Received 6 October 2000; received in revised form 12 February 2001

Abstract

The isolation and structure elucidation of a new lactucopicrin derivative from *Cichorium intybus* is described, together with the revised structures of several sesquiterpene lactones previously isolated from *Cichorium* species. The known eudesmanolide magnolialide and the known guaianolide ixerisoside D, reported for the first time from the plant material, along with the previously known chicory sesquiterpene lactones have been also isolated and identified. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Cichorium intybus*; Asteraceae; Lactuceae; Sesquiterpene lactones; Glycosides; Structure revision

1. Introduction

Leaves and roots of chicory (*Cichorium intybus* L., Asteraceae, tribe Lactuceae) produce bitter sesquiterpene lactones which promote appetite and digestion. A great deal of information exists on the guaianolide aglycone, lactucin (**1**) and its derivatives, in different tissues of the plant (Pyrek, 1985; van Beek et al., 1990; Blaschek et al., 1998). Only one report (Seto et al., 1988) shows the co-occurrence of germacranolides, eudesmanolides and lactucin-like guaianolides, accumulated mainly as glycosides, in chicory roots.

We now report isolation of lactucin (**1**) and structurally related compounds **2**–**10** (Glc = β-glucopyranosyl), the guaianolide **11**, the germacranolide **12**, the eudesmanolide **13**, as well as methyl and ethyl esters of *p*-hydroxyphenylacetic acid and loliolide. Compound **10** is a new natural product and compounds **11** and **13** are described for the first time from *Cichorium intybus*. Structures of *Cichorium* sesquiterpene lactones previously ascribed formulae **17**, **19**, **20**, **21** and **22**, and the eudesmanolide **18** have been revised.

2. Results and discussion

A combination of column and thin layer chromatographies on silica gel followed by semipreparative HPLC of ethanol extracts from root and leaf samples of *C. intybus* yielded sesquiterpenoid aglycones and glycosides. The compounds were then subjected to analytical HPLC for direct comparison with authentic standards wherever possible.

The leaves afforded 11β, 13-dihydrolactucin (**4**), jacquinelin (**5**), a mixture of lactucin (**1**) and **4**, a mixture of 8-desoxylactucin (**2**) and **5**, a mixture of lactucopicrin (**3**) and its derivatives **6** and **9**, crepidiaside B (**7**), compound **10** and loliolide. Of these, compounds **1**–**3** and **9** were previously known as constituents of chicory aerial parts (Pyrek, 1985).

The roots yielded, in addition to a mixture of methyl and ethyl esters of *p*-hydroxyphenylacetic acid, compounds **2** and **7**, mixtures of **3**, **9** and **3**, **6** and **9**, cichorioside B (**8**) and sonchuside A (**12**), previously obtained from chicory roots (Pyrek, 1985; Seto et al., 1988; van Beek et al., 1990). Moreover, compound **10**, ixerisoside D (**11**) (Warashina et al., 1990) and magnolialide (**13**) (El-Feraly et al., 1979) were isolated. The known compounds, except for **9** and **13**, were identified by direct comparison (HPLC, ^{1}H NMR, EIMS or ESIMS) with compounds from our collection isolated from other members of the tribe Lactuceae. The identity

of the methyl ester **9** was established by comparison of its spectral data with those in the literature (Pyrek, 1985; Marco et al., 1992). Compounds **9** and **11** were first reported from *C. intybus* (Pyrek, 1985) and *Ixeris repens* (Warashina et al., 1990), respectively.

Compound **10** was unstable and proved difficult to separate from its mixture with two further compounds (as shown by HPLC), in view of the small amount available. Its structure was established by mass, 1D and 2D ^{1}H NMR spectral analyses, as well as by direct comparison with the spectra of lactucopicrin (**3**). The EI mass spectrum of **10** was in agreement with the molecular formula $C_{23}H_{22}O_7$. The most evident differences between the ^{1}H NMR spectra of **3** and **10** were due to the cyclopentanone ring protons. The spectrum of **10** (Table 1) lacked the downfield signal of the olefinic proton at C-3 and instead three proton resonances were observed upfield at δ 2.60, 2.67 and 3.34. Moreover, the signals for the C-4 hydroxymethylene group (H-15a and H-15b) were replaced by an aldehyde function (δ 9.94, br *d*, $J = 0.8$ Hz). Thus, we tentatively assigned structure **10** for the compound and turned to the ^{1}H–^{1}H COSY spectrum for further proof. The methine signal at δ 3.49 (H-5) was coupled with the signals at δ 3.73 (H-6), δ 2.37 (Me-14) and δ 3.34 (H-4). The latter was coupled with the signals at δ 2.60 and 2.67 assigned to the two methylene protons at C-3 which showed no further couplings. The relative stereochemistry at the carbon centres C-5 to C-8 of **10** was based on a comparison of the coupling constants for H-6 to H-8 with those of **3**, which were in very good agreement. The *trans*-disposition of H-4 and H-5 was deduced from the half bond width ($W_{1/2} = 22.7$ Hz) of H-5 and coupling values of H-4. We possess no firm evidence for absolute stereochemistry of **10**. However, the clear structural similarities between **10** and **3**, isolated from the same plant material, support the structure depicted in the formula. Thus, compound **10** was proved to be 3,4β-dihydro-15-dehydrolactucopicrin, a new natural product. In the plant extract **10** formed a mixture with two further structurally closely related compounds. The ^{1}H NMR spectrum of the mixture showed, in addition to the proton signals of **10**, two further aldehyde proton doublets at δ 9.92 ($J = 1.0$ Hz) and δ 9.81 ($J = 1.3$ Hz) due to H-15, two further olefinic methyl proton doublets at δ 2.36 ($J = 2.2$ Hz) and δ 2.28 ($J = 1.8$ Hz) due to H-14, as well as a secondary methyl proton doublet at δ 1.19 ($J = 6.9$ Hz) and two singlets at δ 5.61 and 6.22 due to H-13, respectively, suggesting the presence of three analogous guaiane derivatives with those of **3**, **6**, and **9**. Similar compounds, derivatives of 15-dehydrolactucin, were reported from *Hypochoeris* and *Lactuca* species (Bohlmann et al., 1981).

Compound **13**, $C_{15}H_{20}O_3$ (by EIMS), revealed ^{1}H NMR spectral features (Table 1) characteristic of an eudesman-12,6-olide with a Δ^4-double bond. The spec-

trum of **13** showed a sharp singlet for the angular methyl group at δ 1.10, a broad singlet for the olefinic methyl group at δ 1.86, a proton under the lactone oxygen as a broad doublet at δ 4.56 ($J=11.6$ Hz), the exocyclic methylene proton doublets at δ 6.15 ($J=3.2$ Hz) and δ 5.47 ($J=3.0$ Hz) and a methine proton *dd* at δ 3.55 ($J=11.5$ and 4.2 Hz). Examination of the literature revealed that two eudesmanolides and one guaianolide with almost identical chemical shift values of the key protons have been described, i.e. magnolialide (**13**), cichoriolide (**17**) and cichopumilide (**21**). Magnolialide (**13**) was isolated from *Magnolia grandiflora* 20 years ago, the structure being confirmed by comparison with synthetic product obtained by cyclization of costunolide-1,10-epoxide (El-Feraly et al., 1979). Cichoriolide (**17**) was reported from *Cichorium intybus* and *C. endivia* (Seto et al., 1988), while cichopumilide (**21**) was found in *C. pumilum* (a subsp. of *C. endivia*) (El-Masry et al., 1984). In the reported ^{1}H NMR spectra of the three compounds the signals at δ 3.55 were ascribed to the methine protons at the C-1 and C-3 positions of the eudesmanolides magnolialide and cichoriolide, respectively, and at the C-1 position of the guaianolide cichopumilide. This unexpected similarity of the ^{1}H NMR spectral data of compound **13** to those of the above mentioned sesquiterpene lactones necessitated its detailed structural analysis. The proton and carbon assignments of **13** (Table 1) were made by ^{1}H–^{13}C correlation (HETCOR) method in combination with COSY and NOESY experiments, as well as by comparison with the complete spectral data of the closely related eudesmanolide artesin (**14**) (Marco, 1989). In the NOESY spectrum Me-14 correlated with H-6β, H-8β, H-9β and H-2α/2β; H-1α correlated with H-2α/2β, H-3α and H-9α, while H-7α with H-8α, H-9α and H-13a. On the basis of the above findings, the identity of compound **13** with magnolialide was considered. This consideration was supported by positive sign of optical rotations of both compounds and by comparison of their ^{13}C NMR data which were in good agreement. The carbon resonances of **13** were also indistinguishable from those of cichoriolide (**17**), after reassignments of the signals from C-1, C-2 and C-3 according to the structure of **13**, giving evidence in favour of the identity of **13** and **17**.

Additional support for the above, as well as for the identity of **13** and **21** was obtained from a comparison of physical and spectral data reported for their 11β, 13-dihydroderivatives, i.e. **14** (mp 172°C or 177°C cited by Marco, 1989), **18** (mp 173–175°C) (Miyase and Fukushima, 1987), and **22** (mp 176°C) (El-Masry et al., 1984). Again, the chemical shift values of ^{13}C NMR signals of **14** were identical with those of **18** when reassigned in accord with the structure of **14**. The ^{1}H NMR spectral properties of the three dihydroderivatives were also very similar, in particular when more complete data of **22** were compared with those of **14**. Accordingly, compounds **17**, **18** and **21**, **22** have been reassigned the revised structures **13** and **14**, respectively. This, in turn, give rise to the revision of the previously assigned structures of *Cichorium* glycosides **19** and **20**, now correctly represented by **15** and **16**, respectively. Cichorioside (**19**) was isolated from *C. endivia* (Seto et al., 1988), while sonchuside C (**20**) was obtained from *C. intybus* (Seto et al., 1988) following previous isolation from *Sonchus oleraceus* (Miyase and Fukushima, 1987). Cichopumilide (**21**) and its 11β, 13-dihydroderivative (**22**) first reported from *C. pumilum* (El-Masry et al., 1984) were then identified in *Sonchus macrocarpus* (Mahmoud et al., 1984).

The sesquiterpene lactone chemistry of *Cichorium* species is dominated by lactucin-like guaianolides and their glycosides, present in roots and aerial parts. Moreover, roots of the plants produce a small number of germacrane- and eudesmane-type sesquiterpene lactones and their glycosides. All eudesmanolides isolated to date possess Δ^4-double bonds and hydroxyl groups at the C-1 positions. These compounds have also been reported from *Sonchus* species of the tribe Lactuceae, along with biogenetically related derivatives of reynosin (Mahmoud et al., 1984; Miyase and Fukushima, 1987; Shimizu et al., 1989).

3. Experimental

3.1. General

CC: silica gel Merck Art. 7733 and Art. 7754; TLC: silica gel Merck Art. 5553; semiprep. and analytical HPLC: Delta-Pak C 18 cartridge column (particle size 15 μm, 25 mm×100 mm, flow rate of 3 ml min^{-1}) and μ-Bondapack C 18 column (particle size 10 μm, 2 mm×300 mm, flow rate of 0.5 ml min^{-1}), respectively, using MeOH–H_2O systems as mobile phase and monitoring with a UV photodiode-array detector.

3.2. Plant material

Leaves and roots of *C. intybus* were collected on 31 July 1998 from plants in the first year of their vegetation period, growing in the Garden of Medicinal Plants of the Institute of Pharmacology, Polish Academy of Sciences, Kraków, where a voucher specimen was deposited.

3.3. Extraction and isolation of compounds

Dried and powdered leaves (500 g) were exhaustively extracted with EtOH at room temperature with shaking and the residue (33 g), obtained by removal of the solvent under vacuum, was coarsely prefractionated on a silica gel column using successively hexane, hexane–

EtOAc (1:1), EtOAc and EtOAc–MeOH (1:1) to give four fractions, 2 l each. Fractions containing lactone constituents, eluted with hexane–EtOAc (1:1) and EtOAc, were combined and the solvent was removed giving 15 g of residue which was chromatographed on a silica gel column using hexane–EtOAc (up to 100% EtOAc) followed by EtOAc–MeOH (up to 10% MeOH) gradient solvent systems. The relevant fractions were further separated and purified by prep. TLC using $CHCl_3$–MeOH (19:1 and 9:1) mixtures as mobile phases. Fractions from hexane–EtOAc (1:1) elution afforded loliolide (11.5 mg), **5** (2.6 mg), a mixture of **2** and **5** (ca. 1:6, 18.6 mg), a mixture of three sesquiterpene aldehydes (ca. 1:1:0.2, 7.5 mg) described below and a mixture of **3**, **6** and **9** (ca. 1:3:0.3, 15.9 mg). More polar fractions, eluted with EtOAc, yielded **4** (21.2 mg), a mixture of **1** and **4** (ca. 1:7, 24.2 mg) and **7** (17.2 mg).

Fresh roots (1.5 kg) were cut into small pieces and transferred into boiling EtOH, and left to stand in a cold room. The solvent was evaporated under reduced pressure and the residue (108 g) was prefractionated on silica gel as described above to give fraction (7.5 g) eluted with hexane–EtOAc (1:1) and EtOAc. The fraction was chromatographed on a silica gel column using the above mentioned gradient solvent system. Elution of the column with hexane–EtOAc (7:3) yielded **13** (15.5 mg). Further elution with hexane–EtOAc (6:4 and 1:1) afforded a mixture of methyl and ethyl esters of *p*-hydroxyphenylacetic acid (ca. 9:1, 10.1 mg), **2** (85.6 mg), a mixture of three sesquiterpene aldehydes (ca. 2:1:0.3, 6.4 mg), containing **10** as a major constituent, a mixture of **3**, **6** and **9** (ca. 2.4:2:1, 16.2 mg) and a mixture of **3** and **9** (ca. 3:1, 7.9 mg), in that order, after separation by prep. TLC ($CHCl_3$–MeOH, 19:1). Sesquiterpene lactone glycosides, eluted with EtOAc and EtOAc–MeOH (19:1), were separated from crude fractions by repeated prep. TLC ($CHCl_3$-MeOH, 17 : 3) to give **12** (18.6 mg), **11** (2.7 mg), **7** (13.4 mg) and **8** (36.8 mg). The leaf and root sesquiterpene aldehyde mixtures (13.9 mg) were further separated by repeated semiprep. HPLC using MeOH–H_2O (1:1) to give almost pure **10** (3.2 mg). Other mixtures, indicated by ^{1}H NMR, were not separated further as the ^{1}H NMR signals could be readily assigned to the respective compounds on the basis of their relative amounts.

*3.4. 3,4β-Dihydro-15-dehydrolactucopicrin (**10**)*

Solid. EIMS *m*/*z* (rel. int.): 410 $[M]^+$ (1.5), 257 $[M–RCO_2H–H]^+$ (10.0), 229 (8.4), 135 (47.5), 107 (100); ^{1}H NMR: Table 1.

Abstract

Four novel diterpenes were isolated from the brown alga *Bifurcaria bifurcata* collected off the Atlantic coast from Morocco, and their structures established by spectral and chemical methods. These compounds are acyclic diterpenes derived from (*S*)-12-hydroxygeranylgeraniol. One of them is its dehydration product at C-12, while the others are its oxidation derivatives : the methyl ester of the acid at C-1 and two stereoisomers (*Z* and *E*) of the aldehyde at C-1. These results are discussed from a chemotaxonomic point of view. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Bifurcaria bifurcata*; Cystoseiraceae; Brown alga; Acyclic diterpenes; (*S*)-12-Hydroxygeranylgeraniol derivatives; Chemotaxonomy

1. Introduction

As part of a phytochemical study of the Atlantic brown alga *Bifurcaria bifurcata* (Phaeophyceae) (Combaut and Piovetti, 1983; Valls et al., 1986, 1993a, 1995; Semmak et al., 1988; Culioli et al., 1999a,b, 2000), we describe the isolation and structure elucidation of four novel diterpenes. They were isolated from a specimen collected at Oualidia (Morocco) together with previous diterpenes described in this alga: **1** (Valls et al., 1986), **2a** (Semmak et al., 1988) and geranylgeraniol (Culioli et al., 1999a). It must be specified that these compounds are (*S*)-12-hydroxygeranylgeraniol derivatives instead of (*S*)-13-hydroxygeranylgeraniol ones, as for the secondary metabolites isolated from the same alga collected at Quiberon and Roscoff (France) (Culioli et al., 1999b).

2. Results and discussion

The ether extract of dried *B. bifurcata* collected at Oualidia was fractionated by liquid chromatography using silica gel. The fraction eluted with EtOAc–isooctane (3:7) was further purified by HPLC on normal phase silica. From this separation, we obtained the sterols and pure geranylgeraniol, as well as a small amount of two new compounds (**2b**, **3**). In the same way, fraction eluted with EtOAc-isooctane (1:1) led to (*S*)-12-hydroxygeranylgeranic acid (**2a**) and a mixture of two new compounds (**4**, **5**) which were subsequently separated and purified by analytical HPLC on normal phase silica [eluant EtOAc–isooctane (1:1)]. The more polar fraction eluted with EtOAc-isooctane (7:3) led to the known diterpene: (*S*)-12-hydroxygeranylgeraniol (**1**).

Diterpene **2b**, $C_{21}H_{34}O_3$ (HRMS), was an optically active oil, the identity of which was readily established by comparison of its spectral properties with those of the acid (**2a**) (Semmak et al., 1988). It showed hydroxyl absorption ($\nu_{OH} = 3400$ cm^{-1}) in its IR spectrum. This functionality corresponded to a secondary hydroxyl group localized at C-12, as was revealed by: (i) the ^{13}C NMR signals at δ 77.2 (C-12) and δ 11.5 (C-18), instead of δ 65.6 and δ 16.3, respectively, when the hydroxyl group is fixed at C-13 (Culioli et al., 1999b); (ii) the ^{1}H NMR signals at δ 3.97 (*t*, $J = 7$ Hz, H-12) and δ 5.36 (*t*, $J = 7$ Hz, H-10), instead of δ 4.37 (*ddd*, $J = 8.2$, 8.2, 5.3 Hz, H-13) and δ 5.18 (*t*, $J = 6.7$ Hz, H-10), when the hydroxyl group is fixed at C-13 (Culioli et al., 1999b).

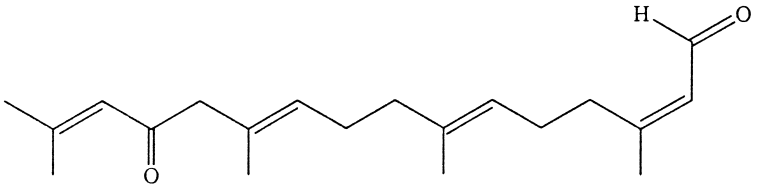
7 Eleganonal



8 Isoeleganonal

The all *E* configuration of the double bonds of the isoprenoid chain was verified with the position of the C-18, C-19 and C-20 methyl signals observed above δ 20 in the ^{13}C NMR spectrum (Couperus et al., 1976; Coates et al., 1978).

The main difference with compound **2a** was the presence of a methyl ester function (δ 167.2 and δ 50.7 in its ^{13}C NMR spectrum; δ 3.68 (3H, *s*) of a methyl group in its ^{1}H NMR spectrum) instead of the acidic group (δ 171.3 in the ^{13}C NMR spectrum of **2a**). The assignment of proton and carbon signals (Tables 1 and 2 respectively) was confirmed by means of homonuclear (COSY) and heteronuclear (XHCORR) experiments. Moreover, the structure of **2b** was totally confirmed by : (i) the methylation with diazomethane of **2a** which led to the same methyl ester as **2b**; (ii) the reduction of **2b** with lithium aluminium hydride to give **1** as the end product of the reaction, with the same absolute configuration at C-12 [Horeau determination (Horeau and Nouaille, 1971)].

The second novel compound (**3**) had the molecular formula $C_{20}H_{32}O$ (HRMS). It was isolated as an optically inactive oil. This compound showed several spectral features in common with other geranylgeraniol-derived diterpenes, particularly with **6**. The main difference with geranylgeraniol was the presence of a –CH=C(CH_3)–CH=CH– unit as indicated by the inspection of UV (λ 245 nm, log ε 4.18), ^{1}H and ^{13}C NMR data (Tables 1 and 2). In particular the ^{1}H and ^{13}C signals at δ 6.05 (1H, *d*, H-10), δ 5.51 (1H, *dt*, H-9), δ 5.35 (1H, *t*, H-12) and δ 2.81 (2H, *t*, H-13) showed that the C-10 double bond of geranylgeraniol was replaced in **3** by a system of two conjugated double bonds at C-9 and C-11, respectively. The *E* configuration of the double bond at C-9 was revealed by the value of the coupling constant between H-9 and H-10 ($^{3}J_{\text{H-H}} = 15$ Hz). The assignment of proton and carbon signals (Tables 1 and 2 respectively) was confirmed by means of homonuclear (COSY) and heteronuclear (XHCORR) experiments. In particular, the location of the double bond at C-9 was precisely determined with the $^{3}J_{\text{H-H}}$ correlations between H-9/H-10 and H-9/H-8, as well as the location of the double bond at C-11 with the H-12/H-13 and H-12/H-18 correlations.

The third novel compound (**4**) had the molecular formula $C_{20}H_{32}O_2$ (HRMS). It was isolated as an optically active oil. This compound showed several spectral features in common with other acyclic diterpenes, particularly with **7** for the first isoprenic unit and with **2a** for the other three. It showed hydroxyl absorption ($\nu_{OH} = 3430$ cm^{-1}) in its IR spectrum. This functionality corresponded to a secondary hydroxyl group localized at C-12, as that was indicated by ^{1}H, ^{13}C NMR data (Tables 3 and 4) and comparison with those of **1**, **2a** and **2b**. This location showed that **4** was also a (*S*)-12-geranylgeraniol- derived diterpenoid. As for **2a** and **2b**, the all *E* configuration of the double bonds of the isoprenoid chain was verified with the position of the C-18, C-19 and C-20 methyl signals observed above δ 20 in the ^{13}C NMR spectrum. The only one difference with the compounds **1**, **2a** and **2b** resulted from the spectral data corresponding to the first isoprenic unit. A

conjugated carbonyl absorption was revealed in its IR spectrum ($\nu_{C=O}=1688$ cm^{-1}). From the ^1H NMR spectrum (Table 3) it was apparent that this functionality is embodied in a formyl group: δ 9.88 (1H, *d*, H-1), which was established by ^1H–^1H COSY experiment to be adjacent to an olefin proton, which was in turn allylically coupled with the methyl group resonating at δ 2.08 (3H, *s*, H-20). These data suggest the novel meta-

bolite is an oxidation product of the known (*S*)-12-hydroxygeranylgeraniol (**1**). The assignment of proton and carbon signals (Tables 3 and 4 respectively) was confirmed by means of homonuclear (COSY) and heteronuclear (XHCORR) experiments. This inference was supported by the comparison of both ^1H and ^{13}C NMR spectra with those of **1**, **2a**, **2b** and **7**, and definitely proved by the partial oxidation of **1** which gave two geometric isomers, one of which was indistinguishable from **4**. Moreover, the *E* configuration of the double bond at C-2 was confirmed by a ^1H–^1H NOESY experiment which showed a spatial correlation between H-1 and H-20.

The last novel metabolite isolated (**5**) is an isomer of **4**, to which it resembles closely in the mass fragmentation. Also the ^1H NMR spectrum of **5** is very similar to that of **4** (Table 3), a single characteristic difference being the downfield shift of the methylene protons at C-4 from δ 2.15 in **4** to δ 2.55 in **5** and the concurrent upfield shift of the C-20 vinyl methyl group from δ 2.08 in **4** to δ 1.93 in **5**. That is in agreement with a change of the geometry of the C-2 double bond from *E* in **4** to *Z* in **5**. As expected, the ^{13}C NMR spectrum of **5** (Table 4) differs from that of **4** mainly in the chemical shifts of C-4 (δ 34.1 in **5** as compared to δ 40.5 in **4**) and C-20 (δ 25.8 against δ 17.9). The same spectral features (^1H and ^{13}C NMR) were found in the first isoprenic unit of **8**, a stereoisomer of **7** previously described from *Cystoseira balearica* (Amico et al., 1987). This hypothesis was definitely proved by the partial oxidation of **1** from which the second compound obtained (*Z* isomer of **4**) was indistinguishable from **5**. It must be specified that the aldehyde **5** is a labile compound that, at room temperature, slowly converts into its more stable isomer **4**.

2.1. Chemotaxonomic relationships

Our previous studies of the geographical variations in the diterpenoid composition of *B. bifurcata* (Valls et al., 1993a,b, 1995) had revealed that the lipid extract of this species collected off the Moroccan coast, in the Oualidia zone (between El Jadida and Oualidia), was clearly distinguishable from the extracts obtained from the other zones of collection, with the presence as main constituents of (*S*)-12-hydroxygeranylgeraniol (**1**) and derivatives. The re-investigation of the lipid extract from *B. bifurcata* collected in the Oualidia zone led us to show : (i) the presence of four other derivatives from **1** ; (ii) the presence for the first time of geranylgeraniol; (iii) the absence of both (*S*)-13-hydroxygeranylgeraniol and 13-ketogeranylgeraniol, and their derivatives. This work showed that the only diterpene present in all the lipid extracts of *B. bifurcata* studied was geranylgeraniol (precursor of the acyclic diterpenes). On the other hand, 13-ketogeranylgeraniol which was present in all the lipid extracts from the other zones of collection (Culioli et al., 1999a,b) could not be identified. This chemical particularity led us to think that *B.*

bifurcata collected in the Oualidia zone (Morocco) could be regarded as a ≪ chemical variety ≫ of this species.

3. Experimental

3.1. General

MS: direct inlet, 70 eV; ^{1}H NMR: 200 MHz; ^{13}C NMR: 50 MHz. Chemical shifts are quoted in ppm (δ) relative to TMS and coupling constants are in Hz. Optical rotations were determined using a Perkin Elmer 341 polarimeter. Final purification of all metabolites was achieved by HPLC on silica gel (Lichrosorb Si-60, 5 μm) with RI monitoring.

3.2. Plant material

Bifurcaria bifurcata Ross was collected near Oualidia (32°49′N, 8°57′W), Morocco, in December 1998. A voucher specimen of this species was deposited in the Herbarium of Dr Pellegrini, Laboratoire de Biologie Marine Fondamentale et Appliquée, University of Marseille II, France.

3.3. Extraction and purification

The shade-dried material collected from Oualidia (340 g) was ground and extracted with Et_2O at room temperature. After filtration, the filtrate was evaporated to yield 10 g of a crude extract which was subjected to CC on silica gel eluted with a solvent gradient from isooctane to EtOAc. The two first new compounds (**2b** and **3**), with sterols and geranylgeraniol, were eluted with EtOAc-isooctane (3:7) and subsequently purified by analytical normal phase HPLC (EtOAc–isooctane, 3:7) to give **2b** (275 mg), geranylgeraniol (420 mg) and **3** (220 mg). The two other new compounds (**4** and **5**), with **2a**, were eluted with EtOAc–isooctane (1:1) and subsequently purified by semi-preparative normal phase HPLC (EtOAc–isooctane, 1:1) to give **4** (30 mg), **5** (15 mg) and **2a** (95 mg). The more polar fraction eluted with EtOAc–isooctane (7:3) led to **1** (2.42 g), after purification by semi-preparative normal phase HPLC (EtOAc-isooctane, 7:3).

3.4. Compound *2b*

Oil; $[\alpha]_D^{25}$ −7.7° (CH_2Cl_2; c 5.5); IR ν_{max}^{film} cm^{-1}: 3417, 2924, 2856, 1720, 1649, 1436, 1383, 1358, 1225, 1148, 1049, 864; HRMS: 334.2506 $[M]^+$ (calc. for $C_{21}H_{34}O_3$, 334.2508); EIMS (70 eV) *m/z* (rel. int.): 334 $[M]^+$(0.1), 316 $[M\text{-}H_2O]^+$(0.2), 265(20), 233(100), 215(0.4), 187(0.7), 137(21), 123(60), 107(19), 93(65), 81(40), 69(58), 55(53) ; ^{1}H and ^{13}C NMR: Tables 1 and 2.

3.6. Compound *4*

Oil; $[\alpha]_D^{25}$ −3° (CH_2Cl_2; c1.0); IR ν_{max}^{film} cm^{-1}: 3410, 2965, 2904, 2852, 1688, 1649, 1438, 1383, 1272, 1079, 882, 803; HRMS: 304.2408 $[M]^+$ (calc. for $C_{20}H_{32}O_2$, 304.2402); EIMS (70 eV) *m/z* (rel. int.): 304 $[M]^+$(0.02), 286 $[M\text{-}H_2O]^+$(0.90), 235 (6), 217(7), 199 (6), 189 (3), 159 (14), 149 (7), 147 (9), 135 (18), 133 (16), 123 (20), 109 (24), 107 (30), 95 (100), 93 (71), 81(86), 69 (68), 55 (83); ^{1}H and ^{13}C NMR: Tables 3 and 4.

3.7. Compound *5*

Oil; IR ν_{max}^{film} cm^{-1}: 3415, 3067, 2968, 2915, 2868, 1690, 1656, 1436, 1380, 1268, 1140, 1078, 885; HRMS: 304.2410 $[M]^+$ (calc. for $C_{20}H_{32}O_2$, 304.2402); EIMS (70 eV) *m/z* (rel. int.): 304 $[M]^+$(0.05), 286 $[M\text{-}H_2O]^+$(0.16), 235 (34), 217 (4), 199 (4), 189 (3), 159(11), 149 (10), 147 (8), 135 (9), 133 (14), 123 (20), 109 (24), 107 (23), 95 (55), 93 (91), 81 (87), 69 (72), 55 (100); ^{1}H and ^{13}C NMR: Tables 3 and 4.

3.8. Reduction of *2b* with *LiAlH$_4$*

A cold solution of **2b** (20 mg) in dry Et_2O (1 ml) containing $LiAlH_4$ (30 mg) was stirred at 0°C for 1.3 h. Excess reagent was destroyed by slow addition of EtOAc. Addition of saturated $MgSO_4$ solution and extraction with Et_2O yielded 15 mg of an oil. After purification by semi-preparative normal phase HPLC (EtOAc–isooctane, 7:3), the corresponding reduction product (10 mg) was found to be identical to **1** by comparison of spectral data, and with the same absolute configuration of C-12 (Horeau determination: see Valls et al., 1986 for details).

3.9. Partial oxidation of *1*

One hundred milligrams of **1** were added to a solution of pyridinium dichromate (156 mg in 50 ml of dry CH_2Cl_2) and the mixture was stirred at room temperature for 12 h. The solution was then diluted with Et_2O, filtered on celite, dried on $MgSO_4$ and subsequently subjected to CC on silica gel eluted with Et_2O. After evaporation, the residue was purified by semi-preparative

normal phase HPLC (EtOAc–isooctane, 1:1) to give **4** (43 mg) and **5** (22 mg).

Diterpenes from the bark and seeds of *Colophospermum mopane*

Paul P. Mebe*

Department of Chemistry, University of Zimbabwe, PO Box MP 167, Mount Pleasant, Harare, Zimbabwe

Received 13 September 2000; received in revised form 12 January 2001

Abstract

The $CHCl_3$ extract of the bark and seeds of *Colophospermum mopane* gave three new diterpenes, dihydrogrindelic acid and dihydrogrindelaldehyde and methyl labd-13E-en-15-oate. The structures were assigned on the basis of detailed spectroscopic data analyses. The aldehyde showed significant cytotoxic activity against a human breast cancer cell line. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Colophospermum mopane*; Leguminosae; Diterpenes; Dihydrogrindelic acid; Dihydrogrindelaldehyde; Methyl labd-13*E*-en-15-oate

1. Introduction

Colophospermum mopane Kirk ex J. Leonard is a tree widespread in the dry regions of Southern Africa. It is used in traditional medicine as a remedy for syphilis and sore eyes (Watt and Breyer-Brandwijk, 1962). The $CHCl_3$ extract of the bark and seeds of *C. mopane* led to the isolation of three new labdane diterpenes: dihydrogrindelic acid, dihydrogrindelaldehyde and methyl labd-13-en-15-oate. Dihydrogrindelic acid has only been reported in the literature as a synthetic derivative of grindelic acid (Mangoni and Belardin, 1963; Adinolfi et al., 1988). To our knowledge, this is the first report of hydrogrindelic acid as a natural product. Grindelic acid has been isolated from a number of species of Grindelia, Solidaco and Chrysothamnus (Pannizi et al., 1961, 1962; Mangoni and Belardini, 1962; Anthonsen et al., 1969). The crude $CHCl_3$ extract showed significant cytotoxic activity against a human breast cancer cell line. We report herein the isolation and identification the new diterpenes and evaluations of their cytotoxicity.

2. Results and discussion

The bark and seeds of *C. mopane* were separately extracted with $CHCl_3$. The crude extracts appeared similar on TLC and were combined, and partitioned with *n*-hexane and MeOH. The *n*-hexane fraction was successively purified by silica gel CC and prep. TLC to give two new derivatives of grindelic acid **1** and **2** and a new diterpenoid labdane **3**. The crude $CHCl_3$ extract showed significant cytotoxic activity ($ED_{50} = 2.0$ μg/ml) in vitro against MCF7 (human breast cancer) cell line.

Compound **1** was obtained in large quantities as a colourless gum, and had a molecular formula of $C_{20}H_{34}O_3$ as deduced from the EIMS which displayed two major peaks at m/z 322 $[M]^+$ and 183 $[M-C_{10}H_{15}O_3]^+$. The molecular formula was supported by the ^{13}C NMR and DEPT spectra which showed 20 carbon signals which consisted of five methyl carbon signals, eight methylene carbon ones, two methine carbon ones and five quaternary carbon ones. The ^1H NMR spectrum showed signals of four methyl groups attached to quaternary centres at δ 0.79, 0.85, 0.94 and 1.37, and methyl adjacent to a methine at δ 1.05. Closer inspection of the above spectral data suggested that the structure of **1** was a labdane diterpene. The methyl signal at δ 1.37 indicated the presence of a methyl on a carbon bearing an oxygen and this was supported by the ^{13}C NMR spectrum which showed two peaks for carbons bearing oxygen at δ 81.29 and 96.75. These exceptionally downfield signals suggested that these carbons were quaternary and were bridged by an ether linkage, since the spectral data did not show the presence of an alcoholic hydroxyl group. The IR spectrum showed bands at 1705 ($>C=O$) and 2500–3400 cm^{-1} (−OH), both assignable to a carboxylic group and this was corroborated by the

3

singlet signal in the ^{13}C NMR spectrum at δ 172.60 and a broad signal at δ 10.74 in the ^{1}H NMR spectrum. All the three oxygens in the formula of **1** were thus accounted for.

The presence of isolated two proton signals at δ 2.46 (*d*, $J=15$ Hz) and 2.68 (*d*, $J=15$ Hz) was consistent with the placement of the methylene at C-14, α to the carboxylic group and adjacent to a fully substituted carbon at C-13. The presence of a methyl doublet signal at δ 1.05 ($J=7$ Hz) was assignable to the C-17 methyl because it is consistent with a labdane diterpene structure.

A combination of NMR experiments (COSY, HETCOR, NOE and DEPT), allowed the assignments (Table 1) of all the proton and carbon signals in the ^{1}H and ^{13}C NMR spectra. The ^{1}H–^{1}H COSY contour map which showed two strong correlations between the

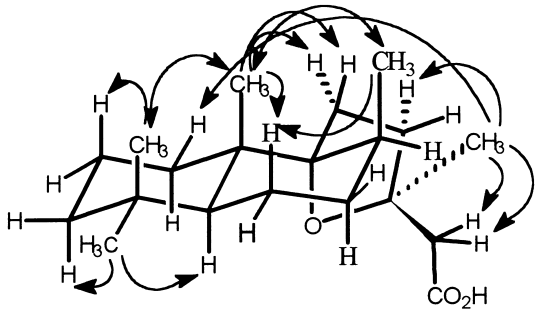

Fig. 1. Significant NOEs observed for compound **1** in the NOE difference spectra.

methylene signals at δ 2.46 and 2.68, and also between the C-17 methyl and the H-8 signals at δ 1.05 and 1.82, respectively. The methylene signals also showed long range corrolations with the C-16 methyl signal at δ 1.37, confirming the placement of these groups in **1**. With the C-17 methyl observed as a doublet, the ether linkage must therefore be restricted to C-9 and C-13 and therefore the C-16 methyl resonating at δ 1.37 was paced at C-13. The relative stereochemistry of **1** was deduced from studies of the difference NOE experiments whose correlations are shown in Fig. 1. The NOE spectra revealed the fact that H-19, H-20, H-11 and H-17 were on the β-side of the molecule, while the H-18, H-5 and H-8 were on the α-side. This follows from irradiations of the H-18, H-19 and H-20 methyl signals. Furthermore, it was noted that irradiation of the C-16 methyl signal had NOE effects on the H-12α, H-1α and the H-14 signals, but not on the H-8 signal. The latter observations indicated that the C-16 methyl was on the α-side of the tetrahydrofuran ring.

The mass spectrum showed significant and diagnostic fragmentation ions that are rationalized in Scheme 1. Structure **1** rearranged via intermediate **I** to structure **II** before any fragmentation occurred. Structure **II** then became the main structure from which most of the observed characteristic fragments were derived. McLafferty rearrangement of II produced fragment ions at *m*/*z* 262 and 170 due to the loss of acetic acid. This rearrangement also accounted for the ion at *m*/*z* 123 derived from fragment ion at *m*/*z* 183, the base peak. The ion at *m*/*z* 165 was due to the elimination of H_2O from fragment ion at *m*/*z* 183. The rest of the observed fragment ions at *m*/*z* 197, 183 and 169 were due to simple carbon–carbon cleavages. On the basis of the above spectral data analysis and the survey of spectral data of related grindelic derivatives (Rose, 1980; Rose et al., 1981; Jakupovic et al., 1986), structure **1** was elucidated as dihydrogrindelic acid.

Compound **2**, $C_{20}H_{34}O_2$ showed a molecular ion at *m*/*z* 306 and a peak at *m*/*z* 263 $[M-CH_2CHO]^+$ and the IR spectrum showed a strong peak at 1730 cm^{-1}. The spectral (^{1}H and ^{13}C NMR) characteristics of compound **2** were very similar to those of **1** suggesting that **2** is a derivative of **1**. Differences in the ^{1}H NMR spectra of the two compounds were apparent at the region about δ 2.50 where compound **1** had two doublets at δ 2.46 and 2.68, and compound **2** had instead two doublet of doublets ($J=6$, 15 Hz) at δ 2.43 and 2.67 ascribed to the C-14 methylene protons. The other noted difference in compound **2**, was a triplet signal at δ 9.84 ($J=6$ Hz) ascribed to the H-15, aldehyde proton. The coupling constant ($J=6$ Hz) clearly indicated the adjacent positions of the above groups. This assignment was confirmed by the ^{1}H–^{1}H COSY spectrum of **2** which showed the latter signals correlated. The presence of the C-15 aldehyde carbonyl group was further confirmed by the ^{13}C NMR and DEPT spectra of **2** which had a doublet signal at δ 206.31. Comparison of this spectral data of compound **1** and **2**, led to the elucidation of the structure of compound **2** as dihydrogridelaldehyde.

Compound **3** possessed a molecular formula of $C_{21}H_{36}O_2$ and a molecular ion *m*/*z* 320 as indicated by the EIMS. The IR indicated a strong carbonyl band at 1698 cm^{-1} suggesting that it has an α, β-unsaturated carbonyl group. The ^{1}H NMR spectrum showed three singlets which were absent in **1** and **2**, at δ 2.16 (vinyl C-13 methyl), δ 3.67 (methoxyl) and δ 5.68 (vinyl proton). In addition, the spectrum showed three tertiary methyl signals at δ 0.83, 0.88 and 0.92, and a secondary methyl signal at δ 1.04 ($J=7$ Hz) assignable to the C-17 methyl.

The upfield multiplet signals for **2** were similar to the signals observed in ^{1}H NMR spectrum of **1**. The ^{13}C NMR spectrum confirmed the presence of a methyl ester functionality by the presence of signals at δ 183.67 (C=O) and 50.79 (CH_3O). The presence of only two olefinic carbon signals at δ 147.64 and 115.03 in the ^{13}C NMR spectrum and an IR band at 1698 cm^{-1} confirmed the existence of the α,β-unsaturated ester group. The ^{1}H NMR spectrum of **3** was similar to that of methyl hydroxy-labd-13E-en-15-oate (Ates et al., 1982; Zdero et al., 1990). The relative stereochemistry was determined by the NOE experiment. The NOE effects of substituents on rings A and B were similar to those of compound **1** (Fig. 1), indicating that compound **3** was a normal labdane. Irradiation of the olefinic proton signal at δ 5.68 showed enhancement of signal at δ 2.25 attributed to the H-12, but no enhancement of the H-16 signal at δ 2.17 (*s*, 3H) was observed. Thus, the stereochemistry of the double bond was deduced to be 13E. On the basis of the above spectral data analysis **3** was identified as methyl labd-13E-en-15-oate.

The isolates were evaluated for their cytotoxic activity (ED_{50} <20 μg/ml) against a cancer cell line, MCF7 (breast adenocarcinoma). Only compound **2** showed a significant activity at 3.5 μg/ml level, accounting for some, but maybe not all, of the activity of the crude extract. The other compounds showed no cytotoxic activity.

3. Experimental

3.1. Plant material

The bark and seeds were collected from Matebeleland South, in Zimbabwe. A voucher specimen has been deposited at National Herbarium, Harare.

3.2. Extraction and isolation

The air dried and finely powdered stem bark and seeds of *C. mopane* (80 g, bark) and (60 g, seeds) were separately extracted with $CHCl_3$ and MeOH consecutively using a Soxhlet apparatus. The $CHCl_3$ and MeOH extracts of each plant material were separately concentrated using a rotary evaporator at a maximum temp. of 45°C to yield 7.1 and 6.4 g of bark residue and 8.2 and 3.02 g of seed residue, respectively.

The $CHCl_3$ extracts were combined and fractionated in *n*-hexane and 90% MeOH mixture and the *n*-hexane residue (1.9 g) was then fractionated by silica gel 60 CC eluting with a step-gradient of *n*-hexane-EtOAc mixture of increasing polarity. Further purification of the resulting fractions using CC and eluting with *n*-hexane–EtOAc (8.5:1.5), led to the isolation of **1** (857 mg), **2** (48 mg) and **3** (26 mg).

