mycelial extracts of each fermentation were combined and subjected to column chromatography using increasing concentrations of EtOAc in petrol.

6.1. 2α-Hydroxyaromadendr-1(10)-en-9-one (2)

(PDB, 9 mg; BEM, 23 mg) oil; $[\alpha]_D$: −160° ($c=1.0$, $CHCl_3$); IR ν_{max} cm^{-1} 3438 (OH), 2935, 1621 (C=O); UV ($CHCl_3$) λ_{max} (log ε) 234 (3.07); EIMS *m/z* (rel. int.) 250.1580 (6) ($[M]^+$, $C_{15}H_{22}O_3$, 250.1569), 179 (100), 161 (55), 159 (40), 152 (52), 149 (51), 137 (99), 91 (54); ^1H NMR: δ 1.08 (3H, *d*, *J* = 6.6 Hz, H-15), 1.30 (3H, s, H-12), 2.83 (1H, *dd*, *J* = 5.1, 15.2 Hz, H-8), 3.35 (1H, *d*, *J* = 11.1 Hz, H-13), 3.44 (1H, *d*, *J* = 11.1 Hz, H-13), 4.31 (2H, bs, H-14).

6.7. 10α-Hydroxy-1,2-epoxyaromadendran-9-one (8)

(BEM, 3 mg) oil; $[\alpha]_D^{25}$: −12° ($c=0.85$, $CHCl_3$); IR ν_{max} cm^{-1} 3442 (OH), 2362, 1643 (C=O), 1107 (C–O–

C); EIMS m/z (rel. int.) 250.1561 (6) ($[M]^+$, $C_{15}H_{22}O_3$, 250.1569), 219 (13), 155 (34), 128 (36); ^{1}H NMR: δ 0.62 (1H, *dd*, $J=6.0$, 8.9 Hz, H-6), 0.68 (1H, *dd*, $J=5.6$, 8.9 Hz, H-7), 0.96 (3H, *d*, $J=7.0$ Hz, H-15), 1.08 (3H, *s*, H-13), 1.13 (3H, *s*, H-12), 1.32 (1H, *m*, $\frac{w}{2}=4.5$ Hz, H-3), 1.48 (3H, *s*, H-14), 1.90 (1H, *m*, $\frac{w}{2}=15.5$ Hz, H-5), 2.02 (1H, *d*, $J=1.3$ Hz, H-3), 2.22 (1H, *m*, $\frac{w}{2}=7.0$ Hz, H-4), 2.40 (1H, *bt*, $J=23.4$ Hz, H-8), 2.74 (1H, *dd*, $J=5.7$, 12.0 Hz, H-8), 3.77 (1H, *s*, H-2), 4.13 (1H, *s*, OH).

7. Insecticidal activity

The assays were conducted according to the method described previously (Porter et al., 1995). Briefly, adult *Cylas formicarius elegantulus* (Summer) were reared in the laboratory in glass aquaria on sweet potato tubers, *Ipomoea* sp., and were then used for insecticidal screening four weeks after adult emergence. Ten insects were transferred to each petri dish where the compounds in acetone were applied to the insects' abdomens using a Hamilton microapplicator. Applications of 2, 4 or 6 μl were done from stock solutions of 1.0% (w/v, 2.0 mg in 0.2 ml acetone) prepared for each compound. Each assay was performed in duplicate. The controls received only 2, 4 and 6 μl of acetone. The number of dead insects was recorded at 24, 48 and 72 h.

Acknowledgements

This work was supported in part by funds secured under the University of the West Indies/Interamerican Development Bank (UWI/IDB) Programme and the granting of a UWI Postgraduate Scholarship to DOC. The authors are grateful to Professor D. John Faulkner (Scripps Institute of Oceanography) for providing NMR spectra for millecrone B and, more recently to Professor Michael Davies-Coleman (Rhodes University, South Africa) for the generous gift of a sample of the compound. The authors acknowledge Professor Herbert L. Holland (Brock University) and Dr. Lawrence A. D. Williams (UWI) for helpful discussions. Optical rotations were measured at the Bureau of Standards, Kingston. Fermentations were carried out in the Biotechnology Centre, UWI.

Blend effects in the toxicity of the essential oil constituents of *Ocimum kilimandscharicum* and *Ocimum kenyense* (Labiateae) on two post-harvest insect pests

Jembere Bekele[1], Ahmed Hassanali*

International Centre of Insect Physiology and Ecology (ICIPE), PO Box 30772, Nairobi, Kenya

Received 12 October 2000; received in revised form 12 January 2001

Abstract

The lethal toxicity of major components of the essential oils of *Ocimum kilimandscharicum* and *O. kenyense* and of selected blends of these against *Sitophilus zeamais* and *Rhyzopertha dominica* were compared with those of the full blends of the essential oils. The compounds were assayed in amounts and proportions present in the minimum 100% lethal dose of the oils. Whereas a major component of *O. kilimandscharicum* was found to be largely responsible for the toxic action of its essential oil against *R. dominica,* the results with the other treatments indicated that the toxic action of the essential oils were due to the combined effects of different components, either with or without significant individual toxic action of their own against the insects. The significance of the results and their implication in screening and using plants and their phytochemicals for pest and microbial control are highlighted. © 2001 Elsevier Science Ltd. Keywords: *Ocimum kilimandscharicum*; *O. kenyense*; Labiateae; *Sitophilus zeamais*; *Rhyzopertha dominica*; Essential oils; Blend effects; Synergism

1. Introduction

Ethnobotany has played a very important role in traditional methods of protection against storage pests in Africa and Asia (Hassanali et al., 1990; Tierto Niber, 1994; Tiwari, 1994; Talukder and Howse, 1995). In view of the potential of plant products in small-scale farm holdings typical of the bulk of grain production in Africa, there has been growing interest in evaluating their efficacies and in elucidating the basis of their protective action (Weaver et al., 1991, 1994a,b; Schmidt and Streloke, 1994; Tierto Niber, 1994; Jembere et al., 1995; Bekele et al., 1996, 1997; Obeng-Ofori et al., 1997). Previously, we evaluated crude products prepared from three species of the genus *Ocimum* against three serious post-harvest pests in Africa (the maize weevil, *Sitophilus zeamais* Mots, the lesser grain borer, *Rhyzopertha dominica* (F.) and the angoumois grain moth, *Sitotroga cerealella*), and found varying degrees of repellent, toxic and protective effects against the pests (Jembere et al., 1995; Bekele et al., 1996, 1997). The effects of two specific constituents of the plants on the insects have also been reported (Obeng-Ofori and Reichmuth, 1997; Obeng-Ofori et al., 1997). The aim of the present study was to compare the toxicity of the essential oils of *O. kilimandscharicum* and *O. kenyense* with those of their major constituents, individually and in selected blends, with the purpose of identifying the constituents important in conferring the biological activities of the two plants against the stored product pests. It was envisaged that this information would help guide the selection and use of appropriate varieties of such plants in traditional post-harvest practices.

2. Results

2.1. Essential oil compositions

The GC profiles of the oil samples of *O. kilimandscharicum* and *O. kenyense* which were tested for insect activity are shown in Fig. 1A and B, respectively.

Constituents present in >0.45% were identified by GC–MS and co-injections with standards (Table 1). The relative amounts of compounds of oils of *O. kilimandscharicum* collected from different locations varied sharply, e.g. the proportion of camphor in the oil from plants collected at Siaya district was higher (>70%) than that collected from Ngong (Nairobi) area (~40%). The former was used as a basis of toxicity tests described in this study.

2.2. Toxicity of individual and blends of constituent compounds of the essential oils in Petri dish assays

2.2.1. Ocimum kilimandscharicum

In a minimum dose of 1.44 mg per cm^2 of filter paper, *O. kilimandscharicum* essential oil caused 100% mortality of *S. zeamais* with LC_{50} of 0.76 mg per cm^2. None of the six major compounds of the essential oil (camphor, limonene, 4-terpeneol, 1,8-cineole, camphene and *trans*-caryophyllene) in amounts present at that dose of the oil (1.44 mg per cm^2), was toxic to the insect (Table 2). However, 100% mortality of the insect was obtained when all the six compounds were present. In subtraction assays (Table 2, Treatments 8–14), absence of camphor caused the largest drop in the activity of the resulting 5-component blend, showing that this component contributes most to the activity of the essential oil. Subtraction of any of the other five components, except 1, 8-cineole, did not cause any significant drop in the toxicity of the resulting blends. A binary blend of camphor and 1,8-cineole (Treatment 16) was moderately active (47±2.4%). The activity of the tertiary blend of the three most abundant components, camphor, limonene and 1,8-cineole (Treatment 17) was high (82±2.0%) but not 100%, showing that the other components also contribute to the activity of the essential oil. All combinations of the compounds tested in the absence of camphor did not cause any mortality of the weevil (data not shown) indicating that the presence of this compound was essential for the toxicity of the oil.

For *R. dominica*, a minimum dose of 0.8 mg per cm^2 caused 100% mortality, with LC_{50} at 0.7 mg per cm^2 (Table 2). Toxicity of the oil against *R. dominica* appears to be largely due to camphor (Treatment 2). No mortality of the insect was obtained in the absence of this constituent (Treatments 3–7, 9, 11). The presence of

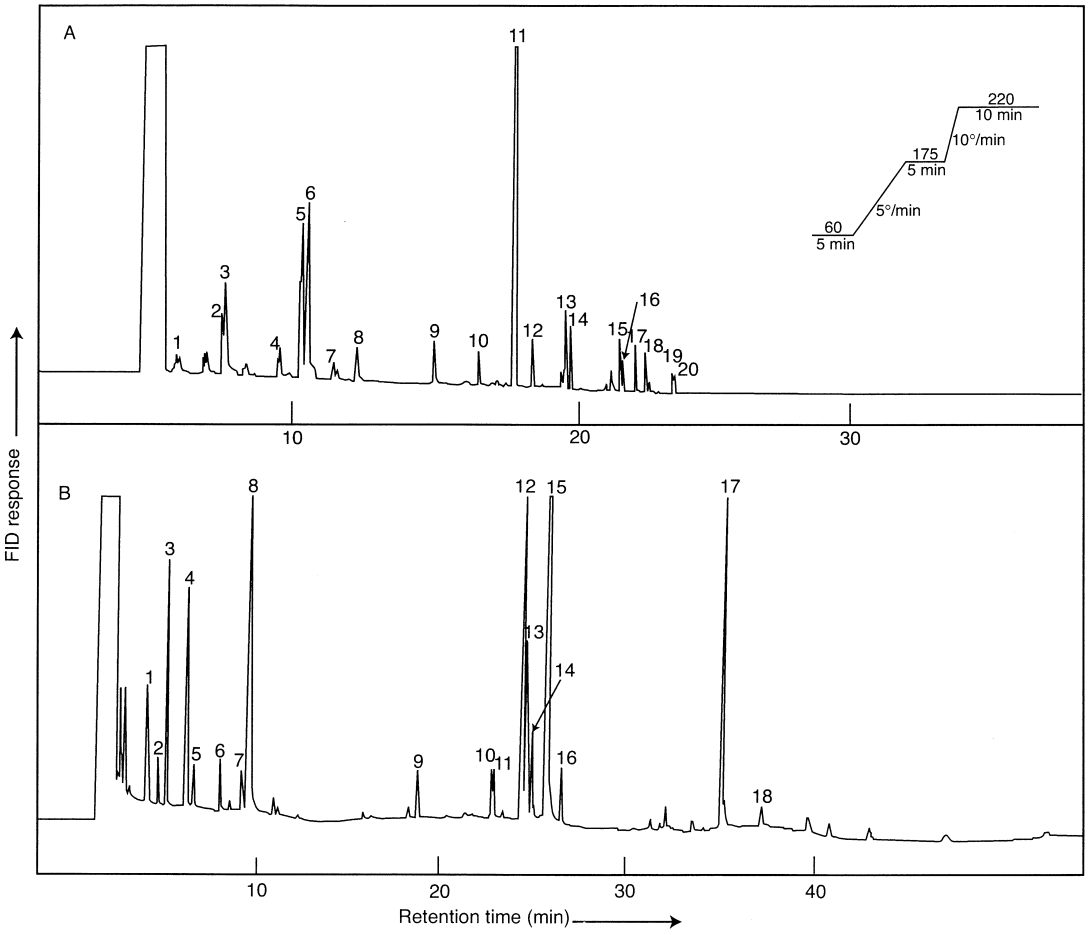

Fig. 1. Gas chromatograms of essential oils of (A) *Ocimum kilimandscharicum* (collected in the Siaya district, Kenya), and (B) *O. Kenyese* (collected from Nairobi): 50 m fused silica capillary column, 0.22 μm i.d., coated with carbowax (0.32 μm) on Hewlett Packard 5890A GC.

any of the other components with camphor had no antagonistic effect on the toxic effect of this compound (Treatments 8, 10, 12–17).

2.2.2. Ocimum kenyense

A minimum dose of 2 mg per cm^2 of the filter paper was needed to effect 100% mortality of *S. zeamais* with LC_{50} at 0.85 mg per cm^2. Among constituents of the essential oil of *O. kenyense* tested, 1,8-cineole and *iso*-eugenol showed significant toxic effects against *S. zeamais* at levels present in the lethal dose of the essential oil (Table 3, Treatments 5 and 6). The presence of the two compounds in other blends (Treatments 7–10, 14, 16) caused high (100%) mortality of the insect. In subtraction assays, absence of 1,8-cineole (Treatment 5) caused a significant drop in the activity of resulting blend; however, that of *iso*-eugenol (Treatment 12) had no significant effect.

For *R. dominica,* 100% mortality was obtained with a minimum dose of 0.6 mg per cm^2 of *O. kenyense* essential oil, with its LC_{50} at 0.36 mg per cm^2 (Table 3). None of the compounds of *O. kenyense* essential oil tested individually, with the exception of *iso*-eugenol (which was weakly active), caused any mortality of *R. dominica* in amounts present in the minimum lethal dose of the oil (Table 3, Treatments 2–6). On the other hand, a combination of the 5 major constituents in the same relative amounts resulted in 100% mortality of the insect (Treatment 7). Subtraction of any of the five components (Treatments 8–12), had either no or only a small effect on the toxicity of the resulting four-component blends.

3. Discussion

Previously, we showed that products derived from *Ocimum* spp. provide varying degrees of protection against three major stored product insect pests (Jembere et al., 1995; Bekele et al., 1996, 1997). In the present study, we compared the toxic effects of major constituents of the oils of *O. kilimandscharicum* and *O. kenyense* and various blends of these with those of the full blends of the essential oils against *S. zeamais* and *R.*

Table 1
Major identified constituents of *Ocimum kilimandscharicum* and *O. kenyense* essential oils and their relative proportion in the oils

Ocimum kilmandscharicum			*Ocimum kenyense*		
GC peak number	Component (%)		GC peak number	Component (%)	
3	Camphene	(5.07)	3	Ethyl isovalerate	(2.99)
5	Limonene	(6.23)	4	β-Pinene	(2.86)
6	1,8-Cineole	(7.20)	7	α-Terpineol	(0.55)
11	Camphor	(70.43)	8	1,8-Cineole	(36.93)
12	Linalool	(0.47)	10	*trans*-Caryophyllene	(0.66)
13	4-Terpineol	(1.44)	11	4-Terpineol	(0.79)
14	*trans*-Caryophyllene	(2.80)	12	Methyl chavicol	(12.86)
15	α-Terpineol	(0.60)	13	α-Humulene	(2.78)
16	Endo-borneol	(0.60)	15	β-Selinene	(23.57)
20	Myrtenol	(1.30)	16	γ-Cardinene	(0.78)
			17	*iso*-Eugenol	(8.23)

dominica, respectively. Our aim was two-fold: to elucidate the roles and relative importance of the major constituents of the oils in conferring some of the observed biological effects of the plants, and to use this information to guide effective deployment of such plants by small-scale farmers in post-harvest grain protection.

Of the essential oils, that of *O. kilimandscharicum* was more toxic to both insects consistent with the relative performance of products derived from these plants (Jembere et al., 1995; Bekele et al., 1997). On filter papers in Petri dish assays, the minimum lethal dose (giving 100% mortality) of this oil was found to be 1.4 mg cm^{-2} for *S. zeamais* and 0.8 mg cm^{-2} for *R. dominica*, confirming the greater sensitivity of the latter to the oil. Of special interest is the contrasting ways in which the major components of the oil contribute to its toxicity to the two test insects (Table 2). In amounts present in the minimum lethal dose of the oil, none of the six individual components (camphor, limonene, 4-terpeneol, 1,8-cineole, camphene and *t*-caryophyllene) that were tested, had significant toxic effect against *S. zeamais*. However, the mixture of these six components and that minus *t*-caryophyllene, were as effective as the essential oil, showing clearly that the toxic action of the oil results from the combined action of five of its major constituents. Subtraction assays provided an additional insight into the relative contribution of these components. Absence of camphor in the blend resulted in the largest drop in the toxic action of the resulting blend, identifying it as the most important component of the active blend. On the other hand, a single component, camphor, in the amount present in the lethal dose of the oil, was found to be responsible for the toxic action of the oil against *R. dominica*. The blend of the other five components was non-toxic to this insect. Their presence in the blends with camphor had no deleterious or antagonistic effect on the toxicity of this compound.

The minimum 100% lethal dose of the oil of *O. kenyense* against *S. zeamais* and *R. dominica* (2.0 and 0.8 mg cm^{-2}, respectively) showed that the latter was also the more sensitive insect to this oil. Of the individual major constituents tested (methyl chavicol, ethyl isovalerate, α-humulene, 1,8-cineole and *iso*-eugenol), only 1,8-cineole and *iso*-eugenol were significantly toxic to *S. zeamais*. On the other hand, except for the weak toxic action of *iso*-eugenol, none of the components was active against *R. dominica*. Subtraction assays and tests involving different combinations of the constituents against *S. zeamais* and *R. dominica* also indicated the special potency of some of the mixtures (Table 3). Three variants of blend effects may be noted from these results: production of an active blend from inactive constituents; enhancement of the activity of an active compound by an inactive constituent; and synergism between moderately active compounds to give a mixture that is more active than a linear summation of the individual activities

Table 2

[b] Minimum lethal dose of 2.0 mg cm^{-2} for *S. zeamais* and 0.85 mg cm^{-2} for *R. dominica*.

of the constituents. The first variant is illustrated by the high lethal activity of the quaternary mixture of methyl chavicol, ethyl isovalerate, α-humulene and 1,8-cineole against *R. dominica*. As in the case of the five major components of *O. kilimandscharicum* with respect to *S. zeamais,* none of the components of the quaternary mixture were individually toxic to *R. dominica*. The second variant is illustrated by significant enhancement of the activities of 1,8-cineole and *iso*-eugenol against *S. zeamais* from 44 to 100% and from 39 to 82%, respectively, in blends with methyl chavicol. The third, probably the most frequently reported in the past, is illustrated by 100% mortality of *S. zeamais* exposed to the binary mixture of 1,8-cineole and *iso*-eugenol, which individually caused 44 ± 3.0% and 39 ± 2.4% mortality, respectively.

These results stress the importance of evaluating plant components in blends to elucidate their full potency in a given bioactivity. A number of previous studies on the effects of essential oils on post-harvest and other pests focused on the identification of active components rather than mixtures (e.g. Klocke et al., 1989; Kurowska et al., 1991; Shaaya and Vladmir, 1991; Shaaya et al., 1991; Weaver et al., 1991; Regnault-Roger et al., 1993; Seck et al., 1993). In the present study, the result obtained with camphor (the major component of the oil of *O. kilimandscharicum*) against *R. dominica*, where it appears to be largely responsible for the toxicity of the oil, may be less common. Blend effects in the bioactivity of plant products may well be the norm. Indeed, there is accumulating evidence of adaptive value of phytochemical diversity in ecological interactions among plants and their associated herbivores and pathogens (Berenbaum and Zangerl, 1996; Cates, 1996). This has an important practical implication in the strategy adopted in the search for and use of plants and their phytochemicals for pest and microbial control.

4. Experimental

4.1. Mass rearing of the test insects

Mass rearing of the test insects was carried out following the method of Santhoy and Rejesus (1975) and Jembere et al. (1995). The two insect pests (*S. zeamais* and *R. dominica*) were obtained from stocks maintained at the International Centre of Insect Physiology and Ecology (ICIPE) and the Kenya Agricultural Research Institute (KARI) laboratories. Maize and sorghum seeds (local varieties) were obtained from farmers in Kisii, Ugunja and Kitale districts of Kenya. Prior to the experiments, the seeds were disinfested by keeping them in an oven at 40°C for 4 h (Santhoy and Rejesus, 1975). Twenty pairs of each test insects, sexed following the methods of Halstead (1963) and Stenley and Wilbur (1966), were introduced into glass jars (1l) containing disinfested maize and sorghum seeds, respectively. The jars were covered with nylon mesh and held with rubber bands and kept in a room maintained at 60±5% relative humidity and 26±1°C using heaters and water troughs. The adults of *S. zeamais* and *R. dominca* were allowed to stay in the glass jars for 30 and 15 days (optimum oviposition time), respectively, after which they were removed and discarded. The seeds were kept in the room until the emergence of the first progeny. On days 35–65 and 27–42, respectively, after the first introduction of the two insects, the new progenies that emerged daily were transferred into their respective disinfested grains in the glass jars. A sieve of mesh number 10 (sieve size 2 mm, Endecotts LTD, London) was used to sieve out the insects. The ages of the insects in each jar were recorded.

4.2. Plant materials and isolation of their essential oils

Fresh aerial parts of *O. kilimandscharicum* collected from the Siaya district and *O. kenyense* collected from around Nairobi (Kenya) were brought to the laboratory and stored at 4°C. Voucher specimens are kept at the University of Nairobi herbarium in the Botany Department. The fresh plant materials comprising leaves, inflorescence and succulent stems were subjected to steam distillation to obtain the essential oils. The distillation process was carried out using a clavenger type of apparatus (Gunter, 1946). The condensing oil was collected in hexane (Aldrich, HPLC grade). The hexane solution was filtered through a filter paper containing anhydrous sodium sulphate to remove traces of moisture. Hexane was then removed by distillation at 60°C, the residual oil collected and weighed.

4.3. Analysis of the essential oils

The chemical components of the essential oils were initially identified on a VG Masslab 12–250 mass spectrometer (GC–MS) equipped with data system linked to Hewlett Packard 5790 gas chromatograph (GC). The identity of each component was confirmed by co-injection with authentic compounds on a Hewlett Packard 5890A gas chromatograph equipped with a splitless injector and a flame ionization detector. Helium and nitrogen gases were used as carrier gases for GC–MS and GC, respectively. In both GC–MS and GC analyses, a fused silica capillary column (Hewlett Packard 50 m long, 0.22 mm id) coated with carbowax (0.32 μm film) was used. The column temperature programme in both analyses comprised of an initial temperature of 60°C (5 min), a rise to 175°C at 5 min, a hold at 175°C (5 min), another rise to 220°C at 10°C/min and final hold at 220°C for 10 min.

4.4. Comparative toxicity tests of essential oil and its constituents

These were conducted in Pyrex glass Petri dishes, 10 cm dia. (Weaver et al., 1991). A sample of each essential oil was weighed, dissolved in 1 ml of acetone (Merck 95–97%) and delivered to a Whatman No 1 filter paper (9 cm dia.) in the petridishes. Various doses of the essential oils (2.5–0.5 mg cm^{-2}) were used to identify the minimum doses which gave 100% mortality of the two insects. The minimum doses of *O. kilimandscharicum* essential oil used against *S. zeamais* and *R. dominica* were 1.44 and 0.8 mg cm^{-2}), while that of *O. kenyese* oil against both insects were 2.0 and 0.64 mg cm^{-2}, respectively. Acetone was allowed to evaporate off (20 min) prior to the introduction of the insects. Acetone treated filter papers were used as controls. 10 pairs of *S. zeamais* or *R. dominica* were introduced and the Petri dishes were kept for 24 h in the laboratory maintained at $26 \pm 1^{\circ}C$ and $60 \pm 5\%$ relative humidity.

The number of dead insects was counted after 24 h. Insects were considered dead if they were immobile and did not react to three probings with a blunt dissecting probe. The experiment was repeated with commercially available constituents (Aldrich) of the essential oils and blends of these at their natural proportions (GC) in the oils and in amounts present in the minimum 100% lethal dose of the oils, with each component absent (subtracted) from the blend in turn to determine its relative contribution to the overall toxicity of the natural oil (Owaga et al., 1988).

4.5. Data analysis

The mortality data obtained in the different treatments were analyzed using analysis of variance following the method of Gomez and Gomez (1984). Appropriate data transformation methods (arc sine and square root) were applied where necessary. Probit analysis for the determination of LC_{50} was based on the methods of Busvine (1971) and Finney (1978).

Received 28 September 2000; received in revised form 7 February 2001

Abstract

Methanolic extracts of seeds of several *Carex* species were found to antagonise the action of 20-hydroxyecdysone in the *Drosophila melanogaster* microplate-based B_{II} cell bioassay. Bioassay-guided HPLC analysis of seeds of *Carex pendula* (drooping sedge) provided one previously unknown tetrastilbene (*cis*-miyabenol A) and two known oligostilbenes (kobophenol B and *cis*-miyabenol C) as the biologically active compounds (EC_{50} values were 31, 37 and 19 μM, respectively, vs. 5×10^{-8} M 20-hydroxyecdysone). The structures and relative stereochemistries of these compounds were deduced by comprehensive 1D- and 2D-NMR experiments. These compounds are isolated from *Carex pendula* for the first time. In vitro experiments with dipteran and lepidopteran ecdysteroid receptor proteins demonstrate that the oligostilbenes are able to compete with radiolabelled ecdysteroid ([^{3}H]ponasterone A) for occupancy of the ligand binding site. IC_{50}/K_i values are similar to the EC_{50} values obtained in the B_{II} bioassay. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Cyperaceae; *Carex*; Antagonist; Ecdysteroid; Steroid hormone receptor; Stilbenoid

1. Introduction

Carex species (family: Cyperaceae) are rich in oligostilbenes (Kawabata et al., 1989) and a number of oligostilbenes have been isolated and identified (Suzuki et al., 1987; Kurihara et al., 1990, 1991; Kawabata et al., 1991). Oligostilbenes are resveratrol-type oligomeric phenols and most of them show antimicrobial activity (Sotheeswaran and Pasupathy, 1993) and other interesting biological activities. We are searching for plant natural products which act as agonists or antagonists of the insect steroid hormone (ecdysteroid) receptor (Dinan et al., 1999). Ecdysteroids are important regulators of development, metamorphosis and reproduction in arthropods and probably other invertebrates too (Koolman, 1989). Consequently, the intracellular ecdysteroid receptor is an attractive target for new invertebrate pest control agents. Plant natural products should be a good source of lead compounds for such control agents. We now report the isolation, structural elucidation and biological activity of one previously unknown tetrastilbene, *cis*-miyabenol A (**1**), together with the known tetrastilbene, kobophenol B (**2**) and the known tristilbene, *cis*-miyabenol C (**3**), from the seeds of *Carex pendula* (drooping sedge). These oligostilbenes are isolated as constituents from *C. pendula* for the first time and they exhibit ecdysteroid antagonist activity. Antagonists of ecdysteroid action in invertebrate systems will be useful as biochemical probes for the investigation of the control of gene expression by ecdysteroids as well as lead compounds for the development of new insect pest control agents (Dinan, 1995; Keckeis et al., 2000).

2. Results and discussion

2.1. Ecdysteroid antagonist activity in Carex spp

Initial studies revealed that methanolic seed extracts of several species in the genus *Carex* (including *C. pendula*) antagonise the activity of 20-hydroxyecdysone on

3

the *Drosophila melanogaster* B_{II} cell line (Table 1). We also examined extracts of leaves and roots of four of the *Carex* species, but activity appears to be highest in seeds. Consequently, the identities of the active principle(s) from this source were pursued.

2.2. Isolation and structural elucidation

Bioassay-guided HPLC analysis of the active fractions from solid-phase extraction (SPE) on C_{18}-cartridges of a MeOH extract (defatted with hexane) of the seeds of *C. pendula* resulted in the isolation of a previously unknown tetrastilbene *cis*-miyabenol A (**1**) and two known oligostilbenes, kobophenol B (**2**) (Kawabata et al., 1991) and *cis*-miyabenol C (**3**) (Ono et al., 1995). The compounds were identified on the basis of comprehensive analysis of their 1D- and 2 D-NMR spectra and, in the case of the known compounds, by comparison of their UV, MS, ^{1}H NMR and ^{13}C NMR and NOESY data with published data (Kawabata et al., 1991; Ono et al., 1995).

Compound **1** is a colourless glassy solid. LSIMS (+ve ion-mode) gave an $[M+H]^+$ ion at m/z 907 and an $[M+Na]^+$ ion at 929 compatible with the molecular formula $C_{56}H_{42}O_{12}$, which was supported by the ^{13}C and ^{1}H NMR spectra (Table 2) and was compatible with a tetrastilbene (Kurihara et al., 1991). The UV spectrum with an absorption maximum (λ_{max}) at 286 nm was similar to those of other *Carex* oligostilbenes (Ono et al., 1995). The ^{1}H NMR spectrum (Table 2) showed eight sets of ortho-coupled aromatic hydrogens, assignable to four 4-hydroxylphenol groups ("A"-rings of **1**), and signals from four other 3,5-dihydroxyphenol systems ("B"-rings of **1**), characteristic for four resveratrol units. In addition, three sets of coupled methines (each set containing a deshielded oxymethine; δ 3.88 [d, $J=2.7$ Hz]/δ 5.40 [*d*, $J=2.7$ Hz], δ 3.99 [*d*, $J=6.3$ Hz]/δ 5.02 [*d*, $J=6.3$ Hz] and δ 4.40 [1H, $J=2.0$]/δ 5.12 [*d*,

[b] 25 mg samples were extracted 3×1 ml with methanol at 55°C, the pooled extracts were mixed with 1.3 ml H_2O and partitioned against 2 ml hexane to give 4.3 ml methanolic extract. Aliquots (10 μl) of 1-, 10- and 100-fold dilutions were assessed in the agonist and antagonist versions of the B_{II} bioassay; - - -, inactive; + - -, active as neat extract; +(+)-, active as 10-fold dilution; + + +, active as 100-fold dilution; C- -, cytotoxic as neat extract; (+), weak activity.

$J = 2.0$ Hz]) and pair of coupled olefinic protons at δ5.85 (*d*, $J = 12$ Hz) and δ 5.90 (*d*, $J = 12$ Hz) in the ^{1}H NMR spectrum, revealed that this tetrastilbene contains three dihydrofuran rings and a double bond in a structure which was similar to another known *Carex* tetrastilbene, miyabenol A (Suzuki et al., 1987). However, some differences in the ^{1}H and ^{13}C NMR signals between **1** and miyabenol A, especially the comparatively smaller chemical shifts of the hydrogens on the double bond of **1** (δ 5.85 *d* and 5.90 *d* compared to δ 6.63 *d* and δ 6.87 *d* in miyabenol A) and lower coupling constants between the two olefinic protons in **1** ($J = 12$ Hz compared to $J = 16.2$ Hz in miyabenol A; Kawabata et al., 1995) indicated that the double bond in **1** is *cis*, not *trans*. ^{1}H–^{1}H COSY experiments confirmed the coupling patterns between the three sets of methine protons (H-7–H-8, H-7′–H-8′and H-7″–H-8″) in the three dihydrofuran rings, between the four sets of ortho-coupled aromatic hydrogens in the four 4-hydroxyphenol groups (H-2,6–H-3,5, H-2′,6′–H-3′,5′, H-2″,6″–H-3″,5″ and H-2‴,6‴–H-3‴,5‴) and the two protons on the double bonds (H-7‴–H-8‴) as mentioned above. A ^{1}H–^{13}C HMQC spectrum (Table 3) identified all ^{1}H–^{13}C direct ^1J correlations and thus confirmed the assignment of all methine carbons. The other connections of the molecule were determined unambiguously by HMBC spectra (Table 3). Among the correlation peaks observed in the HMBC spectra, the most important were: from H-7 to C2, 6, H-8 to C-9, H-8 to C10, 14, H-8 to C10′, H-8 to C11′, H-7′ to C-2′,6′, H-8′ to C-9′, H-8′ to C-10″, H-8′ to C-11″, H-8″ to C-9″, H-8″ to C-10‴ and C-11‴, H-7″ to C-2″,6″, H-8‴ to C-9‴ and H-7‴ to C-2‴, 6‴. Thus, **1** was deduced to be *cis*-miyabenol A, a previously undescribed isomer of miyabenol A.

The relative stereochemistry of **1** was assigned from NOESY experiments (Table 4). On ring C, NOE interactions were clearly observed between H-7/ H-10 (14), H-8 /H2 (6), which indicates a *trans*-2, 3-diaryl substitution on ring C. In a similar manner, NOEs between H-7′/H-14′, H-8′/H-2′ (6′) and H-7″/H-14″, H-8″/H-2″(6″) support the trans-diaryl substitution on rings C' and C″. The relative stereochemical relationship among rings C, C′ and C″ is more difficult and the NOESY experiments are again informative to determine it. Strong NOEs between H-8, H-8′ and H-8″ showed the three hydrogens H-8, H-8′ and H-8″ are located in spatial vicinity of each other, and the NOEs between H-8 to H-7‴ and H-8‴, H-8′ to H-7‴ and H-8‴, H-8″ to H-7‴ and H-8‴ showed the three hydrogens (H-8, H-8′ and H-8″) are also spatially close to the double bond. The NOEs between H-2′/H-6′ and H-7‴, H-8‴ showed the *cis*-double bond is in spatial vicinity with ring-A' as well. Molecular modelling suggested that the stereochemical relationship among rings C, C' and C'' in **1** is as shown in order to meet the requirement of the vicinity of the double bond with ring-A′ and the three hydrogens (H-8, H-8′ and H-8''). Thus, the relative stereochemistry of **1** was concluded to be *rel*-(7*R*, 8*R*, 7′*S*, 8′*S*, 7″*R*, 8″*R*).

Compound **2** was isolated as a yellowish powder. LSIMS (+ve ion-mode) showed an $[M+H]^+$ ion at *m*/*z*

905, suggesting the molecular formula $C_{56}H_{40}O_{12}$, compatible with a tetrastilbene. By analysis of its ^{1}H NMR, ^{13}C NMR, HMQC, HMBC, NOESY spectra and comparison with published data (Kawabata et al., 1991), it was confirmed as kobophenol B.

Compound **3** was white and amorphous. LSIMS (+ ve ion-mode) showed an $[M+H]^+$ ion at m/z 681, suggesting the molecular formula $C_{42}H_{32}O_9$, compatible with a tristilbene. By analysis of its ^{1}H NMR, ^{13}C NMR, HMQC, HMBC, NOESY spectra and comparison with published data (Ono et al., 1995), it was confirmed as *cis*-miyabenol C. It would appear that **3** is the biogenetic precursor of **1**, since the A/B, A′/B′ and A″/B″ portions of the molecules have the same stereochemistries and **1**

[a] Spectra obtained in CD_3OD.

can be formed by the addition of a further resveratrol unit to the 7″/8″ double bond of **3**.

It is worth mentioning that *cis*-miyabenol A and *cis*-miyabenol C are not fully stable. When exposed to light, they readily isomerise to the *trans*-isomers. So although NMR experiments and bioassay tests were performed immediately after the compounds were purified by HPLC, there were still minor amounts of the *trans*-isomers present (5 to 10% according to ^1H NMR areas) together with their *cis*-isomers.

Compounds **1**, **2** and **3** are isolated for the first time from *C. pendula*, and *cis*-miyabenol A and *cis*-miyabenol C are the first oligostilbenes with *cis*-double bonds isolated from *Carex* species. Among the three oligostilbenes, kobophenol B is the most prominent component (1.27% of the seed weight), as has been found for other *Carex* species (Kawabata et al., 1991), while *cis*-miyabenol A and *cis*-miyabenol C are present in much smaller amounts.

2.3. Biological activity

Purified compounds **1**, **2** and **3** were found to be active as ecdysteroid antagonists. In the *Drosophila melanogaster* B_{II} cell bioassay (Clément et al., 1993), compounds **1** (95% purity according to ^1H NMR peak areas, containing a minor amount of the *trans*-isomer), **2** (100% purity) and **3** (90% purity, containing a minor amount of the *trans*-isomer according to ^1H NMR peak areas) antagonised the action of 20-hydroxyecdysone (5×10^{-8} M) with 50% responses at 3.1×10^{-5} M, 3.7×10^{-5} M and 1.9×10^{-5} M, respectively. Their antagonist activities in this bioassay are similar to those of other stilbenoids previously isolated from *Paeonia suffruticosa* (Sarker et al., 1999) and *Iris clarkei* (Keckeis et al., 2000). The EC_{50} values of all these compounds are within the range of 1×10^{-5} M to 5.3×10^{-5} M and, at high concentration, all of them are cytotoxic. Prior to the identification of the three oligostilbenes from *C. pendula*, we had found the monomeric (resveratrol), dimeric (ampelopsin B) and trimeric (α-viniferin and suffruticosols) resveratrol-type stilbenes are antagonistic. *cis*-Miyabenol A and kobophenol B add tetrameric resveratrol-type stilbenes to the active stilbenoids and provide more data to consider the interesting question of the steric interaction of molecules of such differing size with the binding site, which will be useful for deducing the relationship between steroid hormone receptors and non-steroidal ligands and, thus, designing new chemicals for invertebrate pest control (Keckeis et al., 2000).

2.4. Interaction with the ligand-binding site of ecdysteroid receptors

There are many possible sites of action for steroid hormone antagonists. In order to clarify the mode of

action of these stilbenoids, we tested the ability of the compounds isolated from *C. pendula* to compete with radiolabelled ecdysteroid for the ligand-binding site of dipteran and lepidopteran ecdysteroid receptor complexes. Fig. 1 shows the results of competition experiments involving bacterially-expressed *Drosophila melanogaster* EcR/USP complexes. It is apparent that all three of the stilbenoids are able to compete with specifically-bound [^{3}H]ponasterone A. The IC_{50} values (kobophenol B, 13 μM [$K_i = 5.6$ μM]; *cis*-miyabenol A, 33 μM [$K_i = 14.2$ μM]; *cis*-miyabenol C, 100 μM [$K_i = 42.9$ μM]) are similar to the EC_{50} values presented above. These values compare to an IC_{50} value of 0.12 μM for 20-hydroxyecdysone ($K_i = 5.2\times10^{-8}$M; cf. EC_{50} for 20-hydroxyecdysone in the B_{II} bioassay $= 7.5\times10^{-9}$ M; Clément et al., 1993). Since the stilbenoids are antagonists, their activities in the B_{II} assay will depend on their relative potencies and concentrations in relation to the added 20-hydroxyecdysone (5×10^{-8} M), so EC_{50} values in the bioassay and IC_{50} values in the cell-free receptor assays cannot be directly compared. However, these results demonstrate that the affinity of the stilbenoids for the ligand binding site on the receptor is probably adequate to account for their activity as antagonists in the B_{II} assay. Also included in Fig. 1 are data for *trans*-resveratrol. We have previously shown that *cis*-resveratrol is an antagonist in the B_{II} bioassay ($EC_{50} = 1.2\times10^{-5}$ M; Sarker et al., 1999), while *trans*-resveratrol is inactive

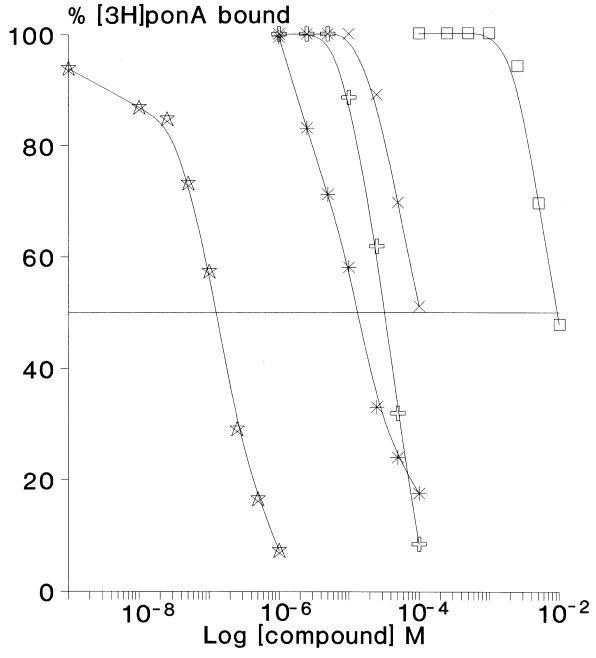

Fig. 1. Competition of test compounds with radiolabelled ecdysteroid for the ligand binding site of the *Drosophila melanogaster* ecdysteroid receptor complex. The ability of 20-hydroxyecdysone (☆), kobophenol B (*), *cis*-miyabenol A (✠), *cis*-miyabenol C (×) and *trans*-resveratrol (□) to compete with [^{3}H]ponasterone A (0.2 nM) for specific binding to DmEcR/DmUSP. Unbound material was removed by the addition of dextran-coated charcoal.

(Dinan et al., 2001). The competition experiments with DmEcR/DmUSP demonstrate clearly that *trans*-resveratrol has a very poor affinity for the ligand-binding site ($IC_{50} = 10^{-2}$ M), thus explaining the lack of activity of this compound in the bioassay.

Similar experiments with CfEcR/CfUSP (data not shown) demonstrate that kobophenol B (**2**) and *cis*-miyabenol A (**1**) also compete with [^{3}H]ponasterone A with this receptor (IC_{50}/K_i values are 25/20 and 40/32 μM, respectively). It was not possible to assess *cis*-miyabenol C (**3**) in this assay owing to the paucity of the amount isolated.

3. Experimental

3.1. General experimental procedures

UV spectra were obtained in MeOH. NMR spectra were performed in CD_3OD or acetone-d_6 on a Brüker AVANCE DRX400 instrument using Bruker microprograms. LSIMS (+ve ion-mode); glycerol matrix using a Cs^+ primary beam on a VG Quattro triple quadruple mass spectrometer (VG Biotech, Altrincham, UK); SPE; Sep-Pak Vac 35cc (10 g) C_{18} cartridge (Waters/Millipore, Watford, Herts., UK) was used for pre-HPLC fractionation; HPLC: (a) preparative/semipreparative; Gilson Model 806 HPLC coupled with a Gilson UV-visible detector, (b) analytical; Gilson model 811 HPLC coupled with a Gilson 160 diode-array detector and using Gilson Unipoint computer program (Anachem, Luton, Beds., UK); RP-semiprep. HPLC columns: Spherisorb analytical and semipreparative C_{18} and C_6 reversed-phase columns (Waters/Millipore) and Apex II semiprep. Diol normal-phase column (Jones Chromatography, Hengoed, Mid-Glamorgan, U.K.). Chromatographic separations were monitored at 223 and 283 nm.

3.2. Plant material

Seeds of *C. pendula* were purchased from B&T World Seeds. A voucher specimen has been retained at the Department of Biological Sciences, University of Exeter. The sources of other seed samples are given in Table 1.

3.3. Bioassay

Ecdysteroid antagonist activities of the seed extracts, SPE fractions, HPLC fractions and the pure compounds were assessed with a microplate-based bioassay using the *Drosophila melanogaster* B_{II} cell line (Clément et al., 1993). All samples were tested in quadruplicate. Pure compounds were tested at concentrations ranging from 10^{-7} to 10^{-3} M. 20-Hydroxyecdysone at 5×10^{-8} M was used in the antagonist version of the bioassay.

3.4. Extraction and isolation

Ground seeds (19 g) were extracted three times (3×24 h) with 3×400 ml MeOH at 55°C with stirring using a magnetic stirrer. Extracts were pooled and reduced by evaporation to 210 ml. This was made to a 70% aq. methanolic solution by adding 90 ml water. After being defatted with *n*-hexane (4×150 ml), the extract was concentrated by rotary evaporation at a maximum temperature of 45°C. The defatted extract was subjected to SPE fractionation (using MeOH/H_2O step-gradient) which afforded seven fractions. Two fractions (eluted with 30 and 50% aq. MeOH) showed ecdysteroid antagonist activity. The two fractions were pooled and subjected to RP-semiprep. HPLC (eluted at 2 ml/min with a linear gradient from 30% MeOH in H_2O to 70% MeOH in H_2O over 30 min, followed by elution with MeOH for another 10 min) which afforded three fractions (P-1, P-2 and P-3). P-2 showed ecdysteroid antagonist activity. The further isolation of P-2 proceeded by C_6-semiprep. HPLC, eluted with 45% MeOH in H_2O at a flow rate of 2 ml/min, affording **2** (240.4 mg) and another two bioactive fractions (P-2-2 and P-2-4). P-2-2 was subjected to NP-HPLC on a semiprep. diol column, eluted with 8% MeOH in dichloromethane and then to RP-HPLC on an analytical C_{18} column, eluted with 40% MeOH in H_2O, and **1** (3.93 mg) was obtained. P-2-4 was further purified, using both a semiprep. C_{18} column and an analytical C_6 column, eluted with 40% MeOH in H_2O and 38% MeOH in H_2O, respectively, yielding **3** (0.94 mg).

cis-Miyabenol A (**1**), white amorphous, UVλ_{max}^{MeOH} nm (log ε) = 286 (4.46); LSIMS (+ve ion-mode): *m*/*z* 907 $[M+H]^+$. ^1H NMR and ^{13}C NMR (in CD_3OD) see Table 1.

Kobophenol B (**2**), pale-yellow needles, UV λ_{max}^{MeOH} nm (log ε) = 285 (4.05), LSIMS (+ve ion-mode): *m*/*z* 905 $[M+H]^+$. ^1H NMR and ^{13}C NMR (in CD_3OD) see Table 1. ^1H NMR (in acetone-d_6), as published data (Kawabata et al., 1991).

cis-Miyabenol C (**3**), white amorphous, UVλ_{max}^{MeOH} (log ε) = 286 (4.40), LSIMS (+ve ion mode): *m*/*z* 681 $[M+H]^+$. ^1H NMR and ^{13}C NMR data (in CD_3OD) see Table 1. ^1H NMR (in acetone-d_6), as published data (Ono et al., 1995).

3.5. Receptor assay

Bacterially-expressed DmEcR, DmUSP, CfEcR and CfUSP were generously provided by Dr. Tarlochan Dhadialla (Rohm & Haas Co.). EcR protein (15 μl) and USP (1 μl) were incubated with 84 μl 10 mM Tris/HCl (pH 7.2, containing 1 mM DTT and 0.4 mg fatty acid free BSA), [24,25,26,27-^{3}H]ponasterone A (0.2 nM; 150 Ci/mmol; ARC Inc., St Louis, MO, USA) and known concentrations of 20-hydroxyecdysone, **1**, **2**, **3** or *trans*-resveratrol. Non-specific binding was determined by the inclusion of a 500-fold excess of unlabelled ponasterone A. Assays were incubated for 16 h (DmEcR + DmUSP) or 3 h (CfEcR + CfUSP) at 7°C. Dextran-coated charcoal (25 μl: 500 mg acid-washed charcoal + 50 mg T70 dextran in 20 ml 10 mM Tris/HCl buffer, pH 7.2) was added to each tube and incubated for 5 min at 7°C before centrifuging at 13,000 × *g* for 5 min. Aliquots of the supernatants (100 μl) were radioassayed after the addition of 1 ml scintillation cocktail (Emulsifier-Safe; Packard Bioscience, Groningen, The Netherlands). IC_{50} values for compounds were converted to K_i values according to the formula $K_i = IC_{50}/(1 + [ponA]/Kd)$, where [ponA] is the concentration of [^{3}H]ponasterone A used (0.2 nM) and Kd is the equilibrium dissociation constant for the interaction of the receptor complex with [^{3}H]ponasterone A (determined by Scatchard analysis; 0.15 nM for DmEcR/DmUSP and 0.8 nM for CfEcR/CfUSP; Bourne, unpublished).

Received 28 September 2000; received in revised form 12 February 2001

Abstract

Three bufadienolides, hellebortin A (5-[β-D-glucopyranosyloxy]-10,14,16-trihydroxy-19-nor-{5β,10β,14β,16β}-bufa-3,20,22-trienolide [**1**]), hellebortin B (5-[β-D-glucopyranosyloxy]-3,4-epoxy-14-hydroxy-19-oxo-bufa-20,22-dienolide [**2**]) and hellebortin C (5-[β-D-glucopyranosyloxy]-3,4-epoxy-10,14-dihydroxy-19-nor-bufa-20,22-dienolide [**3**]), together with 20-hydroxyecdysone 3-*O*-β-D-glucoside (**4**) and 20-hydroxyecdysone (**5**) have been isolated by bioassay- and RIA-directed HPLC analyses of a methanol extract of the seeds of *Helleborus torquatus*. The structure and relative stereochemistry of the novel bufadienolide hellebortin A (**1**) and the structures of hellebortin B (**2**) and hellebortin C (**3**) were determined unambiguously by comprehensive analyses of their 1D and 2D NMR data. These five compounds are isolated from *Helleborus torquatus* for the first time. The biological activities of compound **1**, **4** and **5** as ecdysteroid agonists and antagonists have been assessed. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Ranunculaceae; Ecdysteroid; Bufadienolides; *Helleborus torquatus*; Hellebortin *A* (5-[β-D-glucopyranosyloxy]-10, 14, 16-trihydroxy-19-nor-{5β, 10β, 14β, 16β}-bufa-3, 20, 22-trienolide [**1**]); Hellebortin B (5-[β-D-glucopyranosyloxy]-3, 4-epoxy-14-hydroxy-19-oxo-bufa-20, 22-dienolide [**2**]); Hellebortin C (5-[β-D-glucopyranosyloxy]-3, 4-epoxy-10, 14-dihydroxy-19-nor-bufa-20, 22-dienolide [**3**]); Bioassay

1. Introduction

Helleborus species are evergreen, rhizomatous plants belonging to the family Ranunculaceae. Some plants from this genus have important biological activities and medicinal effects. For example, *H. foetidus* shows anti-insect activity (Pascual-Villalobos and Robledo, 1998) and poisonous activity towards cattle (Holliman and Milton, 1990), *H. niger* is used in homeopathy and as an adjuvant therapy in the treatment of tumour patients in anthroposophical medicine in Germany (Bussing and Schweitzer, 1998) and a transcutaneous implantation of the root of *H. purpurascens* is used to provoke leucocytosis and neutrophils for better healing of chronic diseases in Romanian traditional medicine (Bogdan et al., 1990). With regard to the chemical constituents of the genus of *Helleborus*, many kinds of compounds have been isolated, including lipids and fatty acids (Aitzetmüller et al., 1999; Colombo et al., 1991), a steroidal sapogenin (Vladimirov et al., 1991) and phytoecdysteroids (Kissmer and Wichtl, 1987; Liedtke et al., 1997). The bufadienolide helleborin (**6**), a cardiac glycoside which was formerly used in therapy for heart rhythm irregularities, was isolated from *Helleborus* spp. (Muhr et al., 1995). The co-occurrence of ecdysteroids and bufadienolides in *Helleborus* spp. has been investigated (Hardman and Benjamin, 1976). However, no previous studies on the chemical constituents of *H. torquatus* Archer-Hind (syn. *H. serbicus* Adamovic) have been reported. Here we report the isolation, structural elucidation and biological assessment of three new bufadienolides (hellebortin A [**1**], hellebortin B [**2**] and hellebortin C [**3**]) and two phytoecdysteroids (**4** and **5**) from the seeds of this species.

Phytoecdysteroids are analogues of insect steroid hormones and are believed to contribute to the deterrence of invertebrate predators by acting as antifeedants

PII: S0031-9422(01)00070-X

or by disrupting hormone balance on ingestion. Phytoecdysteroids are detectable in 5–6% of plant species, sometimes in very high concentrations. Differences in the presence and profiles of phytoecdysteroids in related species may have chemotaxonomic value (Dinan, 1995; Dinan et al., 1999b).

Bufadienolides are important cardiac glycosides which increase the contractile force of the heart by inhibiting the enzyme Na^+, K^+–ATPase (Akizawa et al., 1994). They also show toxic activities to livestock (Steyn and van Heerden, 1998). Some bufadienolides have antineoplastic and cell growth inhibitory properties (Yamagishi et al., 1988). A number of bufadienolides have been isolated from both plant and animal sources (Steyn and van Heerden, 1998), but only six families of plants have been studied for their bufadienolide components. Within the Ranunculaceae, *Helleborus* is the only genus known to contain these compounds; three bufadienolides (all derivatives of hellebrigenin, the steroid aglycone of hellebrin) had previously been isolated from *Helleborus* spp. (Steyn and van Heerden, 1998). The discovery of two new 19-nor-bufadienolides (hellebortins A and C) in *H. torquatus* is the first detection of 19-nor-bufadienolides from any source.

2. Results and discussion

Initial bioassay/RIA assessment of a seed extract of *Helleborus torquatus* revealed the presence of ecdysteroid agonist activity and considerable amounts of RIA-positive material (72.6 μg ecdysone equivalents/g with the ecdysteroid-specific DBL-1 antiserum), strongly indicating the presence of phytoecdysteroids. On hydrolysis with a mixture of hydrolases from *Helix pomatia*, the RIA-response increased considerably, demonstrating the additional presence of conjugated ecdysteroids. No antagonist activity was detected.

