Considerations of possible biogenesis, the identical molecular formula and chemical and physicochemical similarity of retusapurpurin A to candenatone (**3**), the necessity to assign three singlets in the ^{1}H NMR spectra, and 2D NMR spectroscopic data obtained for retusapurpurin A led to the partial structure **4**.

The carbon at δ 139.26 was assigned to C-6′, which is linked to the isoflavan moiety, because it showed three-bond correlations in the HMBC spectrum with the aliphatic protons H-2 and H-4, and one of the two partially overlapping singlet signals at δ 7.27. The latter displayed NOEs with all aliphatic protons indicating that there is free rotation around the bond connecting the C-ring of the isoflavan A/C-ring system to the rest of the molecule. One of these two singlet signals was assigned to C-5′ because of its three-bond correlations to two oxygen-bearing carbons at δ 180.09 and 159.31. The singlet signal at δ 6.33 was assigned to C-8′ because of its two-bond correlation to the carbon at δ 159.31, assignable to C-8′a, and based on the three-bond HMBC correlations to C-6′ and a carbon at δ 112.57 assignable to C-4′a. The carbonyl carbon signal at δ 180.09 (supported by the carbonyl absorption at 1635 cm^{-1} in the IR spectrum) was left to be assigned to C-7′ thus suggesting a quinonemethide structure for the chromophore. The chromophore's complete structure was deduced from further HMBC correlations. C-4′a displayed a cross peak with δ 7.27 to which four other cross-peaks belonged, e.g. the carbon at δ 152.7 to C-4′, which also showed a three-bond correlation with the doublet at δ 7.25 belonging to a *para*-substituted ring, and to the carbon at δ 158.03, which showed a three-bond correlation to a doublet at δ 7.82 belonging to the *ortho* position of the 1,2,4-trisubstituted aromatic ring. The NOE between this latter proton and the singlet assigned to C-8′ allowed the deduction of the connectivity of the two aromatic rings to the chromophore. The NOE cross-peak between signals at δ 7.23 and 3.83 represents interaction between the proton at H-3′ and methyl protons confirming that the methoxy group is in the *ortho* position in the 1,2,4-trisubstituted aromatic ring whose connection to the central ring system is thus defined. NOEs were also expected between H-5′ and H-2‴/6‴, H-3′ and H-2‴/6‴, and between H-2 or H-4 and H-2‴/H-6‴ but were not detected due to spectral overlap (Table 2, Fig. 2). NOE was expected also between H-3′ and H-6'' but was not detected.

The assignment of a methoxy group to ring A of the isoflavan unit was corroborated by the positive ion ESI MS spectrum which exhibited a peak at m/z 387 which resulted from RDA cleavage of **1a** at the isoflavan C-ring.

The NMR and MS data established that retusapurpurin A is a quinonemethide represented by the structural formula **1a** (Fig. 1). The stability and simplicity of the ^{1}H NMR spectrum indicated that, of the at least four tautomeric structures of retusapurpurin A, **(1a)** is by far the most stable in DMSO solution at ambient temperatures. Addition of deuterium chloride (DCl) caused the color to change (hypsochromic shift) from blue to orange, consistent with the conversion of the quinonemethide into a pyrylium chromophore. Furthermore, the

addition of DCl shifted nearly all the signals downfield in the ^{1}H NMR spectrum. While most overlapping signals in the downfield region were resolved, some of the signals in the upfield region became congested. Comparison of the **1a** spectra and that of the protonated form (**2**), however, made assignment of the signals possible. The isoflavan partial structure was corroborated by 2D NMR spectral data obtained for the protonated form (**2**). All NOEs were positive except for the one between the protons at δ 4.30 and 3.61, which, we assume, was evidence of a three-spin effect between methine and methylene protons. NOE between the singlet at δ 8.20 and a 2H doublet (H-2‴ and 6‴) corroborated the connectivity of the *para*-substituted aromatic ring to the rest of the molecule. NOE between the singlet at δ 8.20 and the proton signal at δ 8.23 belonging to the 1,2,4-trisubstituted ring was expected but could not be detected because of spectral overlap. The signals for protons belonging to hydroxyl groups predicted by the molecular formula were apparently missing. ^{13}C NMR as well as 2D NMR spectroscopic data provided an overdetermined system of correlations from which the unambiguous structure **2** could be deduced. The 2,4-diarylbenzopyrylium structure of **2** is in complete agreement with **2** being the protonated form of the quinonemethide **1a**.

Retusapurpurin A (**1a**) is the first example of a new type of C_{30} isoflavan whose formation can be rationalized to occur via regioselective oxidative coupling of the isoflavan neovestitol (Ingham, 1979) to 4,4′-dihydroxy-2′-methoxychalcone (Carlson and Dolphin, 1982).

Retusapurpurin A belongs to a relatively small group of natural products: isoflavonoids condensed with a chalcone unit. The closest relative is candenatone (**3**), in which the A-ring of an isoflavan (Hamburger et al., 1988) is coupled to the chalcone unit (6→β linking). The orange pigments of sandalwood (*Pterocarpus santalinus, P. soyauxii,* and *P. osun*; Arnone et al., 1977a,b, 1981) and camwood (*Baphia nitida*; Arnone et al., 1975) have an entirely different fused ring system formally derived from two-point linking of an isoflavonoid to a chalcone.

The structures of the other fluorescent and non-fluorescent purple pigments of *D. parviflora* cell cultures have not been elucidated thus far. Based on chromatographic behavior, UV spectral data (not shown) and preliminary NMR spectroscopic data, at least some of these fluorescent pigments appear to have the same skeleton as retusapurpurin A (**1a**). The differences may be in ring substitution, and some of the minor pigments may be similar to candenatone (**3**) or represent other bimolecular coupling modes.

D. parviflora wood was reported to contain arylbenzofurans, neoflavonoids, and a benzophenone (Muangnoicharoen and Frahm, 1981, 1982). The wood from which candenatone (**3**) was isolated as the major heartwood pigment (Hamburger et al., 1988) was identified in our laboratory as *D. parviflora* by direct comparison to authentic samples of *D. parviflora* collected in Java and Borneo and *D. candenatensis* collected in Singapore, each supported with herbarium vouchers. Botanical literature also supports our determination of the red wood which is the source of both candenatone and retusapurpurin A. *D. parviflora* is a giant liana that develops a dark red heartwood; records of its use as a medicinal plant and for incense date back into the middle ages (Prain, 1904; Burkill, 1935). *D. candenatensis* is a climbing shrub of no economic importance (Chayamarit, 1986; Niyomdham et al., 1997). There exists a possible source of confusion about these two species which might have passed down in botanical literature since a monograph of Indian *Dalbergia* (Thothathri, 1987) apparently misquoted an earlier work (Kurz, 1877) attributing the red wood *D. parviflora* to *D. candenatensis*. Identification of the botanical sources of candenatone and retusapurpurin A as same means that candenatone and simple isoflavonoids hitherto attributed to *D. candenatensis* (Hamburger et al., 1987, 1988) should be referred to *D. parviflora*.

A rigorous comparison of the tissue culture- and heartwood-derived pigment has been carried out to support the premise that stress metabolism pathways that are shared with heartwood-type secondary metabolism subpathways are active in *Dalbergia* cell cultures. Retusapurpurin A purified from callus tissue of *D. retusa* and *D. parviflora*, respectively, and from *D. parviflora* wood had identical color reactions, fluorescence, UV/VIS spectrum, solvatochromic, and thermochromic behavior, molecular weight determined by ESI MS, and they comigrated in HPLC and several TLC solvent systems (see Experimental).

The subpathway to 4,4′-dihydroxy-2′-methoxychalcone (Carlson and Dolphin, 1982) is already known at the level of genes in alfalfa, and most of the genes for the isoflavan pathway are known (Akashi et al., 1998; Dixon et al., 1998). Retusapurpurin A represents an extension of the known isoflavonoid pathway in the direction of heartwood-type metabolism, and the biosynthetic gene(s) must be responsive to both stress and developmental cues. The next challenge is to identify the substrates undergoing coupling, and to determine whether the enzymatic coupling is as regioselective in vitro as in vivo. Identification of the enzyme(s) will afford access to genes involved in stress metabolism common to several species and possibly support research into the yet uncharted heartwood-type metabolic and cellular differentiation.

3. Experimental

3.1. General experimental procedures

For structural assignments, NMR spectra were recorded on solutions (0.8 ml) of **1a** and **2** in DMSO-d_6

(Cambridge Isotope Laboratories, Andover, MA) with a Varian INOVA 500 spectrometer (^{1}H NMR, 500.163 MHz, ^{13}C NMR, 125.781 MHz) at 25°C. The resonances were measured relative to internal DMSO-d_6 and the chemical shifts are expressed in parts per million (δ). Standard Varian supplied pulse sequences were used for gradient enhanced absolute value COSY, phase-sensitive double quantum filtered DQF-COSY, phase sensitive NOESY, and gradient enhanced HMQC and HMBC experiments. Mass spectra were recorded on a VG Trio 3 triple quadrupole instrument (Beverly, MA); the ESI and APCI sources were designed by Analytica (Branford, CT). IR spectrum of **1a** was recorded on a Perkin Elmer FTIR 1600 Series instrument (16 scans, resolution: 4 cm^{-1}).

3.2. Plant materials

The comparative phytochemical analysis included heartwood samples (h) and cell cultures (c) of the species listed below. Callus cultures were initiated from in vitro germinated seedlings or from explants of plants cultivated in the greenhouse.

Baphia nitida Lodd. (h,c), *Caesalpinia bonducella* (L.) Fleming (h,c), *C. cacalaco* Bonpl. (c), *C. coriaria* (Jacq.) Willd. (c), *C. decapetala* (Roth) Alston (c), *C. ferrea* Mart. (c), *C. gilliesii* (Wall. *ex* Hook.) Dietr. (c), *C. pulcherrima* (L.) Swartz (c), *C. sepiaria* Roxb. (c), *C. spinosa* (Mol.) O. Kuntze (c), *C. tinctoria* Dombey *ex* DC. (c), *C. vesicaria* L. (c), *C. violacea* (Mill.) Standl. (h,c), *Dalbergia arbutifolia* Baker (c), *D. assamica* Benth. (c), *D. balansae* Prain (a), *D. bariensis* Pierre (h), *D. baroni* Baker (h), *D. boehmii* Taubert (h), *D. brownei* (Jacq.) Urban (h,c), *D. calycina* Benth. (h,c), *D. cambodiana* Pierre (h), *D. candenatensis* (Dennst.) Prain (h,c), *D. cearensis* Ducke (h), *D. chermezonii* R. Viguier (h), *D. chlorocarpa* R. Viguier (h), *D. cochinchinensis* Pierre ex Laness. (h,c), *D. congestiflora* Pittier (h), *D. cubilquitzensis* (J. D. Smith) Pittier (h,c), *D. cultrata* Graham (h,c), *D. cuscatlanica* (Standley) Standley (h), *D. decipularis* Rizz. & A. Mattos (h), *D. densa* Benth. *var. australis* (c), *D. ecastaphyllum* (L.) Taubert (h,c), *D. floribunda* Craib (h), *D. foliolosa* Benth. (h), *D. frutescens* (Vell. Conc.) Britton (h), *D. funera* Standley (h), *D. fusca* Pierre (h), *D. glabra* (Miller) Standley (h,c), *D. granadillo* Pittier (h), *D. greveana* Baillon (h), *D. hainanensis* Merr. & Chun (c), *D. hupeana* Hance (h,c), *D. hypoleuca* Pittier (h), *D. latifolia* Roxb. (h,c), *D. lineata* Pittier (h), *D. louvelii* R. Viguier (h), *D. madagascariensis* Vatke (h), *D. maritima* R. Viguier (h), *D. mammosa* Pierre (h), *D. martinii* F. White (c), *D. melanocardium* Pittier (c), *D. melanoxylon* Guillemin & Perrottet (h,c), *D. miscolobium* Benth. (h,c), *D. nigra* (Vell.) Allemão ex Benth. (h,c), *D. nigrescens* Kurz (h,c), *D. nitidula* Welw. ex Baker (h), *D. obovata* E. Meyer (c), *D. obtusa* Lecomte (h), *D. oliveri* Gamble (h,c), *D. ovata* Graham (h), *D. palo-escrito* Rzedowski & L. I. Guridi-Gomez (h), *D. parviflora* Roxb. (h,c), *D. pterocarpifolia* Baker (h), *D. retusa* Hemsley (h,c), *D. sericea* G. Don (c), *D. sissoo* Roxb. (h,c), *D. spruceana* Benth. (h), *D. stevensonii* Standley (h), *D. trichocarpa* Baker (c), *D. tucurensis* J. D. Smith (h,c), *Haematoxylon braziletto* Karst. (h,c), *H. campechianum* L. (h,c), *Pterocarpus angolensis* DC. (h,c), *P. antunesii* (Taub.) Harms (c), *P. erinaceus* Poir. (c), *P. indicus* Willd. (h,c), *P. macrocarpus* Kurz (h,c), *P. rotundifolius* Druce (h,c), *P. santalinus* L.f. (h), *P. soyauxii* Taub. (h), *P. tinctorius* Welw. (h,c).

D. candenatensis stem and live plants were collected in Pulau Semakau (Singapore) and identified by Dr. Hugh T.W. Tan (School of Biological Sciences, The National University of Singapore, herbarium vouchers for our samples are SINU Nos. SM DC 27 Sep 1996, and SM DC 2). Sample labeled as '*D. candenatensis*' was a gift from Dr. N. Ruangrungsi (Faculty of Pharmaceutical Sciences, Chulalongkorn Univ., Bangkok). The sources of *D. parviflora* wood samples were as follows. Sample RTIw7917 (for abbreviations of institutional wood collections see Stern, 1988), collected in Indonesia (cut off from a larger sample supported by a voucher: Herbarium Bogoriense #8326) and sample without number, Borneo, were from Dr. Iep Wiselius (I.W.R.A. Consultancy, Woodsection, Westzaan, The Netherlands). Commercial samples identical to *D. parviflora* were from the Kamwo Trading Co., New York, NY (Herbal Catalog #HA108). Seeds were from Dr. Ir. Suhirman, Bogor Botanic Gardens, Indonesia. *D. retusa* seeds were from C. Elevich (AgroForester Tropical Seeds, Holualoa, Hawaii), and the wood samples were RBHw 4807, RBHw 16229, and MADw 42824. Additional information on the sources of plant materials can be obtained from the authors.

Seeds and leaves were surface sterilized with mercuric chloride (0.1% v/w, 15 min). The seeds were incubated in sterile moist cotton. Rescue of living tissue by excision from the testa was necessary with old seeds (*D. calycina*, *D. miscolobium, D. parviflora*) in which large portions of the cotyledon or the embryo were dead. The tissues rescued from seeds, cotyledons or leaves cut from germinated seeds, and the surface sterilized leaves were placed on callus induction medium (26–28 °C; continuous illumination, 30–50 μmol m^{-2} s^{-1}; mixture of incandescent and cool white fluorescent tubes: Sylvania and Power-Twist Vita-Lite 40 W).

All tissue culture media were supplemented with 30 g l^{-1} sucrose, solidified with Bacto agar 7 g l^{-1}, and sterilized in a pressure cooker (109 °C, 35 kPa, 25 min); the pH was adjusted to 5.8 before autoclaving. DM-1 medium contained MS (Murashige and Skoog, 1975) basal salts (Sigma Fine Chemicals) 4.3 g; KH_2PO_4 (6% [w/v]), 3 ml; *myo*-inositol, 100 mg; vitamin B_1, 1 mg; vitamin

B_6, 0.1 mg; glycine, 0.2 mg, nicotinic acid, 0.1 mg, folic acid, 0.05 mg, biotin, 0.1 mg, and supplemented with the plant growth regulators adenine hemisulfate, 10 mg; picloram, 0.12 mg; indole-3-butyric acid, 1 mg; 2,4-dichlorophenoxyacetic acid, 0.5 mg; isopentenyladenine, 0.5 mg; and *trans*-zeatin, 0.5 mg per liter. DM-2 medium was DM-1 supplemented with 0.1 M mannitol. DM-3 medium differs only in the plant growth regulators: adenine hemisulfate, 10 mg; 2,4-dichlorophenoxyacetic acid, 0.2 mg per liter; thidiazuron 0.022 mg. DM-4 contained Anderson's (Anderson, 1984) rhododendron basal salt mixture (Sigma Fine Chemicals) 1.89 g, vitamins of DM-1, and supplemented with the plant growth regulators; 2,4,5-trichlorophenoxy acetic acid, 0.04 mg per liter; thidiazuron 0.022 mg. DM-5 contained MS salts 4.3 g and 0.022 mg thidiazuron. DM-6 was MS salts, 4.3 g; vitamins of DM-1; adenine hemisulfate, 10 mg; 1-naphthaleneacetic acid, 0.2 mg l^{-1}; thidiazuron 0.022 mg. DM-7 was the same as DM-6 except that it contained 0.2 mg l^{-1} picloram instead of 1-naphthaleneacetic acid. DM-8 was the same as DM-1 except that it contained also 3 mg thidiazuron, and as much as 60 mg adenine hemisulfate per liter. DM-9 contained CLC/Ipomoea (CP) Basal salt mixture (Chée et al., 1992; Sigma Fine Chemicals) 6.7 g, vitamins of DM-1, and supplemented with the plant growth regulators; 2,4,5-trichlorophenoxyacetic acid, 0.04 mg per liter; thidiazuron 0.022 mg. DM-10 contained C2d vitis basal salt mixture (Chée and Pool, 1987, Sigma Fine Chemicals) 4.47 g, vitamins of DM-1, 2,4,5-trichlorophenoxyacetic acid, 0.04 mg, and thidiazuron, 0.022 mg.

All *Baphia*, *Caesalpinia*, *Haematoxylon*, and *Pterocarpus* as well as most *Dalbergia* species developed callus on DM-1 medium; the exceptions are listed in Table 1. In *D. melanocardium,* primary callus formed at the base of shoot tips excised from in vitro germinated seedlings and inserted into DM-5 medium, and this callus was maintained on DM-6 medium.

3.3. Pigment survey and isolation

Pigments extracted in ethanol were separated by paper electrophoresis (in 50% acetic acid, 25 V/cm on Whatman 3MM paper spanned between the buffer chambers connected to platinum electrodes) and TLC on silica gel (250 μm on polyester backed flexible plates, PE SIL G, Whatman) in solvent systems I (ethylacetate–methanol–water 100:16:13) and II (chloroform–methanol–water 80:20:2) (Hamburger et al., 1988).

For purification on a preparative scale, *Dalbergia retusa* callus pieces showing red coloration were repeatedly extracted with ethanol at 66 °C to give rise to a deep orange red solution. Crude pigment was precipitated from a preconcentrated ethanol extract by addition of H_2O. Fractionation was performed by suspending the precipitate in H_2O (1 g per 200 ml H_2O) with stirring. The resulting brownish red solid was collected by centrifugation and fractionation was repeated thrice with fresh H_2O (200 ml). The water insoluble pellet was further fractionated by suspending in benzene (1 g per 200 ml) with stirring and incubation at 50°C. Benzene extraction was repeated thrice. The insoluble pigment was collected by centrifugation, and redissolved in ethanol to give a dark brownish red solution. Preparative scale separation of the ethanol extract by TLC on Whatman PK5 preparative silica gel plates (1 mm on glass, pore size: 25–150 Å) was carried out first in solvent system II. There were at least three high mobility UV fluorescent (pink) and several UV absorbent purple/red components of lower mobility. The main component, retusapurpurin A (third band from top, R_f 0.63, color in HCl fumes is orange yellow, HCl + UV: orange yellow, in NH_3 red purple, NH_3 + UV: mauve pink, intermediate colors under neutral conditions), was subjected to rechromatography first in solvent system I (R_f 0.71) to separate it from traces of contaminants, then twice in solvent system II. Yield was approximately 0.01% of dry weight.

Retusapurpurin A was identified in the ethanol extract of *D. parviflora* heartwood as the main fluorescent pink band. It was isolated from the heartwood and callus by the procedure applied to *D. retusa* callus (yield was about 0.03 and 0.01% of dry weight, respectively).

3.4. Retusapurpurin A (*1a*)

Deep red amorphous powder. UV/VIS (EtOH–0.1 M Na-citrate (pH 5.0) 2:1 (v/v)): λ_{max} nm: 533 *sh*, 510, 392, 320 *sh*, 279. + $NaHCO_3$: 567, 533 sh, 419, 401, 323, 300, 288 sh, 271. + $AlCl_3$ + HCl or + HCl alone: 490, 420 *sh*, 284. λ_{max} (DMSO): 610, 571 sh, 526 *sh*, 433, 388, 338, 280. IR ν_{max} (KBr) cm^{-1}: 1635. MS (ESI, positive ion mode): 523 $[M+H]^+$ and *m/z* 413 (7), 399 (8), 387 (48), 371 (7), and 233 (10). MS (APCI, high capture voltage): $[M+H]^+$ 523. NMR: Table 2.

Retusapurpurin A isolated from *D. retusa* callus appeared homogeneous and comigrated on TLC with samples isolated from *D. parviflora* callus and wood in systems I (pink/red, UV: pink; R_f 0.71), II (R_f 0.63), III (toluene-methanol-water 140:77:3, R_f 0.60), IV (chloroform-tetrahydrofuran-water 40:70:2, R_f 0.33), V (ethylacetate–tetrahydrofuran–water 40:23:2, R_f 0.57), and in HPLC: 4.92 min (normal phase silica, 5 μm × 10 cm, 100 Å (Microsorb-MV) in MeOH-$CHCl_3$ (1:19), isocratic separation on a Beckman Model 332 gradient liquid chromatograph using a Model 165 variable wavelength detector).

Acknowledgements

Received 29 June 2000; received in revised form 29 August 2000

Abstract

The first triflavanoids with both C–C and C–O–C interflavanyl bonds, epioritin-(4β→6)-epioritin-(4α→4)-epioritin-4β-ol, epioritin-(4β→3)-epioritin-(4β→6)-epioritin-4β-ol and epioritin-(4β→3)-epioritin-(4β→6)-epimesquitol-4α-ol, were identified in the heartwood of *Acacia caffra*. The ethereal interflavanyl bond is readily susceptible to reductive cleavage with sodium cyanoborohydride in trifluoroacetic acid/dichloromethane which hence permits the unequivocal assignment of the absolute configuration of constituent flavanyl units. © 2001 Elsevier Science Ltd. Keywords: *Acacia caffra*; Leguminosae; Triflavanoids; Pro-/leucoanthocyanidins; Pro-/leucoteracacinidins; Pro-/leucomelacacinidins; Absolute configuration; Reductive cleavage

1. Introduction

The proanthocyanidin pool in heartwoods usually involves the presence of carbon–carbon bonds linking predominantly flavan-3-ol constituent moieties (Porter, 1994; Ferreira and Bekker, 1996; Ferreira and Li, 2000). Such an ensemble of flavan-3-ol units originates *via* electrophilic aromatic substitution of flavan-4-yl carbocations (or their equivalents) derived from flavan-3,4-diols and the nucleophilic centers of the *m*-oxygenated A-rings of flavan-3-ols (Hemingway, 1989; Ferreira et al., 1999). In the absence of these potent flavan-3-ol nucleophiles with their aptitude for the formation of carbon-carbon bonds, alternative centers emerge as participants in interflavanyl bond formation. This is especially prevalent in natural sources containing precursors with a 7,8-dihydroxy functionality of their A-rings where carbon-carbon coupled proanthocyanidins are often accompanied by ether-linked leucoanthocyanidins (Foo, 1989; Coetzee et al., 1998a, b; Bennie et al., 2000). We now report the structures of a new dimeric leucoteracacinidin, epioritin-(4β→4)-epioritin-4β-ol **1**, and the first triflavanoids with both a C–C and a C–O–C interflavanyl bond, epioritin-(4β→6)-epioritin-(4α→4)-epioritin-4β-ol **15**, epioritin-(4β→3)-epioritin-(4β→6)-epioritin-4β-ol **17**, and epioritin-(4β→3)-epioritin-(4β→6)-epimesquitol-4α-ol **19**, from *Acacia caffra*. Reductive cleavage of the ether bonds permits the unequivocal definition of the absolute configuration of constituent flavanyl units.

2. Results and discussion

Besides the known leucoteracacinidins *ent*-oritin-(4α→4)-epioritin-4α-ol, epioritin-(4β→4)-epioritin-4α-ol **3**, epioritin-(4β→3)-epioritin-4β-ol **9**, epioritin-(4β→3)-epioritin-4α-ol **11**, epioritin-(4β→3)-oritin-4α-ol **13**, and the 'mixed' leucomelacacinidin/leucoteracacinidin epimesquitol-(4β→4)-epioritin-4β-ol **5** (Bennie et al., 2000), the MeOH extract of the heartwood of *A. caffra* also affords epioritin-(4β→4)-epioritin-4β-ol **1**. The above dimers are accompanied by the first trimeric analogues, epioritin-(4β→6)-epioritin-(4α→4)-epioritin-4β-ol **15**, epioritin-(4β→3)-epioritin-(4β→6)-epioritin-4β-ol **17**, and epioritin - (4β→3) - epioritin - (4β→6) - epimesquitol - 4α - ol **19**. Owing to the complexity of the

phenolic mixture, these compounds were purified and identified as their permethylaryl ether acetate derivatives **2**, **16**, **18** and **20**.

In addition to the one *O*-acetyl and three *O*-methyl resonances the ^1H NMR spectral data (Table 1) of the epioritin-(4β→4)-epioritin-4β-ol derivative **2** only display an AB- and an AA′BB′-spin system in the aromatic region as well as only one AMX-system for protons of the heterocyclic ring. However, the chemical shifts of the latter protons are typical of similar derivatives of the (4-*O*-4)-bis-leucoanthocyanidins (Coetzee et al., 1998b; Bennie et al., 2000). The dimeric nature of compound 2 is accordingly confirmed by HREIMS analysis which indicates a molecular ion at $[M^+]$ 730.2703 ($C_{40}H_{42}O_{13}$).

Compound **2** is hence a symmetrical (4-*O*-4)-bis-leucoteracacinidin since only this mode of linkage could introduce a plane of symmetry into the molecule. The coupling constants ($^3J_{2,3}=1.5$; $^3J_{3,4}=3.0$ Hz) are reminiscent of 2,3-*cis*-3,4-*trans* relative stereochemistry (Malan and Sireeparsad, 1995; Coetzee et al., 1998a,b; Bennie et al., 2000). Although the CD spectrum of derivative 2 exhibits a high-amplitude negative Cotton effect at 246.7 nm ($[\theta]=-6.386\times10^4$), this cannot be related to chirality at C-4 due to the absence of a second phenyl chromophore in close proximity of this stereocenter (De Angelis and Wildman, 1969; Barrett et al., 1979; Botha et al., 1981; Van der Westhuizen et al., 1981). Reductive cleavage of the (4-*O*-4)-ether linkage with sodium cyanoborohydride [$Na(CN)BH_3$] in trifluoroacetic acid (TFA)/dichloromethane affords 3-*O*-acetyl-7,8,4-tri-*O*-methylepioritin **24** as the sole product (*vide infra*). Comparison of ^{1}H NMR and CD spectral data of **24** with those of an authentic sample supports the assignment of 2*R*,3*R* absolute configuration to both the C- and F-rings (Korver and Wilkins, 1971; Van Rensburg et al., 1999; Coetzee et al., 2000). The 4*S* configuration of both C- and F-rings of **2** is assigned using the $^3J_{3,4}$-value which indicates a 3,4-*trans* relative stereochemistry for each heterocyclic ring.

FAB-MS analyses of the permethylaryl ether acetate derivatives **16**, **18** and **20** of compounds **15**, **17** and **19** indicate molecular formulas of $C_{60}H_{62}O_{19}$ (*m*/*z* 1086) for **16** and **18**, and $C_{61}H_{64}O_{20}$ (*m*/*z* 1116) for **20**. When taken in conjunction with the number of *O*-methyl and *O*-acetyl resonances in their ^{1}H NMR spectra (Table 2) these formulas confirm the trimeric nature of all three analogues. The ^{1}H NMR spectra, conspicuously free of the effects of dynamic rotational isomerism about the interflavanyl bonds, indicate three *O*-acetyl resonances, one aromatic proton singlet, two aromatic AB- and three AA′BB′-spin systems as well as three AMX-spin systems for protons in the heterocyclic region for derivatives **16** and **18**. The data suggest trimeric structures comprising derivatized 7,8,4′-trihydroxyflavan-3-ol constituent units linked via one ether and one carbon–carbon interflavanyl bond. In the ^{1}H NMR spectrum of derivative **20**, one of the aromatic AA′BB′-spin systems is replaced by an ABX-system hence indicating a trimer comprising one derivatized 7,8,3′,4′-tetrahydroxy- and two derivatized 7,8,4′-trihydroxyflavan-3-ol constituent units.

The three heterocyclic AMX-spin systems of derivative **18** exhibit coupling constants reminiscent of 2,3-*cis*-3,4-*trans* ($^3J_{2,3}=1.5$; $^3J_{3,4}=3.0$ Hz for the I-ring, and $^3J_{2,3}=1.0$; $^3J_{3,4}=2.0$ Hz for the C- and F-rings) relative configuration (Steynberg et al., 1991; Malan and Sireeparsad, 1995). Two of the AMX-spin systems of derivatives **16** and **20** similarly indicate 2,3-*cis*-3,4-*trans* relative configuration ($^3J_{2,3}=1.5$, 1.0, and $^3J_{3,4}=3.0$, 2.0 for both **16** and **20**). The third AMX-system is reminiscent of 2,3-*cis*-3,4-*cis* ($^3J_{2,3}=1.0$; $^3J_{3,4}=4.5$ Hz for both **16** and **20**) relative stereochemistry (Coetzee et al., 1998b). Such all-*cis* configurations are confirmed by NOE associations between 2- and 4-H which indicate that these protons are coplanar hence occupying the same face of the heterocyclic ring. For the rings with 2,3-*cis*-3,4-*trans* relative configurations, these n.O.e. associations are conspicuously absent.

Longe range coupling ($^4J_{HH}$) observed from a COSY experiment, together with n.O.e. associations between the respective 2′,6′-protons (B-, E-, H-rings) and the

heterocyclic 2-H resonances, differentiate between the three AA′BB′-systems in derivatives **16** and **18** hence establishing the C/B-, F/E- and I/H-ring junctions. Differentiation of the two AA′BB′-systems in derivative **20** is also possible *via* $^4J_{HH}$ coupling between the respective 2- and 2′,6′-protons of each constituent unit. The ABX-system of its H-ring is assigned in terms of the $^4J_{HH}$ coupling between 2′- and 6′-H (H-ring) and the corresponding 2-H (I-ring). Pronounced benzylic coupling between the respective 4- and 5-protons facilitates definition of the A- and C-, the D- and F-, as well as the G- and I-ring junctions.

The locations and mode of the interflavanyl linkage are accessible via NOE studies. Thus, the association between 5-H(D) and both 4-H(C) and 4-H(F) confirms the C-4(C)→C-6(D) interflavanyl bond in derivative **16**. N.O.e. correlations of 3-H(F) with both 3-H(I) and 4-H(I), and of 4-H(F) with both 3-H(I) and 4-H(I) confirm the C_4–*O*–C_4 linkage between the DEF- and GHI-epioritin moieties. Such a mode of linkage is supported by the chemical shifts of the heterocyclic protons of these units (Coetzee et al., 1998b; Bennie et al., 2000). One of the AMX-spin systems in the ^{1}H NMR spectra of derivatives **18** and **20** comprises a conspicuously deshielded 4-H resonance (δ5.66 and 6.17, respectively) that is indicative of a 4-*O*-acetyl substituent and hence a flavan-3,4-diol 'terminal' GHI-unit. Benzylic coupling and the observed n.O.e. associations of 5-H(G) with both 4-H(F) and 4-H(I) are reminiscent of the C-4(F)→C-4(G) interflavanyl linkages in derivatives **18** and **20**. The chemical shifts of the heterocyclic protons of the C- and F-rings are indicative of a C_4–*O*–C_3 bond between the ABC- and DEF-epioritin units (Coetzee et al., 1998a; Bennie et al., 2000). This is unequivocally confirmed via NOE associations of 3-H(F) with both 3- and 4-H(C) and of 4-H(F) with 5-H(A) for derivative **18**, and by associations of 4-H(F) with both 4-H(C) and 5-H(A) and of 3-H(C) with 3-H(F) for derivative **20**.

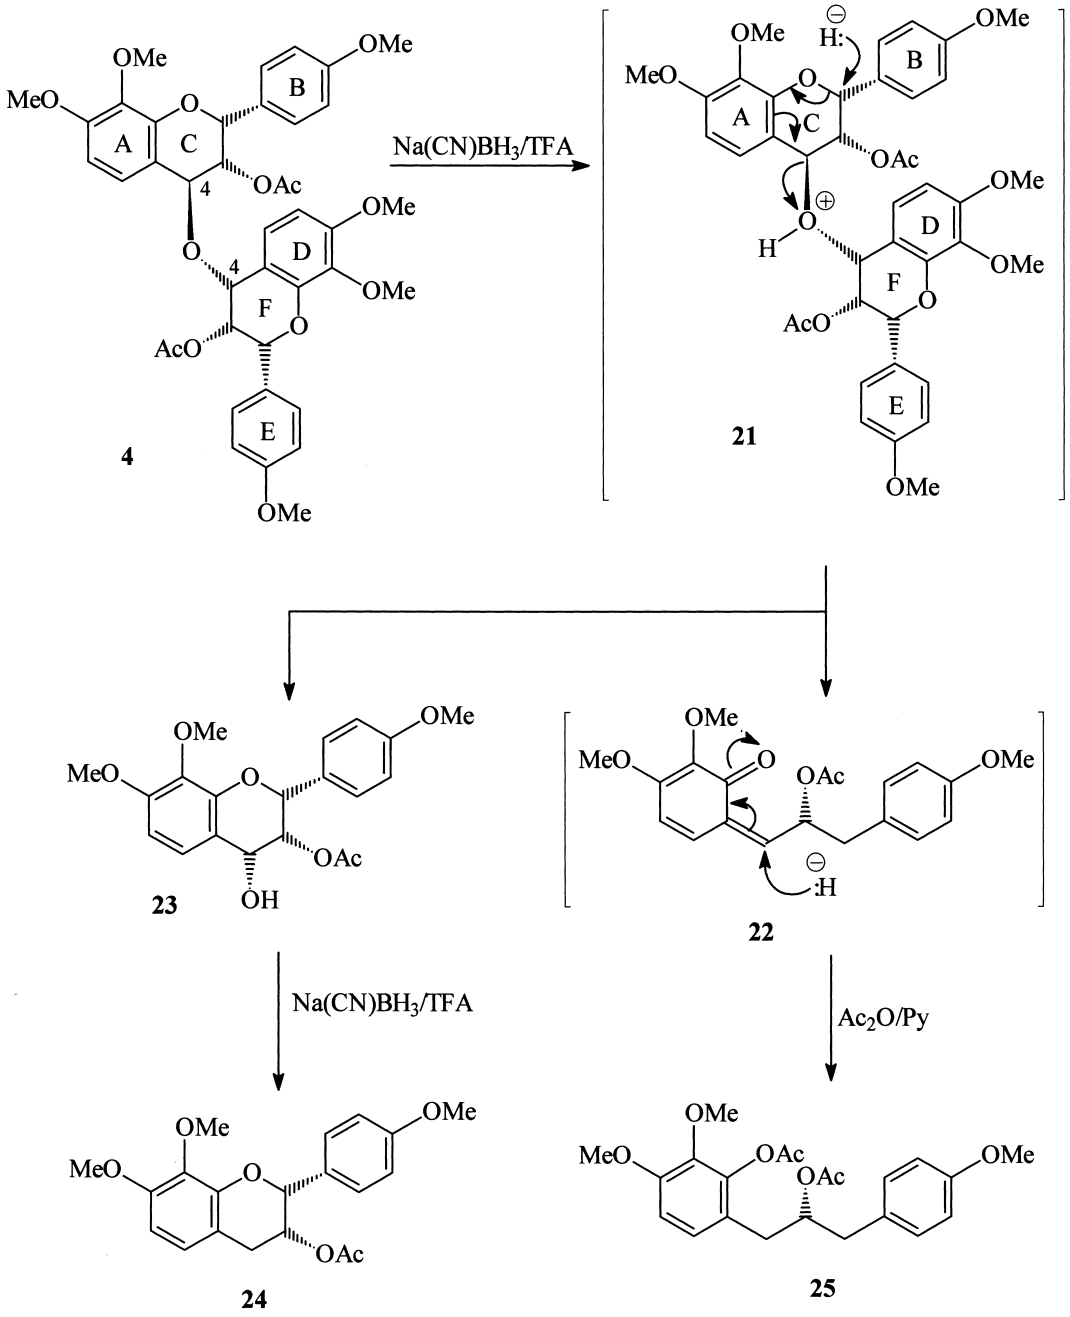
The 2*R*, 3*R*, 4*R*(C): 2*R*, 3*R*, 4*R*(F): 2*R*, 3*R*, 4*S*(I), 2*R*, 3*R*, 4*S*(C): 2*R*, 3*R*, 4*R*(F): 2*R*, 3*R*, 4*S*(I), and 2*R*, 3*R*, 4*S*(C): 2*R*, 3*R*, 4*R*(F): 2*R*, 3*R*, 4*R*(I) absolute configurations of **15**, **17** and **19**, respectively, are confirmed by reductive cleavage of the C–O–C interflavanyl bonds (vide infra) and subsequent comparison of CD and ^{1}H NMR spectral data of the resulting monomeric and dimeric units with those of authentic samples.

The absence of a second aromatic chromophore in close proximity of the C-4 stereocenter in ether linked leucoanthocyanidins at both the di- and trimeric levels, precludes assessment of its absolute configuration by chiroptical methods. The facile reductive cleavage of the C–O bond of the acetal functionality in A-type proanthocyanidins (Steynberg et al., 1997; Lou et al., 1999) thus prompts application of the same protocol to the ethereal bonds of leucoanthocyanidins in order to gain insight into the mode of the interflavanyl linkages and to assess the absolute configuration of the constituent flavanyl units.

Treatment of the epioritin-(4β→4)-epioritin-4α-ol hexamethylether diacetate **4** with $Na(CN)BH_3$ (7 molar excess) in TFA for 45 min at 0°C under N_2 (Scheme 1) affords epioritin-tri-*O*-methylether acetate **24** (35% yield) and the (2*R*)-1,3-diarylpropan-2-ol derivative **25** (32%). Thus, delivery of the equivalent of hydride ion at C-2(C) of the protonated intermediate **21** (Steynberg et al., 1995) effects the concurrent rupture of the O-C_2 bond of the pyran C-ring and the C–O–C interflavanyl bond to give the flavan-3,4-diol derivative **23** and the *o*-quinomethane **22**. The benzylic C_4–OH of the former is then further reduced to the epioritin derivative **24** and the latter to the (2*R*)-1,3-diarylpropan-2-ol derivative **25**. The retention of the absolute configuration at C-2 during the sequence leading to the formation of **25** has previously been demonstrated (Steynberg et al., 1995) and is confirmed by comparison of the CD data (see Experimental) of compound **25** with those of related analogs (Augustyn et al., 1990). Assignment of the 2*R*, 3*R* absolute configuration of **24** and hence its identification as an epioritin derivative is evident from comparison of its ^{1}H NMR and CD spectral data with those of an authentic sample (Van Rensburg et al., 1999; Coetzee et al., 2000). Preference for initial cleavage of the C_4 β–OH bond in the protonated intermediate **21** stems from the leaving group aptitude of such near-*axial* bonds and the remarkable stability of the equatorial C_4–OH bond of the F-ring towards similar fission (Clark-Lewis and Williams, 1967; Coetzee et al., 1999).

In an attempt to prevent cleavage of the heterocyclic ring of one of the constituent units and hence the formation of 1,3-diarylpropan-2-ols of type **25**, milder reaction conditions comprising CH_2Cl_2 containing 10 molar equivalents of TFA were employed. Treatment of the hexa-*O*-methylether diacetate **4** with $Na(CN)BH_3$ (7 molar excess) and TFA (10 molar excess) in CH_2Cl_2 for 45 min at 0°C under N_2 affords a mixture comprising the starting material 4 (7%) and epioritin-tri-*O*-methylether acetate **24** (65%) (Scheme 2). Under these conditions the protonated C_4 β-OH bond of the C-ring is presumably preferentially cleaved due to the anchimeric effect of the *axial* C_3-OH bond (Coetzee et al., 1998a,b). The flavan-3,4-diol derivative **23** that accompanies the epioritin derivative **24** is eventually reduced to afford the C_4-deoxy analogue **24**. Under similar conditions the hexamethylether diacetate derivative **2** also yields epioritin-tri-*O*-methylether acetate **24** (43%). The C_4–*O*–C_4 interflavanyl bond in the dimeric derivatives **6** and **8** (Bennie et al., 2000) with their epimesquitol and epioritin constituent units is similarly susceptible to reductive cleavage affording in each instance epioritin-tri-*O*-methylether acetate **24** (49 and 33%, resp.) and epimesquitol-tetra-*O*-methylether acetate **26** (28 and 62%, resp.).

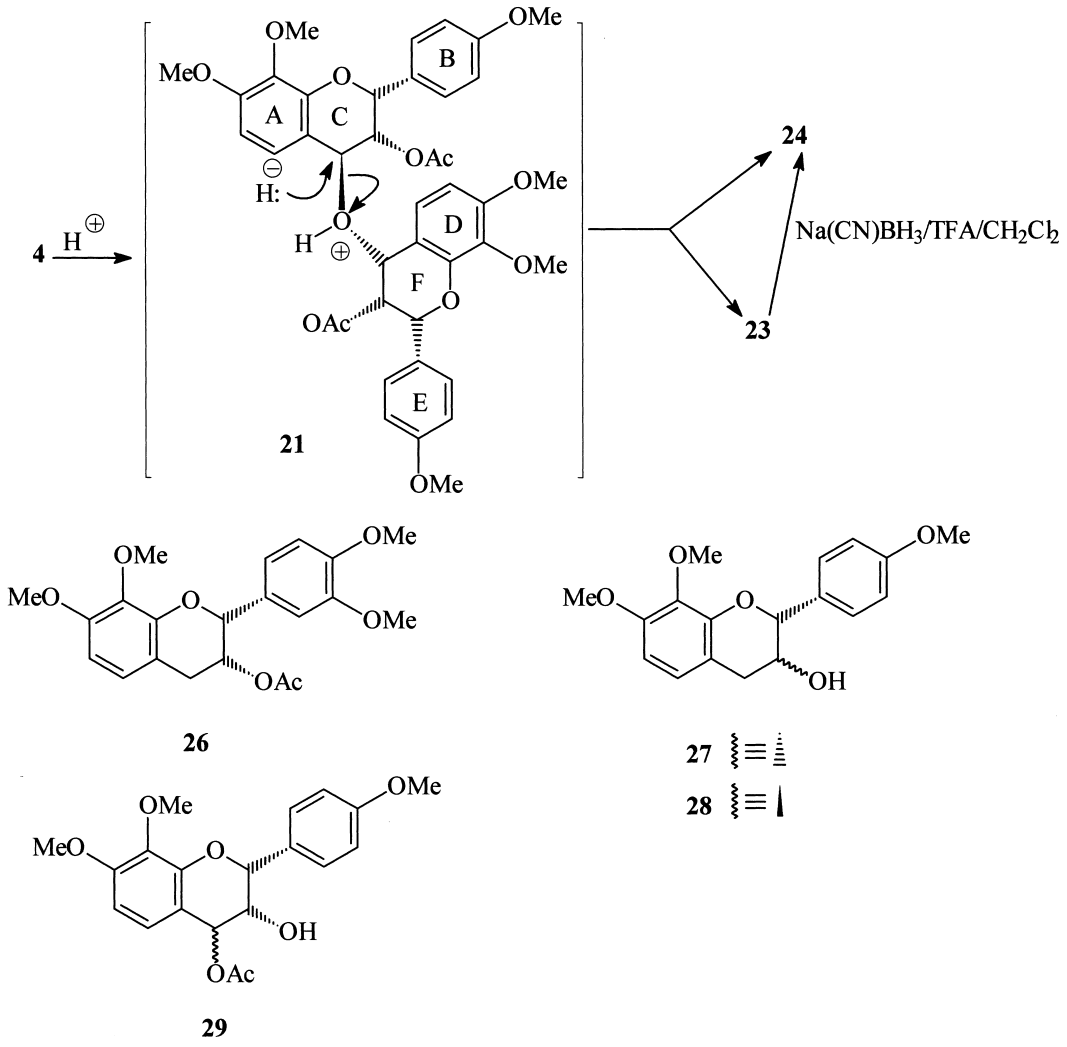
Under similar conditions the C_4–*O*–C_3 interflavanyl bond in the dimeric leucoteracacinidin derivatives **10**, **12** and **14** is prone to facile cleavage to give the constituent



Scheme 1. Reductive cleavage of the C–O–C bond in dimeric leucoteracacinidin **4** using $Na(CN)BH_3$ in TFA.

flavan-3-ol units. Derivatives **10** and **12** are reduced to epioritin-tri-*O*-methylether acetate **24** (37 and 63%, resp.), representing the ABC constituent unit, and epioritin-tri-*O*-methylether **27** (49 and 21%, resp.), representing the DEF unit. Derivative **14** affords epioritin-tri-*O*-methylether acetate **24** (36%) and tri-*O*-methyloritin **28** (58%). The mechanism of the reactions leading to the formation of these products again involves reduction of the more labile protonated C_4 β–OH bond. Reduction of the C_4–OAc bond in the ensuing flavan-3,4-diol derivative of type **29** then leads to the formation of flavan-3-ol derivatives of types **27** and **28**, characterized by a 'labeled' C_3-hydroxyl group, *i.e.* an OH group at the point of the interflavanyl bond to one of the constituent units.

The CD spectra of derivatives **24**, **26** and **27** all exhibit the high-amplitude negative Cotton effects for both the ^1L_a ($[\theta]_{238,6} = -2.916\times10^3$ for **24**; $[\theta]_{240.5} = -2.063\times10^3$ for **26**; $[\theta]_{240.4} = -5.495\times10^3$ for **27**) and ^1L_b ($[\theta]_{274.2} = -3.270\times10^3$ for **24**; $[\theta]_{280.4} = -1.868\times10^3$ for **26**; $[\theta]_{277.4} = -2.105\times10^3$ for **27**) transitions that are reminiscent of (2*R*,3*R*)-flavan-3-ols (Van Rensburg et al., 1999). Derivative **28** similarly displays the Cotton effects for the ^1L_a and ^1L_b transitions ($[\theta]_{244.0} = +1.717\times10^4$; $[\theta]_{280.0} = -$



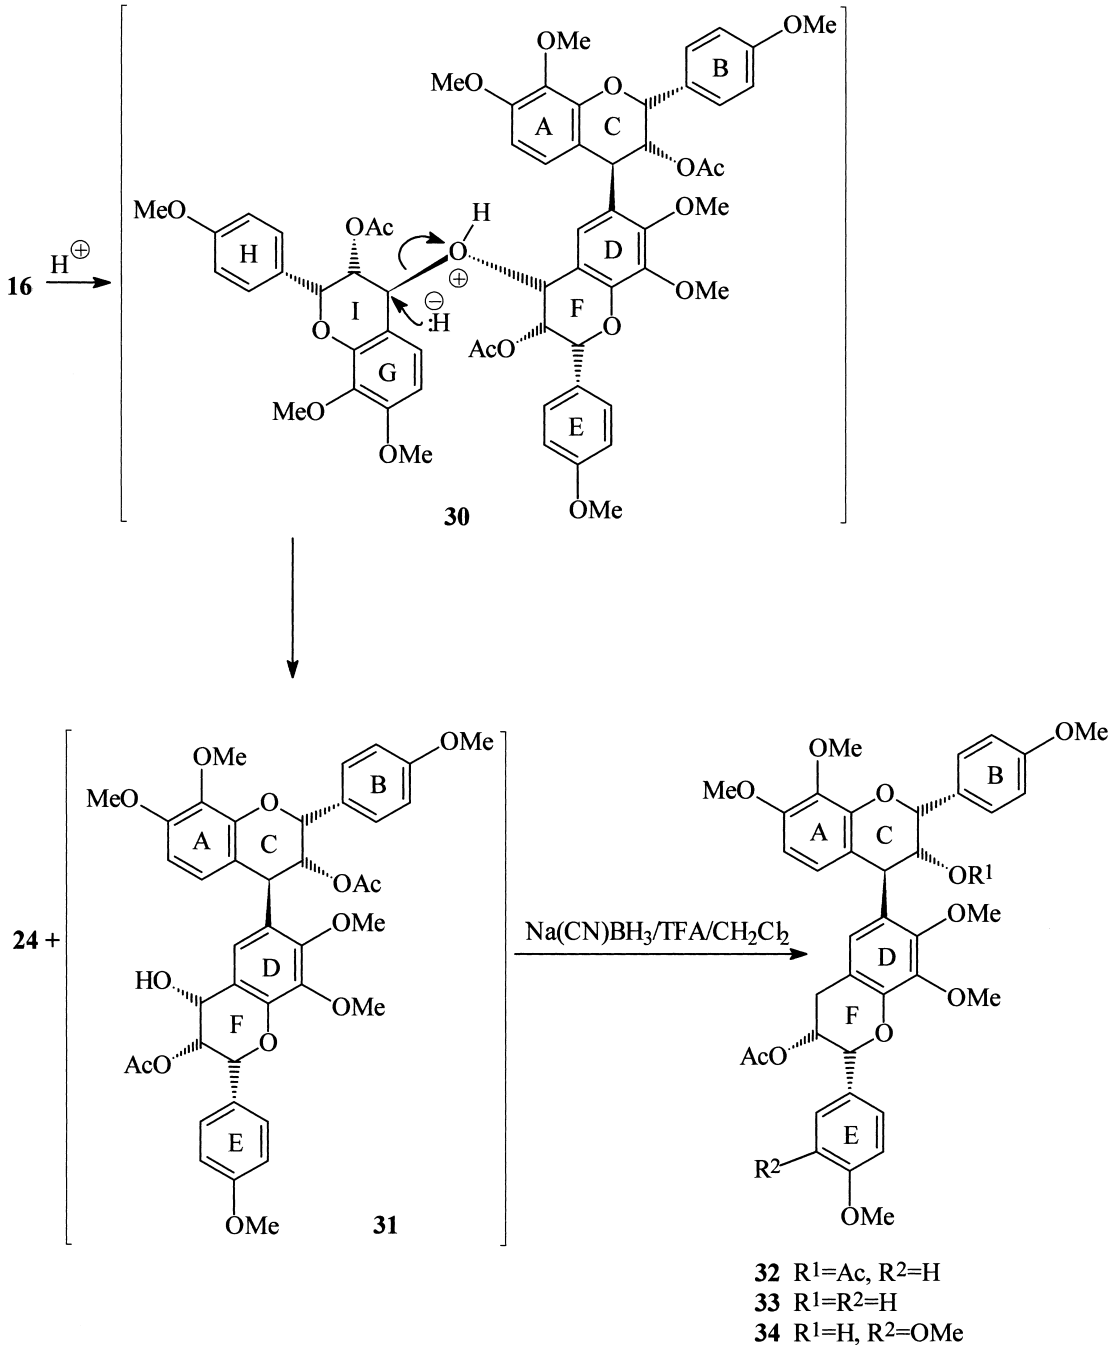
Scheme 2. Reductive cleavage of the C–O–C bond in leucoteracacinidin **4** using $Na(CN)BH_3$/TFA in CH_2Cl_2.

2.762×10^4) that characterize (2*R*,3*S*)-flavan-3-ols (Korver and Wilkins, 1971; Van Rensburg et al., 1999). Collectively the data then provide conclusive evidence for the absolute configurations of the C_4–*O*–C_4 and C_4–*O*–C_3 leucoanthocyanidins as indicated in formulations **1**, **3**, **5**, **7**, **9**, **11** and **13**.

The high-amplitude negative Cotton effects at ca 280 nm in the CD spectra of the trimeric derivatives **16**, **18** and **20** probably indicate the cumulative effects of the ^1L_b transitions of all the constituent flavanyl units exhibiting 2*R* absolute configuration (Korver and Wilkins, 1971; Van Rensburg et al., 1999). Positive Cotton effects in the 220–250 nm region are then reflecting ^1L_a transitions as well as contributions resulting from the biphenylmethylidine chromophore hence indicating a C-4β orientation of the flavanyl unit in the C-C coupled biflavanyl moieties (De Angelis and Wildman, 1969; Van der Westhuizen et al., 1981). In order to validate such chiroptical conclusions, these derivatives were also subjected to reduction of their C–O–C interflavanyl bonds.

Treatment of derivative **16** with $Na(CN)BH_3$ (7 molar excess) and TFA (10 molar excess) in CH_2Cl_2 for 2 h at 0°C under N_2 (Scheme 3), affords a mixture comprising starting material (26%), the epioritin-(4β→6)-epioritin hexa-*O*-methylether diacetate **32** (33%) and epioritin-tri-*O*-methylether acetate **24** (40%). Separate treatment of derivatives **18** and **20** under similar conditions gives the corresponding bis-epioritin and epioritin-(4β→6)-epimesquitol derivatives **33** (41%) and **34** (36%), respectively, as well as epioritin-tri-*O*-methylether acetate **24** (30 and 60%, resp.). These degradation products again form via preferential cleavage of the protonated C–4β ether bond of intermediate **30**, and subsequent reduction of the benzylic hydroxyl group of the flavan-3,4-diol unit in the dimeric intermediate **31**. Cleavage products **33** and **34** again carry a 'free' hydroxyl group at C-3 of the upper epioritin moiety, hence 'labeling' the location of the C–O–C ether linkage in the parent triflavanoid derivatives **18** and **20**.

The structures and relative configuration of the dimeric derivatives **32**, **33** and **34** are readily evident



Scheme 3. Reductive cleavage of the C–O–C bond in trimeric derivative **16** using $Na(CN)BH_3$/TFA in CH_2Cl_2.

from the ^1H NMR spectral data that are collated in Table 1. The CD data of all three derivatives are virtually identical to those of the corresponding 4–OAc (F-ring) analogues that were previously synthesized (Malan and Sireeparsad, 1995). Thus, the high-amplitude negative Cotton effect at ca 280 nm is indicative of the ^1L_b transition of flavan-3-ol constituent units with 2*R* absolute configuration. The high-amplitude positive Cotton effect at ca 240 nm reflects the 4β-flavanyl substituent by application of the aromatic quadrant rule (De Angelis and Wildman, 1969). When taken in conjunction with CD data of the epioritin derivative **24** (vide supra), the absolute configuration of the natural products is thus unambiguously established as indicated in structures **15**, **17** and **19**.

We have thus developed a simple but concise protocol to unequivocally establish the structures and absolute configuration of the constituent flavanyl units in di- and trimeric ether-linked leucoanthocyanidins. Such rigorous structure elucidation is a prerequisite towards the understanding of the intricate physicochemical interaction of this class of compounds with other biomolecules.

The co-occurrence of the considerable number of ether-linked leucoteracacinidins and leucomelacacinidins in the heartwood of *A. caffra* in addition to some carbon–carbon bonded analogues, is yet a further manifestation of the much reduced nucleophilicity of the pyrogallol A-ring (Botha et al., 1981; Foo, 1989) which permits other centers to participate in the formation of interflavanyl bonds.

3. Experimental

^{1}H NMR spectra were recorded on a Bruker AVANCE DPX 300 spectrometer for solns. as indicated, with Me_4Si as internal standard. FAB mass spectra were recorded on a VG-70E instrument with a VG 11-250J data system and an iontech saddlefield FAB gun. TLC was performed on precoated Merck plastic sheets (silica gel 60 PF_{254}, 0.25 mm) and the plates were sprayed with H_2SO_4-HCHO (40:1, v/v) after development. Preparative plates (PLC) [20×22 cm, Kieselgel PF_{254} (1.0 mm)] were air dried and used without prior activation. Column chromatography was carried out on Sephadex LH-20 in various columns, solvent systems and flow rates (to be specified in each instance). Methylations were performed with an excess of CH_2N_2 in MeOH–Et_2O over a period of 48 h at −15°C while acetylations were conducted in Ac_2O–pyridine at ambient temperature. Evaporations were carried out under reduced pressure at ambient temp. in a rotary evaporator, and freeze drying of aqueous solutions on a Virtis 12 SL freezemobile.

3.1. General procedure for the sodium cyanoborohydride reductions with CH_2Cl_2 as solvent (mild conditions)

The appropriate dimer or trimer and $Na(CN)BH_3$ (7 eq.) were dissolved in CH_2Cl_2 (2 ml) under an N_2-atmosphere at 0°C. After 15 min trifluoroacetic acid (TFA, 10 eq.) was added and the mixture was stirred for a further 45 min at 0°C. The reaction was quenched by the careful addition of H_2O and the pH adjusted to ca 6.5 (saturated $NaHCO_3$-soln.). After extraction with EtOAc (10 ml×3) the combined organic layers were dried (Na_2SO_4) and evaporated under reduced pressure.

3.2. Synthesis of epioritin-(4β→4)-epimesquitol-4α-ol hepta-O-methylether diacetate **8**

Epioritin-4β-thiobenzylether (100 mg, 2.52×10^{-4} mole) and epimesquitol-4α-ol (155 mg, 5.04×10^{-4} mol, 2 eq.) were dissolved in dry THF (15 ml) and the mixture was stirred under an N_2-atmosphere for 15 min at 0°C before solid $AgBF_4$ (2.5 eq.) was added and the mixture stirred for a further 90 min. After the addition of H_2O (150 ml) and extraction with EtOAc (50 ml×6) the combined organic layers were dried (Na_2SO_4) and evaporated to dryness. Methylation of the residue and subsequent PLC separation in benzene–Me_2CO–EtOAc (7:2:1; v/v) gave three bands at R_f 0.60 (11.1 mg), 0.42 (15.5 mg) and 0.32 (91.7 mg).

3.3. Epioritin-(4β→4)-epimesquitol-4α-ol hepta-O-methylether diacetate **8**.

Acetylation of the R_f 0.42 band followed by PLC purification in benzene–Me_2CO (9:1; v/v) afforded compound **8** (R_f 0.33, 4.2 mg,) as a white amorphous solid. (Found: M^+, 760.2731. $C_{41}H_{44}O_{14}$ requires M, 760.2731); δ_H (Table 1); CD $[\theta]_{206.4}$ 20300, $[\theta]_{213.1}$ 6262, $[\theta]_{221.9}$ 13560, $[\theta]_{226.2}$ 184, $[\theta]_{228.6}$ −4458, $[\theta]_{232.7}$ −311, $[\theta]_{241.0}$ −14 70, $[\theta]_{256.9}$ −1104, $[\theta]_{274.2}$ −3976 and $[\theta]_{291.5}$ −204. The remaining bands afforded compounds that will be dealt with elsewhere.

3.4. Isolation of phenolic compounds

The extraction of the heartwood of *A. caffra* and column separation to give fractions A-UU were comprehensively described in Part 32 (Bennie et al., 2000) and need not be repeated.

3.5. Epioritin-(4β→4)-epioritin-4β-ol hexa-O-methylether diacetate **2**

Methylation of a portion (200 mg) of fraction W followed by PLC in benzene–Me_2CO–EtOAc (7:2:1; v/v) gave five bands at R_f 0.65 (12.6 mg), 0.57 (11.9 mg), 0.47 (12.8 mg), 0.39 (26.2 mg) and 0.19 (6.4 mg). Acetylation of the R_f 0.39 band followed by PLC in benzene–Me_2CO (9:1; v/v) afforded two main bands at R_f 0.53 (2.1 mg) and 0.41 (2.7 mg). The former band yielded compound **2** as a white amorphous solid. (Found: M^+, 730.2703. $C_{40}H_{42}O_{13}$ requires M, 730.2704); δ_H(Table 1); CD $[\theta]_{237.8}$ 6891, $[\theta]_{240.0}$ 197 $[\theta]_{246.7}$ −63860, $[\theta]_{267.4}$ −2628 and $[\theta]_{282.2}$ 3967. The remaining bands contain related leucoanthocyanidin-type compounds which were reported previously (Bennie et al., 2000).

3.6. Epioritin-(4β→6)-epioritin-(4α→4)-epioritin-4β-ol nona-O-methylether triacetate **16**

A portion (200 mg) of fraction HH was methylated and the mixture separated by PLC in benzene–Me_2CO–EtOAc (7:2:1; ×2; v/v) to give five bands at R_f 0.68 (14.4 mg), 0.63 (21.2 mg), 0.51 (19.7 mg), 0.47 (20.7 mg) and 0.39 (19.2 mg). Acetylation of the R_f 0.68 band followed by PLC in benzene–Me_2CO (9:1; v/v) afforded one main band at R_f 0.49 (3.3 mg). Further purification by PLC in hexane–Me_2CO–EtOAc (13:4:3; ×2; v/v) yielded compound **16** (R_f 0.17, 2.3 mg) as a white amorphous solid. (Found: M^+, 1086.3886. $C_{60}H_{62}O_{19}$ requires M, 1086.3885); δ_H(Table 2); CD $[\theta]_{221.7}$ 74, $[\theta]_{228.1}$ −6210,

$[\theta]_{232.2}$ 121, $[\theta]_{236.9}$ 3485, $[\theta]_{242.1}$ 6630, $[\theta]_{247.5}$ 67, $[\theta]_{252.8}$ −1732, $[\theta]_{283.3}$ −4788 and $[\theta]_{295.4}$ 5. The remaining bands yielded proanthocyanidin trimers that will be dealt with elsewhere.

3.7. Epioritin-(4β→3)-epioritin-(4β→6)-epioritin-4β-ol nona-O-methylether triacetate **18**

Methylation of a portion (179 mg) of fraction DD followed by PLC in benzene–Me_2CO–EtOAc (7:2:1; v/v) gave two bands at R_f 0.54 (19.3 mg) and 0.46 (32.4 mg). Acetylation of the R_f 0.54 band and PLC purification in benzene–Me_2CO (9:1; ×2; v/v) afforded two main bands at R_f 0.74 (2.9 mg) and 0.65 (4.5 mg). The latter band yielded compound **18** as a white amorphous solid. (Found: M^+, 1086.3884. $C_{60}H_{62}O_{19}$ requires M, 1086.3885); δ_H (Table 2); CD $[\theta]_{215.5}$ 47, $[\theta]_{221.3}$ 6666, $[\theta]_{233.1}$ 70, $[\theta]_{235.9}$ −1549, $[\theta]_{241.0}$ 470, $[\theta]_{246.8}$ −1459, $[\theta]_{255.4}$ −357, $[\theta]_{279.2}$ −4497 and $[\theta]_{297.2}$ 2. TLC showed that the remaining bands contained higher oligomeric material and were therefore not further investigated.

3.8. Epioritin-(4β→3)-epioritin-(4β→6)-epimesquitol-4α-ol deca-O-methyl-ether triacetate **20**

A portion (200 mg) of fraction LL was methylated and the mixture separated by PLC in benzene–Me_2CO–EtOAc (7:2:1; ×2; v/v) to give a main band at R_f 0.42 (29.8 mg). Acetylation and PLC purification in benzene–Me_2CO (9:1; ×2; v/v) yielded compound **20** (R_f 0.53, 3.1 mg) as a white amorphous solid. (Found: M^+, 1116.3990. $C_{61}H_{64}O_{20}$ requires M, 1116.3991); δ_H(Table 2); CD $[\theta]_{215.4}$ 49, $[\theta]_{226.0}$ 5688, $[\theta]_{233.6}$ 2368, $[\theta]_{244.7}$ 3416, $[\theta]_{258.3}$ 2, $[\theta]_{284.3}$ −7250 and $[\theta]_{297.2}$ 3.

3.9. Reductive cleavage of epioritin-(4β → 4)-epioritin-4α-ol hexamethylether diacetate **4** with TFA as solvent

The epioritin-(4β→4)-epioritin-4α-ol hexa-*O*-methylether diacetate derivative **4** (Bennie et al., 2000) (10 mg) was dissolved in TFA (2 ml) under an N_2-atmosphere at 0°C. After 15 min $Na(CN)BH_3$ (6 mg, 9.58×10^{-5} mol, 7 eq) was added in one portion and the mixture was stirred for another 45 min at 0°C. The reaction was quenched by the addition of H_2O and the pH adjusted to ca. 6.9 (saturated $NaHCO_3$–soln.) before extraction with EtOAc (15 ml×3). The combined organic layers were stirred for 15 min after the addition of 3 drops of a tetrabutylammonium fluoride (TBAF) soln. in THF. The solvent was dried (Na_2SO_4) and evaporated under reduced pressure.

3.10. Epioritin-tri-O-methylether acetate **24**

Acetylation of the residue and subsequent PLC separation in benzene–Me_2CO (95:5; ×2, v/v) afforded two main bands at R_f 0.58 (4.9 mg) and 0.49 (3.3 mg). The R_f 0.58 band yielded compound **24** (35.3%) as a white amorphous solid. δ_H (Table 3); CD and MS data identical to those in the literature (Coetzee et al., 2000).

3.11. 2R-Acetoxy-1-(2-acetoxy-3,4-dimethoxyphenyl)-3-(4-methoxyphenyl)-propane **25**

The R_f 0.49 band yielded compound **25** (31.7%) as a white amorphous solid. δ_H ($CDCl_3$) 7.12 (2H, *d*, 9.0, H-2,6), 6.91 (1H, *d*, 9.0, H-5), 6.83 (2H, *d*, 9.0, H-3,5), 6.76 (1H, *d*, 9.0, H-6), 5.14 (1H, *m*, H-2), 3.87 (OMe), 3.82 (OMe), 3.80 (OMe), 2.85–2.62 (4H, *m*, –CH_2–, H-2,3),

Table 3
^{1}H NMR (300 MHz, 296 K) spectral data of flavan-3-ol derivatives **24**, **26**, **27** and **28** in $CDCl_3$. Splitting patterns and *J*-values are given in parentheses

3.12. Epimesquitol-tetra-O-methylether acetate 26

Reduction of epimesquitol-(4β→4)-epioritin-4β-ol hepta-*O*-methylether diacetate **6** (Bennie et al., 2000) (7 mg, 9.20×10^{-6} mol) according to the general procedure, followed by work-up and PLC separation in benzene–Me_2CO (9:1; v/v) afforded three main bands at R_f 0.57 (1.6 mg), 0.48 (1.0 mg) and 0.41 (1.0 mg). The R_f 0.57 band afforded compound **24** while the R_f 0.48 band yielded compound **26** as a white amorphous solid. (Found: M^+, 388.1526. $C_{21}H_{24}O_7$ requires M, 388.1522); δ_H (Table 3); CD $[\theta]_{219.0}$ 1326, $[\theta]_{224.8}$ 443, $[\theta]_{231.3}$ 838, $[\theta]_{235.2}$ −22, $[\theta]_{240.5}$ −2063, $[\theta]_{252.1}$ −269, $[\theta]_{280.4}$ −1868 and $[\theta]_{292.6}$−8.

3.13. Oritin-tri-O-methylether 28

Epioritin-(4β→3)-oritin-4α-ol hexa-*O*-methylether diacetate **14** (Coetzee et al., 1998a) (4 mg, 5.47×10^{-6} mol) was reduced according to the general procedure and afforded a mixture which was resolved by PLC in benzene–Me_2CO (9:1; v/v) to give two bands at R_f 0.57 (0.7 mg) and 0.30 (1.0 mg). The R_f 0.57 band comprised compound **24** (35.7%) while the R_f 0.30 band yielded compound **28** (57.7%) as a white amorphous solid. δ_H(Table 3); CD and MS data identical to those in the literature (Van Rensburg et al., 1999; Coetzee et al., 2000).

3.14. Epioritin-tri-O-methylether 27

Hexa-*O*-methylether diacetate derivatives **10** and **12** (10 mg, 1.37×10^{-5} mol) were separately reduced according to the general procedure. PLC separation in benzene–Me_2CO (9:1; v/v) afforded two bands at R_f 0.57 (3.1 and 1.8 mg for **10** and **12**, resp.) and 0.34 (1.0 and 2.1 mg for **10** and **12**, resp.). The R_f 0.57 bands comprised compound **24** while the R_f 0.34 band yielded compound **27** as a white amorphous solid. δ_H(Table 3); CD and MS data identical to those in the literature (Van Rensburg et al., 1999; Coetzee et al., 2000).

3.15. Epioritin-(4β→6)-epioritin hexa-O-methylether diacetate 32

Epioritin-(4β→6)-epioritin-(4α→4)-epioritin-4β-ol nona-*O*-methylether triacetate 16 (2.3 mg, 2.12×10^{-6} mol) was reduced according to the general procedure and PLC separation in benzene–Me_2CO (9:1; v/v) afforded three main bands at R_f 0.57 (0.3 mg), 0.53 (0.5 mg) and 0.47 (0.6 mg). The R_f 0.57 band comprised compound **24** while the R_f 0.53 band yielded compound **32** (33.2%) as a white amorphous solid. (Found: M^+, 714.2676. $C_{40}H_{42}O_{12}$ requires M, 714.2676); δ_H (Table 1); CD $[\theta]_{228.7}$ −49, $[\theta]_{231.5}$ −1920, $[\theta]_{233.5}$ −84, $[\theta]_{240.7}$ 25290, $[\theta]_{251.4}$ −26, $[\theta]_{282.7}$ −5474 and $[\theta]_{299.6}$ −233.

The R_f 0.47 band contained the unreacted starting material **16** (26.1%).

3.16. Epioritin-(4β→6)-epioritin hexa-O-methylether acetate 33

Epioritin-(4β→3)-epioritin-(4β→6)-epioritin-4β-ol nona-*O*-methylether triacetate **18** (8 mg, 7.36×10^{-6} mol) was reduced according to the general procedure. PLC separation in benzene–Me_2CO (9:1; v/v) afforded two main bands at R_f 0.57 (1.0 mg) and 0.26 (2.0 mg). The R_f 0.57 band comprised compound **24** while the R_f 0.26 band yielded compound **33** (40.5%) as a white amorphous solid. (Found: M^+, 672.2570. $C_{38}H_{40}O_{11}$ requires M^+, 672.2571); δ_H (Table 1); CD $[\theta]_{229.5}$ 364, $[\theta]_{235.4}$ 3010, $[\theta]_{239.1}$ 1491, $[\theta]_{246.3}$ 12870, $[\theta]_{259.7}$ −7, $[\theta]_{283.7}$ −5993 and $[\theta]_{298.2}$ −23.

3.17. Epioritin-(4β→6)-epimesquitol hepta-O-methylether acetate 34

Epioritin-(4β→3)-epioritin-(4β→6)-epimesquitol-4α-ol deca-*O*-methyl-ether triacetate **20** (3.1 mg, 2.78×10^{-6} mol) was reduced according to the general procedure. PLC separation in benzene–Me_2CO (9:1; v/v) afforded three main bands at R_f 0.57 (0.6 mg), 0.31 (0.7 mg) and 0.20 (0.1 mg). The R_f 0.57 band comprised compound **24** while the R_f 0.31 band yielded compound **34** (36.0%) as a white amorphous solid. (Found: M^+, 702.2679. $C_{39}H_{42}O_{12}$ requires M^+, 702.2676); δ_H (Table 1); CD $[\theta]_{220.3}$ 2218, $[\theta]_{224.4}$ 3250, $[\theta]_{231.3}$ 455, $[\theta]_{240.1}$ 16210, $[\theta]_{247.5}$ 19, $[\theta]_{249.5}$ −701, $[\theta]_{254.0}$ 18, $[\theta]_{257.3}$ 351, $[\theta]_{2261.9}$ 5, $[\theta]_{283.5}$ −3243 and $[\theta]_{292.6}$ 16.

The R_f 0.20 band contained unreacted starting material **20** (3.2%).

Abstract

The cuticle of higher plants functions primarily as a protective barrier for the leaves and fruits, controlling microbial attack as well as the diffusion of water and chemicals from the outside environment. Its major chemical constituents are waxes (for waterproofing) and cutin (a structural support polymer). However, the insolubility of cutin has hampered investigations of its covalent structure and domain architecture, which are viewed as essential for the design of crop protection strategies and the development of improved synthetic waterproofing materials. Recently developed strategies designed to meet these investigative challenges include partial depolymerization using enzymatic or chemical reagents and spectroscopic examination of the intact polyesters in a solvent-swelled form. The soluble oligomers from degradative treatments of lime fruit cutin are composed primarily of the expected 10,16-dihydroxyhexadecanoic and 16-hydroxy-10-oxo-hexadecanoic acids; low-temperature HF treatments also reveal sugar units that are covalently attached to the hydroxyfatty acids. Parallel investigations of solvent-swollen cutin using 2D NMR spectroscopy assisted by magic-angle spinning yield well-resolved spectra that permit detailed comparisons to be made among chemical moieties present in the intact biopolymer, the soluble degradation products, and the unreacted solid residue. © 2001 Elsevier Science Ltd. 1. Introduction

The leaves and fruit of terrestrial plants are protected by a cuticular membrane that mediates wettability, permeability, and microbial resistance. Plant cuticles consist of waxes and cutin, a polyester structural support (Fig. 1). Although it was established two decades ago that cutin's major monomeric constituents are C_{16} hydroxylated fatty acids (Kolattukudy, 1984), the molecular architecture responsible for its support functions has been more elusive because of the biopolymer's insolubility. Recently, partial degradation of tomato and lime fruit cutin by enzymatic or chemical means has been used to generate soluble oligomeric products that retain essential covalent connectivities from the native plant polyester (Osman et al., 1995; Ray et al., 1998; Ray and Stark, 1998).

The current report reviews the architectural information derived from these cutin oligomers and presents two new approaches to molecular structure determination in fruit cuticles. First, a low-temperature hydrogen fluoride treatment has been used to selectively cleave neutral sugar linkages (Mort and Bauer, 1982; Stark et al., 2000), producing both soluble oligomers and an insoluble residue for spectroscopic analysis. Secondly, the intact polymer has been swelled in organic solvents, generating a suspension from which high-resolution NMR spectra may be obtained using magic-angle spinning (Stark et al., 2000). The results of these studies provide evidence for both hydroxyfatty acid and glycoside building blocks of fruit cutins, and they validate novel spectroscopic strategies for molecular structure determination in cutins, suberins, and related plant materials.

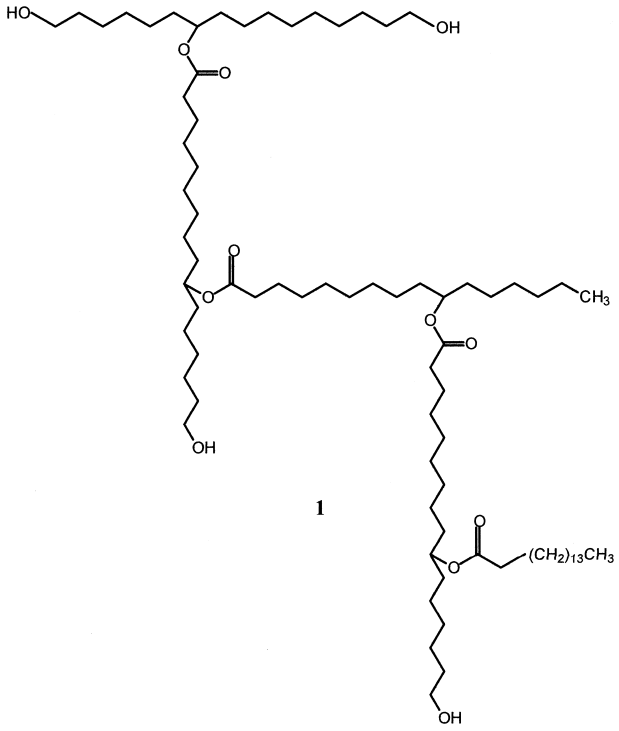
2. Results

2.1. Oligomers from chemical and enzymatic treatments of fruit cutins

In order to augment the identification of molecular groupings in plant polyesters by solid-state ^{13}C NMR (Zlotnik-Mazori and Stark, 1988; Garbow et al., 1989), a variety of procedures have been developed for partial breakdown of covalent linkages in fruit cutins (Osman et al., 1995; Ray and Stark, 1998; Stark et al., 2000). With each of these approaches, the isolated oligomers retain valuable information regarding the covalent bonding patterns of the native biopolymers.

Using a strategy of partial alkaline hydrolysis, several monomers and a dimer were isolated from the tomato fruit cutin polyester (Osman et al., 1995). The proposed dimer structure contains a primary alcohol ester linkage between two units of 10,16-dihydroxyhexadecanoic acid, the most abundant tomato cutin monomer (Holloway, 1982). Any higher oligomers were deemed undetectable by chemical ionization mass spectrometry (MS). By contrast, enzymatic hydrolysis with *Fusarium solani* cutinase yielded only monomeric products. Nonetheless, this study clearly demonstrated the usefulness of partial degradation procedures in elucidating the essential covalent linkages of protective plant polymers.

Reaction of lime fruit cutin with the enzyme porcine pancreatic lipase, which requires the presence of substrate aggregates and specifically cleaves esters of primary alcohols (Hamosh, 1990), produced a mixture of soluble monomers and oligomers. The pentamer structure **1** was deduced from electron-impact MS experiments tailored for molecular weights up to 1500 amu and with supporting evidence from solution-state NMR spectroscopic analyses (Ray and Stark, 1998). Three of the four building blocks of the pentamer correspond to the principal monomeric fatty acid constituents of Citrus cutins: 10,16-dihydroxyhexadecanoic acid, hexadecanoic acid, and 10-hydroxyhexadecanoic acid (Holloway, 1982; Kolattukudy, 1984; Ray et al., 1995). Notably, this oligomer structure is assembled solely with linkages between the esters of secondary alcohols, and it lacks the ω-hydroxyoxo fatty acid monomers found abundantly in lime cutin. All four building blocks of the pentamer have molecular structures that render them capable of both polymer chain elongation and cross-link formation within the cutin support structure.

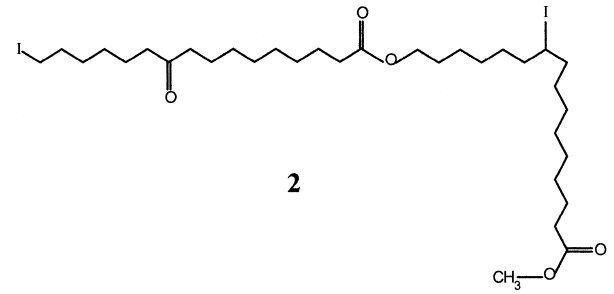


1

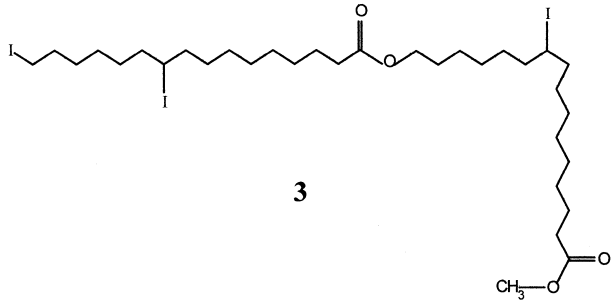
Using the mild chemical deprotecting reagent iodotrimethylsilane, which in organic solution is known to favor hydrolysis of sterically hindered esters of secondary alcohols (Purdy and Kolattukudy, 1975a,b), it was possible to improve the yield of soluble lime cutin fragments from ~5 to 22%. Both monomers and the soluble oligomers **2–4** were identified using two-dimensional multinuclear NMR and liquid secondary-ion mass spectrometry (Ray et al., 1998). The oligomeric materials are each comprised of the two most common Citrus cutin monomers, 16-hydroxy-10-oxo-hexadecanoic acid and 10,16-dihydroxyhexadecanoic acid. Although their covalent architectures are based exclusively on esterification of primary alcohols, the CHI moieties found in the oligomer structures also provide strong evidence for secondary ester linkages in the parent biopolymer.

Finally, we report herein a complementary chemical degradation strategy involving a low-temperature hydrogen fluoride treatment. This type of protocol is known to cleave sugars from glycoproteins (Mort and Lamport,

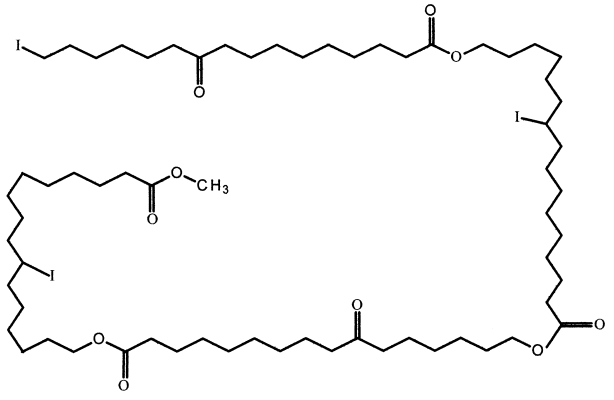
1977) and to break glycosidic linkages of neutral sugars in polysaccharides preferentially (Mort and Bauer, 1982). Thus, the resulting oligomeric fragments should retain any ester linkages to sugars from cell-wall polysaccharides of the cutin polyester. The low-temperature HF procedure was accompanied by a 23% loss in mass for lime fruit cutin, ensuring that the breakdown products reflect the molecular structure of the intact biopolymer to a significant degree.



2



3



4

A complete structural determination of the soluble products and residues derived from HF treatment is in progress; however, the cutin oligomers examined to date by high-resolution NMR and MS reveal interesting compositional and architectural trends as well as impediments to structural elucidation. The conclusions outlined below are drawn from the following spectroscopic methods: ^{1}H and ^{13}C NMR chemical shifts and integrations; 2D total correlated spectroscopy (TOCSY; Griesinger et al., 1988); gradient-assisted heteronuclear-multiple quantum correlation (gHMQC; Hurd and John, 1991) and gradient-assisted heteronuclear-multiple-bond-correlation (gHMBC; Rinaldi and Keifer, 1994) experiments for through-bond connectivities *within* each monomeric constituent and *between* successive momomer units, respectively; and matrix-assisted laser desorption time-of-flight mass spectrometry (MALDI-TOF MS; Cotter, 1997) for molecular weights.

First, the most abundant Citrus cutin monomer (16-hydroxy-10-oxo-hexadecanoic acid) is present in all of the oligomers, but the other major lime fruit cutin monomer (10,16-dihydroxyhexadecanoic acid) is absent. The soluble products of low-temperature HF depolymerization also include units of hexadecanoic acid and 16-hydroxyhexadecanoic acid, which were reported previously among the lime cutin monomers and in the pentamer **1** derived from lipase treatment. At least one oligomer structure contains unanticipated sugar moieties, as detailed below. Thus, the significant diversity in monomer composition exhibited by the various oligomers underscores the importance of examining products from several complementary degradative treatments when assembling a molecular picture of the original biopolymer.

Second, the covalent linkages present in the products of low-temperature HF treatment (and the products of other chemical treatments) consist predominantly of primary alcohols esterified to carboxylic acids; only pentamer **1** exhibits secondary ester connectivities. Nevertheless, it would be inappropriate to conclude that lime fruit cutin is lacking in cross-links. Since the reported degradative treatments (Osman et al., 1995; Ray et al., 1995, 1998; Ray and Stark, 1998) are generally incomplete, it is reasonable to assume that heavily cross-linked regions of the insoluble biopolymer are less accessible to the reagents. Moreover, the presence of secondary ester cross links in the intact cutin polymer has been inferred from its extreme insolubility and confirmed by its solid-state ^{13}C NMR spectra and spin-relaxation times (Zlotnik-Mazori and Stark, 1988; Garbow and Stark, 1990). Supporting evidence for such sequestered regions of lime cutin also comes from the solvent swelling experiments described below.

Third, despite the definitive evidence for ester linkages obtained from long-range through-bond NMR connectivities (Ray et al., 1998; Stark et al., 2000), neither the position of the mid-chain oxo- groups nor the sequence of the monomeric units may be determined from these analyses. As illustrated by oligomer **4**, this limitation occurs because the carboxyl, carbonyl, and mid-chain hydroxyl functionalities occur repeatedly and are well separated by spectroscopically degenerate methylene groups. Nevertheless, 10-oxo and/or 10-hydroxy substitution patterns are likely based on the cutin monomer structures found in lime fruit (Ray et al., 1995) and other plant materials (Kolattukudy, 1984). It is also possible, for instance, to verify an alternating arrangement of 16-hydroxy-10-oxo-hexadecanoic acid and 16-

hydroxyhexadecanoic acid units, provided that MS fragmentation patterns or isolated dimers are available (Ray et al., 1998).

Fourth, at least one lime fruit cutin oligomer contains a sugar unit in addition to the hydroxyfatty acid moieties. GC analysis indicates arabinose, glucose, and other unidentified sugar moieties among the chloroform-soluble HF cleavage products, and both the NMR chemical shifts and scalar coupling networks of one purified oligomer are consistent with an unusual 2-deoxyfuranose structure. If the cutin polyester in native Citrus fruit is indeed bound covalently to polysaccharides, then this functionalization of the cell wall may reduce its vulnerability to microbial pathogens, as has been proposed for suberized wound periderm (Zucker and Hankin, 1970).

Finally, each of these cutin oligomers poses challenges for MS determination of molecular weights and fragmentation patterns. As noted for the tomato and lime cutin hydrolysates isolated previously (Osman et al., 1995; Ray et al., 1998), volatility will drop off precipitously for compounds larger than dimers. In our hands, liquid secondary-ion mass spectrometry (Aberth et al., 1982) and MALDI-TOF MS (Cotter, 1997) have sometimes failed to give molecular ions for cutin trimers and tetramers; in most cases these techniques will also fail to provide structurally informative fragments. Either derivatization or optimized MS protocols will be needed to confirm and augment the NMR-based structural elucidation of these intriguing plant materials.

2.2. High-resolution NMR of a solvent-swelled lime cutin polymer

Although intact plant cuticular materials may be examined directly by cross polarization magic-angle spinning (CPMAS) solid-state NMR spectroscopy, the resulting ^{13}C spectral lines are broader than those observed for monomeric and oligomeric fragments in solution (Stark et al., 1989). The corresponding ^{1}H NMR spectra display very broad features, even with rapid MAS. These spectral characteristics, which stem from the anisotropic chemical environment at each nucleus and the relative lack of molecular motion, limit the molecular-level structural information available in such amorphous solid materials. Nevertheless, it is possible to regain much of the desired information by swelling cutin in organic solvents (to enhance molecular mobility) and conducting the NMR experiments with MAS (to average chemical shift anisotropy, eliminate dipole-dipole interactions, and minimize magnetic susceptibility line-broadening) (Keifer et al., 1996; Millis et al., 1997; Stark et al., 2000).

Fig. 2 makes a quantitative comparison of MAS ^{1}H NMR spectroscopic data for dry and solvated lime cutin, verifying that all of the functional groups observable with vigorous magic-angle spinning are represented in their correct proportions upon swelling of the polyester. The potential of the swelling strategy for molecular structure determination is supported by the high-field MAS ^{1}H NMR spectrum of cutin in DMSO (Fig. 3), which exhibits all resonances typical of hydroxyalkanoic acids as well as the oxymethylenes that are diagnostic for esters of primary alcohols (Ray et al., 1998). The improved spectral resolution of this latter spectrum compares favorably with that of a typical lime cutin oligomer (data not shown), demonstrating that near solution-state linewidths may be achieved at slightly elevated temperatures (50°C) and using modest spinning rates (2.5 kHz).

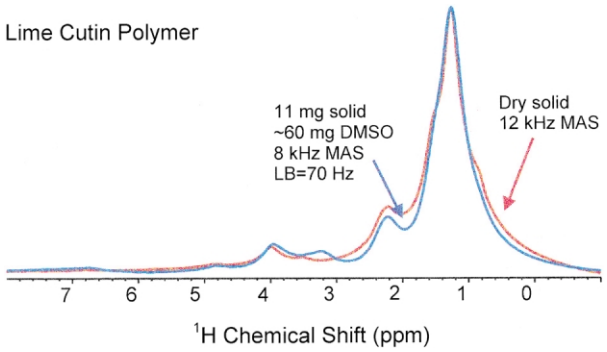


Fig. 2. 300-MHz MAS ^{1}H NMR spectrum of intact lime fruit cutin, prepared as a dry solid (red trace) and swelled at 1:6 (w/w) in DMSO (blue). Magic-angle spinning speeds were 12 and 8 kHz, respectively. NMR spectral data for the swelled sample were apodized to produce a line broadening of 70 Hz, in order to facilitate comparison with data for the dry solid.

When MAS NMR spectroscopy is combined with standard two-dimensional solution-state spectroscopy, it is possible to elucidate through-bond ^{1}H–^{13}C interactions and make detailed comparisons between the intact polymer, its soluble degradation products, and its HF-resistant residue. Comparable resolution is observed in the gHMQC contour plots of polymer, residue, and oligomer, again indicating the liquid-like state of the

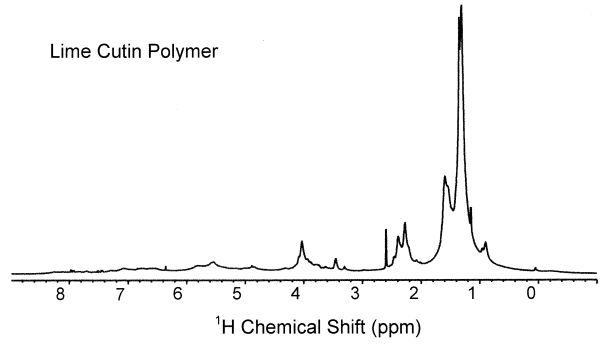

Fig. 3. 600-MHz MAS ^{1}H NMR spectrum of lime fruit cutin, swelled at 1:30 (w/w) in DMSO at 50°C and spun at 2.5 kHz. The sharp peak at 2.5 ppm comes from the solvent.

swelled moieties and showing the promise of the MAS NMR approach.

Fig. 4 displays the 2D MAS-assisted gHMQC data obtained for intact swelled lime cutin (center panel) and for a hydroxyfatty acid-based oligomer derived from low-temperature hydrogen fluoride treatment (top panel). The HMQC 'fingerprints' of directly-bonded carbon-hydrogen pairs are somewhat similar for the polymer and oligomer, supporting the presence of numerous distinguishable CH_2O and CH_2 groups in both materials. Surprisingly, no correlations to protonated carbons resonating above 70 ppm are observed in either 2D spectrum, though such resonances have been observed in prior CPMAS ^{13}C spectra of the dry solid (Zlotnik-Mazori and Stark, 1988) and attributed to CHOC=O, CHOH, aromatic, and doubly bonded functionalities. These signals could be missing from the spectrum of the soluble oligomer because of incomplete breakdown of the parent cutin (see above). Their absence from the gHMQC spectrum of the intact polymer suggests that despite solvent swelling, the combination of motional averaging and 2.5-kHz MAS is insufficient to produce high-resolution NMR spectra for its most heavily cross-linked regions.

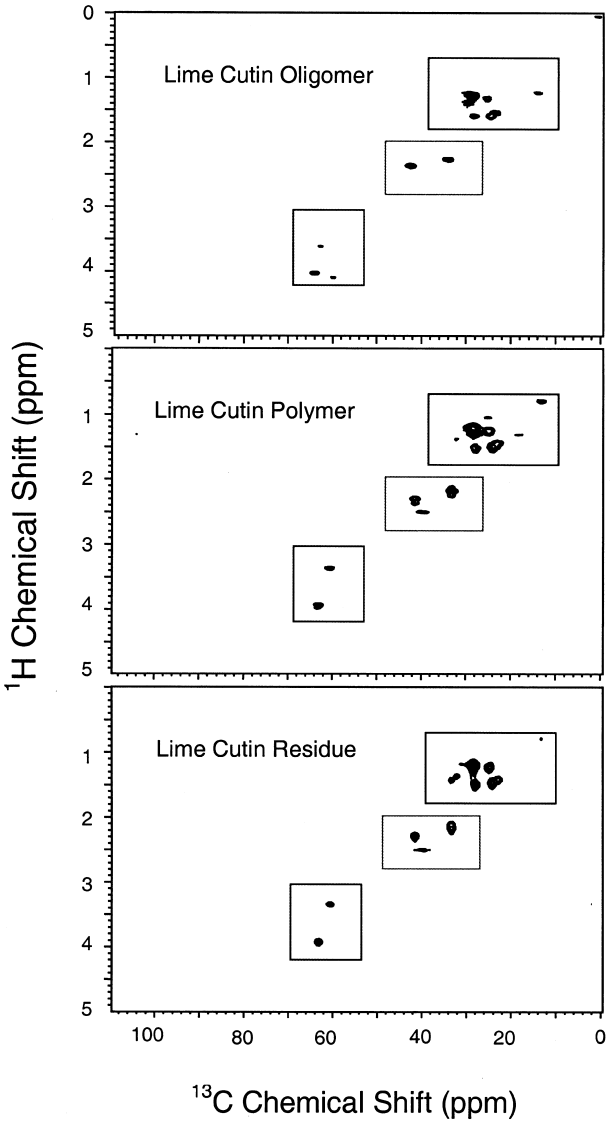

Fig. 4. Contour plots from 600-MHz gradient-assisted heterocorrelated multiple-quantum correlation (gHMQC) NMR of lime cutin, obtained with 2.5-kHz MAS and 11 G/cm z-axis pulsed field gradients. Top panel: a trimer dissolved in $CDCl_3$ at room temperature; center panel: intact plant polymer swelled in DMSO at 50°C; bottom panel: solid residue after HF treatment, swelled in DMSO at 50°C. The spectral regions highlighted by boxes are described in the text.

As compared with intact cutin, the upfield regions of the oligomer spectrum display cleaner correlation patterns for bulk methylene groups (highlighted by boxes in the upper right-hand corner of each plot) and segments alpha to ester and keto carbonyls (middle boxes). Specific changes in molecular structure are also evident among the oxymethylene groups (lower left boxes). The polymer $\underline{CH_2}OR$ resonance at (61, 3.4 ppm) disappears in the oligomer, while a new CH_2OH resonance (63, 3.6 ppm) suggests bond cleavage, and the appearance of $CH_3\underline{CH_2}OC{=}O$ (60, 4.1 ppm) and $\underline{CH_3}CH_2OC{=}O$ (14, 1.2 ppm) signals is indicative of a terminal ethyl ester. An analogous comparison between gHMQC spectra of the polymer and the unreacted residue after HF treatment is also shown in Fig. 4 (center and bottom panels). In this latter case the NMR fingerprints are almost identical, exhibiting differences only among the intensities of selected bulk methylene and terminal methyl cross peaks.

3. Discussion

A detailed understanding of the molecular architecture of plant cutins can point the way toward the design of improved crop protection protocols and robust synthetic waterproofing materials. Although the intractability of these and related plant biopolymers has slowed their structural characterization, it is possible to overcome many of these difficulties using two complementary strategies: partial depolymerization to produce soluble oligomers and high-resolution spectroscopy of the intact cuticular materials.

Soluble oligomers isolated from a variety of chemical and enzymatic degradation treatments on fruit cutins have revealed many of the essential primary and secondary ester linkages present in the native cuticular polymer. Although the through-bond correlations mapped out in 2D NMR spectra provide invaluable structural clues to the identity of these oligomeric materials, important information regarding their molecular weights and positional isomerism remains challenging to obtain routinely by MS methods. Taken together, the monomeric compositions of the oligomers are in reasonable accord with the expectations of exhaustive depolymerization studies, but no single protocol offers a reliable

molecular view of the biopolymer. Esters of secondary alcohols may be underrepresented among the soluble cutin oligomers, because the most heavily cross-linked regions of the biopolymer could be inaccessible to the depolymerization reagents. The possible presence of a novel glycoside oligomer also suggests a role for cutin in blocking access of pathogens or cell-wall degrading agents.

Insoluble cutin polymers and unreacted residues have been rendered amenable to high-resolution NMR structural analysis by swelling them in organic solvents and applying magic-angle spinning techniques. Although this hybrid (semi-solid) NMR strategy must be applied with caution to the cutin regions of heaviest cross-linking, it can provide well-resolved spectral data from both one- and two-dimensional NMR experiments. Thus, it has been possible to compare chemical moieties of the intact cutin polymer to both soluble oligomers and insoluble residues and to delineate some of the corresponding molecular transformations.

The results presented above for lime fruit cutin illustrate the feasibility of obtaining structural information on both oligomeric constituents and intact polymers. Such chemical and spectroscopic approaches also offer promise for detailed investigations of molecular architecture in a wide variety of complex plant materials, including suberins, lignins, and cell-wall polysaccharides.

4. Experimental

4.1. Isolation of lime fruit cutin

Fruit cutin was isolated from the skin of limes (*Citrus aurantifolia*) using a three-step protocol (Pacchiano et al., 1993): (1) peeling and separation of the cuticle by treatment with pectinase; (2) enzymatic digestion of cell-wall polysaccharides with successive cellulase, pectinase, and hemicellulase treatments; (3) exhaustive dewaxing using successive Soxhlet extraction with methanol, methylene chloride, and tetrahydrofuran. All reagents were obtained from Sigma or Aldrich Chemical Companies. In a typical preparation, 200 limes yielded 5.0 g of dry cutin.

4.2. Generation of lime cutin oligomers

In order to produce oligomeric fragments, 502 mg of powdered lime fruit cutin was reacted for 0.5 h with anhydrous HF at 0°C and quenched by diethyl ether in liquid nitrogen (Mort, 1983). After evaporating the ether-HF mixture (120 mg) to dryness, the reaction products were extracted to yield 22 mg of water solubles and 95 mg of chloroform solubles. The unreacted solid residue was reserved for analysis by magic-angle spinning NMR. The chloroform fraction was dried and then extracted with acetonitrile.

Purification of the acetonitrile extract was achieved using reversed-phase HPLC conducted on a Hewlett-Packard Model 1100 instrument equipped with a quaternary solvent delivery system, UV detector, and diode array detector. Separations were performed with 5 μm analytical and semi-preparative C_{18} columns, using UV detection at 210 nm, a 1-ml/min flow rate, and gradient elution (acetonitrile/H_2O/THF, varied from 75:20:5 to 95:0:5 during a period of 20 min). Isolated compounds (typical yield, 0.5 mg) were checked for purity by re-injection in two solvent systems.

4.3. Gas chromatography

Sugars were analyzed as their trimethylsilyl methyl glycosides using slight changes to the procedure of Chaplin, (1982) as previously modified by Komalavilas and Mort (Maness and Mort, 1989). After at least 3 h of methanolysis at 80°C using 1.5 M HCl in dry methanol containing 10% methyl acetate as a water scavenger, a few drops of *t*-butanol were added and the sample was evaporated to dryness. A 25–40 μl aliquot of a 1:3 v/v mixture of Tri-Sil concentrate (Pierce Chemical Co.): pyridine was added. After 15 min the sample was evaporated just to dryness and then dissolved in 100 μl isooctane. A 1-μl aliquot was injected via a cold on-column injector (J&W Scientific) fitted to a Varian 3300 chromatograph with a flame ionization detector. The column was a 30 m×0.25 mm I.D., 0.25-μm film DB-1 capillary from J&W Scientific with a constant head pressure of 12 psi helium for the carrier gas. During the injection the oven was held at 105°C. After a 1-min hold the temperature was raised to 160°C at a rate of 10°C/min. After a 4-min hold the temperature was then raised to 200°C at 2°C/min for the separation. The temperature was raised to 240°C after each separation to purge the column in preparation for subsequent injections.

4.4. Solution-state NMR spectroscopy

NMR spectra were acquired on a Varian ^{UNITY}INOVA spectrometer operating at ^{1}H and ^{13}C frequencies of 599.95 and 150.87 MHz, respectively. Cutin oligomer samples were dissolved in $CDC1_3$ to provide a field-frequency lock signal and contained 1% tetramethylsilane (TMS) to provide an internal chemical shift standard (Aldrich). One dimensional ^{1}H spectra were acquired using a Varian nanoprobe (see below). Typical experimental conditions included 16 repetitions, 2.0 s between successive acquisitions, 26,240 time-domain points, and a spectral width of 7200 Hz. Data processing and ^{1}H peak integration were done using VNMR software; ^{13}C chemical shift predictions were made using database software from Advanced Chemistry Development (Toronto, Canada).

Several two-dimensional NMR experiments were used to establish through-bond connectivities within and

between monomer units of the oligomer structures. ^{1}H–^{1}H total correlation spectroscopy ('clean' TOCSY) (Griesinger et al., 1988) was conducted with an effective spin-lock field of 6.25 kHz and a mixing period of 70 ms in order to allow magnetization transfer throughout each scalar-coupled spin system. Heteronuclear multiple quantum correlation (^{13}C HMQC) spectroscopy (Muller, 1979) was used to identify bonded proton-carbon pairs using a polarization transfer time corresponding to $^{1}J_{CH} = 140$ Hz. Heteronuclear multiple bond correlation (^{13}C HMBC) spectroscopy (Bax and Summers, 1986) was employed to delineate long-range proton-carbon bonded interactions, using a polarization transfer time corresponding to $^{3}J_{CH} = 10$ Hz. In proton-detected HMQC experiments, the GARP sequence (Shaka et al., 1985) was used for ^{13}C decoupling, and pulsed field gradients (Hurd and John, 1991; Rinaldi and Keifer, 1994) were used for coherence selection and to minimize spectral artifacts. The HMQC data were typically acquired with spectral widths of 7200 Hz for ^{1}H and 27,150 Hz for ^{13}C, a relaxation delay of 1.0 s between transients, and an array of 2 K× 256 points, zero-filled to 2K×1K points. The HMBC data were typically acquired with spectral widths of 7200 Hz for ^{1}H and 36,200 Hz for ^{13}C, a relaxation delay of 1.0 s between transients, and an array of 2K× 256 points, zero-filled to 2K×1K points.

4.5. Magic-angle spinning NMR spectroscopy

MAS ^{1}H spectra of swelled cutin samples were acquired either at 600 MHz (as described above) or on a Varian UNITY*plus* spectrometer operating at a ^{1}H frequency of 300.001 MHz. The former experiments were performed with a 4-mm Varian inverse-detection HX nanoprobe equipped with pulsed field gradients, using 1–2 mg of solid sample and magic-angle spinning typically regulated at 2.200±0.001 kHz. The latter experiments were performed on 30-mg samples in a Doty 5-mm XC5 probe spinning at 8.000±0.005 kHz. Spectra were obtained at either room temperature or 50°C, as noted. ^{1}H chemical shifts were referenced to DMSO at 2.50 ppm or $CDCl_3$ at 7.24 ppm, and ^{13}C chemical shifts were referenced to DMSO at 39.51 ppm.

4.6. Mass spectrometry

Electron-impact mass spectrometry was carried out at 70 eV using a Finnigan MAT-90 double focusing spectrometer and an accelerating potential of 5 keV, as described previously (Ray and Stark, 1998). Liquid secondary ion mass spectrometry was conducted with a VG ZAB-T high-resolution spectrometer equipped with a 30 kV cesium gun ionizing source, accelerating potential of 8 kV, and dithiothreitol/dithioerythritol matrix (Ray et al., 1998). Matrix-assisted laser desorption time-of-flight mass spectrometry (MALDI-TOF MS) was carried out using a Perseptive Biosystems Voyager instrument in the positive-ion mode. The matrices used in these experiments were trihydroxyacetophenol or indolacrylate (2 mg/ml) in acetone. Data were acquired by signal averaging of 40–70 scans, each obtained with an accelerating voltage of 25 kV and a low-mass gate of 300 amu.

Special Issues Devoted to the Biosynthesis of Woody Plant Biopolymers and Related Substances

These Special Issues (Vol. 57/6 and 57/7) are largely derived from the presentation of papers given at the Millennium Symposium of the American Chemical Society (ACS) entitled, "Biosynthesis of Woody Plant Biopolymers and Related Substances", held in San Francisco from the 26–29 March 2000. It was organized by G.P. Bolwell and N.G. Lewis, under the auspices of the ACS Cellulose, Paper and Textile Division. The meeting was devoted to fundamental research on the biosynthesis, assembly and properties of plant cell walls which underpin their use as industrial feedstocks and other aspects that impinge on daily life such as dietary fiber. Of special interest was the way in which chemistry is being augmented with genomic, proteomic and metabolic studies to unravel the complex processes involved in plant cell wall assembly, and in combination with molecular breeding to improve fiber properties.

The rationale of the gathering was directed at integrating the present knowledge of the synthesis and assembly of carbohydrate and phenolic biopolymers in woody tissues. That notwithstanding, additional communications were given on those components that have been rather neglected in the past but which are important in preserving and enhancing both the integrity and function of specialized cell walls. These contributions focus upon specialized phenolics and lipids of secretory, cuticular, suberized and heartwood tissues.

We have organized these issues in several thematic sections, which mainly reflect the range of topics covered at the meeting. Authors were encouraged to update their contributions in the time since the meeting. The first section primarily deals with structural and anatomical aspects but contain protein and gene expression data that help understand the complexity of individual cell types within woody tissues. Four papers (McCann, Haigler and Lewis) largely relate to polysaccharide biosynthesis and cell wall assembly at the cellular level, while within the second group, two (Donaldson and Ruel) summarize spatial aspects of lignin biosynthesis and others (Lewis and Gross) describe the processes involving specialized depositions of lignins/lignans and tannins, in woody tissues, respectively.

The next section has an emphasis on chemical aspects and plant component analysis. The first begins with a comprehensive review on pectins (Mohnen) and is presented together with a research paper describing novel linkages between heterogeneous pectins (Ishii). Another contribution (Murray) describes an intriguing occurrence of oligosaccharides which might be related to glucan biosynthesis. A second chemistry section has two papers (Iiyama and Ralph) which describe some observations that they believe affect lignin assembly and a third by Stange indicates that the lignin formed by the wounding of cucumber is actually largely *p*-coumaraldehyde. Marton and Ferreira describe additional complex flavonoid derived structures found within specialized cell walls containing phenolic polymers, including that of heartwood. The final paper in this section (Stark) summarizes our knowledge of the lipid components associated with phenolics in cuticular structures.

The next sections address progress made on the biochemistry and molecular biology of carbohydrate and phenolic polymers. We begin with protein biochemistry and metabolism of wall carbohydrate synthesis. Further characterization of the synthesis of polysaccharides in vitro is described in two contributions (Carpita and Bolwell). This is followed by a study on metabolism of monosaccharides (Magel) which is also related to the provision of phenolic precursors for heartwood deposition. The biosynthesis of monolignols is reviewed with respect to metabolic channeling of individual monolignol pathways (Dixon) with three other papers following on coniferyl alcohol metabolism (Savidge and Ros Barcelo). Bernards and Cornish summarize the important advances being made in suberin and rubber biosynthesis, respectively. In the year in which the Arabidopsis genome was completed, molecular genetics have not been left out. It is apt that as we strive to identify the genes responsible for cell wall polysaccharide biosynthesis that we present a review that is germane to such studies (Brown). Five articles describe results on the regulation and manipulation of lignin biosynthesis, and these complete the two special issues (Kawaoka, Legrand, Ye, Grima-Pettenati and Bolwell). Such study represents the immediate take-off point for present commercially oriented work.

As Editors of this Special Issue, we are extremely grateful for the timely preparation and updating of

PII: S0031-9422(01)00161-3

these articles by the authors. We hope that they and the readers will find these an important and stimulating series of articles on the present status of our yet very incomplete understanding of the biosynthesis of woody plant biopolymers and related substances. In this respect, we have strived in these two volumes to compile a range of views, which sometimes differ on the same topic.

It would be remiss if we did not wholeheartedly thank financial support provided by a number of organizations without whose help neither symposium nor special issues would have been possible. These include, Applied Phytologics, Inc., American Chemical Society, Elsevier Science Ltd., the S.R. Noble Foundation, Waters Corporation and the Weyerhaeuser Company.

Insight into multi-site mechanisms of glycosyl transfer in (1→4)β-D-glycans provided by the cereal mixed-linkage (1→3),(1→4)β-D-glucan synthase

Marcos S. Buckeridge[a], Claudia E. Vergara[b], Nicholas C. Carpita[b,*]

Received 31 July 2000; received in revised form 23 October 2000

Abstract

Synthases of cellulose, chitin, hyaluronan, and all other polymers containing (1→4)β-linked glucosyl, mannosyl and xylosyl units have overcome a substrate orientation problem in catalysis because the (1→4)β-linkage requires that each of these sugar units be inverted nearly 180° with respect to its neighbors. We and others have proposed that this problem is solved by two modes of glycosyl transfer within a single catalytic subunit to generate disaccharide units, which, when linked processively, maintain the proper orientation without rotation or re-orientation of the synthetic machinery in 3-dimensional space. A variant of the strict (1→4)β-D-linkage structure is the mixed-linkage (1→3),(1→4)β-D-glucan, a growth-specific cell wall polysaccharide found in grasses and cereals. β-Glucan is composed primarily of cellotriosyl and cellotetraosyl units linked by single (1→3)β-D-linkages. In reactions in vitro at high substrate concentration, a polymer composed of almost entirely cellotriosyl and cellopentosyl units is made. These results support a model in which *three* modes of glycosyl transfer occur within the synthase complex instead of just two. The generation of odd numbered units demands that they are connected by (1→3)β-linkages and not (1→4)β-. In this short review of β-glucan synthesis in maize, we show how such a model not only provides simple mechanisms of synthesis for all (1→4)β-D-glycans but also explains how the synthesis of callose, or strictly (1→3)β-D-glucans, occurs upon loss of the multiple modes of glycosyl transfer to a single one. © 2001 Published by Elsevier Science Ltd.

1. Introduction

The cell walls of higher plants are chemically characterized as amalgams of cellulose microfibrils tethered by several kinds of (1→4)β-linked cross-linking glycans and embedded in a pectin-rich matrix (McCann and Roberts, 1992; Carpita and Gibeaut, 1993). Research spanning over three decades has left us with yet a limited understanding of how plant polysaccharides are made. Cellulose synthesis in vitro has never been convincingly demonstrated with isolated membranes from plants (Delmer, 1999). The lack of progress in identifying polysaccharide synthase polypeptides to probe the mechanisms of catalysis has been attributed to the difficulties most investigators have encountered in maintaining synthase activities in vitro. In contrast, several non-cellulosic polysaccharide synthase activities have been stabilized in isolated Golgi membranes. These include the synthases of xyloglucan (Gordon and Maclachlan, 1989; Desveaux et al., 1998), glucuronoxylans (Hobbs et al., 1991), glucomannan (Piro et al., 1993), galactomannan (Reid et al., 1995), and the mixed-linkage (1→3),(1→4)-β-D-glucan (hereafter, called β-glucan) synthase (Gibeaut and Carpita, 1993).

Like cellulose, all major cross-linking glycans contain (1→4)β-linkages that invert one sugar residue almost

180° with respect to each neighbor. This structural feature creates a fundamental problem in the mechanism of synthesis. With each single addition of glycosyl residue the position of the O-4 of the glycosyl acceptor at the non-reducing terminus is moved. This means that with each monosaccharide addition the catalytic site must also invert, the acceptor glycosyl unit at the terminus of the polysaccharide must invert, or the glycosidic bonds of both substrate and acceptor must be stretched or twisted alternatingly to rotate each sugar into its proper orientation to preserve linkage solely at the O-4 position (Fig. 1). Alternatively, we and others proposed that *two* sites of glucosyl transfer residing within a single catalytic subunit generate disaccharide units that are added iteratively (Carpita et al., 1996; Albersheim et al., 1997; Koyama et al., 1997; Carpita and Vergara, 1998; Buckeridge et al., 1999). In this model, glycobiosyl units, or even-numbered units, are added to the non-reducing end, assuring that (1→4)β-linkages are strictly preserved without inversion of substrate, active site, or terminus of the growing chain.

Our studies of the synthesis in vitro of the mixed-linkage β-glucan, a cell wall polysaccharide found in grasses and cereals (Carpita, 1996), lend support to a multiple-site model for catalysis of (1→4)β-linked polysaccharides. The glucan is not a random mixture of (1→3)β- and (1→4)β-linkages, but has a defined structure of cellotriosyl and higher cellodextrins each connected by single (1→3)β-linkages (Fig. 2). The cellotriosyl unit is the smallest and most abundant cellodextrin unit found in the polymer, i. e. no alternating (1→4)β- and (1→3)β-linkages are ever observed. The ratio of the odd-numbered cellodextrin oligomers is generally about two-fold greater in abundance than the next higher even-numbered oligomers in the series (Wood et al., 1994). This type of β-glucan is not found in angiosperm species outside the Poales (Smith and Harris, 1999). The only other organism known to synthesize β-glucan is the lichen *Cetraria islandica*, which has predominately a cellotriosyl unit structure comprising 86% of the polymer, with the remainder mostly cellopentosyl units (Wood et al., 1994).

Within this short review of (1→4)β-glycan synthases, we demonstrate how the linkage of primarily odd numbered cellodextrins by single (1→3)β-linkages at near saturating concentrations of UDP-Glc in vitro provides unique insight into comparative mechanisms inherent in the (1→4)β-glycan synthases. We proposed further that the trisaccharide unit of β-glucan can be formed if an ancestral cellulose synthase complex was modified to contain a third glucosyl transferase activity in addition to the cellobiose generating activity (Carpita et al., 1996). However, the acquisition of a mechanism to add primarily an odd number of glucosyl units means that the first and third residues are not inverted 180° with respect to each other, and this feature restricts the non-reducing terminal sugar of the growing chain so that it is always oriented to expose the O-3 hydroxyl for attachment instead of the O-4 (Fig. 1). Hence, the odd-numbered cellodextrin units of β-glucan will always be linked by single (1→3)β- rather than (1→4)β-linkages. An analysis of the deduced amino acid sequences of diverse members of the *Ces*A gene family give important

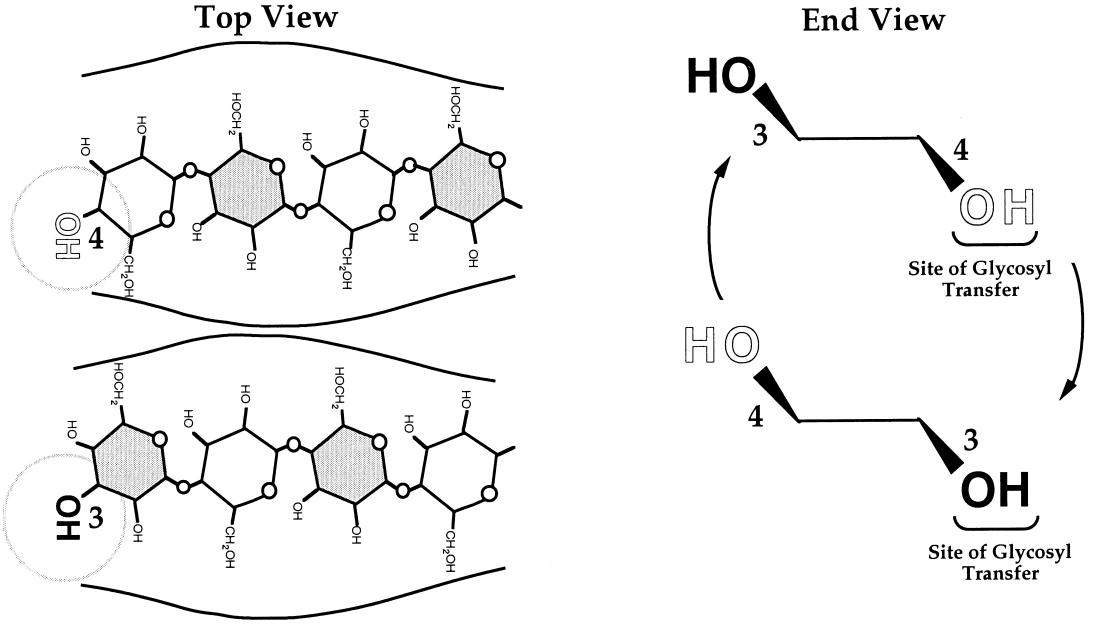

Fig. 1. *Top view*: Two possible positions of the non-reducing terminal acceptor glucosyl unit of a growing chain can be made either by rotating the chain over or processively adding a single glucosyl unit from a fixed site of glycosyl transfer. *End view*: Both (1→4)β- and (1→3)β- linkages are possible, so positioning of the non-reducing terminal sugar to expose either the O-3 or O-4 must be tightly controlled during synthesis of glucans with a defined linkage structure.

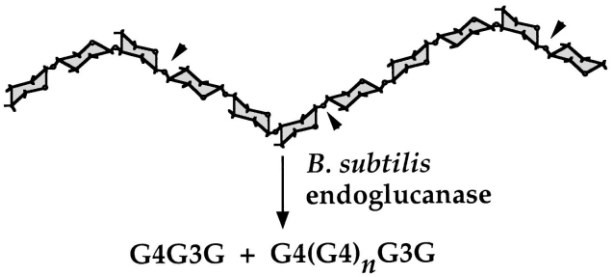

Fig. 2. General structure of the mixed-linkage (1→3),(1→4)β-D-glucan from cereal grasses. About 90–95% of the polymer is composed of cellotriosyl and cellotetraosyl units connected by single (1→3)β-linkages. The remainder of the polymer contains longer cellodextrins, with each connected by single (1→3)β-linkages. In the native polymer the cellotriose units outnumber the cellotetraosyl units about 2.5 to 1. The arrows marked the linkages that are hydrolyzed by the *Bacillus subtilis* endoglucanase, which cleaves (1→4)β-linkages when the previous linkage was (1→3)β.

clues as to the motifs that might be essential in modulating glycosyl transfer in (1→4)β-D-glycan synthases as well as differentiate them from β-glucan synthases.

2. Results

2.1. β-Glucan structure in the maize coleoptile

The structure of β-glucan is determined specifically with a sequence-dependent *Bacillus subtilis* endoglucanase (lichenase), which cleaves (1→4)β-D-glucosyl units only if preceded by (1→3)β-units. This hydrolysis yields primarily a diagnostic trisaccharide, cellobiosyl-(1→3)-D-glucose, and a tetrasaccharide, cellotriosyl-(1→3)-D-glucose (Anderson and Stone, 1975), which are separated and detected by HPAEC-PAD (Fig. 3A). Laminaribiose, or β-D-glucosyl-(1→3)-D-glucose, is not observed as a product, indicating that the polymer does not contain alternating (1→4)-D- and (1→3)-D-linked glucosyl units-the cellotriosyl unit is the smallest cellodextrin in the polymer. In β-glucans of the maize coleoptile, calculation of the mole fractions of each cellodextrin oligomer demonstrated that the cellotriose units are well over twice as abundant as the cellotetraose units, and the pentamer units are twice as abundant as the hexamers (Table 1).

2.2. β-Glucan synthesis in vitro

β-Glucan formed in vitro at suboptimal UDP-Glc concentrations of 5–250 μM was assayed by digestion with the *B. subtilis* endoglucanase, and the molar amounts synthesized were determined from the specific activity of the UDP-[^{14}C]-D-glucose provided to the membranes (Fig. 3B). At concentrations of UDP-Glc greater than 5 mM, radioactive substrate was no longer needed as the glucose incorporated could be determined by pulsed amperometry alone (Fig. 3C).

The incorporation of glucose into β-glucan is biphasic and appears to saturate between 5 and 20 mM UDP-Glc but then increases markedly above 20 mM UDP-Glc (Fig. 4A and B). The amounts of cellotriose formed relative to both cellotetraose and cellopentaose increased with increasing concentrations of UDP-Glc to about 250 μM (Fig. 4A). However, the marked increase in β-glucan synthase activity above 20 mM was primarily a result of the synthesis of cellotriosyl and cellopentaosyl units, but not cellotetraosyl units (Fig. 4B). The cellopentaose units are a small mole fraction of the total β-glucan at suboptimal UDP-Glc concentrations but become twice as abundant as cellotetraose units at high substrate concentrations (Table 1).