Abstract

Three flavonol glycosides quercetin 7-*O*-(6-*trans*-caffeoyl)-β-glucopyranosyl-(1→3)-α-rhamnopyranoside-3-*O*-β-glucopyranoside (**1**), kaempferol 7-*O*-(6-*trans*-caffeoyl)-β-glucopyranosyl-(1→3)-α-rhamnopyranoside-3-*O*-β-glucopyranoside (**2**), and kaempferol 7-*O*-(6-*trans*-*p*-coumaroyl)-β-glucopyranosyl-(1→3)-α-rhamnopyranoside-3-*O*-β-glucopyranoside (**3**), together with the known β-3,4-dihydroxyphenethyl β-glucopyranoside, were isolated from the flowers of *Aconitum napellus* subsp. *neomontanum*. Their structures were elucidated by spectroscopic methods, including 2D NMR spectral techniques. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Aconitum napellus* subsp. *neomontanum*; Ranunculaceae; Flavonoids

1. Introduction

The *Aconitum* genus is mainly characterized by the presence of diterpene alkaloids that being highly toxic, have been used in the past in China as source of arrow poison (Bisset, 1981). The alkaloid composition of different species of European *Aconitum* was analysed by Katz and Staehelin (1980); particularly qualitative and quantitative variations in diterpenoid alkaloids of the *A. napellus* subsp. *neomontanum* (Wulfen) Gáyer have been studied during its onthogenetic cycle (Colombo et al., 1988). Subsequent investigations of the seeds of the same subspecies showed the presence of norditerpenoid and diterpenoid alkaloids (Fuente et al., 1988; Liu and Katz, 1996). In the last years the study of *Aconitum* genus was directed to the other secondary metabolites such as flavonoids. The flavonol composition of the aerial parts of *A. jaluense* (Wang et al., 1994), A. *pseudolaeve* (Kim, et al., 1996), and *A. chiisanense* (Jeong et al., 1997) have been reported. Recently the flavonoids of five Korean species in the *A. jaluense* complex have been studied for recognising the relationships and levels of differentiation (Lim et al., 1999). Regarding the European species, the flowers of *A. paniculatum* have shown the presence of three new flavonol glycosides (Fico et al., 2000). In this paper we describe the isolation and structure elucidation of three new flavonol glycosides, compounds **1**–**3**, and the known, but new for the entity under study, β-3,4-dihydroxyphenethyl β-glucopyranoside, from the flowers of *A. napellus* subsp. *neomontanum*.

2. Results and discussion

The *n*-butanol fraction of the methanol extract from the flowers of *A. napellus* subsp. *neomontanum* was chromatographed successively on Sephadex LH-20 and RP-HPLC (C-18) to give pure compounds **1**–**3**, and β-3,4-dihydroxyphenethyl β-glucopyranoside.

Compound **1**, a yellow amorphous solid, showed molecular formula $C_{42}H_{46}O_{24}$ that was determined from its HPLC-MS, ^{13}C NMR (Table 2), and ^{13}C-DEPT data. The mass spectrum showed a $M+H^+$ peak at *m*/*z* 935 and fragment ions at *m*/*z* 773, 465, and 303. The UV spectrum of **1** showed two absorption maxima at 333 and 265 nm, indicating the presence of substituted aromatic rings and α,β unsaturated ketone in the molecule (Agrawal, 1989). The 600 MHz ^1H NMR spectrum of compound **1** (Table 1) showed a typical pattern of a

flavonol with a quercetin aglycon together with signals ascribable to sugar moieties and acyl residue. The three anomeric protons arising from the sugar moieties appeared at δ 5.41 (1H, *d*, *J*= 1.8 Hz), 5.38 (1H, *d*, *J*= 7.8 Hz), and 4.54 (1H, *d*, *J*= 7.8 Hz), which correlated respectively with signals at 99.2, 104.3 and 106.4 ppm in the HSQC spectrum. The ^{1}H NMR spectrum showed also the presence of a caffeoyl residue (Table 1). All the ^{1}H and ^{13}C NMR signals of **1** were assigned using ^{1}H–^{1}H COSY, HOHAHA, HSQC, and HMBC experi-

[a] Coupling constants (J in Hz) are given in parentheses.

ments. Particularly ^{1}H–^{1}H COSY spectra together with a HOHAHA experiment allowed to identify the spin systems of each sugar residues. In particular the lower field shifts of H-6‴ (δ 4.53, 4.54) of one glucosyl unit together with the lower field shifts of C-3″ (83.6 ppm) and C-6‴ (δ 64.8) signals suggested the substitution pattern of glycosyl and acyl moieties. Unequivocal information could be obtained by 2D NMR spectra; the HMBC experiment indicated connections between δ 5.38 (H-1″) and 136.1 (C-3); δ 5.41 (H-1‴) and 83.6 (C-3‴); δ 4.53 and 4.54 (H-6⁗) and 169.0 (COO); δ 5.41 (H-1‴) and 163.0 (C-7) and 72.0 (C-2‴); δ 4.54 (H-1⁗) and 83.6 (C-3‴). Chemical shifts, multiplicity of the signal, absolute values of the coupling constant and the magnitude in the ^{1}H NMR, ^{1}H–^{1}H COSY, and 1D-TOCSY spectra as well as ^{13}C NMR data indicated the presence of two glucopyranosyl moieties with β-configuration at the anomeric carbon and one rhamnopyranosyl residue with α-configuration. On the basis of all this results the structure of compound **1** was established as quercetin 7-*O*-(6-*trans*-caffeoyl)-β-glucopyranosyl-(1→3)-α-rhamnopyranoside-3-*O*-β-glucopyranoside.

To compound **2** was assigned the molecular formula $C_{42}H_{46}O_{23}$ by HPLC–MS, ^{13}C NMR (Table 2), and ^{13}C-DEPT data. The UV spectrum of **2** showed absorptions at 341 and 255 nm (Agrawal, 1989). The ^{1}H NMR spectrum of **2** (Table 1) was very similar to **1** except for signals of ring B of the aglycon moiety that in **2** were typical of a kaempferol. The ^{1}H NMR and ^{13}C NMR exhibited signals which can be ascribed to the kaempferol and caffeoyl moieties along with those of three anomeric protons identified with the help of ^{1}H–^{1}H COSY and HOHAHA experiments as two glucose (δ 5.35 and 4.55, J = 7.8 Hz) and one rhamnose (δ 5.41, J = 1.8 Hz). The assignments of all protonated carbons were accomplished by interpretation of the HSQC NMR spectrum while HMBC experiment correlations were similar to those of compound **1** (H-1″-C-3; H-1‴-C-3‴, H-1‴-C-7, H-1‴-C-2‴; H-6⁗-COO; H-1⁗-C-3‴). From these results, the structure of **2** was concluded to be kaempferol 7-*O*-(6-*trans*-caffeoyl)-β-glucopyranosyl-(1→3)-α-rhamnopyranoside-3-*O*-β-glucopyranoside.

Finally the molecular formula of compound **3** was determined as $C_{42}H_{46}O_{22}$ from the HPLC–MS. NMR and other spectroscopic data were nearly identical with those of **2**; the only difference was that a *trans-p*-coumaroyl ester group appeared instead of the caffeoyl of **2**. In conclusion, the structure of the new compound **3** was determined to be kaempferol 7-*O*-(6-*trans-p*-coumaroyl)-β-glucopyranosyl-(1→3)-α-rhamnopyranoside-3-*O*-β-glucopyranoside.

The known compound, β-3,4-dihydroxyphenethyl β-glucopyranoside, was identified by comparison of its spectral and physical data with those reported in the literature (Shimomura et al., 1987).

3. Experimental

3.1. General

Melting points (uncorrected) were determined with a Kofler apparatus. Optical rotations were measured on a Perkin-Elmer 241 polarimeter equipped with a sodium lamp (589 nm) and a 1 dm microcell. The mass and UV-vis spectra (HPLC–MS) were performed on a HP 1090L instrument with a Diode Array Detector, managed by a HP 9000 workstation interfaced with a HP 1100 MSD

API-electrospray. A Bruker DRX-600 NMR spectrometer, operating at 599.19 MHz for ^1H and 150.86 MHz for ^{13}C, using the UXNMR software package was used for NMR experiments; chemical shifts are expressed in δ (ppm) referring to the solvent peaks, δ_H 3.34 and δ_C 49.0 for CD_3OD. ^{13}C-DEPT NMR experiments were performed using a transfer pulse of 135° to obtain positive signals for CH and CH_3 and negative ones for CH_2. Polarization transfer delays were adjusted to an average CH coupling of 135 Hz. ^1H–^1H DQF–COSY, ^1H–^{13}C HSQC, and HMBC experiments were carried out using the conventional pulse sequences as described in the literature. HOHAHA spectra were acquired using a waveform generator-based GAUSS shaped pulse, at mixing times ranging from 80 to 100 ms and a MLEV-17 spin-lock field of 10 kHz preceded by a 2.5 ms trim pulse. HPLC separations were performed on a Shimadzu LC-8A series pumping system equipped with a Waters R401 refractive index detector and with a Waters μ-Bondapak C_{18} column and Shimadzu injector. TLC was conducting on silica 60 F_{254} gel-coated aluminium sheets (Merck).

3.2. Plant material

The flowers of *A. napellus* subsp. *neomontanum* were collected in Val di Peio (Trento, Italy), 1200 m above sea level, during the late summer of 1998. A voucher specimen (no. An-201/2) has been deposited in Dipartimento di Biologia, Università di Milano.

3.3. Extraction and isolation

The air-dried powdered flowers (90 g) of *A. napellus* subsp. *neomontanum* were defatted with *n*-hexane and successively extracted with $CHCl_3$, $CHCl_3$–MeOH (9:1) and MeOH, each solvent for three times to give 1.6, 1.2, 2.0 and 17.0 g of residues, respectively. The methanol extract was chromatographed on Sephadex LH-20, using MeOH as eluent, to obtain one-hundred fractions of 12 ml, combined together into twenty-one groups according to TLC separations [Silica 60F_{254} gel-coated aluminium sheets; eluent: *n*-BuOH–CH_3COOH–H_2O (60:15:25)]. Group 12 was submitted to RP-HPLC on a C_{18} μ-Bondapak column (300 × 7.8 mm, flow rate 2.5 ml min^{-1}) with MeOH–H_2O (40:60) to yield respectively β-3,4-dihydroxyphenethyl β-glucopyranoside (7 mg) (t_R = 5 min), **1** (17 mg) (t_R = 10.8 min), **2** (25 mg) (t_R = 15.3 min), and **3** (19 mg) (t_R = 22.5 min).

3.4. Quercetin 7-O-(6-trans-caffeoyl)-β-glucopyranosyl-(1→3)-α-rhamnopyranoside-3-O-β-glucopyranoside (*1*)

Amorphous orange-yellow powder, mp 185–187°C; $[\alpha]_D^{25}$: −38.3° (*c* 0.1, MeOH); UV: λ_{max} (MeOH) 265, 333 nm; ^1H and ^{13}C NMR spectral data (CD_3OD): Tables 1 and 2; HPLC–MS *m/z*: 935 $[M+H]^+$, 773 [M-(glc) + H]$^+$, 465 [M-(rha + glc + caffeoyl) + H]$^+$, 303 [M-(glc + rha + glc + caffeoyl) + H]$^+$; Found: C, 53.89; H, 4.98; O, 41.13. $C_{42}H_{46}O_{24}$ requires: C, 53.96; H, 4.96; O, 41.08%.

3.5. Kaempferol 7-O-(6-trans-caffeoyl)-β-glucopyranosyl-(1→3)-α-rhamnopyranoside-3-O-β-glucopyranoside (*2*)

Amorphous yellow powder, mp 180–182°C; $[\alpha]_D^{25}$: −84.7° (*c* 0.1, MeOH); UV: λ_{max} (MeOH) 255, 341 nm; ^1H and ^{13}C NMR spectral data (CD_3OD): Tables 1 and 2; HPLC–MS: *m/z* 919 $[M+H]^+$, 757 [M-(glc) + H]$^+$, 449 [M-(rha + glc + caffeoyl) + H]$^+$, 287 [M-(glc + rha + glc + caffeoyl) + H]$^+$; Found: C, 54.84; H, 5.08; O, 40.08. $C_{42}H_{46}O_{23}$ requires: C, 54.90; H, 5.05; O, 40.05%.

3.6. Kaempferol 7-O-(6-trans-p-coumaroyl)-β-glucopyranosyl-(1→3)-α-rhamnopyranoside-3-O-β-glucopyranoside (*3*)

Amorphous yellow powder, mp 175–177°C; $[\alpha]_D^{25}$: −52.0° (*c* 0.1, MeOH); UV: λ_{max} (MeOH) 268, 321 nm; ^1H and ^{13}C NMR spectral data (CD_3OD): Tables 1 and 2; HPLC–MS: *m/z* 903 $[M+H]^+$, 741 [M-(glc) + H]$^+$, 449 [M-(rha + glc + *p*-coumaroyl) + H]$^+$, 287 [M-(glc + rha + glc + *p*-coumaroyl) + H]$^+$; Found: C, 55.82; H, 5.16; O, 39.02. $C_{42}H_{46}O_{22}$ requires: C, 55.88; H, 5.14; O, 38.99%.

Abstract

Three new quercetin 3,3′,4′-tri-*O*-β-D-glucopyranosides isolated from leaves of *Eruca sativa* (Mill.) were identified as quercetin 3,3′,4′-tri-*O*-β-D-glucopyranoside, quercetin 3′-(6-sinapoyl-*O*-β-D-glucopyranosyl)-3,4′-di-*O*-β-D-glucopyranoside, and quercetin 3-(2-sinapoyl-*O*-β-D-glucopyranosyl)-3′-(6-sinapoyl-*O*-β-D-glucopyranosyl)-4′-*O*-β-D-glucopyranoside. The structures were established by one- and two-dimensional ^{1}H and ^{13}C NMR spectra as well as by ESI MS/MS spectra 3 © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Nowadays the leaves of *Eruca sativa* (Mill.) are widely used as salad or food ingredients. Information about their constituents is surprisingly scarce. Most attention has been focused on seeds of *E. sativ*a, in which thiocyanates, isothiocyanates and their precursors, the glucosinolates, have been extensively studied (Hamence and Taylor, 1978; Adhikari et al., 1989; Mahran et al., 1992). In this paper, we describe the isolation and identification of three novel tri-*O*-β-D-glucosides of quercetin from *E. sativa* (Mill.) leaves. In the last decade, quercetin, which is ubiquitously present in plants in various glycosidically bound forms (Harborne, 1999), has attracted interdisciplinary research activities owing to its potential bioactivity. A number of its activities including cell cycle regulation, interaction with type II estrogen binding sites, and tyrosine kinase inhibition make it a potential anti-cancer agent (Lamson and Brignall, 2000). Its antioxidant properties are also well documented (Duthie et al., 2000; Madsen et al., 2000; O'Reilly et al., 2000). In spite of their β-glycosidic sugar conjugation, quercetin glycosides have been found to be absorbed in humans (Hollman et al., 1999). Interestingly, the sugar moiety affects their bioavailability. According to recent data of Olthof et al. (Olthof et al., 2000), the glucosides are more rapidly absorbed than glycosides. Thus, plants containing glucosidically bound quercetin might be of particular interest in the diet of man.

2. Results and discussion

From a water–methanol extract of leaves of *E. sativa* (Mill.) a glycosidic fraction was obtained by chromatography on Amberlite XAD. The screening for glycosides in the methanolic fraction after Amberlite XAD chromatography was done by HPLC coupled with an evaporative light scattering detector (ELSD) using a RP-18 column. Three major peaks (compounds **1–3**) were obtained at retention times between 12 and 15 min. In addition, the extract was analyzed by HPLC–DAD to check the peaks detected by ELSD for UV activity. This second profile was nearly identical to that achieved by HPLC–ELSD analysis. The UV spectra of compounds **2** and **3** were quite similar: for **1–3** λ_{max}^{MeOH} at 214, 248, 266 and 338 nm, 212, 241, 272 and 330 nm, as well as

PII: S0031-9422(01)00059-0

224, 242, 273 and 330 nm, respectively, were observed. Purification was achieved by reversed phase preparative liquid chromatography yielding **1–3** in pure forms.

The fraction obtained by chromatography on Amberlite XAD as well as the purified compounds **1–3** were then analysed by HPLC–ESI–MS/MS (positive mode) to get structural information. The spectral data are outlined in Table 1. The data reveal that compound **1** is a triglycoside (loss of three hexose residues) of an aglycone with a molecular mass of 302 and that compounds **2** and **3** contain the same aglycone as well as at least two hexose substructures. In addition, the ESI–MS/MS spectra of **2** and **3** showed an intense fragment with m/z 207, indicating a further substructural unit. Moreover, the spectra exhibited quasimolecular ions $[M+H]^+$ at m/z 789, 995 and 1201 for compounds **1–3**, respectively.

The IR spectra gave additional information about the substructures of compounds **2** and **3**. The three isolated glycosides showed intense IR signals at 3400 cm^{-1} (O–H) and at 1645 cm^{-1} (α,β-unsaturated C=O), indicating a flavonol-like structure such as quercetin (Li et al., 1998). The additional signals at 1700 cm^{-1} for compound **2** as well as at 1680 and 1700 cm^{-1} for compound **3** indicated the presence of conjugated ester moieties in the molecules.

Finally, structural evaluation was performed by a number of NMR experiments. The structures of **1–3** (Fig. 1) were determined by 1D and 2D NMR studies using DEPT, sel-COSY, sel-TOCSY (Stott et al., 1995), HSQC and HMBC techniques including gradient selection and linear prediction. Due to severe signal overlap even at 600 MHz, we achieved a complete assignment not only for the carbon but also for the proton signals.

The ^1H and ^{13}C chemical shifts and characteristic HMBC connectivities of compounds **1–3** are summarized in Table 2. In the low-field part of the ^1H NMR spectrum of **1** two different spin systems were identified, one pair of doublets at 6.44 (1H, *d*, $J_{meta}=2.0$ Hz) and 6.21 (1H, *d*, $J_{meta}=2.0$ Hz), respectively, indicating one 1,2,3,5-tetra-substituted (mainly with oxygen functions) aromatic ring. The signal at 8.08 (1H, *d*, $J_{meta}=2.2$ Hz), 7.89 (1H, *dd*) and 7.37 (1H, *d*, $J_{ortho}=8.6$ Hz), respectively, form a separate spin system indicating the presence of an 1,2,4-tri-substituted aromatic ring. The upfield part of the spectrum exhibits three separated doublets 5.28 (1H, *d*, 7.6 Hz), 5.02 (1H, *d*, 7.6 Hz) and 4.99 (1H, *d*, 7.3 Hz), respectively, and further signals in the range 3.95–3.15 (18H, *m*) in strong overlapping. For assignment of these signals the selective 1D TOCSY (Stott et al., 1995) measurements proved to be the method of choice allowing the complete analysis of the sugar signals and identification of three β-glucose moieties. The ^{13}C NMR signals of the aglycone (180–94 ppm) consist of 15 peaks, corresponding to 5 sp^2 methines, 9 quaternary sp^2 C atoms and 1 conjugated C=O group (179.6), respectively. A comparison of the ^{13}C chemical shift of **1** (Table 2) with literature data of flavonol glycosides (Breitmaier and Voelter, 1987) strongly supports the presence of quercetin as aglycone.

The connectivities of the monosaccharide units were established on the basis of HMBC cross peaks (Table 2) indicating long-range ^{13}C–^1H couplings. The anomeric proton with the largest chemical shift (C1: $\delta=5.28$) correlates with C-3 (136.2). The B1 anomeric proton ($\delta=5.02$) gives a strong cross-peak with C-4′ signal (151.8), whereas the HMBC response between A1 (4.99)

and C-3′ (148.3) proves the position of the attached sugar unit.

In the ^{1}H and ^{13}C NMR spectra of **2** and **3** similar chemical shifts were observed accompanied with additional signals corresponding to one and two sinapoyl substituents, respectively. The high value of the coupling constants ($J_{H\text{-}\alpha,H\text{-}\beta} = 15.9$ Hz) proves the E-configuration of the double bond of sinapoyl substituents. The chemical shifts of the carbohydrate protons exhibit a strong deshielding where the sinapoyl moieties are attached. In this respect the straightforward assignment and differentiation of the three sugar units is also very important. The series of selective 1D TOCSY spectra of **2** measured with different mixing times prove that the above mentioned downfield-shift appeared at the methylene protons A6a and A6b. Strong HMBC cross-peaks were observed between these protons and the ester C=O carbon atom unambiguously proving the site of the sinapoyl substituents.

In conclusion, three new quercetin 3,3′,4′-tri-*O*-β-D-glycopyranosides were isolated from leaves of *E. sativa* (Mill.), i.e. quercetin 3,3′,4′-tri-*O*-β-D-glucopyranoside (**1**), quercetin 3′-(6-sinapoyl-*O*-β-D-glucopyranosyl)-3,4′-di-*O*-β-D-glucopyranoside (**2**) and quercetin 3-(2-sinapoyl-*O*-β-D-glucopyranosyl)-3′-(6-sinapoyl-*O*-β-D-glucopyranosyl)-4′-*O*-β-D-glucopyranoside. The flavonol tri-*O*-β-glucosides **1–3** show an uncommon sugar substitution pattern; a flavonol glycoside with this substitution pattern (rhamnetin 3,3′,4′-tri-*O*-glucoside) has been reported previously from *Pyrola chlazantha* and *P. vizeus* (Pyrolaceae) (Averett and Bohm, 1986). Also acylation at position 2 of glucose in compound **3** is uncommon; mainly, acylated flavonol glycosides show a linkage between the acid and the sugar at position 6 of the sugar moiety (Ferreres et al., 1995).

3. Experimental

3.1. Extraction and isolation

Fresh leaves of *E. sativa* (Mill.) (500 g; origin Italy, cultivar not specified; obtained by a local wholesaler) were homogenized in a Waring blender with 1250 ml of a methanol-water mixture (7:3 v/v). After maceration for 24 h at room temperature, the homogenate was filtered, the filtrate concentrated under reduced pressure to approximately 50 ml, and rediluted with water to approximately 500 ml. The aqueous extract was applied onto a glass column (8×75 cm) filled with Amberlite® XAD-2 (Supelco, Bellefonte, USA). After washing with water (1 l) and subsequently with diethyl ether (1 l) the glycosides were eluted with methanol (1.5 l). The glycosidic eluate was concentrated under reduced pressure and the residue lyophilized to yield 1.1 g dry powder. The lyophilsate was redissolved in 5 ml of water. Fractionation was done by LC on a RP-18 column (2.5× 20 cm; LiChrospher®, Merck, Darmstadt, Germany) using a methanol-water gradient starting with 100% water (100 ml) and increasing the proportion of methanol in steps of 10% (each step 100 ml) to end up with 100% methanol. Seven ml-fractions were collected and analysed by HPLC-ELSD. Fractions of the same composition were combined, concentrated under reduced pressure and lyophilized. In fractions 48–52, 61–62 and 67–68 pure compounds **1–3** were obtained in yields of 25, 15, and 12 mg, respectively.

3.2. NMR spectroscopy

NMR spectra were recorded in CD_3OD using a Bruker Avance DRX-600 spectrometer. Chemical shifts are given on the δ-scale and were referenced to TMS. In the 1D and 2D NMR experiments pulse programs were taken from the Bruker software library.

3.3. IR spectroscopy

IR spectra (KBr) were recorded on a Perkin Elmer IR spectrophotometer (model 1310).

3.4. HPLC–DAD

HPLC–DAD analysis was performed with a Hewlett Packard gradient pump (series 1100) and a Hewlett Packard photodiode array detector (series 1100) including Hewlett Packard software. UV spectra were monitored from 190 to 480 nm in steps of 1 nm. HPLC was carried out on an Eurospher 100 C-18 column (250×4.6 mm I.D., 5 μm) (Knauer) with a water (0.05% TFA)-acetonitrile linear gradient at a flow rate of 1.0 ml min^{-1} from 5 to 100% acetonitrile in 30 min.

3.5. HPLC–ELSD

HPLC–ELSD analysis was performed with a Knauer HPLC Maxi Star including Eurochrom 2000 software and a Sedere Evaporative Light Scattering Detector (ELSD, model Sedex 55). The temperature of the detector was set to 40°C and compressed air was used at a pressure of 240 kPa. HPLC was carried out as described above.

3.6. HPLC–ESI MS

Mass spectrometry was performed on a Finnigan triple-stage quadrupole TSQ 7000 HPLC-MS/MS system (Finnigan MAT, Bremen, Germany) with electrospray ionization (ESI) as interface in positive mode. For HPLC, an Applied Biosystems (Foster City, CA, USA) Model 140B pump was used. For ESI in the positive ion mode the spray capillary voltage was set to 4 kV and the

temperature of the heated inlet capillary was set to 230°C. Nitrogen served both as sheath gas (482 MPa) and as auxiliary gas. HPLC was carried out on an Eurospher 100 C-18 column (100×2 mm I.D., 5 μm) (Knauer) with a water (0.05% TFA) — acetonitrile linear gradient at a flow rate of 0.2 ml min^{-1} from 5 to 100% acetonitrile in 30 min. Positive ions were detected scanning from m/z 200 to 1500 with a total scan duration of 1.0 s. The MS/MS experiments were performed at a collision energy of −15 to −25 eV with Argon (0.24 Pa) serving as collision gas, scanning a mass range from m/z 20 to 1250.

3.7. Elemental analysis

The data for compounds **1**, **2** and **3** are as follows: compound **1** (found: C, 50.4; H, 5.2. $C_{33}H_{40}O_{22}$ requires: C, 50.3; H, 5.1%). Compound **2** (found: C, 53.3; H 5.1. $C_{44}H_{50}O_{26}$ requires: C, 53.1; H, 5.1%). Compound **3** (found: C, 55.2; H, 5.1. $C_{55}H_{60}O_{30}$ requires: C, 55.0; H, 5.0%).

Abstract

A benzophenone glycoside has been isolated from *Davallia solida*. Its structure was elucidated by chemical and spectral means as 4-*O*-β-D-glucopyranosyl-2,6,4′-trihydroxybenzophenone. It bound with moderate affinity to the purified C-terminal cytosolic domain of P-glycoprotein, but the binding affinity was 6- to 10-fold increased for its aglycone derivative and other related benzophenones. © 2001 Elsevier Science Ltd. Keywords: *Davallia solida*; Davalliaceae; Benzophenones; P-Glycoprotein; Drug resistance

1. Introduction

Resistance of neoplasic cells towards chemotherapeutic agents is a major obstacle in clinical cancer treatment. A large number of cancer cells are intrinsically resistant to chemotherapy, while others initially respond to treatment but progressively acquire resistance to the drugs used as well as to other drugs. The best studied mechanism of drug resistance is the overexpression of the *MDR*1 gene product P-glycoprotein (P-gp) that rejects chemotherapeutic drugs out of the cell, using ATP hydrolysis as an energetic source. (Gottesman et al., 1993; Gros and Buschmann, 1993). P-gp is composed of two homologous halves, each comprising a membrane domain, and a cytosolic domain. The site of ATP binding is present on the cytosolic domain. Among the various classes of plant secondary metabolites, flavonoid compounds have been reported as modulators of P-gp (Critchfield et al., 1994; Shapiro and Ling, 1997; Comte et al., 2001). They are able to interact with P-gp cytosolic moiety through binding to both steroid- and ATP-binding sites within NBD2, the C-terminal cytoplasmic domain of mouse P-glycoprotein (Conseil et al., 1998). On a structural point of view, the presence of the 4-carbonyl and of the 3- and/or the 5-hydroxyl groups are required for ATP mimicry. Xanthones, which are structurally related to flavonoids through the presence of a 9-carbonyl and of 1- and 8-hydroxyls, have been demonstrated to interact with NBD2 as well (Noungoué-Tchamo et al., 2000). In a previous work, mangiferin and a *C*-pentosyl xanthone have been found in *Davallia solida* (Rancon et al., 1999). The present study is oriented to the isolation of benzophenones, which are biosynthetic precursors of xanthones (Bennett and Lee, 1989), from the same plant species. In addition, most naturally occurring benzophenones possess the structural requirement (7-carbonyl plus 2-hydroxyl) for interaction with ATP-binding sites. Therefore benzophenones can be regarded as potential P-gp modulators. In this paper the isolation and the identification from *Davallia solida* of a new *O*-glucosyl benzophenone **1** is described. The results of the NBD2 interactions with compound **1**, its corresponding aglycone **2**, and three

other related benzophenones **3–5** are presented for the first time and discussed.

2. Results and discussion

Air dried rhizomes were sequentially extracted with solvents of increasing polarities as previously described (Rancon et al., 1999). The butanolic extract was submitted to a combination of chromatography techniques (gel filtration on Sephadex® LH-20, preparative TLC on cellulose, and finally column chromatography on RP-18) leading to the isolation of 4-*O*-β-D-glucopyranosyl-2,6,4′-trihydroxybenzophenone **1**.

The FAB–MS spectrum showed quasi-molecular ion peaks at $m/z = 431$ $[M+Na]^+$ and $m/z = 409$ $[M+H]^+$. The molecular formula $C_{19}H_{20}O_{10}$ was established on the basis of both NMR and MS data and confirmed by HR–MS experiments on the ion peak at m/z 431 $[M+Na]^+$ (see Experimental).

The presence of a sugar moiety was shown on the positive FAB–MS spectrum by the ion peak at m/z 247 $[M–Glc+H]^+$ and confirmed in the NMR data by signals noted in the ranges 3.00–5.00 ppm and 60.0–80.0 ppm in ^1H and ^{13}C NMR spectra, respectively. β-D-Gluco pyranose was identified on the basis of its ^1H and ^{13}C NMR data (Agraval, 1989, 1992; Breitmaier and Voelter, 1989) and after acidic hydrolysis. The glycosidic chaining was furthermore unambiguously confirmed by 2D NMR COSY, HSQC and HMBC experiments. Chemical shifts of both C-1″ at δ 100.7 and H-1″ at δ 4.87 showed the *O*-linkage between the sugar moiety and the aglycone part.

The ^{13}C NMR spectrum also indicated shielded aromatic methines at δ 95.9 (C-3), δ 98.1 (C-5), δ 133.2 (C-2′ and C-6′) and δ 115.2 (C-3′ and C-5′) typical of phenolic natural compounds. Among the quaternary carbon atom signals, 4 corresponded to *O*-linked aromatic carbons (145–165 ppm), while the signal noted at δ 197.7 showed the presence of a carbonyl group (Breitmaier and Voelter, 1989).

Moreover, the use of 1D NMR spectra together with 2D NMR correlation maps showed the presence of a *para*-disubstituted aromatic ring together with a phloroglucinol-type one.

The linkage between the glucosyl moiety and the genine was unambiguously demonstrated by the correlation noted between H-1″ (δ 4.87) and C-4 (δ 159.7) in the 2D NMR ^1H–^{13}C HMBC experiment. UV spectra in methanol and classical reagents, which were characteristic of a phenolic compound substituted by hydroxyl with neighbouring ketone and free hydroxyl groups, corroborate the product to be a benzophenone. Finally, acidic hydrolysis of **1** yielded, besides glucose, an aglycone the chromatographic behaviour of which was identical to that of synthetic 2,4,6,4′-tetrahydroxybenzophenone **2**. Compound **1** was thus identified to 4-*O*-β-D-glucopyranosyl-2,6,4′-trihydroxybenzophenone, a new natural product.

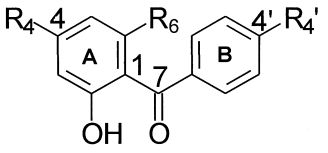
The naturally occurring benzophenone glucoside **1**, its acidic-hydrolysis product **2** and commercial or synthetic benzophenone aglycones **3–5**, were later assayed for their affinity towards P-gp. Our study, however, was not carried out on the whole transporter for three main reasons: (1) the low availability of purified whole transporter; (2) the difficulty to get the fully-active transporter after using denaturating detergent; and (3) the lack of efficient overexpressing system. Alternatively, interaction of ligands can be studied with recombinant cytosolic domains containing the ATP binding sites, after overexpression in bacteria and purification. The recombinant protein is highly soluble and can be easily purified by affinity chromatography when fused to a hexahistidine tag. Our work was carried out on nucleotide binding domain 2 (NBD2), one of the two cytosolic domains from mouse P-gp. The domain contains a tryptophan residue and is appropriate for monitoring interactions by recording changes in intrinsic fluorescence, from the analysis of which apparent K_D values can be derived, as described previously for flavonoids (Conseil et al., 1998). Table 2 shows that glycosylated derivative **1** bound 6-fold less strongly ($K_D = 12.75 \pm 1.72$) than its aglycone **2** ($K_D = 2.19 \pm 0.72$). Methylation of the 4′-hydroxyl group as in synthetic benzophenone **3** further slightly increased the apparent affinity for quenching ($K_D = 1.27 \pm 0.59$ μM) as compared with **2** ($K_D = 2.19 \pm 0.72$ μM). The similar affinities displayed by compounds **3** and **4** suggest that the 6-hydroxyl group plays a minor, if any, role in the interaction, and that the absence of B-ring substitution is still more

Table 2
Role of benzophenone substituents on the affinity for NBD2



Benzophenones	Substituents				
	R_6	R_4	$R_{4'}$	ΔF_{max} (%)	Apparent K_D (μM)
1	OH	O-glc	OH	32.27±1.88	12.75±1.72
2	OH	OH	OH	30.30±3.41	2.19±0.72
3	OH	OH	OCH_3	19.57±2.53	1.27±0.59
4	H	OH	H	17.12±1.44	1.15±0.36
5	H	OCH_3	H	35.0±2.70	3.12±0.61

advantageous than the presence of a polar 4′-hydroxyl. Finally, methylation of the 4-hydroxyl in **5** produced a rather negative effect as compared to benzophenone **4**. Similar effects have been obtained in the past with flavonoid series (Conseil et al., 1998), i.e. increased affinity with compounds having non polar B-ring (either unsubstituted or 4′-methoxy-substituted, such as galangin or kaempferide compared to kaempferol), and decreased affinity in the case of glycosides (such as rutin compared to quercetin). However, the affinities obtained here for benzophenones were higher than those of flavonoids. On the contrary, the maximal fluorescence quenching values, ΔF_{max}, were rather small as compared to flavonoids, indicating a different modification of the tryptophan environment. This might reflect a different positioning within, or overlapping of, the binding site when comparing benzophenones and flavonoids.

Benzophenone derivatives are of common use in photolabelling of proteins (Andrus et al., 2000; Dorman and Prestwich, 1994; Fleming, 1995). Upon UV irradiation, they are able to couple with a wide range of protein regions, including hydrophobic ones, through a radical mechanism. Taking into account the fact that (i) information is lacking about the structures of the binding sites of P-gp, (ii) the NBD2 domain indeed contains a hydrophobic interacting region, and (iii) our previous labelling attempts using radioactive azido flavones have failed (De Wet et al., 2001), the possibility to use benzophenone derivatives directly as photolabelling probes for P-gp is open now.

3. Experimental

3.1. General

Prep. TLC was carried out on cellulose Macherey Nagel 301 plates. Gel filtration was performed on Sephadex® LH-20 (850×75 mm). LPLC was carried out on a Lobar® (310×250 mm) Lichrosorb RP 18 40-63 μm column.

NMR spectra were recorded using a 300.13 MHz (^{1}H) or a 75.48 MHz (^{13}C) apparatus. The solvent signal was used as internal reference. Complete proton and carbon assignments were based on 1D ^{1}H and ^{13}C, 2D ^{1}H–^{1}H COSY, ^{1}H–^{13}C HSQC and ^{1}H–^{13}C HMBC experiments. Anhydrous phloroglucinol, 2,4-dihydroxy- and 2-hydroxy-4-methoxybenzophenones were purchased from Lancaster (Strasbourg, France). 4-Hydroxy- and 4-methoxybenzonitriles were from Aldrich (St Quentin Fallavier, France).

3.2. Plant material

Davallia solida (Forst.) Swartz was collected and identified by Dr. Pierre Cabalion. A specimen is deposited at the Pharmacognosy department (Laboratory of Pharmacognosy, Faculty of Pharmacy, 8 Avenue Rockfeller, 69373 Lyon Cedex 08, France).

3.3. Extraction and isolation

The extraction and fractionation have been described (Rancon et al., 1999). The *n*-BuOH layer was chromatographed on Sephadex LH-20 using MeOH as mobile phase: 5 fractions (85 ml) were collected. The first one was purified by prep. cellulose TLC using aq. AcOH 15% as solvent (R_f 0,93). Final separation was carried out on a reverse phase LOBAR column using aq. MeOH (linear gradient) as solvent. The fraction eluted with 30% aq. MeOH afforded 27 mg of pure benzophenone **1**.

3.3.1. 4-O-β-D-Glucopyranosyl-2,6,4′-trihydroxybenzophenone *1*

UV λ MeOH nm: 221, 288; +$AlCl_3$: 248, 305, 365; +$AlCl_3$+HCl: 221, 296, 345; +NaOH: 245, 328, 361; +NaOAc: 225, 291, 339; FAB$^+$MS (thioglycerol) (*m*/*z*): 431 $[M+Na]^+$, 409 $[M+H]^+$, 247 $[M–Glc+H]^+$; HRMS (FAB): Calculated for $C_{19}H_{20}O_{10}$•Na^+: 431.0954. Found: 431.0954; NMR data : see Table 1.

3.3.2. Synthesis of 2,4,6,4′-tetrahydroxybenzophenone *2*

Nine grams (71 mmol) of anhydrous phloroglucinol were dissolved in dry Et_2O. To this solution were added 2.0 g (14.7 mmol; 0.2 eq.) of powdered fused $ZnCl_2$, followed by 10.0 g (83.9 mmol; 1.2 eq.) of 4-hydroxybenzonitrile. The medium was cooled to 4°C (ice bath) and saturated with HCl gas (prepared by the addition of 200 ml conc. hydrochloric acid to 200 ml conc. H_2SO_4). After 24 h at 4°C, the ether supernatant was decanted from the oily residue which deposited at the bottom of the flask. The oil was dissolved in 150 ml

H_2O (warm) and the solution was refluxed for 24 h. Filtration and cooling of the aqueous solution led to the crystallisation of 0.92 g of 2,4,6,4′-trihydroxybenzo phenone as white crystals. ^{1}H NMR (300 MHz, acetone-d_6): δ 5.99 (2H, *s*, H-3/5), 6.86 (2H, *d*, $J=8.7$ Hz, H-3′/5′), 7.62 (2H, *d*, $J=8.7$ Hz, H-2′/6′), 9.14 (2H, *brs*, OH-4/4′), 10.22 (2H, *brs*, OH-2/6). ^{13}C NMR (75.5 MHz, acetone-d_6): δ 96.9 (C-3/5), 106.6 (C-1), 116.1 (C-3′/5′), 133.4 (C-2′/6′), 134.4 (C-1′), 162.8 (C-4′), 164.0 (C-2/6), 164.6 (C-4), 198.9 (C-7).

3.3.3. Synthesis of 2,4,6-trihydroxy-4′-methoxybenzophenone **3**

Similar reaction of 4.0 g (31.7 mmol) of anhydrous phloroglucinol, 0.8 g (5.9 mmol; 0.2 eq.) of powdered fused $ZnCl_2$ and 5.0 g (37.6 mmol; 1.2 eq.) of 4-methoxybenzonitrile in dry Et_2O yielded 1.5 g of 2,4,6-trihydroxy-4′-methoxybenzophenone as white crystals. ^{1}H NMR (300 MHz, acetone-d_6): δ 3.88 (3H, *s*, OMe-4′), 5.99 (2H, *s*, H-3/5), 6.96 (2H, *d*, $J=8.9$ Hz, H-3′/5′), 7.68 (2H, *d*, $J=8.9$ Hz, H-2′/6′), 9.20 (1H, *s*, OH-4), 10.29 (2H, *s*, OH-2/6). ^{13}C NMR (75.5 MHz, acetone-d_6): δ 56.8 (OMe-4′), 96.9 (C-3/5), 106.5 (C-1), 114.6 (C-3′/5′), 133.0 (C-2′/6′), 135.5 (C-1′), 164.2 (C-2/6), 164.5 (C-4′), 165.8 (C-4), 199.1 (C-7).

3.4. Biological assays

The recombinant C-terminal cytosolic domain of P-pg, H_6–NBD2 was overexpressed and purified as described previously (Conseil et al., 1998). Fluorescence experiments were performed at 25.0 ± 0.1°C using a SLM-Aminco 8000C spectrofluorimeter with spectral bandwidths of 2 and 4 nm, respectively, for excitation and emission. H_6–NBD2 was diluted in 1.2 ml of dialysis buffer at pH 6.8, containing 20 mM potassium phosphate, 0.5 M NaCl, 20% glycerol, and 0.01% methyl-6-*O*-(*N*-heptylcarbamoyl)-α-D-glycopyranoside, in the presence of increasing concentrations of dimethyl sulfoxide solutions of the products. Tryptophan-intrinsic fluorescence of H_6–NBD2 was studied by scanning emission in the 310–360 nm range upon excitation at 295 nm, and integrating the spectrum area. The binding of the product was monitored by quenching of emission fluorescence produced by addition of increasing ligand concentrations. Corrections for inner-filter effect and dimethyl sulfoxide were determined under the same conditions by using *N*-acetyltryptophanamide. Curve fitting of ligand binding related to fluorescence decrease was performed with the Grafit program (Erithacus software) as previously described (Divita et al.,1993). Two main parameters of the binding were determined from the fitting: the maximal quenching of fluorescence (as the difference between starting maximal fluorescence and final minimal fluorescence), and the apparent dissociation constant, $K_D \pm$ S.D.

Two flavonoids and other compounds from the aerial parts of *Centaurea bracteata* from Italy

Guido Flamini*, Elena Antognoli, Ivano Morelli

Dipartimento di Chimica Bioorganica e Biofarmacia, Università degli Studi di Pisa, Via Bonanno 33, 56126 Pisa, Italy

Received 15 November 2000; received in revised form 8 February 2001

Abstract

The flowering aerial parts of *Centaurea bracteata* Scop. (Asteraceae) have been studied for the first time. Nineteen compounds were isolated and identified, namely a sterol glucoside, two phenolic acids, three quinic acid derivatives, and 13 flavonoids, two of which, are new natural products. Structural elucidation was performed mainly by mean of FABMS, 1D and 2D NMR spectroscopy. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Centaurea bracteata*; Asteraceae; Fiordaliso bratteato; Flavonoids; Quercetin 3-*O*-β-D-Glucopyranoside-3′-sulphate; Centabractein; Isokaempferide 7-*O*-β-D-glucopyranouronide; Bracteoside

1. Introduction

Centaurea bracteata Scop. (Asteraceae), known in Italy as "fiordaliso bratteato" is a herbaceous plant placed by Pignatti (1982) in the *Centaurea jacea* group, together with 10 other species. The plant is not used in the Italian folk medicine, although other species of the same genus (i.e. *Centaurea cyanus* and *Centaurea scabiosa*) are used against coughs and as ophthalmic drugs (Poletti, 1978). The studies on this genus deal mainly with sesquiterpene lactones, while flavonoids are less investigated; the species *C. bracteata* has never been studied at all.

This paper deals with the isolation and characterisation of 19 substances belonging to various classes of compounds, in particular three quinic acid derivatives, a sterol glucoside, two phenolic acids, and 13 flavonoids, two of which are new natural products.

2. Results and discussion

From the *n*-hexane residue (R_H), by repeated flash chromatographies, two compounds were isolated, namely β-sitosterol 3-*O*-β-D-glucopyranoside and jaceidin, which were identified by comparison of their physical and spectroscopic properties with literature reports (Roitman and James, 1985; Reher and Budensisky, 1992).