Reversed-phase chromatographic analysis of the seed extract of *H. torquatus* by RP–HPLC revealed the presence of two major UV-absorbing peaks, one of which co-chromatographed with 20-hydroxyecdysone and the other, eluting slightly earlier, was RIA- and bioassay-positive only after hydrolysis with *Helix* enzymes. Following fractionation of the extract by C_{18} SPE cartridge, RP– and NP–HPLC chromatography of the 60% MeOH in H_2O fraction guided by bioassay/RIA resulted in the isolation of 20-hydroxyecdysone 3-*O*-β-D-glucoside (**4**), 20-hydroxyecdysone (**5**) and two novel bufadienolides hellebortin B (5-[β-D-glucopyranosyloxy]-3,4-epoxy-14-hydroxy-19-oxo-bufa-20,22-dienolide [**2**]) and hellebortin C (5-[β-D-glucopyranosyloxy]-3,4-epoxy-10,14-dihydroxy-19-nor-bufa-20,22-dienolide [**3**]). Further chromatographic analyses of the non-RIA-positive components of the 60% MeOH in H_2O SPE fraction afforded another new bufadienolide, hellebortin A (5-[β-D-glucopyranosyloxy]-10,14,16-trihydroxy-19-nor-{5β,10β,14β,16β}-bufa-3,20,22-trienolide [**1**]). The structures of the two known compounds (**4** and **5**) were readily identified by comparing their retention times with those of reference compounds and comparing their ^1H and ^{13}C NMR spectra with those published (Lafont and Wilson, 1996). The structure and relative stereochemistry of **1** were unambiguously determined by extensive analysis of its 1D and 2D NMR experiments. The structures of compounds **2** and **3** were also determined by analyses of their 1D and 2D NMR spectra.

Compound **1** was a colourless glassy solid. LSIMS (-ve ion-mode) gave a $[M–H]^+$ ion at m/z 563 compatible with the molecular formula $C_{29}H_{40}O_{11}$, which was supported by the ^{13}C NMR (DEPT) spectra (Table 2). The ^1H NMR (Table 1) and ^{13}C NMR spectra of **1** showed very similar features to hellebrin which was isolated from *H. niger* (Muhr et al., 1995), suggesting that **1** was also a bufadienolide. Compound **1** had only one sugar unit attached to the genin, which was confirmed by the presence of only one anomeric carbon signal (δ 97.0) in the ^{13}C NMR spectrum. The identity of the sugar unit in **1** was readily established as a β-D-pyranoglucose by comparing the chemical shifts and coupling constants of the characteristic anomeric proton (δ 4.64 [1H, *d*, 7.7 Hz]) and five other oxymethine protons at δ 3.19 (*t*, 7.7), 3.34 (*dd*, 8.5, 7.7), 3.28 (*t*, 8.5), 3.22 (*ddd*, 8.5, 5.5, 2.2), 3.64 (*dd*, 12, 5.5) and 3.80 (*dd*, 12, 2.2) with those published (Agrawal, 1992). The ^{13}C NMR data of the genin part of **1** were very similar to those of the genin of hellebrin except for some differences in rings A and D (Table 2). Compared with that of hellebrin, the ^{13}C NMR spectrum of **1** showed no 19-aldehyde signal, but showed four oxygenated carbon signals in its genin instead of the three oxygenated carbons (δ 74.8 [*d*], 75.0 [*s*] and 84.1 [*s*]) for hellebrin. In addition to the signals associated with the two double bonds of a α-pyrone ring (δ_C 111.5 [*d*], 151.4 [*d*], 119.0 [*s*] and 150.3 [*d*]), there were two other olefinic carbon signals (δ_C 131.4 [*d*] and 131.1 [*d*]). The ^1H–^1H COSY spectrum of **1** confirmed all connections of protons to adjacent carbons and that the two olefinic carbons were associated with a double bond connected to C-2. Additionally, one oxygenated carbon signal (δ 72.1 [*d*]) could be assigned to C-16. The structure of **1** was determined as 5-[β-D-glucopyranosyloxy]-10,14,16-trihydroxy-19-nor-{5β,10β,14β,16β}-bufa-3,20,22-trienolide [**1**] (hellebortin A). This was fully supported by HMQC and HMBC spectra which identified all ^1H–^{13}C direct ^1J and ^2J, ^3J correlations, especially all connections to quaternary carbons, such as attachment of the glucose unit to C-5 (δ 77.8 [*s*]), the double bond situated between C-3 and C-4, the α-pyrone ring linked to C-17, and the two other hydroxyl groups situated at C-10 (δ 73.5 [*s*]) and C-14 (84.1 [*s*]).

The relative stereochemistry of **1** has been assigned from NOESY experiments (Fig. 1). On ring B and ring

C, strong NOE interactions observed between H-8/H-6a, H-8/H-11a, H-8/H-18, H-9/H-7a and H-9/H-12a were typical 1,3-diaxial correlations on a six-membered ring in the chair conformation, indicating that ring B and ring C existed in chair conformations and are *trans*-fused. On ring C and ring D, the NOEs observed clearly between H-17/H12a (H-12e), H-15a/H-9 and H-18/H-22 not only suggested ring C and ring D are *cis*-fused, but also supported that the 18-methyl group and H-17 are *trans* on ring D. That H-16 and H-17 were *cis* on ring D was readily confirmed by NOEs between H-16 and H-17. Similarly, NOEs between H-9/H-2a, H-11e/H-1e, H-1′/H-6a (H-6e) and H-4/H-6e demonstrated that H-9 and the 10-hydroxyl group are *trans* on ring B, and also confirmed the *cis*-connection of rings A and B. Therefore, the relative stereochemistry of hellebortin A was unambiguously determined as shown in Fig. 1.

Compound **2** was a white glassy solid. LSIMS (-ve ion-mode) showed $[M–H]^+$ ion at *m*/*z* 575 compatible with the molecular formula $C_{30}H_{40}O_{11}$. ^1H NMR (Table 1) and ^{13}C NMR (Table 2) showed similar features to those of hellebortin A (**1**) and hellebrin (**6**), indicating that **2** was also a bufadienolide. The sugar unit of **2** was identified as β-D-pyranoglucose by comparing the chemical shifts and coupling constants of the characteristic anomeric proton (δ 4.64 [1H, *d*, 7.5 Hz])

[a] 500 MHz, MeOH-d_4, MeOH signal was used as internal standard (δ_C 49.0).
[b] Signals obscured by H_2O peaks, but could be observed by HMBC.

and five other oxymethine protons at δ 3.20 (*dd*, 7.8, 7.5), 3.37 (*dd*, 8.5, 7.8), 3.36 (*t*, 8.5), 3.32 (*ddd*, 8.5, 5.5, 2.2), 3.65 (*dd*, 12, 5.5) and 3.84 (*dd*, 12, 2.2) with those published (Agrawal, 1992). The ^{13}C NMR data of the genin part of **2** were very similar to those of the genin part of hellebrin except there were some differences in ring A. Besides the oxymethine protons from the glucose unit, the presence of two other oxygen-bearing methine groups at δ 3.38 and 3.09 (*d*, 3.4) in the ^{1}H NMR spectrum and two corresponding oxygenated carbon at δ 53.2 and 57.1 in the ^{13}C NMR spectrum of **2** could be explained by an epoxide ring, which would agree with the calculated degree of unsaturation ($n=11$) of **2**. ^{1}H–^{1}H COSY, HMQC and HMBC spectra of **2** (as a mixture with **3**) located this epoxide ring at C-3 and C-4, and confirmed that the glucose unit was linked to C-5, as in hellebortin A. Thus, the structure of **2** was unambiguously deduced as 5-[β-D-glucopyranosyloxy]-3,4-epoxy-14-hydroxy-19-oxo-bufa-20,22-dienolide (hellebortin B).

Compound **3** was a white glassy solid. LSIMS (-ve ion-mode) showed an $[M\text{-}H]^+$ ion at m/z 563 compatible with the molecular formula $C_{29}H_{40}O_{11}$, one carbon less than compound **2**. ^{1}H NMR (Table 1) and ^{13}C NMR (Table 2) of **3** were in good agreement with those of **2** except that there were no signals corresponding to 19-aldehyde group, and the chemical shift of C-10 was at lower field (δ 72.2) compared with that of **2** (δ 52.0). This indicated that a hydroxyl group was attached to C-10. ^{1}H–^{1}H COSY, HMQC, HMBC spectra of **3** (as a mixture with **2**) confirmed all connections in the molecule. Therefore, the structure of **3** was unambiguously deduced as (5-[β-D-glucopyranosyloxy]-3,4-epoxy-10,14-dihydroxy-19-nor-bufa-20,22-dienolide (hellebortin C).

After final purification, the amounts of compounds **2** and **3** isolated were too low to be able to determine their relative stereochemistries through NOESY experiments.

The biological activities of compound **1**, **4** and **5** as ecdysteroid agonists and antagonists were assessed. 20-hydroxyecdysone 3-*O*-β-D-glucoside (**4**) and 20-hydro-

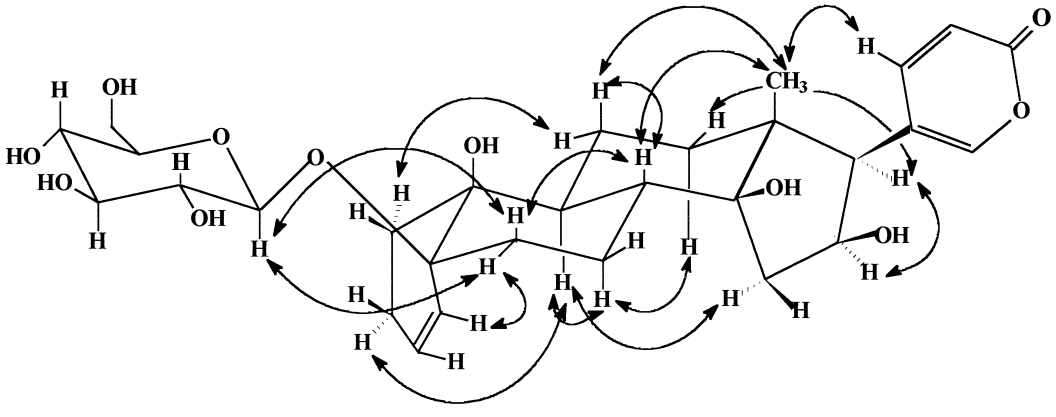

Fig. 1. The key NOEs in Hellebortin A (**1**).

xyecdysone (**5**) possess agonist activities with EC_{50} values of 1.3×10^{-5} M and 7.5×10^{-9} M, respectively (Dinan et al., 1999a), but hellebortin A (**1**) showed no agonist or antagonist activity within the concentration range of 10^{-6} M to 10^{-3} M in the B_{II} cell line assay. The activities of hellebortins B (**2**) and C (**3**) could not be tested because of their limited availability.

3. Experimental

3.1. General experimental procedures

UV spectra were obtained in MeOH. NMR spectra were performed in CD_3OD on a Brüker AVANCE DRX400 instrument using Brüker microprograms. LSIMS (-ve ion-mode); glycerol matrix using a Cs^+ primary beam on a VG Quattro triple quadrupole mass spectrometer (VG Biotech, Altrincham, UK); Sep-Pak Vac 35 cc (10 g) C_{18} solid-phase extraction (SPE) cartridge (Waters/Millipore, Watford, Herts., UK) was used for pre-HPLC fractionation; HPLC: (a) preparative/semipreparative; Gilson Model 806 HPLC coupled with a Gilson UV-visible detector; (b) analytical; Gilson model 811 HPLC coupled with a Gilson 160 diode-array detector and using Gilson Unipoint computer program (Anachem, Luton, Beds., UK); RP and NP stand for reversed-phase and normal-phase, respectively. Spherisorb semipreparative C_{18} and C_6 columns, an Apex II semiprep. Diol column and Spherisorb 5 ODS(2) analytical C_{18} and C_6 columns (Jones Chromatography, Hengoed, Mid-Glamorgan, UK) were used. Chromatographic separations were monitored at 242 and 300 nm.

3.2. Radioimmunoassay and bioassay

RIA was performed according to the procedure described previously (Dinan, 1992) using the ecdysteroid-specific antiserum DBL-1, which was generously donated by Professor Jan Koolman (University of Marburg, Germany). The cross-reactivities of this antiserum with a range of phytoecdysteroids are given elsewhere (Dinan, 1995). Ecdysteroid agonist activities of the extract, SPE fractions, HPLC fractions and purified compounds were assessed with a microplate-based bioassay using the *Drosophila melanogaster* B_{II} cell line (Clément et al., 1993).

3.3. Extraction

Seeds of *H. torquatus* were purchased from B&T World Seeds. A voucher specimen has been retained at the Department of Biological Sciences, University of Exeter. Seeds (9.7 g) were ground and extracted four times (4×24 h) with 3×200 ml of MeOH at 55°C with constant stirring using a magnetic stirrer. Extracts were pooled and evaporated to 210 ml and this was made to a 70% aq. methanolic solution by adding 90 ml H_2O. After being defatted with *n*-hexane (4×150 ml), the extract was concentrated using a rotary evaporator at a maximum temperature of 45°C to give 0.84 g residue.

3.4. Isolation of the compounds

The residue was subjected to SPE fractionation (using a MeOH/H_2O step-gradient) which afforded five fractions. According to the results of bioassay and RIA, Fraction 3 (eluted with 60% MeOH in H_2O) contained most of RIA-positive material. Fraction 3 was subjected to RP(C_6)-semiprep. HPLC (with a linear gradient from 30% MeOH in H_2O to 70% MeOH in H_2O over 45 min, followed by elution with MeOH for another 10 min), which afforded four fractions (P-1, P-2, P-3 and P-4). P-2 and P-3 showed ecdysteroid agonist activity. The further isolation of P-2 and P-3 proceeded by C_6-semiprep. HPLC, eluted with 40% MeOH in H_2O at a flow rate of 2 ml/min, and then by diol-semiprep. HPLC, eluted with 6% MeOH in CH_2Cl_2 at a flow rate 2 ml/min, affording **4** (460 μg) and 5 (1.1 mg). Calculations based on the peak areas of the original chromatogram of the extract indicated that the true amounts of **4** and **5** were 385 μg/g seeds and 250 μg/g seeds, respectively. The further isolation of P-1 proceeded by C_6-semiprep. HPLC, eluted with 35% MeOH in H_2O at a flow rate of 2 ml/min, and then by NP–HPLC with a semiprep. diol column, eluting with 6% MeOH in CH_2Cl_2, afforded **1** (5.47 mg). Bioassay data also showed that P-4 contained some RIA-positive material. The further isolation of P-4 using the same procedure as that of P-1 afforded **2** (490 μg) and **3** (510 μg).

Hellebortin A (5-[β-D-glucopyranosyloxy]-10,14,16-trihydroxy-19-nor-{5β,10β,14β,16β}-bufa-3,20,22-trienolide [**1**]). A colourless, glassy solid. UV λ_{max}^{MeOH} nm (log ε) 296 nm (3.84). LSIMS (-ve ion-mode) m/z 563[M–H]$^+$. ^{1}H NMR see Table 1, ^{13}C NMR see Table 2.

Hellebortin B (5-[β-D-glucopyranosyloxy]-3,4-epoxy-14-hydroxy-19-oxo-bufa-20,22-dienolide [**2**]). A white glassy solid. UV λ_{max}^{MeOH} nm (log ε) 299 nm (3.06). LSIMS (-ve ion-mode) m/z 575[M–H]$^+$. ^{1}H NMR see Table 1, ^{13}C NMR see Table 2.

Hellebortin C (5-[β-D-glucopyranosyloxy]-3,4-epoxy-10,14-dihydroxy-19-nor-bufa-20,22-dienolide [**3**]). A colourless glassy solid. UV λ_{max}^{MeOH} nm (log ε) 299 nm (3.64). LSIMS (-ve ion-mode) m/z 563[M–H]$^+$. ^{1}H NMR see Table 1, ^{13}C NMR see Table 2.

20-Hydroxyecdysone 3-*O*-β-D-glucoside (**4**), amorphous. UV, ^{1}H NMR and ^{13}C NMR data as reported (Lafont and Wilson, 1996).

20-Hydroxyecdysone (**5**), amorphous. UV, ^{1}H NMR and ^{13}C NMR data as reported (Lafont and Wilson, 1996).

Induced emissions of apple fruit volatiles by the codling moth: changing patterns with different time periods after infestation and different larval instars

Alan Hern, Silvia Dorn *

Institute of Plant Sciences, Applied Entomology, Swiss Federal Institute of Technology (ETH), CH 8092 Zurich, Switzerland

Received 28 August 2000; received in revised form 5 February 2001

Abstract

The changes in the emission of volatiles from mature apple fruits in response to larval feeding by the codling moth (*Cydia pomonella*) under laboratory conditions are reported. A time course experiment investigated the emission of volatiles throughout the period of larval development following infestation. The volatiles consisted mainly of esters, a few aldehydes, and the terpene α-farnesene. Infested apples emitted the same compounds as healthy apples. The quantities of volatiles released were much higher for infested as compared to healthy fruits for an initial three day period. Following this period there was a decrease in volatile emissions (days 6–9), eventually declining back to the levels emitted from healthy apples or below by 9–21 days after infestation. In a separate experiment, the volatile emissions from healthy and artificially damaged fruits were compared to those from herbivore damaged fruits for each of the five larval instars of *C. pomonella*. The results from the discriminant analysis indicate that the most effective induction of volatiles occurred when fruits were infested with first instar larvae. Induction by first instar larvae was generally higher than after infestation by later instars, and for most compounds it also exceeded the emission from artificially damaged fruits.

1. Introduction

Herbivore feeding often induces volatile emissions from plants, and such emissions have been well documented (reviewed by Karban and Baldwin, 1997; Baldwin and Preston, 1999; Vet, 1999). In a tri-trophic context, volatile chemicals emitted by plants may potentially act as semiochemicals to both insect herbivores and their natural antagonists (Vet and Dicke, 1992; Vet, 1999). Most of these studies have been carried out under standardised laboratory conditions and only a few deal with field situations (for example, Bernasconi et al., 1998, for herbivores, and De Moraes et al., 1998, for natural antagonists). The plant's role in these interactions is an active one, due to the signalling of its status of health or infestation via changes in the emission of volatile semiochemicals (for example, Dicke and Sabelis, 1988, 1989; Turlings et al., 1990; Turlings and Tumlinson, 1991; Tumlinson et al., 1992, 1993; Vet and Dicke, 1992; Dicke, 1994).

The majority of herbivore induced plant volatiles studies deal with phyllophagous herbivores i.e. those which feed on leaves. In contrast, studies upon the chemical effects triggered by insects which feed on the fruit, i.e. carpophagous insects, are scarce. A previous study in which apple fruitlets (*Malus domestica* Borkh. (Rosaceae)) were freshly picked or still attached to the tree was used to investigate herbivore induced emissions from apple fruits (Boevé et al., 1996). This study demonstrated that apple fruitlets respond to the feeding of the European apple sawfly, *Hoplocampa testudinea*, by emitting volatile chemicals in greater amounts than undamaged fruits. Picked apple fruitlets released significantly higher amounts of *E,E*-α-farnesene, β-ocimene and an unidentified terpenoid. The methodology employed, however, imposed limitations upon the number of samples

which could be evaluated, with the consequence that statistical analysis of the field derived data was not feasible.

In this study, our goal was to elucidate the temporal pattern of volatile emissions from fruit in response to herbivory, and to gain an insight into the effect of each larval instar on volatile emissions. This contrasts with the study by Boevé et al. (1996), not only with respect to the herbivore used, but as the response of apple fruits was characterised from the beginning to the end of the period of larval development of the herbivore. In addition, the response of apple fruits to the different larval instars has been analysed.

Laboratory conditions offer a number of advantages for this purpose. Environmental variables which affect volatile sampling can be held constant, such as temperature. In addition, the number of replicates with fruits of the same age and degree of maturation can be high enough to allow statistical evaluation of the data. For the purpose of these experiments fruit standardisation is crucial as apple fruits can show a large variation in their volatile emissions in the course of maturation (Sutherland et al., 1977; Carle, et al., 1987).

Thus we have chosen to model this system using mature apple fruits and in conjunction with a key pest of fruit orchards, the codling moth, *Cydia pomonella* L. (Lepidoptera: Tortricidae). The codling moth larva has five instars all of which feed inside the fruit. The larvae bore into the centre of the fruit and consume the seeds. The objectives of this study were to (1) characterise changes in the emission of induced apple volatiles over the period from initial infestation with newly emerged larvae until their maturation to final instar larvae within the apple and (2) to compare the effect of the individual herbivore instars on the volatile emissions from fruits.

2. Results and discussion

2.1. Time course of volatile emissions

Apples infested by *C. pomonella* emitted the same compounds as healthy apples. Both of the volatile blends consist mainly of esters, with a few aldehydes and the terpene α-farnesene (both the *Z,E* and *E,E* isomers). The temporal pattern of the emissions for the individual compounds was relatively uniform (Table 1). In general, for the first 3 days after infestation the amount of each compound collected from the infested fruits was higher than those collected from the healthy fruits. Following this period (9–21 days), the amount of each compound collected from infested fruits generally decreased to levels equivalent or lower than those collected from healthy fruits (Table 1).

In order to test the hypothesis that the blend of volatiles from infested and non-infested apples were different, we have used linear discriminant analysis. This statistical method evaluates differences or similarities between groups using a multivariate data set. The results of these analyses clearly demonstrate differences between the volatile blends emitted by healthy and infested fruits at eight of the nine sampling periods (except day 15) (Table 2). Therefore, we conclude that the effect of infestation goes beyond an induction of volatiles which is typically measured in the initial phase of infestation, and that it is pervasive for virtually the complete period of herbivore development. In the later phases of the experiment a marked decrease, or even the absence of some compounds from infested as compared to healthy fruits is noted (Table 1).

Infestation of apple fruits with first instar *C. pomonella* larvae caused marked changes in the volatile emissions of the fruits. Although these increases in the emissions of volatiles were of a relatively short duration (ca 3–6 days), even towards the end of the larval development within the fruit, i.e. at 21 days, the volatile blends from the healthy and infested fruits were still different as shown by the linear discriminant analysis.

Boevé (1996) suggested that differences in volatile emissions after fruit infestation by *H. testudinea* may represent an induced defence in fruits. Under this scenario the volatile chemicals induced by herbivory act as synomones to natural enemies which negatively affect the herbivore and have a positive effect on the plant (for example, Dicke and Sabelis, 1989; Turlings et al., 1990; Turlings and Tumlinson, 1991; Dicke, 1994 see Dick and van Loon (2000) for a recent review). In the present tritrophic system, there is evidence that the herbivore induced plant volatiles may act as synomones for a parasitoid. For example, using an experimental system fully comparable to that used in the present study, an insect parasitic wasp of *C. pomonella* preferentially discriminates in favour of infested fruits. *Hyssopus pallidus* spent more time searching on an infested apple than either an artificially damaged or on an healthy apple (Mattiacci et al., 1999). The authors postulated that the cues responsible are probably chemical, our data demonstrates that such chemical differences between the two types of fruit exist (Tables 1 and 2). *H. pallidus* prefers to parasitise fourth or fifth instar *C. pomonella* larvae (Zaviezo and Mills, 1999) and the oviposition of the parasitoid is greatly enhanced in the presence of cues related to apple fruits (Mattiacci et al., 2000). However, to gain a comprehensive understanding of the ecological ramifications of herbivore induced plant volatiles in this particular perennial system will require more investigations.

Defensive mechanisms of the plant are considered to be metabolically costly (Karban and Baldwin, 1997; Baldwin and Preston, 1999, and references therein). Using apples which are removed from sources of further nutrient supplies we found that the initial induction of volatile emissions was short lived which may be related to the high metabolic cost of this induced process (Table 1).

Table 2
Summary of linear discriminant analysis for each time interval since infestation[a]

Time (days)	*F*-approximation of Wilks' lambda	DF	*P*	Number of cases misclassified [b]
1	16.2	4,15	0.0001	Healthy 0 Infested 0
2	6.05	2,17	0.01	Healthy 0 Infested 2
3	9.77	3,16	0.001	Healthy 1 Infested 2
6	19.59	1,18	0.001	Healthy 1 Infested 2
9	9.79	2,17	0.01	Healthy 2 Infested 2
12	23.76	3,16	0.001	Healthy 1 Infested 0
18	8.73	2,17	0.01	Healthy 2 Infested 1
21	29.95	3,16	0.0001	Healthy 0 Infested 0

[a] Note that for time 15 no statistically significant ($P > 0.05$ for the *F*-approx. of Wilk's lambda) model could be found and no results for this time period are reported.
[b] Based on Mahalanobis distance square from group means and posterior probabilities of group membership being 0.5 in each case.

2.2. Effect of different herbivore instars on volatile emissions

The majority of the compounds showed significant quantitative differences between the treatments (Examples are given in Fig. 1a and b). For example, *E,E*-α-farnesene was found in higher amounts in the samples from the herbivore infested and artificially damaged fruits than from the healthy fruits (*F*-value 11.4, DF = 6,98; $P < 0.001$) (Fig. 1a). Perusal of Fig. 1a and b indicates that the different larval instars had quite different effects on the amount of each compound collected. In general terms, the highest degree of volatile induction occurred when fruits were infested with first instar larvae, whilst second instar larvae were less effective in eliciting an induced response.

In order to more completely understand the data, we have used linear discriminant analysis to highlight differences between treatments applied to the fruits (summarised in Table 3). Wilk's Lambda indicates that there are highly significant differences between the treatments (*F*-approx. 19.02; DF = 18, 272; $P < 0.001$). By comparing the *F*-matrix it is apparent that the largest differences between the infested treatments are between first instar infested fruits and the other instars (second to fifth inclusive). Differences between the second to fifth instar infested fruits were much smaller (*F*-values are in the range 0.14–3.23). In addition, there are large differences

Table 3
Summary of linear discriminant analysis for the data from treated apples either *Cydia pomonella* larvae infested, instar I–V inclusive, artificially damaged or healthy apple fruits, *Malus domestica* cv. Bohnäpfel[a]

	Between groups F-matrix DF3,96						Number of cases misclassified[b]
	I	II	III	IV	V	AD	
I							3
II	22.90						8
III	32.37	3.23					9
IV	31.15	2.88	1.70				12

AD	9.10	20.73	26.47	32.50	32.40		4
H	59.35	19.80	31.59	21.80	20.40	71.14	2

[a] Wilks' lambda: lambda = 0.0998; DF = 3,6,98; approx. $F = 19.02$; DF = 18,272, $P < 0.001$.
[b] Based on Mahalanobis distance square from group means and posterior probabilities of group membership being 0.143 in each case.

between all the types of infested fruits as compared to the artificially damaged fruits, although the *F*-value for the first instar larvae is ca. 2–3×smaller than the other instar treatments. Our analysis also indicates large differences between the healthy fruits and all of the other treatments (*F*-values range from 19.8 for second instar infested fruits to 71.14 for artificially damaged fruits) (Table 3). It is clear form the classification matrix within Table 3 that the most easily separated groups are first instar infested fruits, artificially damaged fruits and healthy fruits. The other types of infested fruits are most difficult to separate and tend to be miss-classified as either second to fifth instar inclusive.

There is a substantial induction of volatiles from the apple fruits during *C. pomonella* infestation. The amounts of volatiles are clearly different from those produced by the artificially damaged or healthy fruits. Previous studies with potato plants have demonstrated that the biochemical response can be considered specific for herbivore damage as compared to the response which occurs to a general wound (Korth and Dixon, 1997).

All larval instars of *C. pomonella* were capable of inducing volatile emissions. Therefore, the effects observed in the time-course study may not solely be related to the development of larvae as induced volatile emissions were not observed in the later phases of the experiment. In a phyllophagous herbivore of *Zea mais* L., *Pseudaletia seperata*, young instar larvae induced a much greater change in volatile emissions than sixth instar larvae. Only leaves infested with young larvae were attractive to the parasitic wasp *Cotesia kariyai*. This effect could be mimicked by the application of regurgitant from larvae onto artificially damaged leaves. This would suggest that the saliva or buccal secretions of the larvae differ in composition and that the plant responds differently to these secretions (Takabayashi et al., 1995).

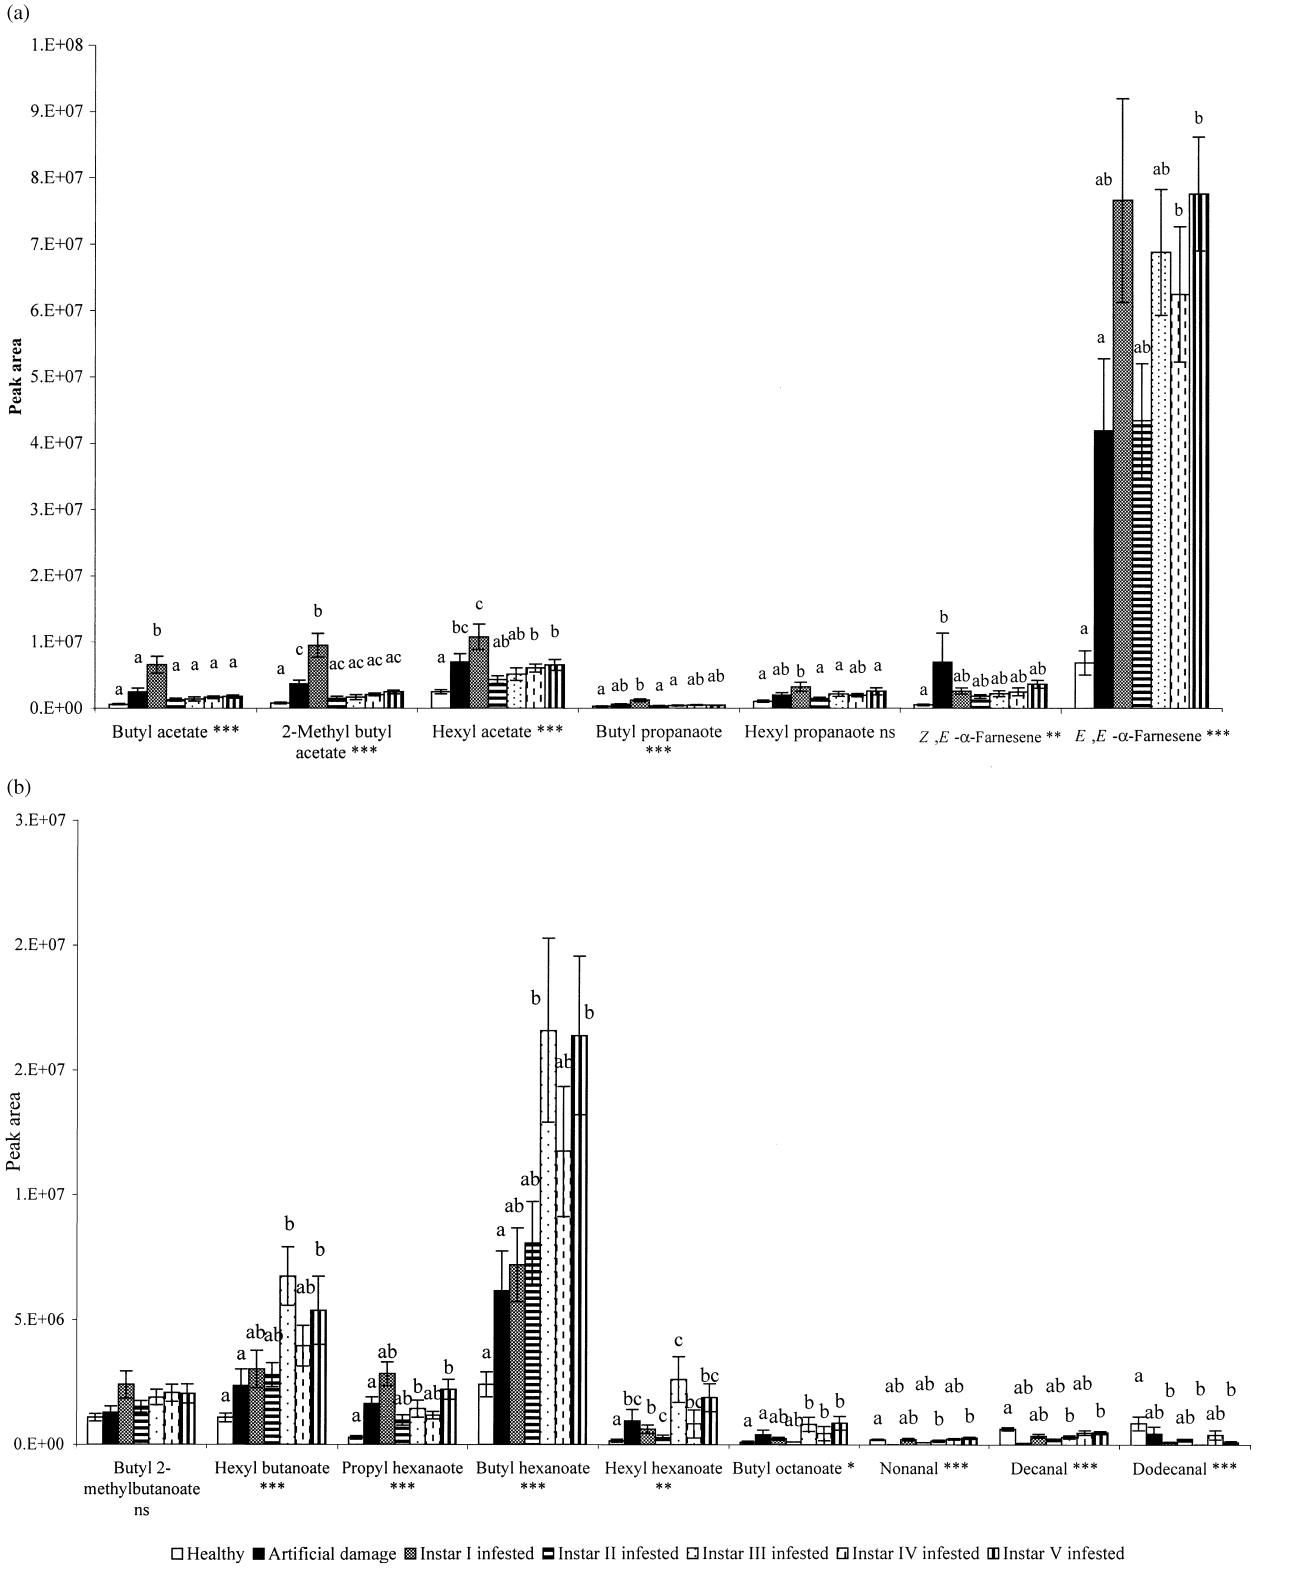

Fig. 1. (a) and (b) Mean ± S.E. peak area from treated apples either *Cydia pomonella* larvae infested, instar I–V inclusive, artificially damaged or healthy apple fruits, *Malus domestica* cv. Bohnäpfel. Columns with different letters indicate the result of Tukey pairwise multiple comparisons ($P < 0.05$). $N = 15$ for each treatment. Following the compound name the result of an ANOVA analysis for overall treatment effect is illustrated, ns = $P > 0.05$; * = $P < 0.05$; ** = $P < 0.01$; *** = $P < 0.001$.

In contrast, volatiles induced in *Brassica oleracea* L. var. *gemmifera* by different larval instars of *Pieris brassicae* could not be discriminated amongst by *Cotesia glomerata* (Mattiacci and Dicke, 1995a). After landing on the infested plant, however, the duration of searching by the parasitic wasp was affected differently by cues related to the presence of the herbivore of different age classes (Mattiacci and Dicke, 1995b).

For *C. pomonella* the elicitor of induced volatiles emitted by *M. domestica* is unknown, but in the systems analysed so far the elicitor is present in the oral secretion of the larva (Mattiacci et al., 1994; Turlings et al., 1993). The enzyme β-glucosidase in *P. brassicae* oral secretions elicits volatile synomone production in cabbage plants (Mattiacci et al., 1995). A different compound, volicitin (*N*-(17-hydroxylinolenoyl)-L-glutamine), accounts for the total activity of beet army worm (*Spodoptera exigua*) oral secretions in eliciting volatile induction in corn seedlings (Alborn et al., 1997).

Our results are consistent with the hypothesis that an elicitor from *C. pomonella* larvae induces the emission of volatiles from apple fruits. Either quantitative or qualitative differences in the elicitor(s) exist depending upon the instar of *C. pomonella* larva.

3. Experimental

3.1. Apple fruits

Mature apple fruits Malus domestica Borkh. (Rosaceae) cv. Bohnäpfel were obtained from an organic commercial farm and stored at 4°C for up to 6 months.

3.2. Cydia pomonella

Larvae were reared from adults purchased from a commercial breeding station within Switzerland. First instar larvae were obtained from eggs and used to infest apples on the first day following emergence. Other instars were reared on an artificial diet (Huber et al., 1972) at 25°C; RH 70% and a light dark photoperiod of 18:6. Larval development was assessed by means of head capsule widths: first instar 0.33 mm (mean duration 4 days); second instar 0.5 mm (mean duration 2 days); third instar 0.8 mm (mean duration 3 days); fourth instar 1.15 (mean duration 4 days) and fifth instar 1.52 mm (mean duration 11 days) (Ashby et al., 1985).

3.3. Time-course experiment

Infested apples were obtained by placing two larvae on each fruit. Volatile sampling (as described below) was carried out every day for the first three days following infestation and then at three day intervals until 21 days after infestation.

Healthy apples were treated in an identical manner to the infested fruits but left uninfested. Therefore, a total of 10 volatile samples were taken over the 21 day period for each fruit used. Experiments were conducted in an insectary at 23±2°C, 60±10% RH and 18:6 LD.

A Mann–Whitney test was used to test for significant differences between healthy and infested fruits at each sampling time; as the data are not statistically independent, no comparisons between sampling times were made. In addition, linear discriminant analysis of the data was conducted. Huberty (1994) discusses this statistical technique and Robertson et al. (1991) give an example of the application of this analysis in the context of insect chemical ecology. Such multivariate methods as discriminant analysis offer advantages over univariate methods for analysing data. For example, Hunter et al. (1997) suggest that many attributes in a multivariate dataset may be highly correlated. These correlations can complicate data interpretation as it is tempting to assume that each attribute, or in the present case each compound, supplies an independent element of information.

The linear discriminant analysis was carried out in a backward stepwise fashion, to eliminate variables which contributed least to the model. This was evaluated by the *P*-value associated with the *F*- value of each variable in the model, a *P*-value of 0.05 was used to eliminate variables from the model. This conservative value was used to reduce the problem of correlations between variables affecting the overall analysis.

3.4. Effect of the individual larval instars on volatile emission

Artificially damaged apples were obtained by piercing a fruit twice near the calyx with a needle (1 mm in diameter) to a depth of 2.5 cm. Infested apples were obtained by placing two larva of a given instar, first to fifth, on a healthy fruit. Three days later the volatiles from the fruit were collected and analysed as described below. Healthy apples were treated in an identical manner to the other fruits but were left undamaged. Environmental conditions were as described above. The volatiles of 15 apple fruits were analysed for each treatment.

Transformed data (squareroot datum + 0.5) were analysed using ANOVA. In order to compare which treatments differed, a Tukey test was employed. A linear discriminant analysis of the data as described above was also performed.

3.5. Volatile collection system

In all experiments volatiles were collected using solid phase microextraction (SPME). The fibre used was a 100 μm poly dimethyl siloxane (PDMS) fibre. Volatile collections were made from the apples placed in a dilated glass tube (length 35 cm; diameter 6 cm). The dilated

glass tube was sealed with a PTFE or glass stopper with a PTFE/silicon septa. The SPME fibre was exposed to the headspace of the apple through this septa and sampling was carried out for one hour. Volatile collections were carried out between 15.00±2 h (CET) which corresponds with the middle of the photophase under the light conditions of this experiment.

3.6. Chemical analysis

The samples were analysed using a Hewlett Packard GC–MS instrument (GC 6890 mass selective detector 5973). The analysis details were as follows: injector operated in splitless mode, purge valve on @ 2.00 min; flow 50 ml/min; injection temperature 250°C; helium flow rate 1.0 ml min (constant flow); column HP-1 (poly dimethyl siloxane) 30 M in length; 250 μm diameter; 1.00 μm film thickness; oven temperature 50°C for 2 min then ramped to 300 at 8°C per min; MS transfer line 280°C MS source 230°C MS Quad 150°C; MS operated in scan mode low mass 25, high mass 800; threshold 50. Prior to sampling the SPME fibre was thermally conditioned at 250°C for 1 h in the injection port of a GC (Hewlett Packard 5890 series II+). Both of these instruments were fitted with a SPME inlet liner (0.75 mm id; Supelco).

The sample spectra were compared to library spectra, both a commercial database (NIST98) and a user created library of authentic standards and the retention time of the standard was also matched with the sample in all cases. Standards for this process were either purchased from chemical suppliers or samples were obtained from other laboratories.

Acknowledgements

We would like to offer our sincere thanks to Dr. R. Kaiser (Givaudan-Roure, Dubendorf, Switzerland) who has provided us with many chemical standards for use in compound identification. In addition we thank Dr. A. Dutly (ETH Technical Chemistry) and D. Tunnah (Scottish Agricultural Science Agency) for advice on the chromatographic methods employed and Dr. L. Mattiacci for advice on aspects of the experimental design and for commenting on an earlier version of this manuscript.

Received 4 April 2000; received in revised form 19 October 2000

Abstract

Methyl jasmonate (MJ), a naturally-occurring plant cellular signal molecule, was found to induce production of lipophilic secondary metabolites in *Echinacea pallida* seedlings. Seedling aerial parts were sprayed with 100 ppm MJ, and roots were harvested and extracted 24 h later. Lipophilic root extracts, separated by HPLC, revealed significant increases ($P < 0.05$) in six alkamides or related ketoalkene/ynes produced by 34 day-old plants and in seven compounds produced by 58 day-old plants. © 2001 Published by Elsevier Science Ltd. All rights reserved.

Keywords: *Echinacea pallida*; Asteraceae; Secondary metabolite induction; Alkamides; Ketoalkene/ynes; Methyl jasmonate

1. Introduction

Jasmonic acid (JA) and methyl jasmonate (MJ) are widely distributed regulatory signal molecules derived from linolenic acid in plants in a pathway first described by Vick and Zimmerman (1984). Farmer and Ryan (1990) described the effects of jasmonates on growth, senescence and as a predominant signal in wound-induced defense. MJ induces resistance towards insect herbivory in both tobacco and cabbage crops (Avdiushko et al., 1997).

Echinacea, endemic to North America, is a plant genus known for its traditional medicinal qualities (Hobbs, 1989). The secondary chemistry of commercial *Echinacea* species (*E. purpurea, E. pallida* and *E. angustifolia*) has been well-characterized (Bauer et al., 1988; Bauer and Remiger, 1989; Cheminat et al., 1988; Bohlmann and Hoffmann, 1983; reviewed in Bauer and Wagner, 1991; Bauer, 1998) and remains the primary method of botanical identification for marketed *Echinacea* plant materials.

Echinacea possesses a high level of constitutive diversity within each of its numerous classes of defense compounds, particularly the family of alkamides, polyacetylenes and ketoalkene/ynes, some of which are known insecticides (Jacobson, 1967). Diversity within phytochemical classes is a common defensive strategy against herbivory (Karban et al., 1997). Another strategy is a rapid increase in quantity and/or variability of phytochemical defenses in response to wounding or fungal infection, which can be simulated by application of the signal molecule MJ. The induction of *Echinacea* phytochemicals whether naturally or by MJ is important for increased efficacy and efforts to standardize *Echinacea* phytomedicines.

Identified alkamides and polyacetylenes in *Echinacea* spp exhibit other biological activities in vitro, including fungicidal (Binns et al., 2000) and immunostimulatory activities (Bauer and Wagner, 1991). Here we report that the volatile chemical signal MJ induces alkamide and ketoalkene/yne biosynthesis in *Echinacea pallida*.

2. Results and discussion

The alkamide composition of *Echinacea* is known to vary quantitatively and qualitatively throughout growth and development (Letchamo et al., 1998) and in our experiments, alkamide levels tended to decline naturally between 34 days and 58 days in *E. pallida* roots of control plants (Figs. 1 and 2). The only qualitative difference observed was the formation of the ketoalkyne **1*** as the roots aged (compounds denoted by an asterisk are ketoalkene/ynes, while the others are alkamides).

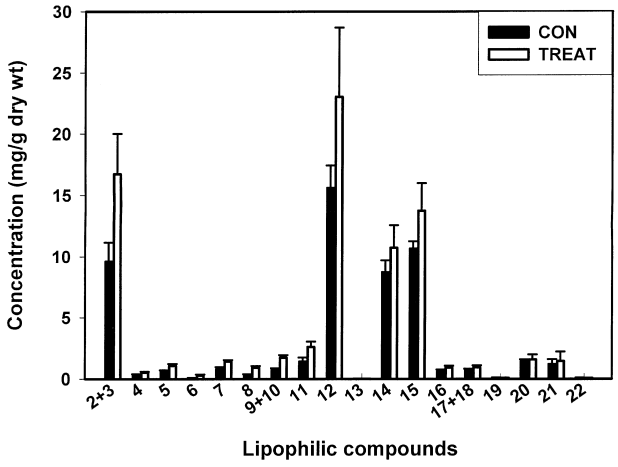

Fig. 1. Lipophilic compounds (mean + SE) in *Echinacea pallida* roots aged 34 days ($n = 10$) from methyl jasmonate-treated (TREAT) and control plants (CON).

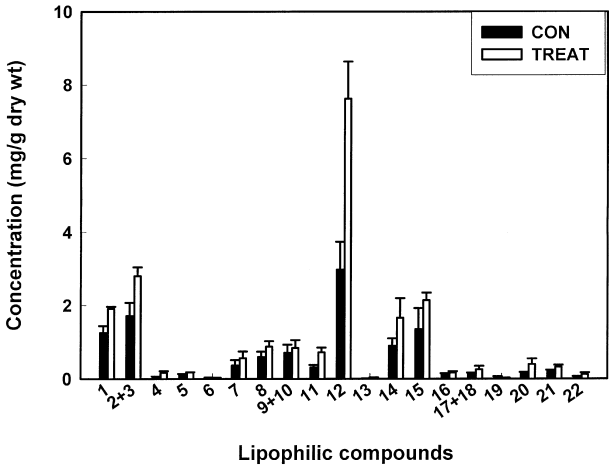

Fig. 2. Lipophilic compounds (mean + SE) in *Echinacea pallida* roots aged 58 days ($n = 10$) from methyl jasmonate-treated (TREAT) and control plants (CON).

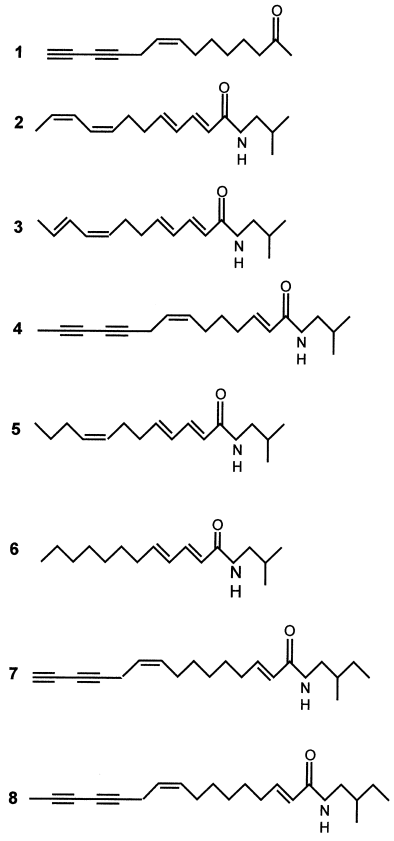
Compound **1*** is used in the marketplace to distinguish older *E. pallida* roots from *E. angustifolia*, which has the isomers **2** + **3** as its major constituents, but lacks **1*** (Bauer and Remiger, 1989). In our trials with very young (34 day old) roots, the formation of **2** + **3** in high concentrations (control and treated) occurs early in development (Fig. 1), followed by a remarkable decrease later (58 day old) when **1*** begins to appear (Fig. 2).

After treatment with 100 ppm MJ, the majority of compounds identified showed an increase in concentration in the MJ-treated plants over the concentrations in control roots (Figs. 1 and 2) at both plant ages. Statistically significant increases were observed with a number of compounds and ranged from 54 to 353% (mg/g dry wt) (Table 1). MJ treated *E. pallida* plants aged 34 days contained significantly higher levels ($P < 0.05$) of compounds **4**, **5**, **6**, **7**, **8** and **9** + **10*** compared to control plants of the same age (Fig. 1, Table 1). MJ treated *E. pallida* plants aged 58 days contained significantly higher levels of compounds **2** + **3**, **4**, **11**, **12**, **13*** and **1*** compared to



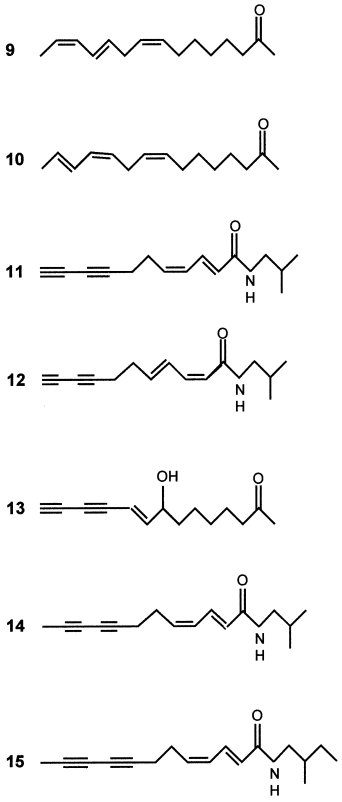


Table 1
Alkamides and ketoalkene/ynes in *E. pallida* roots of two age classes (34 days and 58 days) that showed a statistically significant increase by methyl jasmonate treatment

13	8-Hydroxytetradeca-9*E*-ene-11,13-diyn-2-one[c]	+	0.269[b]	**353**	0.001[b]

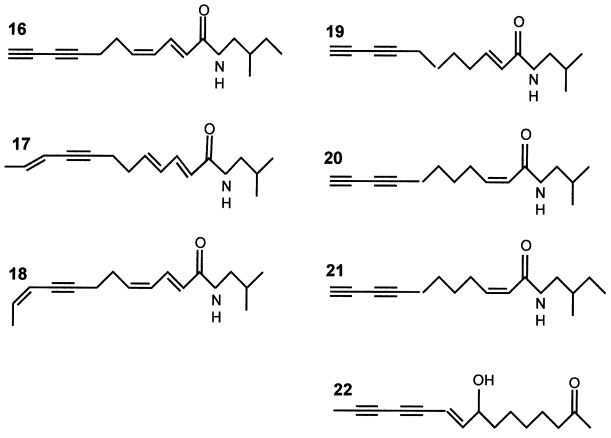
Notes: Significantly different means were determined at $\alpha = 0.05$ by a two-tailed *t*-test using SYSTAT software and original quantitative data for MJ treated and control plants. + Denotes an increasing trend that was not statistically significant.

[a] % increase = treatment mean/control mean ×100.

[b] Original data transformed by Log_{10} to meet assumptions for statistical analyses.

[c] Denotes ketoalkene/ynes without amide group. AIBA = acid isobutylamide. $n = 10$ each age class.

control plants of the same age (Fig. 2, Table 1). The compounds found in treated and control *E. pallida* roots common to both ages were **2+3**, **12**, **14** and **15**. Younger roots contained approximately five times more of these common constituents than did the older roots (Figs. 1 and 2).



The statistically significant increases presented here suggest that alkamides and ketoalken/ynes are inducible defense compounds in *Echinacea* plants. In-depth investigation of this phenomenon and possible species variation is currently being studied in our laboratory.

3. Experimental

3.1. Plant material

E. pallida achenes from a wild population (DAO #EPA013, coll. S. Binns, Arkansas, 1998) were germinated and grown to 34 days and 58 days in 2:1 soil: vermiculite in a controlled environment chamber at 25°C under a 16:8 light to dark regime. Voucher specimens are deposited in the National Herbarium of Canada—Department of Agriculture, Ottawa, Canada.

3.2. Treatment

Initial trials at 10, 100 and 1000 ppm MJ showed the best induction at 100 ppm and this concentration was used in trials reported here. Half of the individuals at each life stage were designated control plants ($n = 10$). Treated plants were sprayed with MJ solution and control plants were sprayed with dH_2O and DMSO. MJ (100 ppm) was prepared in aqueous solution of 19 μl MJ, 19 μl DMSO and 200 ml distilled water. Treated plants were isolated from control plants in different growth chambers, under identical conditions, to avoid inter-plant communication through airborne MJ (Farmer and Ryan, 1990).

3.3. Extraction and isolation

Twenty-four hours after MJ treatment, entire roots of all plants were harvested, cleaned, weighed and extracted using 95% aqueous ethanol for another 24 h under moderate mechanical agitation (70 rpm). Extraction time after MJ treatment was based on time-course experiments (2–72 h) with dill (*Anethum graveolens*), which showed maximum phytochemical induction by MJ after 24 h (Belzile, 1998). Filtered extracts (No. 1 Whatman, Buchner funnel) were concentrated in vacuo (not to dryness) and root tissue residues dried (50°C). The dry weight of root residues was used to calculate the volume of solvent required to adjust each extract to a standard concentration of 0.01 g extracted dried root/ml 95% ethanol.

Extracts were then filtered with 0.2 μm nylon membranes prior to separation of lipophilic constituents using HPLC. Chromatography was achieved using a solvent system of acetonitrile:water (6:4) at 1 ml/min and 5 μl injection on a 7.5 cm reversed phase C-18 column (3 mm particle size). Lipophilic compounds were detected at 210 and 260 nm and identified by comparison with reference standards. Reference standards **2** + **3**, **6**, **7** and **11** were isolated previously in our laboratory by column chromatography on silica gel (Bergeron et al., 2000). Spectra obtained for these by ^{1}H, ^{13}C NMR, EI–MS conformed with reported values (Perry et al., 1997; Yasuda et al., 1981). Other compounds were identified based on relative retention time and online UV spectra (Bauer and Remiger 1989). The standard **2** + **3** was used to calculate a response factor for the HPLC detector. Quantitation of each previously reported compound (μg/per ml injected) was achieved using peak area multiplied by the response factor. This figure was then divided by the original concentration of 0.01 g extracted dried root/ ml sample and multiplied by 10^3 to reach mg/g dry wt of whole root.