Table 1
Mol percentage contributions of each of the cellodextrin units of β-glucan from the maize coleoptile and that synthesized in vitro[a]

	β-Glucan source			
	Maize coleoptile	Reaction products		
Cellodextrin unit		5 μM	250 μM	30 mM
		Mol fraction[a]		
Cellotriose	0.68	0.56	0.75	0.76
Cellotetraose	0.26	0.37	0.20	0.07
Cellopentaose	0.04	0.05	0.03	0.14
Cellohexaose	0.02	0.02	0.01	0.03

[a] Values were determined from integration of HPAEC-PAD signals and response factors calculated from standards. The results are from at least two and typically three separate experiments. Variance was less

3. Discussion

3.1. Special features of β-glucan synthase in vitro

As a result of the early work on the synthesis of non-cellulosic polysaccharides at the Golgi apparatus, a common misconception developed that these synthases are saturated at μM concentrations of nucleotide-sugar substrate (for review, see Gibeaut and Carpita, 1994a). Originally thought to be true for xyloglucan synthase, Gordon and Maclachlan (1989) demonstrated that the

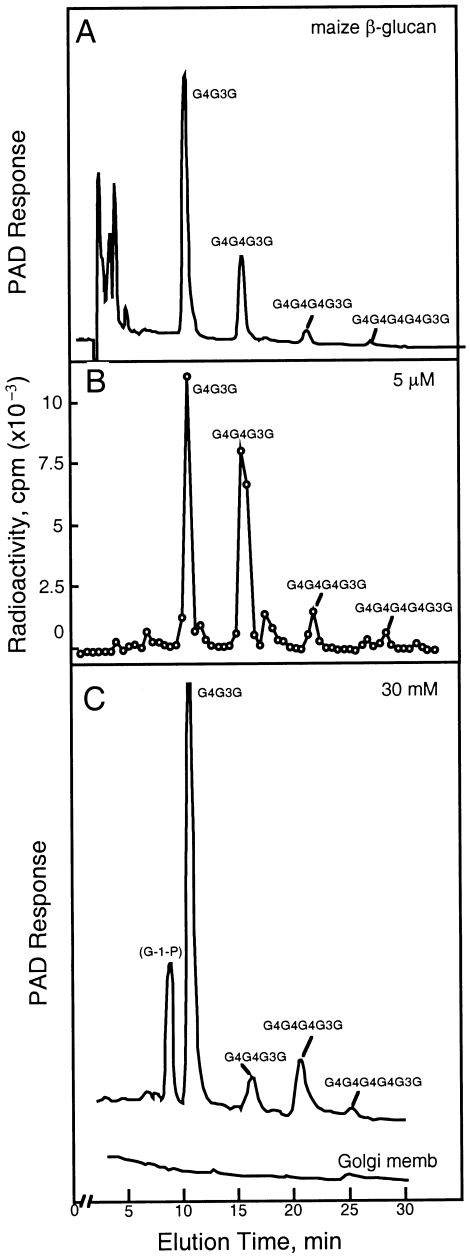

Fig. 3. HPAEC-PAD separation and detection of labeled cellodextrin-(1→3)-D-glucose oligosaccharides from β-glucan synthesized in vitro. A. Pulsed amperometric detection of cellodextrin-(1→3)-D-glucose oligosaccharides from β-glucan. B. Separation of the β-glucan cellodextrin products synthesized at low substrate concentrations. Radioactivity from 0.5-ml fractions was determined by liquid scintillation spectroscopy after acidification of the NaOH with acetic acid. C. Separation of the β-glucan cellodextrin products synthesized at high substrate concentrations. The cellodextrin-(1→3)-D-glucose oligosaccharides from β-glucan made in vitro were quantified by pulsed amperometric detection.

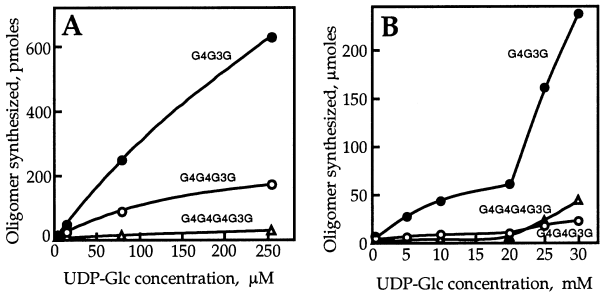

Fig. 4. A. Rates of β-glucan synthesis at low concentrations of UDP-Glc. Product made was determined from total radioactivity and specific activity of substrate or from calibration of the pulsed amperometric signal. B. Rates of β-glucan synthesis at high concentrations of UDP-Glc. The molar ratios based on incorporation of radioactivity were corrected based on the number glucosyl units per cellodextrin-(1→3)β-glucose oligosaccharide, whereas the mass detected by pulsed amperometry was calibrated by direct assay of eluted oligosaccharides.

synthesis demanded a precise ratio of UDP-Glc to UDP-Xyl but formation of hepta-saccharide units of true xyloglucan required mM, not μM concentrations of substrate. β-Glucan synthase has features that resemble cellulose synthase more than other Golgi-associated synthases (Buckeridge et al., 1999). The synthase requires Mg^{2+} (or Mn^{2+}) and has a high apparent K_m for UDP-Glc; maintenance of a high pH external to the Golgi lumen promotes prolonged synthesis of the glucan (Gibeaut and Carpita, 1993). The synthase activity preserved in vitro synthesizes a product containing a distribution of cellotriosyl and cellotetraosyl units similar to that of the native β-glucan when about 250 μM UDP-Glc is provided. Unlike non-gramineous plants, a callose synthase is associated with the Golgi apparatus as well as the plasma membrane, and increases in its activity coincide with loss of β-glucan synthase by action of protonophores or detergent solubilization of the Golgi membranes (Gibeaut and Carpita, 1993, 1994b).

Amor et al. (1995) proposed that the association of sucrose synthase (SuSy) with cellulose synthase provides a mechanism for metabolic channeling of UDP-Glc. In support of this idea, fibrils of callose were synthesized from sucrose and UDP on immobilized tobacco plasma membrane sheets (Hirai et al., 1998). In maize, SuSy is detected immunocytochemically in both a plasma membrane-enriched and Golgi membrane-enriched fractions, whereas in soybeans, the enzyme is detected only in plasma membranes (Buckeridge et al., 1999). Hence, if β-glucan synthase is derived from an ancestral cellulose synthase and possesses a similar mechanism of synthesis, then part of this mechanism may include the association of SuSy to control the supply of UDP-Glc to the active site(s) of the glucan synthase. For this mechanism to work, the catalytic domain of β-glucan synthase would reside on the cytosolic face of the Golgi membranes. The xyloglucan synthase complex is located completely within the lumen of the Golgi apparatus and dependent upon UDP-Glc transport (Muñoz et al., 1996), whereas the plasma membrane-associated callose synthase is predominately on the cytosolic face (Wu and Wasserman, 1993), consistent with the expected topology of substrate acceptor. The membrane topology of the β-

glucan synthase has never been established. We propose that the catalytic domain is on the cytosolic face of the Golgi membrane, and the β-glucan chains, like those of cellulose, are extruded through the membrane into the lumen of the Golgi apparatus.

The unit structure of β-glucan can be altered drastically depending on the UDP-Glc concentration (Fig. 4A and B). We found that sub-optimal UDP-Glc concentrations favor the synthesis of the longer cellodextrin units in β-glucan, particularly the cellotetraosyl unit, whereas at the highest UDP-Glc concentrations tested, the cellotriose and cellopentaose comprised over 90% of the total polymer synthesized (Table 1). The distribution of cellodextrin units in β-glucan synthesized in vitro at high concentrations of UDP-Glc is similar to that of the β-glucan from the lichen *Cetraria islandica* (Wood et al., 1994). Therefore, as saturation with substrate is approached, the polymers are composed of mostly cellotriose units, and cellopentaose units become the next most abundant unit (Fig. 4B).

The mechanism of glucosyl transfer indicated by our data suggest three different modes of glucosyl transfer from UDP-Glc to the non-reducing terminus of the glucan chain, instead of two as in the mechanism of cellulose synthase (Fig. 5A and B). The accumulation of cellopentaose units instead of cellotetraose units at high substrate concentration is fully consistent with the three-mode model of glycosyl transfer. If, as part of a structural regulatory mechanism, the additional mode is of lower affinity than the conserved modes of the ancestral cellulose synthase, then absence of substrate in the third site will introduce a cellobiosyl unit. This terminal unit will be inverted relative to its usual position when the unit moves into the non-reducing acceptor position. This inversion places the O-4 in the active position, and linkage of a subsequent cellotriose unit in the next round will generate a cellopentaosyl unit (Fig. 5C). Two consecutive cellobiosyl units form the cellotetraosyl unit, but such a linkage must create instability in the positioning of the growing chain in the synthase such that it inverts to once again place the O-3 of the non-reducing terminal unit in the acceptor position for the next round of processive transferase activity. Control of cellodextrin unit structure may occur by regulations of substrate concentration channeled to the sites of glycosyl transfer, e.g. via SuSy, or by conformational changes at the catalytic sites by changes from high affinity to low affinity states induced by other regulatory factors.

3.2. Possible relationship of cellulose and β-glucan synthase to callose synthase

Both cellulose and β-glucan synthases appear to "default" to callose synthases when disrupted (Delmer, 1977; Carpita and Gibeaut, 1993). Our model not only distinguishes the mechanisms of cellulose and β-glucan synthase but also predicts that callose synthase arises by loss of function of the multiple modes of glycosyl transfer and "default" to a single one (Fig. 5D). The best evidence for this default pathway comes from discovery of the cellulose synthase gene from *Dictyostelium* (Blanton et al., 2000). *Dictyostelium* makes no callose in vivo but exhibits cellulose and callose synthase activity in vitro (Blanton and Northcote, 1990). A mutation in the *Ces*A gene results in the inability to synthesize either (1→4)β- or (1→3)β-linked glucans, indicating that the product of the *Ces*A gene makes both products in vitro.

An *Agrobacterium* (1→3)β-glucan synthase gene contains the four U-motifs expected of a *Ces*A gene, even though the glucose units are not inverted during synthesis (Stasinopoulos et al., 1999). Such a gene may have derived from an ancestral cellulose synthase, but the encoded synthase may have lost the function of one of the two glycosyl transfer activities. Although it may be reasonable to suggest that callose synthesis may result from damage to cellulose and β-glucan synthases when the plasma membrane and Golgi membranes are disrupted, callose is made naturally at several stages of cell development and can be activated as a wound response. It is more likely that this callose is made by specific callose synthases encoded by genes unrelated to *Ces*A. Cui et al. (2001), Doblin et al. (2001) and Hong et al. (2001) have recently cloned distinct callose synthase homologs of fungal FKS1 synthases. These polypeptides are over 200 kD, are predicted to contain 16 membrane spanning domains, and are associated with other polypeptides thought to be part of the synthase mechanism or its regulation. However, while these findings indicate there may be several distinct synthases of 3-linked glucans, there are no precedents for distinct synthases of (1→4)β-glycans other than those with D,D,D,QxxRW domains.

3.3. Are β-glucan synthase and cellulose synthase both encoded by CesA genes?

The discovery of a higher plant cellulose synthase gene by Pear et al. (1996) has made it possible to compare the deduced amino acid structure of the active site with rational models of catalysis. The *Ces*A genes encode polypeptides of about 110 kDa with the presumed active site comprising a large cytosolic domain with four highly conserved "U" motifs. Each of the first three contains an essential aspartyl residue, and the fourth possesses a QxxRW motif. These four U-motifs of the *Ces*A gene are conserved in the genes encoding several processive glycosyl transferases in which repeating β-glycosyl unit structures are synthesized (Saxena et al., 1995). Some examples include hyaluronan synthases (DeAngelis et al., 1993; Spicer et al., 1997), chitin synthases (Bulawa et al., 1986), and the NodC synthase (Geremia et al., 1994), all of which make consecutive β-glycosidic linkages in which one sugar is oriented nearly

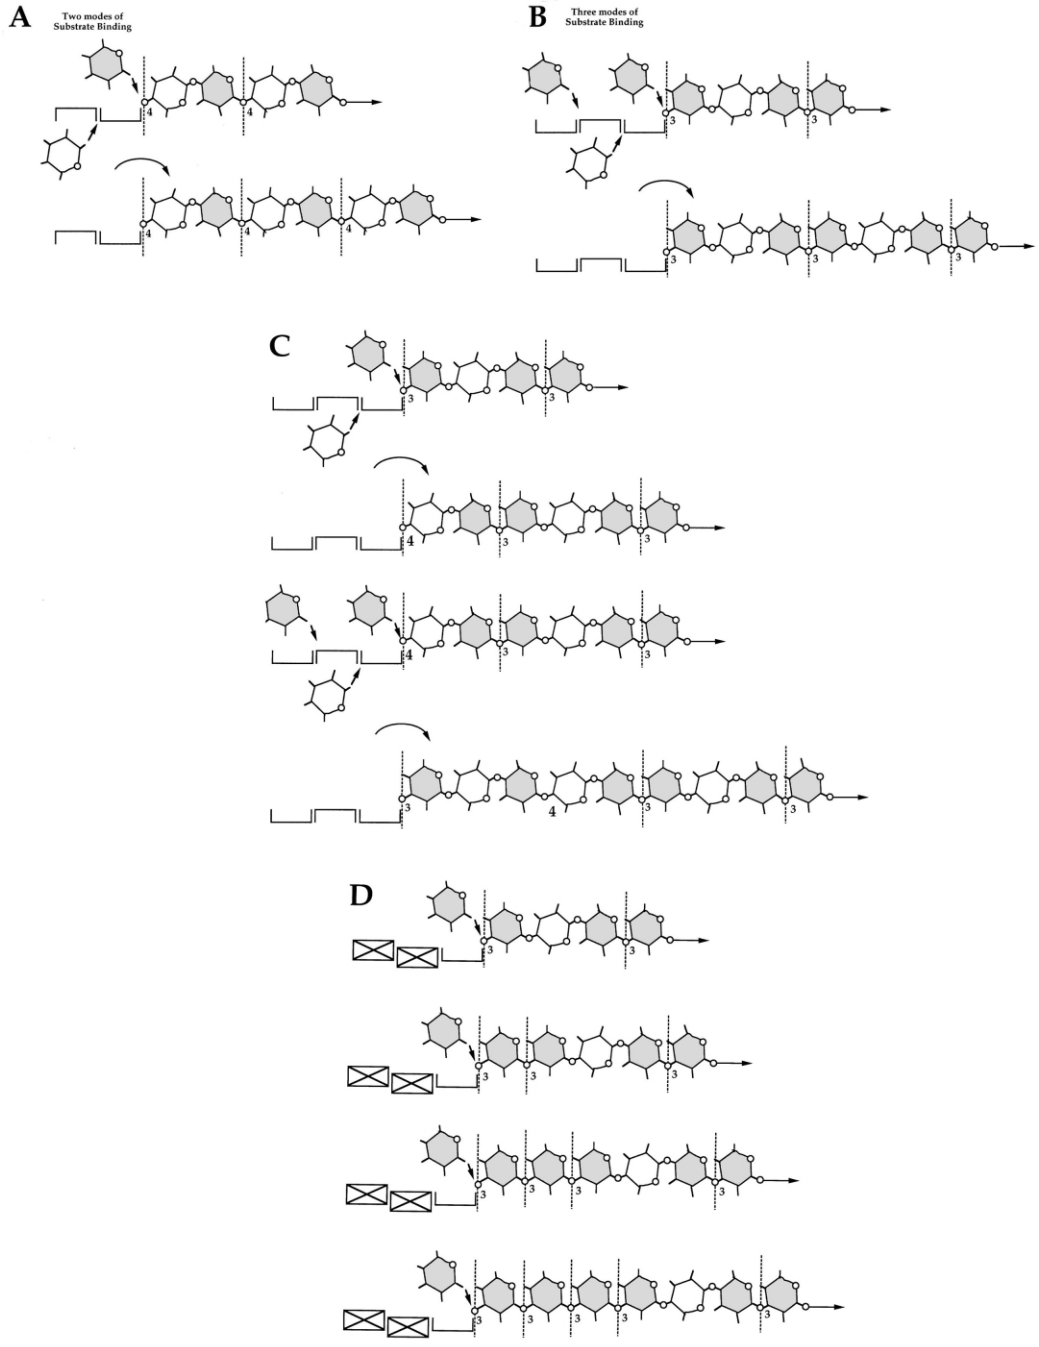

Fig. 5. A model to explain the mechanism of synthesis of (1→4)β-linked glycans, the special case of the (1→3),(1→4)β-D-glucans, and (1→3)β-D-glucans. A. If a single mode of linkage occurs without changing the position of the active site, then a polymer generates an alternating (1→4)β-, then (1→3)β-linkage pattern. However, if two complementary modes of glycosyl transfer occur juxtaposed to each other, then cellobiosyl units are generated and the non-reducing terminal unit will always expose its O-4 position for linkage. This two-mode mechanism assures that the entire polymer is composed of (1→4)β-linkages. A similar mechanism may have been adopted by synthases of the backbones of xyloglucans, xylans, and gluco- and galactomannans. B. Acquisition of a third mode of glucosyl transfer would generate cellotriosyl units instead of cellobiosyl units, and because the first and third units are not inverted, the non-reducing acceptor sugar exposes the O-3 for linkage instead of the O-4 position. Hence, when all three modes are used the polymer made is composed entirely of cellotriosyl-(1→3)β-D-glucosyl units. C. The third mode of transfer may be one of lower affinity than the cellobiosyl generating glucosyl transferases, and failure to fill it produces the longer cellodextrins. If only a cellobiose unit is formed, then its O-4 position is exposed in the active site when this unit occupies the non-reducing terminus position. If a cellotriose is generated in the next round, then a cellopentaosyl unit is made and the O-3 will once again be exposed in the next round of synthesis. Cellotetraosyl units are made if two consecutive cellobiosyl units are added, and cellohexaosyl units are made if three consecutive cellobiosyl units are added. Chain stability must be compromised in these instances because chain rotation to expose the O-3 must occur. Otherwise, celloheptaosyl and cellononaosyl units are made. D. If the multiple modes of glycosyl transfer collapse to a single mode, then no inversion of glucose residues occurs and the O-3 position will always be positioned at the non-reducing end of the growing chain. Callose becomes the only product possible.

180° with respect to each neighboring sugar. These and other "inverting" type processive synthases comprise the family 2 NDP-sugar glycosyl transferases (Campbell et al., 1997). A comparison of arabidopsis, maize, and other higher plant species reveals that the *Ces*A gene family clusters into several sub-classes (Holland et al., 2000). A unique feature of the *Ces*A genes is a plant-specific insertion of sequence that, upon examination of the few *Ces*A sequences, appeared to be highly mutable and was called the "hypervariable region" (Pear et al., 1996; Delmer, 1999). Analysis of the predicted amino acid sequences of a great many *Ces*A genes that had been examined since then revealed motifs of consecutive acidic and basic residues, cysteine residues, proline residues, and aromatic residues that are well conserved in a sub-class specific manner (Vergara and Carpita, 2001). Conservation of these motifs into specific sub-classes indicates that their roles in catalysis of glycosyl transfer or its regulation remain to be defined. However, determination of how these motifs alter the conformation of the active site to direct different modes of glycosyl transfer must await 3-dimensional structure determination and their possible interaction with other proteins. Several mutants of specific members of the *Ces*A gene family are now available and are beginning to shed light on the polymers made by them.

4. Experimental

4.1. Plant material and preparation of membranes

Maize (*Zea mays* L.) seeds (caryopses) were soaked overnight in deionized water bubbled with air at 30°C, sown in trays of moist medium-grade vermiculite, and incubated in darkness at 30°C for 2 days. All procedures were performed essentially as described by Buckeridge et al. (1999). Freshly isolated 2-day-old coleoptiles were collected in a chilled beaker and overlaid with an equal volume of ice-cold homogenization buffer (HB) of 84% sucrose in 20 mM Hepes [KOH], pH 7.2, containing 20 mM KCl, 5 mM EDTA, 5 mM EGTA, 10 mM DTT, and 0.2 mM PMSF. In addition, 2 g of activated charcoal was sprinkled on coleoptiles before addition of HB to absorb inhibitory phenolics released by the maize coleoptiles during mashing (Gibeaut and Carpita, 1993). The homogenate was squeezed through a nylon mesh (47-μm^2 pores), and about 15 ml of the homogenate was pipeted into a 38.5-ml Ultraclear centrifuge tube (Beckman) onto a cushion of 50% (w/v) sucrose in a gradient buffer 20 mM Hepes [BTP], pH 7.6, and overlaid with 8 ml each of 34 and 25% sucrose (w/v), 7 ml of 18% (w/v) sucrose in gradient buffer, and the remaining volume was made up with 9.5% (w/v) sucrose in the same buffer. After sucrose gradient centrifugation at 140,000 *g* in a Beckman SW28 rotor for 45 min, the interfaces containing the enriched Golgi membranes were collected with a Pasteur pipet. These membranes were used directly for β-glucan synthase reactions at low substrate concentration or were diluted with 1.08 M sucrose in gradient buffer and concentrated by centrifugation at 140,000 *g* for 30 min in an SW28 rotor for assays at high substrate concentration (Buckeridge et al., 1999). Samples of the other layers were also taken for protein determination and enzyme marker assays. Protein was determined by bicinchoninic acid assay (Pierce), and assays for IDPase (Golgi), NADH oxidase (mitochondria), vanadate-sensitive ATPase (plasma membrane), NADP reductase (endoplasmic reticulum), and NO_3-sensitive ATPase (vacuole) were performed as optimized for maize from published methods described in Gibeaut and Carpita (1994b).

4.2. Glucan synthase reactions

Reactions were performed with freshly isolated membranes at 30°C for up to 2 h. Reactions at low substrate concentrations were performed in 4-ml borosilicate glass vials and contained, at final substrate concentrations indicated, 0.5–2.0 μCi of UDP-D-[U-^{14}C]Glc (250 mCi/mmol; ICN Radiochemicals), 20 mM KCl, 1.08 M sucrose, 10 mM $MgCl_2$, 10 mM Hepes[BTP], pH 7.6. One-half of a milliliter each of a reaction buffer and membrane fraction (50 to 100 μg protein) were mixed in vials and placed at 30°C. Reactions without radioactivity at high substrate concentrations were performed with concentrated membranes (200 μg protein), and $MgCl_2$ concentrations were 1.5 times that of the UDP-Glc concentration. Reactions were stopped with 3 ml of ethanol, capped, and placed in an oven at 105°C for 5 min. The reaction mixtures were cooled to ambient temperature then centrifuged for 5 min at 10,000 *g*. The pellet was washed extensively with hot 80% ethanol after heating and recentrifuged.

4.3. Digestion with *B. subtilis* endoglucanase as a specific assay for (1→3),(1→4)β-D-glucan

The washed and dried products of the glucan synthase reactions were suspended in 200 μl of water. For reactions at low substrate concentration, 200 μg of barley β-glucan (Sigma) were added as carrier. Ten to fifty μl of a preparation of *B. subtilis* endo-β-D-glucanase (Gibeaut and Carpita, 1993) in 20 mM Na acetate, 20 mM NaCl, pH 5.5, were added, and the samples were incubated 3 h at 37°C. The products released from digestion of purified β-glucan are mostly cellobiosyl- and cellotriosyl-(1→3)-D-glucose, with decreasingly smaller amounts of cellotetraosyl- and cellopentaosyl-(1→3)-D-glucose. The reactions were terminated by heating for 2 min in a boiling water bath, cooled to ambient temperature, and centrifuged at 10,000 *g* for 5 min. Radioactivity in β-glucan was estimated as the difference in dpm in the supernatants

between digested and undigested samples. The remaining insoluble radioactivity from in vitro synthase reactions, which is greater than 90% (1→3)-linked glucosyl units was attributed to callose (Gibeaut and Carpita, 1993).

4.4. HPAEC-PAD

The oligomers from digestion of the in vitro reaction products were separated on a Carbo-Pac PA1 anion exchange column equilibrated in 0.5 N NaOH and eluted in a linear gradient of Na acetate in 0.5 N NaOH as described (Gibeaut and Carpita, 1993). With reactions products from low concentrations of UDP-Glc, the radioactivity in 0.5-ml fractions collected in 1.0 ml of 2 N acetic acid was determined by liquid scintillation spectroscopy, whereas the β-glucan products of high UDP-Glc concentrations and native β-glucans from alkali extracts were determined by pulsed amperometric detection (Buckeridge et al., 1999).

Abstract

The behaviour of four membrane-bound glycosyl transferases involved in cell wall polysaccharide synthesis has been studied in relation to the effects of a graded series of organic solvents on their activity and type of product formed. Relative enzyme inhibition observed for some solvents was in direct relationship to the hydrophilicity of the product. This was in the order of arabinan synthase > callose synthase > xylan synthase > β-1,4-glucan synthase. The former two were always inhibited, the xylan synthase rather less so. However, the β-1,4-glucan synthase showed significant increases in substrate incorporation in the presence of solvents. A graded series of primary alcohols were much more effective in enhancing activity than acetone, ethyl acetate and dimethyl formamide. In the presence of the most effective solvent, methanol, there was considerable activation of β-1,4-glucan production. This reciprocal nature of the behaviour of the β-1,4- and β-1,3-glucan synthases in organic solvent is supportive of recent molecular data that the two types of glucans are catalysed by separate enzyme systems. However, the results reported here do not totally negate the proposition that either enzyme is capable of synthesising the other linkage in minor amounts in vitro. © 2001 Elsevier Science Ltd. Keywords: Glucan; Xylan; Arabinan; Glycosyl transferase; Organic solvent

1. Introduction

The plant cell wall represents a major component of the dry mass of plant tissue. It has long been the major source of dietary fibre and is recognised to play a critical role in determining the rheological properties of plants and food texture. Moreover, it is a dynamic structure and thus has a vital role during plant development and responses to pathogen attack and environmental stress (Bolwell, 1993; Carpita and Gibeaut, 1993). However, our understanding of the biosynthesis of plant cell wall components is limited particularly with respect to polysaccharides. Although considerable progress is at last being made with the molecular identification of the gene family coding for plant cellulose synthase (Pear et al., 1996; Arioli et al., 1999; Taylor et al., 1999), and cDNAs and genes coding for a fucosyl transferase (Perrin et al., 1999) and a galactosyl transferase (Edwards et al., 1999), there is still an enormous lack of knowledge of polysaccharide synthases at the protein level.

The site of synthesis of the matrix polysaccharides has been localised to the Golgi by biochemical studies of fractionated endomembranes (Bolwell, 1988), organelle subfractions (Baydoun and Brett, 1997), and by elegant immunogold localisation of the nascent polysaccharides within the Golgi stack (Moore et al., 1991). However, there are few reports of extensive direct characterisation and identification of the glycosyl transferases involved. A notable exception is the fucosyl transferase specific for a side chain of xyloglucan, a major hemicellulose of the dicot cell wall (Hanna et al., 1991; Perrin et al., 1999), which was purified as an M_r 51,000 protein before confirmation by molecular cloning. Other glycosyl transferases purified are arabinan and xylan synthases as M_r 70,000 and 50,000 proteins, respectively (Rodgers and Bolwell, 1992), and a number of callose synthases including that from French bean as a complex of M_r 65,000 and 55,000 polypeptides (McCormack et al., 1997) and from pea (M_r 70,000 and 55,000) (Dhugga and Ray, 1994). Most other polysaccharide synthases such as galacturonosyl transferases in pectin synthesis (Bolwell et al., 1985; Doong and Mohmen, 1998), glucosyl and xylosyl transferases of primary wall xyloglucan synthesis (White et al., 1993a,b) and glucuronosyl

transferases of secondary wall xylan synthesis (Baydoun and Brett, 1997) remain only partially characterised in membrane and solubilised preparations.

Although identification of the genes coding for such glycosyl transferases may well arise from large sequencing projects (Bolwell, 2000; Gibeaut, 2000), for instance there are many putative cellulose synthase genes in the Arabidopsis dbEST and genomic data bases, there will still be a need for the demonstration of activity in vitro for the expressed gene products. Part of the reason for the difficulties in purifying these enzymes is the loss of activity on solubilisation which is not entirely due to the release of hydrolytic activity.

In theory, the basis for some of these problems of loss of activity probably resides in their relationship to water (Bolwell, 1993). The glycosidic bond is of relatively low energy and can be readily made and broken. Thus, there are abundant reports of enzymatic transglycosylation reactions for plant glycosidases. The exclusion of water could, therefore, promote glycosidic bond formation and reflect a situation appertaining to proteins associated with membranes in vivo. There are now numerous examples in the literature that glycosidases can be driven in reverse under non-aqueous conditions. Examples include the synthesis of cellulose by *Trichoderma* cellulase using β-cellobioside fluoride as substrate (Kobayashi et al., 1991, 1996a) and polymers of xylan and chitin have also been produced in a similar manner (Kobayashi et al., 1996b,c). Even hetero-oligosaccharides have been produced using glycosidases (Bucke et al., 1999). We know of no reports of glycosyl transferases from plants being assayed under non-aqueous conditions as yet.

Overall there has been increasing interest recently in the behaviour of enzymes in organic media in general (Carrea and Riva, 2000; Kilbanov, 2001). Increased stability, catalysis of reactions impossible in water and changes in enzymatic selectivity even to the extent of inversion in the solvent have all been reported. We have tested such hypotheses by exposing plant glycosyl transferases, either in their membrane-bound or solubilised form, to aqueous environments and observing changes in their behaviour. A number of polysaccharide synthases were examined in relatively increased hydrophobic environments. Those enzymes that synthesise relatively hydrophilic products were inhibited whilst those with hydrogen-bonded products were stimulated. A dehydrating effect would be consistent with in vivo conditions for glycosyl transferase activity and may be useful for further characterisation of these enzymes.

2. Results and discussion

Membrane preparations were exposed to a graded series of organic solvents and assayed for arabinan synthase, xylan synthase and glucan synthase (Figs. 1 and 2). Arabinan synthase was inhibited by all solvents and at all concentrations used. Arabinan is a soluble plant polysaccharide therefore increasing the hydrophobicity of the assay medium might be expected to result in reduced production of product. Xylan synthase activity was much less affected by solvents although no marked stimulation of activity was observed. The glucan synthases showed significant differences in behaviour. Under conditions favouring the synthesis of callose, the effect of organic solvents was to almost universally inhibit callose synthase activity. This is consistent with callose being made under conditions of cell damage, reduced membrane integrity as at cell plates, or where the membranes are exposed to aqueous phases such as at plasmodesmata, sieve plates or during plasmolysis.

In contrast, organic solvents increased the activity of β-1,4-glucan synthase of which there are at least two cellular sites of activity in vivo. The synthesis of this linkage and the formation of aggregated polymers is likely to be favoured by the exclusion of water (Bolwell, 1993). Reduction of water activity by inclusion of organic solvents led to increased activity, particularly in the presence of methanol, ethanol (Fig. 1C) and ethyl acetate (Fig. 2B). It was not possible to synthesise enough product to attempt methylation analysis. However the products were characterised by solubility properties, susceptibility to specific enzyme digestion and chemical analysis (Table 1). This showed the β-1,4-synthase product to be polymeric in nature but showed no evidence of a crystalline structure. Enzyme digestion liberated both β-1,4- and β-1,3-linked glucose from the product synthesised under conditions favouring β-1,4-glucan synthesis. However, this ratio was markedly increased from 2:3 to 15:1 for release of β-1,4- and β-1,3-linked glucose in the product synthesised in the presence of organic solvent. In contrast, under the assay conditions favouring β-1,3-glucan synthase activity, the membrane preparation and a solublilised protein preparation synthesised products with the ratios 1:2 and 1:3, respectively, for release of β-1,4- and β-1,3-linked glucose (McCormack et al., 1997). Addition of 40% methanol under conditions favouring β-1,3 glucan synthesis virtually abolished this activity (Fig. 1D). Thus, the addition of organic solvent provided stimulatory assay conditions for β-1,4-glucan synthase, but inhibited β-1,3-glucan synthesis.

Glycosidases, including those from plants, have been the subject of a large number of investigations with regard to the reverse activity which is often promoted in the presence of organic solvents (Kobayashi et al., 1991; 1996a,b,c). This is important biotechnologically as it affords a method for the directed synthesis of biologically active oligosaccharides (Bucke et al., 1999). The present work describes the behaviour of plant glycosyl transferases involved in cell wall homopolymer biosynthesis as these may also be useful reagents in defined

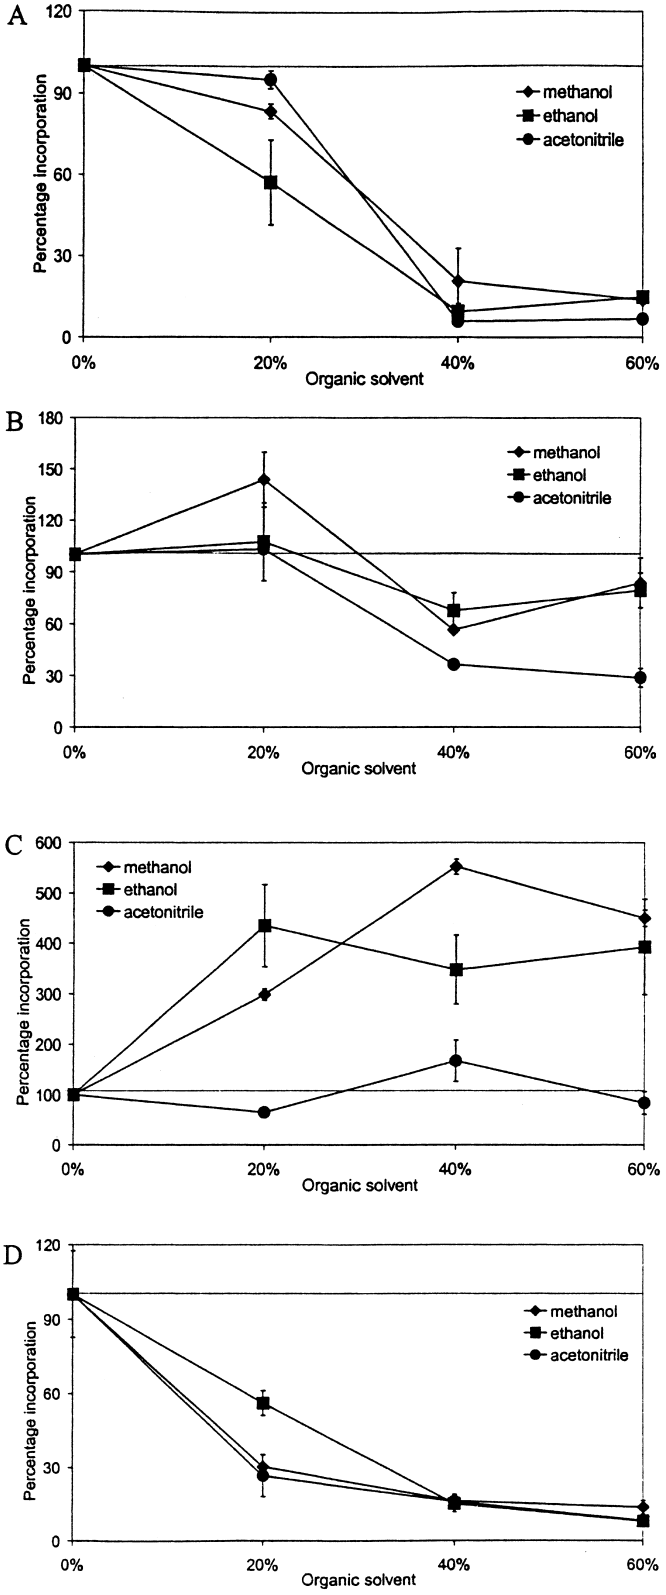

Fig. 1. Comparison of the effect of methanol (diamond), ethanol (square) and acetonitrile (circle) in H_2O on the activities of (A) arabinan synthase; (B) xylan synthase; (C) β-1,4-glucan synthase and (D) callose synthase in microsomal membranes from French bean. Two hundred grams of cells were used to derive the microsomal membranes from the different sources of French bean cells specific for each enzyme. The specific membrane fraction was used for the assay of each individual enzyme in the presence of various concentrations of organic solvent. Incorporation of radioactive substrate into characterised polysaccharide is shown as a percentage value in comparison to the same assay in the absence of organic solvent. Repeated experiments resulted in the same trends and the error bars are shown for three replicates of a representative experiment.

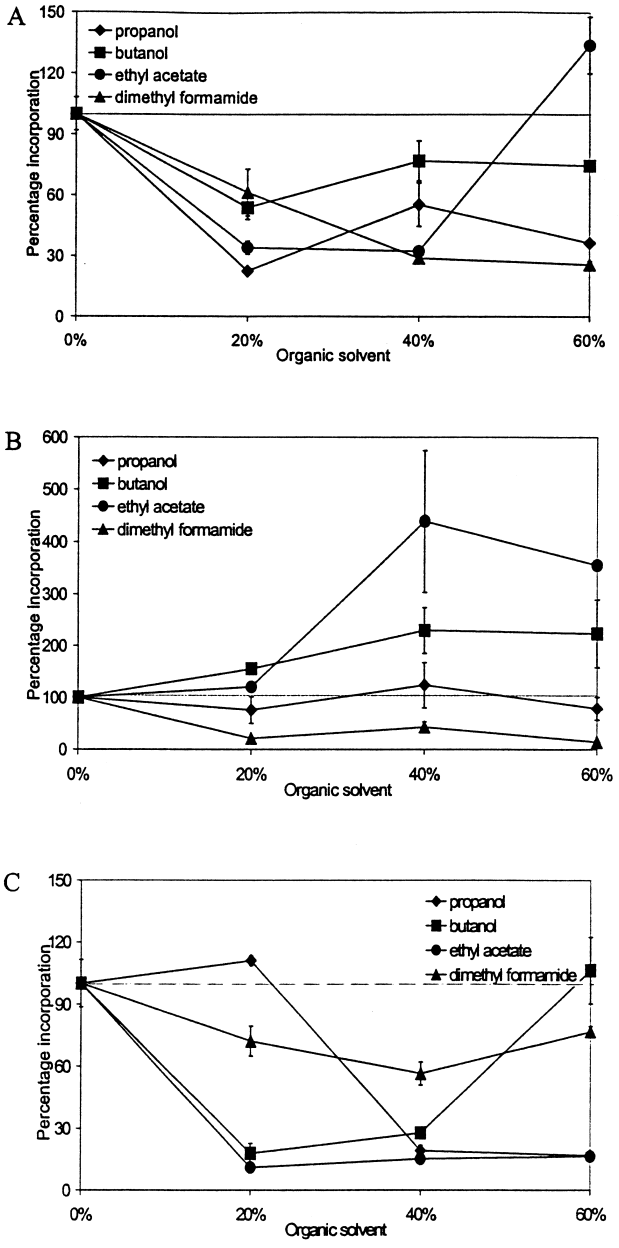

Fig. 2. Comparison of the effect of propan-2-ol (diamond), butan-2-ol (square), ethyl acetate (circle) and *N*,*N*-dimethylformamide (triangle) in H_2O on the activities of (A) xylan synthase; (B) β-1,4-glucan synthase and (C) callose synthase in microsomal membranes from French bean. Experiments were performed as for Fig. 1. Arabinan synthase was completely inhibited by these solvents at all concentrations.

synthesis of oligosaccharides. In addition if their activity were to be potentiated, this might be useful in improving recoveries during isolation and purification, so improving understanding and characterisation of these poorly described plant enzymes. Furthermore, suppression of competing reactions may also be desirable, as seen for the effect on the glucan synthases.

We have examined a number of polysaccharide synthases in relatively increased hydrophobic environments

Table 1
Characterisation of the β-1,4-glucan product synthesised with and without the addition of 40% methanol in H_2O[a]

Treatment	Product made by membranes	Product made in the presence of 40% methanol in H_2O
Radioactivity remaining in dialysis bag (%)	61.8	93
Radioactivity solubilised by laminarinase (%)	46	6.2
Radioactivity solubilised by cellulase (%)	75.1	92.4
Radioactivity soluble in DMSO (%)	98	83
Radioactivity soluble in NaOH (%)	97	67
β-1,4-:β-1,3-linked glucose liberated	2:3	15:1

[a] The polysaccharide product made under the conditions for β-1,4-glucan synthesis was analysed from membranes without the addition of organic solvent and in the presence of 40% methanol in H_2O, the condition observed to give highest stimulation of activity (five-fold).

and have found that those enzymes that synthesise relatively hydrophilic products were inhibited while those synthesising extensively hydrogen-bonded products were stimulated, particularly in the presence of primary and secondary alcohols. Thus, the synthesis of arabinan which is amongst the most soluble polysaccharide known was completely inhibited in the presence of organic solvent. Callose synthase which appears to be activated in situations where the plasmamembrane is exposed during stress, such as pathogen attack or developmentally at plasmodesmata or sieve plates (McCormack et al., 1997; Brown et al., 1998) was also inhibited by inclusion of organic solvents.

However, synthesis of the two products which favour hydrogen-bonding, xylan and β-1,4-glucan were relatively unaffected or increased. The dehydrating effect of organic solvent would be consistent with theoretical considerations of the optimum conditions for glycosyl transferase activity and may be useful in the further characterisation of these important but elusive plant enzymes. Clearly this favours β-1,4-glucan synthesis in preparations containing both β-1,4- and callose synthase activities. The fact that callose synthase activity can be virtually suppressed while β-1,4-glucan synthase is activated may support the growing molecular evidence that these are separate enzyme systems, which could not be resolved previously using biochemical data. However, there is no compelling reason to reject the notion that both enzymes have a limited capacity for synthesising small amounts of the other linkage in vitro. This would explain the apparent presence of mixed linkages in the products. However within the intact cell this specificity would be much less redundant due to the complex regulation of cellulose and callose synthesis.

3. Experimental

3.1. Materials

Suspension cultures were derived and maintained as previously described (Dixon and Lamb, 1979). Cell suspension cultures were subjected to biotic stress between 4 and 6 days after subculture. *Colletotrichum lindemuthianum*-derived elicitor was added to a concentration of 30 μg/ml glucose equivalents and cell samples taken at intervals. Over the period of elicitor treatment no gross effects on cell growth were observed (Bolwell et al., 1985). Uniformly labelled UDP-[^{14}C]-glucose (295 mCi mmol^{-1}) and UDP-[^{14}C]-xylose (266.7 mCi mmol^{-1}) was obtained from NEN, Stevenage, Herts., UK. UDP-[^{3}H]-arabinose was made as previously described (Bolwell and Northcote, 1981).

3.2. Preparation and treatment of plant extracts

For studies of glucan synthase activities, 4–6 day post sub-culture cells were homogenised in 50 mM Tris–HCl pH 7.2, 10 mM magnesium chloride, 1 mM dithiothreitol, 0.3 M sucrose, 1% (w/v) polyvinyl pyrrolidone at 4°C. The extract was filtered through three layers of muslin and centrifuged at 10,000 *g* for 10 min to remove cellular debris. The resultant supernatant was spun at 100,000 *g* for 90 min to pellet the microsomes, which were resuspended in 50 mM Tris pH 7.2 to give a final protein concentration of between 15 and 30 mg per ml, as determined using the Bradford protein assay (Read and Northcote, 1981).

Studies of arabinosyl transferase activity, were carried out using microsomes prepared from unelicited bean cell cultures 2–4 days after sub-culture (Rodgers and Bolwell, 1992). After harvesting the cells by vacuum filtration, microsomes were prepared as described above.

For studies of xylosyl transferase activity, 13 day old bean hypocotyls (Rodgers and Bolwell, 1992) were homogenised in 50 mM Tris–HCl pH 7.2, 10 mM magnesium chloride, 1 mM dithiothreitol, 0.3 M sucrose, 1% (w/v) polyvinyl pyrrolidone at 4°C. The extract was filtered through three layers of muslin and centrifuged at 10,000 *g* for 10 min to remove cellular debris. The resultant supernatant was spun at 100,000 *g* for 90 min to pellet the microsomes, which were resuspended in 50 mM Tris pH 7.2 to give a final protein concentration of between 15 and 30 mg per ml, as determined using the Bradford protein assay (Read and Northcote, 1981).

3.3. Enzyme assays

3.3.1. β-1,4-Glucan synthase

β-1,4-Glucan synthase activity was determined by a modification of the method of Ray (1980). Reaction mixtures contained membrane fractions in 40 mM Tris–HCl (pH 8.0), 3 mM $MgCl_2$ and 0.71 μM UDP-[^{14}C]-glucose final concentration in a total volume of 50 μl. Reactions were terminated after 10 min with the addition of 0.5 M EDTA to 10 mM and incorporation of radioactive glucose into polymeric products determined by high voltage paper electrophoresis which causes migration of the UDP-glucose away from the origin which contains the synthesized glucan (Bolwell and Northcote, 1981). Incorporation into lipid, glycoprotein and polysaccharide was determined after fractionation of the products (Bolwell and Northcote, 1983) and was a further check for incorporation into glucans.

3.3.2. Callose synthase

Callose synthase activity was determined by a modification of the method of Delmer (1987). Membranes were incubated in 100 mM HEPES buffer (pH 6.8) containing 3 mM $CaCl_2$, 1 mM UDP-glucose and 0.7 μM UDP-[^{14}C]-glucose final concentration in a total volume of 50 μl. Reactions were terminated after 10 min with the addition of 0.5 M EDTA to 10 mM. Total incorporations were determined by high voltage paper electrophoresis. The products were also fractionated as described.

3.3.3. Arabinan synthase and xylan synthase

Incubation conditions using radiolabelled substrate were as described previously (Bolwell and Northcote, 1981, 1983). Product analysis was carried out by high voltage paper electrophoresis in 8% acetic acid, 2% formic acid (w/w) also previously described (Bolwell and Northcote, 1981), or by precipitation and multiple washes of the polymer with cold 70% ethanol containing 1 mM EDTA before (Bolwell and Northcote, 1983). Determination of radioactivity was by liquid scintillation counting.

3.4. Characterisation of β-1,4-glucan product

The product was dialysed overnight to give an indication of the minimum M_r (30 kDa cut-off). and the radioactive material retained was determined by liquid scintillation. Enzyme digestion was performed with *Trichoderma* laminarinase (EC 3.2.1.6, Sigma) or *Aspergillus niger* cellulase (EC 3.2.1.4, Sigma) at 1 mg/ml in 50 mM sodium acetate buffer pH 5.0, at 37°C overnight. Following dialysis the remainder was counted by liquid scintillation. Solid ethanol-precipitated product was dissolved in dimethyl sulfoxide (DMSO) or 4 M sodium hydroxide. Dissolution and centrifugation of the pellet allowed observation of the ^{14}C remaining and incorporated into polymeric material.

Received 1 September 2000; received in revised form 17 November 2000

Abstract

Most tree species show in the inner parts of their woody axes often a dark colored zone, the heartwood. Its formation is a genetically determined, programmed cell death which is characterized by the activation of metabolic pathways which lead to the formation of phenolic heartwood extractives. In the present paper we report on the key position of the oxidative pentose phosphate pathway (OPP) for this process. The OPP plays a crucial role in anabolic processes and is involved in the interconversion and rearrangements of sugar-phosphates with the net production of NADPH. In tissues of *Robinia pseudoacacia* L. which are transferred to heartwood, enhanced activities of glucose-6-phosphate dehydrogenase (G6PDH) and 6-phosphogluconate dehydrogenase (6PGDH) are present. A consequence of these increased enzyme activities is a shift in the pyridine nucleotide pool towards NADP + NADPH at the expense of NAD + NADH. These alterations in the metabolism and the redox status probably provide precursors and reduction equivalents being required for the synthesis of heartwood phenolics. The non heartwood forming species *Acer pseudoplatanus* L. shows neither a radial gradient nor seasonal changes in the amounts of pyridine nucleotides across the trunkwood. The results are discussed in connection with programmed cell death, mitochondrial activity, and heartwood formation.

1. Introduction

In cross-sections of freshly felled trees at least two colored zones can usually be observed: a pale-colored outer zone — the sapwood — and a dark-colored inner core — the heartwood. The sapwood has been defined as "the portion of the wood that, in the living tree, contains living cells and reserve materials (e.g. starch)" (Anon., 1957). Heartwood, on the other hand, is defined as "the inner layers of the wood, which, in the growing tree, have ceased to contain living cells, and in which the reserve materials (e.g. starch) have been removed or converted into heartwood substances" (Anon., 1957).

This distinction into different colored zones of the trunk is not verified in all tree species. *Alnus glutinosa, Tilia cordata,* and species of *Acer* are examples for trees which do not form heartwood. These species are called sapwood trees. Heartwood must not necessarily be of darker color; e.g. trees of *Picea abies* contain a pale-colored heartwood, named ripewood. In roots, heartwood is formed in the region near the stem wood.

The formation of heartwood results from cell death due to internal factors and represents a phenomenon associated with the annual cycle of the life of a tree. It was demonstrated that cell death during heartwood formation starts with the depletion of starch components in the parenchyma cells which is based on enhanced amylolytic activity. Additionally, hydrolysis of sucrose plays an important role in the transformation of sapwood into heartwood. Recent findings make it plausible that enhanced enzyme activities are regulated by gene expression (Hauch and Magel, 1998). In the beginning of heartwood formation, products of sucrose breakdown are utilized as substrates for glycolytic and respiratory

energy production (Magel, 2000). In a later stage of heartwood formation — when mitochondrial respiration is blocked — carbon compounds are increasingly used for the in situ synthesis of phenolic extractives. In *Robinia pseudoacacia* L. (black locust), flavonoids which accumulate within the heartwood are formed by an increased catalytic activity of the key enzymes of the phenyl propanoid pathway, phenylalanine ammonia-lyase, and of the flavonoid pathway, chalcone synthase. At least in *Robinia*, the accumulation and cellular distribution of these phenolic compounds within heartwood tissues seem to involve a mechanism of an enzymatically initiated but chemically driven copolymerization of the phenolic derivatives and the preexisting cell-wall macromolecular components including lignins and lignin-polysaccharide complexes (Magel et al., 1995). This mechanism explains the occurrence of a relative increase in lignin content of heartwood which, however, is not due to an increase in monolignol polymerization. Thus, at least in angiosperm trees, a de novo synthesis of lignin during heartwood formation can be excluded.

Histochemical investigations revealed that the oxidative pentose phosphate pathway (OPP) might be a prerequisite for the synthesis of heartwood phenolics (Baqui and Shah, 1985). Key enzymes of the pathway are two dehydrogenases, glucose-6-phosphate (G6PDH) and 6-phosphogluconate dehydrogenase (6PGDH). These two dehydrogenases are involved in the supply of sugar phosphates and reduction equivalents.

In the present paper, we give evidence for the important role of the OPP during heartwood formation. Applying enzymic cycling techniques we followed the generation of reduction equivalents starting in the transition zone between sapwood and heartwood. Simultaneously, we measured the catalytic activities of G6PDH and 6PGDH in the trunkwood of the heartwood forming *R. pseudoacacia* L. at different seasons of the year. As a reference, we used the non heartwood forming "sapwood" tree *Acer pseudoplatanus* L.

2. Results and discussion

The oxidative pentose phosphate pathway (OPP) plays a prominent role in plant metabolism. Metabolic challenges such as vigorous growth during cambial differentiation (Magel et al., 1996; Gahan et al., 1997), cold-hardening (Sagisaka, 1974), and dormancy release (De Meillon et al., 1990) are accompanied by enhanced activities of this pathway. Increased amounts of transcript and activities of the key enzymes of OPP characterize stress responses to heavy metals (Kampfenkel et al., 1995; Slaski et al., 1996) or infection (Norman et al., 1994; Fahrendorf et al., 1995; Batz et al., 1998; Sindelar et al., 1999). In these cases, the activity of the OPP is connected with the production of phenolics as part of an active defense mechanism. Recently, enzymes of OPP (G6PDH and 6PGDH) were ascribed to play an important role in the process of programmed cell death (Tian et al., 1999).

Many features of heartwood formation in trees resemble programmed cell death. Both events have loss of cell integrity and formation of phenolics in common. Thus, it seems reasonable to speculate that the oxidative pentose phosphate pathway might also be an important switch for carbon flow into the formation of heartwood phenolics. Our results show that both reduction equivalents and substrates for heartwood formation are provided by this pathway. This was proven by enhanced activities of the two key enzymes of the pathway, G6PDH and 6PGDH, and a dominance of the tri-phospho-pyridine nucleotides, NADP and NADPH, within the tissues transformed into heartwood.

2.1. Catalytic activities of glucose-6-phosphate dehydrogenase (G6PDH) and 6-phosphogluconate dehydrogenase (6PGDH)

Regarding enzyme properties such as Michaelis–Menten type saturation kinetics, apparent K_m values (40 μM G6P, 10 μM NADP for G6PDH and 54 μM 6PG and 7.5 μM NADP for 6PGDH), pH optima (7.8 and 7.4 for G6PDH and 6PGDH, respectively) and dependence on magnesium ions, G6PDH and 6PGDH from black locust sapwood tissues (data not shown) are very similar to respective enzymes from other green and non-green plant tissues (Guttenberger et al., 1994, and references therein).

Tree to tree variations of the enzyme activities were small as shown for four trees which were harvested in January (Fig. 1A and B). Thus we conclude that results from one tree are representative for the respective tissue and sampling date.

On a protein basis, the living bark contains low activities of both G6PDH and 6PGDH. In the wood, catalytic enzyme activities vary with trunk depth and season (Fig. 1A and B). In April, G6PDH and 6PGDH activities are high in the outer sapwood (Fig. 1A) and seem to be involved in xylem differentiation and cell wall synthesis, predominantly lignin (Magel et al., 1996). Involvement of the enzymes of OPP in xylem differentiation (including lignification) is reported for *Populus gelrica* (Sagisaka and Asada, 1981) and also for non-woody species (Pryke and apRees, 1976; Miller et al., 1985). Samples harvested in January or September showed enhanced enzyme activities both in the outermost, youngest tissue and at the sapwood heartwood transition zone. In November, however, the activity of G6PDH steadily increased from the bark to the inner sapwood. In any case, G6PDH activity dropped from the transition zone up to the heartwood boundary and was absent in the heartwood proper (Fig. 1A). For 6PGDH, the activity profile over

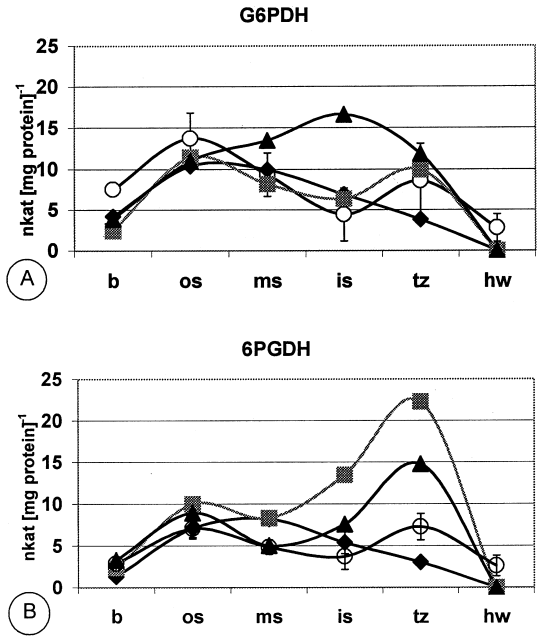

Fig. 1. Extractable catalytic activities of glucose-6-phosphate dehydrogenase (G6PDH; upper panel A) and 6-phosphogluconate dehydrogenase (6PGDH; lower panel B) in a radial stem transect of *Robinia pseudoacacia* L.. The samples were collected in January (○), April (◆), September (■), and November (▲). For the samples harvested in January standard deviation is given for four trees [bark (b), outer (os), middle (ms) and inner (is) sapwood, sapwood–heartwood transition zone (tz) and heartwood (hw)].

a radial transect peaked at the sapwood heartwood transition zone. This was most pronounced in samples collected in September and November. As no lignification takes place during heartwood formation (Magel et al., 1995), enzymes of the OPP should contribute to the supply of reduction equivalents and of precursors for the in situ synthesis of phenolic heartwood compounds. Activities of key enzymes of the OPP and those of flavonoid biosynthesis (phenylalanine ammonia-lyase and chalcone synthase) are closely correlated (Daniels et al., 1990; Magel et al., 1991; Magel and Hübner, 1997). Thus, these two pathways coincide in time and location with heartwood formation.

The activity of G6PDH depends on the water status of the tissue (Eichhorn and Corbus, 1988) and on the NADPH/NADP ratio (Ashihara and Komamine, 1974; Oka et al., 1981). The drop in the catalytic activities of G6PDH in contrast to that of 6PGDH (Fig. 1) within the transition zone in November might be due to a different sensitivity of this enzyme to the physiological changes and thus status of the tissues being transformed into heartwood. From the redox modulation of the G6PDH activities a presumable plastidic localization of the oxidative pentose phosphate pathway (Graeve et al., 1994, VonSchaeven et al., 1995) with only limited cooperation with the cytosolic OPP (Averill et al., 1998) can be concluded.

Commonly, the ratios of the activities of G6PDH/6PGDH are about 2 or higher (Guttenberger et al., 1994). In the trunkwood of black locust, however, the ratio is about 1 or even lower, indicating an optimized flux through the OPP (DeMeillon et al., 1990).

The ageing of the sapwood and heartwood formation in *Robinia* is accompanied by genetic alterations, as shown by changed similarity indices of the tissues based on RAPD-PCR investigations (DeFilippis and Magel, 1998). 6PGDH isoenzyme patterns are used for genetic studies in both woody (Solar et al., 1994; Bergmann and Gillet, 1997) and non-woody species (Bletsos et al., 1998). During heartwood formation, G6PDH (one activity band) and 6PGDH (two activity bands; data not shown) showed no differences in banding pattern. Thus, enzymes of the OPP do not contribute to the genetic differences connected with ageing of the sapwood.

2.2. Pool sizes of pyridine nucleotides

Pyridine nucleotides play a crucial role in such diverse processes like flower induction (Bonzon et al., 1983), wound reactions (Brinkman et al., 1982), leaf senescence (Meyer and Wagner, 1986), and cambial growth of trees (Magel et al., 1996). However, their role in one of the most important secondary differentiation processes of trees, the formation of heartwood, has still to be elucidated.

The total amounts of pyridine nucleotides in mature wood of *Robinia* and *Acer* are in the range of values reported for other green and non-green plant tissues and are considerably lower than within the actively growing, differentiating cambial tissue (Magel et al., 1996).

In the heartwood forming *R. pseudoacacia*, the pyridine nucleotides NAD, NADH, NADP, and NADPH were present in all stem tissues investigated. With increasing age of the sapwood and thus declining amount of living cells present within the tissue, the pool of total pyridine nucleotides decreased. In the dead, physiologically inactive heartwood, a low but constant pool is found (Fig. 2A–C).

Like in other plant tissues, NAD is the dominating pyridine nucleotide in bark and sapwood. Its contents are high in the bark and the outermost wood tissue, gradually decrease with increasing age of the sapwood and reach lowest values within the heartwood. The tissue specific contents of NADH, NADP and NADPH are lowest in the inner sapwood and increase towards both, the younger, physiologically active sapwood and the physiologically inactive heartwood (Figs. 2A–C). In specimens harvested in November, the amounts of the reduced forms (NADH and NADPH) peak in the youngest heartwood zone adjacent to the transition zone (Fig. 2C). In contrast, the wood of *A. pseudoplatanus* shows neither a pronounced radial gradient nor seasonal fluctuations in the amounts of pyridine nucleotides

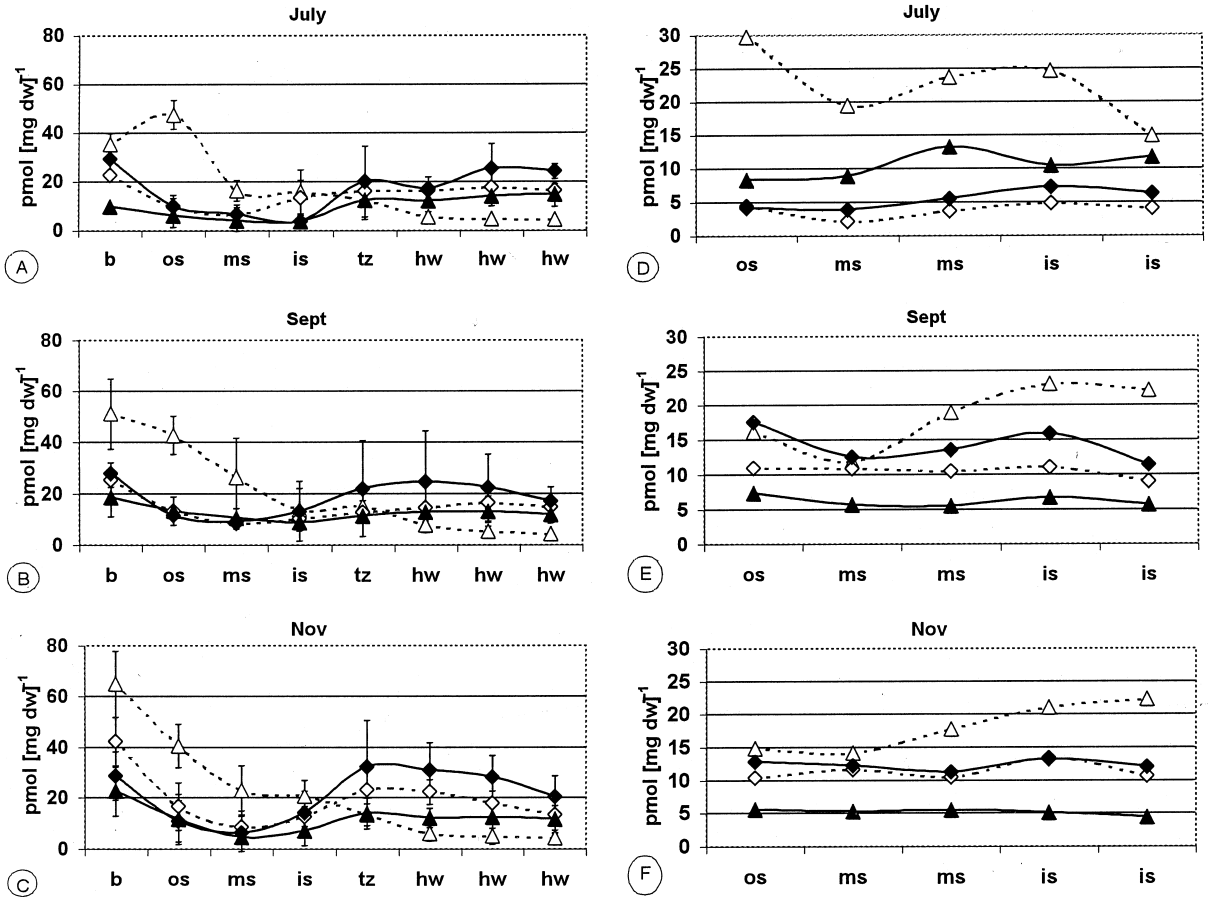

Fig. 2. Pools of the pyridine nucleotides NAD (△), NADH (◇), NADP (▲), and NADPH (◆) in radial stem transects of the heartwood forming *Robinia pseudoacacia* (A to C) and the sapwood tree *Acer pseudoplatanus* (D to F) are shown. The samples harvested in July (A, D), September (Sept; B, E) and November (Nov; C, F) are compared. Standard deviation is given for three trees [for legend, see Fig. 1, except that heartwood tissues of increasing age (hw) are shown].

(Figs. 2D–F and 3A). NAD constitutes the dominating pyridine nucleotide in all wood tissues.

Like in many other plant tissues showing predominantly maintenance metabolism, di-phospho-pyridine nucleotides dominate within the sapwood of maple and black locust. The ratio of tri-phospho-pyridine nucleotides to di-phospho-pyridine nucleotides is lower than 0.6 (Fig. 3A). In *Robinia*, the change in the pyridine nucleotide pool towards higher amounts of tri-phospho-pyridine nucleotides within the sapwood heartwood transition zone coincides with physiological alterations such as cell death, enhanced activities of the enzymes of the oxidative pentose phosphate pathway, and formation of phenolic substances. This shift is based on both a decrease in the pool of di-phospho-pyridine nucleotides and an increase in the pool of tri-phospho-pyridine nucleotides (Fig. 3B). It can be assumed that increased activities of a NAD-kinase (Magel et al., 1996) are involved in generating this shift. In dead heartwood tissue, the presence of pyridine nucleotides and the maintained preponderance of the NADP-system point towards a sudden cell death accompanied by an incomplete withdrawal of metabolites during heartwood formation.

Within the sapwood of black locust trunks, the redox state of the NAD-system (ratio of NADH to NAD; Fig. 4A) is below 1, and thus in a range reported for other plant tissues and species. The pronounced increase in this ratio up to 3.5 within the transition zone and the outermost heartwood is an indication for physiological and structural changes of these particular tissues. The increase in the NADH pool might be due to enhanced glycolysis, characteristic for heartwood formation (Hauch, 1997; Magel, 2000). The question whether the formation of NADH is due to reversible hydrogen transfer between NADPH and NAD by transhydrogenases (Bykova et al., 1999), or via the catalysis by phosphatases from NADPH (Schmidt and Schuck, 1996) cannot be answered at present. The redox state of the NADP-system (ratio of NADPH to NADP; Fig. 4A) ranged between 1 and 2.5 and is thus higher than in other plant tissues. In all tissues of the trunks harvested in July (except bark), the NADPH/NADP ratios were between 1.5 and 2, with no tissue specific pattern. In trunks collected in September

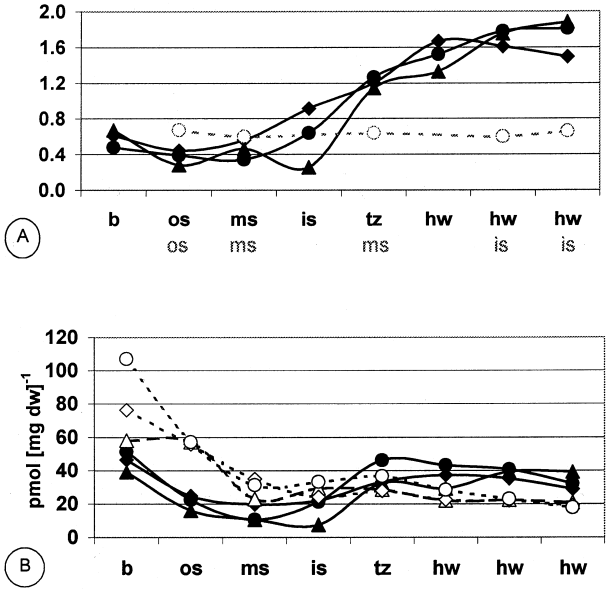

Fig. 3. (A) Calculated ratios of tri-phospho-pyridine nucleotides and di-phospho-pyridine nucleotides (NADP + NADPH/NAD + NADH) in radial stem transects of the heartwood forming *Robinia pseudoacacia* at different times of the season (▲, July; ◆, September; ●, November) and the sapwood tree *Acer pseudoplatanus* (○). (B) Content of tri-phospho-pyridine nucleotides (▲, ◆, ●) and di-phospho-pyridine nucleotides (△, ◇, ○) in radial stem transects of the heartwood forming *R. pseudoacacia* at different times of the season (▲, △, July; ◆, ◇, September; ●, ○, November). For legend, see Fig. 2.

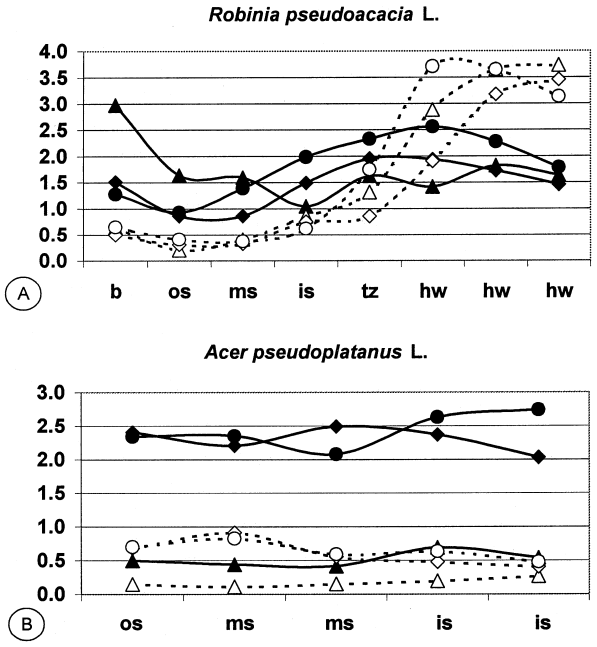

Fig. 4. Calculated redox state of the NADP-system (NADPH/NADP; ▲, ◆, ●), and the NAD-system (NADH/NAD; △, ◇, ○) in radial stem transects of the heartwood forming *Robinia pseudoacacia* (A) and the sapwood tree *Acer pseudoplatanus* (B) at three different times of the season (▲, △, July; ◆ ◇, September; ●, ○, November). For legend, see Fig. 2.

and November, the NADPH/NADP ratios were elevated in the transition zone and the outer heartwood. This coincided with the activation of the enzymes of the OPP. Increased pools of both NADH and NADPH within the innermost wood tissues might reflect reduced rates of NAD(P)H oxidation by NAD(P)H dehydrogenases (Moeller, 1997). The inactivation of these enzymes can be seen in context with the disturbance of the integrity of the mitochondria which was shown by electron microscopic investigations (Magel, unpublished data) or, as the activities of both enzymes are Ca^{2+} dependent, on free, cellular Ca^{2+}-concentrations (Hillinger, Magel and Wagner, unpublished data). NADH and NADPH inhibit in part the penetration of ADP through the outer mitochondrial membrane (Lee et al., 1996): the result is a rise in cytosolic NADH pools which in turn negatively affects glycolysis by inhibition of phosphofructokinase (Gottschalk and Kemp, 1981). This enhances metabolic flow through the OPP.

It is noteworthy that, in contrast to *Robinia*, the sapwood tree *Acer pseudoplatanus* L. showed no pronounced alterations in metabolism with ageing of the tissue. In this tree species no change in the redox state of the NAD-system or the NADP-system across the trunkwood occurs (Figs. 2 D–F, 3A and B and 4B). We thus conclude that during heartwood formation in *Robinia* the redox system of the pyridine nucleotide system is increased. As a consequence of these events catabolic pathways are inhibited and reducing equivalents are predominantly diverted to anabolic pathways, such as the synthesis of phenolic compounds which are accumulated in the heartwood.

3. Materials and methods

3.1. Plant material

Stem discs were collected from the heartwood forming tree species *Robinia pseudoacacia* L. and from *Acer pseudoplatanus* during one season in a forest near Munich, Germany. Freeze-stopping of metabolic processes within the specimen was achieved by deep-freezing the samples in liquid nitrogen immediately after withdrawal from the trunk. After freeze-drying, the specimens were divided into inner bark and individual growth ring tissues. In *Robinia*, the latter were separated into outer, middle, and inner sapwood, the sapwood–heartwood transition zone, and the heartwood proper by macroscopic (color) and microscopic (starch distribution), features. Depending on growth conditions of the individual trees, each tissue comprised, at least one growth ring. In the sapwood tree *Acer*, outer (2–5 years old growth rings), middle (10–11, and 14–15 year-old increments), and inner sapwood (oldest, 20–21, and 24–25 year-old tissue), were separated. Homogenization of the tissue to a fine powder was done by using a wood file.

3.2. Preparation of crude enzyme extracts

Lyophilized wood powder, PVPP and DOWEX 1×2-200 (pre-equilibrated with the extraction liquid; 1/1/1) were extracted with a 15-fold volume (w/v) of extraction buffer (0.1 M Tris–HCl pH 7.4, 0.01% BSA, 0.15% PEG (20000), 40 mM sucrose, 0.1 mM $CaCl_2$, 64 mM β-mercaptoethanol), for 20 min at 4°C. After filtration (Büchner filter), the filtrate was centrifuged for 18 min at 35,000 *g* (Beckman centrifuge J2-21). The supernatant was used as crude enzyme extract.

Protein was determined according to Bradford (1976), using the Bio-Rad Bradford microassay protein assay.

3.3. Assay of catalytic activities of glucose-6-phosphate dehydrogenase (G6PDH) and 6-phosphogluconate dehydrogenase (6PGDH)

In a total volume of 1 ml, 40-μl aliquots (three parallels each) of the crude enzyme extract were incubated at 37°C in a reaction mix containing 0.1 M Tris–HCl, 1.08 mM NADP, and 10 mM $MgCl_2$. For G6PDH, the reaction mix had a pH of 7.8 and was supplemented with 3 mM of G6P. For 6PGDH, the pH was 7.4 and 0.54 mM of 6PG was added. The reaction was followed in a thermostat-controlled chamber (37°C) over 20 min at 2.5-min intervals at 340 nm and in a microplate reader and rates were calculated from the linear parts of the kinetics. By different assays (containing only one or both substrates) it could be shown that 6-phosphogluconate dehydrogenase does not interfere with assaying glucose-6-phosphate dehydrogenase. Moreover, in order to trace possible losses of enzyme activity or interference of tissue-specific substances during sample preparation or measurement, commercially available enzyme preparations of known catalytic activity were added prior to extraction as internal standard. Recovery was around 92% for the enzymes analyzed. Thus, we conclude that neither interference of sample constituents with enzyme activities nor degradation of the reaction products occurred.

3.4. Determination of pyridine nucleotides

The oxidized (NAD and NADP) and reduced pyridine nucleotides (NADH, NADPH) were extracted from 10 mg of dry weight, with 50 mg of PVPP added, with 1 ml of 0.1 M HCl for 4 min at 95°C, or with 0.1 M 2-mercaptoethanol, pH 10.8, for 10 min at 80°C, respectively. Per sample, three replicates were done. Quantification of the individual metabolites was by enzymatic cycling (for details of this technique, see Lowry and Passonneau, 1972; Kato et al., 1973; Hampp et al., 1984, 1990). Twenty-five μl of the neutralized extracts (four parallels each) were incubated with 25 μl of cycling reagent for 60 min at ambient temperature for the NAD(H)-cycle, and 90 min at 37°C for the NADP(H)-cycle, respectively. After termination of the cycling step by heat (100°C, 20 min), one of the products formed during cycling [malate in the NAD(H)-cycle; 6-P-gluconate in the NADP(H)-cycle] was measured by addition of 1 ml of indicator reagent. In this last step, the product is coupled enzymatically to the reduction of pyridine nucleotides. The amount of NADH or NADPH formed in this indicator reaction was measured fluorometrically (340 nm excitation, 455 nm emission). In order to assay possible losses of pyridine nucleotides during handling, recovery experiments were carried out in which duplicate samples of different tissues were prepared. A measured amount of a mixture of oxidized (NAD, NADP) and reduced pyridine nucleotides (NADH, NADPH) was added as internal standard before extraction to one set of the samples. All samples were treated similarly, as outlined above, for extraction, cycling, and measurement. The recovery was 97 and 103% for NAD and NADH, and 87 and 96% for NADP and NADPH, respectively. Thus, the recovered redox status obviously reflects the in vivo situation.

3.4.1. Cycling reagents

The cycling reagent for the NAD(H)-cycle consisted of 0.25 M Tris, pH 8, 0.74 M ethanol, 5 mM 2-mercaptoethanol, 0.05% BSA, 5 mM oxalacetate, 24 U/ml malate dehydrogenase, and 72 U/ml alcohol dehydrogenase. The NADP(H)-cycle reagent was made from 0.25 M Tris-buffer, pH 8.1, containing 2.5 mM glucose-6-phosphate, 0.25 mM 5′-ADP, 20 mM 2-oxoglutarate, 25 mM NH_4Cl, 11.2 U/ml glucose-6-phosphate dehydrogenase, and 24 U/ml glutamate dehydrogenase.

3.4.2. Indicator reagents

The malate reagent (NAD, NADH cycle) contained 0.14 M 2-amino-2-methylpropanol, pH 9.9, 31 mM Na-glutamate, 1.2 mM NAD, malate dehydrogenase, 8 U/ml, and glutamate-oxalacetate-transaminase (GOT), 1.4 U/ml. The 6-P-gluconate reagent (NADP, NADPH cycle) consisted of 0.22 M Tris-buffer, pH 8.1, 0.28 mM EDTA, 170 mM NH_4Cl, 28 mM $MgCl_2$, 1.2 mM NADP, and 0.23 U/ml of 6-P-gluconate dehydrogenase.

Review

The biosynthesis of monolignols: a ''metabolic grid'', or independent pathways to guaiacyl and syringyl units?

Richard A. Dixon*, Fang Chen, Dianjing Guo, Kota Parvathi

Received 17 July 2000; received in revised form 16 October 2000

Abstract

Lignin is a complex polymer formed by the oxidative polymerization of hydroxycinnamyl alcohol derivatives termed monolignols. The major monolignols in dicotyledonous angiosperm lignin are monomethylated guaiacyl (G) units derived from coniferyl alcohol, and dimethylated syringyl (S) units derived from sinapyl alcohol. The biochemical pathways leading to the formation of monolignols feature successive hydroxylation and *O*-methylation of the aromatic ring and conversion of the side chain carboxyl to an alcohol function. The current view of the monolignol biosynthetic pathway envisages a metabolic grid leading to G and S units, through which the successive hydroxylation and *O*-methylation reactions may occur at different levels of side chain oxidation. The present article assesses biochemical and genetic evidence for and against such a model, including recent data on the methylation reactions of monolignol biosynthesis in alfalfa. We draw attention to portions of the currently accepted monolignol pathway that may require revision, and suggest an alternative model in which metabolic channeling allows for independent pathways to G and S lignin. © 2001 Elsevier Science Ltd. Fig. 1. Pathways to monolignols. The complete metabolic grid of reactions is shown. All enzyme reactions shown with a solid arrow have been demonstrated to occur in vitro. Reactions shown in smaller type may not occur in vivo. The reactions shown in green seem the most likely route to G lignin in vivo. The reactions in red represent those reactions consistent with both in vivo and in vitro evidence for being involved specifically in S lignin biosynthesis. The intermediate in orange is common to both G and S lignin pathways.

1. Introduction

Lignin is a major structural component of secondarily thickened plant cell walls. It is a complex polymer of hydroxylated and methoxylated phenylpropane units, linked via oxidative coupling that is probably catalyzed by both peroxidases and laccases (Boudet et al., 1995). Lignin imparts mechanical strength to plant stems and trunks, and hydrophobicity to water-conducting vascular elements. Dicotyledonous angiosperm lignins contain two major monomer species, termed guaiacyl (G) and syringyl (S) units (Fig. 1). G units are characterized by a single methoxyl substituent on the aromatic ring, whereas S units are di-methoxylated (Fig. 1). The S and G units in lignin are joined through at least five different types of linkages (Davin and Lewis, 1992). The mechanisms that determine the relative proportions of these linkage types in a particular lignin polymer are currently

unknown. It has, however, become increasingly apparent that lignin is not simply a random polymer of monolignol units, and lignin composition is developmentally programmed, both temporally and spatially (Terashima et al., 1993).

Softwood gymnosperm lignins essentially lack S residues and are, therefore, highly condensed. They are less amenable to chemical pulping than are hardwood lignins. Lignin levels increase with progressive maturity in stems of forage crops, including legumes such as alfalfa (Jung et al., 1997b) and in grasses such as tall fescue (Buxton and Redfearn, 1997). In addition, the lignin composition changes with advanced maturity towards a progressively higher S/G ratio (Buxton and Russell, 1988). Both lignin concentration (Albrecht et al., 1987; Casler, 1987; Jung et al., 1997a) and lignin methoxyl content (S/G ratio) (Sewalt et al., 1996) have been negatively correlated with forage digestibility for ruminant animals. Small reductions in lignin content may have correspondingly larger impacts on digestibility (Casler, 1987). Although a number of studies have linked decreased forage digestibility to increased S/G ratio as a function of increased plant maturity (Buxton and Russell, 1988; Grabber et al., 1992), other studies have questioned the effect of lignin composition on digestibility (Grabber et al., 1997).

Because of the impact of lignin on forage quality and paper pulping efficiency, there is considerable interest in genetic manipulation to alter the quantity and/or quality of the lignin polymer (Whetten and Sederoff, 1991; Dixon et al., 1996; Boudet and Grima-Pettenati, 1996; O'Connell et al., 1998). To predict the outcome of transgenic modification, it is necessary to understand the sequence of reactions in the pathway being manipulated. This understanding was believed to exist in the case of lignin biosynthesis until the mid 90s, when evidence emerged for previously unsuspected routes to the monolignols. Currently, the "text book" view of lignin biosynthesis presents the pathway as a metabolic grid, through which side chain reduction and ring hydroxylation/methylation can occur at several different levels (Fig. 1). Such a model appears, however, to be inconsistent with recent findings on enzyme specificity and the results of modification of lignin biosynthetic enzyme activities through transgenic approaches. Because of the complexity of lignin structure, the difficulty of accurately determining the composition of the entire lignin polymer, the complex temporal and spatial controls affecting lignin biosynthesis and deposition, and the possibility of significant species differences, any new hypothesis for lignin biosynthesis must be evaluated with caution. By critically evaluating the evidence for the metabolic grid model, and proposing an alternative model that is equally consistent with present evidence, at least for the forage legume alfalfa, we hope to stimulate experimental re-evaluation of the monolignol pathway.

2. Developmental control of lignin composition

In hardwoods, monolignols are first incorporated into the middle lamella of the primary cell wall during the S_1 and S_2 developmental stages of the secondary wall, whereas incorporation into the secondary wall takes place mainly after the S_3 stage (Terashima et al., 1993). Lignification of the vessel wall, cell corner and middle lamella starts in the early stages of xylem differentiation, whereas lignification of fiber secondary walls proceeds most actively in the middle and late stages.

High-resolution microautoradiography of developing hardwood xylem has revealed that the three monolignol units are incorporated at different stages of cell wall formation. H (*p*-hydroxyphenyl) units are incorporated in the earliest stages mainly in the cell corner and middle lamella during the period of formation of the S_1 layer. The deposition of G lignin continues through the early to late stages. S lignin is deposited mainly in the middle and late developmental stages, mostly in the secondary fiber wall, when formation of the inner layer of the secondary wall has already commenced (Terashima et al., 1986, 1993; Fukushima and Terashima, 1990). A somewhat similar situation appears to occur during development of vascular tissues of monocots (Lam et al., 1990; He and Terashima, 1991).

The fact that different monolignols are incorporated into the cell wall at different stages of vascular differentiation, and in different regions of the wall, strongly argues for tightly regulated pathways to G and S lignins that can function either independently or together. Independent pathways, rather than a metabolic grid, provide the greatest potential for such tight developmental control.

3. A metabolic grid based on in vitro biochemistry

Current ideas on the ring substitution reactions of lignin biosynthesis have evolved from the initial premise, based on substrate specificity studies with assumed substrates that were readily available, that successive ring hydroxylations and *O*-methylations take place at the level of hydroxycinnamic acid precursors (Neish, 1968). In angiosperms, the enzyme known as caffeic acid *O*-methyltransferase (COMT) was first identified as converting caffeic acid to ferulic acid, and was later shown to also convert 5-hydroxyferulic acid to sinapic acid (Davin and Lewis, 1992) (Fig. 1). Genes encoding this enzyme have been cloned from a variety of plant species (Ibrahim et al., 1998), initially based on enzyme purification using the hydroxycinnamic acids as substrates. COMT has a subunit M_r of approximately 43 kD, and characteristic sequence signatures of the plant *O*-methyltransferase superfamily (Ibrahim et al.,

1998; Joshi and Chiang, 1998). Its properties from a selection of species are summarized in Table 1.

The concept of a single pathway for ring methylation at the level of hydroxycinnamic acids received its first revision when it was demonstrated that caffeoyl CoA *O*-methyltransferase (CCOMT) was likely to be involved in lignin biosynthesis in differentiating tracheary elements of *Zinnia elegans* (Ye et al., 1994). CCOMT is also a bifunctional enzyme, converting caffeoyl CoA to feruloyl CoA and 5-hydroxyferuolyl CoA to sinapyl CoA (Inoue et al., 1998; Grimmig et al., 1999). CCOMT genes have now been cloned from many species, including *Z. elegans*, Arabidopsis, tobacco, parsley, and alfalfa. CCOMT has a subunit M_r of approximately 30 kD, and is more closely related at the amino acid sequence level to mammalian catechol OMT than to plant caffeic acid OMT (Joshi and Chiang, 1998). Its properties are summarized in Table 1.

The demonstration that both COMT and CCOMT are bi-specific, acting on both the 3, 4-dihydroxy- and 3-methoxy, 4, 5-dihydroxy-substituted aromatic nuclei, led to a picture of two pathways to monolignol biosynthesis, best designated, at least on paper, as the two upper parallel pathways in the metabolic grid shown in Fig. 1.

The three successive ring hydroxylation reactions of monolignol biosynthesis are catalyzed, respectively, by the well characterized cinnamate 4-hydroxylase (C4H) cytochrome P450 (Pierrel et al., 1994), a yet to be characterized enzyme believed to be a coumarate 3-hydroxylase, and the ferulate 5-hydroxylase (F5H) cytochrome P450 (Meyer et al., 1996). Although earlier studies had suggested that hydroxylation of coumarate might be carried out by a copper-containing phenolase enzyme (Bolwell and Butt, 1983), phenolase activity does not appear to be co-regulated, either temporally or spatially, with other enzymes of lignin biosynthesis. It has been suggested that a more specific membrane-associated hydroxylase might catalyze the aromatic 3-hydroxylation reaction (Kojima and Takeuchi, 1989). The mode of hydroxylation of the 4-hydroxycinnamoyl moiety represents the first "black box" in the monolignol pathway.

Recent enzyme specificity studies suggest that, if operational, the metabolic grid to monolignols could theoretically involve ring substitution at most, or all, levels of modification of the monolignol side chain, but that there may be kinetically favored paths through the resultant "grid". Thus, the enzyme designated as F5H has a higher affinity for coniferyl aldehyde than for ferulic acid, at least in sweet gum (Osakabe et al., 1999) and Arabidopsis (Humphreys et al., 1999) (Table 1) and may not hydroxylate ferulic acid itself in vivo. Likewise, COMT from aspen and alfalfa has a significantly higher affinity for 5-hydroxyconiferyl aldehyde than for caffeic or 5-hydroxyferulic acids (Table 1). It has been proposed that inhibition of COMT-mediated methylation of caffeic acid in vitro by 5-hydroxyconiferyl aldehyde could essentially prevent flux from caffeic acid to ferulic acid from occurring in vivo (Li et al., 2000).

The above substrate preferences are consistent with involvement of COMT primarily in the formation of S lignin via methylation of 5-hydroxyconiferyl aldehyde, a conclusion in agreement with the results of transgenic modification of COMT activity (see below). We have recently shown that recombinant alfalfa COMT exhibits significantly greater catalytic efficiency with caffeoyl aldehyde, caffeoyl alcohol, 5-hydroxyferuloyl aldehyde and 5-hydroxyferuolyl alcohol than it does with the corresponding hydroxycinnamic acids (Parvathi et al., 2001), suggesting that COMT could be involved in both the 3- and 5-methylation reactions of S lignin biosynthesis at either the aldehyde or alcohol levels.

If C3H turns out to be a P450 with similar substrate preference to F5H, it is possible that hydroxylation of the coumarate moiety also occurs at the aldehyde level, and that coumarate itself might not, therefore, be a natural intermediate in monolignol biosynthesis. This would then imply that caffeic acid is not a substrate for COMT in the monolignol pathway, consistent with the substrate preferences of this enzyme (Li et al., 2000; Parvathi et al., 2001) and the results of transgenic experiments outlined below.

Reduction of hydroxycinnamic acids to their corresponding alcohols is initiated by formation of coenzyme A thioesters, that are reduced successively to the corresponding aldehydes by cinnamoyl CoA reductase(s) (CCR) and cinnamyl alcohol dehydrogenase(s) (CAD). Hydroxycinnamate: CoA ligases have been characterized at the molecular level from many plant species. In general, these enzymes exhibit highest activity against coumaric, caffeic and ferulic acids, with little activity against cinnamic and sinapic acids (Ehlting et al., 1999), although there are reports of sinapate CoA ligase activity in extracts from some plants. For example, we have shown that, although crude extracts from alfalfa stems appear to lack sinapate CoA ligase activity, this activity can be recovered following ammonium sulfate fractionation (K. Inoue and R.A. Dixon, unpublished results). The apparent lack of activity of 4CL against sinapic acid in several plants does, however, call into question the role of sinapate as a lignin precursor, and therefore also questions whether the conversion of 5-hydroxyferulic acid to sinapic acid by COMT in vitro actually occurs in vivo. Thus, one must question whether any of the free hydroxycinnamic acids beyond coumaric acid is a natural substrate for monolignol biosynthesis, even though radiolabeling studies have indicated that ferulic acid and sinapic acid are incorporated into lignin in poplar (Terashima et al., 1986). In such labeling studies, it is possible that exogenously applied precursors do not enter the same pools used by endogenous precursors.

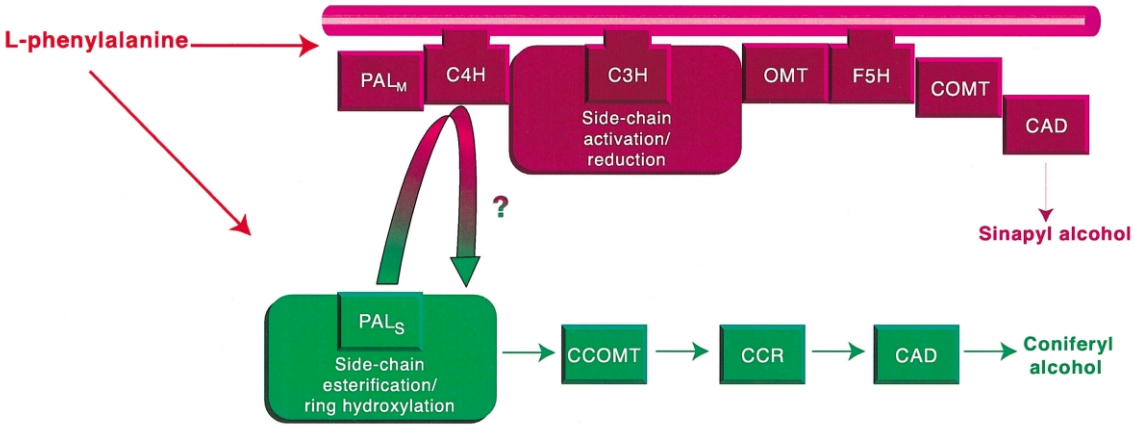

Fig. 2. A metabolic channel model for independent pathways to G and S monolignols. The hypothetical metabolic channel leading to S lignin (in red) is proposed to involve a microsomal-associated form of PAL (PAL_M) that directly channels its product, cinnamic acid, to the ER-associated cinnamate 4-hydroxylase (C4H) cytochrome P450. 3-Hydroxylation (possibly via a second P450 enzyme) and CoA esterification and reduction of the side chain then occur, although it is not clear whether hydroxylation occurs before or after side chain modification. These reactions are followed by the first *O*-methylation reaction (by COMT?) that produces coniferaldehyde, the substrate for the ER-associated F5H. The second methylation reaction is then catalyzed by COMT (perhaps associated with F5H) to yield sinapyl aldehyde, which is reduced by CAD to yield sinapyl alcohol. The hypothetical pathway to G units (in green) is proposed to involve a soluble form of PAL (PAL_S), that either provides cinnamate for C4H in an unchanneled reaction, or by-passes C4H by hydroxylation of the aromatic ring at the level of a side chain esterified intermediate. CCOMT then catalyzes the single *O*-methylation reaction, and coniferyl alcohol is formed via soluble forms of CCR and CAD. In an alternative model, the pathway to G units might also be membrane associated.

4. In vivo labeling studies support novel routes to S lignin

It has recently been shown by in vivo labeling studies in *Magnolia kobus* that S lignin can be derived from coniferyl alcohol. In these studies, side-chain labeled coniferyl alcohol was incorporated into S lignin with complete retention of label, indicating direct incorporation (Matsui et al., 1994; Chen et al., 1999). Consistent with a pathway for hydroxylation and methylation at the alcohol level, COMT from alfalfa has a significantly higher affinity for 5-hydroxyconiferyl alcohol than for caffeic acid (Parvathi et al., 2001). Furthermore, because alfalfa COMT is also active against caffeoyl aldehyde and alcohol (Parvathi et al., 2000), coniferyl alcohol could be formed from caffeoyl alcohol in addition to the accepted pathway from feruloyl CoA via coniferaldehyde. This idea finds support from a recent study indicating incorporation of labeled caffeoyl alcohol in both G and S lignin in several woody dicotyledonous angiosperms (Matsui et al., 2000). These new pathways to S lignin are indicated in red in Fig. 1.

5. Cellular and subcellular localization of monolignol biosynthetic enzymes

The cellular and subcellular localization of the enzymes is of critical importance in evaluating whether linear pathways, or a metabolic grid, underlie monolignol biosynthesis. Obviously, all the enzymes of the potential grid must be present in the same cell type for the metabolic grid hypothesis to hold.

There is ample evidence for the location of the enzymes of the core phenylpropanoid pathway at cellular sites of lignification. Early studies confirmed the localization of PAL to differentiating xylem (Rubery and Northcote, 1968). Subsequent studies with various *PAL* promoter reporter gene fusions in transgenic plants confirmed vascular specific expression of *PAL* genes in several species, including tobacco (Liang et al., 1989; Shufflebottom et al., 1993) and alfalfa (Guo et al., 2001). Likewise, the Arabidopsis C4H promoter confers vascular tissue specific expression of the GUS reporter gene in transgenic Arabidopsis (Bell-Lelong et al., 1997), and C4H has been immunolocalized to cells adjacent to differentiating xylem in bean (*Phaseolus vulgaris*) hypocotyls (Smith et al., 1994). The parsley *4CL1* promoter is active in vascular tissue of tobacco and Arabidopsis (Hauffe et al., 1991, 1993; Lee et al., 1995), and contains a series of positively acting *cis*-elements that confer xylem expression and a negative element that represses phloem expression (Hauffe et al., 1993).

PAL and 4CL are operationally soluble enzymes, although immunolocalization and biochemical fractionation studies have indicated that PAL may also be associated with the endomembrane system (Czichi and Kindl, 1977; Smith et al., 1994; Rasmussen and Dixon, 1999). C4H is a cytochrome P450 enzyme and is therefore localized to the outer surface of the endoplasmic reticulum by virtue of its N-terminal membrane anchor (Chapple, 1998).

As discussed above, the exact nature of the enzyme converting the coumarate moiety to the caffeate moiety during lignin biosynthesis is currently unknown. This 3-hydroxylation activity can be catalyzed by polyphenol oxidase type enzymes that, from different plant species, have been shown to act on 4-coumaric acid itself (Bolwell and Butt, 1983), 4-coumaroyl CoA (Wang et al., 1997) or 4-coumaroyl β-D-glucose (Tanaka and Kojima, 1991). The cellular and subcellular localization of these enzymes is not clear. In contrast, the enzyme known as ferulate 5-hydroxylase is presumably localized to cells producing lignin monomers in view of the blockage in S lignin biosynthesis in Arabidopsis lacking expression of this enzyme, and the increased effect of transgenic up-regulation of the enzyme if targeted to vascular tissues (Meyer et al., 1998; Franke et al., 2000).

Tissue print hybridization analysis indicated that both COMT and CCOMT transcripts are localized to developing xylem elements in alfalfa stems, whereas CCOMT transcripts are also found in phloem (Inoue et al., 1998). Immunolocalization studies at the light and electron microscope levels demonstrated expression of both COMT and CCOMT in the cytoplasm of primary and secondary xylem parenchyma cells in alfalfa stems (Kersey et al., 1999). Both enzymes were also localized to phloem in mature internodes, where COMT was found in cytoplasm and vacuoles, whereas CCOMT was only localized to cytoplasm (Kersey et al., 1999).

In in vitro differentiating tracheary elements of *Zinnia elegans*, COMT transcripts are much more apparent in phloem than in xylem in young internodes, whereas CCOMT transcripts are predominantly located in differentiating xylem (Ye et al., 1994; Ye and Varner, 1995). In mature internodes, both COMT and CCOMT transcripts appear in both xylem and phloem (Ye and Varner, 1995). In tobacco, three different classes of CCOMT transcripts are found in stem tissue, with different temporal patterns of developmental expression (Maury et al., 1999). The specific cell-type localizations of these different forms have yet to be reported.

CCOMT has been localized to secondary xylem in loblolly pine by direct biochemical assay, and the pine CCOMT promoter drives GUS expression in secondary xylem of transgenic tobacco (Li et al., 1999). The parsley CCOMT promoter also drives expression in xylem parenchyma in transgenic tobacco (Grimmig et al., 1999), consistent with the localization of CCOMT transcripts in parsley stems (Ye et al., 1994). Based on the above observations, there is at present no convincing evidence to suggest that the potential parallel pathways of lignin biosynthesis might take place in different cell types, thereby obviating the potential of a metabolic grid.

6. Are all the enzymes of monolignol biosynthesis accounted for?

Several of the enzymes of monolignol biosynthesis are multifunctional, such that more than one reaction in the hypothetical metabolic grid may be catalyzed by the same enzyme. However, it is also possible that other as yet unsuspected enzymes are involved in monolignol biosynthesis, and that new pathways may exist to S and G units. For example, interconversions of hydroxycinnamic acids are known to occur in plants at the levels of metabolically active glucose, shikimate or quinate esters (Strack and Bokern, 1984; Kuhnl et al., 1987; Kneusel et al., 1989; Tanaka and Kojima, 1991), and such alternate pathways have yet to be ruled out in lignin biosynthesis. A cinnamate: glucosyl transferase exists in alfalfa (Edwards et al., 1990), and an enzyme converting 4-coumaroyl glucose to caffeoyl glucose has been reported in sweet potato (Tanaka and Kojima, 1991), and may be present in other plants, where it could potentially by-pass the hydroxylation of coumarate.

Yet other enzymes may catalyze the methylation or hydroxylation reactions shown in Fig. 1. For example, young alfalfa internodes express a different form of COMT (COMT II), having preference for caffeic acid compared to 5-hydroxyferulic acid. This apparently new *O*-methyltransferase can be separated from the previously characterized COMT (COMT I) by anion exchange and hydrophobic interaction chromatography (Inoue et al., 2000). COMT I, but not COMT II, is found in mature internodes. COMT II is not recognized by anti-(COMT I) serum. In addition to substrate preference, COMT II differs from COMT I in its native Mr, pH optimum, and its very low Km for caffeic acid (Inoue et al., 2000). COMT II may therefore be the true caffeic acid OMT (although the enzyme is also active with coenzyme A esters and some flavonoids), and may be involved in formation of ferulic acid in the earliest stages of lignification in young tissues. A similar ''early'' form of COMT has been described in wheat seedlings (Lam, et al., 1996).

Loblolly pine xylem contains a further OMT, termed AEOMT, that methylates hydroxycinnamic acids and their coenzyme A esters with similar efficiency (Li et al., 1997). This enzyme has not been reported from angiosperms, and its subcellular localization has not been investigated.

Analysis of OMT substrate preferences in crude extracts from lignifying stems from wild-type and OMT down-regulated transgenic alfalfa plants has indicated that significant residual OMT activity against caffeoyl CoA and 5-hydroxyferuloyl CoA is observed in extracts that show no CCOMT protein by western blot analysis, and that extracts from lines with no COMT expression still have significant residual activity against caffeic and 5-hydroxyferulic acids, aldehydes and alcohols (Parvathi et al., 2001). These residual activities are greater

Table 2
Modification of lignin content and composition in transgenic plants and mutants with altered expression of lignin biosynthetic enzymes

Gene	Species	Method and activity	Lignin content	Lignin composition	Reference
PAL	Tobacco	Cosuppression to 20%	Decreased to 30%	Decreased G	Sewalt et al., 1997b
	Tobacco	Cosuppression to 17%	Decreased to 57%	Increased methoxyl content	Sewalt et al., 1997a
C4H	Tobacco	Cosuppression; antisense to 20%	Decreased to 20%	Decreased S	Sewalt et al., 1997a
F5H	Arabidopsis	Overexpression		Only S	Meyer et al., 1998
	Arabidopsis	Overexpression		Only S	Marita et al., 1999
	Tobacco; poplar	Overexpression	Decreased to 75%	Increased S	Franke et al., 2000
4CL	Arabidopsis	Antisense to 8%	Decreased to 70%	Decreased G	Lee et al., 1997
	Aspen	Antisense to 10%	Decreased to 55%	[Increased cellulose]	Hu et al., 1999
	Tobacco	Sense and antisense to 1%	Decreased to 66%	Decreased S	Kajita et al., 1996
	Tobacco	Antisense	Unchanged	Decreased S; Increased H	Kajita et al., 1997
COMT	Poplar	Antisense to 10%	Unchanged	Increased G	Lapierre et al., 1999
	Tobacco	Antisense to 40%	Decreased to 65%	More reduction of G than S	Sewalt et al., 1997a
	Aspen	Cosuppresion to 25%	Unchanged	Decreased S	Tsai et al., 1998
	Poplar	Antisense to 5%	Unchanged	Decreased S, new 5-OH G	Van Doorsselaere et al., 1995
	Tobacco	Antisense to 30%	Decreased to 42–85%	Unchanged	Ni et al., 1994
	Tobacco	Sense and antisense to 2–8%	Unchanged	Decreased S [and hemicellulose]	Bernard-Vailhe et al., 1996
	Tobacco	Antisense to 54%	Decreased to 88%	Decreased S	Dwivedi et al., 1994
	Tobacco	Sense and antisense to 2%	Unchanged	Decreased S, new 5-OH G	Atanassova et al., 1995
	Alfalfa	Antisense; cosuppression to 4%	Decreased to 71–87%	Reduction of G, near elimination of S, new 5-OH G	Guo et al., 2001
CCOMT	Tobacco	Antisense to 20-30%	Decreased to 53%	More reduction of G than S	Zhong et al., 1998
	Alfalfa	Antisense to 4%	Decreased to 83%	Reduction of G, no reduction of S	Guo et al., 2001
CCR	Tobacco	Antisense to 30%	Decreased to 53%	Decreased S and G increased S/G	Piquemal et al., 1998
CAD	Poplar	Antisense to 30%	Decreased (slight)	Increased S	Lapierre et al., 1999
	Alfalfa	Antisense to 30%	Unchanged	Decreased S	Baucher et al., 1999
	Tobacco	Antisense to 7–20%	Unchanged	Decreased S	Halpin et al., 1994
	Tobacco	Antisense to 7–20%	Unchanged	Decreased S	Bernard-Vailhé et al., 1998
	Tobacco	Antisense to 8–56%	Unchanged	Decreased S	Yahiaoui et al., 1998
	Loblolly pine	Mutant	Decreased to 91%	Increased coniferaldehyde units	MacKay et al., 1997
	Loblolly pine	Mutant		Increased units derived from DHCA	Ralph et al., 1997
	Sorghum	Mutant	Decreased to 75–85%		Pilonel et al., 1991

than can be accounted for by the activity of COMT for the CoA esters or of CCOMT for the non-esterified hydroxycinnamic acid derivatives, suggesting the involvement of other OMT enzymes. High transcript levels of candidate enzymes have been predicted from in silico analysis of *Medicago* stem ESTs (www.noble.org/medicago/), but the involvement of these enzymes in lignin biosynthesis must await analysis of enzymatic function and tissue-specific localization.

7. Genetic modification of monolignol pathways

Several studies have been published on the modification of lignin content and composition following transgenic up- or down-regulation of the enzymes discussed above, and several naturally occurring mutants in the monolignol pathway have been characterized. The results, which are summarized in Table 2, have often been difficult to interpret, although several consistent patterns have

emerged. The data confirm that COMT, CCOMT, F5H, CCR and CAD are indeed critical for normal wild-type lignin biosynthesis in the various species investigated. However, the data do not fully support the operation of a metabolic grid for monolignol biosynthesis through which intermediates find their way governed only by their cellular concentrations and the affinities of the various enzymes for their substrates.

Large reductions in lignin content have been obtained by down-regulation of PAL or C4H activities in transgenic tobacco, consistent with the positioning of these enzymes at the entry point into monolignol biosynthesis (Bate et al., 1994; Sewalt et al., 1997a,b). Down-regulation of PAL leading to an approximately 50% reduction in Klason lignin results in an increase in S/G ratio (from approximately 1.0 to 1.8). In contrast, down- regulation of C4H leading to a similar decrease in lignin content results in greatly reduced S/G ratio, tending towards complete elimination of S units (Sewalt et al., 1997a,b). This is quantitatively similar to the loss of S lignin observed following down-regulation of COMT (Atanassova et al., 1995; Van Doorsselaere et al., 1995) or F5H (Chapple et al., 1992), but none of the other enzymes of monolignol biosynthesis. There are three possible explanations for this finding: (1) the pathway to G lignin somehow bypasses C4H; (2) C4H catalyzes reactions in monolignol biosynthesis in addition to the 4-hydroxylation of cinnamic acid; (3) some kind of metabolic channeling places a form of C4H in a complex with other enzymes committed to S lignin biosynthesis.

Vascular tissue-directed over-expression of ferulate 5-hydroxylase in transgenic Arabidopsis leads to the formation of lignin composed almost totally of S residues linked predominantly in β-aryl ether units (Meyer et al., 1998; Marita et al., 1999; Franke et al., 2000), whereas down-regulation of F5H leads to lignin with very few S units (Marita et al., 1999). Thus, F5H is clearly a major control point in S lignin synthesis, consistent with the position of the enzyme in the "classical" pathway and its revised position acting primarily on 5-hydroxyconiferyl aldehyde.

There have been several reports on the effects of down-regulation of COMT activity on lignin content and composition in transgenic plants (Ni et al., 1994; Atanassova et al., 1995; Van Doorsselaere et al., 1995; Zhong et al., 1998; Guo et al., 2000), and the *brown midrib3* mutation in maize results from the insertion of a retrotransposon in the *COMT* gene (Vignols et al., 1995). In examples where COMT has been reduced to levels below approximately 20% of wild-type by expression of a homologous transgene, a strong reduction in S/G ratio is accompanied by no apparent change in lignin content (Atanassova et al., 1995; Van Doorsselaere et al., 1995). However, we have recently shown up to 30% decreases in Klason lignin levels in transgenic alfalfa in which COMT down-regulation was targeted using a vascular-tissue specific promoter that resulted in near total down-regulation of COMT transcripts and protein (Guo et al., 2001). However, acetyl bromide soluble lignin was not reduced. Determination of total G and S residues by thioacidolysis implied a greater down-regulation of lignin in COMT suppressed alfalfa plants than observed by determination of Klason lignin.

Studies with transgenic tobacco, poplar and alfalfa have indicated that down-regulation of COMT has a larger impact on S lignin than on G lignin, and that 5-hydroxyguaiacyl residues accumulate, albeit at a low level, in the lignin of COMT down-regulated plants (Atanassova et al., 1995; Van Doorsselaere., 1995). This is also the case in alfalfa, where a low level of 5-hydroxyguaiacyl residues accumulate in the lignin following near complete elimination of thioacidolysis-determined S units by reduction of COMT to 4.5% of wild-type level (Guo et al., 2001).

One problem with studies reporting transgenic modification of lignin biosynthesis is the use of analytical methods for lignin composition that report on only a fraction of the lignin polymer, namely the non-condensed portion. Using thioacidolysis followed by Raney nickel desulfurization, COMT down-regulation in alfalfa has been shown to lead to a loss of S residues in both the β-*O*-4-linked uncondensed fraction and in the condensed fraction resolved as a range of differently linked dimers (Guo et al., 2001). The effect of COMT down-regulation on S lignin therefore likely reflects a true metabolic reduction in S units, rather than a change in lignin composition resulting in appearance of more S units in the non-condensed fraction of the polymer.

In both tobacco and alfalfa, down-regulation of CCOMT leads to a corresponding decrease in Klason lignin levels (Zhong et al., 1998; Guo et al., 2001). However, although near elimination of CCOMT in alfalfa reduced G lignin with no effect on S lignin, the effect was at most an approximately 50% reduction in G units (Guo et al., 2000). This suggests that another methylation enzyme is also involved in the formation of G lignin in alfalfa. This might be COMT in view of the approximately 25% reduction in G lignin that accompanies the larger reduction in S lignin in strongly COMT down-regulated plants. However, it is also necessary to consider the possibility of other, yet to be determined *O*-methyltransferases, as discussed above. Whatever enzyme catalyzes the first step in S lignin biosynthesis in alfalfa, it may not be CCOMT.

The results of down-regulation of 4CL on lignin content and composition are somewhat contradictory. In tobacco, a reduction of 4CL activity resulted in a brownish coloration of the xylem cell walls, which correlated with reductions in overall lignin levels and in cinnamyl aldehyde and S residues in lignin. However, values for S/G ratio varied widely, from 0.45 to 2.0, in

plants with reduced 4CL activity due to large but variable reductions in G lignin (Kajita et al., 1996). In Arabidopsis, reduction of 4CL to less than 10% of wild-type activity resulted in strong reduction in G lignin with no reduction in S lignin, and it was therefore suggested that a route might exist to S lignin that is independent of 4CL activity (Lee et al., 1997). This idea is consistent with the lack of activity of Arabidopsis 4CL against sinapate (Lee et al., 1997), and the transgenic alfalfa data suggesting lack of involvement of CCOMT in S lignin biosynthesis. In quaking aspen (*Populus tremuloides*), it has been reported that down- regulation of 4CL can result in a striking decrease in lignin content with no apparent change in lignin composition (Hu et al., 1999).

Down-regulation of CCR leads to an orange/brown xylem coloration, reductions in lignin content, and increased S/G ratio due primarily to a decrease in extractable G units (Piquemal et al., 1998). However, there was some variation between lines, and one line also showed a significant reduction in S units. These data would, therefore, be consistent with the involvement of CCR in the synthesis of both G and S lignin. Down-regulation of CAD leads to lignin with an increased cinnamaldehyde content (Halpin et al., 1994; Hibino et al., 1995; Stewart et al., 1997). In alfalfa, CAD down-regulation has been reported to decrease the S/G ratio, primarily by causing a decrease in S units (Baucher et al., 1999). It should be noted that the effects of altered CCR or CAD on S/G ratio reported to date are far less striking than the effects of altered F5H or COMT. One explanation would be that F5H and COMT are specific for S lignin biosynthesis, whereas CAD and CCR are common to both S and G lignin biosynthesis.

The above inconsistencies between the results of in vitro and in vivo approaches to studying the monolignol pathway force us to re-evaluate how we have come to arrive at the current "metabolic grid" model for monolignol biosynthesis, namely by extrapolating perceived enzyme substrate preferences in vitro to pathways in vivo.

8. A metabolic channel model for monolignol biosynthesis?

Enzymes of secondary metabolism may be organized in complexes, variously described in the literature as "metabolic compartments", "metabolic channels" or "metabolons" (Hrazdina and Wagner, 1985; Srere, 1987; Hrazdina and Jensen, 1992; Winkel–Shirley, 1999). Metabolic complexes may contain arrays of consecutive, physically associated enzymes that are assembled on membranes or other physical structures, or that interact directly with one another (Cutler et al., 1981; Srere, 1987; Winkel-Shirley, 1999). This can result in the channeling of pathway intermediates from one enzyme to the next without their release into the total cellular metabolic pool.

Evidence for metabolic channeling in the phenylpropanoid pathway includes:

- Immunolocalization of operationally soluble enzymes on membranes or other cellular structures (Hrazdina et al., 1987).
- In vivo labeling and isotope dilution studies, in which potential pathway intermediates are only poorly incorporated into end products, or ineffectively compete with downstream intermediates for incorporation (Rasmussen and Dixon, 1999).
- In vitro channeling studies, in which isolated membrane preparations catalyze consecutive reactions, including at least one that is brought about by an operationally soluble enzyme, and in which the channeled intermediate is a poorer precursor for the end product than an upstream metabolite (Czichi and Kindl, 1975, 1977; Rasmussen and Dixon, 1999).
- Co-immunoprecipitation of consecutive pathway enzymes (Burbulis and Winkel-Shirley, 1999).
- Demonstration of direct physical interactions between consecutive pathway enzymes using the yeast two-hybrid system (Burbulis and Winkel-Shirley, 1999).
- Examination of the effects of genetic modification of pathway enzymes in transgenic plants. In some cases, the outcome is inconsistent with a simple linear pathway in which intermediates reach the next enzyme by a diffusion-limited process (e.g. Sewalt et al., 1997a,b), as discussed above.

The localization of monolignol biosynthesis to a small subset of cells in the developing stem makes it difficult to obtain suitable material for studying channeling of lignin biosynthesis in vivo or in isolated microsomes. Pine cell suspension cultures, which have provided excellent material for the analysis of flux into monolignols by in vivo labeling approaches (Anterola et al., 1999), or differentiating *Zinnia* tracheary elements (Ye et al., 1994), might provide suitable material for such studies in the future. In the pine cell culture system, the very low pool sizes of hydroxycinnamyl CoA, aldehyde and alcohol intermediates are consistent with metabolic channeling in which flux control is exerted upstream of the *O*-methyltransferase reactions (Anterola et al., 1999).

At the subcellular level, the involvement of at least two cytochrome P450 enzymes, C4H and F5H could, by way of the anchoring of such enzymes to the external surface of the ER, provide a basis for the assembly of metabolic complexes for G and S lignin formation. However, although immunolocalization studies indicate that other enzymes of the monolignol pathway are

localized to cytoplasm (Kersey et al., 1999), the resolution of these studies was insufficient to reveal whether these enzymes might exhibit loose ER association. Furthermore, COMT, CCOMT, 4CL, CCR and CAD are all operationally soluble enzymes, and do not appear to contain any sequence elements that might engender membrane localization. To the best of our knowledge, no attempts have been made to assess whether any of these enzymes might be structurally organized within the cell. However, studies on PAL, another operationally soluble enzyme, have suggested that it might be co-localized with C4H on membranes of the ER, and evidence has been presented for channeling of the product of PAL, *trans*-cinnamic acid, in the conversion of phenylalanine to 4-coumaric acid (Czichi and Kindl, 1977; Hrazdina and Jensen, 1992; Rasmussen and Dixon, 1999).

Tobacco contains two families of *PAL* genes (*PAL1* and *PAL2*), each family comprising two very closely related members. Protein gel blot analysis showed that PAL1 is localized in both soluble and microsomal fractions from tobacco stems and cell cultures, whereas PAL2 is only found in the soluble fraction (Rasmussen and Dixon, 1999). This suggests that PAL1 is the form of PAL involved in direct coupling to C4H. Extrapolating further, it is possible to envisage a metabolic complex to S lignin in which three cytochrome P450 enzymes, C4H, putative coumarate (or coumaraldehyde?) 3-hydroxylase and F5H (coniferaldehyde 5-hydroxylase) indirectly anchor other operationally soluble enzymes, including COMT and perhaps specific forms of PAL, 4CL and/or CCR, to the surface of the ER (Fig. 2). This complex might be molecularly and physically distinct from the metabolic system, utilizing CCOMT for 3-*O*-methylation, involved in G lignin biosynthesis. Based on the specificity of alfalfa COMT for caffeoyl and 5-hydroxyferuolyl aldehydes and alcohols, COMT alone could function as the only *O*-methyltransferase involved in the putative channel leading to S lignin.

The model in Fig. 2 does not present a clear picture of the necessary involvement of 4CL and CCR in the biosynthesis of S lignin. These enzymes are shown as interacting, perhaps as soluble enzymes recruited to the complex, with either the cinnamate 4-hydroxylase, coumarate hydroxylase, or the enzyme that catalyzes 3-*O*-methylation (most likely COMT, at least in alfalfa). The uncertainty arises because of our lack of understanding of the level at which the 3-hydroxyl group is introduced into the coumarate moiety, or, put another way, we do not know if CoA esterification and subsequent side chain reduction occur before or after 3-hydroxylation.

Alfalfa, as with most plants, contains a PAL multigene family (Gowri et al., 1991), and it is possible that different forms of PAL may be associated differentially with S and G lignin biosynthesis in the above model, consistent with over-expression of a specific (transgene) PAL form affecting S/G ratio in transgenic tobacco (Sewalt et al., 1997a,b). The advantage of such a channeled model for monolignol biosynthesis is that it allows for the fine control over production of G and S units that is required for the observed temporal and spatial regulation of lignin composition.

9. Conclusions

The currently accepted model for lignin monomer biosynthesis is inconsistent with the results of genetic manipulation experiments. In vitro biochemical studies favor preferred routes to G and S units, but do not provide evidence for the operation of these routes in vivo. Enzymes in addition to those currently identified may play a role in monolignol biosynthesis. Metabolic channeling has been demonstrated in several areas of plant natural product biosynthesis, and could explain how G and S units could be produced by completely separate pathways, even if some common enzymes were involved.

The G lignin pathway would first appear to involve hydroxylation of a coumarate moiety. This may occur at the level of conversion of coumaroyl CoA to caffeoyl CoA, inasmuch as this reaction has been demonstrated in vitro and the enzyme appears to be regulated in a manner consistent with involvement in cell wall phenolic biosynthesis (Kneusel et al., 1989); however, hydroxylation at the level of the free acid (or aldehyde) can not be discounted, in spite of the debate as to whether a specific coumarate hydroxylase exists. The remaining reactions are methylation of caffeoyl CoA by CCOMT, and reduction of feruloyl CoA to coniferyl alcohol via coniferaldehyde. The preferred reactions specific for S lignin biosynthesis in our model are the methylation of caffeoyl aldehyde by COMT, conversion of coniferaldehyde to 5-hydroxyconiferaldehyde by F5H, methylation of 5-hydroxyconiferaldehyde to sinapyl aldehyde (again by COMT), and final reduction of sinapyl aldehyde to sinapyl alcohol by CAD (Fig. 1). The hydroxylation and methylation steps might also take place at the alcohol level, utilizing the same enzyme complex. This pathway, that would still be distinct from the G lignin pathway, would require action of CAD at an earlier stage, such as caffeoyl aldehyde or coniferaldehyde. If hydroxylation of the 4-hydroxycinnamate moiety were to be catalyzed by a cytochrome P450 enzyme, the pathway from the 4-hydroxycinnamate moiety to S units would occur by the sequence P450- OMT-P450- OMT- CAD. This arrangement could exist as an enzyme complex anchored to the surface of the endoplasmic reticulum via the P450s (Fig. 2). In contrast, the G lignin pathway, involving hydrophilic coenzyme A esters as substrates for hydroxylation and methylation, could be localized in the soluble cytoplasm. The nature of the first methylation reaction in S lignin biosynthesis is, in our opinion, still questionable, although COMT is most

likely involved in alfalfa, and the above model does not address where the pathways to G and S lignin might initially diverge.

Abstract

UDPG: coniferyl alcohol glucosyltransferase (CAGT; EC 2.4.1.111) isolated from cambial tissues of *Pinus strobus* was able to convert cinnamyl aldehydes as well as dihydroconiferyl alcohol into their corresponding 4-*O*-β-D-glucosides in vitro. Cinnamyl aldehydes were glucosylated with comparable efficiency to coniferyl alcohol, the physiological substrate for CAGT. Seasonal patterns of CAGT activity for aldehydes were similar to those of coniferyl alcohol. Formation of cinnamyl aldehyde and additional monolignol glucosides indicates that precursor flux and availability for lignification is likely greater than previously recognized.