Fractionation of the $CHCl_3$–MeOH (9:1) extract (R_{CM}) by size-exclusion chromatography, Lobar RP-8 and preparative TLC, led to the isolation of 10 pure compounds. These were luteolin, axillarin, nepetin, 6-methoxy apigenin, isokaempferide, centaureidin, jacein, axillarin 7-glucoside, 5-caffeoylquinic acid and protocatechuic acid, all identified by ^1H and ^{13}C NMR spectroscopy (Collado et al., 1985; Iwahashi et al., 1985; Barbera et al., 1986; Berghöfer and Hölzl, 1987; Wada et al., 1987).

The EtOAc and BuOH residues, after size-exclusion chromatography and repeated Lobar RP-8 flash and preparative TLC chromatographies, gave 3,4-dicaffeoylquinic and caffeic acids, 6-hydroxyluteolin 6,4′-dimethyl ether, apigenin 7-glucoside, 3-caffeoylquinic acid methyl ester and two new flavonoid glycosides, which we named centabractein (**1**) and bracteoside (**2**). Known isolates were identified by comparison with literature data (Radaelli et al., 1980; Iwahashi et al., 1985; Kubo et al., 1986; Nishizawa et al., 1988).

Centabractein (**1**) was obtained as a yellowish amorphous powder that appears on TLC as a yellow-orange arrow-shaped spot after treatment with Naturstoffreagenz A-PEG. The negative FABMS spectrum gave a quasimolecular peak $[M–H]^-$ at 543 m/z, corresponding to the molecular formula $C_{21}H_{20}O_{15}S$, supported

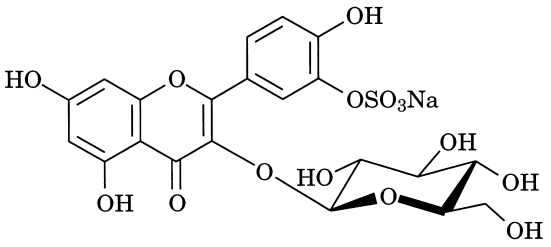
PII: S0031-9422(01)00066-8

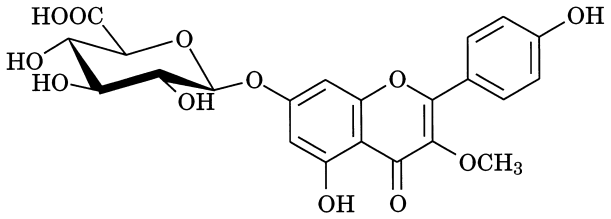
also by elemental analysis (see Experimental Section); another significant ion at m/z 565 ($[M+Na\text{-}H]^-$) showed the presence of sodium in the sample. The ^{13}C NMR spectrum showed 21 resonances, sorted by DEPT experiments into 10 CH, one CH_2 and 10 quaternary C. In the ^1H NMR spectrum obtained in DMSO-d_6 two broad singlets (δ 6.13 and 6.38) were present, really two coupled doublets with a very small J value, as shown by the COSY experiment, typical of the two *meta*-related H-6 and H-8 protons of ring A of a flavonoid unit. Ring B showed an ABM system (δ 7.96, *d*, $J=2.0$ Hz; 7.84, *dd*, $J=8.3$, 2.0 Hz; 6.91, *d*, $J=8.3$ Hz). Moreover, a one-proton doublet ($J=7.3$ Hz) was present at δ 5.40. This suggested the presence of a sugar having a β-configuration because of the J value due to a *trans*-diaxial interaction. The situation was very close to that of a quercetin glycoside, apart from the signals of ring B that resulted deshielded. This circumstance was more evident in the ^1H NMR spectrum recorded in CD_3OD, where the resonances of the ring B protons appeared at very low fields (8.31, *d*, $J=1.9$ Hz; 7.87, *dd*, $J=8.1$, 1.9 Hz; 7.00, *d*, $J=8.1$ Hz). Analysis of the ^{13}C NMR spectrum permitted the identification of the sugar moiety as β-D-glucose and confirmed the 'anomalous' situation of ring B with respect to quercetin. Resonances of ring B carbons showed the typical shifts due to the presence of a sulphate group (Barron et al., 1988): ca. 4.5 ppm upfield for the *ipso* carbon (C-3′) and ca. 7.0, 3.5, 1.5 and 5.0 ppm downfield for C-2′, C-4′, C-5′ and C-6′, respectively. The values are also in good agreement with those from an analogous compound (Seabra and Correia Alves, 1988). Placement of the glucose moiety at C-3 was determined on the basis of the typical glycosilation shifts that occurred with respect to quercetin (Flamini et al., 2000): downfield shifts of C-2 and C-4 (ca. 9.0 and 3.0 ppm, respectively) and an upfield shift of C-3 (ca. 2.0 ppm). Therefore, **1** is quercetin 3-*O*-β-D-glucopyranoside 3′-sulphate sodium salt, which we named centabractein. This structure is supported by its negative FABMS spectrum where, besides the quasimolecular peak at m/z 543, $[M\text{-}H]^-$, and at m/z 565, $[M+Na\text{-}H]^-$, there were peaks due to loss of a sulphate group at m/z 463, $[M\text{-}H\text{-}80]^-$, and of a glucose unit at m/z 301, $[M\text{-}H\text{-}162]^-$. Finally, the presence of sodium was confirmed by the yellow colour obtained by the flame assay; total acid hydrolysis of **1** liberated quercetin, glucose and sulphate, identified by TLC with authentic samples and precipitation with barium chloride, respectively.

Bracteoside (**2**) was obtained as a pale yellow powder that appears on TLC as a green-yellowish spot after treatment with Naturstoffreagenz A-PEG. The negative FABMS spectrum gave a quasimolecular peak $[M-H]^-$ at 475 m/z, corresponding to the molecular formula $C_{22}H_{20}O_{12}$, supported also by elemental analysis (see Experimental Section). The ^{13}C NMR spectrum showed 20 signals, sorted by DEPT experiments into one CH_3, 9 CH, and 10 quaternary C. In the ^1H NMR spectrum obtained in CD_3OD an AA′BB′ system constituted by two two-proton doublets ($J=8.8$ Hz) at δ 8.02 and 6.92, typical of a *para*-substituted B ring of a flavonoid. Two further coupled doublets ($J=1.9$ Hz) at δ 6.78 and 6.48 indicated the presence of the *meta*-related H-6 and H-8 ring A protons. The presence of a methoxyl group was evidenced by the three-protons singlet at δ 3.79. Moreover, a one-proton doublet ($J=7.3$ Hz) was present at δ 5.15, together with a not resolved area between 3 and 4 δ indicating the presence of a sugar having a β-configuration because of the J value due to a *trans*-diaxial interaction. Consequently, we can hypothesise the presence of a methoxykaempferol glycoside. The high resonance value of the methoxyl group (δ 59.7) suggested that both the *ortho* positions should be substituted, so it must be placed at the 3 position (Agrawal et al., 1989). This situation is corroborated by the characteristic downfield shifts observed for C-2, C-3 and C-4 (ca. 10.5, 4.0 and 2.5, respectively) with respect to kaempferol. Moreover, a cross peak was evidenced in the NOESY spectrum between the methoxyl and H-2′/H-6′ resonances. The sugar moiety was easily identified as glucuronic acid and its linkage to the 7-OH was established on the basis of the typical glycosilation shifts experienced by the aglycone, particularly the C-7 upfield shift (ca. 1.5 ppm) and the downfield shifts of the *ortho* (ca. 1.0 ppm) and *para* (ca. 2.5 ppm) carbons. This structure is also supported by its negative FABMS spectrum where, besides the quasimolecular peak at m/z 475, $[M-H]^-$, the peak due to the loss of glucuronic acid $[M-H-176]^-$ at 299 m/z was evident. Therefore, **2** was identified as isokaempferide 7-*O*-β-D-glucopyranouronide, which we have named bracteoside.

Summarising, the aerial parts of *C. bracteata* yielded 19 compounds, among which 13 were flavonoids, 4 caffeoylquinic derivatives, 1 phenolic acid and 1 sterol glucoside. Most of the flavonoids, according to the pattern of this genus, were polymethoxylated and two compounds have been obtained in great amounts (jacein 3650 mg, and jaceidin 750 mg; 0.31 and 0.06% with respect to the dry plant material). The other isolated compounds gave the following yields: β-sitosterol 3-glucoside and axillarin 7-glucoside 0.002%; luteolin, protocatechuic acid, 6-hydroxyluteolin 6,4′-dimethyl ether, caffeic acid and centaureidin 0.0004%; axillarin, nepetin, 6-methoxyapigenin, 3,4-dicaffeoylquinic acid and 5-caffeoylquinic acid 0.0009%; isokaempferide, centabractein (**1**) and bracteoside (**2**) 0.001%, One of the flavonoids, centabractein (**1**) was a sulphate conjugate; these compounds are relatively rare in nature (Williams and Harborne, 1994) and, among the Asteraceae, they are produced only by 4 tribes: Inuleae, Eupatorieae, Senecioneae and Heliantheae (Barron et al., 1988). This is the first report of a flavonoid sulphate ester in the genus *Centaurea* and this finding



1



2

lead to 5 the producing tribes, comprising now also the Centaureinae.

The large diffusion of flavonoid sulphates in water or hydrophyte plants (Tomas-Barberan et al., 1987; Barron et al., 1988; Seabra and Correia Alves, 1988; De Beck et al., 1998) seems to support the view that this conjugation could represent an ecological adaptation to the aquatic habitat. However, *C. bracteata* has been collected in a very arid environment, the normal habitat according to Pignatti (1982), that describes this species as a xerophytic one. Further studies are in progress on the roots of this plant to confirm our findings.

Flavonoids sulphates showed many biological activities, useful both to human health and plant physiology. They are enzymes inhibitors (Haraguchi et al., 1996), allergens (Sallusto et al., 2000), antioxidants (Yagi et al., 1994), regulators of auxin transport (Faulkner and Rubery, 1992). Moreover, rutine sulfate was demonstrated to be not carcinogenic (Habs et al., 1984).

Sesquiterpene lactones, typical compounds of this genus, are not produced at all by *C. bracteata*.

3. Experimental

3.1. General

Melting points (uncorrected) were determined with a Kofler apparatus; optical rotations were measured on a Perkin-Elmer 241 polarimeter; FABMS were recorded, in the negative mode, with a VG ZAB instrument; ^1H and ^{13}C NMR spectra were obtained with a Bruker AC200 spectrometer in CD_3OD, DMSO-d_6, and $CDCl_3$, using TMS as internal standard. All 1D and 2D NMR experiments were performed using the standard Bruker library of microprograms.

The following adsorbents were used for purification: flash chromatography, Merck Kieselgel 60 (230–410 mesh); low-pressure chromatography, Merck Lobar Lichroprep RP-8 (31×2.5 cm); size-exclusion chromatography, Pharmacia Fine Chemicals Sephadex LH-20; analytical TLC, Merck Kieselgel 60 F_{254} precoated plates; chromatograms were visualised under UV light at 254 and 366 nm and/or sprayed with Komarowsky or Cerium Sulphate or Naturstoffreagenz A-PEG reagents.

3.2. Plant material

The flowered aerial parts were collected at Montelaterone, Amiata Mount, South Tuscany, Italy, at 600 m above the sea level, in July 1998. A voucher specimen is deposited in PI (Herbarium of the University of Pisa).

3.3. Extraction and isolation

The dried and ground aerial parts (1160 g) were extracted, successively, in a Soxhlet apparatus with *n*-hexane, $CHCl_3$, $CHCl_3$–MeOH (9:1) (4.5 l×30 h) and, at room temperature, with MeOH (3.5 l×7 days×3 times). After removal of solvents, in vacuo at up to 40°C, the following residues were obtained: R_H (26.1 g), R_C (9.9 g), R_{CM} (46.0 g), and R_M (49.8 g).

R_M was suspended in MeOH-H_2O (7:3) and extracted, in turn, with EtOAc and *n*-BuOH obtaining, after removal of the solvents, the residues R_{MAc} and R_{MBu}.

The R_H residue, after repeated SiO_2 flash chromatographies, gave β-sitosterol 3-*O*-β-D-glucopyranoside (18 mg) and jaceidin (750 mg).

The R_{CM} residue was submitted to Sephadex LH-20 size-exclusion chromatography with MeOH–$CHCl_3$ (4:1) as eluent and the fractions were submitted to Lobar RP-8 and SiO_2 p-TLC chromatographies, obtaining 10 pure compounds: luteolin (4 mg), axillarin (11 mg), nepetin (11 mg), 6-methoxy apigenin (10 mg), isokaempferide (15 mg), centaureidin (8 mg), jacein (3650 mg), axillarin 7-glucoside (22 mg), 5-caffeoylquinic acid (10 mg) and protocatechuic acid (5 mg).

R_{MAc} was chromatographed over Sephadex LH-20 column with MeOH as eluent, obtaining 10 main fractions (A–J). From fractions B,D and F–H, after gravity and flash column chromatography, and SiO_2 p-TLC, axillarin 7-glucoside (18 mg), 6-hydroxyluteolin 6,4′-dimethyl ether (6 mg), caffeic (6 mg), 3,4-dicaffeoylquinic (15 mg) and protocatechuic (4 mg) acids were obtained. Fraction J was filtered over a RP-8 column, using MeOH–H_2O (6:4) as eluent, obtaining pure centabractein (**1**) (12 mg).

The Sephadex LH-20 chromatography (eluent MeOH) yielded 8 main fractions (A′–H′). From fraction D′ a precipitate constituted by pure apigenin 7-glucoside

(10 mg) was separated. Fraction G′ gave, after SiO_2 column chromatography, pure 3-caffeoylquinic acid methyl ester. Bracteoside (**2**) (11 mg) was obtained by precipitation from fraction C′.

3.4. Centabractein (*1*)

Yellowish amorphous solid; $[\alpha]_D^{20}$ −60.0° (MeOH, $c = 0.13$); UV λ_{max} nm MeOH (log ε) 346 (3.90), 267 (4.18); (MeOH + $AlCl_3$) 398 (4.34), 350 (4.62), 267 (4.75); (MeOH + $AlCl_3$ + HCl) 396 (4.50), 341 (4.28), 302 (3.63), 274 (4.55); ^{1}H NMR spectral data (DMSO-d_6, 200 MHz) δ 5.40 (1H, *d*, $J = 7.3$ Hz, H-1″), 6.13 (1H, *br s*, H-6), 6.38 (1H, *br. s*, H-8), 6.91 (1H, *d*, $J = 8.3$ Hz, H-5′), 7.84 (1H, *dd*, $J = 8.3$, 2.0 Hz, H-6′), 7.96 (1H, *d*, $J = 2.0$ Hz, H-2′); ^{1}H NMR (CD_3OD, 200 MHz) δ 3.55 (1H, *m*, H-5″), 3.59 (1H, *m*, H-3″), 3.64 (1H, *m*, H-6″a), 3.72 (1H, *m*, H-2″), 3.77 (1H, *m*, H-6″b), 3.90 (1H, *m*, H-4″), 5.25 (1H, *d*, $J = 7.3$ Hz, H-1″), 6.24 (1H, *br. s*, H-6); 6.45 (1H, *br s*, H-8), 7.00 (1H, *d*, $J = 8.1$ Hz, H-5′), 7.87 (1H, *dd*, $J = 8.1$, 1.9 Hz, H-6′), 8.31 (1H, *d*, $J = 1.9$ Hz, H-2′); ^{13}C NMR data see Table 1; FABMS (negative mode) *m/z* 565 $[M + Na–H]^-$, 543 $[M–H]^-$, 463 [M–H–80]$^-$, 301 [M–H–162]$^-$; Elemental analysis: Found: C 46.19% H 3.79% S 5.96%, requires: C 46.33 H 3.70 S 5.89.

3.5. Bracteoside (*2*)

Pale yellow solid; $[\alpha]_D^{20}$ −42.3° (MeOH, $c = 0.10$); UV λ_{max} nm MeOH (log ε) 248 (*sh*, 3.65), 263 (4.24), 317 (*sh*, 3.22), 352 (3.74); (MeOH + $AlCl_3$) 265 (4.44), 298 (*sh*, 3.08), 354 (3.70), 398 (4.10); (MeOH + $AlCl_3$ + HCl) 266 (4.56), 298 (*sh*, 3.28), 352 (3.92), 398 (4.08); ^{1}H NMR spectral data (CD_3OD, 200 MHz) δ 3.35 (1H, *m*, H-2″), 3.40 (1H, *m*, H-3″), 3.46 (1H, *m*, H-4″), 3.68 (1H, *m*, H-5″), 3.79 (3H, *s*, 3-OCH_3) 5.15 (1H, *d*, $J = 7.2$ Hz, H-1″), 6.48 (1H, *d*, $J = 1.9$ Hz, H-6), 6.78 (1H, *d*, $J = 1.9$ Hz, H-8), 6.92 (2H, *d*, $J = 8.8$ Hz, H-2′, H-6′), 8.02 (2H, *d*, $J = 8.8$ Hz, H-3′, H-5′); ^{13}C NMR data see Table 1; FABMS (negative mode) *m/z* 475 $[M–H]^-$, 299 M–H–176]$^-$; Elemental analysis: Found: C 55.62%, H 4.11%, requires: C 55.47, H 4.23.

3.6. Known compounds

3.6.1. β-Sitosterol-3-glucoside

^{13}C NMR data (py-d_5, 50 MHz) δ 140.6 (C-5), 123.8 (C-6), 102.5 (C-1′), 78.5 (C-3′, C-5′), 78.1 (C-3), 75.3 (C-2′), 71.7 (C-4′), 62.8 (C-6′), 56.8 (C-14), 56.2 (C-17), 50.3 (C-9), 46.0 (C-24), 42.4 (C-13), 39.9 (C-12), 39.3 (C-4), 37.5 (C-1), 36.9 (C-10), 36.4 (C-20), 34.2 (C-22), 32.2 (C-8), 32.0 (C-7), 30.0 (C-2), 29.4 (C-25), 28.5 (C-16), 26.3 (C-23), 24.5 (C-15), 23.4 (C-28), 21.3 (C-11), 20.0 (C-27), 19.4 (C-19), 19.2 (C-26), 19.0 (C-21), 12.2 (C-29), 12.0 (C-18).

3.6.2. Jacein

^{13}C NMR data (DMSO-d_6, 50 MHz) δ 178.4 (C-4), 156.5 (C-2), 156.1 (C-7), 152.1 (C-9), 151.3 (C-5), 150.0 (C-4′), 147.6 (C-3′), 137.8 (C-3), 132.2 (C-6), 122.4 (C-6′), 120.8 (C-1′), 115.7 (C-5′), 112.1 (C-2′), 106.3 (C-10), 100.3 (C-1″), 94.5 (C-8), 77.5 (C-2″), 76.8 (C-3″), 73.3 (C-4″), 69.7 (C-5″), 60.7 (C-6″), 60.4 (6-OMe), 59.8 (3-OMe), 55.8 (3′-OMe).

3.6.3. Jaceidin

^{13}C NMR data (DMSO-d_6, 50 MHz) δ 178.2 (C-4), 157.4 (C-7), 155.5 (C-2), 152.3 (C-5), 151.6 (C-9), 149.8 (C-4′), 147.5 (C-3′), 137.4 (C-3), 131.2 (C-6), 122.2 (C-6′), 120.8 (C-1′), 115.6 (C-5′), 112.0 (C-2′), 104.6 (C-10), 94.1 (C-8), 60.0 (6-OMe), 59.7 (3-OMe), 55.7 (3′-OMe).

3.6.4. Luteolin

^{13}C NMR data (DMSO-d_6, 50 MHz) δ 181.7 (C-4), 164.2 (C-7), 163.9 (C-2), 161.5 (C-5), 157.3 (C-9), 149.7 (C-4′), 145.8 (C-3′), 121.5 (C-1′), 119.0 (C-6′), 116.0 (C-5′), 113.4 (C-2′), 103.7 (C-10), 102.9 (C-3), 98.8 (C-6), 93.8 (C-8).

3.6.5. 5-Caffeoylquinic acid

^{1}H NMR spectral data (DMSO-d_6, 200 MHz) δ 1.86 (4H, *m*, H-2, H-6), 3.86 (1H, *m*, H-4), 5.13 (1H, *m*, H-5), 6.21 (1H, *d*, $J = 15.6$ Hz, H-α), 6.72 (1H, *d*, $J = 8.3$ Hz, H-5′), 6.98 (1H, *m*, H-6′), 7.03 (1H, *br s*, H-2′), 7.43 (1H, *d*, $J = 15.6$ Hz, H-β).

Table 1
^{13}C NMR data for compounds **1** and **2** (50 MHz, in DMSO-d_6)[a]

[a] Multiplicities deduced by DEPT experiments.

3.6.6. Protocatechuic acid

^{13}C NMR data (CD_3OD, 50 MHz) δ 170.3 (-COOH), 151.5 (C-4), 146.0 (C-3), 123.9 (C-6), 123.0 (C-1), 117.7 (C-5), 115.8 (C-2).

3.6.7. Axillarin 7-glucoside

^{13}C NMR data (DMSO-d_6, 50 MHz) δ 178.3 (C-4), 156.4 (C-7), 152.1 (C-5), 151.3 (C-2), 148.9 (C-4′), 145.2 (C-3′), 137.6 (C-3), 132.2 (C-6), 120.7 (C-1′), 120.6 (C-6′), 115.7 (C-2′, C-5′), 106.2 (C-10), 100.1 (C-1″), 94.1 (C-8), 77.2 (C-5″), 76.7 (C-3″), 73.2 (C-2″), 69.6 (C-4″), 60.7 (C-6″), 60.3 (6-OMe), 59.7 (3-OMe).

3.6.8. Axillarin

^{13}C NMR data (CD_3OD, 50 MHz) δ 180.3 (C-4), 158.7 (C-7), 158.1 (C-2), 153.8 (C-5), 150.0 (C-4′), 146.5 (C-3′), 139.2 (C-3), 132.6 (C-6), 122.9 (C-1′), 122.4 (C-6′), 116.5 (C-5′), 105.3 (C-10), 95.0 (C-8), 61.0 (6-OMe), 60.5 (3-OMe).

3.6.9. Nepetin

^{13}C NMR data (CD_3OD, 50 MHz) δ 3.88 (3H, *s*, 6-OMe), 6.56 (1H, *s*, H-8)), 6.90 (1H, *d*, J = 8.3 Hz, H-5′), 7.38 (1H, *s*, H-3), 7.40 (1H, *br dd*, J = 8.3 Hz, H), 7.63 (1H, *d*, J = 1.9 Hz).

3.6.10. Centaureidin

^{13}C NMR data (CD_3OD, 50 MHz) δ 180.3 (C-4), 158.9 (C-7), 157.6 (C-2), 153.8 (C-9), 153.7 (C-5), 151.7 (C-4′), 147.6 (C-3′), 139.5 (C-3), 132.6 (C-6), 124.2 (C-1′), 122.1 (C-6′), 116.2 (C-2′), 112.3 (C-5′), 106.3 (C-10), 95.0 (C-8), 61.0 (6-OMe), 60.6 (3-OMe), 56.4 (4′-OMe).

3.6.11. Isokaempferide

^{1}H NMR spectral data (CD_3OD, 200 MHz) δ 3.78 (3H, *s*, 3-OMe), 6.21 (1H, *d*, J = 2.2 Hz, H-6), 6.42 (1 H, *d*, J = 2.2 Hz, H-8), 6.93 (2H, *d*, J = 8.8 Hz, H-3′ and H5′), 8.00 (2H, *d*, J = 8.8 Hz, H-2′ and H6′).

3.6.12. Hispidulin

^{13}C NMR data (CD_3OD, 50 MHz) δ 184.2 (C-4), 166.4 (C-2), 162.7 (C-7 and C4′), 160.0 (C-9), 153.8 (C-5), 132.4 (C-6), 129.5 (C-2′ and C-6′), 123.3 (C-1′), 117.1 (C-3′ and C-5′), 105.3 (C-10), 103.3 (C-3), 95.7 (C-8), 61.0 (6-OMe).

3.6.13. Caffeic acid

^{1}H NMR spectral data (CD_3OD, 200 MHz) δ 6.22 (1H, *d*, J = 15.6, H-8), 6.77 (1H, *d*, J = 8.2 Hz, H-5), 6.94 (1H, *dd*, J = 8.2 and 2.0Hz, H-6), 7.03 (1H, *d*, J = 2.0 Hz, H-2), 7.51 (1H, *d*, J = 15.6 Hz, H-7).

3.6.14. 6-Hydroxyluteolin-6,4′-dimethylether

^{1}H NMR spectral data (CD_3OD, 200 MHz) δ 3.89 (3H, *s*, 6-OMe), 3.97 (3H, *s*, 4′-OMe), 6.59 (1H, *s*, H-8), 6.65 (1H, *s*, H-3), 6.94 (1H, *d*, J = 7.8 Hz, H-5′), 7.50 (2H, *m*, 6′ and H2′).

3.6.15. Apigenin 7-glucuronide

^{13}C NMR data (DMSO-d_6, 50 MHz) δ 182.0 (C-4), 171.1 (C-6″), 164.3 (C-2), 162.7 (C-7 and C-4′), 161.4 (C-5), 156.9 (C-9), 128.6 (C-2′ and C6′), 120.9 (C-1′), 116.0 (C-3′ and C5′), 105.4 (C-10), 103.1 (C-3), 99.4 (C-6), 94.7 (C-8), 75.9 (C-5″), 75.0 (C-3″), 73.2 (C-2″), 71.5 (C-4″).

3.6.16. 3,4-Dicaffeoylquinic acid

Abstract

A phytochemical investigation of the extracts obtained from bulbs of leek, *Allium porrum* L. has led to the isolation of five flavonoid glycosides based on the kaempferol aglycone. Two of them are new compounds and have been identified as kaempferol 3-*O*-[2-*O*-(*trans*-3-methoxy-4-hydroxycinnamoyl)-β-D-galactopyranosyl]-(1→4)-*O*-β-D-glucopyranoside, and kaempferol 3-*O*-[2-*O*-(*trans*-3-methoxy-4-hydroxycinnamoyl)-β-D-glucopyranosyl]-(1→6)-*O*-β-D-glucopyranoside, on the basis of spectroscopic methods, including 2D NMR. The isolated compounds have been evaluated for their human platelet anti-aggregation activity. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Allium porrum*; Alliaceae; Leek; Flavonoids; Kaempferol glycosides; NMR spectroscopy

1. Introduction

Plants of the genus *Allium* have been recognized as rich sources of secondary metabolites endowed with interesting biological activities (Augusti, 1990; Block, 1992). As a part of a systematic phytochemical study on Mediterranean *Allium* species, we have recently obtained a number of new kaempferol glycosides from the wild garlic, *A. ursinum* L. (Carotenuto et al., 1996), and from the ornamental garlic, *A. neapolitanum* Cyr (Carotenuto et al., 1997), this latter plant also contained some quercetin and isorhamnetin glycosides. We have now continued this investigation by examining the flavonoid glycosides of leek, *A. porrum* L. (Alliaceae). Although this plant is widely distributed and commonly used as a food, no systematic evaluation of its flavonoid composition has been reported yet. Herein we describe the isolation from bulbs of leek of five flavonol glycosides, two of which, based on a kaempferol aglycone and acylated with a 3-methoxy-4-hydroxycinnamoyl moiety, are new products.

All the isolated compounds have been evaluated for their inhibitory activity on human platelet aggregation, an action already evidenced for kaempferol (Landolfi et al., 1984). In particular, kaempferol has been reported to inhibit markedly (IC_{50} 20 μM) platelet aggregation and ATP release of platelets induced by arachidonic acid or collagen. In addition, kaempferol also acts as a thromboxane receptor antagonist, and it has been claimed as an active agent in the prevention of atherosclerosis and acute platelet thrombus formation (Tzeng et al., 1991).

2. Results and discussion

Plants of *Allium porrum* L. were collected near Benevento (Campania, Italy), during September 1999. The fresh bulbs (988 g) were extracted at room temperature with *n*-hexane, $CHCl_3$, $CHCl_3$/MeOH 9:1, and then MeOH, in sequence. The *n*-butanol soluble material of the methanol extract was subjected to repeated chromatographic separations on reverse-phase silica gel to yield the flavonol glycosides **1**–**5** in the pure state. The structures of the known compounds **1**–**3** have been assigned on the basis of their mass, UV and ^1H NMR

spectral data in comparison with data reported in the literature. In particular, astragaline (**1**) and kaempferol-3-*O*-neohesperidoside (**2**) have been isolated from several sources comprising also some species of Alliaceae (Nakano et al., 1981), whereas compound **3** has been reported only as constituent of *Quercus suber* (Cupuliferae) (Romussi et al., 1991) and *Eryngium campestre* (Saniculoideae) (Hohmann et al., 1997).

The new compound **4**, a yellow powder with $[\alpha]_D^{25} = -9°$ (MeOH; *c* 0.02), gave a deprotonated molecule at *m/z* 785.2015 $(M-H)^-$ in the negative-ion high-resolution FAB mass spectrum consistent with the molecular formula $C_{37}H_{38}O_{19}$ (calcd. *m/z* 785.2007). The UV spectrum of **4** (Table 1) showed the characteristic absorptions of a kaempferol substituted at position 3, as indicated by the bathochromic shifts after addition of diagnostic reagents (Mabry et al., 1970). The ^1H and ^{13}C NMR spectra confirmed this structural hypothesis (Table 2) and also revealed that two sugar residues and a cinnamoyl-like subunit should account for the remaining atoms implied from the molecular formula. The combined analysis of these spectra was greatly aided by interpretation of 2D HMQC and HMBC data, allowing $^1J_{C\text{-}H}$ and $^{2,3}J_{C\text{-}H}$ connections, respectively.

In particular, the ^1H NMR signals of a *trans* olefinic double bond (δ 7.67 and 6.39, $J = 15.8$ Hz) conjugated with an aromatic ring system (two coupled doublets at δ 7.09 and 6.81, one singlet at δ 7.19), a methoxy singlet at δ 3.90, and the relevant ^{13}C NMR signals (Table 2) well fitted with data reported in the literature (Carotenuto et al., 1996) for a 3-methoxy-4-hydroxy-*trans*-cinnamoyl (feruloyl) moiety. The location of the methoxy group at position 6^{IV} was secured by the ROESY coupling between H_3-10^{IV} and H-5^{IV} (δ 7.19).

Going on, two anomeric proton signals at δ 4.69 and 5.17 were identified in the ^1H NMR spectrum, and associated with the relevant anomeric carbons (δ 102.8 and 104.3, respectively) through the 2D HMQC spectrum. The large coupling constants of the above protons (Table 2) indicated a β-configuration for both monosaccharides.

When the anomeric proton at δ 5.17 (H-1″) was used as a starting point, analysis of COSY and HOHAHA spectra allowed the identification, in sequence, of four oxymethine and one oxymethylene group (see Table 2). The sugar was identified as β-glucopyranose on the basis of the large coupling constants observed for all the oxymethine protons, implying their axial-axial relationship. In addition, the ROESY couplings of H-1″ with H-3″ and H-5″ and of H-2″ with H-4″ further supported this conclusion. Starting from the anomeric signal at δ 4.69 (H-1‴) we could identify, on the basis of COSY and HOHAHA data, the sequence of another hexose unit extending up to an oxymethylene residue via four oxymethine protons. The relative stereochemistry of this monosaccharide unit was elucidated by the analysis of coupling constants in the ^1H NMR spectrum. In particular, this sugar unit was characterized by large axial-axial couplings H-1‴/H-2‴, H-2‴/H-3‴, while the axial-equatorial relations H-3‴/H-4‴, H-4‴/H-5‴ were deduced by the small coupling constants between these protons. These data and the ROESY correlation peak between H-3‴ and H-5‴ were in accordance with the β-galactopyranose nature of this sugar. Finally, the relative

downfield shift of H-2‴ (δ 4.88) appeared in accordance with an acylation at this position, thus suggesting the *trans*-feruloyl linkage site.

In order to confirm the nature of the sugar residue, compound **4** (2 mg) was subjected to acid methanolysis followed by silylation with trisil-Z. The GC analysis of the released saccharides revealed the presence of glucose and galactose in the ratio 1:1.

The HMBC spectrum was used in order to unambiguously interconnect the above determined four substructures. It showed a correlation between the proton at δ 5.17 (H-1″) and C-3 (δ 134.5), indicating the linkage site of β-glucose to the aglycone. In addition, the HMBC correlation between the proton at δ 4.69 (H-1‴) and C-4″ (δ 80.0), and the ROESY coupling of H-1‴ with H-4″ both indicated C-4″ as the interglycosidic linkage position. Finally, the HMBC cross peak between H-2‴ and C-1^{IV} (δ 162.2) unambiguously confirmed that the feruloyl moiety is linked to the position 2 of the galactose. If we assume that both sugars belong to the commonly found D-series, the chemical structure of **4** is defined as kaempferol 3-*O*-[2-*O*-(*trans*-3-methoxy-4-hydroxycinnamoyl)-β-D-galactopyranosyl]-(1→4)-*O*-β-D-glucopyranoside.

Compound **5**, yellow powder $[\alpha]_D^{25} = -13^\circ$ (MeOH; *c* 0.02), gave a deprotonated molecule at *m*/*z* 785.2000 $(M-H)^-$ in the negative-ion high-resolution FAB mass spectrum, consistent with the same molecular formula of **4** ($C_{37}H_{38}O_{19}$). The close structural relationship of these two compounds was also evident by their ^1H and ^{13}C NMR spectra, showing virtually identical resonances for both the aglycone and the 3-methoxy-4-hydroxy cinnamoyl moiety. The UV spectrum of **5** (Table 1), that

[a] Overlapped with other signals.

showed characteristic absorption bands for a kaempferol substituted at position 3, confirmed this similarity.

Also in the case of **5** two monosaccharide units constitute the sugar portion, as indicated by two anomeric proton signals at δ 4.75 and 5.14 in the ^{1}H NMR spectrum, correlated with the relevant anomeric carbons (δ 102.8 and 104.5, respectively) through the HMQC spectrum. In particular, the ^{1}H and ^{13}C NMR data (Table 2) indicated that the inner sugar was unchanged. The second one, whose anomeric proton signal resonates at δ 4.75, was identified as a further β-glucopyranose due to the large value of the vicinal coupling constants interrelating all the oxymethine protons, arranged in sequence through COSY and HOHAHA experiments. Also in this case, the chemical shift of H-2‴ at relatively low field (δ 4.82) clearly pointed to the acylation site at this position.

As for compound **4**, the nature of the sugar portion of **5** was confirmed by GC analysis of the persilyl methylsaccharides obtained by methanolysis followed by treatment with trisil Z.

The HMBC spectrum, showing cross-peaks of H-1″ with C-3 (δ 134.0), and of H-2‴ with C-1^{IV} (δ 163.1), allowed an unambiguous connection among the deduced substructures. Furthermore, the key HMBC cross peak of C-1‴ (δ 102.8) with H_2-6″ (δ 4.25 and 3.92) defined the interglycosydic linkage site, which was also confirmed by the ROESY coupling of H-1‴ with H_2-6″. Compound **5** was therefore defined as kaempferol 3-*O*-[2-*O*-(*trans*-3-methoxy-4-hydroxycinnamoyl)-β-D-glucopyranosyl]-(1→6)-*O*-β-D-glucopyranoside.

The isolated compounds (**1**–**5**) were evaluated for their inhibitory activity on platelet aggregation induced by ADP. Compounds **1** and **2**, at a concentration of 10^{-3} M, were the only active inhibitors of platelet response to collagen (percentage of aggregation: control, 45.13 + 1.56%; reference compound kaempferol, 10.12 + 0.63%; compound **1**, 12.54 + 1.56%; compound **2** 20.35 + 0.83%). Compounds **3**–**5**, in the same conditions, showed no significant activity. This result is in agreement with our previous finding (Carotenuto et al., 1996) that the presence of a cinnamoyl esterification consistently lowers the in vitro anti-aggregating activity of the flavonoid glycosides. However, it should be noted that these results could be not strictly related to the in vivo activity, since this is greatly affected by absorption and metabolism. In particular, some metabolic reactions (hydrolysis, deacylation, etc.) could improve the anti-aggregating activity of the isolated kaempferol glycosides and acylated glycosides.

3. Experimental section

3.1. General experimental procedure

FABMS (recorded in glycerol matrix) were measured on a VG Prospec (FISONS) mass spectrometer (CsI ions). Optical rotations were determined on a Perkin-Elmer 192 polarimeter equipped with a sodium lamp (589 nm) and a 10-cm microcell. ^{1}H and ^{13}C NMR spectra were recorded at 500 and 125 MHz, respectively, on a Bruker AMX-500 spectrometer. Chemical shifts were referenced to the residual solvent signal (CD_3OD: $\delta_H = 3.34$, $\delta_C = 49.0$). The multiplicities of ^{13}C resonances were determined by DEPT experiments. ^{1}H connectivities were determined by using COSY and HOHAHA experiments. The 2D HOHAHA experiments were performed in the phase-sensitive mode (TPPI) using the MLEV-17 (mixing time 125 ms) sequence for mixing. One-bond heteronuclear ^{1}H-^{13}C connectivities were determined with 2D HMQC experiments with a BIRD pulse sequence followed by a delay of 0.5 s before each scan to suppress the signal from proton not directly bonded to ^{13}C. The interpulse delays were adjusted for an average ($^1J_{CH}$ of 125 Hz). Two- and three-bond heteronuclear ^{1}H–^{13}C connectivities were determined with 2D HMBC experiments optimized for a $^{2,3}J_{CH}$ of 8 Hz. Nuclear Overhauser effect (NOE) measurements were performed by 2D ROESY experiments. MPLC purification was performed on a Büchi 861 apparatus. HPLC in isocratic mode was performed on a Varian apparatus equipped with RI-3 refractive index detector and μ-Bondapack C18 columns.

3.2. Extraction and isolation

Plants of *Allium porrum* L. (1.6 kg) were collected near Benevento (Italy) in September 1999. The sample was sown about 6 months before its collection. Reference specimens have been deposited at the Dipartimento di Chimica delle Sostanze Naturali, Università di Napoli Federico II, Italy, with the voucher number 2025. The fresh bulbs (988 g) were air-dried immediately after collection, under controlled temperature (22°C) and without exposure to the light. They were chopped and then exhaustively extracted (79 g, dry weight after extraction) at room temperature with the following solvents: *n*-hexane, $CHCl_3$,$CHCl_3$/MeOH (9:1), and MeOH. Each extraction was repeated four times using 500 ml of solvent, under stirring. The *n*-butanol soluble material of the MeOH extract was concentrated in vacuo to afford a crude extract (5.5 g) which was subjected to silica RP-18 MPLC (gradient solvent system from H_2O to MeOH). Fractions eluted with H_2O/MeOH 3:7 (181 mg) were separated by preparative RP HPLC [μ-Bondapack C18 (7.8 × 300 mm) column, H_2O/MeOH 1:1] to obtain pure astragaline (**1**, 15.1 mg) and kaempferol-3-*O*-neohesperidoside (**2,** 8.8 mg). Fractions eluted with H_2O/MeOH 2:8 (147 mg) were separated by preparative RP HPLC [eluent H_2O/MeOH 6:4] thus obtaining pure compound **3** (5.5 mg) and crude compounds **4** and **5**. Consequently, the former was isolated carefully by analytical RP HPLC [μ-Bondapack C18 (3.9×300 mm) column, H_2O/MeOH 6:4] to yield pure compound **4** (8.1

mg). The latter was subjected to the same purification procedure which afforded 6.5 mg of pure compound **5**.

3.3. Kaempferol 3-O-[2-O-(trans-3-methoxy-4-hydroxy cinnamoyl)]-β-D-galactopyranosyl-(1→4)-O-β-D-glucopyranoside (**4**)

Yellow amorphous solid. $[\alpha]_D^{25} = -9°$ (MeOH; *c* 0.02); UV spectra: see Table 1; ^{1}H NMR and ^{13}C NMR spectra: see Table 2; FABMS (negative ion): *m/z* 785 (100), 285 (30) [M-H]$^-$. HR-FABMS (negative ion): *m/z* 785.2015 [M-H]$^-$, calcd. for $C_{37}H_{37}O_{19}$ *m/z* 785.2007.

3.4. Kaempferol 3-O-[2-O-(trans-3-methoxy-4-hydroxy-cinnamoyl)]-β-D-glucopyranosyl-(1→6)-O-β-D-glucopyranoside (**5**)

Yellow amorphous solid. $[\alpha]_D^{25} = -13°$ (MeOH; *c* 0.02); UV spectra: see Table 1; ^{1}H NMR and ^{13}C NMR spectra: see Table 2; FABMS (negative ion): *m/z* 785 (100), 285 (26) [M-H]$^-$. HR-FABMS (negative ion) *m/z* 785.2000 [M-H]$^-$, calcd. for $C_{37}H_{37}O_{19}$ *m/z* 785.2007.

3.5. Methanolysis and sugar analysis

A solution of **4** (2 mg) in anhydrous 2 M HCl–MeOH (0.5 ml) was heated at 80°C in a stoppered reaction vial for 8 h. Once cooled, the reaction mixture was neutralized with Ag_2CO_3, centrifuged and the supernatant evaporated to dryness. The residue was treated with TRISIL Z for 15 min at room temp. GLC analysis (Hewlett-Packard 5890, 25 m, SBB-I; column temp. 140°C, injector temp. 200°C; helium carrier flow 10 ml/min) gave peaks that co-eluted with those of authentic methyltrisilglucoside [R_t (min): 37.6 and 42.8 (1 mol)] and methyltrisilgalactoside [R_t (min): 28.2 and 33.4 (1 mol)]. By repeating the same analysis for compound **5** (2 mg), only the peaks of methyltrisilglucoside were obtained.

3.6. Platelet anti-aggregation test

Blood (20 ml) was withdrawn by cardiac puncture from rats into plastic syringes containing 1/10 vol. of 3.8% sodium citrate and mixed immediately. Platelet-rich plasma (PRP) was prepared by centrifugation of the anti coagulated blood at 250 × *g* for 10 min. Platelet-poor plasma (PPP) was obtained from centrifugation of the residue at 650 × *g* for 10 min. All procedures were performed at room temperature. Platelet aggregation was monitored in an Elvi Pyton (Born) light transmission aggregometer. PPP was used to adjust to 100% transmittance. For all experiments 250 μl of PRP and 5 μl of the aqueous test samples solutions, or vehicle, were left in contact at room temp., for 10 min. Then, they were incubated at 37°C for 1 min with stirring and ADP (10 μg/ml) was added as aggregating agent. Results obtained were analyzed by ANOVA one-way followed by Dunnett's test for multiple comparison; a value of $P < 0.05$ was taken as significant.

Received 7 November 2000; received in revised form 12 March 2001

Abstract

Three flavones, 5,7-dihydroxy-2′,3′,4′,5′-tetramethoxyflavone, 5,4′-dihydroxy-7,2′,3′,5′-tetramethoxyflavone, and 5,7,4′-trihydroxy-2′,3′,5′ -trimethoxyflavone were isolated from the leaf exudate of *Psiadia punctulata*, together with the previously reported 5-hydroxy-7,2′,3′,4′,5′-pentamethoxyflavone and 5,7,3′-trihydroxy-2′,4′,5′-trimethoxyflavone. The two phenylpropenoids, *Z*-docosyl-*p*-coumarate and *E*-docosyl-*p*-coumarate were also isolated. The structures were determined on the basis of spectroscopic evidence.