Received 8 August 2000; received in revised form 11 January 2001

Abstract

Bioassay-directed fractionation of the stems of *Rollinia mucosa* led to the isolation of new *N*-methoxycarbonyl aporphine alkaloids, romucosine A (**1**), romucosine B (**2**), romucosine C (**3**), and romucosine D (**4**), along with the known alkaloid, *N*-methoxylcarbonyl-nornuciferine (**5**). Alkaloids **1** and **4** exhibited significant inhibition of collagen, arachidonic acid, and platelet activating factor-induced platelet aggregation, and alkaloid **3** also showed an inhibitory effect on arachidonic acid induced platelet aggregation. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Rollinia mucosa*; Annonaceae; *N*-Methoxycarbonyl aporphines; Antiplatelet activity

1. Introduction

The genus *Rollinia* (Annonaceae) is comprised of 65 species (Leboeuf et al., 1982), some of which were investigated previously for their chemical composition and pharmacological activities (Hartwell, 1982; Caetano and Dabun, 1987; Chen et al., 1996b,c; 1996; Paulo et al., 1991; Liaw et al., 1999). Within the genus, *Rollinia mucosa* Baill. has been used as a traditional medicine for the treatment of tumors in the West Indies and Indonesia (Hartwell, 1982). In further biological evaluation, alkaloidal extracts were shown to exhibit antimicrobial and antifungal activities (Caetano and Dabun, 1987). In Brazil and Peru, the lignans isolated from this species were reported to be active against a wide variety of insects (Paulo et al., 1991). In previous studies, numerous aporphine alkaloids and acetogenins were isolated from this plant (Chen et al., 1996a,c; Zafra-Polo et al., 1996, 1998; Alali et al., 1999; Liaw et al., 1999). In the course of our studies on bioactive natural substances, the alkaloid fraction of the stems of *R. mucosa* was found to exhibit a significant inhibitory effect on antiplatelet aggregation induced by several aggregating agents. Bioassay-directed fractionation led to the isolation of four new *N*-methoxycarbonyl aporphine alkaloids, romucosine A–D (**1**–**4**), and a known alkaloid, *N*-methoxylcarbonyl-nornuciferine (**5**) (Tschesche et al., 1964). Their isolation, structural elucidation and biological activity are reported herein.

2. Results and discussion

Romucosine A (**1**) was obtained as a brown amorphous powder. The HREIMS revealed a $[M]^+$ at m/z 325.1309 (calc. 325.1314) corresponding to the molecular formula $C_{19}H_{19}O_4N$. The base peak at m/z 237 $[M–H–(NCOOCH_3)]^+$ (M-88) in EIMS, derived from a retro-Diels–Alder fragmentation, and the UV absorptions at 237, 285, and 307 nm, revealed **1** as a 1,2-disubstituted *N*-methoxycarbonyl aporphine (Shamma, 1972; Chen et al., 1996b). The IR spectrum of **1** showed absorption bands at 3400 and 1690 cm^{-1}, indicating the presence of phenolic hydroxyl and carbonyl groups,

	R_1	R_2	R_3	R_4	6a
1	OCH_3	OH	H	H	*R*
2	OCH_3	OH	Cl	H	*S*
3	OCH_3	OCH_3	H	OH	*S*
4	OCH_3	OCH_3	H	OCH_3	*S*
5	OCH_3	OCH_3	H	H	*S*

respectively. The ^{1}H NMR spectrum showed a doublet at δ 8.30 (1H, *d*, $J=8.0$ Hz) and multiplets for three protons in the range δ 7.28–7.32 which demonstrated the presence of an unsubstituted D-ring. The aromatic proton at δ 6.75 (1H, *s*) was assigned to H-3 (Chen et al., 1996b). Two signals due to methoxy groups at δ 3.56 and 3.76 (each 3H, *s*) were evident. Based on the ring current of twisted A/D rings and the correlation from the NOESY spectrum, the methoxyl at δ 3.56 which correlated to H-11 was unambiguously assigned to C-1 (Shamma, 1972). The methoxyl at δ 3.76 was assigned to the methoxyl on the *N*-methoxycarbonyl group (Chen et al., 1996b). In the aliphatic region of the ^{1}H NMR spectrum resonances were observed at δ 4.22 (1H, *d*) for H-5a and at δ 4.66 (1H, *dd*) for H-6a. These spectral data were similar to those of romucosine (Chen et al., 1996b), but with a different substitution. The stereochemistry at C-6a was elucidated as the *R* configuration by the $[\alpha]_D^{25}$ -105° (Shamma, 1972). Based on the results mentioned above, the structure was determined as **1**, and named as romucosine A.

Romucosine B (**2**) was obtained as a white amorphous powder. The HREIMS revealed a $[M]^+$ at *m/z* 359.0915 (calc. 359.0924) corresponding to the molecular formula $C_{19}H_{18}O_4NCl$. The fragment ion at *m/z* 271 (M-88) and the UV absorption maximas at 245 and 285 nm revealed the typical pattern of a 1,2,3-trisubstituted *N*-methoxycarbonyl aporphine (Shamma, 1972; Chen et al., 1996b). MS fragments at *m/z* 359 $[M]^+$, 361 $[M+2]^+$ (3:1), and 323 $[M–Cl]^+$ suggested the presence of one chlorine atom. The IR and ^{1}H NMR spectra of **2** were similar to those of **1**, except for the disappearance of H-3. Thus, it was apparent that H-3 was replaced by chlorine. The configuration of C-6a was deduced to be *S* by the $[\alpha]_D^{25}$ $+153^\circ$ (Shamma, 1972). Therefore, the structure was elucidated as **2**, and named as romucosine B.

Romucosine C (**3**) was obtained as a brown amorphous powder. The HREIMS revealed a $[M]^+$ at *m/z* 355.1419 (calc. 355.1419) corresponding to the molecular formula $C_{20}H_{21}O_5N$. The fragment ion at *m/z* 267 (M-88) and the UV absorption maximas at 265, 280, and 305 nm revealed **3** as a 1,2,10-trisubstituted *N*-methoxycarbonyl aporphine (Shamma, 1972; Chen et al., 1996b). The IR absorption bands at 3350 and 1698 cm^{-1} of **3** indicated the presence of hydroxyl and carbonyl groups, respectively. In the ^{1}H NMR spectrum, the aromatic region presented an ABX pattern, which matched the observed UV absorptions. Furthermore, the appearance of a methoxyl group at δ 3.76 and the downfield shifted aliphatic protons at δ 4.29 (H-5a) and 4.69 (H-6a) demonstrated the presence of a *N*-methoxycarbonyl group. In the NOESY spectrum, correlations between H-3/H-4/H-5, H-8/H-9 and H-11/1-OMe were observed (Fig. 1). Therefore, the hydroxyl group was located at C-10. The configuration of C-6a was determined by the $[\alpha]_D^{25}$ $+140^\circ$, which indicated it as *S* (Shamma, 1972). From the above indications, the structure was determined as romucosine C (**3**).

Romucosine D (**4**) was isolated as a brown amorphous powder. The HREIMS revealed a $[M]^+$ at *m/z* 369.1575 (calc. 369.1576) corresponding to the molecular formula $C_{21}H_{23}O_5N$. A characteristic fragment ion at *m/z* 281 (M-88) was also observed. The UV, IR, and ^{1}H NMR spectra were similar to those of **3**, except for the appearance of one more methoxyl group (δ 3.84). In the NOESY spectrum, the methoxyl group was correlated to H-11 and H-9. In contrast to **3**, compound **4** therefore possessed a methoxyl group at C-10. The configuration of C-6a was deduced to be *S* by $[\alpha]_D^{25}$ $+145^\circ$ (Shamma, 1972). The structure was determined as romucosine D (**4**).

N-Methoxylcarbonyl-nornuciferine (**5**) was isolated as a white amorphous powder. The HREIMS revealed a $[M]^+$ at *m/z* 339.1474 (calc. 339.1471) corresponding to

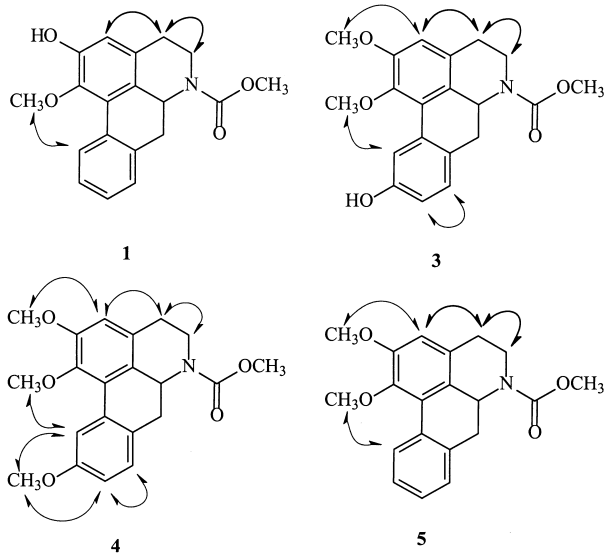

Fig. 1. NOESY correlations of compounds **1**, **3**, **4** and **5**.

the molecular formula $C_{20}H_{21}O_4N$. The UV and ^1H NMR spectra **5** were similar to those of **1**, except for the appearance of methoxyl signal at δ 3.95 in ^1H NMR. This methoxy resonance was correlated to H-3 in the NOESY spectrum (Fig. 1), and was assigned to C-2. The configuration of C-6a was also considered as *S* from the $[\alpha]_D^{25}$ +165° (Shamma, 1972). Therefore, the structure of **5** was determined as illustrated. Because the parent aporphine, nornuciferine, was easily obtained from annonaceous plants, *N*-methoxycarbonyl-nornuciferine was prepared using the established method (Chen et al., 1996b). The spectral data of the reaction product matched those of **5**, and established **5** to be *N*-methoxycarbonyl-nornuciferine. Alkaloid **5** is described here from natural sources and its spectral assignments are revealed for the first time.

Alkaloids **1**–**5** were evaluated for antiplatelet aggregation induced by thrombin, arachidonic acid (AA), collagen, and platelet-activating factor (PAF). As indicated in Table 1, alkaloid **4** was more active in AA-, collagen-, and PAF-induced platelet aggregation among these isolates. From the data presented in Table 1, the results were implied as follows: (i) alkaloids **1** and **4** displayed significant inhibition of the platelet aggregation induced by AA; (ii) methoxyl substitution of C-10 enhanced the activity more than hydroxyl substitution (among alkaloids **3**, **4**, and **5**); (iii) *N*-methoxycarbonyl aporphines, a new class of aporphines, presented a higher selectivity to AA-induced platelet aggregation than the parent aporphines (Chen et al., 1996a).

3. Experimental

3.1. General experimental procedures

The UV spectra were obtained on a Hitachi 200-20 spectrophotometer, IR spectra were measured on a Mattson Genesis II spectrometer. NMR spectra were obtained on Varian NMR spectrometers (Unity Plus 400 MHz and Gemini 200 MHz) using $CDCl_3$ as solvent. Low-resolution EIMS were collected on a Jeol JMS-SX/SX 102A mass spectrometer or Quattro GC/MS spectrometer having a direct inlet system. High-resolution EIMS were measured on a Jeol JMS-HX 110 mass spectrometer. Silica gel 60 (Merck, 230–400 mesh) was used for column chromatography. Semi-preparative columns (LichroCART, Licrosphere 250-10, Merck) were used for HPLC analysis (Shimadzu LC-10AT), and the fractions were recorded using a UV detector (Shimadzu SPD-10A). TLC spots were detected by spraying with 50% H_2SO_4 and heating.

3.2. Plant material

Fresh stems of *Rollinia mucosa* (11.5 kg) were collected from Chia-Yi, Taiwan in August 1997. A voucher specimen was identified by Dr. Hsin-Fu Yen and is deposited in the Graduate Institute of Natural Products, Kaohsiung Medical University, Kaohsiung, Taiwan.

3.3. Extraction and isolation

Fresh stems of *R. mucosa* (11.5 kg) were extracted repeatedly with MeOH at room temperature. The combined MeOH extracts were evaporated under reduced pressure to yield a dark-brown syrup (305.5 g). The syrup was partitioned between $CHCl_3$ and H_2O to give two layers. The $CHCl_3$ layer was then extracted with 3% HCl to give a $CHCl_3$ solution (Fraction A) (108.7 g) and an acidic aq. layer. The latter aq. layer was basified with NH_4OH and extracted with $CHCl_3$ to give Fraction B (3.1 g). Fraction B gave a positive alkaloidal test with Dragendorff's reagent. The crude alkaloid portion (Fraction B) was subjected to silica gel chromatography and eluted with increasingly polar mixtures of $CHCl_3$–MeOH to afford 21 Fractions. Romucosine B (**2**) (1.4 mg, $CHCl_3$–*n*-hexane 3:1 $R_f = 0.6$) was isolated as an insoluble powder from acetone in Fraction 5. Fraction 14 was separated by silica gel CC with increasingly polar mixtures of $CHCl_3$–MeOH to give 5 Fractions. Further separation of Fraction 14-1 by reverse phase

HPLC (MeOH–H_2O 80:20, flow rate = 2.0 ml/min) yielded romucosine C (**3**) (1.5 mg, t_R = 23.5 min) and romucosine D (**4**) (2.6 mg, t_R = 21.0 min). Fraction 15 (0.4 g) was subjected to CC ($CHCl_3$–*n*-hexane 1:3) to give romucosine A (**1**) (2.5 mg, $CHCl_3$–*n*-hexane 1:2, R_f = 0.47) and *N*-methoxycarbony-nornuciferine (**5**) (3.0 mg, $CHCl_3$-*n*-hexane 3:2, R_f = 0.56), respectively.

3.4. Platelet aggregation assay

The platelet aggregation assays were carried out according to established protocols (Chen et al., 1996a).

3.4.1. Romucosine A (*1*)

[2-Hydroxy-1-methoxy-4,5,6a,7-tetrahydro-dibenzo[*de,g*]quinoline-6-carboxylic acid methyl ester]. Brown amorphous powder; $[\alpha]_D^{25}$ −105° ($CHCl_3$; *c* 0.1,); UV λ_{max}^{MeOH}nm (log ε): 237 (4.40), 285 (4.22), 307 (4.05); IR ν_{max}^{KBr} cm^{-1}: 3400 (−OH) and 1690 (>C=O) ^1H NMR ($CDCl_3$, 400 MHz): δ 8.30 (1H, *d*, *J* = 8.0 Hz, H-11),7.28–7.32 (3H, *m*, H-8, 9 and 10), 6.75 (1H, *s*, H-3), 4.66 (1H, *dd*, *J* = 15.2, 3.6 Hz, H-6a), 4.22 (1H, *d*, *J* = 11.2 Hz, H-5a), 3.76 (3H, *s*, *N*-COOCH_3), 3.56 (3H, *s*, C1–OCH_3) and 2.65–2.98 (5H, *m*, H-4a, 4b, 5b and 7); EIMS (70 eV) *m*/*z* 325 $[M]^+$ (71), 310 (43), 294 (4), 237 (100); HREIMS *m*/*z* $[M]^+$ 325.1309 (calc. $C_{19}H_{19}O_4N$ 325.1314).

3.4.2. Romucosine B (*2*)

[3-Chloro-2-hydroxy-4,5,6a,7-tetrahydro-dibenzo[*de,g*]quinoline-6-carboxylic acid methyl ester]. White amorphous powder; $[\alpha]_D^{25}$ +153° ($CHCl_3$, *c* 0.05); UV λ_{max}^{MeOH} nm (log ε): 245 (4.43) and 285 (4.25); IR $\nu_{max}^{KBr}cm^{-1}$: 3400 (−OH) and 1700 (>C=O); ^1H NMR ($CDCl_3$, 400 MHz): δ 8.34 (1H, *d*, *J* = 8.0 Hz, H-11), 7.20–7.38 (3H m, H-8, 9 and 10), 4.72 (1H, *dd*, *J* = 13.2, 3.6 Hz, H-6a), 4.48 (1H, *d*, *J* = 10.8 Hz, H-5a), 3.76 (3H, *s*, *N*-COOCH_3), 3.62 (3H, *s*, C1–OCH_3) and 2.63–3.06 (5H, *m*, H-4a, 4b, 5b and 7); EIMS (70 eV) *m*/*z* 361 (15), 359 (46), 346 (7), 344 (21), 323 (12), 271 (63); HREIMS *m*/*z* $[M]^+$ 359.0915 (calc. $C_{19}H_{18}O_4NCl$ 359.0924).

3.4.3. Romucosine C (*3*)

[10-Hydroxy-1,2-dimethoxy-4,5,6a,7-tetrahydro-dibenzo[*de,g*]quinoline-6-carboxylic acid methyl ester]. White amorphous powder; $[\alpha]_D^{25}$ +140° ($CHCl_3$, *c* 0.05); UV λ_{max}^{MeOH} nm (log ε): 265 (4.25), 280 (4.02), 305 (4.35); IR $\nu_{max}^{KBr}cm^{-1}$: 3350 (−OH) and 1698 (>C=O); ^1H NMR ($CDCl_3$, 400 MHz): δ 7.98 (1H, *d*, *J* = 2.8 Hz, H-11), 7.15, (1H, *d*, *J* = 8.4 Hz, H-8), 6.77 (1H, *dd*, *J* = 8.4, 2.8 Hz, H-9), 6.68 (1H, *s*, H-3), 4.69 (1H, *br d*, *J* = 17.2 Hz, H-6a), 4.29 (1H, *br s*, H-5a), 3.90 (3H, *s*, C2-OCH_3), 3.76 (3H, *s*, NCOOCH_3), 3.68 (3H, *s*, C1–OCH_3) and 2.60–3.03 (5H, *m*, H-4a, 4b, 5b and 7); EIMS (70 eV) *m*/*z* 355 $[M]^+$ (70), 340 (13) and 267 (100); HREIMS *m*/*z* $[M]^+$ 355.1419 (calc. $C_{20}H_{21}O_5N$ 355.1419).

3.4.4. Romucosine D (*4*)

White amorphous powder; $[\alpha]_D^{25}$ +145° ($CHCl_3$, *c* 0.05); UV λ_{max}^{MeOH} nm (log ε): 263 (4.33), 275 (4.22), 307 (3.75); IR ν_{max}^{KBr} cm^{-1}: 3350 (−OH); ^1H NMR ($CDCl_3$, 400 MHz): δ 8.11 (1H, *d*, *J* = 2.8 Hz, H-11), 7.19 (1H, *d*, *J* = 8.4 Hz, H-8), 6.83 (1H, *dd*, *J* = 8.4, 2.7 Hz, H-9), 6.68 (1H, *s*, H-3), 4.70 (1H, *dd*, *J* = 13.4, 4.7 Hz, H-6a), 4.45 (1H, *d*, *J* = 10.8, H-5a), 3.90 (3H, *s*, C2-OCH_3), 3.84 (3H, *s*, C10–OCH_3), 3.75 (3H, *s*, NCOOCH_3), 3.68 (3H, *s*, C1–OCH_3) and 2.61–3.05 (5H, *m*, H-4a, 4b, 5b and 7); EIMS (70 eV) *m*/*z* (rel. int.) 369 $[M]^+$ (60), 354 (10), 281 (100); HREIMS *m*/*z* $[M]^+$ 369.1575 (calc. $C_{21}H_{23}O_5N$ 369.1576).

3.4.5. N-Methoxylcarbonyl-nornuciferine (*5*)

White amorphous powder; $[\alpha]_D^{25}$ +165° ($CHCl_3$, *c* 0.05); UV λ_{max}^{MeOH} nm (log ε): 235 (4.23), 285 (4.20), 307 (3.36); IR $\nu_{max}^{KBr}cm^{-1}$: 1690 (>C=O); ^1H NMR ($CDCl_3$, 400 MHz): δ 8.38 (1H, *d*, *J* = 8.0 Hz, H-11), 7.25–7.34 (3H, m, H-8, 9 and 10), 6.94 (1H, *s*, H-3), 4.77 (1H, *dd*, *J* = 13.2, 4.0 Hz, H-6a), 4.44 (1H, *br d*, *J* = 11.2 Hz, H-5a), 3.76 (3H, *s*, *N*-COOCH_3), 3.56 (3H, *s*, C1–OCH_3), 3.61 (3H, *s*, C2-OCH_3) and 2.65–3.02 (5H, *m*, H-4a, 4b, 5b and 7); EIMS (70 eV) *m*/*z* (rel. int.) *m*/*z* 339 $[M]^+$ (33), 324 (23), 309 (6), and 251 (100); HREIMS *m*/*z* $[M]^+$ 339.1474 (calc. $C_{20}H_{21}O_4N$ 339.1471).

3.4.6. Preparation of N-methoxylcarbonyl-nornuciferine (*5*)

(+)-Nornuciferine (10 mg) in dry CH_2Cl_2 (10 ml) was dissolved in triethylamine (5 μl) with stirring at 0°C for 10 min, and then methyl chloroformate (2 ml) was added dropwise. The reaction mixture was stirred for 10 min, and H_2O was added to quench the excess reagent. The mixture was partitioned with $CHCl_3$ and then passed through a disposable pipette (0.6×6 cm) containing silica gel (230–400 mesh) and eluted with $CHCl_3$ repeatedly to afford a white amorphous powder (10.2 mg, 84%) which was identical with **5** (mixed mp, co-TLC, UV, IR, and ^1H NMR).

Abstract

Papaya (*Carica papaya*) seeds were extracted in an aqueous buffer or in organic solvents, fractionated by chromatography on silica and aliquots tested for anthelmintic activity by viability assays using *Caenorhabditis elegans*. For all preparations and fractions tested, anthelmintic activity and benzyl isothiocyanate content correlated positively. Aqueous extracts prepared from heat-treated seeds had no anthelmintic activity or benzyl isothiocyanate content although both appeared when these extracts were incubated with a myrosinase-containing fraction prepared from papaya seeds. A 10 h incubation of crude seed extracts at room temperature led to a decrease in anthelmintic activity and fractionated samples showed a lower benzyl isothiocyanate content relative to non-incubated controls. Benzyl thiocyanate, benzyl cyanide, and benzonitrile were not detected in any preparations and cyanogenic glucosides, which were present, could not account for the anthelmintic activity detected. Thus, our results are best explained if benzyl isothiocyanate is the predominant or sole anthelmintic agent in papaya seed extracts regardless of how seeds are extracted. © 2001 Published by Elsevier Science Ltd. 1. Introduction

Papaya seeds have been used for centuries as a vermifuge in India (Lal et al., 1976), Central and South America (Roig y Mesa,1974) and throughout the world (Werner, 1992). Clinical trials with humans have led to seemingly contradictory results with Robinson (1958) claiming that papaya seeds are effective and Fernando (1959) claiming they are not. However, laboratory studies have confirmed that various preparations of papaya seeds can kill helminths effectively in vitro and in infected animals (Krishnakumari and Majumder, 1960; Dar et al., 1965; Lal et al.,1976).

The number and identity of anthelmintic compounds present in papaya seeds has not yet been established. Previous work has shown that seeds ground and extracted with either water or organic solvents, including alcohol, all produce crude extracts with anthelmintic activity and contain bioactive compounds such as benzyl isothiocyanate (BITC) (Dar et al., 1965; Ettlinger and Hodgkins, 1956; Krishnakumari and Majumder, 1960; Tang, 1971; Tang et al., 1972). In some cases, diethyl ether could be used to concentrate the bioactive principle(s) from water soluble seed extracts but, while the material that partitioned to the diethyl ether or organic solvent layer was shown to have anthelmintic activity and contain BITC, fractions that were produced by the initial extraction of the seeds with water or which partitioned to the water layer were apparently never tested for anthelmintic activity (Ettlinger and Hodgkins, 1956; Tang, 1971, 1973). Steam distillates using water-soluble extracts of papaya seeds also yielded BITC and the activity of this fraction against helminths was demonstrated (quoted in Ettlinger and Hodgkins, 1956). Since BITC is volatile and relatively insoluble in water, distillation of this compound from an aqueous solution

at a relatively low temperature is not surprising. However, the steam distillation carried out by these researchers would not have identified any other putative bioactive compounds that may have been heat-labile. Given the variety of solvents and extraction conditions that can produce extracts with bioactive properties against helminths, there is little compelling evidence that BITC is the only anthelmintic principle that can be extracted from papaya seeds.

The anthelmintic effect of papaya seeds has been variously ascribed to carpaine (an alkaloid) and carpasemine (later identified as benzyl thiourea by Panse and Paranjpe, 1943), and BITC (Krishnakumari and Majumder, 1960; Tang, 1971). Benzyl thiourea is reported to be an artifact that arose during purification of the bioactive principle due to a reaction between ammonia and BITC (Ettlinger and Hodgkins, 1956) and it was present in preparations from seeds at a concentration of one-tenth that of BITC. Subsequently, Dar et al. (1965) tested BITC and benzyl thiourea individually for bioactivity and showed BITC to be about 20 times more toxic to *Ascaris lumbricoides* than benzyl thiourea. Since this study only tested compounds already known to be present in papaya seed extracts it falls short of proving that BITC is the only active anthelmintic principle in these seeds.

In addition to anthelmintic properties, papaya seed extracts also contain antimicrobial activity (Ettlinger and Hodgkins, 1956; Emeruna, 1982) due, at least in part, to BITC (Das et al., 1954). Again, however, it is not clear whether all the antibiotic activities are due to one or more compounds present in these seed preparations.

In papaya seeds, BITC is formed from benzyl glucosinolate (Gmelin and Kjær, 1970; Tang, 1973; Bennett et al., 1997), the major or perhaps only glucosinolate present. Glucosinolates in the seeds of many plants are metabolized to yield isothiocyanates by the action of enzymes commonly called myrosinases (thio-glucoside hydrolases, EC 3.2.3.1) (Ettlinger and Hodgkins, 1956; Palmieri et al., 1982), enzymes that are brought into contact with their substrate(s) upon damage to seeds in which they are found. The myrosinase and glucosinolates are in different compartments of the papaya seed (the endosperm and sarcotesta of the seed, respectively), although a small fraction of substrate and enzyme reside together in the embryo (Tang, 1973). It follows that papaya seeds must be crushed or otherwise damaged to produce substantial amounts of the antibiotic BITC.

Different myrosinase/glucosinolate combinations give rise to different products, with some producing a combination of thiocyanates and isothiocyanates, others a mix of nitriles, thiocyanates and isothiocyanates and still others isothiocyanates alone (Saarivirta and Virtanen, 1963; Virtanen, 1965). It remains to be determined whether the myrosinase/benzyl glucosinolate combination of papaya seed gives rise to all the possible products listed above or only BITC.

More recently, Bennett et al. (1997) found that papaya leaves and stems contain cyanogenic glucosides. This finding was unanticipated because plants that contain glucosinolates do not, as a rule, contain cyanogenic glucosides (Bennett et al., 1997; Conn, 1980). However, cyanogenic glucosides offer a potential source of highly toxic cyanide if they are also present in seeds. The prospect of cyanide contributing to the antibiotic properties of papaya seed preparations is difficult to address since seeds were not tested for these glucosides in the earlier study (Bennett et al., 1997) and so we felt it necessary to test for the presence of cyanogenic glucosides in papaya seeds.

In this study we elected to use *C. elegans* as an endpoint to measure anthelmintic activity. While *C. elegans* is a free living nematode and not a parasite, it is considered to be a good nematode model with important genetic similarities to parasitic nematodes (Blaxter, 1998). Furthermore, parasitic nematodes have yet to be propagated outside of their hosts. Our findings show that anthelmintic activity is present or recovered from either water-soluble (''aqueous'') or non-polar organic solvent (''nonaqueous'') extracts prepared from papaya seeds and that BITC is present in both extracts. We propose that BITC is the major and probably only source of anthelmintic activity present in papaya seeds and that it is produced in preparations of these seeds primarily, and probably exclusively, as the result of the action of resident myrosinase(s).

2. Results

Commercial BITC (98% pure) was toxic to *C. elegans,* as expected (Table 1). Extracts of fresh papaya seeds prepared with water were also toxic to *C. elegans* and were shown to contain BITC (Table 1). A volume of 10–20 μl of these aqueous extracts, when freshly prepared, representing the contents of about 1.2–2.4 mg of seed, was sufficient to kill *C. elegans* in our 0.5 ml assay. BITC was also found in oil concentrates prepared from seeds that were Soxhlet extracted with pentane and between 0.04 and 0.1 μl of this oil, representing the contents of 4–10 mg of seed, killed the nematodes in our assay (Table 1). If one considers the measure of toxicity as the LC90 or the concentration of the compound needed to kill $>90\%$ of the nematodes within 4–5 h, this value is roughly equivalent regardless of the source of BITC (Table 1).

Exposures for periods exceeding 12 h were generally lethal to all the nematodes in the assay when the concentration of BITC was at the LC90, irrespective of the source of BITC. Fig. 1 shows the log of the concentration of BITC in commercial BITC and in the aqueous and oil extracts of papaya seeds plotted against the log of the minimum volume of these preparations needed to kill 90% of the nematodes. A highly significant constant

Table 1
BITC and papaya seed extracts decrease the viability of *Caenorhabditis elegans*[a]

Preparation		Dose to kill > 90% nematodes		BITC	
		Volume (μl)	Seed number[c]	Concentration (M)	LC90[d] (μM)
BITC standard[b]		0.001–0.002	–	7.46	15.30
Seed extract	Crude aqueous	10–20	0.03–0.06	0.0006	12–24
	Crude oil	0.04–0.1	0.1–0.25	0.196	16.39

[a] Representative results shown, experiment was repeated three times.
[b] Commercially available, 98% pure.

[d] Concentration of BITC in the 0.5 ml nematode viability assay required to kill >90% of the *C. elegans* in 4–5 h.

relationship is found with an r^2 of 0.989, an outcome that is best explained if BITC is the active anthelmintic principle in each of these preparations.

When the seed residue, after having been thoroughly extracted with pentane to remove BITC, is re-extracted with water, the resulting extract is still a potent anthelmintic (100 μl of this extract kills >90% of *C. elegans*). This could be explained if one or more of the active principles present is soluble in water and not in pentane, or if a water-soluble precursor of the active principle is converted to the active principle, that is only then soluble in pentane. Since benzyl glucosinolate is water soluble, is known to be present in papaya seeds (Tang, 1973; Bennett et al., 1997) and is a precursor of BITC that, in turn, is soluble in pentane, the latter hypothesis is plausible and could explain why both extractions yield BITC (Table 1).

Myrosinase, an enzyme that catalyzes the conversion of glucosinolates to isothiocyanates (Tang, 1973; Palmieri et al., 1982), was present in water extracts of ground papaya seeds and was found to elute in the void volume of a Sephadex G-50 column, as expected, because of the high molecular weight of myrosinases (Botti et al., 1995). Anthelmintic activity eluted much later from the column and was absent from the void volume (results not shown). The results in Table 2 show that aqueous extracts of seeds ground after heat-treatment of the seed exhibit no apparent nematode killing activity relative to extracts of untreated seeds at the volumes tested. Also, subjecting the extract of heat-treated seeds to a cyclocondensation reaction with benzene dithiol (Zhang et al., 1992) produced an absorption spectrum with no symmetrical peak at 365 nm thus giving no evidence for the presence of BITC (Fig. 2A). However, when extracts from these heat-treated seeds were incubated with an aliquot of the void volume obtained from a Sephadex G-50 column loaded with an extract prepared from fresh seeds, the nematode killing potential of the mixture increased markedly (Table 2). When this preparation was subjected to the cyclocondensation reaction described above, the absorbance spectrum produced (Fig. 2B) is typical of that published for pure isothiocyanates processed in the

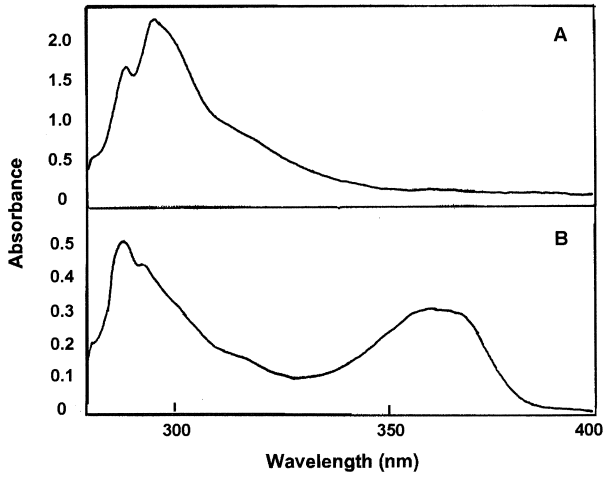

Fig. 2. Absorption spectra of an extract of heat-treated seed before (A) and after (B) incubation of the extract with a VoG50 fraction containing myrosinase activity. For panel B, the sample was incubated for 30 min and diluted eight fold with 10 mM potassium phosphate (pH 6) buffer before measurement.

same fashion (Zhang et al., 1992). No nematode killing activity was found in samples where the fresh seed extract obtained from the void volume of a Sephadex G-50 column was boiled for 10 mm prior to incubation with the heat-treated seed extract (Table 2). In a comparable experiment the LC90 of BITC for the sample subjected to activation conditions was determined to be 20 μM. This LC90 is similar to that listed for all the preparations used in Table 1, again suggesting that BITC is the active nematode killing principle here.

An oil fraction of papaya seed, prepared by Soxhlet extraction with pentane, was applied to a silica column and compounds present were separated by elution from the column with increasingly polar organic solvents. The BITC content and the *C. elegans* killing activity eluted in the same fraction (Table 3). In preliminary experiments, 40–60% of the nematode killing activity eluted in a 90% hexane (H)/10% dichloromethane (DCM) mixture with the balance of the killing activity eluting in a 75% H/25% DCM mixture. The 90% H/10% DCM fraction was examined by GC and found to contain a single prominent peak that upon subsequent examination by mass spectroscopy and infrared spectroscopy, was found to correspond to BITC (analysed by the Center for Mass Spectrometry, McMaster University). The 75% H/25% DCM fraction was examined by TLC, and upon exposure to iodine vapour, was found to contain a number of spots, so no further tests were performed with this fraction (results not shown). In subsequent fractionations, all the BITC and all the anthelmintic activity co-eluted from the column in a mixture of 85% H/15% DCM (Table 3). Despite the presence of other compounds as shown by TLC and a recovery of BITC that was less than 100% of the crude, this fraction yields an LC90 estimate which is similar to that determined for the crude oil from which it was produced and one that lies within the range of values quoted in Table 1.

We noted that the nematode killing power of aqueous extracts of papaya seeds incubated at room temperature for 10 h decreased to 30–50% of a freshly prepared extract (Table 4). Aqueous extracts of papaya seeds were either extracted immediately with diethyl ether or following a 10 h incubation at room temperature. Both diethyl ether extracts were then fractionated on a silica column and the *C. elegans* killing activity and BITC content of each solvent fraction were determined. For both the unincubated and incubated samples, the nematode killing activity and BITC co-eluted in the 85% H/15% DCM fraction (Table 4). In the case of the sample that had first been incubated for 10 h, the BITC content of the 85% H/15% DCM fraction was only half that found in the same fraction of the unincubated

Table 2
Loss of toxicity in aqueous papaya seed extracts due to heat treatment can be restored upon incubation with a protein fraction prepared from fresh papaya seeds[a]

Incubation mixture		Dosage tested in nematode viability test	
Main component[b]	Addition[c]	Volume (μl)	Nematodes killed (%)
Buffer	VoG50[d]	100	0
Extract of heat-treated seed in buffer	Buffer[e]	100	0

sample (Table 4). In separate experiments aliquots of the aqueous extract were incubated for up to 9 h at room temperature before extraction with diethyl ether. The diethyl ether layer was then assayed for anthelmintic activity and BITC content. After six hours of incubation, only 75% of the anthelmintic activity and 70% of BITC remained relative to those measured for the non-incubated sample. After nine hours of incubation, these values decreased to 50 and 39% for anthelmintic activity and BITC level, respectively. Thus, the same conclusion was reached, *C. elegans* killing activity and BITC content decreased with the length of incubation.

In an effort to identify other putative anthelmintic compounds in papaya seed extracts we attempted to obtain carpaine from the papaya seeds following the procedure of Govindachari et al. (1965) but all our attempts were unsuccessful. Seed extracts *of Lepidium sativum* have been found by colorimetric methods to contain BC (benzyl cyanide) and BTC (benzyl thiocyanate) as well as BITC, their proportions varying with extraction conditions (Virtanen, 1962; Saarivirta and Virtanen, 1963, 1965; Gil and MacLeod, 1980). Preparations from *Tropaeolum* and *Sinapsis alba* seeds, on the other hand, contained only BITC (Saarivirta and Virtanen, 1963).

Papaya seeds have not been examined specifically for their content of BTC, BC and benzonitrile (BN). An aqueous preparation of seeds was extracted twice with diethyl ether, the diethyl ether layer was evaporated in vacuuo and the resulting oil resuspended in hexane. This sample, which contained all the anthelmintic activity from the extracted seeds, was applied to a silica column and the anthelmintic activity containing fraction (85% H/15% DCM), was subjected to GC under conditions that separate BITC, BTC and BC (Fig. 3, inset). BITC was found as was an unknown compound tentatively identified as butylated hydroxytoluene (BHT is introduced as the stabilizing additive for the diethyl ether) but no BTC or BC was detected in this preparation (Fig. 3). By an in vitro assay, BITC was more potent as an anthelmintic than BTC and far more potent than BC (Table 5). Taken together, these observations indicate that BTC and BC do not appear to contribute significantly towards the anthelmintic power of papaya seed extracts. A commercial source of benzonitrile (BN) was also examined for its toxicity towards *C. elegans* and was found to have a very high LC90 of >19 mM (Table 5). Also, BN has a retention time of 2.98 min when subjected to the same GC elution conditions as used to separate BITC, BTC and BC (data not shown) and no such peak was noted on the chromatograph shown in Fig. 3.

Therefore, insufficient BN is present in the biologically active fraction for BN to be considered responsible for killing *C. elegans*.

Bennett et al. (1997) reported that leaves and stems of papaya seedlings contained cyanogenic glucosides with the highest concentration found in leaves (extracts showing 8 μM cyanide) but seeds were not tested. We found that the *C. elegans* LC90 for KCN exceeded 100 μM in our killing assay (Table 5) and while cyanide at this concentration caused nematodes to move more slowly relative to the assay without cyanide, they recovered completely within 5 h. The cyanide content of aqueous extracts of papaya seeds was always less than 28 μM even after the extracts had been incubated with β-glucosidase at room temperature for two hours. When these extracts are used in a nematode killing assay, the final concentration of cyanide present in the assay at which 90% of the nematodes are killed is less than 5 μM, a concentration well below the 100 μM KCN found to be non-lethal to nematodes. Processing a papaya seed sample with KCN added to a final concentration of 20 μM yielded a sample whose concentration was equivalent to that of the original sample plus

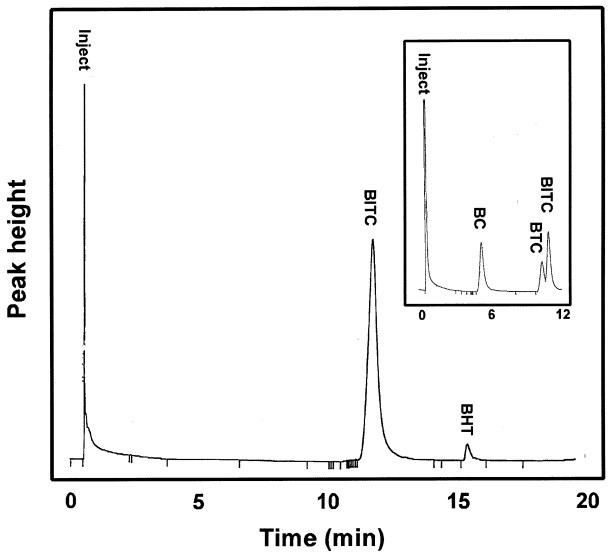

Fig. 3. GC analysis of papaya seed preparations with anthelmintic activity shows that BITC is present but BC and BTC are absent. An aqueous papaya seed extract was extracted with diethyl ether, concentrated and dissolved in hexane and this was fractionated on a silica column. The 85% H/15% DCM fraction containing anthehnintic activity was evaporated to dryness and dissolved in CS_2 for GC analysis (see Experimental). This experiment was performed twice with similar results. The inset shows a GC separation of commercially available BC, BTC and BITC.

Table 5
Toxicity of various compounds to *Caenorhabditis elegans*

Compound[a]	LC90 (μM)
BITC	15–45
Benzyl thiocyanate	200
Benzyl cyanide	5000
BN	>19,000
KCN	>100

[a] Commerically available compounds were dissolved in DMSO. DMSO controls had no negative effect on nematodes.

the added KCN, demonstrating that cyanide was not disappearing from the extract during the extraction procedure. BITC added to extracts and to the cyanide assay mixture did not give rise to cyanide, hence there was no complication from endogenous glucosinolates or BITC. It follows from the above that the cyanide/cyanogenic glucoside contents of the papaya seed extracts do not contribute to their anthelmintic power.

3. Discussion

3.1. BITC is the active compound in papaya seed preparations

Our results show that the anthelmintic activity of papaya seed extracts prepared using water or pentane co-purifies with BITC during column chromatography. Further, re-extraction of aqueous extracts with diethyl ether leads to a complete recovery of both bioactivity and BITC in the diethyl ether fraction. We noted that changes in nematode killing activity of preparations were paralleled by changes in their BITC content. For example, the increase in anthelmintic activity obtained by incubating extracts of heat-treated seeds with a soluble protein fraction containing myrosinase activity is accompanied by an increase in BITC concentration. Also, when extracts are left for 10 h at room temperature, there is a decrease in killing activity of the extract that coincides with a decrease in BITC concentration. Aqueous extracts of papaya seeds do not appear to contain enough cyanogenic glucosides to be toxic to nematodes nor is there any detectable BTC, BC or BN in the fraction containing the anthelmintic activity. Taken together with the previous literature, all these results indicate that the main and perhaps the only effective anthelmintic in the papaya seed preparations we investigated is BITC. This conclusion supports the earlier proposal by Dar et al. (1965), but provides a more thorough investigation of possible candidate bioactive compounds naturally occurring in the papaya seed extract.

3.2. Toxicity of papaya seed preparations

According to our measurements it takes the equivalent of 1.2–2.4 mg of seed to kill >90% of the *C. elegans* in our 500 μl assay within 4–5 h and completely rid the assay mixture of live nematodes within 12 h. Given these in vitro viability results and assuming that the volume of the small intestine of an adult human is approximately 1.3 l (Masoro, 1973), then a dose of 3.1–6.2 g of papaya seeds would be equivalent to that which is effective against *C. elegans* in our assay. However, this dosage is likely to be an underestimate given that it does not consider factors that would reduce the intestinal BITC concentration over time including the movement of contents through the gut [with the residence time of a bolus being very short for the stomach and 3–7 h for the small intestine, (Osterwald, 1990; Fleisher et al., 1999)], and the likelihood that BITC is absorbed by the intestinal epithelium. Our calculated dose approaches the published daily dose recommended for the medicinal use of papaya seeds in Cuba (1–1.5 g three times a day, Roig y Mesa, 1974). If one gives the equivalent of 3.1–6.2 g of seeds to a 55 kg human, this amounts to a dose of 56–112 mg/kg. Despite the speculative nature of this dosage, this value was shown to be non-lethal to mice and rats (Chinoy et al., 1994) and a 5–10-fold lower dose was shown to be effective against *Ascaris* in children (Robinson, 1958).

A consideration relevant to the medicinal use of papaya seeds, is that BITC must be released from benzyl glucosinolate by a papaya myrosinase. It follows that factors that could inhibit myrosinase or inactivate BITC could compromise the concentration of BITC in the small intestine. One such factor might be exposure to acid (pH 2) in the stomach (Magee, 1973). We tested the effect of acid exposure on the potency of papaya seed extracts by deliberately acidifying aqueous seed extracts to pH 2.6 with HCl and then neutralized the extract to pH 6.5 with 2 M Na_2CO_3 either immediately or after one hour. Comparison of the in vitro anthelmintic activity of these acidified and neutralized extracts relative to that of an untreated control seed extract showed that all the preparations were of equivalent potency. An additional consideration that was not evaluated in this study is that there may be variability among papayas with respect to myrosinase or glucosinolate content. Such variation or indeed any factor that could affect BITC content of seed extracts would, in turn, lead to differences in nematode killing potency between preparations.

The BITC content of papaya seeds could be lethal to some beneficial as well as harmful intestinal microorganisms (Emeruna, 1982). Thus while treatment with papaya seeds might eliminate intestinal bacteria, this treatment would not lead to an infection of the intestine by eukaryotic parasites, such as *Candida,* since they would also be killed by the BITC (Stoll and Seebeek, 1948).

In addition to nematode killing activity, BITC appears to elicit several biological effects. BITC inhibits chemically induced carcinogenesis in animal models and cell cultures (reviewed in Wattenberg, 1977; Zhang and Talalay, 1994) but is potentially toxic at therapeutic dosages since it is reported to be goitrogenic, carcinogenic and mutagenic (Yamaguchi, 1980; Fenwick et al., 1983). Thus a concern in any therapeutic application of BITC must address how different are the therapeutic and toxic/lethal doses of the vermifuge.

Fenwick et al. (1983) analysed data that suggests that BITC is goitrogenic and proposed that the goitrogenic effect is probably more associated with iodine deficiency

than to a direct effect of BITC alone. If such is the case, any adverse effects of BITC might be averted by an iodine supplement.

Lohiya et al. (1994) showed that papaya seed extracts administered to male rats for 30–60 days (at a dose equivalent to 67–333 mg/kg/day) can result in temporary but completely reversible sterility. This daily dose is comparable to our speculative dosage (see above), but the comparatively short duration for therapy to kill nematodes in humans should pose no threat in this regard.

Yamaguchi (1980) found that BITC at 50 μM (roughly equivalent to 7.5 mg of papaya seed/l) doubled the spontaneous reversion rate of *Salmonella typhimurium* strain TA100 and that activation by rat liver extract S-9 had no effect on this reversion rate. TA100 is much more sensitive than the wild type strain to mutagens and a petri dish assay is very different from the inside of a mammalian intestine, but the 7.5 mg seed/l is only slightly greater than that used to kill *C. elegans* in our assay (2.4–4.8 mg of seed/l) and could be, therefore, a source of concern. In contrast, at much higher concentrations in experimental animals, BITC seems to act as an anticarcinogen that seems to be due to the antagonistic effect of BITC on the enzymatic activation of mutagens (Wattenberg, 1977; Zhang and Talalay, 1994; Talalay and Zhang, 1996; Fahey et al. 1997). Isothiocyanates, formed from their respective glucosinolates, have been found in a number of different plants (notably in members of the Cruciferae) where they have been shown to have anticarcinogenic properties (Wattenberg, 1977; Zhang and Talalay, 1994; Talalay and Zhang, 1996).

With respect to cyanide/cyanogenic glucosides in papaya seeds, a fatal dose of KCN for humans, according to Merck (1989), is between 1.85 and 2.22 mM and the fatal blood level of CN is reported as 115 μM (Henry, 1979). These levels are obviously well above those found by us in the seeds, let alone the levels expected after dilution by the digestive tract, the bloodstream and inter- plus intrastitial water.

It would appear from the foregoing discussion and from many generations of traditional use of papaya seeds as an anthelmintic that this work, based upon chemical and biological analysis of papaya seed extracts, supports existing practices and provides insight into how they may be improved.

4. Experimental

4.1. Strains and materials

Caenorhabditis elegans strain N2 was obtained from Dr. J. Culotti, Hospital for Sick Children, Toronto, ON, Canada. BITC, 1,2 benzenedithiol, BTC, BC, BN, *N*-chlorosuccinimide, succinimide, pyridine and barbituric acid were from Aldrich. Papaya (*Carica papaya*) was purchased locally.

4.2. Growth and maintenance of C. elegans and toxicity assay

C. elegans was maintained on solid NGM medium (Sulston and Hodgkin, 1988). Between 20 and 50 nematodes were placed in 500 μ1 of S medium (Sulston and Hodgkin, 1988) in microtitre wells (Falcon No 3047, Becton Dickinson) containing 30 μl of a 5 times concentrated overnight culture of *E. coli* WP2 *(uvrA trp malB,* Witkin, 1975) resuspended in S medium. Aliquots (5–100 μl) of aqueous extracts (in water or 10 mM potassium phosphate, pH 6) were added directly to the wells while concentrated oils, fractions in non-aqueous solvents and commercial BITC were diluted with dimethyl sulfoxide (DMSO) prior to being added to the wells as 10 μl volumes. Dilute extracts prepared in non-aqueous solvents were concentrated first by evaporation under N_2, the residue resuspended with 1 ml of hexane, dried with air and the final residue was dissolved in 10 μl of DMSO which was then added to the test wells. Controls with the equivalent volumes of DMSO alone were negative. Nematode survival was measured 4–5 h after addition of the extracts and again 12–13 h later.

4.3. Preparation of seed extracts

Seeds harvested from papaya fruit had their mucilaginous coating removed prior to extract preparation. "Aqueous extracts" were prepared by grinding seeds with a mortar and pestle using distilled water (1 g seeds to 10 ml water), at room temperature and removing the debris by centrifugation at 16,000 *g* at 4°C for 30 min. "Oils" were prepared by grinding seeds in a mortar and pestle, with no added solvent and then adding the ground material to a thimble and extracting by refluxing 10 times in 8 volumes of pentane, in a Soxhlet extractor. The final extract in pentane was concentrated in vacuuo at 38°C. A typical extraction of 14 g of seeds yielded approximately 0.9 ml of crude oil following Soxhlet extraction.

4.4. Fractionation of extracts

Aqueous extracts (10 ml), prepared as described above, were extracted with 10 ml of diethyl ether and the aqueous phase was recovered and re-extracted two more times with 10 ml of diethyl ether each time. The three diethyl ether fractions were pooled and evaporated in vacuuo. The resulting residue was dissolved in 1 ml of hexane and 0.45 ml was loaded onto a 10 g silica (Silica gel, 63–200 μm mesh, BDH) column (23×1.3 cm). Oil prepared from seeds (described above) was also

fractionated by a comparable silica column. In this case, oil (0.45 ml) was loaded without further preparation onto the matrix. For fractionation of either aqueous or oil extracts, samples were eluted from the column at a rate of 0.7 ml min^{-1} with successive 100 ml volumes of 100% hexane, 85% hexane/15% dichloromethane, 100% dichloromethane and 100% methanol. The resulting eluates were evaporated in vacuuo at 42°C and the residues were made to a final volume of 500 μl with hexane and stored at −18°C. Aliquots (10–100 μl) of each fraction were evaporated to dryness, the residue dissolved in 10 μl DMSO which was then used in the nematode killing bioassay to titre the potency of the fraction.

4.5. Activation of heated seed extracts with myrosinase

Seeds (with their mucilaginous coats removed) were either left unheated or were heat-treated by immersing a tube containing seeds in boiling water for 10–20 mm or by autoclaving the seeds at 18 psi for 20 mm. Aqueous extracts were then prepared from the unheated and heat-treated seeds by grinding 1 g seeds with 10 ml of 10 mM potassium phosphate (pH 6) buffer. One milliliter of extract from unheated seeds was loaded onto a Sephadex G-50 column (10 ml bed volume). The fraction eluting in the 3.5 ml void volume (VoG50) contained the myrosinase activity (1.25 μmol sinigrin disappearing min^{-1} ml^{-1}, using the assay of Palmieri et al., 1982). Heat-treated seed extracts (0.5 ml) were incubated with 0.2 ml of the above VoG50 fraction for 30 mm at room temperature and then placed on ice. L-Ascorbic acid was included at a final concentration of 1 mM in the activation incubations. Aliquots of the activated extract were removed and used to measure killing of *C. elegans* as described above (5–100 μl per assay) and measure BITC concentration (10–100 μl for colorimetric determinations or 1–5 μl of 10–50-fold diluted preparation for GC measurements).

4.6. Measurement and detection of compounds

TLC was used as an initial method for determining purity of extracts. Samples were spotted onto silica Gel-G plates, developed in methanol–*n*-butanol–conc. HCl–H_2O (10:10:1:1; v/v/v/v), and plates were then exposed to iodine vapours to visualize organic compounds

Colorimetric measurement of BITC was made following a procedure modified from that described by Zhang et al. (1992). Two aliquots of a sample to be measured were each made to a final volume of 500 μl with 10 mM Tris–HCl (pH 7.5). To one aliquot, 500 μl of 13 mM benzene dithiol in methanol was added while to the second aliquot 500 μl of methanol (control) was added. A blank reaction with buffer and benzene dithiol was also prepared. All of the reactions were incubated at 65°C for 60 min in a microfuge tube and then microfuged for 5 min. Absorbance of the supernatant was taken at 365 nm with a Uvikon 930 spectrophotometer and compared to those of a standard curve prepared using commercial BITC.

For BITC determinations, measurement using GC was found to have greater specificity. GC was performed on a Hewlett Packard 5790A equipped with a flame ionization detector. The column was a Megabore DBI column with a 30 m length, 0.52 mm inner diameter and 0.24 μm film thickness. The carrier gas was H_2 maintained at a flow rate of 12 ml min^{-1}. Injector port and flame ionization detector were set at 250 and 300°C, respectively. Hydrogen and compressed air were delivered to the detector at flow rates of 120 and 300 ml min^{-1}, respectively. Typical injection size was 1–3 μl of sample dissolved in CS_2 or diethyl ether. At injection, the oven temperature was 65°C and was maintained at that temperature for 4 min and then increased at a rate of 5°C per min to a final temperature of 160°C. The output signals from the detector were recorded and integrated with a Shimadzu CR3A Chromatopac Integrator. Calibration using a dilution series of standards with known concentrations was analysed prior to each set of sample measurements. Concentrations were determined by comparing the responses from samples with those of the standards for injections of the same volume. For GC analysis, papaya oil samples were diluted directly in CS_2 or diethyl ether. Aqueous samples were extracted into diethyl ether and either injected directly into the GC or evaporated under N_2 gas, the residue dissolved in CS_2 and then injected as above.