Keywords: *Pinus strobus*; Coniferophyta; Pinaceae; Eastern white pine; Cinnamyl aldehyde; Cinnamyl alcohol; Dihydroconiferyl alcohol; Glucoside; Glucosyltransferase; Seasonal cambial growth

1. Introduction

The 4-*O*-β-D-glucopyranosides of *trans*-cinnamyl alcohols, i.e. *E*-coniferin and *E*-syringin, frequently accumulate in the cambial region of woody plants, and they have long been considered as participants in lignification, conceivably as either storage reserves (see, for example, Terazawa and Miyake, 1984) or transported forms of monolignols (Freudenberg and Torres-Serres, 1967). While coniferin is known to accumulate in conifer cambial tissues (earlier examples include: Freudenberg and Harkin, 1963; Marcinowski and Grisebach, 1977; Schmid and Grisebach, 1982; Terazawa and Miyake, 1984; Terazawa et al., 1984a,b; Savidge, 1988, 1989, 1991), it has also been isolated from cambial tissues of various angiosperms (Terazawa et al., 1984a,b), needles of Douglas fir (Morris and Morris, 1990) and Norway spruce (Slimestad and Hostettmann, 1996), cell suspensions of *Linum flavum* (van Uden et al., 1990), *Paulownia tomentosa* bark (Sticher and Lahloub, 1982), flue-cured tobacco leaves (Ito et al., 2000), *Daphne oleides* stems (Ullah et al., 1999) and leaves and stems of *Viscum album* ssp. (Deliorman et al., 1999). However, its accumulation evidently is greatest in conifers, such as *Pinus banksiana* (Leinhos and Savidge, 1993; Leinhos et al., 1994; Förster and Savidge, 1995), *Larix laricina* (Savidge, 1991) and *Picea abies* (Schmid and Grisebach, 1982), where the contents of endogenous coniferin were reported to be as high as 10 mmol/g_{fw}. In isolated cambial protoplasts the concentration of coniferin reached 1.6 mM and accounted fully for the content found in tissue extracts (Leinhos and Savidge, 1993; Leinhos et al., 1994), indicating that very little if any was present in walls of the primary-walled radially expanded cambial derivatives from which the protoplasts were obtained.

In springtime, the cinnamyl alcohol glucosides accumulate in cambial derivatives of conifers in the complete absence of lignification (Savidge, 1988, 1989, 1991; Förster and Savidge, 1995; Fukushima et al., 1997; Rowland and Arora, 1997; Savidge et al., 1998); however, there is ample evidence that once lignification is

underway they can contribute to that process (Förster et al., 1999, 2000), as earlier surmised by Freudenberg and Harkin (1963). In order for coniferin to accumulate to high levels, it must either be compartmentally shielded or produced many times more rapidly than it turns over (Marcinowski and Grisebach (1977) report a half-life of 60–120 h for coniferin) or is utilised in support of lignification. Freudenberg (1964) reported that when the coniferyl alcohol moiety of coniferin was radiolabelled, the radioactivity was readily incorporated into spruce lignin. The incorporation of isotopically labelled monolignol glucosides into lignin has been further investigated in autoradiographic studies by Terashima et al. (1986, 1993, 1995, 1997), Terashima and Fukushima (1988) and Eglinton et al. (2000). Monolignol glucosides enriched with carbon-13 at specific side chain carbons were administered to growing tree stems resulting in newly formed lignin shown to be carbon-13 enriched at the side chain carbons corresponding to those of the glucosides (Terashima et al., 1995; Xie and Terashima, 1991; Xie et al., 1994).

In agreement with the concept that the activity of coniferin-hydrolysing β-glucosidase may influence the rate of lignification (Grima-Pettenati and Goffner, 1999), a β-glucosidase specific to coniferin and of much lower abundance and/or activity than numerous other β-glucosidases of wood and cambial tissues was isolated, primarily on the basis of its unique ability to hydrolyse authentic coniferin to *E*-coniferyl alcohol, as confirmed by GC/MS (Leinhos et al., 1994). It remains unclear whether that coniferin-specific β-glucosidase is identical to the enzyme investigated by Dharmawardhana et al. (1995, 1999), the N-terminal sequences of the two being notably distinct although both evidently have similar p*I* values, or to the enzyme isolated from inner secondary cell walls in young spruce seedlings by Marcinowski et al. (1979), or that localized to xylem epi-, endo- and exodermis in stems and roots of chick pea seedlings by Burmeister and Hösel (1981). A problem may exist, however, in using antibodies for localisation; supposedly specific antibodies have been repeatedly observed to bind non-specifically with lignified secondary cell walls (R.A. Savidge, unpublished data).

Coniferin has been found present in the cambial zone and its derivatives throughout the period of cambial growth, but it becomes undetectable at the onset of cambial dormancy in autumn, before the last cambial derivatives have completed their maturation into latewood (Savidge, 1988, 1989, 1991; Förster and Savidge, 1995; Savidge et al., 1998). Coniferin has never been detected in stems during cambial dormancy (Freudenberg and Harkin, 1963; Terazawa and Miyake, 1984; Savidge, 1988, 1989, 1991; Förster and Savidge, 1995; Savidge et al., 1998). Quantitative investigations of endogenous indol-3-ylacetic acid, sucrose and coniferin in *Larix laricina* cambium revealed that, of the three, only coniferin content varied parallel to seasonal cambial activity (Savidge, 1991), and biochemical investigations revealed that the presence or absence of UDPG: coniferyl alcohol glucosyltransferase (CAGT; EC 2.4.1.111) activity is the explanation for the qualitative seasonal variation of coniferin, indicating that seasonal variation in coniferin has its explanation in seasonal change in gene expression (Förster and Savidge, 1995; Savidge and Förster, 1998; Förster et al., 2000).

Ibrahim and Grisebach (1976) were first to report purification and characterization of a CAGT, isolated from suspensions of Paul's scarlet rose. The enzyme catalysed the transfer of glucose from UDPG to coniferyl alcohol and had the highest substrate specificity reported to date for a CAGT ($K_m = 3.3\times10^{-9}$ M for coniferyl alcohol; $K_m = 2\times10^{-5}$ M for UDPG). In 1977, Ibrahim confirmed the substrate specificity using CAGT isolated from young lignifying stems of *Forsythia ovata*, demonstrating it to be distinct from other glucosyltransferases, which are capable of nonspecifically glucosylating hydroxy phenols, flavonols, anthocyanidins and phenolic acids.

Schmid and Grisebach (1982) purified and characterized CAGT from *Picea abies*, and found coniferin to inhibit CAGT in a noncompetitive manner, with product inhibition starting at approximately 10 mmol/g. Schmid et al. (1982) also immunolocalized CAGT to the epidermis, subepidermis and vascular bundles of young *P. abies* seedlings. Intracellularly, it was located in the parietal cytoplasmic layer, indicating that CAGT is a soluble enzyme of the cytoplasm, in agreement with Ibrahim (1977). Förster and Savidge (1995) reported that coniferin below 10 mmol/g_{tissue} showed no inhibitory effect on activity of CAGT of *Pinus banksiana*, but it did inhibit CAGT above 10 mmol/g. The catalytic activity of the coniferin-specific β-glucosidase isolated from lignifying tissues was not found to reside in CAGT obtained from the same tissues, at the same developmental stage (Savidge and Förster, 1998). Recently, Förster et al. (1999, 2000) confirmed the pronounced specificity of CAGT for UDPG; however, they unexpectedly found that CAGT from *P. strobus* also expressed high activity when UDP-galactose was supplied to the enzyme.

E-Coniferaldehyde has been detected in the cambial sap of conifers (Freudenberg and Neish, 1968), bamboo (Tanaka et al., 1998) and oak (Fernààndez de Simòn et al., 1996). Despite the generally low endogenous coniferylaldehyde levels in plants and the efficient reduction of cinnamyl aldehydes to cinnamyl alcohols, coniferyl aldehyde glucosides have nevertheless been isolated from bark of *Syringa velutina* (Park et al., 1999) and *Kolopanax pictus* (Sano et al., 1991).

Cinnamyl aldehydes have also been reported as suitable substrates for CAGT (Ibrahim and Grisebach, 1976; Schmid and Grisebach, 1982; Förster et al., 1999, 2000). Preliminary investigations indicated that CAGT

catalysed the conversion of cinnamyl aldehydes to their corresponding 4-*O*-β-D-glucosides in vitro (Förster et al., 1999, 2000). CAGT from *Pinus strobus* appeared to produce higher amounts of cinnamyl aldehyde glucosides than monolignol glucosides; however, the specific turnover rate (i.e. ratio between administered substrate and obtained product) was approximately 8 times lower (Förster et al., 2000). In seasonal investigations of CAGT activity, Förster et al. (2000) presented evidence for in vitro generation of coniferyl aldehyde glucoside to parallel similar seasonal patterns to that observed for coniferin. In the present study, we confirm, for the first time, by proton NMR spectroscopy, the enzymatic glucosidic turnover of cinnamyl aldehydes catalysed by CAGT isolated from pine cambial tissue. Seasonal patterns of CAGT activity for monolignols and cinnamyl aldehydes are provided and their K_m values reported for the first time. This is the first report of in vitro biosynthesis of dihydroconiferyl alcohol glucoside.

2. Results and discussion

Molecular structures of the predicted enzymatic products were confirmed by ^{1}H NMR spectroscopic analyses. Two-dimensional COSY and HMQC NMR spectra were obtained to aid in structure elucidation. For both semi-preparative and analytical HPLC, an assay was developed to effectively separate the cofactor uridine 5′-diphosophoglucose (UDPG), the monolignol substrates and the corresponding product glucosides, allowing exact quantitation of the catalysed reaction. Based on this assay, enzymatic products were separated using semi-preparative HPLC techniques, collected and lyophilized, resulting in mg quantities of the desired compounds.

The monolignol-specific UDPG was extracted and partially purified (Savidge and Förster, 1998) from approximately 400 g of differentiating xylem from *Pinus strobus* harvested in late May. IEF and native PAGE indicated purification to homogeneity, however, SDS–PAGE and N-terminal sequencing of the resulting major band revealed the presence of two proteins, one without any evident homology to known proteins and the other yielding perfect homology to the internal sequence of a glucosyltransferase precursor. Because of the almost identical physico-chemical features (p*I* 5.0 and molecular weight 43 kDa) of both proteins, complete purification could not yet be achieved (Förster et al., 2000).

All substrates tested in the assay were successfully converted to their 4-*O*-β-D-glucosides, as evidenced by the chemical shifts of the glucosyl moieties (not reported) in the ^{1}H NMR spectra. The glucosyl moiety did not bond to the alcoholic hydroxyl group of the phenylpropane side chain of the monolignol substrates (i.e. as in *iso*-coniferin), which is in agreement with Schmid and Grisebach's (1982) findings for *Picea abies*. Although Ibrahim (1977) obtained small amounts of *iso*-coniferin (i.e. *trans*-coniferyl alcohol-1-*O*-β-D-glucoside) from *Forsythia ovata*, this isomer of coniferin to our knowledge has not yet been reported in conifers.

^{1}H NMR data for the enzymatic products, along with that of coniferyl alcohol, are presented in Table 1, while corresponding molecular structures are found in Fig. 1. Carbon 9 (Table 1) refers to either the primary alcoholic carbon atom (i.e. as in coniferin (**1**), syringin (**2**), dihydroconiferyl alcohol glucoside (**5**) and coniferyl alcohol) or the aldehydic carbon atom (i.e. as in coniferyl aldehyde glucoside (**3**) and sinapyl aldehyde glucoside (**4**)). As evidenced by large coupling constants for the 7-H/8-H of the double bond (i.e. $J = 15.8$, 15.8, 16.6 and 14.8 Hz for **1–4**, respectively), products **1–4** maintained a *trans* orientation. Chemical shifts for glucosyl hydrogens are not reported, but were observed ranging from $\delta = 3.1$–3.8 ppm.

Chemical shifts of 9.61 and 9.63 ppm, corresponding to the aldehyde hydrogens for **3** and **4**, respectively, clearly demonstrate that the glucosyl moiety must have attached at the 4′-position of the aromatic ring, as opposed to the primary alcohol of the phenylpropane side chain.

When comparing the ^{1}H NMR spectra of coniferin and coniferyl alcohol, a larger up-field shift (i.e. up to 0.38 ppm) is observed for the aromatic hydrogens compared to the aliphatic ones. This suggests the glucose attached to the phenol oxygen, and not that of the primary alcohol. Since the structures and chemical shifts for **2** and **5** are similar to **1**, the same conclusions were obtained.

As previously mentioned, *E*-coniferin formation has been reported in various plants throughout the plant kingdom; however, by way of contrast, American beech exceptionally accumulates *cis*-monolignols. Yamamoto et al. (1990) reported a glucosyltransferase in bark of *Fagus grandifolia*, which showed an unusual preference for *Z*-coniferyl alcohol catalysing the formation of *Z*-coniferin. The glucosyltransferase isolated from cambial tissues of *Pinus strobus* did not accept *cis*-coniferyl alcohol and a mixture of *cis* and *trans* substrates always resulted in formation of *E*-coniferin, as evidenced by HPLC separation (results not shown). Plausibly, the maintenance of a *trans* orientation during catalysis is an essential requirement for converting suitable substrates to 4-*O*-β-D-glucosides in the cambium of *Pinus strobus*.

The catalytic activity of UDPG: CAGT in the formation of monolignol glucosides increased more than 3-fold in early June compared to CAGT isolated in mid-May (Fig. 2). The data agree with results obtained from cambial tissue of *Pinus banksiana* (Savidge and Förster, 1998); however, considerable differences in CAGT activity observed between cambium and developing xylem of *Pinus banksiana* did not appear in corresponding tissues of *Pinus strobus* (data not shown). Seasonal fluctuations in CAGT activity and levels of monolignol

Fig. 1. Structure of monolignol glucosides.

glucosides in cambial tissue parallel each other (Fig. 2, Savidge et al., 1998) with comparable efficiencies in the formation of aldehydic and alcoholic glucosides.

In addition, dihydroconiferyl alcohol (DHCA) was accepted as a suitable substrate for the pine CAGT and converted to its corresponding 4-*O*-β-D-glucoside (Fig. 1, Table 1). The 4-*O*-β-D-glucoside has been reported in needles of *Pinus contorta* (Higuchi et al., 1977). Ralph et al. (1997) recently reported dihydroconiferyl alcohol as a main constituent of lignin in a mutant loblolly pine. The involvement of dihydrophenylpropanoids in the biosynthesis of plant pigments (Schmitt and Schneider, 1999) suggests, in general, that dihydro-compounds play a role in secondary metabolism.

The effective turnover of both cinnamyl alcohols and cinnamyl aldehydes by CAGT during the growing season was confirmed by the determination of the apparent K_m values of the various substrates (Table 2). The apparent K_m values were obtained from Lineweaver–Burk plots at saturating concentrations of UDPG. For coniferyl alcohol, when assayed in phosphate buffer at pH 7.6, a K_m of 120 μM was obtained. Sinapyl alcohol, although not synthesized in pines, also served as a substrate with an apparent K_m of 154 μM. The data confirm former results for *Pinus banksiana*, where sinapyl alcohol reached 96% of the relative activity of coniferyl alcohol (Savidge and Förster, 1998). A comparable K_m value (250 μM) was reported for spruce (Schmid and Grisebach, 1982).

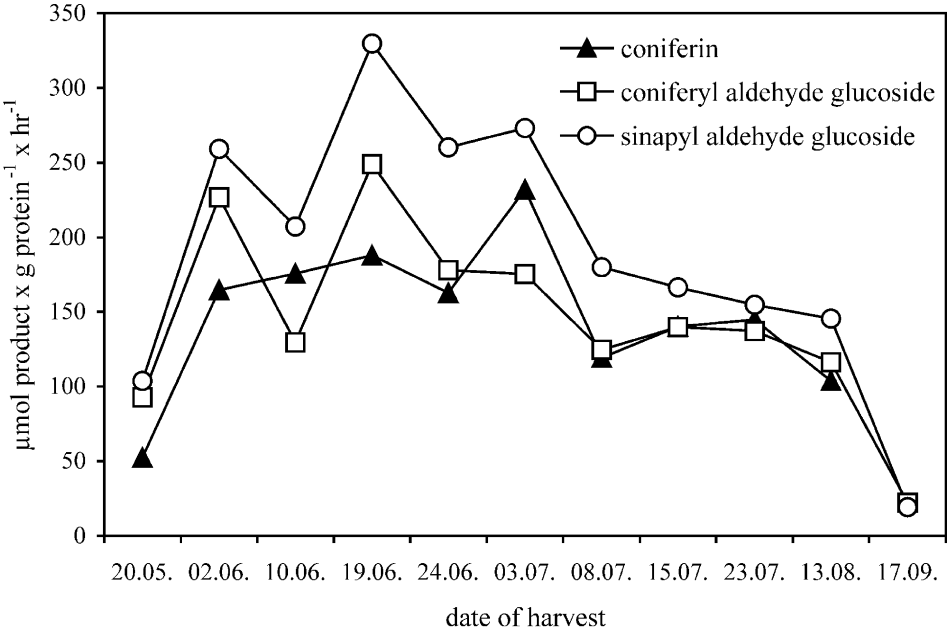

Fig. 2. Seasonal activity pattern of UDPG:CAGT in developing xylem of *Pinus strobus* as determined by in vitro experiments.

Table 2
Enzymatic parameters of the partially purified UDPG:CAGT from cambium of *Pinus strobus*

Substrate	Enzymatic product	K_m (µM)	V_{max} ($nM \times mg^{-1}_{protein} \times min^{-1}$)
Coniferyl alcohol	Coniferin	119.6	1.17
Sinapyl alcohol	Syringin	153.5	1.54
Coniferaldehyde	Coniferaldehyde-4-*O*-β-D-glucopyranoside	317.4	1.85
Sinapaldehyde	Sinapaldehyde-4-*O*-β-D-glucopyranoside	241.7	1.38

Coniferyl aldehyde and sinapyl aldehyde glucosylation resulted in K_m values of 317 and 242 µM, respectively, thus working in close proximity to the order of cinnamyl alcohols. Nevertheless, existing differences in the enzymatic turnover of cinnamyl alcohols and aldehydes, evident by the reported K_m values, underline that the hydroxyl group of the phenylpropane side-chain constitutes a more efficient substrate configuration. As reported before (Förster et al., 2000), cinnamyl alcohols and cinnamyl aldehydes compete with each other for CAGT when provided as dual substrates, with alcohols being more efficient in inhibiting the formation of cinnamyl aldehyde glucosides.

Cinnamyl aldehydes have been previously reported as appropriate substrates; however, structure and physiological relevance was not investigated. The amount of aldehydic glucosides obtained in investigations of the substrate specificity of CAGT in *Picea abies* (Schmid and Grisebach, 1982) and suspension cultures of Paul's Scarlet Rose (Ibrahim and Grisebach, 1976) was expressed as relative activity in comparison to coniferyl alcohol. Because of the lack of authentic compounds for co-chromatography, the structure of the presumed glucosidic products could not be unequivocally elucidated. Hence, the data in this report based on HPLC separation and NMR investigation (Table 2) confirm, to our knowledge for the first time the real structure of the enzymatic products (Fig. 1). In contrast to the glucosyltransferase purified from *Forsythia ovata* (Ibrahim, 1977) and in agreement with the glucosyltransferase purified from *Picea abies* (Schmid and Grisebach, 1982) the CAGT from *Pinus strobus* expressed almost no activity with cinnamic acids (Förster et al., 2000). The glucosylation of cinnamic acids (Nurmann and Strack, 1980; Lorenzen et al., 1996; Fons et al., 1998; Wang and Ellis, 1998) has been demonstrated previously, with the glucosyl moiety attached to the carboxyl group of the side-chain.

The observed seasonal fluctuations of both cinnamyl alcohol and aldehyde glucoside formation (Fig. 2) coincide with events of wood formation, i.e. formation of primary walled radially enlarged cells and the first appearence of differentiated tracheids undergoing secondary-wall formation and lignification (Savidge and Förster, 1998). Preliminary examination revealed both high activities of the glucosyltransferase and developmental processes during June and July (Fig. 2) in the cambial zone, thus concentrating the characterization and purification of the CAGT to this time of the season. Lignification is not developmentally correlated to the formation of monolignol glucosides as shown previously

(Leinhos and Savidge, 1994; Savidge and Förster, 1998). However, some observed metabolic connections to wood formation and lignification once the glucosides are produced in abundance needs further clarification.

CAGT, in catalyzing the formation of cinnamyl alcohol glucosides, evidently competes with coniferyl alcohol dehydrogenase (CAD) and monolignol oxidising enzymes for coniferyl alcohol. Our data (Fig. 2, Table 2) indicate that the glucosyltransferase must also compete with CAD for available cinnamyl aldehydes by forming the corresponding aldehydic glucosides (Fig. 1).

Results obtained in the past few years have prompted a reconsideration of the established lignin biosynthetic pathway. It is clear now that inter-conversions of lignin precursors may occur at varied points along the lignification pathway, and not necessarily solely at the phenylpropanoid acid stage. In addition, the ratio of guaiacyl to syringyl units can be modified at the level of CoA esters (Grimmig et al., 1999), cinnamyl aldehydes (Osakabe et al., 1999), cinnamyl alcohols (Chen et al., 1999a,b) and monolignol glucosides (Matsui et al., 1996).

Taken together, the questions of if and how CAGT (i.e. alone or in a regulatory manner with the coniferin-specific β-glucosidase) may participate in controlling availability of cinnamyl alcohols and/or cinnamyl aldehydes for lignin formation deserves further efforts.

3. Experimental

3.1. General experimental

Coniferyl alcohol, sinapyl alcohol, coniferyl aldehyde and sinapyl aldehyde were purchased from Aldrich. E-coniferin was isolated from *P. strobus* (Savidge, 1989) and dihydroconiferyl alcohol was obtained as previously described by Savidge (1987). Before processing and HPLC analysis, handcut sections of cambium and developing xylem were examined by microscopy as previously described by Savidge (1988).

3.2. Trees

Healthy *Pinus strobus* between 15 and 18 years old growing in the University of New Brunswick Woodlot, Fredericton, NB, Canada, were selected. Sufficient amounts of protein for this study were isolated for purification from a number of trees harvested in late May 1997. Individual trees were harvested during the growing season (April–September) for investigations into seasonal CAGT activity patterns. On each date, stem segments from the main axis were removed with a handsaw and brought directly to the laboratory for processing. The bark was peeled from the wood and the exposed inner bark surface (i.e. cambial zone) and wood surface (i.e. developing xylem) were scraped individually into cryogenic vials (Savidge et al., 1982). The tissue was then stored in liquid nitrogen until preparation for CAGT analysis.

3.3. Enzyme isolation

Buffer systems used include: extraction buffer (0.2 M phosphate (Na_2HPO_4, NaH_2PO_4), 10% polyvinylpyrroli done, 7.5% glycerol, 15 mM aminocaproic acid, 10 mM dithiothreitol, 14 mM β-mercaptoethanol, pH 7.6), equilibration buffer (0.1 M phosphate (Na_2HPO_4, NaH_2PO_4), 14 mM β-mercaptoethanol, pH 7.6), sodium phosphate buffer (Na_2HPO_4, NaH_2PO_4, 100 mM, pH 7.6). Cambial tissue was pulverized to a homogeneous powder and extracted for 1 h in extraction buffer. The suspension was filtered and the filtrate centrifuged for 20 min (4°C) at 15,500×*g*. The supernatant was centrifuged (1 h, 4°C) at 100,000×*g* to remove microsomes. Protein in the supernatant was precipitated with $(NH_4)_2SO_4$. Protein precipitated between 40 and 85% $(NH_4)_2SO_4$ was collected by centrifugation (23,300×*g*, 20 min, 4°C). The resulting pellet was resuspended in phosphate buffer (2.5 ml), then applied to Sephadex G-25 (20 mm i.d.×100 mm, previously equilibrated in equilibration buffer). One ml fractions of soluble protein were collected. Fractions showing transferase activity were pooled and concentrated by centrifugation at 2455×*g* using a Centricon YM-10 concentrator. All subsequent isolation and purification of UDPG: coniferyl alcohol glucosyltransferase (CAGT) was carried out according to Förster and Savidge (1995) and Savidge and Förster (1998).

3.4. Protein determination

Protein concentrations were determined using the method developed by Lowry et al. (1951), modifying final volumes to 40% of the original assay. The UDPG: CAGT was then applied in a 40-fold dilution, using bovine serum albumin as a standard, and measured at 578 nm.

3.5. Semi-preparative HPLC and product separation

Reversed-phase HPLC of the enzyme assay aliquots was performed according to Savidge (1989) on a Milton Roy system with a semi-preparative C18 ODS Ultrasphere column (Beckman, 5 μm spheres, 150×10 mm i.d.). Assays were carried out on a larger scale (i.e. total volume 2 ml) in order to obtain sufficient product for analytical investigations. The enzyme incubation mixture consisted of 100 mM phosphate buffer (pH 7.6), 2 mM UDPG, 1mM of the substrates in question and approximately 800 μg protein. Enzyme assay incubation time was 60 min at 36°C. Product separation was achieved with a linear gradient over 30 min (5–100% MeOH, adjusted to pH 3.0 with acetic acid) with a flow

rate of 5 ml/min and UV detection at 260 nm: R_t coniferin 8.0 min, 266 nm: R_t syringin 8.7 min, 330 nm: R_t coniferyl aldehyde glucoside 9.0 min, 320 nm: R_t sinapyl aldehyde glucoside 9.8 min, 262 nm: R_t *p*-coumaryl alcohol glucoside 8.7 min, 276 nm: R_t dihydroconiferyl alcohol glucoside 8.3 min., 266 nm. Enzymatic products were collected from semi-preparative HPLC eluant and freeze dried. The compounds were characterised by GC–MS and ^{1}H NMR and used as standards in analytical HPLC.

3.6. Ultraviolet-visible spectra

Ultraviolet-visible spectra of the purified enzymatic products were obtained using a computer-controlled UV/vis spectrophotometer (Shimazu, UV-2102-PC). Spectra were recorded from 195 to 450 nm and compared to spectra obtained in analytical HPLC work-up.

Coniferin (**1**) λ_{max} (MeOH) nm (log ε): 260 (1,3), 214, λ_{min} (MeOH) nm: 238, $\lambda_{shoulder}$ (MeOH) nm: 296; syringin (**2**) λ_{max} (MeOH) nm (log ε): 266, (1,23), 221, λ_{min} (MeOH) nm: 240; coniferyl aldehyde glucoside (**3**) λ_{max} (MeOH) nm (log ε): 330 (1,16), 236, λ_{min} (MeOH) nm: 266, $\lambda_{shoulder}$ (MeOH) nm: 306; sinapyl aldehyde glucoside (**4**) λ_{max} (MeOH) nm (log ε): 320 (0,55), 236, λ_{min} (MeOH) nm: 268; dihydroconiferyl alcohol glucoside (**5**) λ_{max} (MeOH) nm: 276, 224, λ_{min} (MeOH) nm: 248.

3.7. Nuclear magnetic resonance

Approximately 1–2 mg of coniferin, coniferyl aldehyde glucoside, syringin and sinapyl aldehyde glucoside were each dissolved in 600–700 μl deuterated methanol and placed in individual 5 mm NMR tubes. Only microgram quantities of dihydroconiferyl alcohol glucoside were available, which was subsequently dissolved in approximately 600 μl deuterated methanol, and placed in a 5 mm NMR tube. ^{1}H spectra were recorded on a 400 MHz, Unity 400 NMR spectrometer, at 25°C. The residual solvent peak, CHD_2OD, (3.30 ppm) was used as an internal standard. Two-dimensional COSY spectra and one-dimensional spectra were obtained.

3.8. Analytical HPLC and glucosyltransferase assay

Analytical HPLC was performed on a computer-controlled Jasco system consisting of an autosampler (AS950-10), multiwavelength detector (MD 910), ternary gradient unit (LG 980-02) and a 3-line-degasser (DG 980-50) on a Peltier-thermostated Sepsil C18 column (Jasco, 5 μm spheres, 125×3 mm i.d.). Cinnamyl alcohol glucosides were eluted in low pressure gradient mode in H_2O: MeOH (containing 1% HCO_2H) over 55 min (2–39% MeOH for 35 min, 39–100% MeOH for 15 min), and cinnamyl aldehyde glucosides over 70 min (2–60% MeOH for 50 min, 60–100% MeOH for 20 min) with a flow rate of 0.5 ml/min. Column temperature was adjusted to 26°C. Data analysis was accomplished using Borwin PDA (version 1.0) and chromatography (version 1.22.03 B) software.

The enzyme incubation mixture (i.e. total volume 200 μl) contained 200 nM UDPG in 10 μl H_2O, various amounts of substrate in 10 μl MeOH, 80 μl sodium phosphate buffer and approximately 100 μg protein dissolved in sodium phosphate buffer. The various substrates were incubated for 10 min at 36°C, then terminated using 20 μl HOAc (50%). K_m values were calculated at fixed concentration of UDPG (1 mM) by linear regression of 1/v vs. 1/s (Lineweaver-Burk plot) with Grafit (version 4.0.1). All experiments were performed in triplicate and compared to a control containing all constituents but terminated prior to catalytic activity by HOAc precipitation of the enzyme.

Acknowledgements

We would like to thank Dr. L. Calhoun for support on compilation of the NMR data for the cinnamyl glucosides. V.J.S. and R.A.S. thank NSERC for research funding. HF was supported by a Grant-in-Aid (FO 271/4-1) of the Deutsche Forschungsgemeinschaft (Bonn, Germany).

Received 25 July 2000; received in revised form 26 January 2001

Abstract

Coniferaldehyde and NADPH when incubated with microsomes isolated from developing xylem of *Pinus strobus* yielded coniferyl alcohol and dihydroconiferyl alcohol in vitro. D-(+)-Pinitol was also found to be a microsomal constituent. Endogenous *E*-coniferyl alcohol content, quantified in dormant buds, cambium, bark and needles of *Pinus resinosa* and *P. strobus* by isotope-dilution combined gas chromatography mass spectrometry (GC/MS) using ring-$^{13}C_6$-coniferyl alcohol, was at a level similar to that of endogenous indol 3-ylacetic acid (IAA). Wounding (branch girdling) induced more than a 10-fold increase in content of endogenous *E*-coniferyl alcohol in dormant non-lignifying cambium, a clear indication that monolignol biosynthesis is not coupled to lignification. © 2001 Elsevier Science Ltd. Keywords: *Pinus resinosa*; *Pinus strobus*; Coniferophyta; Pinaceae; Red pine; Eastern white pine; Cambium; Phenylpropanoid; Lignification; Microsomes

1. Introduction

The potential to alter lignin content and chemistry of vascular tissues through recombinant DNA technologies, combined with perception of economic gains accruing from such genetic modification, has taken lignification research from a state of neglect less than two decades ago into an area of major activity today. Reports of new enzymes, precursors and products of phenylpropanoid metabolism have transformed the former three-pronged *p*-hydroxyphenyl (H), guaiacyl (G), syringyl (S) model of lignification biochemistry (Neish 1960; Freudenberg and Neish 1968) into a more complex metabolic network having competence to generate novel as well as H, G and S lignins (Li et al., 1997, 1998, 1999, 2000; Goffner et al., 1998; Chen et al., 1999; Humphreys et al., 1999; Osakabe et al., 1999; Halpin et al., 2000; Matsui et al., 2000). However, the overall mechanism of lignification still remains less than well elucidated, and immense strings of ''unknown-function'' DNA remain to find meaning within physiological genomics.

The overriding difficulty is one of definition: *What is lignin?* Lignin is commonly described as a complex ''polymer'' (singular) although there is abundant evidence that H, G and S lignins co-occur as distinct entities within the same cell-wall material. Microscopic observations based not only on varied histochemical reactions but also on quantitative differences in UV fluorescence, energy dispersive X-ray, autoradiographic and fine structural data have indicated lignin heterogeneity within cell-wall layers, across cell walls, and between woody cell types (Fergus and Goring, 1970; Parham and Côté, 1971; Wood and Goring, 1971; Kutscha and Gray, 1972; Wardrop, 1981; Saka et al., 1982; Terashima et al., 1986, 1988; Terashima and Fukushima, 1988; Maurer and Fengel, 1990; Daniel et al., 1991; Downes et al., 1991). Despite microscopically detectable differences, chemical analyses have with few exceptions (e.g. Kim et al., 1994) melded any molecular heterogeneity within woody tissues into one pot, and then attempted to deduce polymeric structure in terms of a singular substance (Obst and Kent Kirk, 1988). In addition to H, G and S lignins, wall-bound hydroxybenzoic acids of poplar wood, also found in cell walls of mosses, arguably qualify as a component of lignin (Wilson et al. 1989; Fukushima et al., 1994; Kim et al., 1995). Thus, the

PII: S0031-9422(01)00142-X

statement by Neish (1960) that "no one knows how many different kinds of lignin exist" remains valid today.

Lignin-carbohydrate complexes are a well-known feature of in situ lignins in wood cell walls, and it could be that co-valent linkages between polysaccharide and H, G and/or S polyphenolic substances are what distinguish 'true' lignins from unbound or weakly bound cell-wall polyphenolics, in which case the catalytic mechanism for carbohydrate bonding is all important in defining and understanding lignification. Alternatively, whether or not H, G, S and other polyphenolics are linked to wall carbohydrates, they might be considered as lignins (as has been the case when synthetic model dehydrogenation polymers of *p*-coumaryl, coniferyl and sinapyl alcohols have been investigated), making precursor polymerisation mechanism(s) the focus (compare Gang et al., 1999; Kwon et al., 1999; Sederoff et al., 1999).

Progress in lignification biochemistry undoubtedly depends on development of improved separation methods as a preliminary to chemical analysis. In this respect, ethanol-soluble, 'organosolv' or native "lignin" macromolecules can be readily obtained (Desmet, 1961; Sakakibara et al., 1987), e.g. from *Populus* spp., and separated electrophoretically or by gel permeration chromatography (Desmet, 1961; Košíková et al., 1990; Niku-Paavola, 1991).

In addition to defining and solving the macromolecular structure(s) of lignin, there is a need to know what substances are able to serve as "precursor" (as opposed to "monomer") and to understand what cellular mechanisms facilitate precursor allocation as lignin is deposited. Coupling of monolignol radicals into "dilignols" (which pedantically could be considered as 'lignans') does not necessarily have anything to do with lignification, even in lignifying tissues where 'free' lignans and lignin co-exist (Lewis and Davin, 1998). Deciding whether low abundance moieties such as *p*-coumaryl, coniferyl and sinapyl aldehydes and the reduced dihydro forms of the corresponding monolignols are normal precursors, products of post-polymerative monolignol processing, or artefacts of chemical analysis ultimately requires answering several additional questions: (1) What putative precursors are actually present in the exoplasmic space during lignification? (2) What catalytic activities are actually present in relation to those precursors? (3) What is the exoplasmic environment (e.g. pH, $[O_2]$, $[H_2O_2]$, etc.) where catalysts and substrates generate lignin? Remarkably, after more than a century of research, definitive information remains crudely unfocussed and/or incomplete in relation to each of those three questions.

Here we address aspects of the first two of those three questions, focussing on coniferyl alcohol metabolism (Fig. 1). *E*-Coniferyl alcohol has often been portrayed as the immediate precursor for G lignin, but it is by no means

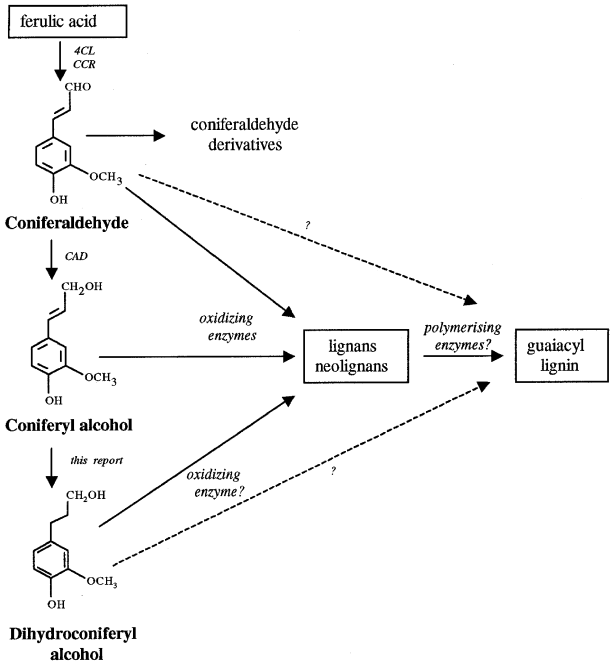

Fig. 1. Possible metabolic flow supporting guaiacyl lignin formation.

exclusively used in lignification, being convertible into coniferaldehyde, lignans, glucosides and, as indicated in the present study, also into dihydroconiferyl alcohol (Fig. 1). The coniferaldehyde moiety is found in G lignin at least in small quantities and was abundant in "lignin" of a mutant pine species (Peng and Westermark, 1997; Ralph et al., 1997, but compare Lewis, 1999). As indicated in Fig. 1, coniferaldehyde arises by 4-coumarate: CoA ligase (4CL) converting ferulic acid into the CoA thioester and the latter being de-esterified through the action of cinnamoyl-CoA reductase (CCR). Cinnamyl alcohol dehydrogenase (CAD) is well established to interconvert coniferaldehyde and coniferyl alcohol, but immense glucosyltransferase activity in the growing cambium (at least that of conifers) provides a mechanism to deplete the coniferyl alcohol pool in support of *E*-coniferin accumulation, thus ensuring that CAD favours the coniferaldehyde to coniferyl alcohol conversion (Savidge 1989; Förster et al., 1999, 2000). Coniferaldehyde can also be converted into various derivatives that, at best, affect lignification only indirectly by reducing substrate supply (Förster et al., 1999, 2000; Sy and Brown, 1999; Li et al., 2000). Thus, although coniferaldehyde conceivably is incorporated into the lignin matrix directly or, perhaps, as a component of a lignan, the mere presence of coniferaldehyde in a tissue is not an indication that lignification is either occurring or about to occur. For example, coniferaldehyde, vanillin and related compounds occur in non-lignified (but heavily suberized) bark of cork oak (Conde et al., 1997). Low concentrations of *E*-coniferaldehyde have been reported in cambial sap of conifers (Freudenberg and

Neish, 1968), as well as in extracts of bamboo (Tanaka et al., 1998) and oak (Fernàndez de Simòn et al., 1996).

Dihydroconiferyl alcohol has been obtained from kraft black liquors of conifer woods (Löwendahl et al., 1978; Niemelä, 1989), sap of maple (Lee et al., 1981), developing xylem of pine (Savidge, 1987), and pyrolysed *Cryptomeria japonica* wood (Kuroda et al., 1994). Dihydroconiferyl alcohol was also reported to be elevated in "lignin" of the same mutant pine tree containing abundant coniferaldehyde (Ralph et al., 1997). As explained above, it remains uncertain whether dihydroconiferyl alcohol per se serves as a precursor for lignification, or if it is even biosynthesised (Lewis, 1999).

2. Results and discussion

2.1. Coniferyl alcohol and dihydroconiferyl alcohol from coniferaldehyde

Pure coniferaldehyde and NADPH in phosphate buffer were provided to purified microsomes from lignifying xylem of *Pinus strobus*. Following 15 min, 1, 4 and 8 h, the incubations were stopped, centrifuged, the supernatants extracted into ethyl acetate (EtOAc), and each EtOAc fraction dried under a stream of nitrogen. The residue was taken up in a small volume of methanol (MeOH), adjusted to 95% water [pH 3.0 acetic acid (HOAc)] and the soluble constituents profiled by C18 reversed phase high performance liquid chromatography (HPLC) using a 95% water (pH 3.0 HOAc) to 100% MeOH gradient, monitoring UV absorbance at 262 nm, collecting all major peaks and, following trimethylsilylation, analyzing them by combined gas chromatography–mass spectrometry (GC/MS) in scanning mode. The HPLC data (Fig. 2) indicated that residual coniferaldehyde eluting at 13.2 min was present after all incubations, separating at baseline resolution from a major peak at 11.2 min.

To determine whether the unknown chromatographic peak was an endogenous microsomal constituent, as opposed to a product of coniferaldehyde/NADPH incubation, freshly prepared microsomes were extracted with phosphate buffer and analyzed by HPLC. Other freshly prepared microsomes were extracted with EtOAc, the EtOAc dried, and the residue trimethylsilylated and analyzed by GC/MS. Those investigations yielded no evidence for any of the aromatic substances shown in Fig. 1, but they did yield D-(+)-pinitol, distinguished by its GC retention time and highly diagnostic fragments, in particular *m*/*z* 260 (Fig. 3). Pinitol is a well known metabolite of general occurrence in conifers (Kretz, 1973) and is thought to modulate drought, salinity and low temperature stresses, also to scavenge hydroxyl radicals (Orthen et al., 1994). To our knowledge this is the first report of pinitol in microsomes.

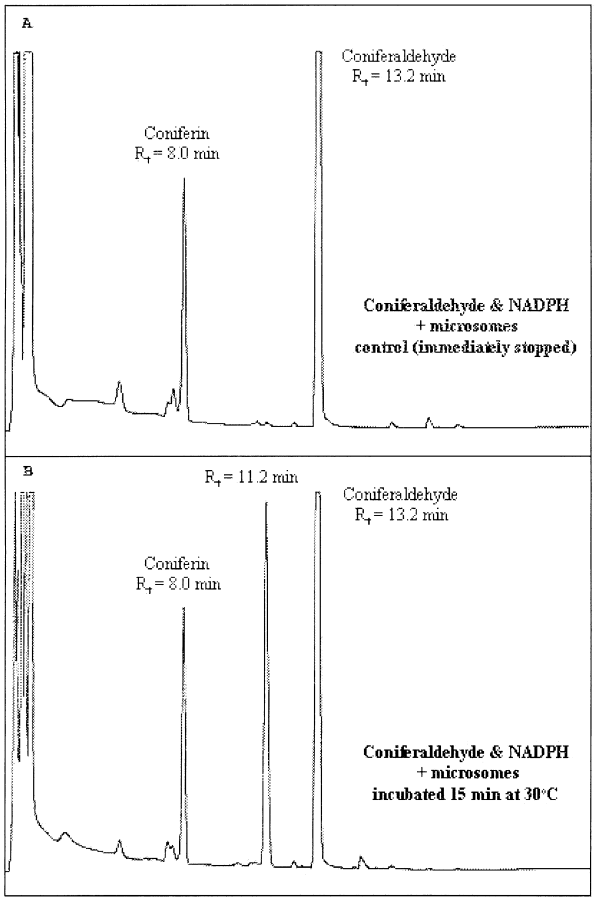

Fig. 2. HPLC traces showing λ 262 nm peaks generated after 0 min (A) and 15 min (B) incubation of coniferaldehyde and NADPH with microsomes. The fraction eluting at 11.2 min (B) yielded coniferyl alcohol and dihydroconiferyl alcohol by GC/MS. Note the residue of endogenous coniferin remaining despite extensive washing of the microsomes prior to incubation.

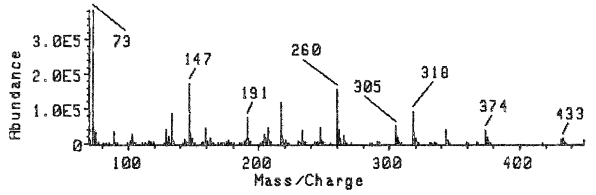

Fig. 3. EI mass spectrum of trimethylsilylated D-(+)-pinitol at 13.936 min obtained from microsome 'control' (no coniferaldehyde or NADPH provided).

The 11.2 min HPLC peak generated by incubating coniferaldehyde and NADPH with microsomes comprised two compounds by GC/MS: dihydroconiferyl alcohol and coniferyl alcohol (Figs. 4 and 5). Microsomes alone were devoid of both compounds. Dihydroconiferyl alcohol and coniferyl alcohol were both readily detected within the first 15 min of in vitro incubation (Fig. 2), and they exhibited increasing accumulation in the 1, 4 and 8 h incubations. *E*-Coniferyl alcohol abundance was approximately four times that of dihydroconiferyl alcohol. When coniferaldehyde and NADPH

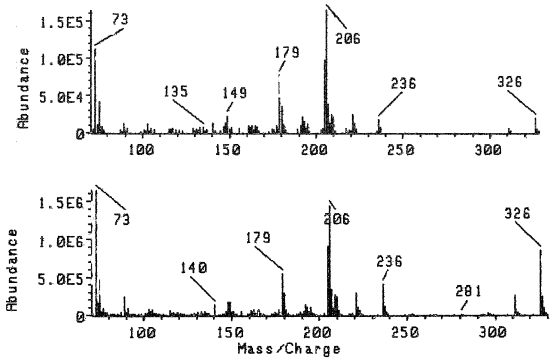

Fig. 4. EI mass spectra (70 eV) of dihydroconiferyl alcohol (as di-TMSi ether) produced in vitro in the presence of microsomes provided coniferaldehyde and NADPH (top), and as the synthetic standard (bottom), both with GC retention times of 13.5 min.

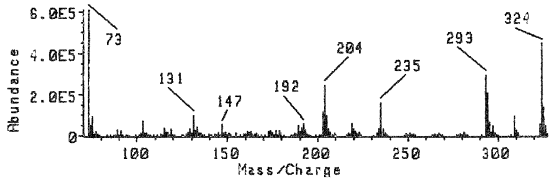

Fig. 5. 70 eV EI mass spectrum of the di-TMSi ether of coniferyl alcohol produced in vitro in the presence of microsomes incubated with coniferaldehyde and NADPH.

were incubated in buffer lacking microsomes, a trace amount of coniferyl alcohol was detected by selected-ion-monitoring (*m*/*z* 324), but no dihydroconiferyl alcohol was detected by either HPLC or GC/MS. Microsomes provided coniferaldehyde but not NADPH yielded neither coniferyl nor dihydroconiferyl alcohol. Coniferin was invariably associated with microsomes (Fig. 2); thus, some evidently is membrane associated. Based on data from our controls, microsomes contained little if any coniferin-specific β-glucosidase activity.

Dihydroconiferyl alcohol has previously been obtained from sap, bark, wood and other sources, as noted above; however, catalytic mechanisms for hydrogenation of C–C double bonds are still obscure, with a few exceptions (Hirata et al., 2000; Fillgrove and Anderson, 2000). Our data indicate that coniferaldehyde in the presence of NADPH is reduced to coniferyl alcohol which is further reduced to dihydroconiferyl alcohol by one or more microsomal enzymes. *Saccharomyces cerevisiae* evidently converts coniferaldehyde into coniferyl alcohol and dihydroconiferyl alcohol under fermentation conditions (Larsson et al., 2000). Acetaldehyde and ethanol are abundantly present in both hardwoods and conifers (MacDonald and Kimmerer, 1991; N. Forneris and R.A. Savidge, unpublished data), in agreement with O_2 not uncommonly being in short supply during cambial growth (Eklund and Klintborg, 2000). Thus, under anaerobic conditions dihydroconiferyl alcohol biosynthesis in cambium likely occurs by a mechanism similar to that occurring in yeast. Based on the extensive washing associated with preparation of the microsomal fraction (see Experimental), there can be little doubt that the hydrogenation catalyst(s) was somehow associated with the membrane fraction of developing xylem. Whether the reducing enzyme(s) is actually an integral part of microsomal membranes remains to be unequivocally determined, but there is evidence that the entire phenylpropanoid pathway is conducted on membrane associated enzyme complexes (Hrazdina and Wagner, 1985).

2.2. Endogenous coniferyl alcohol

Prior to this work, *E*-coniferyl alcohol had been repeatedly observed by GC/MS to be a common constituent in pine needles of different ages at all seasons (RAS, data not shown). We had also observed that *E*-coniferin accumulates in cambium above a girdle (Savidge, 1989; Steeves and Savidge, 2000) and that UDPG:coniferyl alcohol glucosyltransferase activity in both cambium and developing xylem is tightly coupled to seasonal cambial growth (Savidge and Förster, 1998). In view of an earlier report that ^{14}C-labelled quinic acid was transported from pine needles to the stem (Kretz, 1973), the possibility that coniferyl alcohol exported from needles to stem could explain coniferin accumulation above a girdle was investigated. To answer this question, ring-$^{13}C_6$-*E*-coniferyl alcohol was synthesized from $^{13}C_6$-vanillin and used as internal standard during extraction, purification and isotope dilution GC/MS (Figs. 6 and 7).

Applications (10 μg) of exogenous $^{13}C_6$-coniferyl alcohol were made to cut apical surfaces of *P. resinosa* needles intact on stem segments standing upright in water in the laboratory, followed by a time study over 1–24 h to determine whether the coniferyl alcohol was moving through the needle. At each time, needles were removed, cut into 2-cm segments, frozen and pulverized in liquid nitrogen, extracted with phosphate buffer, the latter extracted with EtOAc and the EtOAc dried down, trimethylsilylated and analyzed by GC/MS in selected-ion monitoring mode (*m*/*z* 309, 324, 315, 330). Analysis of the content of $^{13}C_6$-coniferyl alcohol present at increasingly more basal positions along the needle from the site of application of $^{13}C_6$-coniferyl alcohol, as well as in the cambium at the stem region associated with the needle, yielded no indication that coniferyl alcohol was exported from needles to stem (data not shown).

Endogenous *E*-coniferyl alcohol was present in dormant buds, needles and cambia of *Pinus resinosa* and *P. strobus* (Table 1). The content of coniferyl alcohol during dormancy was low, similar to endogenous IAA, and it is unclear what if any role such a low level of coniferyl alcohol fulfils in dormant tissues.

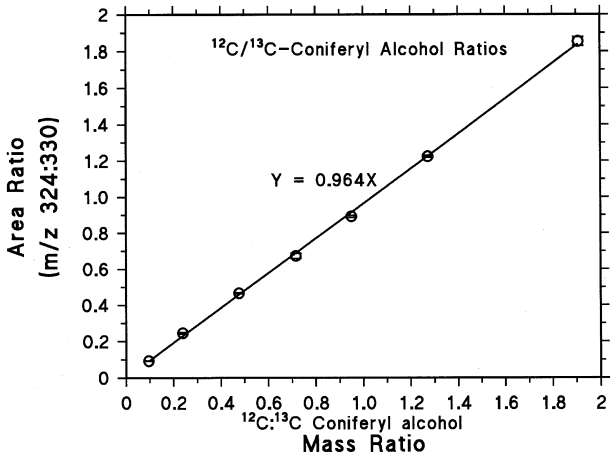

Fig. 6. Integrated peak area ratio as a function of mass ratio of *E*-coniferyl alcohol. Standard errors of the mean are indicated for triplicate analyses.

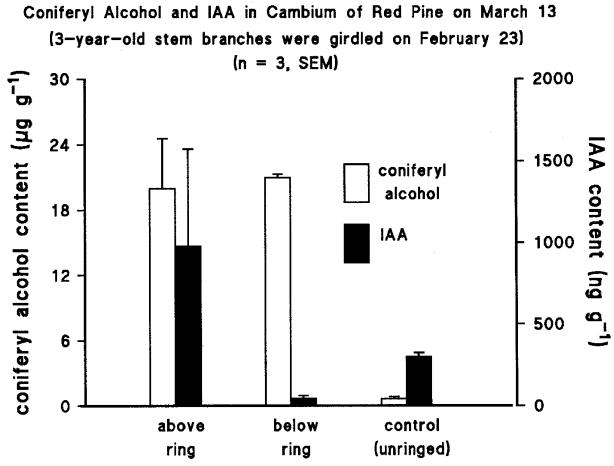

Fig. 7. Endogenous *E*-coniferyl alcohol and IAA per gram fresh weight of tissue found by isotope dilution GC/MS in dormant cambium of *Pinus resinosa* 18 days after branches were ring girdled at the three-year-old position. Standard errors of the mean are indicated for three distinct genotypes.

Coniferyl alcohol content began to increase in cambium immediately before initiation of cell-division activity in late winter (Table 1: 19 April). This perhaps explains the abrupt appearance of *E*-coniferin in early spring, it having been observed that UDPG:coniferyl alcohol glucosyltransferase activity resumes at that time (Savidge and Förster, 1998).

Our girdling experiments gave no indication that coniferyl alcohol specifically accumulated above the ring of removed bark (Fig. 7), and neither was coniferin detected by HPLC in either girdled or control tissues, in agreement with previous observations that coniferin is absent from conifer cambium during dormancy (Savidge et al., 1998). We were surprised to observe that stem girdling stimulated more than a 10-fold increase in cambial content of coniferyl alcohol below as well as above the girdle (Fig. 7). The elevated and similar levels of coniferyl alcohol above and below the girdle indicate that wounding induced coniferyl alcohol biosynthesis. Temperatures remained relatively cool from date of girdling until when tissues were harvested, ambient never exceeding 12°C and temperatures at nights commonly below zero. Water content in the tissue was that characteristic of the dormancy state (approximately 55%, in contrast to >90% during growth). Cambium both above and below the girdles remained dormant throughout the experiments, and no microscopy evidence was seen for lignification having occurred. Possibly our observations are related to induction of CAD activity by ozone and fungal elicitors (Walter et al., 1988; Galliano et al., 1993), but further research is needed to determine the nature and extent of ancillary metabolism needed to produce coniferyl alcohol in response to wounding under such limiting environmental conditions.

In contrast to coniferyl alcohol, the phytohormone IAA accumulated above the girdle and decreased below, relative to non-girdled control branches (Fig. 7). This confirms an earlier report of IAA being exported from needles and buds and moving basipetally in the dormant stem (Savidge and Wareing, 1982), and it is additional evidence that the heightened coniferyl alcohol content found below the girdles cannot be explained in terms of export from another source.

Biosynthesis of coniferyl alcohol by cambium when there is neither lignification occurring nor any obvious need for it in support of lignification agrees with the observation that coniferin is also generated quite precociously in relation to its perceived role in lignification (Savidge, 1989; Savidge et al., 1998; Savidge and Förster, 1998; Förster et al., 2000). As previously noted (Savidge, 1989), the evidence indicates that monolignol biosynthesis and lignification are distinct, developmentally uncoupled phenomena, and it follows that CAD activity is not specific to lignin synthesis. During xylogenesis, a mechanism must operate to allocate monolignols to lignification.

3. Experimental

3.1. General experimental procedures

Reversed-phase HPLC was performed at 5 ml/min according to Savidge (1989) on a Milton Roy system connected to a semi-preparative C18 ODS Ultrasphere column (Beckman, 5 µm spheres, 150×10 mm i.d.). Protein was determined by the method of Lowry et al. (1951) with bovine serum albumin for calibration, and measured at 578 nm.

Table 1
Endogenous coniferyl alcohol content per gram fresh weight in dormant tissues of *Pinus* spp. as estimated by isotope-dilution GC/MS

Tissue analyzed	Date harvested	Coniferyl alcohol (μg/g)	Comments
Terminal buds from a 15-year-old *P. resinosa*	6 February	0.44	Bud scales were included
One-year-old needles from a 15-year-old *P. resinosa*	6 February	0.91	
One-year-old phloem and cambium from a 15-year-old *P. resinosa*	6 February	0.32	Cambium dormant, bark did not peel
Two-year-old needles from a 15-year-old *P. resinosa*	6 February	0.87	
Three-year-old needles from a 15-year-old *P. resinosa*	6 February	0.93	
Three-year-old phloem and cambium from a 15-year-old *P. resinosa*	6 February	0.32	Cambium dormant, bark did not peel
Three-year-old outer bark from a 15-year-old *P. resinosa*	6 February	0.43	Cambium dormant, bark did not peel
Cambial region from a 3 year-old branch of a 15 year-old *P. resinosa*	13 March	0.42	Cambium dormant, bark did not peel
Cambial region from a 3 year-old branch of a 15 year-old *P. strobus*	31 March	1.85	Cambium dormant, bark did not peel
Cambial zone from the 3 year-old main stem of a 15 year-old *P. strobus*	9 April	1.81	Bark peeled, CZ on wood only, Cambium dormant
Cambial zone from the 4 year-old main stem of a 12 year-old *P. strobus*	19 April	6.52	Bark peeled, CZ on wood, protoplasm Cleaning but no cell division activity yet

3.2. Plant material

Eastern white pine (*Pinus strobus* L., 12- to 18-year-old) and red pine (*Pinus resinosa* Ait., 12-year-old) trees growing in the University of New Brunswick woodlot, Fredericton, NB, Canada, were used for these investigations. Girdling during winter of three red pine trees was done by cutting the bark with a sharp razor blade around the circumferences of branches. Two rings, one centimetre apart, were cut in the central region of three-year-old internodes of seven-year-old branches. The bark and cambial zone were removed from between the two cuts by scraping down to the wood with a knife. All lateral branches basal to the girdle were cut off and all basal-to-girdle needles were also removed from the main axis of each of the seven-year-old branches investigated. The investigation was repeated during two successive winters with the same result (Fig. 7).

3.3. Microsome preparation

Eastern white pine (12- to 18-year-old) was harvested in late May and thereafter. Stem segments from the main axis were removed by hand saw and immediately transferred to the laboratory for processing. Handcut sections were examined by microscopy to determine the stage of cambial growth, as previously described (Savidge et al., 1998; Savidge, 2000), and only developing xylem exhibiting secondary-wall formation was used. To isolate developing xylem, the bark was scored along the long axis with a razor sharp knife and peeled from the wood as previously described (Savidge et al., 1982, 1998). The tissue on the exposed wood surface was scraped into cryovials and immediately submerged in liquid nitrogen, where it was continually maintained until processed for microsomes.

All subsequent processing was done at 4°C, pre-cooling all equipment before use. Pre-weighed developing xylem (10–15 g) was ground in mortar with pestle in the presence of extraction buffer (1 mg ml^{-1} 0.2 M sodium phosphate, containing 150 ml glycerol, 0.744 g KCl, 2.032 g $MgCl_2 \cdot 6H_2O$, 180 μl mercaptoethanol, 0.932 g Na_2EDTA adjusted to pH and made up to 1.0 l with water), and left to stand at 4°C for 30 min. The suspension was filtered through 4 layers of cheesecloth and the filtrate centrifuged 10 min at 2500×*g*; then the supernatant was decanted and re-centrifuged 20 min at 23,500 ×*g*. The supernatant was decanted and again centrifuged 1 h at 100,000 ×*g*. The supernatant was discarded and the 100,000 ×*g* pellet re-suspended in extraction buffer, homogenized in a 15 ml Wheaton Tissue grinder, again centrifuged 1 h at 100,000×*g*, and the supernatant again discarded. The pellet was suspended in 3 ml of sodium phosphate buffer (0.1 M, pH 7.6), homogenized in a Wheaton Tissue grinder, measured for protein content, and adjusted to a protein content of 3 mg ml^{-1}. Microsomes prepared in this way were used immediately.

3.4. Microsomal incubation

Microsomes (3 mg protein equivalent) prepared as described and suspended in sodium phosphate buffer (0.1 M, pH 7.6) were provided 1 mM *E*-coniferaldehyde (Sigma-Aldrich) and 1 mM NADPH (Sigma-Aldrich), incubated at ambient temp. and stopped after 1, 4 and 8 h by addition of HOAc (100 μl). Controls containing microsomes and NADPH in buffer were stopped after 1 h. The stopped incubations were centrifuged (23,500×*g*, 4°C, 10 min). The supernatant was extracted three times

with an equal volume of EtOAc and the three EtOAc extracts combined and dried under nitrogen. The microsomal pellet was extracted overnight with EtOAc, centrifuged (23,500×*g*, 4°C, 10 min) and the EtOAc dried under nitrogen, derivatized with N,O-bis(trimethylsilyl)trifluoroacetimide (Pierce) and heated at 70°C for 1 h prior to GC/MS.

3.5. Gas chromatography — mass spectrometry

Fractions collected from the HPLC were freeze dried, transferred to tapered microvials in MeOH, dried under nitrogen, derivatised with *N,O*-bis(trimethylsilyl)trifluoroacetimide (BSTFA, Pierce), capped and heated at 70°C for 1 h prior to GC/MS. Combined gas chromatography–mass spectroscopy (HP 5890A GC, HP 5970B MS, HP 59970C ChemStation) was done in scanning mode (*m*/*z* 70–500) or selected-ion monitoring mode (coniferyl alcohol: *m*/*z* 309, 324, 315, 330; dihydroconiferyl alcohol: *m*/*z* 206, 311, 326; IAA: *m*/*z* 202, 208, 319, 325). Splitless injections into a deactivated glass liner at 200°C were separated using a 30-m HP-1 (0.25 mm i.d., 1 μm cross-linked methylsilicone) open tubular column, temperature programming from 40 to 300°C at 16°C/min, He flowing at 0.5 ml/min. The ion source (EI) was at 70 eV. Endogenous D-(+)-pinitol was confirmed to be associated with microsomes using a D-(+)-pinitol standard (Sigma-Aldrich) and analysing the pentatrimethylsilyl derivative.

3.6. $^{13}C_6$-coniferyl alcohol synthesis

$^{13}C_6$-Coniferyl alcohol was produced by a slightly modified method of Daubresse et al., 1994). Vanillin (100 mg, ring-$^{13}C_6$, 99%, Cambridge Isotope Laboratories CLM-1515) was acetylated using pyridine-acetic anhydride (1:1 v/v, 1.0 ml) in a sealed vial at 120°C for 1 h, cooled on ice and extracted thrice with equal volumes of CH_3Cl. The combined CH_3Cl extracts were dried under a stream of N_2. CH_2Cl_2 (1.76 ml), Tris-[2-(2-methoxyethoxy)-ethyl]amine (TDA-1, 0.167 g), and saturated aqueous K_2CO_3 (2.76 ml) were added to a 10 ml tapered reacti-vial and stirred vigorously to form an emulsion. Acetylated vanillin (~126 mg) dissolved in CH_2Cl_2 (1 ml) and (1,3-dioxolan-2-yl)methyltriphenylphosphonium bromide (0.333 g) were added to the emulsion, and it was left overnight at room temp., stirring slowly. The organic phase (upper layer) was removed to a clean 10 ml tapered reacti-vial, and the aqueous residue was extracted twice with CH_2Cl_2 (2×2.6 ml) and the CH_2Cl_2 extracts combined with the organic layer. HCl (10%, 2.6 ml) was added to CH_2Cl_2 and the solution was stirred for 12 h at room temp. The aqueous phase (upper layer) was decanted, diluted by addition of 4 ml H_2O, and extracted with CH_2Cl_2 (2×2.6 ml). After combining these CH_2Cl_2 extracts with the organic phase, it was washed with saturated $NaHCO_3$ (2 ml) followed by saturated NaCl (2 ml). Dry $MgSO_4$ (50 mg) was added to dry the organic layer, and the CH_2Cl_2 was then centrifuged (3000 × *g*) and the supernatant evaporated under a stream of N_2. The dry material was dissolved in CH_2Cl_2: EtOAc (90:10) and subjected to high performance liquid chromatography (normal phase silica gel, 5 μm, 10 mm i.d.×150 mm column, Jones Chromatography) using isocratic conditions (CH_2Cl_2–EtOAc 90:10, 5 ml min^{-1}) and monitoring at λ 260 nm. The major peak eluting from 2–4 min was collected, and that fraction combined from successive HPLC runs was dried under N_2 to yield a dark brown oil. The oil was dissolved in MeOH and stored at −18°C to yield, by GC–MS of the non-derivatized compound, crystals of *E*-3-(4-acetoxy-3-methoxyphenyl)-2-propenal. The crystals were recovered by filtration through GF/F glass microfibre (Whatman), dissolved in MeOH and transferred to a reacti-vial (7 ml MeOH). Under a stream of N_2, KH_2PO_4 (0.612 g) was added, then the solution was chilled in an ice bath and $NaBH_4$ (42.5 mg) slowly added, followed by stirring for 1 h at 0°C. Ice cold H_2O (7 ml) was added slowly and the solution adjusted to pH 4 (5% aqueous HCl) followed by removal of the MeOH in vacuo by rotary evaporation at 30°C. The aqueous residue was extracted with CH_2Cl_2 (3×5 ml), the combined CH_2Cl_2 extracts washed with H_2O (2×5 ml), dried with $MgSO_4$, centrifuged at 3000 rpm, and the CH_2Cl_2 dried to give a yellowish oil of *E*-3-(4-acetoxy-3-methoxyphenyl)-2-propen-1-ol (AMPP), which after trimethylsilylation yielded the expected M^+ 294 by GC–MS. AMPP was dissolved in 95% ethanol- 0.2 M KOH (8 ml) that had been pre-purged with N_2 and stirred for 12 h under N_2 at 0°C. H_2O (5 ml) was added and the pH of the suspension adjusted using 5% aqueous HCl with stirring until a clear solution was obtained (pH 4.0), followed by removal of the EtOH in vacuo by rotary evaporation at 30°C. The aqueous residue was extracted with peroxide-free diethyl ether (3×5 ml), the combined ether extracts washed with H_2O (2×2 ml), the ether dried with $MgSO_4$, centrifuged at 3000 rpm, and the supernatant evaporated under N_2. Following reversed phase C_{18} HPLC purification using conditions previously described (Savidge, 1989), pure ring-$^{13}C_6$ *E*-coniferyl alcohol, as confirmed by GC–MS, ^{13}C and ^1H NMR, was obtained. The yield was approximately 10 mg.

3.7. Coniferyl alcohol and IAA extraction, purification and quantification

Tissues were ground in liquid nitrogen in a mortar with a pestle. The powder was weighed and extracted with potassium phosphate buffer (0.1 M, pH 7.0) containing a known mass of $^{13}C_6$-coniferyl alcohol and a known mass of $^{13}C_6$-IAA (Cambridge Isotope

Laboratories). The samples were frozen and thawed, then centrifuged (20,000×*g*, 4°C, 10 min). The supernatant was partitioned thrice against ethyl acetate (EtOAc), the EtOAc extracts combined and dried under nitrogen. The dry residue was dissolved in a small volume of MeOH, adjusted to 5% MeOH with pH 3.0 acetic acid, and purified by reversed phase C_{18} HPLC, collecting the fractions corresponding to standard coniferyl alcohol and IAA. The collected fractions were dried in vacuo by rotary evaporation at 30°C, trimethylsilylated with BSTFA and analysed in selected ion monitoring mode by GC/MS (coniferyl alcohol *m*/*z* 330, 324, 315, 309; IAA *m*/*z* 325, 319, 208, 202).

Oxidation of cinnamyl alcohols and aldehydes by a basic peroxidase from lignifying *Zinnia elegans* hypocotyls

A. Ros Barceló *, F. Pomar

Department of Plant Biology (Plant Physiology), University of Murcia, E-30100 Murcia, Spain

Received 7 June 2000; received in revised form 1 November 2000

Abstract

The xylem of 26-day old *Zinnia elegans* hypocotyls synthesizes lignins derived from coniferyl alcohol and sinapyl alcohol with a G/S ratio of 43/57 in the aryl-glycerol-β-aryl ether core, as revealed by thioacidolysis. Thioacidolysis of *Z. elegans* lignins also reveals the presence of coniferyl aldehyde end groups linked by β-*0*-4 bonds. Both coniferyl and sinapyl alcohols, as well as coniferyl and sinapyl aldehyde, are substrates of a xylem cell wall-located strongly basic peroxidase, which is capable of oxidizing them in the absence and in the presence of hydrogen peroxide. This peroxidase shows a particular affinity for cinnamyl aldehydes with k_M values in the μM range, and some specificity for syringyl-type phenols. The affinity of this strongly basic peroxidase for cinnamyl alcohols and aldehydes is similar to that shown by the preceding enzymes in the lignin biosynthetic pathway (microsomal 5-hydroxylases and cinnamyl alcohol dehydrogenase), which also use cinnamyl alcohols and aldehydes as substrates, indicating that the one-way highway of construction of the lignin macromolecule has no metabolic "potholes" in which the lignin building blocks might accumulate. This fact suggests a high degree of metabolic plasticity for this basic peroxidase, which has been widely conserved during the evolution of vascular plants, making it one of the driving forces in the evolution of plant lignin heterogeneity.

Keywords: Cinnamyl alcohols; Cinnamyl aldehydes; Lignification; Peroxidase; Xylem; *Zinnia elegans*

1. Introduction

Lignins are complex cell wall phenolic heteropolymers covalently associated with both polysaccharides and proteins (Lewis et al., 1999). They are mainly localized in the impermeable water transport conduits of the xylem and other supporting tissues, and result from the oxidative polymerization of cinnamyl alcohols in a reaction that is mediated by both peroxidases (Ros Barceló, 1995; Wallace and Fry, 1999) and H_2O_2-independent oxidases (Bao et al., 1993; Sterjiades et al., 1993), leading to an optically inactive heteropolymer (Ros Barceló, 1997; Lewis, 1999). Although most of the building blocks found in natural lignins are mainly derived from cinnamyl alcohols, recent evidence has suggested that cinnamyl aldehydes are also incorporated in the growing lignin polymer (Higuchi et al., 1994; Lapierre et al., 1995), a situation which is especially evident in CAD (cinnamyl alcohol dehydrogenase)-depleted mutant or transgenic plants (Ralph et al., 1997; Lapierre et al., 1999). Even in wild-type plants, a certain amount of cinnamyl aldehydes escapes reduction by CAD, and accumulates in plant cells in their free forms (Osakabe et al., 1999) or as derivatives (Sy and Brown, 1999). These cinnamylaldehydes may then be deposited in the xylem cell walls, where they co-polymerize with cinnamyl alcohols to yield a highly heterogeneous alcohol/aldehyde lignin polymer (Higuchi et al., 1994). This escape of cinnamyl aldehydes from reduction to cinnamyl alcohols is co-substantial with the nature of the CAD-catalyzed reaction. In fact, CAD catalyzes the following reaction:

$$\text{cinnamyl aldehyde} + \text{NADPH} + \text{H}^+ \leftrightarrows \text{cinnamyl alcohol} + \text{NADP}^+$$

which is no more than an equilibrium. This means that if cinnamyl alcohols are not removed either by transport or conjugation, a certain amount of cinnamyl aldehydes,

PII: S0031-9422(01)00050-4

depending on the NADPH/$NADP^+$ cellular pool, will escape from CAD-mediated reduction. It might be expected that these aldehydes, together with their corresponding cinnamyl alcohols, would ultimately be incorporated into the cell wall lignins. The formation of these highly heterogeneous red lignins, which results from both cinnamyl aldehyde and cinnamyl alcohol copolymerization, apparently occurs in the xylem of *Z. elegans* hypocotyls, as is deduced from the dye reaction of the *Z. elegans* xylem with the phloroglucinol/HCl test (Ros Barceló and Aznar-Asensio, 1999), a specific reaction for cinnamaldehyde groups (Geiger and Fuggerer, 1979).

Zinnia elegans is a seasonal-cycle flowering plant belonging to the Asteraceae family, which is considered to be one of the most evolved families within the dicotyledon angiosperms. Cell walls of *Z. elegans* hypocotyls contain a basic peroxidase of high pI, which shows coniferyl alcohol oxidase activity (Ros Barceló and Aznar-Asensio, 1999) and which has a spectrum typical of a high spin heme class III peroxidase. This strongly basic peroxidase has been localized in the lignin-forming xylem from *Z. elegans* hypocotyls by means of competitive inhibitor-dissected histochemistry (Ros Barceló et al., 2000), and it is considered a marker of tracheary element differentiation in *Z. elegans* cell cultures (Sato et al., 1995a,b). In this work, the substrate specificity of this peroxidase, in the absence and the presence of hydrogen peroxide, for both cinnamyl alcohols and aldehydes is studied. The results illustrate that this cell wall peroxidase shows both a great affinity and a broad substrate specificity towards cinnamyl alcohols and aldehydes. This fact suggests a high degree of metabolic plasticity for this basic peroxidase, which has been widely conserved during the evolution of vascular plants (Ros Barceló et al., 1998), making it one of the driving forces in the evolution of plant lignin heterogeneity.

2. Results and discussion

2.1. Cinnamyl alcohols and cinnamyl aldehydes in the lignifying xylem of Z. elegans hypocotyls

The lignifying xylem from *Z. elegans* hypocotyls gives rise to an intense reaction with both the Maüle ($KMnO_4$) reagent and the Wiesner (phloroglucinol) test (Ros Barceló and Aznar-Asensio, 1999). Since the Maüle reaction is specific for syringyl moieties in lignins (Meshitsuka and Nakano, 1979), while the Wiesner test is specific for cinnamaldehyde groups (Geiger and Fuggerer, 1979), it was concluded that lignins from the *Z. elegans* xylem are rich in syringyl moieties and cinnamaldehyde groups.

To confirm these initial observations on the nature and heterogeneity of *Z. elegans* lignins, cell walls isolated from lignifying *Z. elegans* hypocotyls were subjected to thioacidolysis, and the recovered thioethylated monomers were analyzed by gas chromatography-mass spectrometry. The results showed that thioacidolysis of lignifying *Z. elegans* cell walls gave, as main products, the thioethylated monomers (both *erythro* and *threo* isomers) arising from aryl-glycerol-β-aryl ether structures derived from coniferyl [$m/z = 269$ (100), 75 (18) 73 (15) 235 (8)] and sinapyl [$m/z = 299$ (100), 73 (20) 265 (6)] alcohols. The guaiacyl (G)/syringyl (S) molar ratio for this β-*O*-4 lignin fraction was 43/57. In addition to these thioethylated monomers, thioacidolysis also revealed the presence of significant amounts of the thioethylated monomer arising from the coniferyl aldehyde end group [$m/z = 269$ (100), 73 (57) 135 (6), 209 (5), 295 (4), 239 (4), 192 (3), 418 (1)]. These results suggest that the linear β-*O*-4 lignin fraction from *Z. elegans* hypocotyls contains both coniferyl and sinapyl alcohols to approximately the same extent and, additionally, *O*-4 coniferyl aldehyde-end groups.

2.2. Oxidation of cinnamyl alcohols and cinnamyl aldehydes by cell walls isolated from lignifying Z. elegans hypocotyls

Since coniferyl alcohol, sinapyl alcohol and coniferyl aldehyde are incorporated in *Z. elegans* cell wall lignins, as revealed by thioacidolysis, the following step was to study the in situ ability of *Z. elegans* cell walls to oxidize cinnamyl alcohol and cinnamyl aldehydes. The results showed that cell walls isolated from lignifying *Z. elegans* hypocotyls were able to oxidize cinnamyl alcohols (coniferyl and sinapyl alcohol) and cinnamyl aldehydes (coniferyl and sinapyl aldehyde) in the absence and in the presence of H_2O_2 (Table 1). In fact, almost all the cinnamyl alcohols and cinnamyl aldehydes were oxidized in the presence of 500 μM H_2O_2 by lignifying cell walls within the first hour of incubation.

In the absence of H_2O_2, only minor percentages of oxidation, which never exceeded 10%, were observed (Table 1). This capacity of lignifying *Z. elegans* cell walls

Table 1
Oxidation of cinnamyl alcohols and cinnamyl aldehydes by cell walls isolated from lignifying *Zinnia elegans* hypocotyls

Substrate	μmol Substrate oxidized g^{-1} FW[a]	
	$-H_2O_2$	$+H_2O_2$
Coniferyl alcohol	0.04±0.03 (8.2)	0.48±0.00 (92)
Coniferyl aldehyde	0.02±0.01 (4.1)	0.52±0.02 (100)
Sinapyl alcohol	0.01±0.00 (1.1)	0.52±0.01 (100)
Sinapyl aldehyde	0.01±0.00 (1.9)	0.52±0.01 (100)

[a] The reaction medium contained 50 mM Tris–acetate pH 5.0, an amount of cell walls equivalent to 0.2 g FW, 50 μM of each substrate and, when used, 500 μM H_2O_2, in a total volume of 2.0 ml, which was incubated at 25°C for 2 h. Values are means±S.E. ($n = 3$). Values in parentheses correspond to the percentage of substrate oxidized.

to oxidize coniferyl alcohol, both in the absence and in the presence of H_2O_2, has previously been demonstrated to reside in a cell wall-located class III basic peroxidase (Ros Barceló and Aznar-Asensio, 1999), whose catalytic properties against cinnamyl alcohols and aldehydes were the next subject of study.

2.3. Oxidation of cinnamyl alcohols and cinnamyl aldehydes by the basic peroxidase isolated from lignifying Z. elegans hypocotyls

The oxidation of cinnamyl alcohols and aldehydes by the *Z. elegans* basic peroxidase was monitored by the decay in absorbance in the ultraviolet region. For this, the extinction coefficients for the substrates (coniferyl alcohol, coniferyl aldehyde, sinapyl alcohol and synapyl aldehyde), and the extinction coefficients for each one of the oxidative reactions, $\Delta\varepsilon = \varepsilon_s - \varepsilon_p$ (where ε_s is the extinction coefficient for the substrate and ε_p is the extinction coefficient for the oxidation products), were determined at maximal wavelength by measuring the oxidation of the respective substrates, in the presence of the *Z. elegans* basic peroxidase and an excess of H_2O_2, until no further changes in the spectra occurred. The extinction coefficients calculated are given in Table 2.

Similarly to lignifying *Z. elegans* cell walls (Table 1), the *Z. elegans* basic peroxidase was also capable of oxidizing the two cinnamyl alcohols and the two cinnamyl aldehydes, both in the absence and in the presence of H_2O_2 (Table 3). In the presence of H_2O_2, the catalytic activity of *Z. elegans* peroxidase was in the order: sinapyl alcohol > sinapyl aldehyde > coniferyl aldehyde > coniferyl alcohol (Table 3). This means that *Z. elegans* peroxidase oxidizes sinapyl moieties better than coniferyl moieties, this substrate preference being in accordance with that recently reported for other angiosperm plant peroxidases by Wallace and Fry (1999).

When the ability of the *Z. elegans* basic peroxidase to oxidize cinnamyl (coniferyl and sinapyl) alcohols was expressed on a protein basis, it was surprisingly found that, in the absence of H_2O_2, this protein oxidizes coniferyl and sinapyl alcohol with a similar specific activity to that shown by plant laccases (Table 4). Besides, it was much more able to oxidize coniferyl alcohol than the oxidase isolated from *Pinus strobus* (Table 4), despite the class III peroxidase nature of the *Z. elegans* enzyme (Ros Barceló and Aznar-Asensio, 1999). In the presence of H_2O_2, the specific activity of the *Z. elegans* basic peroxidase against cinnamyl alcohols was substantially greater than the specific activity shown by plant laccases (Table 4), confirming the observation made by Wallace and Fry (1999) on the better catalytic activities of peroxidases compared with laccases in the lignification process.

Table 2
Extinction coefficients calculated for cinnamyl alcohols and cinnamyl aldehydes, and for their corresponding oxidative reactions ($\Delta\varepsilon$) catalyzed by peroxidase

Substrate	ε (mM^{-1} cm^{-1}) (λ [nm])	$\Delta\varepsilon$ (mM^{-1} cm^{-1}) (λ [nm])[a]
Coniferyl alcohol	17.7±1.5 [262]	9.75±0.5 [262]
Coniferyl aldehyde	20.6±0.6 [341]	13.4±0.5 [341]
Sinapyl alcohol	8.12±0.5 [271]	4.14±0.0 [271]
Sinapyl aldehyde	18.6±0.1 [340]	11.9±0.2 [340]

[a] The extinction coefficients for the oxidative reactions ($\Delta\varepsilon$) were determined by oxidation of the respective substrates by *Zinnia elegans* peroxidase in the presence of an excess of H_2O_2 until no further change in the UV spectra occurred. Values are the mean±S.E. ($n=3$).

Table 3
Oxidation rates of cinnamyl alcohols and cinnamyl aldehydes by the *Zinnia elegans* basic peroxidase at 25°C

Substrate	nmol Substrate oxidized min^{-1} g^{-1} FW[a]	
	$-H_2O_2$	$+H_2O_2$
Coniferyl alcohol	3.83±3.10	143.4±6.32
Coniferyl aldehyde	1.20±0.65	352.2±11.0
Sinapyl alcohol	12.0±8.10	467.2±7.80
Sinapyl aldehyde	3.20±2.43	409.4±11.3

[a] The reaction medium contained 50 mM Tris–acetate pH 5.0, 100 μM of each substrate and, when used, 100 μM H_2O_2. Values are means±S.E. ($n=3$).

2.4. Kinetic of the oxidation of cinnamyl alcohols and aldehydes by the Z. elegans basic peroxidase

The oxidation of cinnamyl alcohols and aldehydes by the *Z. elegans* basic peroxidase yields hyperbolic curves, as was the case for sinapyl alcohol (Fig. 1). This fits wells with the irreversible ping-pong mechanism previously validated by us for peroxidase-catalyzed reactions involved in lignin biosynthesis (Ros Barceló et al., 1998), a mechanism which is characterized by a three-step cycle involving a two-electron enzyme oxidation:

$$\mathrm{FeIII} + \mathrm{H_2O_2} \xrightarrow{k_1} \mathrm{CoI} + \mathrm{H_2O} \quad (1)$$

followed by two one-electron reductions:

$$\mathrm{CoI} + \mathrm{RH} \xrightarrow{k_2} \mathrm{CoII} + \mathrm{R^\bullet} \quad (2)$$

$$\mathrm{CoII} + \mathrm{RH} \xrightarrow{k_3} \mathrm{FeIII} + \mathrm{R^\bullet} \quad (3)$$

where FeIII, CoI, CoII and RH are the native enzyme, compound I, compound II, and the phenolic compound, respectively. The most striking characteristic of this kinetic (see Ros Barceló et al., 1998, for details) is

Table 4
Specific activity, in the absence and in the presence of H_2O_2, of the *Zinnia elegans* basic peroxidase against coniferyl and sinapyl alcohols, in comparison with other oxidases involved in the polymerization of cinnamyl alcohols to lignins

Acer pseudoplatanus laccase	6.6	–	18.3		Sterjiades et al. (1993)
Pinus strobus oxidase	0.085	–	–	–	Udagama-Randeniya and Savidge (1995)

[a] Activity was monitored with an O_2 electrode (Bao et al., 1993).

the lineal continuous dependence of both the apparent V_{max}^{RH} values and the apparent k_M^{RH} values for the reducing substrate (i.e. cinnamyl alcohols and aldehydes) on the H_2O_2 concentration:

$$V_{max}^{RH} = 2Ek_1[H_2O_2] \quad (4)$$

and

$$k_M^{RH} = (k_1/k_3)[H_2O_2] \quad (5)$$

as well as the lineal dependence between V_{max}^{RH} and k_M^{RH} values:

$$V_{max}^{RH} = 2Ek_3k_M^{RH} \quad (6)$$

This is also true for the dependence of both the apparent $V_{max}^{H_2O_2}$ and the apparent $k_M^{H_2O_2}$ values for H_2O_2 on the RH (cinnamyl alcohols and aldehydes) concentration (Ros Barceló et al., 1998):

$$V_{max}^{H_2O_2} = 2Ek_3[RH] \quad (7)$$

and

$$k_M^{H_2O_2} = (k_3/k_1)[RH] \quad (8)$$

where there is also a lineal dependence between the $V_{max}^{H_2O_2}$ values and $k_M^{H_2O_2}$ values:

$$V_{max}^{H_2O_2} = 2Ek_1k_M^{H_2O_2} \quad (9)$$

As expected, these kinetic lineal relationships were completely fulfilled by the basic peroxidase isolated from *Z. elegans* hypocotyls for the four substrates (coniferyl and sinapyl alcohol, and coniferyl and sinapyl aldehyde). Figs. 2 and 3 illustrate these lineal plots in the case of sinapyl alcohol.

It should be pointed out that the lineal plots of $V_{max}^{H_2O_2}$ values and $k_M^{H_2O_2}$ values against sinapyl alcohol concentration cross the coordinate origin (Fig. 2B and D), while the lineal plots of V_{max}^{RH} values and k_M^{RH} values against H_2O_2 concentration intercept the ordinate axis at a positive (non zero) value (Fig. 2A and C). This means that there is a residual activity of the *Z. elegans* basic peroxidase at zero H_2O_2 concentration, i.e. the pseudo oxidase activity that is developed by this peroxidase in the absence of exogenous H_2O_2 (see Table 3).

2.5. k_M Values for the peroxidase reaction

The best way to know the affinity of an enzyme for its substrates is to compare the apparent k_M^{RH} values, which, in the case of peroxidase, show a special peculiarity frequently forgotten in the literature: they depend on H_2O_2 concentration [see Fig. 2C and Eq. (5)]. These apparent k_M^{RH} values may also suggest for which particular metabolic reaction of the complex process of lignin assembly a given enzyme has been designed in the course of the evolution of vascular plants. An example of the importance of these values is the recent observation that microsomal 5-hydroxylases, previously named ferulate-5-hydroxylases, hydroxylate coniferyl aldehyde ($k_M = 1$–2.7 μM) and coniferyl alcohol ($k_M = 3$ μM) with a greater affinity than ferulate ($k_M = 286$–1000 μM) (Humphreys et al., 1999; Osakabe et al., 1999), so that there is a tendency to call them coniferyl aldehyde-5-hydroxylases.

This observation is particularly important in the case of peroxidase, since this enzyme is capable of performing multiple metabolic functions (Morales and Ros Barceló, 1997), and is unable to discriminate between

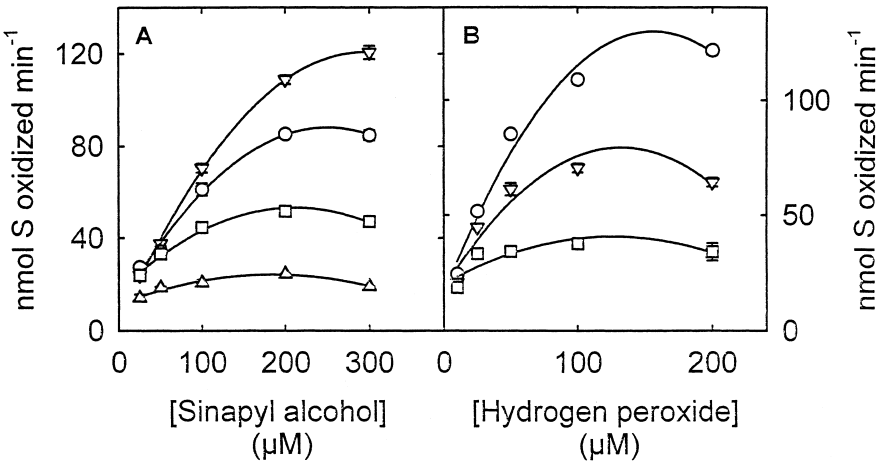

Fig. 1. Dependence of the sinapyl alcohol oxidation rate by the *Zinnia elegans* basic peroxidase on sinapyl alcohol (A) and H_2O_2 (B) concentration. In A, the reaction media contained 10 μM (Δ), 25 μM (□), 50 μM (○) and 100 μM (▽) H_2O_2. In B, the reaction media contained 50 μM (□), 100 μM (▽) and 200 μM (○) sinapyl alcohol. Other details are described in the Experimental section.

cinnamyl alcohols and cinnamyl aldehydes (Table 3). To cast light on this question, the k_M^{RH} values of the *Z. elegans* basic peroxidase for cinnamyl alcohol and aldehydes were examined in detail (Table 5). From these data, it can be concluded that the *Z. elegans* basic peroxidase shows k_M^{RH} values in the μM range, illustrating the great affinity of *Z. elegans* peroxidase for monomeric lignin precursors, especially for cinnamyl aldehydes, which were oxidized with greater affinity than the cinnamyl alcohols.

At this point, it should be recalled that the same weak preference is shown by other enzymes specific for the lignin biosynthetic pathway, such as the microsomal 5-hydroxylases (Humphreys et al., 1999). Nevertheless, the small differences in affinity shown by the *Z. elegans* basic peroxidase for cinnamyl aldehydes are apparently not sufficient to segregate its function towards cinnamyl aldehyde polymerization, since the local concentration of alcohols in the lignifying xylem is probably substantially greater than the local concentration of aldehydes, as may be deduced from their levels in cultured cells undergoing lignification (Anterola et al., 1999) and from the equilibrium constant of CAD (Lewis et al., 1999).

Table 5
k_M^{RH} Values for cinnamyl alcohols and cinnamyl aldehydes during their oxidation by the *Zinnia elegans* basic peroxidase at pH 5.0 for different H_2O_2 concentrations

Substrate	k_M^{RH} (μM)				
	H_2O_2 (μM)				
	5	10	25	50	100
Coniferyl alcohol	13.8	33.8	nd[a]	91.0	244.6

Sinapyl alcohol	nd	21.2	40.1	73.7	174.0
Sinapyl aldehyde	nd	2.7	12.6	22.9	60.6

[a] nd, Not determined.

2.6. k_M Values for the pseudo oxidase reaction

A striking feature of the *Z. elegans* basic peroxidase is that it shows a hydrogen peroxide-independent oxidase activity against both cinnamyl aldehydes and cinnamyl alcohols (Table 3). The pseudo-oxidase activity of this peroxidase may be due, as occurs during the oxidation of other phenols (Singleton, 1987; Jiang and Miles, 1993), to a residual peroxidase activity that is switched on by the traces of hydrogen peroxide formed during the slow phase of both cinnamyl alcohol and cinnamyl aldehyde auto-oxidation:

$$2RH \rightarrow 2R^- + 2H^+ \quad (10)$$

$$2R^- + 2O_2 \rightarrow 2R^\bullet + 2O_2^- \quad (11)$$

$$2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2 \quad (12)$$

where R^- is the phenoxy anion and $R^\bullet$ the phenoxy radical, and which yields, as balance, a net H_2O_2 production:

$$2RH + O_2 \rightarrow 2R^\bullet + H_2O_2 \quad (13)$$

This H_2O_2 formed at trace level could initiate the normal catalytic cycle of the enzyme described in Eqs. (1)–(3). Eqs. (10)–(13) could explain the partial sensitivity of such pseudo-oxidase reactions of peroxidase to both superoxide dismutase and catalase (Badiani et al.,

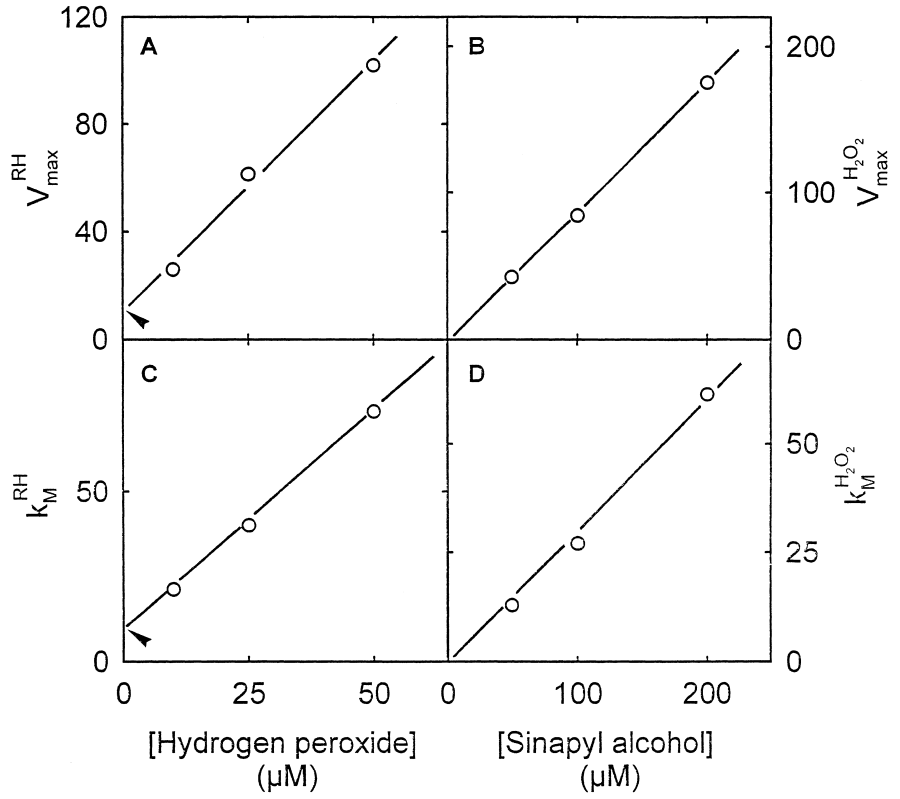

Fig. 2. Plot of V_{max}^{RH} values against H_2O_2 concentration (A), plot of $V_{max}^{H_2O_2}$ values against sinapyl alcohol concentration (B), plot of k_M^{RH} values against H_2O_2 concentration (C), and plot of $k_M^{H_2O_2}$ values against sinapyl alcohol concentration (D), for the oxidation of sinapyl alcohol by the *Zinnia elegans* basic peroxidase. Other details are described in Fig. 1 and in Experimental.

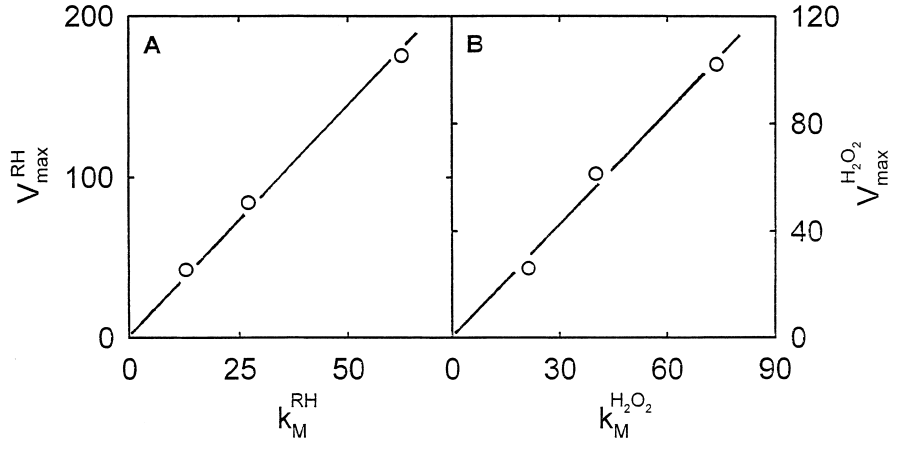

Fig. 3. Plot of V_{max}^{RH} values against k_M^{RH} values (A) and plot of $V_{max}^{H_2O_2}$ values against $k_M^{H_2O_2}$ values (B), for the oxidation of sinapyl alcohol by the *Z. elegans* basic peroxidase. Other details are described in Fig. 1 and in Experimental.

1990; Jiang and Miles, 1993), as well as the observation that basic peroxidases show a greater pseudo-oxidase activity than acidic peroxidases (Chabanet et al., 1993; Ros Barceló et al., 1998), due mainly to the special low k_M values of basic peroxidases for H_2O_2 (Ros Barceló et al., 1998).

The strong affinity of basic peroxidases for H_2O_2 is also true in the case of the *Z. elegans* basic peroxidase, which showed particularly low k_M values for H_2O_2 when coniferyl and sinapyl alcohols were used as reducing substrates (Table 6). These results suggest that this basic peroxidase is well adapted to the H_2O_2-containing lignifying xylem cells of *Z. elegans* hypocotyls (Ros Barceló, 1998a,b). In addition, that the pseudo-oxidase activity of the *Z. elegans* basic peroxidase is directly related to its capacity to use H_2O_2, especially at low concentrations, is clear when the oxidation rates of cinnamyl alcohols and aldehydes in the absence of H_2O_2

(Table 3) (which follow the order: sinapyl alcohol > coniferyl alcohol > coniferyl aldehyde) are compared with its efficacy ($V_{max}^{H_2O_2}/k_M^{H_2O_2}$ values) to use H_2O_2 (Table 7) (which follows the same order: sinapyl alcohol > coniferyl alcohol > coniferyl aldehyde).

Table 6
$k_M^{H_2O_2}$ Values for H_2O_2 during their reduction by the *Zinnia elegans* basic peroxidase at pH 5.0 for different cinnamyl alcohol and cinnamyl aldehyde concentrations

Table 7
Efficacy ($V_{max}^{H_2O_2}/k_M^{H_2O_2}$ values) in H_2O_2 utilization by the *Zinnia elegans* basic peroxidase at pH 5.0 for the different cinnamyl alcohol and cinnamyl aldehydes

Substrate	Efficacy ($V_{max}^{H_2O_2}/k_M^{H_2O_2}$) (nmols s^{-1} mg^{-1} protein μM^{-1})
Coniferyl alcohol	94.28 ± 12.38
Coniferyl aldehyde	18.09 ± 1.90
Sinapyl alcohol	282.83 ± 41.90
Sinapyl aldehyde	nd[a]

[a] nd, Not determined.

For this reason, the k_M values for cinnamyl alcohols and aldehydes during this particular pseudo-oxidase reaction were also calculated. This was done from an extrapolation of the dependence of the k_M values for cinnamyl alcohols and aldehydes on H_2O_2 at zero H_2O_2 concentration (Fig. 2C). The k_M^{RH} values for the pseudo-oxidase reactions are given in Table 8 and, like those obtained for the peroxidase reaction, they were in the μM range. In the absence of exogenous H_2O_2, the *Z. elegans* basic peroxidase also showed a great affinity for the monomeric lignin precursors, especially for coniferyl aldehyde, which is oxidized with greater affinity than coniferyl and sinapyl alcohols (Table 8). Furthermore, in the absence of exogenous H_2O_2, the *Z. elegans* basic peroxidase showed an affinity for the monomeric lignin precursors similar to that shown by an angiosperm (*Populus euroamericana*) laccase, and three orders of magnitude greater than that shown by a gymnosperm (*Pinus taeda*) laccase (Table 8).

Finally, all these k_M values for the lignin precursors shown by the *Z. elegans* basic peroxidase were in the same range as those shown by the peroxidase-preceding enzymes of the lignin biosynthetic pathway, cinnamyl alcohol dehydrogenase and microsomal 5-hydroxylases, which also use both cinnamyl alcohols and aldehydes as substrates (Table 8). The nature of these biochemical constants, which is in accordance with the predictions that may be made from the observed pools and metabolic fluxes of monolignols in lignifying cells (Anterola et al., 1999), implicitly indicates that the one-way highway of lignin macromolecule construction, which properly starts with the reduction of cinnamoyl-CoA's by cinnamoyl-CoA reductases, contains no metabolic "potholes", in which the lignin building blocks might be accumulated.

Table 8
k_M^{RH} Values for cinnamyl alcohols and cinnamyl aldehydes during their oxidation by the *Z. elegans* basic peroxidase at pH 5.0 in the absence of H_2O_2. For comparison, the k_M^{RH} values for cinnamyl alcohols and aldehydes for other enzymes involved in the lignin biosynthetic pathway which use cinnamyl alcohols and cinnamyl aldehydes as substrates are also shown

Enzyme	k_M^{RH} (μM)				
	Alcohol		Aldehyde		Reference
	Coniferyl	Sinapyl	Coniferyl	Sinapyl	
Zinnia elegans basic peroxidase	7.9	7.6	5.1	–

Arabidopsis thaliana ferulate 5-hydroxylase	3.0		1.0		Humphreys et al. (1999)
Liquidambar styraciflua coniferyl aldehyde 5-hydroxylase	–	–	2.77	–	Osakabe et al. (1999)

2.7. Conclusion

A strongly basic peroxidase, located in the aldehyde lignin-forming xylem from *Z. elegans* hypocotyls, is capable of oxidizing both cinnamyl alcohols and cinnamyl aldehydes in the absence and in the presence of H_2O_2. This basic peroxidase shows a particular affinity for cinnamyl aldehydes and some specificity for syringyl-type phenols. Its affinity for cinnamyl alcohols and aldehydes is similar to that shown by the preceding enzymes of the lignin biosynthetic pathway, which also use cinnamyl alcohols and cinnamyl aldehydes as substrates, indicating that the one-way highway of construction of the lignin macromolecule has no metabolic potholes where the lignin building blocks would accumulate. This fact suggests a high degree of metabolic plasticity (versatility) for this basic peroxidase, which has been widely conserved during the evolution of vascular plants, making it one of the driving forces in the evolution of plant lignin heterogeneity.

3. Experimental

3.1. Plant material

EC system standard seeds of *Zinnia elegans* were purchased from W.R. Vanderschoot (Hillegom, The Netherlands). Seedlings were grown for 26 days in a greenhouse under daylight conditions at 25°C (Ros Barceló and Aznar-Asensio, 1999). Fully grown (lignifying) hypocotyls were used for these studies. These hypocotyls showed a xylem cell wall lignification gradient which varied from the top (beginning) to the bottom (advanced), as tested by both the Wiesner test and the Mäule reaction.

3.2. Isolation of cell walls

Lignifying *Z. elegans* cell walls were prepared by a Triton X-100 washing procedure exactly as described (Ros Barceló and Aznar-Asensio, 1999).

3.3. Thioacidolysis of lignifying cell walls

Thioacidolysis of lignifying *Z. elegans* cell walls, which solubilizes the β-*O*-4 lignin core, and GC–MS (Hewlett Packard 5890-HP 5972) analyses were performed essentially as described by Lapierre et al. (1995). MS spectra were recorded at 70 eV.

3.4. Oxidation of cinnamyl alcohols and cinnamyl aldehydes by cell walls isolated from lignifying Z. elegans hypocotyls

To monitor both cinnamyl alcohol and cinnamyl aldehyde oxidation by isolated cell walls, an amount of purified cell walls, equivalent to 0.2 g FW, was incubated with stirring for 2 h at 25°C in an assay medium (2.0 ml) containing 50 μM of the substrate in 50 mM Tris–acetate buffer (pH 5.0), in the presence and in the absence of 0.5 mM H_2O_2. Controls were performed in the presence of a heat (100°C)-denatured cell wall fraction. After this time, the cell walls were centrifuged at 1100 *g* for 5 min at 5°C, the amount of cinnamyl alcohol and cinnamyl aldehyde oxidized being determined from the decay in absorbance at λ_{max} of the supernatants, using the $\Delta\varepsilon$ for each reaction given in Table 2.

3.5. Purification of the basic peroxidase from the intercellular washing fluid from lignifying Z. elegans hypocotyls

The *Z. elegans* basic peroxidase was obtained and purified from intercellular washing fluids of lignifying hypocotyls, as previously described (Ros Barceló and Aznar-Asensio, 1999).

3.6. Spectrophotometric determinations

The oxidation of cinnamyl alcohols and aldehydes by the *Z. elegans* basic peroxidase, in the presence and in the absence of H_2O_2, was assayed spectrophotometrically at 25°C in a reaction medium containing 50 mM Tris–acetate buffer (pH 5.0) using the $\Delta\varepsilon$ for each reaction given in Table 2. The reaction was initiated by the addition of 0.175 μg protein. Other assay conditions have been described previously (Ros Barceló and Aznar-Asensio, 1999), or are described in the figure legends and tables. Protein was determined according to Bradford (1976).

3.7. Chemicals

Coniferyl alcohol, coniferyl aldehyde, sinapyl alcohol and sinapyl aldehyde were purchased from Sigma (Madrid, Spain). The rest of the chemicals were obtained from various other suppliers and were of the highest purity available.

The poly(phenolic) domain of potato suberin: a non-lignin cell wall bio-polymer

Mark A. Bernards *, Fawzi A. Razem

Department of Plant Sciences, University of Western Ontario, London, ON N6A 5B7, Canada

Received 6 July 2000; received in revised form 17 October 2000

Abstract

Suberized plant cell walls have three distinguishing features: (1) tissue specificity, (2) a poly(aliphatic) domain and (3) a unique, "lignin-like" poly(phenolic) domain. With respect to the latter, comparisons have often been made to lignin, but the unique phenolic composition of suberized cells yields a unique polymer better designated as a poly(phenolic) domain. Potato tubers that have been induced to suberize through wounding make an excellent model system with which the chemistry, biochemistry and macromolecular assembly of the suberin poly(phenolic) domain can be monitored. For example, wound healing potato tubers have been used to determine the unique hydroxycinnamic acid nature of its poly(phenolic) domain using specific carbon-13 labeling studies and specific chemical degradation techniques (e.g. thioacidolysis). Furthermore, a suberization-associated anionic peroxidase has been purified from suberizing potato tubers and subsequently shown to oxidize hydroxycinnamic acids (and their derivatives) in preference to monolignols, as well as yield an unique polymer in vitro. We have since extended these studies to begin analyzing the macromolecular assembly process leading to the deposition of this suberized tissue specific domain. To this end we have begun to describe an H_2O_2-generating system with NAD(P)H-dependent oxidase-like properties that is temporally associated with the formation of potato suberin poly(phenolics) during suberization. Herein we describe our progress to date. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

During normal growth and development the cell walls of many cell types, from both woody and herbaceous plant species, become modified to carry out specific functions. For example, xylem vessel and fiber cell walls become lignified to provide the necessary mechanical strength for axial water transport and an upright growth habit. Similarly, the epidermal tissues of underground plant parts (e.g. roots, stolons, tubers), the endodermis and the cells of bark tissue (i.e. cork, periderm) become suberized to provide a nearly perfect barrier to apoplastic water transport, as well as a pre-formed defense against many potential pathogens (e.g. Kolattukudy, 1980, 1984; Lulai and Corsini, 1998). In either case, lignification and suberization have the hallmark of being highly tissue/cell specific. Indeed, cells that ultimately become suberized or lignified either derive from specific progenitor cells in meristems or arise from a distinct cambium.

Both lignification and suberization involve the formation of a three dimensional poly(phenolic) matrix initially within the carbohydrate matrix of the primary cell wall followed by the deposition of additional carbohydrate, protein and poly(phenolic) containing layers, often referred to as secondary cell wall thickenings. In addition to this phenolic component, suberized cells develop a distinct poly(aliphatic) layer with associated phenolic acids (Kolattukudy, 1980), typically deposited between the primary cell wall and the plasma membrane prior to secondary wall formation (reviewed in Bernards and Lewis, 1998). This multi-layered aliphatic polymer, with its associated waxes, is thought to provide suberized tissues with their water impermeability (Soliday et al., 1979; Kolattukudy, 1980, 1984; Vogt et al., 1983; Lulai and Orr, 1994). The poly(aliphatic) domain of

suberized cells has been described as a polyester connected through primary ester bonds between the major aliphatic components (esp. α,ω-dioic acids and ω-hydroxyalkanoic acids), as well as phenolic acids. Recently, however, it has been shown that glycerol makes up a significant proportion of aliphatic suberins (up to 41% in *Pseudotsuga menziesii*) (Graca and Pereira, 1999), and may in fact act as a bridge between the poly(aliphatic) domain and the cell wall-bound poly(-phenolic) domain (PPD).

Given the duality of the cell wall modification that occurs during suberization (i.e. including both poly(-phenolic) and poly(aliphatic) domains), it is argued here that the term *suberin* is insufficient to describe it. Indeed, in the literature, the most common use of the term suberin is in reference to the poly(aliphatic) matrix. The (mis)use of the word suberin is exacerbated by other terms such as *suberinic acids* and *suberans* that have been used (Marques et al., 1996; Bolwell et al., 1997) to describe the aliphatic compounds released by alkaline hydrolysis and the fact that the tissue remaining after alkaline hydrolysis is considered to be "de-suberized"(e.g. Gil et al., 1997). The term *aromatic suberin* has been used to define the alkali-soluble hydroxycinnamic acids readily removed from suberized tissues, typically along with the aliphatics after alkaline hydrolysis or transesterification (e.g. Schreiber et al., 1999). This represents an important subset of phenolics found in suberized tissues and should be recognized as such. Historically, the PPD of suberized tissues has been likened to that of lignified tissues in both composition and structure (Kolattukudy, 1980, 1984), i.e. a polymer assembled from the common "monolignols" *p*-coumaryl alcohol **1**, coniferyl alcohol **2**, and/or sinapyl alcohol **3** (Scheme 1). But, as alluded to above, suberized and lignified tissues have evolved for different purposes in plants, and are found in distinct, specific tissues. These two characteristics argue against their being identical in structure and composition. Indeed, while most suberized tissues do contain small amounts of covalently-linked monolignols (i.e. lignin), relative to lignified tissues, they also contain a significant amount of associated hydroxycinnamic acids such as *p*-coumaric **4**, caffeic **5** and ferulic **6** acids, some of which are covalently cross-linked through bonds other than esters (see Bernards and Lewis, 1998). Interestingly, there is no direct evidence for sinapic acid **7** or its derivatives, other than the relatively large amounts of sinapaldehyde released by alkaline nitrobenzene oxidation (Borg-Olivier and Monties, 1989, 1993).

The common description of the PPD of suberized tissues as "lignin-like" is clearly misleading since it contains little monolignol, and a significant amount of hydroxycinammic acid. Therefore, a more appropriate term is simply "suberin poly(phenolic) domain" or SPPD, which distinguishes it from lignin and indicates its tissue/cell origins and unique phenolic composition.

It is essential to point out that not all suberized tissues are equivalent in the amount of PPD they contain or in their phenolic composition. For example there exists a wide variability in the degree of suberization in tissues ranging from highly suberized cork cells in the outer bark of woody plants to the radial-wall-restricted suberization of the Casparian band in the endodermis. Compared to lignified cells isolated from the same plant tissue, suberized cells studied thus far appear to have a lower monolignol content, higher hydroxycinnamate content and yield different relative amounts of both monomeric and dimeric products upon degradation (e.g. Schreiber, 1996; Zeier and Schreiber, 1997, 1999; Zeier et al., 1999). Indeed, the major difference between lignified and suberized cell wall phenolic polymers appears to be in the covalent incorporation of hydroxycinnamic acids into an otherwise monolignol-based macromolecule, during suberization (Bernards and Lewis, 1998). This may reflect the role of suberized tissues as antimicrobial barriers in plants since hydroxycinnamates are known to have antimicrobial properties (e.g. Friedman, 1997; Cowan, 1999).

Scheme 1. Phenylpropanoids found in the poly(phenolic) domain of suberized potatoes.

The predominantly hydroxycinnamate-based SPPD of potato tubers (Bernards et al., 1995; Negrel et al., 1996), which appears to contain a unique cell wall phenolic polymer, arguably represents an extreme example of how suberized cells can differ from typical lignified cells. Nevertheless, potato tubers have long been used as a model system to study the process of suberization since they suberize quickly and uniformly in response to wounding and are amenable to the exogenous application of metabolic precursors, inhibitors, etc. (e.g. Bernards and Lewis, 1992; Bernards et al., 1995).

The macromolecular assembly of potato SPPD is hypothesized to occur via a peroxidase-mediated free radical coupling process (Kolattukudy, 1980), analogous to the process suggested for lignin formation from monolignols. We have begun to characterize, at the biochemical level, an anionic peroxidase isolated from wound healing potatoes (Bernards et al., 1999) that was first purported to be associated with suberization by Kolattukudy's group (e.g. Espelie and Kolattukudy, 1985; Espelie et al., 1986). Interestingly, this enzyme shows a marked preference for hydroxycinnamates (esp. ferulic acid **6** and its derivatives, such as **8**) over the corresponding monolignols **1–3** and, when incubated with ferulic acid **6** in vitro, produces a polymer characterized by the retention of side chain unsaturation (Bernards et al., 1999). One question that remains is where does the H_2O_2 necessary for peroxidative oxidation of phenolics come from? While several H_2O_2 generating systems have been described in plants (e.g. Elstner and Heupel, 1976; Gross and Janse, 1977; Gross et al., 1977; Angelini and Federico, 1989; Vianello and Macri, 1989, 1991; Cross and Jones, 1991; Wojtaszek, 1997) an NADPH-dependent oxidase has been implicated in the generation of H_2O_2 during the lignification of *Zinnia elegans* (Ros Barceló, 1998a). Independent of this we have obtained data that supports a similar process during wound-induced suberization in potato tubers. In this report we describe our progress in characterizing a wound-induced oxidase that appears to be involved in suberization.

2. Results and discussion

2.1. Potato suberin poly(phenolic) domain: evidence for a unique polymer

Our current model for suberized potato tuber cells depicts a cell wall-associated poly(phenolic) domain with a covalently attached poly(aliphatic) domain residing between the cell wall and plasma membrane (Fig. 1; reviewed in Bernards and Lewis, 1998). The most significant revelation in our understanding of the potato SPPD came from specific carbon-13 labeling studies using [1-^{13}C]-, [2-^{13}C]- and [3-^{13}C]-phe coupled with in situ solid state carbon-13 CP-MAS NMR spectroscopy (Bernards et al., 1995), which demonstrated that the polymer contained a significant proportion of covalently cross-linked hydroxycinnamic acids. This was subsequently verified by the isolation of an *N*-feruloyltyramine **7** derivative from potato suberin after thioacidolysis (Negrel et al., 1996). Importantly, these conclusions were preceded by a series of studies (using spectroscopic and degradative techniques) that strongly suggested that the SPPD had a unique composition and therefore structure (reviewed in Bernards and Lewis, 1998). Equally important was the observation that the aromatic and aliphatic domains of suberized potato tubers are spatially distinct (Lulai and Morgan, 1992) but covalently linked (Stark and Garbow, 1992; Yan and Stark, 1998). These latter points have now also been demonstrated in the suberized cells of *Quercus suber* cork using sophisticated NMR relaxation studies (Gil et al., 1997). Moreover, glycerol has been described as a linker between domains, and as a site for phenolic acid esterification (e.g. Graca and Pereira, 1999) although its presence in suberized tissues has been described earlier (e.g. Schmutz et al., 1993, 1994). Finally, chemical analysis of isolated endodermal or hypodermal tissues from *Clivia miniata*, *Zea mays*, *Cicer arietum* and others (Schreiber, 1996; Zeier and Schreiber, 1997, 1999; Zeier et al., 1999) has revealed that these suberized tissues differ qualitatively and quantitatively from the lignified xylem tissues isolated from the same plants.

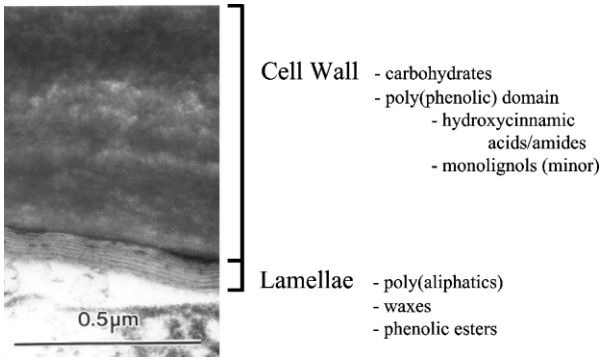

Fig. 1. Anatomy of a suberized potato tuber cell wall. Wound induced suberization of potato tubers results in the formation of a poly(-phenolic) domain, comprised of a hydroxycinnamic acid/amide-monolignol composite polymer embedded in the cellulosic matrix of the primary cell wall. A poly(aliphatic) matrix, evident as a series of alternating light and dark bands (lamellae) is also laid down, but between the cellulosic cell wall and the plasma membrane. This layer also contains waxes and esterified phenolic acids. The image is a TEM micrograph of a potato tuber cell wall, five days post wounding. (Courtesy of L.H. Levine.)

2.2. Biosynthesis of the suberin poly(phenolic) domain

The differences in phenolic biopolymer composition between lignifying and suberizing tissues is also apparent in the metabolic fate of hydroxycinnamoyl-CoA

thioesters during lignin/SPPD formation. For example, we have found that the enzyme hydroxycinnamoyl-coenzyme A oxido-reductase (CCR) is not induced in wounded (i.e. suberizing) potato tubers. By contrast, CCR is strongly induced in cell cultures of *Pinus taeda* when treated under culture conditions that induce lignification (Bernards et al., 2000). Instead, wounding of tubers induces hydroxycinnamoyl transferases (Negrel, et al., 1993, 1995; Lotfy et al., 1994) capable of biosynthesizing feruloyltyramine **8** and ferulate esters **9**. Together, these data suggest that during suberization of potato tubers, hydroxycinnamoyl-CoA derivatives are channeled into metabolic endpoints other than monolignols, (i.e. their apparent metabolic fate during lignification).

2.3. H_2O_2 generation during formation of the suberin poly(phenolic) domain

In order for phenolics to be assembled into the SPPD, they have to be polymerized. The current model used to describe this process involves the oxidative cross-linking of phenolics via an anionic peroxidase. We have begun to characterize this enzyme at the biochemical level (Bernards et al., 1999) and have shown it to prefer hydroxycinnamic acids (esp. **6**, and its derivatives, e.g. **8**) over their corresponding hydroxycinnamyl alcohols (e.g. **2**) in in vitro assays. Moreover, an in vitro polymer prepared from [8-^{13}C] ferulic acid using the purified anionic peroxidase and the slow addition of H_2O_2 had a number of unique features, principally the retention of side chain unsaturation (Bernards et al., 1999). Therefore, it seems as though, at least in suberizing potato tubers, the macromolecular assembly of a poly(phenolic) matrix during suberization favours the polymerization of hydroxycinnamates both in the biosynthesis of monomers as well as in their utilization. However, in order to be effective in the macromolecular assembly of the SPPD, the hydroxycinnamate-preferring anionic peroxidase must be localized to the cell wall, where it is needed. In part this has been done (Espelie et al., 1986), but the specificity of the antibody used was not confirmed, and the resolution of the detection method (fluorescence label) not sensitive enough to discriminate between cell walls and the plasma membrane–cell wall interface. To address this question, we are obtaining specific antibodies to the anionic peroxidase of potato (using deglycosylated native and denatured enzyme), with the intention of using them for immuno-gold-based immunocytochemical localization studies.

In order for peroxidases to function, they require H_2O_2 as oxidant. It follows that in order for the suberization-associated anionic peroxidase to function during SPPD formation, there must be a supply of H_2O_2 generated in situ. We have begun experiments to (1) demonstrate the requirement for H_2O_2 in the SPPD assembly process and (2) identify the source of H_2O_2 that is used.

Using the peroxidase-mediated oxidation of tetramethylbenzidine (TMB) as a histochemical marker (Ros Barceló, 1998b), it can be shown that H_2O_2 is actively synthesized de novo in the SPPD forming layers during wound healing (Fig. 2). Furthermore, the de novo synthesis of H_2O_2 can be inhibited by treatment with diphenyleneiodonium (DPI; Fig. 2), a known inhibitor of NAD(P)H-dependent oxidases (Deme et al., 1994; Dwyer et al., 1996). Still it is not clear whether the source of H_2O_2 is an NAD(P)H-dependent oxidase since it has also been shown that DPI can inhibit the H_2O_2 generating function of peroxidases (e.g. Baker et al., 1998; Bolwell et al., 1998). However, several observations combine to favour an NAD(P)H-dependent oxidase over a peroxidase in suberizing potato tubers during this process: (1) H_2O_2 generation is all but eliminated with $\leqslant$10 μM DPI (Fig. 2), a concentration that only partially inhibits this function of peroxidases (Bolwell et al., 1998), (2) NAD(P)H-dependent oxidases have been implicated in other Solanaceous species induced to generate H_2O_2 in response to stress (e.g. Doke and Miura, 1995; Allan and Fluhr, 1997; Bolwell et al. 1998; Amacucci et al., 1999) and (3) our experiments are

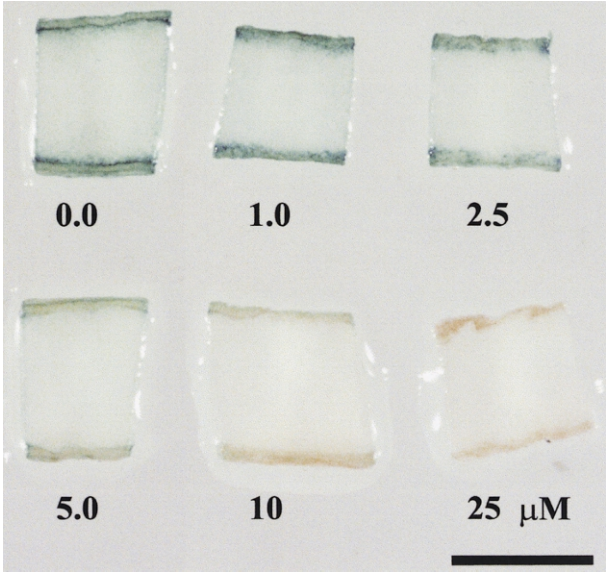

Fig. 2. Inhibition of hydrogen peroxide generation during suberin poly(phenolic) domain formation in wound healing potato tubers. Thin, hand-cut sections (250–500 μm) from wound healing potato tubers (5 days post wounding) were soaked in 1 mM ascorbic acid solution (1 min) and subsequently incubated with 0.0–25 μM diphenyleneiodonium (DPI) for 15 min. Tissues were transferred to 0.15 mg ml^{-1} TMB and the formation of blue-green stain taken as an indication of the presence of H_2O_2 (Ros Barceló, 1998b). Control tissue (0.0 μM DPI) was incubated with water only (after ascorbate treatment) followed by TMB staining. Note the restriction of staining to the layers of cells immediately below the sites of suberization. (Scale bar = 0.5 cm.)

performed without the addition of exogenous NAD(P)H. The last point is particularly important since the H_2O_2 generating capacity of peroxidases generally requires high levels (>1 mM) of NAD(P)H (Ros Barceló et al., 1998). Thus it seems likely that the H_2O_2 hypothesized to be required for SPPD formation is generated by an NAD(P)H-dependent oxidase, presumably present in the plasma membrane of suberizing cells. This observation, however, requires further experimental verification.