1. Introduction

The leaves of *Psiadia punctulata* (DC) Vatke are extensively covered by an exudate, especially when young. The exudate is most likely responsible for the unpalatability (to herbivores) and drought resistance (as we have observed) which is exhibited by this shrub, in a manner comparable to that described for *Larrea* spp. (Rhoades, 1977). The chemistry of the exudate could also explain the use of the species for relief of fever and abdominal pains (Kokwaro, 1976) as well as its use for expunging ectoparasites from cattle (Beentje, 1994).

In an earlier communication we described the presence of kaurene and trachyloban diterpenes in the exudate (Midiwo et al., 1997). We compared these metabolites with the diterpenes reported from *P. arabica* Jaub and Spach, with which *P. punctulata* is sometimes confused (Abou-Zaid et al., 1991), and suggested that there were differences which could be used to delineate them as distinct taxa.

Plant leaf exudates are known to most often contain mixtures of terpenoids and non-polar flavonoids (Wollenweber, 1988). In this paper we report on the isolation and characterisation of five flavones, three of which are new, along with two geometrically isomeric phenylpropenoid docosyl esters, one of which has not been reported before.

2. Results and discussion

Fresh leaves of *P. punctulata* were dipped in ethyl acetate for short periods (ca. 20 s) providing a gummy extract on removal of solvent. We have established (see Experimental) that the average exudate to dry leaf weight is about 1:4. TLC analysis of the extract revealed seven major spots of phenolic nature (254 nm UV light, ferric chloride spray reagent). Silica gel chromatography led to the successful isolation and characterization of five flavones and two phenylpropenoids.

The first compound (**1**) characterised was a flavone. The presence of the flavone moiety was deduced from the UV (λ_{max} 270 and 362 nm), ^{1}H NMR (δ 7.10 for H-3) and ^{13}C NMR (δ 162.7 for C-2, 110.6 for C-3 and 183.3 for C-4) spectra. The ^{1}H NMR spectrum also indicated the presence of a chelated hydroxyl, a free hydroxyl, meta-coupled H-6 and H-8 protons, a single B-ring proton and four methoxyl substituents. In the EIMS, the molecular ion was established as 374 ($C_{19}H_{18}O_8$), and a fragment ion appearing at m/z 153 derived from retro-Diels–Alder fragmentation (Mossa et al., 1992), suggested the presence of two hydroxy groups in ring A, at C-5 and C-7. The four methoxyl

7

groups must therefore be placed in ring B, at positions C-2′,-3′,-4′, and -5′. The ^{13}C NMR resonances for the methoxyl carbons (Table 1) confirmed that three were di-*ortho* substituted (resonances > 59.5 ppm) while one had a free *ortho* position (resonance < 58.5 ppm) (Panichpol and Waterman, 1978). In a NOESY experiment the singlet at δ 7.22 (H-6′) was observed to interact with the methoxyl resonance at δ 3.84. On these grounds and comparison with data for 5-hydroxy-7,2′,3′,4′,5′-pentamethoxyflavone (**2**) (Mossa et al., 1992), compound **1** was identified as 5,7-dihydroxy-2′,3′,4′,5′-tetramethoxyflavone.

A second flavone (**3**) was similar to compound **1**, the NMR spectra indicating a tetramethoxyflavone with the same substitution pattern and with EIMS showing M^+ again at 374. However, the EIMS of this compound revealed that it had a methoxyl and a hydroxyl group in ring-A due to the presence of a fragment ion at *m/z* 167, with the hydroxyl group being placed at C-5 (chelated proton at δ 12.78 in the ^1H NMR spectrum). The ^{13}C NMR spectrum indicated the same B-ring oxygenation pattern as in **1** with the chemical shift for the ring-B methoxyls (δ 61.4, 61.3, 56.3 and 56.0) indicating that two of them were di-*ortho* substituted. Thus it was concluded the C-5′ was methoxylated with C-2′, C-3′ and C-4′ bearing two methoxyls and one hydroxyl. This hydroxyl group was deduced to be at the 4′-position because of the 40 nm shift in band I in the UV spectrum on addition of NaOH (Markham, 1982). This requires that compound **3** was 5,4′-dihydroxy-7,2′,3′,5′-tetramethoxyflavone. This assertion was confirmed by NOE interactions between the 4′-hydroxyl proton and two methoxy methyls (δ 3.86 and 4.02) and between one methoxyl (δ 3.89) and H-6 and H-8 and one methoxyl (δ 3.86) and H-6′.

The third flavone (**4**) showed the same oxygenation pattern but with only three methoxyl substituents. The EIMS indicated M^+ at 360 ($C_{18}H_{16}O_8$), with a fragment at *m/z* 153 which places two hydroxyl groups on ring A. The presence of hydroxyl groups at C-5 and C-7 were established by observation of bathochromic shifts for band I at 326 nm on addition of $AlCl_3$ (no change with HCl) and a NaOAc shift of bands II, respectively. This leaves three methoxyls and a further hydroxy group in ring B. The spectroscopic evidence (Experimental and Table 1) indicated that its ring B was identical to that of compound **3**. Compound **4** was therefore designated as 5,7,4′-trihydroxy-2′,3′,5′-trimethoxyflavone.

The other flavones isolated from this exudate were shown to be 5-hydroxy-7,2′,3′,4′,5′-pentamethoxyflavone (**2**) and 5,7,3′-trihydroxy-2′,4′,5′-trimethoxyflavone (**5**) which had previously been isolated from *P. arabica* (El-Feraly et al., 1990; Mossa et al., 1992).

The complexity of the non-polar flavone profile in the *P. punctulata* exudate is much less than that in *P. arabica*. Furthermore the *P. punctulata* flavones appear to be exclusively B-ring tetra-oxygenated while for *P. arabica*

[b,c,d] Values in the same column are interchangeable.

examples are observed of mono-, di-, tri- and tetra-oxygenation in this ring (Abou-Zaid et al., 1991). The differences in flavonoid composition sets the two taxa apart in the same manner as the diterpenoid disparities already noted. Therefore their proposed synonymy (Abou-Zaid et al., 1991) may not be correct.

Together with the flavones two isomeric *p*-coumarate esters were isolated. Compound **6** was identified as E-docosyl *p*-coumarate which is already known from the stems of *Bauhinia manca* (Achenbach et al., 1986). Compound **7** had similar characteristics to **6** and was shown to be its *Z*-isomer, which seems to be reported here for the first time. While the main components of aerial exudates are non-polar flavonoids and terpenes these two non-polar esters indicate that they are sometimes other minor components of the hydrophobic external exudate.

3. Experimental

3.1. General

Mps: uncorr. Analytical TLC: Merck pre-coated silica gel 60 F_{254} plates. CC on silica gel 60 (70–230 mesh). EIMS: direct inlet, 70 eV. ^{1}H NMR (500 MHz) and ^{13}C NMR (125 MHz) were run on a DRX-500 (Brüker) spectrometer using solvent resonances to calibrate the spectra.

3.2. Plant material

The material used and vouchers have been described previously (Midiwo et al., 1997).

3.3. Extraction

Extraction with ethyl acetate was done as previously described (Midiwo et. al., 1997) to give 494 g of exudate from aerial parts which when dried weighed 1700 g. The crude extract (100 g) was adsorbed onto silica gel (100 g) and added to a silica gel (500 g) column under *n*-hexane. Elution was achieved with *n*-hexane/CH_2Cl_2/MeOH mixtures of increasing polarity to give **1** (2.2 g), **2** (2.0 g), **3** (58 mg), **4** (10 mg), **5** (130 mg), **6** (267 mg), **7** (60 mg).

3.4. Physical and spectral data of isolated compounds

Received 4 August 2000; received in revised form 24 October 2000

Abstract

A flavonoid trioside and its coumaryl ester together with seven known flavonoids and five phenolic acids were isolated from the leaves of *Reseda muricata*. Their structures were elucidated by spectroscopic methods including UV, FAB MS, ^{1}H, ^{13}C and 2D-NMR, DEPT, HMBC and HMQC experiments. The two compounds were identified as kaempferol 3-*O*-β-D-glucopyranosyl-(1‴ → 2″)-*O*-α-L-rhamnopyranoside 7-*O*-β-D-glucopyranoside and kaempferol 3-*O*-β-D-glucopyranosyl-(1‴ → 2″)-*O*-α-L rhamnopyranoside 7-*O*-β-D-(6‴-*O*-*E*-coumarylglucopyranoside), respectively. © 2001 Elsevier Science Ltd. Keywords: *Reseda muricata*; Resedaceae; Kaempferol trioside; Kaempferol coumaryltrioside; Flavones; Phenolic acids

1. Introduction

Reseda muricata C. Presl., a herb distributed in southeast Egypt, represents one of 6 genera and is one of some 75 species that comprise the family Resedaceae (Täckholm, 1974). The Resedaceae is a part of the phyletic group which also contains the Crucifereae and Capparidaceae (Rizk, 1986). Although very little information about *R. muricata* is reported (Rizk, 1986), earlier chemical screening of related *Reseda* species detected flavonoids and phenolic acids (Goris et al., 1961; Jacquin-Dubreuil, 1972; Pagani, 1983; Rizk, 1986), non-protein amino acids (Meier et al., 1979), glucosinolates (Olsen and Soerenson, 1979) and alkaloids (Nakhatov et al., 1977). Pharmacological studies of extracts of various *Reseda* species showed anti-inflammatory (Susplugas-Taillade et al., 1988; Susplugas et al., 1993) and antimicrobial (Watt and Breyer, 1962) activities. In traditional medicine, extracts of *R. muricata* are being used in external treatments of hemorrhoids and for stomach aches and diarrhea (Boulos, 1983). We here report the isolation and identification of two new compounds, the kaempferol trioside **1** and its *p*-coumaryl ester **2** together with twelve other known flavonoids and phenolic acids.

2. Results and discussion

The known compounds apigenin, luteolin, kaempferol and its 7-*O*-glucoside and 3-*O*-rhamnoside, quercetin and its 7-*O*- glucoside, as well as chlorogenic, ferulic, caffeic, coumaric and *p*-hydroxybenzoic acids were identified by comparison of their ^{1}H and ^{13}C NMR spectra with literature data. The UV spectra in methanol and with diagnostic reagents of the new compounds **1** and **2** were both in accord with 3,7-di-*O*-substituted flavonols (Mabry et al., 1970); for **2** an additional peak, which was observed at 315 nm in MeOH, is consistent with the presence of a coumaryl group (Markham, 1982). These findings were confirmed by acid hydrolysis; both compounds afforded kaempferol, glucose and rhamnose; in addition, **2** gave coumaric acid. The presence of the coumaryl group in **2** was also supported by ^{13}C DEPT experiments, which showed two methylene, one methyl, 27 methine and 12 quarternary carbons which, together with FAB MS, established a molecular formula for **2** of $C_{42}H_{46}O_{22}$. Compound **1** was subjected to mild hydrolysis and the intermediate known compound kaempferol

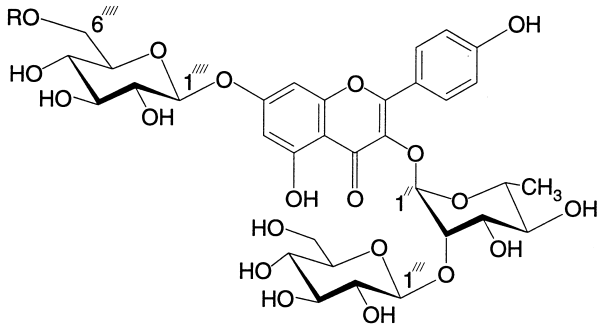
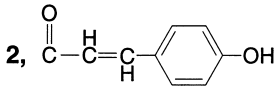
3-*O*-rhamnoside 7-*O*-glucoside was detected; this compound was also isolated from the plant. Attempts to obtain the intermediate diglycoside from **2** were unsuccessful.



1, R = H



2,

The ^{1}H NMR spectra of both new compounds **1** and **2** exhibited A and B ring signals typical for a kaempferol 3,7-diglycoside (Mabry et al., 1970), and signals for three anomeric protons of three sugar moieties were detected for both compounds: one for a 3-*O*-rhamnosyl at δ 5.58 for **1** and δ 5.6 for **2** both *d*, $J = 1.1$ Hz, a signal for the anomeric proton of a 7-*O*-glucosyl at δ 5.05 for **1** and δ 5.06 for **2**, both *d*, $J = 7.5$ Hz and a third signal typical for a glucosyl unit linked to one of the other sugars at δ 4.25 for **1** and δ 4.33 for **2**, both *d*, $J = 7.8$ Hz. In addition, **2** exhibited doublets at δ 6.18 and δ 7.43, both $J = 15.85$ Hz plus signals for four protons at δ 6.69 and δ 7.35 *d*, both $J = 8.7$ Hz, indicative of a *trans p*-coumaryl group (Nasr et al., 1986; Schaufelberger et al., 1987).

The remaining structural questions for both **1** and **2** concerned the position of attachment of the terminal glucosyl moiety and, for **2**, the position of attachment of the coumaryl group. For both **1** and **2** the second glucosyl was assigned to the 2″-position of the 3-*O*-rhamnosyl moiety since the rhamnosyl H-2″ signal was shifted downfield to δ 4.11 for **1** and δ 4.13 for **2** (*t*, $J = 3.29$, 1.28 Hz). This assignment was confirmed by ^{13}C NMR spectroscopic analyses which showed the C-2″ downfield at δ 81.8 for **1** and δ 81.43 for **2**. HMQC and HMBC experiments for both **1** and **2** established correlations between C-1″ at δ 100.39 with H-1″ at δ 5.60, C-1″ with H-2″ at δ 4.13, C-3 at 134.28 with H-1″, C-2″ with H-1‴ at δ 4.33, thus confirming for both **1** and **2** assignment of the terminal glucosyl to the C-2 position of the rhamnosyl moiety.

The coumaryl group in **2** was established by NMR and FAB MS. The ^{1}H NMR spectrum of **2** showed the two protons for one C-6 methylene glucosyl shifted downfield to δ 4.23 m, and δ 4.14 *dd* ($J = 12$, 2.5 Hz) confirming acylation at the C-6 position (Yoshida et al., 1987; Kim, 1998; Zahir et al., 1999; Liu et al., 1999). The ^{13}C NMR spectrum also showed that the carbons of one of the C-6 methylenes was shifted downfield to δ62.81 further confirming acylation at the 6-position of a glucosyl moiety (Bloor and Falshaw, 2000). The assignment of the coumaryl group to C-6 of the 7-*O*-glucosyl was confirmed by an HMBC experiment which showed a correlation between the C=O of the coumaryl ester and H-6 of the 7-*O*-glucosyl at δ 4.14; significantly, the C-1‴″ carbon is also correlated to the same H-6 (Bloor, 1999). In the FAB MS of **2** a molecular ion peak $[M-H]^{-1}$ was observed at *m*/*z* 901; in addition an ion for the loss of the terminal glucosyl but without loss of the coumaryl group appeared at *m*/*z* 739 [M-H- 162]$^-$, thus establishing that the coumaryl moiety must be attached to the 7-*O*-glucosyl substituent.

Based on all these data the structure of **1** was assigned as kaempferol 3-*O*-β-D-glucopyranosyl-(1‴ → 2″)-*O*-α-L-rhamnopyranoside 7-*O*-β-D-glucopyranoside and **2** as kaempferol 3-*O*-β-D-glucopyranosyl-(1‴ → 2″)-*O*-α-L-rhamnopyranoside 7-*O*-β-D-(6‴″-*O*-*E*-coumarylglucopyranoside). Both **1** and **2** are new compounds.

3. Experimental

3.1. Spectral data

^{1}H and ^{13}C NMR spectra were recorded on a 500 MHz Bruker AMX and/or a Varian Unity Inova with TMS as an internal standard and DMSO-d_6 as solvent. FAB mass spectra were obtained using a Finigan MAT TSQ 700 spectrometer while UV in MeOH were recorded using a Shimadzu UV 240 spectrophotometer.

3.2. Plant material

Aerial parts of *Reseda muricata* were collected in 1999 in the Wadi Valley on the Dahb-Sharm El-Shaikh Road 140 Km from Sharm in the South of Sinai. A voucher specimen has been deposited in the Desert Research Centre Herbarium, Cairo, Egypt.

3.3. Extraction and isolation of flavonoids and phenolic acids

The dried aerial parts of *Reseda muricata* (500 g) were extracted with 70% EtOH (2.5 l×3). The EtOH extract was evaporated under reduced pressure affording (120 g) of crude extract. The latter was extracted with $CHCl_3$ and the residue (80 g) was examined by two dimensional PPC using benzene:acetone:water BAW and 15% HOAc as developing systems. A part of the latter extract was subjected to successive PPC using Whatmann No. 3MM paper and BAW and 15% HOAc for elution. Final purification was effected with a Sephadex LH-20 column using MeOH–H_2O (1:1) as eluant.

3.4. Hydrolysis experiments

Mild acid hydrolysis was carried out by treating 2–3 mg with 0.1 N HCl at 100° C for 1 h. Aliquots were removed after 5, 10, 15 and 20 min and immediately examined by paper chromatography using BAW as the developing solvent and with authentic samples. The final aqueous acidic mixture was treated with EtOAc then the residue was neutralized for determination of the released sugar moieties. Complete acid hydrolysis was carried out using 2 N HCl in aqueous MeOH for 2 h at 100°C. The final hydrolysate was treated as in the mild hydrolysis procedure.

3.5. Kaempferol 3-O-β-D-glucopyranosyl-(1‴ → 2″)-O-α-L-rhamnopyranoside 7-O-β-D-glucopyranoside) (1)

Yellow amorphous powder (12 mg), soluble in H_2O and 70% EtOH. $R_f \times 100 = 22$ and 77 in BAW and 15% HOAc, respectively. It gave a brown color which changed to yellowish brown with ammonia vapor under UV light; it gave a dirty green color with $FeCl_3$. UV λ max MeOH: 269, 350+ $AlCl_3$, 274, 305sh, 359sh, 407; +HCl 265, 302sh; 356, 405; NaOMe 275, 304, 365; NaOAc 269, 395, 397; NaOAc+ H_3BO_3 267, 305sh, 352. FAB MS *m/z* 755 $[M-H]^-$, 593 $[M-H-162]^-$.

^{1}H NMR of **1** (DMSO-d_6): δ 7.8 (2H, *d*, $J = 8.8$ Hz, H-2′, 6′), 6.9 (2H, *d*, $J = 8.7$ Hz, H-3′, 5′). 6.7(*d*, $J = 2$ Hz, H-8), 6.4 (*d*, $J = 2$ Hz H-6), 5.58 (*d*, $J = 1.1$ Hz, rham–3 H-1‴), 5.05 (*d*, $J = 7.5$ Hz, *glc*-7 H-1⁗), 4.25 (*d*, $J = 7.8$ Hz, *glc* terminal H-1‴), 4.11 (*t*, $J = 3.29$, 1.28 Hz, rham-3 H-2″), 3.7 (2H, *dd*, $J = 10.7$, 2 Hz *glc*-7 H-6 *a,b*), 3.55 (2H *m*, *glc*-3 terminal H-6 *a,b*), 3-3.5 (*m*, sugar protons), 0.88 (^{1}H, *d*, $J = 6$ Hz, rham- 3 CH_3). ^{13}C NMR; δ 176.58 (C-4), 162.7 (C-7), 159.6 (C-5), 157.6 (C-4′), 152.7 (C-2,9) 134 (C-3), 162.7 (C-7), 159.6 (C-5), 157.6 (C-4′), 105.6 (C-1‴), 105.4 (C-10), 100.3 (C-1″), 99.8 (C-1⁗), 99 (C-6), 94.4 (C-8), 81.8 (C-2″), 77.3 (C-3‴,3⁗), 75.4 (C-5‴,5⁗), 73 (C-2‴,2⁗), 70.9 (C-4″), 69.9 (C-3″), 69.6 (C-5″), 68.7 (C-4⁗), 68.3 (C-4‴), 62.8 (C-6⁗), 60 (C-6‴), 17.9 (CH_3 rham).

3.6. Kaempferol 3-O-β-D-glucopyranosyl-(1‴ → 2″)-O-α-L-rhamnopyranoside 7-O-β-D-(6⁗-O-E-coumaryl-glucopyranoside) (2)

Yellowish brown amorphous powder (15 mg), soluble in H_2O and 70% EtOH, $R_f \times 100 = 38$ and 62 in BAW and 15% HOAc, respectively. It gave the same color changes as **1**. UV λ max MeOH: 269, 315, 350;+$AlCl_3$ 274, 301 sh, 320, 360, 400 +HCl, 266, 300, 318, 395; +NaOAc 267, 320, 360, 390, +H_3BO_3 266, 302, 352. FAB MS *m/z*: 901 $[M-H]^-$, 739 $[M-162-H]^-$, 593 $[M-162-146-H]^-$, 447 $[M-162-146-146-H]^-$.

^{1}H NMR (DMSO-d_6): δ 7.74 (2H, *d*, $J = 8.8$ Hz, H-2′,6′), 7.43 (*d*, $J = 15.85$ Hz, *p*-coum H-7), 7.35 (2H, *d*, $J = 8.7$ Hz, *p*-coum H-2,6), 6.89 (2H, *d*, $J = 8.8$ Hz, H-3′5′), 6.69 (2H, *d*, $J = 8.7$ Hz, *p*-coum H-3,5), 6.66 (*d*, $J = 2.1$ Hz, H-8), 6.4 (*d*, $J = 2.1$ Hz, H-6), 6.18 (*d*, $J = 15.85$ Hz, *p*-coum H-8), 5.6 (*d*, $J = 1$ Hz rham-3 H-1″), 5.06 (*d*, $J = 7.5$ Hz, *glc*-7 H-1⁗), 4.33 (*d*, $J = 7.8$ Hz, terminal *glc* H-1‴), 4.23 (2H, *m* *glc*-7-H-6a), 4.14 (*dd*. 12.0, 2.5 Hz, *glc*-7 H-6_b), 4.13 (*t*, $J = 3.29$, 1.28 Hz, rham-3 H-2″), 3–4 (*m*, sugar protons), 0.91 (3H, *d*, $J = 6$ Hz, rham-3 CH_3).

Received 19 July 2000; received in revised form 22 January 2001

Dedicated to the memory of Dr. P. Agendia

Abstract

The stem bark of *Ochna afzelii* furnished three biflavonoids among which two are new. Their structures were established from spectroscopic and chemical evidences. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Ochna afzelii*; Ochnaceae; Stem bark; Biflavonoids; Chalcone dimers; Lophirones

1. Introduction

In the continuation of our search for flavonoids in Cameroonian medicinal plants (Pegnyemb et al., 1998) we examined the MeOH extract of the stem bark of *Ochna afzelii* Oliv. (Ochnaceae), a small tree of the Ochnaceae family, found in groups on rocky peaks in forest areas in tropical Africa. Prominent medical uses include treatment of jaundice, toothache, female sterility, menstrual complaints, lumbago and dysentery. Recent phytochemical studies on related members of the Ochnaceae family led to the isolation of some bi-and tetraflavonoids (Bouquet, 1969; Ghogomu et al., 1989; Tih et al., 1992; Pegnyemb et al., 1994, 1998). No previous phytochemical studies on *O. afzelii* have been reported. In this paper, we report the isolation and the structural elucidation of two novel biflavonoids: isolophirone C, **2** and dihydrolophirone C, **3** obtained alongside with the known lophirone C, **1**.

2. Results and discussion

The methanol extract of the air-dried stem bark is a dark brown. Constituents were first separated by repeated column chromatography over silica gel with different eluting systems and then followed purified by gel chromatography on sephadex LH20 affording lophirone C, isolophirone C and dihydrolophirone C.

When analysed by CIMS, compound **1** gave a pseudomolecular ion $[M+H]^+$ at m/z 511, with the molecular formula $C_{30}H_{22}O_8$. It was identified as lophirone C after the comparison of its IR, ^1H and ^{13}C NMR spectra with those of an authentic sample (Ghogomu et al.,1989) from *L. lanceolata* (Table 1).

The IR spectrum of **2** was very similar to that of **1** and showed absorption bands at 3302 cm^{-1} (phenolic hydroxyl), 1635 cm^{-1} (conjugated carbonyl), 1625 cm^{-1} (conjugated double bonds) and at 1510 cm^{-1} (aromatic rings). Mass spectrometric studies revealed a molecular formula of $C_{30}H_{22}O_8$ suggesting that **2** is an isomer of **1** with the $[M+H]^+$ ion at m/z 511 in its chemical ionisation spectrum.

Peracetylation of **2** (Ac_2O/Py) afforded a pentaacetate derivative **4,** with no residual OH absorption in its IR . CIMS of **4** gave a $[M+H]^+$ ion at m/z 721 leading to a molecular mass of 720 for the pentaacetate derivative, confirmed by the appearance of five sharp singlet signals on its NMR spectrum. Hence **2** had five hydroxyl groups.

The ^{13}C NMR spectrum of **2** displayed signals for 30 carbon atoms which indicated two methylenes, 28 sp^2 carbons among which two were carbonyls, 13 sp^2 methine protons and seven quarternary carbons of which six are oxygenated.

The ^1H NMR spectrum displayed signals for two vicinal methylenes and 13 aromatic protons (Table 1).

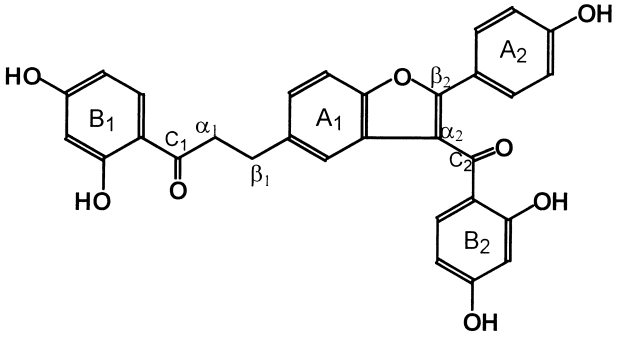
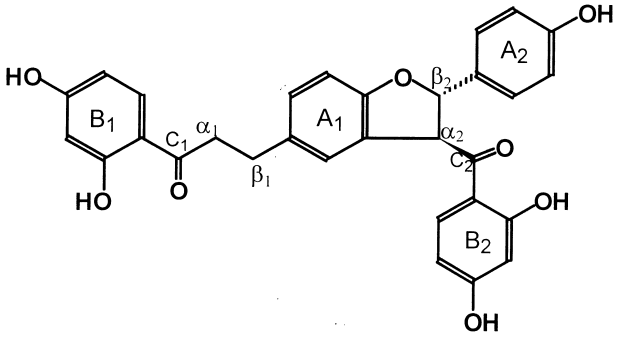
1 : Lophirone C.



2 : Isolophirone C.



3 : Dihydrolophirone C.

From the analysis of the ^1H–^1H COSY spectrum, it was deduced that the aromatic protons were distributed into three 1, 2,4-trisubstituted (A_1, B_1 and B_2) and one para-disubstituted (A_2) aromatic rings. From the HMBC spectrum of compound **2**, correlations were noticed between the carbonyl carbon signal at 204.8 (C_1) and the aromatic proton at δ_H 7.79 (H-6 on the B_1-ring). The methylene carbon at δ_C 30.9 (β_1) was further correlated to the protons of the 1, 2, 4-trisubstituted aromatic A_1-ring. These results suggested a dihydrochalcone moiety. The upfield carbonyl carbon atom at δ_C 196.1 (C_2) showed long-range correlation with the H-6 proton (7.38 ppm) of the aromatic B_2-ring and the carbon at 156.5 (β_2) was correlated to the aromatic protons H-2′,H-6′ (7.61 ppm) of the para-disubstituted aromatic A_2-ring. Above evidence leads to structure **2** for which the name isolophirone C has been proposed.

Compound **3** also had an IR absorption very similar to **1** but its EI mass spectrum had the $[M]^+$ ion at m/z 512 which was resolved for $C_{30}H_{24}O_8$, hence having two hydrogens more than lophirone C **1**. The ^1H and ^{13}C NMR spectra of both compounds were similar suggesting a close relation between their structures. The presence of two carbonyl carbon atoms (δ_C 201.5 and 204.7), as well as one 1,4-disubstituted and three 1,2,4-trisubstituted aromatic rings, was evident in the spectrum of **3** as in the structure of **1**. Major differences in the ^{13}C NMR spectra of the two compounds, arise from the presence of another two sp^3 type carbon atoms at δ_C 40.2 and 29.5 in the spectrum of **3**, instead of two sp^2 methine carbon signals at δ_C 119.3 and 144.8 in the spectrum of **1**. The ^1H NMR spectrum of **3** differed from that of **1** mainly in the replacement of the AB system at δ_H 7.69 and 7.78 by an aliphatic A_2X_2 system at δ_H 3.17 (2H) and 2.88 (2H). Evidence that **3** had five phenolic hydroxyl groups was established when its complete acetylation furnished a penta-acetate derivative, (CIMS: $[M+H]^+$ at m/z 723). Chemical shift assignments were enabled through 2D NMR, HMBC data (Table 1). Higher NOE values were observed between H-α_2 and H-6 (B_2-ring) (24%) and between H-β_2 and H-(2′ + 6′, A_2-ring) (6%). While weaker NOE values were observed between H-α_2 and H-β_2 (2%), H-(2′ + 6′, A_2-ring) and H-2′ (A1-ring). This suggested a *trans* configuration of H-α_2 and H-β_2 and led to structure **3** for dihydrolophirone C.

3. Experimental

3.1. General

IR spectra were obtained using KBr discs. NMR ^1H, 300 MHz and ^{13}C, 75 MHz spectra were performed in Me_2CO-d_6 solution on a Bruker WM 300 instrument using TMS as internal standard. For the HMBC spectra, the delay was 70 ms ($J_{CH} \approx 7$ Hz).

3.2. Plant material

The stem bark of *Ochna afzelii*, Oliv. was harvested in Yaounde, Center Province of Cameroon in April 1997. A voucher specimen (No. 23456 /SRF/CAM) is on deposit at the National Herbarium in Yaounde, Cameroon.

3.3. Extraction and isolation

Ochna afzelii stem bark was chopped into small pieces, air-dried and finally reduced to a fine powder (7 kg)

which was extracted at room temperature with cold MeOH for 24 h in an iron tank equipped with a mechanical stirrer. Evaporation of the solvent yielded a dark brown gummy residue (400 g) which was fractionated by cc on silica gel using a CH_2Cl_2/MeOH gradient mixture starting from proportion 1/1 to pure MeOH, giving 11 fractions (OA_1 to OA_{11}). Fraction OA4 was a mixture of biflavonoids which was first chromatographed over silica gel (CH_2Cl_2/MeOH:20/1) to give crude fractions OA_4D and OA_4F which were further purified using sephadex LH20 (MeOH) to yield pure Lophirone C (18 mg), isolophirone C (17 mg) and dihydrolophirone C (12 mg).

3.4. Lophirone C, **1**, $C_{30}H_{22}O_8$

Yellow crystals, mp 190–191° (Me_2CO), lit: 191–193 °C [2]. $[\alpha]_D^{25} = -16.4°$ (Me_2CO; *c*, 0.5), CIMS (NH_3) *m/z* 511 $[M+H]^+$, 493 $[M-H_2O+H]^+$, EIMS (110°, 70 eV) *m/z* (%): 510 (0.4, M^+), 508 (2), 493 (24), 461 (1), 400 (13), 388 (11), 374 (10), 355 (13), 328 (2), 263 (17), 250 (9), 238 (7), 207 (6), 178 (7), 137 (75), 110 (80), 94 (58), 81 (47), 55 (65), ^{1}H and ^{13}C NMR: Tables 1 and 2.

3.5. Isolophirone C, **2**, $C_{30}H_{22}O_8$

Yellow crystals, mp 194–195° (Me_2CO) CIMS(NH_3) *m/z*: 528 $[M+NH_4]^+$, 511$[M+H]^+$ EIMS, (110°, 70eV), *m/z* (%): 510 (0.3, M^+), 498 (7), 467 (2), 418 (24), 359 (74), 343 (41), 327 (5), 309 (32), 297 (8), 273 (13), 267 (37), 249 (10), 217 (7), 203 (6), 177 (4), 137 (100), 110 (54), 94 (12).^{1}H and ^{13}C NMR: Tables 1 and 2.

3.6. Isolophirone C penta-acetate **4**

Compound **2** (10 mg) was dissolved in a mixture of pyridine (2 ml) and Ac_2O (2 ml). The reaction mixture was maintained at 50°C in a H_2O bath for 6 h after which it was concentrated to dryness under vacuum. The resulting crude acetate was first purified by prep. tlc followed by gel permeation cc over sephadex LH20 using MeOH as eluent yielding **4** (5 mg). CIMS (NH_3) *m/z*: 738 $[M+NH_4]^+$ 721 $[M+H]^+$. EIMS (110°, 70 eV) *m/z* (%): 720 (13, M^+), 660 (22.4), 636 (12.7), 618 (18.3), 576 (22.2), 533 (7.6), 457 (8.2), 442 (8.4), 441 (7.6), 400 (6.1), 373 (5.6), 355 (9.7), 261 (4.1), 236 (8.6), 179 (40.8), 163 (6.7), 137 (100), 121 (37.2). Received 12 July 2000; received in revised form 12 January 2001

Abstract

From the aerial parts of *Cassia kleinii* two new oxanthrone esters, kleinioxanthrone-1 and kleinioxanthrone-2 have been isolated. Their structures were established as 1,8-dihydroxy-3-methyl-6-methoxy-9(10H)-anthracenone-10-oxydecanoate **1** and 1,8-dihydroxy-3-methyl-9(10H)-anthracenone-10-oxytetradecanoate **2** respectively based on degradative and spectroscopic evidence. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Cassia kleinii*; Leguminosae; Kleinioxanthrone-1; Kleinioxanthrone-2

1. Introduction

Cassia kleinii W&A (Leguminosae family) is a rather diffuse undershrub distributed in southern India (Hooker, 1978) and is a member of the predominantly tropical genus *Cassia*. *Cassia* species are known to be rich in anthraquinones, anthrones, flavonoids and triterpenes. *Cassia* leaves and pods have long been used widely as purgatives and laxatives. The anthraquinone derivatives; anthronic, dianthronic and anthraquinone glycosides present in *Cassia* are responsible for their purgative action (Muffat et al., 1986; Muller et al., 1989). 1,8-Dihydroxy anthraquinone derivatives particularly their glycosides are shown to have purgative activity (Selvaraj and Chander Subhas, 1978). A lot of herbal preparations for liver diseases contain hydroxy anthraquinones whose medicinal property has been attributed to their laxative activity only. Cascarosides A, B and aloe emodin which are hydroxy anthraquinone derivatives isolated from *Rhamnus purshianus* bark a well known cathartic drug (Mannito et al., 1990, 1993) was found to show significant hepatoprotective effect on primary cultured hepatocytes against galactosamine cytotoxicity. Chrysophanol glycoside isolated from *Cassia tora* also showed hepatoprotective activity (Wong et al., 1989). Hydroxy anthraquinone derivatives, which have been known for their purgative, laxative and cathartic activities are now considered to be potent hepatoprotective drugs.

C. kleinii which is used for its antihepatotoxic activity in traditional medicine has remained an uninvestigated species till now. So far, only the occurrence of saponins has been reported from *C. kleinii* (Rao and Subhashini, 1986). This is the first report of a systematic phytochemical investigation on this plant. Herein, we report the isolation and structure elucidation of two new oxanthrone esters from the aerial parts of *C. kleinii*. The name kleinioxanthrone-1 and kleinioxanthrone-2 are proposed for the new compounds **1** and **2**. Three known compounds *n*-triacontanol, hentriacontanoic acid and β-sitosterol were also isolated from the aerial parts.

2. Results and discussion

Compound **1**, klenioxanthrone-1, was isolated as yellow needles from hexane, mp 196–197°C. The molecular formula $C_{26}H_{32}O_6$ was deduced from the positive ion FABMS $(M+H)^+$ 441. The UV spectrum displayed bands at 445 and 290 nm assignable to an anthrone system. The IR spectrum showed absorption bands at 3500 cm^{-1} (−OH), 1629 cm^{-1} (chelated−C=O) and 1735 cm^{-1} (ester, –C=O).

The 300 MHz ^1H NMR ($CDCl_3$) spectrum showed two broad one proton singlets at δ 12.1 and 12.3 which are characteristic of two chelated hydroxyl groups. It also showed two doublets at δ 6.69 (J 3 Hz) and δ 7.37

PII: S0031-9422(01)00114-5

(J 3 Hz) which are assigned to H-4 and H-2 and two broad singlets at δ 7.09 and 7.63 assigned to H-5 and H-7 of 1. The occurrence of a three proton singlet at δ 3.94 is typical of an aromatic methoxyl group and the one proton multiplet at δ 3.5–3.9 is assigned to the oxymethine proton at C-10 of an oxanthrone system. The three proton singlet at δ 2.45 is characteristic of an aromatic methyl group. The triplet at δ 2.28 accounts for a $-OCO\underline{CH_2}-$ group. The broad singlet at δ 1.25 which integrates to 14 H, is characteristic of methylene groups belonging to an aliphatic straight chain. The triplet at δ 0.85 is typical of a terminal $-CH_3$ group. This data except for the one proton multiplet at δ 3.90 and the peaks due to the aliphatic ester side chain at δ 0.85–2.28 conform to that of physcion-9-anthrone (Tamano and Koketsu, 1982). So **1** was identified tentatively as a derivative of physcion-9-anthrone with an aliphatic side chain at C-10 position.

The EI MS of **1** gave the molecular weight of the corresponding anthraquinone, physcion, M^+ 284 due to cleavage of the side chain to form the oxonium ion (Monache et al., 1987) and hence the anthraquinone. The loss of fragments with mass 28 and 43 which is characteristic of fatty acid esters and formation of the oxonium ion (m/z 285) by loss of m/z 127 helps to identify the side chain ester as decanoic acid ester. The structure was further confirmed by alkaline hydrolysis which yielded decanoic acid. Decanoic acid was methylated and compared by co-TLC with authentic sample of methyldecanoate. Thus **1** was identified as 1,8-dihydroxy-3-methyl-6-methoxy-9(10H)-anthracenone-10-oxydecanoate.

Compound **2**, kleinioxanthrone-2, obtained as yellow needles, mp 188–189°C gave a $(M+H)^+$ at m/z 467 in the positive ion FAB MS attributable to the molecular formula $C_{29}H_{38}O_5$. Absorption bands at 440 and 229 nm were observed in the UV spectrum. The IR spectrum showed absorption bands at 3500 cm^{-1} (−OH), 1626 cm^{-1} (chelated –C=O) and 1749 cm^{-1} (ester −C=O).

The 300 MHz ^1H NMR ($CDCl_3$) spectrum showed two broad one proton singlets at δ 12.1 and 12.0 which is characteristic of two chelated hydroxyl groups. It also showed an ABC pattern of multiplets at δ 7.8 (J 9Hz), δ 7.7 (J 9Hz), δ 7.3 (J 9Hz) assigned to H-7, H-6 and H-5 of **2**. Two broad singlets were present at δ 7.6 and 7.1 in the aromatic region and were assigned to H-2 and H-4. The one proton multiplet at δ 3.9 was assigned to the oxymethine proton at C-10 of an oxanthrone. The three proton singlet at δ 2.47 was characteristic of an aromatic methyl group. The triplet at δ 0.85 was typical of a terminal aliphatic methyl group. This data except for the one proton multiplet at δ 3.90 and the peaks due to the aliphatic ester side chain at δ 0.85–2.31 conform to that of chrysophanol-9-anthrone (Tamano and Koketsu, 1982). So the compound was tentatively identified as a derivative of chrysophanol-9-anthrone with an aliphatic side chain.

From the EI MS (M^+ 254) and the FABMS of **2** the side chain was deduced as tetradecanoic acid ester. The structure was confirmed by degradation as in the case of **1**. Thus **2** was identified as 1,8-dihydroxy-3-methyl-9(10H)-anthracenone-10-oxytetradecanoate.

This is the first report of the natural occurrence of oxanthrone esters. Oxanthrones can be easily converted to their corresponding anthraquinones and their derivatives. Compounds **1** and **2** could serve as valuable intermediates in the development of hepatoprotective drugs.

3. Experimental

3.1. Plant material

Cassia kleinii W&A was collected from Neyyatinkara, Thiruvananthapuram and identified by Dr. N. Sasidharan, Scientist, Kerala Forest Research Institute (KFRI), Peechi, Kerala and was deposited at the Herbarium of the KFRI and the voucher number is 7564.

3.2. Extraction and isolation

Dried and finely powdered aerial parts of the plant were extracted (Soxhlet) with petrol (60–80°C), and subsequently with chloroform for 48 h. The petrol extract and the chloroform extract were evaporated and the residues were chromatographed separately over silicagel (60–120 mesh) using hexane and hexane:EtOAc (98:2, 95:5) as eluents. **1** and **2** were crystallized from the hexane:EtOAc (98:2) fractions of the hexane extract and the chloroform extract respectively.

3.3. Kleinioxanthrone-1

$[\alpha]_D^{25}$ −5.6° ($CHCl_3$, c 1.04) UV: λ_{max} 445, 290 nm. IR KBr ν_{max} cm^{-1} 3500 (OH), 1629 (chelated−CO), 1735 (ester−CO), FAB MS (M+1) 441, M^+ 440 EI MS 284 (100), 254 (23), 241 (14), 226 (12), 213 (21), 198 (14), 185 (19), 152 (10), 139 (32), 128 (38), 115 (29), 89 (12), 77 (34). ^{13}C NMR (75 MHz $CDCl_3$) δ 162.5 (C-1), 106.8 (C-2),

165.2 (C-3), 108.2 (C-4), 124.5 (C-5), 148.4 (C-6), 121.3 (C-7), 166.5 (C-8), 190.8 (C-9), 69.2 (C-10), 133.2 (C-11), 113.7 (C-12), 110.2 (C-13), 135.3 (C-14), 22.1 (-CH_3), 56.1 (-OCH_3), 182.0 (C-1′), 30.6 (C-2′), 19.3–21.4 (C-3′-9′), 12.4 (C–10′).

3.4. Kleinioxanthrone-2

$[\alpha]_D^{25}$ −16° ($CHCl_3$, *c* 1.40) UV: λ_{max} 440, 229 nm. IR KBr ν_{max} cm^{-1} 3500 (OH), 1626 (chelated−CO), 1749 (ester−CO), FAB MS (M + H) 467 M^+ 466 EI MS 254 (100), 226 (16), 198 (10), 152 (10), 115 (10), 77 (21), 39 (24). ^{13}C NMR (75 MHz $CDCl_3$) δ 162.5 (C-1), 115.7 (C-2), 149.2 (C-3), 124.4 (C-4), 124.2 (C-5), 136.8 (C-6), 119.7 (C-7), 162.2 (C-8), 192.4 (C-9), 68.0 (C-10), 133.1 (C-11), 123.1 (C-12), 121.2 (C-13), 133.5 (C-14), 22.5 (-CH_3), 181.8 (C-1′), 31.7 (C-2′), 22.1–29.5 (C-3′-13′), 13.9 (C-14′).