Measurement of cyanogenic glucosides and cyanide followed the procedure of Halkier and Møller (1989). Papaya seeds were ground with 50 mM Mes-NaOH (pH 6.5) and extracts incubated at room temperature with almond β-glucosidase at 1 mg ml^{-1} (Sigma G-0395) for 2 h. Reaction mixtures were adjusted to 0.83 M NaOH and incubated for 1 h to liberate free CN. A 50 μl aliquot of glacial acetic acid was then added to each reaction mixture and the whole mixture was assayed for CN content (Halkier and Møller, 1989). The absorbance of the coloured complex formed was read at 585 and 650 mm and the difference in absorbance values were used to quantify CN levels by comparison to a standard curve prepared with KCN.

Abstract

The phytochemical investigation of the hexane extract of *Iryanthera juruensis* (Myristicaceae) fruits led to the isolation of two tocotrienols and four lignans which exhibited antioxidant activity towards β-carotene on TLC autographic assay. Two inactive quinones and three ω-arylalkanoic acids were also isolated. The isolates were investigated for their redox properties using cyclic voltammetry. The structure elucidation of the new compounds (one tocotrienol, one quinone and three ω-arylalkanoic acids) was based on analysis of spectroscopic data. © 2001 Elsevier Science Ltd. Keywords: *Iryanthera juruensis*; Myristicaceae; Tocotrienol; Plastoquinone; ω-Arylalkanoic acid; Lignan; Antioxidant

1. Introduction

Iryanthera juruensis is a widespread Amazonian species known as ucu-úba, which means fat-producing tree, this being a general designation given to myristicaceous species. Their seeds are valued in Brazil for their high yields of fatty acids, mainly myristic acid (C-14), which is extensively used in pharmaceutical and cosmetic industries. Other *Iryanthera* species were reported to have their crushed leaves used by Amazon indians for healing seriously infected wounds and cuts and to have their latex from the barks mixed with warm water for treating stomache infections (Schultes and Holmstedt, 1971). In the course of our systematic studies on *Iryanthera*, we have demonstrated the presence of tocotrienols with higher antioxidant activity than α-tocopherol in fruits of *I. grandis* and *I. lancifolia,* evaluated through malondialdehyde (MDA) and chemiluminescence (CL) assays (Barros et al., 1993) and of antioxidant dihydrochalcones and flavonolignans in *I. lancifolia* (Silva et al., 1999). Studies on tocotrienol biological activities revealed the ability of α- and γ-tocotrienol in inhibiting solid tumour growth of sarcoma 180 and also the highly metastic Lewis lung carcinoma cells (Komiyama et al., 1992). Moreover, these tocotrienols are effective against vascular smooth muscle cell proliferation, which plays a central role in atherosclerosis (Azzi et al., 1992). Oxidative damage to cell components is the initial event in several human disease processes including cancer and atherosclerosis (Gordon, 1996), and this has intensified the search for natural antioxidants. The antioxidant activity of a compound depends ultimately on its ease of oxidation and, for a variety of natural or synthetic compounds, good correlations have been observed between antioxidant activities and low oxidation potentials (Born et al., 1996). In this work we report on the isolation of antioxidant compounds of *I. juruensis* fruits guided by the β-carotene TLC assay (Pratt and Miller, 1984) and the evaluation of their oxidation potentials through cyclic voltammetry. Further examination of the lipophyllic constituents led to isolation of inactive compounds, which were also investigated electrochemically.

2. Results and discussion

Dried and powdered fruits were extracted with hexane. Fractionation of the crude extract guided by the antioxidant TLC assay afforded **1**, **2** and **6**–**9**. In addition, inactive metabolites **3**, **4** and **5a**–**c** were isolated (see Experimental).

The structural determination of compounds **1** and **2** was based on analysis of their NMR and MS spectra as well as on comparison with literature data for similar

PII: S0031-9422(00)00477-5

compounds (Vieira et al., 1983a). The ^{1}H NMR spectra of compounds **1** and **2** showed two doublets at δ 5.47±0.02 (*d*, J = 9.7±0.1 Hz) and δ 6.17±0.02 (*d*, J = 9.7±0.1 Hz) assigned to H-3 and H-4, respectively, typical of the chromene ring of C-3 unsaturated tocotrienols, which had only been found previously in brown seaweeds from genera *Sargassum* and *Stypopodium* (Kusumi et al., 1979; Gerwick and Fenical, 1981). The other spectral features are similar to those of C-3 saturated tocotrienols; therefore, ^{1}H and ^{13}C NMR data could be assigned by comparison with δ-tocotrienol and 17-carboxy-δ-tocotrienol, previously isolated from pericarps of *I. lancifolia* and fruits of *I. grandis* (Vieira et al., 1983b; Lopes et al., 1998). Tocotrienol **2** was identified as sargachromenol, originally isolated from *Sargassum serratifolium* (Kusumi et al., 1979). The new tocotrienol **1** differs from **2** by one additional methyl group on the chromene ring (C-7); its only aromatic proton was placed at C-5 after observation of NOE interactions between H-5 and H-4. Further NOE observations, COSY and DEPT as well as ESMS data led to elucidation of **1** as 2,7,8-trimethyl-2-[(*3E,7Z*)-4,12-dimethyl-8-carboxyl-3,7,11-tridecatrienyl]-3-chromen-6-ol for which we propose the name 7-methyl-sargachromenol.

The ^{13}C NMR spectra of **3** and **4** showed two signals at δ 187.7 ± 0.2 and δ 187.9 ± 0.1 for two ketone groups conjugated to sp^2 carbons, which were assigned, respectively, to C-1 and C-4 of the quinone ring. DEPT 135° experiments indicated the presence of six methyl groups in compound **3** and five methyl groups in **4**. The ^{1}H NMR spectra of **3** and **4** showed one doublet at δ 3.05 (J = 7.1 Hz) integrating for two hydrogens on a sp^3 carbon linked to two sp^2 carbons. The ^{1}H–^{1}H NMR spectrum showed the correlation of this signal with the multiplet centered at δ 5 and the signal at δ 6.39, assigned to H-2′ and H-3, respectively, and confirms the placement of the only quinone ring hydrogen of compound **3** on C-3. The additional methyl group of compound **3** was then placed at C-5. The remaining spectral data were consistent with the proposed structures, including the placement of a carboxyl group on the isoprenic chain, determined through MS data (Fig. 1). The structure of this new quinone, named as 3-methyl-sargaquinoic acid, was established as 2,3-dimethyl-6-[(2*E*,6*E*,10*Z*)-3,7,15-trimethyl-11-carboxyl-2,6,10,14-hexadecatetraenyl]-2,5-cyclohexadiene-1,4-dione. Compound **4**, which was identified as sargaquinoic acid after comparison of its NMR spectrum and MS profile with literature data, was originally isolated from the brown algae *Sargassum serratifolium* (Kusumi et al., 1979) and differs from **3** only concerning the quinone ring substitution pattern. The new compounds **1** and **3** follow the γ-tocotrienol pattern, while the known **2** and **4** follow the δ-tocotrienol substitution pattern.

Compounds **5a–c** were identified as ω-arylalkanoic acids based on a broad singlet at δ 1.18 of a methylene chain and the absence of a terminal methyl group, (ca. δ 0.8, *t*) in the ^{1}H NMR spectrum, associated to the signal at δ 179.4 on the ^{13}C NMR spectrum and the presence of an aromatic ring. The substitution pattern of this ring, linked to the methylene chain, was defined through observation of two doublets at δ 6.61 (J = 1.6 Hz) and δ 6.66 (J = 7.7 Hz) and one doublet of doublets at δ 6.55 (J = 1.6 and 7.7 Hz) in the ^{1}H NMR spectrum. The presence of a methylenedioxy group was inferred through observation of signals at δ 5.85 and δ 100.6 in the ^{1}H and ^{13}C NMR spectra, respectively. The LC–UV–MS analysis of the mixture of **5a–c** evidenced the presence of three substances (R_T 15.0, 16.1 and 17.1 min.), which absorbed at λ_{max} 284 nm. The ESMS analysis indicated a molecular weight of 362, 390 and 418 for compounds **5a–c**, inferred from base peaks at m/z 385, 413 and 441 ($[M+Na]^+$), respectively. The on-line analysis showed additional peaks at 363, 391 and 419 ($[M+1]^+$) which confirmed the length of the methylene chains of these compounds. The ω-arylalkanoic acids **5a–c** result biogenetically from condensation of substituted dihydrocinnamic acid and lauric, myristic and palmitic acids, respectively. As these ω-arylalkanoic acids proved to be new natural products, their isolation was subsequently undertaken. Their EIMS spectra showed base

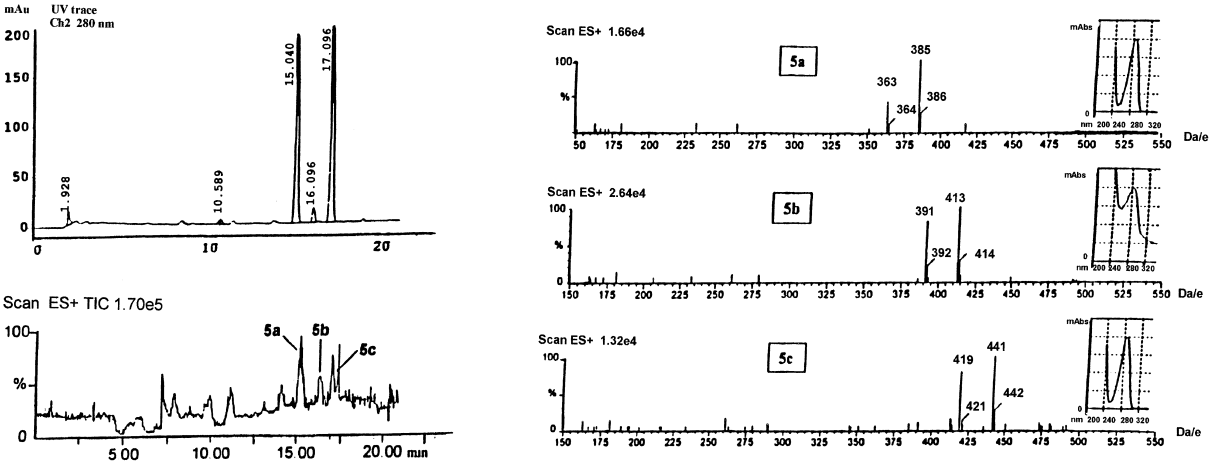

Fig. 1. LC/UV/ESMS analysis of fraction 5 from hexane extract of *Iryanthera grandis* fruits, containing ω-arylalkanoic acids **5a**–**c**.

peaks at m/z 135 $[C_7H_5.CH_2O_2]^+$, which confirmed the proposed structures for these compounds. These ω-arylalkanoic acids had not been isolated from natural sources yet and are probably the biosynthetic precursors of juruenolides, ω-arylalkanoic acids condensed with pyruvic acid followed by γ-lactonization, found in the trunk wood of *Iryanthera juruensis* (Vieira et al., 1983b) and pericarps of *Virola surinamensis* (Lopes et al., 1998).

Lignans **6**–**9** were identified as *epi*-guaiacin, guaiacin, verrucosin and nectandrin B, respectively, from their spectroscopic data and comparison with literature (Majunder et al., 1972; Gottlieb et al., 1976; Joshi et al., 1979; Moro et al., 1987; Ward, 1997).

Antioxidative properties of compounds **1**–**9** were evaluated against β-carotene (Pratt and Miller, 1984). By using β-carotene as a TLC spray reagent, tocotrienols **1** and **2** and lignans **6**–**9** (10 μg) appeared as yellow spots against a white background, meaning these compounds inhibited the bleaching of β-carotene. The same amounts of quinones **3** and **4** and ω-arylalkanoic acids **5a**–**c** were completely inactive.

The evaluation of the redox properties of tocotrienols **1** and **2** was carried out electrochemically in order to compare their voltammetric behaviour and to correlate the corresponding oxidation potentials with antioxidant properties of these compounds (Born et al., 1996). Firstly, the electrochemical behaviour was investigated with α-tocopherol being used as reference compound. In addition, taking into consideration that oxidation products of tocopherols and tocotrienols can be electrochemically reduced, the reduction of the oxidized products of tocotrienols **1** and **2**, previously generated on the electrode surface after oxidation step were also studied and compared to the voltammetric behaviour of plastoquinones **3** and **4**. The cyclic voltammograms of α-tocopherol and tocotrienols **1** and **2** showed oxidation peaks at +0.28, +0.23 and +0.32 V (Table 1) respectively, suggesting a higher antioxidant capacity for tocotrienol **1**, when compared to α-tocopherol. The comparison among oxidation potentials of tocotrienols **1** and **2** and α-tocopherol shows that **1** is the most easily oxidizable compound. Alkyl groups *meta* to the aromatic hydroxyl have little effect on the oxidation ability of phenolic compounds, but inductive effects from either *ortho* or *para* alkyl groups may lower the oxidation potential and make the molecule even easier oxidized than the phenol itself (Marcus and Hawley, 1970). This could explain the lower oxidation potential of **1** when compared to **2**, as they possess the aromatic substitution pattern of γ- and δ-tocotrienol, respectively. The lower oxidation potential of **1** when compared to α-tocopherol might be due to its C-3 double bond, which is conjugated with the aromatic ring and stabilizes the intermediate cation previous to completion of oxidation steps.

The structure–activity relationship indicates, in this case, that the stabilizing effect of the C-3 double bond on the intermediate cation due to the presence of one aromatic methyl group *ortho* to the hydroxyl (e.g. compound

[a] Reduction potentials of the oxidized products of α-tocopherol and tocotrienols **1** and **2**, generated on the electrode surface.

1) overcomes, although slightly, the stabilizing effect of two aromatic methyl groups *ortho* to the hydroxyl, if the C-3 double bond is absent (e.g. α-tocopherol). The contribution of this double bond is, however, not enough to keep up the intermediate cation stability if no methyl group *ortho* to the hydroxyl group is present in the molecule, as in compound **2**. The electrochemical behaviour of quinones **3** and **4** was compared to those of the oxidized products of tocotrienols **1** and **2**, respectively. The great similarity observed for the reduction potentials of these oxidation products and tocotrienols **1** and **2** suggests that the products generated after oxidation of tocotrienols **1** and **2** are structurally closely related to quinones **3** and **4**, respectively.

The high oxidation potential of the ω-arylalkanoic acids **5a**–**c** is probably a result of the lack of aromatic hydroxyl groups in these molecules. The absence of oxidation peak in the cyclic voltammograms of **3** and **4** as well as the high value (+1.52) for **5a**–**c** are in agreement with the inactivity observed on the β-carotene assay for these compounds.

The cyclic voltammograms of lignans **6**–**9** showed oxidation potentials in the range 0.8–0.9 V, suggesting that they should act as rather less effective antioxidants than tocotrienols **1** and **2**. The structure–activity correlations of these results can not be promptly inferred, as electron donor groups *ortho* to a hydroxyl should enhance the stabilization capacity of the molecule after hydrogen radical loss (Rice-Evans et al., 1996). The lower oxidation potential of tocotrienols might nonetheless be explained by the stabilization of the molecule conferred by the C-3 double bond conjugated with the aromatic ring, which might enhance the ease of oxidation of tocotrienols more efficiently than the methoxyl group *ortho* to the hydroxyl group in lignans **6**–**9**. Nevertheless, the qualitative analyses of the antioxidative properties of tocotrienols **1**, **2** and lignans **6**–**9** through the β-carotene assay showed all these compounds were active, as previously referred.

3. Experimental

3.1. General experimental procedures

The UV and IR spectra were recorded on a Perkin-Elmer Lambda 3B and a Perkin-Elmer FT-IR 1750 spectrophotometer, respectively. NMR spectra (^1H, ^{13}C, COSY and NOE experiments) were measured on a Brüker DPX-300 spectrometer (300 MHz for ^1H and 75 MHz for ^{13}C) in $CDCl_3$ for all compounds; the chemical shifts are reported in ppm with TMS as internal standard, and coupling constants (*J*) are given in Hz. EIMS spectra were measured at 70 eV on a HP 5988-A. Elemental analyses were performed on a Perkin-Elmer CHN Elemental Analyzer 2400.

3.2. Plant material

Fruits were collected in Reserva do Mocambo, in the Amazon Forest, in the rainy season and identified as *Iryanthera juruensis* Warburg by Botanist Nelson Rosa. A voucher specimen was deposited at the Herbarium João Murça Pires at Museu Paraense Emílio Goeldi.

3.3. Extraction and isolation

The dried fruits were grounded and extracted with hexane. The extract was dried under reduced pressure and partitioned between hexane and 90% methanol. The hydroalcoholic fraction (7.6 g) was submitted to vacuum column chromatography over silica gel, which was eluted with hexane/EtOAc mixtures of increasing polarity to yielded 8 fractions (A–H). Flash column chromatography over silica gel of fraction B eluted with gradient of hexane/EtOAc afforded **2** (31 mg), **4** (53 mg) and other 13 pooled fractions. Purification of fractions B-5 and B-11 through prep. TLC (hexane/EtOAc 8:2) gave **3** (15 mg) and **1** (12 mg), respectively. Purification of fraction B-8 through prep. TLC (hexane/EtOAc 8:2) gave the mixture of the ω-arylalkanoic acids **5a**–**c**, which was further purified by HPLC (RP-18, MeOH/H_2O 85:15) to afford **5a** (5 mg) and **5c** (6 mg). Compound **5b** was not isolated as the HPLC analysis indicated it was a minor compound (~ 5% of the mixture of **5a**–**c**). Flash column chromatography over silica gel of fraction E eluted with a gradient of hexane/EtOAc gave 6 pooled fractions (A′–F′). Purification of fraction C′ through prep. TLC (hexane/EtOAc 1:1) and HPLC (RP-18, MeOH/H_2O 86:14) gave **6** (8 mg). Partial dissolution of fraction D′ in $CHCl_3$ gave a precipitate which was further washed with MeOH to give **7** (60 mg). Purification of fraction E′ through prep. TLC ($CHCl_3$/MeOH 95:5) and HPLC (RP-18, MeOH/H_2O 78:22) gave **8** (6 mg) and **9** (4 mg).

3.4. LC/UV/MS

The separation of compounds **5a**–**c** was achieved by using MeOH:H_2O in the isocratic mode (85:15, 1 ml/min.). UV spectra were recorded from 200 to 400 nm. For MS, the temperature of the electrospray (ES) source block was set to 75°C. The cone voltage was 70 V and ionization was achieved in the positive mode at an ionization voltage of 4.5 kV. Nitrogen was used as a nebulizing and curtain gas. Nebulizer gas was set to 0.5 l/min, curtain gas to 5.0 l/min. Full-scan spectra from *m*/*z* 150 to 550 were recorded every 1.2 s.

3.5. 2,7,8-Trimethyl-2-[(3E,7Z)-4,12-dimethyl-8-carboxyl-3,7,11-tridecatrienyl]-3-chromen-6-ol (1)

Brown oil. Found: C, 76.62; H, 8.76. $C_{28}H_{38}O_4$ requires: C, 76.71; H, 8.68%. UV λ_{max}^{MeOH} nm (ε): 326 (3800). IR

ν_{max}^{film} cm^{-1}: 3408, 2923, 1686, 1634. ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.27 (3H, *s*, H-7), 1.50 (6H, *s*, H-14′, H-16′), 1.59 (3H, *s*, H-13′), 1.9–2.2 (8H, *m*, H-1′, H-2′, H-5′, H-10′), 2.04 (3H, *s*, H-2), 2.05 (3H, *s*, H-8), 2.2–2.3 (2H, *m*, H-9′), 2.50 (2H, *dd*, J = 14.4, 7.3 Hz, H6′), 5.45 (1H, *d*, J = 9.6 Hz, H-3), 6.14 (1H, *d*, J = 9.6 Hz, H-4), 6.22 (1H, *s*, H-5); ^{13}C NMR (75 MHz, $CDCl_3$): δ 11.5 (*q*, Me-8), 11.9 (*q*, Me-7), 15.7 (*q*, C-16′),17.5 (*q*, C-14′), 22.6 (*t*, C-2′), 25.4 (*q*, Me-2), 25.8 (*q*, C-13′), 27.8 (*t*, C-6′), 28.1 (*t*, C-10′), 34.4 (*t*, C-1′), 39.0 (*t*, C-5′), 40.9 (*t*, C-9′), 77.7 (*s*, C-2), 109.9 (*d*, C-5), 118.7 (*s*, C-4a), 122.8 (*d*, C-4), 123.5 (*d*, C-3′), 123.6 (*s*, C-8), 125.1 (*d*, C-11′), 125.1 (*s*, C-7), 129.6 (*d*, C-3), 130.6 (*s*, C-12′), 132.1 (*s*, C-4′), 134.2 (*s*, C-8′), 144.7 (*s*, C-8a), 144.8 (*d*, C-7′), 146.9 (*s*, C-6), 171.6 (*s*, C-15′). 3.10. Bleaching experiment on β-carotene

The test was carried out on TLC plates. After developing and drying, plates were sprayed with a 0.02% solution of β-carotene (Aldrich) in CH_2Cl_2. Plates were

placed under natural light until discoloration of background. The yellow spots remaining indicated the presence of antioxidant substances.

3.11. Electrochemical assay

The cyclic voltammograms were carried out with a Polarecord E-506 (Metrohm) potentiostat. A three electrode system (663 VA, Metrohm) with a working electrode of glassy carbon (GC), a Ag/AgCl reference electrode and a carbon auxiliary electrode was used. Dichoromethane (Merck) was used as solvent and tetra-*n*-butyl ammonium tetrafluorborate (Merck), as the supporting electrolyte. Vitamin E (Aldrich) was used as reference compound. The working electrode was polished with aluminium oxide 0.3 μm (Buehler) and special polishing cloth (Buehler) prior to each measurement, because formation of a polymeric film inactivated the electrode after each scan. The electrode was then washed thoroughly with water, dried and cycled several times in the range −1.6 to +0.6 V in order to reassure the absence of voltammetric signal due to the supporting electrolyte. Each compound was dissolved to concentrations of 10–20 mM in dichloromethane and added to a 15 ml aliquot of the supporting electrolyte. The solns. were then deoxygenated with nitrogen for 10 min. and the cyclic voltammograms were carried out at scan rate of 50 mV/s.

Received 13 December 2000; received in revised form 8 February 2001

Abstract

The essential oils of mosses of the genera *Mnium, Plagiomnium*, *Homalia, Plagiothecium* and *Taxiphyllum* (Musci) have been investigated by gas chromatography and mass spectrometry. The new sesquiterpenes (+)-10-*epi*-muurola-4,11-diene and 10,11-dihydro-α-cuparenone were isolated by preparative gas chromatography and identified as major constituents of the hydrodistillation products of *Mnium hornum* (Hedw.) using NMR and mass spectrometry. In addition, (+)-dauca-8,11-diene and two new butenolides, 3,4,5-trimethyl-5-pentyl-5*H*-furan-2-one and 3,4-dimethyl-5-pentyl-5*H*-furan-2-one were identified as constituents in *Plagiomnium undulatum* (Hedw.) T. Kop. Although the amounts of volatiles present in the investigated mosses are generally smaller than in liverworts, the spectrum of terpenoid compounds is similar. The investigated mosses also generate aliphatic compounds of greater abundance and structural variety. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Mnium hornum*; *Plagiomnium undulatum*; Musci; Terpenoid compounds; Butenolides; Sesquiterpene hydrocarbons; 10-*epi*-Muurola-4, 11-diene; Dauca-8, 11-diene; 10, 11-Dihydro-α-cuparenone

1. Introduction

The chemistry of liverworts (Hepaticae) has been subject to intensive investigations over the last decades mainly because of the abundance of terpenoid and aromatic compounds in this plant family (Asakawa, 1995; Mues, 2000). Much less interest was devoted to the mosses (Musci) which are represented by approximately 10,000 species worldwide and which differ by the lack of oil bodies which are common in the cells of most liverworts. On the contrary, most review articles on the chemistry of bryophytes (Huneck, 1983; Zinsmeister et al., 1991; Asakawa, 1995; Mues, 2000) emphasized the absence or only scattered occurrence of terpenoid compounds, particularly of sesquiterpenes, in mosses. The first proof of the presence of a sesquiterpene hydrocarbon, *ent*-β-cedrene, together with a diterpene alcohol, dolabella-3,7-dien-18-ol, in a Japanese moss was reported by Toyota et al. (1998). After submission of this paper we became aware of a recent publication (Suire et al., 2000) reporting on the chemical constituents of 13 moss species, including some of the *Mnium* and *Plagiomnium* family. Among other compounds the occurrence of several sesquiterpenes and higher terpenoid constituents was described. A kaurane type diterpene alcohol was identified in *Saelania glaucescens* (Nilsson and Mårtensson, 1971).

Led by the observation that some mosses generate a distinct, sometimes pleasant, odour in the fresh state we have collected the volatile constituents of mosses by hydrodistillation of fresh or air-dried plant material and analyzed them by gas chromatography–mass spectrometry (GC–MS) and by comparison of the mass spectra and retention indices with a spectral library which was established under standardized experimental conditions (Joulain and König, 1998). Some unknown compounds were isolated by preparative GC and investigated by 1- and 2-dimensional NMR techniques. In some cases absolute configurations were determined by chemical correlations with known compounds and by enantioselective GC with cyclodextrin stationary phases. Although numerous mosses were investigated, only the results of a few selected

species are discussed in this report on the terpenoid chemistry of Musci.

2. Results and discussion

The plant material was collected at different locations in Europe all over the year. No large variations in the pattern of constituents according to seasonal or local changes were observed. Before hydrodistillation the plant material was carefully inspected for contaminations. Conifer needles, other plant material and soil were completely removed. The possibility of contamination was also reduced by investigating the same plant growing in different locations and plant communities. The volatiles of most mosses were abundant in aliphatic and aromatic aldehydes (*n*-heptanal, *n*-nonanal, *E,E*-2,4-decadienal, benzaldehyde, phenylacetaldehyde), aliphatic alcohols (*n*-octanol, 1-octen-3-ol, etc.) and acids (C-12–C-18, saturated, mono- and di-unsaturated, arachidonic acid). It can be assumed that *E,E*-2,4-decadienal is a metabolite formed by oxidation of linolic acid (Spiteller and Spiteller, 2000), an abundant constituent in many of the investigated mosses. Another aliphatic compound, heneicosa-6,9,12,15-tetraene, which was described as a constituent of the moss *Polytrichum commune* before (Karunen, 1974), was also present in most samples. In addition, a great variety of terpenoid compounds was detected. Some of them could be readily identified by their characteristic mass spectra and seem to be almost ubiquitous in mosses such as β-cyclocitral (**1**), α- (**2**) and β-ionone (**3**) and geosmin (**4**) (Fig. 1). **1** was before reported as a constituent of the genus *Microcystis* (Cyanobacteria) (Jüttner, 1976), while **4** was observed in the cyanobacteria *Symploca muscorum* (Safferman et al., 1967) and *Oscillatoria tenuis* (Medsker et al., 1968). Very common constituents of the essential oils of musci are furthermore the monoterpene hydrocarbons α- and β-pinene, camphene, sabinene, myrcene, limonene, *p*-cymene, α-terpinene and γ-terpinene as well as camphor, borneol, bornylacetate, terpinen-4-ol, α-terpineol and α-terpinylacetate. Occasionally also Δ-3-carene (in *Plagiomnium undulatum* and *Plagiothecium undulatum*), *trans*-pinocarveol (in *Homalia trichomanoides*), pinocarvone (in *Plagiomnium undulatum*), myrtenal and carvone (in *Plagiothecium undulatum*) and myrtenol (in *H. trichomanoides*) were detected.

Surprising was the high abundance and variability of sesquiterpene hydrocarbons, which could be identified by comparison of their mass spectra and retention indices with a data bank (Joulain and König, 1998). Particularly β-barbatene (**5**) is a common constituent of mosses and was found in all investigated species. Table 1 lists the identified compounds in mosses. Many of these compounds have also been found previously as constituents of liverworts. Thus, 4,8a-dimethyl-1,2,3,4,6,7,8,8a-octalin (**6**) (Wu et al., 1991; Rieck et al., 1995), (+)-(4*S*,4a*S*,5*R*,8a*S*)-4a,5-epoxydecalin (**7**) (Rieck et al., 1995), 10,11-dihydro-α-cuparenone (**8**) (Mekem Sonwa et al., in preparation) and α-cuparenone (**9**) (Benesova, 1976), found before in *Lophocolea bidentata*, were now identified in *Plagiothecium undulatum* and *M. hornum,* respectively. A sesquiterpene, peculiaroxide (**10**), which was earlier identified in the Taiwanese liverwort *Plagiochila peculiaris* (Wu et al., 1993), was detected in *H. trichomanoides*. In the same species the sesquiterpene hydrocarbons pentalenene (**11**) and maali-1,3-diene (**12**), which were earlier found as constituents of the liverworts *Porella obtusata* (Joulain and König, 1998; Fricke, 1999) and *Calypogeia muelleriana*, respectively (Warmers et al., 1999), and the sesquiterpene spirolactone fukinanolide (bakkenolide A) (**13**), earlier identified as a constituent of *Petasites japonicus* (Abe and Onoda, 1968) and *P. albus* (Brunke et al., 1992), were identified. Remarkable is also the occurrence of maalin-5-ol (**14**) in *Mnium marginatum* and *M. stellare*, which was already identified as a constituent of *Plagiochila ovalifolia* (Matsuo et al., 1979), and mintsulfide (**15**) (Yoshida et al., 1979) in *M. marginatum*. As also shown in Table 1, the sesquiterpene alcohols α-cadinol and T-cadinol are common, while diterpenes as 16-kaurene, rosa-5,15-diene, 8(14), 15-isopimaradiene and manool were occasionally present in the investigated species.

Some mosses predominantly generate one specific sesquiterpene hydrocarbon. This is apparent in *M. hornum*, which produces relatively large amounts of (+)-10-*epi*-muurola-4,11-diene (**16**) (Fig. 2). The epimer (−)-muurola-4,11-diene (**17**) was recently described as a constituent of the essential oil of *Amyris balsamifera* (König et al., 1999). The NMR data of both compounds are listed in Table 2. (−)-β-Caryophyllene is a major constituent of *Mnium spinulosum* and (+)-dauca-8,11-diene (**18**) is the main constituent of the essential oil of *Plagiomnium undulatum* (Fig. 3). (−)-Amorpha-4,11-diene (**19**), which was found before as a constituent of *Viguiera oblongifolia* (erroneously named cadina-4,11-diene) (Bohlmann et al., 1984) and *Artemisia annua*, where it functions as an intermediate in artemisinin biosynthesis (Bouwmeester et al., 1999) and the unusual (−)-enantiomer of β-cedrene are also present in *Plagiomnium undulatum* as minor constituents. All these identifications are based on comparisons of mass spectra (Joulain and König, 1998) in connection with retention indices on different polysiloxane and cyclodextrin derived chiral stationary phases with reference compounds of known absolute configuration and, in the case of new compounds, by NMR investigations after micro-preparative isolation.

Finally, the structures of two new butenolides, 3,4,5-trimethyl-5-pentyl-5*H*-furan-2-one (**22**) and 3,4-dimethyl-5-pentyl-5*H*-furan-2-one (**23**), could be elaborated by mass spectrometric and NMR spectroscopic investigations.

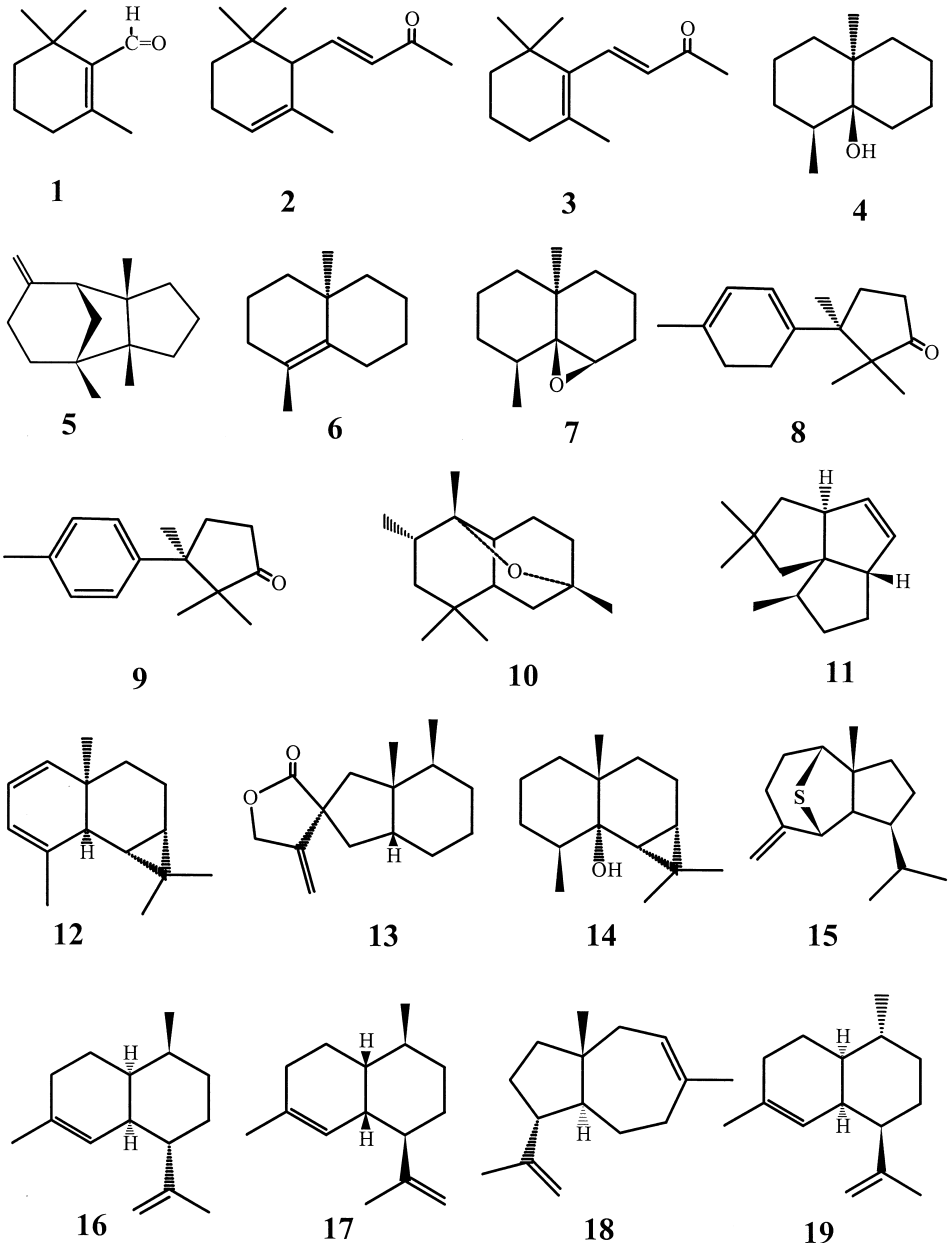

Fig. 1. Structures identified as constituents of mosses.

Hydrocarbon **16**, the main sesquiterpene constituent of *M. hornum*, was isolated by preparative GC and gave a molecular ion signal at *m/z* 204 corresponding to the elemental composition of $C_{15}H_{24}$. It is not distinguishable from muurola-4,11-diene (**17**) by capillary gas chromatography on several polysiloxane and cyclodextrin derived chiral stationary phases with only one exception [octakis(2,6-di-*O*-methyl-3-*O*-pentyl)-β-cyclodextrin]. Moreover, the mass spectra are absolutely identical. In this case the epimers **16** and **17** could only be discriminated by NMR.

The ^{13}C NMR spectrum (Table 2) showed signals of 15 carbon atoms, four of which absorbed in the olefinic region at δ 148.6, 133.2, 126.0 and 110.9 corresponding to two double bonds and a bicyclic structure. Inspection of the ^{1}H NMR data (Table 2) confirmed the presence of an exocyclic olefinic methylene group by a broad singlet at δ 4.87 and a multiplet at δ 4.86, corresponding to 2 protons. One additional olefinic proton absorbs at δ 5.57. In the absorption range of methyl groups 2 singlets are found at δ 1.63 and 1.69 indicating bonding of the methyl groups to olefinic double bonds. An additional methyl doublet is found at δ 0.91. From the DEPT spectrum the presence of 3 primary, 5 secondary, 5 tertiary and 2 quaternary carbons can be concluded. The ^{1}H- and ^{13}C data of **16** and **17** show only small differences (Table 2). More detailed structural information with respect to coupling correlations can be derived from the

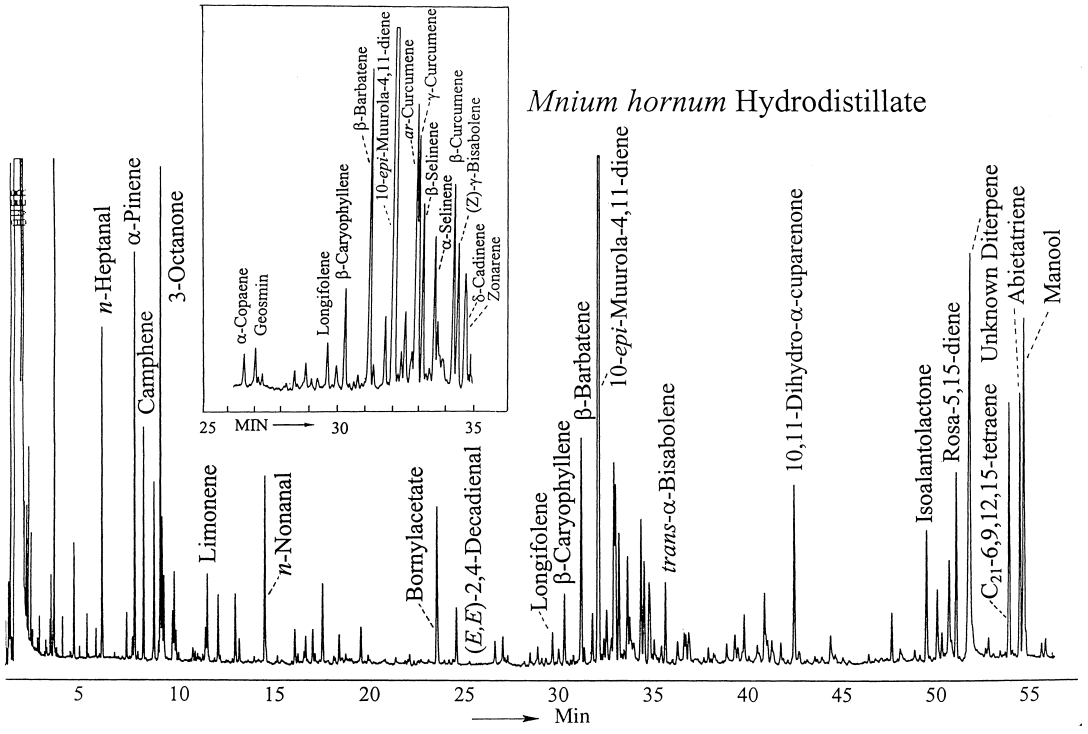

Fig. 2. Gas chromatogram of the hydrodistillate of *Mnium hornum*. 25 m Fused silica capillary column, CPSil 5, column temp. 50°C, temp. progr. 3°C/min to 230°C.

two-dimensional NMR spectra. ^1H–^{13}C-COSY, HMQC and ^1H–^1H-COSY allow the assignment of partial structures A, B and C (Fig. 4). Information about the connection of the partial structures is obtained from the HMBC correlations as shown in Fig. 5. With all these informations a bicyclic sesquiterpene of the type 1,2,3,4,4a,5,6,8a-octahydro-4,7-dimethyl-1-(methylethenyl)-naphthalin (D in Fig. 4) can be derived. The relative configuration, particularly the presence of a *cis*-fused ring system of **16**, was derived from a NOESY spectrum. NOE correlations were observed between the C-14 methyl protons and the protons at C-1 and C-6 (Fig. 5). The absolute configuration was deduced by a chemical correlation with both enantiomers of γ-muurolene with an excess of the (−)-enantiomer (Fig. 6) after partial hydrogenation of the exocyclic double bonds of the γ-muurolene enantiomers and **16**, in correspondence to a published procedure (König et al., 1999).

The molecular formula of 10,11-dihydro-α-cuparenone (**8**) was calculated as $C_{15}H_{22}O$ by mass spectrometry

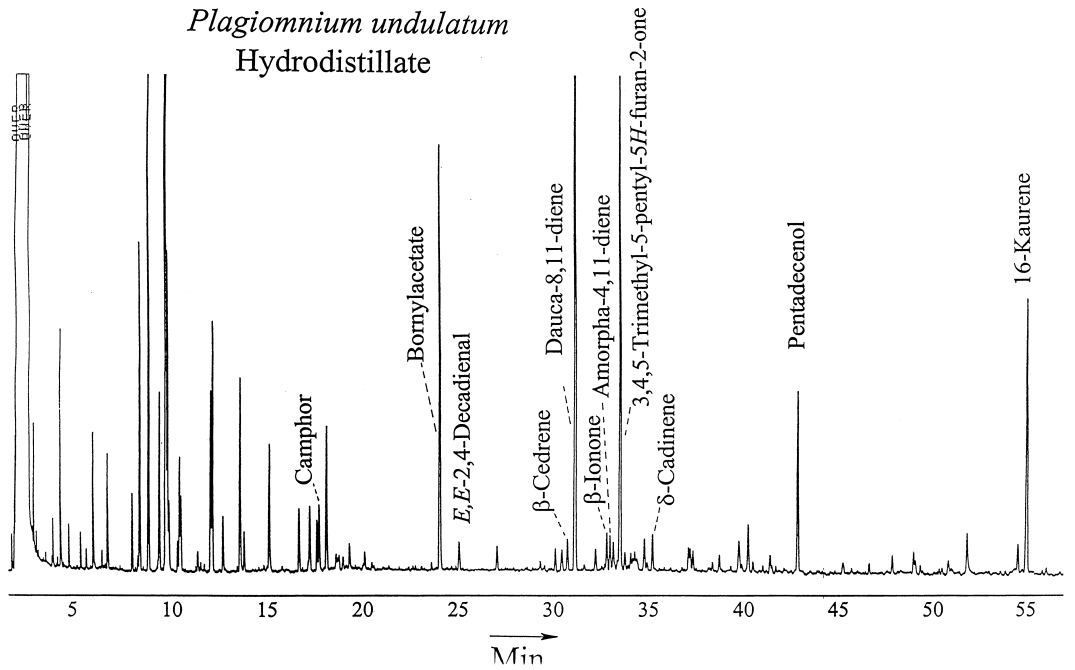

Fig. 3. Gas chromatogram of the hydrodistillate of *Plagiomnium undulatum*. 25 m Fused silica capillary column, CPSil 5, column temp. 50°C, temp. progr. 3°C/min to 230°C.

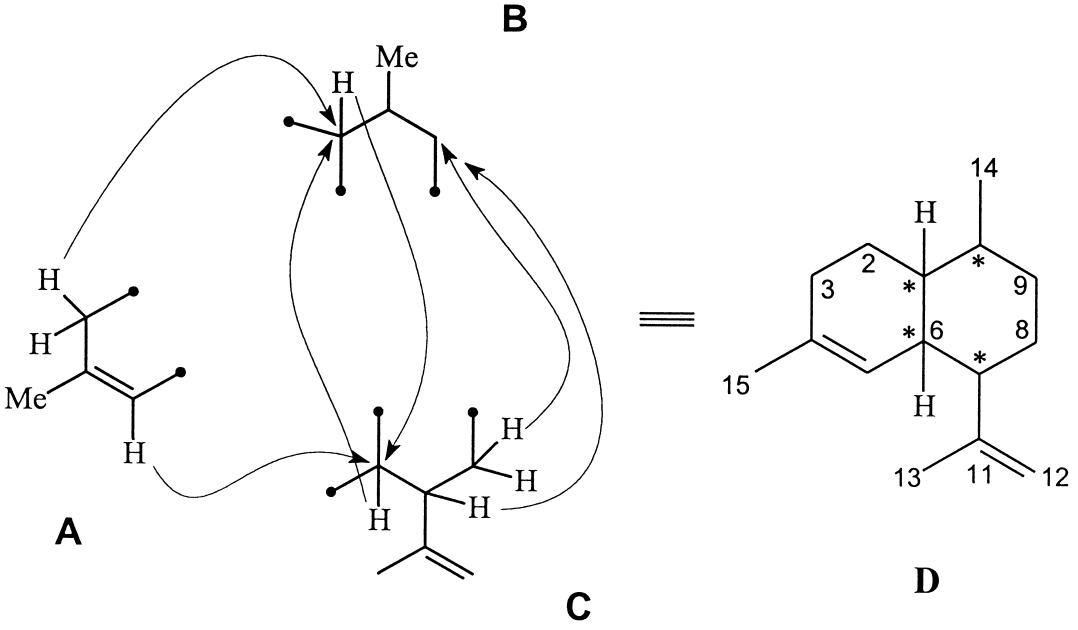

Fig. 4. Partial structures and HMBC correlations for 10-*epi*-muurola-4,11-diene (**16**).

([M]$^+$ = 218). The ^{13}C NMR and DEPT spectra of the compound showed 15 carbon atoms with four methyl groups, two methylene groups, two olefinic methine carbons, four quaternary carbon atoms, two being olefinic, and one carbonyl carbon. The two methyl groups CH_3-14 (δ 0.72) and CH_3-15 (δ 1.07) show strong coupling correlations to each other in the ^{1}H–^{1}H COSY spectrum which are indicative of geminal methyl groups. This assumption is confirmed by the HMBC diagram of the compound: protons of the methyl group CH_3-14 show long-range correlation to the quaternary carbons C-1 and C-5, the carbonyl carbon C-2 and carbon C-15 while the protons of the methyl group CH_3-15 show connectivities to the carbons C-1, C-5, C-2 and C-14 leading to the partial structure C–C$(CH_3)_2$–CO–. The methyl group CH_3-13 (δ 0.75) has a long-range coupling correlation (W coupling) with the proton $H_{8\alpha}$ (δ 1.86) which also couples with the proton $H_{8\beta}$ (δ 1.25). These

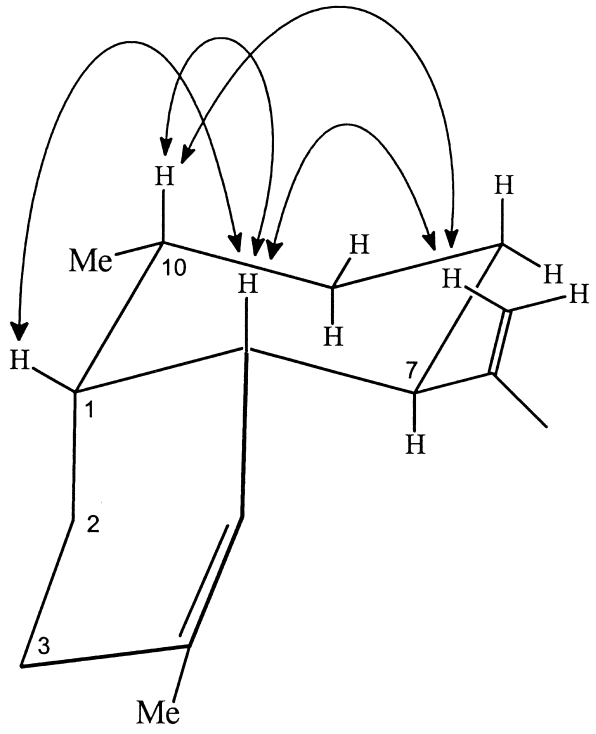

Fig. 5. NOE correlations for 10-*epi*-muurola-4,11-diene (**16**).

two protons couple further with the C-3 methylene-group (δ 1.98; δ 2.08) to give the substructure CH_3–C–CH_2–CH2–. In the HMBC spectrum protons of CH_2-4 are long-range correlated to carbons C-3, C-2, C-5, C-1 and C-13. Those of CH_2-3 show correlations to carbons C-4, C-2, C-1 and C-5 while protons of the methyl group CH_3-13 are correlated to C-4, C-1, C-5 and C-6. All these informations give the partial structure consisting of the five membered ring A (Fig. 6). The methylene group CH_2-11 (δ 2.50; δ 2.58) couples with the methylene group CH_2-10 (δ 2.51; δ 2.50) leading to the partial structure CH_2–CH_2. The two olefinic methine protons CH-8 (δ 5.37) and CH-7 (δ 5.36) couple to each other resulting in substructure C=CH–CH=C. In the HMBC spectrum the methyl group CH_3–12 is long-range correleted to carbons C-10, C-9, C-8. Methylene group CH_2-11 shows connectivities to carbons C-6, C-10, C-9 C-7 and C-5. The observed correlations can be rationalized to form a six-membered ring B (Fig. 7) and allow the assumption of a cuparane skeleton and the structure of 10,11-dihydro-α-cuparenone (**8**) for the molecule. The 8,11-dihydro-isomer of **8** is a constituent of the liverwort *Reboulia hemisphaerica* and was described by Morais et al. (1988).

The main sesquiterpene hydrocarbon (**18**) of the hydrodistillate of *Plagiomnium undulatum* showed the elemental composition of $C_{15}H_{24}$ ($M^+ = 204$) and was isolated by preparative GC. From the ^{1}H NMR, ^{1}H–^{1}H COSY, HMBC and HMQC data a daucane skeleton with 2 olefinic double bonds in positions 8 and 11 was identified. The ^{1}H NMR spectrum of **18** (Table 3) contains one quaternary methyl group (δ 0.90, *s*), two olefinic methyl groups (δ 1.73, *s*, and 1.84, *br. s*), two methylene protons of an exocyclic olefinic double bond (δ 4.92, *br. s*, and 4.94, *m*) and an olefinic proton (δ 5.58, *m*). The ^{13}C NMR and DEPT spectra showed 15 carbon signals: three methyl (δ 18.7, 19.2, 27.7), six methylene (δ 24.4, 27.1, 34.7, 41.3, 41.7, 111.3), three methine (δ 52.3, 57.4, 123.4) and three quaternary carbons (δ 42.4, 139.7, 147.9). The inspection of the ^{1}H–^{1}H COSY and HMQC spectra allowed to derive partial structures **A–C**. The connection of these partial structures was deduced from the HMBC spectrum (Fig. 8). The combination of the total NMR information allowed to assign the structure of dauca-8,11-diene to compound **18**.

The NOESY spectrum clearly indicated a strong correlation signal between H-4 and the CH_3-15 protons, indicating a *trans* correlation of methyl group C-15 and the isopropenyl group in position 4. The reported literature data for dauca-8,11-diene are quite intriguing. In the ^{13}C NMR spectrum of our compound **18** signals

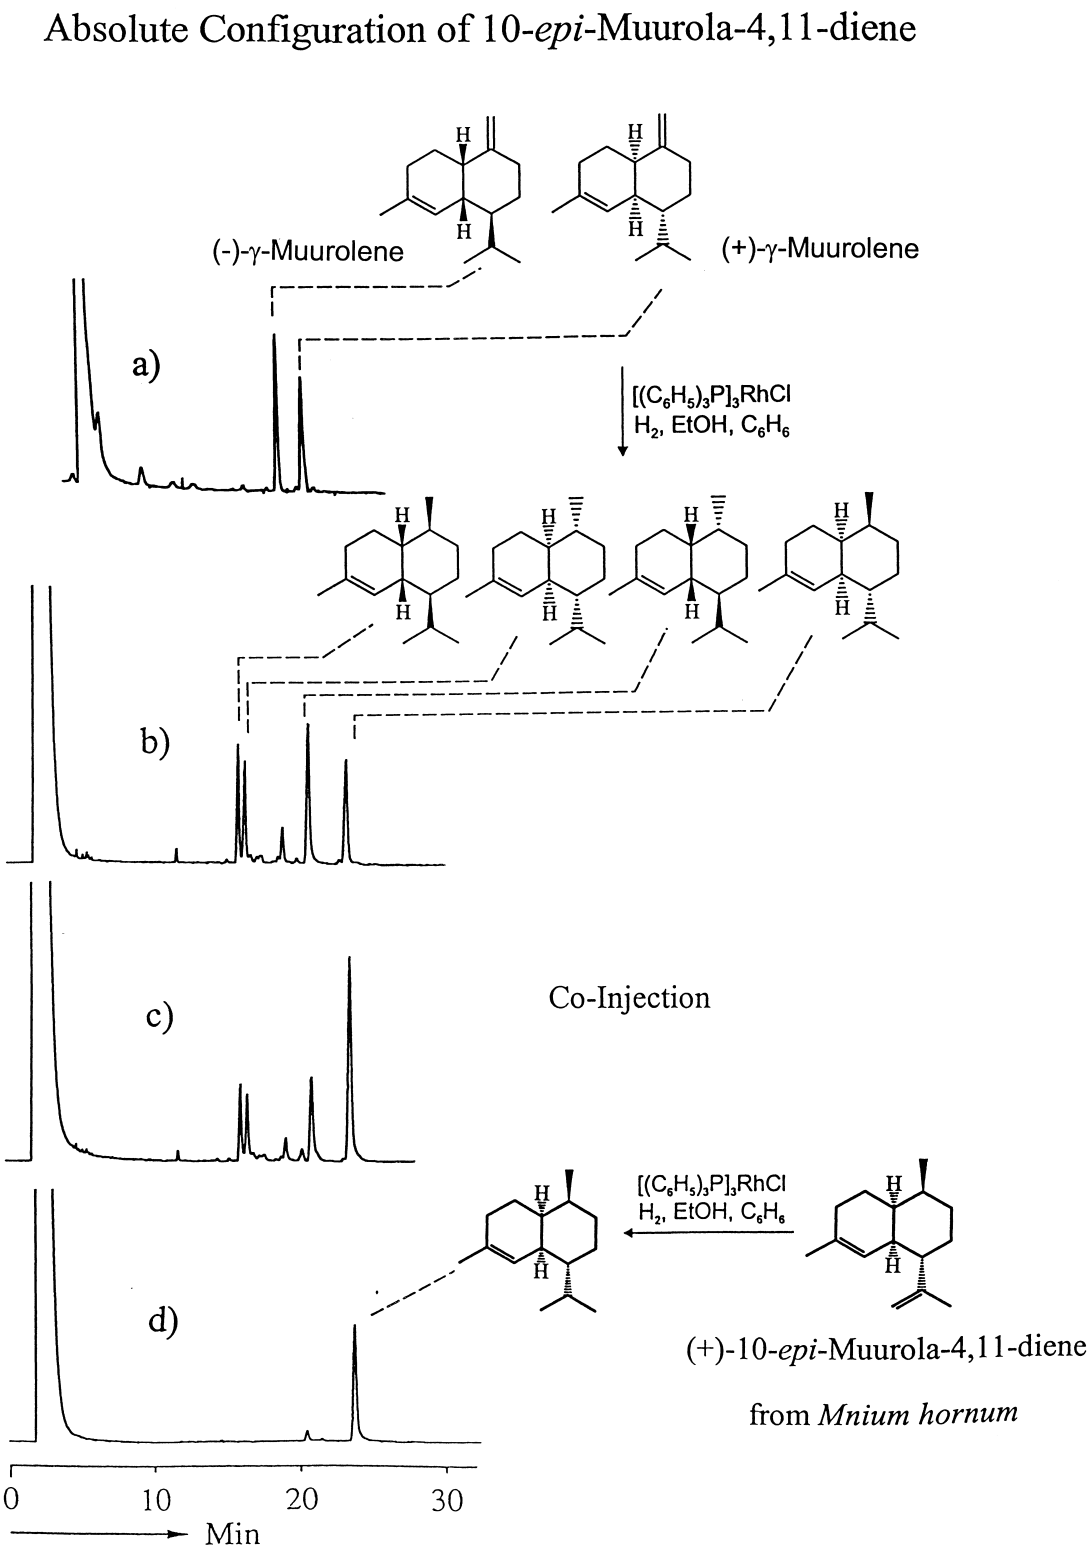

Fig. 6. Investigation of the absolute configuration of 10-*epi*-muurola-4,11-diene (**16**) by comparing products of partial hydrogenation of both enantiomers of γ-muurolene with those of 16 by enantioselective gas chromatography. 25 m Fused silica capillary column with heptakis(2,6-di-*O*-methyl-3-*O*-pentyl-)-β-cyclodextrin (50% in polysiloxane OV1701, w/w) at 110°C. (a) enantiomer separation of γ-muurolene [excess of (−)-enantiomer]; (b) separation of 2 enantiomeric pairs of diastereomeric dihydro derivatives of γ-muurolene; (c) co-injection with product obtained by partial hydrogenation of 10-*epi*-muurola-4,11-diene (**16**); (d) partial hydrogenation product of 10-*epi*-muurola-4,11-diene (**16**).