Notwithstanding the data presented above, it must also be verified that H_2O_2 is in fact *required* for SPPD formation. To address this question we have incubated potato disks on agar plates containing 25 μM DPI and compared both the soluble and cell wall bound phenolic compounds with those of controls (incubated on agar alone). As can be seen in Fig. 3, when incubated in the presence of DPI, wound healing tuber slices accumulate soluble compounds not present in control tissue (i.e. wound healed in the absence of DPI). For example, a large peak (retention time approx. 17 min) present in the chromatograms obtained from the extractives of DPI-treated tissues is all but absent from control extracts. The 17-min peak represents a pair of phenolic glycosides that remain unidentified to date. It is not clear at this point what role these compounds play in the suberization process, but it is proposed that if not for the presence of DPI in the treatment, both would have been covalently cross-linked into the SPPD.

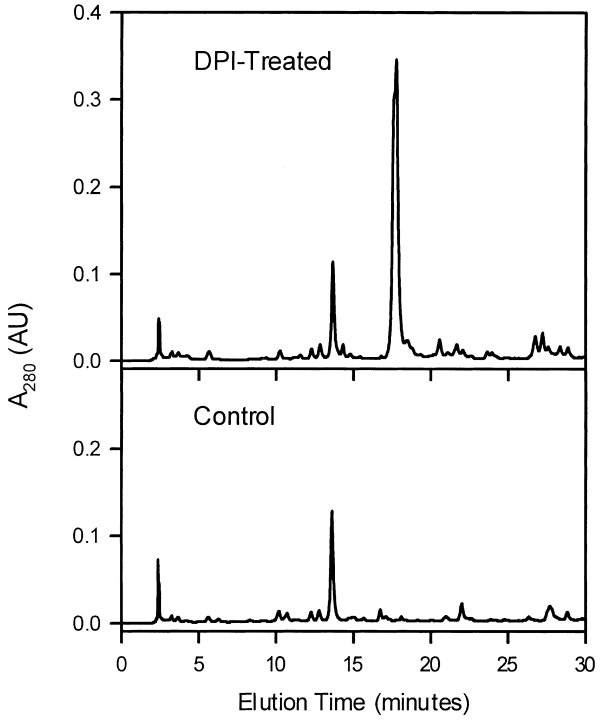

Fig. 3. High pressure liquid chromatographic analysis of soluble potato tuber extracts. Total soluble extracts (80% MeOH) prepared from wound healing potato tubers (7 days post wounding) incubated with (upper trace) and without (lower trace) 25 μM diphenyleneiodonium (DPI) were subject to Nucleosil C-18 reversed phase column chromatographic anaylses using a gradient of MeOH–CH_3CN–H_2O (1:1:1) in phosphoric acid (1.5% in H_2O) (see Experimental). The presence of new (phenolic) compound(s) is (are) evident in the large peak at approx. 17 min, present in the DPI-treated tissue. See text for details.

The presence of new soluble compounds in the extracts of DPI-treated tissues does not necessarily mean that the deposition of poly(phenolics) into the cell wall has also been inhibited by the treatment. Therefore, we also subjected extractive free cell walls of the suberized tissues isolated from control and DPI-treated tubers to both the thioacidolysis and DFRC methods of poly(phenolic) analysis. While the data remains preliminary (so far only single samples have been analyzed), yields were extremely low, as has been reported for suberized potato tubers before (Borg-Olivier and Monties, 1989, 1993; Lapierre et al., 1996). (These data do, however, point to a significant difference between suberized and lignified tissues, since the latter yield much larger amounts of product after either thioacidolysis or DFRC.) Notwithstanding the low yields, DPI-treated cells contained much lower amounts (in some cases only traces) of released phenolics, (data not shown) suggesting that formation of the SPPD was indeed interrupted by the treatment. Importantly, these data, support the need for H_2O_2 in the SPPD forming process, and a role for an NAH(P)H-dependent oxidase in its formation.

3. Concluding remarks

The question of how representative potato SPPDs are of suberized tissues in general remains to be answered, and it will be some time before the details revealed about it in the last decade can be readily transferred to other plant species (especially woody ones). Certainly, supportive evidence for the uniqueness of the PPD of suberized tissues has been obtained from endodermal and hypodermal tissues of several plant species including *Clivia miniata*, maize and *Cicer arietinun* (Schreiber, 1996, Zeier and Schreiber, 1997, 1999; Zeier et al., 1999). Arguably, the uniqueness of the SPPD has been evident in the literature for many years (Bernards and Lewis, 1998) but is now becoming more apparent, particularly through the careful chemical analysis of the suberized tissues from which they are found.

In the present paper, we have provided new preliminary evidence supporting the hypothesis that the SPPD of potatoes is assembled via an H_2O_2-dependent process, and that the H_2O_2 required for it is likely generated by an NAD(P)H-dependent oxidase system. Based on our data, and on models proposed for the oxidative burst that occurs during pathogenesis (Wojtaszek, 1997; Graham and Graham, 1999) and lignification in *Zinnia elegans* (Ros Barceló, 1998a), we have

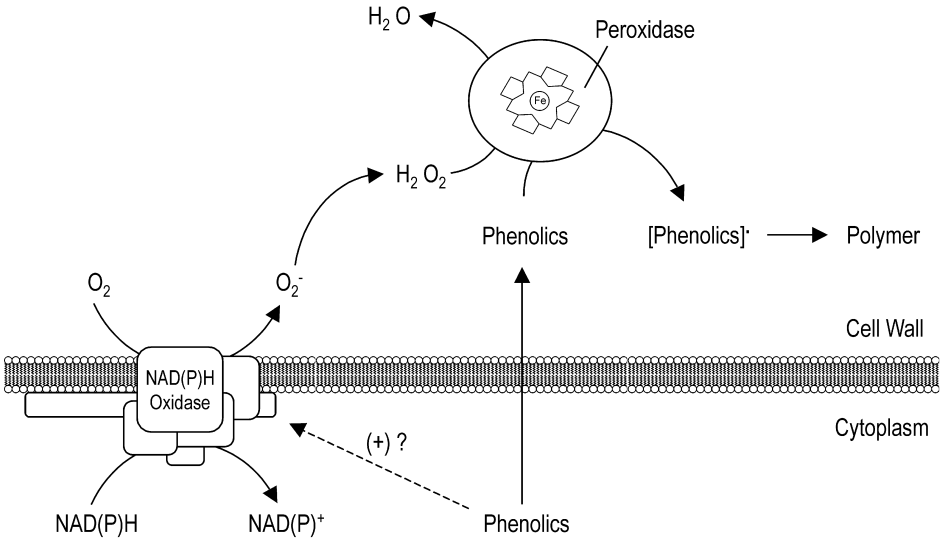

Fig. 4. Model for the macromolecular assembly of the potato suberin poly(phenolc) domain. Phenolics synthesized in the cytoplasm are transported to the carbohydrate matrix (by an as yet unknown mechanism) and may also act as stimulators of an NAD(P)H-dependent oxidase in the plasma membrane. The NAD(P)H-dependent oxidase generates superoxide on the exoplasmic face of the membrane, where it disproportionates to H_2O_2 in the presence of H^+ (or superoxide dismutase). The H_2O_2 formed can then be used by a cell wall associated peroxidase to catalyze the free radical-mediated coupling of phenolics into the poly(phenolic) domain. Adapted from Wojtaszek (1997) and Graham and Graham (1999).

constructed a model combining the H_2O_2-generating properties of a plasma membrane-bound NAD(P)H-dependent oxidase with the H_2O_2-utilizing properties of a cell wall bound peroxidase (Fig. 4) to account for the final stages of the macromolecular assembly of potato wound SPPD. Briefly, phenolics synthesized in the cytoplasm are transported to the cell wall (by an as yet unknown mechanism), where they are polymerized into the SPPD by a wall-associated peroxidase. The H_2O_2 required for this process likely comes from a plasma membrane-bound NAD(P)H-dependent oxidase. It is possible that soluble (cytoplasmic) phenolics serve to allosterically regulate the NAD(P)H-dependent oxidase in an analogous fashion to the "competency factor" role of genistein in soybeans (Graham and Graham, 1999). While speculative, our model is supported by the evidence collected to date, and continues to serve as a basis from which to design new experiments to explore the biosynthesis and macromolecular assembly of the potato SPPD.

4. Experimental

4.1. Plant material

Potato (*Solanum tuberosum* L. cv. Russet Burbank) tubers were grown locally from certified seed, and stored at 5°C until used. Suberization was initiated by cutting tubers (i.e. wounding) under sterile conditions as described (Bernards and Lewis, 1992).

4.2. DPI treatment, phenolic extraction and cell wall analysis

Tuber disks (1.5 cm diameter×0.5 cm thick) were incubated on water-agar plates (1.5% agar) with and without DPI (25 μM final concentration) for up to seven days. The suberized tissue collected from the lower surface of each disk was exhaustively extracted (i.e. 24 h) with 80% aqueous MeOH in a Soxhlet extractor. The MeOH solubles were concentrated and analyzed by HPLC on a Nucleosil C-18 reversed phase column (4.6× 150 mm, 5 μm, Machery-Nagel). Compounds were eluted using a gradient of organic solvent (MeOH–CH_3CN–H_2O, 1:1:1; solvent B) in 1.5% (v/v) aqueous phosphoric acid (solvent A). Initial column conditions: 10% solvent B in A. Gradient: 10–75% B in A over 30 min at 1 ml min^{-1}. The eluent was monitored over the range of 200–350 nm with a photodiode array detector.

The residues obtained from soxhlet extraction were dried with acetone and subjected to thioacidolysis according to Zeier and Schreiber (1997) and DFRC analysis according to Lu and Ralph (1997).

Review

Similarities and differences in rubber biochemistry among plant species

Katrina Cornish*

USDA-ARS, Western Regional Research Center, 800 Buchanan Street, Albany, CA 94710, USA

Received 19 September 2000; received in revised form 28 December 2000

Abstract

This report reviews aspects of the biochemical regulation of rubber yield and rubber quality in three contrasting rubber-producing species, *Hevea brasiliensis*, *Parthenium argentatum* and *Ficus elastica*. Although many similarities are revealed, considerable differences also exist in enzymatic mechanisms regulating biosynthetic rate and the molecular weight of the rubber biopolymers produced. In all three species, rubber molecule initiation, biosynthetic rate and molecular weight, in vitro, are dependent upon substrate concentration and the ratio of isopentenyl pyrophosphate (IPP, the elongation substrate, or monomer) and farnesyl pyrophosphate (FPP, an initiator), but these parameters are affected by intrinsic properties of the rubber transferases as well. All three rubber transferases are capable of producing a wide range of rubber molecular weight, depending upon substrate concentration, clearly demonstrating that the transferases are not the prime determinants of product size in vivo. However, despite these commonalities, considerable differences exist between the species with respect to cosubstrate effects, binding constants, effective concentration ranges, and the role of negative cooperativity in vitro. The *P. argentatum* rubber transferase appears to exert more control over the molecular weight it produces than the other two species and may, therefore, provide the best prospect for the source of genes for transformation of annual crop species.The kinetic data, from the three contrasting rubber-producing species, also were used to develop a model of the rubber transferase active site in which, in addition to separate IPP and allylic-PP binding sites, there exists a hydrophobic region that interacts with the linear portion of allylic-PP initiator proximal to the pyrophosphate. Substrate affinity increases until the active site is traversed and the rubber interior of the rubber particle is reached. The kinetic data suggest that the hydrophobic region in *H. brasiliensis* and *F. elastica* is about 1.8 nm long but only 1.3 nm in *P. argentatum*. The estimates are supported by measurements of the rubber particle monolayer membrane using electron paramagnetic resonance spectroscopy. Published by Elsevier Science Ltd.

1. Introduction

All natural rubber currently in commercial use comes from a single plant species, the Brazilian rubber tree (*Hevea brasiliensis*), and the United States is completely dependent on imports from developing countries (Davis, 1997), for the manufacture of more than 40,000 products, including more than 400 medical devices. Asia now produces about 90% of the world demand for *H. brasiliensis* natural rubber, which, in 1998, was 6.61 million tonnes [40% of the total rubber demand; the remaining 60% is synthetic rubber produced from petroleum (data from the International Rubber Study Group)]. The United States, with no natural rubber production, is the largest single consumer of this material. In 1998, the United States imported nearly 1.2 million tonnes of natural rubber for product manufacture, at a cost approaching $2,000,000,000. In addition, the United States imports a considerable quantity of finished goods: in 1998, valued at $8,060,000,000 containing 349,000 tonnes of natural rubber (data from US Department of Commerce, Office of Trade and Economic Analysis). Natural rubber consumption closely tracks production, preventing the accumulation of large stockpiles (Fig. 1) (Mooibroek and Cornish, 2000).

Primarily due to its molecular structure and high molecular weight (>1 million Da), natural rubber has high performance properties that cannot be matched by synthetic rubber produced from petroleum. These properties include resilience, elasticity, abrasion and impact resistance, efficient heat dispersion, and malleability at cold temperatures. Despite the best efforts of the chemical industry, these properties have not been achieved by synthetic materials, or non-rubber natural polymers or blends, in many high performance applications, including tires, and surgical gloves and latex balloon devices. As a result, the amount of synthetic rubber produced has reached a plateau, whilst annual natural rubber production is steadily increasing to meet demand (Fig. 2), and probably will soon exceed the synthetic rubber market share. The *H. brasiliensis* crop consists almost entirely of plantation-grown clonal trees, and is one of the most genetically-restricted crops under cultivation. This lack of genetic diversity leaves the crop highly susceptible to pathogenic attack and failure, as demonstrated by the devastation caused by leaf blight in South American plantations (Davis, 1997). A dependable supply is endangered by many other factors, including diminishing acreage as growers in developing countries move away from rubber farming toward higher value agriculture, increasing global demand, and changing political positions (Reisch, 1995; Davis, 1997). Higher-yielding germplasm cannot indefinitely meet increased natural rubber demand and many new plantations will be required. *H. brasiliensis* also has strict climatic requirements, which limit its cultivation to specific tropical regions.

In addition to strategic and economic incentives to develop a renewable US-based natural rubber supply, the recent widespread occurrence of life-threatening "latex allergy" to *H. brasiliensis* rubber products, which

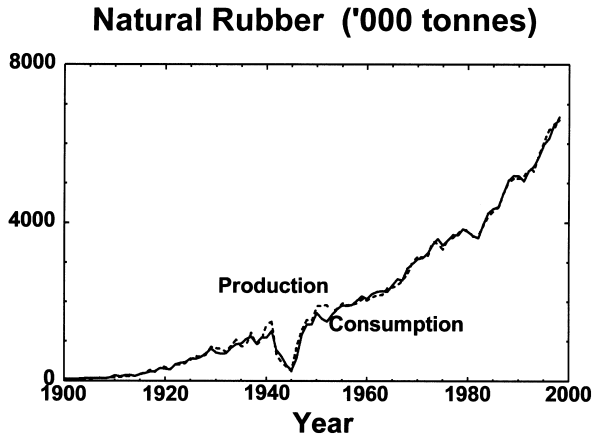

Fig. 1. Global production (dashed line) and consumption (solid line) of natural rubber during the twentieth century.

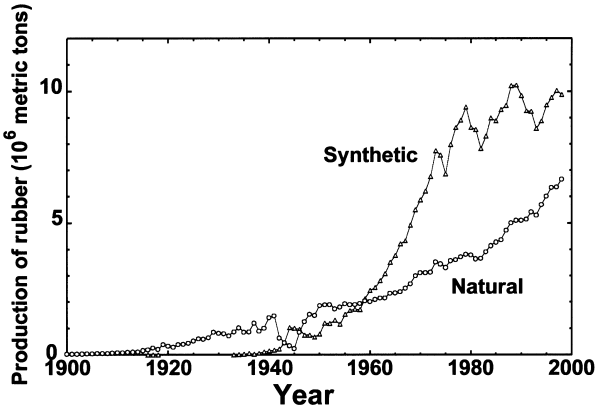

Fig. 2. Global production of natural (○) and synthetic (△) rubber during the twentieth century. Synthetic rubber production was established largely because of the drop in natural rubber production during World War II. Rubber consumption figures have closely tracked production.

affects an estimated 20,000,000 Americans, strengthens the need for development of alternative sources of natural rubber (Morales et al., 1989; Slater, 1989; Tomazic et al., 1992; Kekwick 1993; Pailhories, 1993; Ownby et al., 1994; Nakayama et al., 1996; Siler and Cornish, 1994a; Carey et al., 1995; Siler et al., 1996). Also, although synthetic rubber cannot replace natural rubber in many applications, the converse is not true. Large-scale, domestic natural rubber production will be needed in the future, even without a natural rubber supply crisis, to first supplement, then replace the 60% market share currently enjoyed by synthetic rubbers because these are derived from petroleum, a non-renewable resource. A decline in global oil production may begin within the next 10 (Campbell and Laherrere, 1998) or 20 (Monastersky, 1998) years. Thus, commercialization and natural rubber production from domestic crops is in the best short- and long-term interests of developed countries such as the United States.

Some 2500 plant species, many of which are tropical, produce natural rubber (Bowers, 1990; Ray, 1993). Most, however, do not produce the high molecular weight polymers required for high performance commercial products [molecular weight is strongly correlated with rubber quality (Swanson et al., 1979)]. Of the possible rubber-producing plant species for the US, *Parthenium argentatum* (guayule) has received the most sustained research and development effort over the years (Bowers, 1990; Whitworth and Whitehead, 1991) and is closest to domestication and commercial production. Currently, guayule is being introduced as a biennial crop in the southwestern United States to supply high performance, nonallergenic latex (Siler and Cornish, 1994a; Siler et al., 1996; Cornish and Lytle, 1999) to the medical products market (Cornish, 1996, 1998, patents exclusively licensed to Yulex Corporation). This crop may be able to fully supply the medical market but is unlikely to generate sufficient rubber for other large markets, such as tires, because it cannot tolerate the snowy winters and severe temperatures experienced by much of the United States and many other temperate countries. Also, although it may prove practical to generate new higher yielding lines, it cannot be grown as an annual crop because it produces its rubber in bark parenchyma cells and most of the rubber is synthesized during winter months. Thus, one season's growth gives a plant containing little bark parenchyma and little rubber. Additional alternative rubber-producing annual crops are, therefore, required to supply rubber to meet non-medical market requirements, and to engender a much-needed biodiversity.

Ideally, rubber-producing crop plants should be rapidly-growing, have large biomass, and be annual crops, which can be more readily included in on-farm crop rotations and farming systems, and could be readily planted and plowed-out in response to market needs and farmer production considerations. Cropping systems, such as trees, that must remain in place for many years are not well suited to changing market demand and fluctuations. Most of the 2500 known rubber-producing plant species produce small amounts of poor quality, low molecular weight rubber. Successful conversion of candidate crop species, whether or not they already produce rubber naturally, into domestic rubber-producing crops requires the generation of lines capable of producing commercially-viable yields of high quality rubber. This can only be accomplished by basing genetic engineering strategies upon a thorough understanding of biochemical factors affecting rubber yield (biosynthetic rate, substrate availability and rubber particle size, number and ontogeny) and rubber quality (primarily rubber molecular weight).

2. Rubber particles and their components

Many different dicotyledonous plants make natural rubber. Most of this review concentrates on the similarities and differences in rubber production among three plant species, each from a different superorder of the Dicotyledonae, i.e. *Hevea brasiliensi* Müll. Arg. (Rosidae), *Ficus elastica* Roxb. (Dilleniidae), and *Parthenium argentatum* Gray (Asteridae). In all three species, natural rubber is compartmentalized within subcellular rubber particles, located in the cytosol of cells, whether these be specialized laticifers (pipe-like anastomosized cell systems which produce latex), as in *H. brasiliensis* (d'Auzac et al., 1989) and *F. elastica* (Heinrich, 1970) or generalised cells, such as the bark parenchyma of *P. argentatum* (Whitworth and Whitehead, 1991). The average size of the particles varies among species [e.g. *F. elastica* 3.8 μm, *Euphorbia lactiflua* 0.42 μm (Siler et al., 1997; Wood and Cornish, 2000)], and differently-sized subsets of particles can even be found in the same plant. *H. brasiliensis*, for example, has two distinct subsets of particles with mean diameters of 1.0 and 0.2 μm (Cornish et al., 1993; Wood and Cornish, 2000).

Very little is known about rubber particle ontogeny, largely because small, electron-dense rubber particles cannot be readily distinguished from other small electron-dense particles in cytoplasm (Backhaus, 1985). However, studies of rubber particle structure and biochemical components suggest a likely origin in the rough endoplasmic reticulum. The overall structure of rubber particles is similar in all species examined so far, in that they contain a homogeneous rubber core surrounded by an intact monolayer membrane (Cornish et al., 2000; Wood and Cornish, 2000). The glycosylated moieties of some of the particle-bound proteins and the hydrophilic head groups of the phospholipids enable the particles to interface with the aqueous cytosol. However, within the shared architecture, the rubber particle components are quite different, the compartmentalized

rubber being of much lower molecular weight in *F. elastica* than in the other two species, and all three possessing a species-specific complement of lipids and proteins (Cornish et al., 1993; Siler et al., 1997). The lipid fraction of *P. argentatum* rubber particles is typical of many plant cell membranes, and appears to reflect the very ordinary cells (bark parenchyma) in which the rubber particles are formed. It seems likely that the rubber particle membrane in different species is made up of readily available lipid components, and that highly conserved structure and chemical composition are not required. Also, the amount of protein associated with rubber particles varies tremendously between species, ranging from 4.8% in *E. lactiflua* to less than 0.1% in *P. argentatum* (Siler et al., 1997), and the number of different proteins is remarkably different. The most complicated rubber particles currently known are those of *H. brasiliensis*. These contain upwards of 80 different proteins across a size range of 5 to over 200 kDa. However, other rubber particles contain far fewer proteins, perhaps less than 10 in *F. elastica* and *P. argentatum*, for example (Cornish et al., 1993). The architecturally-analogous cytoplasmic oil bodies (Huang, 1992) are much more highly conserved from one species to another in their protein and lipid components, but these organelles must export their contents, not merely retain them, and so require a sophisticated secretion system. Rubber is a secondary product that is not catabolized during the life of the plant, and rubber particles only need to effectively compartmentalize the rubber. The non-conserved nature of the particular rubber particle biomembrane components suggests that few, if any, specific genes may be required to generate a rubber particle once a rubber transferase enzyme begins rubber synthesis. Thus, normally non-rubber-producing species transformed with genes encoding rubber transferase may be able to effectively compartmentalize rubber using cytosolic membrane components. Information on factors regulating the number of rubber particles made in a tissue will probably not be obtained until transformed plants with enhanced rubber biosynthetic activity have been generated.

Very large proteins or protein complexes appear to be present in all species (Cornish et al., 1993; Siler and Cornish, 1993, 1994a,b), and they all contain an integral, membrane-bound, rubber-synthesizing *cis*-prenyl transferase enzyme or enzyme complex (rubber transferase, EC 2.5.1.20). This enzyme synthesizes rubber from hydrophilic substrates obtained from the cytoplasm and the hydrophobic polymer is compartmentalized into the rubber particle interior. Thus, the polymerization reaction must take place at the rubber particle surface, and it has been proven that rubber transferase is an integral membrane protein or protein complex (Madhavan et al., 1989; Cornish and Backhaus, 1990; Cornish, 1993; Cornish and Siler, 1996).

The identity of the rubber particle-bound rubber transferase remains equivocal. Two different proteins on *H. brasiliensis* rubber particles have been implicated in activity, namely the 14.6 kD "rubber elongation factor" (Dennis and Light, 1989) and the 24 kD "small rubber particle protein" (Oh et al., 1999). Although the case for both has yet to be substantiated, the data supporting the role of the 24 kD protein seems more convincing than for the 14.6 kD protein (Cornish, 1993), which relied solely on immunoinhibition of activity in latex, not in washed rubber particles. Oh et al. (1999), used a combination of immunoinhibition and direct addition of expressed protein to affect activity. However, it seems worthwhile to point out that meaningful immunoinhibition experiments must be performed using purified antibody. Crude sera can lead to reproducible and substantial inhibition of rubber transferase activity in washed rubber particles that is not antibody specific (Fig. 3). Also, immunoblots of sera against *H. brasiliensis* latex proteins have shown that experimental animals frequently contain antibodies to *H. brasiliensis* latex proteins before being challenged with purified protein(s) (Siler and Cornish, unpublished). The animals have presumably reacted to contact with the latex gloves worn by their handlers and/or the rubber stoppers commonly used to support the water supply tubes.

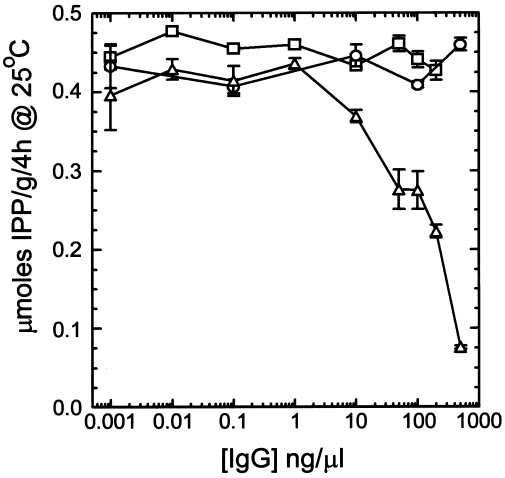

Fig. 3. Rubber transferase activity in rubber particles purified from *Hevea brasiliensis* latex. Ascites fluid (crude sera) from mice challenged with a low-density lipoprotein was the generous gift of Dr. Alex Karu, UC Berkeley Hybridoma Center. IgG was purified from the ascites fluid by chromatography on a 1 ml bed volume Protein G column (Hi-Trap, Pharmacia) according to the manufacturer's instructions. A non-specific purified mouse ascites IgG (Pierce) was used as a negative control. The serum and purified IgG samples were incubated with the rubber particles for 15 h on ice before the remaining rubber transferase activity was assayed as described (Cornish, 1993). 465 µg dw of rubber particles in 500 µl were assayed for 4 h at 25°C in imM IPP, 20 µM FPP and 1 mM Mg^{2+}. Each value is the mean of 3±S.E. In the absence of IgG or ascites, 0.412±0.034 µmol IPP were incorporated. The experiment was repeated with similar results (not shown).Key: (○) control IgG; (Δ) serum; (□) purified lipoprotein IgG.

Thus, pre-immune bleed evaluations are essential and, in this laboratory, we use animals born and reared in latex-free environments.

The situation has been complicated again recently by the identification and cloning of a bacterial gene encoding undecaprenyl diphosphate synthase (Shimizu et al., 1998), another member of the *cis*-prenyl transferase family, followed by the isolation of various related enzymes through sequence homology. Although it seemed possible that rubber transferase also might be identified as a homologue, it seems increasingly unlikely that the homology between the two enzymes is high enough for successful homogue-based cloning. This is perhaps not surprising, because the undecaprenyl diphosphate synthase is a soluble enzyme and makes relatively short polymer (55 carbons), whereas the rubber transferase is membrane-bound, possibly a complex, and can make product many thousands of carbons long (Cornish et al., 1993, 2000; Castillón and Cornish, 1999).

However, even though the degree of relationship between the UDP synthase and rubber transferase is unknown, immuno-inhibition experiments indicate that rubber transferase activity does appear to be associated with a 376 kDa rubber particle-bound protein in *F. elastica* (Cornish et al., 1994). Cross-specific immunoinhibition and immunoprecipitation studies, with purified IgG antibodies and purified rubber particles, also have indicated that some structural similarities probably exist between the rubber transferases of *F. elastica*, *H. brasiliensis* and *P. argentatum* (Siler and Cornish, 1993, 1994b; Cornish et al., 1994).

3. Rubber biosynthesis

3.1. Regulation of initiation and biosynthetic rate

Natural rubber is produced by a simple side-branch of the ubiquitous isoprenoid pathway (Chappell, 1995) from an allylic pyrophosphate (allylic-PP) and isopentenyl pyrophosphate (IPP) (Fig. 4). Several allylic-PP's, namely dimethylallyl-PP (DMAPP), geranyl-PP (GPP) and *trans,trans*-farnesyl-PP (FPP) are synthesized, by soluble enzymes, in the same cytosolic compartment as rubber transferase and so could be used by the rubber transferase. The IPP polymerized by the rubber transferase is probably derived from the mevalonate pathway, also located in the cytosol (Chappel, 1995). However, IPP derived from the deoxy-xylulose pathway (reviewed by Lichtenthaler, 1999) may diffuse from the plastids and join the cytosolic pool. The importance of the soluble *trans*-prenyl transferases in rubber biosynthesis lies in their synthesis of allylic-PP's, essential initiators of rubber biosynthesis.

The rubber particle-bound rubber transferases of *F. elastica*, *H. brasiliensis* and *P. argentatum* have considerable similarities in their substrate requirements,

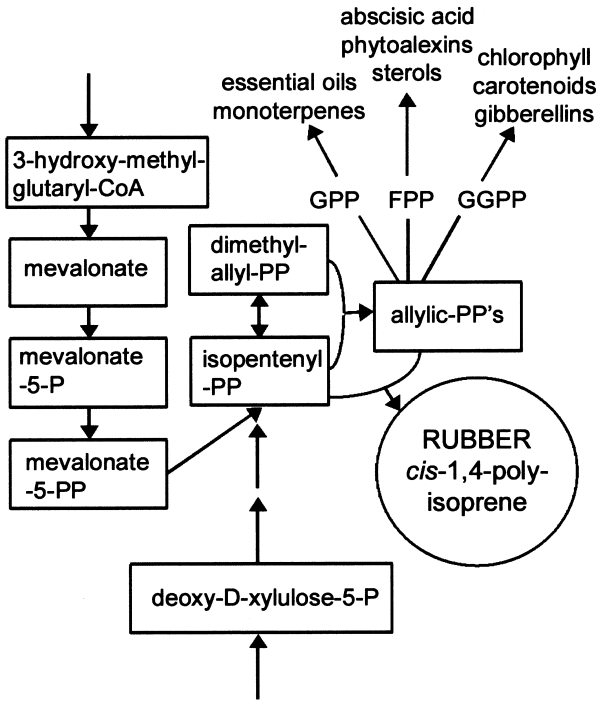

Fig. 4. The relationship of rubber biosynthesis to the isoprenoid pathway. The rubber particle membrane-bound rubber transferase (a *cis*-prenyl transferase) binds an allylic pyrophosphate (allylic-PP) to initiate a new rubber molecule and then elongates the polymer by *cis*-1,4-polymerization of isopentenyl monomers derived from isopentenyl pyrophosphate (IPP). Cytosolic IPP is produced by the mevalonate pathway, but the endogenous pool size may be supplemented by IPP produced by the deoxy-*D*-xylulose pathway in the plastids. Dimethyl allyl pyrophosphate (DMAPP) is produced by IPP-isomerase, and allylic-PP's larger than DMAPP are synthesized by soluble *trans*-prenyl transferases. All the allylic-PP's shown can be used as initiators by rubber transferase. All reactions shown require a divalent cation cofactor such as magnesium. Given the multidisciplinary nature of the intended audience of this paper, a brief summary of essential terms is given. IPP is the "elongation" or "polymerization" substrate, or the "monomer" in the rubber biosynthetic reaction. Polymer "elongation" is equivalent to "polymerization" and to "propagation". Allylic-PP is the initiation substrate, one being needed for each new polymer. Allylic-PP also can displace the elongating rubber molecule from the enzyme's active site and so acts as a "chain transfer agent" in addition to its role as an initiator. PP, pyrophosphate; GPP, geranyl pyrophosphate; FPP, farnesyl pyrophosphate; GGPP = geranylgeranyl pyrophosphate.

kinetic constants, and pH dependencies (Lynen, 1969; Archer and Audley, 1987; Madhavan et al., 1989; Cornish and Siler, 1996; Cornish et al., 1998). Rubber molecules are synthesized from one allylic-PP molecule, which initiates the reaction; the rubber polymer (*cis*-1,4-polyisoprene) is then made by sequential condensations of the non-allylic IPP (divalent cations, such as magnesium or manganese, are a required cofactor) with release of a diphosphate at each condensation (Archer et al., 1963). After initiation and elongation, a termination event occurs in which the rubber molecule is released from the enzyme. However, despite these similarities, remarkable differences exist between these species with

respect to enzymatic reaction mechanisms and product molecular weight.

Many different allylic-PP's are effective initiators of rubber biosynthesis, including DMAPP (C_5), GPP (*trans*, C_{10}), FPP (all-*trans*, C_{15}) and geranylgeranyl-PP (GGPP) (*trans*, C_{20}) (Lynen, 1969; Archer and Audley, 1987; Madhavan et al., 1989; Cornish et al., 1998). Only the first three of these are likely initiators of rubber biosynthesis in vivo because only the corresponding short-chain prenyl transferases share the cytosolic compartment with rubber transferase. Geranylgeranyl-PP synthase is located in the plastids (e.g. Dogbo and Camara, 1987). Also, GPP synthase is not a common cytosolic enzyme and is usually only found in abundance in specialized secretory cells such as in mint oil glands (Burke et al., 1999). However, the gene encoding a GPP synthase is present in *P. argentatum* (from EST homologues, Mau and Cornish, unpublished). Direct NMR-based structural evidence supports FPP as the principal initiator in vivo, at least in *H. brasiliensis* (Tanaka, 1989; Tanaka et al., 1996) and the mushroom *Lactarius volemus* (Ohya and Tanaka, 1998). Also, biochemical studies have shown that the apparent K_m value for FPP is lower than those for GPP or DMAPP in all three species (Table 1) (Cornish et al., 1998) and so the affinity of rubber transferase is greater for FPP than for the other two initiators.

In *H. brasiliensis*, *F. elastica* and *P. argentatum*, many other allylic-PP's can initiate rubber polymerization in vitro (Archer and Audley, 1987; Cornish et al., 1998). Thus, rubber transferases in general are very tolerant of both size and stereochemistry of the allylic-PP. This is in contrast to most known prenyl transferases which have strict substrate structural requirements for the elongation reactions they catalyze. Nonetheless, in vitro experiments have shown that the particular initiator supplied to the rubber transferase has a considerable impact on rubber biosynthetic rate. This appears to result from different initiation rates being caused by different $K_m^{\text{allylic-PP}}$'s as well as by direct effects on the IPP incorporation rate (Cornish and Siler, 1995; Castillón and Cornish, 1999; Cornish et al., 2000). In general, biosynthetic rate increases with the size of the *trans*-allylic-PP from DMAPP until either FPP (in *P. argentatum*) or GGPP (in *H. brasiliensis* and *F. elastica*) (Cornish and Siler, 1995; Cornish et al., 1998). In line with the increase in biosynthetic rate, the apparent K_m for the different allylic-PP's declines (Table 1).

Table 1
K_m's of three rubber transferases[a]

Initiator	*Hevea brasiliensis*	*Ficus elastica* (μM)	*Parthenium argentatum*
DMAPP	13.2	33.9	3.4
GPP	3.9	1.6	0.7
FPP	1.5	0.6	0.01
GGPP	1.4	0.3	0.01
IPP in FPP	363	115	385

[a] K_m's were determined from Hill plots of log $\upsilon/(V_{max}-\upsilon)$ against log substrate concentration. Assays in varying allylic-PP were performed at 25°C for *H. brasiliensis* and *F. elastica* and 16°C for *P. argentatum* in the presence of 1 mM [^{14}C]IPP. Assays in varying IPP were performed similarly except that 20 μM FPP was used.

Kinetic data were used to develop a model of the rubber transferase active site which contains a catalytic site and separate IPP and allylic-PP binding sites. The allylic-PP binding site is composed of a specific binding region which recognizes the allylic-PP moiety and a non-specific region which interacts with the hydrophobic portion of allylic-PP initiator. Increasing the length of the initiator increases the hydrophobic interaction and thus the affinity of the enzyme for the substrate. Substrate affinity increases until the active site is traversed and the interior of the rubber particle is reached. At this point, no additional change in affinity occurs with an increase in initiator length. The kinetic data indicate that FPP is of sufficient size to traverse the rubber transferase active site in *P. argentatum*, because V_{max} and K_m are similar for FPP and GGPP in this species, whereas GGPP is large enough to do the same in the rubber transferase active sites of *H. brasiliensis* and *F. elastica*. The model was successfully tested using a variety of stereoisomers of the allylic-PP's (unpublished data). The data suggest that the hydrophobic region in *H. brasiliensis* and *F. elastica* is about 1.8 nm long but is only 1.3 nm in *P. argentatum*. These estimates are supported by measurements of the *P. argentatum* rubber particle monolayer membrane using electron paramagnetic resonance spectroscopy (Cornish et al., 1999). When the hydrophilic pyrophosphate region of FPP is aligned with the hydrophilic phospholipid region of the monolayer membrane, the rubber interior of the particle is reached at almost exactly the same place (Fig. 5). This seems noteworthy because the tertiary structure of the enzyme or enzyme complex would not make such a coincidence actually necessary, even though a minimization of active site structure has obvious advantages.

3.2. Regulation of molecular weight

Many different plant species produce natural rubber, but only a few produce the high molecular weights required for high performance commercial products. As mentioned earlier, the biochemical regulation of molecular weight must be understood so that genetic-engineering strategies may be designed that increase yield while maintaining or conferring high molecular weight. In vitro investigations have now shown that, in the three different species discussed in this review, rubber

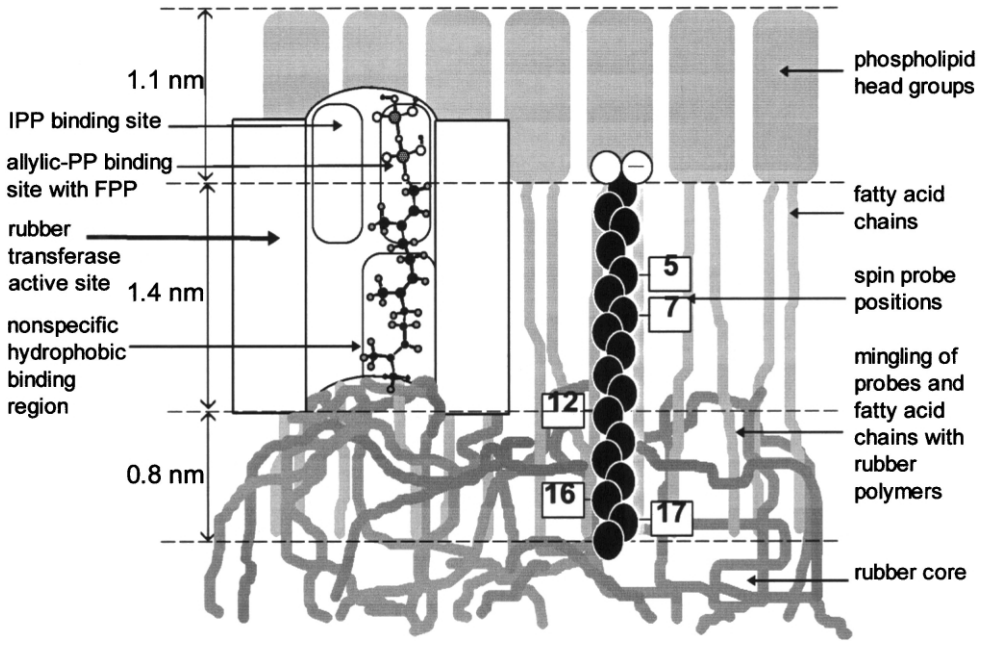

Fig. 5. A schema depicting, to scale, a section of the surface monolayer biomembrane surrounding a *Parthenium argentatum* rubber particle and the intermingling of the phospholipid fatty acid chains with the pure rubber core (from Cornish et al., 1999). The major phospholipids are phosphatidyl choline and the major fatty acids are 16:0, 18:0, 18:1, 18:2 and 18:3 comprising 95% of the phospholipids (Siler et al.,1997). The predominate protein, allene oxide synthese, a 52 kDa glycoprotein (Pan et al., 1995), is a partially embedded amphiphilic protein (not shown) that penetrates the monolayer only as far as the 5- and possibly the 7-doxyl spin probe positions. The orientation of the stearic acid spin probes in the monolayer is depicted with the stearic acid chain in the all *trans* configuration and the doxyl spin probe shown as a rectangular box attached to a specific methylene carbon (black ball) indicated by the number in the box. The positions of all the probes used are depicted on a single stearic acid instead of on individual ones for the sake of space, and indicate the region of the monolayer probed. The stearic acid chain is aligned parallel to the phospholipid fatty acid chains with its polar head group localized in the aqueous media between the phospholipid head groups. The intermingling of the fatty acid chains of the phospholipids with the pure rubber of the particle core begins at the C-12 doxyl position and ends somewhere in the vicinity of the terminal methyl of the stearic acid chain. The rubber transferase active site with FPP bound into the allylic-PP binding site is positioned so that the hydrophilic pyrophosphate of FPP is aligned to the polar head group region of the membrane. The kinetic studies suggest that FPP traverses the active site as shown. Both models show the same physical position for the membrane-rubber interface.

molecular weight is greatly affected by substrate concentration and type, and especially by the concentration of allylic-PP initiator. In general, the higher the allylic-PP concentration, the lower the rubber molecular weight that results, while the converse is true for IPP, i.e. the higher the concentration of IPP the greater the molecular weight (Castillón and Cornish, 1999; Cornish et al., 2000). It appears that competition for the allylic-PP binding (initiation) site occurs between free allylic-PP (although it should be noted that only FPP has been tested in all three species) and the allylic-PP moiety of the growing polymer. This site binds the original FPP initiator and all the allylic-PP intermediates formed as the rubber polymer grows (the terminal five-carbon unit always includes the pyrophosphate and allylic carbon). The higher the FPP concentration, the more likely that free FPP, acting as a reinitiation (or chain transfer) reagent, could displace the polymer and initiate a new rubber molecule, which in turn accounts for the shortening of the rubber polymer observed with increasing FPP concentration. The affinity of FPP would probably not be very much lower than the affinity of the growing rubber polymer because only a relatively small piece of the rubber molecule appears to be positioned within the active site at any time (see Fig. 5 and related discription). The same effect of increasing concentration causing shorter polymers is caused by GPP in *P. argentatum* and would probably occur in the other two species as well.

Presumably, the rubber transferase enzymes would be similarly affected in vivo. The polymer molecular weights produced by rubber transferase vary without exhaustion of free substrate, and in many cases without large changes in substrate concentration. Competition between FPP and the IPP donor site which could signal a non-productive terminal extensions and hence chain extension seems unlikely because such competition has only been observed in the *P. argentatum* rubber transferase (Castillón and Cornish, 1999) but not in the *H. brasiliensis* or *F. elastica* rubber transferases (Cornish et al., 2000). The rubber transferase system in vitro does appear to be able to terminate the polymers and initiate new molecules. For example, the incorporation rate of allylic-PP, under saturating concentrations of IPP and either FPP or GPP, was linear over 6 h in *P. argentatum* (Cornish and Siler, 1995) and so the rate of termination and reinitiation (the chain transfer reaction rate),

remained constant under these conditions. Very little is known about the termination event of rubber polymer biosynthesis. Different termination functional groups have been characterized by NMR spectroscopic analyses and indicate that rubber dephosphorylation and release may involve esterification, cyclization or hydrolysis in different species (Tanaka, 1989; Tanaka et al., 1996).

The studies of molecular weight regulation in vitro, summarized above, clearly indicate that additional mechanisms must be involved in regulating chain length in vivo. Also, although the three rubber transferases appear to be similar in many ways, a closer look at their regulation of rubber molecular weight reveals quite different mechanisms. For example, the *P. argentatum* and *H. brasiliensis* rubber transferase enzymes, despite their different allylic-PP kinetic constants and kinetic behavior in vitro (Table 1), produce similar molecular weights in any particular substrate mixture (Castillón and Cornish, 1999; Cornish et al, 2000). However, the *F. elastica* enzyme consistently produces rubber twice as large as in the other two species, even though this is primarily a low molecular weight producer in vivo (Cornish et al., 1993). This higher molecular weight may be caused by the lower K_m^{IPP} (Table 1), which is a third that of the other two species in the presence of FPP. The greater affinity of the *F. elastica* rubber transferase for IPP may lead to a more rapid polymerization (elongation or propagation) rate which, in turn, could produce the higher overall molecular weights observed over the four hour reaction period used. Also, K_m's reflect the substrate concentration around which the particular enzyme operates most effectively and are believed to reflect the endogenous, or physiological, substrate concentration in vivo (Segel, 1993). Thus, the rubber transferase K_m^{IPP} and the allylic-PP K_m's can be considered to predict the ideal conditions for the enzyme (high IPP levels, low allylic-PP levels). The high rubber transferase K_m^{IPP} ensures that rubber is made at times when IPP is non-limiting for other prenyl transferases, all of which have lower K_m^{IPP}'s much closer to the allylic-PP K_m's (reviewed by Ogura and Koyama, 1998). Under optimal conditions, and if no other factors are involved, the rubber molecular weight synthesized would presumably reflect the substrate equilibrium, and can be calculated from the K_m^{IPP} to $K_m^{allylic\text{-}PP}$ ratio. In *P. argentatum*, the ratio of K_m^{IPP} to K_m^{FPP} does translate to match the high molecular weight of over 1,000,000 Da produced in vivo (Table 2) in this species. Similarly, in *F. elastica* the same ratio is consistent with the low molecular weight it produces in vivo (Table 2). However, in *H. brasiliensis*, the K_m^{IPP} to $K_m^{allylic\text{-}PP}$ ratio predicts that *H. brasiliensis* would produce low molecular weight rubber in vivo (Table 2), which is, of course, untrue.

In vitro biochemical studies, showing that all three species can make high and low molecular weight rubber depending upon substrate concentrations, demonstrate that the rubber transferases, themselves, are not the cause of the low molecular weight rubber normally produced by *F. elastica*, nor of the high molecular weight produced by *P. argentatum* and *H. brasiliensis*. Other *cis*-prenyl transferases investigated make fixed product sizes as do most *trans*-prenyl transferases (Ogura and Koyama, 1998; Wang and Ohnuma, 1999). The rubber transferases clearly represent a distinct class of *cis*-prenyl transferases, despite similar substrate and cofactor requirements and similar pH dependencies.

Table 2
Some kinetic parameters and projected and in vivo rubber molecular weights produced by three different rubber transferases[a]

Parameter	*Hevea brasiliensis*	*Ficus elastica*	*Parthenium argentatum*
K_m^{IPP}/K_m^{FPP}	242	192	38,500
Projected M_r from K_m ratio (Da)	16,632	13,232	2,618,176
Actual rubber M_r in vivo (Da)	$>10^6$	10^3–10^4	$>10^6$

[a] The ratios of apparent K_m's were calculated from Table 1. The projected rubber molecular weight (M_r) from in vitro experiments (Refs. 41 and 42) was calculated, assuming that the ratio of K_m^{IPP}/K_m^{FPP} reflects the number of isoprene units incorporated, as (K_m^{IPP}/K_m^{FPP}) 68 + 176. (Molecular weight of isoprene subunit = 68, pyrophosphate with one negative charge = 176).

3.3. The role of negative cooperativity

It appears for rubber transferases, in general, that once an allylic-PP binds to the active site, the polymer that begins to form restricts access to the allylic-PP binding site by free allylic-PP. This probably occurs because the enzyme has a high affinity for the end of the rubber polymer. The enzyme product is not soluble and is certainly not fully released from the active site during the polymerization reaction. Thus, IPP polymerization can proceed even though the apparent K_m^{IPP} is much higher than K_m^{FPP} (Table 1). However, in addition to the affinity of the rubber transferases for the allylic-PP terminal C_{15} or C_{20} portion of the growing polymer, Hill plots of IPP incorporation rate as a function of FPP concentration demonstrate, by gradients $\ll 1$, that all three rubber transferases exhibit regions of strong negative cooperativity (Fig. 6) (Cornish et al., 2000). At these FPP concentrations, an additional hinderance to the binding of FPP to the allylic-PP binding site occurs, in that after one FPP has bound to the allylic-PP site it becomes much more difficult for a second molecule to bind. This change in binding affinity probably results from a conformational change in the enzyme caused by the first FPP binding event. Thus, free FPP cannot easily displace the elongating rubber polymer, i.e. the chain transfer reaction is inhibited over the FPP negative cooperativity concentration range. The *P. argentatum*

rubber transferase shows a remarkably wide concentration range of negative cooperativity, operating from its K_m^{FPP} to more than two orders of magnitude above it (Fig. 6). In contrast, *H. brasiliensis* and *F. elastica* have much shorter concentration ranges of strong negative cooperativity. In *H. brasiliensis*, the negative cooperativity region falls at the high end of the range for *P. argentatum*, whereas that of *F. elastica* falls just beyond the *P. argentatum* range (Fig. 6). Another measure of the negative cooperativity operating in these rubber transferases is reflected by the ratio of the FPP concentration at 0.75 V_{max} ($y=3$ in Fig. 6) to the FPP concentration at 0.5 V_{max} ($y=1$ in Fig. 6). Values of 3 reflect Michaelis-Menton kinetics, less than 3 indicate positive cooperativity, and greater than 3 indicate negative cooperativity (Segel, 1993). Using this measure, it is clear that negative cooperativity is much stronger in *P. argentatum* than in the other two species ($[S]_{0.75}/[S]_{0.5}$ for *H. brasiliensis* is 6.91, for *F. elastica* is 8.04, and for *P. argentatum* is 53.8).

The FPP negative cooperativity also appears directly to affect IPP incorporation rate, although IPP incorporation is dependent upon IPP concentration in *P. argentatum* (Castillón and Cornish, 1999). In *H. brasiliensis* and *F. elastica*, IPP only enhanced IPP incorporation at FPP concentrations where negative cooperative operated, when IPP and FPP concentrations were rate-limiting (Cornish et al., 2000).

When the regulation of molecular weight is considered, it is clear that the negative cooperativity properties of the different rubber transferases directly affect the molecular weight they produce under different substrate conditions, beyond the effects mediated by their different K_m's. For example, as described earlier, for *P. argentatum* rubber transferase, Hill plots of $\upsilon/(V_{max}-\upsilon)$ against [S] indicate negative cooperativity (gradient $\ll 1$, Fig. 6) over a much wider concentration range than in the other two species. Over this range, the *P. argentatum* rubber transferase active site is insensitive to the presence of unbound FPP, and the rubber polymers produced are considerably larger than would be the case if free FPP had the same ability to compete with the elongating polymers, and displace the rubber molecules from the active site, that it has at concentrations outside this negative cooperativity range (as discussed in the previous section). Also, in all three species, it appears that increasing IPP concentrations only can increase the molecular weight of the rubber polymers either when the initiator concentration is limiting (below the $K_m^{allylic\text{-}PP}$) or, under nonlimiting concentrations, when the particular enzyme exhibits negative cooperativity (Fig. 7; Cornish et al., 2000).

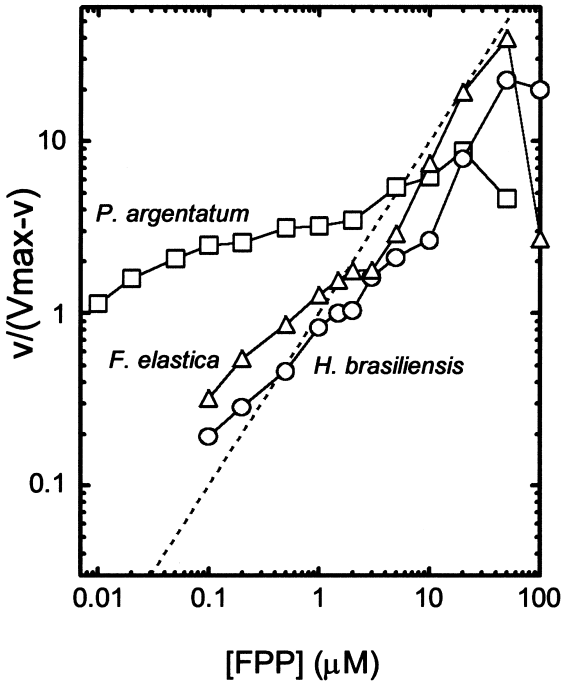

Fig. 6. Hill plot of IPP incorporation rate as a function of FPP concentration for *Hevea brasiliensis*, *Ficus elastica* and *Parthenium argentatum*. The intercept at $y=1$ is the K_m. Regions with a gradient $<<1$ indicate concentration ranges of negative cooperativity.

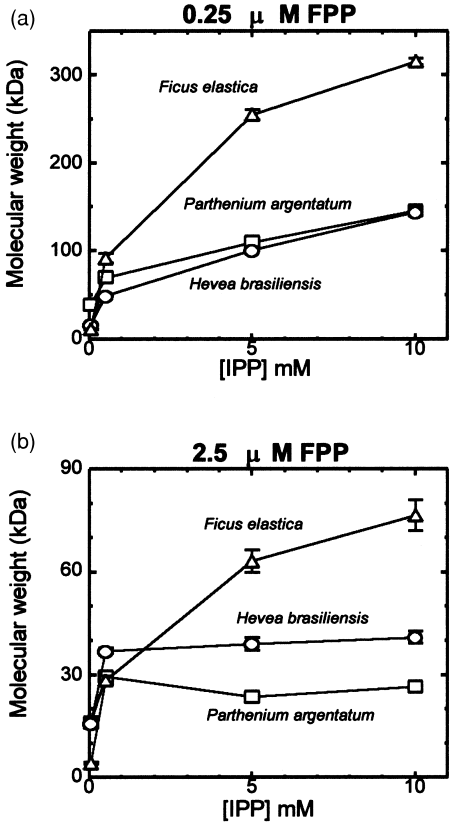

Fig. 7. Mean molecular weight (kDa) of rubber molecules synthesized by *Hevea brasiliensis*, *Ficus elastica* and *Parthenium argentatum* at various IPP concentrations at either (a) 0.25 μM or (b) 2.5 μM FPP. Each value is the mean of three replicates ± S.E.

3.4. Competition and activation

Additional similarities and differences between the three rubber transferases become apparent when co-substrate effects are considered (Castillón and Cornish, 1999; Cornish et al., 2000). For example, substrate activation appears to operate in the *P. argentatum* and *H. brasiliensis* rubber transferases. In these enzymes, IPP enhances the rate of FPP binding, but is significant in *H. brasiliensis* only at rate-limiting FPP concentrations instead of at all FPP concentrations as in *P. argentatum*. By contrast, the *F. elastica* rubber transferase was insensitive to increasing IPP concentrations and is the only species of the three in which IPP may slightly inhibit FPP incorporation at all FPP concentrations tested.

In all three species, the initiator FPP appears to activate IPP incorporation, but the *P. argentatum* rubber transferase differs from the other two in that IPP incorporation rate was enhanced by increasing FPP concentration at all IPP concentrations. By contrast, for the *H. brasiliensis* and *F. elastica* rubber transferases, IPP incorporation rates were only markedly FPP-dependent at rate-limiting IPP concentrations of near or below the K_m^{IPP}'s.

For the *H. brasiliensis* and *F. elastica* rubber transferases, under conditions where the FPP concentration is near or below the K_m^{FPP}, but when the IPP concentration is above K_m^{IPP}, IPP incorporation rate is a function of the IPP concentration and is insensitive to FPP concentration. This is apparent also for the *P. argentatum* rubber transferase when GPP is used is the initiator. It seems likely that the same result would be found with FPP, in this species, but lower FPP concentrations, than as yet explored, would be needed to achieve conditions below its K_m^{FPP}.

Although competition at the allylic-PP site has not been observed (Cornish et al., 2000), IPP and allylic-PP do appear to compete for the IPP binding site in the *P. argentatum* rubber transferase (Castillón and Cornish, 1999), although catalysis only occurs if IPP is bound. Interestingly, this also is a species-specific phenomenon, such competition not being apparent with either *H. brasiliensis* or *F. elastica* rubber transferase.

4. Conclusions

Prospects for the biotechnological development of alternative rubber producing crop plants suitable for temperate zone agriculture will improve as our knowledge of the factors regulating rubber biosynthesis progresses. In vitro investigations have indicated promising strategies for the enhancement of rubber yield, such as the transformation of rubber-producing plants with genes for substrate synthesis. However, the production of high molecular weight rubber seems more uncertain because in vitro biochemical studies have shown that a combination of factors must contribute to the molecular weight of rubber produced in vivo. The *P. argentatum* rubber transferase appears to exert more control over the molecular weight it produces than those from *H. brasiliensis* or *F. elastica* and the corresponding gene(s) may, therefore, provide the best prospect for genetic transformation of candidate annual crop species. However, in vitro experiments have not yet provided a unifying biochemical mechanism that could explain the different rubber molecular weights found in vivo in different plant species, such as the high molecular weight rubber in *H. brasiliensis* and *P. argentatum* and the low molecular weight rubber in *F. elastica*. It is possible that these evolutionarily-divergent species employ different mechanisms to regulate molecular weight but, given the general similarities in rubber biosynthesis enjoyed by the species, similar endogenous regulatory factors probably operate in vivo. Thus, molecular weight probably will be affected by endogenous substrate concentrations, the intrinsic properties of the rubber transferases involved and by other, as yet unknown, endogenous factors. These factors, and their interaction, must be understood before effective metabolic engineering strategies can be designed to maximize biosynthetic rate while simultaneously maintaining or conferring high rubber molecular weight. It may then be possible to achieve the goal of engineering temperate zone annual crops to produce commercially-viable yields of high quality rubber.

Acknowledgements

The author would especially like to thank past and present researchers, namely Javier Castillón, Mary H. Chapman, Christopher J.D. Mau, Deborah J. Scott and Deborah J. Siler, who, working in her laboratory, contributed considerably to our current knowledge of natural rubber biosynthesis.

Received 18 September 2000; received in revised form 2 February 2001

Abstract

A combined structural and functional model of the catalytic region of cellulose synthase is presented as a prototype for the action of processive β-glycosyltransferases and other glycosyltransferases. A 285 amino acid segment of the *Acetobacter xylinum* cellulose synthase containing all the conserved residues in the globular region was subjected to protein modeling using the genetic algorithm. This region folds into a single large domain with a topology exhibiting a mixed alpha/beta structure. The predicted structure serves as a topological outline for the structure of this processive β-glycosyltransferase. By incorporating new site-directed mutagenesis data and comparative analysis of the conserved aspartic acid residues and the QXXRW motif we deduce a number of functional implications based on the structure. This includes location of the UDP–glucose substrate-binding cavity, suggestions for the catalytic processing including positions of conserved and catalytic residues, secondary structure arrangement and domain organization. Comparisons to cellulose synthases from higher plants (genetic algorithm based model for cotton CelA1), data from neural network predictions (PHD), and to the recently experimentally determined structures of the non-processive SpsA and β4-galactosyltransferase retest and further validate our structure-function description of this glycosyltransferase. © 2001 Published by Elsevier Science Ltd. 1. Introduction

Cellulose is an abundant polysaccharide produced most notably by plants and in varying degrees by several other organisms including algae, bacteria, social amoeba, and tunicates. The polymerization reaction is catalyzed by the enzyme cellulose synthase, a glycosyltransferase that uses UDP–glucose as the substrate. Most glycosyltransferases transfer monosaccharides from a nucleotide sugar donor to hydroxyl groups of acceptor carbohydrates. A glycosyltransferase may catalyze the transfer of a single sugar residue to an acceptor (non-processive) or transfer more than one sugar residue to the acceptor (processive). Glycosyltransferases exhibit specificity for both the donor and the acceptor molecules and are involved in making a specific linkage (α- or β-linkage) between specific atoms of the sugar and the acceptor molecule. Since each linkage is catalyzed by a specific glycosyltransferase, most compounds that either have different kinds of sugars and/or different linkages would require a number of glycosyltransferases for their synthesis. Alternatively, a single enzyme may recognize more than one sugar donor and catalyze more than one type of linkage (for example, hyaluronan synthase in the synthesis of hyaluronic acid). Based upon the linkage at the anomeric carbon, glycosyltransferases can be classified as retaining glycosyltransferases or inverting glycosyltransferases. Since the catalytic mechanism in the two types (retention or inversion) of glycosyl transfer reactions is different, it is generally believed that the two classes of glycosyltransferases would have different sequence and structure characteristics.

The catalytic machinery of glycosyltransferases involves a general acid-base catalysis mechanism that involves acidic residues (aspartate and/or glutamate) whose side chains have the property to act as the general base for acceptor activation or as the nucleophile for formation of a glycosyl–enzyme intermediate. These acidic residues are also involved in the catalytic mechanisms of glycosyl hydrolases where once again they act either as a general base or as a nucleophile (Davies and Henrissat, 1995). Active site glutamate residues have also been shown to be essential for the ADP-ribosyltransferase activity of certain bacterial toxins (Barth et al., 1998) as well as the glycosylphosphatidylinositol (GPI)-anchored and secretory ADP–ribosyltransferases of eucaryotic cells (Okazaki and Moss, 1998). The carboxylate group of an aspartic acid residue (Asp 100) in the active site of T4 β-glucosyltransferase has been shown to be in a position where it activates the 5-hydroxymethyl group on the DNA for nucleophilic attack on the glucose of the donor UDP–glucose (Moréra et al, 1999). Enzymes that catalyze the different glycosyl transfer reactions and that use NDP–sugar as substrates were classified into 26 families based upon sequence similarity (Campbell et al., 1997) and the list now includes 47 families (http://afmb.cnrs-mrs.fr/~pedro/CAZY/gtf.html). Family 2 β-glycosyltransferases include both the processive and the non-processive enzymes. The processive enzymes (for example, cellulose synthase, chitin synthase, hyaluronan synthase, NodC protein) are generally membrane-proteins that synthesize a polysaccharide/oligosaccharide chain. None of these proteins have been characterized and compared structurally; however, the different proteins are related based on sequence characteristics (especially identification of putative catalytic residues). The presence of the conserved catalytic residues in members of the same glycosyltransferase family suggests that they catalyze glycosyl transfer reactions by similar mechanisms and in all likelihood have very similar active-site architecture. Processive glycosyltransferases stay attached to the growing end of a glucan chain, and there is considerable interest in identifying the amino acid residues and the structure of the region that is involved in holding the glucan chain.

Cellulose biosynthesis offers a simple and elegant system for studies on the synthesis of polysaccharides, especially as studied in the bacterium *A. xylinum*. Although the detailed features of cellulose biosynthesis may not be common to the synthesis of other polysaccharides, the structure of the catalytic region of cellulose synthase and other glycosyltransferases may show some conserved features. A prediction of the structure of the globular region of cellulose synthase based on the available data will therefore be helpful in understanding the structure and function of glycosyltransferases, especially the processive β-glycosyltransferases. Moreover it will be important to confirm the relevance of the conserved residues in these glycosyltransferases and to determine their spatial relationship within the three-dimensional structure. More recently the structures of a few β-glycosyltransferases have been determined experimentally (Vrielink et al., 1994; Charnock and Davies, 1999; Gastinel et al., 1999). Although these structures show some similarities, they also exhibit sufficient variations making it all the more important to predict or determine the three-dimensional structures of as many glycosyltransferases for understanding the catalytic properties of this group of enzymes (Breton and Imberty, 1999).

1.1. Sequence relationship between cellulose synthases and other glycosyltransferases

Genes for cellulose synthase were first cloned from the bacterium *A. xylinum* (Saxena et al., 1990; Wong et al., 1990). Sequence comparisons of the derived amino acid sequence of the bacterial cellulose synthase with other proteins revealed the presence of conserved aspartic acid residues and a QXXRW motif in the processive β-glycosyltransferases (Saxena et al., 1995). Since the catalytic machinery of glycosyltransferases is likely to involve residues whose side chains have the proper reactivity to act as

a general base or a nucleophile, the conserved aspartic acid residues are predicted to be involved in the catalytic reaction as acid-base catalysts. The QXXRW motif is present in all the processive β-glycosyltransferases analyzed so far, and this sequence motif is believed to be involved in the processivity function of the enzyme, possibly required for holding the growing glycan chain in the active site. The 'D, D, D35QXXRW' motif has also been identified in a large number of transmembrane proteins involved in the synthesis of a variety of polysaccharides/oligosaccharides (Saxena and Brown, 1997). This motif is present in a large and contiguous globular region that is predicted to be localized in the cytoplasm. Apart from the identification of this motif in proteins whose functions are known (for example, cellulose synthase, chitin synthase, hyaluronan synthase, NodC protein) this motif has been identified in a number of other sequences in the sequence databases. The precise function of a number of these proteins remains to be determined, as in the case of the *E. coli* YhjO polypeptide (Sofia et al., 1994) whose sequence is very similar to the sequence of the *A. xylinum* cellulose synthase.

A substantial number of sequences identified in higher plants also contain the 'D, D, D35QXXRW' motif, and these proteins are characterized either as cellulose synthase or cellulose synthase-like proteins (http://cellwall.stanford.edu/cellwall/). In at least three reports, proteins with the 'D, D, D35QXXRW' motif have been identified as cellulose synthases (CelA1, Rsw1, and Irx3) based on experimental evidence (Pear et al., 1996; Arioli et al., 1998; Taylor et al., 1999). The globular region that contains the 'D, D, D35QXXRW' motif is much larger in these higher plant cellulose synthases (the globular region of CelA1 and Rsw1 is predicted to be 534 and 538 amino acids in length, respectively) in comparison to the globular region of the *A. xylinum* AcsAB cellulose synthase (285 amino acids). Analysis of the regions present between the three conserved aspartic acid residues and the QXXRW motif shows that while the number of amino acids between these residues is similar in the higher plant cellulose synthases, they differ from that of the *A. xylinum* cellulose synthase which is much more similar to the cellulose synthase-like proteins from higher plants and the *E. coli* YhjO polypeptide.

[a] Specific activity is defined as picomoles of glucose incorporated into alkali-insoluble product per minute per milligram protein.

1.2. Functional analysis of conserved residues in cellulose synthase and other glycosyltransferases

Although different numbers of amino acids may separate them, the conserved residues in cellulose synthases are predicted to be present at structurally similar positions in the active site. To determine the role of the conserved aspartic acid residues (D189, D236, and D333) and residues in the QXXRW motif (Q369, R370, V371, R372, and W373) of the *A. xylinum* cellulose synthase (AcsAB), we substituted the D189, D236, D333, Q369, R370, and R372 residues with other amino acids using site-directed mutagenesis. Mutants of cellulose synthase with the following non-conservative substitutions- D189Y, D236Y, D333R, Q369M, R370Q, R370P, and R372A were obtained and analyzed for in vitro cellulose synthase activity using *A. xylinum* membrane preparations. The D189Y and D236Y mutations have been described earlier (Saxena and Brown, 1997) and the effect of the remaining mutations on cellulose synthase activity is shown in Table 1. Apart from substitutions in these conserved positions and R370, we also obtained mutations in which the aspartic acid residue at position 188 was replaced with a more conservative (D188N) and a non-conservative (D188P) amino acid. As shown in Fig. 1, cellulose synthase activity in mutants with substitutions at the conserved positions D189, D236, D333, Q369, and R372 was barely detectable, suggesting that these residues are involved in the enzyme activity. Moreover, amino acid substitutions at the non-conserved positions (D188 and R370) adjacent to the conserved residues also led to a reduction in enzyme activity. The level of expression of the mutated cellulose synthase protein in the *A. xylinum* membrane preparations was examined by western blot analysis using antibody raised against the 93 kDa cellulose synthase polypeptide (Chen and Brown, 1996). The 93 kDa cellulose synthase polypeptide was not detected by western analysis in the *A. xylinum* mutant strains AY41-34 and AY41-34-895 (Fig. 2, lanes 1 and 2) (Saxena and Brown, 1995). AY41-34-895 was therefore used as the host strain for expression of the wild-type and mutant cellulose synthase genes cloned in the plasmid pRK311 (Ditta et al., 1985). The amount of cellulose synthase in strains expressing the wild-type protein, and the D188P, D188N, D333R, Q369M, R370Q, R370P, and R372A substitutions was found to be at comparable levels as determined by western analysis (Fig. 2). Cellulose synthase was also detected at similar levels in a strain where

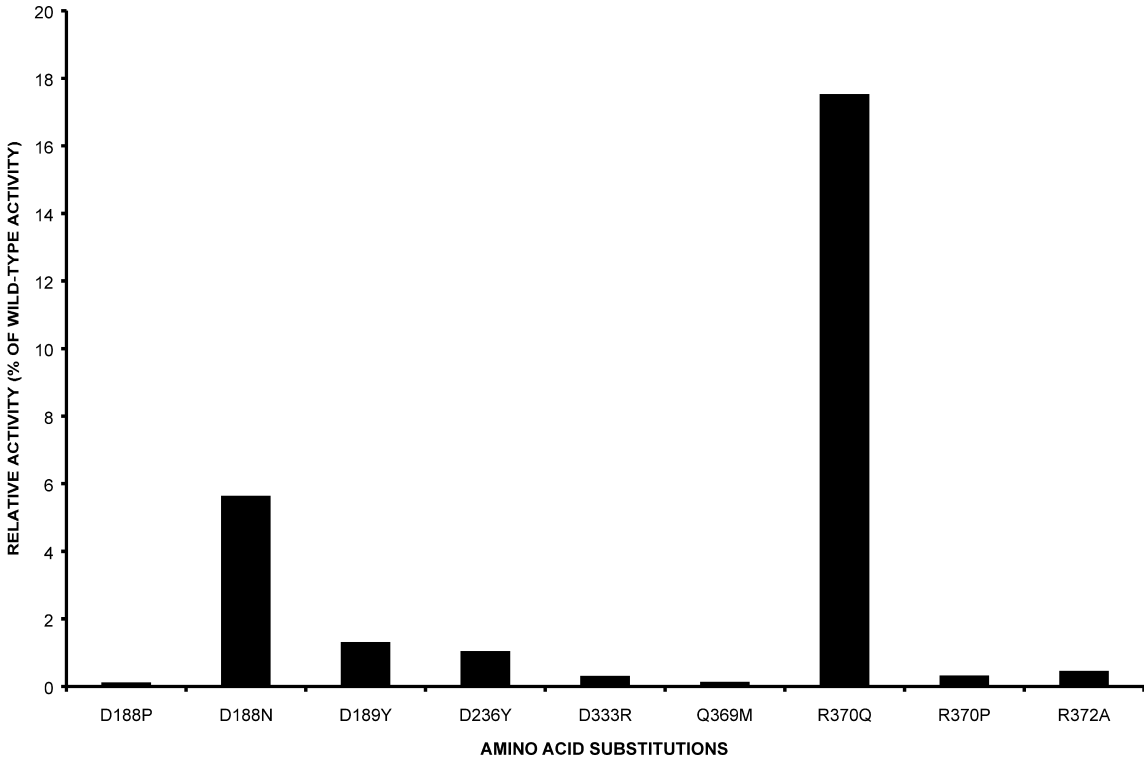

Fig. 1. Effect of amino acid substitutions on the *A. xylinum* cellulose synthase (AcsAB) activity determined in vitro.

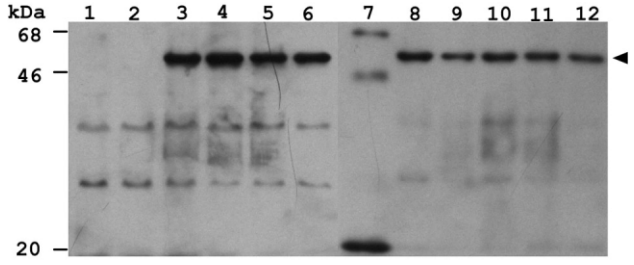

Fig. 2. Western blot analysis of membrane preparations of *A. xylinum* using anti-93 kDa antibody to detect the cellulose synthase. Lanes 1 and 2 contain membrane preparations from *A. xylinum* strains AY41-34 and AY41-34-895 respectively. Lanes 3–6, and 8–12 contain membrane preparations from *A. xylinum* AY 41-34-895 with plasmids expressing wild type cellulose synthase (lane 3), a chimeric cellulose synthase in which the globular region of the *A. xylinum* AcsAB cellulose synthase is replaced by a globular region encoded by *Arabidopsis thaliana* EST T88271 (lane 4), and cellulose synthase with amino acid substitutions D188P (lane 5), D188N (lane 6), D333R (lane 8), Q369M (lane 9), R370Q (lane 10), R370P (lane 11), and R372A (lane 12). Lane 7 contains the molecular weight markers. The cellulose synthase polypeptide fragment detected using the anti-93 kDa antibody is shown by an arrowhead.

the *A. xylinum* AcsAB globular region was substituted with the globular region of an *Arabidopsis thaliana* β-glycosyltransferase (Fig. 2, lane 4).

Whether the conserved residues are involved as catalytic residues, in substrate-binding, in maintaining the architecture of the active site or in some other function has not been determined for the *A. xylinum* cellulose synthase. Support for the idea that the conserved residues function in enzyme activity is also obtained from analysis of a few other glycosyltransferases (Fig. 3). Substrate-binding experiments done using a plasmid construct that expresses the globular region of the cotton CelA1 cellulose synthase in *E. coli* showed that the expressed protein bound to UDP–glucose (Pear et al., 1996). However, when the *N*-terminal part that includes the first conserved aspartic acid residue (corresponding to D189 of the *A. xylinum* AcsAB protein) was missing from this protein, no UDP–glucose binding was observed. These observations suggest that this region, which includes the conserved aspartic acid residue, is essential for binding the substrate. Site-directed mutagenesis experiments using the chitin synthase 2 of yeast showed that the conserved aspartic acid residues and the conserved residues in the QXXRW motif are required for chitin synthase activity (Nagahashi et al., 1995). A conserved aspartic acid residue identified in the β-glycosyltransferases also has been identified in a number of other glycosyltransferases, including the yeast α-1,3-mannosyltransferase (Mnn1p) (Wiggins and Munro, 1998) and large clostridial cytotoxins (Busch et al., 1998). This conserved aspartic acid residue is present in the DXD motif in a variety of glycosyltransferases, and the first aspartic acid in this motif corresponds to D236 of the *A. xylinum* cellulose synthase. In almost all cases the DXD

Fig. 3. Proteins in which the conserved residues identified in β-glycosyltransferases (Saxena et al., 1995) have been analyzed by site-directed mutagenesis- AcsAB, *A. xylinum* cellulose synthase (Saxena and Brown, 1997; this work); SacChs2, *S. cerevisiae* chitin synthase 2 (Nagahashi et al., 1995); Mnn1p, *S. cerevisiae* α-1,3-mannosyltransferase (Wiggins and Munro, 1998); LT, *C. sordellii* lethal toxin (Busch et al., 1998), KfiC, *E. coli* glycosyltransferase (Griffiths et al., 1998), and by assaying a deleted globular region in which one of the conserved residues (conserved aspartic acid in region 1) is missing- CelA1, *G. hirsutum* cellulose synthase (Pear et al., 1996). The regions in which these conserved residues are present and the motifs identified in these regions are indicated. Residue numbers are shown at the start of each amino acid segment for AcsAB. Asterisks indicate the conserved residues identified in the β-glycosyltransferases. Residues analyzed by site-directed mutagenesis for each of the proteins are underlined. Positions in which substitution of the conserved residue resulted in loss of enzyme activity or substrate binding are indicated in bold.

motif is flanked by four hydrophobic residues on the *N*-terminal side, with the third of these often being an aromatic residue (Wiggins and Munro, 1998). Site-directed mutagenesis of the conserved aspartic acid residues and the flanking residues in Mnn1p showed that the aspartic acid residues are essential for α-1,3-mannosyltransferase activity. Furthermore the aspartic acid residues in the DXD motif were shown to have no effect on protein multimerization, and were suggested to be involved in catalysis. Substitution of the aspartic acid residues in the DXD motif of the *Clostridium sordellii* lethal toxin (LT) led to a loss of the binding of the substrate UDP–glucose, suggesting that these residues are important for UDP–glucose binding (Busch et al., 1998). One possible function of the DXD motif in the catalytic site could be in binding a metal ion that is used to coordinate the phosphates of the NDP–sugar in the active site. A DXD motif is also conserved in DNA polymerases where the aspartates are in the active site coordinating manganese and magnesium ions that hold the phosphates of the nucleotide triphosphate substrate (Pritchard and McHenry, 1999).

Although three aspartic acid residues have been identified at conserved positions in the processive β-glycosyltransferases, at present there is insufficient evidence to suggest which of these aspartic acid residues actually functions as a base during the catalytic reaction. Our prediction that at least two glycosidic linkages are formed simultaneously or sequentially during the synthesis of cellulose and a few other polysaccharides would require at least two aspartate residues to function as bases. There is only a single conserved aspartic acid residue in regions 3 and 4 (Fig. 3) present in domain B of the processive β-glycosyltransferases and this aspartic acid residue probably functions as a base. On the other hand, regions 1 and 2 (Fig. 3) present in domain A of both the processive and the non-processive β-glycosyltransferases and a number of other proteins, contains two conserved aspartic acid residues. The catalytic mechanism for glycosyl transfer with inversion of configuration requires a single base and so a single aspartic acid residue is sufficient for this function. However, where glycosyl transfer reaction takes place with retention of configuration, at least two amino acid residues are required, with one residue functioning as a nucleophile and the other as an acid/base. Interestingly, two amino acid residues are conserved in regions 1 and 2 of β-glycosyltransferases, and only one conserved residue is observed in the other proteins, including the α-1,3-mannosyltransferases and α-1,3-fucosyltransferases. Moreover this conserved residue present in region 2 is part of the DXD motif that has been identified in both α- and β- glycosyltransferases. The role of the aspartic acids in the DXD motif is suggested to be in the binding of the NDP–sugar substrate. Therefore, the aspartic acid residue present in region 1 of the β-glycosyltransferases (Fig. 3) may function as a catalytic residue in this group of enzymes. However, in the structure determined for the SpsA protein (Charnock

and Davies, 1999), the conserved aspartic acid residues that align with regions 1 and 2 of the β-glycosyltransferases are shown to contact the UDP portion of the UDP-sugar donor (the nature of the sugar is not known at present). Furthermore, it is speculated that the aspartate that functions as a catalytic base resides about 100 residues C-terminal to the conserved aspartate in region 2. This aspartate could be in a position similar to the aspartate present in region 3 of the β-glycosyltransferases. However, there is no QXXRW motif in the SpsA sequence and not much sequence similarity in the C-terminal portion of SpsA and regions 3 and 4 of the processive β-glycosyltransferases.

1.3. Architecture of the active site of cellulose synthase: a structural model for the active-site region of processive β-glycosyltransferases

Cellulose synthase is a transmembrane protein that has not been sufficiently purified from any source for structural analysis. Since the conserved residues predicted to be involved in catalysis and processivity are present in a globular region, we have attempted to predict the folding of this region from the *A. xylinum* cellulose synthase and determine if this structure is conserved in the other β-glycosyltransferases. To this end, a 285 amino acid segment (residues 128 to 412 of AcsAB) which contained all the conserved amino acid residues in a globular region of cellulose synthase was subjected to modeling. A BLAST search of the PDB protein sequences database using the 285 amino acid segment of *A. xylinum* cellulose synthase as a query did not identify any significant sequence matches in the database, nor did, incidentally, the related sequences YhjO, CelA1, and Rsw1. Similarly, no structural relatives were found applying the PHD server (Rost and Sander, 1996), iterative searches [PSI-BLAST (Altschul et al., 1997)] or sequence-based three dimensional structural homology searches [sophisticated search techniques after Huynen et al. (1998), as well as the direct SCOP blast server (Hubbard et al., 1999)]. Furthermore, there were no similarities to known domains using the latest version of SMART (Schultz et al., 1998) or ProDom (Corpet et al., 1998).

In the absence of any structural information for modeling, we decided to obtain an ab initio model using the genetic algorithm (Dandekar and Argos, 1994). The algorithm evolves protein structure predictions in parallel in a computer evolution, recombining and selecting "fittest" structures according to basic protein building principles. These include heavy selection against structural clashes and globular packing and more complex ones such as cooperative growth of secondary structure and sheet formation. Detailed criteria for these and their respective selection weights have been described previously and validated on a test battery of 20 proteins with known structure and a wide range of topologies, yielding correct topology predictions and an average RMSD error of 4-6 Å (Dandekar and Argos, 1996). As an additional structure selection criterion derived from experimental data (see Dandekar and Argos, 1997 for such selection parameters), catalytic aspartic acid residues were rewarded when being close together. The combination of experimental data with the genetic algorithm model has previously been shown to be an effective modeling tool including blind tests for topology description and prediction (Dandekar and Leippe, 1997; Saxena et al., 1997; Tribble et al., 2000). The algorithm folded the region of the cellulose synthase starting from sequence and secondary structure (using several available standard packages for secondary structure prediction) with the assumption that it has a globular solution structure and is an independent folding unit. The fittest and also the topologically most satisfying structure obtained from all the simulations is shown in Fig. 4a. The less fit structures had similar topologies but were not packed as well. The dimensions of the predicted structure of the globular region of the *A. xylinum* cellulose synthase are roughly 60 × 60 × 70 Å (less than half of this box is filled by the protein) and the topology of the folded structure shows 10 strands and 8 alpha-helices (Fig. 4b). The globular region has a mixed topology of beta-strands and alpha-helices (Table 2) and does not exhibit a true alpha-beta barrel as observed in the structure of some other proteins. As seen in Fig. 4a and b, the helices and strands in the globular region of cellulose synthase as predicted by the genetic algorithm do not alternate regularly and are interrupted by long loop regions. Note that the exact arrangement of the strands is only roughly indicated by the algorithm and has not been refined further (Fig. 4a and b). However the topological sketch is sufficient to indicate and compare their overall connectivity and arrangement (Fig. 6). In a similar way, the nucleotide-binding fold is delineated, but the arrangement of strands is again only approximately given.

The predicted structure of the globular region of the *A. xylinum* cellulose synthase shows the presence of a central cavity between the conserved aspartic acid residues. The distances between the conserved aspartic acid residues are estimated to be 20 Å between D189 and D236, 7 Å between D189 and D333, and 18 Å between D236 and D333. From these estimates, the central, elongated cavity can accommodate two UDP–glucose residues (each UDP–glucose residue having a dimension of about 8 Å) as shown in Fig. 4c and predicted in the model for cellulose biosynthesis (Saxena et al., 1995). We note that a suitable cavity size to accommodate the UDP–glucose was by no means predefined by the selection criteria. For instance, having the three catalytic residues maximally close together would have satisfied best the additional structure selection criterion. However, optimizing among all selection criteria by the genetic

algorithm achieved, nevertheless, the correct, suitable cavity size, indicating one internal control for the prediction. Moreover, the residues in the QXXRW motif are present in a region close to the central cavity that is believed to be the catalytic pocket. Our model suggests that helix H6 with the conserved aspartate D333 is

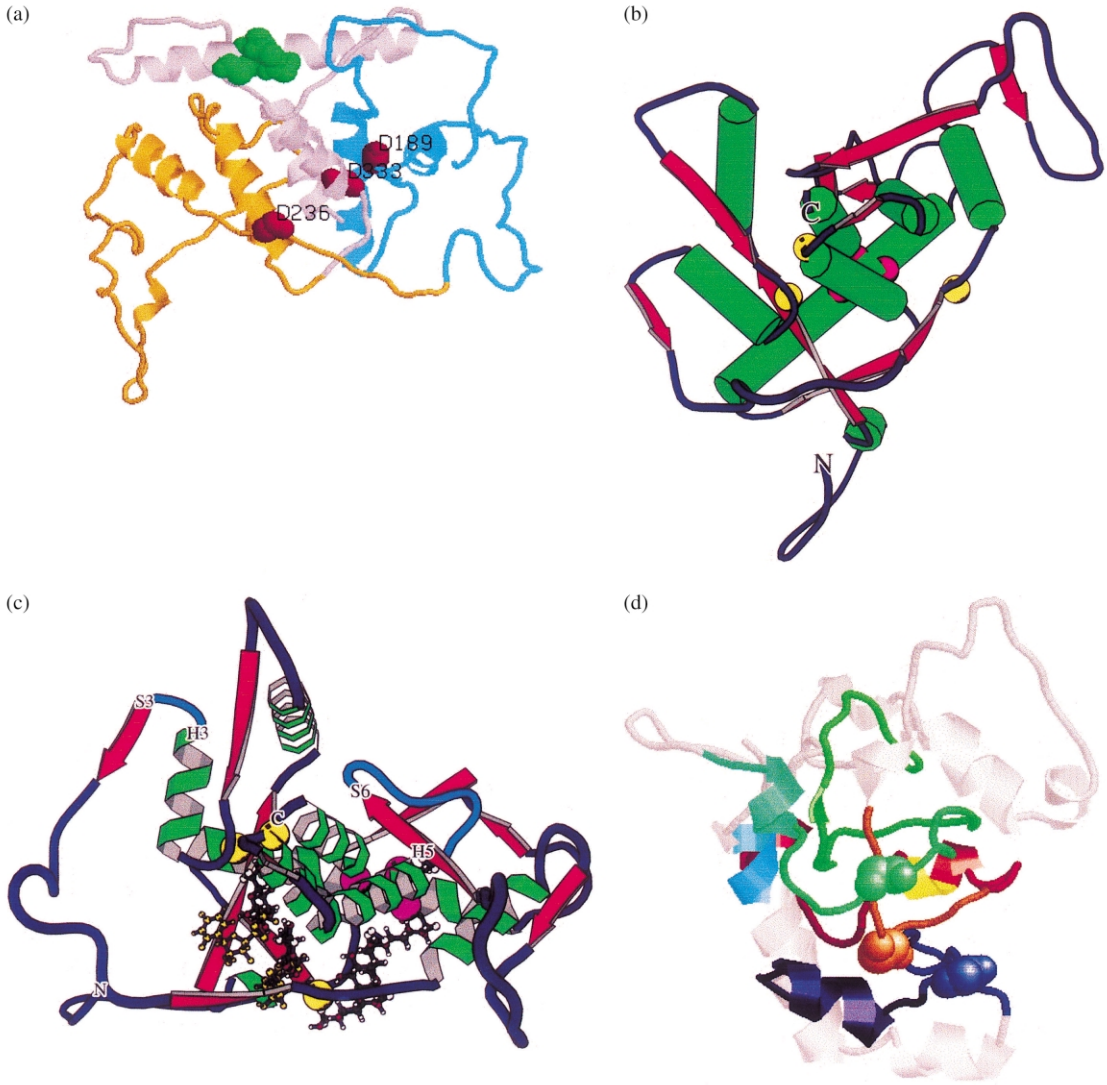

Fig. 4. (a) A ribbon model of the globular region (amino acid residues 128–412) of the *A. xylinum* cellulose synthase (AcsAB) as determined by genetic algorithm. Helical regions are indicated as such. The chain trace of the 285 amino acid globular region is shown starting from cyan (AcsAB residues 128–227) to gold (AcsAB residues 228-327) and grey (AcsAB residues 328–412). The catalytic aspartic acid residues are labeled and shown in red and spacefill representation. The QRVRW conserved motif is shown in green and spacefill. The model was drawn using the program Rasmol by Roger Sayle; (b) a schematic representation of the topology of the globular region of *A. xylinum* cellulose synthase. The alpha-helices are shown as cylinders and the beta-strands as arrows. Small balls indicate the aspartic acid residues (yellow) and the QXXRW motif (purple); (c) ribbon diagram of the globular region of the *A. xylinum* cellulose synthase showing the presence of two UDP-glucose molecules in the central cavity. The conserved aspartic acid residues are shown as yellow balls and the QXXRW region is shown in purple. The loop regions between H3 and S3 and S6 and H5 (shown in cyan) are the regions where insertions are observed in the cellulose synthases from plants. The glucose residues are arranged in a way that they could contact the catalytic aspartic acid residues and would form a cellobiose unit after removal of the UDP moieties during chain initiation. To prevent cluttering of the view in the catalytic cleft, the UDP moieties are a bit more spread out; the position of the right UDP moiety indicates also that the helix with the QXXRW motif can easily be reached (shown as an arrow in the general model in Fig. 7) after further growth of the carbohydrate chain. A glucan chain of 6 glucose residues is shown in the extended catalytic site. The reducing end of the glucan chain is on the top (probably close to the QXXRW motif) and the non-reducing end (the growing end of the glucan chain) is shown close to the second conserved aspartic acid residue (D236CD in the DXD motif); (d) a ribbon model of the globular region (534 residues; amino acids 225-758) of the *G. hirsutum* cellulose synthase (CelA1) as determined by genetic algorithm. This is a coarse model in which every third residue was modeled (a total of 178 residues were modeled) to confirm the general model for processive β-glycosyltransferases. The model depicts the large insertions in the cellulose synthases from plants (shown in white) and the spatial arrangement of the catalytic aspartates (shown thick in spacefill representation) and residues in the QXXRW motif (shown in yellow). The chain trace is color-coded- N-terminus of the chain is blue, C-terminus is red.

Table 2
Secondary structures predicted by genetic algorithm in the globular region of *Acetobacter xylinum* cellulose synthase

Pattern of helices and strands	Amino acid residues[a]	Amino acid sequence
H1	144–146	NPD
S1	150–157	TVDIFVPT
H2	159–173	NEELSIVRLTVLGSL
S2	182–187	VRVHIL

S10	396–401	QRLCYL
H8	402–411	SAMTSFLFAV

[a] The amino acid residues correspond to the complete AcsAB sequence.

central and close to the cleft. Moreover, this helix or helix H7 that contains the QXXRW motif are involved dynamically (perhaps with a structural change) in the enzymatic reaction. The tryptophan residue in the QXXRW motif is perhaps required in glucan binding. Furthermore, the long loop flanked by beta-strands S3 and S4 may help to accommodate the growing glucan chain. Residues making contact with the substrate include the conserved aspartic acid residues. A key region making contact includes residues I234, F235, and D236 while Y231 and I232 are flanking residues. Besides D333, H335 is also in close contact to the substrate. Similarly, besides D189, R191 could also be important. Further away residues I319 to V330 make up the flanking region. The structure determined by the genetic algorithm shows a globular model in accordance to the information from sequence and experiment. The loop regions apparent from the model agree as an independent test well with the accessibility predictions available for the sequence from PHD, an independent prediction algorithm using a neuronal network (Rost and Sander, 1996). Moreover, experiments done with the globular region of the cellulose synthase (CelA1) from plants suggest that the N-terminus of this region is required for UDP–glucose binding (Pear et al., 1996) and the model positions it not far away from the catalytic cleft.

As mentioned earlier, the globular region of cellulose synthases from plants is much larger than the *A. xylinum* cellulose synthase with large insertions between the conserved aspartic acid residues. In CelA1 these regions have been identified as P-CR (plant-conserved region) between the first and the second conserved aspartic acid residues and HVR (hypervariable region) between the second and the third conserved aspartic acid residues (Pear et al., 1996). Similar regions have now been identified in other plant cellulose synthases as well (Arioli et al., 1998; Taylor et al., 1999). The significance of these regions is not known at present. Upon alignment of the globular regions of the *A. xylinum* cellulose synthase (AcsAB), the *E. coli* YhjO polypeptide, and the CelA1 and Rsw1 cellulose synthases from plants, we have determined the position of these regions with respect to the predicted structure of the globular region of the *A. xylinum* cellulose synthase (Fig. 5). These regions are present in loops with the P-CR present between secondary structures H3 and S3 and the HVR between S6 and H5. These loop regions are on the surface and on the other side such that they can easily accommodate additional amino acid residues without interfering with the catalytic activity.

To further examine and compare the structure predicted for the globular region of the *A. xylinum* cellulose synthase, a coarse model of the globular region of cotton (*Gossypium hirsutum*) cellulose synthase CelA1 (Pear et al., 1996) is also predicted. To derive this model, every third residue was modeled by the genetic algorithm (residues in between were assumed to have identical secondary structural state). Despite long sequence insertions, the spatial arrangement of the conserved aspartic acid residues and the neighboring secondary structures in the cellulose synthase from plants (Fig. 4d) was found to be similar to that in the cellulose synthase from *A. xylinum*. Without providing details in resolution, the structure shown in Fig. 4d is another indication from an independent simulation that our model (Fig. 4a) captures the correct general features.

1.4. Relationship of the predicted structure of cellulose synthase with structures of other β-glycosyltransferases

Although the structure and mechanisms for a number of glycosyl hydrolases was known for some time (Davies and Henrissat, 1995), the structure for only a few β-glycosyltransferases have been determined so far. The structure of the T4 β-glucosyltransferase was first determined by Vrielink et al. (1994) and more recently the substrate binding and catalytic mechanism for this enzyme has been proposed (Moréra et al., 1999). This enzyme transfers a glucose residue from UDP–glucose to hydroxymethylcytosine in modified DNA. The sequence of the T4 enzyme does not show similarity to any of the known glycosyltransferases and so far has not been classified into any glycosyltransferase family (Campbell et al., 1997). However, the structure of the T4 enzyme was found to exhibit similarity to the structure of glycogen phosphorylase. Though no sequence similarities were observed between these two proteins, the similarity in the spatial arrangement and in the

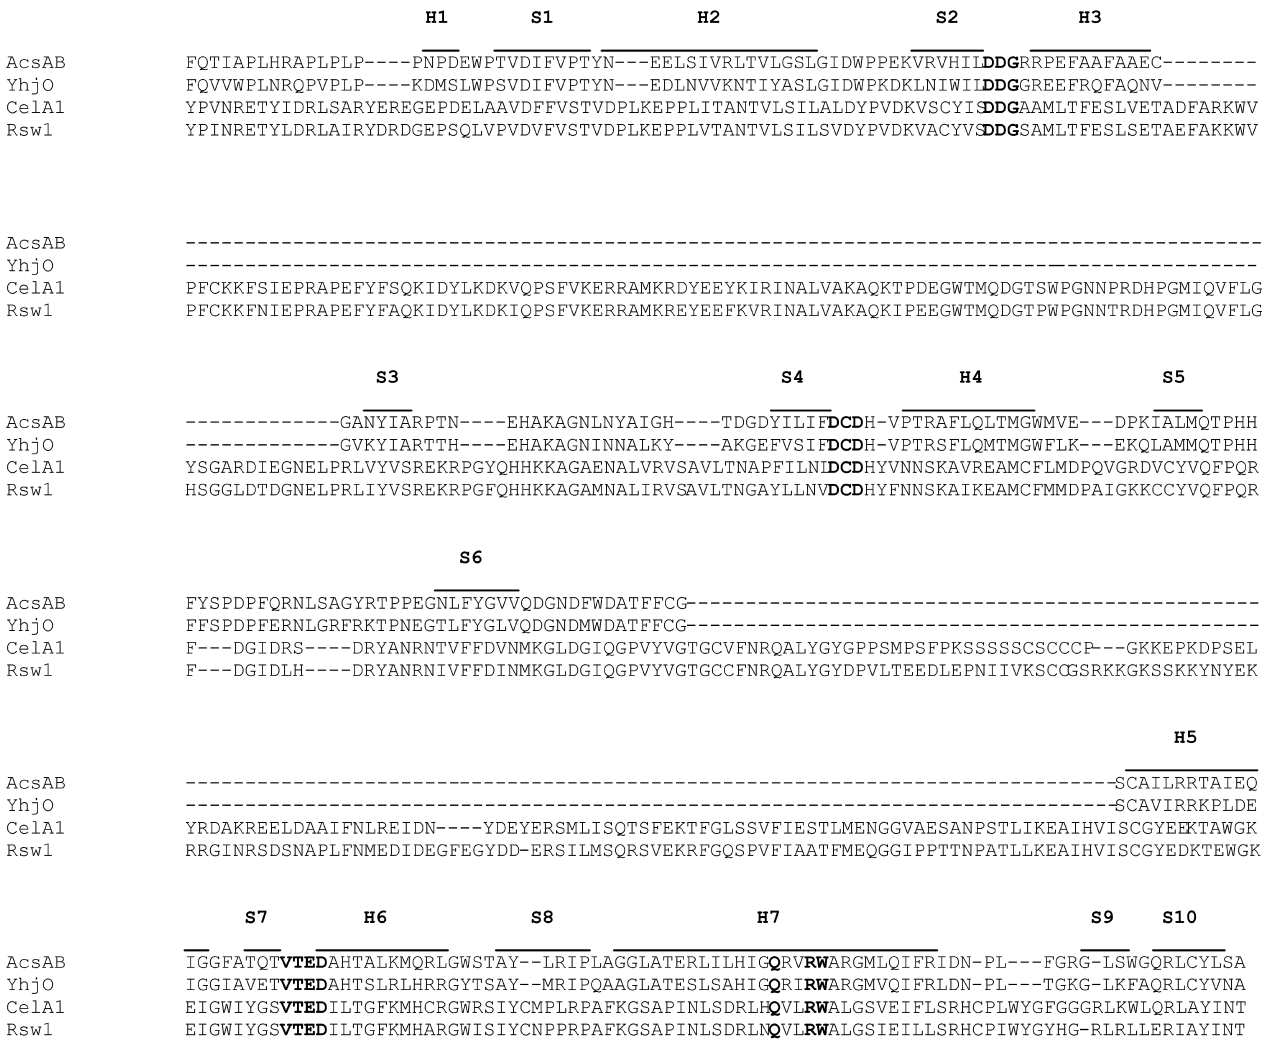

Fig. 5. Multiple alignment of the globular regions of the *A. xylinum* cellulose synthase (AcsAB), *E. coli* YhjO protein, *G. hirsutum* CelA1, and *A. thaliana* Rsw1. The secondary structures identified in the AcsAB globular region by genetic algorithm are shown above the AcsAB sequence.

chemical nature of the substrates suggested an evolutionary relationship between these two proteins based on a structurally conserved catalytic core (Holm and Sander, 1995). The predicted fold of the α-1,3-fucosyltransferases has also been suggested to show similarity to the structure of the T4 β-glucosyltransferase (Breton et al., 1998). Recently, the structures of two more β-glycosyltransferases have been determined experimentally. The structure of SpsA, a glycosyltransferase from *Bacillus subtilis* has been solved (Charnock and Davies, 1999). The substrate and acceptor specificity for this protein is not known, but it is presumably involved in the synthesis of the spore coat. This protein shares sequence homology with the glycosyltransferases in family 2 which includes enzymes that catalyze sugar transfer by an inversion mechanism. This family includes both non-processive as well as processive enzymes. From sequence analysis, SpsA is a non-processive enzyme that transfers a single sugar residue from a nucleotide–diphospho–sugar donor to a specific acceptor. The structure of SpsA shows that it is a two-domain protein with a nucleotide-binding domain and an acceptor binding domain. On the other hand, the structure of β4Gal-T1 reveals a single large domain and the overall fold was found to be different from any fold previously determined (Gastinel et al., 1999).

The modeled topology of the cellulose synthase as a prototype of a processive β-glycosyltransferase fits well in the range of structures experimentally described (Charnock and Davies, 1999; Gastinel et al., 1999) or predicted for other glycosyltransferases (Breton and Imberty, 1999). None of these structures were used for our prediction. They also cannot be used, as there is not sufficient homology for a homology prediction. At the same time, the genetic algorithm prediction is an *ab initio* prediction and does not provide a homology model. The

connectivity of the folds determined for SpsA and β4Gal-T1, and that predicted for cellulose synthase is shown in Fig. 6. Specifically comparing the structure of SpsA (Charnock and Davies, 1999) with the cellulose synthase structure as modeled by the genetic algorithm, we note that the first 100 *N*-terminal residues in SpsA provide the nucleotide binding fold and consist of four parallel β-strands flanked on either side by two helices. In our predicted structure there is a similar arrangement of helix alternating with strand for the first three helices and four strands (no helix was found between strands 3 and 4). Strands 1, 2 and 4 participate in the nucleotide-binding region and strand 8 (later in the chain trace) joins this. Furthermore, in our model strand 3 and helix 3 loop out (which is not the case in the SpsA structure but has been noted for strand 1 and helix 1 of the β4Gal-T1 structure). A more refined model (including refinement of strand positions to each other) may be expected to lead to a better topology of the nucleotide-binding site. On the other hand, re-screening the complete cellulose synthase region modeled here for hidden regular nucleotide-binding domains using IMPALA (Schaffer et al., 1999) showed that none of these are present, indicating by an independent method that cellulose synthase seems to be different in this respect and therefore the need for an *ab initio* model. The C-terminal part of the SpsA structure is a mixed β-sheet flanked by three helices on one side and one helix on the other. In our model of the cellulose synthase, the C-terminal part shows a similar but less regular succession of helices and strands as compared to the N-terminal part. Strands 9, 10 and 6 form a sheet region with helices interspersed and the flanking strand 8 adds to the nucleotide-binding region. The cellulose synthase fold is more integrated than the SpsA structure, which shows a clear split between the N-terminal nucleotide-binding part and the C-terminal part. In fact the compactness of the cellulose synthase is closer in relationship to the β4Gal-T1 structure.

The β4Gal-T1 structure (Gastinel et al., 1999) reveals eleven strands and eight helices (two of them being short 3_{10} helices) in comparison to the cellulose synthase structure that shows ten strands and eight helices. The nucleotide-binding region of β4Gal-T1 is part of the central eight-stranded mixed and twisted β-sheet surrounded by two α-helices on one side and by four α-helices on the other. This bigger sheet is neither predicted for the cellulose synthase nor found in the SpsA structure. However, the sequence of helices and strands in the nucleotide-binding region of β4Gal-T1 looks similar to our predicted cellulose synthase fold and is not as regular as it is in SpsA. The C-terminal part of β4Gal-T1 contains a small sheet region with a similar arrangement as found in our model of cellulose synthase. The β4Gal-T1 fold is again different from the structure of the T4 phage β-glucosyltransferase (Vrielink et al., 1994).

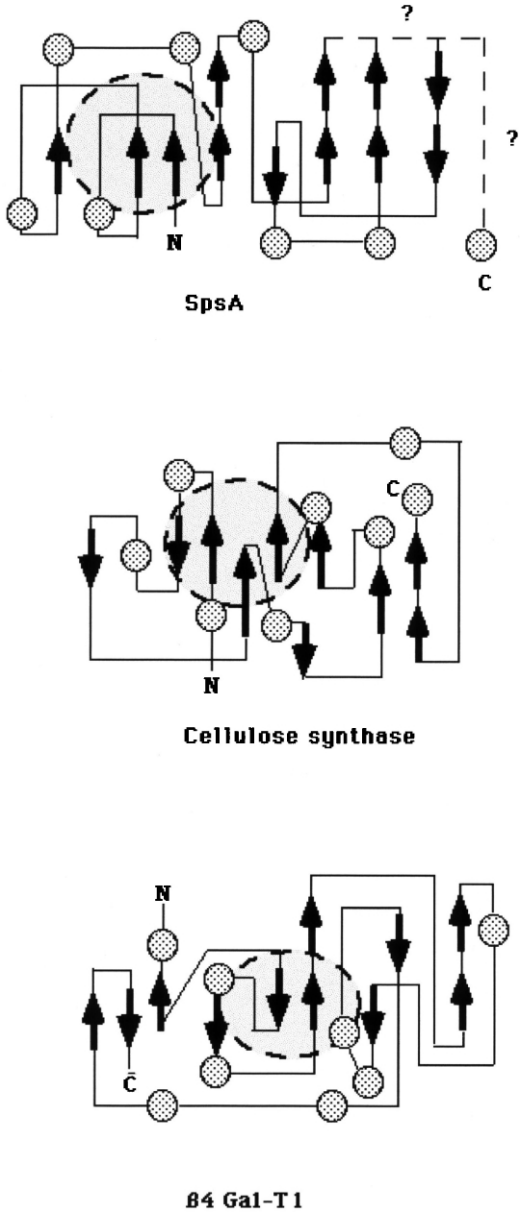

Fig. 6. Topological comparison of the *B. subtilis* SpsA protein, bovine β4Gal-T1 catalytic domain, and the *A. xylinum* cellulose synthase globular region. The circle represents the approximate nucleotide-binding site in each protein.

1.5. Possible mechanisms for synthesis of cellulose and other polysaccharides

Since every glucose unit in the cellulose chain is oriented 180° with respect to its neighbor, we had proposed a model in which two UDP–glucose molecules are positioned in the active site of cellulose synthase at an 180° orientation. Upon catalysis, the glucose units are linked simultaneously or sequentially to extend the cellulose chain two units at a time (Saxena et al., 1995). This model proposed that the active site of the enzyme has an extended region that carries not only the catalytic

residues, but also a region that holds the growing chain (glucan-binding region). Since the catalytic region is predicted to have two UDP–glucose binding sites and as no primer requirement is observed, initiation of cellulose synthesis probably takes place by the formation of a cellobiose unit in the catalytic pocket. In such a case, the UDP-portion of the first UDP-glucose is cleaved, leaving an exposed reducing end in the first glucose (terminal residue) and this glucose is linked via its non-reducing end to the second glucose by a β-1,4–linkage. The cellobiose unit thus formed moves, as it has no bonding in the catalytic pocket, into the glucan-binding region, but does not leave the enzyme because it is in a twisted conformation. In this conformation the cellobiose unit is associated with the glucan-binding region and does not move or slide. In the next step of chain elongation, two new UDP–glucose molecules enter the catalytic pocket and two new β-1,4-linkages are formed either sequentially or simultaneously. The formation of a covalent bond at the non-reducing end of the cellobiose unit present in the glucan-binding region makes this cellobiose unit to adopt an extended conformation and allows it to slide further in the glucan-binding region. This model of the catalytic and glucan-binding region of cellulose synthase is similar to the one proposed, based on direct structural data, for the catalytic domain of CBHI (Divne et al., 1998). Both cellulose synthase and CBHI are processive enzymes that have to be tightly associated with the cellulose chain. In CBHI, the cellulose chain is passaged through a tunnel-like structure in which the protein interacts with at least 10 glucose residues. For the glycosyl hydrolases, the tunnel-like structure probably imposes a steric confinement for the stabilization of a sugar conformation that is able to undergo catalysis, and in this the ring distortion is thought to play an important role (Divne et al., 1998). A similar structure can also be visualized for the cellulose synthase and possibly other processive glycosyltransferases where a glycan chain is passed through a tunnel-like structure where it is held in a conformation that allows both its tight association as well as allows it to slide. The amino acid residues involved in the sugar-protein interaction are usually aromatic residues, such as tryptophan with its indole ring and tyrosine, and we expect them to be conserved in the glucan-binding region of the processive glycosyltransferases.

Is there a need for two catalytic centers in cellulose synthase and possibly other processive β-glycosyltransferases? The requirement for two catalytic centers in these enzymes was proposed to account for the two-fold symmetry of the glucose residues in a cellulose chain where every residue is rotated 180° with respect to its neighbor (Saxena et al., 1995). The absence of duplicated active sites in the cellulose synthase catalytic subunit has led others to suggest that there can be as much as 120° rotation about the β-1,4-linkage. Accordingly all glucose residues can be added in a particular orientation at a single site and the alternating residues can relax into opposing orientations after they have exited the catalytic site (Delmer, 1999). This leads into the nature of the glucan chain in the active site of the enzyme. Do the glucose residues in the glucan chain at this point of synthesis have intramolecular H-bonds to stabilize the chain or do these H-bonds form at a later point? The intramolecular H-bonds between O3′ and O5 exist in crystalline cellulose, and it will be interesting to determine if they are also present in the glucan chain in the active site. In the structure of CBHI from *Trichoderma reesei* bound to cellulose, the cellulose chain has torsion angles at the linkages that are similar to other cellobiosyl linkages (Divne et al., 1998).

The two catalytic centers were also thought to be required for synthesis of polysaccharide chains that have alternating sugar residues that are different and that are linked by different linkages as in the case of hyaluronan (DeAngelis, 2000) and type 3 capsular

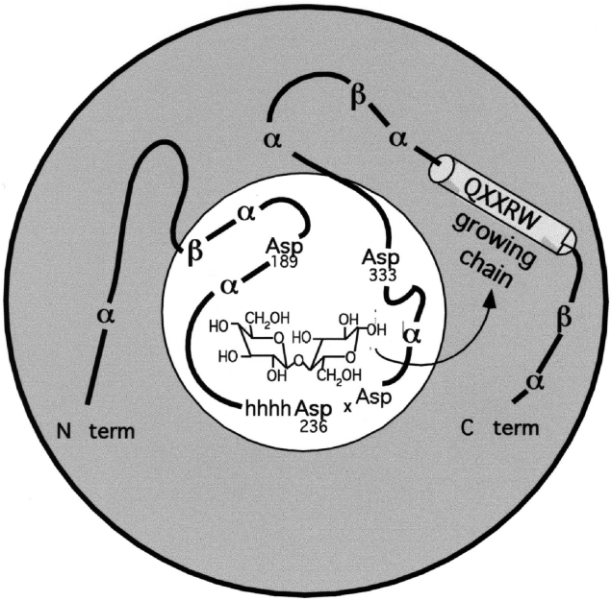

Fig. 7. A cartoon presenting a general model for the globular region of processive glycosyltransferases. The black line represents the main chain trace of the globular region of the *A. xylinum* cellulose synthase. The globular topology of this region is indicated by the grey circle and the globular arrangement of the catalytic residues is shown in the center. The three conserved catalytic residues are indicated by Asp (aspartate, sometimes also glutamate residues; the numbers are only given to identify the corresponding residues in the *A. xylinum* cellulose synthase). α and β indicate stable secondary structure elements that provide a framework for the catalytic residues. The QXXRW motif (alpha-helix with these residues; see text) holds the growing glucan chain (chain itself is only written as text in the cartoon). The processive assembly of the glucan chain takes place by the sequential or simultaneous addition of two glucose residues to the growing end. Functional motifs flank the key catalytic residues (for instance the DXD motif with accompanying *N*-terminal hydrophobic and aromatic residues for Asp 236). h represents hydrophobic residues.

polysaccharide of *Streptococcus pneumoniae* (Cartee et al., 2000). These polysaccharides have a disaccharide repeat and current evidence suggests that the enzymes required for their synthesis are capable of forming all of the glycosidic linkages present in these polysaccharides. Moreover, it is envisaged that a single polypeptide catalyzes the transfer of two distinct sugars in the case of hyaluronan and type 3 capsular polysaccharide. The transfer of the two different sugars to the growing polysaccharide chain is probably catalyzed by a mechanism similar to that proposed for cellulose biosynthesis. Whether catalysis involves a single active site or two independent sites for transfer of the two sugars to the growing chain is not very well understood, although two separate glycosyltransferase activities have been implicated for the synthesis of hyaluronan and other polysaccharides. The *Pasteurella multocida* hyaluronan synthase (PmHasA) shows the presence of duplicated domains A (A1 and A2) instead of domains A and B, and mutational analysis suggests the presence of two relatively independent glycosyltransferase activities on a single polypeptide chain (Jing and DeAngelis, 2000). Moreover, the transfer of sugars by this enzyme has been shown to take place in a sequential manner instead of simultaneous addition of a disaccharide subunit (DeAngelis, 2000).

The similarity between the different β-glycosyltransferases and in their mode of action has been further strengthened by the recent demonstration of the elongation of the growing chain from the non-reducing end as in the case of cellulose (Koyama et al., 1997), chitin (Sugiyama et al., 1999), chitin oligosaccharide (Kamst et al., 1999), hyaluronan (DeAngelis et al., 2000), and type 3 capsular polysaccharide (Cartee et al., 2000). This mechanism of chain growth from the non-reducing end is similar to that observed for the synthesis of starch and glycogen. In all these cases growth occurs by direct polymerization from a nucleotide sugar.

2. Significance

A combination of functional and modeling studies offers an insight into the folding pattern and the arrangement of conserved amino acids in the globular region of the *A. xylinum* cellulose synthase and other processive β-glycosyltransferases. The protein structure calculated by the genetic algorithm was carefully optimized and is the overall fittest from a total of 11 million solution trials. The fitness criteria applied had been validated on 20 proteins with known crystal structure and different topologies (Dandekar and Argos, 1996). The structure calculated is supported by the predicted spatial constraints (size of the UDP–glucose binding pocket; transfer of the growing chain to the QXXRW region), the available experimental data (requirement of the first conserved aspartic acid and *N*-terminus in UDP–glucose binding experiments is supported in the model where the *N*-terminus is flanking the catalytic cleft; requirement of the conserved aspartic acid residues for enzyme activity as determined by site-directed mutagenesis and activity measurements), and sequence analysis (identification of the conserved residues and the QXXRW motif in the globular region). As an independent test, the distribution of accessible loop regions agrees well with that derived by neuronal network prediction (Rost and Sander, 1996). Nevertheless, we suspect the RMSD error in several areas of the model to be still high (higher than 5 Å). However, the structure is useful to get a first approximation view at the spatial arrangement of the catalytic residues, the glucan holding residues (QXXRW region) for the growing cellulose chain and, also importantly, of all the neighboring residues acting in concert with these central ones. These features as well as the alpha/beta mixed topology without a regular succession of helices and strands predict a simplified and general model for the structure and action of processive β-glycosyltransferases (Fig. 7). We hope that this first structure-function characterization of cellulose synthase will stimulate further research and will be an incentive for new studies.

Transcriptional control of lignin biosynthesis by tobacco LIM protein

Akiyoshi Kawaoka *, Hiroyasu Ebinuma

Nippon Paper Industries Co., Ltd, Pulp and Paper Research Laboratory, 5-21-1, Oji, Kita-ku, Tokyo 114-0002, Japan

Received 5 July 2000; received in revised form 1 November 2000

Abstract

Lignin is a complex phenolic plant polymer that is essential for mechanical support, defense, and water transport in higher plants. The AC-rich motif, Pal-box is an important *cis*-acting element for gene expression in phenylpropanoid biosynthesis. We isolated a cDNA clone (*Ntlim1*) encoding a Pal-box binding protein by Southwestern screening. The deduced amino acid sequence of Ntlim1 is highly similar to members of the LIM protein family that contain a zinc finger motif. Moreover, Ntlim1 had a specific DNA-binding ability and transiently activated transcription of a β-glucuronidase reporter gene driven by the Pal-box sequence. The results of transient expression assays with tobacco cultured cells showed that fusion proteins between GFP and Ntlim1 can enter nuclei. Transgenic tobacco plants with antisense Ntlim1 showed low levels of transcripts from some key phenylpropanoid pathway genes such as phenylalanine ammonia-lyase, hydroxycinnamate CoA ligase and cinnamyl alcohol dehydrogenase. Furthermore, a greater than 20% reduction in lignin content was observed in transgenic tobacco with antisense *Ntlim1*. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Transcription factor; LIM domain; Gene expression; Lignin; Phenylpropanoid

1. Introduction

Lignin is a complex phenolic polymer that reinforces the walls of certain cells in vascular tissues, and plays an important role in mechanical support, water transport and pathogen resistance in higher plants. In the pulp and paper industry, lignin must be removed by harsh chemical treatments, which is costly both to the mill and the environment. Genetic modification of the lignin content and composition of woody plants is currently receiving considerable attention in forest biotechnological studies and wood formation. In addition, the lignin polymer is intimately associated with cell wall polysaccharides, such as cellulose and hemicellulose of forage. Lignin interferes with the digestibility of these carbohydrates. Thus, the modification of lignin content and monomer composition by biotechnological procedures is of significant commercial interest.

Lignin is derived from the dehydrogenative polymerization of monolignols, *p*-coumaryl alcohol, coniferyl alcohol, and sinapyl alcohol. Based on tracer experiments and subsequent enzymatic analysis of the intermediate steps, it has been shown that monolignols are synthesized through the phenylpropanoid biosynthetic pathway (Higuchi, 1985). The lignin biosynthetic pathway has been relatively well studied, and most genes encoding the enzymes in this pathway have been identified in several plant species (Whetten et al., 1998). The targeted manipulation of specific genes and enzymes has complemented the chemical characterization of lignin mutants in a variety of plant species (Whetten et al., 1998). These studies have exploited a range of different genes encoding enzymes involved in the control of lignification at three levels. The first enzymes are those of the common phenylpropanoid pathway: phenylalanine ammonia-lyase (PAL), cinnamate 4-hydroxylase (C4H) and hydroxycinnamate CoA ligase (4CL). The second group consists of those in the hydroxylation/methylation step of monolignol biosynthesis: caffeate/5-hydroxyferulate-*O*-methyltransferase (COMT), caffeoyl CoA/5-hydroxyferuloyl CoA-*O*-methyltransferase (CCoAOMT) and ferulate-5-hydroxylase (F5H). The third group consists of those in the last steps of monolignol biosynthesis: hydroxycinnamoyl-CoA:NADPH oxidoreductase (CCR) and

cinnamyl alcohol dehydrogenase (CAD). Several attempts to produce transgenic tobacco with antisense or sense-suppression methods have led to the modification of lignin content and monomeric composition (Boudet, 1998).

Most of the genes involved in lignin biosynthesis have been identified and their promoter regions have been studied. The AC rich-element Pal-box is an important *cis*-acting element (Boudet, 1998). The horseradish peroxidase (HRP) encoded by the *prxC2* gene is involved in lignification (Kawaoka et al., 1992). We previously reported the cloning of a cDNA encoding *TFHP1*, which specifically bound to the G-box motif in the *prxC2* promoter (Kawaoka et al., 1994). In a later report, analysis of the regulatory properties of the *prxC2* promoter revealed another positive *cis*-acting element, POP (Pal-box related *cis*-acting element of *prxC2*), which contained a Pal-box like motif between −178 and −136 bp from the translation start site (Kaothien et al., 2000). The Pal-box motif, CCA (C/A) (A/T) A (A/C) C (C/T) CC, is a highly conserved sequence that is involved in the expression of phenylpropanoid biosynthetic genes such as *PAL* (Cramer et al., 1989; Lois et al., 1989; Ohl et al., 1990), *4CL* (Douglas et al., 1987), *CHS* (Dron et al., 1988) and *CAD* (Feuillet et al., 1995). The Pal-box motif appears to be similar to the nucleotide sequence bound by MYB transcription factors. The first evidence for the role of MYB proteins in the regulation of genes in the phenylpropanoid pathway came from the study of a flower-specific MYB from *Antirrhinum*. Overexpression of two *Antirrhinum* MYB genes in transgenic tobacco down-regulated the expression of some genes in phenylpropanoid biosynthesis (Tamagnone et al., 1998). This result suggests that MYB-type transcription factors might be involved in regulating the expression of genes in lignin biosynthesis. However, there are many members of the *MYB* gene family in a plant genome and the DNA-binding specificity of plant MYB proteins varies considerably (Martin and Paz-Ares, 1997). The binding-site performance and affinity of MYB proteins is also likely to be strongly influenced by other protein factors that interact with them (Jin and Martin, 1999). Hence, it is difficult to believe that the MYB-type transcription factors alone play a pivotal role in the expression of lignin biosynthetic genes.