3.5. Hydrolysis of kleinioxanthrone-1 and kleinioxanthrone-2

Kleinioxanthrone-1 (8 mg) and kleinioxanthrone-2 (6 mg) were taken separately in 2.5% alcoholic KOH (5 ml) refluxed for 1 h until an aliquot showed the disappearance of the original compound on TLC. It was then cooled and treated with water. The aqueous layer was neutralized with dil. HCl and extracted with ether and dried with Na_2SO_4. The acids **3** and **4** were obtained from **1** and **2** respectively.

3.6. Methylation of *3* and *4*

Compounds **3** (2 mg) and **4** (2.5 mg) were separately dissolved in methanol and 0.5 ml, 2% H_2SO_4 in methanol was added. The reaction mixture was refluxed for 30 min. It was then cooled, treated with water, extracted with hexane and washed with saturated sodium bicarbonate and water. The methyl esters obtained were identified by co-TLC with methyldecanoate and methyltetradecanoate respectively.

Abstract

Four ellagic acid rhamnosides were isolated from the stem bark of *Eucalyptus globulus*. Their structures have been established on the basis of the analysis of their ^{1}H NMR, ^{13}C NMR, HMBC, IR and MS spectral data. The HMBC data of these compounds were most useful for their structure determinations, with these bring determined to be 3-*O*-methylellagic acid 3′-*O*-α-rhamnopyranoside, 3-*O*-methylellagic acid 3′-*O*-α-3″-*O*-acetylrhamnopyranoside, 3-*O*-methylellagic acid 3′-*O*-α-2″-*O*-acetylrhamnopyranoside, 3-*O*-methylellagic acid 3′-*O*-*a*-4″-*O*-acetylrhamnopyranoside, respectively. Their antioxidant activities were evaluated by measuring the inhibition of lipid peroxidation using rat liver microsomes, with IC_{50} values of 10.0–14.0 μg/ml. © 2001 Elsevier Science Ltd. Keywords: *Eucalyptus globulus*; Myrtaceae; Stem bark; Ellagic acid rhamnosides; Antioxidant activity

1. Introduction

Eucalyptus globulus Labill (Myrtaceae) grows under a wide range of climatic conditions and is widely distributed throughout Australia. Moreover *Eucalyptus* species have been utilized for medicinal purposes; for example, their barks and leaves have been used to treat colds, influenza, toothaches, snakebites, fevers, diarrhea and other complaints (Elliot and Jones, 1984; Lassak and McCarthy, 1983; Barr, 1993). Because of its fast growth and good quality, *E. globulus* is being established in plantations in many countries, mainly for pulp and paper production. Up to now, the bark is a waste material from the pulp industry, and the purpose of this study was to recover potentially useful compounds from the bark as by-products. Additionally, several biologically active compounds were isolated mainly from the leaves of *Eucalyptus*; Euglobals, isolated from the buds and leaves of *E. globulus,* show potent granulation inhibiting activity (Sawada et al., 1980; Amano et al., 1981; Kozuka et al., 1982a,b). Grandinol also was isolated from adult tissue of *E. grandis* as a rooting inhibitor (Crow et al., 1977), and robustadials are antimalarial compounds isolated from *E. robusta* (Xu et al., 1984). Lastly, the sesquiterpene aromadendrene, the main component of a commercially available distillation tail of the oil of *E. globulus*, has been exploited as a chiral pool synthon for the synthesis of several sesquiterpene derivatives (Gijsen et al., 1990, 1991, 1992, 1994).

We are interested in antioxidant substances from natural products and have reported several new natural antioxidants (Kim et al., 1996, 1997, 1999; Lee et al., 1996, 1999). We present here the isolation and structural elucidation of four antioxidants (**1**–**4**) from the stem bark of *E. globulus* and their antioxidant activities.

2. Results and discussion

The 80% aqueous methanolic extract of the stem bark of *E. globulus* was successively partitioned with $CHCl_3$ and EtOAc. Successive column chromatography of the EtOAc extract on silica gel, Sephadex LH-20 and C-18, followed by preparative HPLC on a C-18 column yielded an ellagic acid rhamnoside (**1**) and three ellagic acid acetylrhamnosides (**2**–**4**).

PII: S0031-9422(01)00146-7

The physico-chemical properties of **1**–**4** were very similar to each other. The IR absorptions suggested the presence of α,β-unsaturated lactones (around 1725 cm^{-1}) and hydroxyl groups (around 3400 cm^{-1}). The UV spectra of these compounds in methanol were almost the same, which indicated the presence of similar chromophores.

	R_1	R_2	R_3
1	H	H	H
2	H	CH_3CO	H
3	H	H	CH_3CO
4	CH_3CO	H	H

Compound **1** was obtained as a yellow powder. The HRFAB-MS measured with negative ion mode gave a parent ion peak at *m/z* 461.0727 ($[M-H]^-$ calc. for $C_{21}H_{17}O_{12}$ requires 461.0720). These results together with ^{13}C NMR spectroscopic analysis proposed the molecular formula $C_{21}H_{18}O_{12}$ for **1.** The IR spectrum displayed characteristic absorptions for hydroxyl groups (3411 cm^{-1}), α, β-unsaturated lactone functions (1727 cm^{-1}) and aromatic rings (1606 cm^{-1}). In its ^1H NMR spectrum, nine proton signals including two aromatic singlets (δ 7.46 and 7.47), a singlet methoxyl signal (δ 4.12), and five oxygenated methine protons were observed, along with a doublet methyl signal (δ 1.21, $J = 6.2$ Hz) indicating the existence of one 6-deoxysugar.

The glycoside was easily determined as rhamnose through analysis of the chemical shifts and coupling patterns of its proton signals, which were connected by a ^1H–^1H COSY spectrum. The anomeric proton signal appeared as a doublet at δ 5.73, attributed from the small coupling constant of 1.6 Hz to an α-configurated anomeric proton. The ^{13}C NMR spectrum of **1** exhibited 21 signals (Table 2), with two overlapped ester carbons (–COOR) at δ 161.8 due to α,β-unsaturated lactones, six oxygenated aromatic carbons, four aromatic quaternary carbons (=C<), two isolated aromatic methine carbons (=CH–) at δ 114.0 and 115.2, a methoxyl carbon at δ 61.6, and a methyl carbon at δ 17.9 and five oxygenated methine carbons due to rhamnose. These results, and the UV-visible spectrum measured in MeOH (246, 260, 285, 360, 375 nm), suggested the structure as *O*-methylellagic acid with rhamnose. The mass spectrum of **1** was dominated by two fragment ion peaks at *m/z* 315 and 145 due to the aglycone and the rhamnose moiety, respectively. Compound **1** was very similar to 3-*O*-methylellagic acid 4′-rhamnoside (Yazaki and Hillis, 1976) in its UV, IR and ^1H spectral data. However, the attachment position of sugar moiety to aglycone was different. The rhamnose attachment position and the structure of **1** were established through the interpretation of pulse field gradient (PFG)-HMQC and HMBC spectral data. From the HMQC spectrum, aromatic carbons (δ 114.0 and 115.2) bearing singlet methine protons (δ 7.46 and 7.47, respectively) were correlated (C-5 and C-5′, respectively).

In the HMBC spectral data (Fig. 1), ^1H–^{13}C long-range correlations were observed between the methoxyl protons (δ 4.12) to C-3 (δ 143.5), from the aromatic proton at δ 7.46 (H-5) to the lactone carbonyl carbon at δ 161.8 (C-7), and two quaternary carbons at δ 112.3 (C-1) and δ 143.5 (C-3). Long-range correlations from the other aromatic proton at δ 7.47 (H-5′) to another lactone carbonyl carbon at δ 161.8 (C-7′), the quaternary carbon at δ 110.6 (C-1′) and an oxygenated aromatic carbon at δ 140.3 (C-3′) were also observed in the aglycone of **1**. In the sugar moiety, the ^1H–^{13}C long-range correlation from the anomeric proton at δ 5.73 to C-3′ ascertained that the sugar was attached to C-3′-*O* at the aglycone. The other ^1H–^{13}C long-range correlations observed in the sugar moiety indicated that the sugar was rhamnose. All of the ^1H NMR and most of the ^{13}C NMR chemical shifts were assigned unambiguously from the data obtained from HMQC and HMBC, except that a few quaternary carbons (C-2, C-4, C-6, C-2′, C-4′ and C-6′) could not be unambiguously assigned. All of the NMR assignments were in good agreements with those of ellagic acid derivatives reported by Li et al. (1999). Accordingly, **1** was established as 3-*O*-methylellagic acid 3′-*O*-α-rhamnopyranoside.

During the structural elucidation, it was revealed that **2** and **3** were obtained as a mixture of regioisomers with the same molecular weight. Because of the small amount and difficulty of separation of these compounds, the

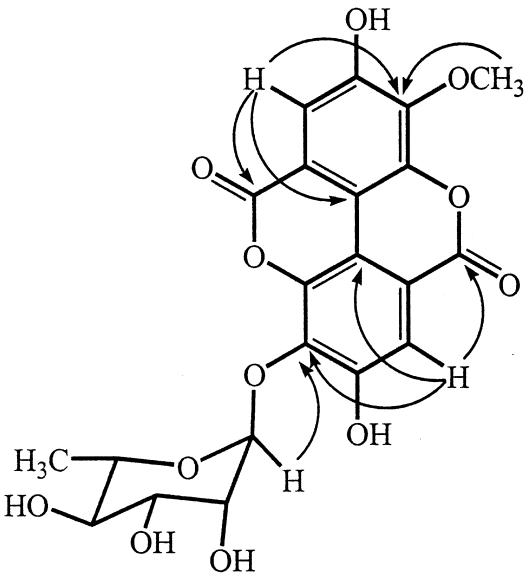

Fig. 1. ^{1}H–^{13}C long-range correlations of **1** in the PFG-HMBC spectrum.

structure determination of **2** and **3** was conducted in the mixture state. The physico-chemical properties of mixture of **2** and **3** were very similar to those of compound **1** except for the larger molecular weight. The UV and IR spectral data was almost the same with those of compound **1,** suggesting the 3-*O*-methylellagic acid structure. The molecular formulae of **2** and **3** were deduced to be $C_{23}H_{20}O_{13}$ from the parent ion peak at *m/z* 503.0835 ([M-H]$^{-}$, calc. for $C_{23}H_{19}O_{13}$, 503.0825) in the negative HRFAB–MS spectrum measured as mixture state. The integration of the proton signals of **2** and **3** in the ^{1}H NMR suggested that the ratio of these compounds in the mixture was 3:2. The ^{1}H, ^{13}C NMR and PFG-HMBC spectral data of these two compounds were almost the same as those of **1** in the aglycone regions, indicating that the aglycones of **2** and **3** were 3-*O*-methylellagic acid. However, the spectral data of the sugar moieties of these three compounds were different. The ^{1}H NMR data of **2** and **3** in the sugar regions exhibited each of six signals due to four methine protons, a methyl group and an acetyl group. The position of acetyl groups in **2** (δ 2.12) and **3** (δ 2.09) were determined carefully by the analysis of chemical shift values of methine protons and mostly by the ^{1}H–^{13}C long-range correlations in the HMBC spectra (Fig. 1). The long-range correlations from the down-field shifted methine proton at δ 5.24 (H-3″) to the carbonyl carbon of acetyl group at δ 172.7 and other long-range correlations in the sugar confirmed that the sugar moiety of **2** was 3″-*O*-acetylrhamnopyranoside. The ^{1}H–^{13}C long-range correlation from the anomeric proton at δ 5.64 to C-3′ (δ 138.6) confirmed the structure of **2** as 3-*O*-methylellagic acid 3′-*O*-α-3″-*O*-acetylrhamnopyranoside.

In the same manner, the structure of **3** was established. From the ^{1}H–^{13}C long-range correlations of the down-field shifted methine proton at δ 5.49 (H-2″) with the carbonyl carbon of acetyl group at δ 172.0 and other correlations in the sugar, the structure of **3** was determined as 3-*O*-methylellagic acid 3′-*O*-α-2″-*O*-acetylrhamnopyranoside.

The spectral data of **4** obtained from the negative HRFAB-MS (*m/z* 503.0828, [M-H]$^{-}$, calcd for $C_{23}H_{19}O_{13}$, 503.0838) and NMR experiments were almost the same as those of **2** and **3** except for the position of the acetyl group on the rhamnose-moiety, which suggested that **4** was a regioisomer of **2** and **3** with 3-*O*-methylellagic acid structure as the aglycone. By the ^{1}H–^{13}C long-range correlations from the down-field shifted methine proton at δ 5.04 (H-4″) to the carbonyl carbon of acetyl group at δ 172.6 and other correlations in the sugar moiety of **3** (Fig. 1), the complete structure of **3** was determined to be 3-*O*-methylellagic acid 3′-*O*-α-4″-*O*-acetylrhamnopyranoside. It was considered that one or two of compounds **2**, **3** and **4** might be an artifact(s) formed by acyl migration during the extraction and/or isolation procedure.

This is the first report of compounds **1**–**4** from a natural source, although the methyl or dimethyl ellagic acid derivatives which contain rhamnose as a sugar, 3-*O*-methylellagic acid 4′-rhamnoside (Yazaki and Hullis, 1976) and 3,3′-di-*O*-methylellagic acid 4′-O-α-L-rhamnoside (Malhotra and Misra, 1981) from *Eucalyptus* and 4-(α-rhamnopyranosyl)ellagic acid (Yang et al., 1998) has been reported previously.

The antioxidant activities of the compounds were evaluated by a thiobarbituric acid method using rat liver microsomes. Fig. 2 shows that the concentration effects of **1**, mixture of **2** and **3**, and **4** on the inhibition of lipid peroxidation in rat liver microsomes. The IC_{50} values of

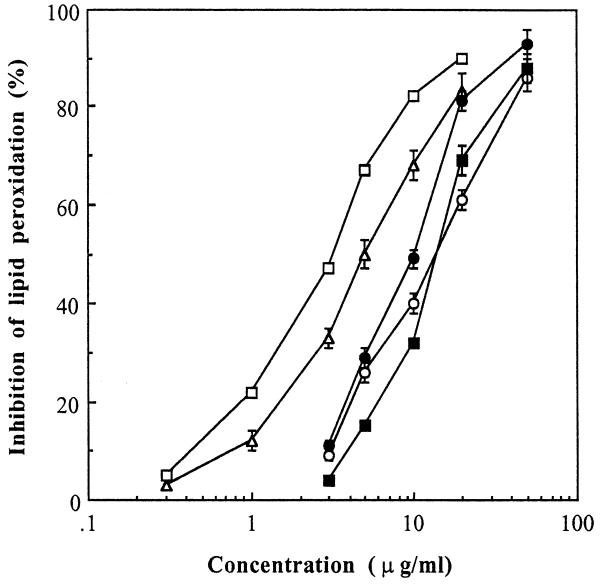

Fig. 2. Concentration effects of antioxidative activity of **1** (○), 3:2 mixture of **2** and **3** (●), **4** (■), BHA (□) and α-tocopherol (△). The values are mean ±S.E. of three independent test tubes.

them were 13.0, 10.0 and 14.0 mg/ml respectively, which were slightly weaker than those of α-tocopherol (IC_{50} 4.8 μg/ml) and butylated hydroxyanisole (BHA, IC_{50} 3.0 μg/ml).

3. Experimental

3.1. General

CC: silica gel 60 (Merck, 70–230 mesh), C_{18} gel (60–230 mesh) and Sephadex LH-20, the eluents were $CHCl_3$–MeOH (100:1–1:1), MeOH–H_2O (50:1–95:5), and MeOH, respectively. UV-visible: MeOH soln. IR: KBr discs. Negative HRFAB–MS spectra were measured on a Jeol HX-110 spectrometer using glycerol as a matrix. NMR: 400 MHz for ^1H, and 100 MHz for ^{13}C in CD_3OD with TMS as int. standard. Chemical shifts are given in δ from TMS. The 2D-NMR spectroscopy experiments were carried out on a Jeol JNM-A α-600 NMR spectrometer operating at 600/150 MHz for ^1H and 150 MHz for ^{13}C. For HMQC and HMBC experiments, duration time was optimized for $^1J_{CH} = 145$ Hz and $^nJ_{CH} = 8.3$ Hz, respectively. Prep. HPLC was performed on a C_{18} column (20×250 mm) using a MeOH–H_2O gradient, and by monitoring with a photodiode-array detector (200–650 nm).

3.2. Plant material

The stem bark of an eight-year old *G. globulus* tree was provided by Hansol Forem Co, and the voucher specimen is deposited at Korea Research Institute of Bioscience and Biotechnology.

3.3. Extraction and isolation

The dried stem bark (4 kg) was extracted with 80% aq. MeOH at room temp. for 5 days. The extract was filtered and concd under red. pressure. The residue was distributed between $CHCl_3$ and H_2O. The active aqueous phase was further partitioned between EtOAc and H_2O. The EtOAc layer was conc. in vacuro, and the residue (71.2 g) was applied to CC on a silica gel column eluted with a $CHCl_3$–MeOH gradient from (100:1–1:1). The fractions of interest were collected and subjected to further silica gel column chromatography with the same condition and the Sephadex LH-20 chromatography with MeOH as eluant, followed by C_{18} CC eluted with a MeOH–H_2O gradient (50:1–95:5). Further purification of the fractions of interest by prep. HPLC (C_{18}, MeOH–H_2O = 1:1) gave **1** (18.0 mg), mixture of **2** and **3** (20.0 mg) and **4** (8.2 mg). The ratio of **2** and **3** was 3:2 in the mixture.

3.4. Compound *1*

3.7. Antioxidant activity

Antioxidant activity was evaluated by the inhibitory activity of compounds against lipid peroxidation in rat liver microsomes according to the thiobarbituric acid method (Ohkawa et al., 1979) with minor modifications. The reaction was initiated by the addition of 100 μM $FeSO_4$ $7H_2O$ into a mixture of ascorbic acid (0.2 mM), a microsomal suspension (0.5 μg protein ml^{-1}) and each concentration of the samples dissolved in methanol. Lipid peroxidation was assessed by measuring the thiobarbituric acid reaction products at 532 nm.

Received 27 November 2000; received in revised form 8 February 2001

Abstract

Two alkaloids, furomegistine I (**1**) and furomegistine II (**2**), were isolated from the bark of *Sarcomelicope megistophylla*. Their structures have been elucidated on the basis of MS and NMR data. Both belong to the category of furanopyridine alkaloids and should be considered as oxidation products of a furo[2,3-*b*]quinoline precursor. The two alkaloids exhibited moderate cytotoxic activity. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Sarcomelicope megistophylla*; Rutaceae; Furanopyridine; Alkaloids; Furomegistine I; Furomegistine II

1. Introduction

Sarcomelicope megistophylla Hartley (Rutaceae) is a small to medium sized tree, 8–12 m high, easily recognized by its pubescent leaves, exceptionally large for the genus (up to 35 cm long). This species is endemic to the region of Néaoua, New Caledonia (Hartley, 1986). Recently, we described the chemical constituents of its leaves (Skaltsounis et al., 1995; Fokialakis et al., 1999) and the major alkaloids of the bark (Fokialakis et al., 2000; Papageorgiou et al., 2000). In a continuation of our studies of the genus *Sarcomelicope*, (Mitaku et al., 1986, 1987, 1989, 1995; Tillequin, 1997) we report here the isolation and structure determination of two new alkaloids, furomegistine I (**1**) and furomegistine II (**2**) from the bark of *Sarcomelicope megistophylla*. Both of them derive from a furanopyridine basic core and should be considered as *seco*-furoquinolines.

2. Results and discussion

Furomegistine I (**1**) was obtained as a yellow amorphous compound, and its molecular formula was determined by HRMS as $C_{15}H_{15}NO_7$. The ^1H NMR spectrum indicated two protons associated with a bisubstituted furano ring, four OCH_3 groups (two belonging to methyl ester functional groups and two placed on sp^2 carbons), and one deshielded olefinic proton (δ 5.28). The ^{13}C NMR spectrum confirmed the above observations and showed the presence of two carbonyl groups which correspond to $COOCH_3$ groups (δ 167.3, 165.4) and also the presence of six quaternary aromatic or olefinic carbons. Based on the HMBC spectrum (Fig. 1) it was clear that five of them constitute a penta-substituted pyridine ring and the sixth takes part in a double bond attached as a side chain to the pyridine ring. This side chain additionally includes a protonated olefinic carbon (δ 94.8), one $COOCH_3$ group (δ 3.54) and a OCH_3 group (δ 3.88) attached to the quaternary olefinic carbon. The chemical shift of the protonated olefinic carbon, which is highly shielded, is in good agreement with the theoretical value of the specific trisubstituted double bond (Pretsch et al., 1989).

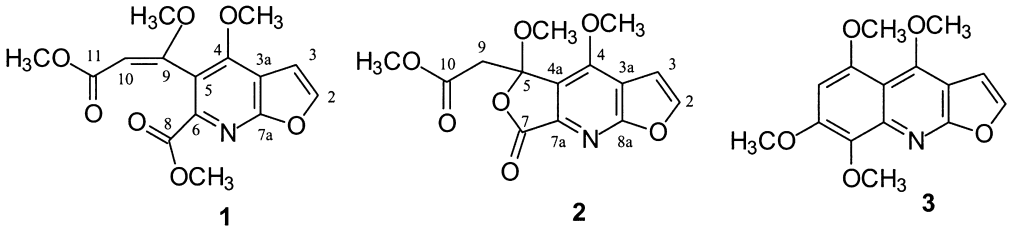
.



The type of fusion between the pyridine and the furano ring was found to be [2,3-*b*] based on the chemical shift of carbon 7a (163.5) which was identified by its J_3 correlation with the furano protons H-2 and H-3. This chemical shift indicates that this carbon is simultaneously attached to the nitrogen and oxygen atom. The OCH_3 group at 4.26 ppm was correlated with an aromatic carbon at 159.7 ppm, which was identified as C-4 by its J_3 correlation with the furano proton H-3. This arrangement was also confirmed by the NOE correlation of H-3 with the OCH_3 group. The side chain was attached on C-5 (δ 119.9), which was identified by its J_3 correlation with the olefinic proton H-10. The chemical shift of this carbon excluded the possibility that the site of attachment was C-6. Consequently C-6 was bearing the resting $COOCH_3$ group. Finally the stereochemistry of the 9, 10 double bond was investigated with NOESY experiments. The observed strong correlation between H-10 and OCH_3-9 was compatible only with the *cis*-isomer.

Furomegistine II (**2**) was obtained as a yellow amorphous compound, and its molecular formula was determined by HRMS as $C_{14}H_{13}NO_7$. From the IR spectrum ($\nu = 1789$) it was obvious that this molecule contained in its structure a five-membered lactone ring. As in the case of **1**, the ^1H NMR spectrum indicated two protons associated with a bisubstituted furano ring, and also three OCH_3 groups (one belonging to a methyl ester functional group, one placed on sp^2 carbon and one placed on a doubly oxygenated sp^3 carbon), and two equivalent aliphatic protons (δ 3.33). The ^{13}C NMR spectrum confirmed the above observations and showed the presence of two carbonyl groups, one corresponding to a $COOCH_3$ group (165.4) and one corresponding to a lactone (168.1). It also showed the presence of five quaternary aromatic carbons, of one doubly oxygenated aliphatic quaternary carbon and of one methylene carbon. As in **1** the five quaternary aromatic carbons constituted a pyridine ring fused with a furano ring with the same type of fusion.

From the HMBC spectrum (Fig. 1) it was clear that the methylene (H-9) was bearing the $COOCH_3$ group and it was attached to the doubly oxygenated carbon. This carbon (C-5) was included in the lactone ring and was also bearing an OCH_3 group. As in **1** the other OCH_3 group was attached on C-4 of the pyridine ring. The lactone ring was fused with the other two pyridine carbons C-4a and C-7a. The type of fusion was assigned by the chemical shift of C-4a which was identified by its J_3 correlation with the methylene protons H-9. This chemical shift (δ 121.9) is not consistent with the α-position of a pyridine nucleus and thus the opposite type of fusion is excluded. Furomegistine II (**2**) was optically inactive although a chiral center is included in its structure, indicating that the isolated compound was a racemate mixture.

From a biogenetic point of view, furomegistine I (**1**) and furomegistine II (**2**) most probably arise from the oxidation of the benzene aromatic ring of a furo[2,3-*b*]quinoline precursor, such as acronycidine (**3**), which is one of the major alkaloids isolated from the bark (Papageorgiou et al., 2000). The presence of three electron-donating groups on the A ring of this furoquinoline should greatly facilitate the oxidative cleavage of the C-7, C-8 double-bond, to give the furanopyridine skeleton of furomegistine I (**1**). Further recyclization of a *seco*-furoquinoline of this type, through C-5 and the

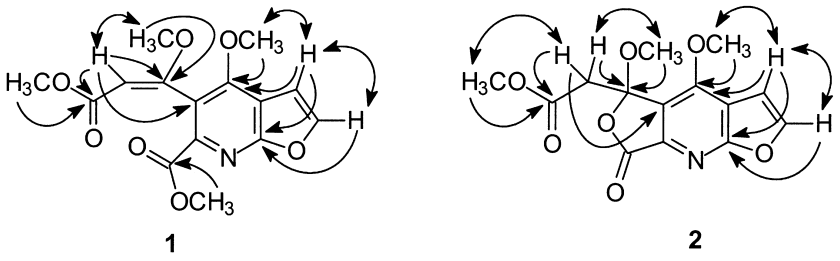


Fig. 1. HMBC (→) and NOESY (↔) correlations for furomegistine I (**1**) and furomegistine II (**2**).

carboxylic function at C-8, is a possible route to the formation of the fused furanolactone system of furomegistine II (**2**). It is interesting to note that a similar biogenetic origin, involving the oxidative ring opening of the aromatic ring, had been postulated, in the acridone series, for 1-methyl-4-quinolone-2,3-dicarboxylic acid dimethylester isolated from *Sarcomelicope dogniensis* (Mitaku et al., 1995) and for fareanine obtained from *Medicosma fareana* (Habtemariam et al., 1996). To the best of our knowledge, only one *seco*-furoquinoline (furanopyridine) alkaloid, dimethylrhoifolinate from *Zanthoxylum rhoifolium* (Arruda et al., 1992) and *Metrodorea nigra* (Müller et al., 1995), has been previously described.

It is interesting to point out that compound **2** possesses the heterocyclic ring system of furano[3,2-*b*]furano[3,4-*b*]pyridine that has never been described either from natural or synthetic origin.

The two new alkaloids **1** and **2** were tested for their cytotoxicity against A549 and HT-29 cells and exhibited a moderate activity with IC_{50} = 90 and 100 μM, respectively.

3. Experimental

3.1. General experimental procedures

UV spectra were recorded on a Shimadzu-160A spectrophotometer. The IR spectrum was obtained on a Perkin-Elmer Paragon 500 instrument. NMR spectra were recorded on Bruker DRX 400 and Bruker AC 200 spectrometers [^{1}H (400 and 200 MHz) and ^{13}C (50 MHz)]; chemical shifts are expressed in ppm downfield to TMS. The 2D NMR experiments were performed using standard Bruker microprograms. EIMS and HRMS were determined on HP-6890 and AEI MS-902 spectrometers, respectively.

3.2. Plant material

The plant material was collected at Nouméa (New Caledonia) in May 1984. A voucher sample (Pusset-Chauvière 261) is kept in the herbarium of the Centre ORSTOM at Néaoua (New Caledonia).

3.3. Extraction and isolation

Extraction of alkaloids was as described (Papageorgiou et al., 2000). The crude alkaloid mixture was chromatographed over a column containing Si gel (Merck 0.04–0.06 mm; flash), using a cyclohexane/EtOAc gradient to give 7 fractions. Fraction 6 was submitted to flash chromatography on silica gel with CH_2Cl_2 to afford furomegistine I (5 mg) and furomegistine II (12 mg).

3.4. Furomegistine I (*1*)

UV λ^{MeOH} nm (log ε): 298 (*sh*), 345 (2.64). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 7.76 (1H, *d*, J = 2.6 Hz, H-2), 7.06 (1H, *d*, J = 2.6 Hz, H-3), 5.46 (1H, *s*, H-10), 4.26 (3H, *s*, OMe-C4), 3.95 (3H, *s*, OMe-C8), 3.88 (3H, *s*, OMe-C9), 3.54 (3H, *s*, OMe-C11). ^{13}CNMR ($CDCl_3$, 50 MHz): δ 167.3 (C-11), 166.7 (C-9), 165.4 (C-8), 163.5 (C-7a), 159.7 (C-4), 148.3 (C-6), 145.7 (C-2), 119.9 (C-5), 109.8 (C-3a), 105.9 (C-3), 94.8 (C-10), 59.9 (OMe-C4), 57.1 (OMe-C9), 53.1 (OMe-C8), 51.2 (OMe-C11). 3.6. Cytotoxicity assay

Compounds **1** and **2** were tested for their cytotoxic activity on the following solid tumour cell lines: human lung carcinoma A549 and human colon adenocarcinoma HT29 (European Collection of Cell Cultures, Salisbury, UK). All cell lines were cultured in Dulbecco's minimal essential medium supplemented with penicillin (100 U/ml), streptomycin (100 μg/ml) and 10% fetal bovine serum (media and antibiotics from Biochrom KG, Berlin, Germany) in an environment of 5% CO_2, 85% humidity, 37°C. Cells were routinely subcultured using a trypsin 0.25%– EDTA 0.02% solution. The cytotoxicity assay was performed by a modification of the MTT-method (Denizot and Lang, 1986).

Received 24 October 2000; received in revised form 4 December 2000

Abstract

Two new alkaloids, haplotubinone (**3**) and haplotubine (**4**), were isolated from the aerial parts of *Haplophyllum tuberculatum* together with the known lignan diphyllin. The structures of the new alkaloids were established by spectroscopic methods in conjunction with X-ray crystallographic analysis of **3**. In addition, the amide *N*-(2-phenylethyl)-benzamide has been identified in this source for the first time. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Haplophyllum tuberculatum*; Rutaceae; Alkaloids; Haplotubinone; Haplotubine; *N*-(2-Phenylethyl)benzamide; X-ray crystallography

1. Introduction

Previous phytochemical work on *Haplophyllum tuberculatum* (Forssk.) A. Juss. (Rutaceae) collected in Saudi Arabia described the isolation of (+)-dihydroperfamine (Al-Yahya et al., 1991), tuberine (McPhail et al., 1990), tubacetine, tubasenecine and 7-hydroxy-8-(3-methyl-2-butenyl)-4-methoxyfuro[2,3b]quinoline (Al-Yahya et al., 1992). In addition, a number of known alkaloids were also isolated from this source, including buchapine, 3-dimethylallyl-4-dimethylallyloxy-2-quinolone, γ-fagarine and flindersine (Al-Rehaily, 1992). The present paper reports on the isolation and characterization of the new alkaloids haplotubinone (**3**) and haplotubine (**4**) from the aerial parts of *H. tuberculatum*, together with the known amide *N*-(2-phenylethyl)benzamide (**1**) (Batsuren et al., 1992) and the lignan dyphyllin (**2**) (Gozler et al., 1984).

2. Results and discussion

The methylene chloride extract of the aerial parts of *H. tuberculatum* was partitioned between *n*-hexane and acetonitrile. The acetonitrile extract was fractionated by flash column chromatography using mixtures of toluene and increasing concentrations of acetone. Compound **3** eluted first and yielded colorless crystals from ether, mp 177.0–178.0°C. Its molecular formula was established as $C_{19}H_{23}NO_4$ by FAB (*m*/*z* 352 for $[M+Na]^+$), ^{13}C and ^1H NMR spectral data. The UV spectrum exhibited absorption bands at λ_{max} 237, 262(sh), 352 nm, indicating the presence of a 2,4-quinoldione chromophore (Sheriha et al., 1987). The IR spectrum displayed absorption bands at ν_{max} 3450 (OH group), 1702 (C=O), 1673 (HN–CO) and 1611 cm^{-1} (C=C). The PND ^{13}C NMR (Table 1) and DEPT spectra revealed the presence of four methyls, one methylene, seven methines and seven quaternary carbons. On the other hand, the ^1H NMR spectrum of compound **3** (Table 1) showed resonances for four aromatic protons at δ 7.89 (*d*, *J* = 7.4 Hz, H-5), 7.22 (*t*, *J* = 7.6, H-6), 7.63 (*dd*, *J* = 6.9, 7.2 Hz, H-7) and 7.16 (*d*, *J* = 8.1 Hz, H-8). The relative deshielding of H-5 and H-7 was attributed to the 4-carbonyl function. In addition, there was one oxygenated methine proton resonating at δ 3.42 (*d*, *J* = 9.5 Hz, H-1′), one methine proton at δ 1.82 (*ddd*, *J* = 11.1, 3.4, 3.4 Hz, H-2′), two methyls as part of a dimethylallyl unit, and two methyls attached to an oxygenated quaternary carbon. The dimethylallyl unit was defined by the three proton ABX system comprising the nonequivalent AB methylene protons (H-3′) at δ_A 2.22 as a doublet and δ_B

2.14–2.07 as a multiplet, the X vinylic proton at δ_X 4.52 (H-4′) as a doublet, and the nonequivalent vinylic geminal dimethyl singlets at δ 1.42 and 0.85.

Based on these data, it was clear that compound **3** was a C-3 substituted 4-ketoquinolone. The C-3 substituent contained a dimethylallyl function, an epoxide, and two methyls on an oxygenated quaternary carbon. In an effort to try to establish these bonding patterns, a 2D-inadequate experiment was conducted. All of the aliphatic connectivities were observed, except for those between δ_C 74.2 and 62.3. The 2D-inadequate was not conclusive, however, and there was an unusually upfield olefinic methyl signal (δ_H 0.85).

A single-crystal X-ray analysis established unequivocally the complete structure and relative stereochemistry of compound **3**. A view of the solid-state conformation is illustrated in Fig. 1. Bond lengths are all in accord with expectations (Allen et al., 1987). The hydroxy group is intramolecularly hydrogen-bonded to the epoxide oxygen atom [O(11′)...O(11) = 2.835(5) Å]. Pairs of enantiomers of **3** are associated by N–H...O hydrogen bonds [N(1)...O(9) = 2.877(6) Å] about crystallographic centers of symmetry.

Full assignments of the ^{1}H and ^{13}C signals of compound **3** were secured by the ^{1}H–^{1}H COSY, HMQC and HMBC spectra (Table 1). The HMBC spectrum of **3** showed ^{1}H–^{13}C long-range correlations between methine proton at δ 3.42 (H-1′) and δ 45.6 (C-2′), 62.3 (C-3) and 170.3 (C-2), and between the methine proton at δ 1.82 (H-2′) and δ 74.2 (C-1′), 73.8 (C-8′), 27.5 (C-9′ / C-10′), 29.8 (C-10′/C-9′) and 123.0 (C-4′). There were also long-range correlations between H-9′ and H-10′ and the carbons resonating at δ 45.6 (C-2′) and 73.8 (C-8′). It is interesting to note that X-ray-crystallography indicated that the C-6′ methyl was hovering right above the benzene ring of the quinoldione system. This perhaps explains the abnormally shielded chemical shift value of this vinylic methyl group at δ 0.85. This is the first reported isolation of this alkaloid from nature and it was given the trivial name haplotubinone.

Compound **4** was obtained as an amorphous yellow powder. Its UV spectrum exhibited absorption bands at λ_{max} 250, 320, 332 nm, characteristic of a furoquinoline alkaloid (Sangster and Stuart, 1965) and the spectrum remained unaffected by the addition of alkali. The IR spectrum showed a strong band at ν_{max} 3430 cm^{-1}

supporting the presence of a hydroxyl absorption. The mass spectrum of compound **4** disclosed, in addition to the molecular ion $[M]^+$ at *m/z* 415 ($C_{23}H_{29}NO_6$), significant fragments at *m/z* 400 $[M-15]^+$, 356 $[M-59]^+$, 245 $[M-170]^+$ (100%) and 227 $[M-188]^+$. The ^{13}C NMR spectrum (Table 2) of **4** exhibited 23 carbon signals manifested via DEPT spectrum as five methyls, three methylene, six methines, and nine quaternary carbons. The ^{1}H NMR spectrum of compound **4** (Table 2) confirmed its furoquinoline nature and displayed signals for two methoxy groups at δ 4.11 and 4.42; the latter signal is indicative of a methoxy group at C-4, based on the proton chemical shift data characteristic of 4-methoxyfuro-quinoline alkaloids (Ayafor and Okogun, 1982). On the other hand, the second methoxy group could be safely positioned at C-8 owing to its deshielded carbon resonance (δ 61.6) (Panichpol and Waterman, 1978) leaving position C-7 for the side chain moiety. A pair of AB doublets at δ 7.04 and 7.58 ($J = 2.8$ Hz) corresponded to the two furan protons, while the other two aromatic protons appeared as doublets at δ 7.21 ($J = 9.2$ Hz) and 7.97 ($J = 9.6$ Hz), suggesting their positions at H-6 and H-5, respectively (Robertson, 1963).

In addition, the ^{1}H NMR spectrum (see Table 2) showed the presence of three tertiary methyl groups at δ 1.13, 1.15, and 1.75, with that at δ 1.75 deshielded enough to be on an olefinic functional group, three methylene groups, one olefinic methine proton (δ 5.61, *ddd*, $J = 1.2$, 6.6, 6.6 Hz), and one methine proton (δ 3.31, *dd*, $J = 1.6$, 10.6 Hz) on an oxygen-bearing group. These assignments, along with the loss of a fragment of *m/z* 170, pointed to the presence of a 6′,7′ - dihydroxygeranyloxyl moiety (Ulubelen et al., 1995), confirmation of which was derived from the correlations observed in ^{1}H–^{1}H COSY, HMQC and HMBC spectra (Table 2). In the HMBC spectrum of **4** the H-1′ (δ 4.79, *d*) signal showed $^{2}J_{C-H}$ and $^{3}J_{C-H}$ correlations with the ^{13}C signals at δ 120.4 (CH, C-2′), 141.6 (C, C-3′) and 151.3 (C, C-7), while H-2′ (δ 5.61, *ddd*) showed three-bond correlations with the signals at δ 36.5 (CH_2, C-4′) and 16.6 (CH_3, C-10′). Similarly, H-4′ (δ 2.20–2.12 and 2.32–2.29, m) exhibited two- and three-bond correlations with the carbon signals at δ 29.3 (CH_2, C-5′), 141.6 (C, C-3′), 120.4 (CH, C-2′) and 77.7 (CH, C-6′). The H-5′ signals (1.48–1.43 and 1.62–1.58, m) displayed correlations with the carbons signals at δ

36.5 (CH_2, C-4′), 77.7 (CH, C-6′) and 141.6 (C, C-3′). On the other hand, the H-6′ signal (δ 3.31) showed long-range correlations with δ 36.5 (CH_2, C-4′), 23.1 (CH_3, C-9′) and 72.9 (C, C-7′), which in turn was coupled to δ 1.15 and 1.13 (H-8′ and H-9′, respectively). These findings established the structure of **4** and it was given the trivial name haplotubine.

Haplophyllum tuberculatum also yielded compounds **1** and **2** which proved to be known compounds. Compound **1** was identified as *N*-(2-phenylethyl)benzamide which was previously found to occur in *Oxytropis muriceta and Oxytropis pseudoglandulosa*, members of the Fabaceae family (Batsurens et al., 1992). The present work is the first reported isolation of this compound from the genus *Haplophyllum* and the family Rutaceae. In contrast, compound **2** was identified as the lignan diphyllin which was previously isolated from *Haplophyllum tuberculatum* and other *Haplophyllum* species (Sheriha and Abou Amer, 1984).

3. Experimental

3.1. General

Melting points were determined in capillary tubes using an Electrothermal 9100 capillary melting-point apparatus and are uncorr. The UV spectra were recorded on a Hewlett-Packard HP-845 UV-vis spectrophotometer, while the FTIR spectra were determined on a Nicolet Impact 410 spectrophotometer. Specific rotations were measured as solutions in methylene chloride on a Perkin-Elmer 242 MC polarimeter. The ^{1}H and ^{13}C NMR spectra were obtained in $CDCl_3$ using either Varian INOVA-400 or a Bruker DRX-500 NMR spectrometers operating at 400 and 100 or 500 and 125 MHz, respectively, and using standard pulse sequences. The chemical shift values are reported as ppm using tetramethylsilane (TMS) as internal standard and coupling constants *J* are expressed in Hz. Low resolution MS were recorded on a Fison VG Autospec Spectrometer, while the high resolution spectra were taken in sodium m-nitrobenzyl alcohol, using a Bioapex FTMS with electrospray ionization. Thin layer chromatographic analyses were carried out on pre-coated silica gel 60 F254 (Merck) using acetone-toluene mixtures as solvent systems and spots were visualized under short and long wavelength UV light and by spraying with Dragendorff reagent. The adsorbent used for column chromatography was silica gel 60/230–400 mesh (EM Science). X-ray diffraction data were recorded at 296 K on an Enraf-Nonius CAD-4 diffractometer (Cu-K_α radiation, graphite monochromator, $\lambda = 1.5418$ Å).

3.2. Plant material

Haplophyllum tuberculatum (Forssk.) A. Juss. was collected in April 1987, near the Riyadh-Gassim highway, 100 miles from Riyadh, in central Saudi Arabia.

The plant material was identified by Dr. Sultanul Abidin of the Department of Pharmacognosy, College of Pharmacy, King Saud University, Riyadh, Saudi Arabia, and voucher specimens are being kept at the local herbarium.

3.3. Extraction and isolation

The air-dried, aerial part (2.0 kg) was extracted with methylene chloride in a Soxhlet for 72 h. The extract (58 g) was partitioned between n-hexane and acetonitrile, 4×300 ml of each. The two solvents were presaturated with each other. The acetonitrile layer, after evaporation of the solvent, was subjected to flash chromatography on silica gel using toluene and increasing concentrations of acetone to give 6 fractions (A–F).

Fraction A was subjected to silica gel CC using ether/*n*-hexane (30:70) as eluent, to give first the known alkaloid buchapine, as previously reported (Al-Yahya et al., 1992) then the known alkaloid *N*-(2-phenylethyl)benzamide (**1**) (5 mg). Fraction B was flash chromatographed on silica gel using benzene/acetone (98:2) to yield first the known alkaloid 7-hydroxy-8-(3-methyl-2-butenyl)-4-methoxyfuro[2,3*b*]quinoline, as previously reported (Al-Yahya et al., 1992), followed by a yellow residue, which after crystallization from EtOAc–EtOH, furnished the known lignan diphyllin (**2**) (60 mg) as yellow needles. Further elution provided a fraction that yield upon crystallization the known alkaloid flindersine, as previously reported (Al-Yahya et al., 1992). Flash chromatography of the mother liquor on silica gel using *n*-hexane/acetone (60:40) afforded compound **3** as colorless crystals (100 mg) and compound **4** as an amorphous yellow powder (20 mg).

3.4. N-(2-Phenylethyl)benzamide (*1*)

White amorphous powder, mp 115.0–116.0°C (lit. Batsuren et al., 1992, 117.0–118.0°C); UV, IR, MS and NMR matched the literature data (Batsuren et al., 1992, Kita et al., 1986, Stamm et al., 1985).