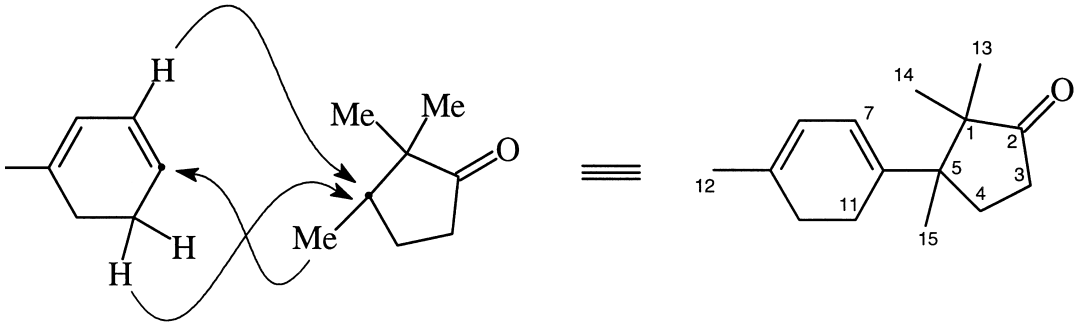

Fig. 7. Partial structures and HMBC correlations for 10,11-dihydro-α-cuparenone (**8**).

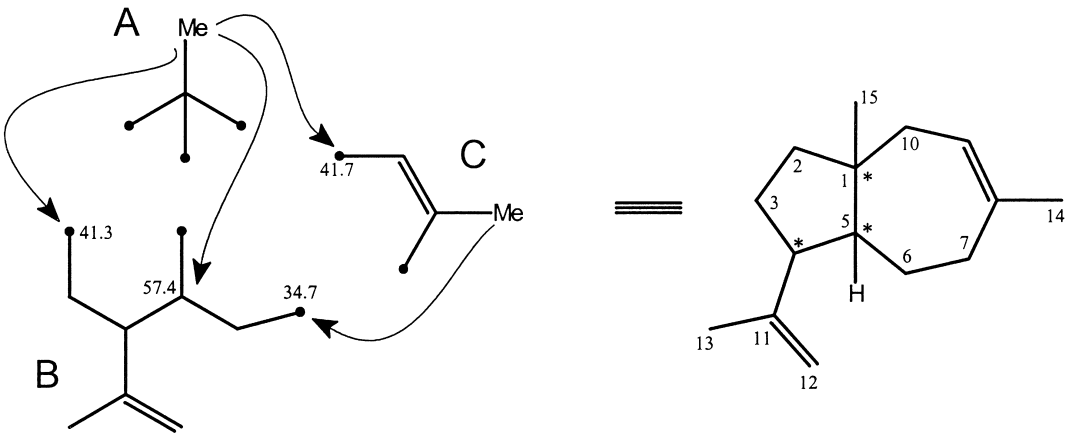

Fig. 8. Partial structures and HMBC correlations for dauca-8,11-diene (**18**).

were observed in excellent agreement with chemical shift values reported by Cassidy and Ghisalberti (1993), who isolated dauca-8,11-diene from a marine sponge and assigned a structure with *trans* ring junction and *trans* correlation of methyl C-15 and the isopropenyl group. However, for the same compound isolated from *Rosa rugosa* leaves a set of different ^{13}C data was reported by Hashidoko et al. (1992) and again, differing from these data, for a compound of structure **18** isolated from the composite *Vernonia galpinii* by Bohlmann and Zdero (1982). We have, therefore, carried out a chemical correlation by comparing the fully hydrogenated products of **18**, (+)-daucene (**20**) and dauca-3,8-diene (**21**) by enantioselective GC. **20** and **21** were isolated from the product mixture which is obtained by dehydration of carotol, as reported by Bülow and König (2000). Carotol was isolated from commercial carrot seed oil by preparative GC. As expected, 4 fully hydrogenated products were obtained from dauca-3,8-diene (**21**) (Fig. 9). Also 4 out of 8 possible products were obtained from (+)-daucene (**20**) and 2 products from compound **18**. Comparison by capillary GC with several different cyclodextrin derived chiral stationary phases revealed that the retention times of the 2 hydrogenated products originating from **18** were identical with 2 out of 4 products from hydrogenated (+)-daucene (**20**), thus proving the identity of the absolute configuration of **18** and **20** at carbon 1. The identity of 2 out of 4 products originating from hydrogenated dauca-3,8-diene (**21**) with hydrogenated **18**, proved the identity of the absolute configuration at carbon atoms 1 and 5, as illustrated in Fig. 9. In contrast to the isomer identified by Cassidy and Ghisalberti (1993), our compound **18** shows a positive optical rotation. Thus, the absolute configuration of **18** is correlated with (+)-daucene and (1*S*,5*R*)-dauca-3,8-diene as obtained from carotol (with known absolute configuration).

The isolation of the butenolide **22** was achieved by preparative gas chromatography. It has the molecular formula $C_{12}H_{22}O_2$ ([M^+], m/z = 196), while its homologue

Table 4

			C-12	23.7 (*q*)

23, which is always present as a minor component, has the elemental composition $C_{11}H_{19}O_2$ ([M^+], $m/z = 182$), according to high resolution MS. The presence of a pentyl group was concluded from the loss of a C_5H_{11} radical from the molecular ion to $m/z = 125$ in **22** and $m/z = 111$ in **23.** The ^{13}C- and DEPT spectra (Table 4) permitted the identification of 2 olefinic carbons, 1 carbonyl carbon, 1 quaternary carbon, 4 methylene groups and 4 methyl groups. The presence of a carbonyl group (δ 172.72) and an oxygenated quaternary carbon (δ 86.74) suggested an ester function. The DEPT spectra also indicated that the olefinic carbons (δ 160.93 and 123.43) are quaternary. Further, the ^1H NMR spectrum (Table 4) showed the presence of 3 tertiary methyl groups

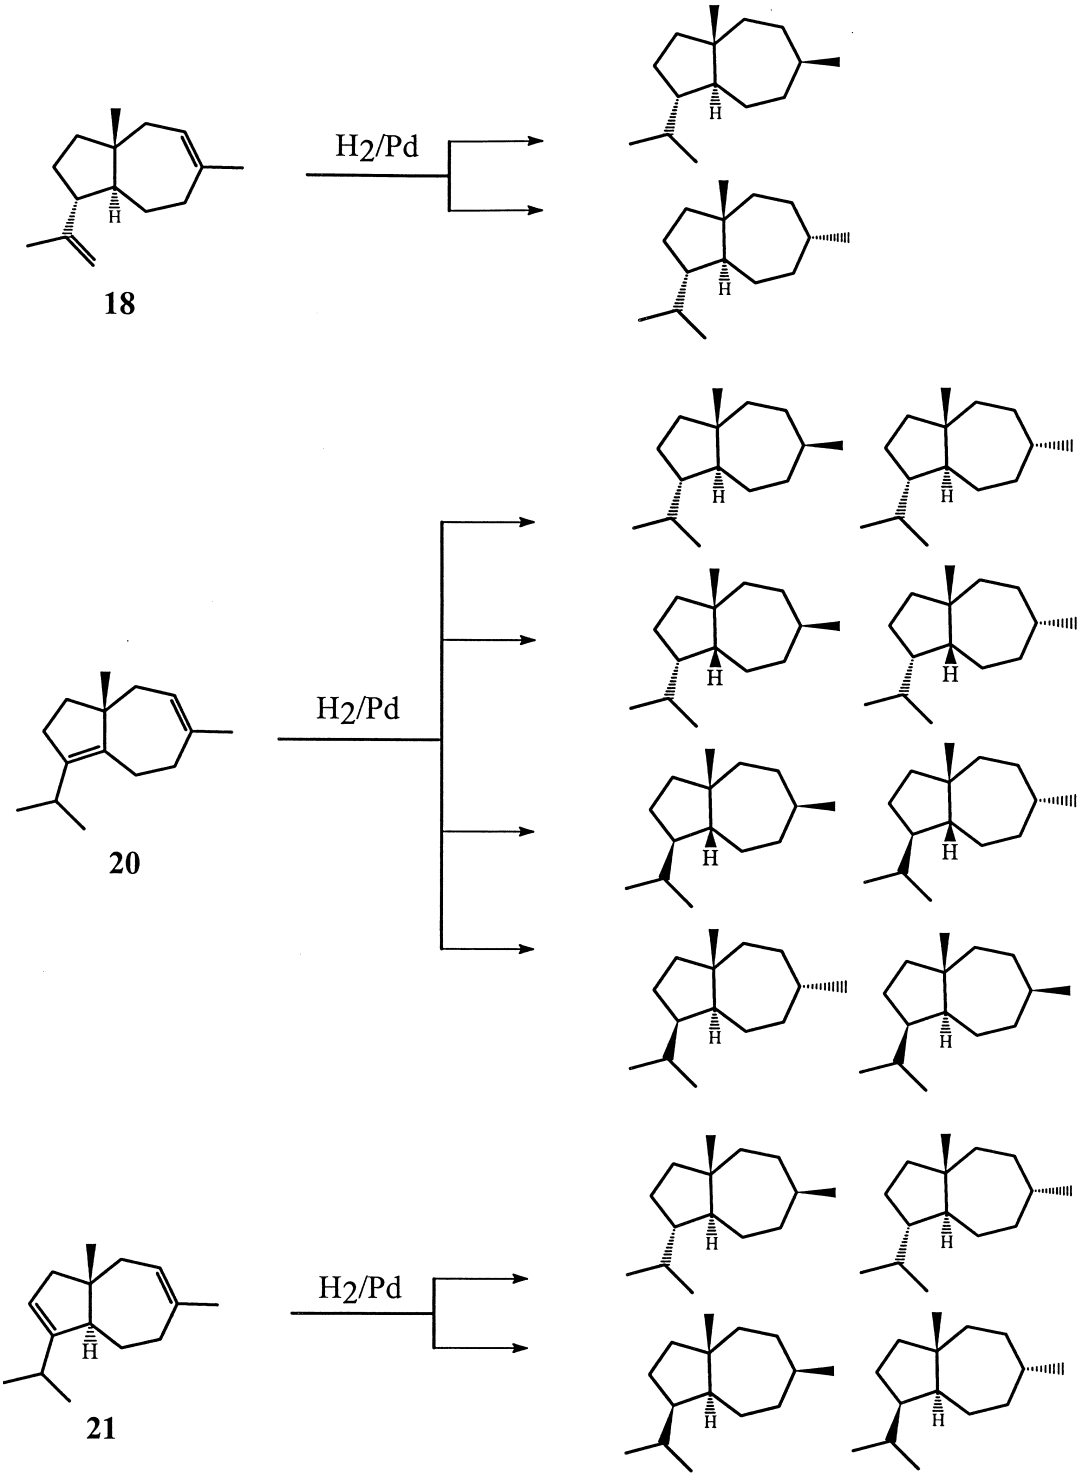

Fig. 9. Possible hydrogenation products of (+)-dauca-8,11-diene (**18**), (+)-daucene (**20**) and dauca-3,8-diene (**21**).

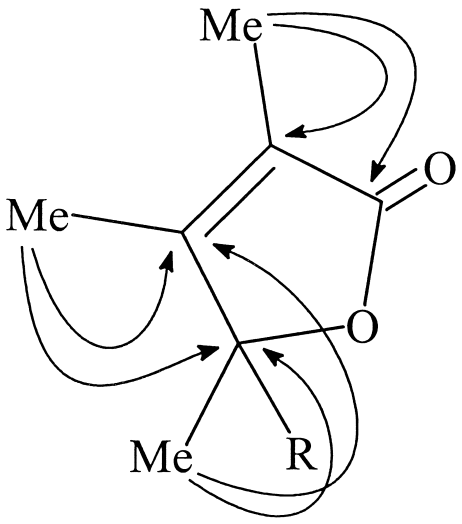

Fig. 10. HMBC correlations for 3,4,5-trimethyl-5-pentyl-5*H*-furan-2-one (**22**).

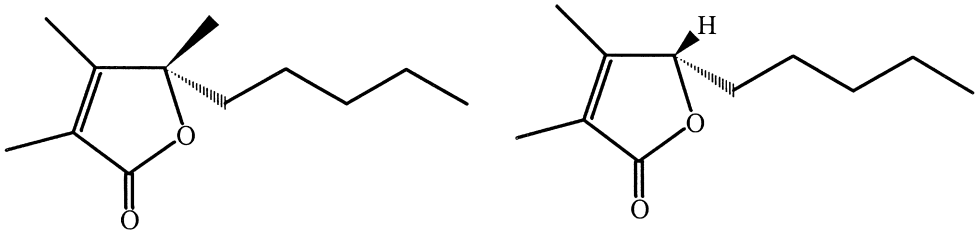

22 **23**

Fig. 11. Structures of butenolides **22** and **23** from *Plagiomnium undulatum*.

at δ 0.97, 1.17 and 1.59. A secondary methyl group was detected at δ 0.81 as a doublet. The HMBC spectrum showed a characteristic pattern of correlation peaks in the region between δ 80 and 172 for the methyl groups at δ 1.59, 1.17 and 0.97. From different correlations of the methyl protons to the olefinic carbons (δ 160.92, 123.44), carbonyl carbon (δ 172.72) and the quaternary carbon (δ 86.73) the partial structure of the butenolide **21** was derived (Fig. 10). From the HSQC spectrum it was concluded that the multiplet signal at δ 1.45 is part of the resonance of a methylene group (δ 37.11) which in the HMBC spectrum shows a correlation to the quaternary carbon at δ 86.73 and to the olefinic carbon at δ 160.92. The second proton of the methylene group is detected at δ 1.15 as part of overlapping signals in the ^{1}H NMR at δ 1.09–1.16. Further analysis of the ^{1}H–^{1}H COSY, HSQC and HMBC spectra led to the identification of three additional methylene groups of the pentyl chain. The absolute configuration of the butenolides **22** and **23** (Fig. 11) was not determined, but compound **21** is optically active and has a positive optical rotation. The structural assignment of **22** is only based on the homology of the mass spectra of **22** and **23** and on exact mass measurements by high resolution MS.

The identified butenolides seem to be quite common as constituents of mosses. **22** was also found in the hydrodistillation products of *Hylocomium splendens* and *H. brevirostre*.

3. Conclusion

Mosses produce a great variety of volatile metabolites, which can be isolated from their essential oils after hydrodistillation and identified by spectroscopic methods. Like liverworts, mosses generate a great variety of mono-, sesqui- and diterpenes and, in addition, many aliphatic metabolites.

4. Experimental

4.1. Plant material

Mosses were collected in various forests in Germany, Austria, France and Italy and identified by the authors (H. Muhle, R. Mues):

Mnium hornum: near Hamburg; Ilsetal (Harz mountains); Gräfinthal (Saarland).

M. marginatum: Sonthofen, Altmühl valley (Bavaria), Blaustein (Baden-Württemberg).

M. stellare: Altmühl valley (Bavaria)

Homalia trichomanoides: Lonsee, Beuron (Baden-Württemberg); Irsee (Bavaria), Gräfinthal (Saarland).

Plagiomnium undulatum: near Hamburg, Irsee, Neu-Ulm (Bavaria), Zachersmühle (Baden-Württemberg), Chamonix (France), Sicily (Italy).

Plagiothecium undulatum: near Hamburg, Niederwürzbach (Saarland), Pitztal (Austria).

Taxiphyllum wisgrillii: Immenstadt (Bavaria).

Plant samples are deposited in the Abteilung Allgemeine Botanik, University of Ulm and Fachrichtung 8.1 Botanik, University of Saarbrücken.

4.2. Hydrodistillation

The essential oil was prepared by hydrodistillation (2 h) of aq. homogenates of fresh and green or air-dried plants using *n*-hexane as collection solvent. Because of the greatly differing weight the fresh material was not weighed.

4.3. Capillary GC

Orion Micromat 412 double column instrument with 25 m fused silica capillaries with polysiloxane CPSil 5 and CPSil 19 (Chrompack); Carlo Erba Fractovap 2150, 4160 instruments with 25 m fused silica capillaries with heptakis(2,6-di-*O*-methyl-3-*O*-pentyl)-β- and-γ-cyclo dextrin, respectively, and heptakis(6-*O*-t.butyldimethyl silyl-2,3-di-*O*-methyl)-β-cyclodextrin, all in polysiloxane OV1701 (50 wt.%); split injection, flame ionization detection; carrier gas 0.5 bar hydrogen.

4.4. Preparative GC

Isolation of compounds **8**, **16**–**18** and **20**–**22** was performed by prep. GC on a modified Varian 1400 instrument, equipped with a stainless steel columns with 2.5% heptakis(6-*O*-t.hexyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin/SE30 (1:1, w/w;) on Chromosorb G-HP (2.00 m×4.3 mm) or with 6.4% polydimethylsiloxane SE30 on Chromosorb W-HP (1.85 m×4.3 mm); flame ionization detection; helium as carrier gas at a flow rate of 240 ml/min (Hardt and König, 1994).

4.5. Partial hydrogenation of *16*

This was carried out by adding approx. 1 mg of Wilkinson catalyst $[(C_6H_5)_3P]_3RhCl$. **18** was fully hydrogenated by adding 0.5 mg Pd/C to a solution of approx. 1 mg of sample in 500 μl *n*-hexane. In both cases the suspension was treated with H_2 and stirred under H_2 at room temp. for 4 hours and 1 hour, respectively. After that the reaction mixture was filtered and the reaction products were analysed by GC–MS and GC on capillary columns with conventional polysiloxane stationary phases and cyclodextrin derivatives.

4.6. Dehydration of carotol

To a solution of approx. 1 mg of carotol from carrot seed oil in 1 ml of pyridine 0.1 ml of $SOCl_2$ was added and left for 20 min at 0° C. To the reaction mixture 10% $NaHCO_3$-solution was added and the products extracted with *n*-hexane. From the organic extract (+)-daucene (**2**) and dauca-3,8-diene (**21**) were isolated by prep. GC.

4.7. NMR spectroscopy

NMR measurements were carried out with Bruker WM 500 or WM 400 instruments using TMS as internal standard.

4.8. Polarimetry

Only the sense of the optical rotation was determined, since the isolated sample amounts were too small for an accurate determination of the *specific* optical rotation.

4.9. Mass spectrometry

GC–MS measurements (EI, 70 eV) were carried out with a Hewlett Packard HP 5890 gas chromatograph coupled to a VG Analytical 70-250S mass spectrometer. Exact mass measurements were performed at a resolution of 5000 with PFK masses as reference.

High molecular weight lipids from the trilaminar outer wall (TLS)-containing microalgae *Chlorella emersonii*, *Scenedesmus communis* and *Tetraedron minimum*

B. Allard*, J. Templier

Laboratoire de Chimie Bioorganique et Organique Physique, UMR CNRS 7573, E.N.S.C.P., 11 rue Pierre et Marie Curie, 75231 Paris Cedex 05, France

Received 11 December 2000; received in revised form 12 February 2001

Abstract

High molecular weight lipids were isolated from *Chlorella emersonii*, *Scenedesmus communis* and *Tetraedron minimum*, thin trilaminar outer wall (TLS)-containing freshwater microalgae producing an insoluble non-hydrolysable biopolymer (i.e. algaenan). Molecular weight determination by gel permeation chromatography indicated that their molecular weights range from ca. 400 to 2000 Da. Flash pyrolysis with in situ methylation using tetramethylammonium hydroxide (TMAH) and alkaline hydrolysis showed that the high molecular weight lipids isolated from *C. emersonii* and *S. communis* are mainly composed of saturated *n*-C26 and *n*-C28 fatty acids and alcohols and of saturated *n*-C30 and *n*-C32 α,ω-diols and ω-hydroxy acids. In contrast the high molecular weight lipids isolated from *T. minimum* are predominantly composed of long-chain fatty acids and ω-hydroxy acids. Aromatic moieties were also identified in small amounts in the thermochemolysate and in the hydrolysate. Chemical structural models containing long-chain mono- and polyesters were proposed for the high molecular weight lipids isolated from the three microalgae in agreement with analytical and spectroscopic data. Structural similarity between the outer cell wall of these microalgae and the cuticular membrane of higher plants is suggested. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Chlorella emersonii*; *Scenedesmus communis*; *Tetraedron minimum*; Long-chain esters; Polyesters; Tetramethylammonium hydroxide (TMAH) thermochemolysis; Trilaminar outer walls (TLS); Algaenan

1. Introduction

A number of recent studies of green freshwater and marine microalgae from the class of Chlorophyceae, Dinophyceae and Eustigmatophyceae indicated the existence of microalgae exhibiting a characteristic membrane-like trilaminar cell wall structure (TLS) (Derenne et al., 1992; Gelin et al., 1999; Allard and Templier, 2000). It has also been shown that in most cases such outer walls are predominantly composed of a biopolymer (so-called algaenan) exhibiting a high resistance to drastic non-oxidative chemical treatments (de Leeuw and Largeau, 1993). However, the absence of a one-to-one relationship between the presence of a TLS and the occurrence of algaenan has been noted (Brunner and Honegger, 1985; Allard and Templier, 2000). Through recent pyrolysis and chemical degradation studies it has been suggested that these biopolymers consist mainly of linear polyester chains cross-linked by ether bridges (Blokker et al., 1998a,b). Our continued phytochemical investigations of TLS-containing microalgae have resulted in the isolation of high molecular weight lipids from the three TLS- and algaenan-containing microalgae *Chlorella emersonii*, *Scenedesmus communis* and *Tetraedron minimum*. We now report the isolation and the tentative identification of these new high molecular weight lipids using pyrolysis in the presence of tetramethylammonium hydroxide (TMAH) and alkaline hydrolysis techniques.

2. Results

The dry biomass was extracted with chloroform. After concentration of the solvent, addition of acetone to the crude neutral lipid extract yielded a precipitate

(NL-2). The yield of NL-2 depends on the age of the culture and was higher for cultures harvested in the stationary phase of growth. This precipitated material accounts for ca. 10–30% of the total extract for the microalgae harvested at the end of linear phase of growth and has been isolated as level up to 70% of the total neutral lipid extract for some aged cultures of *T. minimum*. However, once dried, these precipitates became insoluble in usual organic solvents. The supernatants (NL-1) contained the same lipids as previously identified in neutral lipids of the three microalgae (Allard and Templier, 2000).

2.1. Spectroscopic features

FTIR spectra of the NL-2 samples are shown in Fig. 1. All NL-2 samples show absorption bands at ca. 3400 cm^{-1} (OH stretching vibrations), 2920 and 2850 cm^{-1} (symmetric and asymmetric stretching of methylene groups), 1470 cm^{-1} (methylene deformation mode), 720 cm^{-1} (methylene rocking mode) and 1735 cm^{-1} (carbonyl stretching vibrations) suggesting the presence of long-chain esters in these samples. The band progression caused by methylene wagging modes between ca. 1380 and 1170 cm^{-1} is clearly observed in spectra of the NL-2 samples from *C. emersonii* and *S. communis* (see inset of Fig. 1) and is consistent with the presence of long-chain *n*-alkyl compounds (Jones et al., 1952; Holland and Nielsen, 1962). The low intensity of the absorption band at ca. 1375 cm^{-1} due to symmetric methyl deformation mode is indicative of the low degree of branching in these lipids.

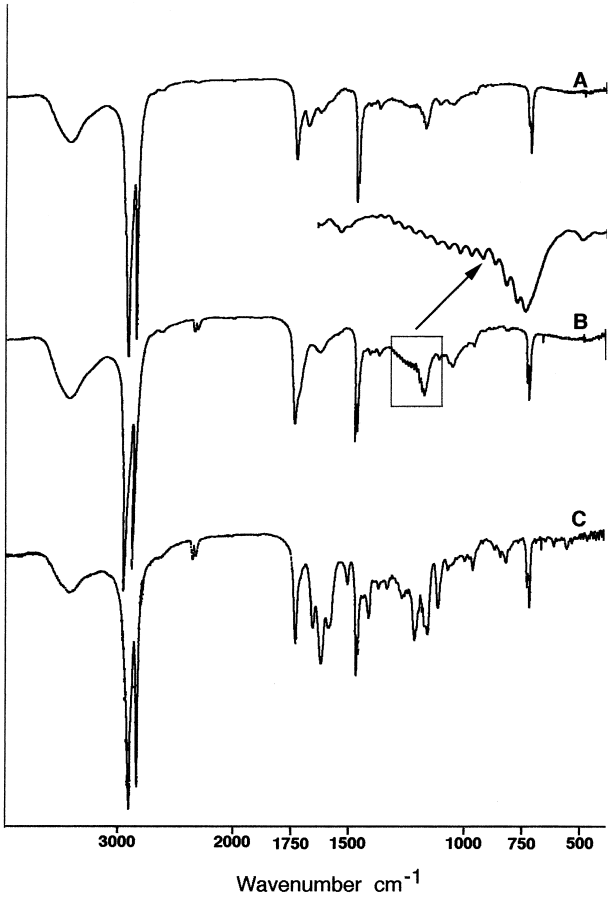

Fig. 1. FTIR spectra of NL-2 samples isolated from (**A**) *Chlorella emersonii*, (**B**) *Scenedesmus communis*, (**C**) *Tetraedron minimum*.

In the region 1500–1750 cm^{-1} several differences are observed between the FTIR spectra of the NL-2 samples isolated from the microalgae studied. A shoulder at ca. 1710 cm^{-1} which can be assigned to carboxyl groups is present in the FTIR spectrum of the NL-2 sample from *S. communis*. In this region the FTIR spectrum of the NL-2 sample originated from *T. minimum* shows strong absorption bands at ca. 1660, 1625 and 1595 cm^{-1}. These bands were not shifted by pH changes. If we consider (i) the strong intensity of these bands, (ii) the low intensity of the absorption band near 3400 cm^{-1} and (iii) the low nitrogen content of the sample (0.7% as determined by elemental analysis) it seems unlikely that these bands arise from amide groups. Additionally, these latter bands seem to be associated with the presence of several bands in the region 1100–1250 cm^{-1} corresponding to C–O stretching vibrations. Therefore, it can be suggested that these three absorption bands could represent different populations of C=O groups, likely ester groups, with different intermolecular and/or intramolecular hydrogen bonding. Nevertheless if we consider the presence of absorption bands between 750 and 1000 cm^{-1} the contribution of unsaturated and/or aromatic groups to these absorption bands cannot be ruled out.

2.2. Molecular weight determination

The NL-2 samples isolated from the different microalgae became soluble in 2-methyl-1-propanol at temperatures higher than 90°C. Therefore, when immediately handled, these samples can be assayed for molecular weight determination by gel permeation chromatography (GPC). The GPC traces of the NL-2 samples were given in Fig. 2. The total observed molecular weight range was between ca. 400 and 2000 Da for all samples. Calibrated GPC revealed prominent peaks at M_r ca. 430, 860 and 1530 Da, 430 and 630 Da and 640, 1150 and 1920 Da for the NL-2 samples isolated respectively from *C. emersonii*, *S. communis* and *T. minimum*.

2.3. Tetramethylammonium hydroxide (TMAH) thermochemolysis

Pyrolysis with in situ methylation using tetramethylammonium hydroxide (TMAH) has been introduced by Challinor (1989, 1994) for the characterisation of polar macromolecules. This technique has been

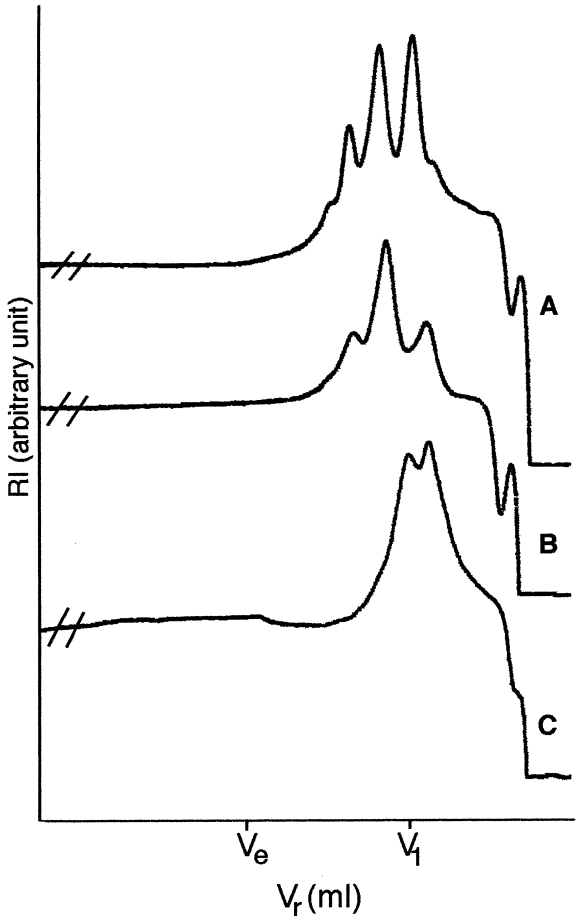

Fig. 2. GPC traces of NL-2 samples isolated from (**A**) *Tetraedron minimum*, (**B**) *Chlorella emersonii*, (**C**) *Scenedermus communis*. Styragel HR-2 column, eluent: THF, flow rate: 1 ml min^{-1}, RI detection. V_e: exclusion volume, V_1: retention volume of docosanyl docosanoate.

applied to characterise geo- and biopolymers (de Leeuw and Baas, 1993; Martin et al., 1994; McKinney et al., 1995; del Rio et al., 1994, 1998; Challinor, 1995; Clifford et al., 1995; Mckinney and Hatcher, 1996) and humic materials (Hatcher and Clifford, 1994; del Rio et al., 1995, 1996; del Rio and Hatcher, 1996). This technique yields methyl esters of carboxylic acids and methylates compounds containing hydroxyl groups, yielding products volatile enough for GC analyses. It has been shown that TMAH thermochemolysis is effective for the transesterification of fatty acids associated with humic substances (Hatcher and Clifford, 1994) and cleaves activated alkyl aryl labile ether bonds, such as ether bond activated by an α-hydroxy group in lignin, but does not chemically attack non activated ether linkages (McKinney et al., 1996).

Fig. 3 shows the total ion current (TIC) traces of the TMAH thermochemolysis products obtained from the NL-2 samples isolated from the three species of microalgae. The major peaks, identified by their MS fragmentation (see experimental) are shown in Table 1. The reported relative percentages of thermochemolysis products (Table 1) were based on integrated area of the GC–MS peaks.

Under thermochemolysis conditions the NL-2 samples from *C. emersonii* yielded saturated fatty acid methyl esters (FAMEs) from *n*-C16 to *n*-C30, with *n*-C28 as the major component, alcohol methyl ethers from *n*-C26 to *n*-C30, with *n*-C26 and *n*-C28 as the predominant components, saturated α,ω-diol di-methyl ethers and ω-methyl ether fatty acid methyl esters from *n*-C30 to *n*-C32. Significant amounts of *n*-alkane/*n*-alk-1-ene doublets were identified in the chromatogram. This homologous series probably results from conventional flash-pyrolysis and may be due to one of two possibilities (1) the too high flash pyrolysis temperature (650°C) leading to the thermal degradation of the esters and/or ethers produced by TMAH thermochemolysis or (2) the presence of non-hydrolysable bonds in the NL-2 sample isolated from *C. emersonii*. The presence of non-hydrolysable ether linkages seems unlikely. Indeed in the FTIR spectrum of this NL-2 sample no strong absorption was observed in the range expected (1150–1050 cm^{-1}) for C–O–C stretching vibrations of ether groups (Fig. 1). Moreover, the pyrolysis of alkyl ether-linked moieties should give mid-chain ketones in addition to the series of *n*-alkane/*n*-alk-1-ene doublets. However, no ketone, even in trace amount, was detected in the thermochemolysis chromatogram of the NL-2 sample from *C. emersonii*. The type of functionalities identified in the chromatogram together with the absence of tri-functional moieties indicate the presence of linear ester type bonds in this sample in agreement with the FTIR data.

Under thermochemolysis conditions the NL-2 sample from *S. communis* yielded saturated and mono-unsaturated alcohol methyl ethers from *n*-C22 to *n*-C30, saturated and to a lesser extent mono-unsaturated FAMEs with saturated *n*-C28 as the predominant component, α,ω-diol di-methyl ethers and ω-methyl ether fatty acid methyl esters with saturated *n*-C32 as the major components. In contrast to the thermochemolysis products of the NL-2 sample from *C. emersonii* only very low amounts of *n*-alkane/*n*-alk-1-ene doublets was observed in this chromatogram (Fig. 2). As in the case of *C. emersonii* the nature of compounds released during TMAH thermochemolysis of this NL-2 sample and the absence of tri-functional moieties indicate the occurrence of linear ester type linkages in these lipids.

In sharp contrast, no straight-chain alcohol methyl ethers were present in the thermochemolysis products of the NL-2 sample isolated from *T. minimum* and only very small amounts of α,ω-diol di-methyl ethers and ω-methoxy FAMEs were detected. Under thermochemolysis conditions this sample yielded predominantly saturated *n*-C24, *n*-C26 and *n*-C28 FAMEs. In addition to FAMEs, methoxy phytol and methoxylated benzene structures were identified. The major aromatic compounds identified were 1,3,5-tri-methoxybenzene (P1) and tetra-methoxybenzene (P3). Other minor aromatic compounds were identified as 1,2-di-methoxybenzyl methyl ether, 3,4,5-tri-

methoxybenzyl methyl ether, 1,3-benzenedicarboxylic acid di-methyl ester, di-methoxybenzoic acid methyl ester and tri-methoxyacetophenone. However, at this point, there is no evidence that all methoxy groups of aromatic rings derive from the alcohol counterparts of an ester structure and some of them could be present as such in the original sample. In the same way, it is not possible to ensure that methoxy phytol identified in the thermochemolysate derives from an ester structure or originates from free phytol precipitated with the high molecular weight lipids.

[a] The composition was estimated from the GC chromatograms of acetoxy and 2-methyl-1-propyl ester derivatives.
[b] Identified as acetoxy 2-methyl-1- propyl ester.
[c] Identified as acetoxy 2-methyl-1-propyl ester and 2-methyl-1-propyl ester TMSi ether.

2.4. Hydrolysis of the NL-2 samples

The NL-2 samples isolated from the different microalgae were saponified in 2-methoxyethanol/H_2O (Daffé et al., 1983). Upon extraction, very low amounts of products were recovered in the organic phase and an interfacial material containing the hydrolysis products developed between the organic and aqueous phases whatever the solvent used. The esterification of gathered organic phase and interfacial material with HCl/2-methyl-1-propanol allowed the solubilisation of all products released during hydrolysis. These latter were identified by GC–MS of their 2-methyl-1-propyl ester TMSi ethers and acetoxy 2-methyl-1-propyl esters (see experimental). The composition of hydrolysis products of each NL-2 sample is shown in Table 2.

Upon hydrolysis the NL-2 sample from *C. emersonii* yielded saturated *n*-C26, *n*-C28 and *n*-C30 fatty alcohols and fatty acids with saturated *n*-C26 and *n*-C28 as major components and saturated α,ω-diols and ω-hydroxy acids with *n*-C32 ω-hydroxy acid as the pre dominant constituent. The structure of the hydrolysis products and the absence of tri-functional moieties are in good agreement with the TMAH thermochemolysis data and corroborate the linear ester type structure for this NL-2 sample.

Saponification of the NL-2 sample isolated from *S. communis* yielded saturated and mono-unsaturated alcohols from *n*-C22 to *n*-C32, fatty acids from *n*-C16 to *n*-C30 with saturated *n*-C28 acid as predominant constituent. In contrast to the thermochemolysis products only low amounts of saturated *n*-C32 α,ω-diol and ω-hydroxy acid were detected in the hydrolysis products.

This discrepancy may be due to the fact that thermochemolysis and hydrolysis have been carried out with NL-2 samples isolated from two different cultures.

The hydrolysis products of the NL-2 sample originated from *T. minimum* consist of saturated and mono-unsaturated fatty acids from *n*-C16 to *n*-C30 with saturated *n*-C26 and *n*-C28 as major constituents and ω-hydroxy acids from *n*-C28 to *n*-C36. As in the case of thermochemolysis no alcohol and α,ω-diol was present in the hydrolysis products of this NL-2 sample. In contrast to the TMAH thermochemolysis products phytol has not been detected in the hydrolysis products. The random presence of phytol suggests that phytol identified in the thermochemolysate is likely present as free phytol which has been co-precipitated with the NL-2 sample. In addition to the acids and ω-hydroxy acids aromatic compounds have been identified in trace amount in the GC–MS chromatogram of the hydrolysate of this NL-2 sample. The major aromatic compounds identified were 3,5-di-methoxy tri-methyl silyloxy benzene (corresponding to the peak P1 of TMAH thermochemolysis), 3-methoxy-2-tri-methylsilyloxy benzyl tri-methylsilyl ether (corresponding to the peak P2 of TMAH thermochemolysis) and 2-methoxy-3-tri-methylsilyloxy benzoic acid 2-methyl-1-propyl ester. The nature of the substitutents on the aromatic rings identified in the hydrolysis products, methoxy or tri-methylsilyloxy, indicates that some methoxy groups identified in the TMAH thermochemolysis chromatogram do not derive from free hydroxyl groups. The very low amounts of the aromatic structures in the hydrolysis products and the content of ω-hydroxy acids which accounts for ca. 18% of the hydrolysate suggest that in this NL-2 sample linear ester-type structures likely predominate over alkyl-aryl ester-type structures.

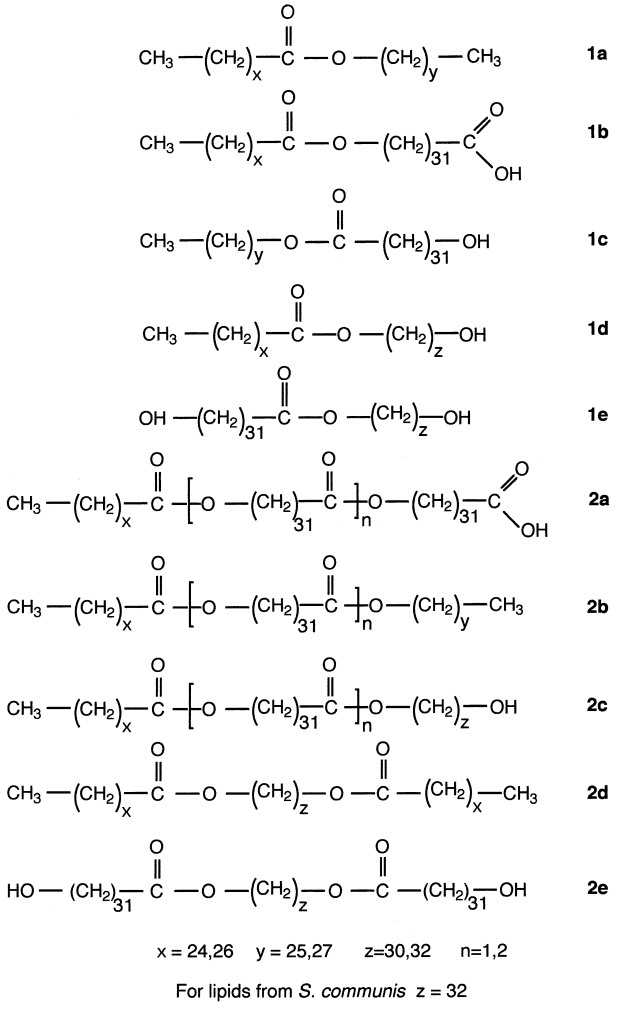

Fig. 4. Proposed chemical structures for the constituents of the high molecular weight lipids isolated from *Chlorella emersonii* and *Scenedesmus communis*.

3. Discussion

High molecular weight lipids with M_r ranging from ca. 400 to 2000 Da have been isolated from the neutral lipids of three TLS-containing freshwater microalgae and have been analysed by thermochemolysis in the presence of TMAH and alkaline hydrolysis.

From the data collected in this study we can devise structural models for the high molecular weight lipids biosynthesised by these algae which takes into account spectroscopic, GPC, TMAH thermochemolysis and hydrolysis results. The results obtained about *C. emersonii* suggest that these lipids are probably constituted of (i) long-chain saturated alcohols, acids, ω-hydroxy acids and/or α,ω-diols monomers corresponding to the peak at M_r ca. 430 Da in the GPC chromatogram, (ii) long-chain saturated monoester(s) corresponding to the GPC peak at M_r ca. 860 Da. Their possible structures depicted in Fig. 4 (compounds **1a**–**d**) are consistent with TMAH thermochemolysis and hydrolysis data, (iii) higher molecular weight ester(s) with M_r at ca. 1530 Da which could be constituted of polyester(s) having two or three ester groups per chain. Taking into account the products identified in the thermochemolysate and/or in the hydrolysate, the number of possible structures for this type of polyesters becomes very large. Possible structures of these polyesters represented by compounds **2a**–**e** are shown in Fig. 4.

The high molecular lipids isolated from *S. communis* have lower molecular weight than those isolated from *C. emersonii* and are likely constituted of long-chain saturated and, to a smaller extent, mono-unsaturated monomers (alcohols, acids, ω-hydroxy acids and/or α,ω-diols) and of monoester(s). From the analytical data obtained about these lipids, similar structural models than those depicted for monoesters isolated from *C. emersonii* (compounds **1a**–**e** in Fig. 4) can be proposed for these latter. However, considering the large amounts of diols and hydroxy acids identified in the thermochemolysate

the possibility of biosynthesis of higher polyesters by this microalga cannot be ruled out.

In contrast to the two other microalgae, the high molecular weight lipids isolated from *T. minimum* do not yield any alcohol and α,ω-diol upon TMAH thermochemolysis and hydrolysis. Moreover, this microalga is the only one which biosynthesises high molecular weight lipids yielding aromatic moieties upon thermochemolysis and hydrolysis although in small quantities. This indicates the possibility of ester linkages between long chain fatty acids and aromatic alcohols in these lipids. Similar aromatic compounds have been identified in the TMAH thermochemolysate of the cutan biopolymer derived from the leaf cuticles of *Agave americana* (McKinney et al., 1996), and these authors proposed a new chemical structure containing long chain *n*-alkyl units linked to aromatic rings by ester linkages for the cutan biopolymer. However, the quantitative analysis of the thermochemolysate and the hydrolysate which consist predominantly of saturated *n*-C26 and *n*-C28 acids is difficult to correlate with the GPC data (Fig. 2). Indeed, the contribution of mono- and polyester(s) is relatively large in comparison with that of monomers, in this case fatty acids and ω-hydroxy acids, and therefore greater amounts of ω-hydroxy acids were expected in the thermochemolysate. Some of the possible structures of mono- and polyesters which can account for both GPC and qualitative analytical data are shown in Fig. 5.

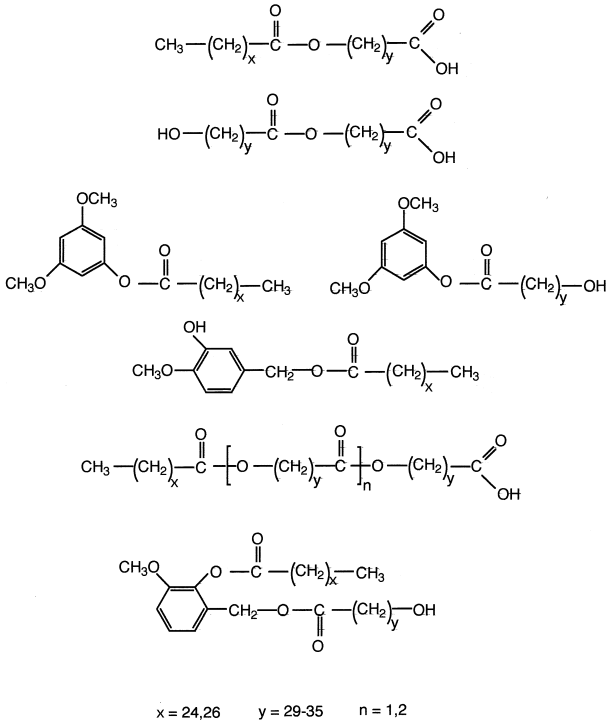

Fig. 5. Proposed chemical structures for the constituents of the high molecular weight lipids isolated from *Tetraedron minimum*.

Monoesters from C24 to C50 have already been detected, although in trace amount, in microalgae belonging to the genus *Chlorella* and *Scenedesmus* (Rezanka and Podojil, 1986; Allard and Templier, 2000). However, to our knowledge, polyesters have never been identified in microalgae probably because of their high molecular weight and their insolubility in the usual solvents. However, this type of polymeric esters, the estolides, formed from a series of ω-hydroxy acids either by interesterification or by esterification with long-chain diols are well known as constituents of higher plant epicuticular waxes (Bianchi, 1995). Moreover, rather unusual monoesters formed by esterification of benzoic acid with C22 to C26 fatty alcohols or by esterification of C22 to C28 fatty acids with benzyl alcohol and 2-phenyl ethanol have been found as well in epicuticular waxes of several plants (Gültz and Marner, 1986; Prasad and Gültz, 1990a,b). Therefore we can suggest that at least some TLS-containing microalgae are able to biosynthesise wax lipids which may have the same protective role against environmental factors and pathogenic infections as higher plants epicuticular waxes.

The microalgae studied show a membrane-like trilaminar outer wall (TLS) which contains algaenan, an insoluble biopolymer resistant to drastic non-oxidative chemical treatments (Derenne et al., 1991; Afi et al., 1996; Allard and Templier, 2000). It is noteworthy that no such high molecular weight lipids were found in neutral lipids of *Chlorella vulgaris* a TLS- and algaenan-devoid microalga (Afi et al., 1996) and of *Chlorella marina* and *Chlorella minutissima marina* TLS-containing microalgae which do not produce algaenan (Allard and Templier, 2000). Therefore, a relationship between the presence of high molecular weight lipids in the microalga and its ability to produce algaenan can be suggested. These high molecular weight lipids could be involved in the formation of the outer cell walls of the TLS- and algaenan-containing microalgae. They could be a less condensed form of the algaenan. Such a similarity of chemical structure between insoluble algaenan and soluble high molecular weight aliphatic lipids has been already demonstrated for the colonial Chlorophycea *Botryococcus braunii* (Metzger and Largeau, 1999). If this hypothesis is confirmed the outer cell wall of TLS- and algaenan-containing microalgae could be described as an insoluble biopolymer (i.e. algaenan) embedded in a complex mixture of highly aliphatic lipid classes (i.e. monomers and esters constituting the high molecular weight lipids). The structure of the outer cell walls of these microalgae would thus display great similarities with the cuticular membrane of higher plants. Such similarities would be consistent with the evolutionary lineage that led to land plants. Similarities of some of the biological functions of cutin and algaenan have been already suggested (Blokker et al., 1998a).

4. Materials and methods

4.1. General

FTIR spectra were recorded on a single-beam Bruker 45 spectrometer. The discs were prepared by mixing 1% (w/w) of the sample with KBr.

Analytical GC was performed on a fused silica RSL-300 capillary column (25 m × 0.25 mm i.d., 0.2 μm film thickness) programmed from 100 to 300°C at 4°C min^{-1}. GC–MS analyses were carried out using a HP5890 gas chromatograph equipped with a fused silica CPSil5CB capillary column (25 m × 0.22 mm i.d., 0,4 μm film thickness) programmed from 100 to 300°C at 3°C min^{-1} coupled to a HP5989 mass spectrometer operated at 70 eV.

Axenic strains of *C. emersonii* (CCAP 211/8P), *S. communis* (CCAP 276/4b) and *T. minimum* were cultured under air-lift conditions and continuous illumination as previously described (Allard and Templier, 2000). Neutral lipids were extracted as previously described (Allard and Templier, 2000).

4.2. NL-2 Sample isolation

Neutral lipid extracts were dissolved in $CHCl_3$ at room temperature. Acetone was added until the formation of a precipitate and the resulting mixture was kept at 4°C for 2–4 days. The precipitate was filtered trough a millipore FH 0.5 μm filter, washed with acetone and dried.

4.3. Gel permeation chromatography

Analyses were performed on a HPLC instrument (Waters) fitted with a differential refractometer thermostated at 30°C, using a Styragel HR-2 column (Waters, 7.8 × 300 mm; effective molecular weight range 500–20000) thermostated at 25°C. The samples were eluted with THF at a flow rate of 1 ml min-[1]. Calibration of the column was performed with standards of polyethylene glycols (Polymer Laboratories).

4.4. Flash pyrolysis with in situ methylation using tetramethylammonium hydroxide (TMAH)

NL-2 Samples (0.5–2 mg) were loaded in tubular ferromagnetic wires (Curie temperature 650°C). Five microliters of 25% TMAH in methanol were added four times in 2 h. The wires were placed into the pyrolysis unit (Fisher 0316M) connected to a high frequency generator which heated them inductively in 0.15 s to the Curie temperature. This temperature was maintained for 10 s. The pyrolysis unit was directly coupled to a HP5890 gas chromatograph equipped with a fused silica CPSil5CB capillary column (25 m × 0.22 mm i.d., 0.4 μm film thickness) programmed from 80 to 300°C at 3°C min^{-1} coupled to a HP5989 mass spectrometer operated at 70 eV.

4.5. Alkaline hydrolysis

NL-2 Samples (10–20 mg) were saponified by refluxing for 1 h with 5% KOH in 2-methoxy ethanol/H_2O, 88/12 (v/v) (Daffé et al. 1983). The reaction mixture was neutralised with 6 N HCl and extracted with $CHCl_3$. The organic phase and the interfacial material developed between aqueous and organic phases were combined, dried and subjected to further derivatisation.

The mixture was treated with 2-methyl-1-propanol/HCl for 1 h at 90°C to convert acids into their 2-methyl-1-propyl esters. After evaporation of the solvent the residue was dissolved in 2-methyl-1-propanol and reduced to dryness once more to completely remove HCl.

For conversion of hydroxyl groups into *O*-trimethylsilyl groups the esterified mixture was treated with a mixture of anhydrous pyridine/1,1,1,3,3,3-hexamethyldisilazane/chlorotrimethylsilane (20/2/1 v/v/v). The mixture was centrifuged and the supernatant analysed.

For conversion of hydroxyl groups into acetoxy groups the esterified mixture was acetylated with a mixture of acetic anhydride/pyridine (1/1 v/v). After addition of H_2O the solvents were evaporated and the residue dissolved in CH_2Cl_2.

4.6. GC–MS identification, characteristic fragmentation ions

4.6.1. Alcohol

TMSi ether: *m/z* 75 (base peak); $M^+ - CH_3$. Acetoxy: *m/z* 61 $[CH_3CO_2H_2]^+$; $M^+ - CH_3$; $M^+ - CH_3CO_2H$.

4.6.2. Acid

2-Methyl-1-propyl ester: *m/z* 56 $[(CH_3)_2CHCH_2 - 1]^+$; *m/z* 57 (base peak); M^+; $M^+ - 56$; $M^+ - OCH_2CH(CH_3)_2$.