To understand the regulation of lignin biosynthesis, we focused on a transcription factor that controls the expression of genes encoding enzymes in this pathway. We describe here the functional analysis of a tobacco protein, called *Ntlim1*, which specifically bound to the Pal-box sequence. The Ntlim1 protein has two LIM domains which are cysteine-rich polypeptides composed of two special zinc fingers separated by a two-amino acid spacer. Other reports on plant LIM proteins describe sunflower PLIM1 and WLIM1 (Baltz et al., 1992; Mundel et al., 2000). Although the LIM domain is comprised of a double, semi-conservative zinc finger motif, there is still not enough proof for its DNA-binding activity. Furthermore, the LIM domain may function as an interface for protein-protein interaction (Crawford et al., 1992; Sadler et al., 1992). In this report, we show that the Ntlim1 protein acts as a potential transcription factor in lignin biosynthesis by binding to a specific DNA sequence. Moreover, suppression of Ntlim1 caused simultaneous reduction in the transcript levels of some phenylpropanoid pathway genes and a low lignin content in transgenic plants.

2. Results

2.1. Molecular cloning of a cDNA encoding Pal-box binding protein

To investigate the existence of a protein that binds to the Pal-box like motif in tobacco nuclear protein, we prepared a double-stranded oligonucleotide probe P that corresponded to three tandem copies of the Pal-box like motif (-CCACTTGAGTAC-) in the horseradish peroxidase *prxC2* promoter region. The binding of nuclear protein to probe P was tested by a gel retardation assay using the nuclear extracts from tobacco stems. As shown in Fig. 1, several retarded bands appeared in the presence of nuclear extracts from tobacco stems and were maintained even in the presence of poly (dI-dC)·poly (dI-dC) as a non-specific competitor. On the other hand, in the presence of excess amounts of the homologous non-labeled DNA fragment as a specific competitor, the retarded complexes were not observed, confirming the presence of nuclear factors that specifically bind to the Pal-box like motif in tobacco stems.

To isolate cDNAs which encode the Pal-box binding protein, a λgt11 expression library constructed with mRNA from tobacco stems was screened using probe P. From the screening of one million recombinant phages, one positive clone was obtained. The cDNA insert of the positive clone was 1.0 kb in length and contained an open reading frame that encodes a protein of 200 amino acid residues (Fig. 2a). From a GenBank database search, the deduced amino acid sequence of the clone proved to be highly homologous to a plant LIM protein, the PLIM1 of late pollen genes in the sunflower (Baltz et al., 1992) and Arabidopsis L2 (GenBank accession no. X91398). We designated the protein encoded by this cDNA as Ntlim1. The LIM motif defines one class of zinc-binding domains and was originally recognized in, and named after, the protein products of the *lin-11*, *isl-1* and *mec-3* genes (Taira et al., 1995). Furthermore, the results of the motif search showed that the deduced amino acid sequence of the Ntlim1 protein contains two repeats of conserved amino acid sequences of the LIM domain (LIM1 and LIM2; Fig. 2b). To determine the

number of genes in the tobacco genome that are related to the gene for Ntlim1, Southern hybridization was carried out. Three hybridizing bands were obtained with genomic DNA digested with either *Eco*RV or *Dra*I, indicating that there are at least three copies of *Ntlim1* in the tobacco genome (data not shown). Total RNA extracted from tobacco roots, stems and leaves was subjected to electrophoresis, blotted, and the accumulation of *Ntlim1* mRNA in each organ was determined by Northern hybridization. The *Ntlim1* mRNA was abundant in stems and was also detected in leaves and roots (Kawaoka et al., 2000).

2.2. Ntlim1 protein is a transcription factor

To determine whether the Ntlim1 protein indeed binds to the Pal-box like sequence, we prepared protein extracts from *Escherichia coli* carrying the expression vector pGEX-2TK, which produces glutathione-S-transferase (GST) fusion protein, by isopropyl-β-D-thiogalactopyranoside (IPTG) induction. The fusion protein, GST-Ntlim1, was purified through Glutathione-Sepharose 4B resin. After digestion with thrombin protease, the band of purified Ntlim1 protein (24 kDa) was observed by SDS–PAGE. The DNA-binding ability of the purified Ntlim1 was tested by gel retardation assay using radiolabeled probe P (Fig. 3). A retarded band showing DNA-binding activity of Ntlim1, which disappeared in the presence of an excess amount of non-labeled probe P, was observed (lanes 3 and 4). The Pal-box binding specificity of Ntlim1 was also confirmed by a competition assay using an excess amount of another non-labeled Pal-box sequence of bean Pal2 (-CCAC-CAACCCCC-, lanes 5 and 6).

Ntlim1 has three notable domains: the LIM1 domain, the LIM2 domain and the acidic domain (amino acids 164-200). To confirm whether *Ntlim1* functions as a transcription activator in vivo, we constructed an effector plasmid that was a full-length *Ntlim1* cDNA under the control of the cauliflower mosaic virus (CaMV) 35S core promoter, and two kinds of chimeric GUS genes used as reporter plasmids (Fig. 4a). The P reporter plasmid was constructed using double-stranded synthetic oligonucleotides. A three-copy sequence of the Pal-box like motif was ligated to the -90 bp CaMV 35S minimum promoter. Transient expression of GUS in tobacco leaves was measured 24 h after the effector and reporter were co-introduced by particle bombardment. As shown in Fig. 4b, the co-introduction of reporter P with the effector construct led to many blue spots, indicating GUS expression. However, when the reporter plasmid alone was introduced, no blue spots were obtained.

To investigate the localization of the Ntlim1 protein in tobacco cells, two kinds of chimeric genes were constructed between the Ntlim1 protein and Green Fluorescent Protein (GFP) under the control of the 35S

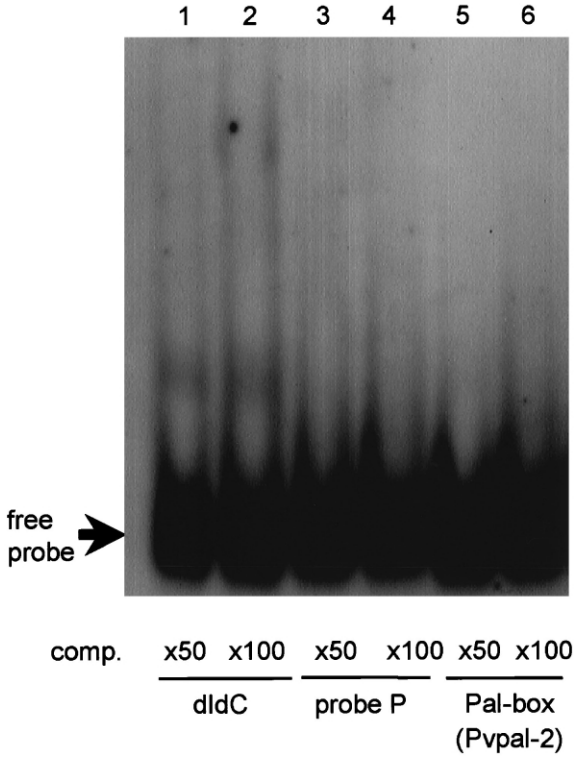

Fig. 3. Gel retardation assay of the Ntlim1 protein expressed in *Escherichia coli*. The purified Ntlim1 was incubated with DIG-labeled probe P in either the presence of excess amounts of non-labeled probe P (lanes 3, 4) or non-labeled double-stranded oligonucleotide corresponding to the Pal-box sequence of the bean *pal2* gene (lanes 5, 6), which were used as competitors, or without an excess of non-labeled probe P (lanes 1, 2).

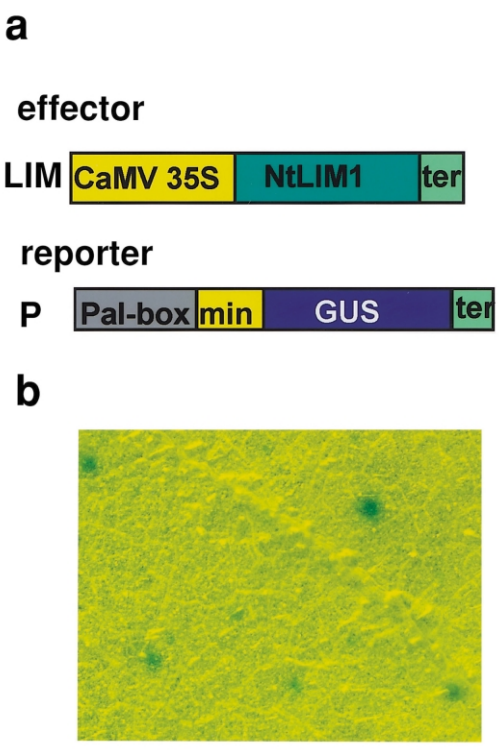

Fig. 4. *trans*-Activation by Ntlim1 in tobacco leaf tissue. (a) Reporter and effector constructs. The construct names are shown at the left side of each construct. Pal-box, three copies of Pal-box like motif; min, 35S promoter truncated at position-90; GUS, uid A coding region; ter, nopaline synthase terminator; CaMV35S, 35S promoter; Ntlim1, sequence encoding full-length Ntlim1. (b) *trans*-Activation of Pal-box sequence by Ntlim1. Effector and reporter constructs were co-introduced into tobacco leaves by particle bombardment, and blue spots indicating GUS activity were measured after 24 h of incubation.

promoter. GFP-LIM and LIM-GFP were translationally ligated to the GFP gene at the N- or C-terminal of Ntlim1, respectively (Fig. 5a). These genes were introduced into tobacco cultured BY-2 cells by particle bombardment. At 48 h after introduction, fluorescence microscopy studies showed both types of fusion proteins at high levels exhibiting bright green mainly in nuclei (Fig. 5b), whereas no green fluorescence was detected in the untransformed BY-2 cells. We also introduced GFP alone into BY-2 cells and strong green fluorescence was observed in the cytoplasm of these cells (data not shown). Ntlim1 appears to be a nuclear protein.

2.3. *Ntlim1* affects gene expression of lignin biosynthesis

To investigate the molecular effects of *Ntlim1* on lignin biosynthesis, a 1.0-kb fragment of *Ntlim1* was inserted in the antisense orientation between the CaMV 35S promoter and the 3′ terminator sequence of the nopaline synthase gene. This construct was introduced into tobacco plants by Agrobacterium-mediated transformation. Twenty independent primary transgenic plants (T1) were produced and all lines contained the respective T-DNA determined by PCR analysis. Subsequently, seven antisense lines were screened by measuring the *Ntlim1* transcript levels in the stems, and were grown to maturity in a greenhouse. Their self-pollinated seeds (T2) were collected and used for further investigation. Ten T2 kanamycin-resistant transgenic plants were grown in a greenhouse. All of them showed a normal growth rate and flowered at similar times. No remarkable abnormal growth or flower color changes were found in the transgenic lines, except that several lines showed a slightly increased stem height. We isolated cDNA clones encoding some of the structural genes, *PAL*, *4CL* and *CAD*, involved in phenylpropanoid biosynthesis from tobacco by PCR. The expression levels of these structural genes, the transgene, and the endogenous *Ntlim1* were estimated by Northern blotting using random-primed probes. Total RNAs were extracted from stems in the kanamycin-resistant T2-transgenic A9 and A19 plants. Signals of the antisense *Ntlim1* gene were not detected in either plant carrying the antisense *Ntlim1*

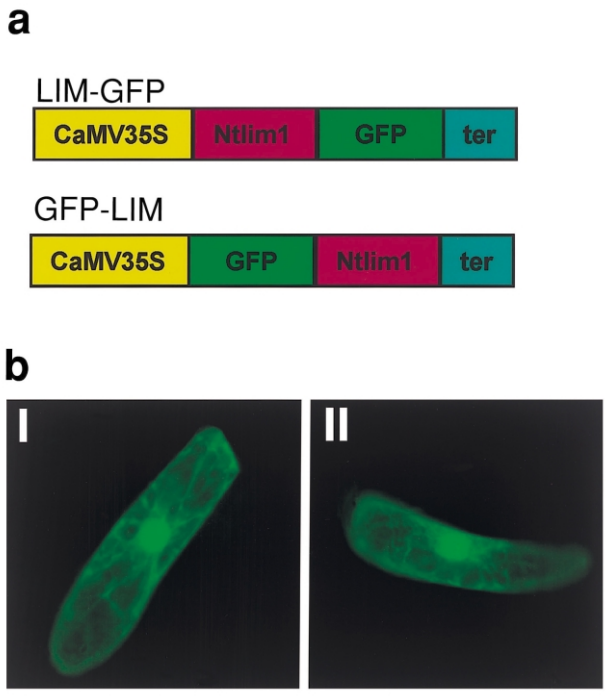

Fig. 5. Localization of the fusion protein between Ntlim1 and GFP. (a) Constructs of the chimeric genes. Two kinds of chimeric plasmids (LIM-GFP and GFP-LIM), under the control of the 35S promoter, were produced. (b) Fluorescence image of LIM-GFP (I) and GFP-LIM (II).

gene. The antisense Ntlim1 transcript is probably unstable in tobacco cells. In antisense plants, endogenous *Ntlim1* (1.2 kb) expression was suppressed and the mRNA levels of *PAL, 4CL* and *CAD* were also lower than those in the wild-type plant (Fig. 6).

To examine the effect of the simultaneous reduction of the transcript levels in many lignin biosynthetic genes, the content and monomeric composition of lignin in transgenic plants were analyzed. The lignin content of the cell wall residue (CWR) of stem xylem tissues was

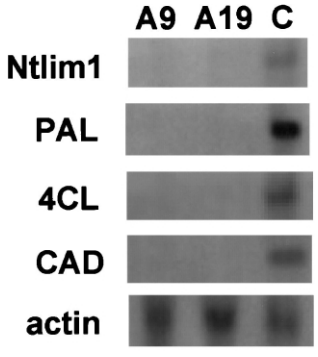

Fig. 6. RNA gel blot analysis showing the expression of genes in the phenylpropanoid biosynthesis pathway. Total RNA was extracted from stems of wild-type (C) and T2-transgenic plants with the antisense (A9 and A19) construct. The transgenic plants were grown in the greenhouse for 10 weeks. Accumulation of the mRNA of *Ntlim1*, *PAL*, *4CL* and *CAD* was investigated.

Table 1
Lignin content in transgenic plants

Line	Lignin content[a]	*S* (μmol/g)[b]	*V* (μmol/g)[b]	*S*/*V*
C	21.2±0.6 (100)	124.4±3.1	157.2±4.8	0.79
A9	15.5±0.3 (73)	31.5±0.9	67.3±3.7	0.47
A19	15.9±0.5 (75)	45.2±4.6	65.7±8.3	0.69

[a] Lignin content is expressed as a percentage (w/w) of cell wall residues (CWR) by Klason lignin.

[b] Syringaldehyde and vanillin were obtained when CWR was treated by the alkaline nitrobenzene oxidation procedure. Values are expressed as μmol per gram of CWR. All values represent the mean ±S.D. of results from the analysis of three to six plants.

measured by the gravimetric Klason procedure. Lignin determinations were carried out on the T2 kanamycin-resistant transgenic line after 10 weeks of growth in a greenhouse. The lignin contents of the basal stem part (5 internodes from the bottom) in the A9, A19 and control plants were measured. Reductions of more than 20% were observed in these antisense plants (Table 1).

To determine the monomeric composition of lignin in the CWR, we examined the CWR from each plant by alkaline nitrobenzene oxidation analysis. Vanillin and syringaldehyde are generated from the non-condensed fraction of lignin by this procedure (Chiang and Funaoka, 1988). Vanillin and syringaldehyde are considered to be derived from guaiacyl and syringyl units in lignin, respectively. The relative abundance of guaiacyl and syringyl units in lignin can be summarized as the S/V ratio (the ratio of the amounts of syringaldehyde and vanillin). The A9 and A19 plants showed lower S/V ratios and decreased amounts of total aldehydes. These results suggest that lignin in the transgenic plants with a decreased expression level of *Ntlim1* contained more condensed units that could not be degraded by oxidation procedures.

3. Discussion

Lignin is the second most abundant polymer on earth after cellulose. Although vital to plant fitness, lignin negatively impacts paper pulp processing and feed for livestock. Much of the cost, complexity and pollution associated with the pulping process is due to the removal of lignin from wood to produce high-quality paper. The regulation of lignin biosynthesis might lead to sizable economic benefits when using woody plants for pulping and forage crops. Transgenic experiments that assess the genes for many steps in this pathway have provided important results indicating the review of this proposal by Whetten et al. (1998).

From the results of transient expression analysis using tobacco protoplasts, the Pal-box like motif has been shown to be a *cis*-acting element for expression of the

basic horseradish peroxidase *prxC2* gene (Kaothien et al., 2000). The Pal-box is a common *cis*-acting element for several phenylpropanoid biosynthetic genes (Boudet, 1998). Antirrhinum *MYB* genes are known to have a Pal-box binding function and to regulate phenylpropanoid biosynthesis (Tamagnone et al., 1998). In this study, we isolated a novel Pal-box binding factor by Southwestern screening from an expression library of tobacco stems. The predicted amino acid alignment of the isolated clone exhibited a high similarity to LIM proteins. The cloned Pal-box motif-binding factor encodes a protein consisting of 200 amino acid residues and shares a 55% identity with sunflower PLIM-1 protein, which is a transcription factor required for the expression of late pollen genes (Baltz et al., 1992). This protein contains a consensus amino acid sequence defined as the LIM domain which is a unique cysteine-rich motif with two zinc fingers connected by a short spacer of invariably two amino acid residues (Dawid et al., 1995). LIM proteins form a diverse group which includes LIM-homeodomain proteins, LIM-only protein and LIM-kinase (Taira et al., 1995). Very little is understood about the function of the LIM proteins in higher plants. The LIM domain may provide an interface for protein-protein interaction (Crawford et al., 1992; Sadler et al., 1992) and the LIM-only protein Lmo2 is part of a sequence-specific DNA-binding complex (Wadman et al., 1997). The sunflower pollen protein PLIM-1 reportedly binds to nucleic acids in vitro, but no specific DNA-binding sequence was described (Baltz et al., 1996). Thus, there is still not enough evidence to suggest that the LIM domain is able to bind to DNA. We have shown that the Ntlim1 protein expressed in *E. coli* binds to a Pal-box like motif in vitro. Furthermore, either the LIM1 or the LIM2 domain was sufficient for its DNA-binding (Kawaoka et al., 2000). The results presented in Fig. 5 indicate that Ntlim1 also bound to the Pal-box motif in vivo. Transient *trans*-activation experiments indicate that *Ntlim1* has a domain that acts as a transcription activator. The most likely candidate for this domain is the C-terminal 37-amino acid acidic polypeptide. No homology to known transcription activation domains has been observed and there are no distinctive features in its amino acid sequence in the C-terminal region of Ntlim1. Random acidic amino acid peptides from *E. coli* have been reported to substitute for the acidic activator domain of Gal4 in yeast (Ma and Ptashne, 1987). The Gal4 activator can activate transcription in tobacco (Ma et al., 1988). Plant transcription factors, such as maize VP1 and Dof1, have acidic domains that function in transcriptional activation in plants (McCarty et al., 1991; Yanagisawa and Sheen, 1998). All of this evidence supports the hypothesis that an acidic domain of Ntlim1 may function in transcriptional activation.

Northern blot analysis showed that at least two genes encoding enzymes of general phenylpropanoid metabolism (*PAL* and *4CL*) and one in the lignin branch (*CAD*) were affected by Ntlim1 at the transcriptional level (Fig. 6). Transgenic plants with the antisense *Ntlim1* showed decreased expression of these genes. Thus, suppression of *Ntlim1* expression could block many steps in phenylpropanoid biosynthesis and Ntlim1 might also regulate the expression of some other genes in this pathway that contain the Pal-box sequence in their promoter regions. The Pal-box has been reported to be a common recognition site of MYB proteins (Grotewold et al., 1994; Douglas, 1996). Overexpression of *AmMYB308* repressed the expression of *C4H*, *4CL* and *CAD* in tobacco, but did not affect the steady-state level of *PAL* transcript (Tamagnone et al., 1998). Different *MYB* factors could coordinately regulate the expression of *PAL* (Tamagnone et al., 1998). Many copies of the *MYB* gene family have been identified in the plant genome and their DNA-binding specificities vary considerably (Martin and Paz-Ares, 1997). From our previous result, the sequence recognized by the Ntlim1 protein is similar to that recognized by MYB proteins, although the last 6 bases in the consensus of the Ntlim1 recognition sequence are not rigid (Kawaoka et al., 2000). Therefore, the discrepancy in the effect on the *PAL* gene expression between Ntlim1 and AmMYB308 protein might result from the smaller difference in their recognition sequences. It is also possible that both Ntlim1 and AmMYB308 proteins are members of the Pal-box binding complex although they compete with each other in binding to the Pal-box. The Ntlim1 may bind to the *PAL* promoter while AmMYB308 does not. To clarify this matter, further analysis of the Pal-box binding complex by an immunological experiment is needed.

The low expression level of *PAL*, *4CL* and *CAD* in the A9 plant with antisense *Ntlim1* resulted in a 27% reduction in its lignin content compared with that in control plants. Several attempts to reduce the lignin content by inhibiting the activity of enzymes in the phenylpropanoid biosynthesis pathway have been reported (Douglas, 1996). Transgenic plants with repressed COMT or CAD activities resulted in a modified lignin structure instead of reduced lignin content, suggesting that neither enzyme limits lignin accumulation (Dwivedi et al., 1994; Halpin et al., 1994). However, a reduced expression of *PAL* or *4CL* has previously been shown to cause lower lignin content and altered lignin composition in transgenic plants (Elkind et al., 1990; Lee et al., 1997). Lignin is an essential component of the plant cell wall and a severe reduction in lignin content ($>40\%$) can cause an abnormal growth phenotype in herbaceous plants. For example, transgenic tobacco with suppression of *PAL* or overexpression of *MYB*-related transcription factors showed an abnormal growth phenotype (Sewalt et al., 1997; Tamagnone et al., 1998). Transgenic tobacco plants with antisense *CCR* showed a 47% reduction in Klason lignin, but normal plant growth was severely

affected (Piquemal et al., 1998). CCoAOMT antisense tobacco plants with up to a 66% reduction in lignin content grew as normally as wild-type plants, but their vessel shape was significantly collapsed (Zhong et al., 1998). However, transgenic aspen trees with down-regulated 4CL and a lignin content reduction of up to 45% exhibited a normal phenotype because the reduction in the lignin content was compensated by an increase in cellulose content (Hu et al., 1999). In this study, we detected no visible abnormal growth in the transgenic tobacco with sense and antisense *Ntlim* and we also found no sign of vessel collapse in the A9 plant with up to 27% reduction in the lignin content. Thus, Ntlim1 may function as a weak activator that helps maintain basal expression of the genes encoding enzymes in the phenylpropanoid biosynthesis pathway which leads to retained basal enzyme activities in lignifying tissues. Our results suggest that genetic engineering of the transcription factor involved in lignin biosynthesis may be an efficient strategy for producing plants with improved pulping characteristics or digestibility.

4. Experimental

4.1. Plant material

Nicotiana tabacum cv Petit Havana SR-1 was used. Tobacco plants were grown in a greenhouse at 25°C under a 16-h light and 8-h dark photo-period.

4.2. Screening of the library and DNA sequencing

Total RNA was isolated from stems of tobacco plants that were grown for 6 weeks in a greenhouse. Using oligo (dT) and random primers, a cDNA library was constructed in λgt11 vector (Stratagene, La Jolla, CA, USA). The amplified library was screened with a digoxigenin (DIG)-labeled double-stranded oligonucleotide fragment that corresponded to a triple repeat of a Pal-box like motif, -CCACTTGAGTAC-. We used essentially the same screening protocol as Singh et al. (1988). An inserted DNA fragment of a positive clone was amplified by polymerase chain reaction using forward and reverse primers for λgt11 vector. The amplified DNA fragment was recloned into pNoTA/T7 vector by PCR Cloner (5 Prime, 3 Prime Inc., Boulder, CO, USA). Sequence analysis was performed on double-stranded DNA templates using a DyeDeoxy™ Terminator Cycle Sequencing Kit (Perkin Elmer, Foster City, CA, USA).

4.3. Expression of Ntlim1 in Escherichia coli

E. coli cells, JM109, carrying the expression vector pGEX-2 TK (Amersham Pharmacia Biotech, Buckinghamshire, UK) containing the cDNA sequence encoding *Ntlim1* were grown to an absorbance at 660 nm of 0.8 in LB broth. IPTG was added to the culture at a final concentration of 1 mM and the cells were cultured at 25°C for an additional 2 h. Cells were harvested by centrifugation and the crude extract was used for purification of the Ntlim1 protein by Glutathione-Sepharose 4B according to the manufacture's instructions (Amersham Pharmacia Biotech).

4.4. Gel retardation assay

The binding reaction was carried out in a 20 μl reaction mixture containing protein, 2 ng of DIG-labeled DNA probe, 10 mM Tris–HCl pH 8.0, 80 mM KCl, 0.016% NP40, 7.5% glycerol, 1 mM DTT, and 1 μg poly (dI-dC)·poly (dI-dC) (Amersham Pharmacia Biotech). The reaction mixtures were pre-incubated at 23°C for 15 min, mixed with radiolabeled DNA probe, and allowed to react for a further 30 min at 23°C. Each sample was applied without dye onto a 5% non-denaturing polyacrylamide gel in 0.5×TBE buffer. Electrophoresis was carried out at 15 V/cm in 0.5×TBE buffer. Following the electrophoresis, the gel was dried and exposed overnight to X-ray film. For a competitive binding assay, excess amounts of non-labeled DNA fragments (competitors) were added to the reaction mixture at the pre-incubation step.

4.5. Plasmid construction of effector

Effector plasmids were constructed under the control of the CaMV 35S promoter in a modified pBI221-mcs plasmid that placed a multi-cloning site into the GUS structural gene. A double-stranded synthetic oligonucleotide based on the synthetic linker III for a multi-cloning site (Malik and Wahab, 1993) was inserted at the *Bam*HI-*Sac*I site in pBI221 (Jefferson et al., 1987). To generate LIM, which has a full-length cDNA of Ntlim1, the *Bam*HI fragment of Ntlim1 was ligated into the same site of pBI221-mcs.

4.6. Construction of reporter plasmids and particle bombardment

The P reporter plasmid was constructed using double-stranded synthetic oligonucleotides. A three-copy sequence of the Pal-box like motif (-CCACTTGAGTAC-) was ligated to the *Eco*RV site at-90 bp of the CaMV 35S promoter. The correctness of orientation of the inserted oligonucleotides was checked by sequencing. Biolistic particle bombardment of the tobacco leaves was carried out following the manufacture's protocol (Bio-Rad, Hercules, CA, USA). GUS activity was assayed by a method described by Jefferson et al. (1987) using X-glucuronide as the substrate.

4.7. GFP fusion plasmids

The GFP coding region was amplified from pbluesGFP(S65T)nos KS (a gift from Yasuo Niwa, University of Shizuoka) using specific primers and transitionally subcloned into the pBI221-mcs with Ntlim1 at the N- or C-terminal. The resulting plasmids, GFP-LIM and LIM-GFP driven by the 35S promoter, were introduced into cultured tobacco BY-2 cells (a gift from Seiichiro Hasezawa and Toshiyuki Nagata, University of Tokyo).

4.8. Transformation of tobacco

Chimeric genes of antisense and sense *Ntlim1* cDNA under the control of the 35S promoter were ligated into the binary vector pBI121 (Clontech, Palo Alto, CA, USA). Tobacco was transformed with *Agrobacterium tumefaciens* LBA4404 (Life Technologies, Rockville, MD, USA) that the binary vector introduced by an electroporation using the leaf disk transformation method (Rogers et al., 1986).

4.9. Isolation of tobacco PAL, 4CL and CAD cDNA clones

Tobacco *PAL*, *4CL* and *CAD* cDNAs were amplified by PCR using the specific primers as described previously (Kawaoka et al., 2000).

4.10. Lignin determinations

Lignin determination was performed on the dried insoluble cell wall residues (CWR) of samples soxhlet-extracted with toluene/ethanol, ethanol, and water. Klason lignin was measured by the method used by Effland (1977). Alkaline nitrobenzene oxidation was performed according to Kajita et al. (1996).

Abstract

A number of plant species contain the class II of genes encoding the cytochrome P450, CYP73, the cognate protein of which cinnamic acid 4-hydroxylase, is the second enzyme of the phenylpropanoid pathway. In order to begin to determine possible functionality, tobacco has been transformed with a truncated French bean class II cinnamate hydroxylase (CYP73A15) in the sense and antisense orientations. Signals for C4H protein could be detected in vascular tissue from wild-type plants using heterologous probes. The transformed plants showed a normal phenotype, even though detectable C4H protein was much reduced in tissue prints. Young propagated transformants displayed a range of reduced C4H activities, as well as either reduced or no phloroglucinol-stainable lignin. However, all mature tobacco plants showed the accumulation of lignin, even though its deposition was apparently delayed. This was not due to induction of tyrosine ammonia-lyase activity, which was not detected, but instead it is presumed due to sufficient C4H residual activity. Analysis of the lignin content of the plants showed reductions of up to 30% with a slightly reduced syringyl to guaiacyl ratio as compared to wild type. This reduction level was favourable in comparison with some other targets in the lignification pathway that have been manipulated including that of class I cinnamate 4-hydroxylase. It is proposed that the class II cinnamate 4-hydroxylase might also function in lignification in a number of species including French bean and tobacco, based on these data. © 2001 Elsevier Science Ltd. Keywords: Tobacco; *Nicotiana tabacum*; Solanaceae; Transformation; Cinnamate 4-hydroxylase; Antisense expression; Tyrosine ammonia-lyase; Lignin

1. Introduction

Cinnamate 4-hydroxylase is the second enzyme of the phenylpropanoid pathway and integral to the biosynthesis of the most abundant of the phenolics in vascular plants. It has been identified and classified as a cytochrome P450, CYP73. Molecular cloning of a large number of stress-inducible CYP73 orthologues was achieved initially, but more recently a number of divergent members of the family have appeared in data bases. These divergent members show about 60% sequence similarity to the initially cloned cinnamate 4-hydroxylases enabling them to be classified within the same family. CYP73A15 from French bean falls into this category and was shown to code for a cinnamate 4-hydroxylase following heterologous expression in yeast (Nedelkina et al., 1999). However, it differs from other CYP73s in several domains. It is completely divergent in the N-terminus while three internal domains and the C-terminus are highly divergent. It has thus been classified as a class II C4H. It has not been established hitherto of why there is more than one form of the enzyme. This

could be due to multiple forms having evolved to respond to differing developmental and environmental stimuli or it could reflect subtle differences in specificity as has been found for the other cytochrome P450s involved in phenylpropanoid and lignin metabolism (Humphreys et al., 1999; Osakabe et al. 1999).

There is continued interest in modifying lignin content and monomer composition as a means of improving the efficiency of pulp and paper making for quality, economic and environmental reasons (O'Connell et al., 1999). A second target is forage crops since lignin-polysaccharide complexes are anti-nutritional (Boudet et al., 1996).

A considerable number of individual steps in phenylpropanoid and monolignol biosynthesis have now been subjected to antisense and sense supression using tobacco as a model plant with varying results. For example, down-regulation of the class I form CYP73A3 from *Medicago* in tobacco resulted in reduced Klason lignin contents and a decreased syringyl/guaiacyl ratio (Sewalt et al., 1997). In the same study, the preceding enzymatic step, catalysed by phenylalanine ammonia-lyase was also subjected to down-regulation. This also resulted in significant lignin reduction, as well as an increase in the syringyl/guaiacyl (S/G) ratio. Other steps in the phenylpropanoid pathway that have been modified in tobacco include 4CL, COMT, F5H, CCR and CAD. That is, 4-coumarate ligase levels have been genetically manipulated in tobacco (Kajita et al., 1996) and *Arabidopsis* (Lee et al., 1997), as well as with more striking results in aspen (Hu et al., 1999). COMT has also been modified in tobacco where strong down-regulation (Atanassova et al., 1995) led to a drastic reduction of S-units, and detection of 5-hydroxyguaiacyl units but with no overall reduction in lignin. F5H is now believed to act at the level of coniferyl aldehyde (Humphreys et al., 1999; Osakabe et al., 1999, Li et al., 2000) and is responsible for introduction of the final aromatic hydroxyl group for the incorporation of syringyl groups in lignin (Meyer et al., 1996, 1998). CCR has been altered in tobacco (Piquemal et al., 1998), the down-regulation of which led to a reduction in lignin of up to 50% with an increased S/G ratio. CAD, the final enzyme of monolignol biosynthesis, was one of the first to be targetted (Halpin et al., 1994). Manipulation of CAD has been proposed to lead to a type of brown midrib phenomenon due to a reported increase of the incorporation of aldehyde residues into lignin. However, there was no overall reduction in lignin reported.

In order to further evolve such strategies it is necessary to saturate the manipulation of the pathway. Manipulation of several steps have been reported including class I C4H. Preliminary evidence from model systems suggested that the class II C4H might also be related to vascular differentiation rather than stress responses (Nedelkina et al., 1999). This evidence, based on expression in cell cultures undergoing xylogenesis, suggested it was subjected to the same hormonal control thought to be involved in vascular differentiation. In contrast, it was not highly induced by fungal elicitor action, unlike many other CYP73s, particularly, CYP73A2 and A3 which are class I forms. The possible function of the class II enzyme has been investigated in transgenic tobacco by subjecting it to antisense and sense suppression in the present study. Transgenic tobacco already exists expressing antisense CYP73A3. In the latter case, the effects on lignification were significant, considering it resulted in down-regulation of an enzyme early in the pathway (Sewalt et al., 1997). In the case of the class II C4H, lignin analysis has been performed so that its down-regulation may be evaluated in the context of manipulation of other enzymes of the lignin pathway.

2. Results

2.1. Generation of tobacco plants engineered for antisense and partial sense expression of CYP73A15

HD5 is a 1.1 kb clone of CYP73A15 which lacks about 100 amino acids at the N-terminus of the cognate protein including the membrane insertion sequence. Tobacco leaf discs were transformed using *Agrobacterium* strains containing HD5 in antisense or sense orientation inserted into the binary vector pJR1Ri. Initially 24 antisense and 32 partial sense transformants were produced of which 20 of the former and 29 of the latter survived. They were routinely maintained in sterile culture and propagated from cuttings every 3 months. All plants were tested for the presence of the insert using PCR and found to be positive (data not shown). Selected plants were grown through to maturity although all the data in the present work pertains to T_0 transformants.

2.2. Analysis of transgenic tobacco plants

Stems of tobacco plants were analysed at the young plant stage (about 10 cm in height) generated from cuttings and grown under sterile conditions. Mature tobacco was grown under greenhouse conditions for which the stem tissue in the fourth internode was analysed. The young plants were analysed for cinnamate 4-hydroxylase activity (Fig. 1) and for the presence of the enzyme as detected immunologically in tissue prints (Fig. 2). Stem sections from both types of plants were subjected to phloroglucinol and to Mäule staining (Fig. 3). Fig. 1 shows a range of recoverable enzyme activity in young plants or from over 110% to as low as 10%. Although there were no instances of no detectable activity, some lines had a considerable down-regulation of activity.

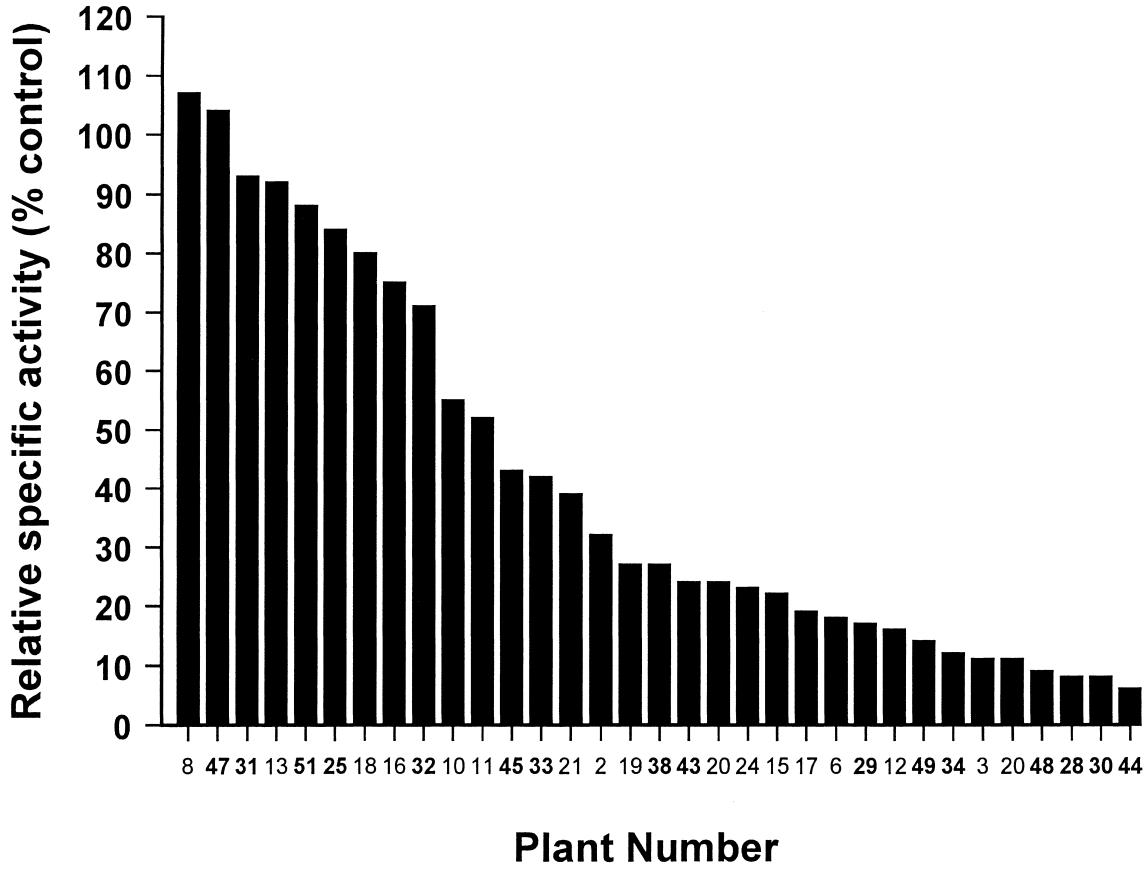

Fig. 1. Range of cinnamate 4-hydroxylase activity in transgenic lines. Activity was determined in stems of regenerated cuttings under sterile conditions. Numbers in plain font are antisense lines; in bold sense lines.

Lines showed activities over the whole range; there was no evidence of clusters or a reduction favoured by antisense or partial sense constructs. Fig. 2 summarises tissue prints of two of these lines, No. 2 (Fig. 2B) and No. 34 (Fig. 2C), which have no immunodetectable C4H subunits even when subjected to extended incubation with substrate compared with wild type (Fig. 2A). However, there is residual activity in these two lines (Fig. 1) so these levels are outside the limits of immunological detection. Some of the young plants showed very low stainable lignin (Fig. 3).

This trend was not found in mature stems. In these samples, enzyme activity was not able to be detected, even though all transgenic lines stained positively for lignin. Compared with young stems there is a delayed accumulation of lignin. In all cases, the red staining in young and mature stems was typical of high syringyl:guaiacyl ratio lignin, which was consistent with the analysis of lignin in these plants.

The possibility that lignin deposition may be due to an induction of tyrosine ammonia-lyase (TAL) activity was examined in young plants and fifth internodes. However, no TAL activity was detected in either the wild type or transgenic plants (data not shown). Hence, even in the down-regulated plants, there must be enough residual C4H activity to allow accumulation of lignin precursors over time and hence synthesis and detection of stainable lignin.

2.3. Analysis of lignin

The total lignin content by the acetyl bromide method (Iiyama and Wallis, 1990) and the syringyl/guaiacyl ratio by thioacidolysis (Lapierre et al., 1986; Rolando et al., 1992) for a number of transgenic lines in comparison with wild type plants is shown for fourth internode sections (Table 1). The wild type lignin is typical for that reported in a number of studies with a lignin content of around 20% and an S/G ratio of 0.85. With the exception of plants Nos. 32 and 45, all transgenic lines showed reduction of lignin content. This was considerable in line No. 30 and compares favourably with other targets for manipulation (Table 2).

3. Discussion

A member of the CYP73 family of plant cytochrome P450s from French bean (CYP73A15) has been identified recently that shows only about 60% sequence similarity

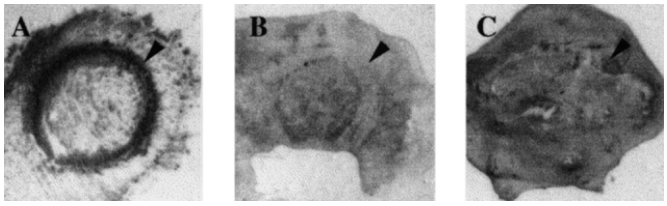

Fig. 2. Tissue prints of control (wild type WT, A) and two transgenic lines (No. 2, B; No. 34, C) using anti-C4H-serum.

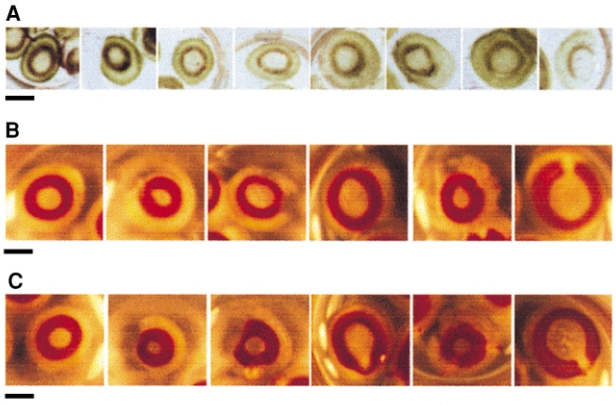

Fig. 3. Lignin staining of control and anti-C4H tobacco. In each case the first image is of WT followed by various lines. A are stems of young seedlings showing reduced lignin staining, B and C are fourth internodes treated with phloroglucinol (B) and the Mäule test (C) reagents respectively. Bar = 400 μm (A), 2500 μm (B and C).

Table 1
Lignin analyses for transgenic tobacco plants: lignin contents and compositions for the fourth internode as determined by acetyl bromide and thioacidolysis methods

Samples, fourth internode of lines	Lignin content (%)	*G* (μmol g^{-1} cell wall residue)	*S* (μmol g^{-1} cell wall residue)	*S*/*G*
C4H WT[a]	20.15±0.12	197.4±25.77	162.1±20.01	0.82

Peroxidase	Isoform only	60–90	0.6–0.9	Blee et al., unpublished data

to class I C4Hs. It is, however, a C4H when expressed in yeast and has been designated a class II C4H (Nedelkina et al., 1999). Although a class I enzyme is also present in tobacco, cross-hybridisation at the stringencies used is unlikely due to lack of sequence similarity. A class II C4H has been identified in tobacco (D. Werck-Reichhart, personal communication). The present work describes successful antisense and sense suppression of C4H activity in tobacco stems in an effort to investigate a possible function of the class II cinnamate 4-hydroxylase in lignification.

Tobacco subjected to expression of the truncated French bean class II C4H regenerated into plants that showed a normal phenotype in common with other targets in lignification (Atanassova et al., 1995; Dwivedi et al., 1994; Halpin et al., 1994; Sewalt et al., 1997) but not all (Piquemal et al., 1998). However, these lines showed reduced activity and immunodetectable C4H, which also somewhat affected lignin content.

Young stems produced by cuttings of T_0 lines and grown under sterile conditions appeared to have a much-reduced lignin content as indicated by staining and in some cases even a lack of phloroglucinol-detectable lignin staining. That is, onset of lignification was apparently developmentally delayed since when plants were transferred to glasshouse conditions, lignin, as exemplified by samples taken from the fourth internode, appeared of normal and near to wild-type composition with respect to colour in the Mäule reaction. However, a detailed analysis of mature stems revealed some lines with reduced lignin content with a slight reduction in S/G ratios, this being similar to the result of manipulating class I C4H with partial sense and antisense CYP73A4 from *Medicago* (Sewalt et al., 1997). Overall the class II C4H proved to be a target for manipulation with similar value to other targets (Table 2).

Inspecting the accumulated data for transformations, it would appear that manipulation of targets in the phenylpropanoid pathway (PAL, C4H and 4CL) in tobacco and *Arabidopsis* reduces the lignin content and, with the exception of PAL, generally shows higher *G* to *S* ratios (Kajita et al., 1996; Sewalt et al, 1997). This may indicate that reduction of flux through the pathway leads to selective depletion of the intermediates that go through to *S* units and *G* units, since there is growing evidence that these pathways may be differentially regulated in different cell types. In contrast, down regulation of enzymes of monolignol biosynthesis (CCR and CAD) leads to limited effects on total lignin but with drastic and opposing changes in S/G ratios (Halpin et al., 1994; Piquemal et al., 1998). However, there is much current debate about the actual flow through the later stages of the pathway and compartmentation. This has centered on CYP84 and its actual substrate, ferulic acid or coniferyl alcohol (Humphreys et al., 1999; Osakabe et al., 1999) and the relative roles of COMT and CCOMT. Since not all these targets have yet been manipulated in tobacco, but rather in *Arabidopsis* and *Populus*, there is not yet one complete inventory of the result of manipulations of all possible targets in one species. The dissection of the polymerization process is complicated by, among other considerations, the number of isoforms of peroxidase and laccase present in any one species. Antisense manipulation of a peroxidase isoform of tobacco did however result in some reduction in lignin (K.R. Blee, J.W. Choi, N.G. Lewis and G.P. Bolwell, unpublished data).

Nevertheless, modest reductions in lignin have commercial and environmental benefits (Baucher et al., 2000). Indeed these studies reveal that the lignin does not need to be reduced to improve significantly the pulping performance as found for CAD and COMT. Furthermore, these results of the present study indicate that in subsequent investigations on manipulation of C4H levels in different species, it will be important to consider that more than one class of C4H may be present. Finally, a combinatorial approach in selection of species for transformation and subsequent manipulation could involve differential targets determining both flux and composition.

4. Experimental

4.1. Materials

[U-^{14}C] tyrosine (16.6 GBq/mmol) and [2-^{14}C] cinnamic acid (2.0 GBq/mmol) were obtained from Amersham. Anti-(cinnamate 4-hydroxylase) serum was obtained as described previously (Smith et al., 1994). The tobacco strain used throughout was *Nicotiana tabacum* cv Samsun.

4.2. Determination of enzyme activity

Phenylalanine ammonia-lyase was determined by the spectrophotometric assay following the production of cinnamic acid at 290 nm. Tyrosine ammonia-lyase activity was determined radiometrically and determination of incorporation into *p*-coumaric acid following separation by TLC. Cinnamate 4-hydroxylase activity was determined radiometrically (Nedelkina et al., 1999).

4.3. Immunological detection of cinnamate 4-hydroxylase

Plant stems were removed and cut transversely with a razor blade and blotted immediately onto nitro-cellulose or nylon membrane pre-wetted with methanol (Cassab and Varner, 1987). The stems were printed for approximately one minute applying some pressure to obtain a good imprint upon the membrane. The prints were then left to air-dry. Immunolocalisation with anti-bean C4H was carried out after first blocking the prints in 25 mM

Tris–HCl (pH 7.5), 0.15 M NaCl (PBS)/4% BSA for 30 min, rinsed in PBS (5×5 min) and then incubated in 1:3000 WGA (Sigma) for 1–2 h. This was followed by further rinses in PBS (5×5 min) and then application of the primary antibody at 1:1000 dilution. The membrane was left shaking overnight followed by rinses in PBS, and then incubated with anti-rabbit IgG-alkaline phosphatase conjugate (2–3 h), followed by washes with PBS/1% Triton. The membrane was colour developed with nitroblue tetrazolium (NBT) and bromo-chloro-indolyl-phosphate (BCIP) in 100 mM Tris–HCl pH 9.5, 100 mM NaCl, 5 mM $MgCl_2$ for 10–30 min.

4.4. Generation of tobacco plants transgenic for *CYP73A15*

The partial CYP73A15 clone HD5 (Nedelkina et al., 1999) was inserted into the binary vector pJR1Ri in antisense and sense orientation. Disarmed *Agrobacterium tumefaciens* LB404 harboring this Bin 19 binary vector was used for all experiments. Within the T-DNA region pBin19 constructs contained kanamycin resistance and, in the reverse orientation with respect to the promoter, the full length HD5 cDNA. CaMV/35S promoter and nopaline synthase terminator were used to regulate expression from the antisense constructs and kanamycin resistance within the T-DNA. The pBin19 also contained a bacterial kanamycin resistance gene for selection. After transformation of *A. tumefaciens* with pBin19 antisense constructs cultures were initiated in 100 ml of Luria-Bertani medium containing 50 μg ml^{-1} kanamycin and allowed to grow 12 h at room temperature with shaking. *A. tumefaciens* cells were collected by centrifugation and resuspended in liquid MS medium. Leaf strips were cut from genetically identical tobacco plants (*Nicotiana tabacum* cv Samsun) generated by vegetative propagation. Leaf strips were incubated in the resuspended *A. tumefaciens* cells for 20 min before being placed on to solid MS medium containing 1 μg ml^{-1} BAP and 0.1 μg ml^{-1} NAA for 2 days. The leaf strips were transferred to solid MS medium containing 1 μg ml^{-1} BAP, 0.1 μg ml^{-1} NAA, 500 μg ml^{-1} carbenicillin, and 100 μg ml^{-1} kanamycin and left for 5 weeks to form shoots. Shoots were excised from the leaf strips and pushed into solid MS medium containing 500 μg ml^{-1} carbenicillin and 100 μg ml^{-1} kanamycin and allowed 4 weeks for rooting. Rooting on selective medium was repeated before transferring rooted plants to solid growth matrix of equal amounts of Minster Economy No3 Compost (Heatherwood Nurseries, Ashington, Wimborne, UK) and Sinclair Growers Potting and Bedding Compost (William Sinclair Horticulture Ltd, Firth Road, Lincoln, UK with 10 ml of Osmocote Plus controlled release fertilizer (Scotts Europe B.V., The Netherlands) in 15 cm pots. The plants were glasshouse grown, watered once daily to field capacity, and received natural lighting.

4.5. Analysis of transgenic plants

DNA was isolated from leaf tissue using the Fast DNA Kit for plants (Bio 101, Carlsbad, CA, USA) and added to Ready to Go PCR beads (Amersham Pharmacia Biotech, Buckinghamshire, UK) with CaMV/35S promoter and nopaline synthase terminator primers 5′-CAATCCCACTATCCTTCGC-3′ and 5′-CATCG-CAAGACCGGCAACAG-3′ respectively. Cycling proceeded after 7 min at 95°C with 40 cycles of 1 min at 95°C, 1 min at 58°C, and 2 min at 72°C.

4.6. Lignin detection

Using a razor blade, 3 freehand sections 2–3 mm in thickness were excised from growing tobacco plant stems approximately 2.5 cm above the soil level, or at agar level for plants still on tissue culture medium. Immediately after being excised, the tissue sections from respective plants were placed in water filled microtiter-plate-wells. Two sets of sections from each plant were collected and then subjected to lignin staining using either the phloroglucinol–HCl or permanganate methodology.

For phloroglucinol–HCl staining, water was first removed and then 0.1% phloroglucinol in 70% ethanol was added. After incubation (15 min), the solution was removed and 18% aqueous HCl was added. The sections remained in this solution until photographs were taken, approximately 50–60 min.

Permanganate staining followed after removal of water from the second set of stem sections to which 0.5% potassium permanganate was added. After incubation for 8 min the sections were rinsed with distilled water and decolorized for 7 min with the addition of 18% aqueous HCl. After removal of the decolorization solution 20% aqueous ammonium hydroxide was added. The sections remained in this solution until photographs were taken, approximately 50–60 min.

4.7. Sample preparation for lignin analysis

The xylem tissues of transgenic tobacco plants were carefully isolated using a scalpel from both the phloem and cortex, respectively, with each ball-milled to a fine powder. The extractives were removed through sequential extraction with water, ethanol and ethanol/toluene (1/1, v/v), using a soxhlet extraction apparatus for each solvent for at least 8 h (Yahiaoui et al., 1998). The resulting extractive-free samples were dried in vacuo and stored in a desiccator until needed.

4.8. Determination of lignin contents by the acetyl bromide method

The method was modified from Iiyama and Wallis, 1990: Samples (4–6 mg) were individually placed in 5 ml

glass vials, containing a solution of 25% (w/w) AcBr in glacial acetic acid (2.5 ml) and perchloric acid (70%, 0.1 ml). Each bottle was sealed with a PTFE-coated silicon cap and placed in an oven at 70°C for 30 min, with each vial swirled gently at 10 min intervals. The resulting solutions were next transferred to volumetric flasks (50 ml), containing 2 M NaOH (10 ml) and glacial acetic acid (12 ml). Each vial was rinsed with a minimum amount of acetic acid, and the solution made up to 50 ml with glacial acetic acid. Each solution was then subjected to UV analysis (280 nm), calibrated against the absorbance of the corresponding blank solution (lacking only sample). Lignin contents were determined by using an absorptivity value for lignin of 20.09 g^{-1} l cm^{-1} for the absorbance at 280 nm. All data were mean values for three determinations.

4.9. Thioacidolysis

S and *G* ratios were determined by thioacidolysis (Lapierre et al., 1986; Rolando et al., 1992): Samples (14–16 mg) were individually dispersed with thioacidolysis reagent (15 ml, 0.2 M BF_3-etherate in a 8.75:1 (v/v) dioxane:ethanethiol) in a 20 ml glass tube fitted with a Teflon-lined screwcap under nitrogen atmosphere. Thioacidolysis was performed by placing each sample in a heating block held at 100°C for 4 h. After cooling the reaction tubes in ice-water, each reaction mixture was individually poured into CH_2Cl_2 (20 ml). Each reaction tube was then rinsed with water (3×5 ml) with the aqueous solutions added to the reaction mixtures. To this was added internal standard (tetracosane C_{24}, ca 0.8 mg) following which, each aqueous phase was adjusted to pH 3–4 with 0.4 M $NaHCO_3$. Each organic phase was next separated by decantation, with the aqueous phases resulting extracted with CH_2Cl_2 (3×30 ml); the combined organic phases were dried (anhydr. Na_2SO_4) and evaporated to dryness.

Each thioacidolysis residue was dissolved in CH_2Cl_2 (2 ml), with an aliquot (20 μl) silylated at room temperature with N,O bis (trimethylsilyl) trifluoroacetamide (BSTFA, 100 μl) in pyridine (40 μl) in a reaction vial (200 μl). The resulting derivatives were applied to a HP 6890 Series GC System equipped with a HP-5 (cross-linked 5% phenyl methyl siloxane, 30 m×0.25 mm× 0.25 μm) column; product identity was established by reference to retention times of authentic silylated standards, and by mass spectrometric analyses using the HP 5973 MS detector (EI mode, 70 eV). Column conditions: 160–250°C at 2°C/min until the final temperature, this being held at 250°C for a further 5 min. For quantitative analyses, authentic standards (G-CHSEt-CHSEt-CH_2SEt and S-CHSEt-CHSEt-CH_2SEt) were used to calculate the response factors for both monomeric *G* and *S* units, respectively. All samples were analyzed in duplicate.

Acknowledgements

Received 17 July 2000; received in revised form 22 January 2001

Abstract

Among the different enzymatic steps leading to lignin biosynthesis, two methylation reactions introduce the methyl groups borne by guaiacyl (G) and syringyl (S) units. Tobacco possesses a complex system of methylation comprising three classes of CCoAOMTs (caffeoyl-CoA-*O*-methyltransferases) and two classes of COMTs (caffeic acid OMTs). Antisense plants transformed with the CCoAOMT sequence alone or fused to COMT I sequence have been produced and compared to ASCOMT I plants in order to study the specific role of each OMT isoform in lignin biosynthesis, plant development and resistance to pathogens. Tobacco plants strongly inhibited in OMT activities have been selected and analyzed. Whereas antisense COMT I plants exhibited no visual phenotype, CCoAOMT repression was shown to strongly affect the development of both single and double transformants: a reduction of plant growth and the alteration of flower development were observed in the most inhibited plants. Lignin analysis performed by Klason and thioacidolysis methods, showed a decrease in the lignin quantity and changes in the lignin structure of ASCCoAOMT and ASCCoAOMT/ASCOMT I transgenics but not in ASCOMT I plants. Inhibition of COMT I in single as well as in double transformed tobacco was demonstrated to decrease S unit synthesis and to provoke the accumulation of 5-hydroxyguaiacyl lignin units. ASCCoAOMT/ASCOMT I tobacco was affected in lignin amount and composition, thus demonstrating additive effects of inhibition of both enzymes. The changes of lignin profiles and the phenotypical and molecular alterations observed in the different transgenic lines were particularly prominent at the later stages of plant development. © 2001 Elsevier Science Ltd. Keywords: *Nicotiana tabacum*; Solanaceae; Tobacco; Antisense RNA expression; Lignin; Phenylpropanoid metabolism; *O*-Methyltransferases

1. Introduction

Phenylpropanoid metabolism provides monolignols, the building units of lignin but also a large array of compounds implicated in plant development and interactions of plants with the environment. Among them, there are pigments such as flavonoids, antibiotics (termed phytoalexins) such as isoflavonoids, coumarins and stilbenes, and signals produced by wounded plants that are involved in the recognition of symbionts (*Rhizobium* sp.) and pathogens (*Agrobacterium* sp.). On the other hand, the deposition of phenylpropanoids in the cell wall of resistant hosts has often been implicated in the mechanisms of defense developed by plants toward fungi, bacteria or viruses. In fact, phenolic polymers, esters and amides have been found in increased quantities in the walls of infected cells and participate in cell wall thickening that represents a general response of plants to pathogen attack.

Intense efforts have been made recently aiming at modifying the content and/or the composition of lignin by genetic engineering as a means of improving the pulping process of trees or of increasing digestibility of animal forages (Baucher et al., 1998; Boudet, 1998; Whetten et al., 1998; Grima-Pettenati and Goffner, 1999). The analysis of transgenic plants affected in distinct biosynthetic steps has produced unexpected findings leading to a profound reappraisal of our understanding of the phenylpropanoid metabolic grid (Atanassova et al., 1995; Van Doorsselaere et al., 1995) and suggested the

PII: S0031-9422(01)00098-X

occurrence of alternative pathways (Kajita et al., 1997; Sewalt et al., 1997a,b; Zhong et al., 1998; Hu et al., 1999). In several cases, lignin from transgenic plants was shown to incorporate unusual components, thus demonstrating a certain degree of plasticity in lignin biosynthesis (Halpin et al., 1994; Baucher et al., 1996; Chapple and Carpita, 1998; Ralph et al., 1998; Whetten et al., 1998). Some transgenic plants, affected in lignin biosynthesis, have been reported to display visual phenotypes. For example, transgenic tobacco plants with a strong decrease in phenylalanine ammonia-lyase (PAL) activity had a reduced lignin content and were severely affected in their development (Elkind et al., 1990). Tobacco, poplar and aspen plants depressed in cinnamyl alcohol dehydrogenase (CAD) had a red coloration of the xylem (Halpin et al., 1994; Higuchi et al., 1994; Baucher et al., 1996; Tsai et al., 1998; Lapierre et al., 1999) and tobacco down-regulated for cinnamoyl-CoA reductase (CCR) exhibited an altered development and a reduction of the plant size (Piquemal et al., 1998). In contrast, in transgenic aspen trees transformed with 4-coumarate: CoA ligase (4CL), the reduction of lignin content had no deleterious effect on plant development, perhaps due to a compensatory increase of cellulose synthesis (Hu et al., 1999).

In order to study the impacts of the modification of phenylpropanoid pathway activity, we attempted to repress OMT genes by expressing antisense RNA. Tobacco was transformed with *O*-methyltransferase sequences that had been isolated from cDNA libraries representing transcripts from tobacco leaves infected with tobacco mosaic virus (TMV) (Jaeck et al., 1992; Martz et al., 1998). Lignin of tobacco down-regulated for caffeic acid/5-hydroxyferulic acid *O*-methyltransferase (COMT I) was shown to have a decreased content in S units, an abnormally high content in 5-hydroxy G units and a higher G unit content (Fig. 1). Taken together, these results indicated that COMT I inhibition specifically affected the second methylation step of the pathway and that another enzyme, namely caffeoyl-CoA OMT (CCoAOMT) catalyzed the first methylation reaction leading to G unit synthesis. Tobacco CCoAOMTs have been cloned and shown to belong to a small gene family composed of three distinct classes (Martz et al., 1998; Maury et al., 1999).

Here we report on the production, selection and analysis of tobacco plants transformed by CCoAOMT cDNA alone or by CCoAOMT and COMT I sequences in the antisense orientation. Plant transformation resulted in a strong OMT gene repression whose outcomes were examined at the level of phenylpropanoid gene expression and of whole plant development. It appeared that, whereas the repression of COMT I induced no visual phenotype, the introduction of the antisense CCoAOMT sequence, alone or together with COMT I, provoked important morphological and developmental alterations. Lignin analysis demonstrated that COMT I repression in double transformants induced a profound change in lignin composition with a decreased content of syringyl units and an accumulation of 5-hydroxy G unit, as observed previously in single transformants (Atanassova et al. 1995). CCoAOMT inhibition resulted in lower lignin quantity in transgenics compared to wild plants and had no effect on lignin S unit content. In double antisense tobacco the effects of both gene inhibition on lignin biosynthesis could be observed. In all transgenic lines we have obtained, the consequences of transformation were enhanced when plants aged, thus illustrating the importance of developmental cues in phenyl propanoid metabolism regulation.

2. Results and discussion

2.1. The tobacco system of *O*-methylation

Table 1 schematically presents the *O*-methylation system of tobacco that comprises two classes of COMTs (COMT I and II) and 3 classes of CCoAOMTs, based on sequence analysis of cloned cDNAs (Pellegrini et al., 1993; Jaeck et al., 1996; Martz et al., 1998). The 3 CCoAOMT classes have been recently shown to display different expression patterns and to encode protein isoforms of 27 and 32 kDa (Maury et al., 1999). Concerning COMTs, class I is highly expressed in lignifying tissues whereas COMT II expression is barely detectable in healthy tissues but is strongly induced in leaves hypersensitively reacting to TMV infection (Pellegrini et al., 1993; Jaeck et al., 1996). COMT I is also stimulated by infection but to a lower extent than COMT II (Legrand et al., 1978). Therefore, COMT I is considered primarily involved in lignin biosynthesis and COMT II may be regarded as a pathogenesis-related enzyme that participates in plant defense response to biotic and abiotic stress. Moreover, the promoter of the COMT II gene has been recently shown to be inducible by various chemicals and environmental cues (Toquin, 1999). In vivo, COMT I catalyzes the second methylation step leading to syringyl lignin unit (Fig. 1) and CCoAOMT activity methylates caffeoyl-CoA into feruloyl-CoA.

Fig. 1 summarizes the most striking effects of COMT I inhibition: S unit content was strongly decreased as evidenced by the disappearance of the red coloration observed after Maüle staining of transgenic stem sections and the changes in GC profiles after lignin thioacidolysis (Fig. 1). Recent studies of substrate specificity of tobacco OMTs using recombinant enzymes expressed in *E. coli*, have shown that, in vitro, CCoAOMTs and more surprisingly COMTs, methylate caffeoyl- and 5-hydroxyferuloyl-CoA (Maury et al., 1999). COMT I was also shown to be active with the cognate free acids, aldehydes, and alcohols as substrates, indicating that, in

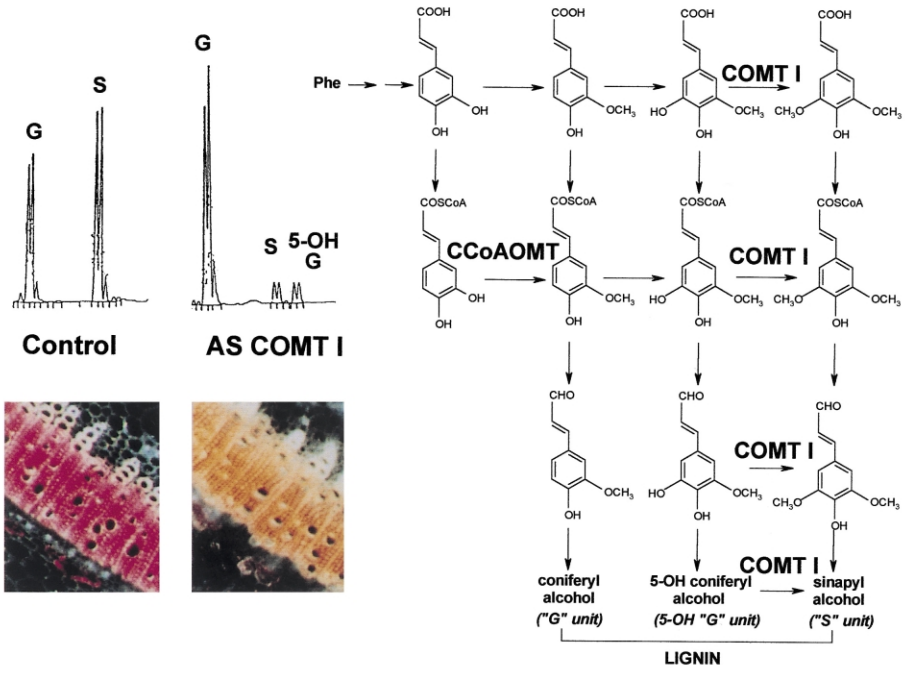

Fig. 1. The role of CCoAOMT and COMT I in lignin synthesis as deduced from the analysis of ASCOMT I tobacco. On the left hand are presented histochemical and chemical analysis data of wild type and transgenic tobacco. The disappearance of the red Maüle coloration of ASCOMT I section compared to control section is due to the decrease of lignin S unit content that is also shown in upper GC profiles obtained after lignin thioacidolysis. The new peaks in transgenic lignin indicate the presence of 5-OH guaiacyl unit. The scheme on the right hand summarizes our current view of the metabolic grid on the basis of recent in vivo and in vitro data.

Table 1
The *O*-methyltransferases of tobacco cDNAs and enzyme isoforms were obtained from TMV-infected tobacco leaves

Class	COMTs		CCoAOMTs		
	I	II	1	2	3
cDNAs	2	1	5	1	1
Isoforms	1	2	1	1	1
Molecular mass (kDa)	39.5	42 + 43	27	27	32

planta, syringyl unit synthesis may operate at the level of free acids, CoA esters, aldehydes or alcohols (Humphreys et al., 1999; Maury et al., 1999; Osakabe et al., 1999). In vitro data showing COMT I activity toward 5-hydroxyconiferyl alcohol were corroborated by the observations of Chen et al, (1999) who demonstrated by in vivo labelling experiments that coniferyl alcohol can be incorporated into the lignin syringyl unit.

2.2. Production of antisense tobacco plants inhibited in OMT gene expression

Agrobacterium tumefaciens was used to transform tobacco plants with the different constructs presented in Fig. 2. The T-DNA of the pBF8 (Atanassova et al., 1995) included between the right (RB) and left (LB) borders, the cloning cassette where the OMT sequence was inserted, the kanamycin resistance gene for transformant selection and the *GUS* gene as a marker of position effects. For the double construct, CCoAOMT and COMT sequences were transcriptionally fused in antisense orientation. Plants transformed with the pFB8 vector without the OMT gene were used as controls. For the different genotypes, populations of in vitro plants were analysed at first and the most strongly inhibited individuals were selected, transferred to the greenhouse and studied further.

2.2.1. Study of the control population

Plants transformed with an empty plasmid (without the OMT gene) constituted the control population. Seventeen 8 week-old in vitro plantlets were tested for CCoAOMT activity and data are presented in Fig. 3A. Large fluctuations in CCoAOMT activity values were recorded, indicating that natural variation of CCoAOMT activity occurs in wild type tobacco as was found previously for COMT I activity (Atanassova et al., 1995). The distribution of enzyme activity values was shown to be normal by Probit analysis, with a mean activity value of 10.7 nkatal/g protein and a standard deviation of 4.4 nkatal/g. The solid line and the two dotted lines in Fig. 3A indicate the mean activity value and standard deviation values of control population, respectively.

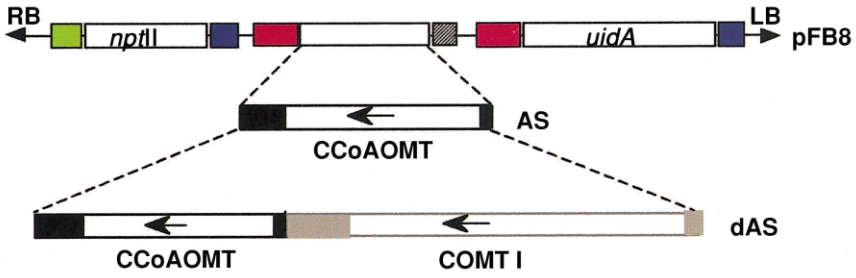

Fig. 2. The pBF8 vector. It contains the *npt* II gene under the control of *nos* promoter (in green) and terminator (in blue) for selection of transformants. The *uid* A (GUS) gene is an internal marker controlled by CaMV 35 S RNA promoter (in red) and the *nos* terminator. Antisense OMT sequences were introduced in the cloning cassette controlled by 35 S RNA promoter and terminator. Untranslated 5 and 3 regions of CCoAOMT and COMT I cDNAs are indicated in black and gray color, respectively. AS: antisense; dAS: double antisense.

2.2.2. Screening of the ASCCoAOMT population

Data of enzyme activity measurements on the population of plants transformed with CCoAOMT are presented in Fig. 3B. Again, some fluctuations were observed, however, 10 individuals had an enzyme activity below the standard deviation of controls indicated by the horizontal dotted line (Fig. 3B). Those particular transformants presented residual activity values of about 20–50% of the mean activity value of controls. In order to check if the decrease of mean CCoAOMT activity in transgenics was due to the repression of CCoAOMT genes, the amounts of enzyme were evaluated in immunoblotting experiments (Fig. 3C). As expected from previous work (Maury et al., 1999) two bands were revealed in control stems (Fig. 3C, control). In the transformants inhibited in CCoAOMT activity the intensity of both bands decreased, indicating that the introduction of one CCoAOMT sequence (member No. 2 of class 1, Martz et al., 1998) in the plant genome repressed the expression of all the members of the tobacco CCoAOMT gene family.

2.2.3. Screening of the ASCCoAOMT/ASCOMT I population

In order to investigate the possibility of obtaining strong and simultaneous inhibitions of both types of OMT in the same tobacco genotype, we transformed plants with the double construct depicted in Fig. 2. Only six double transformants out of 16, rooted and survived on the selection medium. These transformants were tested toward caffeoyl-CoA (Fig. 4B) and caffeic acid (Fig. 4A) as substrates. In vitro substrate specificity studies have shown that caffeic acid is almost exclusively methylated by COMT I but that both CCoAOMT and COMT I accept caffeoyl-CoA as a substrate (Maury et al., 1999). Therefore, enzyme inhibitions were measured at the protein level by western analysis, using antibodies specific for each OMT type (Hermann et al., 1987; Maury et al., 1999). Band intensities were measured by scanning the immunoblots and the relative protein amounts, quantified using imaging software, are presented in Figs. 4C and D. Protein quantities appeared correlated to activity values presented in Fig. 4A and B. Thus, transformation by the double antisense construct proved an efficient means for inhibiting the expression of all the members of CCoAOMT and COMT I gene families of tobacco.

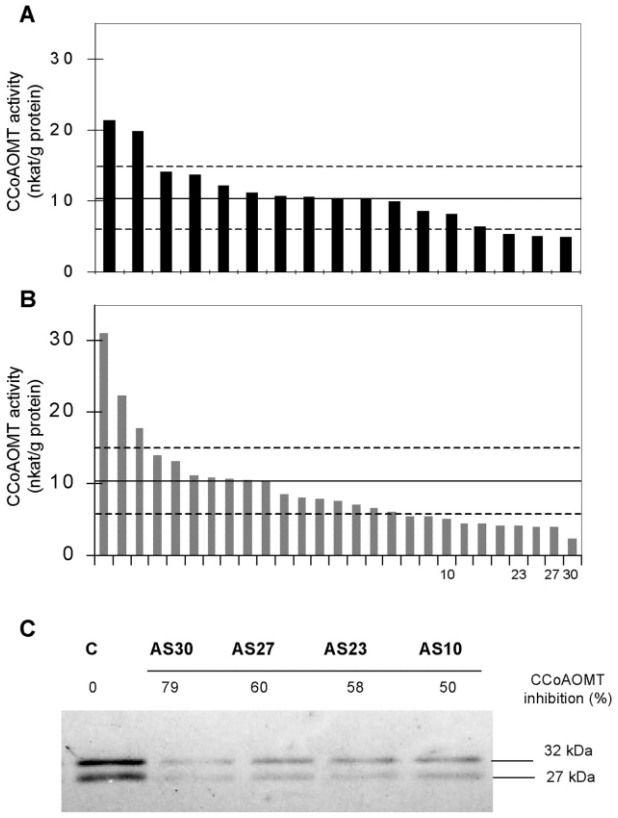

Fig. 3. CCoAOMT expression in control and transgenic population of tobacco plants. The activity value of each individual of control (A) and transgenic (B) population is shown. The solid horizontal line and the dotted lines indicate the mean value and the standard deviation values of control population, respectively. Immunoblotting (C) of controls (c) and of some selected inhibited plants (Nos. 10, 23, 27, 30) revealed 2 bands whose intensity was inversely correlated to CCoAOMT inhibition level.

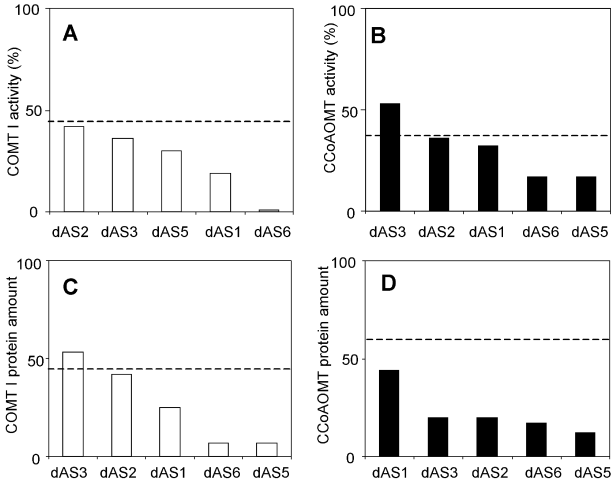

Fig. 4. COMT I and CCoAOMT activity and protein amounts in tobacco plants transformed with the double antisense construct. COMT I; (A) and CCoAOMT; (B) activities were measured with caffeic acid and caffeoyl-CoA as substrate, respectively. Enzyme amounts were calculated from band intensities measured on immunoblots probed with specific antibodies (C) and (D). Values are expressed relative to the mean value of control population taken as 100%. The dotted line in each graph indicates the lower value of standard deviation of control population.

2.3. Impact of OMT gene inhibition on plant development

Transgenic tobacco plants, belonging to the different genotypes and strongly down-regulated in OMT expression, were transferred to the greenhouse for investigating possible impacts of the transformation on plant growth and development. Fig. 5A shows tobacco plants transformed with COMT I, or CCoAOMT or double COMT I/CCoAOMT constructs after three months of growth. Compared to the untransformed controls, B10 (T2) plants which are homozygous for the COMT I transgene, displayed no visible phenotype, in agreement with previous observations carried out on primary transformants (Atanassova et al., 1995). In contrast, a clear reduction of the size of plants transformed with the CCoAOMT sequence alone or the CCoAOMT sequence fused to COMT I sequence, was observed. Growth inhibition was observed for three ASCCoAOMT primary transformants (out of 27) whereas all the six primary double transformants that survived were affected. In fact, the mean stem internode length of these plants was shorter and accounted for their smaller size compared to controls. We noticed that this phenotype was particularly pronounced at the stem extremities i.e. for oldest and youngest tissues of the stem. These effects found in many transformants down-regulated for CCoAOMT are in stark contrast to the results of Zhong et al. (1998) who did not observe any effect of CCoAOMT inhibition in single or double transformants (inhibited for CCoAOMT and COMT I). In those transgenics the important reduction of lignin synthesis did not affect plant growth.

As shown in Fig. 5 leaf and flower development of dAS plants was also affected. Most of the transgenic leaves had a narrower shape (Fig. 5B) and in some cases the stamen of flowers were shorter than those of controls (Fig. 5C). The reduction of stamen size made natural fertilization impossible. However, manual pollination yielded about as many seeds as control flowers, thus indicating that the repression of OMT genes had no impact on fertility.

2.4. Molecular analysis of tobacco transformants

2.4.1. Genetic analysis

To select the primary transformants likely to generate stable transformed lines, we performed genomic analysis of the most inhibited plants by Southern blotting and by analysing the segregation of the kanamycin resistance trait in the progeny obtained by selfing. After plant DNA extraction and digestion with XbaI restriction enzyme, the cut DNA preparations were analyzed by Southern blotting (not shown). Blots were hybridized to an *nptII* probe and the number of radioactive bands measured the number of T-DNA copies integrated into the plant genome. Results obtained for a few ASCCoAOMT primary transformants are presented in Table 2 along with the proportion of plants resistant to kanamycin that were found in the progeny obtained by selfing of those plants. In the three progenies, the ratio was close to 1:3 i.e. the theoretical value expected for the Mendelian segregation of one insertion locus (Table 2). In one case the analysis revealed the presence of two insertions (plant No. 23, Table 2) and for one plant (plant No. 19), resistance trait segregation in the progeny was aberrant and did not allow us to draw any sound conclusion. Genotypes 23 and 30 that were highly inhibited (see Fig. 3) were analysed in the next generation. Analysis of T2 tobacco plants confirmed the presence of one TDNA copy in No. 30 genotype and demonstrated that the two copies detected in transformant No. 23 segregated independently (data not shown). Inhibited monocopy plants have been selected and will be used to produce homozygous seeds.

2.4.2. Enzyme inhibition levels fluctuate during development

Inhibition levels were measured in the 5th internode of stems at the stage of 6 weeks and 12 weeks of development (Fig. 6). Surprisingly enough, at the 6 week developmental stage, CCoAOMT inhibition was lost in transgenic plants which have been selected on the view of their low enzyme activity at the in vitro plantlet stage. When the same genotypes were tested 6 weeks later at the 12 week stage, a high degree of inhibition was recovered (Fig. 6). This was true at the activity and protein levels as evidenced by the decreased intensity of protein bands detected on western blots (not shown). Our data

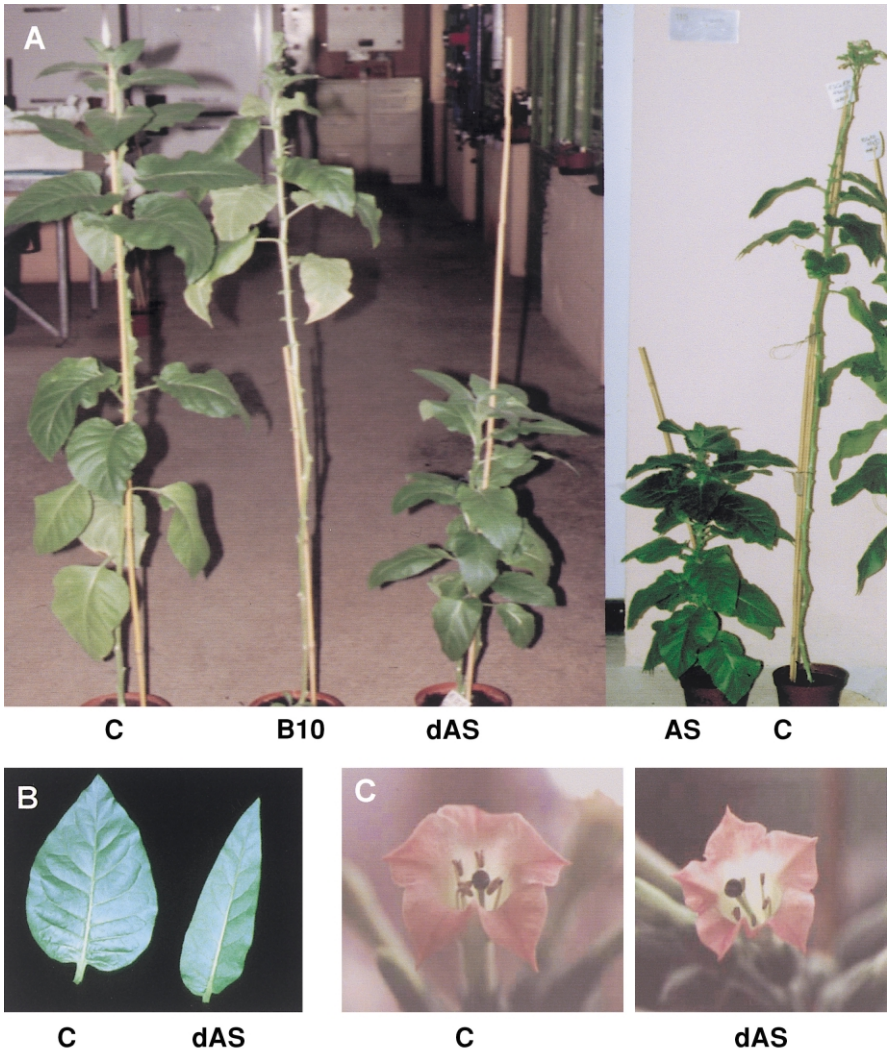

Fig. 5. Phenotypes of tobacco plants inhibited in CCoAOMT or/and in COMT I activity. A: size of transformed and untransformed plants. AS: ASCCoAOMT plants; B10: ASCOMT I plants; dAS: ASCCoAOMT/ASCOMT I plants. B: Effect on leaf shape. C: Effects on flower development.

Table 2
Genetic analysis of ASCCoAOMT plants. The number of inserted T-DNA copies of primary transformants was determined by Southern blotting and the progeny obtained by selfing was analyzed for the segregation of kanamycin resistance

	Plants

[c] Inferred from Southern blot analysis.

illustrate the fact that the molecular analysis of transformants must be performed at different stages of development before sound conclusions can be drawn regarding the relationship between gene expression and any observed phenotype.

2.4.3. CCoAOMT inhibition affects the expression of other phenylpropanoid genes

Previous studies have shown that COMT I repression in antisense tobacco affects CCoAOMT expression (Martz et al., 1998). We investigated whether CCoAOMT inhibition in ASCCoAOMT plants had an effect on the level of expression of COMT I and CAD that are situated downstream in the pathway. To that aim, antisense primary transformants were in vitro propagated and analysed by western blotting. Fig. 7 presents the results obtained for three genotypes that displayed various degrees of CCoAOMT inhibition as illustrated by the

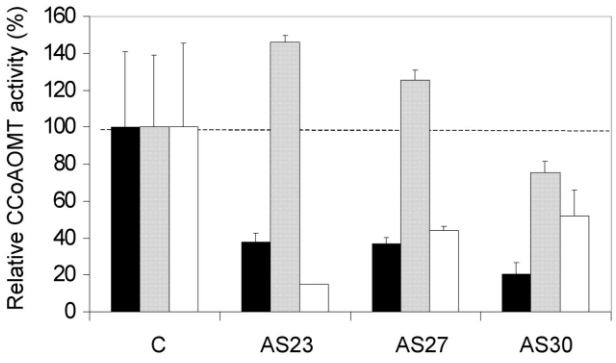

Fig. 6. Variation of inhibition levels during development. CCoAOMT activity is expressed relative to control mean value taken as 100% (c). Enzyme activity was measured in the whole stems of (■) plants grown for 6 weeks in vitro, or in the 5th internode of stems of plants transferred (■) for 6 weeks or for (□) 12 weeks in the greenhouse. Error bars calculated from duplicate values are shown.

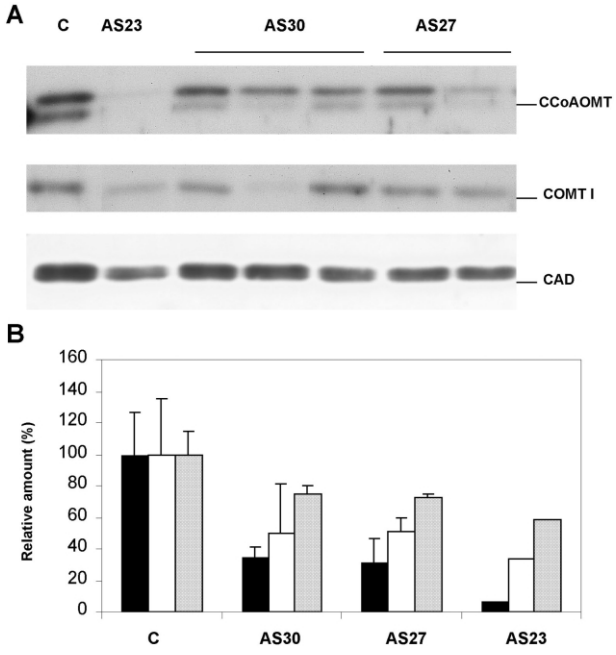

Fig. 7. Effects of CCoAOMT repression on the expression level of other genes of the pathway. Expression levels were estimated after immunoblotting with specific antibodies (A) and relative enzyme quantities were calculated from the band intensity values (B), taking control values (c) as 100%. Controls were assayed in triplicates and one, two or three plants of AS23, AS27 and AS30 genotype respectively, were propagated in vitro and analysed independently. (■) CCoAOMT; (□) COMT I; (■) CAD.

variable intensity of the two CCoAOMT bands detected on the blots probed with specific antibodies (Fig. 7A). In the same samples COMT I and CAD proteins were detected by antibodies raised against COMT I or CAD and their quantities were shown to decrease in plants with low CCoAOMT amounts. This is clearly shown in Fig. 7B, where band intensities were normalized relative to controls (lane c): AS23 genotype that was the most inhibited for CCoAOMT was also the most affected in COMT I and CAD expression. These data indicate that variations of the metabolic flux through the pathway due to the inhibition CCoAOMT affect the expression of COMT I and CAD genes that are downstream in monolignol synthesis. The underlying regulation mechanism is not known and may involve the control of intermediate pool size. Anyhow, the simultaneous repression of several biosynthetic genes would undoubtedly reinforce the effects of the transformation but would also complicate the interpretation of the data. A careful analysis of intermediate pool sizes and of the carbon flow in transgenic plants should bring about new insights into the regulation of phenylpropanoid metabolism.

2.5. Impact on lignin content and composition

Repression of lignin biosynthetic genes has been shown to affect the quantity and/or the quality of the lignin of transgenic plants (for review see Baucher et al., 1998; Boudet, 1998; Whetten et al., 1998). We compared lignin content and composition in untransformed and transformed tobacco genotypes at the age of 12 weeks. As shown in Table 3, CCoAOMT inhibition in single (genotypes 30 and 27) or double transformants (dAS5 plants) resulted in lower Klason lignin amounts. However, the effects on lignin structure were quite different for the two types of transgenics : whereas S unit content and β–*O*–4 bond frequency remained unchanged in ASCCoAOMT plants, the simultaneous inhibition of the two OMTs changed both lignin amount and composition as evidenced by the decrease of S unit and β–*O*–4 bond contents of transgenic lignin (Table 3). The decrease of S unit content in dAS tobacco was accompanied by the accumulation of 5-hydroxyguaiacyl unit (not shown) that is a COMT I inhibition signature (Atanassova et al., 1995; Van Doorsselaere et al., 1995). It is most probably the decrease of lignin synthesis that is responsible for the reduction of growth we observed for these tobacco genotypes (Fig. 5). It is noteworthy that Zhong et al. (1998) obtained tobacco plants displaying 40–60% reduction in lignin content and which grew however normally. In our studies we noticed a reduction of growth rate under greenhouse and in vitro conditions, although lignin content decrease was in about the same range (48% of control value, Table 3). These discrepancies may originate from different growth conditions, the use of different gene vectors or may have another unknown origin. A few cases are known where the diminution of lignin content of transgenic plants has been demonstrated to have negative impacts on the growth rate of transgenic plants (Elkind et al., 1990; Piquemal et al., 1998). Unexpectedly, repression of lignin synthesis in aspen tree transformed with antisense 4-coumarate CoA ligase gene, promoted cellulose accumulation and growth (Hu et al., 1999). This contrasts with what was observed in transgenic tobacco where 4-CoA

Table 3
Lignin analyses for wild type and selected transformants[a]

	Plants	Plant code		
	Control	30	27	dAS5
% Klason lignin	17.4±0.6	16.0±0.7	14.8±0.2	8.4±0.1
% Units only in β–*O*–4 bonds	51.3± 1.4	52.0 ± 3.0	47± 2.0	37.5±1.5
% of S unit in β–*O*–4 bonds	51.3± 1.4	49.6± 3.9	51.3± 1.5	44 ± 1.1

[a] Lignin quantity was evaluated by using the method of Klason and lignin composition was analysed after thioacidolysis. Plants, Nos. 30 and 27 are single transformants (ASCCoAOMT) and dAS5 is a double transformant (ASCCoAOMT/ASCOMT I). Values were calculated from 2 or 3 replicates harvested at the age of 12 weeks.

ligase inhibition provoked the appearance of brownish xylem tissues (Kajita et al., 1997). All these data indicate that phenylpropanoid metabolism repression may have diverse and unpredictable impacts on plant physiology, may be due to the multiple functions of the compounds synthesized through this pathway.

2.5.1. Concluding remarks

We have shown here that the inhibition of CCoAOMT and COMT I gene expression alone or together in transgenic tobacco differently affects lignin synthesis. CCoAOMT inhibition decreases total lignin content whereas COMT I inhibition changes lignin S unit content. In tobacco transformed with a double antisense construct, cumulative effects were observed, both the quantity and the quality of lignin being changed. Changes in lignin composition induced by COMT I inhibition had no impact on plant development in contrast to the multiple effects of CCoAOMT inhibition (Fig. 5).

Lignin has a negative impact on the exploitation of the biomass. Therefore, many attempts have been made recently to modify lignin content and structure by genetic engineering in order to facilitate delignification of paper pulp or to increase digestibility of cattle fodder. CAD inhibition has indeed been shown to change lignin composition (Halpin et al., 1994; Baucher et al., 1996) and in turn to increase lignin extractability (Baucher et al., 1996; Lapierre et al., 1999) and fiber degradability (Bernard-Vailhé et al., 1996a; Sewalt et al., 1997b; Baucher et al., 1999). In contrast, the decrease in S unit content in lignin of COMT I-repressed plants lowered the efficiency of kraft pulping (Lapierre et al., 1999; M. Petit-Conil, personal communication) and increased cell wall degradability (Bernard-Vailhé et al., 1996b).

Phenylpropanoid metabolism is strongly activated upon pathogen attack and participates to the establishment of resistance (Fritig et al., 1972; Legrand et al., 1978; Legrand, 1983; Jaeck et al., 1992). An increased susceptibility toward the fungal pathogen *Cercospora nicotianae* was reported for tobacco repressed in PAL expression, may be due to the inhibition of the developmental accumulation of chlorogenic acid (Maher et al., 1994). However, PAL repressed tobacco was not affected in the hypersensitive response to TMV primary infection (i.e. in lesion development) but did not display systemic acquired resistance toward a secondary TMV infection (Pallas et al., 1996). Transgenic tobacco plants affected in OMT expression displayed variable level of resistance toward virus infection: repression of COMT I or CCoAOMT alone had no detectable impact on antiviral resistance (measured by TMV lesion growth) but double transgenic tobacco developed larger necrotic lesions upon TMV infection (Maury et al., 1999; Hoffmann et al., 2000; Maury, 2000). Analysis of soluble and insoluble phenolic content of healthy or infected tobacco genotypes repressed in different steps of phenylpropanoid synthesis should bring new information about the role of particular phenolics in plant resistance mechanism to a given pathogen.

3. Experimental

3.1. Plant material

Transgenic tobacco plants (*Nicotiana tabacum* cv Samsun NN) were grown in vitro under a light/dark regime of 12 h (24°C)/12 h (20°C) for 6 weeks after germination. The nutritive MS medium contained kanamycin (150 mg/l) as selective agent. The plants were transferred to the greenhouse and cultivated on soil under a light–dark period of 16 h/8 h at 22 ± 2°C.

3.1.1. Vector construction

The binary vector pFB8 was derived from pBI 101 as described by Atanassova et al. (1995) and is shown in Fig. 2. The double construct contained CCoAOMT and COMT I sequences (including 5 and 3 untranslated parts) fused in antisense orientation. The different constructs were introduced into *Agrobacterium tumefaciens* by electroporation and 10 day old tobacco seedlings were transformed by infiltration of agrobacteria (Rossi et al., 1993).

3.1.2. Enzyme assays

Tobacco tissues were ground with a pestle and a mortar in liquid nitrogen and then in 0.1 M sodium phosphate buffer, pH 7.5, 10 mM DTT, containing quartz and polyclar AT (Serva). After centrifugation at

13000 rpm for 15 min at 4°C, the supernatant was filtered on glass wool and tested for OMT activity. COMT I activity was assayed in the presence of 3 mM caffeic acid and 50 μM ^{3}H-SAM (10^5 cpm in 1 ml). After 1 h incubation, 100 μl of 9N H_2SO_4 was added. The reaction product, ferulic acid, was extracted with 5 ml NA scintillation solution (Ready Organic, Beckman) and its radioactivity measured in a Beckman LS 6500 apparatus. For CCoAOMT measurement, 15 μl of enzyme extract was incubated for 15 min at 30°C in the presence of 40 μM caffeoyl-CoA and 40 μM ^{3}H-SAM (40000 cpm in 10 μl). At the end of incubation, ferulic acid was added as a radiochemical carrier and the reaction product, feruloyl-CoA was hydrolyzed with 3 μl of 5 N NaOH for 15 min at 40°C. After the addition of 3 μl of 6 N HCl and 0.2 ml H_2O, ferulic acid was extracted with 0.5 ml EtOAc and counted with MP scintillation solution (Ready Gel, Beckman). Protein was measured by the method of Bradford (1976).

3.1.3. Synthesis of CoA esters

Caffeoyl-CoA and feruloyl-CoA were prepared according to the method of Stöckigt and Zenk (1974) and identified and quantified as described by Lüderitz et al. (1982).

3.1.4. SDS–PAGE and immunoblotting

The basic procedures for electrophoresis under denaturing conditions and for immunoblotting have been described previously (Legrand et al., 1987). Alkaline phosphatase activity was revealed using a chemiluminescent substrate (BioRad CDP-Star). After scanning of the blots with a Argus II AGFA scanner, proteins were quantified using imaging software (MacBAS version 2.2).

3.1.5. Lignin analysis

Lignin quantity was estimated by the Klason method and lignin composition was analysed after thioacidolysis as previously described (Lapierre, 1986).

Acknowledgements

We thank Dr. B. Fritig for continuous support. We are grateful to Dr. C. Halpin (Dundee, UK) for the gift of CAD antibodies. We thank R. Wagner, S. Staerck and M. Kerneis for taking good care of our tobacco plants. This work was supported by the Commission of European Communities (ECLAIR-OPLIGE AGRE 0021 and FAIR-TIMBER CT 95-0424)

Abstract

Lignin, a complex phenylpropanoid compound, is polymerized from the monolignols *p*-coumaryl alcohol, coniferyl alcohol and sinapyl alcohol. These three monolignols differ only by the 3- and 5-methoxyl groups. Therefore, enzymatic reactions controlling the methylations of the 3- and 5-hydroxyls of monolignol precursors are critical to determine the lignin composition. Recent biochemical and transgenic studies have indicated that the methylation pathways in monolignol biosynthesis are much more complicated than we have previously envisioned. It has been demonstrated that caffeoyl CoA *O*-methyltransferase plays an essential role in the synthesis of guaiacyl lignin units as well as in the supply of substrates for the synthesis of syringyl lignin units. Caffeic acid *O*-methyltransferase has been found to essentially control the biosynthesis of syringyl lignin units. These new findings have greatly enriched our knowledge on the methylation pathways in monolignol biosynthesis. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Caffeoyl CoA *O*-methyltransferase; Caffeic acid *O*-methyltranferase; Guaiacyl lignin units; Syringyl lignin units; Lignin biosynthesis

1. Introduction

The ability for plants to make lignin, a complex phenylpropanoid polymer, was thought to evolve when land plants first emerged on the land from aquatic environments (Raven et al., 1999). Lignin provides the mechanical strength to the walls of conducting tracheary elements (TEs) for enduring the negative pressure generated from transpiration. It also renders the walls of maturing TEs undigestible by hydrolytic enzymes released during autolysis of xylogenesis. In addition, deposition of lignin in the walls of sclerenchyma cells, which adds physical toughness and chemical durability to the wall, may deter feeding by herbivores. Lignin is often deposited at the sites of wounding or pathogen invasion, which may provide a physical barrier for protection of adjacent tissues from further damage.

Lignin is polymerized from three monolignols, *p*-coumaryl alcohol, coniferyl alcohol, and sinapyl alcohol, of which the proportions differ among plants. These monolignols are synthesized through the common phenylpropanoid biosynthetic pathway. Since the first elucidation of the pathway through tracer experiments, many enzymes and the corresponding genes involved in the phenylpropanoid pathway have been identified and characterized in detail. These biochemical and molecular analyses confirmed the existence of enzymes carrying out each step in the pathway. However, in the last decade, we have seen some significant modifications of the lignin biosynthetic pathway. It has been found that caffeoyl coenzyme A (CoA) *O*-methyltransferase (CCo AOMT) is essential for lignin biosynthesis (Ye et al., 1994), and caffeic acid *O*-methyltransferase (COMT) controls the synthesis of syringyl lignin units (Atanassova et al., 1995; Van Doorsselaere et al., 1995; Li et al., 2000). It has also been shown that ferulic acid 5-hydroxylase (F5H), which was traditionally thought to use ferulic acid as its substrate, preferentially converts coniferaldehyde and coniferyl alcohol into 5-hydroxyconiferaldehyde and 5-hydroxyconiferyl alcohol, respectively (Humphreys et al., 1999; Osakabe et al., 1999; Li et al., 2000). We have seen breakthroughs in understanding of the process controlling monolignol polymerization. It has been discovered that a group of proteins named dirigents may control the coupling of monolignols in a stereoselective manner (Davin et al., 1997; Davin and Lewis, 2000). All these new findings have greatly enriched our knowledge on the biosynthesis of lignin. It is clear that our quest on lignin biosynthesis

is far from the end. We are still not clear how monolignols are exported from the cytosol to the wall, and once they are in the wall, how they are polymerized into the ordered structure. We know little about the regulatory mechanisms controlling the coordinate expression of genes involved in the lignin biosynthetic pathway. Further study of these issues will not only satisfy our curiosity about the synthesis of lignin, the second most abundant natural product on earth, but also help to develop ideal strategies for genetic engineering of lignin biosynthesis in order to reduce pollution from pulping and increase digestibility of forage crops. In this short review, we will focus on the role of CCoAOMT in the biosynthesis of lignin. One can find some recent comprehensive reviews on lignin by Boudet (1998), Whetten et al. (1998), Lewis (1999), and Sederoff et al. (1999).

2. Early view on the methylation pathway in lignin biosynthesis

Recent biochemical and molecular studies have strongly suggested that methylation of the 3-hydroxyl group of hydroxycinnamates occurs on the CoA ester form, instead of on the free acid form. Although this is an important finding in lignin biosynthesis, this new view can trace back to the early proposed methylation pathway by Neish (1968). Neish put forward a lignin biosynthetic pathway in which the carboxyl group was first activated on cinnamic acid or on *p*-coumaric acid, and the subsequent reactions including methylation occurred on the ester forms. This pathway was proposed based on the following lines of evidence. First, ester forms of *p*-coumaric acid, caffeic acid, and ferulic acid were detected in plants (El-Basyouni et al., 1964; El-Basyouni and Neish, 1966; Brown, 1966, 1969). Second, the free acids would tend to be insoluble in the acidic environment, so the ester forms would be preferred intermediates (Brown, 1969). However, this proposed methylation pathway using the ester forms instead of the acid forms was largely neglected since then. In the subsequent literature, it was proposed that methylation of the 3- and 5-hydroxyl groups occurred at the acid forms of hydroxycinnamates (summarised in Lewis and Yamamoto, 1990). This probably resulted from the identification of the *O*-methyltransferase (OMT) capable of using caffeic acid and 5-hydroxyferulic acid as substrates. The view that COMT was the sole OMT involved in lignin biosynthesis was not challenged until the identification of CCoAOMT using caffeoyl CoA as its substrate.

3. First identification of CCoAOMT in parsley and carrot

CCoAOMT was first identified in parsley and carrot cultured cells challenged with fungal elicitors (Matern et al., 1988; Kühnl et al., 1989; Pakusch et al., 1989). CCoAOMT from parsley and carrot specifically methylates caffeoyl CoA (Fig. 1) but not caffeic acid. Identification of CCoAOMT led Kühnl et al. (1989) to question the conventional view of methylation reactions on the acid forms and they proposed roles of CCoAOMT in the biosynthesis of phenylpropanoid-derived compounds such as lignin. However, this proposal was not immediately recognized due to lack of substantial evidence for the involvement of CCoAOMT in lignin biosynthesis. First, CCoAOMT in the cultured cells induced by fungal elicitors was thought to play a role in defense because no lignin was detected in treated cells (Pakusch et al., 1989). Second, no correlative evidence was available to suggest that CCoAOMT expression was associated with lignification. The importance of CCoAOMT in lignin biosynthesis was not realized until the finding that CCoAOMT was specifically expressed in all lignified cells in Zinnia.

4. Ubiquitous distribution of CCoAOMT in plants

After identification of the elicitor-inducible CCo AOMT in parsley and carrot, Schmitt et al. (1991) purified CCoAOMT, sequenced its peptides, and finally cloned CCoAOMT cDNA from parsley using probes based on the peptide sequence. Based on their homology to the parsley CCoAOMT, CCoAOMT cDNAs and genomic DNAs have been isolated from a number of other plants such as zinnia, quaking aspen, poplar, tobacco, alfalfa, pine, *Arabidopsis*, maize, eucalyptus, rice, *Stellaria longipes*, and *Vitis vinifera*. CCoAOMTs from different plants share high sequence identity at the amino acid level, but they show little sequence similarity to COMT except for the consensus regions involved in *S*-adenosyl-L-methionine and metal binding (Vidgren et al., 1994; Ibrahim et al., 1998). It is interesting to note that CCoAOMTs share significant amino acid similarity to catechol OMT from rat and human (Salminen et al., 1990; Bertocci et al., 1991).

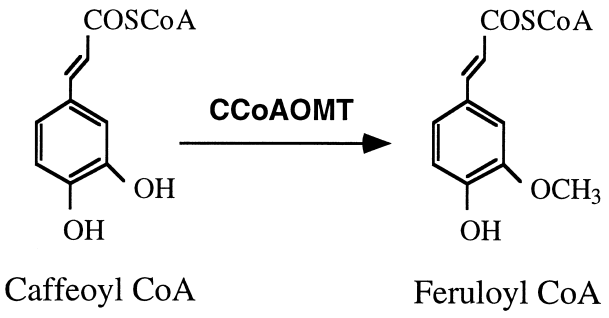

Fig. 1. CCoAOMT catalyzes methylation of caffeoyl CoA to feruloyl CoA. CCoAOMT was first identified in cultured parsley and carrot cells challenged with fungal elicitors.

5. Association of CCoAOMT expression with lignification in Zinnia

During the study of genes expressed in the in vitro-cultured TEs of Zinnia, Ye et al. (1994) have found a close association of CCoAOMT activity with lignification. The Zinnia system used in this study is ideal for biochemical and molecular dissection of enzymes and genes involved in the biosynthesis of polysaccharides and lignin. In this system, single mesophyll cells are mechanically isolated from young leaves, and then cultured in a liquid medium containing an appropriate ratio of auxin and cytokinin (Fukuda, 1996). In general, the cultured cells start to deposit secondary wall materials after 48 h of culture, and lignin deposition is evident between 60 and 72 h. Therefore, the time course of xylogenesis and gene expression can be monitored and used for functional analysis of the genes induced during xylogenesis.

In cultured Zinnia cells, the CCoAOMT gene expression was found to be markedly induced after 48 h induction, and CCoAOMT activity also dramatically increased after 60 h of induction (Fig. 2; Ye et al., 1994). The time course of CCoAOMT induction was coincident with the timing of lignification, and it exhibited an identical pattern to that of cinnamate 4-hydroxylase, a known gene involved in the phenylpropanoid pathway. This clearly indicated that CCoAOMT might play an important role in lignin biosynthesis.

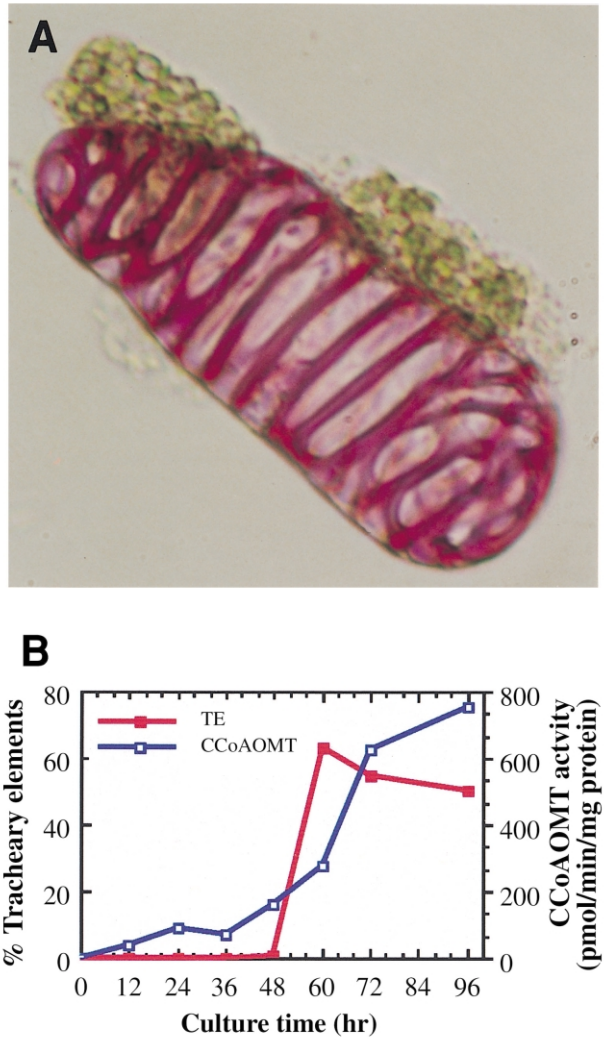

Fig. 2. Induction of CCoAOMT activity during in vitro TE formation in Zinnia. A. TE transdifferentiated from an isolated zinnia mesophyll cell. Lignified secondary wall is stained red with phloroglucinol-HCl. B. Time course of TE formation and CCoAOMT activity in isolated zinnia mesophyll cells. Mesophyll cells were cultured in the TE induction medium and monitored for TE formation and CCoAOMT activity. It is apparent that the dramatic increase of CCoAOMT activity correlates with timing of TE formation.

Examination of the gene expression pattern of CCo AOMT in the Zinnia plant further supported its possible involvement in lignification. It was found that the CCoAOMT gene was specifically expressed in all lignifying tissues in Zinnia including phloem fibers and xylem (Ye et al., 1994; Ye and Varner, 1995). Immunolocalization in Zinnia showed that CCoAOMT was present in TEs, xylary fibers and phloem fibers, and also in xylem ray parenchyma cells (Fig. 3; Ye, 1997). Based on these findings, it was proposed that the CCoAOMT-mediated methylation pathway was essential for lignin biosynthesis (Ye et al., 1994; Ye and Varner, 1995; Ye, 1997), in addition to its proposed role in defense (Matern et al., 1988; Kühnl et al., 1989; Pakusch et al., 1989).

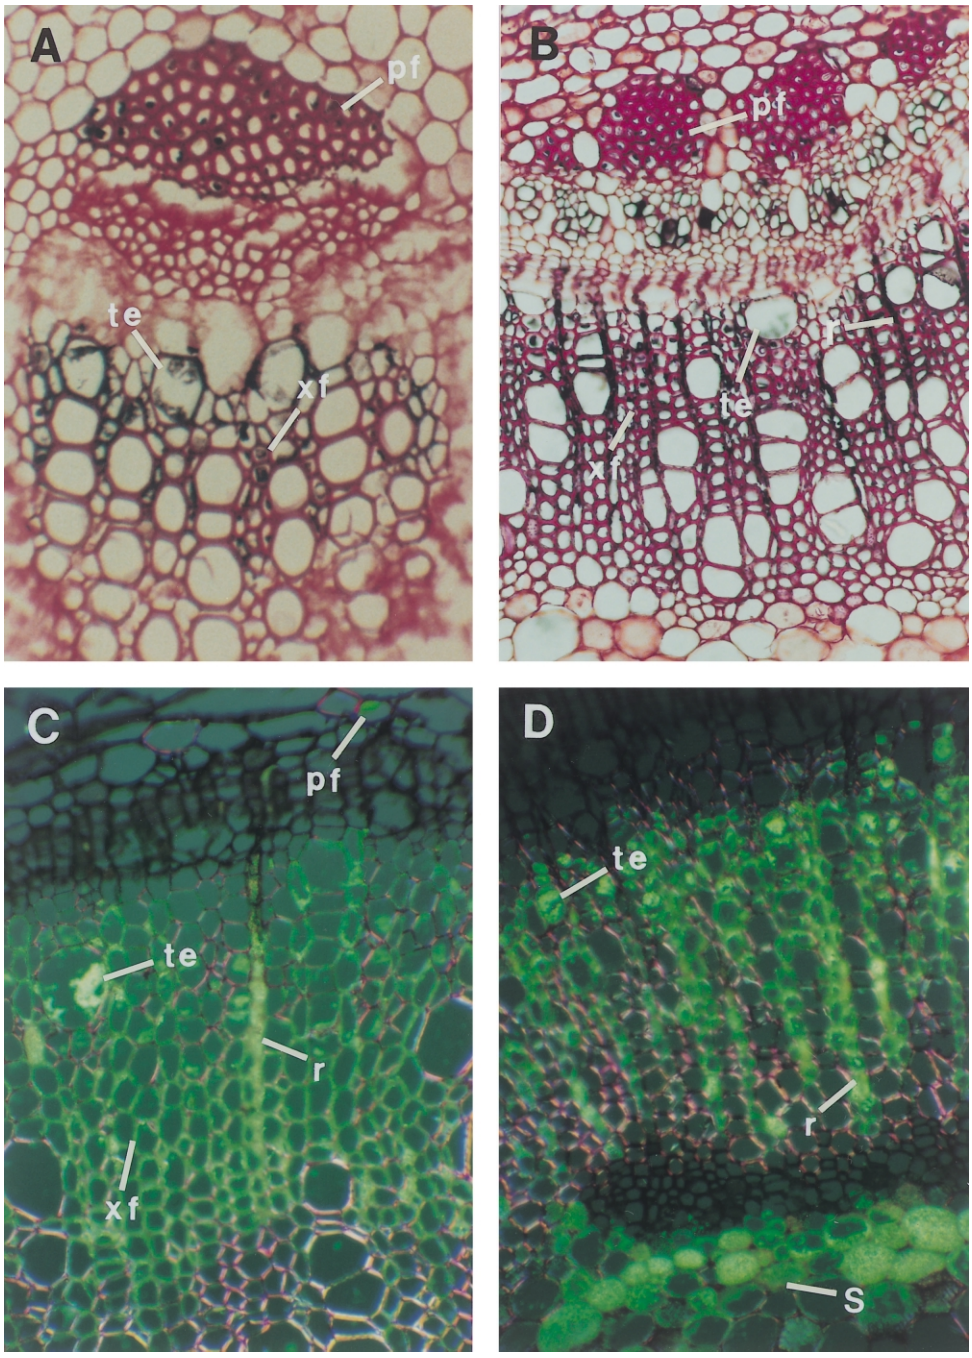

Fig. 3. Association of CCoAOMT with cells undergoing lignification. Stem sections of Zinnia (A), poplar (B), tobacco (C), and forsythia (D) were probed with polyclonal antibodies raised against Zinnia recombinant CCoAOMT and detected with gold-conjugated secondary antibody. The signal was amplified with silver enhancement, and seen either as black under bright field (A and B) or as yellow-green under UV epifluorescence (C and D). It is evident that CCoAOMT signal is present in TEs, xylary fibers, phloem fibers, sclerenchyma cells, and xylem ray parenchyma cells. Abbreviations: pf, phloem fiber; r, ray parenchyma cells; s, sclerenchyma cells; te, tracheary elements; xf, xylary fiber.

6. Ubiquitous association of CCoAOMT expression with lignification in plants

After the finding that CCoAOMT expression was closely associated with lignification in zinnia, the next important issue was to determine whether this expression pattern was common in plants. Localization of CCoAOMT at the protein or mRNA level confirmed that CCoAOMT was expressed in lignifying tissues in both herbaceous plants including parsley, tobacco, tomato, soybean and alfalfa, and woody plants including forsythia and poplar (Ye, 1997; Inoue et al., 1998; Kersey et al., 1999; Chen et al., 2000; Zhong et al., 2001). Similar to that in Zinnia, CCoAOMT was found to be present in TEs, xylary fibers, phloem fibers and xylem ray parenchyma cells in these plants (Fig. 3). Studies of CCoAOMT activity and its gene expression in tobacco, quaking aspen and pine also showed a close correlation with lignification in xylem (Martz et al., 1998; Meng and Campbell, 1998; Li et al., 1999; Maury et al., 1999). Taken together, these results further indicated that association of CCoAOMT with lignification was ubiquitous in both herbaceous and woody plants.

7. Down-regulation of CCoAOMT in transgenic plants reduces lignin content

Along with the demonstration of the close association of CCoAOMT with lignification, results from transgenic studies of COMT also indicated that other OMTs in addition to COMT might be involved in lignin biosynthesis (Dwivedi et al., 1994; Atanassova et al., 1995; van Doorsselaere et al., 1995; Tsai et al., 1998). COMT had long been thought to be the sole OMT involved in lignification. However, down-regulation of COMT expression in both transgenic tobacco and poplar proved that this was not the case. Transgenic plants with down-regulation of COMT showed an almost complete loss of syringyl lignin units but with little effect on guaiacyl lignin units (Atanassova et al., 1995; van Doorsselaere et al., 1995; Tsai et al., 1998; Jouanin et al., 2000; Fig. 4). In addition, no significant reduction in total lignin content was found in these transgenic plants. The only exception was the transgenic poplar plant with no detectable COMT activity, which showed 17% reduction in lignin content (Jouanin et al., 2000). Although these results clearly demonstrated that COMT was probably the sole enzyme responsible for the synthesis of syringyl lignin units, it suggested that COMT was not essential in the synthesis of guaiacyl lignin units. Even if COMT does contribute to guaiacyl lignin synthesis, other OMTs must have compensated for the loss of COMT. One of the best candidates of such OMTs was logically proposed to be CCoAOMT.

The unequivocal demonstration of the essential role of CCoAOMT in lignin biosynthesis came from transgenic studies (Zhong et al., 1998). It was shown that down-regulation of CCoAOMT in transgenic tobacco

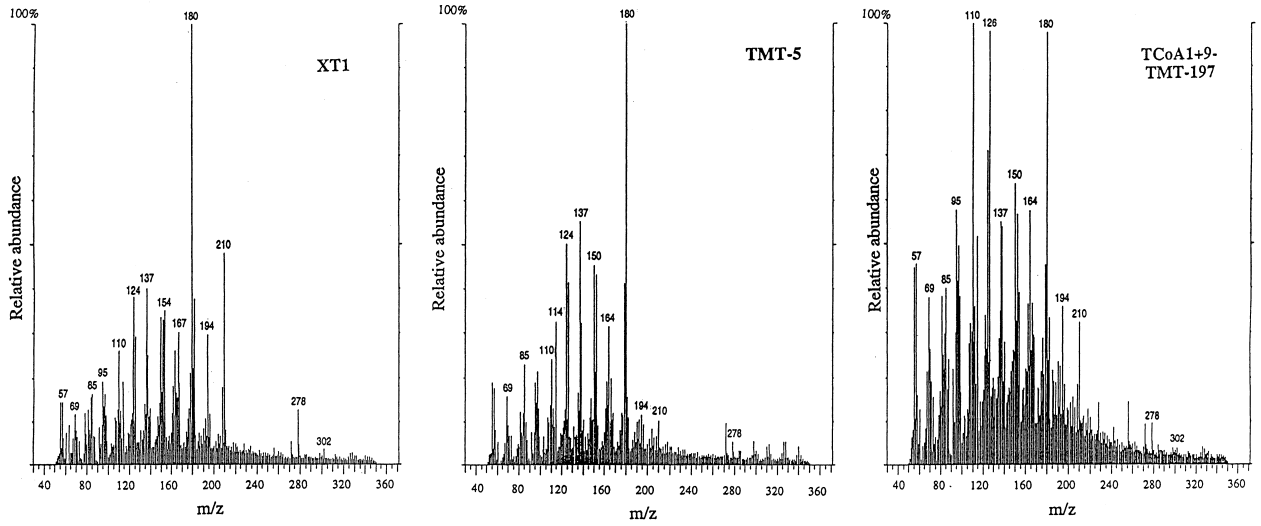

Fig. 4. Down-regulation of CCoAOMT effectively reduces the synthesis of guaiacyl lignin units in transgenic tobacco plants. Cell walls of the wild type (XT1), a transgenic line with down-regulation of COMT (TMT-5), and a transgenic line with down-regulation of both CCoAOMT and COMT (TCoA1 + 9-TMT-197) were analyzed with in-source pyrolysis mass spectrometry. Mass peaks of guaiacyl lignin had m/z values of 124, 137, 138, 150, 152, 164, 166, 178, and 180. Mass peaks of syringyl lignin had m/z values of 154, 167, 168, 180,182, 194, 208, and 210. Mass peaks of cellulose and amylose had m/z values of 57, 60, 73, 85, 86, 96, 98, 100, 102, 110, 112, 126, and 144. Mass peaks of hemicellulose had m/z values of 58, 85, 86, and 114. Down-regulation of COMT (TMT-5) dramatically decreases the syringyl lignin unit as evidenced by a reduction in the relative ratio of mass peaks of m/z 194 and 210 (syringyl lignin unit) over m/z 110 and 126 (polysaccharides) compared with the wild type (XT1). Simultaneous down-regulation of CCoAOMT and COMT (TCoA1 + 9-TMT-197) reduces both guaiacyl and syringyl lignin units as evidenced by a reduction in the relative ratio of mass peaks of m/z of 124, 150 and 180 (guaiacyl lignin unit) and 180, 194 and 210 (syringyl lignin unit) over m/z 110 and 126 (polysaccharides) compared with the wild type (XT1).

plants not only dramatically reduced total lignin content, but also decreased both guaiacyl and syringyl lignin units. The important role of CCoAOMT in the synthesis of guaiacyl lignin units was best exemplified in plants with down-regulation of both CCoAOMT and COMT (Fig. 4). While down-regulation of COMT resulted only in a reduction in syringyl lignin units, further down-regulation of CCoAOMT together with COMT effectively decreased both guaiacyl and syringyl lignin units.

In addition to the essential role of CCoAOMT in lignification in herbaceous tobacco plants, it has also been shown that CCoAOMT plays a similar role in lignin biosynthesis in woody poplar plants (Meyermans et al., in press; Zhong et al., in press). Reduction of CCoAOMT in transgenic poplar plants led to a decrease in both lignin content (Fig. 5) and guaiacyl and syringyl lignin units. Taken together, the transgenic studies in both tobacco and poplar have clearly confirmed the early hypothesis that the CCoAOMT-mediated methylation pathway is essential for lignin biosynthesis under normal plant growth and development. They also demonstrate that the methylation reactions in lignin biosynthesis are catalyzed by both COMT and CCoAOMT.