3.5. Diphyllin (*2*)

Yellow needles, mp 282.0–285.0°C (lit. Sheriha et al., 1984, 282.0–285.0°C); UV, IR, MS and NMR were indistinguishable from those reported (Gozeler and Gozeler, 1984).

3.6. Haplotubinone (*3*)

Colorless crystals from ether, mp 177.0–178.0°C; $[\alpha]_D^{22}$ zero° (*c*; 0.500 in CH_2Cl_2); UV λ_{max} (MeOH) nm (log ε): 237 (4.40), 262 (*sh*) (3.50), 352 (3.70); IR ($CHCl_3$) ν_{max} cm^{-1}: 3450, 2976, 2930, 1702, 1673, 1611, 1486, 1371, 907 and 755; ^1H NMR ($CDCl_3$, 500 MHz) and ^{13}C NMR ($CDCl_3$, 125 MHz), see Table 1; EIMS *m*/*z* (rel. int. %) 330 $[M+H]^+$ (4.7), 256 (13.3), 242 (16.4), 214 (24.8), 200 (23.3), 177 (89.9), 161 (27.8) and 43 (100); HRMS: obsd 352.1586 (calc. for $C_{19}H_{23}NO_4$ + Na 352.1524).

3.7. Haplotubine (*4*)

Amorphous yellow powder; $[\alpha]_D^{22}$ −6° (*c*; 1.2 in CH_2Cl_2); UV λ_{max} (MeOH) nm (log ε): 250 (4.87), 320 (3.90), 332 (3.88); IR ($CHCl_3$) ν_{max} cm^{-1}: 3430, 2973, 2936, 2870, 1627, 1614, 1581, 1507, 1492, 1369, 1267, 1336, 1098, 1045 and 966; ^1H NMR ($CDCl_3$, 400 MHz) and ^{13}C NMR ($CDCl_3$, 100 MHz), see Table 2; EIMS *m*/*z* (rel. int. %) 415 $[M]^+$ (1.2), 400 (1.2), 356 (3), 245 (100) and 227 (96); HRMS: obsd 438.1888 (calc. for $C_{23}H_{29}NO_6$ + Na 438.1892).

3.8. X-ray crystal structure analysis of haplotubinone (*3*)

Crystal data: $C_{19}H_{23}NO_4$, $M_r = 329.40$, monoclinic, space group $P2_1/c(C_{2h}^5)$, $a = 15.939(2)$, $b = 6.123(1)$, $c = 19.041(3)$ Å, $\beta = 110.53(1)°$, $V = 1740.3(9)$ Å, $Z = 4$, $D_c = 1.257$ g cm^{-3}, μ(Cu-K_α radiation, $\lambda = 1.5418$ Å) = 6.8 cm^{-1}; crystal dimensions: 0.02×0.14×0.60 mm.

Check reflections remeasured every 2 h throughout data collection showed no significant decay (< 1.0%). Intensity data ($\theta_{max} = 65°$; 3064 + h, + k, ±1 total reflections, 2947 independent after merging equivalent reflections, $R_{merge} = 0.04$) were corrected for Lorentz, polarization, and absorption [$T_{max.}$:$T_{min.}$(rel.) = 1.00:0.92] effects. The crystal structure was solved by direct methods. Full-matrix least-squares refinement of atomic parameters (anisotropic C, N, O; calculated hydrogen positions), during which $\Sigma w\Delta^2\left[w = 1/\sigma^2(|F_o|), ?\Delta = (|F_o| - |F_c|)\right]$ was minimized, converged (max. shift: esd = 0.03) at $R = 0.055$ ($R_w = 0.063$, GOF = 1.21) over 1225 reflections with $I > 2.0\sigma(I)$. A final difference Fourier synthesis contained no unusual features $\left[\Delta\rho\left(e/\mathring{A}^3\right) = 0.18(\max), -0.22 (\min)\right]$. Atomic coordinates and thermal parameters, bond lengths, bond angles, and torsion angles have been deposited at the Cambridge Crystallographic Data Centre, Lensfield Road, Cambridge CB2 1EZ, UK.

Received 4 October 2000; received in revised form 8 February 2001

Abstract

Three new indole alkaloids with methyl chanofruticosinates skeletal system, viz., methyl 12-methoxy-N_1-decarbomethoxychanofruticosinate, methyl 12-methoxychanofruticosinate and methyl 11,12-dimethoxychanofruticosinate, in addition to methyl 11, 12-methylenedioxy-N_1-decarbomethoxychanofruticosinate, have been isolated from the leaves of *Kopsia flavida* Blume. The structures of these three new indole alkaloids were assigned by NMR spectral data using various 2D-techniques. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Kopsia flavida* Blume; Apocynaceae; Leaves; Indole alkaloids; Methyl chanofruticosinate skeletal system

1. Introduction

Many *Kopsia* species have been investigated chemically and are known to contain indole alkaloids of various structural types (Sevenet et al., 1994). In Penisular Malaysia, about 18 species are found distributed in the lowland forests including four species in Sarawak and north Borneo (Markgraf, 1970; Ashton, 1988; Sevenet et al., 1994). Some of these species have been subjected to phytochemical studies by several workers, which has resulted in the discovery of many novel compounds as well as some useful bioactivities (Awang et al., 1992; Kam et al., 1993b, 1994, 1996a,b,c, 1999; Kam and Yoganathan, 1996). In Malaysia, the roots of many *Kopsia* species are used in traditional medicine for the treatment of ulcerated noses in tertiary syphilis (Burkill, 1966). In the present paper, we report the isolation of three new indole alkaloids with methyl chanofruticosinate skeletal system together with a known alkaloid from the leaves of the yet uninvestigated *K. flavida* Blume (family: Apocynaceae).

2. Results and discussion

The alkaloidal extract of the leaves of *K. flavida* was obtained in the usual manner. Flash column chromatography of the crude mixture on silica gel, followed by

	R_1	R_2	R_3

extensive column and preparative thin layer chromatography yielded four indole alkaloids with methyl chanofruticosinate skeletal system, viz., methyl 12-methoxy-N_1-decarbomethoxychanofruticosinate **1**, methyl 12-meth-x11dummy;oxychanofruticosinate **2**, methyl 11,12-dimethoxychano-fruticosinate **3** and methyl 11, 12-methylenedioxy-N_1-decarbomethoxychano-fruticosinate **4**. The first three are new alkaloids.

The structures of the new compounds were elucidated by a combination of EI mass spectrometry, ^{1}H and ^{13}C NMR spectra in combination with 2D NMR techniques (COSY-45, HMQC and HMBC). The known compound **4** was identified by comparison of their spectroscopic properties (UV, ^{1}H and ^{13}C NMR) (Chen et al., 1981; Kam et al., 1993a). The UV spectrum of all four alkaloids showed absorption maxima typical of a dihydroindole chromophore. The mass spectra of all the compounds exhibited fragmentation patterns typical of indole alkaloids with methyl chanofruticosinate skeletal system, with typical base peak corresponding to $[M-CO_2Me]^+$ fragment.

The HREIMS mass spectrum of compound **1** showed a $[M]^+$ molecular ion at m/z 382.1897 corresponding to $C_{22}H_{26}N_2O_4$. The ^{1}H and ^{13}C NMR spectra (Tables 1 and 2, respectively) of **1** showed that it is the methoxy derivative of methyl N_1-decarbomethoxychanofruticosinate which has been reported in *K. arborea* (Kam et al., 1993a), as indicated by appearance of a singlet (3H) at δ 3.84 belonging to an aromatic methoxy group signal in ^{1}H NMR. The position of the methoxy group was assigned to the 12-position in the benzene ring by the HMQC and HMBC experiments.

The mass spectrum of compounds **2** and **3** showed $[M]^+$ at m/z 440.1952 and 470.2061, corresponding to the formulae $C_{24}H_{28}N_2O_6$ and $C_{25}H_{30}N_2O_7$, respectively. Based on the ^{1}H NMR and ^{13}C NMR spectrums, compounds **2** and **3** were very similar to each other except for the presence of an additional methoxyl moiety in the latter. The connectivities between protons and carbons in the HMBC and HMQC spectrums indicated that proton singlets at δ 3.85 in both compounds were due to methoxyl attached to C-12. Another methoxyl signal at δ 3.79 in spectrum for compound **3** was connected to C-11. The coupling patterns of the aromatic protons in the ^{1}H NMR spectrums support the assignment of compound **2** and **3** as methyl 12-methoxychanofruticosinate and methyl 11,12-dimethoxychano-fruticosinate, respectively.

3. Experimental

3.1. Plant material

The plant material were collected from the Forest Research Institute of Malaysia (FRIM), Malaysia and identified as *Kopsia flavida* by taxonomist Norseha Ayop from FRIM and deposited as a voucher specimen in the herbarium of FRIM, Malaysia.

3.2. Extraction and isolation

The dry powdered sample of the leaves (624.5 g) was extracted with MeOH (2 l) for 3 days at room tempera-

ture (30°C) and concentrated under reduced pressure to yield 48.5 g of the crude extract which was then triturated in 5% aqueous H_2SO_4 (150 ml) followed by basification with 10% Na_2CO_3 and then extracted into $CHCl_3$. The organic layer was washed with distilled water, dried (Na_2SO_4) and concentrated to yield 2.9 g of crude alkaloids. The alkaloid mixture (2.5 g) was purified by flash column chromatography (silica gel, MERCK 230–400 mesh) using *n*-hexane–EtOAc (1:1; 200 ml), $CHCl_3$ (100%; 150 ml), EtOAc (100%, 150 ml) and then MeOH (100%, 100 ml) as eluents. Several fractions (50 ml each) were collected, analysed by TLC and grouped accordingly. The *n*-hexane–EtOAc (1:1) eluates were subjected to repeated column chromatography followed by SiO_2 medium-pressure liquid chromatography (acetone–$CHCl_3$; 1:25) to afford methyl 12-methoxy-N_1-decarbomethoxychanofruticosinate **1** (1.5 mg). Further purification of the same fraction using ODS reverse phase column chromatography (H_2O–MeOH; 1:1) gave methyl 11, 12-methylenedioxy-N_1-decarbomethoxychanofruticosinate **4** (4.5 mg). Methyl 12-methoxychanofruticosinate **2** (54.8 mg) and methyl 11,12-dimethoxychanofruticosinate **3** (2.5 mg), were obtained from EtOAc fractions (100%) after further purification by preparative TLC (SiO_2, *n*-hexane–EtOAC; 1:1).

Received 13 November 2000; received in revised form 19 February 2001

Abstract

We describe the composition of novel polyhalogenated homosesquiterpenic acids from the red alga *Plocamium* collected during summer on Maltese Islands and Corsica. The compounds, predominantly derivatives with unique groups (bromine, chlorine, and diene), were identified by means of ^{1}H and ^{13}C NMR, MS, IR and UV spectra. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Polyhalogenated homosesquiterpenic acids; Red alga; *Plocamium*; NMR, MS, IR and UV spectra

1. Introduction

Plocamium cartilagineum (L.) Dixon (Gigartinales) has a wide range of distribution (Cormaci et al., 1997; Frick et al., 1996). This species is cosmopolitan in all of the worlds' temperate oceans. *P. cartilagineum* grows in the mid to low intertidal zone and down to 20 m subtidally. It can live in sheltered to moderately exposed and exposed open coast habitats. This species is generally epilithic, growing on rocks, sand covered rocks or shell fragments. *P. cartilagineum* has also been found as an epiphyte on articulated coralline algae (Bischoff-Bäsmann and Wiencke, 1996).

Red algae of the genus *Plocamium* have been shown to be a rich source of halogenated monoterpenes and other compounds (Faulkner, 2000; Abreu et al., 1997). In the course of our investigation of the chemical composition of algae of fresh water (Rezanka et al., 1983; Rezanka and Podojil, 1984) and marine origin (Rezanka et al., 1988; Dembitsky et al., 1993), we describe in this paper the elucidation of the structure of four new polyhalogenated homosesquiterpenic acids from *P. cartilagineum* collected on Maltese Islands and Corsica.

2. Results and discussion

A fresh sample of *P. cartilagineum* was separately and successively extracted with a mixture of CH_2Cl_2 and MeOH. Fractionation of the extracts by chromatography on Sephadex LH-20 afforded three main fractions. The third fractions were purified by means of a preparative RP–HPLC to yield four acids (Table 1 and Fig. 1). Compound (**1**) was determined to have the molecular formula $C_{16}H_{19}O_3BrCl_2$ by HREIMS with major fragment peaks at m/z 372, 374 and 376 $[M–HCl]^+$, m/z 293 and 295 $[M–HCl–Br]^+$ and m/z 257 $[M–2xHCl–Br]^+$. The IR spectrum was consistent with the presence of an α, β-unsaturated ketone (1685 cm^{-1}) and a carboxylic group (1710 cm^{-1}). Compound **1** showed an UV maximum at 243 nm, typical for a conjugated en-one system. The ^{1}H NMR spectrum showed vinylidene protons at δ_H 6.16 and 5.86, which were found to be attached to C-14 (δ_C 126.8) from the HMQC experiment, and showed long-range correlations with C-4 (^{3}J) and C-3 (^{2}J) (δ_C 200.8 and 143.4, respectively) in the HMBC spectrum.

A weak carbon signal at δ_C 173.9 (C-1), which showed a ^{2}J interaction with δ_H 3.24 (H_2-2), was assigned to a carboxylic acid. The H_2-2 signal also exhibited HMBC interactions with C-3, C-4 and C-14. Finally, the positions of the two methyl groups were determined by the HMBC experiment (see Table 2). For example, Me-15

Table 1
Content of novel polyhalogenated homosesquiterpenic acids from the red alga *Plocamium cartilagineum* collected on Maltese Islands and Corsica (in mg on 100 g of dried alga)

Acid	Maltese Islands	Corsica
A (**1**)	5.4	–
B (**2**)	2.3	–
C (**3**)	–	3.8
D (**4**)	–	1.9

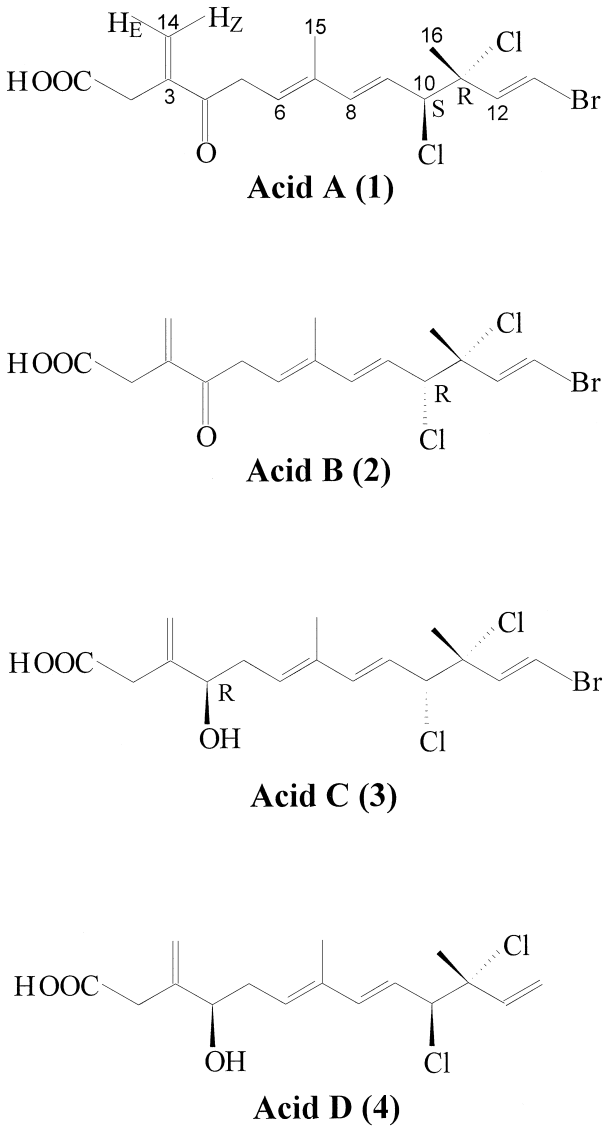

Fig. 1. The structure of acids A–D (**1**–**4**) from *Plocamium cartilagineum*.

had correlations with C-6, C-7 and C-8 and Me-16 with C-10, C-11 and C-12. The ^{1}H NMR spectrum of **1** (Table 2) displayed also two methyl signals at δ 1.78 and 1.56. DQF–COSY measurements allowed the following spin systems to be discerned: an AB quartet $-$CH=CHX at δ 6.45 (H-12) and δ 6.58 (H-13) and a three-proton AMX system $(R)_3C$–CH=CH–CHX– at δ 6.36 (H-8), δ 6.42 (H-9) and δ 4.55 (H-10).

The *E* stereochemistry of trisubstituted Δ^6 double bond is based on the relative upfield shift of the vinylic methyl group (C-15) (δ_C 15.7) and NOESY γ-correlations between this methyl group and the methylene group at C-5 (Blunt et al., 1985).

The stereochemistry of the double bonds Δ^8 and Δ^{12} was assigned as *E* on the basis of the interproton coupling constants J_{8H-9H} = 16.1 Hz and $J_{12H-13H}$ = 13.4 Hz. The coupling constants of olefinic protons in (3*E*,7*E*)-2,6-dimethyloctadiene polyhalogenated monoterpenes lie in the range of 13.5 to 15.9 Hz (Jongaramruong and Blackman, 2000). In the ^{13}C NMR spectrum of **1** (Table 3), the chemical shift of C-13 δ 110.8 indicated a vinyl bromide functionality. The remaining three sp^2 olefinic carbons absorb at δ 132.4 (C-12), δ 124.6 (C-8), and δ 136.5 (C-9). The halogen substitution at C-5 and C-6 was established by comparison of the ^{1}H NMR, ^{13}C NMR, and MS of 1 with those of known compounds (Grible, 1996). The proton and carbon chemical shifts of the C-16 methyl group δ 1.56 and δ 26.2 suggest a (10*S**,11*R**) stereochemistry, in accordance with the empirical rules of Mynderse and Faulkner (1975) and Crews and Kho-Wiseman (1974).

Thus, NMR spectroscopy indicated that the structure of compound **1** is that of (6*E*,8*E*,12*E*)-3-methylene-4-oxo-7,11-dimethyl-(10*S**,11*R**)-dichloro-13-bromo-trideca-6,8,12-trienoic acid.

Acid B (**2**) was isolated from the same fraction as **1** and a sesquiterpene skeleton with the formula $C_{16}H_{19}O_3BrCl_2$ was indicated by HREIMS; it had the same molecular weight as **1** but the some spectral characteristics were different. In support of this, the main MS fragment peaks were at *m*/*z* 293 and 295. The ^{13}C NMR spectrum (Table 3) indicated that Cl on C-10 had an opposite configuration, i.e. *R**. This assumption was proved by the ^{1}H NMR chemical shift of H-16 protons, in keeping with literature data (Mynderse and Faulkner, 1975; Crews and Kho-Wiseman, 1974). The stereochemistry at the C-10 and C-11 centers was assigned on the basis of NMR spectra (see above) and positive optical rotation ($[\alpha]_D^{21} = +37.6^\circ$). Acid B (**2**) is (6*E*,8*E*,12*E*)-3-methylene-4-oxo-7,11-dimethyl-(10*R**,11*R**)-dichloro-13-bromo-trideca-6,8,12-trienoic acid.

Acid C (**3**), the most polar of the four compounds, had the formula $C_{16}H_{21}O_3BrCl_2$, as determined by HREIMS. Comparison of its ^{1}H and ^{13}C NMR spectral data with those of compounds **1** and **2** suggested that the structure of **3** was similar, except for the presence of one substituent. The change of ketone group on C-4 to a hydroxyl group. Giving rise to another chiral carbon was indicated by the optical rotation. The fact that the end of the molecule has the same chemical shifts in ^{1}H and ^{13}C NMR as acid B (**2**), proved that the two were

identical. The strongly shielded nature of H-4 (δ 4.02) and C-4 (δ 74.6) indicated the presence of a hydroxyl group, and its *R** configuration was determined by means of Mosher's esters. Treatment of each hydroxy acid with (*R*)-(−)-MTPACl or (*S*)-(+)-MTPACl converted them into (*S*)- and (*R*)-2-methoxy-2-trifluoromethyl phenylacetic acid (MTPA) esters (**3s**, and **4s** and **3r** and **4r**, respectively). The values of $\Delta\delta = [\delta$(S-MTPA ester) − δ(R-MTPA ester)] in the ^{1}H NMR spectra suggested that the absolute configurations at C-4 of compounds **3** and **4** were (R) (Ohtani et al., 1991a,b). The data are shown in Table 4. Compound **3** could also be denoted (6*E*,8*E*,12*E*)-3-methylene-(4*R*)-hydroxy-7,11-dimethyl-(10*R**,11*R**)-dichloro-13-bromo-trideca-6,8,12-trienoic acid.

Table 4

[a] Resonances of H directly attached to esterified carbon are not analyzed and/or values < |3 Hz| have not been included.

Acid D (**4**), with the molecular formula $C_{16}H_{22}O_3Cl_2$, had a homosesquiterpene structure, as in **1**. However, the chain lacked one bromine atom. A 3-chloro-1-butenyl end of the chain was indicated by mass fragmentation (base peak at *m*/*z* 89) and ^{1}H NMR assignments of a tertiary methyl group and clean vinylic ABX system at δ 5.21 (H-13a), δ 5.38 (H-13b) and δ 6.02 (H-12). Therefore, the bromine at the end of chain (on C-13) is obviously missing. The further part of the molecule is the same as that of acid C (**3**). All the above data indicate that acid D (**4**) is (6*E*,8*E*,12*E*)-3-methylene-(4*R*)-hydroxy-7,11-dimethyl-(10*S**,11*R**)-dichloro-13-bromo-trideca-6,8,12-trienoic acid.

In terms of biosynthesis, halogenated homosesquiterpenic acids may be biosynthesized by elongation of the know a halogenated monoterpenes described in *Plocamium* many times (Jongaramruong and Blackman, 2000; Crews and Kho-Wiseman, 1974; König at al., 1990).

Although this alga has a worldwide distribution, which is restricted to temperate seas, it is of interest to

note that this Mediterranean Sea collection afforded new metabolites and provides yet another example of chemical variability of marine natural products.

3. Experimental

The algal material *Plocamium cartilagineum* (L.) Dixon (Gigartinales) was collected at two places at Maltese Islands and Corsica.

UV spectra were measured by a Cary 118 (Varian) apparatus in EtOH within the range of 200–350 nm. A Perkin-Elmer Model 1310 (Perkin-Elmer, Norwalk, CT, USA) infrared spectrophotometer was used for scanning infrared spectroscopy of methyl esters as neat film. NMR spectra were recorded on a Brüker AMX 500 spectrometer (Bruker Analytik, Karlsruhe, Germany) at 500.1 MHz (^{1}H), 125.7 MHz (^{13}C). High- and also low-resolution mass spectra were recorded using a VG 7070E-HF spectrometer (Micromass, Manchester, UK). The ionizing condition was 70 eV.

The air dried samples (250 and 300 g) from both collections were separately extracted with mixture of CH_2Cl_2–MeOH (1:1, v/v). The extracts were concentrated under N_2. The total lipid extract, viscous dark oil, was subjected to a Sephadex LH-20 column with CH_2Cl_2–MeOH (1:5) and further separated by semi-preparative RP–HPLC, a C_{18} reversed phase column (5 μm, 7.8×250 mm, Supelco, USA) was employed. A linear gradient from 20% H_2O and 80% acetonitrile to 1% water and 99% acetonitrile over 25 min, flow rate 2 ml/min was used to separate all of the compounds in crude extract. The acids **1**–**4** were detected by UV absorption at 208 nm.

(*S*)-MTPA esters. To a stirred solution of ~1.0 mg of hydroxy compound in 0.3 ml of dry pyridine was added 20 μl of (−)-MTPA chloride. After stirring the mixture under N_2 at room temperature for 1 h, the solvent was removed by blowing with N_2. The residue was redissolved in 2 ml of 30 ml EtOAc–hexane and filtered through a Sep-Pak silica column. After removing the solvent under vacuum, the residue was separated by reversed-phase HPLC (ODS column, 100% MeCN) to yield ~1.0 mg of *S* ester as a colorless gum; ^{1}H NMR spectra ($CDC1_3$), see Table 4.

(*R*)-MTPA esters. Prepared as described for ***S*** esters. From ~1.0 mg of compound and 20 μl of (+)-MTPA chloride 0.9 mg of *R* esters were obtained as a colorless gum; ^{1}H NMR spectra ($CDCl_3$), see Table 4.

Acid A (**1**) is (6*E*,8*E*,12*E*)-3-methylene-4-oxo-7,11-dimethyl-(10*S**,11*R**)-dichloro-13-bromo-trideca-6,8,12-trienoic acid (5.4 mg; 0.0054%), $[\alpha]_D$ −43.1° (*c* 0.17, MeOH); UV λ_{max}(EtOH) (log ε) 243 nm (2.37); IR (film) ν_{max} 2950, 2910, 1710 (COOH), 1685 cm^{-1} (α, β-unsaturated ketone); LREIMS *m*/*z* (% of base peak) 372 (15), 374 (16) and 376 (5) [M–HCl]$^+$, *m*/*z* 293 (11) and 295 (5) [M–HCl–Br]$^+$, *m*/*z* 257 (15) [M–2xHCl–Br]$^+$ HREIMS (*m*/*z*) 408.3247, (calc. for $C_{16}H_{19}O_3{}^{79}Br^{35}Cl_2$ 408.3251). NMR data, see Tables 2 and 3.

Acid B (**2**) is (6*E*,8*E*,12*E*)-3-methylene-4-oxo-7,11-dimethyl-(10*R**,11*R**)-dichloro-13-bromo-trideca-6,8,12-trienoic acid (2.3 mg; 0.0023%), $[\alpha]_D$ +37.6° (*c* 0.14, MeOH); UV λ_{max} (EtOH) (log ε) 243 nm (2.37); IR (film) ν_{max} 2950, 2910, 1710 (COOH), 1685 cm^{-1} (α, β-unsaturated ketone); LREIMS *m*/*z* (% of base peak) 372 (14), 374 (15) and 376 (4) [M-HCl]$^+$, *m*/*z* 293 (9) and 295 (4) [M–HCl–Br]$^+$, *m*/*z* 257 (13) [M–2xHCl–Br]$^+$ HREIMS (*m*/*z*) 408.3247, (calc. for $C_{16}H_{19}O_3{}^{79}Br^{35}Cl_2$ 408.3251). NMR data, see Tables 2 and 3.

Acid C (**3**) is (6*E*,8*E*,12*E*)-3-methylene-(4*R*)-hydroxy-7,11-dimethyl-(10*R**,11*R**)-dichloro-13-bromo-trideca-6,8,12-trienoic acid (3.8 mg; 0.0038%), $[\alpha]_D$ +30.1° (*c* 0.14, MeOH); UV λ_{max} (EtOH) (log ε) 243 nm (2.37); IR (film) ν_{max} 3450 (OH), 2950, 2910, 1715 (COOH); LREIMS *m*/*z* (% of base peak) 374 (17), 376 (19) and 378 (7) [M–HCl]$^+$, *m*/*z* 295 (10) and 297 (4) [M–HCl–Br]$^+$, *m*/*z* 259 (11) [M–2xHCl–Br]$^+$ HREIMS (*m*/*z*) 410.3406, (calc. for $C_{16}H_{21}O_3{}^{79}Br^{35}Cl_2$ 410.3409). NMR data, see Tables 2 and 3.

Acid D (**4**) is (6*E*,8*E*,12*E*)-3-methylene-(4*R*)-hydroxy-7,11-dimethyl-(10*S**,11*R**)-dichloro-13-bromo-trideca-6,8,12-trienoic acid oil (1.9 mg; 0.0019%), $[\alpha]_D$ 15.4° (*c* 0.18, MeOH); UV λ_{max}(EtOH) (log ε) 243 nm (2.37); IR (film) λ_{max} 3450 (OH), 2950, 2910, 1715 (COOH); LREIMS *m*/*z* (% of base peak) 296 (14) and 298 (6) [M–HCl]$^+$, *m*/*z* 259 (17) [M–2xHCl]$^+$ HREIMS (*m*/*z*) 332.3483, (calc. for $C_{16}H_{22}O_3{}^{35}Cl_2$ 332.3489). NMR data, see Tables 2 and 3.

Received 27 July 2000; received in revised form 13 November 2000

Abstract

A cyclic peptide containing thiazole and oxazole moieties was isolated from *Nostoc* 31 and its structure determined by chemical degradation detailed NMR and mass spectroscopic analyses. The compound is stereochemically pure and closely related to nostocyclamide in which D-valine is replaced by D-methionine. Therefore, it differs from tenuecyclamide C reported to contain L-methionine. It shows allelopathic activity against *Anabaena* 7120, but is inactive against grazers. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Cyanobacteria; *Nostoc*; Cyclic peptide; Thiazole; Allelopathic compounds; NMR

1. Introduction

Thiazole-containing cyclic and linear peptides have recently gained much pharmacological interest. Some of them turned out to be potent agents against multidrug resistance (Williams and Jacobs, 1993; Ogino et al., 1996) that develops in cancer cells resistant to chemotherapy. Marine seahares and ascidians were the first sources of several structural variants, among them dolastatins, patellamides and tawicyclamides (Michael and Pattenden, 1993; McDonald et al., 1992). The extreme variability of concentration of these compounds in the animals was taken as an indication that in ascidians these compounds were accumulated from symbiotic prochlorophytes and in seahares from cyanobacterial food rather than synthesized by the animals. In recent years similar cyclopeptides have been isolated from cultured freshwater and terrestrial cyanobacteria. The importance of the diet for the accumulation of cyclic peptides became clear when the same compound was isolated from the ascidian *Lissoclinum bistratum* and a pure cyanobacterial culture (*Westiellopsis prolifica*). The compounds were independently named cycloxazoline (Hambley et al., 1992) and westiellamide (Prinsep et al., 1992) In *Stigonema dendroideum*, three cyclic peptides were found which were called dendroamides (Ogino et al., 1996). They exhibited a basic structure in which two thiazole rings and a methyloxazole moiety were connected via amide bonds and which differed only in their substituents. *Nostoc spongiaeforme* was the source of several tenuecyclamides (Banker and Carmeli, 1998) and raocyclamides were isolated from *Oscillatoria raoi* (Admi et al., 1996, Freeman and Pattenden, 1998). Recently we described nostocyclamide (**2**) that was isolated from a freshwater *Nostoc* strain and exhibited grazer toxicity and allelopathy against related cyanobacteria (Todorova et al., 1995). In this investigation we report on another cyclic peptide from this cyanobacterium that reveals anticyanobacterial activity.

2. Results and discussion

During the investigation of nostocyclamide from the freshwater cyanobacterium *Nostoc* 31 (Todorova et al., 1995) a second component was observed that had the features of a cyclic peptide, but the small amounts available at that time did not allow the structural elucidation. In the present study this component was isolated

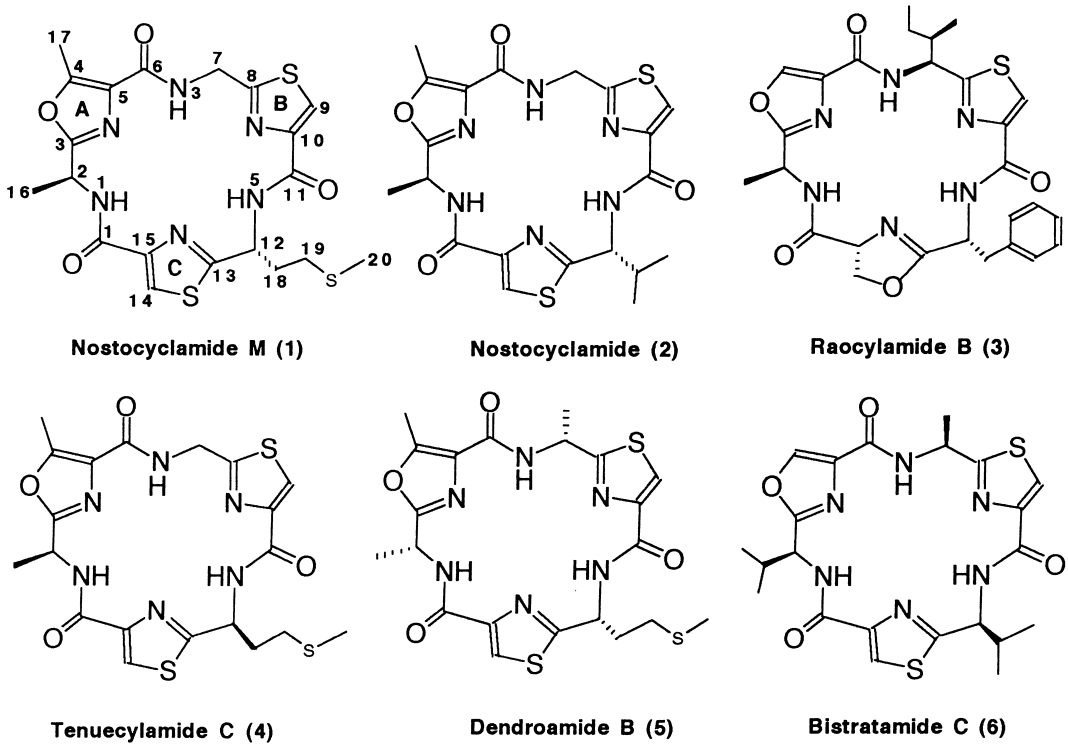
PII: S0031-9422(00)00470-2



in amounts that were sufficient to determine its structure. Several features of this compound resembled those of nostocyclamide, such as the strong UV absorption and the intense sulfur signal shown by a sulfur specific detector during separation on a GC column, and some identical products that were obtained after acid hydrolysis. Mass spectrometric, chemical, and NMR studies showed that this compound has the same basic structure as the one for nostocyclamide, but the valine moiety is replaced by methionine. Using the one letter code of amino acids we named this compound nostocyclamide M (**1**).

Nostocyclamide M exhibits a quasi-molecular ion of *m/z* 507 $[M+H]^+$ when ESMS is applied in the positive mode. After GC separation of the underivatized molecule electron impact ionization affords a molecular ion (EIMS *m/z* 506 $[M^+]$) and important fragment ions that are indicative for thiazole (*m/z* 139) and oxazole (*m/z* 136) fragments. Intense sulfur-containing fragment ions at *m/z* 47 (CH_3–S), *m/z* 61 (CH_3–S–CH_2) and *m/z* 75 (CH_3–S–CH_2–CH_2) are observed along with the corresponding cleavage products of the molecule, *m/z* 458 (M-48 [CH_3–SH]), *m/z* 445 (M-61 [CH_3–S–CH_2]) and the base peak *m/z* 432 (M-74 [CH_3–S–CH=CH_2]). The molecular ion and the base peak obtained with the ^{15}N labelled molecule exhibit a shift of 6 mass units from *m/z* 506 to 512 and *m/z* 432 to 438, and indicate the presence of six nitrogen atoms in the molecule. The products of acid hydrolysis, that were trifluoroacetylated and transferred into the methyl ester for GC–MS analysis, afford alanine and two thiazole-containing amino acids derived from ring B and C. The derivative of ring B is identical in the retention time and mass fragmentation pattern (*m/z* 268 $[M^+]$ and strong fragment ions at *m/z* 236, 208 and 139) with that obtained from nostocyclamide. The derivative of ring C (*m/z* 342 $[M^+]$ exhibits prominent sulfur-containing fragment ions at *m/z* 47 [CH_3–S], *m/z* 61 [CH_3–S–CH_2], *m/z* 75 [CH_3–S–CH_2–CH_2] and *m/z* 268 [M-74] as the base peak. The fragmentation pattern is consistent with the presence of a CH_3–S–CH_2–CH_2 substituent.

The pure compound is sparingly soluble in MeOH and MeCN but easily soluble in DMSO and CH_2Cl_2. It crystallizes from aqueous solutions in very thin needles. Suitable crystals for X-ray diffraction have not been obtained so far. The molecular formula $C_{20}H_{22}N_6O_4S_3$ for nostocyclamide M was deduced from mass spectral data and NMR spectroscopy.

Nostocyclamide M was subjected to a detailed ^1H and ^{13}C NMR investigation. The 1D proton and carbon-13 and the 2D ^1H,^1H and ^1H,^{13}C correlated spectra were obtained in $CDCl_3$ solution on a 600 MHz spectrometer. For further details see the experimental section. The proton spectrum exhibits signals for the following groups: 1 C*H*$_3$(CH), 1 C*H*$_3$(C), 1 C*H*$_3$(S), 3 C*H*$_A$*H*$_B$, 1 C*H*(CH$_3$), 1 C*H*(CH$_2$), 2 H-C(sp^2), and 3 NH signals in the 8.5-8.6 ppm region, corresponding to a total of 22 hydrogen atoms (Table 1). The carbon-13 spectrum obtained with proton decoupling shows eight signals in the aliphatic region and 12 signals in the sp^2-carbon range. Based upon ^1H,^{13}C 2D correlation experiments (HSQC and HMBC) there are 3 CH_3, 3 CH_2, 2 (sp^3)

CH, 2 (sp^2)CH, and 10 nonprotonated carbon atoms (Table 1). Thus, nostocyclamide M has a $C_{20}H_{22}$ skeleton just as nostocyclamide.

Closer inspection of the 1D spectra reveals that there are no signals for an isopropyl group (valine) while the typical AB system of the glycine methylene group and the CH_3CHNH group of alanine are still present. As a new feature, compared with nostocyclamide, the aliphatic region of the proton spectrum reveals the presence of a $–CH(CH_2CH_2SCH_3)$ side chain for which we also have strong evidence from the mass spectrum (M-74, M-75). On the other hand, the characteristic $CH_3C(O)$ signal from the oxazole methyl group and the two isolated thiazole CH signals of nostocyclamide are still present in the new compound which points to the same basic skeleton of both structures.

The tentative conclusions are corroborated by 2D COSY and TOCSY $^1H,^1H$-correlations and $^1H,^{13}C$ 2D HSQC and HMBC correlations. The most significant correlation cross peaks are also listed in Table 1 and support the common skeleton for the two nostocyclamides. Moreover, from the TOCSY pattern the new side chain can be identified as arising from methionine ($HN(5)–C(12)H–C(18)H_AH_B–C(19)H_AH_B–S–CH_3$) that is replacing valine in nostocyclamide.

Nostocyclamide M (**1**) thus proves to have the same constitution as tenuecyclamide C (**4**) (Banker and Carmeli, 1998), and the ^1H and ^{13}C chemical shifts can be fully assigned. In fact, the ^1H and ^{13}C spectral data of the two compounds are virtually identical within experimental error limits. However, tenuecyclamide C differs in the UV absorption and was reported to contain L-methionine whereas our chemical degradation of nostocyclamide M gave D-methionine as the dominating sulfur containing cleavage product (vide infra). The excellent agreement of the NMR data of both compounds, in particular of the methionine side chain and its immediate surrounding is not what one would expect for a diastereoisomeric relationship. The open question remains to be settled by X-ray diffraction of suitable crystals.

The absolute configuration of the two chiral centers of nostocyclamide M was determined with the amino acids obtained after acid hydrolysis. The trifluoroacetylated methyl ester of alanine resulting after methanolysis from the oxazole ring was separated on a chiral GC column to give the pure L-stereoisomer. To analyze the configuration at C(12), the thiazole ring was reacted with ozone that gave methionine sulfone upon acid hydrolysis. The D-enantiomer was found to represent 91% of the total

methionine, indicating that racemization has taken place only at a low rate. The presence of L-alanine and D-methionine sulfone upon ozone treatment and acid hydrolysis was also confirmed by Marfey's analysis on a C18 HPLC column by superposition with authentic compounds.

Stereochemically pure amino acids were only obtained when nostocyclamide M was analyzed that had undergone a short isolation procedure. Extracts separated on silica gels exhibited upon HPLC separation several isomers of nostocyclamide M that eluted closely to each other. Stereochemical analysis of these isomers gave mixture of the stereoisomeric alanines and methionine sulfones. Because these isomers turned out to be artifacts, they were not further investigated, and only freshly isolated material served for the final analysis.

In the HPLC chromatograms of cartridge-purified extracts of *Nostoc* an additional peak was observed that eluted much earlier (8.2 min) than nostocyclamide M (12.4 min) and exhibited an ESMS that was consistent with the two diastereomeric nostocyclamide M sulfoxides. These compounds were present in much lower concentrations in fresh extracts that have not been concentrated in a rotary evaporator. When purified nostocyclamide M was brought to dryness and redissolved, around 12% of the nostocyclamide M was oxidized to these sulfoxides. The same compounds were obtained by treatment of nostocyclamide M with hydrogen peroxide. Fresh extracts from *Nostoc* that were isolated under strict exclusion of oxygen under a nitrogen gas atmosphere in a closed apparatus (Wendel and Jüttner, 1996) afforded only a small signal in the HPLC chromatograms of which it was not clear whether it was the sulfoxides or another contaminant. These experiments indicate that the sulfoxides are not, or in only very small amounts, present in the live *Nostoc* and are in the observed amounts actually isolation artifacts.

Small portions of 100 ml standing cultures of *Nostoc* (0.7 mg d.w.) were used to determine quantitatively nostocyclamide M and nostocyclamide by integration of the UV absorption peaks of HPLC chromatograms. For calculating the concentrations of the nostocyclamide M sulfoxides the same molar extinction coefficient was used as for nostocyclamide M. The concentration of nostocyclamide M and nostocyclamide M sulfoxides, which were taken together, and nostocyclamide were 10 and 26 μg per mg chlorophyll *a*, respectively, in a four week old standing culture.

The low solubility of nostocyclamide M in water did not allow us to perform bioassays in liquid media without addition of solubilizers. Even at low concentrations of around 4 nM white needles, the typical crystalline form of nostocyclamide M, were observed. The much lower water solubility in comparison to nostocyclamide caused by the $(CH_2)_2$–S–CH_3 group may be the reason that toxicity was not observed in the *Thamnocephalus platyurus* bioassay. However, allelopathic activity was easily detectable by the agar plate diffusion assay with cyanobacteria as the indicator organisms. *Anabaena* 7120 was more sensitive than *Anabaena* P-9, and cleared zones in the lawn of *Anabaena* 7120 were obtained when 217 nmol nostocyclamide M were spotted on the mineral ground agar.

Nostocyclamide M is a member of the cyclic peptides which have been found in several structural variations in cyanobacteria and marine ascidians. Most likely the ascidians (*Lissoclinum*) accumulate these compounds from symbiotic prochlorophytes, a subgroup of cyanobacteria, and are not the producers. Peptides of this type are most probably synthesized nonribosomally by a multienzyme thiotemplate mechanism (Marahiel et al., 1997) on peptide synthetases. Amino acids are first activated by ATP, then bound as a thioester, and finally a peptide bond formation takes place. In the state of the thioester, epimerases are known that convert L-amino acids into their D-configuration. The strict control of the amino acid configuration in the cyclic peptides is evident by the occurrence of compounds that are stereochemically pure and characteristic in their configuration for a particular organism. Racemates which have also been observed are most likely produced during the rather lengthy isolation procedures.