4.6.3. α,ω-Diol

TMSi ether: *m/z* 75 (base peak); *m/z* 149 $[(CH_3)_2Si(O)Si(OH)(CH_3)_2]^+$; $M^+ - (CH_3)_3SiOH$; $M^+ - 2 \times (CH_3)_3SiOH$. Acetoxy: *m/z* 61 $[CH_3CO_2H_2]^+$; $M^+ - CH_3CO_2H$; $M^+ - 2 \times CH_3CO_2H$. di-Methyl ether: *m/z* 45; $M^+ - CH_3$; $M^+ - CH_3OH$; $M^+ - 2 \times CH_3OH$.

4.6.4. ω-Hydroxy acid 2-methyl-1-propyl ester

TMSi ether: *m/z* 75; $M^+ - CH_3$; $M^+ - [(CH_3)_2CHCH_2 - 1]^+$; $M^+ - OCH_2CH(CH_3)_2$; $M^+ - OSi(CH_3)_3$. Acetoxy: *m/z* 61 $[CH_3CO_2H_2]^+$; $M^+ - CH_3CO_2H$; $M^+ - HOCH_2CH(CH_3)_2$; $M^+ - [CH_3CO_2H + HOCH_2CH(CH_3)_2]$.

4.6.5. ω-Hydroxy acid methyl ester

Methyl ether: *m/z* 45; *m/z* 74; $M^+ - CH_3$; $M^+ - CH_3OH$; $M^+ - 2 \times CH_3OH$.

Abstract

Six new triterpenoid saponins have been isolated from the stem bark of *Elattostachys apetala* together with four known triterpenoid saponins. Three of these new compounds are glycosides of a newly described genin, 29-hydroxyhederagenin (**1**). On the basis of spectral evidence, the structures of the new saponins were concluded to be α-hederin 28-*O*-[α-L-rhamnopyranosyl-(1→2)-β-D-glucopyranosyl] ester (**2**), sapindoside B 28-*O*-[α-L-rhamnopyranosyl-(1→2)-β-D-glucopyranosyl] ester (**3**), 3-*O*-β-D-xylopyranosyl astrantiasaponin VII (**4**), 3-*O*-[α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl]-28-*O*-[β-D-glucopyranosyl-(1→2)-{β-D-glucopyranosyl-(1→6)}-β-D-glucopyranosyl]-29-hydroxyhederagenin (**5**), 3-*O*-[α-L-arabinopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→2)-α-L- arabinopyranosyl]-28-*O*-[β-D-glucopyranosyl(1→2)-{β-D-glucopyranosyl(1→6)}-β-D-glucopyranosyl]-29-hydroxyhederagenin (**6**), and 3-*O*-[β-D-xylopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl]-28-*O*-[β-D-glucopyranosyl-(1→2)-{β-D-glucopyranosyl-(1→6)}-β-D-glucopyranosyl]-29-hydroxyhederagenin (**7**). © 2001 Elsevier Science Ltd. Keywords: *Elattostachys apetala*; Sapindaceae; Stem bark; Triterpenoid saponins; 29-Hydroxyhederagenin

1. Introduction

The genus *Elattostachys* (Blume) Radlk. (Sapindaceae) comprises fourteen species which are distributed in Malaysia, Australia and Polynesia (Delaude, 1993). *E. apetala* (Labill.) Radlk. (syn. *E. falcata* (A. Gray) Radlk.) is a shrub growing in secondary forests of New Caledonia and named Mako in traditional medicine (Adema, 1993a,b). Its stem bark has been traditionally used as an abortive which is considered dangerous since it may induce female or male sterility (Rageau, 1973). We report here the isolation and structural elucidation of four known saponins: α-hederin, astrantiasaponin VII, clemontanoside-C and sapindoside B, and of six new triterpenoid saponins isolated from the stem bark of this plant.

2. Results and discussion

Ground stem bark of *E. apetala* was extracted with 80% methanol and the methanolic extract was concentrated. The residue was dissolved in pure methanol and poured into acetone to form a precipitate which was finally dialysed against pure water. This extract was then purified using a combination of silica gel column chromatography, preparative TLC and reversed-phase C-18 column chromatography to give ten saponins.

Acid hydrolysis of the crude extract yielded two aglycones identified as hederagenin and 29-hydroxyheder agenin **1**, a new olean-12-ene triterpenoid. The major differences between the ^{1}H and ^{13}C NMR spectra of **1** and hederagenin were due to the replacement of a methyl group by a hydroxymethyl in ring E (Table 1). The ^{1}H NMR spectrum of **1** showed a supplementary two-proton singlet at δ_H 3.2 which correlated with a hydroxymethyl at δ_C 73.4 in an HSQC experiment. The observation of HMBC cross peaks between these protons and four carbons at δ_C 18.6 (CH_3), 28.7 (CH_2), 35.6

[a] Measured in $CDCl_3$.
[b] Measured in CD_3OD.
[c] Not determinated.

(C) and 40.7 (CH_2) suggested that position C-29 or C-30 was oxygenated. The EI MS of **1** lacked a molecular ion but showed fragment ion peaks arising from the characteristic retro Diels–Alder cleavage of ring C at *m/z* 264, 233 (264-CH_2OH), 219 (264-COOH) and 201 (219-H_2O). In the ROESY spectrum, the Overhauser interactions of the β-axial H-18 (δ_H 2.86, *dd*, $J = 13.5$, 3.5 Hz) with the ethylenic proton H-12 (δ_H 5.27) and with the methyl group at δ_H 0.93, therefore, CH_3-30 indicated that the hydroxymethyl group (CH_2OH) was C-29, in an α-equatorial position (Fig. 1). This was confirmed by the observation of an ROE between H-29 and the α-axial H-19 (δ_H 1.71, *t*, $J = 13.5$ Hz). The assignments of other proton and carbon signals of **1** were deduced from analysis of the usual 2D NMR experiments: COSY, HSQC and HMBC (Table 1). The ^{13}C NMR values of the B/C/D/E ring moieties are in good agreement with those reported for dianic acid which possesses a carboxylic acid function instead of a hydroxymethyl group at C-23 (Oshima et al., 1984; Elgamal et al., 1996). Thus sapogenin **1** is 29-hydroxyhederagenin, i.e. the 3β-hydroxy isomer of the previously described aglycone, spinogenin C_5, of *Acanthopanax spinosus* (Miyakoshi et al., 1993).

Three of the new saponins, compounds **2**, **3** and **4**, are bisdesmosides of hederagenin, while three others, saponins **5**, **6** and **7**, have 29-hydroxyhederagenin as the aglycone. Their structures were established as follows.

In the ESI–MS positive mode, pseudomolecular ions $[M+Na]^+$ were detected at *m/z* 1081, $C_{53}H_{86}O_{21}Na$ for saponin **2**, at *m/z* 1213, $C_{58}H_{94}O_{25}Na$ for saponin **3** and at *m/z* 1375, $C_{64}H_{104}O_{30}Na$ for saponin **4**. The molecular formulae were confirmed by the observation of the corresponding $[M-H]^-$ pseudomolecular ions in the negative mode (at *m/z* 1057 for **2**, 1189 for **3** and 1351 for **4**). The common positive fragment ion at *m/z* 773 and negative fragment at *m/z* 749 were attributed to the formation of an α-hederin type substructure (**8**) that was present in the three new compounds. The ^{13}C NMR spectra demonstrated that these three saponins were all glycosides of an α-hederin unit [3-*O*-α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl hederagenin, **8**] (Table 1) (Encarnación et al., 1981; Kimata et al., 1983; Lavaud et al., 1994). The presence of this structural unit was corroborated by analysis of heteronuclear correlations in the HSQC and HMBC spectra of the three compounds. The ^1H and ^{13}C NMR data for compound **2** displayed signals for four anomeric protons at δ_H 5.45 (*d*, $J = 7.3$ Hz), 5.38 (*d*, $J = 1.2$ Hz), 5.18 (*d*, $J = 1.2$ Hz) and 4.57 (*d*, $J = 5.1$ Hz), and carbons at δ_C 95.2, 101.8, 102 and 104.5, respectively. The last two pairs of signals were attributed to the diglycosidic chain [α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl] of α-hederin on the basis of COSY and HSQC connectivities. By comparison with α-hederin, a supplementary methyl carbon at δ_C 18.4 was assigned to a 6-deoxyhexose, and a hydroxymethyl at δ_C 62.5 to a hexose. COSY and HOHAHA experiments allowed full identification of two spin systems: one for a β-D-glucose starting from the deshielded anomeric proton whose chemical shift corresponded to an ester chain, and one for an α-L-rhamnose starting from the anomeric doublet at δ_H 5.38. Sequencing of the diglycosidic ester chain in saponin **2** was achieved by analysis of the HMBC spectrum which showed correlations between C-28 of α-hederin (δ_C 178.1) and H-1 of the glucose ester, and between C-2 of this glucose (δ_C 77.4) and H-1 of the second terminal rhamnose. Thus the structure of the new saponin **2** is 3-*O*-[α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl]-3β, 23-dihydroxyolean-12-en-28-oic acid 28-*O*-[α-L-rhamnopyranosyl-(1→2)-β-D-glucopyranosyl] ester.

Comparison of the NMR spectra of saponin **2** and compounds **3** and **4** indicated that **3** and **4** possessed one and two supplementary sugar units, respectively. The tandem mass spectrum (ESI–MS/MS) of their pseudomolecular ion $[M+Na]^+$ yielded the same intense fragment ion at *m/z* 905 corresponding to the loss of their ester glycosidic chain. A similar result was obtained in the negative mode starting from $[M-H]^-$ with a fragment ion at *m/z* 881 [M-ester chain]$^-$. This indicated that saponin **4** only differed from **3** by the presence of an additional hexose in its ester chain. The MS/MS fragmentation of the product ion yielded intense ions at *m/z* 773 (positive mode) and 749 (negative mode), suggesting that **3** and **4** possessed a supplementary pentose in the glycosidic chain of the α-hederin moiety. Identification of this pentose as a β-D-xylose, was achieved by analysis of COSY, HOHAHA and HSQC spectra. The ROE interactions observed between H-1 [δ_H 4.50 (**3**), 4.47 (**4**)] and H-3 [δ_H 3.35 (**3**), 3.34 (**4**)] and the axial H-5 [δ_H 3.24 (**3**), 3.21 (**4**)], confirmed the α-axial orientation of these three protons and the β-anomeric configuration of this sugar. In the ROESY spectrum of **3**, the anomeric proton of the xylose revealed an intense ROE with

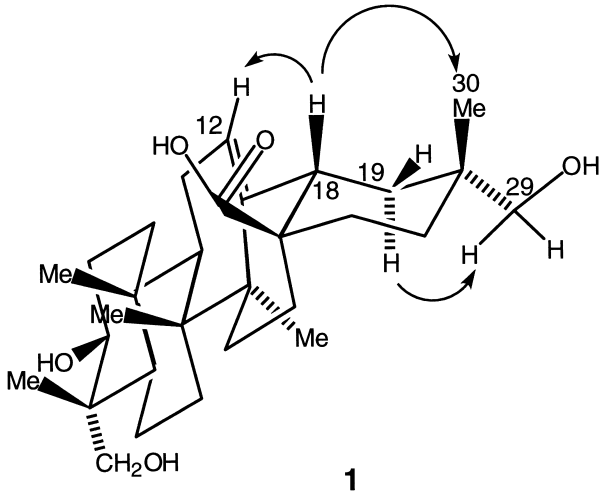

Fig. 1. Significant ROE correlations in ROESY experiment of **1**.

	R_1	R_2	R_3

9		H	H
10		H	H
11	H	H	
H-3 of the rhamnose of the α-hederin part. Thus, the new saponin **3** corresponds to 3-*O*-[β-D-xylopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl]-3β,23-dihydroxyolean-12-en-28-oic acid 28-*O*-[α-L-rhamnopyranosyl-(1→2)-β-D-glucopyranosyl] ester.

The supplementary hexose in the ester chain of saponin **4** was identified as a β-D-glucose by analysis of its proton multiplicities and of COSY and HOHAHA correlations (Table 2). Despite the use of a 500 MHz NMR spectrometer, the presence of six sugar units in **4** resulted in considerable overlap of the glycosidic protons. A relayed COSY experiment was carried out to disentangle the spin systems and obtain unequivocal assignments. This experiment was found particularly useful for the assignments of the glucose H-3 and H-4 protons, which all resonated as large triplets in the same area. The glucose ester (H-1 at δ_H 5.40, C-1 at δ_C 95.2) had its C-6 deshielded (δ_C 69.6) as a consequence of substitution by another sugar unit. The two glycosidic chains of **4** were sequenced by the observation of ROE interactions and HMBC correlations. In the ester triglycosidic chain, ROEs were found between H-1 of the terminal glucose (δ_H 4.33) and the glucose ester H-6 (δ_H 3.74), and between H-1 of the terminal rhamnose (δ_H 5.34) and H-2 and H-3 of the glucose ester. In the triosidic chain at C-3, effects were observed between arabinose H-1 and H-3 of hederagenin, between xylose H-1 and rhamnose H-3, and between rhamnose H-1 and arabinose

H-2 and H-3. HMBC cross-peaks confirmed these results, although they did not permit the definitive assignment of the positions of the rhamnoses in these chains. The comparison of ^{1}H and ^{13}C NMR data of **4** with those found for saponin **3** and sapindoside B (**9**) suggested that these three glycosides possessed the same triglycosidic chain attached at C-3 of hederagenin. Finally, comparison of the carbon chemical shifts of the ester glucose moities with those reported in the literature for the lonicerosides from *Lonicera japonica* (Son et al., 1994), showed coherent values with small differences due to solvent effects ($\Delta\delta$ from -0.2 to $+1.2$ ppm). The structure of saponin **4** was thus deduced as 3-*O*-[β-D-xylopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl]-3β,23-dihydroxyolean-12-en-28-oic acid 28-*O*-[α-L-rhamnopyranosyl-(1→2)-{β-D-glucopyranosyl-(1→6)}-β-D-glucopyranosyl] ester.

The presence of 29-hydroxyhederagenin as the aglycone in the structure of saponins **5**–**7** was deduced from analysis of their proton and carbon NMR spectra

(Tables 1 and 3) and in particular, by the HSQC experiment which showed only five angular methyls. Two hydroxymethyls were detected in the COSY and HSQC experiments: one formed an AB system at δ_H 3.36 and 3.54 (two *d*, $J=11$ Hz) for the CH_2OH-23 (δ_C 64.7), and the second a singlet at δ_H 3.21 for the two accidentally equivalent protons of the CH_2OH-29 (δ_C 74.4). The HMBC correlations of the methyl and hydroxymethyl protons confirmed the presence of 29-hydroxyhederagenin in the three saponins. Analysis of MS/MS fragmentation revealed common intense product ions at *m/z* 789 (positive mode) and 765 (negative mode), suggesting that the same diglycosidic chain rhamnose-arabinose, was attached at C-3 of the aglycone, as in compounds **2**–**4** with α-hederin. The MS/MS of pseudomolecular ions of saponins **6** and **7** differed

from that obtained for **5** by the presence of a product ion at *m/z* 921 in the positive mode displaced to *m/z* 897 in the negative mode. This proved that an additional terminal pentose was present in the osidic chain of **6** and **7** relative to **5**. Comparison of the NMR data of reference saponins **2**–**4** and clemontanoside-C (**10**), and those of **5**, **6** and **7** enabled us to propose the part-structures 3-*O*-α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl-29-hydroxyhederagenin for **5**, 3-*O*-α-L-arabinopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl -29-hydroxyhederagenin for **6** and 3-*O*-β-D-xylopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→2)-α-L-arabino pyranosyl-29-hydroxyhederagenin for **7** (Tables 1 and 3). The mass spectra indicated that saponins **5**–**7** contained the same ester glycosidic chain, which was composed of three hexoses. This was confirmed in the ^{13}C NMR by the detection of three hydroxymethyls at δ_C 62.8, 63.7 and 69.5 (Table 3). As above, the identification of these hexoses as three β-D-glucoses was achieved by analysis of COSY and HOHAHA correlations and from the multiplicities and coupling constants of the osidic protons. The glucose ester [anomeric signals at δ_H 5.45 (*d*, $J=8$ Hz) and δ_C 94] was substituted on positions 2 and 6 as shown by the deshielding of C-2, C-6 and H-6. ROE cross-peaks were detected between H-1 of the two other terminal glucoses (δ_H 4.82 and 4.36) and ester glucose H-2 (δ_H 4.82) and H-6 (δ_H 3.80), respectively. The localisation of the ester chain on the carboxylic function C-28 of 29-hydroxyhederagenin was established by its HMBC correlation with H-1 of the ester glucose. Sequencing of the two glycosidic chains was also confirmed by the observation of $^3J_{H\text{-}C}$ correlations through the glycosidic linkages (HC–O–C) in the HMBC spectrum of saponins **5**–**7**. From all these data, the structure of saponin **5** was assigned as 3-*O*-[α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl]-3β,23,29-trihydroxyolean-12-en-28-oic acid 28-*O*-[β-D-glucopyranosyl-(1→2)-{β-D-glucopyranosyl-(1→6)}-β-D-gluco pyranosyl] ester, that of saponin **6** 3-*O*-[α-L-arabinopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→2)-α-L-arabino pyranosyl]-3β,23,29-trihydroxyolean-12-en-28-oic acid 28-*O*-[β-D-glucopyranosyl-(1→2)-{β-D-glucopyranosyl-(1→6)}-β-D-glucopyranosyl] ester, and that of saponin **7** 3-*O*-[β-D-xylopyranosyl-(1→3)-α-L-rhamnopyranosyl-(1→2)-α-L-arabinopyranosyl]-3β,23,29-trihydroxyolean-12-en-28-oic acid 28-*O*-[β-D-glucopyranosyl-(1→2)-{β-D-glucopyranosyl-(1→6)}-β-D-glucopyranosyl] ester. Saponins **6** and **7** were obtained as a mixture which was not amenable to separation by silica gel chromatography.

Compounds **8**, **9**, **10** and **11** were identified as known saponins by analysis of their spectral data (ESI–MS, ^1H and ^{13}C NMR) and by comparison with literature values. Saponin **8** corresponded to α-hederin (Encarnación et al., 1981; Lavaud et al., 1994), and saponins **9** and **10** sapindoside B and clemontanoside-C (= saponin A from *Sapindus mukurossi*), respectively (Encarnación et al., 1981; Kimata et al., 1983; Thapliyal and Bahuguna, 1993; Lavaud et al., 1994). Saponin **11** was concluded to be astrantiasaponin VII previously isolated from *Astrantia major* (Hiller et al., 1990). Analysis of ESI–MS and 2D NMR spectra permitted full characterisation of this compound for the first time.

These results are a part of our ongoing study on the saponins of species belonging to the family of Sapindaceae. The isolation and structure elucidation of bisdesmosides of hederagenin and of 29-hydroxyhederagenin from the stem bark of *E. apetala* support the chemotaxonomical proposals of Delaude (1993), namely that species of the subfamily Sapindoideae contain saponins with hederagenin as aglycone, while the genins of saponins from species of the subfamily Dodonaeoideae are most often polyhydroxylated triterpenoids.

3. Experimental

3.1. General

^1H and ^{13}C NMR spectra were recorded on a Bruker DRX-500 spectrometer in CD_3OD or $CDCl_3$ at 500 and 125 MHz, respectively. Two dimensional NMR experiments were performed using standard Bruker microprograms (XWIN-NMR version 2.6 software). ESI mass spectra and MS–MS experiments were performed using a Bruker Esquire LC–MS instrument. Optical rotations were measured on a Perkin-Elmer 241 polarimeter.

3.2. Plant material

The leaves and stem bark of *Elattostachys apetala* were collected in Dumbéa, New-Caledonia by J.P. Cosson and identified by one of us (M.L.). The herbarium sample (CORE 1358) is deposited in the herbarium of the botany laboratory at the IRD centre of Nouméa (New Caledonia).

3.3. Extraction and isolation

Powdered stem bark (720 g) was boiled in 20% aq. MeOH (600 ml) for 3 h. After cooling and filtration, the hydromethanolic extract was evaporated to provide a residue (107.5 g) which was dissolved in MeOH (400 ml). The solution was added to 2 l of Me_2CO and the ppt. was filtered and dried over KOH in vacuo. This ppt. was dissolved in H_2O (360 ml) and dialysed in cellulose tubing against H_2O during 48 h. After freeze-drying of the content of the tubes, 13 g of a saponin mixt. was obtained (yield 1.8%).

A part of the dialysed saponin mixt. (4 g) was purified by silica gel CC (160 g) using a gradient of $CHCl_3$–MeOH–H_2O (95:5:0, 8:2:0, 80:20:1, 80:20:2, 70:30:2, 60:40:5). Frs. eluted with 8:2:0 contained saponin **9** (frs.

[18–22]), a mixt. of saponins **8** and **9** (frs. [32–34]) and saponin **10** (frs [35–45]). Frs. [71–84] eluted with 80:20:1 contained saponins **2** and **3**. Frs. eluted with 70:30:2 contained saponin **11** (frs. [130–143]) and saponin **4** (frs. [144–169]). Frs. [180–195] eluted with 60:40:5 contained saponins **5**, **6** and **7**.

Saponins **2** (14.1 mg) and **3** (6.2 mg) were purified by reversed-phase CC eluted with a gradient of MeOH–H_2O (from 5:5 to 65:35) as eluent and then by prep. TLC in $CHCl_3$–MeOH–H_2O (60:40:5). Saponin **4** (4.1 mg) was purified by reversed-phase CC (C-18) eluted with a gradient of MeOH–H_2O (from 3:7 to 6:4) as eluent and then prep. TLC in $CHCl_3$–MeOH–H_2O (60:40:7). Frs. containing saponin **5** (24 mg), and mixt. of saponins **6** and **7** (26.3 mg) were subjected to ion exchange chromatography by using an Amberlite IRN 77 (H^+) resin column before purification by silica gel CC eluted with $CHCl_3$–MeOH–H_2O (from 9:1:0 to 70:30:4); pure compounds were then obtained by prep. TLC in $CHCl_3$–MeOH–H_2O (60:40:5) using two migrations. Saponins **8** (6.7 mg) and **9** (33.4 mg) were obtained by flash CC eluted with a gradient of $CHCl_3$–MeOH (from 100:0 to 8:2) and then purified by prep. TLC in $CHCl_3$–MeOH (8:2). Saponin **10** (3.8 mg) was purified by silica gel CC with of $CHCl_3$–MeOH (from 100:0 to 8:2) as eluent, followed by reversed-phase CC (MeOH–H_2O; from 5:5 to 8:2); frs. eluted with 7:3 were then purified by prep. TLC in $CHCl_3$–MeOH (7:3). Saponin **11** was purified by prep. TLC in $CHCl_3$–MeOH–H_2O (60:40:7; two migrations) of frs. obtained from reversed-phase CC (MeOH–H_2O; from 5:5 to 6:4).

3.4. Acid hydrolysis of saponins

The crude saponin (300 mg) was dissolved in 20 ml of a mixture (1:1) of H_2SO_4 0.02 N and 6.5% $HClO_4$, and heated at 140°C in a sealed tube for 2 h. After cooling, the sapogenin ppt. was filtered, rinsed with H_2O until pH 7 and dried in vacuo over P_2O_5. The acid aq. layer was neutralized with KOH 0.5 M and freeze-dried. Five sugars were identified with authentic samples by TLC [MeCOEt–Me_2CH_2OH–Me_2CO–H_2O (20:10:7:6)] as glucose, rhamnose, arabinose, xylose and galactose. The sapogenin mixt. (255 mg) was purified by CC on silica gel eluted with a gradient of $CHCl_3$–MeOH. Hederagenin (8.5 mg) was in frs. eluted with $CHCl_3$ and was finally purified by prep-TLC in $CHCl_3$–MeOH [97:3]. The polar frs. were purified by silica gel CC eluting with mixts. of $CHCl_3$–MeOH [100:0, 98:2, 95:5]. Frs. 15–32 contained hederagenin (3.2 mg) and frs. 47–77 eluted with $CHCl_3$–MeOH [95:5] contained 29-hydroxyhederagenin **1** (3.7 mg).

3.5. 29-Hydroxyhederagenin (*1*)

Hydroquinone derivatives and monoterpenoids from the Neotropical liverwort *Plagiochila rutilans*☆

David S. Rycroft *, W. John Cole

Department of Chemistry, University of Glasgow, Glasgow G12 8QQ, Scotland, UK

Received 15 November 2000; accepted 26 January 2001

Abstract

The structure of a prenylbenzene derivative isolated previously from a Cuban specimen of the liverwort *Plagiochila rutilans* is revised to 2-methoxy-6-prenylhydroquinone. The hydroquinone was observed as a prominent component of the NMR and GC–MS fingerprints of five recent specimens of the liverwort from Bolivia, Brazil and Costa Rica. The corresponding quinone was observed as a minor component. Two new methylated derivatives of the hydroquinone were observed as prominent components in one specimen from Bolivia; these were isolated, characterized, and their structures elucidated as 2-methoxy-1-*O*-methyl-6-prenylhydroquinone and 2-methoxy-4-*O*-methyl-6-prenylhydroquinone using ^{1}H NMR spectroscopy. The liverwort has a strong peppermint-like odour that is caused by the presence of several menthane monoterpenoids, including notably pulegone, menthone, isomenthone, terpinolene and limonene. One of the Costa Rican specimens contained considerable amounts of the new lactone 3,7-dimethyl-2,6-octadien-1,6-olide as the principal monoterpenoid in place of pulegone. Two Costa Rican specimens distinguished morphologically as *Plagiochila standleyi* (a taxon closely related to *P. rutilans* and reduced elsewhere to a variety of that species) are characterized by large amounts of 3-hydroxy-4′-methoxybibenzyl. *P. standleyi* was also reported to have a peppermint-like odour in the field. Menthane monoterpenoids were again responsible but in this case the major components were limonene, β-phellandrene, α-terpinene and the endoperoxide ascaridole. © 2001 Elsevier Science Ltd. Keywords: *Plagiochila rutilans*; *Plagiochila standleyi*; Hepaticae; NMR spectroscopy; Structural revision; Chemosystematics; Menthane monoterpenoids; Prenylbenzenes; 3-Methoxy-5-(3-methylbut-2-enyl)-benzene-1,2-diol; 2-Methoxy-6-(3-methylbut-2-enyl)-benzene-1,4-diol; 7-Isopropylidene-4-methyl-6,7-dihydro-5*H*-oxepin-2-one

1. Introduction

Plagiochila (Dumort.) Dumort. is the most numerous hepatic genus: a compilation of names up to the end of 1973 includes around 2500 taxa (Inoue, 1989). Revision of Neotropical *Plagiochilae* is establishing extensive synonymy (Heinrichs et al., 1998), and cooperative morphological and phytochemical studies are helping to improve our understanding of this difficult genus (Heinrichs et al., 2000). We have recently been involved in a taxonomic investigation of *Plagiochila rutilans* Lindenb. (Heinrichs et al., 2001), a species that is poorly known despite a notable peppermint-like odour. A previous chemical study by Huneck et al. (1984) resulted in isolation of an oil with a peppermint-like odour (that was not investigated further) and of a dihydroxymethoxyprenylbenzene that was assigned structure **1** on the basis of NMR data and confirmation by synthesis. A second synthesis of the dimethyl ether of **1** was reported very recently (Brunner et al., 2000). Using NMR and GC–MS fingerprinting (Rycroft, 1996, 1998) we have observed a compound that apparently corresponded to **1** and, in addition, two isomeric hydroxydimethoxyprenylbenzenes, both giving NMR spectra with non-equivalent, *meta*-coupled protons. These two isomers could not both have the same oxygenation pattern as **1**. We have elucidated the structures of this pair of isomers independently, using NOE experiments and by comparison of ^{1}H NMR parameters, and discovered that both have 1,2,4-trioxy-substitution (and are new compounds). NOE experiments also established that the dihydroxymethoxyprenylbenzene reported previously by Huneck et al. (1984) has the same oxygenation pattern and that the correct structure is 2-methoxy-6-prenylhydroquinone (**2**). This paper reports details of the characterization and structural elucidation of these compounds and of a new lactone based on the menthane skeleton, identifies several of the monoterpenoids

responsible for the odour of *P. rutilans*, and in addition reports details of the composition of the extracts of nine specimens of *P. rutilans* and two of *P. standleyi* Herzog ex Carl, a closely related taxon that is reduced in another publication to a variety of *P. rutilans* (Heinrichs et al., 2001).

2. Results and discussion

2.1. NMR and GC–MS fingerprinting

Six specimens, (i)–(vi) in Table 1, of *Plagiochila rutilans* and two, (vii)–(viii), of *P. standleyi* collected recently from Bolivia, Brazil and Costa Rica were investigated together with three older specimens, (ix)–(xi), from Ecuador and Cuba, including a voucher from the previous work on *P. rutilans* (Huneck et al., 1984). Data for 26 components identified using NMR and GC–MS fingerprinting are summarized in Table 1. Extracts (i)–(viii) from the eight recent specimens gave good NMR fingerprints whereas extracts (ix)–(xi) from the oldest three specimens were poorer and were discounted when trends in the presence of secondary metabolites were assessed in order to delineate chemical races.

2.2.1. Hydroquinone derivatives

NMR fingerprints of the $CDCl_3$ extracts of specimens (ii)–(vi) were dominated in the aromatic and methoxyl regions by proton signals from a pair of *meta*-coupled protons and one methoxyl group. Comparison within the set of spectra showed that one of the Brazilian specimens, (iv), was particularly rich in the compound responsible and a set of signals was observed that was consistent with that reported for compound **1** (Huneck et al., 1984). GC–MS confirmed that the predominant component of the extract had M_r 208. One-dimensional NOE experiments involving pulsed field gradients (PFGs, cf. Stott et al., 1997) produced NOEs between the allylic methylene protons and only one of the aromatic protons, and between the methoxyl protons and the other aromatic proton. The base peak in the mass spectrum has m/z 152 $[M–C_4H_8]^+$, indicative of a hydroxyl group *ortho* to the prenyl group, whereby the hydroxyl proton can undergo intramolecular transfer to a departing C_4H_7 fragment (Ritchie et al., 1964). This evidence leads to the conclusion that structure **1** should be revised to **2**, namely 2-methoxy-6-prenylhydroquinone. Differences between *ortho*- and *para*-shielding effects in an aromatic ring are rather subtle, so that ^{13}C NMR spectra cannot readily be used to assign structures **1** and **2** a priori. The ^{13}C chemical shifts assigned previously (Huneck et al., 1984) to the oxygenated aromatic carbons are in fact very similar to values reported for an oligoprenyl homologue of **2** (Bonny and Capon, 1994).

GC–MS of the extracts containing **2** always indicated the presence of a component with M_r 206 that was assigned to the corresponding quinone, 2-methoxy-6-prenyl-1,4-benzoquinone (**3**). A set of aromatic, methoxyl and allylic methylene ^1H NMR peaks was observed to correlate with the proportions of this component. and had chemical shifts very close to those of an oligoprenyl homologue (Bonny and Capon, 1994). The proportion of **3** increased slowly as an extract was stored and the proportion derived from GC–MS, performed after the NMR fingerprinting, was often greater than the minor

amount observed in the initial NMR spectrum (Table 1). It is possible that some of the quinone observed was formed by oxidation of **2** during extraction. The base peak in the mass spectrum of **3** has m/z 191 $[M–CH_3]^+$ and is assigned to the chromenium ion **4**, formed following the characteristic intramolecular cyclization of 1,4-benzoquinones prenylated in the *ortho* position (Das et al., 1965). GC–MS of extract (vi) showed a minor peak (24% of **3**) that eluted just before **3** ($\Delta R_i = 4$) and that produced a very similar mass spectrum, the main differences being that the base peak was relatively more intense and the three peaks with m/z 159, 121 and 69 were much less intense. As m/z 69 arises from cleavage producing a prenyl fragment $C_5H_9^+$, the minor component is assigned to the chromenol **5**, the cyclized isomer that is unlikely to eliminate $C_5H_9^+$. The mass spectrum we observed is similar to that obtained for the synthetic compound **5** (Garcías et al., 1991; Saá, personal communication). Reduction of the temperature of the injection port from 250 to 200°C did not affect the ratio of **5** to **3** and provided evidence that **5** was present in the solution before injection. GC–MS of the acetylated extracts showed that **3** could be acetylated along with the hydroxyl-containing compounds; the main product showed an increase in mass of 42 Da and is presumably the monoacetate **6**, formed from both **3** and **5**.

^{1}H NMR spectra indicated that the $CDCl_3$ extracts of the oldest three specimens of *P. rutilans* were weak and few peaks were identifiable in the NMR fingerprints. GC–MS of these extracts nevertheless gave useful information about the phenolic compounds and demonstrated that **2** and **3** were present in both Cuban specimens, (ix) and (x), whereas only the quinone **3** was present in the Ecuadorian specimen (xi). Specimen (i) (Bolivia, 1997) gave a weaker extract than the more recent specimens but the NMR fingerprint was very useful. A dominant pair of methoxyl signals as well as a pair of *meta*-coupled aromatic protons indicated a methylated derivative of **2** and an additional set of analogous minor signals (also observable in the more recent specimens) suggested the presence of a second isomer. GC–MS of the extract confirmed the presence of two components with M_r 222.

The extract of a larger amount of the 1997 Bolivian collection was chromatographed, using $CDCl_3$ as eluent, through a short plug of silica gel in a Pasteur pipette and fractions were collected in NMR tubes. The first fraction contained the less polar, minor hydroxydimethoxy-isomer (0.2 mg). GC–MS high resolution mass measurement confirmed the formula $C_{13}H_{18}O_3$. A hydroxyl group *ortho* to a prenyl group, analogous to **2**, was indicated by the base peak m/z 166 arising from $[M–C_4H_8]^+$. NOE experiments using PFG selective excitation produced an NOE from the allylic methylene protons to the more shielded aromatic doublet. Selective excitation of the latter signal enhanced the more shielded methoxyl signal, whereas selective excitation of the less shielded aromatic doublet enhanced both methoxyl signals. These observations lead to the conclusion that the less polar isomer is 2-methoxy-4-*O*-methyl-6-prenylhydroquinone (**7**). Apart from the side-chain, the chemical shifts are extremely similar to those reported for analogous compounds with straight chain alkenyl and alkyl groups such as belamcandol A (Fukuyama et al., 1991), hierridin (González et al., 1992b) and belamcandaphenol P (Seki et al., 1995).

The fourth fraction from the mini-column contained the more polar, major hydroxydimethoxy-isomer (0.4 mg). GC–MS high resolution mass measurement again confirmed the formula $C_{13}H_{18}O_3$. Attempts to measure NOEs were frustrated by decomposition of the compound in dilute $CDCl_3$ solutions during long experiments, even when an amber tube was used. There are four possible structures remaining with a pair of non-equivalent *meta*-coupled protons. The more polar isomer was assigned structure **8**, 2-methoxy-1-*O*-methyl-6-prenylhydroquinone, on three grounds. First, the chemical shifts are extremely similar to those reported for analogues with a straight chain alkenyl or alkyl group instead of a prenyl group; comparators are a synthetic isomer of hierridin (González et al., 1992a), the (*Z*)-heptadec-10-enyl compound (Marner and Horper, 1992) and irisphenol (Seki et al., 1995). Secondly, the chemical shift, δ4.6, and breadth of the NMR signal of the remaining hydroxyl proton indicate that it is not hydrogen-bonded to an adjacent methoxyl group; in contrast, in **7** the hydroxyl group at C-1 can hydrogen-bond to the methoxyl group at C-2 and the hydroxyl proton is observed as a relatively sharp singlet at δ5.27. Thirdly, the compound elutes more slowly than its isomer **7** both on silica gel and on GC, and structure **8** has the hydroxyl group in the most accessible position. Decomposition presumably occurs via phenolic oxidation and the presence of aromatic protons *ortho* to the hydroxyl group in **8** also accounts for the greater tendency of **8**, compared to **7**, to decompose.

2.1.2. Bibenzyls and ethylbenzenes

The *P. standleyi* specimens, (vii) and (viii), stand apart from the others in containing very large amounts (5% w/w) of 3-hydroxy-4′-methoxybibenzyl (**9**). This bibenzyl, unknown in Nature until it was reported recently from *Plagiochila* sect. *Glaucescentes* Carl (Heinrichs et al., 2000), was generally detectable in only trace amounts in the other extracts.

Although the ^{1}H NMR spectra of the three oldest specimens were generally less informative, extract (ix), from the 1978 Cuban specimen, did show three methoxyl signals and three aromatic signals with relative intensities 12:6:3:4(s):1(d):1(m), respectively, as well as a singlet with relative intensity 2 at an intermediate chemical shift. GC–MS showed two substantial unassigned peaks with M_r 196 and 180 in the ratio 2:1. Although

Table 1
Compounds in $CDCl_3$ extracts of *Plagiochila rutilans* Lindenb., (i)–(vi) and (ix)–(xi), and *Plagiochila standleyi* Herzog ex Carl, (vii)–(viii), in order of elution on GC. Minor components observed only using GC–MS are included if they were >5% in at least of three extracts (i)–(viii), except that some additional peaks with R_i <1200 are included so that the monoterpenoid picture is more complete

[a] The Kováts retention index is in Section 3 (Experimental) if it is not in this column.

[b] Limonene and β-phellandrene are almost coincident under our elution conditions but the mass spectra are distinguishable; the TIC ratios shown against limonene are for the sum of both compounds and '+' indicates that β-phellandrene was also present.

[c] Sum of the TIC ratios of ascaridole and its isomeric thermal transformation product.

the compounds were not isolated, consideration of the signals and ratios observed led to the proposal that the compounds are a pair of ethylbenzene derivatives with structures **10** and **11** respectively; appropriate ethyl NMR signals could also be identified. The published ^{1}H NMR and GC–MS data for compound **10** (Pincock and Wedge, 1994) are extremely similar to those observed in extract (ix). The assignment of structure **11** relies on the close analogy of the data to those of compound **10**.

Ironically, the oxygenation pattern of **10** and **11** is the same as that of **1**, the structure published originally for the prenylhydroquinone derivative **2**. Structures **10** and **11** were in fact assigned before it was realised that the published structure was incorrect. Nevertheless, although the biogenesis of compounds **10** and **11** is unknown, bibenzyls with the same arrangement of oxygen substituents as **10** and **11** have in fact been reported from liverworts (Asakawa, 1995). The NMR signals observed militate in favour of the symmetry of structure **10** rather than the pattern of oxygen substituents in structure **2** and we can find no direct evidence pointing to structures other than **10** and **11**.

Compounds **10** and **11** were also detectable in the extract of the second Cuban specimen, (x), but not in any of the others.

2.1.3. Monoterpenoids

GC–MS of the extracts used for NMR fingerprinting showed the presence of several monoterpenoids (Table 1). In the recent specimens there could be large amounts, e.g. pulegone (**12**) was 3% w/w of specimen (iii). There were still significant amounts of pulegone in the oldest specimen, (ix); here, however, there were much larger amounts of other monoterpenoid ketones, namely menthone and isomenthone, and the most abundant component was 8-*p*-cymenol (**13**). The first report from a liverwort (*Riella helicophylla*) of this compound was made only recently by Becker and Martini (1999). In the present case, the presence in the older specimens of greater amounts than in the newer raises the suspicion that **13** may be formed during storage by oxidation of other monoterpenoids.

Extract (vi) differed significantly from (i)–(v) in that pulegone was absent. However, there were large NMR signals rather similar, but not identical, to those of piperitenone (**14**) (Baeckström et al., 1985) and a COSY experiment showed that the proton connectivity was the same as in **14**. A fraction in which the compound responsible was the major component (0.08 mg) was obtained by evaporating the extract and passing it through a short plug of silica gel using $CDCl_3$ as eluent. The NMR spectrum of the fraction confirmed the set of signals assigned to the compound and high resolution GC–MS gave the molecular formula $C_{10}H_{14}O_2$. Modification of structure **14** by addition of one oxygen so that the ^{1}H NMR spectrum changes minimally can only be achieved by inserting the oxygen between C-3 and C-4 of piperitenone. The alternative, epoxidation of the 4(8) double bond, would not only create a chiral centre that could render the C-5 methylene protons non-equivalent but also shift the methyl groups on C-8 to more shielded positions. The compound is, therefore, the new lactone 3,7-dimethyl-2,6-octadien-1,6-olide (**15**).

The *P. standleyi* extracts, (vii) and (viii), already distinct from the others by virtue of the absence of hydroquinone derivatives and the presence of large amounts of the bibenzyl **9**, are also distinct with respect to the monoterpenoid content. Here there are large amounts of limonene (1–2% w/w of the liverwort) and at least 0.5% w/w each of β-phellandrene, α-terpinene and the endoperoxide ascaridole (**16**), identified from signals in the ^{1}H NMR spectrum (Tokuyama and Nakamura, 1994) and comparison with an authentic sample (as *Oleum Chenopodii anthelminthici*). Ascaridole rearranges thermally to *cis*-1,2:3,4-diepoxy-*p*-menthane (Boche and Runquist, 1968), partially even in the injection port of the GC (Nitz et al., 1989). We could largely avert rearrangement by reducing the injection port temperature to 75°C. The mass spectrum we observed for the rearrangement product was very similar to that reported by Nitz et al. (1989) and to that presented by Adams (1995) as arising from *trans*-ascaridole (sic). The mass spectrum we observed for ascaridole itself with a base peak m/z 121 (Section 3.4.10) was very different and also substantially different from those in the literature for ascaridole, e.g. Nitz et al. (1989), Ogawa et al. (1996) and as *cis*-ascaridole (sic), Adams (1995), where the base peak is m/z 43. These spectra were all obtained from GC–MS and we believe the discrepancy is because rearrangement can occur to different extents in the short section of column in the heated transfer tube between the GC and the MS, depending on the characteristics of the column. We consider that our mass spectrum of ascaridole (after GC on a non-polar column) more closely represents that truly arising from fragmentation of structure **16** in the mass spectrometer. Published mass spectra show only small differences between ascaridole and its rearrangement product whereas our spectra show gross differences. Indeed our mass spectrum of ascaridole, with a large m/z 136 peak, is similar to that of α-terpinene, suggesting that loss of dioxygen is the most important primary fragmentation.

Extract (viii) was stored in a freezer over a weekend after the NMR fingerprint was taken. Despite this precaution, a check of the NMR spectrum before the GC–MS measurements were performed revealed no signals for α-terpinene and an increase in the intensity of the ascaridole signals. This observation raises the question of whether or not ascaridole is present in the liverwort originally. Ascaridole can indeed be produced by chlorophyll-sensitized photooxygenation of α-terpinene (Gollnick, 1968). However, our experience with *P. retrorsa* Gottsche

(Rycroft et al., 2001) using the same working methods was that no ascaridole was ever observed in extracts that contained α-terpinene. We conclude that the ascaridole observed in the extract when first prepared was present in the plant originally.

The present work is the first report of ascaridole from liverworts, although two derivatives are known (Becker and Martini, 1999). A putative degradation product was found in *Jungermannia obovata* (Connolly, 1990), although two menthanoid hydroperoxides have also been isolated (Buchanan et al., 1998) and it is possible that ascaridole is not involved.

It is clear that the compounds principally responsible for the peppermint-like odour of *P. rutilans* are pulegone, menthone, isomenthone, terpinolene and limonene. The *P. standleyi* specimens, (vii) and (viii), were also noticed to have a peppermint-like odour in the field; in this case limonene, β-phellandrene and α-terpinene combine to produce the odour.

2.1.4. Sesquiterpenoids

The extracts contain relatively few sesquiterpenoids. Along with peculiaroxide (Wu et al., 1993), the tricyclic compound now known from several *Plagiochilae* (Rycroft et al., 2001), there are the almost ubiquitous bicyclogermacrene and/or the bicyclogermacrene-derived spathulenol (Toyota et al., 1996).

2.2. Chemosystematics

Some of the secondary metabolite data have been incorporated as characters in the redescription of *P. rutilans* (Heinrichs et al., 2001). The phytochemical basis of this chemotaxonomic application of the data is considered here along with the chemosystematic relationships of *P. rutilans*.

2.2.1. Phytochemical variation

The lipophilic secondary metabolite profiles indicated by the data in Table 1 show a related pattern for specimens (i)–(vi). This group of specimens, representing *P. rutilans*, is characterized by substantial amounts of menthane derivatives (especially with a carbonyl group at C-3) and hydroquinone derivatives. The profiles of specimens (vii) and (viii) clearly represent a chemically distinct taxon. Specimens (vii) and (viii) were collected from the same locality but several metres apart and have been assigned to *P. standleyi*. This taxon currently has species status but is differentiated morphologically only weakly from *P. rutilans*. With the support of the present results, its status is being reduced to that of a variety within *P. rutilans* (Heinrichs et al., submitted).

There is chemical variation even within *P. rutilans* as currently circumscribed. In specimens (ii)–(v) the principal monoterpenoid is pulegone (**12**) and the principal hydroquinone is compound **2**. The profiles of specimens (ix)-(xi) are less well defined, but pulegone and the quinone **3** are always present and these older specimens can be placed with specimens (ii)-(v) to form one group. Specimen (i) is differentiated by the presence of compound **8** as the principal hydroquinone, with **2** absent. Specimen (vi) is differentiated by the presence of lactone **15** as the principal monoterpenoid, with pulegone absent.

2.2.2. Phytochemical relationships

Pulegone (together with the lactone **15**) and the hydroquinone derivatives are good chemical markers for characterizing *P. rutilans*, but, as they are unknown elsewhere in *Plagiochila*, they cannot indicate possible phylogenetic relationships of *P. rutilans*. The large amounts of bibenzyl **9** distinguish *P. standleyi* very effectively in the present case, but *P.* sect. *Rutilantes* Carl (the section containing *P. rutilans* and *P. standleyi*) shows no special affinity to *P.* sect. *Glaucescentes*, the only other section where bibenzyl **9** is known (Heinrichs et al., 2000). Bibenzyls occur rather commonly in liverworts (Asakawa, 1995) and, therefore, they cannot serve as clues to close relationships; the unique presence of ascaridole is equally uninformative. The discovery that *P. rutilans* contains small and *P. standleyi* large amounts of the bibenzyl **9** nevertheless indicates that the chemosystematic position of *P. rutilans* (together with *P. standleyi*) is not as isolated as was indicated (Asakawa, 1995) by the results of the original chemical investigation (Huneck et al., 1984). The factor common to hydroquinones and bibenzyls, namely that they are benzene derivatives, may have chemosystematic significance in being able to differentiate *P. rutilans* from the large group of *Plagiochilae* that produces plagiochilines (2,3-secoaromadendranes) (Asakawa, 1995; Söderström et al., 1999). There appears to be a major divide of chemotypes in *Plagiochila* between species that produce 2,3-secoaromadendranes and those that produce benzene derivatives, and the phylogenetic basis of this division is of interest. There is already some evidence that the two groups are not completely mutually exclusive, as riccardin D, a cyclic bisbibenzyl ether, has been isolated together with several 2,3-secoaromadendranes from *P. cristata* (Sw.) Lindenb. (Valcic et al., 1997). However, the question of the relationships of *P.* sect. *Rutilantes* remains unresolved.

2.2.3. Biosynthetic implications

One of the stereogenic centres in menthone and isomenthone is *alpha* to the carbonyl group and might be equilibrated easily. It is clear, however, that the system is not at thermodynamic equilibrium as the menthone/isomenthone ratio varies between ca 20:1 and 1:2 in different extracts. Recent work has suggested that the reaction mechanisms and enzymes of monoterpenoid biosynthesis are very similar in both liverworts and higher plants (Adam and Croteau, 1998). The variable menthone/isomenthone ratio in *P. rutilans* is consistent

with the possibility that, as in *Mentha piperita* L., different enzymes are involved in the production of the two compounds from the co-occurring pulegone (Burbott and Loomis, 1980; Croteau et al., 1991). Alternatively, or in addition, catabolic processes (Croteau, 1991) may operate with different relative selectivities in different populations.

Few metabolites of presumed mixed terpenoid (mevalonate and/or glyceraldehyde-pyruvate) and shikimate biosynthetic origin are known in liverworts (Asakawa, 1995). Compounds **2**, **7** and **8** are the simplest examples known of such liverwort metabolites and indicate possible relationships with biosynthetic pathways leading to similar compounds in organisms where they have been reported, such as algae and sponges (Bonny and Capon, 1994).

2.3. Epilogue

Correction of the structure of the prenylhydroquinone derivative **2** has highlighted two pertinent points concerning structural elucidation. First, it is possible, with appropriate analytical methods and strategies, to establish structures of components of mixtures in situ. Secondly, it is possible for the classical approach of confirmation of structure by synthesis to be fallible. In the case of the synthetic material **1**, it is evident (with the benefit of hindsight) that comparison with the natural product **2** was too cursory.

3. Experimental

3.1. General experimental procedures

GC, GC–MS, GC–EI–HRMS mass measurements (all 70 eV) and ^{1}H NMR (400 MHz, $CDCl_3$ soln., int. ref. TMS) were generally performed as described previously (Rycroft et al., 1999).

3.2. Plant material

The specimens used (Table 1) were duplicates of material deposited recently in hb. GOET and vouchers of the Cuban material from JE (hb. Huneck) and U. Further details of the specimens can be found elsewhere (Heinrichs et al., 2001). Plant identities were determined or confirmed by Jochen Heinrichs (Department of Systematic Botany, Albrecht von Haller Institute of Plant Sciences, University of Göttingen). For preparation of extracts, shoots of *Plagiochila rutilans* and *P. standleyi* were selected from the specimens, with care taken that all shoots of any other hepatics were removed.

3.3. Extraction and NMR and GC–MS fingerprinting

Extracts were prepared by triturating dried plant material with sufficient $CDCl_3$ to produce 0.6–0.7 ml of a filtered solution. NMR fingerprints (Rycroft, 1996, 1998) were obtained by measuring ^{1}H NMR spectra of the solutions. The weight of liverwort extracted and percentage w/w of compounds in the specimens (calculated from concentrations derived from comparison of NMR integrals with the residual $CHCl_3$ signal integration) are shown in Table 1. Compounds in the extracts and acetylation derivatives were also characterized in situ using GC and GC–MS. The GC column (CP Sil 5 CB) was calibrated with a mixture of *n*-alkanes so that the Kováts retention indices shown in Table 1 could be determined. TIC ratios are also shown in Table 1. Data for the acetylated extracts were compared with data for the untreated extracts in order to identify compounds containing hydroxyl groups that could be acetylated. Known compounds were identified by comparison with authentic samples or data available from previous studies.

3.4. Compound isolation and characterization

Specimen (i) (1.3 g) was ground, extracted ($CDCl_3$), chromatographed (eluent $CDCl_3$) through a short plug of silica gel in a Pasteur pipette and six ca 0.7 ml aliquots were collected in 5 mm o.d. NMR tubes. The first fraction contained the minor hydroxydimethoxy-isomer **7** (0.2 mg). The fourth fraction contained the major hydroxydimethoxy-isomer **8** (0.4 mg). The third fraction contained a similar amount of **8** but was less pure; the fifth and sixth fractions contained much smaller amounts.

3.4.1. 2-Methoxy-6-prenylhydroquinone (*2*)

Observed as a major component in the NMR fingerprints of the liverwort extracts. GC–MS: R_i 1824; *m*/*z* (rel. int.): 208 $[M]^+$ (84), 161 (10), 153 (49), 152 (100), 151 (14), 125 (11), 123 (20), 69 (19). ^{1}H NMR: δ 1.71 (3H, *s*), 1.74 (3H, *s*), 3.30 (2H, *d*, $J=7.4$ Hz, 2H-1′), 3.84 (3H, *s*, 2-OMe), 4.4 (1H, *br*. *s*, 4-OH), 5.25 (1H, *s*, 1-OH), 5.30 (1H, *m*, H-2′), 6.21 (1H, *d*, $J=2.8$ Hz, H-5), 6.31 (1H, *d*, $J=2.8$ Hz, H-3). Acetylation product: GC R_i 1957.

3.4.2. 2-Methoxy-6-prenyl-1,4-benzoquinone (*3*)

Observed as a minor component in the NMR fingerprints of the liverwort extracts. GC–MS: R_i 1674; *m*/*z* (rel. int.): 206 $[M]^+$ (44), 191 (100), 159 (55), 121 (65), 93 (33), 91 (41), 77 (37), 69 (84), 53 (31). ^{1}H NMR: δ 1.64 (3H, *s*), 1.75 (3H, *s*), 3.12 (2H, *d*, $J=7.2$ Hz, 2H-1′), 3.82 (3H, *s*, 2-OMe), 5.14 (1H, *m*, H-2′), 5.87 (1H, *d*, $J=2.4$ Hz, H-3), 6.46 (1H, *dt*, $J=2.4$, 1.7 Hz, H-5). Acetylation product: GC R_i 1745.

3.4.3. 8-Methoxy-2,2-dimethyl-2H-chromen-6-ol (*5*)

Observed as a minor component in extract (vi). GC–MS: R_i 1670; *m*/*z* (rel. int.): 206 $[M]^+$ (25), 191 (100), 176 (19), 148 (7), 119 (4), 91 (9), 77 (4), 69 (9).

*3.4.4. 2-Methoxy-4-O-methyl-6-prenylhydroquinone (**7**)*

GC–EI–HRMS: *m/z* 222.1257 $[M]^+$ ($C_{13}H_{18}O_3$ requires 222.1256), 166.0629 $[M–C_4H_8]^+$ ($C_9H_{10}O_3$ requires 166.0630). GC–MS: R_i 1746; *m/z* (rel. int.): 222 $[M]^+$ (83), 175 (7), 167 (36), 166 (100), 151 (8), 139 (10), 137 (10), 123 (10). ^{1}H NMR: δ 1.73 (3H, *s*), 1.74 (3H, *s*), 3.33 (2H, *d*, $J=7.3$ Hz, 2H-1′), 3.75 (3H, *s*, 4-OMe), 3.85 (3H, *s*, 2-OMe), 5.27 (1H, *s*, 1-OH), 5.31 (1H, *m*, H-2́), 6.30 (1H, *d*, $J=2.8$ Hz, H-5), 6.36 (1H, *d*, $J=2.8$ Hz, H-3). Acetylation product: GC R_i 1846.