It is worth noting that although down-regulation of COMT resulted in an almost complete loss of syringyl lignin units, down-regulation of CCoAOMT did not lead to a similar level of reduction in guaiacyl lignin units. There are several possibilities for this insufficient reduction in guaiacyl lignin units. First, antisense repression does not lead to a complete loss of CCoAOMT activity, so the residual activity present in the transgenic plants might be sufficient to sustain the biosynthesis of substantial amount of lignin. Second, CCoAOMT genes are present in a gene family in tobacco and poplar. Some gene members might not share enough nucleotide sequence homology with the gene used for antisense repression, so that their gene expression might not be affected. Third, some novel OMTs capable of methylating caffeoyl CoA such as the multifunctional OMT from pine (Li et al., 1997) might partially compensate for the loss of CCoAOMT. Fourth, it is possible that, when CCoAOMT expression is repressed, COMT might partially compensate for the synthesis of guaiacyl lignin units. It is clear that more work needs to be done to investigate how many different types of OMTs are involved in the biosynthesis of guaiacyl lignin units.

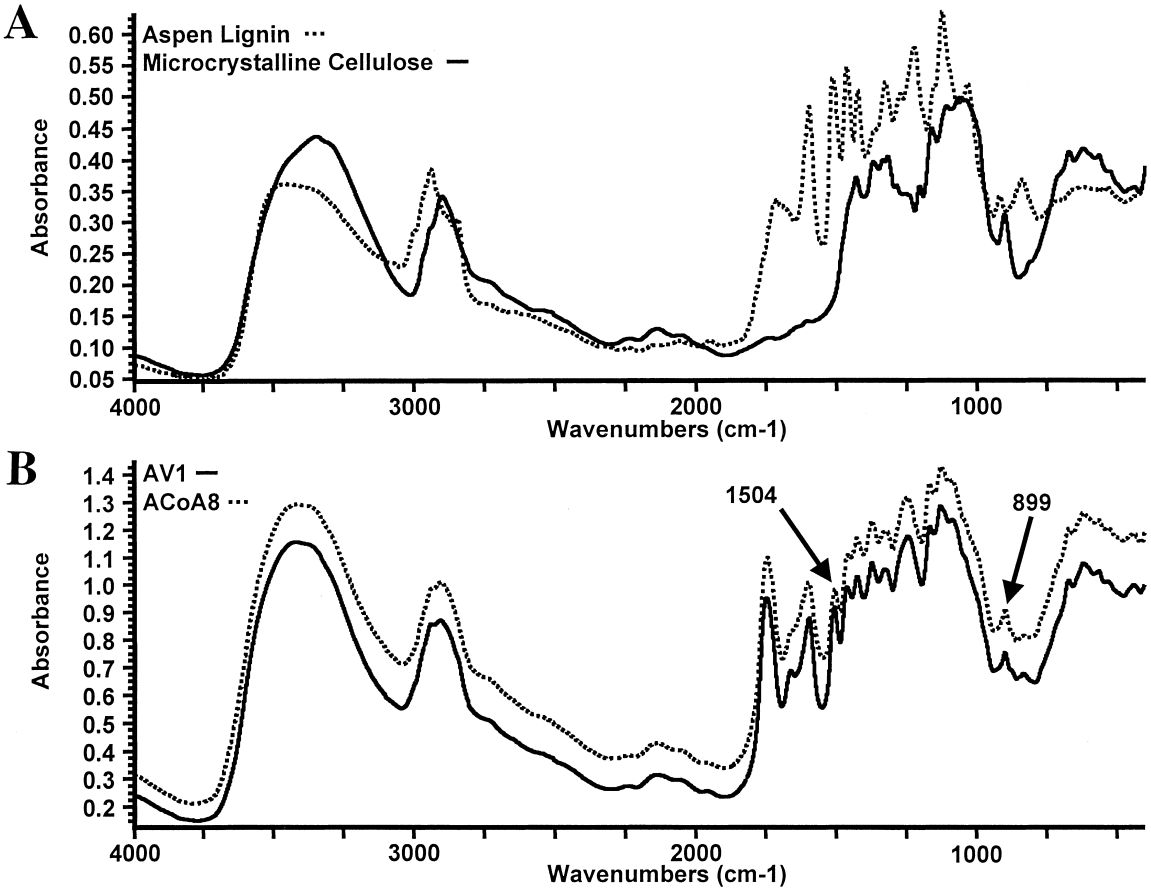

Fig. 5. Down-regulation of CCoAOMT reduces lignin content in woody poplar plants. Cell walls of the wild type (AV1) and a transgenic line with down-regulation of CCoAOMT (AcoA8) were anaylzed with diffuse reflectance infrared fourier transform spectroscopy. A. Spectra of standard lignin and cellulose. B. Spectra of cell walls from transgenic poplar plants. Lignin absorbances at 1504 and 1596 cm^{-1}, and cellulose absorbance at 899 cm^{-1} were used for quantitative analysis, which showed that in ACoA8 lignin was reduced to 56% that of the wild type (AV1).

8. CCoAOMT is induced in the pith of the *elp1* mutants

Genetic analysis of Arabidopsis mutants with ectopic deposition of lignin has further correlated CCoAOMT expression with lignification (Zhong et al., 2000). In the wild-type *Arabidopsis* inflorescence stems, lignin is deposited in the walls of xylem cells and interfascicular fiber cells (Fig. 6). Correspondingly, CCoAOMT is shown to be specifically expressed in these lignifying cells. In the inflorescence stems of the *elp1* mutants, lignin is ectopically deposited in the walls of pith parenchyma cells in addition to it normal deposition in the walls of xylem and fiber cells. In the lignifying pith cells of *elp1*, CCoAOMT is found to be abundantly induced (Fig. 6). The *elp1* mutation was recessive and monogenic. It has been proposed that the *ELP1* locus is involved in the repression of the lignin biosynthetic pathway in the pith. These results further support the conclusion drawn from biochemical and molecular analysis that CCoAOMT is essential for lignin biosynthesis.

9. Recent findings on F5H and COMT

Recently, biochemical characterization of the substrate specificities of F5H and COMT has led to a revolutionary revision of the lignin biosynthetic pathway (Humphreys et al., 1999; Maury et al., 1999; Osakabe et al., 1999; Li et al., 2000). First, the long-held notion that 5-hydroxylation of hydroxycinnamates occurs on the acid form proves not to be correct. Instead, it has been found that F5H preferentially hydroxylates coniferaldehyde and coniferyl alcohol (Humphreys et al., 1999; Osakabe et al., 1999; Li et al., 2000). Second, it has been shown that COMT can efficiently use 5-hydroxyconiferaldehyde and 5-hydroxyconiferyl alcohol as substrates (Humphreys et al., 1999; Maury et al., 1999; Osakabe et al., 1999; Li et al., 2000). Third, radiotracer experiments have proven that wood contains enzymes to convert coniferaldehyde and coniferyl alcohol into sinapaldehyde and sinapyl alcohol, respectively, required for the synthesis of syringyl lignin (Matsui et al., 1994; Chen et al., 1999). These

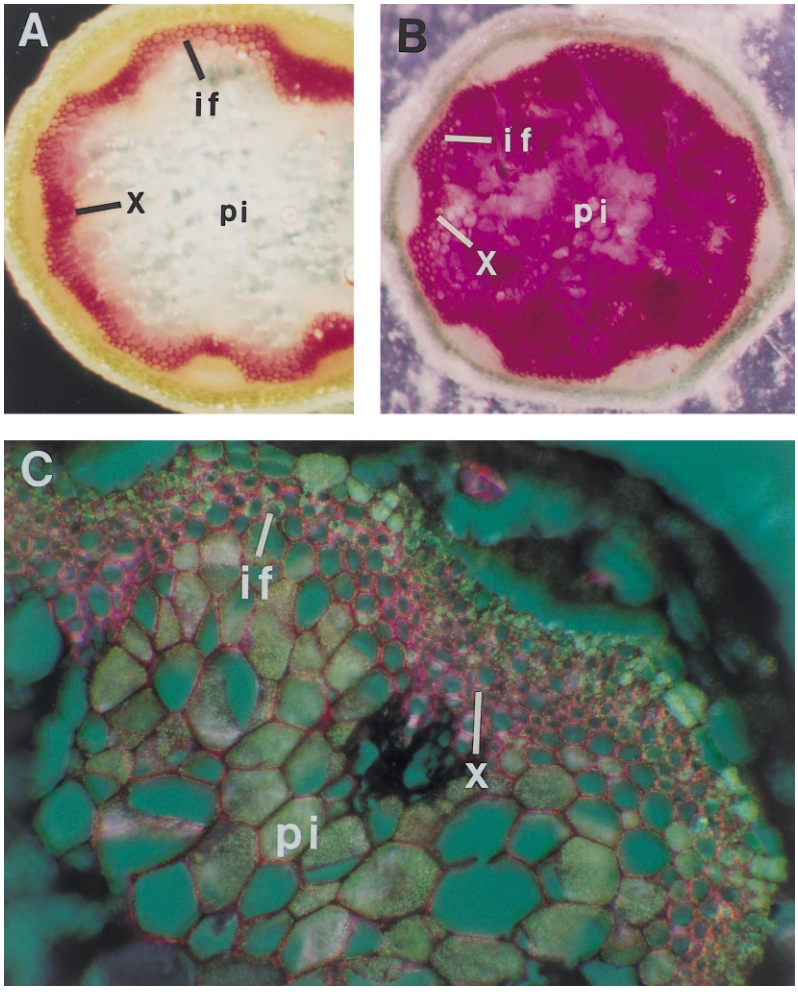

Fig. 6. Ectopic induction of CCoAOMT in the pith cells of *Arabidopsis elp1* mutant. A. Section from the wild-type stem showing lignin staining (red) in xylem and interfascicular fibers. B. Section from the *elp1* mutant stem showing intensive lignin staining in the pith in addition to xylem and interfascicular fibers. C. Immunolocalization of CCoAOMT in the *elp1* stem showing the presence of CCoAOMT signal (yellow-green) in the lignifying pith cells. Abbreviations: if, interfascicular fiber; pi, pith; x, xylem.

results strongly suggest that 5-methoxylation occurs only at the aldehyde and alcohol forms of the phenylpropanoid pathway intermediates. Finally, elegant competitive studies of substrate specificity have demonstrated that COMT does not use caffeic acid as the substrate in the presence of 5-hydroxyconiferaldehyde (Li et al., 2000).

Taken together, these results indicate that CCoAOMT does not contribute to the methylation of 5-hydroxyl groups of hydroxycinnamates because the substrate is not available (Li et al., 2000). This is consistent with the transgenic studies that down-regulation of COMT alone almost completely blocks the biosynthesis of syringyl lignin (Atanassova et al., 1995; van Doorsselaere et al., 1995). These results also suggest that feruloyl CoA is an important intermediate required for the synthesis of both guaiacyl and syringyl lignin units. This conforms with the antisense CCoAOMT results that down-regulation of CCoAOMT, which reduces the production of feruloyl CoA, results in a decrease in both guaiacyl and syringyl lignin units (Zhong et al., 1998).

10. Concluding remarks

The demonstration of the essential role of CCoAOMT in lignin biosynthesis has greatly enriched our knowledge on the biosynthetic pathway of lignin. This finding has also confirmed Neish's early proposal that the intermediates for methoxylation occur on the ester forms (Neish, 1968). The recent novel findings resulted from the study of methoxylation pathways have suggested that the lignin biosynthetic pathway is far more complicated than what we had thought. It appears that our quest on the methylation pathways in lignin biosynthesis has not reached an end. We are still not clear how many different kinds of OMTs participate in the methylation of 3-hydroxyl groups of hydroxycinnamates although CCoAOMT is clearly involved. It seems that the antisense approach may not be able to further address this issue. It is likely that mutational analysis in plants such as *Arabidopsis* would be able to provide conclusive answers on the roles of different OMTs in the methylation of 3-hydroxyl groups of hydroxycinnamates. It is anticipated that further studies of the methylation pathways using biochemical, molecular and genetic approaches will resolve the roles of different OMTs in the biosynthesis of lignin.

Received 25 July 2000; received in revised form 27 November 2000

Abstract

Cinnamoyl-CoA reductase (CCR ; EC 1.2.1.44) catalyses the conversion of cinnamoyl-CoAs into their corresponding cinnamaldehydes, i.e. the first step of the phenylpropanoid pathway specifically dedicated to the monolignol biosynthetic branch. In previous work, we described the isolation and characterisation of the first cDNA encoding CCR in Eucalyptus (Lacombe, E., Hawkins, S., Van Dorsselaere, J., Piquemal, J., Goffner, D., Poeydomenge, O., Boudet, A.M., Grima-Pettenati, J., 1997. Cinnamoyl CoA reductase, the first committed enzyme of the lignin branch biosynthetic pathway: cloning, expression and phylogenetic relationships. Plant Journal 11, 429–441) and shown the role of this enzyme in controlling the carbon flux into lignins (Piquemal, J., Lapierre, C., Myton, K., O'Connell, A., Schuch, W., Grima-Pettenati, J., Boudet, A.M., 1998. Down-regulation of cinnamoyl-CoA reductase induces significant changes of lignin profiles in transgenic tobacco plants. Plant Journal 13, 71–83). Here, we report the characterisation of two functionally and structurally distinct cDNA clones, AtCCR1 and AtCCR2 (81.6% protein sequence identity) in *Arabidopsis thaliana*. The two recombinant proteins expressed in *Escherichia coli* are able to use the three cinnamoyl-CoAs tested but with different levels of efficiency. AtCCR1 is five times more efficient with feruloyl-CoA and sinapoyl-CoA than AtCCR2. In addition, the two genes are differentially expressed during development and in response to infection. *AtCCR1* is preferentially expressed in tissues undergoing lignification. In contrast, *AtCCR2*, which is poorly expressed during development, is strongly and transiently induced during the incompatible interaction with *Xanthomonas campestris* pv. *campestris* leading to a hypersensitive response. Altogether, these data suggest that *AtCCR1* is involved in constitutive lignification whereas *AtCCR2* is involved in the biosynthesis of phenolics whose accumulation may lead to resistance. © 2001 Elsevier Science Ltd. 1. Introduction

Lignins, which are complex aromatic polymers resulting from the oxidative polymerization of hydroxycinnamyl alcohols (*p*-coumaryl, coniferyl and sinapyl alcohols), have played a major role in the successful land colonisation by plants (Lewis and Davin, 1994). Their deposition occurs in the walls of certain specialised cells such as tracheary elements allowing water and nutrient conduction as well as structural support. In addition, induced lignification is one plant defence response to environmental cues such as wounding, mechanical stress or pathogen attack (Vance et al., 1980; Lewis and Yamamoto, 1990; Moerschbacher et al., 1990; Nicholson and Hammerschmidt, 1992). Increased lignification has often been observed in response to infection and is believed to participate in parasite confinement because lignin represents an undegradable mechanical barrier

for most micro-organisms (Kimmins and Wuddah, 1977; Vance et al., 1980; Legrand, 1983; Ride, 1983; Lange et al., 1995; Walter, 1992). In most cases, the tissue location and the monomeric composition of defence lignins are different from those of structural lignins (Lange et al., 1995 and references therein). Taken together, these data suggest that lignin biosynthesis is controlled by two signal transduction pathways, one in the development of vascular tissues, and the other in plant defence responses.

The biosynthesis of lignins begins with the common phenylpropanoid pathway starting with the deamination of phenylalanine and leading to the cinnamoyl-CoA esters which are the common precursors of a wide array of end-products playing key roles during plant development and defence such as flavonoids, coumarins, lignins, phlobaphenes and many small phenolic molecules (Hahlbrock and Scheel, 1989; Dixon and Lamb, 1990). Cinnamoyl-CoA esters are then channelled into the lignin branch pathway to produce monolignols *via* two reductive steps i.e. cinnamoyl-CoA reductase (CCR) and cinnamyl alcohol dehydrogenase (CAD).

The organisation and regulation of phenylpropanoid genes, particularly the first and last step of the "general phenylpropanoid" pathway, catalysed by phenylalanine ammonia-lyase (PAL) and cinnamate-CoA ligase (4CL), have been extensively studied. Depending on the species, PAL and 4CL are encoded by several genes which are largely controlled at the level of transcription during development and in response to environmental cues such as infection, UV light (Chappell and Hahlbrock, 1984; Lawton and Lamb, 1987; Hahlbrock and Scheel, 1989; Dixon and Paiva, 1995). In contrast to the considerable amount of data accumulated on the regulation of these genes, little is known about the steps devoted more specifically to the lignin monomer biosynthesis, such as CCR. A rapid and transient increase of feruloyl-CoA reductase and PAL activities was previously reported in cell suspension of spruce treated with cell wall preparation of *Rhizosphaera kalkhoffii* (Messner and Boll, 1993). Concomitant with this increase in enzyme activities, a rapid accumulation of low molecular weight lignin-like material was observed in the medium, resembling gymnosperms' compression wood lignins (Lange et al., 1995). Whether the same *CCR* gene is under the control of both the developmental programs during normal plant growth and the defensive reactions triggered by environmental cues, is still a totally open question.

The cloning and characterisation of the cDNA encoding CCR was first achieved in *Eucalyptus* (Lacombe et al., 1997), enabling us to address this question and to gain an insight into the regulation of the lignin pathway in developmental and defence processes. Consistent with its role in lignin biosynthesis during plant development, expression of the *CCR* gene was shown to be high in tissues undergoing active lignification, i.e. vascular cambium and differentiating xylem (Lacombe et al., 1997, 2001). Moreover, this enzyme, which occupies a key position between the general phenylpropanoid pathway and the lignin specific branch, has been shown to be a control point regulating the carbon flux towards lignins by gene transfer experiments (Piquemal et al., 1998). Through ectopic expression of a homologous antisense gene, significant down-regulation for CCR has been obtained in transgenic tobacco plants leading to both qualitative and quantitative changes in lignins profiles (Piquemal et al., 1998). CCR is apparently encoded by a single gene per haploid genome in *Eucalyptus* (Lacombe et al., 1997), poplar (Leplé et al., 1998) and tobacco (Piquemal et al., 1998) and by two genes in maize (Pichon et al., 1998). According to Northern blot experiments performed on different organs using specific probes for the two maize genes, it was concluded that *ZmCCR1* was involved in lignification whereas the role of *ZmCCR2*, which is expressed only in roots and at a low level, remains to be elucidated.

The systematic sequencing project of *Arabidopsis thaliana* expressed sequence tags (ESTs) allowed us to identify by homology search, two genes exhibiting high homology with *CCR* genes previously isolated from other species and, therefore, putatively encoding CCR in this species. Using the Darwin software (Gonnet et al., 1992), we built a phylogenetic tree showing that AtCCR1 is closer than AtCCR2 to the core of the dicotyledon CCRs involved in lignin biosynthesis. Since these cDNAs initially derived from two different libraries, a library prepared from mRNA of different *Arabidopsis* organs for *AtCCR1*, and from mRNA isolated from a cell suspension culture inoculated by *Xanthomonas campestris* pv. *campestris* for *AtCCR2*, we made the hypothesis that the two genes may play different roles in *Arabidopsis*. In order to gain insight into the respective role of these genes in *Arabidopsis*, we expressed the recombinant proteins in *E. coli* and compared their specific activities towards three hydroxy-cinnamoyl substrates. The expression patterns of the two genes were also assessed during development and upon infection by pathogenic bacteria.

The characterisation of two structurally and functionally distinct *CCR* genes *AtCCR1* and *AtCCR2*, which are differentially expressed during development and in response to a pathogen challenge enable us to show that the two enzymes serve different physiological functions in *Arabidopsis*. Biochemical and in vivo expression analyses provide evidence that *AtCCR1* is associated with lignin biosynthesis during development. On the other hand, *AtCCR2* mRNA is strongly and transiently induced during the incompatible reaction with *Xanthomonas campestris* pv. *campestris* but not in lignifying tissue, suggesting a role for this enzyme in the formation of phenolic compounds associated with the hypersensitive response in *Arabidopsis*.

2. Results

2.1. Sequence analysis of two CCR cDNA clones from Arabidopsis

The *AtCCR1* cDNA is 1269 nucleotides long and has an open reading frame (ORF) of 1032 nucleotides encoding a 344 amino acid protein (Fig. 1) with a predicted molecular mass of 37.5 kDa and a pI of 6.1. The clone is not full length since the 5′ non coding region is missing. The *AtCCR2* cDNA is 1216 nucleotides long and contains an ORF encoding a protein of 332 amino acids (36.6 kDa) with a calculated pI of 6.09 (Fig. 1). Based on the eukaryotic consensus sequence of Kosak (1984), the ATG at position 63 is the initiation codon with an A at position −3. The position +5 is not occupied by a C in contrast with what is frequently observed in plants (Lütcke et al., 1987). No putative polyadenylation signal was found in either cDNAs. The two nucleotide sequences share 78.2 and 44.2% identity in their coding and 3′ untranslated regions, respectively. Because of their high sequence divergence, the 3′ regions were used to generate specific probes relative to *AtCCR1* and *AtCCR2* sequences, respectively (see Experimental).

The protein sequences deduced from the cDNAs *AtCCR1* and *AtCCR2* show 81.6% identity and 18.7% similarity (Fig. 1). The region in the N terminal portion of CCRs involved in the NADP(H) cofactor binding site (Lacombe et al., 1997) is conserved in both AtCCR sequences (Fig. 1). They also exhibit the signature of CCR, a very well conserved motif (KNWYCYGK), which is thought to be involved in the catalytic site of this enzyme (Lacombe et al., 1997). The alignment of these sequences with the predicted amino acid sequence of the *Eucalyptus gunnii* CCR (EuCCR, Lacombe et al., 1997) revealed a slightly higher homology for AtCCR1 (75% identity + 12% similarity) than for AtCCR2 (73% identity + 12.5% similarity). Based on the PAM distances reported on the phylogenetic tree (Fig. 2) built with the sequences of CCRs from different species, both AtCCRs belong to the group of CCRs from dicot origin. Interestingly, AtCCR1 is slightly closer to the other dicots CCRs than AtCCR2.

2.2. Copy number of CCR genes in A. thaliana

In order to evaluate the complexity of the CCR gene family in the *Arabidopsis* genome, genomic DNA was

Fig. 1. Alignment of the deduced amino acid sequences of AtCCR1 (T41765) and AtCCR2 (Z24528). Symbols (*) denote identical amino acids. The shaded amino acids are putative amino acids involved in cofactor binding. The box indicates the putative signature of CCRs. Sequence alignment was performed using the program Multalin (Corpet, 1988). The positions of the introns in AtCCR1 and AtCCR2 are indicated by white and black arrows, respectively.

digested to completion with either *Eco*RI, *Eco*RV, *Pst*I or *Xba*I, which do not cut the cDNA, or *Bam*HI, which has one restriction site in the *AtCCR1* sequence, and subjected to Southern blot analysis (Fig. 3). A 703 bp fragment of the *AtCCR2* cDNA was used as a probe allowing cross hybridisation between the two cDNA sequences. For each restriction digest, one strong and one weak hybridisation signal was observed. The strong intensity signal corresponded to homologous hybridisation to the *AtCCR2* gene whereas the faint band resulted from cross-hybridisation with the *AtCCR1* gene, showing the occurrence of two CCR-related genes in the *Arabidopsis thaliana* genome. This was further confirmed by the presence in *Arabidopsis* database of only two genomic sequences (AC010924 and AC011713) corresponding to *AtCCR1* and *AtCCR2*, respectively. Both genes are localised on chromosome 1. The sequence corresponding to *AtCCR1* gene (located on BAC clone AC010924) contained four introns at identical positions to introns I, II, III, IV from *Eucalyptus CCR* gene (Lacombe et al, 1997). Surprisingly, only three introns were found in the genomic sequence of *AtCCR2* (located on BAC clone AC011713) at similar positions as the introns II, III, IV in *AtCCR1* and *EuCCR* genes indicating that the first intron is missing.

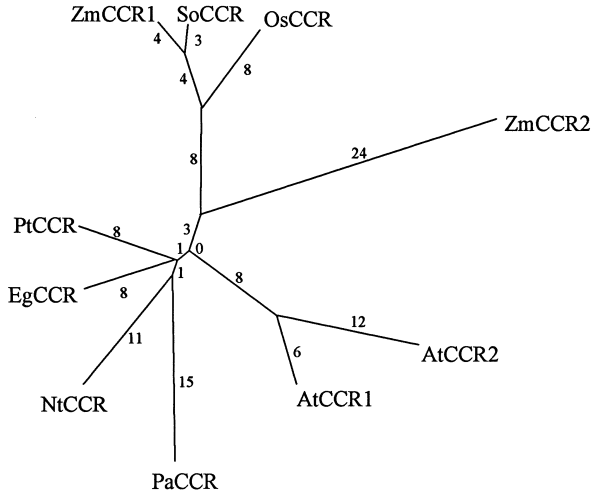

Fig. 2. Phylogenetic tree of AtCCRs and related sequences as obtained using DARWIN (Gonnet et al., 1992). The tree was built using the sequences indexed in EMBL as follows : AtCCR1 (*Arabidopsis thaliana*, T41765) and AtCCR2 (*Arabidopsis thaliana*, Z24528); EgCCR (*Eucalyptus gunnii*, X97433)(Lacombe et al., 1997); ZmCCR1 (*Zea mays*, X98083; Y13734) and ZmCCR2 (*Zea mays*, Y15069) (Pichon et al., 1998); PaCCR (*Picea abies*, Goffner, personal communication); PtCCR (*Populus trichocarpa* x *P. Deltoides*, A47097); NtCCR (*Nicotiana tabacum*, A47101) (Piquemal et al., 1998); OsCCR (*Oriza sativa*, EST D46355); SoCCR (*Saccharum officinarum*, AJ231134).

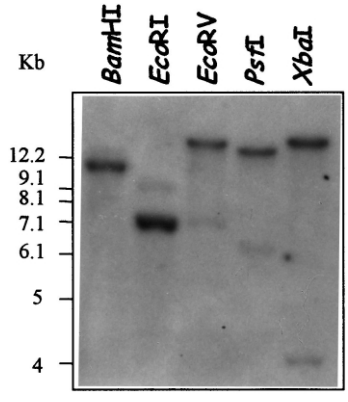

Fig. 3. Southern blot analysis of *Arabidopsis thaliana* genomic DNA. *Arabidopsis thaliana* DNA was digested with *Bam*HI, *Eco*RI, *Eco*RV, *Pst*I and *Xba*I. Hybridization was performed with the *Bgl*II-*Dra*I RaR108 (*AtCCR2*) cDNA fragment. The molecular weight markers are indicated on the left.

2.3. Functional expression of the A. thaliana CCR cDNAs in E. coli

In order to compare the biochemical properties of AtCCR1 and AtCCR2, *E. coli* expressed-GST fusion proteins were purified to 90% homogeneity, as determined by SDS-PAGE (data not shown). Under denaturing electrophoresis conditions, these proteins exhibited a molecular mass of approximately 64 kD, which is in agreement with the size of the fusion proteins GST-AtCCR1 and GST-AtCCR2. Purified fusion proteins were then used to determine the apparent K_m and K_{cat} values for three potential CCR substrates : feruloyl-CoA, sinapoyl-CoA and caffeoyl-CoA (Table 1). Although, the measurements have been performed using fusion proteins and should be confirmed using purified recombinant proteins, the data obtained clearly showed that the two enzymes are able to use the three substrates but with different efficiencies. AtCCR1 exhibited a clear preference for feruloyl-CoA and to a lesser extent for sinapoyl-CoA. AtCCR2 preferentially used feruloyl-CoA but converted sinapoyl-CoA and caffeoyl-CoA with approximately the same lower efficiency. AtCCR1 was 5 times more efficient with feruloyl-CoA and sinapoyl-CoA than AtCCR2 (K_{cat}/K_m). Caffeoyl-CoA, the least favoured substrate, appeared to be used with the same efficiency by both AtCCRs.

2.4. Developmental expression of CCR genes

To investigate the spatial expression of *CCR* genes in *Arabidopsis*, Northern analysis was carried out with RNA extracted from different parts of two month-old plants (Fig. 4). Blots were hybridised with gene-specific probes for *AtCCR1* and *AtCCR2* (see experimental section) corresponding to their 3′ regions. *AtCCR1* specific probe hybridised to a single mRNA species of about 1.6 Kb mainly in stems and at a lower level in leaves and flowers (including petioles and sepals). In contrast, *AtCCR2* mRNA was hardly detectable in these organs by Northern blot analysis, suggesting that the *AtCCR2*

Table 1
Kinetic parameters of AtCCR1 and AtCCR2 fusion proteins

Substrate	K_m (μM)		K_{cat} (min^{-1})		K_{cat}/K_m (min^{-1} μM^{-1})	
	AtCCR1	AtCCR2	AtCCR1	AtCCR2	AtCCR1	AtCCR2
Feruloyl-CoA	0.96	4.7	2.28	2.23	2.37	0.47
Sinapoyl-CoA	6.32	30.7	3.67	3.5	0.58	0.11
Caffeoyl-CoA	12.5	5.16	2.18	0.87	0.17	0.17

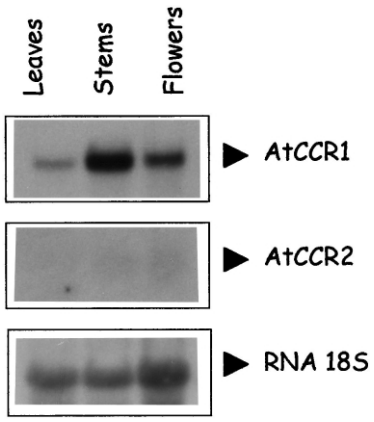

Fig. 4. Northern blot analysis of total RNA (25 μg per lane) from *Arabidopsis thaliana* leaves, stems and flowers, probed with ^{32}P-labeled AtCCR1 and AtCCR2 specific fragments and 18S ribosomal RNA.

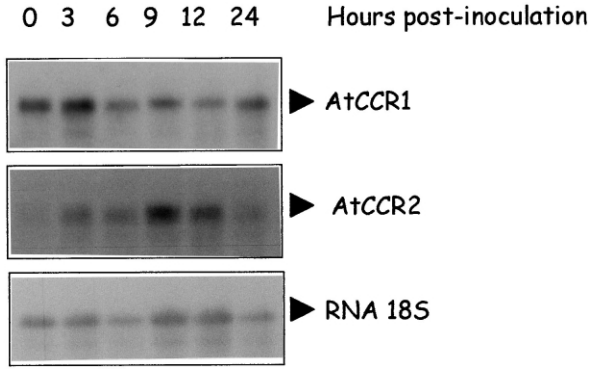

Fig. 5. Northern blot analysis of total RNA from *Arabidopsis* leaves inoculated with *Xanthomonas campestris* pv. *campestris*. Healthy leaves (time O), or leaves from Col-O ecotype (incompatible interaction), inoculated with the *Xanthomonas campestris* pv. *campestris* strain 147, were harvested at different times post-inoculation; RNA was extracted and analysed as described for Fig. 4.

gene is expressed at very low levels in all the organs tested.

2.5. Expression of Arabidopsis CCR upon infection with bacterial pathogens

The fact that the *AtCCR2* cDNA was isolated from *Arabidopsis* cells inoculated with an avirulent isolate of *Xanthomonas campestris* pv. *campestris*, led us to analyse in detail the expression patterns of *AtCCR1* and *AtCCR2* genes during plant-pathogen interactions.

Northern blot analysis was performed from leaf tissues of Col-O ecotype of *Arabidopsis* after challenge by *Xanthomonas campestris* pv. *campestris* isolate 147, an incompatible interaction leading to HR. Total RNA was extracted at different times after pathogen challenge (Fig. 5). In healthy leaves (time 0), a signal corresponding to *AtCCR1* mRNA was observed whereas *AtCCR2* mRNA was virtually undetectable (Fig. 5). At 3 h post inoculation (hpi), the steady-state content of *AtCCR1* mRNA slightly increased, then decreased (6 hpi) and stayed relatively constant (trancripts still being detectable) until 24 hpi). This drop of the *AtCCR1* mRNA level below the basal level (time 0) was consistently observed in independent experiments. In contrast, the level of *AtCCR2* mRNA increased strongly and transiently after inoculation by the pathogen. The hybridisation signal became clearly detectable 3 hpi, reached a maximum at 9 hpi, then decreased to become slightly detectable after 24 hpi. In addition, different compounds known as modulators of stress response in plants such as elicitors, methyl jasmonate, salicylic acid and ethylene were tested on *AtCCR2* expression in *Arabidopsis* plants. An increase of *AtCCR2* transcripts accumulation was detected only in response to exogenous apply of salicylic acid (data not shown).

No significant accumulation of *AtCCR1* and *AtCCR2* mRNA transcripts was seen after infiltration with water nor during a compatible interaction leading to disease (data not shown).

3. Discussion

We report here the functional characterisation of two *CCR* cDNA clones from *Arabidopsis thaliana*, originally obtained from two different cDNA libraries. We have shown that AtCCR1 and AtCCR2 exhibit distinct biochemical properties and that the corresponding genes are differentially expressed during development and in response to pathogen challenge.

Although their deduced protein sequences showed high sequence identity with CCRs previously isolated from other species and shown to be involved in lignin biosynthesis during vascular development (Lacombe et al., 1997; Pichon et al., 1998; Piquemal et al., 1998),

more detailed phylogenetic analysis revealed that AtCCR1 is closer than AtCCR2 to the core of the other dicotyledones CCRs. Taken together with the respective origin of the clones, this result favours the hypothesis that the two genes could play different roles *in planta*.

As a first step towards deciphering their respective functions, we have produced the recombinant fusion proteins in *E. coli* and tested their activities towards three potential CCR substrates. AtCCR1 exhibited a clear substrate preference for lignin-specific substrates (feruloyl-CoA, sinapoyl-CoA) as previously reported for CCR from other species such as *Eucalyptus* (Goffner et al., 1994), spruce (Luderitz and Grisebach, 1981) and poplar (Sarni et al., 1984). The strong preference of AtCCR1 for feruloyl-CoA is consistent with the monomeric composition of lignin in *Arabidopsis* xylem which is mainly composed of guaiacyl G units (Chapple et al., 1992). All together these data suggest that *AtCCR1* might be involved in lignin biosynthesis. On the other hand, AtCCR2 also exhibited a clear preference for feruloyl-CoA but the substrate affinity and the conversion efficiency is 5 times lower as compared to AtCCR1.

In addition to the biochemical analyses, the Northern blot experiments showed that *AtCCR1* is preferentially expressed in stems, this supporting its role in vascular lignification. Further confirmation of the role of *AtCCR1* was provided by antisense experiments performed in parallel to our study leading to *Arabidopsis* plants exhibiting a decreased lignin content (Jouanin, personal communication). In contrast to *AtCCR1*, *AtCCR2* is present only in trace amounts in healthy tissues, suggesting that it is not involved in lignification during development.

Since lignification has been reported as a part of the active mechanisms induced during resistance (Dixon and Lamb, 1990), the question whether the *AtCCR* genes are regulated in response to pathogen infection has been addressed. *AtCCR1* transcript level is not significantly induced during incompatible interaction with *Xanthomonas campestris* pv. *campestris* leading to hypersensitive response (HR). Whereas *AtCCR2* mRNA accumulated strongly and transiently in infected leaves. Therefore it clearly appears that *AtCCR1* and *AtCCR2* genes show a differential expression pattern in response to *Xanthomonas* infection, suggesting a role for *AtCCR2* in the establishment of disease resistance mechanisms. As observed in other pathosystems, lignification can be one important component of the defence response leading to resistance (Fusch and Sacristan, 1996; Tang et al., 1999). Several studies have shown that genes involved in the early or later steps of lignification (phenylpropanoid and monolignols synthesis) are up-regulated in response to pathogen infection (Dong et al., 1991; Buell and Somerville, 1995). For example, an increase in mRNA accumulation of *C4H*, *CAD* and *Eli3* (the latest subsequently identified as a CAD, Logemann et al., 1997) was observed in *Arabidopsis* ecotype Col-O undergoing an HR (Buell and Somerville, 1995). The data presented here are in agreement with these observations suggesting a close relationship between induction of genes of the monolignol pathway and HR-mediated resistance.

Although lignins or "lignin-like material" are known to be synthesised during the hypersensitive reaction to reinforce cell walls, interfering with pathogen penetration, lignification appears only as a late response in the resistance process. In the pathosystem studied here, we would favour the hypothesis that the end products of the *AtCCR2*-mediated pathway may not be lignins or "lignin-like" material but rather intermediary phenolic compounds that could be synthesised more rapidly than the polymer itself and which play a role in defence either by a phytoalexin action or by reinforcing the cell walls, or both. In support to this hypothesis, coniferaldehyde and coniferyl alcohol which are the products of the *CCR* and *CAD*-mediated reactions, respectively, appear to function as phytoalexins in the incompatible interaction between flax and *Melampsora lini* and are involved in the restriction of the fungus growth in the resistant flax leaves (Keen and Littlefield, 1979). Here, we have shown for the first time, the direct implication of a *CCR*-family member, *AtCCR2* in defence responses *via* a strong transcriptional activation during HR. The nature of the phenolic compounds leading to resistance still needs to be addressed. To this end it is worth noting that during plant evolution, the earliest role of intermediary end products of the lignin branch pathway is thought to be related to defence against bacterial, fungal or viral pathogens (Raven, 1977).

In conclusion to this work and in regard to recent data, it seems likely that some members of the gene families encoding enzymes of the monolignol biosynthesis pathway like *AtCCR2*, *COMTII* (Pellegrini et al., 1993), *Eli3* (Logemann et al., 1997 and references therein) are poorly expressed during development and belong to a specifically regulated pathway preceding HR or activated as a consequence of HR establishment.

4. Experimental

4.1. Arabidopsis CCRs

The EST database (dbEST) (Newman et al., 1994; Cooke et al., 1996) was searched using the NCBI GenInfo network BLAST server (Altschul et al., 1990) for CCR-like sequences from *Arabidopsis*, and this resulted in the identification of two cDNAs encoding CCR. The 67e6t7 EST (T41765), initially isolated from a cDNA library prepared from equal portions of poly(A+) mRNA from etiolated seedlings, roots, leaves, and flowering inflorescences (Newman et al., 1994), was obtained from the Arabidopsis Biological Resource Center at

Ohio State University. The RaR108 clone (Z24528) was isolated from an *Arabidopsis* cDNA library prepared from a cell suspension inoculated for one hour with *Xanthomonas campestris* pv. *campestris* in the presence of cycloheximide (Lacomme and Roby, 1996).

4.2. Sequencing and phylogenetic analyses

Nucleotide sequencing was performed automatically, in both directions, using an Applied Biosystems automated sequencer (Perkin Elmer/Applied Biosystems Division). After completion of sequencing of the cDNAs corresponding to the ESTs 67e6t7 and RaR108, they were renamed respectively *AtCCR1* and *AtCCR2*.

Standard sequence analysis was performed using the PCgene software package (IntelliGenetics, Inc.). The phylogenetic tree was obtained using the DARWIN software (Gonnet et al., 1992) with the public server (CBRG@inf.ethz.ch). Multiple alignments were performed using CLUSTAL W (Thompson et al., 1994).

4.3. Plant material

Seeds of *Arabidopsis thaliana* L. (Heynh) ecotypes Col-O were soaked in water for 2 h, then sterilised for 10 min in a 12% Na hypochlorite solution and washed in sterile water. Seeds were spread on MS (Murashige and Skoog, 1962) medium and grown in vitro for one week in a culture chamber (16 h photoperiod, 20°C). The young plantlets were transferred to soil and grown in a growth chamber (9 h photoperiod, 22°C) as described by Lummerzheim et al. (1993).

4.4. Bacterial strain and inoculation procedure

The source and growth conditions of the isolate 147 of *Xanthomonas campestris* pv. *campestris* isolates, as well as the plant inoculation procedure used in this study (manual infiltration of leaves), were as described by Lummerzheim et al. (1993).

4.5. Southern and Northern blot analyses

Genomic DNA was purified from *Arabidopsis* according to the protocol described by Dellaporta et al. (1983), and digested with appropriate restriction enzymes: *Bam*HI, *Eco*RI, *Eco*RV, *Pst*I and *Xba*I, that do not cut *AtCCR2* cDNA. The Southern blot experiment was performed as previously described by Lacomme and Roby (1996), using a *Bgl*II-*Dra*I fragment (position 248 to 951 in *AtCCR2*).

RNA extraction and Northern blot analysis were as previously described by Lummerzheim et al. (1993). Specific probes were generated by PCR: *AtCCR1* specific probe (491bp) was obtained using sense 5AT1 [5′AGCCGAGAGTGCTCGCC3′] and antisense 3AT1 [5′TAAGTGTAATCTATTACATAG3′] primers located respectively at positions 755 and 1246 on the *AtCCR1* cDNA; *AtCCR2* specific probe (402bp) was obtained using 5AT2 [5′GCGCGAGACCGCACT TG3′] and 3AT2 [5′TTTTTAAGAAAGAACAATCA GC3′] primers located respectively at positions 797 and 1191 of the corresponding cDNA. The amplified fragments were gel-purified and radio-labelled by random priming using a Nonaprimer Kit II (Appligene). The absence of cross hybridisation between the two probes was verified on Southern blots.

4.6. Expression in Escherichia coli and purification of fusion proteins

AtCCR1 cDNA was digested with *Eco*RI and *Not*I and ligated into the *Eco*RI-*Not*I linearized pGEX 4T-1 vector (Pharmacia). For convenient cloning of the *AtCCR2* cDNA, an *Eco*RI site was introduced by PCR, fifteen bases downstream from the ATG start codon. PCR reactions were performed using one oligonucleotide 5′ATTGAATTCCTCGTCTGCGTCACC3′ introducing an *Eco*R1 site and the M13 -20 universal primer (Biolabs), located on the pBluescript-SK downstream from the stop codon. The amplified product was digested with *Eco*RI and *Xho*I and ligated into *Eco*RI-*Xho*I linearized pGEX 4T-1 vector. The fidelity of PCR was checked by DNA sequencing. Both constructs were introduced into *E. coli* strain BL21 (DE3) (Studier and Moffat, 1986). Growth and induction of bacterial cells with isopropyl β-D-thiogalactoside at 0.1 mM final concentration were performed as described in Lauvergeat et al. (1995). The fusion proteins CCR-GST were purified from bacterial lysate on a Glutathione Sepharose 4B column (Pharmacia) according to the manufacturer's instructions. Protein concentrations were determined by the Bradford assay (Bradford, 1976).

4.7. CCR activity assay and K_m determination

CCR activity was measured spectrophotometrically and determination of kinetic parameters was performed as previously described in Goffner et al. (1994). The three substrates: feruloyl CoA, sinapoyl CoA and caffeoyl CoA, were synthesised according to the method of Stöckigt and Zenk (1975).

Acknowledgements

The authors are grateful to the *Arabidopsis* Biological Resource Center at Ohio State for DNA material (*AtCCR1* cDNA clone) and to Deborah Goffner for providing the corresponding sequence. We thank François Godard for providing infected plant material used for Northern blot analysis and Saida Danoun for the

synthesis of CCR substrates. This work was financially supported by CNRS, Université Paul Sabatier and INRA funds.

Sesquiterpene lactones from *Smyrnium olusatrum*

Ali A. El-Gamal*

Department of Pharmacognosy, Faculty of Pharmacy, Mansoura University, Mansoura 35516, Egypt

Received in revised form 12 January 2001

Abstract

Fruits of *Smyrnium olusatrum* afforded three sesquiterpene lactones, namely, 1β,8β-dihydroxyeudesman-3,7(11)-dien-8α,12-olide, 1β,8β-dihydroxyeudesman-4(15),7(11)-dien-8α,l2-olide, and 1β,10α,4α,5β-diepoxy-6β-hydroxyglechoman-8α,12-olide. Four related known sesquiterpenes were also isolated and characterized. The structure elucidation of the isolated compounds was based primarily on 1D and 2D NMR analyses. The in vitro cytotoxicity of the extract and isolated compounds against P-388 mouse lymphoma cells will be also discussed. © 2001 Published by Elsevier Science Ltd.

Keywords: *Smyrnium olusatrum*; Apiaceae; Sesquiterpenes; Eudesmen-8α,12-olide; Glechomanolides; Cytotoxic activity

1. Introduction

Several sesquiterpene lactones, furanosesquiterpenes and oxepines have been isolated from members of the genus *Smyrnium* (Ulubelen et al., 1971, 1979, 1984, 1985; Bohlmann and Zdero, 1973; Ulubelen and Abdolmaleky, 1982; Goren et al., 1984; Ulubelen and Oksuz, 1984; Goren and Ulubelen, 1985, 1987a,b; Ulubelen and Goren, 1986; Molleken et al., 1998). The young shoots of *Smyrnium olusatrum* are cultivated and used as pot herb and edible salad in some areas in Libya. The plant is also used as antiscorbutic in Palestine (Jafri and El-Gadi, 1985). This study reports the isolation of three new sesquiterpene lactones **1**, **2** and **5** in addition to four known ones **3**, **4**, **6** and **7** from the fruits of *S. olusatrum* collected from the Libyan desert. The cytotoxicity of the CH_2Cl_2 extract and the isolated compounds is also reported.

2. Results and discussion

Repeated chromatography of the cytotoxic CH_2Cl_2 extract of the fruits of *S. alusatrum* on normal and C18 reversed phase silica gel afforded the new sesquiterpene lactones **1**, **2** and **5**, in addition to the four known sesquiterpenes 1β-acetoxyeudesman-4(15),7(11)-dien-8α,12-olide (**3**), 1β acetoxy, 8β-hydroxyeudesman-4(15),7(11)-dien-8α,12-olide (**4**) (Ulubelen et al, 1985), 1β,10α, 4α,5β-diepoxyglechoman-8α,12-olide (**6**), previously reported as a semi-synthetic derivative (Stahl and Datta, 1972), and 1β,10α, 4α,5β-diepoxy-8α hydroxy-glechoman-8α,12-olide (**7**) (Ulubelen et al., 1985).

The EIMS of **1** displayed a molecular ion peak $[M]^+$ at m/z 264, suggesting the molecular formula $C_{15}H_{20}O_4$ and six degrees of unsaturation. The IR spectrum (KBr) of **1** showed an intense broad absorption band around 3400 cm^{-1}, for hydroxyl groups, 1762 cm^{-1}, for α,β-unsaturated lactone functionality. The ^{13}C and ^1H NMR spectra of **1** (Table 1) were in agreement with a dihydroxy C-8,12 eudesmanolide skeleton for **1** (Ulubelen et al., 1985). The oxygenated doublet of doublets resonating at δ 3.78 ($J = 7.5$ and 7.5) (Table 1), which correlated with the methine carbon resonating at δ 75.2, was assigned to H-1. This was based on the observed ^3J-HMBC coupling between C-1 and the methyl proton singlet resonating at δ 1.59 (H_3-14) (Fig. 1). This was further supported by the observed COSY couplings between H-1 and both proton signals resonating at δ 2.45 and 2.30 (H_2-2). The high $J_{1,2}$ values suggested the α-configuration of H-1 and indicated its axial orientation (Ulubelen et al., 1985). Both H_2-2 also displayed COSY couplings with the broad olefinic singlet resonating at δ 5.40 (H-3) which in turn displayed a ^3J-HMBC coupling with the methyl carbon at δ 21.0 (C-15) (Fig. 1).

The downfield quaternary carbon resonating at δ 105.1 was assigned to C-8. This was suggested by its ^3J-HMBC couplings with both proton signals resonating at δ 2.89 and 2.56 (H_2-6). The carbonyl ester C-12 (δ_C

[a] In pyridine-d_5, 400 MHz for ^{1}H and 100 MHz for ^{13}C NMR. Carbon multiplicities were determined by DEPT135° experiments. *s* = Quaternary, *d* = methine, *t* = methylene, *q* = methyl carbons, coupling constants *(J)* are in Hz, U = unobserved.
[b] In $CDCl_3$, 500 MHz for ^{1}H and 125 MHz for ^{13}C NMR.
[c] In $CDCl_3$, 400 MHz.
[d] Long range with proton number 6 (Ulubelen and Goren, 1986).

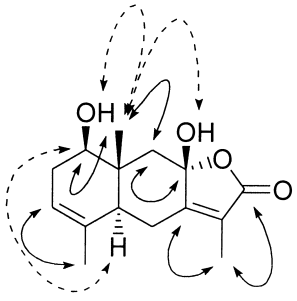

Fig. 1. Important HMBC (solid lines) and NOESY (dashed lines) correlations of **1**.

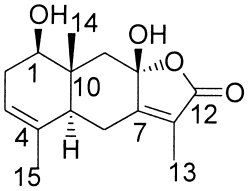
172.7) displayed a ^{3}J-HMBC coupling with the proton methyl singlet resonating at δ 1.87 (H_3-13).

The assignment of the relative stereochemistry of **1** was further supported by NOESY data (Fig. 1) and the study of Drieding model. Thus, the β-oriented C-14 methyl singlet displayed NOESY correlations with both exchangeable proton singlets at δ 6.32 (C-1 OH) and 9.42 (C-8 OH), confirming their β-orientation. Likewise, the α-oriented H-1 was NOESY-correlated with the broad doublet resonating at δ 2.10 (H-5), suggesting their location on the same face of **1**. Compound **1** was, therefore, identified as the new sesquiterpene 1β,8β-dihydroxyeudesm - 3,7(11) - dien - 8α,12 - olide (**1**). It is worth noting that the C-1 acetoxy derivative of **1** was previously reported from *Smyrnium galaticum* (Ulubelen and Goren, 1986).

The EIMS of **2** displayed a molecular ion peak $[M]^+$ at *m/z* 264, suggesting the same molecular formula of **1** ($C_{15}H_{20}O_4$). The IR spectrum (KBr) of **2** showed a similar pattern to those of **1** with an additional absorption band at 890 cm^{-1}, characteristic for an exocyclic methylene group. The ^{13}C and ^{1}H NMR spectral data of **2** (Table 1) were in agreement with those of **1** with the replacement of the $\Delta^{3,4}$ with $\Delta^{4,15}$ system. The two olefinic proton doublets resonating at δ 4.96 and 4.77 which correlated with the methylene carbon at δ 107.6 were assigned H_2-15. Both protons displayed ^{3}J-HMBC couplings with C-5 (δ 50.0) and C-3 (δ 34.3) and ^{2}J-HMBC coupling with the quaternary olefinic carbon at δ 148.8 (C-4). Therefore, **2** is the deacetylated derivative of compound **4**. In fact, comparing the ^{1}H NMR data of **2** in $CDCl_3$ with those of **4** (Table 1) indicate that having significant difference of H_1 proton being 3.35 (*dd*, J = 11.5, 4.4 Hz) in **2** while it is 4.57 (*dd*, J = 11.6, 4.7 Hz) in **4**. Hence, compound **2** was proved to be 1β,8β-dihydroxyeudesm-4(15),7(11)-dien-8α,12-olide.

The EIMS of **5** displayed a molecular ion peak $[M]^+$ at *m/z* 280, suggesting the molecular formula $C_{15}H_{20}O_5$ and six degrees of unsaturation. The IR spectrum (KBr)



1

	R_1	R_2
2	OH	OH
3	OAc	H
4	OAc	OH

	R_1	R_2
5	OH	H
6	H	H
7	H	OH

of **5** showed an absorption band at 3637 cm^{-1} for hydroxyl group and 1756 cm^{-1} for α,β-unsaturated lactone functionality. The ^{13}C and ^{1}H NMR spectra of **5** (Table 1) suggested a monohydroxy C-8, 12 germacranolide skeleton for **5** (Stahl and Datta, 1972; Ulubelen et al., 1985). The oxygenated doublet of doublets resonating at δ 4.69 ($J=6.5$ and 2.9) (Table 1), which correlated with the methine carbon resonating at δ 68.8, was assigned to H-6. This was based on the observed COSY coupling between H-6 and the proton doublet resonating at δ 3.19 (H-5) and the exchangeable proton doublet at δ 2.68 (C-6 OH). The proton H-6 displayed ^{3}J-HMBC coupling with C-4 (δ 60.0) and C-11 (δ 129.6). A ^{2}J-HMBC coupling was also observed between H-6 and C-7 (δ 156.6). The proton doublet of doublets resonating at δ 5.44 which correlated with the oxygenated methine carbon at δ 78.6 was assigned H-8. This was based on its COSY coupling with the doublet of doublets resonating at δ 2.97 and 1.84 (H_2-9). The methylene H_2-9 displayed a ^{3}J-HMBC coupling with C-14 methyl singlet (δ_C 17.4).

Once again, the assignments of the relative stereochemistry of **5** were based on NOESY data. Thus, the β-oriented C-14 methyl singlet displayed NOESY correlation with the proton doublet of doublets at δ 2.97 (H-9b) which in turn showed cross peak with H-8, confirming their β-orientation. The exchangeable proton doublet at δ 2.68 showed NOESY correlation to the methyl singlet at δ 1.25 (H_3-15), suggesting their β-orientation. Likewise, the α-oriented H-1 was NOESY-correlated with the proton doublet resonating at δ 3.19 (H-5), suggesting their location on the same lower face of **5**. Compound **5** was therefore identified as the new germacranolide 1β, 10α, 4α, 5β-diepoxy-6β-hydroxyglechoman-8α,12-olide.

The CH_2Cl_2 extract of the fruits of *S. olusatrum* exhibited significant in vitro cytotoxicity (IC_{50} 9.0 μg ml^{-1}) against P-388 mouse lymphoma cells. (Carmichael et al., 1987; Twentyman and Luscombe, 1987). However, the isolated compounds (**1**, **2**, **3**, **4**, **6** and **7**) showed marginal activity with IC_{50} 60, 65, 42, 58, 94 and 88 μg ml^{-1}, respectively.

3. Experimental

3.1. General

Mps: uncorrected, Yanagimoto MP-3 micro mp apparatus. ^{1}H and ^{13}C NMR: $CDCl_3$ or pyridine with TMS as int. standard, Bruker AM 400 and Bruker AM 500 2D NMR (COSY, NOESY, HMQC and HMBC), EI–MS: 70 eV, Hitachi M-80 or VG Autospec. IR: KBr on a Jasco A-302 or Perkin Elmer 1710. UV: CH_3OH, Hitachi 557. Prep. HPLC: Rp-18 column (10 μm, 30×2.15 cm i.d.). MPLC Rp-18 column (20 μm, 10×2.15 cm i.d.). Kusano Scientific Co. CC: Kieselgel 60, anal. TLC: silica gel $60F_{254}$ and RP-18 F_{254} (0.25 mm) precoated plates. Spots detection: UV light at 254 and/or spraying with 10% H_2SO_4. Cytoxicity bioassay: Tosoh MPR-A4i microplate reader.

3.2. Plant material

The fruits of *Smyrnium olusatrum* were collected from the moist and shady places of the Gebel Akhdar area in Libya in 1996. The plant was identified by Professor Dr. Elgady, Faculty of Science, El-Faateh University, Tripoli, Libya. A voucher specimen is deposited in the Pharmacognosy Department, Faculty of Pharmacy, Mansoura University, Mansoura, Egypt.

3.3. Extraction and isolation

Air dried powdered fruits (750 g) were extracted to exhaustion by hot 70% methyl alcohol. The methanolic extract was concentrated under reduced pressure to give about 100 g of the total extract ($IC_{50}=10.2$ μg ml^{-1} to P-388 cell line). The extract was treated with a minimum volume of alcohol diluted with water and successively partitioned with pet. ether, CH_2Cl_2 and *n*-butanol. The CH_2Cl_2 extract (13 g, $IC_{50}=9$ μg ml^{-1} to P-388 cell line) was applied to the top of silica gel packed column (390 g) and eluted with pet. ether—EtOAc gradient. Similar fractions were combined and subjected either to direct crystallization or to further chromatographic purifica-

tion on normal and C-18 reversed phase silica (using MPLC and HPLC). The CH_2Cl_2 extract afforded four main fractions, fractions 13–15, fraction 20, fractions 26–29 and fractions 30–35. Direct crystallization of fractions 13–15 and 20 gave compounds **3** (70 mg) and **4** (80 mg) respectively. Fractions 26–29 were further purified by using MPLC with H_2O:CH_3CN gradient to give compound **7** (60 mg). Fractions 30–35 were applied to the top of a silica gel packed column using CH_2Cl_2: MeOH gradient to give three main subfractions. Subfractions 6–8 afforded compound **6** (40 mg) on direct crystallization from MeOH while subfractions 13-16 and 19–22 were further purified using HPLC on Rp-18 column with CH_3CN:H_2O (20:80 and 30:70). Fractions 13–16 gave compound **7** (30 mg) while fractions 19–22 gave compounds **1**, **2** and **5** (20, 30 and 3 mg respectively).

Received 11 January 2001; received in revised form 27 April 2001

Abstract

Two monoterpene coumarins, designated ferulagol A and B, as well as three known monoterpene coumarins and three sesquiterpene lactones were isolated from the chloroform extract of the roots of *Ferula ferulago*. The structures of ferulagol A and B were determined to be 7-[(*E*)-3′-hydroxy-3′,7′-dimethyl-4′,6′-octadienyloxy]coumarin and 7-[(3′*Z*,5′*E*)-7′-hydroxy-3′,7′-dimethyl-3′,5′-octadienyloxy]coumarin, respectively. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Ferula ferulago*; Umbelliferae; Roots; Monoterpene coumarin

1. Introduction

Members of the genus *Ferula* are widespread throughout Central Asia and Mediterranean area. The gum resins, which are obtained by incision of the roots of several species are used as spices and drugs in many countries and the resins have been reported to cure stomachic, vermifuge and carminative disorders (Boulus, 1983). The extract of the roots of *Ferula ferulago* enjoys a reputation as a folk medicine and is used as an antispasmodic. The chemistry of the genus *Ferula* has been studied by many groups. The widespread compounds in this genus are characteristic sesquiterpenes (Gonzalez and Barrera, 1995; Appendino et al., 1997; Chen et al., 2000), and sesquiterpene coumarins (Murray, 1989; Ahmed, 1999). Only a few monoterpenes (Grag and Agarwal, 1988; Grag et al., 1989) have been detected. Recently, it has been reported that terpene coumarins showed anti-HIV activity (Zhou et al., 2000). Here we report the isolation and structure elucidation of the two new monoterpene coumarins designated ferulagol A (**1**) and B (**2**).

2. Results and discussion

Finely ground dried roots of *F. ferulago* were extracted with chloroform, and the extract was subjected to column chromatography to give ferulagol A (**1**) and ferulagol B (**2**), as well as three known monoterpene coumarins, 6-methoxy-7-geranyloxy coumarin (**3**) (Talapatra et al., 1973), diversinin (**4**) (Kiseleva et al.,1975), and diversin (**5**) (Kir'yalov, 1969; Kiseleva et al., 1975), and three sesquiterpene lactones malafil (**6**), malafilin (**7**), and malafilinin (**8**) (Rychlewska et al., 1985). Compounds **3** and **5** have been reported from *Feronia elephantum* (Talapatra et al., 1973), and *Machaeranthera scabrella* (Bohlmann and Grenz, 1976), respectively. Monoterpene coumarins **4** and **5** were detected in *F. diversivitata* (Kir'yalov, 1969; Kiseleva et al., 1975).

Ferulagol A (**1**) was shown by HRFABMS (*m*/*z* 315.1611 $[M+H]^+$, Δ +1.4 mmu) to have the molecular formula $C_{19}H_{22}O_4$. The UV and IR spectra showed the presence of hydroxyl and carbonyl groups, and carbon–carbon double bonds. Compound **1** was characterized primarily from its ^1H NMR spectrum (Table 1). This revealed a pattern of aromatic protons typical for a coumarin nucleus substituted only at C-7. The ^{13}C NMR spectrum displays nineteen carbon atoms among which were detected nine sp^2 carbon atoms of the coumarin nucleus and the 10 carbons for a side-chain, which included three methyls, one methylene attached to an oxygen function, one sp^3 methylene, one tertiary alcoholic carbon, and four olefinic carbons. After assignment of all protons directly bonded with carbon atoms by the ^1H–^{13}C shift-correlated measurement (HMQC spectrum), it was possible to assume from ^1H–^1H COSY and HMBC that **1** was a monoterpene coumarin. The ^1H–^1H COSY spectrum showed correlations between the downfield shifted olefinic proton at δ_H 6.49 (1H, *dd*) and the other two olefinic protons at δ_H 5.65 (1H, *d*) and 5.85 (1H, *d*). It is clear from the coupling constant that the geometry of the 4′,5′ double bond is *trans*. Geminal dimethyl protons H_3-8′ and H_3-9′ showed HMBC correlations to olefinic carbons at δ_C 135.9 (C-7′) and 124.2 (C-6′). The remaining methyl protons H_3-10′ showed HMBC correlations to sp^3 methylene carbon at δ_C 40.8 (C-2′), the quaternary carbon at δ_C 72.4 (C-3′), and the olefinic carbon at δ_C 136.2 (C-4′). These findings revealed the side chain structure (C-1′–C-10′). Further, the methylene protons at δ_H 4.21, 4.19 (H-1′) showed an HMBC correlation to an aromatic carbon δ_C 161.9 (C-7), indicating that the side chain is attached to C-7 of the coumarin moiety via an ether linkage. Thus, the structure of **1** was 7-[(*E*)-3′-hydroxy-3′,7′-dimethyl-4′,6′-octadienyloxy]coumarin.

The molecular formula of ferulagol B (**2**) is the same as ferulagol A (**1**) and it was determined to be $C_{19}H_{22}O_4$ by HRFABMS. The IR and UV spectra of **2** were almost identical to those of **1**. The ^1H and ^{13}C NMR spectral data are shown in Table 1. The ^{13}C NMR and DEPT spectral data showed 19 carbons including 3 methyls, two methylenes, 8 methines and 6 quaternary carbon atoms. Extensive NMR experiments (^1H–^1H COSY, HMQC and HMBC) indicated that **2** resembled **1**. All of the signals were assigned by a detailed comparison of NMR spectral data with those of **1** and 7-[(*E*)-7′-hydroxy-3′,7′-dimethyl-2′,5′-octadienyloxy]coumarin (Quader et al., 1992), except for resonances due to the monoterpenyloxy side-chain. The ^1H NMR spectrum contained a series of mutually coupled proton signals at δ_H 5.95 (1H, *d*), 6.46 (1H, *dd*), and 5.76 (1H, *d*), that indicate the presence of conjugated double bonds. The ^1H–^1H COSY spectrum of **2** clarified the connection of the carbon bonds at 3–4, 5–6–8, 1′–2′, and 4′–5′–6′. The H_3–8′ and H_3–9′ dimethyl protons showed HMBC correlations to carbon signals of C-7′ (δ_C 70.7, s) and C-6′ (δ_C 140.3, *d*). The ^{13}C chemical shift of C-7′ and the ^1H

[a] HMQC allowed assignments of protonated carbons.
[b] Signals may be interchangeable.
[c] Signals may be interchangeable.

resonances attributed to two methyls at δ_H 1.31 suggested that C-7′ should be hydroxylated. Also, the olefinic proton 5′-H (δ_H 6.46) showed HMBC correlations to C-7′ and C-3′ (δ_C 133.7, s). Moreover, there were clear HMBC correlations of H_3-10′ with carbon signals C-2′ (δ_C 31.8, t), C-3′ (δ_C 133.7, s) and C-4′ (δ_C 127.5, *d*). The chemical shift of the C-10′ signal at δ_C 24.1 is typical of a *cis* methyl group with respect to an olefinic proton, which was supported by an NOE experiment. Thus, the structure of **2** was 7-[(3′*Z*,5′*E*)-7′-hydroxy-3′,7′-dimethyl-3′,5′-octadienyloxy]coumarin.

3. Experimental

3.1. Plant material

Roots of *F. ferulago* were obtained from the local market in Egypt, in April 1999. A voucher speciment (A. Ahmed 111) is deposited in the Department of Botany, El-Minia University.

3.2. Isolation and purification

Finely ground dried roots (250 g) of *F. ferulago* was soaked in chloroform for 24 h at room temperature, the extract was concentrated, and the residue (60 g) was subjected to silica gel flash chromatography using a step wise gradient with hexane–ether. The ether fraction was applied to a silica gel column with hexane–chloroform (1:4). Fractions of interest were applied to Sephadex LH-20 (hexane–EtOAc, 1:1), and finally preparative TLC to give new compounds **1** (35 mg) and **2** (27 mg), as well as coumarins, 6-methoxy-7-geranyloxy coumarin (**3**) (20 mg), diversinin (**4**) (17 mg), diversin (**5**) (40 mg), and three known sesquiterpenes lactone and malafil (**6**) (30 mg), malafilin (**7**) (60 mg), and malafilinin (**8**) (49 mg).

Abstract

Three quassinoids, iandonosides A and B and iandonone, were isolated from the root of *Eurycoma harmandiana,* along with five known quassinoids, casteloside B, 13 β, 21-dihydroeurycomanone, chaparrinone, glaucarubolone and ailanquassin B as well as the coumarin, scopoletin. The structural elucidations were based on analyses of spectroscopic data. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Eurycoma harmandiana; Simaroubaceae; Quassinoids, Iandonoside A; Iandonoside B; Iandonone; Iandonol

1. Introduction

Eurycoma harmandiana Pierre is a small Simaroubaceous plant (Thai name: Ian-don) distributed in the border regions between Thailand and Laos. In a previous paper (Kanchanapoom et al., 2001), we reported the isolation and structural elucidation of canthin-6-one and β-carboline alkaloids. Further investigation of the root of the same plant afforded nine compounds (**1**–**9**), which included three new unusual 15α-OH quassinoids (**2**, **3**, **5**) together with five known quassinoids (**1, 4, 6**–**8**) and one known coumarin (**9**). The present paper deals with the structural determination of these compounds.

2. Results and discussion

From the ethanolic extract of the roots of *E. harmandiana,* nine compounds (**1**–**9**) were isolated. Five were identified as known quassinoids; casteloside B (**1**) (Chaudhuri and Kubo, 1992), l3β,21-dihydroeurycomanone (**4**) (Morita et al., 1990), chaparrinone (**6**), glaucarubolone (**7**) (Chaudhuri and Kubo, 1992) and ailanquassin B (**8**) (Aono et al., 1994) together with one known coumarin, scopoletin (**9**) by physical data and spectroscopic evidence.

Iandonoside A was obtained as an amorphous powder and determined as $C_{26}H_{38}O_{13}$ by HR–FAB mass spectrometry. The ^{13}C NMR spectrum revealed the presence of one β-glucopyranosyl unit together with 20 carbon signals for the aglycone, which suggested a C_{20} quassinoid skeleton. DEPT experiments indicated the presence of three methyls, two methylenes, 10 methines, as well as five quaternary carbons in the aglycone moiety. The signals at δ 72.3 (C-20) and 110.9 (C-11) in the ^{13}C NMR spectrum were characteristic of an 11β,20-hemiketal moiety. Comparison of the ^{1}H and ^{13}C NMR spectral data of **2** with those of **1** revealed the same relative arrangement of carbons and protons in rings A and B. The chemical shifts of rings C and D suggested differences in the relative configuration of hydroxyl group at C-15. The complete assignments were established by using HSQC, NOESY, difference NOE spectral experiments (Fig. 1) and the coupling constants in the ^{1}H NMR spectrum (Table 1). Irradiation of the H-20 signal (δ 3.70) gave rise to NOE enhancements at H-13 (δ 2.81), H-14 (δ 2.10) indicating the presence of α-configuration of Me-21 (δ 1.24) and β-configuration of H-14. The coupling constant of H-12 (δ 3.97, *d*, $J=5.0$ Hz) confirmed the α-configuration for the hydroxyl group at C-12. The configuration of the hydroxyl group at C-15 was assigned as α by the coupling constant of H-15 (δ 4.50, *d*, $J=4.6$ Hz), and further support was

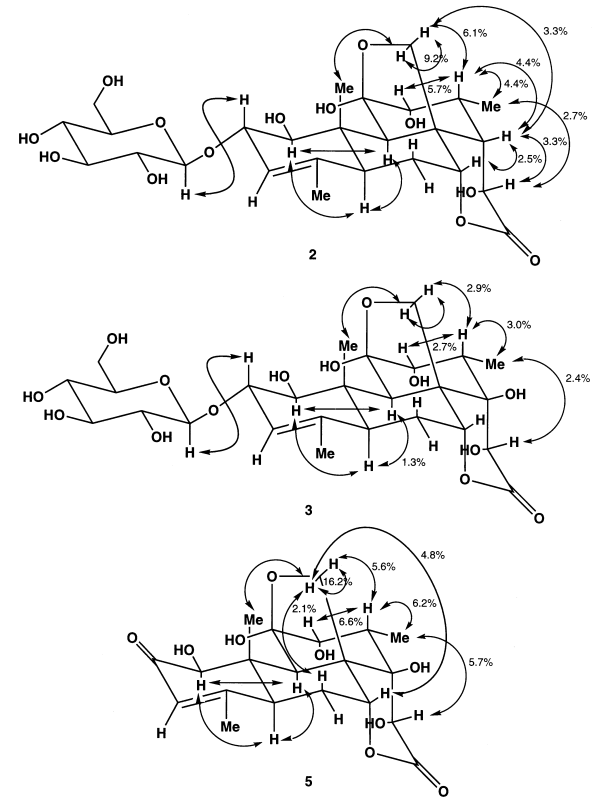

Fig. 1. NOESY and NOE enhancements of **2**, **3** and **5**.

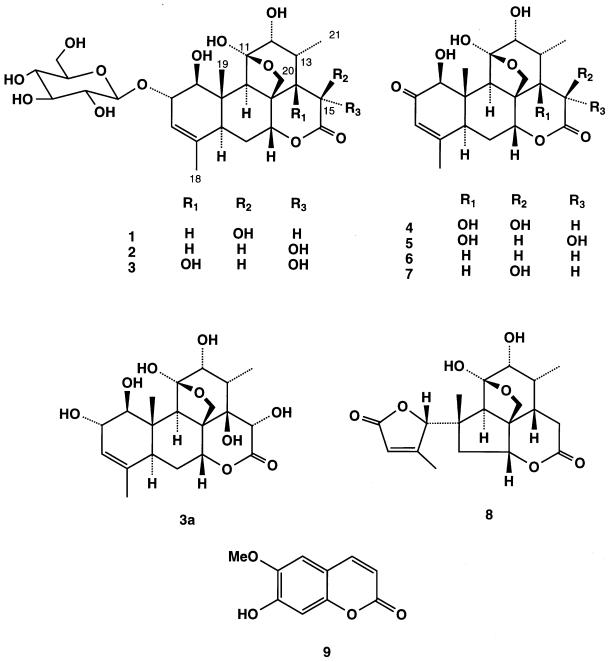

obtained by irradiation of the signal at H-15 which exhibited the NOE enhancements at H-14 and Me-21 but no enhancement at H-9 (δ 3.53). Consequently, the structure of **2** was elucidated as shown.

Iandonoside B (**3**) was obtained as an amorphous powder and determined as $C_{26}H_{38}O_{14}$ by HR–FAB mass spectrometry. Inspection of the ^{13}C NMR spectrum showed the presence of one β-glucopyranosyl unit and 20 carbon signals for the aglycone, which indicated it to be a C_{20} quassinoid glucoside. On enzymatic hydrolysis with crude hesperidinase (Kohda and Tanaka, 1975), **3** gave the new aglycone, named iandonol (**3a**). On going from **3** to **3a**, the chemical shifts were changed for C-2, C-1 and C-3 by +11.2, −1.3 and −2.3 ppm, respectively. This confirmed the location of the glucopyranosyl moiety on C-2. The ^1H and ^{13}C NMR spectral data were similar with those of **2**. However, the signal for H-14 was absent as well as the signal for H-15 (δ 4.73) appeared as singlet. In addition, the carbon signals for C-l4, C-13 and C-15 showed different chemical shifts at δ 76.6, 41.4 and 76.1 (Table 2), respectively, indicating the replacement of a proton (H-14) by a hydroxyl group. The relative configurations were confirmed by using the coupling constants in the ^1H NMR spectrum (Table 1), NOESY and difference NOE spectral experiments (Fig. 1). On irradiation of the signal at δ 2.95 (H-13), the intensity of H-20 (δ 4.53) was enhanced, and irradiation of the H-15 signal (δ 4.73) caused as determined increase in the NOE enhancement at Me-21 only (δ 1.45). Upon irridiation of the H-9 signal (δ 3.88), NOE enhancement was observed for the H-5 a signal (δ 2.76) but not for either the H-12 (δ 4.17) or H-15 (δ 4.73) signals. Thus, the stereochemistry of the hydroxyl groups at C-12 and C-15 were assigned as α, α-configurations, and the also Me-21 has an α-configuration. On the basis of these spectral data, the structure of **3** was determined as the 14β-hydroxy analogue of iandonoside A.

Iandonone (**5**) was obtained as an amorphous powder, with a molecular formula of $C_{20}H_{24}O_9$ by HR–FAB mass spectrometry. The ^{13}C NMR spectrum revealed the presence of 20 carbons, including a δ-lactone carbonyl (δ 171.9), an α,β-unsaturated ketone carbonyl carbon (δ 197.4) and two olefinic carbons (δ 126.2 and 162.2) indicative of a C_{20} quassinoid skeleton. Iandonone showed the same chemical shifts for rings B, C and D with those of **3**, and the chemical shifts of ring A were in full agreement with those of **4**. The stereochemistry of three hydroxyl groups at C-1, C-12 and C-15 were also confirmed by using NOESY difference NOE experiments (Fig. 1) and the coupling constants in the ^1H NMR spectrum (Table 1), led to deduce as β,α,α-configurations, respectively. Therefore, the structure of **5** was elucidated as shown.

100 MHz for ^{13}C NMR) with tetramethylsilane (TMS) as internal standard. MS were recorded on a JEOL JMS-SX 102 spectrometer. Preparative HPLC was carried out on columns of ODS (150×20 mm i.d., YMC) and polyamine II (250×20 mm i.d., YMC) with a Tosoh refraction index (RI-8) detector. The flow rate was 6 ml/min. For CC, silica gel G 60 (Merck), RP-l8 (50 mm, YMC) and highly porous copolymer of styrene and divinylbenzene (Mitsubishi Chem. Ind. Co. Ltd) were used. The solvent systems were: (I) EtOAc–MeOH (9:1), (II) EtOAc–MeOH–H_2O (4:1:0.1), (III) EtOAc–MeOH –H_2O (7:3:0.3), (IV) EtOAc–MeOH–H_2O (6:4:1), (V) 30–50% MeOH, (VI) 80% MeCN, (VII) 12% MeCN, (VIII) 10% MeCN, (IX) CH_2Cl_2, (X) CH_2C1_2–MeOH (19:1), (XI) CH_2Cl_2–MeOH (9:1), (XII) CH_2Cl_2–MeOH (4:1), (XIII) 40–100% MeOH, (XIV) 50–100% MeOH.

3.2. Plant material

The root of *Eurycoma harmandiana* was collected in May 1998 from Nong Khai Province, north-eastern Thailand. The identification of the plant was confirmed by Professor Vichiara Jirawongse, Department of Pharmaceutical Botany and Pharmacognosy, Faculty of Pharmaceutical Sciences, Khon Kaen University. A voucher sample (KKU-0017) is kept in the Herbarium of the Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand.

3.3. Extraction and isolation

The dried root (7.0 kg) of *E. harmandiana* was extracted with 95% EtOH. After removal of the solvent by evaporation, the residue (200 g) was extracted with CH_2Cl_2, EtOAc and *n*-BuOH, successively. The *n*-BuOH extract (45.0 g) was subjected to a column of highly porous copolymer of styrene and divinylbenzene, and eluted with H_2O, MeOH and Me_2CO, successively. The fraction eluted with MeOH was applied to a silica gel column (systems I, II, III and IV, successively) affording nine fractions. Fraction 5 was subjected to a column of RP-18 using system V, then followed by HPLC-polyamine II (system VI) and HPLC–ODS (system VII) to provide compounds **1** (5 mg), **2** (4 mg) and **3** (30 mg). The EtOAc extract (27.5 g) was further separated on a column of RP-18 (system V), and finally purified by HPLC–ODS (system VIII) to give compounds **4** (84 mg) and **5** (21 mg). The CH_2C1_2 extract (90.0 g) was subjected to a column of a silica gel (systems IX, X, XI and XII) affording six fractions. Fraction 2 was repeatedly chromatographed on a silica gel column using gradient system (CH_2Cl_2 to 5% MeOH in CH_2Cl_2) to provide six fractions. Fraction 2-2 was further purified by using a RP- 18 column (system XIII) to afford compounds **9** (53 mg). Fraction 2-4 was similarly purified by using a RP-18 column (system XIV) to give compound **6** (268 mg). Fraction 2-6 was applied to a column of silica gel (system I), this being followed by HPLC–ODS (system VII) to afford compounds **7** (24 mg) and **8** (13 mg).

3.4. Iandonoside A (*2*)

Amorphous powder. $[\alpha]_D^{20}$ +19.1° (MeOH, *c* 0.3); ^{1}H NMR: Table 1; ^{13}C NMR: Table 2; negative HR–FAB–MS, *m*/*z*: 557.2258 $[M-H]^-$ ($C_{26}H_{37}O_{13}$ requires 557.2234).

3.5. Iandonoside B (*3*)

Amorphous powder. $[\alpha]_D^{20}$ +4.1° (MeOH, *c* 0.7); ^{1}H NMR: Table 1; ^{13}C NMR: Table 2; negative HR–FAB–MS, *m*/*z*: 573.2148 $[M-H]^-$ ($C_{26}H_{37}O_{14}$ requires 573.2183).

3.6. Enzymatic hydrolysis of iandonoside B (*3*)

Iandonoside B (**3**) 8 mg was dissolved in 0.5 ml of MeOH. A solution of crude hesperidinase (100 mg in 20 ml of H_2O) was added. After shaking at 37 °C for 24 h, the mixture was extracted with EtOAc. The EtOAc extract was evaporated to provide a new aglycone, iandonol (**3a**) 3 mg. The structure was identified by ^{1}H and ^{13}C NMR spectral analysis.

3.7. Iandonol (*3a*)

Amorphous powder. $[\alpha]_D^{20}$ −72.6° (MeOH, *c* 0.2); ^{1}H NMR: Table 1; ^{13}C NMR: Table 2; positive HR–FAB–MS, *m*/*z*: 411.1691 $[M-H]^-$, ($C_{20}H_{27}O_9$ requires 411.1655).

3.8. Iandonone (*5*)

Amorphous powder. $[\alpha]_D^{20}$ +4.6° (MeOH, *c* 0.4); ^{1}H NMR: Table 1; ^{13}C NMR: Table 2; positive HR–FAB–MS, *m*/*z*: 409.1468 $[M-H]^-$ ($C_{20}H_{25}O_9$ requires 409.1498).

Three clerodane diterpenoids from *Croton eluteria* Bennett

Claire Vigor*, Nicolas Fabre, Isabelle Fourasté, Claude Moulis

Laboratoire Pharmacophores Redox, Phytochimie et Radiobiologie, Faculté des Sciences Pharmaceutiques, 35 chemin des Maraîchers, F-31062 Toulouse, France

Received 13 November 2000; received in revised form 29 March 2001

Abstract

Three furanoid clerodanes have been isolated from the stem bark of *Croton eluteria* Bennett. Their structures have been established by spectroscopic methods. The compounds were named cascarillin B (7α-acetoxy-3,4,15,16-diepoxy-12-oxo-cleroda-13(16),14-dien-20-al), cascarillin C (7α-acetoxy-15,16,12,20-diepoxy-20-hydroxy-cleroda-3,4,13(16),14-triene) and cascarillin D (7α-acetoxy-3,4,15,16-diepoxy-cleroda-13(16),14-dien-20-al). © 2001 Elsevier Science Ltd. Keywords: *Croton eluteria* Bennett; Euphorbiaceae; Furanoid diterpene; Clerodane

1. Introduction

Cascarilla bark, obtained from *Croton eluteria* Bennett (Euphorbiaceae) is a shrub or small tree indigenous to the Bahama Islands. It was reported to be balsamic, digestive, hypotensive, narcotic, stomachic and tonic (Greenish, 1924).

It has been used as a traditional medicine for many applications such as for dysentery, dyspepsia, malaria and fever (Duke, 1984).

From the phytochemical point of view, some terpene derivatives were previously reported and specially some *ent*-clerodane furano-diterpenoids: cascallin, cascarillone and cascarillin A (Halsall et al., 1965; Hegnauer, 1966; Claude-Lafontaine et al., 1976; Hagedorn and Brown, 1991). In this paper, we describe the isolation and structural elucidation of three new related compounds from the stem bark of *C. eluteria* Bennett.

2. Results and discussion

The molecular formula $C_{22}H_{28}O_6$ of compound **1** was determined by ESI mass spectrometry mesured in the positive ion mode (*m/z* 389.2 $[M+H]^+$, *m/z* 411.2 $[M+Na]^+$). Its ^{13}C NMR decoupled spectrum (Table 1) showed 22 signals in agreement with the molecular formula. The characteristic NMR signals for a furan ring were present in the ^1H and ^{13}C NMR spectra (δ_H 6.64 *br s,* 7.40 *br s*, 8.03 *br s*; δ_C 108.6, 144.6, 147.5 and 128.9 *Cq*), as were those of an aldehyde group (δ_H 10.18 *s*; δ_C 206.0), an ester carbonyl group (δ_C 170.3) and a keto group (δ_C 193.6). These functional groups account for five of the six oxygens, and the remaining oxygen was involved in an epoxide unit as indicated by a singlet signal at δ_H 2.85 and δ_C 62.0. In addition, four methyl groups were present and were identified from their chemical shifts and coupling patterns as a doublet for C-17 (δ_H 1.01 *d*, $J=7.3$ Hz; δ_C 13.7), two singlets (C-18: δ_H 1.12 *s*; δ_C 19.9 and C-19: δ_H 1.06 *s*; δ_C 19.2) and an acetyl group (δ_H 2.04 *s*; δ_C 21.6).

Considering the quaternary carbons (δ_C 36.3 and 56.0), the C–H group (δ_C 48.5) and their heteronuclear correlations displayed in the HMBC spectrum, these signals could be assigned, respectively, to carbons C-5, C-9 and C-10 of the decalin moiety. The position of the aldehyde group was deduced from the HMBC spectrum which exhibited cross peaks between the aldehyde carbon and H-8, H-11 and the aldehyde proton with C-9, C-11 (Fig. 1). Its chemical shift agrees with an aldehyde group that we assigned to C-9. The location of the epoxide group (C-3–C-4) was deduced from the HMBC spectrum correlations between C-3 (δ_C 62.0) and H-1a, H-2a, H-18 and C-4 (δ_C 65.1) with H-18, H-19, H-6a, H-6b, H-2a; Fig. 1. In the same way, the acetoxy group was located on position C-7 (correlations

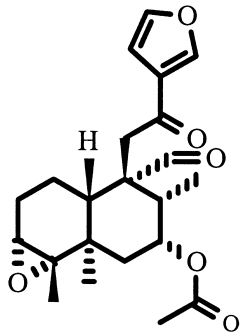
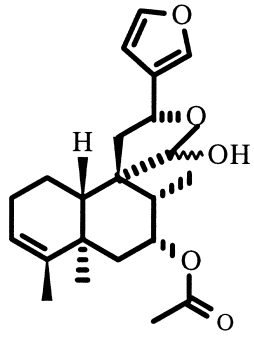
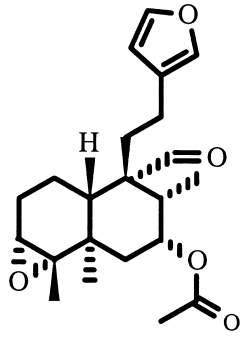
between acetate protons (δ_H 2.04 *s*) and C-7), and the keto group in position C-12 (correlations between the quaternary carbon signal at δ_C 193.6 and H-11a, H-11b and H-14; Fig. 1).



Compound **1**



Compound **2**



Compound **3**

The ^{13}C NMR signal of the shielded Me-19 (δ_C 19.2) suggested a *trans* A/B ring junction for decalin as previously discussed by Manabe and Nishino (1986). The α orientation for the C-3–C-4 epoxy group was proposed on the basis of the ^1H NMR signals of the shielded Me-19 protons (δ_H 1.06 *s*) (Manabe and Nishino, 1986). Finally, an α orientation for the acetoxy group was proposed on the basis of the *J* value $J_{8\beta-7\beta} = 4$ Hz which is in accordance with axial-equatorial coupling and corresponds to an approximate dihedral angle H-7β–H-8β of 70°. This was supported by the coupling constant values of H-6 (see Table 1) and the values reported in the literature (Bedir et al., 1999; Tori et al., 1999).

Thus, these data allowed us to establish **1**, as 7α-acetoxy-3,4,15,16-diepoxy-12-oxo-cleroda-13(16),14-dien-20-al, which we named cascarillin B.

The positive ESI mass spectrum of compound **2** showed peaks at *m/z* 397.2, *m/z* 413.2 and *m/z* 337.0 corresponding to $[M+Na]^+$, $[M+K]^+$, and $[M-OCOCH_3+Na]^+$ respectively, suggesting a $C_{22}H_{30}O_5$ formula. The acetoxy group was still present as supported by the ESI mass spectral data, the carbon at δ_C 172.4, and three protons at δ_H 2.06 ppm. The HMBC spectrum did not allow us to locate the acetoxy group. But, the ^1H–^1H COSY spectrum showed a cross peak between H-17 (δ_H 1.13, d, $J = 7.3$ Hz) and H-8 (δ_H 1.66, *dd*, $J = 7.3$, 3 Hz). The latter proton ($J = 3$ Hz) correlates with a deshielded proton at δ_H 5.03 ppm (*m*) whose chemical shift is in agreement with a CH-7α-acetoxy as already described for **1**. Both epoxide and aldehyde groups were absent from **2** and replaced by a double bound and a lactol function, respectively. This was shown by the characteristic ^1H and ^{13}C NMR signals at δ_H 5.22 ppm (H-3), δ_C 122.3 (C-3) and δ_C 144.6 (C-4) for the first one, and at δ_H 5.85 ppm (H-20), δ_C 101.6 (C-20) and δ_H 5.08 ppm (H-12), δ_C 73.2 (C-12) for the second one. The spectrum unambiguously revealed the C-3–C-4 unsaturation (cross peaks between H-18/C-4 and H-18/C-3). This was confirmed by the ^1H–^1H COSY correlations (H-18/H3). In the same way, the C-20 carbon (δ_C 101.6), involved in the lactol function, was correlated in the HMBC spectrum with H-8, H-11b and H-12. The correlations of C-9 with H-10, H-17, H-11a, H-11b and H-20, confirmed this result. The methine (C-12) at δ_C 73.2 was correlated with H-11b and H-20, and this proton displayed a cross peak with C-16 and C-20. Thus, the structure of **2** was established as 7α-acetoxy-15,16,12,20-diepoxy-20-hydroxy-cleroda-3,4,13(16),14-triene, which we named cascarillin C.

The molecular formula of compound **3** was determined as $C_{22}H_{30}O_5$ based on ESI mass spectrum $[M+Na]^+$ (*m/z* 397.3) and $[M+K]^+$ (*m/z* 413.3). Comparison of the spectral data of this compound with that of **1** indicated that compound **3** differed from **1** through the lack of a keto group in position C-12. These results led us to propose the structure 7α-acetoxy-3,4,15,16-diepoxy-cleroda-13(16),14-trien-20-al for compound **3**, which we named cascarillin D.

3. Experimental

3.1. Instrumentation

^1H NMR (400 MHz) and *J* mod. ^{13}C NMR (100 MHz) were obtained with CD_3OD or $CDCl_3$ as solvent,

on a Brücker ARX-400 spectrometer. Chemical shifts are given in δ (ppm) using the solvent peaks, δ_H 4.87, δ_C 48 ppm and δ_H 7.23, δ_C 77 ppm, respectively, as standards ; ESI–MS: 3.5 kV (MeOH–$CHCl_3$) (Perkin Elmer API Sciex 365 Mass spectrometer); HR–FAB (positive ion mode) mass spectra were recorded on an Autospec 6F mass spectrometer manufactured by Micromass.

3.2. Plant material

Croton eluteria Bennett, collected in Ecuador, was purchased from Richard et Frappa, Aubagne, France. Voucher specimens were identified by Professor Isabelle Fourasté and deposited at the herbarium of the Pharmacognosy Laboratory, Faculty of Pharmacy (Toulouse).

3.3. Extraction and isolation

Air-dried powdered bark (1 kg) of *C. eluteria* Bennett was extracted with Me_2CO at room temperature (24 h). The extract (70 g) was taken up in $CHCl_3$ and chromatographed on silica gel columns eluted with various proportions of $CHCl_3$ and MeOH. The fraction containing the main furanoid diterpenes (revealed on TLC by Ehrlich reagent) was evaporated to dryness and separated on 3 successive silica gel (70–200 μm) columns eluted with a hexane–EtOAc gradient.

Further purification of the crude diterpene by reverse-phase chromatography (Mega Band Elut Varian C18 cartridge: MeOH–H_2O 6:4), followed by medium

pressure (10 bars) silica gel chromatography (silica 60Å, CC chromagel SDS, 6–35 μm) eluted with toluene–EtOAc 95:5 and then another reverse-phase chromatography (C18 cartridge MeOH–H_2O 1:1) gave pure compound **1**.

Concerning compounds **2** and **3**, they were obtained by successive medium pressure (10 bars) silica gel chromatography (silica 60 Å, CC chromagel SDS, 6–35 μm) eluted with a toluene–EtOAc gradient, followed by reverse-phase chromatography (C 18 cartridge: MeOH–H_2O 13:7; 14:6) and preparative HPLC (Varian Dynamax 100 Å, MeOH–H_2O 7:3, 10 ml $min^{-1,}$ 204 nm; MeOH–H_2O 15:5, 10 ml min^{-1}, 204 nm).

Received 9 November 2000; received in revised form 30 January 2001

Abstract

The chloroform fraction of the defatted ethanol extract from the aerial parts of *Caralluma penicillata* yielded three C-15 oxypregnane glycosides, penicillosides A–C. Their structures were established by a combination of spectroscopic methods. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Caralluma penicillata*; Asclepiadaceae; C-15 Acylated oxypregnane glycosides

1. Introduction

In a continuation of our interest in the chemical composition of the genus *Caralluma,* the aerial parts of *Caralluma penicillata* (defl) M.E. Br. indigenous to the Kingdom of Saudi Arabia were investigated (Collenette, 1985). This plant has been used in Saudi traditional medicine for the treatment of snake and scorpion bites (Al-Yahya et al., 1983). A case of toxicity of *C. penicillata* was reported by Hamadan (1980) and was manifested by the death of 50 sheep over a period of 1 month due to grazing on the plant in the Aseer region of the Kingdom of Saudi Arabia. A study of the plant was undertaken by Al-Yahya and Tariq (1983), to evaluate its toxicity and pharmacological properties, and a phytochemical and biological screening was reported by Mossa et al. (1983).

In a previous study, the isolation of four new pregnane glycosides from *Caralluma russeliana* was reported (Al-Yahya et al., 2000). In the present study, we report on the isolation of three oxypregnane glycosides from *C. penicillata*.

2. Results and discussion

The defatted ethanol extract of the aerial parts of *C. penicillata* was suspended in water and extracted with diethyl ether, $CHCl_3$ and *n*-butanol. The $CHCl_3$ soluble fraction was subjected to repeated chromatography to afford three pregnane glycosides **1–3.** Compounds **1–3** gave positive tests for sterols (Liebermann–Burchard reagent) and sugars and/or glycosides, and a negative test for 2-deoxy sugars (Keller–Killiani).

Compound **1** was isolated as white needles, mp 215–217°C, $[\alpha]_D^{25}$ −30° and had a molecular formula $C_{41}H_{62}O_{15}$ as shown by electrospray ionization mass (ESI–MS; *m*/*z* 793 $[M-H]^+$ and 817 $[M+Na]^+$, in the negative and positive ion modes, respectively) and ^{13}C NMR spectroscopic data (DEPT). The IR spectrum of **1** showed the presence of a hydroxyl group (3400 cm^{-1}) and an ester carbonyl group (1720 cm^{-1}). The acid hydrolysis of **1** yielded two sugars, identified as glucose and digitalose, using TLC by comparison with authentic samples. The ^{13}C NMR (DEPT) spectrum of **1** revealed a total of 41 carbon signals, of which five corresponded to methyl carbons, nine to methylene carbons, 21 to methine carbons, and six to quaternary carbons. The NMR spectral data of **1** were very similar to those of russeliosides A–D, pregnane glycosides isolated from *C. russeliana* (Al-Yahya et al., 2000). In the ^1H and ^{13}C NMR spectra of **1**, the proton and carbon signals due to the sugar portion were

3	Glc (1-6) Glc (1-4) Dig	Isovaleroyl	Benzoyl

similar to those of russelioside C (Al-Yahya et al., 2000) and hisianthosides (Qiu et al., 1999) and were due to one D-glucose unit and one D-digitalose unit. Two anomeric protons and their carbon signals resonated at δ_H 4.75, 5.16 and at δ_C 102.3, 105.3, in the ^1H and ^{13}C NMR spectra, respectively. D-Digitalose was determined as the inner sugar unit from the observed correlation between H-1′/C-3 and between H-3/C-1′, in the HMBC spectrum. The β-configuration of all of the sugar units was indicated from the large coupling constants of their anomeric protons (Agrawal, 1992). Comparison of the NMR spectral data of the aglycone part of **1** with those of russelioside C (Al-Yahya et al., 2000) revealed that **1** showed the absence of any double bond in the skeleton, the presence of a benzoyl residue, and a hydroxyl group located at C-15. The identification of the benzoyl unit was deduced from the UV spectrum (λ_{max} 228, 272 and 280 nm) and from the proton signals at δ_H 8.20 (2H, *m,* H-3, H-7), 7.52 (1H, *m,* H-5) and 7.45 (2H, *m,* H-4, H-6), which were correlated with the aromatic methine carbons at δ_C 130.2 (C-3, C-7), 133.6 (C-5) and 128.9 (C-4, C-6), in the ^1H and ^{13}C NMR spectra, respectively (Rasoanaivo, 1991; El Sayed et al., 1995; Halim and Khalil, 1996). The position of the benzoyl moiety was identified as at C-20 based on the long-range correlation between its carbonyl group (δ_H 166.2) and H-20 (δ_H 5.76) in the HMBC spectrum, and from the downfield shift of C-20 (δ_C 74.3) relative to the corresponding carbon in russelioside C (δ_C 68.8) (Al-Yahya et al., 2000). The hydroxylation at C-15 was deduced from the direct correlation between the proton signal at δ_H 4.61 (H-15) and H-16α (δ_H 2.5) and H-16β (δ_H 1.8) in the ^1H-^1H COSY spectrum, and by comparison with related compounds (Konda et al., 1992; Warashina and Noro, 2000). In the HMBC spectrum, the correlations between H-15/C-13, H-15/C-14, H-15/C-16 and H-15/C-17, further confirmed the previous assumption. The determination of the α-configuration of H-15 was achieved from the spatial correlation between H-15/H-9α (δ_H 1.16) and H-15/H-12α (δ_H 1.44), in the NOESY spectrum. The side chain at C-17 was assigned as β from the NOESY spectrum, which showed spatial relation between H-17/H-15α and H-17/H-16α, from the splitting pattern of H-17α (*dd*, $J = 13$, 6 Hz) and by comparison with the data of the previously isolated glycosides from the genus *Caralluma* (Lin et al., 1994; Halim and Khalil, 1996; Qiu et al., 1997, 1999; Al-Yahya et al., 2000). The stereochemistry of C-20 was determined as *S* in a similar way as in russeliosides A–D, and was deduced from the observation of the spatial relations between H-20/H-21, H-20/H-18 and H-l6α/H-21 and was further supported from the absence of any correlation between H-21 and H-l8 (Itokawa et al., 1988; Qiu et al., 1997; Al-Yahya et al., 2000). From the foregoing evidence, the structure of compound **1** was established as 20-*O*-benzoyl-(20*S*)-pregnane-3β, 8β, 14β, 15β, 20-pentaol 3-*O*-β-D-glucopyranosyl (1→4) β-D-digitalopyranoside, and named penicilloside A.

Compound **2** was isolated as a white amorphous powder, $[\alpha]_D^{25}$ −35.2° and had a molecular formula $C_{47}H_{72}O_{20}$ as shown from the ESI–MS (*m/z* 955 $[M-H]^-$ and 979 $[M+Na]^+$, in the negative and positive ion modes, respectively) and the ^{13}C NMR spectral data (DEPT). The IR spectrum of **2** showed similar absorption bands to those of **1**. The ESI–MS showed the presence of a quasimolecular ion peak at *m/z* 979 $[M+Na]^+$, which suggested one additional hexose unit relative to **1**. The presence of three sugar units in **2** was deduced from the ^1H and ^{13}C NMR spectra, which showed the presence of three anomeric protons at δ_H 4.36, 4.40, and 4.60, which are connected to carbon signals at δ_C 102.8, 105.1, and 104.2, respectively. Acid hydrolysis revealed the presence of two sugars, identified as D-digitalose and D-glucose by TLC, and by the comparison of the ^1H and ^{13}C NMR spectra of **2** (Table 1) with those of russelioside D (Al-Yahya et al., 2000). The connections of the sugar units were similar to those in **1**, with an additional glucose unit (glucose-2) located at C-6 of glucose-1. The attachment of glucose-2 to C-6 of glucose-1 was deduced from the HMBC spectrum and from the glycosylation shift of C-6″ (+7.8 ppm) relative to the corresponding carbon in glucose-2 (C-6‴) (Agrawal, 1992). The ^1H and ^{13}C NMR spectral data of the aglycone part of **2** (Table 2 and Experimental) were identical with those of **1**, which indicated that both glycosides have the same aglycone. The previous assumption was supported by the result of acid hydrolysis. The presence of the benzoyl moiety and its attachment to C-20, and the configurations of C-15, C-17 and C-20 were deduced as in **1**. Therefore, the structure of compound **2** was elucidated as 20-*O*-benzoyl-(20*S*)-pregnane-3β, 8β, 14β, 25β, 20-pentaol 3-*O*-β-D-glucopyranosyl (1→6) β-D-glucopyranosyl (1→4) β-D-digitalopyranoside, and named penicilloside B.

Compound **3** was isolated as a white amorphous powder, $[\alpha]_D^{25}$ −46.7° and had a molecular formula $C_{52}H_{80}O_2$, as shown from the ESI–MS (*m/z* 1039 $[M-H]^-$ and 1063 $[M+Na]^+$, in negative and positive ion modes, respectively) and ^{13}C NMR spectral data (DEPT). The acid hydrolysis of **3** yielded two sugars, identified as glucose and digitalose, and a different aglycone from that of **1**

and **2** (TLC). The ^1H and ^{13}C NMR spectral data of **3** (Table 1) showed the presence of three sugar units, which were identified as two glucose units and one digitalose unit. The sugar units were connected in the same sequence as in **2** by comparison of their spectral data (Table 1). Compound **3** showed, in addition to the benzoyl moiety in **1** and **2**, another acyl moiety identified as isovaleric acid. The identification of the isovaleroyl moiety was achieved from the ^1H NMR spectrum, which showed the presence of one methine, one methylene and two methyl proton signals at δ_H 2.14 (1H), 2.18 (2H) and 0.90 (6H), respectively, which correlated with the corresponding carbon signals at δ_C 25.7, 43.9 and 22.2, in the ^{13}C NMR spectrum (Halim and Khalil, 1996; Chen et al., 1999). The position of the benzoyl moiety was determined to be at C-15 from the downfield shift of C-15 (δ_C 76.2) relative to the corresponding carbon in **1,** and from the long-range correlation between the carbonyl group of the benzoyl moiety (δ_C 166.2) and H-15 in the HMBC spectrum. The isovaleroyl moiety was attached to C-20 based on the long-range correlation between the carbonyl group (δ_C 172.2) and H-20 (δ_H 5.48) in the HMBC spectrum. The configuration of the stereocenters in **3** was determined in the same way as in **1**. Therefore, compound **3** was elucidated as 15β-*O*-benzoyl-20-*O*-isovaleroyl-(20*S*)-pregnane-3β, 8β, 14β, 15β, 20-pentao1 3-*O*-β-D-glucopyranosyl (1→6)-β-D-glucopyranosyl (1→4)-β-D-digitalopyranoside, and named penicilloside C.

3. Experimental

Melting points were determined on a Yanagimoto micromelting point apparatus and are uncorrected. Optical rotations were measured using a JASCO DIP-360 automatic polarimeter. UV spectra were measured on Shimadzu UV-2200 UV–VIS spectrophotometer. IR spectra were measured on a JASCO FT/IR-230 IR spectrometer. ^1H and ^{13}C NMR spectra were measured with a JNM-LA400WB Lambada (Jeol) NMR (^1H, 400 MHz; ^{13}C, 100 MHz) or a Varian UNITY 500 spectrometer (^1H, 500 MHz; ^{13}C, 125 MHz), using TMS as internal standard. ESI–MS spectra were measured with Perkin-Elmer SCIEX API III biomolecular mass analyzer. MPLC separations were carried out on LiChroprep RP-18 (Merck, size A) with 5.5 ml flow rate and 4 ml fractions were collected. TLC was carried out on precoated Si gel plates (Kieselgel 60 F_{254}, Merck), using $CHCl_3$–MeOH (9:1), or CH_2Cl_2–MeOH–H_2O (25:8:1) as the developing solvent systems. TLC plates were visualised

by spraying with anisaldehyde reagent followed by heating.

3.1. Plant materials

The aerial parts of *C. penicillata* were collected from the Aseer region of the Kingdom of Saudi Arabia in April 1996. The plant material was kindly identified by Dr. Sultan Ul-Abedin, College of Pharmacy, King Saud University, Riyadh, Saudi Arabia. A voucher specimen was deposited in the herbarium of the College of Pharmacy, King Saud University, Riyadh, Saudi Arabia (No. 11677B).

3.2. Extraction and isolation

The air-dried aerial parts of *C. penicillata* (1 kg) were defatted with petrol followed by extraction with EtOH (10 l) to give a crude EtOH extract (131 g). The EtOH extract (120 g) was suspended in water and extracted with ether, chloroform and *n*-butanol to give extracts of 8, 20 and 18 g, respectively. A portion of the $CHCl_3$ extract (5 g) was applied to a Si gel column (3.8×16 cm) eluted with MeOH/$CHCl_3$ mixtures (10–20%) with fractions being collected (100 ml), to give three main fractions, fr. A (470 mg), fr. B (195 mg) and fr. C (350 mg). Fr. A (200 mg) was purified on MPLC using RP-18 and MeOH–H_2O (73:27) as the eluent, to give compound **1** (100 mg). Fr. B was subjected to rechromatography on a Si gel column (2×40 cm) using $CHCl_3$-MeOH–H_2O (7:2:0.05) as the solvent system to give compound **2** (28 mg). Fr. C was purified on MPLC using RP-18 and MeOH–H_2O (7.5:2.5) as the solvent system, to give compound **3** (35 mg).

3.3. Acid hydrolysis of compounds *1–3*

Compounds **1–3** were hydrolysed according to procedure described by Halim and Khalil (1996).

*Penicilloside A **(1)***. White needles, mp 215–217°C (uncorr.); $[\alpha]_D^{25}$ −30° (MeOH, *c*. 0.09); UV λ_{max}^{MeOH} nm (log ε): 228 (4.0), 272 (2.9), 280 (2.9); IR ν_{max}^{KBr} cm^{-1}:3400, 1720, 1650, 1455, 1080; ^1H NMR (C_5D_5N, 500 MHz), aglycone moiety: δ 1.07 (3H, *s*, H-19), 1.16 (1H, *m*, H-9α), 1.36 (3H, *d*, *J*=6 Hz, H-21), 1.55 (3H, *s*, H-18), 1.80 (1H, *m*, H-16β), 1.98 (1H, *J*=13, 6 Hz, H-17α), 2.50 (1H, *m*, H-16α), 4.61 (1H, *br t*, *J*=8 Hz, H 15α), 5.76 (1H, *m*, H-20), benzoyl moiety: 7.45 (2H, *m*, H-4, H-6), 7.52 (1H, *m*, H-5), 8.20 (2H, *m*, H-3, H-7), sugar mioety, see Table 1; ^{13}C NMR (C_5D_5N, 125 MHz), see Tables 1 and 2; ESI–MS, *m*/*z* (rel. int.): 793 [M−H] (75), 817 $[M+Na]^+$ (100), in negative and positive ion modes, respectively.

Penicilloside B (***2***). An amorphous white powder; $[\alpha]_D^{25}$ −35.2° (MeOH *c*. 0.075); UV λ_{max}^{MeOH} nm (log ε): 228 (3.1), 272 (2.8), 280 (2.7); IR ν_{max}^{KBr} cm^{-1}: 3400, 1710, 1650, 1460, 1060; ^1H NMR (CD_3OD, 400 MHz), aglycone moiety: δ 0.97 (3H, *s*, H-19), 1.07 (1H, *m*, H-9α), 1.18 (3H, *s*, H-18), 1.26 (3H, *d*, *J*=6 Hz, H-21), 1.55 (1H, *m*, H-16β), 1.86 (1H, *m*, H-17α), 2.32 (1H, *m*, H-16α), 4.28 (1H, t, *J*=8 Hz, H-15α), 5.30 (1H, *m*, H-20), benzoyl moiety: 7.46 (2H, *m*, H-4, H-6), 7.58 (1H, *m*, H-5), 7.97 (2H, *m*, H-3, H-7), sugar moiety, see Table 1; ^{13}C NMR (CD_3OD, 100 MHz), see Tables 1 and 2; ESI–MS, *m*/*z* (rel. int.): 955 $[M-H]^-$ (100), 979 $[M+Na]^+$ (100), in negative and positive ion modes, respectively.

*Penicilloside C (**3**)*. An amorphous white powder, $[\alpha]_D^{25}$ −46.7° (MeOH, *c*. 0.1); UV λ_{max}^{MeOH} nm (log ε): 228 (3.2), 255 (2.7), 261 (3.5), 280 (1.9); IR ν_{max}^{KBr} cm^{-1}: 3400, 1710, 1650, 1460, 1060; ^1H NMR (C_5D_5N, 500 MHz): aglycone moiety: δ 1.07 (3H, *s*, H-19), 1.23 (1H, *m*, H-9α), 1.23 (3H, *d*, *J*=6 Hz, H-21), 1.58 (3H, *s*, H-18), 1.80 (1H, *m*, H-16β), 1.90 (1H, *J*=11, 6 Hz, H-17α), 2.50 (1H, *m*, H-16α), 5.90 (1H, *m*, H-15α), 5.48 (1H, *m*, H-20), benzoyl moiety, 7.38 (2H, *m*, H-4, H-6), 7.52 (1H, *m*, H-5), 8.32 (2H, *m*, H-3, H-7), isovaleroyl moiety: 0.90

(6H, *d*, $J = 6$ Hz, H-4, H-5), 2.14 (1H, *m*, H-3), 2.18 (2H, *m*, H-2), sugar moiety, see Table 1; ^{13}C NMR (C_5D_5N, 125 MHz), see Tables 1 and 2; ESI–MS, *m*/*z* (rel. int.): 1039 $[M-H]^-$ (60), 1063 $[M+Na]^+$ (100), in negative and positive ion modes, respectively.

Received in revised form 25 May 1999

Abstract

A steroidal saponin, named tuberoside, together with seven known compounds, were isolated from the seeds of *Allium tuberosum* Rottl. ex Spreng. Its structure was established by spectroscopic data, hydrolysis, and comparison with spectral data of known compounds to be (2α, 3β, 5α, 25*S*)-2,3,27-trihydroxyspirostane 3-*O*-α-L-rhamnopyranoyl-(1→2)-*O*-[α-L-rhamnopyranoyl-(1→4)]-β-D-glucopyranoside. © 2001 Published by Elsevier Science Ltd.

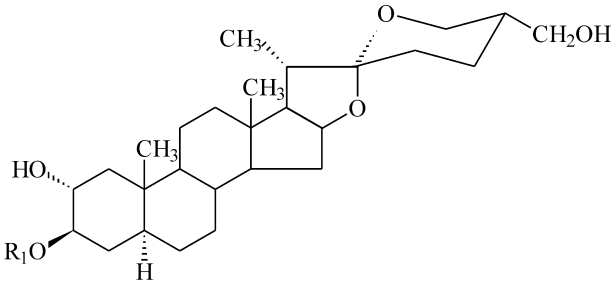
Keywords: *Allium tuberosum*; Liliaceae; Saponin; Spirostanol glycoside; Tuberoside

1. Introduction

Allium tuberosum Rottl. ex Spreng is widely cultivated and used as food in China, whose seeds have been reputedly used as a traditional Chinese medicine for treating both impotence and nocturnal emissions (Jiangsu New Medicinal College, 1979). Species of *Allium* genus are famous for their production of sulfur-containing biologically active natural products. With regard to the saponin constituents of the *Allium* genus, many steroidal saponins have been reported (Zou et al., 1999). However, there has been no exploration of the secondary metabolites of *A. tuberosum* seeds. Our detailed investigation of its seeds has led to the discovery of a new saponin (**1**), together with eight known compounds, gitogenin 3-*O*-α-L-rhamnopyranosyl-(1→2)-β-D-galactopyranoside (Mimaki et al., 1996), S-allylcysteine (**3**), L-tyrosine (**4**), adenosine (**5**), inosine (**6**), allantoin (**7**) and mannitol (**8**). The known compounds were identified by direct comparison with authentic samples (co-TLC, IR, MS, NMR) or with reported spectral and physical data. This paper deals with the isolation and structural elucidation of the new saponin (**1**).

2. Results and discussion

Commercially available seeds of *Allium tuberosum* (9.5 kg) were defatted with petroleum ether followed by extraction with hot 70% EtOH. The concentrated extract was partitioned between $CHCl_3$ and H_2O, then between *n*-BuOH and H_2O. The *n*-BuOH soluble phase was subjected to silica gel column chromatography to give a new compound, named tuberoside (**1**).



1. R_1=α-L-Rha*p*-(1→2)-[α-L-Rha*p*-(1→4)]-β-D-Glc*p*

Tuberoside (**1**) was obtained as an amorphous powder, with the molecular formula $C_{45}H_{74}O_{18}$, which was deduced from the FAB–mass spectrum showing an $[M+H]^+$ ion at *m*/*z* 903 and the ^{13}C NMR spectrum (Table 1). The IR spectrum of **1** showed the characteristic absorption of hydroxyl groups at 3422 cm^{-1}. The FAB–mass spectrometry of compound **1** showed fragment ion

PII: S0031-9422(01)00216-3

peaks at m/z 757 (M + H-146), 611 (M + H-146-146), 449 (M + H-146-146-162), which suggested the sequential loss of two deoxy hexose and one hexose moiety. The NMR spectra (Tables 1 and 2) of **1** also showed the presence of three sugars from the three anomeric protons at δ 5.00 (*d*, $J = 7.3$ Hz), 6.38 (*s*) and 5.38 (*s*) in the ^{1}H NMR spectrum, and the three anomeric carbon signals at δ 102.9, 102.2, 100.9 in the ^{13}C NMR spectrum.

On acid hydrolysis, **1** afforded D-glucose, L-rhamnose, which were identified by co-TLC with authentic samples and aglycone (**1a**). The NMR spectral data (Table 1) indicated **1a** is a spirostanol derivative with three hydroxyl groups, and the base peak at m/z 155 in EI–MS spectrum of **1a** proved a hydroxyl group to be located at the F ring (Cong, 1987). Further analysis of

[a] All assignments were confirmed by ^{1}H–^{1}H COSY, ^{13}C–^{1}H COSY and DEPT spectra.

the ^1H and ^{13}C NMR spectra of **1a** allowed its identification as (2α, 3β, 5α, 25*S*)-spirostan-2,3,27-triol (crestagenin), isolated previously from the leaves of *Digitalis canariensis* (Dolgado et al., 1969; Gonzalez, et al. 1983).

The ^1H and ^{13}C NMR spectral data assignments of compound **1** were performed via analyses of the ^1H–^1H COSY, ^{13}C–^1H COSY and DEPT spectra. The presence of two terminal α-L-rhmnopyranosyl moieties in the molecule of **1** was demonstrated by the two sets of characteristic six carbon signals at δ 102.2, 72.6, 72.7, 73.9, 70.5, 18.6; 102.9, 72.5, 72.7, 74.1, 69.6, 18.6 in the ^{13}C NMR spectrum. The C-5 signals of two rhamnose units at δ 70.5 and 69.6, respectively, indicated their α-configurations (Seo et al., 1978). Comparison of ^{13}CNMR data of the sugar moieties with the corresponding methyl β-D-glucopyranoside (Agrawal et al., 1985) indicated that the C-2 and C-4 of the glucosyl moiety were shifted downfield to δ 78.0 and 78.7 from 73.7 and 70.3, respectively. The significant glycosylation shifts clearly showed the two terminal rhamnopyranoses were linked to the C-2 and C-4 positions of the inner glucopyranose. The β-configuration of the glucopyranose was further confirmed by the large $J_{1,2}$ couplings of its anomeric proton.

The linkage of the sugar chain was concluded to be at the C-3 hydroxyl position of the aglycone because, in the ^{13}C NMR spectrum of **1**, the signal due to C-3 shifted to a lower field by 8.7 ppm, whereas the signals due to C-2 and C-4 moved to upper fields by 2.5 and 3.9 ppm, as compared with those of **1a**. Accordingly, the structure of **1** was elucidated as (2α, 3β, 5α, 25*S*)-2,3,27-trihydroxyspirostane 3-*O*-α-L-rhamnopyranoyl-(1→2)-*O*-[α-L-rhamnopyranoyl-(1→4)]-β-D-glucopyranoside (**1**).

3. Experimental

3.1. General

Mps were obtained on a Boetius miromelting apparatus and are uncorrected. Optical rotations were measured with Perkin-Elmer 241 polarimeter. IR spectra were recorded on a Perkin-Elmer 683 instrument. EIMS was obtained on a VG Zab-2f and FABMS on a VG Zabspec mass spectrometer. The ^1H NMR spectra (500 MHz) and ^{13}C NMR (125 MHz) were recorded on a Brüker AM-500 spectrometer and the chemical shifts are reported in ppm using the solvent as reference.

3.2. Plant materials.

The seeds of *Allium tuberosum* Rottl. ex Spreng were purchased from Beijing Tong-Ren-Tang Group, China, and were identified by Mr. Wei-Ze Liu, Institute of Materia Medica, Chinese Academy of Medical Sciences and Peking Union Medical College, China.

3.3. Extration and isolation.

Air-dried and powdered seeds of *A. tuberosum* Rottl. Ex Spreng (9.5 kg) were defatted by percolation with petroleum ether followed by extraction with hot 75% EtO. The combined EtOH extracts were filtered, evap. under red. press. and the residue suspended in H_2O and partitioned with $CHCl_3$ and *n*-BuOH, respectively.

The *η*-BuOH extract (62 g) was fractionated on a silica gel column with a gradient mixture of $CHCl_3$–MeOH and finally with MeOH to give five Frs. (A_1–A_5). Fr. A_1 was chromatographied on silica gel, eluting with $CHCl_3$–MeOH (9:1) to give compounds **2** (10 mg) and **5** (176 mg), while Fr. A_2 was repeatedly chromatographied on silica gel to give compounds **6** (15 mg) and **7** (7 mg). Fr.A_3 was subjected to silica gel with $CHCl_3$-MeOH (20:3) to give compounds **1** (31mg) and **8** (38 mg). Fr.A_4 was repeatedly chromatographied on silica gel CC to give compound **3** (162mg). Fr. A_5 was subjected to silica gel CC with $CHCl_3$–MeOH (5:1) to give compound **4** (16 mg).

3.4. Tuberoside A (*1*)

$C_{45}H_{74}O_{18}$, amorphous powder, mp 292–293°, $[\alpha]_D^{25}$ −33°; *c* 0.02, MeOH. IR (KBr) cm^{-1} 3422, 2932, 1452, 1381, 1043, 987, 912. FABMS *m/z* 903 $[M+H]^+$, 757 $[M+H\text{-}146]^+$, 611 $[M+H\text{-}2\times146]^+$, 449 [aglycone + H]$^+$, 431, 413. ^1H and ^{13}C NMR data, see Tables 1 and 2.

3.5. Acid hydrolysis of *1*

Compound **1** (20 mg) was heated with 3% H_2SO_4 (EtOH, 1:1) at 100°C for 3 h. After cooling, the reaction mixture was neutralized with 1 N NaOH and partitioned between AcOEt and H_2O. The AcOEt soluble phase was concentrated and subjected to silica gel CC with $CHCl_3$ to give the known crestaganin **1a**.

Compound **1a**: white powder, EI–MS *m/z* 448 (M^+), 155 (100). ^1H NMR ($CDCl_3$) δ 0.97 (3H, *d*, *J* = 7.8 Hz), 0.86 (3H, *s*), 0.76 (3H, *s*), 3.71 (*dd*, *J* = 10.7, 5.1 Hz, CH_2-27), 3.63 (*dd*, *J* = 10.7, 7.1 Hz, CH_2-27), 3.89 (1H, *dd*, *J* = 11.4, 11.1 Hz, CH_2-26), 4.13 (*dd*, *J* = 11.4, 5.2 Hz, CH_2-26). ^{13}C NMR data, see Table 1.

The H_2O soluble phase was concentrated and examined by comparison with authentic samples through TLC ($CHCl_3$–MeOH–H_2O, 7:3:0.1) to detect D-glucose and L-rhamnose.

Abstract

Three flavones, including 4′-*O*-[2′-*O*-*E*-feruloyl-*O*-β-D-glucuronopyranosyl(1→2)-*O*-β-D-glucuronopyranoside]apigenin, 7-*O*-β-D-glucuronopyranosyl-4′-*O*-[2′-*O*-*E*-feruloyl-*O*-β-D-glucuronopyranosyl(1→2)-*O*-β-D-glucuronopyranoside]apigenin and 7-*O*-β-D-glucuronopyranosyl-4′-*O*-[2′-*O*-*p*-*E*-coumaroyl-*O*-β-D-glucuronopyranosyl(1→2)-*O*-β-D-glucuronopyranoside]apigenin have been identified in alfalfa var. Artal. The known flavone 7-*O*-{2-*O*-E-feruloyl-[β-D-glucuronopyranosyl(1→3)]-*O*-β-D-glucuronopyranosyl (1→2)-*O*-β-D-glucurono-pyranoside} apigenin was also isolated. The structures of these compounds were deduced on the basis of their spectral data. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Medicago sativa*; Aerial parts; Acylated apigenin glucuronides

1. Introduction

Alfalfa is a pasture crop rich in good quality protein. Its nutritional value has been, however, influenced by the presence of secondary metabolites including saponins and flavonoids. While saponins have been extensively studied (Oleszek, 2000), very little is known on alfalfa flavonoids (Bisby et al., 1994). In our preliminary HPLC screening of 50 alfalfa varieties obtained from USDA stocks it was clear that flavonoid profiles of all tested samples contained a number of glycosides and were, with some exceptions, very similar to each other (Stochmal et al., 1999). From the Polish variety Boja several novel, acylated with ferulic and coumaric acids apigenin and luteolin glycosides have been isolated and fully characterized (Stochmal et al., 2001). All these flavonoids had only glucuronic acid in the sugar moiety and the acylation occurred on the sugar attached at C-7 of the aglycone. The HPLC profile of the variety Artal showed some dissimilarities with other cultivars and thus, the aim of the present work was to isolate and chemically characterize the unknown compounds.

2. Results and discussion

Preliminary analyses with HPLC (diode array detection) of flavonoids in the aerial parts of alfalfa var. Artal indicated the presence of several flavones, out of which, the one dominant and two minor compounds had UV spectra identical to apigenin glycosides, but their retention times were different from the others so far characterized. The column chromatography of a purified flavonoid fraction afforded four compounds, which were fully characterized by spectral techniques. Compound **4** was identified as 7-*O*-{2-*O*-*E*-feruloyl-[-*O*-β-D-glucuronopyranosyl(1→3)]-*O*-β-D-glucuronopyranosyl (1→2)-*O*-β-D-glucuronopyranoside}apigenin by comparison of its NMR and FAB-MS spectra with previously reported literature data (Stochmal et al., 2001).