In the nostocyclamides **1** and **2**, tenuecyclamide C (**4**), and raocyclamide A (**3**) the alanine moiety has the L-configuration. Both valine and methionine, which replace each other in nostocyclamide and nostocyclamide M, exhibit D-configuration, as does phenylalanine in raocyclamide A. An exception is methionine that is placed in the same position in tenuecyclamide C and has been reported to be in the L-configuration. The dendroamides differ essentially as all amino acids are in the D-configuration, c.f. dendroamide B (**5**), while the structurally related bistratamide C (**6**) that was isolated from *Lissoclinum* (Foster et al., 1992) had the amino acids in the all L-configuration.

It is interesting to note that structurally closely related cyclic peptides are found in phylogenetically very distant cyanobacteria. The heterocyst-forming *Nostoc* 31 and *N. spongiaeforme* are closely related to each other but *Oscillatoria raoi* belongs to the very distant hormogonia-forming group of cyanobacteria.

3. Experimental

3.1. Physical measurements

UV spectra were measured in MeOH on a spectrophotometer Cary 3 (Varian). Low-resolution EIMS were obtained on a combined GC–MS (Fisons MD 800), and ESMS in the positive mode on a mass spectrometer with an electrospray ion source (Vestec VT 201).

The ^{1}H and ^{13}C NMR spectra were measured at 300 K on a Bruker DRX-600 spectrometer at 600 and 150 MHz, respectively. Solutions of 2–3 mg in 0.4 ml of $CDCl_3$ were used. All chemical shifts are referred to TMS as internal standard. 2D spectra were obtained with standard pulse sequences i.e. double-quantum-filtered phase-sensitive COSY, TOCSY, HSQC, and HMBC. For the latter experiments a delay time corresponding to $^{n}J(C,H) = 9$ Hz was used and, therefore, not all conceivable C–H correlation peaks were actually observed.

3.2. Growth

The origin of the axenic culture of *Nostoc* sp. 31 and the conditions of the small and large scale culture to obtain 100-g amounts of wet biomass were described recently (Todorova et al., 1995).

3.3. Analysis

The procedure to obtain EI mass spectra after GC separation, the analysis of products of acid hydrolysis and ^{15}N labeling of the molecule were published previously (Todorova et al., 1995).

3.4. Isolation

The cyanobacterial biomass (160 g fr. wt) that was stored at −20°C was first suspended in 90 ml H_2O. 250 ml of ethanol were added for extraction in an ultrasound water bath (15 min). After centrifugation, the pellets were twice extracted with 125 ml 50% aq. EtOH. The combined extracts were partitioned between aq. EtOH and *tert*-butyl methyl ether (TBME), and the ether phase was washed several times with water and dried with dry Na_2SO_4. The TBME was replaced by 3×20 ml 90% aq. EtOH and supplied to three equilibrated reversed phase C18 cartridges (2 g, Mega Bond Elut, Varian). The first 20 ml of the elutes were collected, brought to dryness in a rotary evaporator, and the residue was dissolved in a minimum of MeOH. 100–300 μl were injected onto a semipreparative reversed phase HPLC column (250×10 mm Spherisorb S 5 ODS, LC-18, 5 μm, Supelco). A gradient (MeOH/H_2O; 50:50 in 12 min up to 100% MeOH and 10 min isocratic, flow rate 3 ml/min) was used to separate (in about 50 runs) a mixture of nostocyclamide and nostocyclamide M (180 mg) at R_t 12.6 min. To remove the major part of nostocyclamide from nostocyclamide M, the crystalline residue was extracted four times with 0.5 ml portions of cold MeOH. The enriched residue of nostocyclamide M was dissolved in MeOH and a small amount of CH_2Cl_2 and separated on a semipreparative HPLC column (Grom-Sil ODS-4 HE, 5 μm, 8.0×250 mm) in a 15 min linear gradient (aq. acetonitrile: 0.01% trifluoroacetic acid (15:85) to 100% acetonitrile). The first eluting peak at R_t 12.4 min was nostocyclamide M and the second at R_t 12.8 min nostocyclamide. The yield of nostocyclamide M was ca. 25 mg and of nostocyclamide ca.100 mg. To obtain nostocyclamide M in high purity, the collected substance was rechromatographed (ca. 100 μg per run) under the same conditions.

3.5. Nostocyclamide M

Nostocyclamide M (**1**): white thin needles, UVλ_{max} (MeOH) 220 nm (ε 41000); EIMS m/z (% rel. int.) 506 (27) [M^+], 432 (100), 139 (84), 61 (79), 136 (61), 112 (56), 75 (54), 141 (49), 276 (49), 235 (45), 249 (37) and 445 (17). For ^{1}H and ^{13}C NMR data see Table 1.

3.6. Hydrolysis

Nostocyclamide M was hydrolysed in 3 M HCl/MeOH at 110°C for 48 h. The dried residue was treated with trifluoroacetic anhydride in CH_2Cl_2 for 60 min at 80°C. The reagent and solvent were blown off with He; the residue was dissolved in 50 μl MeOH. The trifluoroacetylated esters were separated on a DB-1301 (30 m, 0.32 mm i.d., 0.25 μm film thickness) with a temperature program of 1 min 70°C, 10°C/min, 250°C isothermal for 20 min. Three trifluoroacetylated esters were obtained that could easily be deduced from the structure of the molecule: the alanine derivative (R_t 3.87 min) was identical to a reference compound, the amino acid B (R_t 14.35 min) exhibited ions at m/z 268 (M^+, 58%), 236 (100%), 208 (96%), 139 (93%), 69 (82%), 57 (64%), 171 (54%), 45 (52%), 112 (51%), 237 (47%) and the amino acid C (R_t 17.80 min) at m/z 342 (M^+, 1.3%), 268 (100%), 61 (69%), 45 (65%), 69 (63%), 208 (56%), 139 (38%), 236 (37%) and 171 (31%). Further indicative ions of this compound were 281 (M-61, 6.2%), 47 (CH_3S, 18%) and 75 ($CH_3SCH_2CH_2$, 13%).

3.7. Analysis of stereochemistry by chiral GC–MS

The cleavage of the thiazole moieties by ozone and acid hydrolysis was conducted as stated by Ogino (Ogino et al., 1996). 0.7 mg of nostocyclamide M was dissolved in CH_2Cl_2 and bubbled for 10 min with a stream of ozone to give a bluish solution. The solvent was removed in a stream of nitrogen and the residue was treated with 200 μl 3 M HCl/MeOH for 24 h at 110°C. The sample was brought to dryness in a nitrogen gas stream and treated with 100 μl TFA in 100 μl CH_2Cl_2 for 1 h at 80°C. The sample was dried with nitrogen gas and the residue dissolved in 100 μl CH_2Cl_2. 1-μl samples were subjected to gas chromatography–mass spectrometry on a chiral column (25 m, 0.25 mm i.d., Permabond-L-Chirasil-Val, Macherey & Nagel, Düren, Germany) in a temperature program (1 min

80°C, 5°C/min up to 120°C, 20°C/min at 190°C). The retention times were: D-alanine (R_t 4.71 min), L-alanine (R_t 4.98 min), D-methionine sulfone (R_t 25.54 min), and L-methionine sulfone (R_t 26.02 min). The identity of the stereoisomers was established by comparison with authentic compounds and confirmed by superposition. Reference substances were obtained from Sigma.

3.8. Analysis of stereochemistry by Marfey's method

Nostocyclamide M was treated with ozone as stated above for 10 min; the solvent was evaporated in a stream of nitrogen gas and the residue was subjected to vigorous hydrolysis in 6 M HCl. Marfey's analysis was conducted essentially as described by Ogino (Ogino et al., 1996) on a HPLC column (Grom-Sil 120 ODS 4 HE, 5 μm, 4.6×250 mm) at 30°C using a linear gradient of 10–50% acetonitrile and 0.05% aq. triethylamine / phosphate buffer pH 3. 5-Fluoro-2,4-dinitrophenyl-L-alaninamide was used as the reagent. The typical absorption spectra of the amino acid derivatives with maxima at 341 nm and 417 nm were recorded on a Shimadzu LC 10 diode array detector SPDM 10 Avp. D-Alanine and L-alanine were separated efficiently to determine the L-configuration by superposition with an authentic compound, however, separation of the methionine sulfone stereoisomers was not achieved with this and another acidic solvent gradient (acetonitrile/ 0.05% aq. TFA according to Fujii et al. (1997). Separation of the latter isomers was achieved applying an acetonitrile/0.05 M ammonium acetate gradient (10–50% acetonitrile) as stated by Harrigan et al. (1998). L-Methionine sulfone eluted at R_t 24.8 min and D-methionine sulfone at R_t 28.6 min.

3.9. Quantitative analysis

Fresh wet biomass of 20 ml suspension of *Nostoc* was collected on a glass fibre filter (Schleicher & Schuell GF 6) by vacuum filtration. The filter was extracted with 4 ml 85% aq. acetonitrile containing 0.05% trifluoroacetic acid. The extract was separated on a HPLC column. The integrated peak areas at 220 nm were used for quantification of the compounds. The molar extinction coefficient of nostocyclamide M was used to quantify the nostocyclamide M sulfoxides and a redetermined molar extinction coefficient (UVλ_{max} (MeOH) 220 nm (ε 40000) for nostocyclamide.

3.10. Bioassays

The growth of axenic cyanobacteria (Todorova and Jüttner, 1996) and the cyanobacterial agar plate diffusion bioassays were essentially performed as described (Todorova et al., 1995). Samples of nostocyclamide M dissolved in CH_2Cl_2 were spotted on a ground agar (50% cyanobacterial medium solidified with 2% agar). After drying in a sterile bench, an overlay of *Anabaena* 7120 or *Anabaena* P-9 in 0.5% agar was poured over the ground agar and incubated at 25°C and 32 μmol quanta m^{-2} s^{-1} measured at the surface of the Petri dishes. Chlorophyll *a* was determined in methanolic solution using the molar extinction coefficient given by Ogawa and Vernon (1971).

Acknowledgements

We thank Dr. S. Carmeli, Tel Aviv, for NMR spectral information and Professor R.E. Moore for help in HPLC separation of the optical isomers of methionine sulfone and E. Loher, H. Lüthi, and A. Mechsner for valuable technical assistance. F.J. is grateful for financial support from the Swiss National Science Foundation, Bern, and W.v.P. acknowledges generous funding by the Dr. Helmut-Legerlotz Stiftung.

Editorial comment

Global phytochemistry: the Brazilian approach[☆]

One of the hottest issues worldwide is the preservation and sustainable use of biodiversity in the tropics (Fig. 1), and its exploitation by pharmaceutical companies in the race to discover and develop new drug candidates. In Brazil, the Convention on Biological Diversity signed in Rio de Janeiro in 1992 called the attention of a broad audience of scientists, politicians and non-governmental organizations (NGOs). Following the Convention, the issue of biodiversity went through extensive discussions in the media, well beyond the frontiers of research institutes and universities. Last year, Brazil celebrated 500 years of discovery and coincidently the July issue of *Nature* (406, 13 July 2000) published in its cover report the news about an important scientific achievement that made the country of soccer and samba to gain the additional status of a "genomic country" (*The Economist,* 22 July 2000). This was possible as a result of the financial support provided by Fapesp (São Paulo State Foundation for Scientific Research) which enabled a group of 35 laboratories and 200 researchers to describe the first DNA sequence of a plant pathogen — the bacteria *Xylella fastidiosa* — responsible for the citrus variegated chlorosis, a disease causing almost 30% loss in citrus culture every year. Such investment had an immediate and continuing impact. The genome of *Xanthomonas citri* — another citrus disease agent — was next described, and several other important targets of agricultural interest are waiting for sequencing. Solutions to problems related to agriculture, cancer and tropical diseases, and to biological and evolutionary interactions, will emerge from the acquisition and development of sophisticated techniques and mainly by the established competence of the research groups participating in this project.

The ripening of the scientific community in Brazil can also be seen in its awareness of the importance of biodiversity studies, including the bioprospecting of natural products. As an outcome of academic discussions, in public and private sectors, and with the support of the Ministry of Environment and its Secretary of Coordination of Amazonia, the Brazilian Program of Molecular Ecology for the Sustainable Use of the Biodiversity of Amazonia — (PROBEM) was launched and is one of the priorities of the government plan "Avança Brasil", which includes a dozen fast-tracking projects to accelerate the economic development in Amazonia. PROBEM was designed to foster the development of new products from biodiversity, and to encourage the settlement of new enterprises in Amazonia. To steer PROBEM and overcome the bureaucratic hurdles, a social organization (QUANGO — *quasi* autonomous non-governmental organization) named Bioamazônia was created. Its goals include the construction of the Amazonia Biotechnology Center (ABC) in Manaus, the city capital of the Amazon state, and the establishment of a network of Brazilian laboratories to research and develop products from biodiversity. An additional initiative within Bioamazônia is the Amazonia Permanent Trust Fund, created in association with A2R, a financial institution. Inspired by the framework of the Alaska Permanent Fund, which obtains royalties from the oil industry, the APTF will channel its revenues to the environmental management and social development in Amazonia.

The opportunities for investments in Brazil are unique and greater than never before. A recent survey by A.T. Kearney shows that Brazil ranks third, after the USA and China, in terms of reliability for investors, and is at the top position for new investments. Companies as important as Novartis Pharma and Glaxo Wellcome have already established partnership with Bioamazonia, universities, and business interested in the use of biodiversity, even though, insufficiencies in the Brazilian laws have brought about embarrassing, serious bottlenecks for all parties. Since then, the Brazilian federal government issued the provisional act no. 2042 (dated 29/08/2000) ruling the conservation and utilization of components of biological diversity, and the sharing of benefits from its exploitation, including rewards to indigenous and other local communities. The scientific community welcomes the new law, but the bureaucratic hurdles are expected to be many, in different instances, especially regarding the official permits to collect biological materials. Appropriate solutions will be needed in the near future.

Another important initiative in São Paulo State — the Biota Program — is also supported by Fapesp. The

Biodiversity Virtual Institute (www.biotasp.org.br) program, differently from Bioamazônia, does not involve the physical construction of a research institute. Instead, it focus mostly on the strengthening of interdisciplinary groups aiming to systematically evaluate the biodiversity of São Paulo State, including flora, fauna, microorganisms and the development of potential bioactive compounds from plants. The total budget of approximately eighteen million dollars provided for the initial four years is not large considering the number of researchers involved and the benefits expected in terms of basic knowledge to be achieved. Judging from the progress reported at the Fapesp workshop last January by project leaders, researchers, graduate and undergraduate students, additional funds certainly can be expected to continuously support these and other thematic projects.

Both successful programs funded by Fapesp — Genoma and Biota — demonstrate that significant changes in the scientific policy are taking place, but whether or not we are going to have an economy based on genome sequencing or on biodiversity exploitation depends on the establishment of long-term programs such as these. The discovery of new drug candidates to cure diseases from malaria to cancer, using thousands of plants or micro-organisms, is expected to be achieved in the near future with the access to high-throughput screening technologies and interdisciplinary approaches. Further developments to marketable drugs, and the involvement of small local companies are also highly expected. The genome blueprint for biosynthetic pathways of bioactive compounds, or even for a basic process such as that of lignification and its role in the evolution of land plants, plus several other important questions, will certainly be pursued in the near future. Nevertheless, the scientific and technological cooperation among the countries are in need of stimulation simply because a number of basic problems such as the taxonomy of our biodiversity cannot be solved fast enough or independently.

The organization of the phytochemical research community in Brazil has advanced significantly, through the Division of Natural Product Chemistry of the Brazilian Society of Chemistry. This Division, with approximately

220 members, enthusiastically discusses crucial topics related to biodiversity in all their annual meetings. Several new groups have emerged all over Brazil, and equipment facilities for phytochemical investigations are now easily available. A few groups are focused on the search for bioactive compounds, ecological studies, marine compounds, and also on cell tissue cultures and biosynthesis of natural products. The intellectual property rights of the new findings are also under discussion in a number of symposia and courses, and entrepreneurs and scientists alike are finally getting together in meetings. In the South American context, the debate has been initiated by the Latin American Society of Phytochemistry, but the management and the study of biodiversity in the continent as a whole waits for regulation as well.

Following the pressures raised by contracts signed with pharmaceutical companies, the establishment of solid and clear legislation regarding bioprospecting is a top priority for Brazilians, otherwise the hesitation could impair the creativity and the initial successful achievements such as those promoted by the genomic projects. There is an urgent need to develop basic science by means of long-term investment, to ensure a broad range of expertise. Additionally, specific actions from the federal government are required to improve our capacity to solve our own problems and to seed research companies and other enterprises. In this sense, the Ministry of Science and Technology and CNPq (National Council of Scientific and Technological Development) have announced that new funds for the Brazilian Genome Project, and specifically for the biodiversity studies, are on the way.

A new model of exploitation and conservation of biodiversity as the basis of economic development must be the next paradigm for Brazil and this is the way to establish a successful economic and scientific partnership in the globalized world.

Received 18 September 2000; received in revised form 23 January 2001

Abstract

A serine proteinase inhibitor was purified from *Delonix regia* seeds a Leguminosae tree of the Caesalpinioideae subfamily. The inhibitor named DrTI, inactivated trypsin and human plasma kallikrein with K_i values 2.19×10^{-8} M and 5.25 nM, respectively. Its analysis by SDS-PAGE 10–20% showed that the inhibitor is a protein with a single polypeptide chain of M_r 22 h Da. The primary sequence of the inhibitor was determined by Edman degradation, thus indicating that it contained 185 amino acids and showed that it belongs to the Kunitz type family; however, its reactive site did not contain Arg or Lys at the putative reactive site (position 63, SbTI numbering) or it was displaced when compared to other Kunitz-type inhibitors. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Delonix regia*; Leguminosae; Kunitz inhibitor; Serine proteinase; Trypsin; Human plasma kallikrein

1. Introduction

Serine proteinase inhibitors are found in animal tissues, micro-organisms as well as plant tissues. The inhibitors occur in large quantities in legume seeds and in smaller amounts in cereals, cucurbits, potatoes and others tubers (Richardson, 1991). Two families of plant serine proteinase inhibitors are well characterized, Kunitz-type inhibitors with M_r of 18,000–22,000 Da, a low cystine content and one reactive site; Bowman-Birk-type are proteins with relative molecular mass of 8000–10,000 Da, high cystine content and two reactive sites (Birk, 1985).

The presence of proteinase inhibitors in living tissues seems to be essential for natural regulatory processes, for example, plants protecting themselves against insect predation (Garcia-Carrenõ, 1996). The stability of proteinase inhibitors towards enzymes as well as the large quantities present in seeds indicates the importance of protease inhibitors as storage proteins (Ryan, 1973). Besides their biological function, proteinases inhibitors are useful tools in biochemical and physiological studies of proteinases functions (Oliva et al., 1999b); for purification of proteolytic enzymes by affinity chromatography (Sampaio et al., 1974) and for understanding the role of proteolytic enzymes in blood clotting (Hayashi et al., 1994; Oliva et al., 2000a). As a consequence, many aspects of these inhibitors such as occurrence, tissue localization, inhibition specificity, molecular and structural properties, possible regulatory and/or protective function and nutritional significance have been investigated (Bode and Huber, 1992).

Delonix regia (Leguminosae-Caesalpinioideae) is distributed in the north and western parts of Madagascar and is widely cultivated in many tropical countries. The trees of the genus *Delonix* are used as ornamental trees and the seeds of many species are crushed and eaten raw (Puy et al., 1995). The description of a potent inhibitor isolated from *Delonix regia* may contribute to a through understanding of a plasma kallikrein action and eventually to the development of synthetic inhibitors based on its structural properties. In the present work we describe the purification, the primary structure and inhibitory

characteristics of the serine proteinase inhibitor isolated from *Delonix regia* seeds.

2. Results

The inhibitory fraction eluted from a DEAE Sephadex A-50 column was gel filtered on a Sephadex G-75 column and it emerged in the main peak, indicated by "Pool 2" (Fig. 1a). This fraction was further purified on a C-18 μBondapak reversed phase column and then purified further using other reversed phase columns (Fig. 1b). Electrophoretic analysis showed that the inhibitor is constituted by a single polypeptide chain in both its native and reduced conditions and the single protein peak eluted from the column corresponds to the inhibitor. The M_r of inhibitor, estimated by SDS-PAGE10–20%, was ca 22 h Da (inset Fig. 1b). The homogenous form of the inhibitor from reversed phase chromatography in HPLC was used for primary structure determination.

The *N*-terminal region sequence protein, up to residue 50 was established by automated Edman degradation of the protein. Peptide fragments produced by Lys-C, Glu-C and Asp-N cleavage of 4-vinyl pyridine reduced protein, were sequenced following the isolation by reversed phase chromatography. Enough overlaps were obtained to define the primary sequence (Fig. 2). DrTI is related to the Kunitz inhibitor family, the four cysteines residues are conserved, however, in the putative reactive site a glutamic acid was found in the P_1 position instead of Arg or Lys as in most Kunitz inhibitors (Fig. 3).

DrTI inhibited trypsin (K_i 2.19×10^{-8} M) following the slow-tight binding mechanism (Morrison, 1982). Besides trypsin, the inhibitory effect was also assayed on human plasma kallikrein, chymotrypsin, plasmin, factor Xa, tissue kallikrein and thrombin. The inhibitor presented higher affinity toward of human plasma kallikrein (K_i 5.25 nM) with 1:1 stoichiometry. The inhibitory effect of DrTI on trypsin and human plasma kallikrein can be seen in Fig. 4A and B respectively. DrTI did not inhibited factor Xa, plasmin, chymotrypsin, tissue kallikrein and thrombin.

3. Discussion

The purification procedure used to obtain the protein, which show trypsin inhibitor properties, is satisfactory since the products exhibited a single band in SDS-PAGE under reductive conditions, indicating no dimerization of the native inhibitor. DrTI showed M_r of ca 22 h Da, similar to proteinase inhibitors of the Kunitz-type (Richardson, 1991) and the primary structure confirmed this inhibitor as a member of the Kunitz family. The two loops composed by the four half-cysteine show high similarity to other Kunitz inhibitors. This result confirmed the preliminary crystallographic study of DrTI (Polikarpov et al., 1999). An interesting peculiarity of DrTI is that a glutamic acid was found in the expected position for the reactive site (residue 63, SbTI numbering) instead of an Arg or Lys, usually present in other Kunitz inhibitors. The other possibility would be the interaction

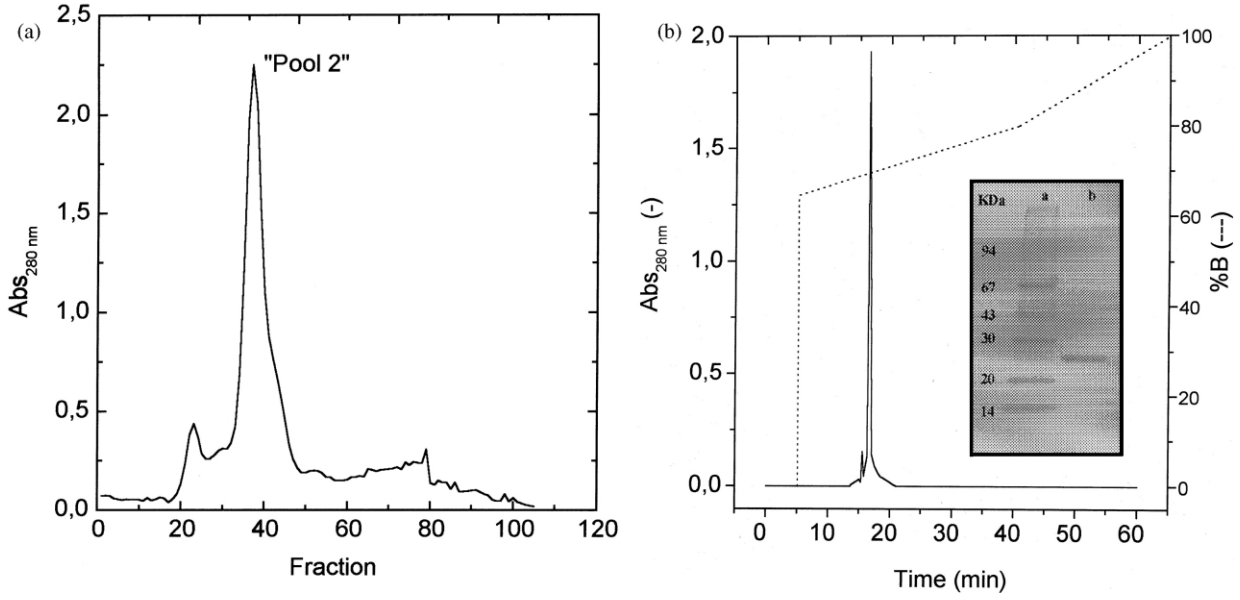

Fig. 1. (a) Gel filtration chromatography profile on Sephadex G-75 column of the DrTI eluted from DEAE Sephadex column. Eluting buffer: 0.05 M Tris–HCl, pH 8.0, 0.15 M NaCl. Flow rate: 12 ml h^{-1}. "Pool 2" indicates antitrypsin activity fraction. (b) Repurification by reversed phase HPLC [C-18 μBondapack column 3.9×300 mm]. of Ser^{64} with the pocket for Arg or Lys found in trypsin and other related proteases. The inhibitor isolated from *Swartzia pickellii* (SwTI) contain a glutamine in the P1 position for the reactive site (Cavalcanti et al., 2001).

Caesalpinia pulcherrima, which also belongs to the subfamily Caesalpinioideae, as well as the *Delonix regia* species, contained only inhibitors of the Kunitz-type, this species is considered to be the most primitive while the species of the subfamily Papilionoideae had only inhibitors of Bowman–Birk type. These facts suggest that there is some relationship between the families of the inhibitors found in leguminous seeds and the evolution of these plants (Norioka and Ikenaka, 1983).

The Bowman Birk-type inhibitors from legume seeds have been found to inhibit both trypsin and chymotrypsin at independent reactive sites. On the other hand, the inhibitory activity characteristics of the Kunitz-type proteinase inhibitor are varied. A few inhibitors are reported to be specific for chymotrypsin and do not inhibit trypsin (Joulbert et al., 1981). Some Kunitz-type inhibitors are potent inhibitors for trypsin but they also inhibit chymotrypsin to varying degrees (Odani et al., 1979). DrTI inhibited trypsin but not chymotrypsin.

There are many physiological inhibitors, such as α-2-macroglobulin and the C1 inhibitor, that efficiently act in control of the cascade of proteins during blood clotting (Travis and Salvesen, 1983). However there are vegetable inhibitors that are relatively easy to obtain and which are also efficient for the study of many properties of those proteins (Sampaio et al., 1990).

Fig. 3. Comparative sequences of related Kunitz inhibitors.1, DrTI (*Delonix regia* trypsin inhibitor); 2, SBTI (soybean trypsin inhibitor, Koide and Ikenaka, 1973); 3, SwTI (*Swartzia pickellii* trypsin Inhibitor, Cavalcanti et al., 2001); 4, LlTI (*Leucaena leucocephala* trypsin Inhibitor, Oliva et al., 2000b); 5, EcTI (*Enterolobium contortisiliquum* trypsin inhibitor, Batista et al., 1996); 6, BvTI-3c (*Bauhinia variegata*, var. *candida* trypsin inhibitor, Di Ciero et al., 1998). Reactive sites are in the box and the cysteine residues are indicated by the gray color. Multiple sequence alignment with hierarchical clustering (Corpet et al., 1998).

DrTI does not inhibit plasmin, tissue kallikrein, factor Xa and thrombin but it is an effective inhibitor of human plasma kallikrein (K_i 5.25 nM) and trypsin (K_i 2.19×10^{-8} M). It is of interest that proteases such as plasmin, tissue kallikrein, factor Xa and thrombin require special structural features of plant inhibitors to suit these enzymes. For example, either Kunitz-type or Bowman–Birk type inhibitors do not inhibit tissue kallikrein, factor Xa and thrombin. Plasma kallikrein, which is not inhibited by Bowman–Birk inhibitors such as lima bean trypsin inhibitor, is usually inhibited by Kunitz-type trypsin inhibitors (Oliva et al., 1999a,b) but not by a Kunitz-type chymotrypsin inhibitor (Souza et al., 1995).

The selectivity of the inhibitor for different proteases, in opposition to SwTI (Cavalcanti et al., 2001), was changed by the presence of Glu^{63} at the putative reactive site

The *Delonix regia* trypsin inhibitor (DrTI) may, therefore, be useful as a tool to investigate the catalytic mechanism of plasma kallikrein. Clinical application of the plant inhibitors might be feasible in the future (Hayashi et al., 1994). Furthermore, as the role of inhibitors in plant seeds is not fully understood, further knowledge concerning trypsin inhibitors in plant seeds such as *Delonix regia* may contribute to the understanding of the interactions between plant protease inhibitors and endogenous animal proteases (Xavier-Filho et al., 1989).

4. General experimental procedures

4.1. Enzymes

Human plasma kallikrein (EC 3.4.21.34) was purified by a previous procedure (Oliva et al., 1982). Tissue kallikrein (EC 3.4.21.35) was from Bayer; Bovine trypsin (EC 3.4.21.4), factor Xa (EC 3.4.21.6), human thrombin (EC 3.4.31.5) and chymotrypsin (EC 3.4.21.1) were Sigma products.

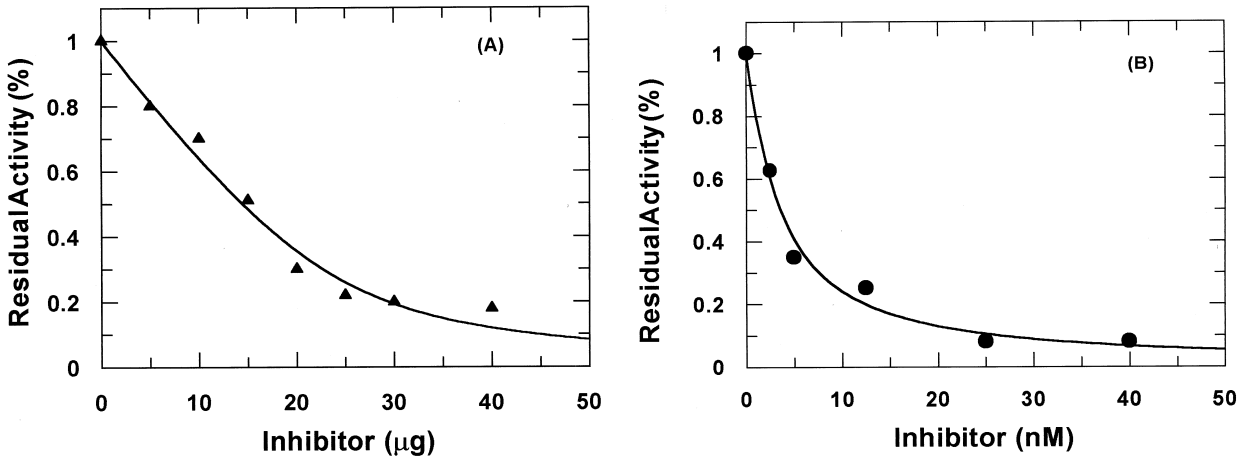

Fig. 4. Curves of trypsin and human plasma kallikrein inhibition by DrTI. (A) trypsin (5 μg) was preincubated (10 min, 37°C, 0.1 M Tris–HCl buffer, pH 8.0) with increasing concentration of the inhibitor. The residual trypsin activity was assayed on DL- Bz-Arg-pNan (0.1 M) as substrate, as described in Experimental. (B) HuPK (40 nM) was preincubated (10 min, 37°C, 0.05 M Tris–HCl buffer, pH 8.0) with increasing amounts of inhibitor. The residual HuPK activity was assayed on Ac-Phe-Arg-pNan (0.8 mM) as substrate, as described in the Experimental.

4.2. Substrates

H-D-Phe-L-Pip-L-Arg-pNan, DL-Bz-Arg-pNan, Bz-Tyr-pNan and Suc-Phe-pNan were from Sigma Chemical Company; *p*-nitrophenyl-*p*′-guanidinobenzoate (NPGB) was from Merck; H-Pro-Phe-Arg-pNan and MeO-Suc-Ala-Ala-Pro-Val-pNan were from Calbiochem; Ac-Phe-Arg-pNan was a gift of Dr Maria Juliano, UNIFESP, Brazil.

4.3. Inhibitor purification

Mature seeds of *Delonix regia* (70 g) were milled to a fine powder and submitted to agitation for 1 h at room temperature with 0.15 M NaCl (10%, wt/ml). The suspension was clarified by centrifugation (3000 *g*, 20 min), the ppt. was eliminated and the supernatant was used for inhibitor purification. Proteins were precipitated with 80% (ml/ml) aqueous acetone with stirring at 4°C. The acetone-dried powder was dissolved in 0.05 M Tris–HCl buffer, pH 8.0 and centrifuged 3000 *g*, 20 min. The clear supernatant solution was applied to a DEAE Sephadex A-50 column (27×1.8 cm), equilibrated with 0.05 M Tris–HCl buffer, pH 8.0, at a flow rate 30 ml h^{-1}. Fractions of 3 ml were collected. The active material from the previous step was submitted to gel filtration on a Sephadex G-75 column (102×1.9cm), equilibrated with 0.05 M Tris–HCl buffer, pH 8.0, 0.15 M NaCl at a flow rate 12 ml h^{-1}. The fractions with inhibitory activity were combined, dialyzed against distilled water, lyophilized then applied to a C-18 μBondapak reversed phase column (Waters System, 7.8×300 mm). A linear gradient of 0–100% of solvent B (60% acetonitrile in 0.1% trifluoroacetic acid, ml/ml) at a flow rate of 2 ml min^{-1} was used. The inhibitor was repurified on a C-18 μBondapak reversed phase HPLC column (3.9×300 mm) at a flow rate 1 ml min^{-1}. The absorbance at 280 nm was used to follow protein elution. Bovine trypsin inhibitory activity was verified as described in the Experimental.

4.4. SDS-PAGE

SDS-PAGE was carried out according to (Laemmli, 1970), using 10–20% polyacrylamide as separation gel and 5% as stacking gel. Samples containing 10 μg of the purified inhibitor, under reducing conditions, were dissolved in 0.08 M Tris–HCl buffer, 2% SDS, 10% glycerol (wt/ml) and 0.02% bromophenol blue, adjusted to pH 6.8 with HCl. Protein bands were stained by Coomassie Brilliant Blue. The M_r standards (Pharmacia) used were phosphorylase B (M_r 94 h Da), bovine serum albumin (67 h Da), ovalbumin (43 h Da), carbonic anhydrase (30 h Da), trypsin inhibitor (20100 Da) and α-lactalbumin (14.4 h Da).

4.5. Sequence determination

DrTI reduction with S-4-pyridylethylation was performed as described by (Friedman et al., 1970).

4.6. Endopeptidase Asp-N, Glu-C and Lys-C cleavage

Samples of S-pyridinethylated-DrTI (20 nmol) were incubated with endopeptidase Asp-N and with endopeptidase Glu-C in 0.05 M ammonium acetate buffer, pH 6.5 and pH 4.0 respectively, for 14 h at 37°C, using an enzyme: DrTI ratio of 1:20. The reaction was terminated by adjusting the pH to pH 2.0 and the produced peptides were separated as described by (Oliva et al., 2000a).

4.7. Sequence analysis and mass spectrometry

Edman degradation was performed with a gas-phase sequence equipment (Shimadzu and 473 Applied Biosystem) using the conditions recommended by the manufacturer.

4.8. Sequence comparison

The database from Max Planck Institute for Biochemistry at Martinsried, Germany, was searched using the Lipmann and Pearson fast protein-searching algorithm FASRP (Lipmann and Pearson, 1985). Alignments were optimized using a computer program (Corpet et al., 1998).

4.9. Trypsin inhibition

The concentration of the inhibitor was determined by its absorbance at 280 nm and the extinction coefficient was determined by experimental determination. The inhibitory activity of DrTI on trypsin was determined by measuring the hydrolysis of DL-Bz-Arg-pNan at pH 8.0, according to (Erlanger et al., 1961). The inhibitor was pre-incubated in different concentrations with enzymes (5 μg) prior to substrate addition in 0.1 M Tris–HCl buffer, pH 8.0, for 10 min at 37°C in 1ml final volume. The reaction was interrupted by addition of 500 μl of 30% acetic acid (ml/ml). The substrate hydrolysis was followed by absorbance of released *p*-nitroaniline at 405 nm.

4.10. Inhibitory activity on other serine proteinases

The inhibitory activities on human plasma Kallikrein, tissue kallikrein, chymotrypsin, plasmin and thrombin were determined by measuring remaining hydrolytic activity towards synthetic specific substrates after pre-incubation with DrTI. Enzymes or enzyme-inhibitor mixtures (20 μl) were added to a solution containing 1 mM substrate in 0.05 M Tris–HCl buffer, pH 8.0, 37°C, in 200 μl final volume. The reaction was followed for 15–30 min and stopped by addition of 50 μl of 30% acetic acid and the substrate hydrolysis was followed by absorbance at 405 nm in an ELISA reader.

4.11. K_i Determination

The dissociation constants of the enzyme-inhibitor complexes were measured following the procedure described by (Morrison, 1982) and the inhibition constants (K_i) were calculated using a graphite program (Knight, 1986).

4.12. Active site titration

Both trypsin and kallikrein site concentration was determined by *p*-nitrophenyl-*p*-guanidinobenzoate (NPGB) titration, as described previously (Sampaio et al., 1984).

Received 25 July 2000; received in revised form 21 February 2001

Abstract

Vanadium haloperoxidases were extracted, purified and characterized from three different species of Laminariaceae — *Laminaria saccharina* (Linné) Lamouroux, *Laminaria hyperborea* (Gunner) Foslie and *Laminaria ochroleuca* de la Pylaie. Two different forms of the vanadium haloperoxidases were purified from *L. saccharina* and *L. hyperborea* and one form from *L. ochroleuca* species. Reconstitution experiments in the presence of several metal ions showed that only vanadium(V) completely restored the enzymes activity. The stability of some enzymes in mixtures of buffer solution and several organic solvents such as acetone, ethanol, methanol and 1-propanol was noteworthy; for instance, after 30 days at least 40% of the initial activity for some isoforms remained in mixtures of 3:1 buffer solution/organic solvent. The enzymes were also moderately thermostable, keeping full activity up to 40°C. Some preliminary steady-state kinetic studies were performed and apparent Michaelis–Menten kinetic parameters were determined for the substrates iodide and hydrogen peroxide. Histochemical studies were also performed in fresh tissue sections from stipe and blade of *L. hyperborea* and *L. saccharina*, showing that haloperoxidase activity was concentrated in the external cortex near the cuticle, although some activity was also observed in the inner cortical region. © 2001 Elsevier Science Ltd. Keywords: *Laminaria saccharina*; *Laminaria hyperborea*; *Laminaria ochroleuca*; Laminariaceae; Vanadium in biology; Vanadium-dependent haloperoxidases

1. Introduction

The bioinorganic chemistry of vanadium has aroused much interest in recent years due to the curious roles and states of this metal in various lower organisms (see reviews by Chasteen, 1990; Wever and Kustin, 1990; Butler and Carrano, 1991; Redher, 1991; Sigel and Sigel, 1995; Tracey and Crans, 1998). One case which received more attention in the last few years is that of the vanadium haloperoxidases, a new class of enzymes that contain vanadium(V), as vanadate, in the active site and catalyse halogenation reactions of several substrates. These enzymes are found in many brown, in some red and in one green marine alga (Butler and Walker, 1993) and in the lichen *Xantoria parietina* (Plat et al., 1987). Recently, vanadium dependent haloperoxidases were also found in some fungi (van Schijndel et al., 1993; Barnett et al., 1998).

All the vanadium haloperoxidases isolated to date share some common features: they are composed of one or more subunits of relative molecular mass around 67 kDa; they can be inactivated by dialysis against EDTA at low pH; their activity is only restored by addition of vanadium (as vanadate) and they seem to have similar coordination of vanadium in the active site (Messerschmidt and Wever, 1996; Messerschmidt et al., 1997; Weyand et al., 1999).

Vanadium haloperoxidases have been traditionally classified as chloro, bromo and iodoperoxidases. Vanadium chloroperoxidases have only been detected in terrestrial organisms, whereas bromo and iodoperoxidases are dominant in the marine environment.

Marine organisms, particularly seaweeds, produce large quantities of halometabolites, which are held within algal membrane bound vesicles and are thought to result from the catalytic activity of haloperoxidases. These halometabolites probably act as hormones or as repellents in biological defence mechanisms (Jordan and Vilter, 1991). Interestingly in this respect, thirty years ago, Siegel and Siegel (1970) proposed that an anomalous substrate specificity of haloperoxidases might be the reason why seaweeds are not lignificated. More recently, Küpper et al. (1998) reported that haloperoxidases might be involved in the uptake of iodide from seawater, a process that, according to these authors, may be related to conditions of oxidative stress. In the same year, ten Brink et al. (1998) reported that marine vanadium haloperoxidases were able to catalyse enantioselective sulfoxidation reactions. Despite these many studies, the reason for the selection of vanadium for these enzymes remains elusive since other more common biological metals, e.g. iron (heme) or manganese could also have been used (Fraústo da Silva and Williams, 1991).

The isolation of more than one form of vanadium haloperoxidase has been reported for *Ascophyllum nodosum* (Krenn et al., 1989). Recently, two papers from our laboratory were published showing that it is also possible to purify more than one form of the enzyme (Almeida et al., 1998; Almeida et al., 2000) from the brown seaweeds *Sacchoriza polyschides* and *Pelvetia canaliculata*. Histochemical tests are a very important control tool in this kind of studies, since contamination of the collected seaweeds with symbiont organisms living in and on the seaweeds is very common (Pedérsen and Fries, 1977). These controls were performed on *A. nodosum* and indicated that the enzyme activity was located on the surface of the cell wall of the thallus and inside the alga between the cortex and the medulla and especially around the conceptacles (Krenn et al., 1989). Similar experiments in *P. canaliculata* revealed that enzyme activity was located, on the surface cuticle of the thallus (Almeida et al., 2000).

Strangely, the seaweeds collected along the Portuguese coast, which were previously studied, exhibited lower haloperoxidase activities than most of the algae from northern regions of the Atlantic Ocean (Almeida et al., 1998; Almeida et al., 2000). To confirm if this is a general trend, which would suggest an environment dependence of the activity, we decided to carry out a comparative study of the properties of the haloperoxidases extracted from *L. saccharina, L. hyperborea* and *L. ochroleuca* since the Portuguese coast is the southern European habitat limit for these species.

2. Results and discussion

2.1. Extraction of the enzymes

The algae from the Laminariaceae family are extremely rich in alginates and polyphenolic compounds that complicate the extraction and purification of these proteins. An aqueous salt/polymer two-phase system was employed for the extraction. We have used polyethyleneglycol (PEG) and potassium carbonate in this system, since previous experience has shown that this salt is the most adequate for the extraction of this particular type of seaweed (Jordan and Vilter, 1991). From several compositions tested, the medium with 22.5% (w/v) K_2CO_3 and 15% (w/v) PEG 1500 in water was found to be the most efficient for the extraction of the haloperoxidases from these algae. The vanadium haloperoxidases (V-HPOs) were mainly found in the top-phase, bounded to the polymer (PEG); the bottom aqueous phase, rich in salts, accumulated most of the alginates and hydrophilic compounds. The separation of the enzyme from the polymer was easily achieved by the addition of acetone. After centrifugation the pellet thus obtained was dissolved in the minimum amount of 50 mM Tris–HCl (pH 9.0). Since the pH is quite high, a partial loss of the prosthetic group occurred; activity was fully restored by addition of vanadate (20 mM).