*3.4.5. 2-Methoxy-1-O-methyl-6-prenylhydroquinone (**8**)*

GC–EI–HRMS: *m/z* 222.1256 $[M]^+$ ($C_{13}H_{18}O_3$ requires 222.1256). GC–MS: R_i 1792; *m/z* (rel. int.): 222 $[M]^+$ (100), 207 (17), 191 (14), 175 (17), 165 (42), 152 (11), 150 (16), 147 (12), 137(11), 69 (12). ^{1}H NMR: δ 1.72 (3H, *s*), 1.73 (3H, *s*), 3.30 (2H, *d*, $J=7.2$ Hz, 2H-1′), 3.74 (3H, *s*, 1-OMe), 3.82 (3H, *s*, 2-OMe), 4.6 (1H, *br. s*, 4-OH), 5.25 (1H, *m*, H-2′), 6.20 (1H, *d*, $J=2.9$ Hz, H-5), 6.30 (1H, *d*, $J=2.9$ Hz, H-3). Acetylation product: GC R_i 1836.

*3.4.6. 3-Hydroxy-4′-methoxybibenzyl (**9**)*

Observed in extracts (vii) and (viii). GC–MS: R_i 2016; *m/z* (rel. int.): 228 $[M]^+$ (20), 165 (1), 152 (1), 121 (100), 106 (1), 91 (2), 78 (3), 77 (5). Acetylation product: GC R_i 2073.

*3.4.7. 5-Ethyl-1,2,3-trimethoxybenzene (**10**)*

Observed in extract (ix). GC–MS: R_i 1446; *m/z* (rel. int.): 196 $[M]^+$ (87), 181 (100), 153 (14), 138 (16), 121 (12), 77 (12), 69 (18), 41 (11). ^{1}H NMR: δ 1.24 (3H, *t*, $J=7.5$ Hz, CH_3CH_2) 2.60 (2H, *q*, $J=7.5$ Hz, CH_3CH_2), 3.83 (3H, *s*, 2-OMe), 3.86 (6H, *s*, 1- and 3-OMe), 6.42 (2H, *s*, 2H-4,6).

*3.4.8. 5-Ethyl-1-methoxy-2,3-methylenedioxybenzene (**11**)*

Observed in extract (ix). GC–MS: R_i 1396; *m/z* (rel. int.): 180 $[M]^+$ (48), 166 (9), 165 (100), 135 (4), 120 (3), 79 (6), 78 (3), 77 (13), 53 (3), 51 (3). ^{1}H NMR: δ 1.22 (3H, *t*, $J=7.5$ Hz, CH_3CH_2) 2.56 (2H, *q*, $J=7.5$ Hz, CH_3CH_2), 3.90 (3H, *s*, 1-OMe), 5.92 (2H, *s*, 2,3-O_2CH_2), 6.36 (1H, *br. s*, H-6), 6.40 (1H, *d*, $J=1.5$ Hz, H-4).

*3.4.9. 3,7-Dimethyl-2,6-octadien-1,6-olide (**15**)*

Major component (0.08 mg) in fraction 1 from mini-columning of extract (vi) through silica gel with $CDCl_3$ as eluent. GC–EI-HRMS: *m/z* 166.0997 $[M]^+$ ($C_{10}H_{14}O_2$ requires 166.0994), 123.0815 $[M–CH_3–CO]^+$ ($C_8H_{11}O$ requires 123.0810). GC–MS: R_i 1384; *m/z* (rel. int.): 166 $[M]^+$ (32), 123 (100), 96 (57), 95 (93), 82 (28), 70 (62), 67 (48), 41 (45), 39(50). ^{1}H NMR: δ 1.67 (3H, *s*), 1.70 (3H, *s*), 1.92 (3H, *s*, 3-Me), 2.39 (2H, *t*, $J=6.4$ Hz, 2H-4), 2.61 (2H, *t*, $J=6.4$ Hz, 2H-5), 5.83 (1H, *q*, $J=1.3$ Hz, H-2).

*3.4.10. Ascaridole (**16**)*

Observed in extracts (vii) and (viii), and as *Oleum Chenopodium anthelminthici*. GC–MS: R_i 1205; *m/z* (rel. int.): 136 $[M–O_2]^+$ (93), 121 (100), 107 (12), 93 (61), 92 (10), 91 (12), 79 (11), 43 (35), 41 (14).

Acknowledgements

This work has emerged from interdisciplinary collaboration with groups in Göttingen and Saarbrücken. We are grateful to Jochen Heinrichs (Göttingen) for sending plant material and for productive e-mail exchanges, Hermann Anton (Saarbrücken) for sending plant material and reference compounds, Dr. José M. Saá (Palma de Mallorca) for sending spectra of compound **5**, Tony Ritchie (Glasgow) for high resolution GC-MS measurements, and Professor Joe Connolly and Dr Bob Hill (Glasgow) for discussions.

Abstract

An approach, using well characterized procedures, is presented that should be of general applicability for the structural elucidation of complex sugar moieties of natural products. The methods used are exemplified by the structure elucidation of a new gitogenin-based steroidal saponin that has a strong leishmanicidal activity similar to preparations used in clinical practice and has been isolated by bioactivity-guided fractionation of the ethanolic extract of *Yucca filamentosa* L. leaves. The saponin has been characterized as 3-*O*-((ß-D-glucopyranosyl-(1→3)- ß-D-glucopyranosy-(1→2))(α-L-rhamnopyranosyl-(1→4)-ß-D-glucopyranosyl-(1→3))-ß-D-glucopyranosyl-(1→4)-ß-D-galactopyranosyl)-25R,5α-spirostan-2α,3ß-diol. © 2001 Published by Elsevier Science Ltd. Keywords: *Yucca filamentosa* L.; Agavaceae; Steroidal saponin; Gitogenin; Leishmaniasis; Sugar analysis

1. Introduction

The complexity of many bioactive natural products containing sugar residues dictates the use of a combination of modern techniques dominated by those involving mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy for structure elucidation. In more and more cases the use of a single technique precludes a satisfactory unambiguous determination. In the majority of cases the approach to the complete unambiguous structure can best be categorized as the elucidation of the sugar unit(s) and the aglycone. Here we outline a general approach shown in Scheme 1 and apply it to the structure elucidation of a complex steroidal saponin isolated from *Yucca filamentosa* L. as example. It should be emphasized here that the aim of the application of these techniques is to obtain an unambiguous structure making the most efficient use of modern instrumental techniques. As such the complete assignment of the NMR data is not a prerequisite and, as the molecules become more complex, often not feasible in a reasonable time span even using the highest field NMR spectrometers.

Y. filamentosa L. belongs to the Agavaceae family which has more than 580 species which are widely distributed in tropic and subtropic dry climate regions throughout the world. It is indigenous to northern and middle America, and in Europe it is cultivated as an ornamental plant. The plant is rich in steroidal saponins (Mahato et al., 1982; Voigt and Hiller, 1987). Our interest in these plants arose from their potential in the treatment of leishmaniasis, an increasing major global public-health problem. The pentavalent antimonials are the preferred drugs for the treatment of most forms of leishmaniasis, although treatment with these agents is not consistently effective and has serious toxic side effects. It is known that natural products have potential in the search for new and selective agents (Akendengue

Sugar identification	**Aglycone identification**
a) Component monosaccharide identification and, when necessary, absolute configuration determination by chromatographic comparisons after acid hydrolysis	a) Molecular weight from MS data
b) Sugar-linkage analysis by GC-MS of partially methylated alditol acetates	b) 1D ^{1}H and ^{13}C data comparison with literature data for known aglycones
c) Sugar unit sequence from fragmentation ion identification in the MS-MS mode of ESI-MS of the native and permethylated molecule	c) Analysis of HMBC spectrum to confirm b) or to elucidate new structure. Most profitable approach involves the elucidation of correlations of the ^{1}H signals with neighbouring carbons two and three bonds removed in the order: i) Correlations from methyl groups ii) Correlations to and from substituents iii) Correlations from hydrogens bonded to heteroatom bonded carbons iv) Correlations to other hydrogens showing well defined ^{1}H signals assigned in the COSY spectrum
Combined data from a) to c) affords the partial identity of sugar units and sugar sequence	
d) Anomeric configuration and sugar conformation from NMR coupling constant ($^{3}J(HH)$ and $^{1}J(CH)$) data	d) Configuration analysis from "through-space" correlations in 1D NOE, and/or 2D NOESY/ROESY
e) Identity and sequence confirmation from correlations in HMBC spectrum	

Scheme 1. Steps required in the structure elucidation of sugar containing natural products.

et al., 1999). In a preliminary screening the ethanolic extract of *Y. filamentosa* L. showed a strong leishmanicidal activity against *Leishmania mexicana amazonensis*, and the bioactivity-guided fractionation of this extract led to the isolation of a new gitogenin-based steroidal saponin, 1. This activity has been studied by extracellular and intracellular assays with promastigote and amastigote forms of *Leishmania* spp. using microscopical and flow cytometric methods (Plock et al., 2001). Its extra cellular effect on promastigote cultures of *L. mexicana amazonensis* is as high as that of pentamidine which is a drug used in clinical practice. In an intracellular assay using macrophages infected with GFP-transfected *Leishmania major*, 1 showed a dose-related decline of the infection rate and of the number of parasites per cell. This leishmanicidal activity was shown to be at least partially due to the action on the parasite membrane. Clearly for a detailed understanding of such effects an unambiguous structure determination of this compound was desirable.

2. Results and discussion

As more and more modern NMR facilities become available it has become routine to use through-bond correlations, such as homonuclear ^{1}H–^{1}H COSY and TOCSY and inverse ^{1}H-detected heteronuclear ^{13}C–^{1}H HMQC and HMBC, for structure elucidation of sugar-containing molecules. Numerous publications report such determinations and in these a full assignment of the ^{1}H and ^{13}C data are usually attempted. However, as structures become more complex, particularly as the number of sugar units increases, this approach has its limitations and additional information from alternative sources is required. In particular information regarding the nature and linkage of the sugar can now be supplied from MS techniques that require only small amounts of material. We have already reported on the power of these techniques for the rapid, comparative analysis of saponin mixtures (Schöpke et al., 1996a). As an extension of this, here we show that a combination of MS and NMR techniques, in which MS data are initially used and are then supplemented with NMR data, afford an unambiguous structure elucidation without necessarily having recourse to a full, and often extremely time-consuming, complete assignment of the NMR data. Thus the step-by-step approach outlined in Scheme 1, and discussed in more detail below for a specific novel compound from *Y. filamentosa* L., has been used to afford structural information about the saponin in which the nature, position of attachment, and sequence of the sugar constituents as well as details of the aglycone have been umambiguously identified.

2.1. Component sugar identification

Initially a bioactivity-guided fractionation of the ethanolic extract of *Y. filamentosa* L. leaves by repeated column chromatography on silica gel and on reversed phase silica gel gave the leishmanicidal steroidal saponin **1**. Acidic hydrolysis yielded the aglycone and the sugars moieties, which by TLC comparison with authentic samples indicated the presence of galactose (Gal), glucose (Glc) and rhamnose (Rha). Although we have not determined the absolute configuration of the sugar units here they can be analysed using methods described by us previously (Schöpke et al., 1996b).

2.2. Sugar-linkage analysis

The sugar substitution pattern can be established after derivatization (methylation analysis) using micro-amounts of material (ca. 1 nmol) by methods originally developed by us for the oligosaccharide mapping of recombinant and natural glycoproteins (Grabenhorst et al., 1995). Thus the GC–MS of the partially methylated alditol acetates derived from **1** showed the presence of six partially methylated alditol acetates representing terminal rhamnose, terminal glucose, 3-substituted glucose, 4-substituted galactose, 4-substituted glucose and 2, 3-disubstituted glucose residues (Table 1). An aliquot of the intact permethylated compound was reserved for a MS–MS analysis reported below.

2.3. Sugar sequence analysis

Electrospray ionization in the positive as well as the negative ion mode, especially in combination with MS–MS techniques, has quickly become the method of choice for sugar sequence analysis. The methodology has the advantage of requiring only minute amounts of substance (<1 μg), and affords a direct analysis of both purified materials and mixtures without the necessity of derivatization. We have used this method previously for comparative analysis of saponin mixtures and have shown that the introduction of sodium salts has the advantage of producing sodium-adduct molecular ions, which resolves ambiguities arising in protonated molecular-ion spectra and afford readily interpretable spectra (Schöpke et al., 1996a). Thus the positive ion mode ESI-mass spectrum of **1** afforded a molecular ion at *m/z* 1412 $[M+Na]^+$. This parent ion was selected using the quadrupole mass analyser and collision-induced decomposition gave daughter ions that were separated in the time-of-flight mass analyser. The resulting MS–MS spectrum showed fragment ions at *m/z* 979 [hex + hex + hex + hex + hex + dhex + Na]$^+$, *m/z* 817 [hex + hex + hex + hex + hex + dhex + Na]$^+$, *m/z* 671 [hex + hex + hex + hex + Na]$^+$, *m/z* 655 [hex + hex + hex + dhex + Na]$^+$, *m/z* 509 [hex + hex + hex + Na]$^+$ and at *m/z* 347 [hex + hex + Na]$^+$. Peaks at *m/z* 1266 [M-dhex + Na]$^+$, *m/z* 1250 [M-hex + Na]$^+$, *m/z* 1104 [M-dhex-hex + Na]$^+$, *m/z* 1088 [M-hex-hex + Na]$^+$, *m/z* 942 [M-dhex-hex-hex + Na]$^+$, *m/z* 780 [M-dhex-hex-hex-hex + Na]$^+$ and at *m/z* 618 [M-dhex-hex-hex-hex-hex + Na]$^+$ were generated through loss of the respective saccharides. The appearance of a peak at *m/z* 979 which is generated by a hexasaccharide + Na-fragment and the presence of two terminal sugar units in the GS–MS analysis above indicates **1** is a monodesmoside with a branched sugar chain.

Table 1
Methylation analyses of **1** (derivatives are listed in the order of elution)

Per-*O*-acetylated derivatives with *O*-Me in position	Type	Interpretation
2,3,4	Rhamnitol	Terminal rhamnose
2,3,4,6	Glucitol	Terminal glucose
2,4,6	Glucitol	3-Substituted glucose
2,3,6	Galacitol	4-Substituted galactose
2,3,6	Glucitol	4-Substituted glucose
4,6	Glucitol	2,3-Disubstituted glucose

The above MS–MS analysis can of course be applied to the permethylated sample, which has to be produced during the sugar-linkage analysis. Such an analysis has the advantage of avoiding ambiguities in the fragmentation pattern of the native molecule. Thus in the present example the sequential elimination of two terminal monosaccharide units yields the same fragment ion mass as the loss of a single disaccharide unit from the native molecular ion, whereas from the permethylated sample these two fragments differ by one methyl group and therefore can be unequivocally distinguished. In addition the number of acidic protons in the aglycone, which are also permethylated, can be determined. The MS–MS analysis of the permethylated derivative of **1** is summarized in Fig. 1.

Thus the combined data indicated that the sugar sequence in 1 is {Glc-hex}{Rha-hex}-Glc-hex-R and are compatible with a molecular formula of $C_{63}H_{104}O_{33}$, Scheme 2.

At this stage in the analysis the combined methods afford information on the number, the nature and linkage positions, but not of the anomeric configuration or the exact sequence, of the constituent monosaccharides in the glycoside. The molecular weight of the agylcone is evident by default. NMR data are now necessary to afford the remaining stereochemical details of the sugars and identification of the aglycone.

In contrast to MS analyses considerably more material is required for NMR analyses. Thus in reality satisfactory 1D and 2D ^{1}H homonuclear spectra can be recorded of amounts >100–500 μg, while the less sensitive 2D inverse ^{1}H-dectected heteronuclear ^{13}C–^{1}H correlations require >1–2 mg of homogeneous material.

2.4. Anomeric configuration and sugar conformation

The anomeric configurations of the various sugar moieties followed from the magnitudes of the vicinal ^{1}H–^{1}H and one-bond ^{13}C–^{1}H coupling constants shown in Tables 2 and 3, respectively. All glucoses and galactose had a ß-configuration and the α-configuration of the rhamnose was unambiguously established from the ^{1}J(CH) of 169.6 Hz (Hansen, 1981). The latter is the most reliable coupling for establishing the rhamnose configuration as the similarity of the gauche dihedral angle for both α and ß anomers leads to similar small vicinal ^{1}H–^{1}H coupling constants. The linkage position of the sugar chain to the aglycone follows from either a

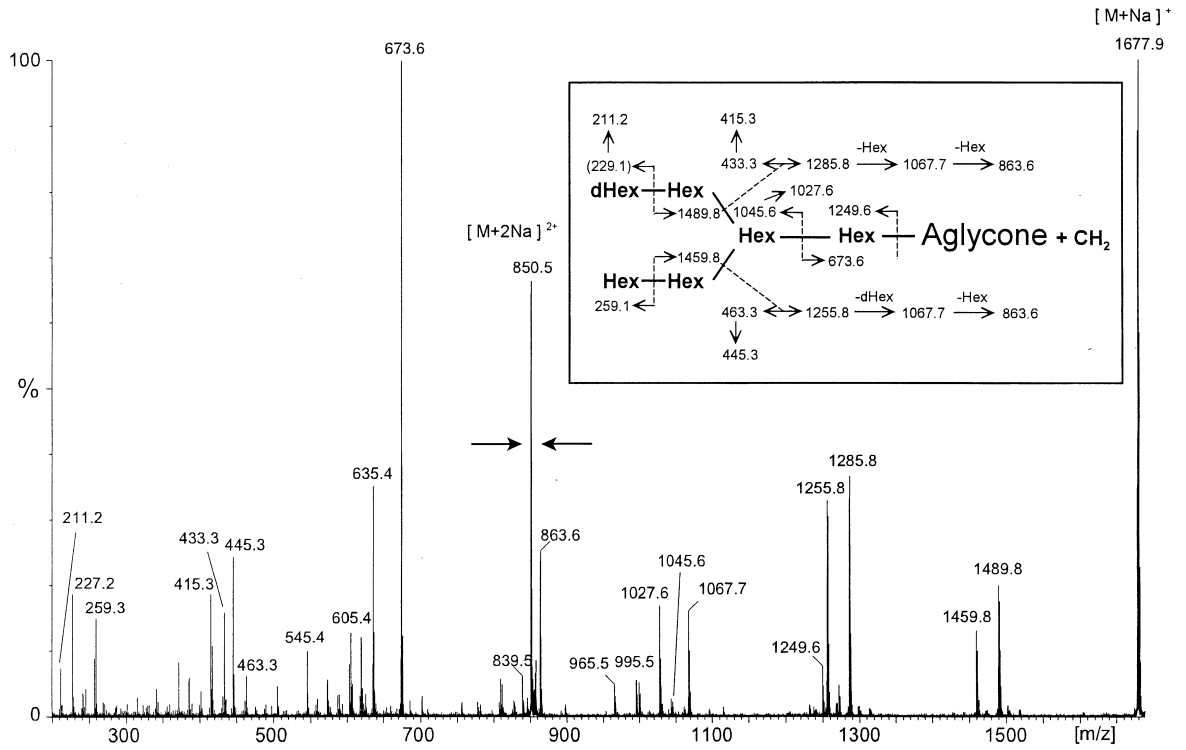

Fig. 1. ESI daughter ion spectrum of the doubly charged $[M+2Na]^{2+}$ permethylated molecular ion of the saponin isolated from *Yucca filamentosa* L. with inserted fragmentation scheme. The fragmentation pattern indicates a branched hexasaccharide glucan structure consisting of five hexose and one deoxyhexose residues.The aglycone has one acidic proton, as is indicated by its derivatisation with one methyl group upon permethylation. Hex = hexose, dHex = deoxyhexose.

a) Component identification: D-galactose (Gal), D-glucose (Glu), L-rhamnose (Rha)

b) Sugar-linkage analysis: 4-Gal, 3-Glu, 4-Glu, 2,3-Glu, terminal Glu, and terminal Rha in a ratio of ca. 1:1:1:1:1:1

c) Sugar sequence:

comparison of ^{13}C data with that of the unsubstituted aglycone or more explicitly from vicinal ^{13}C–^{1}H correlations in the HMBC spectrum (see below, Table 4 and Scheme 2).

2.5. Exact sugar sequence

The identity and exact sugar sequence may already be apparent from the data accumulated above. If this is not the case, as here, then a partial interpretation of the 2D homonuclear and heteronuclear NMR correlations is necessary. The extent of such an analysis depends on the molecule under investigation, but in general will be of the form used for **1**.

The observation of a correlation of the anomeric proton of Gal (Table 2) to a low field carbon (C-3) of the aglycone, evident from further long-range correlations to aliphatic, non-sugar protons, identified the chain linkage to the aglycone. The H1–H4 spin system of the galactose unit was readily identified from the 2D COSY

[a] The magnitude of ^1J(CH) of the anomeric carbons of the sugar moieties, given in parentheses, were determined from the residual cross peaks in the inverse long-range ^{13}C–^{1}H correlation (HMBC).
[b] § The C-6 shifts at 62.7 and 63.1 ppm correspond to ^{1}H shifts at 3.93/3.68 and 3.96/3.64 ppm, respectively (see footnote of Table 2).
[c] $ Shifts at 75.5, 75.6, 75.6, 75.7 ppm.
[d] # Shifts at 77.1, 77.5, 77.8, 78.0, 78.1 ppm.

correlations in which H-4 was to low field and had two small vicinal ^{1}H–^{1}H couplings that are characteristic of this system. These observations implied the galactose unit was adjacent to the aglycone and the other four hexose units were glucose. The anomeric proton of the terminal rhamnose correlated with a sugar carbon at 79.5 ppm, which from the chemical shift must be that of a 4-substituted glucose unit, Glc (D) in Table 3 (C-3 of a 3-substituted glucose unit would be at ca. 87 ppm). Consequently these data and the linkage analysis above indicates the terminal glucose must be bound to the 3-substituted glucose, Glc (B) in Table 3, by default. The only question that now remains is the relative position of these two dissaccharides (glucose 4-1α rhamnose and glucose 3-1ß glucose) on the branching trisubstituted glucose unit, Glc (A) (Scheme 2). Again a partial analysis of the COSY spectrum and the considerable differences in

H-20	C-13, C-17, C-21, C-22, C-23
H-17	C-12, C-13, C-16, C-18, C-20, C-21

[a] In the present case there are no long-range correlations apparent from H-2 and H-3.

[b] There are some differences in the carbons showing correlations due to the stereochemical dependence of the appropriate long-range coupling constants.

chemical shifts of C-2 and C-3 of Glc (A) together with the observation of the respective long-range correlations in the HMBC spectrum from the anomeric protons of Glc (B) and Glc (D), respectively, to these carbons established the relative chain orientations shown in Scheme 2 (e).

Again we emphasize that the unambiguous structure of the sugar unit was established without a complete assignment of the NMR data. Even on close inspection of the 2D correlations a number of assignments both in the ^1H and ^{13}C spectra (Tables 2 and 3, respectively) could not be unambiguously establish even at the high magnetic fields employed here (14 Tesla, 600 MHz: ^1H; 150 MHz: ^{13}C) because of signal overlap. As the complexity of the sugar chains increases full assignments will be even more difficult although it can be anticipated that correlations to the low-field carbons, i.e. those carrying the substituents and hence the information regarding the exact linkage, will still be determinable.

2.6. Aglycone identification

In many cases the aglycone can be readily identified from its molecular weight deduced from the MS data and from careful comparison of the ^1H and ^{13}C data with known literature data. In the present case the aglycone gitogenin was unambiguously identified (Agrawal et al., 1985; Nakano et al., 1988). When this is not possible then a detailed analysis of the heteronuclear and homonuclear "through-bond" NMR correlations is the most rigorous approach, followed by "through-space" data from 1D NOE and/or 2D/NOESY/ROESY spectra to determine the relative configurations of asymmetric centres.

In the present case a systematic inspection of the HMBC data detailed in Scheme 1 (right, c) for **1** yields the sets of correlations given in Table 4. The strongest correlations are from the methyl groups and provide correlations to all adjacent carbons two and three bonds from the respective protons. Additional correlations from the galactose (above) defines the sugar chain position while the correlations from H-26A/B and from a number of the well defined protons identified in the COSY spectrum are sufficient in combination to define the molecular fragments incorporating C-9/C-10(C-19)/C-1→C-5 and C-12/C-13(C-18)/C-14→C-27 of Fig. 2. These data provide unambiguous confirmation of the structure of the known aglycone. They would not, however, be sufficient to unambiguously define an unknown aglycone as the central section C-6/C-7/C-8 and C-11 together with their attached protons remain undefined. In such cases further 2D spectra would be necessary, in particular HMQC and "through-space" correlations.

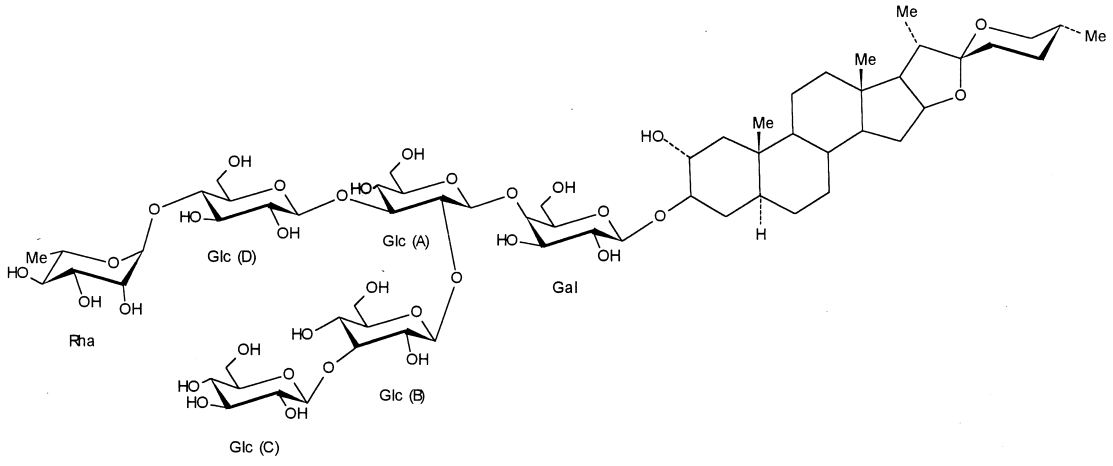

Fig. 2. Structure of **1** from *Yucca filamentosa* L.

3. Conclusion

Adherence to the procedures outlined in Scheme 1 affords an unambiguous identification of complex sugar moieties without recourse to full signal assignments. Similarly known aglycone structures can be readily identified and their structures confirmed with data already present in spectra recorded for the sugar analysis. In those cases where a novel aglycone is present additional NMR data will probably be necessary. In the present case the combined chemical and spectroscopic data, together with reasonable assumptions for the absolute stereochemistries of the sugar moieties, afforded unambiguous evidence for the novel structure for **1** of 3-*O*-((ß-D-glucopyranosyl-(1→3)-ß-D-glucopyranosyl-(1→2)) (α-L-rhamnopyranosyl-(1→4)-ß-D-glucopyranosyl-(1→3))-ß-D-glucopyranosyl-(1→4)-ß-D-galactopyranosyl)-25*R* 5α-spirostan-2α, 3ß-diol, Fig. 2.

4. Experimental

4.1. General experimental procedures

1D (^{1}H, ^{13}C and DEPT-135) and 2D (COSY and HMBC) NMR spectra of compound **1** were recorded in CD_3OD at 300 K on a Bruker AVANCE DMX-600 NMR spectrometer (^{1}H: 600.13 MHz, ^{13}C: 150.92 MHz) using standard Bruker software. Chemical shifts are reported in ppm relative to TMS but were recorded relative to the residual signal of the solvent (^{1}H: 3.35 ppm, ^{13}C: 49.00 ppm) and coupling constants in Hz. The NMR spectra of the aglycone of **1** were recorded in $CDCl_3$ on a Varian 500 MHz spectrometer. A Micromass QTOF2 mass spectrometer equipped with a nonspray ion source was used for ESI–MS and MS–MS. TLC was performed on silica gel 60 F_{254} or on reversed phase 18 silica gel plates or foils (Merck); solvent system A: $CHCl_3$–MeOH–H_2O (6:4:1) and B: MeOH–H_2O (8.5:1.5). The spots of the TLC were detected by 10% H_2SO_4 followed by heating for saponin and sapogenin, and with thymol/H_2SO_4 for sugars.

4.2. Plant material

The leaves of *Y. filamentosa* L. were provided by Dr. Paul Brueckner, Arboretum, Institute of Biology, Humboldt-University of Berlin, Germany, in July 1996. A plant specimen is on file in the Institut für Pharmazie, Humboldt-Unversität, Berlin.

4.3. Extraction and isolation

The air-dried pulverized leaves (500 g) were first macerated with petroleum ether, then with ethyl acetate, each for 90 min. Finally the dried material was extracted with ethanol/water 7:1 in a Soxhlet apparatus for 120 min. After filtration, the solvent was evaporated under reduced pressure to yield 31 g of extract. The isolation of the active component of this extract was performed by bioactivity-guided fractionation. The extract was chromatographed on 2000 g silica gel 60, 0.063–0.2 μm (Merck) with solvent system A as eluent to give 150 fractions. These fractions were combined into pools A–D according to their similar TLC patterns (silica gel, solvent system A). Pool A (6.5 g) showed high leishmanicidal activity and was chromatographed on 600 g reversed phase 18 silica gel material (Merck) with solvent system B as eluent to give pools Aa–Ad. The chromatography of Ac (1.3 g) on 100 g silica gel 60 with $CHCl_3$–MeOH–H_2O (10:3:1, lower phase) led to pure **1** (25.7 mg), (TLC solvent system A; R_f 0,4). **1**: Colorless needles (from MeOH), mp 292–293°C; ESI–MS positive mode *m*/*z*: 1412 $[M+Na]^+$, 1266, 1250, 1104, 1088, 942, 780, 618 (see text for peak assignments). ^{1}H and ^{13}C NMR data are given in Tables 2–4.

4.4. Acidic hydrolysis and aglycone identification

1 was hydrolysed with 1N HCl by refluxing for 90 min on a water bath. The reaction mixture was neutralized with 1 N NaOH and submitted to liquid-liquid partition with diethyl ether. The ether phase was evaporated to dryness under reduced pressure. From the residue gitogenin was identified: colorless needles (from $CHCl_3$), mp 268–270°C; ms 432 $[M]^+$, 417, 318, 289, 139; ^{1}H NMR ($CDCl_3$): $\delta = 0.76$ (3H, *s*), 0.78 (3H, *d*, $J = 6.3$ Hz), 0.86 (3H, *s*), 0.95 (3H, *d*, $J = 6.8$ Hz), 3.30–3.63 (4H, *m*), 4.36 *m* (1H, *m*); ^{13}C NMR ($CDCl_3$, C-1–C-27): 45.0, 73.0, 76.4, 35.6, 44.8, 27.8, 31.8, 34.4, 54.3, 37.6, 21.2, 39.9, 40.6, 56.1, 31.4, 80.8, 62.1, 16.5, 13.6, 41.5, 14.5, 109.2, 32.0, 28.8, 30.3, 66.8, 17.1

4.5. Component monosaccharide identification

1 was hydrolysed at 100°C for 1 h on TLC silica gel plates in a chamber filled with conc. HCl. After separation with solvent system A, galactose (R_f 0.36), glucose (R_f 0.39) and rhamnose (R_f 0.57) were identified by comparison with authentic samples.

4.6. Methylation analysis of the sugar constituents

For linkage analysis, the sample was permethylated as described (Anumula and Taylor, 1992). Purification of the permethylated sample, hydrolysis, reduction and acetylation were performed as described previously (Nimtz et al., 1990). The resulting partially methylated alditol acetates were analysed on a ThermoQuest GCQ ion trap GC/MS system (MS: EI mode, GC: 30 m DB 5 column).

Book reviews

Soil Biochemistry Volume 10
J.-M. Bollag and G. Stotzky (Eds.). Marcel Dekker, New York, $195.00, 519 pp., ISBN 0-8247-8834-6

This is only the 10th volume of *Soil Biochemistry* in over three decades and devotees have learned to wait patiently for the next shot of their favourite review series. The good news is that they won't be disappointed because this time 12 chapters and more than 500 pages contain topics of interest, not only to the soil biochemists but also to microbiologists, microbial and molecular ecologists, and agricultural and environmental scientists.

The chapters range from the obviously topical (environmental remediation, rhizobia genetics, enteric pathogens in soil) to the more esoteric (soil archaeology). All are written (and carefully edited) by experts in their respective fields and, for the most part, present a mixture of fact and thoughtful speculation.

I was particularly drawn to a nice up-to-date review of fungal bioremediation (Paszcznski and Crawford), organised according to various potential substrates (dyes, PAHs, explosives, plastics, etc.), and reasserting the potential of lignocellulose degraders for the removal of environmental pollutants. Another chapter, this time on enzyme activities in soil (Quiquampoix), caught my attention because it presents a succinct (and overdue) theoretical review of the relationships of proteins with clay surfaces and the consequences of these for activity. One particularly intriguing chapter (Hattori and Hattori) revisits (and, at least for me, resuscitates) some of the much maligned traditional plate counting procedures. Other chapters, on the anaerobic dehalogenation of pesticides (Haggblom and Milligan) — now recognised as an important process in anoxic microenvironments and sub-soils — and the genetics and ecology of soybean bradyrhizobia (Minamisawa and Mitsui), are both concise and well-researched.

Two methodology chapters, one on the use of silylation for the extraction of humic matter (Haider et al.) and the other on isoprenoid quinones as microbial biomarkers (Katayama and Fujie) will prove invaluable to the practitioners. Other very detailed chapters on the microbiology of rice fields (Kimura) and the relationships between biomolecules and clays (Violante and Gianfreda) will have their fans.

The final two chapters are, in turn, important (human pathogens in soil by Toranzos and Marcos) and intriguing (interactions of microbes with archaeological materials by Hopkins) and are full of signposts to future research.

Overall, the range of subjects expertly reviewed in this latest volume of *Soil Biochemistry* are a welcome addition to the bookshelf and I am sure that the founding father, Douglas McLaren, would be well pleased with the continued high quality of the series.

Studies in Natural Products Chemistry, Vol. 21: Bioactive Natural Products (Part B)
Atta-ur-Rahman (Ed.). Elsevier Science, Amsterdam, The Netherlands, 2000, 812 pages, ISBN 0-444-50469-9, $ 432.00

This volume, in the extensive series of books initiated by the editor, Professor Atta-ur-Rahman of the H.E.J. Research Institute of Chemistry, University of Karachi, Pakistan, comprises 14 different chapters written by specialists in their respective fields of expertise.

Most chapters deal with bioactive plant constituents. Of particular interest are the contributions which include plant chemistry, modes of action and structure-activity relationships, e.g. the interference of alkaloids with neuroreceptors and ion channels by M. Wink, the chemistry and biological activity of chromone alkaloids by P.J. Houghton, the distribution and potential of polyene

amide derivatives of plant and fungal origin by C. Najara and M. Yus, the potential of plants as anti *Diabetes mellitus* drugs by Lamba et al., the update on bioactive saponins from plants by M.A. Lacaille-Dubois and H. Wagner and the excellent review on biologically active diterpenoids from *Scoparia dulcis* L. by T. Hayashi.

All these chapters are very useful and comprehensive reviews. Also of great interest is the chapter of G.E. Rohr et al. on the various analytical procedures for procyanidins. Another technical but well-written chapter deals with the extraction, identification and biological properties of various essential oils. Three chapters of the book are related to marine natural products. These reviews are nicely presented and accurate and will be of great help for all scientists working in the field of natural products. Finally, the book contains an interesting chapter by S. Michel et al. on prodrugs of natural anthracyclines suited for antibody directed enzyme prodrug therapy and prodrug monotherapy. There is no doubt that the approach presented in this chapter is highly innovative but it is questionable if such a chapter has a place in the present book. It would probably be more useful in a book on medicinal chemistry as it lies somewhat outside the general scope of this volume which has unfortunately one negative aspect — its high price. If the editor could reduce the size of future books in the series, this would also lower the price. Despite this, the present book provides a multitude of useful, accurate and practical information which will be of great help to every natural products chemist. It should be made available in every library, either in academia or in industry. Individual scientists will unfortunately not be able to afford this volume.

Received 18 January 2001; received in revised form 28 February 2001

Abstract

The hydrocarbon fraction of the liverwort *Trocholejeunea sandvicensis* was investigated. Four new sesquiterpene hydrocarbons including the trifaranes (−)-trifara-9,14-diene (**6**) and (−)-3,7-di-*epi*-3,7-trifara-9,14-diene (**7**), as well as (+)-sandvicene (**8**), a sesquiterpene with uncommon skeleton, and the rearranged trifarane sesquiterpene (+)-neotrifaradiene (**9**) were isolated and their structure elucidated. A biogenetic pathway for the four compounds is proposed, with nerolidol as their common precursor. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Trocholejeunea sandvicensis*; *Lejeuneaceae*; Liverwort; Sesquiterpenes; (−)-Trifara-9,14-diene; (−)-3,7-di-*epi*-Trifara-9,14-diene; (+)-Sandvicene; (+)-Neotrifaradiene

1. Introduction

Previous work on the liverwort *Trocholejeunea sandvicensis* focussed on the polar fractions of this plant and resulted in the isolation of pinguisane- and lepidozane-type sesquiterpenes, kaurane-type diterpenoids, aromatic compounds, and flavonoids (Tori et al., 1993; Asakawa, 1995; Lahlou et al., 2000). Trifarienols A–E (**1**–**5**) (Fig. 8), sesquiterpenes with the rare trifarane skeleton, were identified as constituents of the Malaysian liverwort *Cheilolejeunea trifaria*, a member of the taxonomically related Lejeuneaceae family by Hashimoto et al. (1995). Here we report on the investigation of the hydrocarbon fraction of *Trocholejeunea sandvicensis*. Preliminary investigations of the ether extract by GC and GC–MS revealed the presence of more than 30 sesquiterpenes. Four compounds in the hydrocarbon fraction of *T. sandvicensis*, which had also formerly been observed as minor constituents in many *Porella* and *Ptilidium* species, had to be classified as unknown by comparison of their mass spectra with a data bank containing over 300 entries (Joulain and König, 1998). Isolation and structural investigations of these compounds lead to the identification of four new sesquiterpenes. Two of them, **6** and **7**, possess the unusual bicyclo[3.3.1]nonane (trifarane) skeleton. Compound **8** has a previously unknown carbon skeleton, while compound **9** is a rearranged trifarane sesquiterpene. Their structures were determined by spectrocopic methods. All four new compounds **6**–**9** possess a vinyl side chain as encountered in trifarane type sesquiterpenes **1**–**5** which are present in *C. trifaria* (Tori et al., 1993).

2. Results and discussion

The hydrocarbon fraction of *T. sandvicensis* was fractionated by preparative GC. By using a combination of columns with a polydimethylsiloxane and modified cyclodextrin stationary phase four new sesquiter pene hydrocarbons (−)-trifara-9,14-diene (**6**), (−)-3,7-di-*epi*-trifara-9,14-diene (**7**), (+)-sandvicene (**8**) and (+)-neotrifaradiene (**9**) were isolated (Fig. 1). On the base of mass spectrometric evidence several known sesquiterpenes including α-cedrene, β-ylangene, β-duprezianene (Barrero et al., 1996), selina-4(15),5-diene (Bülow and König, 2000), thujopsene, α-pinguisene (Asakawa,

1995), β-barbatene, β-acoradiene, di-*epi*-aristolochene (Joulain and König, 1998), eremophilene and eremophila-1(10),8,11-triene (Rieck et al., 1997) were identified.

2.1. Trifara-9,14-diene (**6**)

The molecular formula of **6** was deduced as $C_{15}H_{24}$ from its mass spectrum ($[M]^+ = 204$). The ^1H and ^{13}C NMR spectra revealed the presence of two tertiary methyl groups, one secondary methyl group, six methylene groups, two of which being olefinic, two quaternary sp^3 carbon atoms and one quaternary sp^2 carbon atom. Four substructures were obtained by combination of the results of ^1H–^1H COSY and the HSQC spectra. The presence of a vinyl group is attested by the methine proton CH-14 (δ 5.78) coupling with the two methylene protons CH_2-15 (δ 4.99). Long-range (^4J) coupling correlations in the ^1H–^1H COSY spectrum, which are observed between the methine proton CH-4 (δ 1.88) and the olefinic methylene group CH_2-10 (δ 4.69 and 4.85), give rise to substructure *a*: CH_2=C–CH–. This substructure is confirmed by the HMBC spectrum where correlations are found between the methylene group CH_2-10 and carbons C-9, C-4 and C-8 (Fig. 2). The methyl doublet CH_3-12 (δ 0.90) correlates with the methine proton CH-7 (δ 1.58), itself coupled to the methylene group CH_2-6 (δ 1.13 and 2.16), which further couples with another methylene group CH_2-5 (δ 1.67 and 1.83). CH_2-5 also couples with the methine proton CH-4 (δ 1.88), leading to partial structure *b*: CH_3–CH–CH_2–CH_2–CH–. The methylene group CH_2-1 (δ 1.54 and 1.56) couples with the methylene group CH_2-2 (δ 1.25 and 2.18) to give substructure *c*: –CH_2–CH_2–. With substructures *a* and *b* having methine group CH-4 in common, a new partial structure CH_2=C–CH–CH_2–CH_2–CH–CH_3 can be derived. The connectivities of the partial structures were deduced from the HMBC experiment (Fig. 2). The methylene protons CH_2-10 showed correlations to C-4, C-8 and C-9. The methyl group CH_3-12 correlated with carbons C-6, C-7 and C-8, while methyl group CH_3-11 (δ 0.92) is correlated with C-7, C-8, C-9 and C-1. Correlations are also observed between the methyl group CH_3-13 (δ 1.01) and C-2, C-3, C-4 and C-14. The vinylic methine proton CH-14 showed long-range correlation to C-3, while the methylenic protons CH_2-15 are correlated to C-3 and C-14. All these observations lead to a trifarane skeleton for the molecule. Its stereostructure was obtained from the NOESY spectrum as illustrated in Fig. 3. NOE's are observed between the methyl group CH_3-13 and the axial proton H_a-1 indicating also an axial orientation for CH_3-13, and thus an equatorial orientation for the vinyl group at C-3. This is confirmed by NOEs between the vinylic methine proton H-14 and the equatorial proton H_e-5 (δ 1.83, *dddd*, *J*: 13.9, 4.1, 4.1, 2.0, 1.0 Hz). A further proof of the equatorial orientation of the vinyl group is the deshielding anisotropic effect exerted on the two axial protons H_a-2 (δ 2.16) and H_a-6 (δ 2.18) (compare their chemical shifts with those of the corresponding protons in compound **7** where the vinyl group is axial; see Table 1). The NOE correlation between methyl group CH_3-12 and the axial proton H_a-5 (δ 1.67, *ddd*, *J*: 13.9, 13.6, 5.7 Hz) indicates that CH_3-12 also is axial. Therefore, compound **7** has the relative configuration as drawn in Fig. 3.

2.2. 3,7-Di-epi-trifara-9,14-diene (**7**)

The second compound has the molecular formula $C_{15}H_{24}$ in agreement with its mass spectrum ($[M]^+ = 204$). The analysis of the NMR spectra of **7** established the same planar structure as in **6** (Fig. 2). The relative

[a] All the measurements were done in C_6D_6. The assignments were established by ^{13}C–^{1}H HMBC and HSQC.

configuration of the compound was derived from the NOESY spectrum and the interpretation of relevant coupling constants. The methyl group CH_3-11 (δ 1.01) correlates with proton H_b-10 (δ 4.76) while methine proton H-4 (δ 2.05) correlates with proton H_a-10 (δ 4.73). The proton at δ 1.34, belonging to CH_2-1 exhibits four scalar coupling constants, $J_1 = 13.9$ Hz (geminal coupling), $J_2 = 13.9$ Hz (axial-axial coupling with H_a-2), $J_3 = 6.3$ Hz (axial-equatorial coupling with H_e-2) and $J_4 = 1.3$ Hz (^4J W-coupling with H-7). Therefore, this proton is axial (H_a-1) and the corresponding geminal proton is H_e-1 (δ 1.65, *dd*, $J_1 = 13.9$ Hz, $J_2 = 6.0$Hz). In the NOESY spectrum correlations are observed between the axial proton H_a-1 and the vinylic proton H-14, showing that the vinyl group at C-3 is in equatorial position. Thus the methyl group CH_3-13 is equatorial. This is confirmed by a correlation between CH_3-13 and the proton H_e-5 (δ 2.03). NOEs are observed between CH_3-12 and the proton H_e-1 (δ 1.65, *dd*, J: 13.9, 6.0), indicating that the methyl group CH_3-12 is equatorial. This is confirmed by the correlations of H_a-7 with H_a-5. The relative configuration of the compound was, therefore, established as **7** (Fig. 3). **7** is a diastereoisomer of **6** with opposite configuration at positions 3 and 7 and therefore the name 3,7-di-*epi*-trifara-9,14-diene is proposed for **7**.

2.3. Sandvicene (*8*)

From the mass spectrum of **8** ($[M]^+ = 204$), it was deduced that it has the molecular formula $C_{15}H_{24}$ and hence four unsaturations. The ^{13}C NMR spectrum suggested the presence of two double bonds (δ 112.30, 120.80, 137.50 and 147.50) in the molecule. The compound was, therefore, assumed to be bicyclic as a consequence of the two remaining unsaturations. Three methyl groups, six methylene and three methine groups were identified as well as three quaternary carbon atoms, one being olefinic. Evidence for a vinyl group was derived from the methine proton CH-14 (δ 5.95) which couples with the olefinic methylene group CH_2-15 (δ 5.15 and 5.16). Three other substructures were extracted from the ^{1}H–^{1}H COSY spectrum. The methylene group CH_2-9 (δ 1.37 and 1.75) couples with methylene group CH_2-10 (δ 1.40 and 1.62) which further couples with the methine proton CH-1 (δ 1.66) to give substructure –CH_2–CH_2–CH–. The methylene group CH_2-7 (δ 2.03 and 2.35) couples with the olefinic proton CH-6 (δ 5.48) yielding the partial structure –CH_2–CH=C–. The methylene group CH_2-3 (δ 1.35 and 1.42) couples to the methylene group CH_2-4 (δ 2.05 and 2.12), giving the partial structure –CH_2–CH_2–. The connectivities of the partial structures were established by the HMBC spectrum. The protons of the methyl group CH_3-11 and CH_3-12 show correlations to carbons C-1, C-2, C-3. The methyl groups CH_3-11 and CH_3-12 show a long-range (W-coupling) correlation to each other in the ^{1}H–^{1}H-COSY spectrum, suggesting a geminal dimethyl group. This is confirmed by ^{1}H–^{13}C long-range correlations

between CH_3-11 and C-12 as well as CH_3-12 and C-11. Protons of the methylene group CH_2-7 show correlations to carbons C-5, C-6, C-9 and C-14 and those of methyl group CH_3-13 are connected to C-7, C-8, C-9 and C-14. The protons of CH_2-15 correlate with C-8 and C-14. The methine proton H-1 correlates with the carbons C-2, C-5, C-10 and C-4. All these observations indicate the skeleton of the molecule as shown in Fig. 4.

The relative configuration of the compound was determined by the NOESY technique. The skeleton of the molecule can take a pseudo-chair conformation as represented in Fig. 4. In the NOESY spectrum of the molecule, the proton H_a-7 correlates with the methyl group CH_3-13 and with the proton H_a-9 which itself correlates with the methine proton H-1. These observations indicate that the methyl group CH_3-13 and the methine proton H-1 are on the same side of the molecule. This is confirmed by the correlation observed between the vinylic proton H-14 and the proton H_a-10 showing that the vinyl group at C-8 is axial. Thus, compound **8** has the relative configuration as shown in Fig. 5 and was called sandvicene.

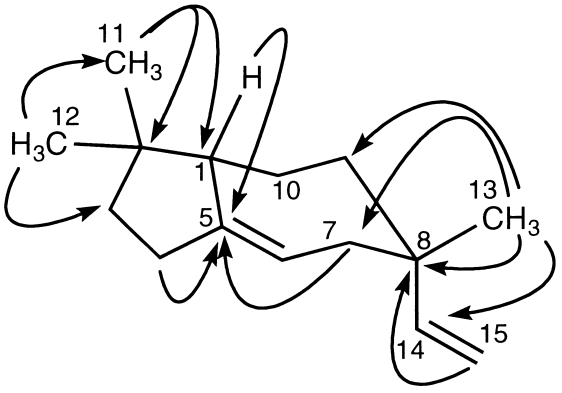

Fig. 4. Long-range correlations observed in the HMBC spectrum of sandvicene (**8**).

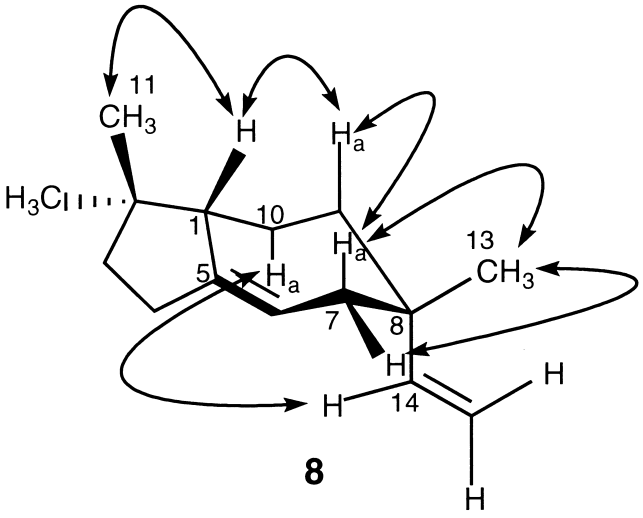

Fig. 5. Spatial correlations derived from the NOESY spectrum of sandvicene (**8**).

2.4. Neotrifaradiene (*9*)

The molecular formula of **9**, $C_{15}H_{24}$, was deduced from its mass spectrum ($[M]^+ = 204$). The ^1H and ^{13}C NMR spectra indicated two tertiary methyl and two secondary methyl groups, four methylene groups, one of which is olefinic, four methine groups, one being olefinic, and two sp^3 and one sp^2 quaternary carbon atoms. Evidence of a vinyl group in the molecule was given by the methine proton CH-10 (δ 5.98) which couples with the olefinic methylene group CH_2-11 (δ 5.13) in the ^1H–^1H-COSY spectrum. Further substructures were obtained from the ^1H–^1H COSY and HSQC experiments. Methyl group CH_3-14 (δ 1.03) correlates with the proton CH-1 (δ 1.98), itself coupled to the methylene group CH_2-2 (δ 2.03 and 2.30), which further couples to the methine proton CH-3 (δ 5.41), resulting in substructure CH_3–CH–CH_2–CH=C–. The methylene group CH_2-6 (δ 1.29 and 1.80) couples with the methylene group CH_2-7 (δ 1.52 and 1.53) giving the substructure –CH_2–CH_2–. The connectivities of the partial structures were determined by HMBC. The methyl group CH_3-15 (δ 1.16) which couples with proton CH-4 (δ 2.55) shows long-range correlations with carbons C-4, C-5 and C-9. The methyl group CH_3-14 correlates with C-1, C-2 and C-8. Methyl group CH_3-12 (δ 1.00) shows correlations with C-1, C-7, C-8 and C-9. Methyl group CH_3-13 (δ 1.05) has long-range correlation to C-4, C-5, C-6 and C-10. The vinyl proton H-10 shows long-range correlations to C-4, C-5, C-6 and C-13. Furthermore, methine proton H-4 shows long-range correlations to C-3, C-5, C-6, C-9 and C-15. These observations lead to the planar structure of **9** as given in Fig. 6.

The relative configuration of the molecule was deduced from the NOESY spectrum. Crosspeaks observed between the axial proton H_a-6 (δ 1.80, *ddd*, $J_{aa} = 11.03$ Hz, $J_{ae} = 6.62$ Hz, $J_{gem} = 13.56$ Hz) and the

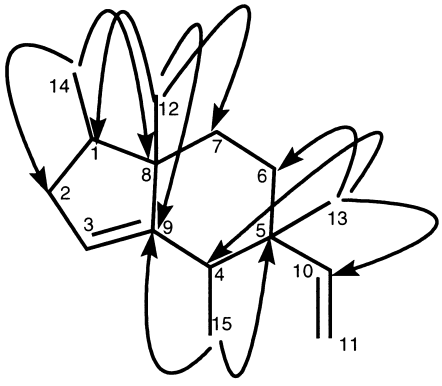

Fig. 6. Long-range correlations derived from the HMBC spectrum of neotrifaradiene (**9**).