Compound **1** gave a molecular ion (ESI–HRMS, negative ion mode) at *m*/*z* 797.1575, which together with the ^{1}H and ^{13}C NMR spectral data (Tables 1 and 2) was consistent with the empirical formula $C_{37}H_{34}O_{20}$.

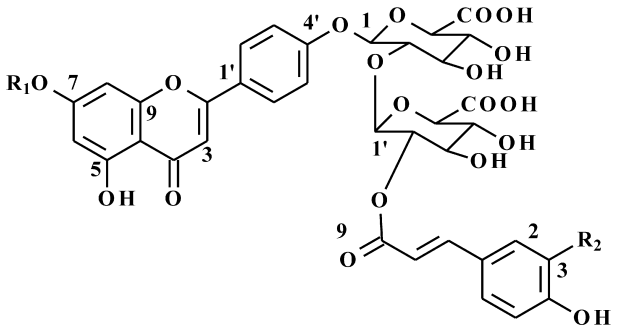
The downfield region of the ^{1}H NMR spectrum (Table 1) showed two spin systems correlated by ^{1}H–^{1}H shift correlation (COSY): an AA'BB' system at δ 7.98 (*d*, 8.7 Hz, H-2′ and H-6′) and δ 7.10 (*d*, 8.7 Hz, H-3′ and H-5′), and an AB system at δ 6.51 (*d*, 1.9 Hz, H-8) and δ 6.19 (*d*, 1.9 Hz, H-6). These two systems together with a singlet at δ 6.87 (H-3) indicated the presence of an apigenin aglycone in compound **1** (Stochmal et al., 2001). The UV and ^{13}C NMR (Table 2) spectra and the ROE correlations between the H-2′/H-6′ signal and the H-3 signal of the apigenin confirmed this structure.

The other group of signals in the downfield region of the ^{1}H NMR spectrum corresponded to a phenolic acyl moiety. An ABX system at δ; 7.26 (*d*, 1.9 Hz, H-2); δ 7.08 (*dd*, 8.2 Hz, 1.9 Hz, H-6) and δ; 6.77 (*d*, 8.2 Hz, H-5), and two doublets at δ 7.50 (H-7) and δ 6.41 (H-8) with a coupling constant of 15.8 Hz typical of an *E*-double bound were observed. The ROE correlation between a methoxyl group signal at δ 3.80 (*s*) with H-2 and the correlation between the double bound signals and the aromatic protons H-2 and H-6 (Fig. 1) suggested the presence of a ferulic acyl moiety, confirmed with the presence of nine signals in the ^{13}C NMR spectrum (Ibrahim and Barron, 1989) (Table 2).

The sugar region of the ^{1}H NMR spectrum showed the presence of two sugar units, with anomeric proton signals at δ 5.32 (*d*, 7.4 Hz, H-1) and δ 4.93 (*d*, 8.2 Hz, H-1′). The ^{13}C NMR spectrum showed 12 signals for two hexose units. Two typical C-6 signals of carboxyl groups at δ 172.5 suggested two glucuronic acid moieties. Their β-configuration was evident from the coupling constant of the anomeric protons.

The connection between the glucuronyl moieties and apigenin was established as 4′-[glucuronopyranosyl (1→2)glucuronopyranosyl] apigenin, from the observed ROE correlation between H-3′ and H-5′ of apigenin and H-1 of the first glucuronic acid and H-2 and H-1′ of both glucuronic acids. The pronounced downfield shift of H-2′ of the second glucuronic acid (δ 4.64) indicated the linkage between the sugar and the acyl moiety at C-2′, and thus **1** is 4′-*O*-[2′-*O*-*E*-feruloyl-*O*-β-D-glucurono pyranosyl(1→2)-*O*-β-D-glucuronopyranoside]apigenin.

Compound **2** showed a molecular ion (ESI–HRMS, negative ion mode) at *m*/*z* 973.1903 according with a molecular formula $C_{43}H_{41}O_{26}$ and peak at 269.0452 corresponding to the aglycone. The ^{1}H and ^{13}C NMR spectra of **2** (Tables 1 and 2) were very similar to those of compound **1**. The additional signals that appeared in its spectra corresponded to a third glucuronic acid moiety. The observed ROE correlation between H-6 and H-8 of the apigenin moiety and H-1″ of the third glucuronic acid determined the structure of **2** as 7-*O*-β-D-glucuronopyranosyl-4′-*O*-[2′-*O*-*E*-feruloyl-*O*-β-D-glucuronopyranosyl(1→2)-*O*-β-D-glucuronopyranoside]apigenin.



1: R_1=H R_2=OCH_3
2: R_1=glucuronic acid R_2=OCH_3
3: R_1=glucuronic acid R_2=H

Fig. 1. Chemical formula of compounds **1**–**3**.

Compound **3** gave a molecular ion (ESI–HRMS, negative ion mode) at *m*/*z* 943.1765 with a molecular formula $C_{42}H_{40}O_{26}$ and peak at 269.0470 corresponding to the aglycone. The only spectroscopic difference between the spectra of compounds **2** and **3** was in the phenolic moiety signals, the ^{1}H NMR spectrum (Table 1) of **3** had two doublets δ 7.40, *d*, 8.5 Hz, H-2 and H-6 and δ 6.74, *d*, 8.5 Hz, H-3 and H-5) typical of a *p*-coumaroyl moiety. The ^{13}C NMR spectrum (Table 2) was in agreement with the structure of the acyl moiety and the ROE effects observed confirmed an identical connection of apigenin, glucuronic acids and coumaroyl moiety as compound **2**. The structure of **3** was stablished as 7-*O*-β-D-glucuronopyranosyl-4′-*O*-[2′-*p*-*E*-coumaroyl-*O*-β-D-glucuronopyranosyl (1→2)-*O*-β-D-glucuronopyranoside]apigenin.

As far as we know, the three flavone glycosides (**1**, **2** and **3**) are reported here for the first time as natural compounds. They, similarly to previous identified apigenin glycosides in alfalfa (Stochmal et al., 2001), possess glucuronic acid as a sole sugar subunit in the sugar chain, and acylation with ferulic and coumaric acids occurred on the glucuronic acid moieties. However, the difference with previously identified compounds is in the acylation position. The three identified glycosides are acylated on sugars attached at C-4′, while all previously reported compounds were acylated on sugars at C-7. These differences may be specific for this particular variety or they may reflect the influence of environmental conditions. Plant material from which present flavonoids were separated was collected from plants grown in Portugal. The four isolated compounds were tested for their antioxidant activity in β-carotene/linoleic acid heterogenous system (Pratt, 1992), and for radical scavenging activity in methanolic solution of DPPH (Lee et al., 1998). They showed no activity in both tests performed. More research is needed, in order to shed some light on the function of acylated glucuronides in the host plant on their adaptation to environmental conditions.

3. Experimental

3.1. General

Flavonoids were chromatographed on Cellulose (Merck) ready to use plates, developed with 15% AcOH and after drying plates were observed under a UV lamp. High-performance liquid chromatography was performed on an HPLC system (Waters) consisting of 616 pump, a 600 s controller, and a 996 photodiode array detector. The Millenium Chromatography Manager was used to monitor chromatographic parameters and to process the data.

^{1}H, ^{13}C and 2D NMR spectra were recorded in CD_3OD and DMSO-d_6 on a Varian UNITY-400 instrument operating at 400 MHz for ^{1}H NMR and 100 MHz for ^{13}C NMR. Chemical shifts are reported in ppm (δ). ESI–HRMS were recorded in the negative ion mode on a Mariner Biospectrometry Workstation (Per Septive Biosystems). UV spectra were recorded on a HP 8453 UV/vis spectrophotometer. The α values were obtained in MeOH at 20°C on a Jasco P-1020 spectropolarimeter. Melting points were uncorrected.

3.2. Plant material and isolation

The lucerne var. Artal (American variety) was seeded in March 1999 in the north of Portugal, at Vairco (near Porto), and the samples were collected on the 23 August 1999, and they were from a 2nd harvest. The material was freeze dried, powdered and used for extraction.

Powdered plant material was extracted in a Soxhlet with chloroform to remove chlorophyl and fats. After drying it was extracted with 70% MeOH at room temperature. After filtration the extract was evaporated in vacuo (40°C) yielding a brown solid. The solid was suspended in water and loaded onto a C18 filled column (30×70 mm, 60 μm, Baker) equilibrated with water. The column was washed with water to remove carbohydrates, and flavonoids were washed out with 40% MeOH. The 40% MeOH fraction was evaporated to dryness, redissolved in 20% MeOH and loaded onto a C18 column (40 ×300 mm, 25–40 μm, Merck). The column was washed with MeOH-H_2O (linear gradient 20–70% MeOH) and 10 ml fractions were collected with a fraction collector. Fractions showing identical chromatographic characteristics (TLC, HPLC) were combined. Four single flavonoids were obtained.

3.2.1. 4′-*O*-[2′-*O*-*E*-Feruloyl-β-D-glucuronopyranosyl (1→2)-*O*-β-D-glucuronopyranoside]apigenin (**1**)

Amorphous yellow powder (15 mg); mp. 197–198°C; UV λ_{max}^{MeOH} nm: 271 *sh*, 325; $[\alpha]_D^{20}$ −74.2°(MeOH, *c* 0.1); HRMS *m*/*z*: 797.1575 [calc. for $C_{37}H_{33}O_{20}$ $[M\text{-}1]^-$, 797.1560], 269.0457 [M–H–ferulic acid–2GluA]$^-$. For ^{1}H and ^{13}C NMR see Tables 1 and 2, respectively.

*3.2.2. 7-O-β-D-Glucuronopyranosyl-4′-O-[2′-O-E-feruloyl -O-β-D-glucuronopyranosyl (1→2)-O-β-D-glucurono pyranoside]apigenin (**2**)*

Amorphous yellow powder (3 mg); mp. 197–198°C; UV λ_{max}^{MeOH} nm: 270 *sh*, 319; $[\alpha]_D^{20}$ −10.23° MeOH, *c* 0.1); HRMS *m/z*: 973.1903 [calc. for $C_{43}H_{41}O_{26}$ $[M\text{-}1]^-$, 973.1881], 269.0452 [M–H–ferulic acid–3GluA]$^-$. For ^1H and ^{13}C NMR see Tables 1 and 2, respectively.

*3.2.3. 7-O-β-D-Glucuronopyranosyl-4′-O-[2′-p-E-coumaroyl-O-β-D-glucuronopyranosyl (1→2)-O-β-D-glucuronopyranoside]apigenin (**3**)*

Amorphous powder (3 mg); mp. 197–198°C; UV λ_{max}^{MeOH} nm: 272 sh, 314; α_D^{20} −52.45° λ_{max}MeOH *c* 0.1); HRMS *m/z*: 943.1575 [calc. for $C_{42}H_{39}O_{25}$ $[M\text{-}1]^-$, 943.1775], 269.0470 [M–H–coumaric acic–3GluA]$^-$. For ^1H and ^{13}C NMR see Tables 1 and 2, respectively.

*3.2.4. 7-O-{2-E-Feruloyl-[β-D-glucuronopyranosyl(1→3)] -O-β-D-glucuronopyranosyl(1→2)-O-β-D-glucurono pyranoside}apigenin (**4**) (10 mg)*

UV, HRMS and NMR data were in accordance with literature data (Stochmal et al., 2001).

Abstract

From the aerial parts of *Hypericum polyanthemum* Klotzsch ex Reichardt (Guttiferae), three chromenes, 6-isobutyryl-5,7-dimethoxy-2,2-dimethyl-benzopyran; 7-hydroxy-6-isobutyryl-5-methoxy-2,2-dimethyl-benzopyran and 5-hydroxy-6-isobutyryl-7-methoxy-2,2-dimethyl-benzopyran were isolated. Their structures were determined by NMR spectroscopic analyses. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Hypericum polyanthemum*; Guttiferae; Benzopyrans; Chromenes; 6-Isobutyryl-5,7-dimethoxy-2,2-dimethyl-benzopyran; 7-Hydroxy-6-isobutyryl-5-methoxy-2,2-dimethyl-benzopyran; 5-Hydroxy-6-isobutyryl-7-methoxy-2,2-dimethyl-benzopyran

1. Introduction

Plants of the Gutifferae contain several constituents with diverse biological activities (Fuller et al., 1999; Verotta et al., 1999; McKee et al., 1998). Recently, the genus *Hypericum*, which contains about 400 species, has received attention for the antiviral action of hypericin and pseudohypericin on lipid enveloped and non-enveloped DNA and RNA viruses. These polycyclic quinones were isolated from *H. perforatum*, the most well-known species, widely employed as an antidepressive (Sommer and Harrer, 1994; Vorbach et al., 1994). The most common compounds isolated from plants of this genus are xanthones (Bennett and Lee, 1989), flavonoids (Rocha et al., 1995), phloroglucinol and filicinic acid derivatives (Jayasuriya et al., 1991; Rocha et al., 1995) and, less frequently, benzopyrans (Décosterd et al., 1986; Ishiguro et al., 1990).

Among the approximately 20 native *Hypericum* species from South Brazil, only *H. brasiliense* has been investigated. From this plant, xanthones and phloroglucinol derivatives were isolated, and its extracts have been found to inhibit monoamine oxidases (MAO), enzymes important in the regulation of levels of some physiological amines and which are thought to contribute to the management of depression (Rocha et al., 1994; Rocha et al., 1995).

In this paper, we deal with the structural elucidation of three new benzopyrans isolated from the aerial parts of *H. polyanthemum*, another species from South Brazil.

2. Results and discussion

From the chloroform extract of the aerial parts of *H. polyanthemum* three major compounds (**1**, **2** and **3**) were isolated. Compound **1** showed an $[M]^+$ at m/z 290.15181 in the HREIMS, which corresponds to a molecular formula of $C_{17}H_{22}O_4$ (calc. 290.1519). The IR spectrum of this compound showed absorptions which indicated the presence of a *gem*-dimethyl group (1383 and 1366 cm^{-1}) and a benzene ring (1603 and 1469 cm^{-1}). The ^{13}C NMR spectrum showed 15 signals, of which two (δ_C 27.82 and 17.88) corresponded to two methyl groups each. In the ^1H NMR spectrum the appearance of a pair of doublets at δ 6.46 and 5.51 (each 1H, $J = 10$ Hz) together with a six-proton singlet at δ 1.42 indicated the presence of a dimethylpyran ring system in the molecule. A singlet at δ 6.19 indicated the

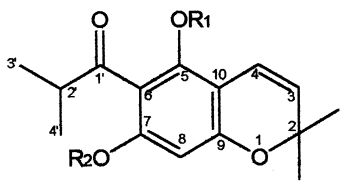
PII: S0031-9422(01)00169-8

existence of a penta-substituted aromatic ring. In the ^{13}C NMR spectrum, the wide disparity in chemical shifts between the oxygenated and non-oxygenated aromatic carbons were indicative of a phloroglucinol oxidation pattern in the aromatic ring. In addition to the IR absorption at 1699 cm^{-1}, attributable to a carbonyl group, the signal at δ 3.03 (1H, *qq*, $J=6.8$, 6.8 Hz) coupled to a six-proton doublet at δ 1.13 in the ^1H NMR spectrum indicated the presence of an isobutyryl substituent in the aromatic ring. Finally, two ^1H signals at δ 3.74 and 3.72 showed the presence of two methoxyl groups attached to the aromatic ring. The resonances of the methoxyl carbons at δ 63.64 and 55.70 indicated that the former was hindered from lying in the plane of the aromatic ring while the latter was substituted *ortho* to the aromatic proton. The structure, 6-isobutyryl-5,7-dimethoxy-2,2-dimethyl-benzopyran, was confirmed by interpretation of HMBC data. Besides the expected cross-peaks for the dimethylbenzopyran moiety (H-3/C-2, C-10, 2-Me_2; H-4/C-2, C-9; 2-Me_2/C-2, C-3), the following correlations were observed: H-8/C-6, C-7, C-9, C-10; H-2′/C-3′, C-4′; H_3-3′ and $H_3$4′/C1′; 5-OMe/C-5; 7-OMe/C-7.



1 R^1=Me, R^2=Me

2 R^1=Me, R^2=H

3 R^1=H, R^2=Me

Compound **2**, also identified as a benzopyran, was obtained as a yellow viscous oil. The UV spectrum revealed a phenolic compound with an extended chromophore. The molecular ion $[M]^+$ at *m/z* 276.13616 (calc. 276.1362) is compatible with the molecular formula of $C_{16}H_{20}O_4$. Major differences in the ^1H NMR spectrum of **2** compared to **1** were the presence of only one methoxyl signal at δ 3.78 and the presence of a signal of an aromatic hydroxyl group at δ 13.09, suggesting that instead of one of the methoxyl groups, a hydroxyl group should be present. This chelated phenolic hydroxyl signal in its ^1H NMR spectrum and a chelated carbonyl group absorption at 1621 cm^{-1} in its IR spectrum demonstrated that the hydroxyl group was at position 5 or 7. The ^{13}C NMR spectroscopic signal of the methoxyl group at δ 63.59 showed that the hydroxyl group should be located at C-7. The placement of the methoxyl and hydroxyl groups (5-OMe, 6-isobutyryl, 7-OH) was confirmed by analysis of the HMBC spectrum which showed the following correlations: 2-Me_2/2-Me_2, C-2, C-3; H-8/C-9, C-10, C-7; H_3-3′ and $H_3$4′/C-3′, C-4′, C-2′, C1′; 5-OMe/C-5; 7-OH/C-7, C-6 and C-8. Further, the NMR spectroscopic data are nearly identical to those of a chromene isolated from *Rhyncholacis penicillata* (Podostemaceae), which only differs in the substituent (methylbutyryl group) at position 6 (Burkhardt et al., 1994).

Compound **3** ($C_{16}H_{20}O_4$) gave rise to a molecular ion $[M]^+$ at *m/z* 276.13616 (calc. 276.1362). As in compound **2**, the UV and IR spectra suggested that an aromatic ring and a chelated hydroxyl group were present. The ^1H NMR spectrum displayed a single methoxyl signal at δ 3.85 and a signal of an aromatic hydroxyl group at δ 14.28. The ^{13}C NMR spectroscopic signal of the methoxyl group appeared at δ 55.59 showing that the hydroxyl should be located at C-5. The NOE effects (7-OMe/H-8; H-8/7-OMe; 2-Me_2/H-3; H-3/H-4; $H_3$3′ and $H_3$4′/H-2′) confirmed the structure to be 5-hydroxy-6-isobutyryl-7-methoxy-2,2-dimethyl-benzopyran.

Chromenes containing an isobutyryl substituent have been previously isolated from *H. revolutum* (Décosterd et al., 1986). The isolated benzopyrans are derivatives of phloroglucinol and thus related to hyperforin. The contribution of these compounds to the pharmacological activity or toxicity of *Hypericum* extracts is still unknown, but will be the subject of future investigations.

3. Experimental

3.1. General procedures

NMR (400 Mhz for ^1H and 100 MHz for ^{13}C), in $CDCl_3$ using the solvent as internal standard; HREIMS: 70 eV; mass spectra were obtained through GC–MS analysis: temp. program 100–270°C (4°/min), injector 250°, transferline 230°, column DB-1, **1** eluted at 27.35 min, **2** at 38.54 min, and **3** at 38.11 min; prep. TLC: 20×20 cm plates coated with 0.5 mm layers of silica gel GF_{254} (Merck); bands were detected in UV light (254 nm).

3.2. Plant material

Plant material of *H. polyanthemum* Klotzsch ex Reichardt (aerial parts) was collected in Guaritas, Caçapava do Sul, Rio Grande do Sul, Brazil, in August, 1998. The voucher specimen is deposited in the Herbarium of the Federal University of Rio Grande do Sul (ICN) (*Hypericum polyanthemum*, Bordignon et al. 1405).

3.3. Isolation procedures

Air dried and powdered plant material (80 g) was extracted in a Soxhlet apparatus with $CHCl_3$ over 12 h and then the extract was evaporated to dryness under reduced pressure. The $CHCl_3$ extract (2.2 g) of *H. polyanthemum* was analyzed by silica gel TLC. Three products were isolated by prep. TLC over silica gel with $CHCl_3$. The compounds **1** (78 mg), **2** (39 mg), and **3** (46 mg) were recovered from the adsorbent using $CHCl_3$.

Diels–Alder type adducts from *Morus cathayana*

Rui-Chao Shen, Mao Lin*

Institute of Materia Medica, Chinese Academy of Medical Sciences and Peking Union Medical College, 1 Xian Nong Tan Street, Beijing 100050, People's Republic of China

Received in revised form 21 February 2001

Abstract

Two natural Diels–Alder type adducts, cathayanon A (**1**) and cathayanon B (**2**), resembling sanggenon C (**4**) and O (**3**), were isolated from the root bark of *Morus cathayana*. Their structures were elucidated on the basis of spectroscopic evidence. The structure of **1** was confirmed by the results of X-ray crystallographic analysis. The absolute configurations of **1** and **2** were determined as 2*S*, 3*R*,14*S*, 19*S*, 20*R* and 2*S*, 3*R*, 14*R*, 19*S*, 20*R*, respectively. The absolute configurations at C-2 and C-3 of two other known isomeric Diels–Alder adducts sanggenon O (**3**) and C (**4**) were deduced as 2*R*, 3*S*. Pharmacological tests indicated that **1** and **2** exhibited potent activities on the inhibition of HL-60 cell adhesion to BAEC at concentrations of 10^{-5} mol l^{-1}, with inhibitory rates of 44.72 and 39.02%, respectively. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Morus cathayana*; Moraceae; Flavanone; Diels–Alder adduct; Cathayanon A; Cathayanon B

1. Introduction

Numerous isoprenoid-substituted phenolic compounds, including flavonoids have been isolated from the Mulberry tree (Nomura, 1988; Nomura and Hano, 1994). Some of these compounds showed interesting activities such as inhibitory activities against arachidonate 5-lipoxygenase (Reddy et al., 1991). In the course of our studies on the antinflammatory agents, we selected the Chinese mulberry tree, *Morus cathayana* Hemsl. for evaluation. Two new Diels–Alder type adducts, cathyanon A (**1**) and cathayanon B (**2**) having the same skeleton as sanggenons C (**4**) and O (**3**), were isolated from the root bark of *M. cathayana* along with 13 known components which were identified as sanggenons O (**3**; Hano and Nomura, 1985), C (**4**), A, and M (Fukai et al., 1998), moracins C, M, O, and P (Nagao, 1981), mulberroside C (Hirakura et al., 1986), scopoletin, umbelliferone, α-amyrin acetate (Jia et al., 1996), and 4-hydroxy-3,5-dimethoxybenzyl alcohol. Moracin O and 4-hydroxy-3,5-dimethoxybenzyl alcohol were isolated from this source for the first time. This paper deals with the isolation and structural determination of two new Diels–Alder type adducts by spectroscopic methods, including determination of their absolute configurations. The structure of **1** was confirmed by X-ray crystallographic analysis. Previously, a number of flavanones having isoprenyl (geranyl) groups and Diels–Alder type adducts have been reported from the root bark of *M. cathayana*. The absolute configurations of the stereocenters of the methylcyclohexene ring have been elucidated distinctively by Nomura, T. (Nomura, 1988). More recently the structures of sanggenons have been revised (Fukai et al., 1998). However, the sterochemistry of C-2 and C-3 have not been reported. This paper also deals with the deduction of the absolute configurations at C-2 and C-3 of two known Diels–Alder type adducts, sanggenons O (**3**) and C (**4**).

2. Results and discussion

Cathayanon A (**1**), pale yellow crystals, mp 180–181°C (*d*), showed $[\alpha]_D^{19}$ −193.9°. The UV spectrum exhibited maxima at 205, 230 (*sh*), 282 and 310 nm, which were similar to those of sanggenons O (**3**) and C (**4**), two flavanone Diels–Alder adducts. The IR spectrum exhibited maxima at 3427, 1633, 1452 and 1146 cm^{-1} similar to those of **3** and **4**. A molecular formula of $C_{40}H_{36}O_{12}$ was determined by the HRFABMS [*m*/*z* 709.2348, $(M+H)^+$] suggesting that **1** was an isomer of **3** and **4**. These results suggested that **1** is a Diels–Alder adduct such as **3** and **4** which are regarded as cycloaddition products of a chalcone and a dehydroprenyl flavanone derivative. This was substantiated by detailed

analyses of ^{1}H NMR, ^{1}H–^{1}HCOSY, ^{13}C NMR and DEPT spectra of **1** and by comparison of the ^{1}H NMR and ^{13}C NMR spectroscopic data of **3** and **4**, obtained from this plant and other *Morus* plants (Nomura et al., 1981). The ^{1}H NMR spectrum of **1** at room temperature showed broad proton signals especially for the protons of H-14, H-19, H-20 of the methylcyclohexene ring. When measured at 90°C in DMSO-*d*, it showed a fairly resolved spectrum as follows: the signals of three sets of ABX type aromatic protons at δ 6.97 (1H, *d*, $J=8$ Hz, 27-H), 6.42 (1H, *dd*, $J=2$, 8 Hz, 26-H), 6.29 (1H, *d*, $J=2$ Hz, 24-H), 6.77 (1H, *d*, $J=8$ Hz, 33-H), 6.22 (1H, *d*, $J=2$ Hz, 30-H), 6.10 (1H, *dd*, $J=2$, 8 Hz, 32-H), 7.39 (1H, *d*, $J=8$ Hz, 6′-H), and 6.00∼6.03 (2H, m, 3′ and 5′-H); the protons of a prenyl group at δ 1.46, 1.67 (each 3H, *s*, 11-CH_3), 2.64 (1H, *dd*, $J=7.5$, 15 Hz, 9-Ha), 2.93 (1H, *dd*, $J=6.9$, 15 Hz, 9-Hb), and 5.23 (2H, *br s*, 10 and 15-H); an aromatic proton at *d* δ 5.65 (1H, *s*, 6-H) and the protons of a trisubstituted methylcyclohexene ring at δ 1.51 (3H, *s*, 16-CH_3), 2.15 (1H, *m*, 18-Ha), 2.48 (1H, *m*, 18-Hb), 4.20 (1H, *br s*, 14-H), 3.82 (1H, *m*, 19-H), and 4.04 (1H, *t*, $J=7$ Hz, 20-H). Both the coupling constants of H-14/H-20, and H-19/H-20, were 7 Hz, suggesting that the relative configurations at C-14, 19, 20 were *cis–trans* adducts, thus resembling those of **3** and **4** (Nomura, 1988). Therefore, the relative configurations of the three substituents on the methylclohexene ring of **1** were the same as **3** and **4**. However, the signal of H-20 at 4.04 ppm of **1** was shifted to high field (−0.57 ppm) compared with **3**. These data led us to presume that the proton of H-20 has been shielded due to the change of chemical environment. The CD curve of **1** showed a positive Cotton effect in the 280–320 nm region. Hence, the absolute configurations of **1** at C-14, 19, 20 were the same as **4** (14*S*, 19*S*, 20*R*) based on the excition chirality theory (Nomura, 1988). The locations of three substituents (methylcyclohexene ring, prenyl, and hydroxy groups) were determined from the ^{13}C-NMR and DEPT spectra as well as being compared with other similar Diels–Alder type adducts, obtained from this plant (Nomura et al., 1981). The ^{13}C NMR spectrum of **1** was similar to those of **3** and **4** (see Table 1). The signal at δ 97.5 was attributed to C-6, indicating that the methylcyclohexene ring was connected to C-8. It has been reported that the Diels–Alder type adducts from *Morus* sp. exhibited positive optical rotation for *cis–trans* adducts. Compound **1** was a *cis–trans* adduct, however its optical rotation was negative, $[\alpha]_D^{19}$ −193.9, indicating that the absolute configurations at C-2 and C-3 of **1** are different from that of **3** and **4**.

The structural determination of **1** was supported by the results of an X-ray crystallographic analysis. The PLUTO drawing and the fractional atomic coordinates of **1** are given in Fig. 1. The determination of the absolute configurations of **1** at C-14, 19, 20 by NMR spectroscopic analysis was identical to the PLUTO drawing as 14*S*, 19*S*, 20*R* and shown in Fig. 1, it can be concluded that Fig. 1 also showed the absolute configuration of **1**. Thus, the absolute configurations of **1** at C-2 and C-3 were determined as 2*S* and 3*R*. Both the C-2 isoprenyl and the C-3 hydroxyl group have an α-orientation. It can be observed from the molecular model of **1** that H-20 was located in the shielding zone of the ring B, and this may account for the high field shift of H-20 in **1**.

There are no previous data concerning the absolute configurations at C-2 and C-3 of **3** and **4**. A positive Cotton effect was observed in the 280–320 nm region in the CD spectrum of **3** as well as in **1** and **4**. This observation indicated that the three chiral centers on the cyclohexenyl ring of **3** have the same absolute configurations as those **1** and **4** (Nomura, 1988). The proton

[a] In acetone-d_6.

H-20 of **3** was not located in the shielding zone of the B ring, because both prenyl and hydroxy groups at C-2 and C-3 have β-orientation by comparing the two molecular models of **1** and **3.** The absolute configurations at C-2 and C-3 of **3** are hence reversed compared with those of **1** and was deduced as 2*R*, 3*S*. In order to confirm the location of the methylcyclohexene group of **3**, a chemical reaction has been employed. An aliquot **4** was treated with 5%K_2CO_3 solution at room temperature (Hano and Nomura, 1985) to give an equilibrium mixture (1:1) of **3** and **4** as determined by HPLC analysis. Thus, the absolute configurations at C-2 and C-3 of **4** were the same as **3** and may be specified as 2*R*, 3*S*.

Cathayanon B (**2**), $[\alpha]_D^{19}$ −733.7°, is a yellow powder. Its UV, IR and FAB–MS spectra were very similar to

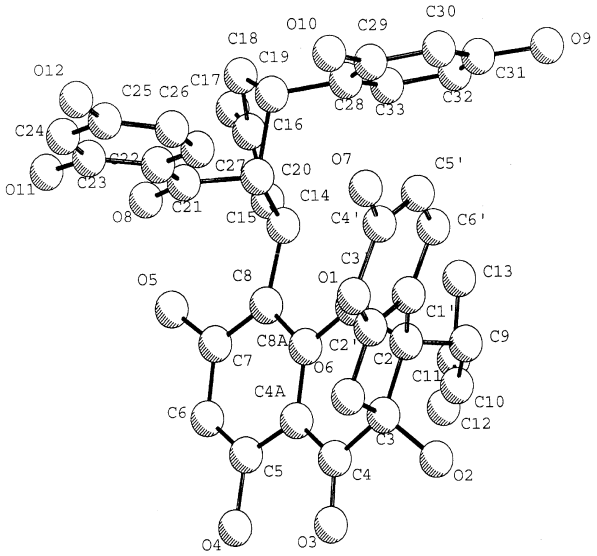

Fig. 1. The PLUTO drawing of **1**.

those of **1**, **3** and **4**. The HRFABMS of **2** revealed an $[M+H]^+$ at *m*/*z* 709.2374 corresponded to the molecular formula $C_{40}H_{36}O_{12}$. The ^{1}H NMR of **2** showed signals corresponding to three sets of ABX type aromatic protons at δ 7.45 (1H, *d*, *J*=8 Hz, 27-H), 5.98 (1H, *dd*, *J*=2, 8 Hz, 26-H), 5.92 (1H, d, *J*=2Hz, 24-H), 6.77 (1H, *d*, *J*=8 Hz, 6′-H), 6.68 (1H, *dd*, *J*=2, 8 Hz, 5′-H), 6.64 (1H, *br s*, 3′-H), 6.31 (1H, *d*, *J*=8 Hz, 33-H), 5.98 (1H, *dd*, *J*=2, 8 Hz, 32-H), and 6.18 (1H, *d*, *J*=2 Hz, 30-H); the protons of a prenyl group at δ 1.52, 1.80 (each 3H, *s*, 11-CH_3), 2.97 (1H, *dd*, *J*=8.4, 15 Hz, 9-Ha), 3.03 (1H, *dd*, *J*=5.6, 15 Hz, 9-Hb) and 5.17 (1H, *m*, 10-H); an isolated aromatic proton at δ 5.74 (1H, *s*, 6-H); and the protons of a trisubstituted methylcyclohexene ring at δ 1.64 (3H, *s*, 16-CH_3), 2.10∼2.20 (2H, *br s*, 18-Ha,b), 5.27 (1H, *br s*, 15-H), 3.75 (1H, *br s*, 19-H), 4.14 (1H, *br s*, 20-H) and 4.21 (1H, *m*, 14-H). The coupling constant of the methylcyclohexene protons H-14/H-20 and that of H-19/H-20 were 11 Hz. Thus, it can be concluded that the relative configurations of the three protons on the trisubstituted methylcyclohexene ring should be an all-*trans* Diels–Alder type adduct, an isomer of **1**, **3** and **4** and of the all-*trans* adduct sanggenon D (**5**; Fukai et al., 1998). Because the CD curve of **2** was similar to that of **5**, which showed a negative Cotton effect in the 280–320 nm region (Nomura, 1988), the absolute configurations at C-14, 19, 20 of **2** were determined as 14*R*, 19*S*, 20*R*. The chemical shift of H-20 of **2** also appeared at a relatively high field (3.96 ppm) resembling compound **1**. The proton H-20 was located in the shielding zone of ring B. This was the same factor that accounted for the shift of H-20 of **2** to high field. Hence, the absolute configurations of **2** at C-2 and C-3 are 2S, 3R. Compared with the ^{13}C NMR spectrum of **1** (see Table 1) the methylcyclohexene ring of **2** would be connected with C-8, similar to **1** and **3** as shown in

Fig. 1. Its absolute configurations at C-2, C-3 would be the same as **1** (2*S*, 3*R*).

The pharmacological tests indicated that the adhesion of HL-60 to BAEC was significantly inhibited by **1** and **2** (1×10^{-5} mol l^{-1}) with inhibitory rates of 44.72 and 39.02%, respectively (Li et al., 2000).

3. Experimental

3.1. General

Melting points were determined on XT4-100X micro-melting point apparatus and are uncorrected. Optical rotations were obtained on a Perkin-Elmer 241 polarimeter. UV spectra were measured on a Shimadzu UV-300 spectrophotometer. IR spectra were recorded on a Perkin-Elmer 683 infrared spectrophotometer. NMR spectra were obtained using an Arian Mercury-300 and Brüker AM-500 spectrophotometers with TMS as internal standard. MS spectra were obtained on an Autospec-Ulma-Tof mass spectrometer. CD spectra were recorded on a JASCO model J-715 spectropolarimeter. HPLC was performed on a Waters 411 equipped with UV-254 detector. Column chromatography was performed using Si gel (Qing Dao Hai Yang Chemical Group Co., Qing Dao, People's Republic of China). Reversed phase column chromatography was performed using Merck Lichroprep RP-8 and RP-18 (40–63 μm) columns, respectively. Analytical column using RP-18(5μm) column (25 cm×4.6 mm) with UV detection at 254 at a mobile phase CH_3CN–H_2O (65:35).

3.2. Plant material

The root bark of *Morus cathayana* was collected at Jiujiang, Jiangxi Province, People's Republic of China in August, 1997 and identified by Professor Ce-Ming Tan. The voucher sample was deposited in our institute (No. 95021).

3.3. Extraction and isolation

The root bark of *M. cathayana* (19 kg) was chipped and extracted with 95% ethanol at room temperature. The resultant extract (820 g) was mixed with silica gel (60–100 mesh) and eluted with $CHCl_3$ and EtOAc sequentially. The $CHCl_3$ solution was concentrated in vacuo and evaporated to yield a residue (229 g), which was submitted to CC on silica gel using cyclohexane-EtOAc (30:1∼7:1) as an eluent to give α-amyrin acetate (6 g), sanggenon M (47 mg) and sanggenon A (17 mg).

Evaporation of the EtOAc solution in vacuo yielded a residue (355 g), which was fractionated over a silica gel column, eluting with $CHCl_3$–MeOH (20:1–6:1) to yield four fractions B-1, B-2, B-3 and B-4. The fraction B-1 (60 g) was applied to a silica gel column eluted with $CHCl_3$–MeOH (20:1), with the fraction of interest being further purified on a RP-18 column with MeOH–H_2O (7:3) as eluent to give scopoletin (10 mg), 4-hydroxy-3,5-dimethoxybenzyl alcohol (46 mg), umbelliferone (73 mg), moracin C (66 mg), moracin P (50 mg) and moracin O (66 mg), respectively. Fraction B-2 (117 g) was fractionated by silica gel CC, RPCC(RP-18) with cyclohexane–EtOAc (5:1) over silica gel, with MeOH–H_2O (7:3) on RP-18 column, with CH_3CN–H_2O (6:4) on RP-8 column to yield **1** (300 mg), **3** (20 mg) and **4** (10 mg). The fraction B-3 (126 g) was separated over silica gel CC with cyclohexane–EtOAc (2:1) and $CHCl_3$–MeOH (20:1) to give sanggenon M (200 mg). Fraction B-4 (150 g) was fractionated in sequence with $CHCl_3$–Me_2CO (10:1∼1:1) over silica gel CC, MeOH–H_2O (6:4) on RPCC(RP-18) column to give **2** (170 mg) and mulberroside (600 mg), respectively.

3.4. Cathayanon A (*1*)

Pale yellow crystal (CH_3OH); mp 180–181°C (d); $[\alpha]_D^{19}$ −193.9° (*c* 0.12, MeOH); UV (MeOH) λ_{max} 205, 230 (sh), 282, 310nm; IR (KBr) ν_{max} 3427, 1633, 1452, 1146 cm^{-1}; ^1H NMR (DMSO-d_6, 300 MHz, 90°C) δ 1.46, 1.67 (each 3H, *s*, 11-CH_3), 1.51 (3H, *s*, 16-CH_3), 2.15 (1H, *m*, 18-Ha), 2.48 (1H, *m*, 18-Hb), 2.64 (1H, *dd*, *J*=7.5, 15 Hz, 9-Ha), 2.93 (1H, *dd*, *J*=6.9, 15 Hz, 9-Hb), 6.97 (1H, *d*, *J*=8 Hz, 27-H), 6.42 (1H, *dd*, *J*=2, 8 Hz, 26-H), 6.29 (1H, *d*, *J*=2 Hz, 24-H), 6.77 (1H, *d*, *J*=8 Hz, 33-H), 6.22 (1H, *d*, *J*=2 Hz, 30-H), 6.10 (1H, *dd*, *J*=2, 8 Hz, 32-H), 7.39 (1H, *d*, *J*=8 Hz, 6′-H), 6.00∼6.03 (2H, *m*, 3′ and 5′-H), 5.65 (1H, *s*, 6-H), 5.23 (2H, *br s*, 10 and 15-H), 4.20 (1H, *br s*, 14-H), 3.82 (1H, *m*, 19-H), 4.04 (1H,*t*, *J*=7 Hz, 20-H); ^{13}C NMR (acetone-d_6, 125 MHz), see Table 1; FABMS *m/z* 709 $[M+H]^+$ (15), 641 (12), 491 (45), 339 (50), 303 (18), 243 (30), 219 (60), 203 (100); HRFABMS calcd for $C_{40}H_{37}O_{12}$, *m/z* 709.2285 $[M+H]^+$, found 709.2348; CD (*c* 7.77×10^{-4}M, MeOH) $[\theta]_{223}$ +4531 (valley), $[\theta]_{237}$ +33243, $[\theta]_{250}$ +4930 (valley), $[\theta]_{276}$ +28178, $[\theta]_{292}$ +12023, $[\theta]_{297}$ +10626, $[\theta]_{305}$ 0, $[\theta]_{328}$ −48820.

3.5. Cathayanon B (*2*)

Yellow powder; $[\alpha]_D^{19}$ −733.7°C (*c* 0.18, MeOH); UV (MeOH) λ_{max} 205, 230 (sh), 282, 310 nm; IR (KBr) ν_{max} 3427, 1633, 1452, 1146 cm^{-1}; ^1H NMR (acetone-d_6, 500 MHz, 20°C) δ 1.52, 1.80 (each 3H, *s*, 11-CH_3), 2.97 (1H, *dd*, *J*=8.4, 15 Hz, 9-Ha), 3.03 (1H, *dd*, *J*=5.6, 15 Hz, 9-Hb), 5.17 (1H, *m*, 10-H), 7.45 (1H, *d*, *J*=8 Hz, 27-H), 5.98 (1H, *dd*, *J*=2, 8 Hz, 26-H), 5.92 (1H, *d*, *J*=2 Hz, 24-H), 5.74 (1H, *s*, 6-H), 6.77 (1H, *d*, *J*=8 Hz, 6′-H), 6.68 (1H, *dd*, *J*=2, 8 Hz, 5′-H), 6.64 (1H, *br s*, 3′-H), 6.31 (1H, *d*, *J*=8 Hz, 33-H), 5.98 (1H, *dd*, *J*=2, 8 Hz, 32-H), 6.18 (1H, *d*, *J*=2 Hz, 30-H), 1.64 (3H, *s*, 16-

CH_3), 2.10∼2.20 (2H, *br s*, 18-Ha,b), 5.27 (1H, *br s*, 15-H), 3.75 (1H, *br s*, 19-H), 4.14 (1H, *br s*, 20-H), 4.21 (1H, *m*, 14-H); ^{13}C NMR (acetone-d_6, 125 MHz), see Table 1; FABMS *m/z* 709 $[M+H]^+$ (40), 641 (30), 625 (11), 491 (24), 353 (5), 203 (15), 137 (100); HRFABMS calcd for $C_{40}H_{37}O_{12}$, *m/z* 709.2285 $[M+H]^+$, found 709.2374; CD (*c* 9.89×10^{-4} M, MeOH) $[\theta]_{223}$ −99485, $[\theta]_{233}$ 0, $[\theta]_{241}$ +16284, $[\theta]_{247}$ 0, $[\theta]_{251}$ −1208, $[\theta]_{253}$ 0, $[\theta]_{270}$ +12840, $[\theta]_{290}$ −28269 (valley), $[\theta]_{294}$ −27329, $[\theta]_{326}$ −61019.

3.6. X-ray crystallographic analysis of **1**

A pale yellow crystal with approximate dimensions of $0.35\times0.35\times0.50$ mm was selected. The following crystallographic data were obtained: monoclinic, space group $P2_1$, lattice constants, $a=10.190$ (1) Å, $b=17.353$ (1) Å, $c=12.557$ (1) Å, $\beta=113.003$ (4)°, $Z=2$. The diffraction data were collected on a MAC DIP-2030K image plate diffractometer with MoK_α radiation ($\lambda=0.71073$ Å), graphite monochromator. A total of 2160 independent reflections were collected in the range of $0°<\theta<25°$ by ω scan technique, of which 2139 reflections ($|F|^2\geqslant10\sigma|F|^2$) were observed and used in structural analysis. The crystal structure was solved by direct methods (SHELXS-86). Forty-six non-hydrogen atoms were located from the E-map. The others were found with successive difference Fourier synthesis. All the non-hydrogen atoms were subjected to anisotropic refinement by full matrix least-squares. The hydrogen atoms were determined with theoretic calculation. The final R_f is 0.058 and the final R_w is 0.065 ($w=1/\sigma^2|F|$), $(\Delta/\sigma)_{max}=0.145$, $(\Delta\rho)_{min}=-0.250$ e/Å^3, $(\Delta\rho)_{max}=0.210$ e/Å^3. The final formula was determined as $C_{40}H_{36}O_{12}(CH_3OH)_3$, which included three molecules of methanol. The corresponding formula weight of **1** was 708.81. The calculated density was 1.303 g/ml. All calculations were carried out with NOMCSDP software.

3.7. Pharmacological tests

HL-60 cells-BAEC (Bovine Arterial Endothalium cells) adhesion assay:

HL-60 cells was labeled with MTT for 2 h and washed (×3) with RPMI 1640 containing 2% FBS (Fetal Bovine Serum). Various numbers of MTT-labeled HL-60 cells were added to BAEC (Bovine Arteroa; Endothalium cells) which were cultured in 96 well multidish and stimulated with 100 U ml^{-1} rh TNF-α for 12 h. After 30 min, all MTT-HL-60 cells accumulated at the bottom of the wells. The supernatants were gently removed and 0.1 ml of DMSO was added. The absorbance at 540 nm was measured (Mean ± S.D, $n=6$). The adhesion of HL-60 to BAEC was significantly inhibited by **1** and **2** (1×10^{-5} mol l^{-1}) with inhibitory rate of 44.72 and 39.02%, respectively.

Acknowledgements

This research program was supported by the National Natural Science Foundation of China (39570836). The authors are grateful for the spectral data afforded by Professor Mitsuo Takasugi (Graduate School of Environmental Earth Sciences, Hokkaido University, Japan) and the literature information provided by Dr. Toshio Fukai (Faculty of Pharmaceutical Sciences, Toho University, Japan). The pharmacological tests were measured by Professor Guifang Chen et al. The Department of Instrumental Analysis in our institute measured the ^1H NMR, ^{13}C NMR, ^1H–^1H COSY, DEPT, ^{13}C ^1H COSY, HMBC, NOE DIF, UV, IR, HRFABMS and X-ray diffraction analysis.

Benzophenone *O*-glucoside, a biogenic precursor of 1,3,7-trioxygenated xanthones in *Hypericum annulatum*

Gerassim M. Kitanov*, Paraskev T. Nedialkov

Department of Pharmacognosy, Faculty of Pharmacy, Medical University of Sofia, Dunav str. 2, 1000 Sofia, Bulgaria

Received 22 January 2001; received in revised form 6 April 2001

Abstract

Two new benzophenones, hypericophenonoside (**1**) and annulatophenone (**2**) were isolated from the methanol extract of the herb of *Hypericum annulatum*. The structures of the benzophenones were established as 2′-*O*-β-D-glucopyranosyl-2,4,5′,6-tetrahydroxy benzophenone (**1**) and 2,3′,5′,6-tetrahydroxy-4-methoxybenzophenone (**2**) based on spectral and chemical evidence. Hypericophenonoside is the second benzophenone *O*-glycoside found in nature. Acid and enzymatic hydrolysis of (**1**) has led directly to the formation of 1,3,7-trihydroxyxanthone (gentisein). This fact confirmed the hypothesis that some xanthones could be formed in plants by dehydration of 2,2′-dihydroxybenzophenones, and the intermediate precursors appear to be benzophenone *O*-glycosides *ortho* to the carbonyl function. © 2001 Elsevier Science Ltd. Keywords: *Hypericum annulatum*; Guttiferae; Benzophenones; Annulatophenone; Hypericophenonoside; Transformation to 1,3,7-trihydroxyxanthone

1. Introduction

In previous studies of *Hypericum annulatum* Moris, subsp. *annulatum* (Robson, 1993), also known as *Hypericum degenii* Bornm. (Jordanov and Kožucharov, 1970), the presence of several flavonols, biapigenin, catechins, two hypericins and four xanthones was demonstrated. Total hydrolysis of purified EtOH extract from the aerial parts of this species has led to the isolation of large amounts of 1,3,7-trihydroxyxanthone (gentisein), but only low quantities of its 3-*O*-glucoside (xanthohypericoside) were found in the plant (Kitanov and Akhtardziev, 1979; Kitanov and Nedialkov, 2000).

This paper describes the isolation and structure elucidation of two benzophenones and transformation of one of them (hypericophenonoside) to gentisein by acid and enzymatic hydrolysis.

2. Results and discussion

The dried aerial parts of *H. annulatum* were defatted with *n*-hexan and then extracted with hot MeOH. The crude MeOH residue was dissolved in hot water and partitioned subsequently with $CHCl_3$ and EtOAc. The EtOAc extract was fractionated by CC on polyamide using H_2O and H_2O–EtOH mixtures as eluent. The fraction containing compound **1** was rechromatographed on polyamide and eluted with $CHCl_3$–MeOH mixtures. Sephadex LH-20 was used as final purification step. The fraction rich in compound **2** was subjected to gel filtration on Sephadex LH-20.

Compound **1** was easily dissolved in water and gave a dark brown color with ferric chloride. Quantitative acid hydrolysis with HCl yielded an aglycone and D-glucose in a ratio 1:1 (57.54 and 42.46%, respectively). The aglycone was identified by UV, IR, EI-MS, ^{1}H NMR spectra and co-TLC as 1,3,7-trihydroxyxanthone (gentisein) (**1d**), previously isolated from this species (Kitanov and Akhtardzhiev, 1979). The main mystery was the presence only of one band at 304 nm in the UV spectrum of compound **1**, while the aglycone showed absorption maxima at 236, 260, 310 and 367 nm typical for xanthones. The similar four maxima were also observed for 3-*O*-β-D-glucoside of 1,3,7-trihydroxyxanthone found not so long ago in the same plant (Kitanov and Nedialkov, 2000). Mild acid hydrolysis of **1** with 0.2–0.5 M HCl and TFA and treatment with β-glucosidase similarly led to the obtaining of gentisein and D-glucose. When monitored by TLC, mild and

enzymatic hydrolysis of **1** showed presence of an intermediate product, which could not be isolated because of its instability.

The IR spectrum of **1** showed absorption bands at 3302 (OH), 1643 (C=O), 1601 and 1516 (C=C) cm^{-1}. The bathochromic shift of the band at 304 nm in the UV spectrum with $AlCl_3$ (+14 nm) and NaOAc (+33 nm) revealed the presence of free hydroxyls *ortho* and *para*, respectively, to the carbonyl function. The HREI-MS of **1** showed the highest peak at *m/z* 244.0383 (rel. int. 100%) corresponding to the molecular formula $C_{13}H_8O_5$ of gentisein **1d**. In the FAB-MS spectrum the $[M+H]^+$ peak at *m/z* 425 was consistent with molecular formula $C_{19}H_{20}O_{11}$, the base peak at *m/z* 263 $[M_{agl}+H]^+$ (rel. int. 100%) with the formula $C_{13}H_{10}O_6$ and an ion peak at *m/z* 245 $[M_{gent}+H]^+$ indicated the gentisein moiety (Fig. 1). Gentisein **1d** was obtained by dehydration of aglycone **1c** ($M_{agl}-M_{gent}=18$). The molecular mass of **1** was also confirmed by elemental analysis data: C = 53.71 and H = 4.82% respectively.

The ^1H NMR spectrum of **1** in acetone-d_6 (Table 1) showed the presence of signals from two chelated

[a] The chemical shifts are expressed in ppm and the coupling constants (*J*) in Hz/s. All protons were assigned by ^{1}H–^{1}H and HETCOR experiments.
[b] Overlapping.
[c] Signal patterns are unclear due to overlapping.

hydroxyl protons at δ 10.96 and a broad signal at δ 8.26 (which were much more expressed in DMSO-d_6 at δ 11.44, 10.38 and 9.15) all disappearing after addition of D_2O. The presence of two hydroxyl groups *ortho* to the carbonyl was confirmed by the appearance of signals from two acetyl groups in lower field at δ 2.30 and 2.35 after peracetylation of **1**. The presence of five substituents of aromatic rings of **1** was confirmed by DEPT experiment (Table 2). The signal at δ 5.91 (*s*, 2H) indicated a symmetrical three substituted phloroglucinol ring A, which was confirmed by the presence of the overlapping signals in ^{13}C NMR at 165.86 ppm (C_2 and C_6) and 96.48 ppm (C_3 and C_5) (Table 2). The signals of three aromatic protons from ring B (acetone-d_6) appeared as two doublets and a quadruplet at δ 7.08, 6.72 and 6.81 with $J=8.8$ and 3.0 Hz respectively. This fact pointed to the *ortho* and *meta* positions of the protons and an asymmetrical structure of this ring.

The signal at δ 4.73 (*d*, $J=7.7$ Hz) and a multiplet at δ 3.23–3.88 were assigned to the sugar residue with β-configuration of the anomeric proton. The positions of all protons were assigned by ^{1}H–^{1}H COSY and HETCOR experiments. Results of ^{13}C NMR and DEPT experiments (Table 2) confirmed the structure of aglycone **1c** as 2,2′,4,5′,6-pentahydroxybenzophenone.

The presence of hydroxyl groups *para* to the carbonyl function and the symmetrical structure of ring A suggest the location of sugar moiety in ring B. To determine the position of the glucose, **1** was methylated and the resultant compound was hydrolyzed by HCl (Fig. 1). The bathochromic shift of the bands at 262 and 369 nm in UV spectra of **1a** with $AlCl_3$ (+19 and +70 nm, respectively) indicated the presence of a free hydroxyl group *ortho* to the carbonyl moiety.

Acetylation of **1a** gave **1b** with mp 121.5–123°C. The EI-MS spectrum of this compound showed a molecular ion $[M]^{+\cdot}$ at *m*/*z* 360 corresponding to the formula $C_{19}H_{20}O_7$ and a peak at *m*/*z* 318 $[M-Ac+H]^+$, which indicated **1b** as a monoacetate. The IR spectrum showed an absorption at 1769 cm^{-1} (–OAc group) and an absence of characteristic band for free hydroxyl groups. The ^{1}H NMR spectrum (Table 1) indicated signals for five aromatic protons, four methoxyl groups, two of which are overlapping at δ 3.68, and an acetyl group at δ 2.03 (3H) *ortho* to the carbonyl function.

Thus the structure of **1** was established as 2′-*O*-β-D-glucopyranosyl-2,4,5′,6-tetrahydroxybenzophenone, named hypericophenonoside. It is a new natural compound and the second benzophenone *O*-glycoside found in the plants (Ferrari et al., 2000).

Compound **2** was isolated as pale yellow needles. It reacted with ferric chloride to give a dark brown color. The IR spectrum established the presence of a hydroxyl (3302 cm^{-1}), a conjugated carbonyl (1645 cm^{-1}) and an aromatic system (1582, 1520 cm^{-1}). The bathochromic shift of the UV maximum after addition of aluminum chloride (+33 nm) and the absence of shift upon addition of sodium acetate revealed free hydroxyl substituents *ortho* to the carbonyl group. The presence of four hydroxyls, two of which *ortho* to the carbonyl function, was confirmed by the presence of two sharp singlets at δ 9.80 (2H) and 9.50 (2H) in the ^{1}H NMR

spectrum in DMSO-d_6 (Table 1), both disappearing after addition of D_2O.

The HREI-MS spectrum showed $[M]^{+\cdot}$ at m/z 276.0642 consistent with the molecular formula $C_{14}H_{12}O_6$ and ion peaks at m/z 167 [$C_8H_7O_4$] derived from ring A and at m/z 137 [$C_7H_5O_3$] from ring B (Fig. 2). The molecular formula of **2** was confirmed by elemental analysis. The data of ^1H NMR and molecular ions of EI–MS support the presence of two symmetrical hydroxyls and a methoxyl group in ring A (phloroglucinol system) and two symmetrical hydroxyls in ring B (resorcinol system).

^1H NMR exhibits a signal of two protons from phloro glucinol ring A at δ 6.02. A doublet at δ 6.62 (2H, $J=2.2$) and a triplet at δ 6.49 (1H) indicated a symmetric resorcinol structure of ring B. The methoxyl group appeared as a singlet at δ 3.81. The assignment of the signals was confirmed by ^1H–^1H COSY, ^{13}C NMR, HETCOR and DEPT experiments (Table 2). Consequently the structure of **2** was established as 2,3′,5′,6-tetrahydroxy-4-methoxybenzophenone, named annulatophenone.

Up to now, only several benzophenone *C*-glucosides were found in *Mangifera indica* L. (Tanaka et al., 1984) and a benzophenone *O*-glucoside together with a *C*-glucoside was recently reported in *Gnidia involucrata* Steut. Ex A. Rich. (Ferrari et al., 2000). Although prenylated benzophenones often occur in the Guttiferae, simple benzophenones are rare in this family and have not been found in species of genus *Hypericum* (Bennett and Lee, 1989). The presence of simple benzophenones in species of this genus and their co-occurrence with simple xanthones may be of taxonomic and biogenetic value.

The biosynthetic pathways to xanthones in higher plants have been discussed in several reviews (Carpenter et al., 1969; Sultanbawa, 1980; Bennett and Lee, 1989; Peres and Nagem, 1997). It has been shown that polyhydroxybenzophenones could be intermediate precursors in the formation of xanthones. The biosynthesis involves shikimate and acetate pathways formation of intermediate benzophenones, which then react intramolecularly to give xanthones. The mechanism for this intramolecular reaction has been postulated involving four possible pathways.

Two alternative pathways of xanthone biosynthesis in cell cultures of *Centaurium erythraea* Rafn. and *Hypericum androsaemum* L. were recently reported (Beerhues, 1996; Schmidt and Beerhues, 1997). In the first one, the intermediate 2,3′,4,6-tetrahydroxybenzophenone was shown to be intramolecularly coupled to 1,3,5-trihydroxyxanthone, whereas in the second one it was coupled to form the isomeric 1,3,7-trihydroxyxanthone. These regioselective oxidative phenol couplings were catalyzed by xanthone synthases, proposed to be cytochrome P_{450} oxydases (Peters et al., 1998).

One of the pathways is dehydration between the hydroxyl groups of the acetate and shikimate derived rings (2,2′-dihydroxybenzophenones) via intermediates such as

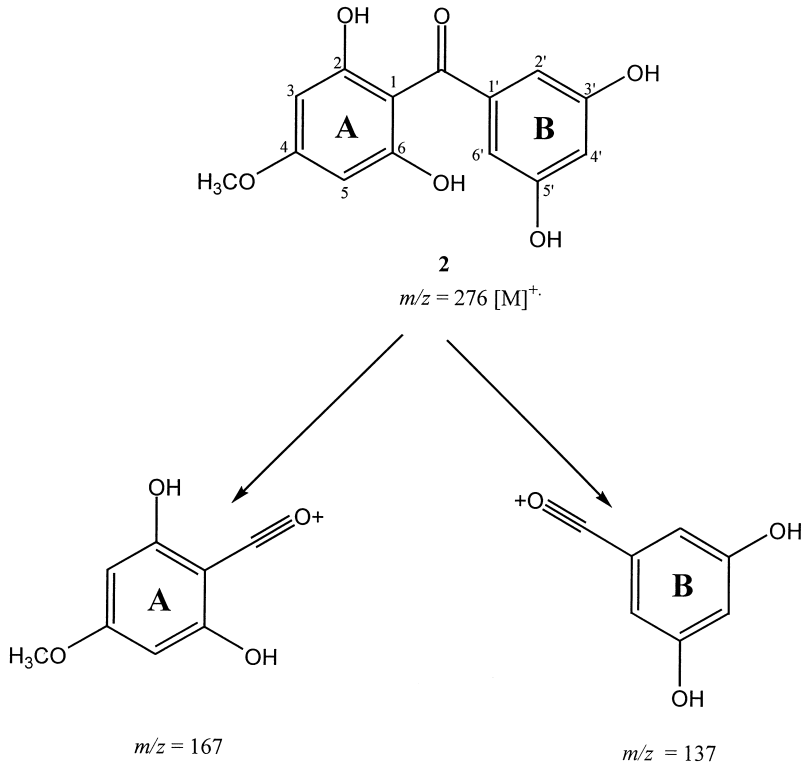

Fig. 2. EI–MS fragmentation of annulatophenone (**2**).

O-pyrophosphates (Carpenter et al., 1969; Sultanbawa, 1980). Up to date however there is no evidence for in vivo formation of polyhydroxyxanthones from benzophenones by dehydration mechanism. The question of the co-occurrence of suitable polyhydroxybenzophenone intermediates and xanthones in plants has not yet found a satisfactory answer.

In our case, in the herb of *Hypericum annulatum* we found the co-occurrence of large amounts of hypericophenonoside **1** (with 2,2′-hydroxyl groups) together with 1,3,7-trihydroxyxanthone (gentisein) **1d**. The benzophenone *O*-glucoside **1** was easily transformed into gentisein by acid or enzymatic hydrolysis. This fact supports the evidence that 2,4,5′,6-tetrahydroxybenzophenone-2′-*O*-glucoside **1** is a precursor of 1,3,7-trihydroxyxanthone. The transformation is realized by elimination of the glucose moiety and subsequent dehydration involving hydroxyls from phloroglucinol ring A and ring B, located *ortho* to the carbonyl group (Fig. 1). These results pointed to the fact, that one of the biosynthetic pathways of xanthone formation in plants is through an intermediate glycosidation at an earlier stage of the benzophenone biosynthesis before cyclization of the two rings.

Finally, it can be concluded that some xanthones are formed in vivo by dehydration of 2,2′-dihydroxybenzophenones. This is a spontaneous reaction which appears to be regulated by deglucosilation of the precursor and the precursors appear to be benzophenones with *O*-glycosilation *ortho* to the carbonyl function.

3. Experimental

3.1. General experimental procedures

Mps uncorr. OR was measured on a Perkin-Elmer 241 polarimeter using MeOH as solvent. UV spectra were run in MeOH and shift reagents on a Specord UV–VIS and IR spectra were recorded in nujol on a Shimadzu FTIR-8101 M instruments. ^{1}H and ^{13}C NMR spectra were obtained on a Bruker ARX 300 apparatus at 300 and 75 MHz, respectively, in acetone-d_6 and DMSO-d_6 (**1** and **2**) and $CDCl_3$ (**1b**), using TMS as internal standard. HREI- and FAB-MS analyses were performed on a Varian MAT 711 mass spectrometer at 70 eV in positive ion mode. Open column chromatography (CC): polyamide S (Woelm, Germany) and Sephadex LH-20 (Pharmacia, Sweden). TLC was performed using silica gel 60 GF_{254} (Merck), $CHCl_3$–MeOH–H_2O (70:20:2) (A), EtOAc–MeCOEt–HCO_2H–H_2O) (25:10:2:4) (B), EtOAc–MeOH–H_2O–AcOH (65:15:15:20) (C) and cellulose (Merck), EtOAc-pyridine–H_2O (12:5:4) (D) mixtures were used as solvents. Hydrolysis of hypericophenonoside **1** was carried out with HCl and TFA (100°C, 2h) and β-glucosidase

(Koch-Light Laboratories) (25°C, 48 h). Methylation of **1** ($Me_2SO_4 + K_2CO_3$ in dry acetone) and acetylation of **1** and **1a** (Ac_2O–pyridine method) were performed by usual procedures. Detection of benzophenones was by spraying with Fast blue salt B (Riedel-De Haën, Germany) in MeOH–H_2O (1:1) and of sugars by anizidine phtalate reagent followed by heating at 110°C for 3–5 min.

3.2. Plant material

The aerial parts of *Hypericum annulatum* (syn. *H. degenii*) were collected during the flowering season from wild habitat at the Central Rhodope Mountains in July 1997. A voucher specimen (No. 144296) has been deposited at the Herbarium of Botany Institute of Sofia (SOM).

3.3. Extraction and isolation

The air dried and powdered herb (1.7 kg) was defatted with *n*-hexan (1 l×6) and extracted with hot MeOH (6 l×8). The crude MeOH residue was dissolved in hot H_2O (2 l), filtered and treated with $CHCl_3$ (300 ml×10). The aq. phase was fractionated with EtOAc (500 ml×7). The EtOAc fraction (52 g) was chromatographed on a polyamide column (150 g), using a 0–60% EtOH linear gradient and gave mixture of **1** and other compounds (H_2O fraction, 5.5 g) and **2** (30–40% EtOH, 2.5 g). The H_2O fraction was rechromatographed (×3) on polyamide (30 g, step gradient $CHCl_3$–MeOH 85:15–80:20). Subsequent Sephadex LH-20 gel filtration (MeOH) gave pure compound **1** (2.1 g). The other fraction, rich in **2**, was further purified on Sephadex LH-20 (MeOH) and by repeated recrystallization from H_2O–EtOH, 383 mg of this compound was obtained.

3.4. Hypericophenonoside (*1*) (2.1 g)

Pale yellow needles (from H_2O), mp 156–158°C. $[\alpha]_D^{20}$ +46.11° (MeOH, *c*1.0300). UV λ_{max}^{MeOH} nm (log ε): 206 (4.327), 225^{sh}, 304 (4.149); +$AlCl_3$ 202, 220, 318; +$AlCl_3$/HCl 202, 220, 315; +NaOAc 337; +NaOAc/H_3BO_3 308. IR ν_{max}^{nujol} cm^{-1}: 3302 (chelated OH); 1643 (>C=O); 1601, 1516 (>C=C<, aromatic). ^1H and ^{13}C NMR: see Tables 1 and 2. HREI–MS *m*/*z* (rel. int.): 244.0383 $[M_{gent}]^{+\cdot}$ $[C_{13}H_8O_5]$ (100), (calcd 244.1993). FAB-MS *m*/*z* (rel. int.): 425 $[M+H]^+$ (42), 263 $[M_{agl}+H]^+$ (100), 245 $[M_{gent}+H]^+$ (16), 163 $[(M_{glu}-H_2O)+H]^+$ (4). Found: C, 53.71; H, 4.82%. $C_{19}H_{20}O_{11}$ requires: C, 53.78; H, 4.75%.

3.5. Acid hydrolysis of *1*

A sample of compound **1** (50 mg) was dissolved in 10 ml of 1 N HCl and refluxed on water bath (100°C). The hydrolysis was monitored by TLC, system A, time interval 5–10 min, for 2 h. After dilution with H_2O and cooling, the aglycone ppt. was filtered and recrystallized from MeOH. The aq. solution was evapd to dryness in vacuo. The residue was dissolved in 50% EtOH and examined for sugar by TLC using solvent systems C and D. The aglycone was identified as 1,3,7-trihydroxyxanthone (gentisein) on the basis of co-TLC, UV, IR, EI–MS and ^1H NMR and the sugar was identified to be D-glucose. The similar procedure was used for mild hydrolysis of **1** with 0.2 M, 0.5 M HCl and 2 M TFA in H_2O–MeOH (1:1).

3.6. Enzymatic hydrolysis of *1*

Compound **1** (15 mg) was dissolved in H_2O and 20 mg of β-glucosidase were added. The solution remained for 48 h at 25°C and then was heated at 80°C for 30 min. The reaction mixture was extracted ×3 with EtOAc to remove the aglycone part and both solutions (H_2O and EtOAc) were evaluated for identification of the components.

3.7. Methylation and hydrolysis of *1*

Compound **1** (200 mg) was refluxed for 46 h with Me_2SO_4 (6 ml) in dry acetone (150 ml), containing dry K_2CO_3 (4 g). After filtration and evapn. to dryness the residue was dissolved in 40 ml MeOH–4% HCl (1:1). The mixture was refluxed on boiling water bath for 3 h and MeOH was removed in vacuo. The aq. solution was extracted with $CHCl_3$ (30 ml×5), dryed and after evapn. of the solvent the residue was purified on Sephadex LH-20 (MeOH). The methylated aglycone was crystallized from MeOH–C_6H_6 to give a solid (76 mg) of **1a**.

3.8. 2′-Hydroxy-2,4,5′,6-tetramethoxybenzophenone (*1a*) (76 mg)

Yellow flakes (from MeOH–C_6H_6), mp 177.5–179°C. UV λ_{max}^{MeOH} nm: 231, 262, 369; +$AlCl_3$ 250^{sh}, 281, 439; +$AlCl_3$/HCl 262^{sh}, 281^{sh}, 369, 439^{sh}; +NaOMe 231^{sh}, 262, 369. IR ν_{max}^{nujol} cm^{-1}: 3300 (w, chelated OH), 1615 (>C=O), 1608, 1587 (>C=C<, aromatic). HREI-MS *m*/*z*: 318.2896 (calcd. 318.3205) $[C_{17}H_{18}O_6]$.

3.9. Acetylation of *1* and *1a*

Samples of **1** (30 mg) and **1a** (20.4 mg) were treated with C_5H_5N (0.6 ml) and Ac_2O (2 ml) and refluxed for 3 h. The reaction mixtures were poured on ice and kept at 4°C for 24 h. The ppts. were filtered, dried and crystallized from EtOH to give 21 mg of **1**-octaacetate and 16 mg of **1a**-monoacetate (**1b**) derivatives.

3.10. 2′-Acetoxy-2,4,5′,6-tetramethoxybenzophenone (**1b**) (16 mg)

Colorless prismatic crystals (from EtOH), mp 121.5–123°C. IR ν_{max}^{nujol} cm^{-1}: 1769 (–OAc), 1659 (>C=O), 1605, 1590 (>C=C<, aromatic). ^1H NMR: see Table 1. EI-MS *m/z* (rel. int.): 360 $[M]^+$ $[C_{19}H_{20}O_7]$ (5), 318 $[M-Ac+H]^+ = [M_{\mathbf{1a}}]^+$ (22), 287 $[M-Ac-OMe]^+ = [M_{\mathbf{1a}}-OMe]^+$ (61), 195 $[M-165]^+$ (7), 168 $[M-192]^+$ (100), 150 $[M-192-H_2O]^+$ (46).

3.11. Annulatophenone (**2**) (383 mg)

Pale yellow needles (from H_2O–EtOH), mp 187–189°C. UV λ_{max}^{MeOH} nm (log ε): 208 (4.371), 222^{sh}, 306 (3.908); $+AlCl_3$ 226^{sh}, 307^{sh}, 339; $+AlCl_3$/HCl 225^{sh}, 303^{sh}, 331; +NaOAc 306; +NaOAc/H_3BO_3 306. IR ν_{max}^{nujol} cm^{-1}: 3302 (chelated OH), 1645 (>C=O), 1582, 1520 (>C=C<, aromatic). ^1H and ^{13}C NMR: see Tables 1 and 2. HREI–MS *m/z*: 276.0642 $[C_{14}H_{12}O_6]$ (calc. 276.241). EI-MS: 276 $[M]^{+\cdot}$ (100), 259 $[M-OH]^+$ (90), 167 $[M-109]^+$ $[C_8H_7O_4]$ (83), 137 $[M-139]^+$ $[C_7H_5O_3]$ (14). Found: C, 60.79; H, 4.47%. $C_{14}H_{12}O_6$ requires C, 60.87; H, 4.38%.

Abstract

From the leaves and branches of *Fernandoa adenophylla*, a lignan glycoside (fernandoside) and a phenylpropanoid glycoside (2″-*O*-β-apiosylverbascoside) were isolated together with 12 known compounds. The structural elucidations were based on analyses of physical and spectroscopic data. © 2001 Published by Elsevier Science Ltd.

Keywords: *Fernandoa adenophylla*; Bignoniaceae; Lignan glycoside; Phenylpropanoid glycoside; Fernandoside; 2″-*O*-β-Apiosylverbascoside

1. Introduction

As part of our ongoing study on Thai medicinal plants, we investigated the constituents of *Fernandoa adenophylla* Steenis (Bignoniaceae, Thai name: Khae-hang-khang) collected from the botanical gardens, Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand. *F. adenophylla* is a tree, 5–13 m high, distributed in south and south-east Asia regions. In Thai traditional medicine, the leaves are used for external treatment of skin diseases. No chemical investigation has been carried out on this genus. The present study deals with the isolation and structural elucidation of 14 compounds (**1**–**14**), including a new lignan glycoside (**8**), a new phenylpropanoid glycoside (**12**) and 12 known compounds (**1**–**7**, **9**–**11** and **13** and **14)** from this plant.

2. Results and discussion

From the methanolic extract of the leaves and branches of *F. adenophylla,* 14 compounds (**1**–**14**) were isolated. Twelve were identified as known compounds; salidroside (**1**) (Schwab and Schreier, 1988), decaffeoylverbacoside (**2**), verbascoside (**3**), isoverbascoside (**4**), leucosceptoside A (**5**) (Miyase et al., 1982), plantaginoside C (**6**) (Miyase et al., 1991), martynoside (**7**) (Sasaki et al., 1978), (6*R*, 9*S*)-oxo-α-ionol glucoside (**9**) (Pabst et al., 1992), hispidulin-7-*O*-β-glucoside (**10**) (Hase et al., 1995), (+)-lyoniresinol 3a-*O*-β-glucoside (**11**) (Achenbach et al., 1992), apigenin-7-*O*-β-glucuronide (**13**) (Hase et al., 1995) and hispidulin-7-*O*-β-glucuronide (**14**) (Subramanian and Nair, 1972) by comparison of physical data with literature values and from spectroscopic evidence.

The molecular formula of compound **8** was determined as $C_{36}H_{44}O_{16}$ by HR–FAB mass spectrometry. The ^{1}H and ^{13}C NMR spectra of **8** were very similar to those of **11**. In addition, the signals of 1,3,4-trisubstituted aromatic ring, one methoxy signal and one ester carbonyl carbon were observed. Comparison of the ^{13}C NMR spectral data of **8** with those of **11** revealed the downfield shift of C-6 (+2.2 ppm) and upfield shift of C-5 (−2.6 ppm) of the glucosyl moiety indicating that the additional unit is an ester located at C-6 of the glucosyl moiety. Moreover, the HMBC spectrum (Fig. 1) revealed the correlation between H-6 (δ 4.56 and 4.33) of the glucosyl moiety and carbonyl carbon (δ 168.0). The methoxyl group of the additional unit was assigned to position C-3″ by a difference NOE experiment in the ^{1}H NMR spectrum. Irradiation of this methoxy signal (δ 3.78) caused an NOE enhancement at H-2″ (δ 7.48, *d*, $J=2.0$ Hz). Consequently, the structure of compound **8**

12

The molecular formula of compound **12** was determined as $C_{34}H_{44}O_{19}$ by HR–FAB mass spectrometry. Inspection of the ^{1}H NMR spectrum revealed the presence of two sets of AMX systems [δ 6.66 (*d*, J = 2.0 Hz), δ 6.63 (*d*, J = 8.1 Hz) and δ 6.52 (*dd*, J = 8.1, 2.0 Hz) for the 3,4-dihydroxy-β-phenylethoxyl moiety; and δ 7.01 (*d*, J = 2.0 Hz), δ 6.73 (*d*, J = 8.1 Hz) and δ 6.90 (*dd*, J = 8.1, 2.0 Hz) for the caffeoyl moiety], two *trans*-olefinic protons [δ 7.24 (*d*, J = 15.9 Hz) and δ 6.23 (*d*,J = 15.9 Hz)] together with three anomeric protons δ 4.41 (*d*, J = 7.8 Hz) for β-glucose, δ 5.00 (*d*, J = 1.3 Hz) for α-rhamnose and δ 5.17 (*d*, J = 2.2 Hz) for β-apiose. Acid hydrolysis with 0.2 N H_2SO_4 afforded rhamnose, apiose and glucose (identified by TLC). Comparison of the ^{13}C NMR spectral data with those of verbascoside (**3**) indicated that glucose is the core sugar with the 3,4-dihydroxy-β-phenylethoxyl moiety located at C-1″ as well as the *trans*-caffeoyl moiety linked at C-4″. The complete assignments were based on the results of COSY, HSQC and HMBC. COSY and HSQC experiments were used to determine the sugar protons (Table 2). HMBC correlations were observed between H-1″ (δ 4.41) and CH_2-

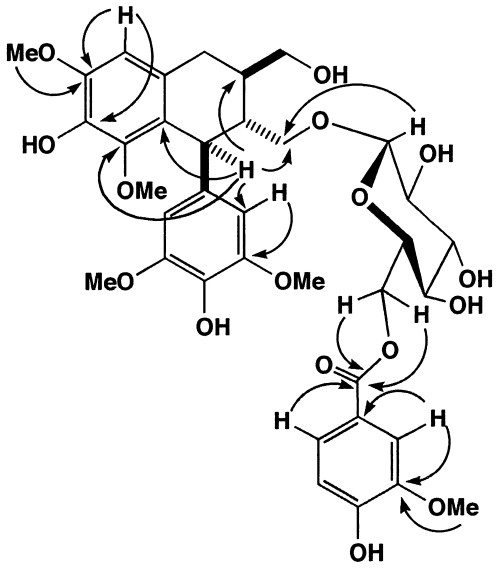

Fig. 1. The HMBC correlations of fernandoside (**8**).

α (δ 72.2); H-2″ (δ 3.47) and C-1″ and C-1‴″ H-3″ (δ 3.87) and C-2″ and C-1‴ as well as H-4″ and a carbonyl carbon (δ 168.3). Also, the reciprocal HMBC correlations were found between H-1‴″ and C-2″; H-1‴ and C-3″. On the basis of the spectral data, the structure of compound **12** was established as 3,4-dihydroxy-β-phenylethoxy - *O* - β - apiofuranosyl - (1→2) - α - rhamnopyranosyl-(1→3)-4-*O*-caffeoyl-β-glucopyranoside (2″-*O*-β-apiosylverbascoside).

3. Experimental

3.1. General

NMR spectral data were recorded in CD_3OD using a JEOL JNM A-400 spectrometer (400 MHz for ^{1}H NMR and 100 MHz for ^{13}C NMR) with tetramethylsilane (TMS) as internal standard. MS were recorded on a JEOL JMS-SX 102 spectrometer. IR were measured with a HORIBA FT 710 infrared spectrometer. UV were recorded on a JASCO V-520 spectrophotometer. Optical rotations were measured with a Union PM-1 digital polarimeter. Preparative HPLC was carried out on columns of ODS (20×150 mm i.d., YMC) and Diol-120 (8.0×300 mm i.d., YMC) with a Tosoh refraction index (RI-8) detector. The flow rates were 6 ml/min for ODS and 3ml/min for Diol-120. For CC, silica gel G 60 (Merck), YMC-gel ODS (50 μm, YMC), polyamide C-200 (Wako) and highly porous copolymer of styrene and divinylbenzene (Mitsubishi Chem. Ind. Co. Ltd) were used. The solvent systems were: (I) EtOAc–MeOH–H_2O (4:1:0.1), (II) EtOAc–MeOH–H_2O (7:3:0.3), (III) 20–70% MeOH, (IV) 10% MeCN, (V) 20% MeCN, (VI) 25% MeCN, (VII) MeCN, (VIII) 15% MeCN and (IX)

100–80% MeCN. The spray reagent used for TLC was 10% H_2SO_4 in 50% EtOH.

3.2. Plant material

The leaves and branches of *Fernandoa adenophylla* Steenis were collected in May 2000 from the botanical gardens, Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand. The identification of the plant was confirmed by Professor Vichiara Jirawongse, Department of Pharmaceutical Botany and Pharmacognosy, Faculty of Pharmaceutical Sciences, Khon Kaen University. A voucher sample is kept in the Herbarium of the Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand.

3.3. Extraction and isolation

The dried leaves and branches (2.5 kg) of *F. adenophylla* were extracted with hot MeOH. After removal of the solvent by evaporation, the residue (240.0 g) was defatted with Et_2O. The aqueous layer was subjected to a column of highly porous copolymer of styrene and divinylbenzene and eluted with H_2O, MeOH and Me_2CO, successively. The fraction eluted with MeOH (25.0 g) was subjected to a column of silica gel (systems I and II, respectively) affording three fractions. Fraction 1 (4.8 g) was applied to a RP-18 column using system III to provide 11 fractions. Fraction 1-1 was purified by prep. HPLC–ODS (system IV) to give compounds **1** (43 mg) and **2** (120 mg). Fractions 1-5 and 1-7 were similarly purified by prep. HPLC-ODS (system V) to afford compounds **3** (1 g) and **4** (620 mg). Fractions 1-8 and 1-9 were further purified by prep. HPLC–ODS (system VI) and HPLC–Diol (system VII) to provide compound **5** (32 mg), **6** (38 mg), **7** (17 mg), **8** (24 mg), **9** (9 mg) and **10** (90 mg). Fraction 2 (8.4 g) was applied to a RP-18 column (system III) to afford 13 fractions. Fraction 2-5 was purified by prep. HPLC–ODS (system VIII) to give compound **11** (160 mg). Fractions 2-8, 2-9 and 2-10 were combined and further separated on a column of polyamide (system IX), then followed by prep. HPLC–ODS (system V) to afford compound **12** (24 mg). Fractions 3 was subjected to a RP-18 column of (system III), then

Amorphous powder, $[\alpha]_D^{26}$ −90.7° (MeOH, *c* 1.40); UV λ_{max}^{MeOH} (nm): 355, 250; IR υ_{max}^{KBr} cm^{-1}: 3400, 2936, 1698, 1604, 1518, 1447, 813; ^1H NMR (CD_3OD) and ^{13}C NMR (CD_3OD): Table 2; negative HR–FAB–MS, *m*/*z*: 755.2413 $[M–H]^-$ ($C_{34}H_{43}O_{19}$ requires 755.2398).

3.6. Acid hydrolysis of 2″-O-β-apiosylverbascoside (**12**)

Compound **12** (5 mg) was dissolved in 0.2 N H_2SO_4 (5 ml) and heated at 95°C for 2 h. After cooling, the reaction mixture was extracted with EtOAc. The aqueous layer was neutralized with $NaHCO_3$, concentrated to dryness, and extracted with pyridine. The pyridine extract was then analyzed on silica gel TLC (EtOAc–MeOH–H_2O–AcOH 13:3:3:4), affording rhamnose (R_f 0.63), apiose (R_f 0.49) and glucose (R_f 0.39).

Abstract

Four flavonoid ketohexosefuranosides, pinnatifinoside A, pinnatifinoside B, pinnatifinoside C, and pinnatifinoside D were isolated from the leaves of *Crataegus pinnatifida* Bge. var. *major* N.E.Br. Their structures were elucidated by spectroscopic analysis (UV, IR, MS and 1D, 2D NMR) and chemical evidence. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Crataegus pinnatifida Bge. var. *major* N.E.Br. (Rosaceae) is widely distributed in the northeast part of China. It is used as a medicinal plant to improve digestion, remove retention of food, promote blood circulation and resolve blood stasis both in traditional and folk medicine (Ammon and Händel, 1981). At the same time, it shows numerous mild, but well documented, pharmacological activities and few side effects. Preparations of *C. pinnatifida* Bge. var. *major* (leaves or fruit) improve the heart function, and there are indications of declining cardiac performance, deficiency of the coronary blood supply and mild forms of arrhythmia (Pöpping et al., 1995; Al Makdessi et al., 1996). To date, more than 50 flavonoids have been isolated from *Crataegus* (Nikolov et al., 1982; Dauguet et al., 1993). Chemical investigation of the leaves of *C. pinnatifida* Bge. var. *major* N.E.Br. led to the isolation of four new compounds, which were named pinnatifinoside A (**1**), pinnatifinoside B (**2**), pinnatifinoside C (**3**), and pinnatifinoside D (**4**).

[a] *J* values are given in Hz.

spectrum were characteristic of hydroxyl, hydrogen bonded carbonyl and aromatic groups, respectively. The UV spectrum of **1** exhibited absorption maxima at 326 (Band I) and 271 nm (Band II; in MeOH), bathochromic shifts of 66, 41, 66 and 66 nm with NaOMe, NaOAc, $AlCl_3$ and $AlCl_3$ + HCl in Band I, respectively, as well as bathochromic shifts of 8 nm with $AlCl_3$ and $AlCl_3$ + HCl, and no shifts with NaOMe and NaOAc in Band II. These data ultimately revealed (see later) that **1** had two free hydroxyl groups at C-5 and 4′ and no free hydroxyl group at C-7 in the flavone skeleton.

In the ^{1}H NMR spectrum (Table 1), a downfield proton at δ 13.20 confirmed the presence of the 5-OH, two set of doublets at δ 7.95 (2H, *d*, J = 8.8 Hz) and 6.94 (2H, *d*, J = 8.8 Hz) that were assigned to H-2′,6′ and H-3′,5′, respectively, and two singlets at δ 6.84 and 6.36 that were due to the protons at C-3 and C-6 in rings A and C. These data indicated the aglycone moiety was analogous to apigenin except for the absence of one proton in ring A. In the ^{13}C NMR spectrum (Table 2), 15 carbon signals from the aglycone moiety were similar to those of vitexin (Lin et al., 1999), but the signals of C-6 and C-9 appeared at δ 93.8 and 151.5, shifted upfield by $\Delta\ \delta$ 4.0 ppm compared with those of vitexin. In addition, six carbon signals from a sugar moiety were evident. In the DEPT spectrum, carbon signals from the sugar moiety resonated at δ 121.6 (C), 83.9 (CH), 80.7 (CH), 76.0 (CH), 60.8 (CH_2) and 31.4 (CH_2). Furthermore, the carbon signal at δ 31.4 was directly attached

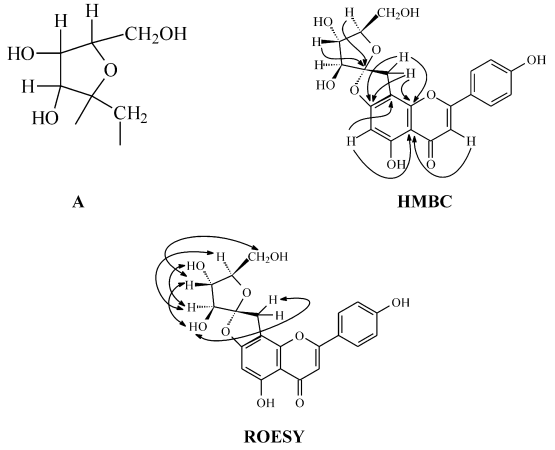

Fig. 1. Structure of fragment A and the key correlation of HMBC and ROESY for **1**.

to the protons at δ 3.67 (1H, *d*, $J=16.7$ Hz, H-1″*a*) and 3.13 (1H, *d*, $J=16.7$ Hz, H-1″*b*) in the HMQC spectrum. In the ^{1}H–^{1}H COSY spectrum, the proton at δ 3.83 (1H, *m*, H-4″) correlated with protons at δ 4.16 (1H, t, $J=5.1$ Hz, H-3″) and 3.88 (1H, *m*, H-5″), while the proton at δ 3.88 (1H, *m*, H-5″) correlated with protons at δ ~3.45 (2H, *m*, H-6″). Consequently, this is taken into consideration of the HMQC and HMBC spectral analyses (Fig. 1), the sugar was a ketohexose skeleton and confirmed the presence of fragment A (Fig. 1). The connectivity of the aglycone and sugar moiety was established on the basis of the following evidence. A downfield quaternary carbon (δ 121.6) of ketohexose C-2″ should be linked to the C-7 oxygen atom due to the absence of a free 7-OH in the UV and ^{1}H NMR spectra, and the signal of C-7 should display an upfield shift compared with the corresponding signals of apigenin (Ternai and Markham, 1976). The downfield chemical shift revealed that C-2″ was at the center of a dioxaspirocycle (Bheemasankara et al., 1988). The signal (δ 31.4) of ketohexose C-1″ was linked to C-8, instead of C-6, of the flavone skeleton, which was confirmed by the HMBC spectrum in which the carbon signals at δ 151.3 (C-9) and δ 163.3 (C-7) were correlated with the protons at δ 3.67 (H-1″*a*), 3.13 (H-1″*b*). The C-8 signal appeared at δ 102.5 (quaternary carbon) in the ^{13}C NMR spectrum. Furthermore, it was essential to clarify the type and relative configuration of the sugar moiety. The ROESY spectrum (Fig. 1) showed cross peaks between protons at δ 4.16 (1H, *t*, $J=5.1$ Hz, H-3) and 3.88 (1H, *m*, H-5), at δ 3.83 (1H, *m*, H-4) and ~3.45 (2H, *m*, H-6), and proton at δ 4.16 (1H, *t*, $J=5.1$ Hz, H-3) and hydroxyl proton at δ 5.50 (1H, *d*, $J=5.1$ Hz, 4-OH), and proton at δ 3.67 (1H, *d*, $J=16.7$ Hz, H-1a) and hydroxyl proton at δ 5.94 (1H, *d*, $J=5.1$ Hz, 3-OH). These data indicated a relative configuration of the sugar moiety as that of α-D-fructofuranose (Agrawal, 1992). Thus, the structure of pinnatifinoside A was elucidated as **1**. It is a new flavonoid.

Compound **2** was obtained as light yellow needles, $[\alpha]_D^{25}$ +58 (MeOH, *c* 0.12). It was identical with **1** in the Mg–HCl color reaction, UV and IR spectra except for the absorption band at 1710 cm^{-1}. The HRESIMS of **2** showed a $[M+H]^+$ at *m*/*z* 457.1167 corresponding to the molecular formula $C_{23}H_{20}O_{10}$ (calc. 456.1128). The ^{1}H and ^{13}C NMR spectra of **2** were analogous to those of **1** (Tables 1 and 2). A methyl singlet at δ 2.03 (*s*) in the ^{1}H NMR spectrum and two carbon signals at δ 20.6 and 170.3 in the ^{13}C NMR spectrum of **2** indicated the presence of an additional acetyl group. Absence of a free hydroxyl group at δ 4.85 of the sugar moiety in the ^{1}H NMR spectrum, a typical downfield shift of C-6″ at δ 63.8 ($\Delta\delta$ 3.0) and an upfield shift of C-5″ at δ 80.5 ($\Delta\delta$ 3.4) in the ^{13}C NMR spectrum, when compared with those of 1, showed acetylation of C-6″-OH. Furthermore, the related stereochemical assignments at the sugar moiety were inferred from 2D NMR spectroscopic studies (^{1}H–^{1}HCOSY, ROESY and HMQC). Alkaline hydrolysis of two with 0.1% KOH afforded **1**. Thus, the structure of pinnatifinoside B was established as **2**, a new compound.

Compound **3** was obtained as yellow needles, $[\alpha]_D^{25}$ −34 (MeOH, *c* 0.16). It was identical with **2** in the Mg–HCl color reaction, UV, ESIMS and IR spectra. The HRESIMS of **3** showed the $[M+H]^+$ at *m*/*z* 457.1178 corresponding to a molecular formula $C_{23}H_{20}O_{10}$ (calc. 456.1128). The ^{1}H and ^{13}C NMR spectra of **3** (Tables 1 and 2) were also analogous to those of **2** except for the signals of the sugar moiety. It was essential to clarify the type and configuration of the sugar moiety. In the DEPT spectrum, carbon signals from the sugar moiety were at δ 121.8 (C), 81.2 (CH), 74.4 (CH), 71.3 (CH), 64.4 (CH_2) and 31.4 (CH_2).

Furthermore, the carbon signal at δ 31.4 was directly attached to the protons at δ 3.69 (1H, *d*, $J=16.7$ Hz) and 3.18 (1H, *d*, $J=16.7$ Hz). Consequently, the sugar was also a ketohexose skeleton. In the ^{1}H–^{1}H COSY spectrum, the proton at δ 4.18 (1H, *t*, $J=5.0$ Hz, H-4″) correlated with the protons at δ 4.12 (1H, *m*, H-5″) and 3.96 (1H, *t*, $J=5.0$ Hz, H-3″), and the proton at δ 4.12 (1H, *m*, H-5″) correlated with the protons at δ 4.39 (1H, *m*, H-6″) and 3.96 (1H, *m*, H-6″). Combined with the HMQC and HMBC spectral data, the presence of fragment A (Fig. 1) was confirmed. Furthermore, cross peaks between protons at δ 3.96 (1H, H-3″) and 4.18 (1H, H-4″) in the NOESY spectrum suggested the relative configuration of sugar moiety as that of β-D-allulofuranose (Yu and Yang, 1999). The connectivity of aglycone and sugar moiety was established using the same method as **1**. Finally, the position of the acetyl group was deduced to be C-6″ in the sugar moiety by the long distance correlations of carbonyl signal at δ 170.3 and the protons at δ 4.39 and 3.96 (H-6″). Thus, the structure of pinnatifinoside C was elucidated as **3**.

Compound **4** was obtained as yellow needles, $[\alpha]_D^{25}$ +25 (MeOH, *c* 0.11). It was identical with **2** and **3** in the Mg–HCl color reaction, UV, ESIMS and IR spectra. The HRESIMS of **4** showed the $[M+H]^+$ at *m*/*z* 457.1170 corresponding to a molecular formula $C_{23}H_{20}O_{10}$ (calc. 456.1128). The ^{1}H and ^{13}C NMR spectra of **4** (Tables 1 and 2) were also analogous to those of **2** and **3** except for the signals of the sugar moiety. The signal of C-1″ and 2″ in the sugar moiety appeared at δ 33.0 and 118.5, which indicated that the configuration of **4** was different from that of **3**. The related stereochemical assignments suggested that the relative configuration of the sugar moiety was the same as that of α-D-allulofuranose (Yu and Yang, 1999). The position of the acetyl group was at C-6″ in the sugar moiety as evidenced by HMBC, HMQC, ^{1}H–^{1}H COSY and NOESY experiments. Thus, the structure of pinnatifinoside D was elucidated as **4**.

3. Experimental

Melting points were taken on an X4 micro-melting point apparatus and are uncorrected. UV spectra were determined with a Hitachi UV-2201 spectrophotometer and IR spectra with a Shimadzu (KBr) IR spectrophotometer. ^{1}H, ^{13}C and 2D NMR spectra were measured on a Brüker ARX at 300 MHz for ^{1}H and 75 MHz for ^{13}C with TMS as an internal standard and coupling constants (J) are given in Hz. Mass spectra were recorded on a Finnigan ESIMS spectrometer. Optical rotations were measured on a Perkin-Elmer 241 digital polarimeter in CH_3OH. HR-mass spectra were recorded on a VG-Autospec-3000 spectrometer.

3.1. Plant material

The leaves of *C. pinnatifida* Bge. var. *major* were collected from Liaoning Province of China, in June 1997. A voucher specimen (970706) was taxonomically identified by Professor Chunquan Xu and deposited in the Herbarium of Department of Traditional Chinese Medicines, Shenyang Pharmaceutical University.

3.2. Extraction and isolation

The leaves (20 kg) were first extracted three times with 80% aq. EtOH under reflux. The extracts were combined and concentrated under reduced pressure. The concentrated extract was suspended in water and was subjected to macroporous resin column chromatography, eluting with 55% EtOH. The solvent was evaporated under reduced pressure to obtain a mixture (120 g). This was applied to a silica gel column eluted with a $CHCl_3$–CH_3OH in gradient to afford Frs, 2, 3 and 4. Fr 2 [1 g, $CHCl_3$–CH_3OH (50:1)] was subjected to polyamide column chromatography with H_2O–EtOH (1:1) to yield **3** (15 mg) and **4** (10 mg). Fr 3 [3 g, $CHCl_3$–CH_3OH (20:1)] was subjected to polyamide column chromatography with H_2O–EtOH (1:1) to yield **2** (19mg). Fr 4 [$CHCl_3$–CH_3OH (10:1)] was applied to a silica gel column eluted with $CHCl_3$–CH_3OH (in gradient) as eluent, with combined fractions [$CHCl_3$–CH_3OH (15:1∼9:1)] being subjected to polyamide column chromatography with H_2O–EtOH (3:2) to yield **1** (24 mg).

3.3. Pinnatifinoside A (*1*)

Yellow needles; mp 185–187°C; $[\alpha]_D^{25}$ +79 (MeOH, *c* 0.24); UV λ_{max} (MeOH) nm: 326, 271; (+MeONa) 392, 271; (+NaOAc) 367, 271; (+$AlCl_3$) 392, 279; (+$AlCl_3$+HCl) 392, 279. IR ν_{max} (KBr) cm^{-1}: 3370, 1650, 1606 and 1520; ESIMS *m/z*: 415 $[M+H]^+$, 397 [415–18], 367 [397–30] and 283 [367–84]; ^{1}H and ^{13}C NMR data Tables 1 and 2.

3.4. Pinnatifinoside B (*2*)

Light yellow needles; mp 240–242°C; $[\alpha]_D^{25}$ +58 (MeOH, *c* 0.12); UV λ_{max} (MeOH) nm: 322, 271; (+MeONa) 393, 271; (+$AlCl_3$) 389, 278; (+$AlCl_3$+HCl) 393, 279; IR ν_{max} (KBr) cm^{-1}: 3370, 1710, 1650, 1606 and 1520; ESIMS *m/z*: 457 $[M+H]^+$, 439 [457–18], 379 [439–60], 351 [379–28], 323 [351–28] and 295 [323–28]; HRESIMS $[M+H]^+$: found 457.1167. Calc. for $C_{23}H_{20}O_{10}$: 456.1128 ^{1}H and ^{13}C NMR data see Tables 1 and 2.

Alkaline hydrolysis of **2**. Compound **2** was heated with 0.1% KOH for 0.5 h at 60°C. The hydrolysate was neutralized with 0.1 N HCl and extracted by EtOAc. The EtOAc extract was evaporated, and the residue was subjected to polyamide TLC using $CHCl_3$: MeOH: MeCOEt (4:1:0.5) and EtOH–H_2O (1:1) as solvent, respectively. The product of hydrolysis was identical with pinnatifinoside A (1) by their R_f values.

3.5. Pinnatifinoside C (*3*)

Light yellow needles; mp 246–248°C; $[\alpha]_D^{25}$ −34 (MeOH, *c* 0.16); UV λ_{max} (MeOH) nm: 324, 270; (+MeONa) 391, 270; (+$AlCl_3$) 390, 278; (+$AlCl_3$+HCl) 390, 279; IR ν_{max} (KBr) cm^{-1}: 3370, 1710, 1650, 1606 and 1520; ESIMS *m/z*: 457 $[M+H]^+$, 439 [457–18], 379 [439–60], 351 [379–28], 323 [351–28] and 295 [323–28]; HRESIMS $[M+H]^+$: found 457.1178. Calc. for $C_{23}H_{20}O_{10}$: 456.1128. ^{1}H and ^{13}C NMR data (Tables 1 and 2).

3.6. Pinnatifinoside D (*4*)

Light yellow needles; mp 248–250°C; $[\alpha]_D^{25}$ +25 (MeOH, *c* 0.11); UV λ_{max} (MeOH) nm: 324, 271; (+MeONa) 391, 270; (+$AlCl_3$) 390, 278; (+$AlCl_3$+HCl) 390, 279; ESIMS *m/z*: 457 $[M+H]^+$, 439 [457–18], 379 [439–60], 351 [379–28], 323 [351–28] and 295 [323–28]; HRESIMS $[M+H]^+$: found 457.1170. Calc. for $C_{23}H_{20}O_{10}$: 456.1128. ^{1}H and ^{13}C NMR data (Tables 1 and 2).

Chemical constituents from *Dendrobium densiflorum*

Chengqi Fan, Wei Wang, Yiping Wang, Guowei Qin, Weimin Zhao*

Department of Phytochemistry, Shanghai Institute of Materia Medica, Shanghai Institute of Biological Sciences, Chinese Academy of Sciences, 294 Taiyuan Road, Shanghai 200031, People's Republic of China

Received 27 October 2000; received in revised form 15 February 2001

Abstract

5-[2′-(3″-Hydroxy-5″-methoxyphenyl)-ethyl]-1,3-benzodioxole and 7-hydroxy-2-methoxy-1,4-phenanthrenedione, along with 16 known compounds were identified from the stems of *Dendrobium densifiorum* Lindl. ex Wall. (Orchidaceae). The structure of a previously reported compound dendroflorin obtained from the plant was revised on the basis of spectroscopic analysis. Among the identified compounds, five were found to exhibit anti-platelet aggregation activity in vitro. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Orchidaceae; *Dendrobium densiflorum*; Densiflorol A and B; Anti-platelet aggregation activity

1. Introduction

The stems of several *Dendrobium* species (Orchidaceae) are used in traditional Chinese medicine as a Yin tonic to nourish the stomach, promote the production of body fluid and reduce fever (Jiangsu New Medical College, 1986). Several chemical components of this species have been identified before (Jan et al., 1975; Talapatra et al., 1984). We herein report the structural elucidation of a new bibenzyl named densiflorol A (**1**) and a new phenanthrenedione named densiflorol B (**2**) and the structural revision of dendroflorin (**3**), a previously reported compound obtained from *D. densiflorum* Lindl. ex Wall. (Talapatra et al., 1984). Besides the above three compounds, 15 other known compounds (**4**–**16**, oleanolic acid and β-sitosterol) were also identified from the plant. Compounds **6**, **7**, **10**, **14** and **15** were found to exhibit anti-platelet aggregation activity in preliminary pharmacological tests.

2. Results and discussion

The stems of *D. densiflorum* Lindl. ex Wall. were powdered and extracted with CH_2Cl_2, and the filtrate was evaporated to dryness to give CH_2Cl_2 extract. The CH_2Cl_2 extract was subjected to a series of column chromatographic steps on silica gel and filtration through Sephadex LH-20 to yield 18 compounds.

Compound **1** was obtained as a white amorphous powder. HREIMS of **1** exhibited a molecular ion peak at m/z 272.1031 [M^+] (calculated for $C_{16}H_{16}O_4$, 272.1048). In the ^{13}C NMR spectrum of **1**, 16 carbon signals were observed as one methyl, three methylenes, six methines and six quaternary carbons. A bibenzyl skeleton with one methoxy, one hydroxyl and one methylenedioxy group were deduced to the structure of **1** according to ^{13}C NMR spectroscopic data. Proton coupling of **1** revealed a 1,3,4-substituted benzene ring [δ 6.60 (1H, *d,* 1.5), 6.55 (1H, *dd,* 1.5, 7.9), 6.65 (1H, *d,* 7.9)] and a 1,3,5-substituted benzene ring [δ 6.15 (2H, *d,* 1.6) and 6.25 (1H, *d,* 1.6)]. On the basis of above evidence and results of HMQC and HMBC spectra, the structure of **1** was established to be 5-[2′-(3″-hydroxy-5″-methoxyphenyl)-ethyl]-1,3-benzodioxole as shown in Figs. 1 and 2. Compound **1** is a new compound named densiflorol A.

Compound **2** was obtained as a red amorphous powder. HREIMS of 2 exhibited a molecular ion peak at m/z 254.0584 [M^+] (calculated for $C_{15}H_{10}O_4$, 254.0579). In the ^{13}C NMR spectrum of **2**, 15 carbon signals were observed including one methyl, six methines and eight quaternary carbons. Among the eight quaternary carbons, two should be carbonyl carbons according to their chemical shifts at δ 180.2 (*s*) and 188.4 (*s*). One hydroxyl and one methoxy group exist in the structure of **2** according to proton signals at 10.45 (1H, *s*) and δ 3.90

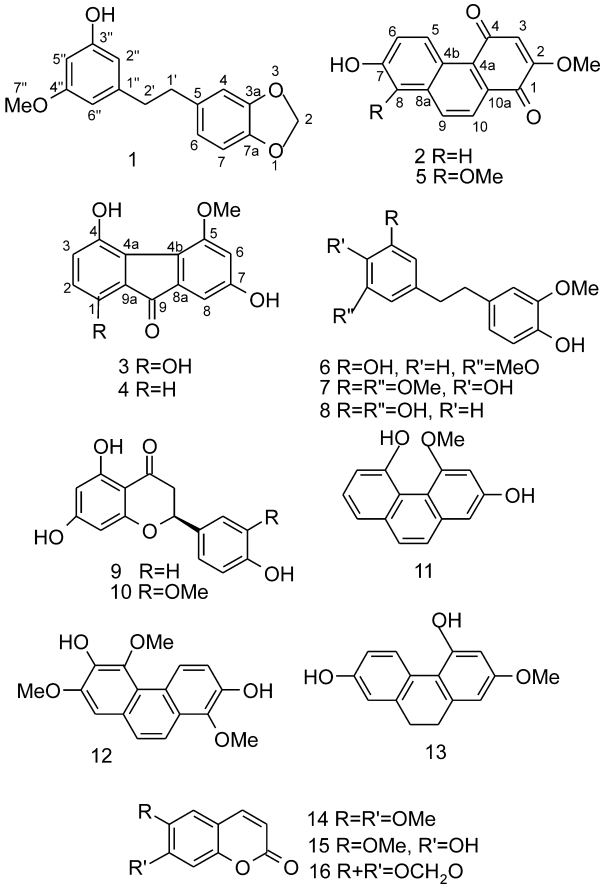

Fig. 1. Structures of compounds **1**–**16**.

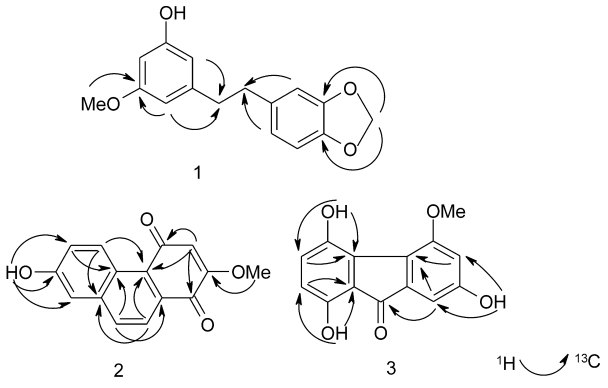

Fig. 2. Main ^{13}C–^{1}H long range correlation signals in HMBC spectra of **1** ($CDCl_3$), **2** and **3** (DMSO-d_6).

(3H, *s*) and downfield carbon signals at δ 158.3 and δ 157.5. Compound **2** was suspected to be an anthrenedione or phenanthrenedione from above NMR spectra data. In ^{1}H NMR spectrum of **2**, three aromatic proton signals at δ 7.25 (*d,* 2.2), 7.30 (*dd*, 2.2, 9.5) and 9.35 (*d,* 9.5) were observed, which enabled the deduction of an aromatic ring with 1,3,4-substitution pattern. Another aromatic ring was suggested to be of 1,2,3,4-substitution pattern according to two coupled protons at δ 7.95 (*d,* 8.6) and 8.10 (*d,* 8.6). NOE correlations were found between proton signals at δ 7.25 and 8.10, between the methoxy proton signal and the proton signal at δ 6.30 (*s*) in a NOESY spectrum. The skeleton of **2** was thus revealed to be phenanthrenedione. According to ^{1}H–^{13}C long range correlation signals in HMBC spectrum of **2**, especially to those between C-4a and H-5 (δ9.35), and between C-4a and H-3 (δ 6.30), the structure was finally established to be 7-hydroxy-2-methoxy-1, 4-phenanthrenedione as shown in Figs. 1 and 2. Compound **2** is a new compound named densiflorol B.

Compound **3** was obtained as a red amorphous powder. HREIMS of **3** exhibited a molecular ion signal at *m*/*z* 258.0515 [M^+] (calculated for $C_{14}H_{10}O_5$, 258.0528). In the ^{13}C NMR spectrum of **3**, 14 carbon signals were observed as one methyl, four methines and nine quaternary carbons, one of which should be a carbonyl carbon (δ 194.6). Three hydroxyl groups and one methoxy group should exist in the structure of **3** according to proton signals at δ 8.70 (1H, *s*), 9.85 (1H, *s*), 10.25 (1H, *s*) and 4.05 (3H, *s*), and methyl carbon at δ 57.0. Aromatic proton signals at δ 6.60 (1H, *d,* 8.9), 6.85 (1H, *d,* 8.9) and 6.65 (1H *d,* 2.0), 6.70 (1H, *d,* 2.0) in ^{1}H NMR spectrum of **3** indicated the existence of two *ortho*-coupled protons and two *meta*-coupled protons. The ^{1}H NMR (acetone-d_6) and MS data of **3** were in accordance to those of a known compound named dendroflorin (1,2,5-trihydroxy-7-methoxy-9*H*-fluoren-9-one) isolated from the same species before (Talapatra et al., 1984; Talapatra et al., 1985). The positions of hydroxy and methoxy groups in the structure of dendroflorin were established by comparing the chemical shifts between dendroflorin and its peracetate. In order to confirm the structure of dendroflorin, NMR spectra of **3** were measured again in DMSO-d_6. In ^{1}H NMR of **3** in DMSO-d_6, three hydroxy proton signals could be clearly observed. A NOESY spectrum of **3** showed correlations not only between the methoxy protons at δ 4.05 (3H, *s*) and proton at δ 6.70 (1H, *d,* 2.0), but also between the methoxy protons and the hydroxy proton at δ 8.70. In addition, NOE correlation signals between the hydroxy proton signal at δ 10.25 and the proton signal at δ 6.65, between the hydroxy proton at δ 8.70 and the proton at δ 6.85, and between the hydroxy proton at δ 9.85 and the proton at δ 6.60, were also observed. On the basis of above evidence and further analysis of its HMBC spectrum, the structure of **3** was established to be 1,4,7-trihydroxy-5-methoxy-9*H*-fluoren-9-one (Figs. 1 and 2). The structure of dendroflorin reported before should thus be revised.

From the CH_2Cl_2 extract of *D. densiflorum,* 11 other known compounds, including cypripedin (**5**; Schmalle and Hausen, 1979), gigantol (**6**; Leslie and Jamieson, 1982), moscatilin (**7**; Majumder and Sen, 1987a), tristin (**8**; Majumder and Pal, 1993), naringenin (**9**; Albach and Redman, 1969), homoeriodictyol (**10**; Liu et al., 1992), moscatin (**11**; Majumder and Sen, 1987b), 2,6-dihydroxy-

1,5,7-trimethoxyphenanthrene (**12**; Tuchinda et al., 1988; Majumder and Sen, 1991), 4,7-dihydroxy-2-methoxy-9, 10-dihydro-phenanthrene (**13**; Shuozo et al., 1983), scopoletin (**15**; Sankar et al., 1982) and ayapin (**16**; Zhu et al., 1992) were identified for the first time from this species. Four other previously reported compounds from this plant, including dengibsin (**4**; Schmalle and Hausen, 1979), scoparone (**14**; Sankar et al., 1982), oleanolic acid and β-sitosterol were also obtained. The structures of all above compounds were identified by spectral analysis and by comparison of spectral data with those reported.

During our investigation of components with anti-platelet aggregation activity from *D. densiflorum,* compounds **6**, **7**, **10**, **14** and **15** were found to exhibit anti-platelet aggregation activity on SD rat platelet aggregation in preliminary pharmacological tests in vitro (Table 1). Among them, scoparone **(14)** has been reported to possess potent anti-platelet aggregation activity before and was used as positive control.

3. Experimental

3.1. Materials and methods

3.1.1. General

IR spectra were obtained using a KBr discs on Perkin-Elmer 599B spectrometer. UV spectra were measured with a Shimadzu UV-3000 spectrometer, whereas NMR spectra were recorded on Bruker AM-400 spectrometer. Chemical shifts were reported in δ (ppm) with residual C_5H_5N signals (7.24/123.5), DMSO signals (2.50/39.5), acetone signals (2.07/30.5) and $CHCl_3$ signals (7.25/77.0) as internal standards. MS spectra were recorded on Finnigan 90 or MAT 95 instruments.

3.1.2. Plant material

Fresh stems of *D. densiflorum* (Orchidaceae) were collected and identified by Professor Ming Zhang from Chongqing Academy of Chinese Materia Medica in April 1999. A voucher specimen (SIMM990418) is deposited in the Herbarium of Shanghai Institute of Materia Medica, Chinese Academy of Sciences.

3.1.3. Extraction and isolation

Fresh stems of *D. densiflorum* (Orchidaceae; 7.5 kg) were powdered and then extracted with CH_2Cl_2 (3×2 l) at reflux and the filtrate was evaporated to dryness to give the extract (18 g). The extract was subjected to column chromatography (CC) on silica gel with petroleum ether-acetone gradient (5:1→4:1→2:1→acetone) to give fractions I–IV. Fractions I–III were further subjected to repeated CC on silica gel eluted with petroleum ether–$CHCl_3$ gradients (1:3→0:1) and on a Sephadex LH-20 column eluted with EtOH. Eighteen compounds were finally obtained. Compounds **1** (12 mg), **11** (14 mg), **12** (23 mg), **14** (156 mg), **16** (117 mg) and β-sitosterol (53 mg) were obtained from fraction I. Compounds **2** (14 mg), **3** (97 mg), **4** (18 mg), **5** (27 mg), **6** (21 mg), 7 (44 mg), **10** (52 mg) and **15** (65 mg) were obtained from fraction II. Compounds **8** (5 mg), **9** (12 mg), **13** (7 mg) and oleanolic acid (15 mg) were obtained from fraction III.

3.1.4. Platelet preparations and aggregations

Blood was removed from venacava inferior of male Sprague–Dawley rats (250–300 g) and mixed with sodium citrate anticoagulant (9:1, v/v). PRP (platelet rich plasma) was obtained by centrifuging blood for 5 min at 200 *g*. For aggregation in PRP, the platelet count was adjusted to 4×10^8 platelets/ml with PPP (platelet poor plasma). Before the addition of ADP at final concentration of 4 μM, platelets were preincubated with the test compounds for 3 min at 37°C. In order to eliminate the effect of the solvent on the aggregation, the final concentration of DMSO was fixed at 5% and vehicle control was used. Platelet aggregations were recorded using Born's method with a MPG-3D aggregometer (Shanghai, China) and percentages of aggregation are presented as means±S.D. (Durand et al., 1996).

3.1.5. Densiflorol A (*1*)

White amorphous powder. EIMS *m/z:* 272 [M^+]; HREIMS *m/z:* 272.1031 [M^+] (calculated for $C_{16}H_{,16}O_4$, 272.1048); IR ν^{KBr} cm^{-1}: 3307 (OH), 1592, 1500 (arom.), 1244 (−OCH_2O−); UV λ_{max}^{MeOH} nm: 281.5; ^{1}H NMR data (400 MHz, $CDCI_3$): δ 6.65 (1H, *d, J*=7.9 Hz, H-7), 6.60 (1H, *d, J*=1.5 Hz, H-4), 6.55 (1H, *dd, J*=1.5 and 7.9 Hz, H-6), 6.25 (1H, *d, J*=1.6 Hz, H-6″), 6.15 (1H, *d, J*=1.6 Hz, H-2″), 6.15 (1H, *d, J*=1.6 Hz, H-4″), 5.85 (2H, *s,* H-2), 3.70 (3H, *s,* H-7″), 2.70 (4H, *m,* H-1′, 2′); ^{13}C NMR data (100 MHz, $CDCl_3$): δ 160.9 (*s,* C-5″), 156.7 (*s,* C-3″), 147.6 (*s,* C-3a), 145.7 (*s,* C-7a), 144.5 (*s,* C-1″), 135.6 (*s,* C-5), 121.3 (*d,* C-6), 109.0 (*d,* C-4), 108.2 (*d,* C-7), 108.1 (*d,* C-2″), 106.8 (*d,* C-6″), 100.8 (*t,* C-2), 99.2 (*d,* C-4″), 55.3 (*q*, C-7″), 38.3 (*t,* C-2′), 37.3 (*t*, C-1′).

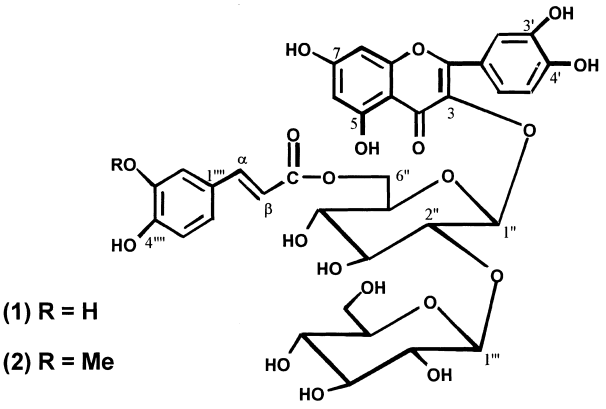
Abstract

From the arial parts of *Bassia muricata*, two acylated flavonoid glycosides quercetin-3-*O*-(6″-caffeoyl)-sophoroside and quercetin-3-*O*-(6″-feruloyl)-sophoroside have been isolated together with two known flavonoid glycosides quercetin-3-*O*-sophoroside and quercetin-3,7-*O*-β-diglucopyranoside, as well as four known triterpenoidal saponins, oleanolic acid-3-*O*-β-glucopyranoside, chikusetsusaponin IVa, chikusetsusaponin IVa methyl ester and oleanolic acid-3,28-β-diglucopyranoside. The structures of the isolated compounds were verified by means of MS and NMR spectral analyses. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Bassia muricata*; Chenopodiaceae; Acylated flavonoid glycosides

1. Introduction

Bassia muricata (L.) Murr. (Chenopodiaceae) is a common sandy herb growing in Egyptian deserts (Tackholm, 1974). The plant is used in folk medicine to treat renal and rheumatic diseases (Al-Yahya et al., 1990). The chloroform and ethanolic extracts of the plant produced pilo-erection, significant hypotension, a remarkable decrease in WBCs counts, and a significant increase in prothrombin time besides their significant contractions of isolated guinea pig ileum. Meanwhile, the ether and benzene extracts showed antimicrobial activities (Al-Yahya et al., 1990). Reviewing current literature showed that only a few species of *Bassia* have been investigated and were found to contain triterpenoidal saponins identified as bassic acid glycosides (Rizk, 1986). This work describes the isolation and structural elucidation of two new acylated flavonoid glycosides (**1**) and (**2**) together with two known flavonoid glycosides and four known triterpenoidal saponins.



2. Results and discussion

The ethanolic extract of the aerial parts of *B. muricata* was defatted with diethylether and the aqueous layer was subjected to column chromatography on Diaion HP-20. The 50% methanol eluate was repeatedly chromatographed on columns of silica gel and then by MPLC and HPLC to afford eight glycosides.

The molecular formula of compound **1** was deduced as $C_{36}H_{36}O_{20}$ from HR FAB-MS spectrometry (see Experimental). Inspection of the ^{13}C NMR and DEPT spectra of **1** (Table 1) displayed the presence of two β-

PII: S0031-9422(01)00240-0

glucopyranosyl units from the anomeric signals at δ 101.5 and 105.6 as well as the other signals characteristic for glucopyranosyl units as shown in Table 1 (Bradbury and Jenkins, 1984). Besides, the spectra showed 15 carbon signals for 3-*O*-glycosylated quercetin (Harborne and Mabry, 1982) and 9 carbon signals for a caffeoyl moiety (Bloor et al., 1998). From ^{1}H NMR spectral data of **1** (Experimental), the doublet at δ 5.11 (J = 7.6 Hz) of the anomeric proton of one of the two glucopyranosyl units indicated its β configuration. The anomeric proton of the second glucosyl unit was obscured by the H_2O signal. However, the β configuration of the glucosyl residues were very obvious from the downfield shifts of their anomeric carbons when compared with those reported for α-anomers in the ^{13}C NMR spectral analysis (Bradbury and Jenkins, 1984). Moreover the coupling constant (15.6 Hz) of the two doublets at δ 5.59 and 7.30 (each 1H) indicated the *trans* configuration of the caffeoyl moiety (Fiasson et al., 1997). In the ^{13}C NMR spectrum of **1**, the downfield shift of C-2″ (δ 82.2) together with the upfield shift of C-1″ (δ 101.5) proved the attachment of the terminal glucosyl unit to this position (Bradbury and Jenkins, 1984). Furthermore, the signal at δ 64.6 was assigned to the C-6 of one of the two glucosyl units to which the caffeoyl moiety is attached (Miyase et al., 1992). To determine the attachment site of the caffeoyl moiety, compound **1** was acetylated and subjected to EI–MS spectral analysis according to the procedure established by Komori et al. (1975) which revealed a characteristic peak at m/z 331 (18%) corresponding to tetraacetylated glucose as a cationic fragment with a molecular formula $(C_{14}H_{19}O_9)^+$ as shown in Fig. 1. This significant peak proved the presence of an unsubstituted terminal glucosyl unit (Komori et al, 1975). Consequently, the attachment site of the caffeoyl moiety must be at C-6 of the internal β-glucosyl unit (C-6) and the structure of compound **1** was assigned as shown.

4″	70.0	70.1			
5″	75.8	76.0			
6″	64.6	64.5			

The molecular formula of compound **2** was determined as $C_{37}H_{38}O_{20}$ from HR FAB–MS spectrometry (see Experimental). ^{13}C and DEPT NMR spectra of 2 were almost similar to those of **1**. However, the signal at δ 56.2 in 2 together with the downfield shift of C-4‴ (+2.1 ppm) indicated the presence of a feruloyl moiety instead of the caffeoyl moiety (Miyase et al., 1992). EI–MS of the acetylated derivative of **2** exhibited the same results as **1**. Consequently, the site of attachment of the feruloyl moiety was proved to be at C-6″ of the internal glucosyl unit and the structure of **2** was determined as shown.

On the basis of ^{1}H and ^{13}C NMR, compounds **3**–**8** were identified as follows: compound (**3**) quercetin-3-*O*-sophoroside (Veit et al, 1990), compound (**4**) quercetin-3,7-*O*-β-diglucopyranoside (Harborne et al., 1982), compound (**5**) oleanolic acid-3-*O*-β-glucopyranoside (Mahato et al., 1988), compound (**6**) chikusetsusaponin IVa (Mohamed et al., 1998), compound (**7**) chikusetsusaponin IVa methyl ester, compound (**8**) oleanolic acid-3,28-β-diglucopyranoside (Mahato et al., 1988).

3. Experimental

^{1}H and ^{13}C NMR (TMS as int. standard): 400 MHz and 100 MHz respectively were recorded on a Jeol JNM

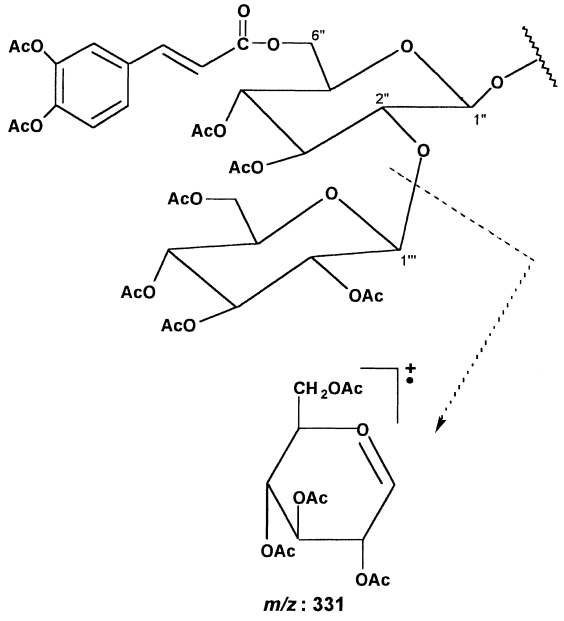

Fig. 1. Results of EI–MS analysis of the acetate derivative of compound **1**.

α-400 spectrometer. MS spectra were recorded on a Jeol JMS-SX 102 spectrometer by direct inlet method at an ionizing voltage of 70 eV. MPLC: RP-18 column (20 mm i.d. ×40 cm); flow rate of mobile phase 3 ml/min. HPLC: D-ODS-5 and polyamine columns (each 20 mm i.d. ×25 cm, YMC) with a Toyo Soda high speed chromatograph HLC-803 D pump and a Tosoh refraction index (RI-8) detector; flow rate of mobile phase 6 ml/min, injection vol. 0.8–1.0 ml. CC: Kieselgel 60 (70-230 mesh, Merck) and Diaion HP 20 (Mitsubishi). TLC: silica gel 60 precoated plates, F-254 and HPTLC using RP-18 precoated plates, F-254 s (Merck).

3.1. Plant material

Aerial parts of *B. muricata* (L.) Murr. were collected from Assiut Valley, Assiut, Egypt, in June 1997. The plant was identified by Professor A. Fayed, Department of Botany, Faculty of Science, Assiut University, Assiut, Egypt. A voucher specimen is deposited at the Herbarium of Department of Pharmacognosy, Faculty of Pharmacy, Assiut University, Assiut, Egypt.

3.2. Extraction and isolation of compounds (*1*–*8*)

The air dried powdered aerial parts of *B. muricata* (2 kg) were extracted with 70% EtOH. The dried ethanolic extract (220 g) was suspended in H_2O and defatted with diethylether. The aq. fr. (115 g) was applied to a column of Diaion HP-20 and eluted with H_2O, 50% MeOH, MeOH and acetone successively. The 50% MeOH eluate (30 g) was chromatographed on silica gel CC using EtOAc–MeOH–H_2O (40:10:1 and 70:30:3) to give 6 fractions. Fraction 4 (4.5 g) eluted with EtOAc–MeOH–H_2O (70:30:3) was subjected to MPLC using ODS column and 40–60% MeOH as a solvent system followed by HPLC using polyamine column and 90% MeCN as solvent to afford compounds **1** (yellow powder, 58 mg), **2** (yellow powder, 42 mg), **3** (yellow powder, 134 mg) and **4** (yellow powder, 97 mg). Fraction 5 (6.7 g) eluted with EtOAc–MeOH–H_2O (70 : 30 : 3) was subjected to MPLC using ODS column and 40–60% MeOH as solvent followed by HPLC using an ODS column and 58% MeOH as solvent to afford compounds **5** (white powder, 137 mg), **6** (white powder, 228 mg), **7** (white powder, 26 mg) and **8** (white powder, 21 mg).

3.2.1. Compound (*1*)

Quercetin-3-*O*-(6″-caffeoyl)-sophoroside. R_t 23 min (polyamine, 90% MeCN). UV λ_{max} MeOH nm: 251, 329 and 295 (sh). HR FAB–MS (negative) *m*/*z*: 787.1736 $[M–H]^-$ $C_{36}H_{35}O_{20}$ (req. 787.1721). ^{13}C NMR (CD_3OD, Table 1). ^1H NMR (CD_3OD): δ 7.65 (1H, *dd*, *J* = 2.0, 8.8 Hz, H-6′), 7.30 (1H, *d*, *J* = 15.6 Hz, H-β), 6.86 (1H, *d*, *J* = 8.8 Hz, H-5′), 6.79 (1H, *bs*, H-2′ or 2‴″), 6.50-6.78 (3H, *m*, H-2‴″, 5‴″, 6‴″), 6.21 (1H, *bs*, H-8), 6.13 (1H, *bs*, H-6), 5.59 (1H, *d*, *J* = 15.6 Hz, H-α), 5.11 (1H, *d*, *J* = 7.6 Hz, H-1″) and H-1″ was obscured by H_2O signal.

3.2.2. Compound (*2*)

Quercetin-3-*O*-(6″-feruloyl)-sophoroside. R_t 21 min (polyamine, 90% MeCN). UV λ_{max} MeOH nm: 253, 330 and 297 (sh). HR FAB–MS (negative) *m*/*z*: 801.1890 $[M–H]^-$ $C_{37}H_{37}O_{20}$ (req. 801.1878). ^{13}C NMR (CD_3OD, Table 1). ^1H NMR (CD_3OD): δ 7.65 (1H, *dd*, *J* = 2.0, 8.5 Hz, H-6′), 7.31 (1H, *d*, *J* = 16.1 Hz, H-β), 6.86 (1H, *d*, *J* = 8.5 Hz, H-5′), 6.79 (1H, *bs*, H-2″), 6.69 (1H, *dd*, *J* = 1.8, 8.1 Hz, H-6‴″), 6.63 (1H, *bs*, H-2‴″), 6.62 (1H, *d*, *J* = 8.1 Hz, H-5‴″), 6.14 (1H, *bs*, H-8), 6.10 (1H, *bs*, H-6), 6.03 (1H, *d*, *J* = 16.1 Hz, H-α), 5.04 (1H, *d*, *J* = 7.6 Hz, H-1″), 4.75 (1H, *d*, *J* = 7.8 Hz, H-1‴) and 3.70 (3H, *s*, −OMe).

3.3. Acetylation of compounds *1* and *2*.

A sample of 10 mg of compounds **1** and **2** was separately dissolved in 2 ml acetic anhydride-dried pyridine (1:1) and left overnight at room temp. The solvents were removed by evaporation under reduced pressure and the residues were subjected to EI–MS spectral analysis.

Abstract

Two isoflavone glycosides, biochanin A 7-*O*-[β-D-apiofuranosyl-(1→5)-β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside] and tectorigenin 7-*O*-[β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside], were isolated from *Dalbergia sissoo*. Their structures were elucidated on the basis of spectral and chemical evidence. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Leguminosae; *Dalbergia sissoo*; Isoflavone glycosides; Isoflavone apioglucosides

1. Introduction

An aqueous extract of the leaves of *Dalbergia sissoo* Roxbg. (Leguminosae) has been used for the treatment of gonorrhea in Arabic countries (El-Dagwy, 1996). Many isoflavonoids and neoflavonoids have been reported from *D. sissoo* (Seshadri, 1972; Sharma et al., 1979, 1980; Ingham, 1983). Our detailed study on the constituents of the above plant led to the isolation of two new isoflavone glycosides (**1**, **3**) together with five known isoflavone glycosides (**2**, **4**–**7**) from the leaves and stem-bark of *D. sissoo* (Kinjo et al., 1987; Ishikura et al., 1989; Rao et al., 1989; Ramesh and Yuvarajan, 1995; Mathias et al., 1998).

2. Results and discussion

The methanol extract of the leaves of *D. sissoo* collected in Egypt was successively partitioned between water and hexane, chloroform, ethyl acetate and *n*-butanol to give the corresponding solubles. The butanol and water soluble fractions were respectively separated to give a new compound **1** and a known compound **2**. The methanol extract of the stem-bark was partitioned between water and chloroform, and between water and *n*-butanol. The *n*-butanol soluble fraction was separated to give a new compound **3** and five known compounds **4**–**7**. These compounds were identified as biochanin A 7-*O*-[β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside] (**2**) (Rao et al., 1989), prunetin 4′-*O*-[β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside] (**4**) (Ramesh and Yuvarajam, 1995), 7-methyltectorigenin 4′-*O*-[β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside] (**5**) (Mathias et al., 1998), genistein 8-*C*-[β-D-glucopyranoside] (**6**) (Kinjo et al., 1987) and prunetin 4′-*O*-[β-D-glucopyranoside] (**7**) (Ishikura et al., 1989) by comparison of the spectral data with the reported data.

Compound **1**, $[\alpha]_D^{25}$ −106.1° (*c* 0.26, MeOH), was found by high-resolution FABMS to have the molecular formula $C_{32}H_{38}O_{18}$. The UV spectrum (λ_{max}^{MeOH} 261 and 327 nm) showed the characteristic absorption of an isoflavone, and a bathochromic shift (271 and 322 nm) on addition of $AlCl_3$ suggested the presence of free 5-OH and substituted 7-OH. The ^{1}H NMR spectrum exhibited one methoxy group [δ 3.8 (3H, *s*)], one set of *meta*-coupled aromatic protons [δ 6.47 (*d*, *J* = 1.8 Hz) and δ 6.63 (*d*, *J* = 1.8 Hz)], two sets of *ortho*-coupled aromatic hydrogens [δ 6.95 (2H, *d*, *J* = 8.4 Hz) and δ 7.46 (2H, *d*, *J* = 8.4 Hz)] and a non-coupled aromatic hydrogen [δ 8.12 (1H, s)] (Table 1). These features are characteristic of a 5,7,4′-trihydroxyisoflavone derivative (Markham and Geiger, 1994). The ^{1}H and ^{13}C NMR spectra (Table 1) revealed three anomeric signals ($\delta_{H\text{-}1''}$ 4.92 (*d*, *J* = 7.3 Hz) and $\delta_{C\text{-}1''}$ 101.5 (*d*), $\delta_{H\text{-}1'''}$ 4.97 (*d*, *J* = 2.6 Hz) and $\delta_{C\text{-}1'''}$ 110.8 (*d*) and $\delta_{H\text{-}1''''}$ 4.96 (*d*, *J* = 2.6 Hz) and $\delta_{C\text{-}1''''}$ 111.9 (*d*)) together with 13 carbon signals in the

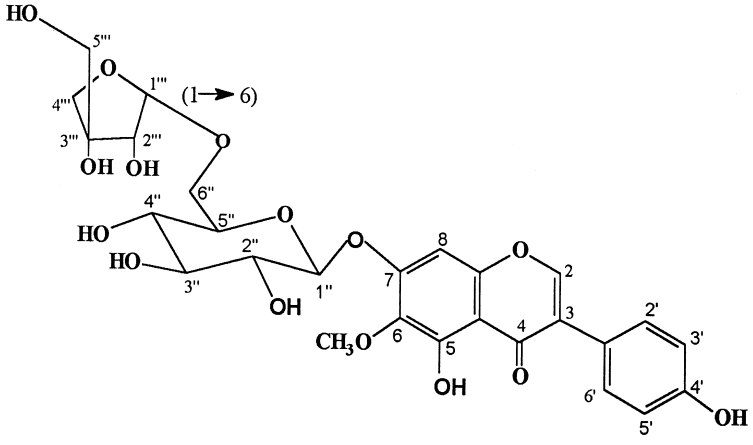
Compound 1 R= H
Compound 8 R= Ac



Compound 3

region of sugars indicated **1** to be an isoflavone-*O*-triglycoside (Agrawal, 1992). The ^{13}C NMR shifts of the three sugars are consistent with those corresponding to one glucopyranosyl and one apiofuranosyl moiety (Rao et al.,1989) with an additional apiofuranosyl moiety. The β-configuration of the glycosidic linkages was evident from the observed ^{13}C NMR chemical shifts for the anomeric carbons of glucose ($\delta_{C\text{-}1''}$ 101.5) and apiose ($\delta_{C\text{-}1'''}$ 110.8 and $\delta_{C\text{-}1''''}$ 111.9) (Ramesh and Yuvarajan, 1995; Mathias et al., 1998). The downfield shifts of C-6″ (δ_C 67.6) and C-5‴ (δ_C 69.3) suggesting that the interglycosidic linkages is apiofuranosyl (1⁗→5‴) apiofuranosyl (1‴→6″) glucopyranoside (Ramesh and Yuvarajan, 1995). The heteronuclear multiple bond correlation spectroscopy (HMBC) spectrum (Table 1) showed cross peaks between H-2′ (6′) δ_H 7.52 and C-4′ (δ_C 159.2) and between $C\underline{H}_3O$ (δ_H 3.8) and C-4′, respectively, determined the position of the methoxy group to be 4′. The identity of the three sugars and their sequence were determined by the exhaustive analysis of the NMR spectral data of the corresponding nonaacetate **8**, which was obtained by acetylation of **1** with acetic anhydride and pyridine in the presence of 4-(dimethylamino) pyridine (DMAP). The NMR data of **8** (see Experimental) are in accor-

dance with this interpretation. In the HMBC spectrum (see Fig. 1), the anomeric proton signal at δ_H 5.197 (6-substituted glucopyranosyl moiety), δ_H 4.956 (5-substituted apiofuranosyl moiety) and δ_H 4.986 (terminal apiofuranosyl moiety) showed long-range correlations with the ^{13}C signals at δ_C 159.9 (C-7 of aglycone), δ_C 66.3 (C-6″ of 6-substituted glucopyranosyl moiety) and δ_C 67.5 (C-5‴ of 5-substituted apiofuranosyl moiety), respectively. The other correlations are in agreement with the proposed structure. Furthermore, acid-catalysed hydrolysis of **1** gave biochanin A (5,7-dihydroxy-4′-methoxyisoflavone). From the above evidence, the structure of **1** was concluded to be biochanin A 7-*O*-[β-D-apiofuranosyl-(1→5)-β-D-apiofuranosyl-(1→6)-β-glucopyranoside].

Compound **3**, $[\alpha]_D^{25}$ −67.0° (*c* 0.28, MeOH), was assigned the molecular formula C_{27} H_{30} O_{15} from its HRFABMS. The UV spectrum showed a bathochromic shift (264 and 330 nm to 274 and 330 nm) on addition of $AlCl_3$, suggesting the presence of free 5-OH and a substituted 7-OH group. The ^1H NMR spectrum exhibited signals at δ 8.35 (1H, *s*), δ 7.38 (2H, *d*, *J* = 8.8 Hz), and 6.38 (2H, *d*, *J* = 8.8 Hz), attributable to hydrogens at H-2 and two sets of *ortho*-coupled aromatic hydrogens at H-2′, 6′ and H-3′, 5′ of an isoflavone derivative as shown in Table 1. A singlet signal at δ 6.89 (1H, *s*) indicated only one hydrogen to be present on the A-ring of the isoflavone. The ^1H and ^{13}C NMR spectra (Table 1) showed two anomeric signals [$\delta_{H\text{-}1''}$ 5.04 (1H, *d*, *J* = 7.3 Hz) and $\delta_{C\text{-}1''}$ 100.3 (*d*) and $\delta_{H\text{-}1'''}$ 4.81 (1H, *d*, *J* = 2.9 Hz) and $\delta_{C\text{-}1'''}$ 109.5 (*d*)] and 9 carbon signals in the region of sugars, indicating that **3** is an isoflavone having two phenolic hydroxyl groups, one methoxy group [δ_H 3.76 (3H, *s*) and δ_C 60.3 (*q*)] and one *O*-diglycosidic group (Agrawal, 1989, 1992). The ^{13}C NMR chemical shifts were in agreement with one glucopyranosyl and one apiofuranosyl moiety (Rao et al., 1989). The chemical shifts of the anomeric carbons at $\delta_{C\text{-}1''}$ 100.3 and $\delta_{C\text{-}1'''}$ 109.5 recognized the β-configuration of the glycosidic linkages (Ramesh and Yuvarajan, 1995; Mathias et al., 1998). The interglycosidic linkage (1‴→6″) was indicated by the downfield shift of C-6″ at δ_C 67.8 (Ramesh and Yuvarajan, 1995). The identity of the two sugars and their sequence were assigned by the ^1H–^1H COSY and HMBC spectra. The HMBC spectrum (Table 1) showed that the signals due to the disaccharide moiety consisted of one glucopyranosyl and one apiofuranosyl moiety. The anomeric proton signals at [δ_H 5.04 (6-substituted glucopyranosyl moiety) and δ_H 4.81 (terminal apiofuranosyl moiety) showed the correlations with the ^{13}C signals at δ_C 156.5 (C-7 of aglycone) and δ_C 67.8 (C-6″ of 6-substituted glucopyranosyl moiety), respectively. The methoxy group was located at C-6 as follows. In the ^{13}C NMR spectrum, the chemical shift values (δ_C 130.1 and 115.1) were assigned to carbon atoms 2′/ 6′ and 3′/ 5′, respectively, suggesting that **3** contained a 4′-hydroxyphenyl group (δ_C 130.0 and 115.2) as in genistein but not a 4′-methoxyphenyl group (δ_C 131.1 and 114.5) as in biochanin (Agrawal, 1989). Also the HMBC spectrum showed cross peak between the methoxy group signal at δ_H 3.76 and the C-6 signal at δ_C 132.5. Furthermore, acid-catalysed hydrolysis of **3** gave tectorigenin (5,7,4′-trihydroxy-6-methoxyisoflavone). From the above evidence, the structure of **3** was determined to be tectorigenin7-*O*-[β-D-apiofuranosyl-(1→6)-β-D-glucopyranoside].

Apiose sugar is not commonly encountered in glycosides. Three isoflavone apioglucosides have been iso-

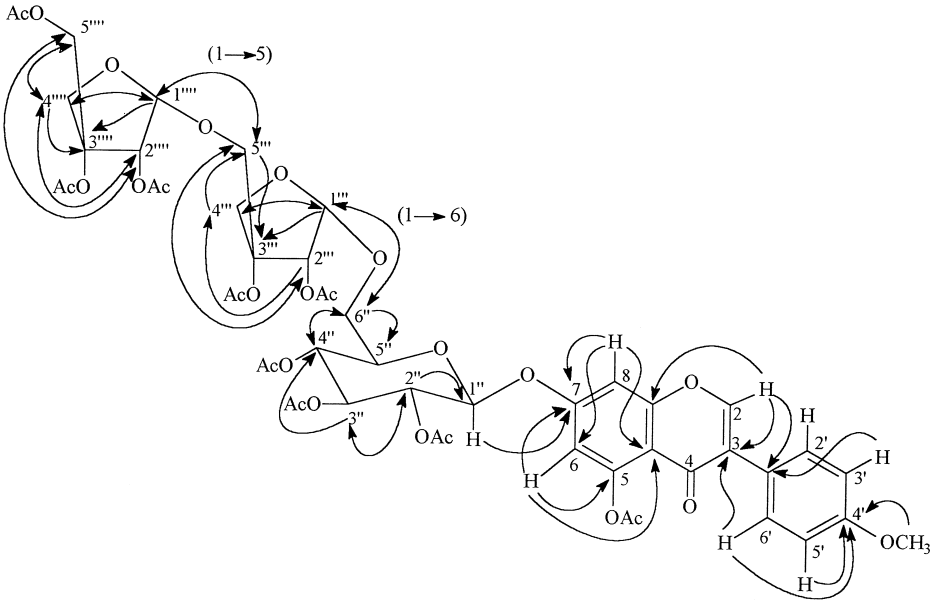

Fig. 1. Significant long range correlations observed in the HMBC spectrum of compound **8**.

lated in three species of *Dalbergia* (Rao et al., 1989; Ramesh and Yuvarajan, 1995; Mathias et al., 1998). In the course of the present work, this is the first report of the occurrence of isoflavone apioglucosides from *D. sissoo* Roxbg. which is of great importance.

3. Experimental

3.1. General

Optical rotations were taken on a JASCO P-1020 polarimeter (cell length 100 mm). UV spectra were measured on a JASCO V-560 UV/VIS spectrophotometer (cell length 10 mm). IR spectra were recorded on JASCO FT/IR-410 infrared spectrophotometer. 1D and 2D NMR spectra were recorded on JEOL A-400 and A-600 spectrometers. FABMS was measured with a JEOL HX-110 spectrometer using *m*-nitrobenzyl alcohol as a matrix. Analytical thin layer chromatography (TLC) was conducted on Si gel GF_{254} (Type 60) (E. Merck) and on precoated aluminium sheets of RP-18 F_{254} (E. Merck). Preparative TLC was performed on Si gel GF_{254} (Type 60) (E. Merck). Column chromatography was performed with Silica gel 60 (E. Merck), Diaion HP-20 AG (75-150 μ, Mitsubishi Chemical Industries Co. Ltd.) and Develosil Lop ODS (30-50 μ, Nomura Chemicals).

3.2. Plant material

The leaves and stem-bark of *D. sissoo* were collected in the campus of Assiut University, Assiut, Egypt, in August 1997. A voucher specimen has been deposited in the Herbarium of the Pharmacognosy Department, Faculty of Pharmacy, Assiut University.

3.3. Extraction and isolation

3.3.1. Extraction and isolation of the leaves

The air-dried leaves (2.0 kg) were powdered and extracted with MeOH (2×15 l) at room temperature. The MeOH extract (100 g) was partitioned between water and *n*-hexane, $CHCl_3$, EtOAc and *n*-BuOH to give the corresponding solubles (40 g), (20 g), (5.0 g), (5.0 g) and H_2O (30.0 g), respectively. The *n*-BuOH soluble fraction (5.0 g) was subjected to column chromatography on Si gel (600 g) and eluted with a stepwise gradient solvent system of $CHCl_3$–MeOH (each 500 ml), to give fractions 1–5, respectively. Fraction 3 (20 mg), eluted with $CHCl_3$–MeOH (7:3), was purified by preparative TLC (EtOAc–acetone–AcOH–H_2O/30:3:1:1) to give compound **2** (5 mg). The water soluble fraction (30.0 g) was chromatographed on Diaion HP-20 using a stepwise gradient solvent system of H_2O–MeOH (H_2O, 50% MeOH, 80% MeOH and MeOH) to give 4 fractions. The fraction eluted with 50% MeOH (8 g) was subjected to column chromatography on Si gel (240 g) and eluted with a stepwise gradient solvent system of $CHCl_3$–MeOH (each 250 ml). The fraction eluted with $CHCl_3$–MeOH (1:1) (70 mg) was purified by reversed-phase column chromatography on ODS (100 g) and eluted with a solvent system of MeOH–H_2O (2:3) to give compound **1** (25 mg).

3.3.2. Extraction and isolation of stem-bark

The air-dried stem-bark (1.0 kg) was ground and extracted with MeOH (2×10 l) at room temperature. The MeOH extract (90 g) was partitioned between $CHCl_3$ and H_2O and *n*-BuOH and H_2O, successively. The *n*-BuOH soluble material (20.0 g) was subjected to column chromatography on Diaion HP-20 using a stepwise gradient solvent system of H_2O–MeOH (H_2O, 50% MeOH, 80% MeOH and MeOH) to give 4 fractions. The second fraction (10.0 g) eluted with 50% MeOH was chromatographed on Si gel using a stepwise gradient solvent system of EtOAc–MeOH. The fraction (2.0 g) eluted with EtOAc–MeOH (7:3) was separated by reversed-phase column chromatography on ODS (250 g) and eluted with MeOH–H_2O (1:3) to give compound **3** (38 mg) and then with MeOH–H_2O (2:3) to give compound **5** (64 mg).The third fraction (1 g) eluted from Diaion HP-20 with 80% MeOH was subjected to column chromatography on Si gel (30 g) and eluted with a stepwise gradient solvent system EtOAc–MeOH (10:0–7:3) (each 100 ml). The fraction (35 mg) eluted with EtOAc–MeOH (9:1) was purified by reversed-phase column chromatography on ODS (100 g) and eluted with a solvent system of MeOH–H_2O (1:1) to give compound **4** (10 mg).

The fourth fraction (5 g) eluted from Diaion HP-20 was subjected to column chromatography on Si gel (150 g) and eluted with a stepwise gradient solvent system EtOAc–MeOH (each 250 ml). The fraction (24 mg) eluted with EtOAc–MeOH (9:1) was purified by reversed-phase column chromatography on ODS (100 g) and eluted with a solvent system of MeOH–H_2O (1:1) to give compound **6** (2.4 mg). The fraction (200 mg) eluted with EtOAc–MeOH (8:2) was purified by reversed-phase column chromatography on ODS (250 g) and eluted with a solvent system of MeOH–H_2O (1:3) to give compound **7** (70 mg).

Compound **1**: yellow amorphous powder. $[\alpha]_D^{25}$ −106.1° (*c* 0.26, MeOH). UV λ_{max}^{MeOH} nm: 261, 327; +$AlCl_3$: 271, 322; +NaOAc : 261, 327. 4. Acetylation of 1

Compound **1** (9.4 mg) was treated with 0.25 ml of acetic anhydride and 2 mg of DMAP in 0.5 ml of pyridine at room temperature for 24 h. After dilution with 5 ml of water, the reaction mixture was extracted twice with 5 ml of ethyl acetate. The organic layer was washed with water and brine and dried over magnesium sulfate. The crude product obtained by evaporation was purified by Si gel column chromatography using $CHCl_3$–MeOH (98:2) to give the corresponding nonacetate **8** (11.0 mg, yield 76%). Compound **8**: colorless amorphous powder. IR (KBr)ν_{max}: 3400, 1652, 1612, 1165, 1075, 825 cm^{-1}; ^1H NMR (600 MHz, $CDCl_3$) δ 7.927 (1H, *s*: H-2), 7.418 (2H, *d*, $J=8.8$ Hz: H-2′ and H-6′), 6.978 (1H, *d*, $J=2.6$ Hz: H-8), 6.930 (2H, *d*, $J=8.8$ Hz: H-3′ and H-5′), 6.634(1H, *d*, $J=2.6$ Hz: H-6), 5.332 (1H, *s*: H-2‴′), 5.312 (1H, *dd*, $J=9.5$, 9.2 Hz: H-3″), 5.303 (1H, *d*, $J=0.7$ Hz: H-2‴), 5.266 (1H, *dd*, $J=9.5$, 7.7 Hz: H-2″), 5.197 (1H, *d*, $J=7.7$ Hz: H-1″), 5.053 (1H, *dd*, $J=10.3$, 9.2 Hz: H-4″), 4.986 (1H, *s*: H-1‴′), 4.956 (1H, *br.s*: H-1‴), 4.705 (1H, *d*, $J=12.5$ Hz: H-5‴′a), 4.606 (1H, *d*, $J=12.5$ Hz: H-5‴′b), 4.371 (1H, *d*, $J=11.0$ Hz: H-5‴a), 4.242 (1H, *d*, $J=10.6$ Hz: H-4‴′a), 4.194 (1H, *d*, $J=9.9$ Hz: H-4‴a), 4.129 (1H, *d*, $J=10.6$ Hz: H-4‴′b), 4.113 (1H, *d*, $J=9.9$ Hz: H-4‴b), 3.946 (1H, *d*, $J=11.0$ Hz: H-5‴b), 3.922 (1H, *ddd*, $J=10.3$, 7.3, 2.2 Hz: H-5″), 3.807 (3H, *s*:-OC$\underline{H}_3$), 3.777 (1H, *dd*, $J=11.0$, 2.2 Hz: H-6″a), 3.552 (1H, *dd*, $J=11.0$, 7.3 Hz: H-6″b), 2.388, 2.063, 2.058, 2.045, 2.042, 2.025, 2.018, 2.002, 1.956 (each 3H, *s* :-OC$\underline{H}_3$). ^{13}C NMR (150 MHz, $CDCl_3$) : δ152.0 (CH: C-2), 125.8 (C: C-3), 174.7 (C: C-4), 151.1 (C: C-5), 102.2 (CH: C-8), 159.9 (C: C-7), 110.2 (CH: C-6), 158.7 (C: C-9), 113.6 (C: C-10), 123.9 (C: C-1′), 130.5 (CH: C-2′ (6′)), 114.7 (CH: C-3′ (5′)), 159.8 (C: C-4′), 98.3 (CH: C-1″), 71.1 (CH: C-2″), 72.78 (CH: C-3″), 68.6 (CH: C-4″), 73.8 (CH: C-5″), 66.3 (CH_2: C-6″), 106.5 (CH: C-1‴), 76.6 (CH: C-2‴), 84.5 (C: C-3‴′), 73.2 (CH_2: C-4‴), 67.5 (CH_2: C-5‴), 106.0 (CH: C-1‴′), 76.3 (CH: C-2‴′), 83.3 (C: C-3‴′), 72.82 (CH_2: C-4‴′), 63.3 (CH_2: C-5‴′), 55.4 (CH_3:-O$\underline{C}H_3$), 21.2, 20.8, 20.5 (each CH_3:-CO$\underline{C}H_3$), 21.3, 20.72, 20.66 (each $2CH_3$:-CO$\underline{C}H_3$), 170.6, 170.3, 169.9, 169.77, 169.76, 169.5, 169.3, 169.29, 169.0 (each C:-$\underline{C}OCH_3$). FAB-MS $[M+1]^+$, m/z 1089 calculated for $C_{50}H_{57}O_{27}$.

5. Acid-catalyzed hydrolysis of 1

Compound **1** (13 mg) was heated in 1 ml of 2 M HCl at 100°C for 2 h. The reaction mixture was evaporated and then dried in vacuo. The residue was separated by Si gel column chromatography using $CHCl_3$–MeOH (98:2) to give an aglycone (3.0 mg, 58% yield). The aglycone was identified as biochanin A by comparison of its ^1H NMR spectral data with those of an authentic sample (commercially available from Sigma-Aldrich Co).

6. Acid-catalyzed hydrolysis of 3

Compound **3** (17 mg) was treated in the same manner as compound **1** to give an aglycone (3.4 mg, 40% yield). The aglycone was identified as tectorigenin by comparison of its ^1H NMR spectral data with those of an authentic sample derived from tectoridin (Farag et al., 1999).

Acknowledgements

The authors thank Dr. Susumu Teramoto, Faculty of Science, Kumamoto University, Japan for an authentic sample of prunetin 4′-*O*-[β-D-glucopyranoside].

Received in revised form 6 April 2001

Dedicated with great compliments to Professor Dr. Dr. h. c. mult. H. Oelschläger on the occasion of his 80th birthday

Abstract

Four pyrrolizidine alkaloids (PA) were isolated from *Ageratum houstonianum* and their structures elucidated by spectroscopical methods. Besides the already known lycopsamine three new PA were found. Their structures are the 2*S*-2-hydroxy-2,3-dimethyl-butanoyl-O^9 as well as the O^7 esters of retronecine and the O^9 derivative of heliotridine. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Ageratum houstonianum* (Mill); Asteraceae; Eupatorieae; Pyrrolizidine alkaloids; Lycopsamine; O^9-(2*S*-2-Hydroxy-2,3-dimethyl-butanoyl)-retronecine; O^9-(2*S*-2-Hydroxy-2,3-dimethyl-butanoyl)-heliotridine; O^7-(2*S*-2-Hydroxy-2,3-dimethyl-butanoyl)-retronecine

1. Introduction

Ageratum houstonianum (Mill) (Asteraceae, tribe Eupatorieae) is a plant widespread in Mexico and southern USA. It is reported that the leaves of this plant show antifungal properties (Pandey et al., 1984). The essential oil contents chromenes and shows antimicrobiotical activities (Menut et al., 1993). Further investigations show the occurence of benzofurans (Anthonsen and Chantarasakul, 1970; Bowers, 1977; Breuer et al., 1987; Siebertz et al., 1988) as well as of flavonoids and methoxyflavones (Minonskowski and Gill, 1973, 1975; Quijano et al., 1982, 1985, 1987). In the Indian medicine of Mexico it is used traditionally. Our own ethnopharmacological studies in the zone of Tlanchinol, Hidalgo, showed that the natives use water decotions of the plant against pain and infections, especially for cleaning external wounds. There the plant is called with its indian (nahuatl) name "Micashihuil". As *A. houstonianum* belongs to the asteraceae family and the tribe eupatorieae the presence of pyrrolizidine alkaloids (PA) could be presumed.

To estimate a possible toxic effect the knowledge of the particular structures of the PA contained is necessary. Therefore aerial parts of the plant *A. houstonianum* were investigated. The plant material was collected in the above mentioned region.

Four PA were isolated and their structures determined by GC–MS and homo- as well as hetero-nuclear 2D NMR correlated spectroscopy. Three of them have not been described previously. The known alkaloid belongs to the retronecine-type and is O^9-(−)-viridifloryl-retronecine (=lycopsamine). The new PA show the structures of the retronecine-O^9- as well as retronecine-O^7-2*S*-2-hydroxy-2,3-dimethyl-butanoic ester and the heliotridine-O^9-2*S*-2-hydroxy-2,3-dimethyl-butanoic ester.

Based on the structure–toxicity relationship (Wiedenfeld and Röder, 1984) for all substances low toxic side effects must be expected.

2. Results and discussion

In our investigation, aerial parts of *A. houstonianum* were extracted as already described (Röder and Wiedenfeld, 1977; Wiedenfeld and Röder, 1979). From the crude alkaloidal extract **1**, **2**, **3** and **4** were isolated (Fig. 1).

The GC–MS spectrum of **1** shows the $[M]^+$ peak at 299 corresponding to the formula $C_{15}H_{25}NO_5$. The further MS fragmentation and also the NMR data are corresponding to those describes earlier (Wiedenfeld and Röder, 1991).

The $[M]^+$ peak in the GC–MS spectrum of **2** occurs at 269 indicating the molecular formula $C_{14}H_{23}NO_4$.

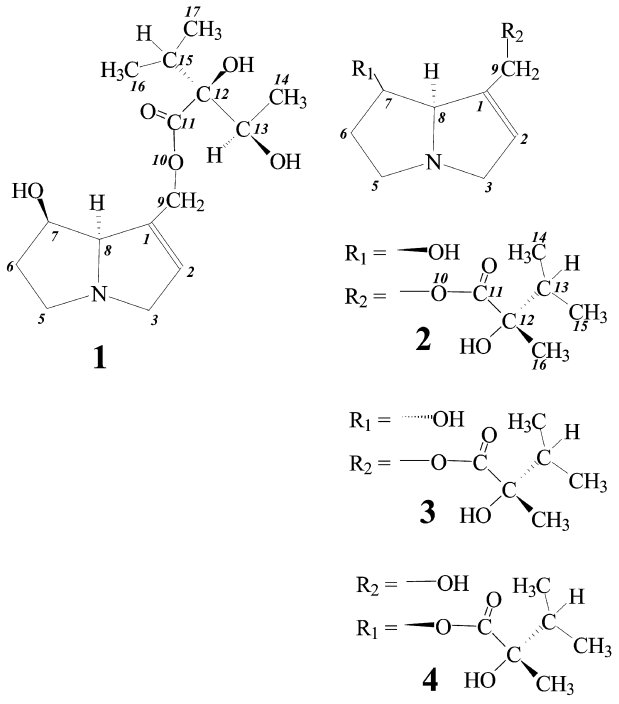

Fig. 1. Structures of the isolated compounds **1**–**4**.

Loss of OH leads to *m*/*z* 252. The ions *m*/*z* 225 and 208 result from $[M]^+ - C_3H_8$ and further loss of OH. The cleavage of the ester function leads to *m*/*z* 138. The fragments *m*/*z* 138, 120, 93 and 80 are typical for retronecine or its isomer heliotridine and are identical with those in **1**. The MS spectra of **3** and **4** are similar to that of **2**; they only differ in the intensities of their fragments.

The ^1H and ^{13}C NMR data of **2**, **3** and **4** are summarized in the experimental part. The assignment was performed by interpretation of H,H- and C,H-correlated spectra. Important structural information is provided by the ^{13}C chemical shift of C-6 (**2**: 35.7; **3**: 33.7; **4**: 34.2 ppm), C-7 (**2**: 70.1; **3**: 73.7; **4**: 74 ppm) and C-8 (**2**: 77.6; **3**: 79.5; **4**: 74.8 ppm) (Jones et al., 1982; Mohanraj and Herz, 1982; Wiedenfeld and Röder, 1991). These signals determine a retronecine-*O*-9 ester **2**, a heliotridine-*O*-9 ester **3** and a retronecine-*O*-7 ester **4**. This is further proofed by the ^1H and ^{13}C shift for C-9: 4.70/61.8 (**2**), 4.67/60.7 (**3**) and 3.97/58.2 (**4**) as well as by the ^1H data for C-7: 4.20 (**2**), 4.16 (**3**) and 5.12 (**4**). The esterifying acid is characterized by the values for C-12 (76 ppm, S), C-13 (1.80 and 35 ppm) and the methyl groups 14/15 (~0.8 and ~17 ppm) as well as for the methyl group 16 (~1.2 and ~23 ppm). The stereochemistry at C-12 can be deduced by interpretation of the shift-difference of the C-9H_2 AB system (Mohanraj and Herz, 1982; Wiedenfeld and Röder, 1991). For this aspect a value near 0 is found indicating the *S*-configuration. These data leads to the structure of a 2*S*-2-hydroxy-2,3-dimethyl-butanoic acid.

Until now, only one report can be found in literature about a PA esterified with a 6-C-acid (Hartmann et al., 1990). There, a *O*-9 and a *O*-7 ester of retronecine with 2-hydroxy-3-methyl-butyric acid is described which were formed after feeding *Creatonotus transiens* butterflies with retronecine.

Our results show that similar structures can occur natively in plant material, too. For the new PA, we propose the names retrohoustine **2**, isoretrohoustine **4** and heliohoustine **3**.

3. Experimental

3.1. General

NMR spectra were measured in $CDCl_3$/DMSO-d_6 at 400 and 100 MHz, respectively. GC–MS: GC: 150 (5 min) –250°C, 10°/min; HP-1, 25 m×0.32 mm; Inj.: 250°C, det.: 280°C; R_t: **1**: 12.94 min, **2**: 10.45 min, **3**: 10.93 min, **4**: 10.72 min; MS: 220°C; interface: 250°C; 2000 emV.

3.2. Plant material

Plants were gathered at several places near Tlanchinol, Hidalgo, Mexico, in the years 1998 and 1999. The material was identified by Enrique Ortíz Bemudes, University of Mexico, a voucher specimen (IMSS14141) was deposited at the herbarium of medicinal plants at the Mexican Institut for Social Security in Mexico City.

3.3. Isolation of alkaloids

Extn of plant material (aerial parts; 500 g) was carried out as described earlier (Röder and Wiedenfeld, 1977; Wiedenfeld and Röder, 1979). Prep. TLC [silica gel F_{254}, CH_2Cl_2–MeOH–NH_4OH (25%), 75:24:1] yielded the alkaloids as oils (4 mg **1**, 12 mg **2** and 8 mg **3** and **4**).

3.4. Retrohoustine 2

GC–MS *m*/*z* (rel. int.): $[M]^+$ $C_{14}H_{23}NO_4$ 269 (0.22); $C_{14}H_{22}NO_3$ 252 (0.65); $C_{11}H_{15}NO_4$ 225 (5.65); $C_{11}H_{14}NO_3$ 208 (1.74); $C_8H_{12}NO$ 138.04 (100); $C_8H_{10}N$ 120 (8.26); C_6H_7N 93 (68.04); C_5H_6N 80 (16.96).

^1H NMR: δ 5.74 (1H, *td*, $J_{2,3a/b}=1.7$ Hz, H-2), 4.70 (2H, *ddt*, $J_{9a,9b}=13.3$ Hz, $J_{9a/b,3a/b}=1.2$ Hz $J_{9a/b,2}=1.0$ Hz, H_2-9), 4.20 (1H, *td*, $J_{7,8}=3.3$ Hz, $J_{7,6}=1.2$ Hz, H-7), 4.10 (1H, *m*, H-8), 3.84 (1H, *dddt*, $J_{3a,3b}=15.6$ Hz, $J_{3a,8}=2.4$ Hz, $J_{3a,2}=1.7$ Hz, $J_{3a,9}=1.2$ Hz, H-3A), 3.33 (1H, *dddd*, $J_{3b,3a}=15.6$, $J_{3b,5b}=5.8$, $J_{3b,8}=1.9$ Hz, $J_{3b,2}=1.7$ Hz, H-3B), 3.17 (1H, *dt*, $J_{5a,5b}=8.5$, $J_{5a,6}=1.7$ Hz, H-5A), 3.1 (2OH), 2.66 (1H, *ddd*, $J_{5b,5a}=8.5$, $J_{5b,3b}=5.8$, $J_{5b,6}=2.9$ Hz, H-5B), 1.88 (1H, *q*, $J_{13,14/15}=6.9$ Hz, H-13), 1.86 (2H, *m*, H_2-6), 1.17 (3H, *s*, H_3-16), 0.85 (3H, *d*, $J_{15,13}=6.9$ Hz, H_3-15), 0.79 (3H, *d*,

$J_{14,13}$ = 6.9 Hz, H_3-14), ^{13}C NMR: δ 179.2 (*s*, C-11), 132.9 (*s*, C-1), 127.8 (*d*, C-2), 77.6 (*d*, C-8), 76.5 (*s*, C-12), 70.1 (*d*, C-7), 62.1 (*t*, C-3), 61.8 (*t*, C-9), 53.3 (*t*, C-5), 35.7 (*t*, C-6), 35.3 (*d*, C-13), 22.7 (*q*, C-16), 16.8 (*q*, C-14), 14.4 (*q*, C-15).

3.5. Isoretrohoustine **4**

GC–MS *m*/*z* (rel. int.): $[M]^+$ $C_{14}H_{23}NO_4$ 269 (0.28); $C_{14}H_{22}NO_3$ 252 (0.13); $C_{11}H_{15}NO_4$ 225 (3.83); $C_{11}H_{14}NO_3$ 208 (0.26); $C_8H_{12}NO$ 138.04 (100); $C_8H_{10}N$ 120 (10.0); C_6H_7N 93 (87.18); C_5H_6N 80 (26.92).

^1H NMR: δ 5.55 (1H, *dd*, $J_{2,3a/b}$ = 1.8 Hz, $J_{2,8}$ = 1.4 Hz, H-2), 5.12 (1H, *ddd*, $J_{7,8}$ = 3.3 Hz, $J_{7,6a}$ = 1.2 Hz, $J_{7,6b}$ = 1.0 Hz, H-7), 4.2 (2OH), 4.18 (1H, *m*, H-8), 3.97 (2H, *dt*, $J_{9a,9b}$ = 11.5 Hz, $J_{9a/b,3a/b}$ = 5.4 Hz, H_2-9), 3.78 (1H, *ddd*, $J_{3a,3b}$ = 14.0 Hz, $J_{3a,8}$ = 6.2 Hz, $J_{3a,9a/b}$ = 5.4 Hz, H-3A), 3.29 (1H, *ddd*, $J_{3b,3a}$ = 14.0, $J_{3b,8}$ = 6.3, $J_{3b,9a/b}$ = 5.0 Hz, H-3B), 3.10 (1H, *dd*, $J_{5a,5b}$ = 9.0, $J_{5a,6}$ = 2.7 Hz, H-5A), 2.66 (1H, *dd*, $J_{5b,5a}$ = 9.1, $J_{5b,3b}$ = 8.2, H-5B), 1.94 (2H, *m*, H_2-6), 1.78 (1H, *q*, $J_{13,14/15}$ = 6.9 Hz, H-13), 1.13 (3H, *s*, H_3-16), 0.81 (3H, *d*, $J_{15,13}$ = 6.9 Hz, H_3-15), 0.73 (3H, *d*, $J_{14,13}$ = 6.9 Hz, H_3-14), ^{13}C NMR: δ 175.3 (*s*, C-11), 139.1 (*s*, C-1), 124.4 (*d*, C-2), 76.2 (*s*, C-12), 74.8 (*d*, C-8), 74.0 (*d*, C-7), 62.7 (*t*, C-3), 58.2 (*t*, C-9), 53.1 (*t*, C-5), 34.7 (*d*, C-13), 34.2 (*t*, C-6), 23.3 (*q*, C-16), 17.2 (*q*, C-14), 15.9 (*q*, C-15).

3.6. Heliohoustine **3**

GC–MS *m*/*z* (rel. int): $[M]^+$ $C_{14}H_{23}NO_4$ 269 (1.09); $C_{14}H_{22}NO_3$ 252 (0.22); $C_{11}H_{15}NO_4$ 225 (4.78); $C_{11}H_{14}NO_3$ 208 (0.11); $C_8H_{12}NO$ 138.04 (100); $C_8H_{10}N$ 120 (5.33); C_6H_7N 93 (81.53); C_5H_6N 80 (19.02).

^1H NMR: δ 5.62 (1H, *t*, $J_{2,3a/b}$ = 1.2 Hz, H-2), 4.67 (2H, *m*(broad), H_2-9), 4.2 (2OH), 4.16 (1H, *t*, $J_{7,8}$ = 2.2 Hz, H-7), 3.98 (1H, *m*, H-8), 3.77 (1H, *ddt*, $J_{3a,3b}$ = 14.6 Hz, $J_{3a,8}$ = 6.6 Hz, $J_{3a,9}$ = 5.2 Hz, H-3A), 3.29 (1H, *dtd*, $J_{3b,3a}$ = 14.6, $J_{3b,5b}$ = 4.1, $J_{3b,8}$ = 2.0 Hz, H-3B), 3.11 (1H, *dm*, $J_{5a,5b}$ = 10.5, H-5A), 2.57 (1H, *ddd*, $J_{5b,5a}$ = 10.6, $J_{5b,3b}$ = 4.8, $J_{5b,6}$ = 1.3 Hz, H-5B), 1.78 (1H, *q*, $J_{13,14/15}$ = 6.7 Hz, H-13), 1.74 (1H, *tm*, $J_{6a,6b}$ = 6.0 Hz, H-6A), 1.62 (1H, *td*, $J_{6b,6a}$ = 6.1 Hz, $J_{6b,5}$ = 5.8 Hz, H-6B), 1.23 (3H, *s*, H_3-16), 0.83 (3H, *d*, $J_{15,13}$ = 6.7 Hz, H_3-15), 0.80 (3H, *d*, $J_{14,13}$ = 6.7 Hz, H_3-14), ^{13}C NMR: δ 175.5 (*s*, C-11), 136.5 (*s*, C-1), 124.4 (*d*, C-2), 79.5 (*d*, C-8), 77.1 (*s*, C-12), 73.7 (*d*, C-7), 61.4 (*t*, C-3), 60.7 (*t*, C-9), 53.7 (*t*, C-5), 35.2 (*d*, C-13), 33.7 (*t*, C-6), 22.8 (*q*, C-16), 17.1 (*q*, C-14), 16.1 (*q*, C-15).

Acknowledgements

We are thankful to Ivan Pérez Samayoa for his great help in collecting and identifying the plant material.

Received 11 January 2001; received in revised form 22 February 2001

Abstract

Preparative RP-HPLC analysis of a methanol extract of the seeds of *Centaurea cyanus* afforded four indole alkaloids: moschamine, *cis*-moschamine, centcyamine and *cis*-centcyamine, the latter two being new natural products. Structures of these compounds were elucidated by comprehensive spectroscopic analyses. General toxicity of the isolates was determined by Brine Shrimp Lethality bioassay. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Centaurea cyanus*; Compositae; Asteraceae; Indole; Moschamine; Centcyamine; Toxicity; Brine Shrimp Lethality bioassay; *Artemia salina*; NMR

1. Introduction

Centaurea cyanus L. (family: Asteraceae *alt*. Compositae), commonly known as "Cornflower" or "Bachelor's button", is a flowering weed indigenous to Iran, Iraq, Turkey and Pakistan in Asia, and Albania, Bulgaria, Greece, Italy and the former Yugoslavia in Europe, and also cultivated and naturalised in many other parts of the world (GRIN database, 2000). Flower-heads of this plant are well-known crude drugs used in European traditional medicine in the treatment of minor ocular inflammation (Bruneton, 1995), and as diuretic and cholagogic agents (Mashkovskii, 1984; Litvinenko and Bubenchikova, 1988). Antimicrobial (Monya et al., 1968), antiinflammatory and immunological activities (Garbacki et al., 1999) of *C. cyanus* flowers have also been reported. Previous phytochemical studies on *C. cyanus* revealed the presence of various types of plant secondary metabolites, e.g. anthocyanins, flavonoid and their glycosides, phenolcarboxylic acids, sesquiterpenes, coumarins, etc. (Dictionary of Natural Products, 1999; Phytochemical and Ethnobotanical database, 2000; ISI database, 2000). We now report on the isolation, structure determination and general toxicity (in Brine Shrimp Lethality bioassay) of four indole alkaloids from the seeds of *C. cyanus*.

2. Results and discussion

RP-HPLC analysis of the MeOH extract of the seeds of *C. cyanus* yielded four indole alkaloids which, on the basis of extensive spectroscopic analyses (e.g. UV, LSIMS, and 1D and 2D NMR), were characterised as moschamine (**1**), *cis*-moschamine (**2**), *(E) N*-(4-hydroxycinnamoyl)-5-metho xytryptamine (**3**) and *(Z) N*-(4-hydroxycinnamoyl)-5-methoxytryptamine (**4**). Compounds **3** and **4** were found to be new natural products and named, respectively, centcyamine and *cis*-centcyamine.

All four compounds show positive colour reactions with Dragendorff's reagent. Their UV absorption maxima are similar to those of indole alkaloids reported previously from *C. moschata* (Sarker et al., 1997). In fact, the UV absorption maxima of the mixture (45:55) of **1** and **2** are identical to those previously published for moschamine and *cis*-moschamine (Sarker et al., 1997). ^{1}H and ^{13}C NMR data of **1** and **2** also match published data (Sarker et al., 1997). LSIMS and 2D-NMR

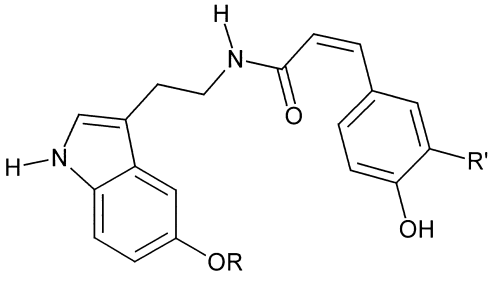
1 R = H R' = OMe

3 R = Me R' = H



2 R = H R' = OMe

4 R = Me R' = H

experiments, *e.g.* COSY, HSQC and HMBC further confirmed the identities of **1** and **2** as moschamine and *cis*-moschamine respectively.

Compounds **3** and **4** were also isolated as an approximately 45:55 mixture of *cis-trans* isomers. Two well-separated peaks could be observed in the RP-HPLC, but on isolation they readily formed the mixture again. Owing to this unavoidable situation, all spectroscopic analyses on **3** and **4** were performed on the mixture. A LSI mass spectrum revealed $[M+H]^+$ (positive ion mode) ion peak at *m/z* 337, suggesting $M_r = 336$ and solving for $C_{20}H_{20}N_2O_3$. ^1H and ^{13}C NMR spectra (Table 1) for this mixture were similar to those for **1** and **2** with the exception that instead of a 3-methoxy-4-hydroxyphenyl, a 4-hydroxyphenyl moiety was present in **3** and **4**. In addition, instead of a 5-hydroxytryptamine (in **1** and **2**), a 5-methoxytryptamine formed the amide linkage with 4-hydroxycinnamoyl moiety **3** and **4**. ^1H–^1H COSY revealed 4 different spin systems: H-7↔H-6↔H-4, H_2-α↔H_2-β, H-7′↔H-8′ and H-2′ (H-6′)↔H-3′ (H-5′).

[a] δ in ppm.

All methyl, methylene and methine carbons were unambiguously assigned from ^1H–^{13}C direct correlation observed in HSQC spectrum. The most crucial ^1H–^{13}C long-range correlation observed in HMBC (Fig. 1) was the ^3J correlation from the methoxyl protons (δ_H 3.81/3.79) to the oxygenated aromatic carbon C-5 (δ_C 148.8) which was related (^3J) to H-7 (δ_H 7.12/7.10). The amide linkage was confirmed from the ^3J correlation from H_2-α (δ_H 3.53/3.45) to the carbonyl carbon (C-9′, δ_C 167.8/169.0). Thus a combination of 1D and 2D NMR techniques allowed the unambiguous characterisation of compounds **3** and **4**. Compounds **1** and **2** were previously isolated from another species, *C. moschata*, but to our knowledge, **3** and **4** are new natural products. Compounds arising from the amide formation between tryptamine (or serotonin) and cinnamic acid (or derivatives) have also been observed in few other species of the family Compositae (Dictionary of Natural Products, 1999). The co-occurence of moschamine (**1**) and *cis*-moschamine (**2**) both in *C. cyanus* and *C. moschata* might be significant from chemotaxonomic viewpoint

Both mixtures, **1** and **2**, and **3** and **4** showed significant toxicity in Brine Shrimp (*Artemia salina*) Lethality bioassay (Meyer et al., 1982). The LD_{50}s for these geometrical isomeric mixtures **1** and **2**, and **3** and **4** were determined, respectively, 21.65 and 14.43 μg/ml. The observed lethality induced by these compounds is comparable to that published for berberine chloride (LD_{50} = 22.5 μg /ml) (Meyer et al., 1982), and both the mixtures

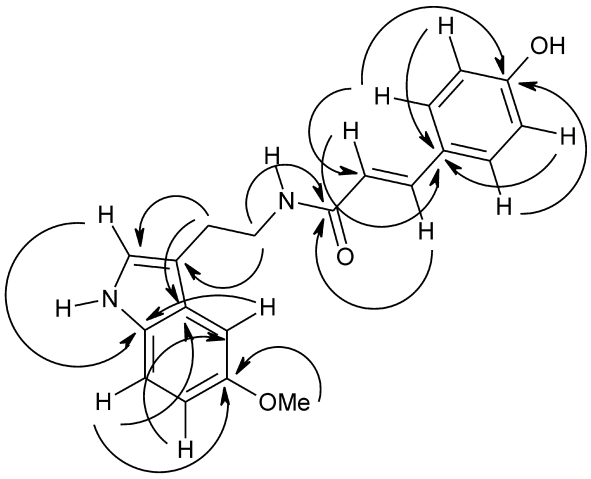

Fig. 1. ^{1}H–^{13}C long-range correlations observed in HMBC of **3**.

are more than 3 times more toxic than strychnine sulfate ($LD_{50} = 77.2$ μg/ml).

3. Experimental

3.1. General

UV spectra were obtained in MeOH. NMR spectra were recorded in CD_3OD using a Varian Unity INOVA 400 MHz NMR Spectrometer. LSIMS (positive ion mode); glycerol matrix using a Cs^+ primary ion beam on a VG Quattro triple quadrupole mass spectrometer (VG Biotech. Altrincham, UK). HPLC separation was performed in the Dionex prep-HPLC System coupled with Gynkotek GINA50 autosampler and Dionex UVD340S Photo-Diode-Array detector. RP stands for reversed-phase C_{18} column. Sep-Pak Vac 35 cc (10 g) C_{18} cartridge (Waters) was used for pre-HPLC fractionation.

3.2. Plant material

Seeds of *C. cyanus* L. (catalogue no: 304 A) were purchased from commercial source (Chiltern Seeds, Bortree Stile, Ulverston, Cumbria LA12 7PB, UK), and a voucher specimen (CA2000005) representing this purchase has been generated in the School of Pharmacy, The Robert Gordon University, Aberdeen, UK.

3.3. Extraction

Ground seeds (11.0 g) of *C. cyanaus* were Soxhlet-extracted successively with *n*-hexane, dichloromethane and MeOH. All these extracts were separately concentrated using a rotary evaporator at a maximum temperature of 45°C.

3.4. Isolation of compounds

The MeOH extract was fractionated on a Sep-Pak, using 20, 40, 60, 80 and 100% MeOH–water mixture (150 ml each) as eluent. Preparative RP-HPLC (isocratic, 32% MeOH in water, 15 ml/min) of the Sep-Pak fraction (40% MeOH in water) yielded compounds **1** and **2** as a mixture (45:55, 3.5 mg), and **3** and **4** also as a similar mixture (45:55, 2.1 mg).

3.5. Moschamine [(E) N-(3-methoxy-4-hydroxycinnamoyl)-5-hydroxytryptamine, **1**] + cis-moschamine [(Z) N-(3-methoxy-4-hydroxycinnamoyl)-5-hydroxytryptamine, **2**]

Amorphous. UV, ^{1}H and ^{13}C NMR (Sarker et al., 1997). LSIMS (positive ion mode) m/z 353 $[M+H]^+$.

3.6. Centcyamine [(E) N-(4-hydroxycinnamoyl)-5-methoxytryptamine, **3**] + cis- centcyamine [(Z) N-(4-hydroxycinnamoyl)-5-methoxytryptamine, **4**]

Amorphous. UV λ_{max} nm: 224, 287, 296, 312. ^{1}H- and ^{13}C NMR (Tables 1). LSIMS (positive ion mode) m/z 337 $[M+H]^+$.

3.7. Brine Shrimp (Artemia salina) Lethality bioassay

Brine shrimp eggs were purchased from Pet Shop, Kittybrewster, Aberdeen, UK. The bioassay was conducted following the procedure published previously (Meyer et al., 1982). LD_{50}s were determined from the 24 h counts using the probit analysis method (Finney, 1971). Percentage mortalities were adjusted relative to the natural mortality rate of the control, following Abbots formula $P = Pi - C/1 - C$, where P denotes the observed non-zero mortality rate and C represents the mortality rate of the control.

Dedicated to my PhD research supervisor, Professor Viqar Uddin Ahmad on his retirement

Abstract

During the phytochemical investigation of *Haplophyllum acutifolium*, two alkaloids named haplophytin-A (**1**) and B (**2**) have been obtained. In addition, some known constituents: flindersine (**3**), kusunokinin (**4**), β-sitosterol, oleanolic acid, cholesterol and hexadecanoic acid, have also been obtained. The known constituents have never been obtained from this source. The structures of all the isolated constituents were elucidated by spectroscopic means. However, the structures of constituents **1** and **2** were further confirmed through HMBC technique. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Haplophyllum acutifolium*; Rutaceae; Haplophytin-A; Haplophytin-B; Structure elucidation; Spectroscopy

1. Introduction

The genus *Haplophyllum* belongs to the family Rutaceae having about 70 species distributed in the Mediterranean countries. Out of 70, seven are found in Pakistan. Chemical literature survey reveals the presence of lignans (Gozler et al., 1996; Evcium et al., 1986; Gozler and Gozler, 1984), lignan-glycosides (Gozler et al., 1994), coumarins (Ulubelen et al., 1993), sterols, flavonoids (Yuldasher et al., 1987), several classes of alkaloids [furoquinoline (Gozler et al., 1996), quinoline (Sheriha et al., 1987), pyranoquinoline (Ulubelen, 1985) and tetrahydrofuroquinoline (Rozsa et al., 1986)] in various species of the genus *Haplophyllum*. Several biologically active secondary metabolites have been detected from various *Haplophyllum* species (Sheriha et al., 1987).

The presence of variety of biologically active chemical constituents form the members of the genus *Haplophyllum* motivated us to start our phytochemical investigation on *H. acutifolium*. In the present communication, we wish to describe the isolation and characterization of two alkaloids named haplophytin-A and B, and several known constituents [flindersine (**3**), kusunokinin (**4**), β-sitosterol, oleanolic acid, cholesterol and hexadecanoic acid] from the titled source.

2. Results and discussion

Haplophytin-A (**1**) was isolated from the methanol soluble part of *Haplophyllum acutifolium*. Lack of optical rotation means that there is probably no chirality in the molecule. The compound **1** gave positive response with UV light (254 nm) and Dragendroff's reagent confirming the presence of conjugated/aromatic system and nitrogen atom, respectively. The presence of unsaturation was further determined through infra-red spectrum which showed an absorption at 1500 cm^{-1} (C=C) together with other absorption bands at 3260 and 1660 cm^{-1} due to the N–H and conjugated amide-carbonyl, respectively. The molecular weight of **1** was confirmed with the help of FDMS and found 257 a.m.u. The formula of the corresponding peak was depicted from HR–EIMS as $C_{15}H_{15}NO_3$.

The proton NMR of **1** showed the presence of three quaternary methyl signals, out of them one appeared at δ 3.90 and the remaining two at δ 1.51 as a common signal of six protons. The spectrum did not contain any

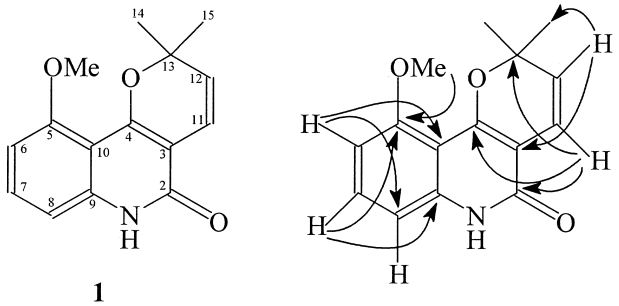
PII: S0031-9422(01)00188-1

methylene however, the same spectrum showed five downfield methine signals at δ 7.26 (*dd*, $J=8.8$, 2.8 Hz, H-6), 7.10 (*d*, $J=8.8$ Hz, H-7), 7.25 (*dd*, 8.8, 2.8 Hz, H-8), 5.54 (*d*) and 6.76 (*d*). The two upfield methine signals at δ 5.54 and 6.76 having the same magnitude of coupling constant ($J=9.9$ Hz) confirming the vicinal orientation attested for C-11 and C-12. The chemical shifts of remaining three methine signals at δ 7.26, 7.10 and 7.25 concluded the presence of aromatic ring in the molecule. The multiplicities of these three methine signals and their corresponding coupling constants showed that they are arranged in the manner that the H-6 and H-8 are *ortho* to H-7. The methoxyl moiety could be fixed either at C-5 or C-8 which was partially confirmed through HMBC experiment (Fig. 1) and finally, by compression with the data of closely related published compounds (Huffman and Hau, 1972).

The broad-band spectrum of **1** displayed 15 carbon signal which were sorted out into three methyls, five methines and remaining seven quaternary carbons. The chemical shift of methoxyl moiety (δ 55.7) inferred the direct attachment of this moiety to aromatic ring. The position of this methoxyl moiety at C-5 was determined through NOE experiment. Upon irradiation at δ 1.51 (H-14, H-15), a 33 and 16% NOE effect of the signals of H-12 and OMe, respectively, was observed. This 16% NOE effect would not have been observed if the methoxyl moiety had been situated at C-8. The other two quaternary methyls (C-14 and C-15) appeared at δ 28.0, found to be attached with a quaternary carbon connected to the electron withdrawing hetero-atom and thus assigned to C-13 (δ 79.0). The most downfield signal at δ 162.4 was due to the conjugated amide whereas the second quaternary downfield signal at δ 155.0 was due to the carbon at which methoxyl moieties is attached (C-5). The two methine signals of the ring having the oxygen as an hetero-atom appeared at δ 126.2 and 117.5 due to C-11 and C-12, respectively. The remaining three aromatic methine signals were observed in the carbon spectrum at their usual positions (δ 103.5, 120.5 and 117.4).

With the help of spectral evidences given earlier, the structure of the discussed compound was assigned as **1**



1

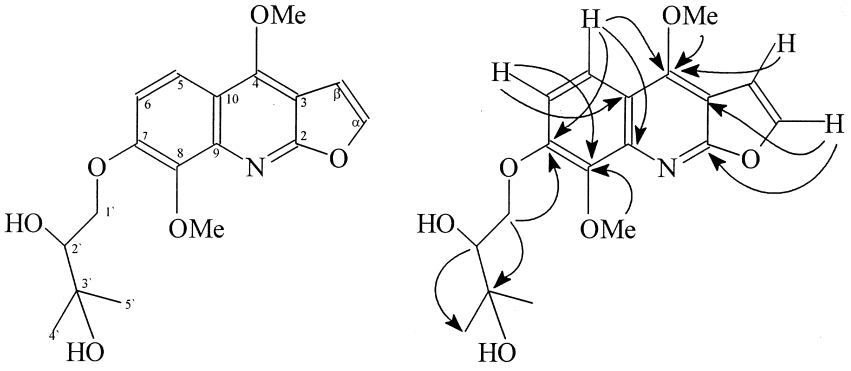
Fig. 1. HMBC connectivities.

and named haplophytin-A which is a new addition in the alkaloidal constituents of *Haplophyllum acutifolium*. Although similar types of compounds are already reported in the literature (Huffman and Hau, 1972) but having no methoxyl at C-5.

Haplophytin-B (**2**) was obtained from the same extract with the elution of 45% ethyl acetate in hexane. It showed positive UV response confirming the presence of conjugated/aromatic system in the molecule. The presence of unsaturation was supported by the absorption at 1500 cm^{-1} (C=C) in the IR spectrum which also showed an intense absorption band at 3320 cm^{-1} due to the hydroxyl function in the molecule. The molecular mass of **2** was determined through FDMS and found 347 a.m.u. The formula of this peak was observed as $C_{18}H_{21}NO_6$ with the aid of HRMS.

The proton spectrum of **2** exhibited four methyl resonances, out of them two at δ 4.47 and 4.10 due to the methoxyl moieties and their chemical shifts suggested direct attachment to the aromatic system. The remaining two quaternary methyl signals appeared at δ 1.29 and 1.25 (H-4′ and H-5′). The molecule contains only one methylene appeared as two separate sets of double-doublets at δ 4.13 ($J=9.9$, 8.0 Hz, Ha-′1) and 3.81 ($J=8.0$, 2.5 Hz, Hb-′1). The same spectrum showed four downfield methine signals at δ 8.01 (*d*, $J=9.4$ Hz, H-5), 7.34 (*d*, $J=9.4$ Hz, H-6), 7.73 (*d*, $J=2.8$ Hz, H-α) and 7.30 (*d*, $J=2.8$ Hz, H-β) and an upfield carbinylic proton at δ 4.49 (H-′2) as a double-doublet ($J=9.9$, 2.5 Hz). The signals at δ 8.01 and 7.34 and their same coupling constant confirmed their *ortho* arrangement and thus assigned to H-5 and H-6, respectively. The methine signal at δ 7.73 showed the presence of an electron withdrawing hetero-atom in the vicinity and attested for H-α. With the help of coupling constant of H-α ($J=2.8$ Hz) the H-β was located in the spectrum at δ 7.30.

The broad-band spectrum of haplophytin-B exhibited 18 carbon signals which were resolved into four methyls, one methylene, five methines and remaining eight quaternary carbon atoms. Out of four methyl signals, two were at δ 60.0 and 61.9 due to the methoxyl moieties in the molecule and their positions were fixed through HMBC experiment (Fig. 2) and literature values (Bessonova and Yunusov, 1986; Rasulova et al., 1987). The remaining two methyl signals appeared at δ 25.0 and 26.9 due to the C-4′ and C-5′, respectively. The only one methylene (C-1′) present in the molecule resonated at δ 72.5. An upfield methine signal resonated at δ 77.8 corresponded to the carbinylic carbon. The molecule contains four downfield methine signals at δ 119.5 (C-5), 114.0 (C-6), 144.3 (C-α) and 106.5 (C-β). The most downfield methine signal at δ 144.3 was due to the direct attachment to an hetero-atom (oxygen). A hydroxyl function attached to the quaternary carbon at which two quaternary methyls are attached appeared at δ 72.8.



2

Fig. 2. HMBC connectivities.

Three more quaternary carbons resonated at δ 153.9 (C-4), 142.1 (C-8) and 142.9 (C-7) were due to the two methoxyl and a side chain containing carbons, respectively. The position of side chain at C-7 was determined through HMBC connectivities (Fig. 2) and n.O.e measurements. Upon irradiation at δ 4.10 (C-8 OMe), a 29 and 13% NOE effect of the signals of H-2′ and H-1′, respectively, was observed suggested the attachment of side chain at C-3. Such a type of skeleton is already reported in literature with either different side chains or sugar units (Bessonova and Yunusov, 1986; Rasulova et al., 1987) and therefore, the previously discussed compound is assigned as **2** and named haplophytin-B. This compound is also a new addition in the alkaloidal constituents of *H. acutifolium*.

In addition to **1** and **2**, six more known constituents have been detected which have never been reported so far from our investigated source and their data are given in Section 3. The new constituents, haplophytin-A and B were found totally inactive against various tested bacteria and fungi.

4

3. Experimental

3.1. General

The ^{1}H and ^{13}C NMR spectra were recorded at 500, 400, 300 and 75,100, 125 MHz, respectively, on Brüker AM-500, AM-400 and AM-300 in $CDCl_3$.

3.2. Collection and identification

The plant material was collected from Quetta (Pakistan) in May 1999 and identified by Dr. R.B. Tareen, Department of Botany, Baluchistan University, Quetta (Baluchistan), where the voucher specimen has been deposited in the herbarium.

3.3. Extraction and isolation

The collected plant material (15 kg) was dried under shade and chopped into small pieces. The dried and chopped material (8 kg) was soaked in MeOH (14 l) for a period of 10 days. The percolation was repeated three times. The MeOH was evaporated under reduced temperature (28°C) and the gummy material thus obtained (276 g) was subjected to silica gel column chromatography using hexane, hexane–ethyl acetate, ethyl acetate, ethyl acetate–methanol and finally, pure methanol as mobile phase.

The fraction obtained with 15% ethyl acetate in hexane showed a strong UV-active spot on TLC with some minor impurities which on washing with methanol yielded **1** as a white powder (13 mg). The same UV active spot on spraying with Dragendroff's reagent changed into an orange spot confirming the presence of nitrogen in the molecule.

Haplophytin-A (**1**): m.p.: 209–210.5°C; $[\alpha]_D$: 0 ($CHCl_3$, *c* 0.506); UV $\lambda_{max}^{CHCl_3}$ nm (log ε): 244 (7.92); IR ($CHCl_3$): 3260 (N–H), 1660 (C=O), 1500 (C=C) cm^{-1}; EI–MS: *m/z* 257 $[M^+]$, 242 $[M–Me]^+$ (100%), 199, 121, 106; FDMS: *m/z* 257; HR–MS: *m/z* 257.9968 ($C_{15}H_{15}NO_3$ requires *m/z* 257.10518); ^1H NMR ($CDCl_3$, 400 MHz): δ 7.26 (1H, *dd*, *J* = 8.8, 2.8 Hz, H-6), 7.25 (H, *dd*, *J* = 8.8, 2.8 Hz, H-8), 7.10 (1H, *d*, *J* = 8.8 Hz,H-7), 6.76 (1H, *d*, *J* = 9.9 Hz, H-12), 5.54 (1H, *d*, *J* = 9.9 Hz, H-11), 3.90 (3H, *s*, OMe) and 1.51 (6H, s, H-14, 15); ^{13}C NMR ($CDCl_3$, 100 MHz): δ 162.4 (C-2), 115.7 (C-3), 156.0 (C-4), 155.0 (C-5), 103.5 (C-6), 120.5 (C-7), 117.4 (C-8), 132.9 (C-9), 106.5 (C-10), 126.2 (C-11), 117.5 (C-12), 79.0 (C-13), 28.0 (C-14, 15) and 55.7 (OMe); HMBC: see Fig. 1.

Elution with 45% ethyl acetate in hexane from the same column afforded another UV and Dragendroff's reagent positive sample as a dirty white powder (16.5 mg) which on washing with a 1:1 mixture of chloroform and hexane yielded **2**.

Haplophytin-B (**2**): mp: 151.5–153°C; $[\alpha]_D$: +63.6° (MeOH, *c* 0.33); UV λ_{max} CD_3OD nm (log ε): 251 (5.16); IR (KBr): 3320 (OH), 1500 (C=C) cm^{-1}; EI–MS: *m/z* 347 $[M]^+$, 287, 227 [M–side chain$^+$] (100%), 216; FDMS: *m/z* 347; HR–MS: *m/z* 347.13711 ($C_{18}H_{21}N$ O6 requires *m/z* 347.13687); ^1H NMR (CD_3OD, 500 MHz): δ 8.01 (1H, *d*, *J* = 9.4 Hz, H-5), 7.73 (1H, *d*, *J* = 2.8 Hz, H-α), 7.34 (1H, *d*, *J* = 9.4 Hz, H-6), 7.30 (1H, *d*, *J* = 2.8 Hz, H-β), 4.49 (1H, *dd*, *J* = 9.9, 2.5 Hz, H-′2), 4.47 (3H, s, C-4 OMe), 4.13 (1H, *ds*, *J* = 9.9, 8.0 Hz, Ha-′1), 4.10 (3H, *s*, C-8 OMe), 3.81 (1H, *ds*, *J* = 8.0, 2.5 Hz, Hb-′1), 1.29 (3H, s, H-′4), 1.25 (3H, s, H-′5); ^{13}C NMR (CD_3OD, 125 M Hz): δ 165.8 (C-2), 115.9 (C-3), 153.9 (C-4), 119.5 (C-5), 114.0 (C-6), 142.9 (C-7), 142.1 (C-8), 159.0 (C-9), 103.3 (C-10), 144.3 (C-α), 106.5 (C-β), 61.9 (C-8 OMe), 60.0 (C-4 OMe), 72.5 (C-′1), 77.8 (C-′2), 72.8 (C-′3), 25.0 and 26.9 (C-′4, C-′5); HMBC: see Fig. 2.

Received 11 January 2001; received in revised form 27 March 2001

Abstract

A new cytotoxic 1,7-dioxa-dispiro[5.1.5.2]pentadeca-9,12-dien-11-one derivative, aculeatin D, and a new alkenone, 5-hydroxy-hexacos-1-en-3-one, have been isolated as minor compounds from the rhizomes of *Amomum aculeatum*. Their structures have been determined mainly by NMR spectroscopy and mass spectrometry. Aculeatin D showed high cytotoxicity against the KB and the L-6 cell line with IC_{50} of 0.38 μg/ml and 1 μg/ml, respectively. Additionally, it revealed remarkable activity against two *Plasmodium falciparum* strains, as well as against *Trypanosoma brucei rhodesiense* and *Trypanosoma cruzi*. 5-Hydroxy-hexacos-1-en-3-one exhibited neither cytotoxic nor antiprotozoal activity, whereas antibacterial testing against *Bacillus cereus*, *Escherichia coli* and *Staphylococcus epidermidis* showed moderate to strong activity for both compounds. © 2001 Published by Elsevier Science Ltd. Keywords: Amomum aculeatum; Zingiberaceae; 1,7-Dioxa-dispiro[5.1.5.2]pentadeca-9,12-dien-11-one; Aculeatin D; Cytotoxicity; Antiprotozoal activity

1. Introduction

Recently we isolated three novel dioxa-dispiroketals as main compounds from the petroleum ether extract of the rhizomes of *Amomum aculeatum* (Heilmann et al., 2000), a plant used in the folk medicine of Papua New Guinea against fever and malaria (Holdsworth and Mahana, 1983). These compounds, which we named aculeatins A–C, represent a novel class of natural products exhibiting high cytotoxicity against the KB cell line and promising activity against the *Plasmodium falciparum* strains K1 and NF54. Further investigation on the petroleum ether extract led to the isolation of two new minor compounds: the first one was established as *rel*-(2*R*,4*S*,6*S*)-4-hydroxy-2-tridecyl-1,7-dioxa-dispiro[5.1.5.2]pentadeca-9,12-dien-11-one (= aculeatin D, **1**) another dioxa-dispiroketal with differing stereochemistry at C-4. The second compound, the alkenone 5-hydroxy-hexacos-1-en-3-one (**2**), is possibly a precursor or a degradation product during the biosynthesis or the metabolism of these dispiroketals.

2. Results and discussion

HRESIMS of compound **1** revealed a pseudomolecular ion $[M+Na]^+$ at m/z 441.2970 which strongly

PII: S0031-9422(01)00174-1

suggested that **1** was a stereoisomer of the 1,7-dioxa-dispiro[5.1.5.2]pentadeca-9,12-dien-11-one derivatives aculeatin A and B. In accordance the ^{13}C NMR experiments (including DEPT 135 and DEPT 90) showed the typical signals of the 1,7-dioxa-dispiro[5.1.5.2]pentadeca-9,12-dien-11-one skeleton: Four methine and one quaternary carbons at δ 184.9 (C-11, *s*), 151.7 (C-9, *d*), 148.7 (C-13, *d*), 127.7 (C-12, *d*) and 127.2 (C-10, *d*) characteristic of a dienone moiety, two quaternary carbons at δ 109.3 (C-6) and 78.1 (C-8) corresponding to the spiro centres as well as 8 signals of methylene carbons between δ 29.3 and 29.6 belonging to the alkyl side chain. The ^1H NMR spectrum resembled those of aculeatin A and B except of remarkable upfield shifts between 0.5 and 1 ppm for protons H-2 (δ 2.93) and H-4 (δ 3.38) indicating different stereochemistry in this part of the molecule (for ^1H and ^{13}C NMR data, see Table 1). ^1H, ^1H-COSY, HSQC and HMBC experiments established identical correlations as for aculeatin A and B confirming again the assumption that all three are stereoisomers. An ROESY experiment revealed strong NOEs between H-2 and H-4 as well as between H-15 (δ 1.78 and 1.13) and H-2/H-4 for compound **1** which confirmed that this compound is the hitherto unknown *rel*-(2*R*,4*S*,6*S*)-4-hydroxy-2-tridecyl-1,7-dioxa-dispiro[5.1.5.2]pentadeca-9,12-dien-11-one. Therefore aculeatin D (**1**) constitutes the fourth representative of the novel class of 1,7-dioxa-dispiro[5.1.5.2]pentadeca-9,12-dien-11-ones.

Aculeatin D (**1**) was evaluated for its cytotoxicity and antiprotozoal activity (see Table 2). Compared to aculeatin B [*rel*-(2*R*,4*R*,6*S*)-4-hydroxy-2-tridecyl-1,7-dioxa-dispiro[5.1.5.2]pentadeca-9,12-dien-11-one], inversion of stereochemistry at C-4 led to a doubled cytotoxicity against the KB cell line (IC_{50} 0.38 μg/ml (**1**) versus 0.82 μg/ml (aculeatin B)). In contrast, activity against the *Plasmodium falciparum* strains K1 and NF54 decreased significantly from aculeatin B to aculeatin D (**1**) (0.18 versus 0.42 μg/ml for *P. falciparum* strain K1 and 0.26 versus 0.47 μg/ml for *P. falciparum* strain NF54). Ongoing studies focus now on the discovery of the hitherto unknown mechanisms of cytotoxicity and anti-

plasmodial activity to find analogous structures with more specific biological effects.

5-Hydroxy-hexacos-1-en-3-one (**2**) exhibited a molecular ion at m/z 394 in the positive DEIMS. ^{13}C NMR experiments sorted 26 C-atoms into one quaternary, two methines, 22 methylenes and one methyl and led to a molecular formula of $C_{26}H_{50}O_2$ for **2** (for ^{13}C NMR data see Table 1). A carbonyl carbon resonating at δ 202.0, a methylene carbon at δ 119.2 and a methine carbon at δ 136.7 suggested the presence of a 1-en-3-one substructure. Twelve methylene signals between δ 29.3 and 29.6 revealed the presence of an alkyl chain and a methine carbon at δ 67.6 indicated an additional hydroxyl group. The suggestions from the ^{13}C NMR were confirmed by the ^1H NMR spectrum which showed signals at δ 6.28 (*dd*, $J=0.8$, 17.7) and δ 5.93 (*dd*, $J=0.8$, 10.5) for H-1, and at δ 6.38 (*dd*, $J=10.5$, 17.7) for H-2, as well as by a multiplet at δ 4.13 corresponding to H-5. ^1H, ^1H-COSY, HSQC and HMBC experiments established the structure and allowed the connection of the substructures as well as the assignment of all ^1H and ^{13}C NMR signals outside the region δ 1.25–1.35 and δ 29.3–29.6, respectively. 5-Hydroxy-hexacos-1-en-3-one (**2**) is also a new compound to the best of our knowledge. Due to the same number of C-atoms and the 5-hydroxy-1-en-3-one substructure, it seemed reasonable to assume that this compound represents possibly a precursor or a degradation product of the aculeatins what has to be clarified in further studies.

5-Hydroxy-hexacos-1-en-3-one (**2**) showed neither cytotoxic nor antiprotozoal activity. The antibacterial testing against *Bacillus cereus*, *Escherichia coli* and *Staphylococcus epidermidis* revealed moderate activity in the same range compared to the aculeatins A-C (unpublished results) but somewhat lower compared to aculeatin D (**1**) (see Table 2).

3. Experimental section

3.1. General

^{13}C NMR spectra were measured on a Bruker AMX-300 spectrometer (operating at 300.13 MHz for ^1H and 75.47 for ^{13}C) at 295 K. All other NMR spectra were recorded on a Bruker DRX-500 spectrometer (operating at 500.13 MHz for ^1H and 125.77 for ^{13}C) at 295 K. Spectra were measured in $CDCl_3$ and C_6D_6 and referenced against residual $CHCl_3$ (^1H δ 7.27) and $CDCl_3$ (^{13}C δ 77.0) or residual C_6H_6 (^1H δ 7.16) and C_6D_6 (^{13}C δ 128.0). DEI-MS (at 70 eV) were measured on a Hitachi-Perkin Elmer-RMUGM mass spectrometer and HRESIMS were recorded on a 4.7T-FT/ICR IonSpec Ultima mass spectrometer. A description of the other instruments used in this study has been provided in previous reports (Quadri-Spinelli et al., 2000; Winkelmann et al., 2000).

3.2. Collection and extraction

Rhizomes and roots of *Amomum aculeatum* Roxb. were collected in the Central Province of Papua New Guinea in September 1996. A voucher specimen is deposited in the Rijksherbarium (Leiden, The Netherlands) with the identification number ETH 96/1. Air dried plant material (659 g) was extracted successively with petroleum ether, CH_2Cl_2, MeOH, MeOH-H_2O 7:3 and H_2O. The extracts were stored under nitrogen at−20°C.

3.3. Isolation

The petroleum ether extract (11.1 g) was subjected to VLC on silica gel (35–70 μm) using a step gradient of hexane, hexane-CH_2Cl_2, CH_2Cl_2, CH_2Cl_2-ethyl acetate, ethyl acetate, ethyl acetate-MeOH and MeOH. The fraction CH_2Cl_2-ethyl acetate 4:6, yielding a mixture of aculeatin B,C and D (**1**), was separated twice by CC on silica gel (60–200 μm) using methyl–*tert*–butylether–diethylether–*n*-hexane 7.5:24.1:0.9 as eluent. Fractions containing aculeatin D were combined and purified on Sephadex LH-20 (cyclohexane–CH_2Cl_2–MeOH 7:4:1) yielding 5.3 mg pure **1**. The CH_2Cl_2-ethyl acetate 8:2 VLC fraction (1.23 g) was subjected to open column chromatography on silica gel (60-200 μm) using diisopropylether-diethylether-*n*-hexane 14.3:36.6:49.1 as eluent. Fractions containing **2** were pooled and further separated on silica gel (60–200 μm) with cyclohexane-CH_2Cl_2-MeOH 7:4:1 as eluent. Fractions containing **2**

were purified with prep. TLC and *n*-hexane-diethylether 1:1 as eluent yielding pure 5-hydroxy-hexacos-1-en-3-one (1.5 mg, **2**).

3.4. rel-(2R,4S,6S)-4-Hydroxy-2-tridecyl-1,7-dioxa-dispiro[5.1.5.2]pentadeca-9,12-dien-11-one (= aculeatin D, **1**)

Yellow oil (5.3 mg). $[\alpha]_D^{20}+46.5$ ($c=1$, $CHCl_3$); UV (MeOH) λ_{max} (lgε) 230 (4.15); positive DEI-MS (rel. intensity) m/z 418 $[M]^+$ (<1), 400 $[M\text{-}H_2O]^+$ (<1), 372 (<1), 281 (1), 235 (6), 165 (19), 107 (100); HRESIMS m/z 441.2970 $[M+Na]^+$ for $C_{26}H_{42}O_4$ (cal. 441.2980).

3.5. 5-Hydroxy-hexacos-1-en-3-one (**2**)

White waxy solid (1.5 mg). $C_{26}H_{50}O_2$; unstable; $[\alpha]_D^{20}-7$ ($c=0.1$, $CHCl_3$,). DEI–MS (pos. mode) m/z 394 $[M]^+$ (2); 339 (14), 297 (11), 98 (58), 97 (100), 55 (95).

3.6. Antiprotozoal activity

3.6.1. Plasmodium falciparum

Antiplasmodial activity was determined using two strains of *P. falciparum*: NF54 (sensitive to all known drugs) and K1 (resistant to chloroquine and pyrimethamine). A modification of the [^{3}H]-hypoxanthine incorporation assay was used (Matile and Pink, 1990). Briefly, infected human red blood cells were exposed to serial drug dilutions in microtiter plates for 48 h. Viability was assessed by measuring the incorporation of [^{3}H]-hypoxanthine by liquid scintillation counting. From the sigmoidal inhibition curves IC_{50} values were calculated.

3.6.2. Trypanosoma cruzi

Rat skeletal myoblasts (L-6 cells) were seeded in 96-well microtiter and infected with trypomastigotes of *T. cruzi* (Tulahuen strain C2C4) containing the β-galactosidase (Lac Z) gene. A serial drug dilution was added and the plates incubated for 4 days. The substrate CPRG/Nonidet was added to the wells and the colour reaction which developed was read photometrically at 540 nm. From the sigmoidal inhibition curves IC_{50} values were calculated.

3.6.3. Trypanosoma b. rhodesiense

Serial drug dilutions in Minimum Essential Medium supplemented according to Baltz et al. (1985) were added to microtiter plates. Trypomastigotes of *T.b.rhodesiense* STIB 900 were added to each well and the plates incubated for 72 h. Viability was assessed by Alamar Blue leading to a colour reaction which was read in a fluorescence scanner (Millipore Cytofluor 2300) (Räz et al., 1997). Fluorescence development was expressed as percentage of the control, and IC_{50} values were determined.

3.7. Cytotoxic activity

The screening for activity against the KB cell line (ATCC CCL 17) was performed as described previously (Ankli et al., 2000).

Activity against L-6 cells (rat skeletal myoblasts) was determined with the Alamar Blue assay using the same protocol as for *T. b. rhodesiense*.

3.8. Antibacterial and antifungal activity

The antimicrobial activity testing against *Bacillus cereus*, *Escherichia coli, Staphylococcus epidermidis* and *Candida albicans* followed the instructions published in Ankli et al. (2000).

Acknowledgements

Special thanks are given to Dr. O. Zerbe (Institute of Pharmaceutical Sciences, ETH Zurich) for recording NMR spectra and many helpful discussions. Mr. M. Wasescha (Institute of Pharmaceutical Sciences, ETH Zurich) is gratefully acknowledged for performing the KB cell assay. The authors are indepted to Dr. W. Amrein, Mr. R. Häflinger and Mr. O. Greter (Institute of Organic Chemistry, ETH Zurich) for recording mass spectra, and Dr. E. Zass (Institute of Organic Chemistry, ETH Zurich) for performing literature searches. Furthermore we wish to express our thanks to P. Piskaut (University of Papua New Guinea), Dr. M. Baltisberger (Geobotanical Institute, ETH Zurich) and Dr. M. M. J. van Balgooy (Rijksherbarium, Leiden, The Netherlands) for identification of plant material. A grant from the Studienstiftung des deutschen Volkes to Stefan Mayr is gratefully acknowledged.

Abstract

An ellagic acid derivative, 3,3′-di-*O*-methylellagic acid 4-(5″-acetyl)-α-L-arabinofuranoside, and two iridoid glucosides, 6α-dihydrocornic acid and 6β-dihydrocornic acid, were isolated from *Cornus capitata* adventitious roots cultured in Murashige–Skoog (Murashige, T., Skoog, F., 1962. A revised medium for rapid growth and bioassays with tobacco tissue cultures. Physiol. Plant. 15, 473–487) liquid medium containing 10 μM $CuSO_4$. Three known related metabolites, i.e. stenophyllin H1, dihydrocornin and cornin were also produced in the root cultures. The chemical structures were characterized by analysis of spectroscopic data. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Cornus capitata*; Cornaceae; Adventitious root; Ellagic acid; Iridoid

1. Introduction

The genus *Cornus* is well known to contain a large amount of polyphenols such as tannins (especially hydrolyzable tannins) (Okuda et al., 1984; Hatano et al., 1989a,b, 1990; Lee et al., 1989) and iridoid compounds (Bate-Smith et al., 1975; Jensen et al., 1973a,b, 1975; Nishino et al., 1988; Stermitz and Krull, 1998). *Cornus capitata,* often decorating the mountainsides in the Himalayas with its bright yellow four bracts, is used as a source of tannin constituents. Recently, polyphenol production in adventitious roots of *C. capitata* was reported (Tanaka et al., 1997, 1998), and high concentrations of galloylglucoses accumulated in the presence of copper ions (Cu^{2+}) in the culture medium (Tanaka et al., 1998). In the course of those studies, a new ellagic acid derivative and two new iridoid glucosides were isolated from the cultures. This paper describes the characterization of the new constituents, together with related known compounds (ellagic compound and iridoids), isolated from the cultures.

2. Results and discussion

2.1. Isolation of metabolites and characterization of known compounds

The aqueous acetone extract of the lyophilized adventitious roots of *C. capitata* cultured in MS medium containing 30 g/l maltose instead of sucrose, 3 mg/l IAA and 10 μM $CuSO_4$ was purified by column chromatography with Sephadex LH-20 and preparative C_{18} gel to afford compounds **1**–**6.** Compounds **2**, **5** and **6** were identified as an ellagic acid derivative, stenophyllin H1 (Nishimura, 1985), iridoid glucosides, dihydrocornin (Jensen et al., 1973a,b; Damtoft et al., 1981) and cornin (Miller, 1928; Jensen et al., 1980; Franzyk et al., 1998), respectively, by comparing their ^{1}H, ^{13}C NMR spectral data and the physical properties with those reported in the literature.

2.2. Characterization of new ellagic compound

Compound **1** was obtained as an off-white amorphous powder. Positive-ion fast atom bombardment mass spectroscopy (FAB–MS) of **1** gave a quasi-molecular ion peak at m/z 527 $[M+Na]^+$, which corresponded to

0031-9422/01/$ - see front matter © 2001 Elsevier Science Ltd. All rights reserved.
PII: S0031-9422(01)00179-0

the molecular formula of $C_{23}H_{20}O_{13}$. The ^1H NMR spectrum of **1** showed two aromatic protons at δ 7.73 (*s*) and δ 7.52 (*s*), and two methoxyl (δ 4.06 and δ 4.09) and one acetyl (δ 2.04) groups, together with six protons arising from a sugar moiety (Table 1). The ^{13}C NMR spectrum of **1** exhibited 12 signals (Table 2, C-1–6 and C-1′–6′) together with two carbonyl carbons at δ 158.4 and δ 158.5 due to α,β-unsaturated lactones, two methoxyl carbons (δ 60.8 and δ 61.5), one acetyl carbon (δ 20.6 and δ 170.3), and five sugar carbons (Table 2, C-1″–5″) whose chemical shifts were identical with those of arabinofuranose. The ^1H and ^{13}C NMR spectra suggested a di-*O*-methylellagic acid structure by comparison of their chemical shifts with those of a reference (Khac et al., 1989). The two methoxyl groups were concluded to be at C-3 and C-3′ positions by their low-field ^{13}C NMR chemical shifts (δ 60.8 and δ 61.5). The position of the arabinose moiety was also concluded to be at C-4 by the NOE spectrum observed between H-5 and arabinose anomeric protons (Fig. 1). The configuration of the anomeric carbon was concluded to be α from the *J*-value (1.5 Hz) in the ^1H NMR spectrum. The position of the acetyl group was also characterized to be at C-5″ by the analysis of the HMBC spectrum (Fig. 1). Therefore, **1** was identified as 3,3′-di-*O*-methylellagic acid 4-(5″-acetyl)-α-L-arabinofuranoside.

2.3. Characterization of new iridoids

Compounds **3** and **4** were obtained as yellow amorphous powders, both exhibiting a $[M–H]^-$ ion peak at *m/z* 483 ($C_{16}H_{24}O_{10}$) upon negative FAB–MS. The ^1H (Table 3) and ^{13}C (Table 4) NMR spectra of **3** and **4** were almost identical to those of the iridoid glucoside, dihydrocornin (**5**) (Damtoft et al., 1981), except for the disappearance of the signal of the carboxyl methyl group (COOMe) which generally is observed in cornaceous iridoid derivatives. From the spectral data mentioned above, **3** and **4** were identified as epimeric constituents of C-6 dihydrocornic acid. The configuration at C-6 position of compounds **3** and **4** was supposed to be β and α, respectively, by the chemical shifts (δ 75.1 and δ 78.8) of C-6 in the ^{13}C NMR (Table 4) (Damtoft et al., 1981). This configuration was also supported by NOE correlations observed between H-5 and H-6 in **3** (Fig. 2), and H-5 and H-7α in **4** (Fig. 3), respectively. The configuration of the anomeric center of **3** and **4** was concluded to be β from the *J*-value (8 Hz) of the H-1′ signals (Table 3). Therefore, **3** and **4** were characterized as 6α-dihydrocornic acid and 6β-dihydrocornic acid, respectively. Although the existence of dihydrocornic acid, an intermediate in the biosynthetic pathway of iridoid metabolism, has been proposed (Bate-Smith et al., 1975), this is the first example of the isolation of dihydrocornic acid from plant material.

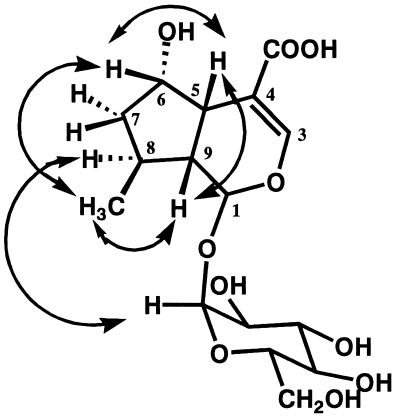
3. Experimental

3.1. General

^{1}H and ^{13}C NMR spectral data were measured at 500 and 125 MHz, respectively. Column chromatography was performed on Sephadex LH-20 (Pharmacia Fine Chemical), MCI-gel CHP 20P (Mitsubishi Chemical Industries) and preparative C_{18} 125 Å (Waters) column-gels. TLC analysis was performed on silica-gel plates (Merck, Kieselgel 60F254), with the mobile solvent benzene–ethylformate–formic acid (1:7:1). Spots of compounds on TLC plates were visualized by exposure to UV (254 nm).



OH
COOH
H
H
H

was concentrated to approximately 60 ml in vacuo at 40°C and was subjected to column chromatogaraphy with Sephadex LH-20 (Pharmacia) using H_2O–MeOH (1:0–0:1) as the eluant to afford four fractions (Fr. 1–4). Fr. 1 was applied to Sephadex LH-20 and preparative C_{18} 125 Å, both using H_2O–MeOH (1:0–0:1) elution solvent, to afford three subfractions (Fr. 11–13). Fr. 11 was further re-applied to preparative C_{18} 125 Å (H_2O–MeOH, 1:0–17:3) and MCI-gel (H_2O–MeOH, 1:0–4:1) chromatography to afford compound **3** (51.4 mg) and subfraction Fr. 111. Fr. 111 was purified by preparative C_{18} 125 Å (H_2O–MeOH, 1:0–7:3) and Sephadex LH-20 (EtOH) to give compound **5** (30.2 mg) and **6** (17.2 mg). Fr. 2 was subjected to preparative C_{18} 125 Å (H_2O–MeOH, 1:0–1:0) to afford compound **4** (4.4 mg). Fr. 3 was applied to preparative C_{18} 125 Å (H_2O–MeOH, 1:0–1:0) and Sephadex LH-20 (EtOH) to give compounds **1** (12.0 mg) and **2** (8.8 mg).

*3.3.1. 3, 3′-di-O-Methylellagic acid 4-(5″-acetyl)-α-L-arabinofuranoside (**1**)*

An off-white amorphous powder, $[\alpha]_D^{28}$ −180.0° (DMSO; *c* 0.13); ^1H and ^{13}C NMR spectral data of **1**, see Tables 1 and 2; positive FABMS *m*/*z* (rel. int.); 527 $[M+Na]^+$ (12.8). (Found: C, 52.53; H, 4.01. $C_{23}H_{20}O_{13}$ H_2O requires: C, 52.87; H, 4.21%).

*3.3.2. Stenophyllin H-1(**2**)*

A yellow amorphous powder, $[\alpha]_D^{28}$ −72.2° (DMSO; *c* 0.09); ^1H and ^{13}C NMR spectral data of **2**, see Tables 1 and 2.

*3.3.3. 6α-Dihydrocornic acid (**3**)*

A yellow amorphous powder, $[\alpha]_D^{28}$ −67.9° (MeOH; *c* 1.34); ^1H and ^{13}C NMR spectral data of **3**, see Tables 3 and 4. Negative FABMS *m*/*z* (rel. int.); 375 $[M-H]^-$ (27.8). (Found: C, 48.59; H, 6.32. $C_{16}H_{24}O_{10}$ H_2O requires: C, 48.73; H, 6.60%).

*3.3.4. 6β-Dihydrocornic acid (**4**)*

A yellow amorphous powder, $[\alpha]_D^{28}$ −271.6° (MeOH; *c* 0.18); ^1H and ^{13}C NMR spectral data of **4**, see Tables 3 and 4. Negative FABMS *m*/*z* (rel. int.); 375 $[M-H]^-$ (27.8). (Found: C, 48.62; H, 6.48. $C_{16}H_{24}O_{10}$ H_2O requires: C, 48.73; H, 6.60%).

*3.3.5. Dihydrocornin (**5**)*

A yellow amorphous powder, $[\alpha]_D^{28}$ −134.0° (MeOH; *c* 0.21); ^1H and ^{13}C NMR spectral data of **5**, see Tables 3 and 4.

*3.3.6. Cornin (**6**)*

An off-white amorphous powder; ^1H NMR (CD_3OD): δ 1.22 (*d*, *J* = 6.7 Hz, H-10), 1.98 (*m*, H-7b), 2.19 (*dt*, *J* = 7.8, 3.0 and 3.8 Hz, H-9), 2.51 (*m*, H-7a), 2.60 (*m*, H-8), 3.51 (*m*, H-5), 3.68–3.62 (*m*, 4H, H-2′, H-3′, H-4′, H-5′), 3.72 (*s*, 11-OCH_3), 3.87 (*m*, H-6b′), 3.91 (*m*, H-6a′), 4.65 (*d*, *J* = 7.8 Hz, H-1′), 5.25 (*d*, *J* = 6.8 Hz, H-1), 7.46 (*s*, H-3); ^{13}C NMR (CD_3OD) : δ 20.57 (C-10), 29.90 (C-8), 43.56 (C-7), 43.72 (C-5), 45.54 (C-9), 51.94 (OCH_3), 62.76 (C-6′), 71.59 (C-4′), 74.67 (C-2′), 77.98 (C-3′), 78.38 (C-5′), 97.10 (C-1), 100.60 (C-1′), 105.52 (C-4), 153.77 (C-3), 168.82 (COO), 215.74 (C-6).

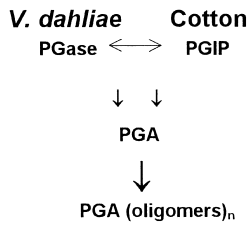
Inhibition of polygalacturonase from *Verticillium dahliae* by a polygalacturonase inhibiting protein from cotton

Jacinda T. James, Ian A. Dubery

Department of Chemistry and Biochemistry, Rand Afrikaans University, PO Box 524, Auckland Park, 2006, South Africa

The inhibition of *Verticillium dahliae* extracellular endo-PGase by salicylic acid-induced PGIP purified from cotton, is reported.



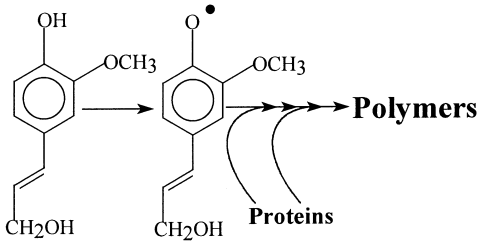
Phytochemistry, 2001, **57**, 157

Cell-wall proteins from Sitka spruce xylem are selectively insolubilised during formation of dehydrogenation polymers of coniferyl alcohol

Gordon J. McDougall

Unit of Plant Biochemistry, Biochemistry and Cell Biology Division, Scottish Crop Research Institute, Invergowrie, Dundee DD2 5DA, Scotland, UK

Extracts from Sitka spruce xylem that are enriched in cell-wall proteins readily produce dehydrogenation polymers from coniferyl alcohol and hydrogen peroxide. Certain polypeptides are insolubilised with the DHPs. The mechanism and selectivity of their insolubilisation is discussed.



Phytochemistry, 2001, **57**, 165

Biosynthesis of diaporthin and orthosporin by *Aspergillus ochraceus*

Jonathan P. Harris, Peter G. Mantle

Biochemistry Department, Imperial College of Science, Technology and Medicine, London SW7 2AY, UK

Co-occurrence of diaporthin (**1**) and orthosporin (**2**) as growth-associated metabolites of an isolate of *Aspergillus ochraceus* in submerged fermentation facilitated radiochemical demonstration of the biosynthesis of diaporthin from acetate and methionine-derived *O*-methylation of orthosporin. In contrast to diaporthin, orthosporin occurring in fermentation broth was affected by the methylation inhibitor ethionine, implying that it arose by de-*O*-methylation of diaporthin.

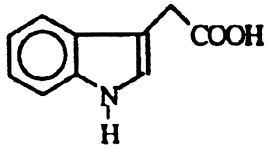
[b]*Department of Forest Genetics and Plant Physiology, The Swedish University of Agricultural Sciences, S901 83, Umeå, Sweden*

The metabolism of indole-3-acetic acid by orange flavedo tissue is studied, in relation to the homeostatic control of the levels of this PGR, at different stages of fruit development. The main metabolites have been positively identified.



indole-3-acetic acid

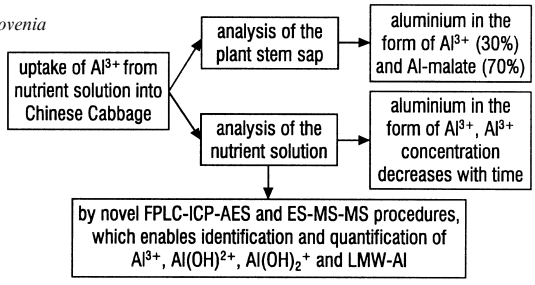
Phytochemistry, 2001, **57**, 189

The uptake and speciation of various Al species in the *Brassica rapa pekinensis*

Tjaša Bantan Polak[a], Radmila Milačič[a], Boris Pihlar[b], Bojan Mitrović[c]

[a]*Department of Environmental Sciences, Jožef Stefan Institute, Jamova 39, 1000 Ljubljana, Slovenia*
[b]*Faculty of Chemistry and Chemical Technology, University of Ljubljana, Aškerčeva 5, 1000 Ljubljana, Slovenia*
[c]*Lek Pharmaceutical and Chemical Company d.d., Celovška 135, 1000 Ljubljana, Slovenia*

Uptake and speciation of Al was investigated in the *Brassica rapa pekinensis*. Speciation analysis indicated that Al^{3+} added to the nutrient solution was not transformed in the growth media, but in the roots transformation to Al-malate occurred. Al was transported from roots to the upper parts of the plant as Al-malate (70%) and Al^{3+} (30%). Al-citrate or Al-malate added to the nutrient solution were transferred to the upper parts of the plant without transformation of their chemical forms.

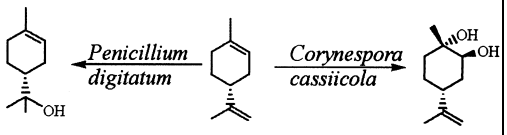


Phytochemistry, 2001, **57**, 199

Biotransformation of (*R*)-(+)- and (*S*)-(−)-limonene by fungi and the use of solid phase microextraction for screening

Jan C.R. Demyttenaere, Kristof Van Belleghem, Norbert De Kimpe

Department of Organic Chemistry, Faculty of Agricultural and Applied Biological Sciences, Ghent University, Coupure Links 653, B-9000 Ghent, Belgium



The biotransformation of (*R*)-(+)- and (*S*)-(−)-limonene by fungi was studied. (*R*)-(+)- and (*S*)-(−)-limonene were converted to (*R*)-(+)- and (*S*)-(−)-α-terpineol resp., by *Penicillium digitatum*, and to (1*S*,2*S*,4*R*)- and (1*R*,2*R*,4*S*)-*trans*-limonene-1,2-diol resp., by *Corynespora cassiicola*. Solid phase microextraction was used as screening and monitoring technique for bioconversion experiments.

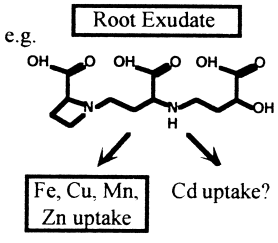
[e]*Department of Soil and Environmental Sciences, University of California, Riverside, CA 92521-0424, USA*
[f]*Crocker Nuclear Laboratory, University of California, One Shields Avenue, Davis, CA 95616, USA*

Metal ion ligands in root exudates of different plant types were examined using multinuclear 2-D NMR and high-resolution MS. Uptake of nutrient transition metals was related to the mugineic acid phytosiderophores while uptake of pollutant Cd appeared to be mediated by a different mechanism.



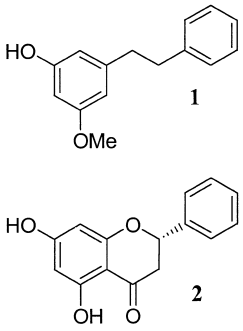
Phytochemistry, 2001, **57**, 223

Phytoalexins from *Pinus strobus* bark infected with pinewood nematode, *Bursaphelenchus xylophilus*

Fujinori Hanawa, Toshihiro Yamada, Tadakazu Nakashima

Forestry and Forest Products Research Institute (FFPRI), PO Box 16, Tsukuba, Ibaraki 305-8687, Japan

From the bark of *Pinus strobus* infected with pinewood nematode, 3-*O*-methyldihydropinosylvin (**1**) and (2*S*)-pinocembrin (**2**) were isolated as inducibly produced antimicrobial compounds. Compound **1** was proved to be nematocidal and time course accumulation of **1** and **2** were analyzed.



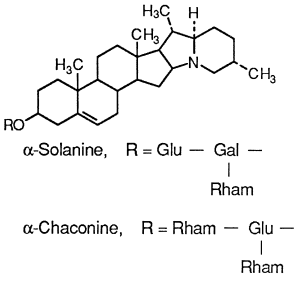
Phytochemistry, 2001, **57**, 229

Synergism between the potato glycoalkaloids α-chaconine and α-solanine in inhibition of snail feeding

David B. Smith[a], James G. Roddick[a], J. Leighton Jones[b]

[a]*School of Biological Sciences, University of Exeter, Washington Singer Laboratories, Perry Road, Exeter EX4 4QG, UK*
[b]*Campden and Chorleywood Food Research Association, Chipping Campden, GL55 6LD, UK*

The potato glycoalkaloids, solanine and chaconine, individually deterred feeding by the snail, *Helix aspersa*, with chaconine being the more active. In combination the two glycoalkaloids produced a synergistic effect. Antifeedant activities of extracts of tuber peel from three potato varieties were compared with equivalent authentic glycoalkaloid solutions.



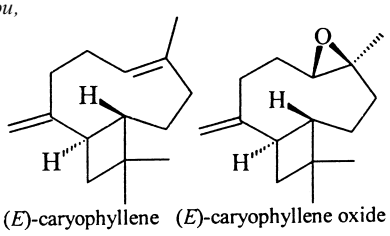
Phytochemistry, 2001, **57**, 235

A chemotaxonomic investigation of volatile constituents in *Stachys* subsect. Swainsonianeae (Labiatae)

Helen D. Skaltsa[a], Anna Mavrommati[a], Theophanis Constantinidis[b]

[a]*Division of Pharmacognosy, School of Pharmacy, University of Athens, Panepistimiopolis, Zografou, GR-157 71, Athens, Greece*
[b]*Botanical Institute, Department of Biology, University of Patras, GR-265 00, Patras, Greece*

The composition of the previously unknown essential oils of *Stachys* subsect. Swainsonianeae (Labiatae) are investigated by GC–MS analyses. Eighteen populations were analyzed and more than two hundred components were identified. The results are subject to statistical analyses and discussed in relation to the taxonomy of the subsection.



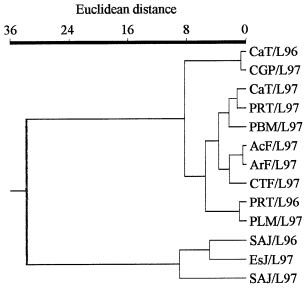
Phytochemistry, 2001, **57**, 245

Essential oils from Azorean *Laurus azorica*

Luis G. Pedro[a], Pedro A.G. Santos[a], Jaime A. da Silva[a], A. Cristina Figueiredo[a], José G. Barroso[a], Stanley G. Deans[b], Anja Looman[c], Johannes J.C. Scheffer[c]

[a]*Centro de Biotecnologia Vegetal, Departamento de Biologia Vegetal, Faculdade de Ciências de Lisboa, Bloco C2, Campo Grande, 1749-016 Lisbon, Portugal*
[b]*Department of Food Science and Technology, SAC, Auchincruive, Ayr KA6 5HW, Scotland, UK*
[c]*Division of Pharmacognosy, LACDR, Leiden University, Gorlaeus Laboratories, PO Box 9502, 2300 RA Leiden, The Netherlands*

The essential oils isolated from the leaves of ten and from unripe berries of eight populations of *Laurus azorica* (Seub.) Franco, collected on five islands of the Azorean archipelago, were analyzed. Cluster analysis of the enantiomeric composition of α- and β-pinene in the leaf oils clearly showed two groups.



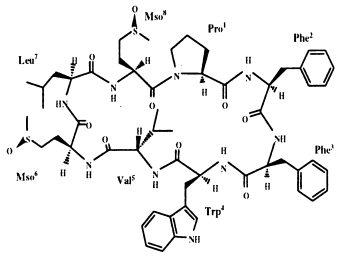
Phytochemistry, 2001, **57**, 251

Cyclolinopeptides F–I, cyclic peptides from linseed

Teruki Matsumoto, Akira Shishido, Hiroshi Morita, Hideji Itokawa, Koichi Takeya

School of Pharmacy, Tokyo University of Pharmacy and Life Science, 1432-1 Horinouchi, Hachioji, Tokyo 192-0392, Japan

Four cyclic peptides, cyclolinopeptides F–I, have been isolated from the seeds of *Linum usitatissimum*.



Structure of cyclolinopeptide F (1)

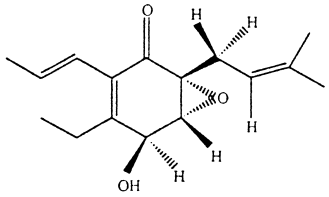
Phytochemistry, 2001, **57**, 261

Jesterone and hydroxy-jesterone antioomycete cyclohexenone epoxides from the endophytic fungus *Pestalotiopsis jesteri*

J.Y. Li, Gary A. Strobel

Department of Plant Sciences, Montana State University, Bozeman, MT, 59717, USA

Jesterone and hydroxy-jesterone are antifungal metabolites from an endophytic fungus.



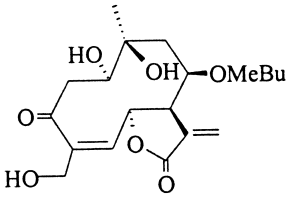
Phytochemistry, 2001, **57**, 267

Sesquiterpene lactones and a myoinositol from glandular trichomes of *Viguiera quinqueremis* (Heliantheae; Asteraceae)

Otmar Spring[a], Reinhard Zipper[a], Sabine Reeb[b], Bernhard Vogler[b], Fernando B. Da Costa[c]

[a]*Institut für Botanik, Universität Hohenheim, D-70599 Stuttgart, Germany*
[b]*Institut für Chemie, Universität Hohenheim, D-70599 Stuttgart, Germany*
[c]*Faculdade de Ciências Farmacêuticas de Ribeirão Preto, Universidade de São Paulo, Av. do Café s/n°, 14040-903, Ribeirão Preto, SP, Brazil*

HPLC analysis and LC NMR experiments revealed the occurrence of 15 germacranolides and a myoinositol derivative in glandular trichome extracts of *Viguiera quinqueremis*. Their structures were determined by spectral analysis.



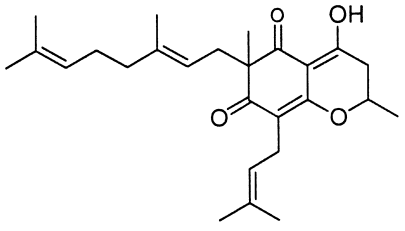
Phytochemistry, 2001, **57**, 273

Benzopyran derivatives from *Mallotus apelta*

Tian-Ying An, Li-Hong Hu, Xiao-Fang Cheng, Zhong-Liang Chen

National Center for Drug Screening, Shanghai Institute of Materia Medica, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, 200031, People's Republic of China

Benzopyran compounds were obtained from the leaves of *Mallotus apelta*. One showed moderate antibiotic activity against *Micrococcus lutens*.

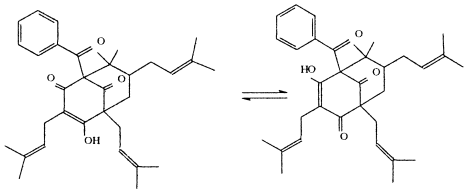


Phytochemistry, 2001, **57**, 279

Nemorosone, the major constituent of floral resins of *Clusia rosea*

Osmany Cuesta-Rubio[a], Herman Velez-Castro[b], Bernardo A. Frontana-Uribe[c], Jorge Cárdenas[c]

[a]*Instituto de Farmacia y Alimentos, Universidad de la Habana, Ave. 23 No. 21425, Lisa, C. Habana, 13600, Cuba*
[b]*Centro de Química Farmacéutica, Calle 200 esq. 21, C. Habana, 13600, Cuba*
[c]*Instituto de Química, Universidad Nacional Autónoma de México, Circuito Exterior, Ciudad Universitaria, Coyoacán C.P. 04510, México DF*



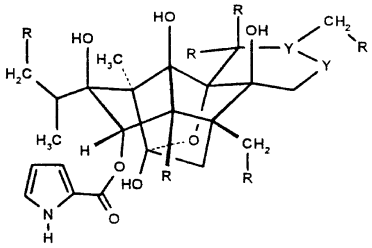
Nemorosone, the major constituent of the floral resin of *Clusia rosea* was isolated after exhaustive chromatography. A keto–enol equilibrium can be observed in this product. The previously announced structure for methyl-nemorosone was corrected on the basis of high field 2D NMR spectroscopic techniques and NOE difference spectroscopy experiments.

Phytochemistry, 2001, **57**, 285

Minor constituents of *Spigelia anthelmia* and their cardiac activities

Harald Hübner[a], Wolfgang Vierling[b], Wolfgang Brandt[b], Melchior Reiter[b], Hans Achenbach[a]

[a]*Department of Pharmaceutical Chemistry, University of Erlangen, D-91052 Erlangen, Germany*
[b]*Institute of Pharmacology and Toxicology, Technical University, D-80802 München, Germany*



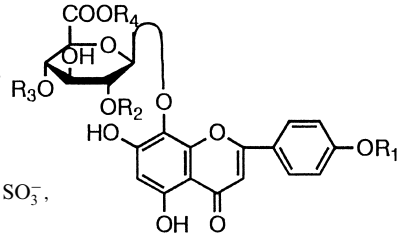
The isolation and structure elucidation of 20 spiganthine and ryanodine like compounds from the aerial parts of *Spigelia anthelmia* L. is reported. Their cardiac and insect antifeedant activities are discussed.

Phytochemistry, 2001, **57**, 297

Flavonoid glucuronides from *Helicteres isora*

Kohei Kamiya[a,b], Yasuhisa Saiki[a], Takao Hama[a], Yasuo Fujimoto[c], Hanani Endang[d], Mansur Umar[d], Toshiko Satake[a,b]

[a]*Faculty of Pharmaceutical Sciences, Kobe Gakuin University, Nishi-ku, Kobe 651-2180, Japan*
[b]*High Technology Research Center, Kobe Gakuin University, Nishi-ku, Kobe 651-2180, Japan*
[c]*College of Pharmacy, Nihon University, 7-7-1, Narashinodai, Funabashi, Chiba 274-8555, Japan*
[d]*Department of Pharmacy, Faculty of Mathematics and Natural Sciences, University of Indonesia, Depok-Jawa Barat, Indonesia*



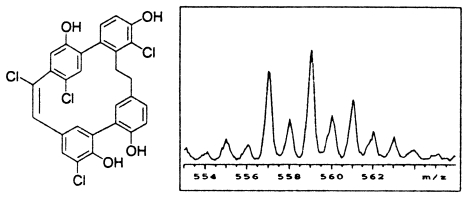
Five flavonoid glucuronides (**1**–**5**) were isolated from the fruit of *Helicteres isora*. These structures were determined by spectroscopic methods and chemical evidence. **1**: $R_1 = CH_3$, $R_2 = R_3 = R_4 = H$; **2**: $R_1 = CH_3$, $R_2 = R_3 = H$, $R_4 = n$–Bu; **3**: $R_1 = CH_3$, $R_2 = SO_3^-$, $R_3 = R_4 = H$; **4**: $R_1 = CH_3$, $R_2 = R_3 = SO_3^-$, $R_4 = H$; **5**: $R_1 = H$, $R_2 = R_3 = SO_3^-$, $R_4 = H$

Phytochemistry, 2001, **57**, 303

Rapid detection of chlorinated bisbibenzyls in *Bazzania trilobata* using MALDI-TOF mass spectrometry

Andreas Speicher[a], Klaus Hollemeyer[b], Elmar Heinzle[b]

[a]*Institut für Organische Chemie, Universität des Saarlandes, PO Box 151150, 66041 Saarbrücken, Germany*
[b]*Institut für Technische Biochemie, Universität des Saarlandes, PO Box 151150, 66041 Saarbrücken, Germany*



Chlorinated bisbibenzyls of the isoplagiochin C/D type are detected in crude bryophyte plant extracts of *Bazzania trilobata* from different locations using MALDI-TOF mass spectrometry.

Phytochemistry, 2001, **57**, 307

Pacifigorgianes and tamariscene as constituents of *Frullania tamarisci* and *Valeriana officinalis*

Claudia Paul[a], Wilfried A. König[a], Hermann Muhle[b]

[a]*Institut für Organische Chemie, Universität Hamburg, Martin-Luther-King-Platz 6, D-20146 Hamburg, Germany*
[b]*Abteilung Spezielle Botanik, Universität Ulm, D-89091 Ulm, Germany*

Several sesquiterpenes were isolated from liverworts and the angiosperm investigated.