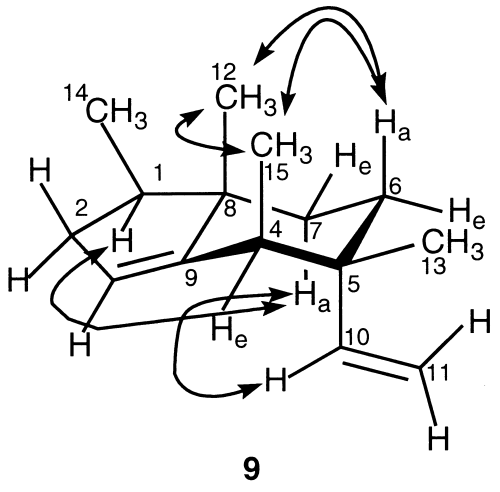
two methyl groups CH_3-12 and CH_3-15 indicate that H_a-6 and the two methyl group are on the same side of the molecule. Due to the proximity of the signal of CH_3-12 and CH_3-14 no conclusion could be deduced from the NOESY. However, another set of correlations between the proton H_a-7 (δ 1.52, *dd*, $J_{aa}=11.03$ Hz, $J_{ae}=3.47$ Hz) and the two protons H-1 and H-10 show that the vinyl group at C-5 is in axial position and that the protons H-1, H_a-7 and H-10 are on the same side of the molecule. The methyl group CH_3-14 is thus on the same side of the molecule as CH_3-12. Therefore, the compound has the relative configuration as shown in Fig. 7.

Although the absolute configuration of the new sesquiterpene hydrocarbons **6**–**9** was not determined, biogenetic considerations suggest that it is identical to that of the trifarienols, which was derived by single crystal X-ray diffraction analysis (Hashimoto et al., 1995).

2.5. Biogenesis of trifarane sesquiterpenoids

The first natural trifarane to be reported was upial, a sesquiterpene aldehyde isolated from the marine sponge *Dysidea fragilis* (Schulte et al., 1980). Later, the alcohols trifarienols A–E (**1**–**5**) were isolated from the Malaysian liverwort *Cheilolejeunea trifaria* (Hashimoto et al., 1995). Two biogenetic pathways have been suggested considering striatane-type and pinguisane-type sesquiterpenes, respectively, as precursors of the trifarane system (Tori et al., 1993; Hashimoto et al., 1995). The four new sesquiterpenes **6**–**9** may be biogenetically related with nerolidol as their common precusor. Indeed trifara-9,14-diene (**6**) and 3,7-di-*epi*-trifara-9,14-diene (**7**) which might be biosynthesized from nerolidol (Hashimoto et al., 1995) are precursors for trifarienols **1**–**5** as shown in Fig. 8. Sandvicene (**8**) and neotrifaradiene might also be formed from nerolidol via monocyclonerolidol and striatol respectively (Fig. 8).



9

Fig. 7. NOE correlations and relative configuration of neotrifaradiene (**9**).

3. Experimental

3.1. NMR spectroscopy

NMR spectra were recorded using a Bruker WM 500 (500 MHz) instrument. The signal of benzene (δ 7.27 in ^{1}H NMR, 500 MHz and δ 128.40 in ^{13}C NMR, 125 MHz) was used as reference.

3.2. GC–MS

GC–MS (EI, 70 eV) measurements were carried on a Hewlett Packard 5890 gas chromatograph with a 25 m fused silica capillary column with polydimethylsiloxane CPSil 5 (Chrompack) coupled to a VG Analytical 70-250S mass spectrometer. Split injection (200°C); carrier gas He, 1 bar head pressure; ion source temp. 200°C.

3.3. Capillary GC

Orion Micromat 412 double column instrument with 25 m fused silica capillaries with polysiloxane CPSil 5 and CPSil 19 (Chrompack); Carlo Erba Fractovap 2150, 4160 instruments with 25 m fused silica capillaries with heptakis(2,6-di-*O*-methyl-3-*O*-pentyl)-β- and-γ-cyclo dextrin, respectively, and heptakis(6-*O*-t.butyldimethyl silyl-2,3-di-*O*-methyl)-β-cyclodextrin, all in polysiloxane OV1701 (50 wt.%); split injection (200°C), flame ionization detection (250°C); carrier gas hydrogen, 0.5 bar head pressure.

3.4. Polarimetry

For polarimetric measurements a Perkin-Elmer 241 polarimeter ($l=1$ dm; $\lambda=589$ nm) was used. Only the sense of the optical rotation was determined, since the isolated sample amounts were too small for an accurate determination of the *specific* optical rotation.

3.5. Plant material

The liverwort *Trocholejeunea sandvicensis* was collected in May 1999 near Tokushima, Japan. A voucher specimen has been deposited at the Institute of Pharmacognosy, Tokushima Bunri University.

3.6. Extraction and isolation

Dried plants of *T. sandvicensis* (1405 g) were extracted at room temp. with 2 l of Et_2O for 1 month. After filtration and evaporation of the solvent a slightly yellow oil (20.51 g) was obtained. The material was chromatographed on

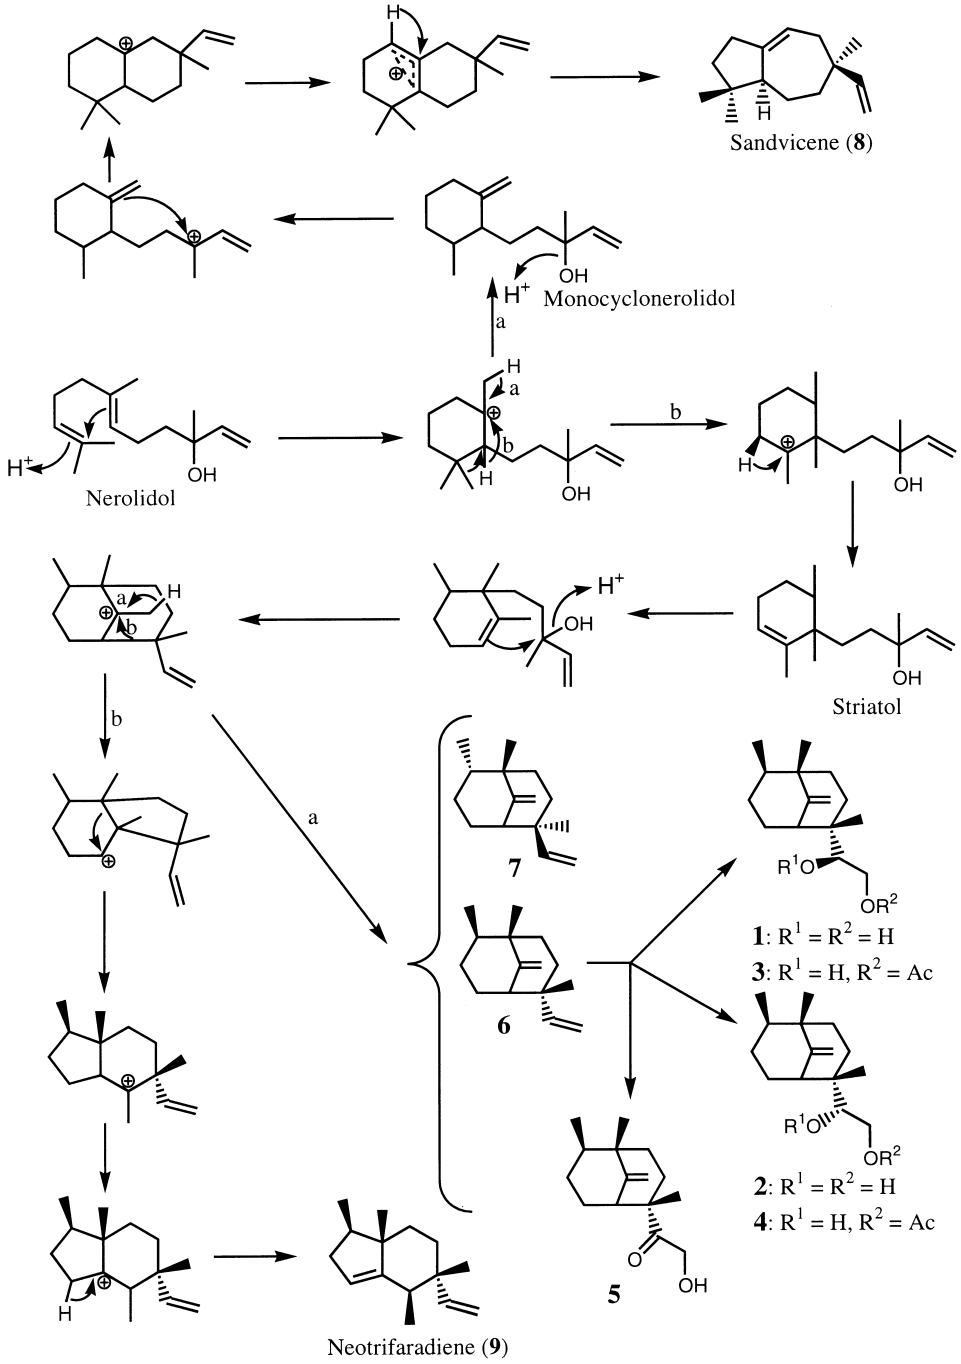


Fig. 8. Proposed biogenetic pathway for the four new sesquiterpenes **6**–**9**.

silica gel (70–230 mesh) column (300 g), using a *n*-hexane–EtOAc gradient to give 12 fractions. Fractions 1–5 (obtained with 100% *n*-hexane as eluting solvent) was subjected to GC–MS and revealed the presence of more than thirty sesquiterpenes. In order to isolate the unknown compounds of the hydrocarbon fraction, it was submitted to preparative GC using a Varian 2800 instrument, equipped with a stainless steel column (1.85 m × 4.3 mm) with 10% polydimethylsiloxane SE 30 on Chromosorb W-HP. Helium was used as carrier gas at a flow rate of 240 ml/min. The sample was injected at 90°C and after 10 min the temperature was allowed to rise at a rate of 2°/min to 180°C. Eleven fractions were collected and analysed by GC and GC–MS. GC–MS analysis of the third fraction showed the presence of three unknown compounds which were separated by preparative GC, using the same instrument, equipped with a stainless steel column (2.00×4.3 mm) containing 2.5% of a modified cyclodextrin heptakis(6-*O*-*t* butyldimethyl silyl-2,3-di-*O*-methyl)-β-cyclodextrin and polydimethyl siloxane SE 30 (1:1, w/w) on Chromosorb G-HP. A three ramp temperature program was used. The

temperature was held constant at 90°C for 15 min and then allowed to rise to 100°C at a rate of 1°/min. At 110°C the rate was changed to 2°/min. Three fractions were collected. The first fraction (TS31) eluting at 39 min contained trifara-9,14-diene (**6**) (1.5 mg), the second one (TS32) eluting at 42 min contained compound **7** (2 mg) and the third one eluting at 48 min contained sandvicene (**8**) (1.5 mg).

Received in revised form 14 December 2000; accepted 8 March 2001

Abstract

Two new pregnene derivatives 14β-15α-dihydroxy-Δ^4pregnene-3,20 dione and 3β-14β, 15α-16α hydroxy-20-oxo- Δ^5pregnene-tetra-ol, in addition to α- and β-amyrin and β-sitosterol, were isolated from *Solenostemma argel* leaves. The structures were established by extensive spectral analysis as well as comparison with reference materials. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Solenostemma argel*; Asclepiadaceae; Hydroxypregnene derivatives

1. Introduction

Solenostemma in the Asclepiadaceae, is a monotypic genus distributed widely in the Arabian desert, North Africa and Palestine (Jafri et al., 1977). *Solenostemma argel* (Hayne), is the only species found in Egypt (El-Hadidi et al., 1994) It is an erect shrub 60–100 cm high, with profuse branching especially in favoured places. It is commonly used in folk medicine for the treatment of coughs and as a purgative (Mahran and Saber, 1964).

So far the phytochemistry of *Solenostemma argel* (Hayne), has been attempted by many authors, with differing results. Mahran et al. (1967), in their study on the leaves, stems, flowers and fruits of *Solenostemma argel*, reported the presence of α and β-amyrins, β-sitosterol, 7-methoxy-3,22-dihydrostigmastene, ethoxy-vangurolic acid in addition to an unknown steroid. In another study (Mahran et al., 1969), using chromatographic examination of the alcoholic extract of *Solenostemma argel* leaves, they reported the presence of two crystalline substances named argelin and argeloside with no detailed spectral analysis or structure determination. The study performed in Hungary (Khaled et al., 1974), on *Solenostemma argel*, showed that the light petroleum and chloroform extracts do not contain steroids or alkaloids and flavonoids, while the methanolic extract was found to be rich in both flavonoids and steroids. The only quaternary base found in considerable amounts was choline. The chemical screening determined in Romania (Younis, 1988), on *Solenostemma argel* leaves, proved the existence of lipids, flavones, antocinan-oxides, mucilages, tannins, amino acids, polyholosides, polyphenolics, phytosterols and carotenoids. The biosynthetic study (Amariei et al., 1991), on the callus and shoots of *Solenostemma argel,* revealed the presence of rutoside, catchin, β-carotene and β-sitosterol.

In a recent study by (Michael, 1998), on the chemical constituents of *Solenostemma argel* leaves, she identified the new natural flavonol glycoside: kaempferol 3,4′-di-*O*-β-D-glucoside beside its 3-glucuronide, 3-rutinoside, 7,4′-diglucoside and the aglycone kaempferol.

In the present study to reach an understanding for the diversity of natural compounds isolated from *Solenostemma argel* by different investigators, we have isolated some known compounds, in addition to two new pregnene derivatives.

2. Results and discussion

Compound **1**, was found to have the molecular formula $C_{21}H_{30}O_4$ based on high resolution mass measurement *m*/*z*, $[M]^+$346. The IR spectrum of compound **1**, showed absorptions at 3405 cm^{-1} due to the hydroxyl group(s), 1706 cm^{-1} due to the carbonyl group, 1375 cm^{-1} due to the methyl ketone and 810 cm^{-1} for

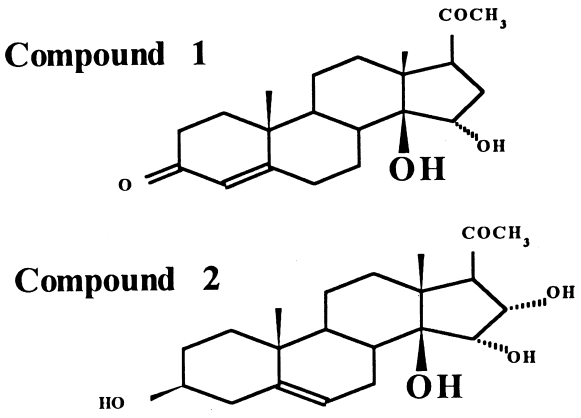
PII: S0031-9422(01)00121-2



trisubstituted double bond. The UV absorption maxima at 238.4 nm, suggesting an unsaturated ketone chromophore. All 21 carbons appeared in the ^{13}C NMR spectrum of compound **1**, and examination of the DEPT spectrum disclosed the presence of 3 methyls, seven sp^3 methylenes, 5 sp^3 methines, 4 sp^3 quaternary carbons and 2 sp^2 quaternary carbons.

The calculated double bond equivalent value of 7 and the violet colour with the Libermann–Burchard test is indicative for a highly oxygenated steroid.

The ^1H NMR spectrum of compound **1**, displayed two singlets at δ 1.09 and δ 1.22 (3H, each) for the two angular methyl groups in the steroid nucleus at C-18 and C-19, in addition to a sharp three proton singlet at δ 2.27 for the methyl ketone group. Also there is a sharp singlet at δ 5.72 for one olefinic proton.

On the basis of the ubiquitous occurrence of the β-configuration of the C-14 hydroxyl group in natural pregnanes (Brandt et al., 1966) the C-14 hydroxyl group in compound **1** was also assigned as β-configuration, which showed the shift for the C-14 at δ 81.94 in the ^{13}C NMR spectrum, in good agreement with published data for natural pregnenes with C-14 hydroxyl group (Yamagishi et al., 1973). From the ^1H NMR spectrum, the second hydroxyl group must, therefore, be in ring D at the C-15 or C-16 position in order to be secondary in nature. The presence of a hydroxyl group at C-15 was derived from the one proton doublet of doublet at δ 4.38 (J= 6.3 and 9.3), suggesting an α-configuration of the C-15 hydroxyl group (Kapur et al., 1967; Sonia et al., 1998) and the correlation was demonstrated from the HMQC and HMBC spectra, where the proton at δ 4.38 correlated with C-15 at δ 73.71 and with C-17 at δ 59.91and C-8 at δ 39.89.

Also the presence of a secondary alcohol group at C-15 was confirmed by ^1H–^1H COSY experiment, which showed coupling with CH_2 at δ 2.60 (1H, *ddd*, J= 9.4,14.9,4.04 Hz) and at δ 1.43 (1H, overlapped with others) and this CH_2 was coupled with the proton at C-17 at δ 2.80 (1H, *dd*, J= 4.04, 10.38 Hz). Also there is a cross signal in NOESY experiment, between the proton at C-8 and the protons of both CH_3-18 and CH_3-19. The HMBC spectrum showed cross peaks between the proton H-4 at δ 5.71 and C-2 (at δ 33.06), C-6 (at δ 33.86) and C-10 (at δ 38.66).

Since some of the oxygen atoms in the suggested Δ^4 pregnene-20-one molecule for compound **1**, is present as hydroxyl group(s), this was demonstrated in the mass spectrum, where the molecular ion peak which appeared at m/z 346 $[M]^+$(45), was observed to lose the expected water molecule, yielding ion peak at m/z 328 $[M–H_2O]^+$ (30). The mass spectrum also displayed fragments representing the loss of acetyl functions at m/z 302 $[M–H–COMe-]^+$ (100); m/z 287 $[M–H–COMe-CH_3]^+$ (30) and 244 $[M–H–2COMe–CH_3]^+$ (23). Acetylation of compound **1** with acetic anhydride in dry pyridine by the customary method, revealed an acetate derivative. Its ^1H NMR spectrum showed signals at δ 2.08 (3H, *s*, $CO.CH_3$), and another signal at δ 2.25 for a methyl ketone group (3H, *s*, $CO.CH_3$), in addition to one proton signal at δ 5.30 for H-15. Its MS spectrum showed a molecular ion peak at m/z 389 $[M+H]^+$ (64), m/z 302 $[M–H–\ 2\ CO.CH_3]^+$ (100). From the above mentioned discussion of the spectral data presented, Compound **1** was suggested to be 14β-15α-dihydroxy-Δ^4pregnene-3, 20 dione (14β-15α-dihydroxyprogesterone), a compound which to our knowledge is not reported before from *Solenostemma argel* or from family Asclepiadaceae or from any other natural source.

Compound **2**, was isolated as colourless crystals, mp 232°C, analysed for $C_{21}H_{31}O_5$. Its IR spectrum displayed absorption bands at 3470, 1375 and 812 cm^{-1}, assigned to hydroxyl, methyl deformations of a methyl ketone and trisubstituted double bond respectively. The nature of the carbonyl function in compound **2**, was established by a positive nitroprusside test (Feigl, 1956), the presence of a three proton singlet at δ 2.27 in the ^1H NMR spectrum and the loss of COMe group from different fragments in the mass spectrum.

The calculated double bond equivalent value of 6 for compound **2**, and the violet colour in the Liebermann–Burchard test, is indicative for the steroidal nature of this compound, which is a C_{21} molecule expected to contain methyl ketone group, hydroxyl group(s) and a double bond(s).

The ^1H NMR spectrum of compound **2**, displayed signals at δ 0.94 (3H, *s*) and δ 1.03 (3H, *s*) indicative of C-18 and C-1angular methyl groups of a normal steroid ring system with Δ^5 double bond, in addition to a 3 proton sharp singlet at δ 2.27 for a methyl ketone group (CH_3–CO). A multiplet centered at δ 3.42, was associated with the α-hydrogen adjacent to the β-hydroxyl group at C-3 commonly reported in natural steroids (Kapur et al., 1967), and the coupling constants of the carbinyl proton (H-3, *dddd*, J= 4.8, 10.9,4.8 and 10.9 Hz) also supported the α- configuration (equatorial) of the hydroxyl group. Also there is a signal integrated for one vinyl proton at δ 5.40 (*d*, J=2.5 Hz) characterised for C-6 (at δ 121.86).

On the basis of the ubiquitous occurrence of the β-configuration of the C-14 hydroxyl group in natural pregnanes (Brandt et al., 1966), the C-14 hydroxyl group in compound **2** was also assigned as β-configuration, which showed the shift for the C-14 at δ 81.94 in the ^{13}C NMR spectrum, in good agreement with published data for natural pregnenes with C-14 β-hydroxyl group. From the ^{1}H NMR spectrum, the rest of hydroxyl groups must, therefore, be in ring D at the C-15 and C-16 position in order to be secondary in nature, since positions C-11 and C-12 are ruled out because of the clear coupling between H-15/H-16 and H-16/H-17 in the ^{1}H–^{1}H COSY spectrum. The configuration of the C-15 hydroxyl group could be extracted from the coupling constant of the 15β-methine proton, which appeared as a doublet at δ 4.05 (1H, *d*, $J=$ 6.8 Hz), suggesting an α-configuration for the C-15 hydroxyl group (Brandt et al., 1966; Sonia et al., 1998). The configuration of C-16 hydroxy group could be assigned from the 16β-methine proton appearing as double doublet at 4.21 ($J=$ 5.5 and 5.7 Hz) with a coupling constant value near to that of proton 15 and so, having the same α-configuration, like C-15 hydroxyl group. The ^{13}C NMR spectrum of compound **2** displayed the 21 carbons expected. Examination of the DEPT spectrum disclosed the presence of 3 methyls, 7 sp^3 methylenes, 6 sp^3 methines, 4 sp^3 quaternary carbons and one sp^2 quaternary carbon. The HMQC and HMBC spectra showed cross peaks between H-16 and C-20 (δ 2.60/ δ214.03), H-16 and C-13 (at δ 46.09), H-16 and C-14 (at δ 81.23), H-16 and C-15 (at δ 80.23), H-17 and C-12 (at δ 38.28), H-17 and C-21 (at δ 30.87), H-9 at δ 2.10 and C-14 (at δ 81.23), H-6 at δ 5.4 and C-8 (at δ 45.69) and C-10 (at δ 31.33), H-19 at δ 1.03 and C-5 (at δ 139.04) and H-3 at δ 3.42 and C-5 (at δ 139.04). Also there are cross signals in the NOESY spectrum between the proton of C-15 and both protons of C-8 and C-17. There is also cross peaks between proton at C-8 and the protons at C-6, C-18 and C-19. Since the oxygen atoms in the suggested Δ^5 pregnene molecule for compound **2**, are present as hydroxyl groups. This was demonstrated from its mass spectrum, which further helped in fixing the positions of these groups. The molecular ion peak $[M]^+$ which appears at *m/z* 365 $[M+H]^+$, was observed to lose the expected 4 water molecules yielding ion peaks at *m/z* 347 $[M–H–H_2O]^+$ (100), 329 $[347- H_2O]^+$ (19), 314 $[329\text{-}CH_3]^+$ (23) and 296 $[314- H_2O]^+$ (19). In addition the loss of the methyl ketone group at C-20, was represented by the fragment ions at *m/z* 304 $[M–H–H_2O–COMe]^+$ (7), 286 $[M–H–2H_2O–COMe]^+$ (10) and 271 $[M–H–2H_2O–CH_3–COMe]^+$ (16).

Acetylation of compound **2** in the same manner as compound **1**, revealed an acetate derivative. The ^{1}H NMR spectrum of the acetate showed the following signals: at δ 4.59 (1H, m, H-3), δ 5.78 (1H, *d*, $J=$ 6.08 Hz, H-15), δ 5.03 (1H, *dd*, $J=$ 3.33 and 6.08 Hz, H-16), δ 2.67 (1H, *d*, $J=3.33$ Hz, H-17), δ 1.00 (3H, *s*), δ 1.01 (3H, *s*), 2.34 (3H, *s*, CH_3-21), three acetate signals at δ 2.07 (3H, *s*), 2.07 (3H, *s*) and 2.12 (3H, *s*).

From the above given discussion, compound **2** is suggested to be 3β-14β,15α-16α-hydroxy-20-oxo-Δ^5pregnene-tetra-ol. A polyhydroxy pregn-ene ketone compound isolated for the first time from *Solenostemma argel* leaves and from family Asclepiadaceae.

3. Experimental

Melting points were measured on an Electrothermal Melting Point Instrument without correction. Optical rotations were measured with a JASCO DIP-360 automatic polarimeter. Infra red (IR) spectra were recorded on Shimadzu IR-470 spectrometer. UV spectra were recorded with a JASCO V-550 spectrometer. ID-NMR spectra were recorded with a Bruker DPX-400 and 2D-NMR spectra were recorded with a Bruker DRX-500 instrument. Chemical shifts were expressed on a δ (ppm) scale with tetramethylsilane (TMS) as the internal standard (*s*, singlet; *d*, doublet; *dd*, double doublet; *m*, multiplet; *t*, triplet). High resolution mass spectra were obtained with VG ZAB sperctrometer. Elemental analysis was conducted using a Perkin-Elmer 240 B instrument. Silica gel (0.063–0.200 mm, E-Merck), was used for column chromatography and silica gel GF_{254} was used for TLC and preparative PTLC purposes.

3.1. Extraction and isolation

Commercial sample (4 kg) of *Solenostemma argel* leaves, purchased from Aswan market, was cleaned from foreign materials, powdered and exhaustively extracted with alcohol 70% in a Soxhlet apparatus. The alcohol extract was condensed under reduced pressure to a syrupy consistency, then diluted with 200 ml distilled water and transfered into a separatory funnel. The extract was shaken with chloroform till exhaustion. The chloroform extract was collected, dried over anhydrous sodium sulphate and condensed under reduced pressure to give 53 g of chloroform soluble material. About 15 g of the chloroform soluble material was slurried with 50 g silica gel and placed on the top of a column packed with 600 g silica gel and elution started with hexane then gradiently with increasing proportions of ethyl acetate. Fractions eluted with hexane–ethyl acetate 9:1 and 8:2 and 7:3 were joined together and separated on preparative thick layers of silica gel GF_{254} and developing solvent composed of benzene–ethyl acetate 8:2, where 3 crystalline compounds were isolated and designated A,B and C. Fractions eluted with hexane–ethyl acetate 1:1, gave a crystalline compound **1**, mp 181°C. Fractions eluted with hexane–ethyl acetate 3:7, gave a crystalline compound **2**, mp 232°C.

Table 1
^{1}H NMR and ^{13}C NMR shifts for compounds **1** and **2**

	Compound **1**		Compound **2**

[a] Overlapped with others, coupling constant in parentheses.

3.2. Compound *A*

Obtained as colourless crystals, mp 201–203°C, gave rose red to pink colour on spraying with 40% H_2SO_4 on TLC (R_f 0.86) and subsequent heating at 100°C for few minutes. This compound has been identified as β-amyrin by comparison with reference sample.

Anal. calc. for $C_{30}H_{50}O$: C, 84.44; H, 11.81. Found: C, 84.73; H, 11.84. Mass spectrum *m/z* 426 $[M]^+$, 218, 203, 189. ^{1}H NMR (CCl_4) ppm: 0.74 (3H, *s*), 0.81 (3H, *s*), 0.87 (6H, *s*), 0.95 (9H, *s*), 1.11 (3H, *s*), 3.12 (1H, *dd*, *J*= 9, 6 Hz), 5.15 (1H, *t*, *J*= 3 Hz).

3.3. Compound *B*

This was similarly obtained from the preparative PTLC (R_f 0.84), and rerystallized from alcohol to give crystalline deposite, mp 185–187°C. Comparison with reference sample and the data presented in the literature, proved this compound to be α-amyrin.

3.4. Compound *C*

This was obtained as colourless plates from ethanol, mp 137–140°C. IR (Kbr) cm^{-1}: 3440 (OH). Although the TLC chromatogram of this compound showed only one spot R_f 0.66 in benzene–ethyl acetate 8:2, its mass spectrum gave parent peaks at *m/z*: 414, 412 and 400 suggesting the presence of a mixture of stigmasterol, campesterol and β-sitosterol.

3.5. Compound *1* (*14β-15α-dihydroxyprogesterone*)

Colourless crystals, mp 181°C; $[\alpha]_D$ +62.6° (*c*=1.31, $CHCl_3$); UV (nm): 238.4 (unsaturated ketone chromophore); IR spectrum cm^{-1}: 3405 (OH), 1706 (C=O), 1375 (CH_3–C=O) and 810 (trisubstituted double bond); mass spectrum *m/z*: 346 $[M]^+$(45). Anal. found 346. 213224 for $C_{21}H_{30}O_4$, C: 72.787514, H: 8.665180; requires 346.214410; C: 72.787264, H: 8.665150, MS *m/z* 328 $[M–H_2O]^+$ (30), 302 $[M–COMe–H]^+$ (100); *m/z* 287 $[M–COMe–CH_3]^+$ (30) and 244 $[M–2COMe–CH_3]^+$ (23). ^{1}H NMR and ^{13}C NMR spectra (Table 1). The acetate derivative, Anal. found 388.224669 for $C_{23}H_{32}O_5$, C: 71.092854, H: 8.242698; requires 388.224974; C: 71.092798, H: 8.242643.

3.6. Compound *2* (*3β-14β,15α-16α hydroxy-20-oxo-Δ^{5}pregnene-tetraol*)

Colourless crystals, mp 232°C; $[\alpha]_D$ −61.1° (c=0.31, $CHCl_3$); UV (nm): 204.4; IR spectrum^{-1}: 3470 (OH), 1706 (C=O), 1375 (CH_3–C=O) and 810 (trisubstituted double bond); mass spectrum *m/z* 365 $[M+H]^+$(5). Anal. found 364.214728 for $C_{21}H_{31}O_5$, C: 69.189953, H: 8.511462; requires 364.214410, C: 69.190013, H:

8.511469. MS, *m/z* 347 $[M–H–H_2O]^+$ (100), 329 $[347\text{-}H_2O]^+$ (14), 314 $[329\text{-}CH_3]^+$ (23) and 296 $[314\text{-}H_2O]^+$ (19), 304 $[M–H–H_2O–COMe]^+$ (7), 286 $[M–H–2H_2O–COMe]^+$ (10) and 271 $[M–H–2H_2O–CH_3–COMe]^+$ (16). ^1H NMR and ^{13}C NMR spectra (Table 1). The acetate derivative, Anal. found 490.257462 for $C_{27}H_{38}O_8$, C: 66.087724, H, 7.751029; requires 490.256669, C: 66.087831, H, 7.751041.

Received in revised form 8 November 2000; accepted 6 March 2001

Abstract

Re-examination of the chemical constituents of the leaves of *Ferula sinaica* afforded a new eudesmanolide and a new carotane. The structures were elucidated by spectroscopic methods. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Ferula sinaica*; Apiaceae; Sesquiterpenes; Eudesmanolide; Carotane

1. Introduction

Ferula sinaica L. (Apiaceae) is widespread on Sinai peninsula, Egypt and its resin has been used in folk medicine for treatment of various diseases (Boulos, 1983). Chemically, the resin of the species is characterized by the presence of sesquiterpenes, sesquiterpene coumarins and monoterpenes (Al-Hazimi, 1986; Ahmed, 1990, 1991, 1999). A previous investigation of the leaves of *F. sinaica* has revealed the presence of a glucose derivative and 2-*C*-methyl-D-erythritol (Ahmed et al., 1996). We report here the isolation and characterization of a new carotane and a rare eudesmanolide constituent from the leaves of *F. sinaica*. Few eudesmanolides have been reported from the genus *Ferula* (Gonzalez and Barrera, 1995).

2. Results and discussion

Fractionation of the dichloromethane–methanol (1:1) extracts of the leaves of *F. sinaica* by column chromatography on silica gel and on Sephadex LH-20 gave a new eudesmanolide **1** and a new carotane **2**.

The spectral data of compound **1** suggested a different skeleton type than those which are common in the genus *Ferula*. ^{1}H NMR spectrum of **1**, in pyridine-d_5, displayed three methyl signals at δ 1.13, 1.15 and 1.47, two being due to two tertiary methyls and two protons geminal to hydroxyl groups were observed at δ 4.90 (J= 6.5, 9.5 Hz) and 3.60 (J=4, 11 Hz). The downfield shift of the signal at δ 4.90 suggested the oxygen function at C-6 could be acylated or lactonized. This proton showed a correlation with a narrow doublet at δ 1.86 and a multiplet at δ 2.58 in the ^{1}H–^{1}H COSY. Additionally, a methyl doublet at δ 1.15 was correlated with a multiplet signal at δ 2.82 which itself correlated with the multiplet at δ 2.58. These data could be assigned to a α-methyl-γ-lactone moiety. The double doublet at δ 3.60 (J= 4, 11 Hz) was characteristic for a proton geminal to equatorial hydroxyl group at C-3. The ^{13}C NMR spectrum of compound **1**, in $CDCl_3$, exhibited 15 nonequivalent carbon atoms. The assignment of the carbon signals was established from DEPT and HMQC experiments. This data suggested the presence of an eudesmanolide structure, a rare constituents in the genus *Ferula* (Gonzalez and Barrera, 1995). Although, the coupling constant suggested the stereochemistry of H-3, H-5 and H-6, NOESY experiment, in pyridine-d_5, supported the proposed stereochemistry. H-6 showed a cross-peak with H-7, H-14 and H-15. While, H-7 exhibited a cross-peak with H-14 and H-11; H-5 showed a correlation

2 R = H

2a R = Ac

with H-3. HREI mass spectrum afforded a molecular ion peak at m/z 268.1660, $C_{15}H_{24}O_4$. Therefore, compound **1** has the structure of a 3α,4β-dihydroxy-5βH, 11α H-eudesman-6,12-olide. Of similar structure related compounds, one has been synthesized and showed cell growth inhibitory activity against lymphocytic leukemia (P-388) in vitro (Ando et al., 1991), the second was a biotransformation products (Amate et al., 1991).

The structure of compound **2** could be easily established by comparison of its spectral data with those of lancerotriol derivatives (Fraga et al., 1985, 1986; Garg et al., 1987; El-Sayed, 1990; Miski and Jakupovic, 1990). An additional sharp singlet signal, integrated for three protons appeared at δ 2.05 and could be assigned to an acetyl group. The chemical shift of H-9 as a multiplet at downfield (δ 5.57), compare to H-9 of lancerotriol 6-vanillate (δ 4.30) indicated the presence of an acetyl group at C-9. The second acyl group was established as p-hydroxybenzoate from the ^{1}H and ^{13}C NMR (Tables 1 and 2). The other ^{1}H and ^{13}C signals were very close to those of lancerotriol derivatives. The HRCI mass spectrum afforded a molecular ion at m/z 417.2251 (calc. 417.2277, $C_{24}H_{32}O_6$). Acetylation of **2** gave the acetyl product **2a**. Its ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2. Moreover, the configuration at C-9 was supported from NOE experiment. Irradiation of H-14 of **2a** enhanced H-6 and H-9.

3. Experimental

3.1. Plant material

Leaves of *F. sinaica* were collected from North Sinai peninsula, El-Arish, Egypt, in March 1997 by one of us (AAA). A voucher specimen (AAA 110) is deposited in the department of Botany, El-Minia University, Egypt.

3.2. Extraction

Air-dried leaves of *F. sinaica* (500 g) were extracted with MeOH–CH_2Cl_2 (1:1). The extract was defatted and chromatographed on Si gel column packed into petroleum ether (bp 40–60°C) and eluted with a petroleum ether–Et_2O step gradient. The fractions eluted with petroleum ether–Et_2O (1:1 and 1:2) were combined and further chromatographed on a Sephadex LH-20 column with an initial solvent of Et_2O–CH_2Cl_2–MeOH (7:4:0.5) to give 9 mg of **1**, and 11 mg of **2**.

3.3. Physical and spectral data

3.3.1. 3α,4β-Dihydroxy-5βH, 11α H-eudesman-6,12-olide (1)

IR ν_{max} $CHCl_3$ cm^{-1}: 3510, 3425, 1785. HREIMS *m/z* (rel. int): 268.1660 $[M]^+$ (45) (calc. 268.1675); molecular formula: $C_{15}H_{24}O_4$.

3.3.2. Lancerotriol 9-acetate-6-p-hydroxybenzoate (2)

IR ν_{max} $CHCl_3$ cm^{-1}: 3445, 2975, 2885, 1700, 1690. HRCIMS *m/z* (rel. int.): 417.2251 $[M+H]^+$ (calc. 417.2277, $C_{24}H_{32}O_6$), 399.2170 $[M+H–H_2O]^+$ (100) (Calc. 399.2171); molecular formula: $C_{24}H_{30}O_5$.

Acetylation of **2**: 8 mg of **2** was heated with Ac_2O in pyridine, at 70°C for 1 h. The mixture was decomposed by distilled water and was extracted with CH_2Cl_2. The organic layer was concentrated and purified by Sephadex LH-20 column (*n*-hexane–CH_2Cl_2–MeOH, 8:3:0.5) to give 6 mg of **2a**. IR ν_{max} $CHCl_3$ cm^{-1}: 2890, 2885, 1695, 1690. HRCIMS *m/z* (rel. int.): 459.2367 $[M+H]^+$ (11) (calc. 459.2383, $C_{26}H_{34}O_7$), 441.2275 $[M+H–H_2O]^+$ (100) (calc. 441.2278); molecular formula: $C_{26}H_{32}O_6$.

Dedicated to the memory of Dr. Hson-Mou Chang (1923–2000)

Abstract

Two furanoditerpenoid lactones, were isolated from the seeds of *Caesalpinia minax* Hance. Their structures and stereochemistry have been established by spectral data and single crystal X-ray analysis. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Caesalpinia minax*; Leguminosae; Furanoditerpenoid lactone; Caesalmin A and B; X-ray analysis

1. Introduction

Plants belonging to the genus *Caesalpinia* have proven to be a rich source of cassane furanoditerpenes (Balmain et al., 1967, 1970; Pascoe et al., 1986; Ogawa et al., 1992; Kinoshita et al., 1996; Kitagawa et al., 1996; Peter et al., 1997, 1998; Lyder et al., 1998). The molecular skeleton of this kind of diterpenoid is constructed from the fusion of three cyclohexane rings and a furan ring. In most cases structural determination was based on spectroscopic methods. However, the absolute configuration of ε-caesalpin (Birnbaum and Ferguson, 1969) and caesaldekarin A (Kitagawa et al., 1994), as shown in Fig. 1, were confirmed by X-ray analyses using the anomalous dispersion method.

Some of the extracts of plants of the genus *Caesalpinia* display interesting biological activities (Hikino et al., 1977; Sharma et al., 1997; Datte et al., 1998). *Caesalpinia minax* Hance, a member of this genus, is a prickly scandent shrub growing in the tropics and subtropics. The seeds of this plant, which is called 'kushilian', have long been used as Chinese folk medicine for the treatment of common cold, fever and dysentery (Jiangsu New Medical College, 1977). We report herein the isolation of two new furanoditerpenoid lactones, designated caesalmin A and caesalmin B, from the chloroform partition of the ethanol (95%) extract of this plant. Their structures were established by spectroscopic methods and single crystal X-ray analysis (Fig. 1).

2. Results and discussion

A 95% EtOH extract of the seeds of *Caesalpinia minax* Hance was suspended in distilled water and extracted successively with hexane, chloroform, ethyl acetate and *n*-butanol. The chloroform extract was subjected to silica gel column chromatography to yield caesalmin A and caesalmin B.

Caesalmin A was obtained as colorless block-like crystals of its 1:1 methanol solvate, $C_{22}H_{28}O_8{\cdot}CH_3OH$, mp 179–180°C, $[\alpha]_D^{20}$ −6.5° (*c* 0.1 in CH_3OH). Assignment of the molecular formula $C_{22}H_{28}O_8$ was based on HRLSIMS (*m*/*z* $[MH]^+$ 421.1847, calculated 421.1854). The ESI mass spectrum showed a $[M\text{-}1]^-$ ion peak at *m*/*z* 419. Its IR (KBr) showed bands at 3422 (hydroxyl), 1803 (saturated γ-lactone) and 1743 cm^{-1} (acetoxyl). The ultraviolet (UV) spectrum of caesalmin A showed a maximum at 219 nm (logε 3.84) which suggested the presence of a furan ring.

The ^1H NMR spectrum (Table 1) indicated the presence of three tertiary methyl group at δ_H 1.18 (6H, *s*, H-18 and H-19) and 1.15 (3H, *s*, H-20), one acetoxyl

PII: S0031-9422(01)00134-0

group at δ_H 2.11 (3H, *s*, H-22), four low-field protons attached to carbon atoms bearing an oxygen function at δ_H 3.61 (1H, *d*, $J=2.6$ Hz, H-1), δ_H 4.03 (1H, *ddd*, $J=2.6$, 4.5, 12.5 Hz, H-2), δ_H 4.81 (1H, *dd*, $J=9.3$, 11.3 Hz, H-7) and δ_H 5.50 (1H, *d*, $J=9.3$ Hz, H-6), and two adjacent α and β double-bond protons at δ_H 6.54 (1H, *d*, $J=2.0$ Hz, H-15) and δ_H 7.38 (1H *d*, $J=2.0$ Hz, H-16) on a furan ring. Except for one acetoxyl group (δ_C 170.79 and 20.67), the ^{13}C NMR and DEPT spectrum of caesalmin A showed 20 carbon atoms: one lactonic carbonyl atom (δ_C 175.13), four olefinic carbon atoms of the furan ring (δ_C 152.74, 114.18, 107.69 and 142.10), five carbon atoms bearing oxygen (δ_C 73.70, 64.92, 83.91, 75.46 and 83.49), two methylene groups (δ_C 41.07 and 21.15), three methyl groups (δ_C 30.60, 24.86 and 15.53), three methine carbons (δ_C 44.69, 32.94 and 41.44) and two quaternary carbon atoms (δ_C 41.34, 44.78), which suggested that caesalmin A possesses a cassane furanoditerpene lactone structure (Peter et al., 1997) as shown in Fig. 1. The full assignments and connectivities were determined by ^1H–^1H COSY, HMQC and HMBC spectrum. The HMQC spectrum revealed a signal at δ_H 4.81 (1H, dd, $J=9.3$, 11.3, H-7) attached to a carbon at δ_C 83.49, and the HMBC spectrum showed that H-7 was correlated to C-6, C-8, C-14 and C-17, suggesting that the γ-lactone was formed by ring closure involving the oxygen atoms bridged to C-7 and C-17.

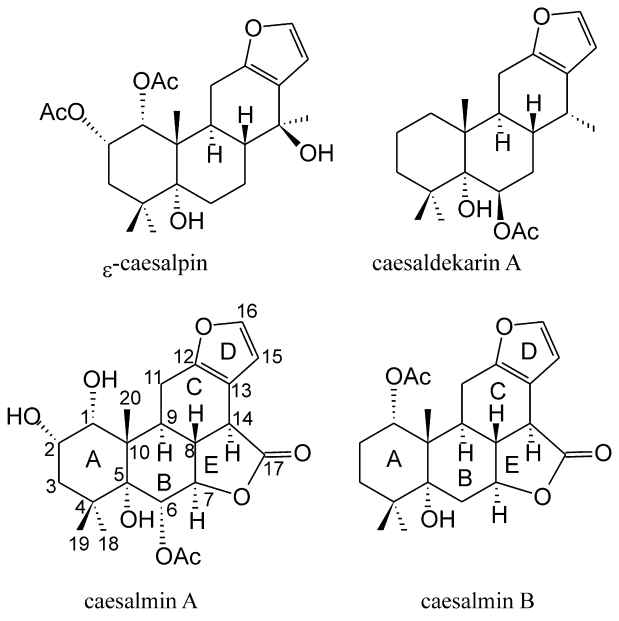

Fig. 1. Chemical formulae of some cassane furanoditerpenoids.

The molecular structure and stereochemistry of caesalmin A were established unequivocally by X-ray crystallographic analysis. The asymmetric unit consists of one independent caesalmin A and one methanol molecule connected by hydrogen bonds O-9 − O-7 (3.035 Å)

[a] ^1H and ^{13}C data were assigned based on DEPT, ^1H–^1H COSY, HMQC and HMBC spectra.

and O-2–O-9 (2.867 Å, -x-1/2, -y, z+1/2). A view of the molecular structure is presented in Fig. 2. Bond lengths and angles are in generally close to normal values. The A and B rings adopt a normal chair conformation with mean torsion angles of 53.6 and 58.3° (the torsion angle of cyclohexane is 56°). The C ring exists in a twist chair conformation due to fusion with the furan ring, which is planar with a maximum deviation of 0.0035 Å. The lactone ring E exists in an envelope conformation with C-8 displaced by 0.722 Å from the least-squares plane of the remaining four atoms.

Caesalmin B was isolated as colorless crystals of its 2:1 acetone solvate. $2(C_{22}H_{28}O_6)\cdot CH_3COCH_3$, mp 148–149°C, $[\alpha]_D^{20}$ +52.5° (c 0.4 in CH_3OH). The molecular formula $C_{22}H_{28}O_6$ was based on HRLSIMS (m/z $[MH]^+$ 389.1951, calculated 389.1956). The IR and UV spectra were nearly the same as those of caesalmin A. The ^1H and ^{13}C NMR spectra of caesalmin B were similar to those of caesalmin A; however, two methine groups in caesalmin A (δ_C 64.92 and 75.46) were replaced by two methylene groups at δ_C 30.66 and 23.04 in caesalmin B (Table 1). ^1H–^1H COSY and HMQC spectra showed that the two methylene groups can be assigned to the 2 and 6 positions. The correlation between the acetate carbonyl signal at δ_C170.65 and the oxymethine proton H-1 (δ_H4.88) in the HMBC spectrum showed that the acetoxyl group is attached at C-1.

The structure of caesalmin B was verified by X-ray analysis. The asymmetric unit consists of two independent, nearly identical caesalmin B molecules and one acetone molecule connected by hydrogen bonds O-3′–O-5 (3.045 Å, x-1, y, z) and a weak C–H interaction C-16–O-7 (3.468 Å). A view of the molecular structure is presented in Fig. 3. The conformation of caesalmin B is similar to that of caesalmin A. The A, B, C, D and E rings adopt chair, chair, twist chair, planar and envelope conformations, respectively.

Both caesalmin A and caesalmin B have the same ring junctions, i.e. A/B *trans*, B/C *trans*, B/E *trans* and C/E *trans*. All furanoditerpenoids from *Caesalpinia* related species have an beta-oriented methyl group at C-10. Since the absolute configuration of both ε-caesalpin (Birnbaum and Ferguson, 1969) and caesaldekarin A (Kitagawa et al., 1994) are well established, the absolute configuration of caesalmin A and caesalmin B can be assigned by analogy as shown in Fig. 1.

3. Experimental

3.1. General

ORD were recorded on a Perkin-Elmer 341 Polarimeter in MeOH solution. Mps were determined using a Fisher Scientific instrument and are uncorrected. The UV spectra were obtained on a Beckman DU650 spectrophotometer in MeOH. IR spectra were recorded on a Nicolet Impact 420 FT–IR spectrometer. The NMR spectra were obtained on a Bruker 300 spectrometer with chemical shifts reported in δ (ppm) using TMS as an internal standard. HRLSIMS measurements were made on an APEX 47e FTMS spectrometer. ESIMS were recorded on a Finnigan MAT TSQ 7000 instrument. X-ray intensities of caesalmins A and B were measured on a Bruker SMART 1000 CCD diffractometer.

3.2. Plant material

The seeds of *Caesalpinia minax* Hance were collected in Guangxi Province, China in September, 1999. The seeds were identified at the Institute of Chinese Medicine,

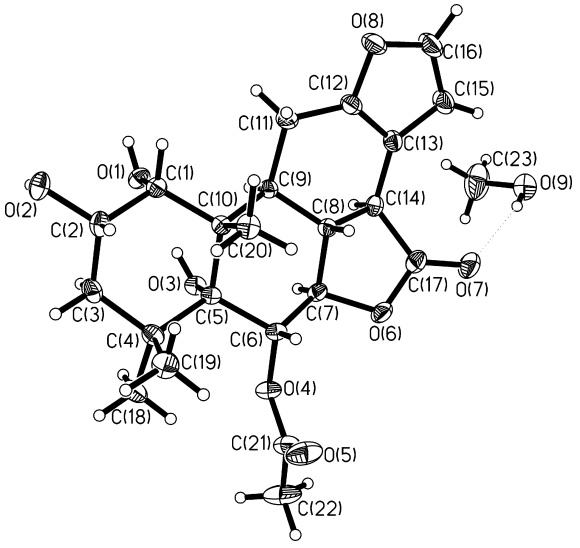

Fig. 2. Molecular structure of caesalmin A, showing the asymmetric unit of its 1:1 solvate with methanol and the atom labeling scheme.

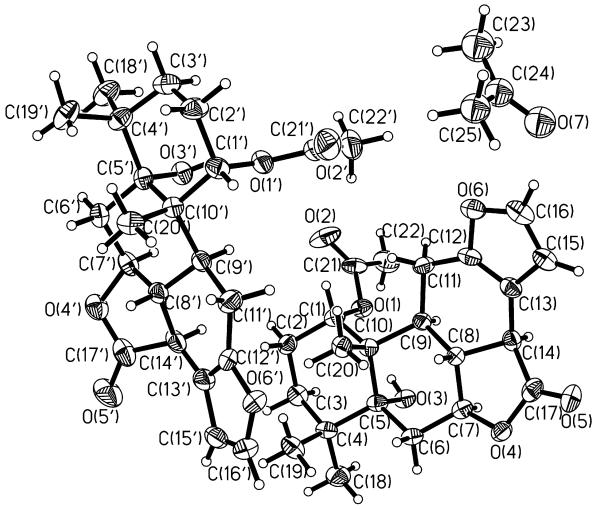

Fig. 3. Molecular structure of caesalmin B, showing the asymmetric unit of its 2:1 solvate with acetone and the atom labeling scheme.

The Chinese University of Hong Kong, where a voucher specimen (No. cm-99) is kept.

3.3. Isolation of caesalmin A and B

The seeds of *Caesalpinia minax* Hance (10 kg) were ground and refluxed with 95% ethanol but reflux temperature. The solubles were then evaporated in vacuo to yield an ethanol extract (892 g) which was then suspended in distilled water and extracted successively with hexane, chloroform, ethyl acetate and *n*-butanol. The chloroform extract (50 g) was subjected to silica gel column chromatography and eluted with hexane/acetone (10:1). Fractions of 150 ml each were taken and 32 fractions collected, and caesalmin A (16 mg) was obtained as a white powder from fractions 24 and 25, and recrystallized from methanol at room temperature. Similarly caesalmin B (50 mg) was obtained as a white powder from fractions 9, 10 and 11, and recrystallized from hexane/acetone (8:1) at room temperature.

3.4. Caesalmin A

Colorless blocks from methanol, $[\alpha]_D^{20}$ −6.5° (c 0.1 in CH_3OH); UV λ_{max}^{MeOH} nm (logε): 219 (3.84); IR (KBr) 3422 cm^{-1}, 1803 cm^{-1}, 1743 cm^{-1}; HRLSIMS *m*/*z* $[MH]^+$ 421.1847, calculated 421.1854. ESIMS 10 eV, *m*/*z* (rel. int.) 419 $[M\text{-}1]^-$ (60), 479 $[M+OAc]^-$ (100). ^1H and ^{13}C spectral data, see Table 1.

3.5. Caesalmin B

Colorless blocks from hexane–acetone mixture, $[\alpha]_D^{20}$ + 52.5° (*c* 0.4 in CH_3OH). UV λ_{max}^{MeOH} nm (log ε): 217 (3.82); IR 3590 cm^{-1}, 1790 cm^{-1}, 1743 cm^{-1}; HRLSIMS (*m*/*z* $[MH]^+$ 389.1951, calculated 389.1956. ESIMS 30 eV, *m*/*z* (rel. int.) 387 $[M\text{-}1]^-$ (5), 59 $[OAc]^-$ (69), 447 $[M+OAc]^-$ (100). ^1H and ^{13}C spectral data, see Table 1.

3.6. X-ray crystallography of caesalmin A — methanol (1/1)

$C_{22}H_{28}O_8{\cdot}CH_3OH$, colorless blocks, mp 179-180°C, M_r = 452.49, orthorhombic, $P2_12_12_1$, a = 7.465 (1), b = 16.806 (3), c = 17.955 (4) Å, V = 2252.6 (8) $Å^3$, Z = 4, d_x = 1.334 gcm^{-3}, $F(000)$ = 968, μ(Mo-K_α) = 0.102 mm^{-1}. Data collection was performed on a SMART CCD using graphite monochromated radiation (λ = 0.71073 Å); 5420 unique reflections were collected to θ_{max} = 28.01°, in which 4593 reflections were observed [$F^2 > 4\sigma(F^2)$]. The crystal structure was resolved by direct methods using SHELXS-97 and refined by full-matrix least-squares method on F^2 using SHELXS-97. Non-hydrogen atoms were refined with anisotropic temperature factors. Hydrogen atoms bonded to carbons were placed at their geometrically ideal positions. Hydrogen atoms bonded to oxygens were located on difference fourier maps and included in the calculation of structure factors with isotropic temperature factors. In the final stage, R = 0.0455, Rw = 0.0567 and S = 1.028.

3.7. X-ray crystallography of caesalmin B — acetone (2/1)

$2C_{22}H_{28}O_6{\cdot}CH_3COCH_3$, colorless blocks, mp 148–149°C, M_r = 834.97, triclinic, $P1$, a = 8.9126 (19), b = 10.586 (2), c = 12.623 (3) Å, α = 96.834 (5), β = 99.642 (5), γ = 107.439 (4), V = 1101.9 (4) $Å^3$, Z = 1, d_x = 1.258 gcm^{-3}, $F(000)$ = 448, μ(Mo-K_α) = 0.091 mm^{-1}. Data collection was performed on a SMART CCD using graphite monochromated radiation (λ = 0.71073 Å); 4848 unique reflections were collected to θ_{max} = 25.21°, in which 3333 reflections were observed [$F^2 > 4\sigma(F^2)$]. The crystal structure was resolved and refined using the same methods as for caesalmin A to R = 0.0561, Rw = 0.0867 and S = 0.996.

Complete lists of refined atomic coordinates and relevant information in standard CIF format for caesalmin A — methanol (1/1) and caesalmin B — acetone (2/1) have been deposited at the Cambridge Crystallographic Data Centre as CCDC Ref. No. 150454 and 150455, respectively.