2.2. Purification of the enzyme — isoforms

The extracts from the three seaweeds were subjected to several chromatographic steps to purify the enzymes. The first stage was a hydrophobic interaction step with phenyl-sepharose. For *L. saccharina* and *L. ochroleuca* two sets of fractions with activity (named Ls1 and Ls2; Lo1 and Lo2, respectively) were obtained, whereas for the *L. hyperborea* extract only one set of active fractions was obtained. When subjected to electrophoresis under non-denaturing conditions all these fractions revealed several bands (results not shown); hence, a second chromatographic step was necessary.

Two different approaches were used for the second purification step; a further hydrophobic interaction chromatography with butyl-sepharose, for *L. saccharina* and *L. hyperborea,* and an ion exchange chromatography with DEAE-Sephacel for *L. ochroleuca*.

The active fraction from *L. hyperborea* yielded, after this second chromatographic step two active bands (named Lh1 and Lh2), while for *L. saccharina* this second step provided separation from most of the contaminants. A chromofocusing chromatography was used as the final purification step and yielded the two forms of the vanadium-haloperoxidases (V-HPO) from *L. saccharina* and *L. hyperborea* species. For *L. ochroleuca* the ion exchange chromatographic step with DEAE-Sephacel resolved the Lo2 fraction into a major fraction

(named α) and a minor fraction (named β). The Lo1 fraction lost its activity very rapidly and could not be reactivated.

Table 1 shows the specific activities of the purified forms from the three Laminariaceae studied. It is clear that the *L. saccharina* isoforms exhibit considerably higher iodoperoxidase (IPO) and bromoperoxidase (BrPO) activities than the isoforms from *L. hyperborea*. It is also interesting to notice that the two forms of the enzyme purified from this seaweed show different types of activity (Lh1 is a IPO while Lh2 is a BrPO). The *L. ochroleuca* fractions exhibited very low IPO activity only, so that we limited the study of the corresponding enzyme to the activity tests, molecular mass determination and reactivation with vanadium(V).

The IPO activity values found for the *L. saccharina* two isoforms of V-HPO (1067 and 320 U/mg) are comparable to the values obtained by Jordan and Vilter (1991) for the two V-HPO isoforms from *L. digitata*, a species commonly related to *L. saccharina* and *L. hyperborea* at higher latitudes (1140 and 797 U/mg, respectively). In a previous work, de Boer et al. (1986), purified only one enzyme form from *L. saccharina* using a classical extraction method. This enzyme had a specific activity in the bromination reaction of 608 U/mg after reactivation with vanadate, which is also much higher than the values obtained in the present study for the same kind of activity. This had already been observed for the haloperoxidase extracted from *P. canaliculata* and *S. polyschides* (Almeida et al., 1998; Almeida et al., 2000) and suggests a decreasing trend in enzymatic power of the vanadium haloperoxidases as one goes south in the habitat of the algae. If real, this trend may derive from specific conditions along the Portuguese coast, perhaps the higher temperature of the seawater, but this requires confirmation since the effect of this variable is not obvious. Another important observation is that the extraction procedure may determine the number of forms of the enzyme purified from these seaweeds. Using aqueous two-phase systems, which involve a delicate balance between hydrophobic and hydrophilic interactions, several isoforms can be separated. The classical extraction procedure used by de Boer et al. (1986) is not so selective; thus the fact that we have used the two-phase aqueous system may explain why we found two isoforms in *L. saccharina*. The reason for the existence of different forms of the enzyme in the same seaweed is not yet understood. It is possible that they have different functions and distribute differently, see below the histochemical tests. A more extensive study is required to clarify both of these aspects. It can not be excluded, however, that the life cycle of the seaweeds determines the production of isoforms since we have observed that for other specimens of *L. saccharina* collected at the same sites but in a different period of the year only one isoform was isolated although we have used the same extraction and purification procedures described in this work.

Table 1
IPO and BrPO specific activity values for the isoforms of V-HPO separated from *Laminara saccharina*, *Laminaria hyperborea* and *Laminaria ochroleuca*

Isoforms	IPO (U/mg)	BrPO (U/mg)
Ls_1	320	12
Ls_2	1067	32
Lh_1	131	–[a]
Lh_2	300	16
Lo1	(0.3)	–[a]
Lo2 (α)	16	–[a]
Lo2 (β)	9	–[a]

[a] The fractions did not show BrPO activity under the test conditions.

2.3. Determination of molecular mass

Each form of V-HPO purified from *L. saccharina* and *L. hyperborea* yielded only one major band on polyacrylamide gels under non-denaturating conditions; these bands stained both for protein and for HPO activity. Compared to standard proteins, these enzymes hardly migrate, indicating a high relative molecular mass, probably due to aggregation of the enzyme. Determination of the relative molecular mass for the enzymes from *L. saccharina* and *L. hyperborea* was difficult at first since in the presence of 0.1% SDS, chosen for this purpose, they were still very strongly aggregated. Subsequently, gel filtration on Sephacryl S-300R was successful, giving two bands, corresponding to relative molecular masses of 169 and 58 kDa (results not shown). The first band probably corresponds to an aggregated form of the enzyme (all peroxidases extracted from seaweeds aggregate easily) while the second band corresponds to the molecular mass of the subunit. On sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE), the purified enzymes showed only one major band, with M_r around 67 kDa (Fig. 1). This is in agreement with the reported values for *L. saccharina* (64 and 66 kDa) subunits (de Boer et al., 1986). Recently, the molecular mass of the *A. nodosum* bromoperoxidase monomer was determined as 60 kDa (Weyand et al., 1999). For *L. ochroleuca* the relative molecular mass of fraction α was determined as 133 kDa on a non-denaturating polyacrylamide gel electrophoresis (Fig. 1) and 65 kDa on a SDS-denaturating polyacrylamide gel electrophoresis, which seem to indicate the presence of two subunits of identical molecular masses.

2.4. Inactivation and reactivation

By extensive dialysis with citrate–phosphate buffer in the presence of EDTA the enzymes were inactivated due to removal of the prosthetic group (Table 2). Some enzymes were easily deactivated, while for others deactivation was incomplete. It is also interesting to

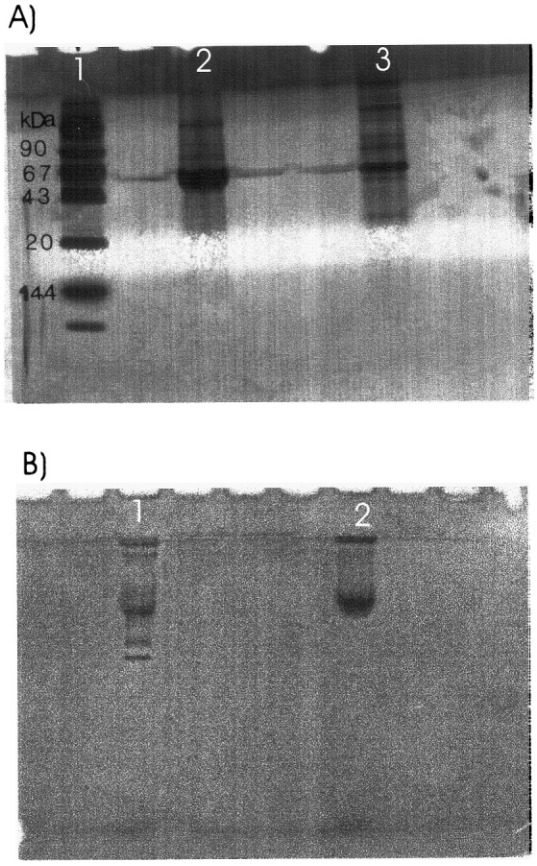

Fig. 1. SDS–PAGE 12.5% as laemmli of V-HPO: (A) V-HPO from *Laminaria saccharina* and *Laminaria hyperborea*: lane 1, standard proteins; lane 2, Ls1 enzyme; lane 3, Lh2 enzyme; (B) V-HPO from *Laminaria ochroleuca*: lane 1, standard proteins; lane 2, Lo2 (α) enzyme.

Table 2
Percentage of IPO specific activity of the isoforms of V-HPO, remaining after deactivation (specific IPO activity before the deactivation process was taken as 100%)[a]

Enzyme	% remaining IPO specific activity

[b] Almeida et al. (1996).

note the differences in deactivation between the two forms of the enzyme. For instance, Ls2 showed a higher resistance to deactivation than Ls1, whereas Lh1 is more resistant than Lh2. A similar behaviour has also been observed for the enzyme extracted from *P. canaliculata*, for which one of the forms showed a higher resistance to deactivation (Almeida et al., 2000). As Fig. 2 illustrates, the time required for complete reactivation of the enzymes was again different for each form of the enzyme. Since vanadium uptake (as vanadate) depends on the polypeptide chain and on the bonding of this species to the active site, the difference may be due to different conformations of the protein near the active site, which may alter the binding of vanadate. We note also, that the values of specific haloperoxidase activity were usually higher after reactivation with vanadate, which means that the vanadate group is not tightly bound at the active site and partial losses during the processes of purification may have occurred.

The effect of other metal ions, such as Mo(VI) (as molybdate), Mn(II) and Fe(III) on the reactivation of the apo-haloperoxidases was also tested; reactivation was always found to be less then 15% of that observed with vanadate.

2.5. Effect of organic solvents

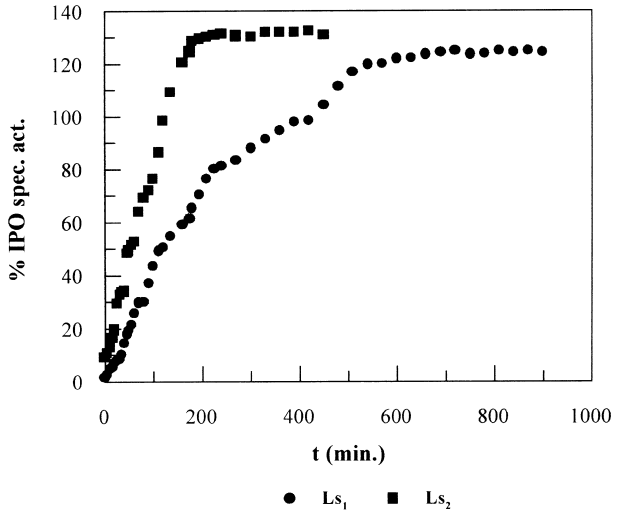
The long term effect of organic solvents on haloperoxidase activity is shown in Fig. 3. After 1 month incubation, the Ls1 form showed the highest activity in the mixtures with 25% of organic solvent (Fig. 3A), especially in the case of acetone when the activity was actually higher than in aqueous media; a possible explanation may be that the enzyme is aggregated in the buffer media and the presence of acetone could contribute to its desaggregation. For the other two forms (Ls2 and Lh2) appreciable activity was still observed after 1 month. For mixtures with 50% of organic solvent (Fig. 3B) the behaviour was quite different. The stability of Ls1 decreased significantly, whereas for Ls2 and Lh2 the decrease was not so pronounced.

It is also curious to notice that for mixtures with 50% organic solvent the forms Ls2 and Lh2 were more stable than Ls1, in clear contrast to what was observed in the mixtures with 25% organic solvent. Clearly, further work is needed to clarify these features of the vanadium haloperoxidases.

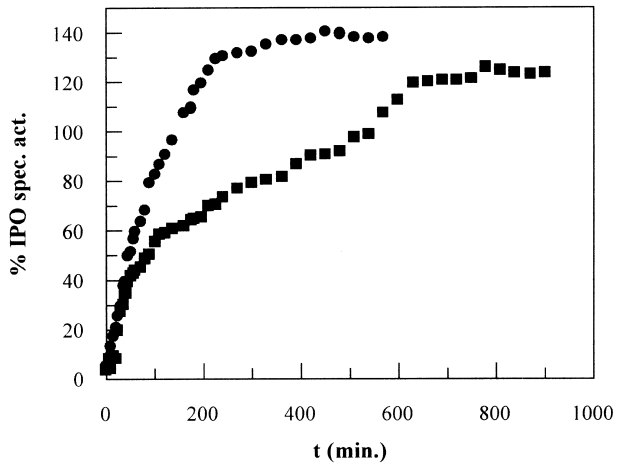
2.6. Thermal stability

The thermal stability of *L. saccharina* enzymes was also investigated. For temperatures in the range 25–50°C the enzymes studied were quite stable, catalysing with considerable efficiency the formation of triiodide (Fig. 4). An enhanced activity was shown by the Ls1 enzyme in the range 30–50°C, with a maximum at 40°C, contrasting the behaviour of Ls2 (Fig. 4). Above 50°C, the catalytic activity of both the Ls1 and Ls2 isoforms is drastically reduced. The thermal stability has also been studied for the haloperoxidases from the red algae *Corallina officinalis* (Sheffield et al., 1993), *Ceramium rubrum* (Krenn et al., 1987), the brown algae *Phyllariopsis brevipes* (Almeida et al., 1996) and *A. nodosum* (Tromp et al., 1989), and the lichen *Xantoria parietina* (Plat et al., 1987). These studies indicate that the thermal stability

A) *L. saccharina*



B) *L. hyperborea*



C) *L. ochroleuca* (Lo2(α))

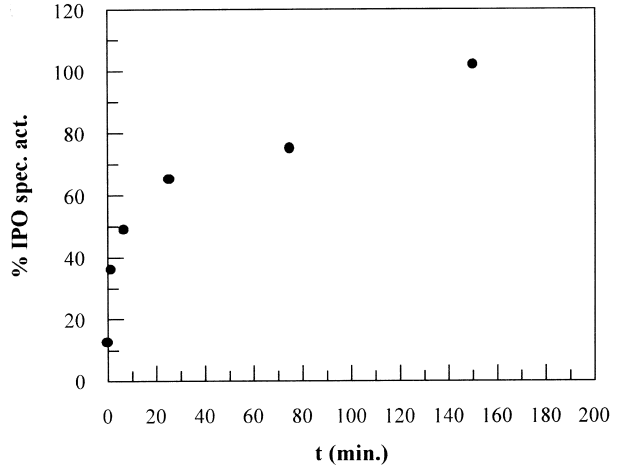


Fig. 2. Reactivaction with V(V) of the enzyme forms purified from *Laminaria saccharina, Laminaria hyperborea* and *Laminaria ochroleuca*. The values of IPO specific activity values the deactivaction/reactivaction process were taken as 100%. The values presented (% IPO specific activity) correspond to a percentage of those initial values.

of V-HPO is generally higher for the lichen comparatively to the seaweeds. This fact is probably related to the nature of the habitat, since *Xanthoria parietina* lives in the terrestrial environment, subject to larger temperature variation while seaweeds live in a more stable marine environment.

2.7. Steady-state kinetics

Some preliminary steady-state kinetic studies were performed by measuring the initial rate of I_3^- formation, catalysed by these enzymes, following the experimental conditions described in the Experimental section for the two substrates used (iodide and hydrogen peroxide) and for three pH values. Values of the apparent Michaelis–Menten constants for the two substrates and the values of maximum rate (V_{max}) were obtained and are presented in Table 3.

This table shows that there are no significant differences between kinetic parameters for the enzymes studied in this work. All the enzyme forms show a V_{max} at pH 6.1.

The apparent Michaelis–Menten constant for the substrate iodide ($K_m^{app\ I-}$) decreased slightly with the decrease of pH, showing that the affinity for iodide decreases when the pH increases. Previous studies on the bromoperoxidases from other seaweeds (de Boer and Wever, 1988; Everett and Butler, 1989; Soedjack and Butler, 1991) gave analogous results. It was not possible to increase the pH further since the non-catalysed reaction between H_2O_2 and I^- interferes strongly with the assay (Vilter, 1995).

The binding of hydrogen peroxide is affected in a different way; since the values of the apparent Michaelis–Menten constant for the substrate hydrogen peroxide ($K_m^{app\ H_2O_2}$) decreased with the increase in pH, this implies that the affinity of hydrogen peroxide for the enzyme increases with the increase of pH. Probably, protonation of a group at lower pH values, possibly a histidine side chain, prevents the reaction with peroxide. Studies carried out with the bromoperoxidase extracted from *A. nodosum* (de Boer and Wever, 1988) did indeed indicate the presence of a group, probably a histidine residue, with a pK_a of 5.7, which may be responsible for the pH dependence of the catalytical process. In fact, it was found for other peroxidases that a histidine with a pK_a between 4 and 6 could control the binding of peroxide to the active center, reflecting the importance of the polypeptide chain on activity (de Boer and Wever, 1988). Recently, the detailed role of a particular histidine residue (His 496) in the catalytic behaviour of haloperoxidases was discussed (Renirie et al., 2000).

2.8. Histochemical tests

From the observation of *L. saccharina* and *L. hyperborea* stained sections, it is possible to confirm that the

haloperoxidases are located, near the cuticle as well as in the external cortex region of the thallus (Fig. 5). However, the *L. hyperborea* sections exhibited also strong haloperoxidase activity around mucilaginous channels. The inner cortex region shows the presence of haloperoxidase activity for *L. saccharina*, absent in *L. hyperborea*. Some residual haloperoxidase activity was also observed in the medullar region of *L. hyperborea*. These results are in agreement with those of Krenn et al. (1989) and Almeida et al. (2000).

3. Experimental

3.1. Collection of algae

All the seaweeds were collected at low tide from the Portuguese west coast, in the northern part of the

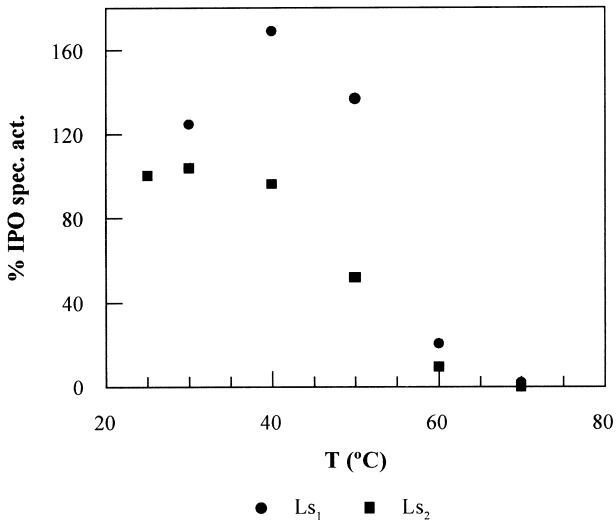

Fig. 4. The effect of temperature on the IPO activity for the two isoforms of V-HPO isolated from *Laminaria saccharina*. IPO specific activity before thermal treatment was taken as 100%.

country, near Viana do Castelo, at the end of summer (*L. hyperborea* and *L. saccharina*) and in spring (*L. saccharina* and *L. ochroleuca*). After collection, the algae were transported to the laboratory, thoroughly washed with distilled water, chopped and stored frozen until required.

3.2. Extraction and purification

For the extraction of HPO, two-phase aqueous systems, formed with an aqueous solution of PEG 1500 and an aqueous solution of potassium carbonate, were used. For each species, the process was optimised in order to select the most effective extraction media. In all cases, the media with 22.5% (w/v) K_2CO_3 and 15% (w/v) PEG 1500 proved to be the best.

After centrifugation for 30 min at 5000 *g* the upper phase was collected and the proteins precipitated by adding an equal volume of acetone. After a second centrifugation (30 min at 10,000 *g*) the resulting pellet was collected and resuspended in 50 mM Tris–HCl (pH

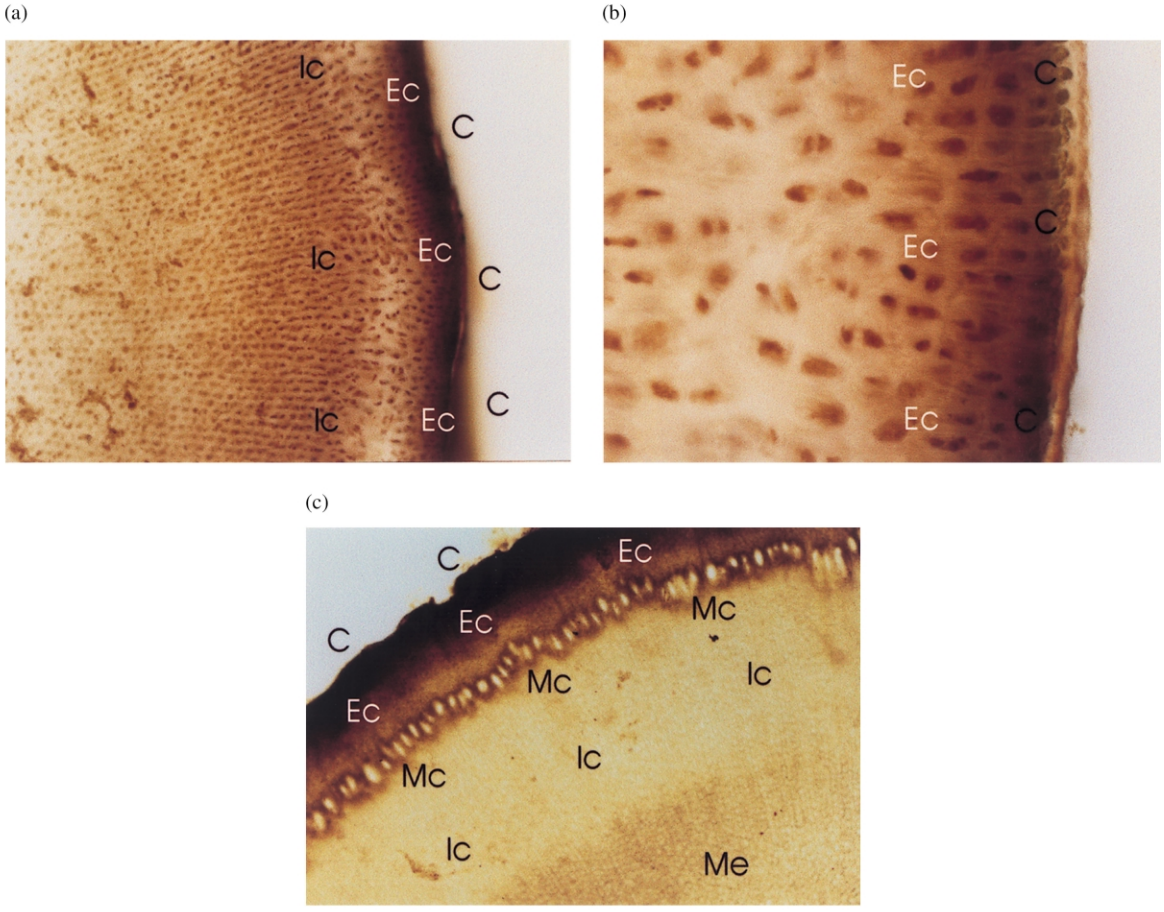

Fig. 5. Histochemical staining of fresh tissue samples of *Laminaria saccharina* and *Laminaria hyperborea*: (a) *Laminaria saccharina* (amplification: 10×); (b) *Laminaria saccharina* (amplification: 50×); (c) *L. hyperborea* (amplification: 10×); (C, cuticle; Ec, external cortex; Mc, mucilaginous channels; Ic, internal cortex; Me, medulla).

9.0) buffer. In order to reactivate the HPO, the extract was dialysed overnight against 20 mM $NaVO_3$ in 50 mM Tris–HCl (pH 9.0).

The sample was then loaded onto a hydrophobic interaction column (phenyl-sepharose from Pharmacia) and eluted with a decreasing linear gradient (1.3–0 M) of $(NH_4)_2SO_4$ in 50 mM Tris–HCl (pH 9.0). Resultant samples were then applied to another hydrophobic interaction column (butyl-sepharose from Pharmacia) and eluted also with a decreasing linear gradient (1.3–0 M) of $(NH_4)_2SO_4$ in 50 mM Tris–HCl (pH 9.0) or alternatively (*L. ochroleuca*) applied to an anionic exchange column (DEAE-Sephacel, from Pharmacia) and eluted with an increasing linear gradient of 0–1.3 M of $(NH_4)_2SO_4$ in 0.2 M Tris–Cl (pH 9.0). For the chromofocusing chromatography step (polybuffer exchanger-PBE 94, from Pharmacia) the samples were eluted with Polybuffer 74-imidazole (pH 4.0) also from Pharmacia.

3.3. Determination of protein content

Protein was determined by Bradford's method (Bradford, 1976), using bovine serum albumin as standard (Sigma).

3.4. Molecular mass determination and electrophoresis

The relative molecular mass was determined by FPLC/gel filtration chromatography on Sephacryl S-300R (Pharmacia) with a mobile phase of 0.5 M NaCl in 50 mM Tris–HCl (pH 9.0). Standard proteins from Pharmacia (ribonuclease A, M_r 13.7 kDa; chymotrypsinogen, M_r 25 kDa; ovalbumin, M_r 43 kDa; aldolase, M_r 158 kDa; and catalase, M_r 232 kDa) were used for the calibration of the column. SDS polyacrylamide gel electrophoresis was carried out on 12.5% gels according to Laemmli (1970). Standard proteins used for molecular mass determination were: phosphorylase b (94 kDa), bovine serum albumin (67 kDa), ovalbumin (43 kDa), carbonic anhydrase (30 kDa), trypsin inhibitor (20.1 kDa) and α-lactoalbumin (14.4 kDa), all from Pharmacia.

3.5. Reactivation studies

The HPO were inactivated at low pH by extensive dialysis for 24–72 h against a citrate–phosphate buffer at pH 3.8, in the presence of 1 mM EDTA, followed by dialysis against 50 mM Tris–HCl (pH 9.0). Reactivation studies with Na_3VO_4 were carried out in 50 mM Tris–HCl (pH 9.0). The final vanadium concentration for reactivation was 240 μM. The same conditions were used in the reactivation studies with other inorganic salts (ferric chloride, ammonium molybdate and manganese chloride).

3.6. Operational stability in organic solvents

The effect of organic solvents upon the haloperoxidase activity was determined by incubation of the enzyme with 25 and 50% (v/v) acetone, ethanol, methanol and 1-propanol mixed with 50 mM Tris–Cl pH 9.0, for 30 days at room temperature. The vials were tightly capped and kept in the dark. Each incubation was carried out in duplicate.

3.7. Thermal stability studies

The purified enzymes were incubated in a thermostated vessel for one hour at temperatures ranging from 25 to 70°C. Activity was determined after subsequent equilibration at room temperature.

3.8. Activity determinations

Activity as iodoperoxidase (IPO) was measured by following the conversion of I^- to I_3^- at 350 nm ($\varepsilon_M = 26400\ M^{-1}\ cm^{-1}$) using H_2O_2 as the electron acceptor (Björkstén, 1968). The H_2O_2 solutions were prepared by dilution of a 30% stock solution of Perhydrol (Merck) and their concentration was determined spectrophotometrically at 240 nm ($\varepsilon_M = 43.6\ M^{-1}\ cm^{-1}$). Bromination activity was measured spectrophotometrically at 290 nm in an assay system containing 50 μM monochlorodimedone ($\varepsilon_M = 20.2\ mM^{-1}\ cm^{-1}$), 2 mM H_2O_2, 100 mM KBr, in 100 mM phosphate buffer (pH 6.5) (Wever et al., 1985). Activity in native electrophoresis gels was detected by incubation of the gel in *o*-dianisidine, iodide and hydrogen peroxide (Vilter, 1981).

3.9. Steady-state kinetic experiments

These experiments were carried out in 0.1 M 2-(morpholino)ethanesulphonic acid (MES) (pH 5.5, 6.1 and 6.7) by measuring the oxidation of I^- by H_2O_2 to I_3^-. For each pH value the initial rate of formation of I_3^- was determined at a constant concentration of hydrogen peroxide (0.8 mM) and the potassium iodide concentration was varied between 0.2 and 10 mM. Alternatively, a constant concentration of potassium iodide (6 mM) was used and the hydrogen peroxide concentration was varied between 0.2 and 1.2 mM. Sodium sulphate was added to keep a constant ionic strength of 0.2 M when the potassium iodide concentration was varied. All measurements were performed at 25.0±0.5°C.

3.10. Steady-state kinetic analysis

The initial rates, v_0 plotted as a function of hydrogen peroxide or iodide concentration were fit to a Michaelis–Menten equation. The apparent kinetic parameters $K_m^{app\ I-}$ and $K_m^{app\ H_2O_2}$ as well as V_{max} were obtained from primary double reciprocal plots.

3.11. Histochemical studies

Tissue samples of fresh seaweeds cut with a blade razor, were immersed in filtered natural seawater followed by incubation with the haloperoxidase activity test solution, containing of 0.19 mM *o*-dianisidine, 6.06 mM KI and 0.8 mM H_2O_2 in distilled water.

After incubation, the tissue samples were washed with distilled water and observed in the light microscope.

The presence of haloperoxidase activity was ascertained from the development of a dark reddish brown colour due to *o*-dianisidine oxidation assisted by iodide. Control tests were performed for each tested tissue sample.

Endoplasmic oleoyl-PC desaturase references the second double bond

Jennifer L. Schwartzbeck, Sook Jung, Albert G. Abbott, Erin Mosley, Shahed Lewis, Gina L. Pries, Gary L. Powell*

Department of Biological Sciences, Clemson University, Clemson, SC 29634-0326, USA

Received in revised form 16 January 2001

Abstract

The regiospecificity for the gene product of *fad2*,[1] the microsomal oleoyl-PC desaturase from higher plants, differs from some previous suggestions. Rather than only referencing the carboxyl group (a Δ^{12} desaturase) or the methyl terminus (an ω-6 desaturase), this desaturase locates the second double bond in its substrates by first referencing the existing double bond. This specificity was demonstrated for the oleoyl-PC desaturase cDNA from the developing seeds of peanut (*Arachis hypogaea* L) expressed in yeast (*Saccharomyces cerevisae*). The expressed enzyme was capable of desaturating monounsaturated fatty acyl groups in membrane lipids. Endogenous palmitoleate was desaturated to *cis*, *cis* 9,12 hexadecadienoate (9(*Z*)12(*Z*)C16:2), endogenous oleate to linoleate (9(*Z*)12(*Z*) octadecadienoate), and *cis* 10-nonadecenoate (provided as a supplement in the growth medium) to 10(*Z*)13(*Z*)C19:2. The rule, Δ^{x+3} where $x=9$ is the double bond location in the substrate, best describes the consistent placement of the second double bond in the above monounsaturated substrates for the oleoyl-PC desaturase of higher plants. © 2001 Elsevier Science Ltd. 1. Introduction

The desaturases introduce double bonds into fatty acid chains producing the mono- and polyunsaturated fatty acids that are important determinants for the quality of commercial plant oils. Mutants for reduced polyunsaturated fatty acid content in seed oils have been selected using conventional breeding practices (see Gorbert and Knauft, 1997 as an example). The oil becomes rancid less quickly, sharing the chemical composition and many of the qualities of olive oil. The oleoyl-PC desaturase is the enzyme that places the second double bond in the fatty acid and catalyzes the first step in polyunsaturated fatty acid biosynthesis. An agronomically important mutant for peanut (*Arachis hypogaea* L) with high oleate oil content has reduced oleoyl-PC desaturase activity (Ray et al., 1993). Mutants for reduced polyunsaturated fatty acid content for several agronomically important crop species have also been obtained using gene suppression technology directed to the oleoyl PC-desaturase (Mazur et al., 1999).

The question of the specificity of the desaturases (reviewed by Shanklin and Cahoon, 1998) is an interesting one because the substrates are featureless, unbranched, hydrocarbon chains with the ester group at one end and the methyl group at the other. The double bonds are found in the middle of this hydrocarbon. If one double bond is present, the usual double bond configuration is *cis* or *Z* (rather than *trans* or *E*). The most common plant monounsaturated fatty acid is oleate with the double bond exactly in the middle of an eighteen-carbon chain. This configuration can be abbreviated as 9(*Z*)C18:1, where 9 is the location of the double bond counted from the carboxyl or ester group, C18 gives the total number of carbons in the chain, and 2

[1] We will employ the convention of using *fad2* for the gene and oleoyl-PC desaturase or FAD2 for the gene product. This permits us to avoid describing the enzyme as a Δ^{12} desaturase, or an ω-6 desaturase. The latter designations involve an assertion about the substrate specificity no longer tenable based on this work. PC is the abbreviation for phosphatidylcholine, the most important phospholipid substrate for this activity. GLC is gas-liquid chromatography. GC/MS spectroscopy is separation by capillary gas chromatography with mass spectral, electron-impact detection.

PII: S0031-9422(01)00081-4

is the total number of double bonds. Second and subsequent double bonds are usually methylene interrupted and unconjugated. The most common polyunsaturated fatty acids in plant tissues are linoleate, 9(*Z*)12(*Z*)C18:2, and linolenate, 9(*Z*)12(*Z*)15(*Z*)C18:3.

Chemical nomenclature references the carboxyl group of the fatty acid as carbon one. This reference for the double bond location is given by the symbol Δ^9. But a desaturase could locate the double bond by starting from the methyl end and counting nine carbons before placing the double bond, i.e. ω-9 for oleate. Note that the result of the activity of a desaturase with Δ^{12} regiospecificity is identical to the product of a desaturase with ω-6 regiospecificity when the double bond is located precisely in the middle of the chain. Thus linoleate can be synthesized from oleate with a desaturase that may have ω-6 or Δ^{12} regiospecificity. Or, ignoring the ends, the desaturase could reference an existing double bond, Δ^{x+3}, placing the new double bond, methylene interrupted or $x+3$ towards the methyl group, from the first carbon of the pre-existing double bond, x. Gurr (1971), in an early consideration of this problem, stated the question of the regiospecificity of this desaturase nicely: "does the enzyme which introduces the second double bond measure from the carboxyl end of the chain, from the methyl end, or solely with reference to the first double bond?"

The regiospecificity of the second desaturation has been experimentally examined in plant materials using unsaturated fatty acids systematically varying in chain length and unsaturation (Gurr, 1971; Howling et al., 1972). *Chlorella,* or slices of castor bean seed, were supplemented with these fatty acids and the new products were identified. These groundbreaking experiments provided several important conclusions. They deduced that two desaturases with differing specificity were present. One desaturase was thought to derivatize monounsaturated fatty acids of variable chain length (C15–C19) but with the double bond at the Δ^9 position always forming the new double bond at Δ^{12} position. This desaturase was said to be a Δ^{12} desaturase. A second desaturase was thought to form the second double bond methylene-interrupted from the first double bond but with the initial double bond and the second double bond counted from the methyl or ω end; this desaturase was called an ω-6 desaturase. Thus, 8(*Z*)C17:1 (ω-9) was desaturated by the latter enzyme to form 8(*Z*)11(*Z*)C17:2 (ω-6 specificity) and 10(*Z*)C19:1 (ω-9) formed 10(*Z*)13(*Z*)C19:2 (also ω-6 specificity). Unfortunately these experimenters were unable to more directly evaluate the number and type of desaturases present in the algae or plant tissue acting on the fatty acids supplied. And β-oxidation of the desaturated products sometimes confused interpretation (Howling et al., 1972).

The question of regiospecificity of the desaturases has been reviewed (Heinz, 1993; Harwood, 1996; Shanklin and Cahoon, 1998; Napier et al., 1999). The *fad2* plant desaturase gene was first cloned using T-DNA tagged *Arabidopsis* mutants (Okuley et al., 1994) and the *fad3* was cloned using T-DNA tagged *Arabidopsis* together with map-based chromosome walking (Arondel et al., 1992). Four additional and different desaturase genes were then obtained by taking advantage of homologies to the above desaturases (reviewed by Ohlrogge and Browse, 1995). The two most common cloned desaturases that place the second double bond in the fatty acids of higher plants are *fad6* for the chloroplast, and *fad2* for the cytoplasm. This finding fulfilled the earlier prediction of the existence of two desaturases based on the substrate specificities (Howling et al., 1972). Cloning of these genes from *Arabidopsis* and other organisms has permitted the expression of the enzymes for desaturases in micro-organisms. Thus one can individually and directly test the specificity of each of the individual desaturases.

Yeast is a good expression system for the *fad2* gene encoding the oleoyl-PC desaturase from higher plants (Covello and Reed, 1996; Broun et al., 1998). *S. cerevisae* contains only a Δ^9 desaturase for the monoenoic fatty acids, palmitoleate and oleate; no desaturase specific for forming a second double bond is present. Significantly, *S. cerevisae* does not appreciably β-oxidize fatty acid supplements. Thus a variety of fatty acids can be provided as supplements to the growth medium. Diunsaturated fatty acids result from the desaturase being expressed. In the present studies, cloned *fad2* from developing peanut seeds was the only source of this desaturase activity in the engineered yeast. Using this system, questions about the specificity of the desaturation of monoenoic fatty acids by the oleoyl-PC desaturase from higher plants are unambiguously resolved.

Of the substrates employed in the study described here, many were either not taken up by the yeast or were not substrates for oleoyl-PC desaturase. However, the products of the desaturation of endogenous palmitoleate and oleate were 9(*Z*)12(*Z*)C16:2 and 9(*Z*)12(*Z*)C18:2 respectively. Supplemented 10(*Z*)C19:1 provided 10(*Z*)13(*Z*)C19:2. Because these products cannot all arise from either the action of a Δ^{12} or an ω-6 desaturase, the specificity for this oleoyl-PC desaturase must be Δ^{x+3}. The evidence suggests that the enzyme first references the location of the existing double bond and then places the new double bond methylene interrupted towards the methyl end of the fatty acid chain.

2. Results and discussion

The *fad2* cDNA from developing peanut seeds was directionally cloned into the multiple cloning site of the shuttle vector pYES2 (Bruner et al., 2001). This vector, containing *fad2,* was expressed in *Saccharomyces*

cerevisae under the control of the GAL1 promoter. When an empty vector was employed, gas chromatographic (GLC) analysis of the methyl esters revealed the monounsaturated fatty acids expected for this yeast, primarily palmitoleate and oleate (Fig. 1); as expected, no polyunsaturated fatty acids were present (Fig. 2). When FAD2 was induced, linoleate appeared, comprising 10–15% of the total fatty acids C16:0, C16:1, C18:0, C18:1, C18:2, and C19:1 (and C19:2, when present).

In a series of preliminary experiments not shown here, the regiospecificity of the oleoyl-PC desaturase was examined by supplying a variety of fatty acids to the medium for uptake and desaturation by the yeast. We were particularly interested in supplying fatty acids with chain lengths or with double bond locations that would demonstrate the specificity of the oleoyl-PC desaturase. While 10(*Z*)C17:1 or 11(*Z*)C20:1 were incorporated into lipids, no new desaturation products were observed. The 10(*Z*)C19:1 was incorporated to an extent of 15–20% and gave a new product readily observable in GLC chromatograms because of the longer retention time, comprising 3–4% of the total fatty acids. This new peak disappeared upon hydrogenation and was absent when cultures had been supplemented with 10(*Z*)C19:1 but were not induced.

These preliminary observations showed the presence of a new product produced by the desaturation of

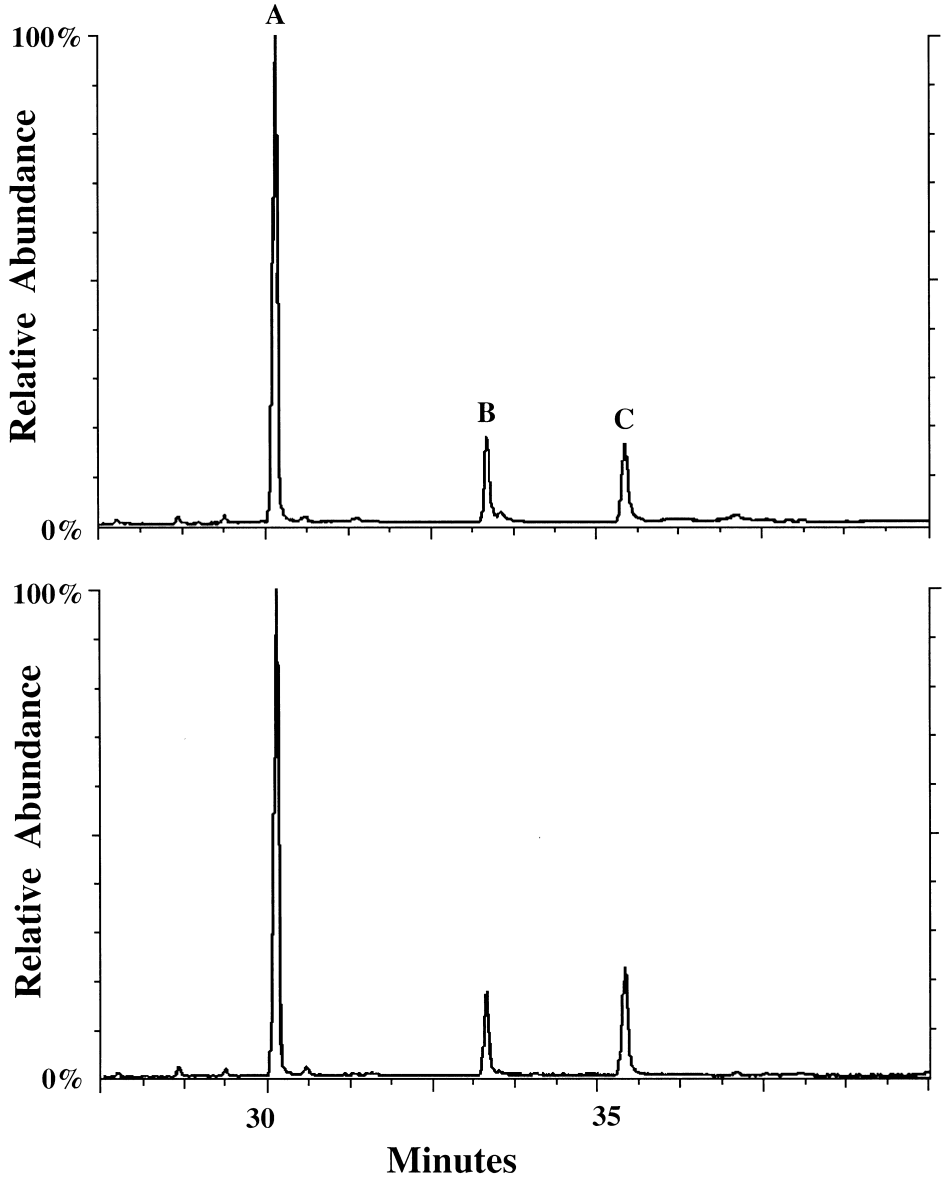

Fig. 1. Monounsaturated dimethyl disulfide methyl esters separated by gas chromatography with total ion mass spectral detection. Yeast fatty acid methyl esters were separated on silver ion columns and the monounsaturated fraction converted to dimethyl disulfide derivatives. (Top) composition after induction of the oleoyl-PC desaturase. (Bottom) composition without induction. The relative abundance scale for the bottom part of the figure is the same as for the top part. The fragmentation mass spectra (not shown) displayed prominent molecular ions and fragments identifying palmitoleate (A), oleate (B), and 9(*Z*) nonadecenoate (C).

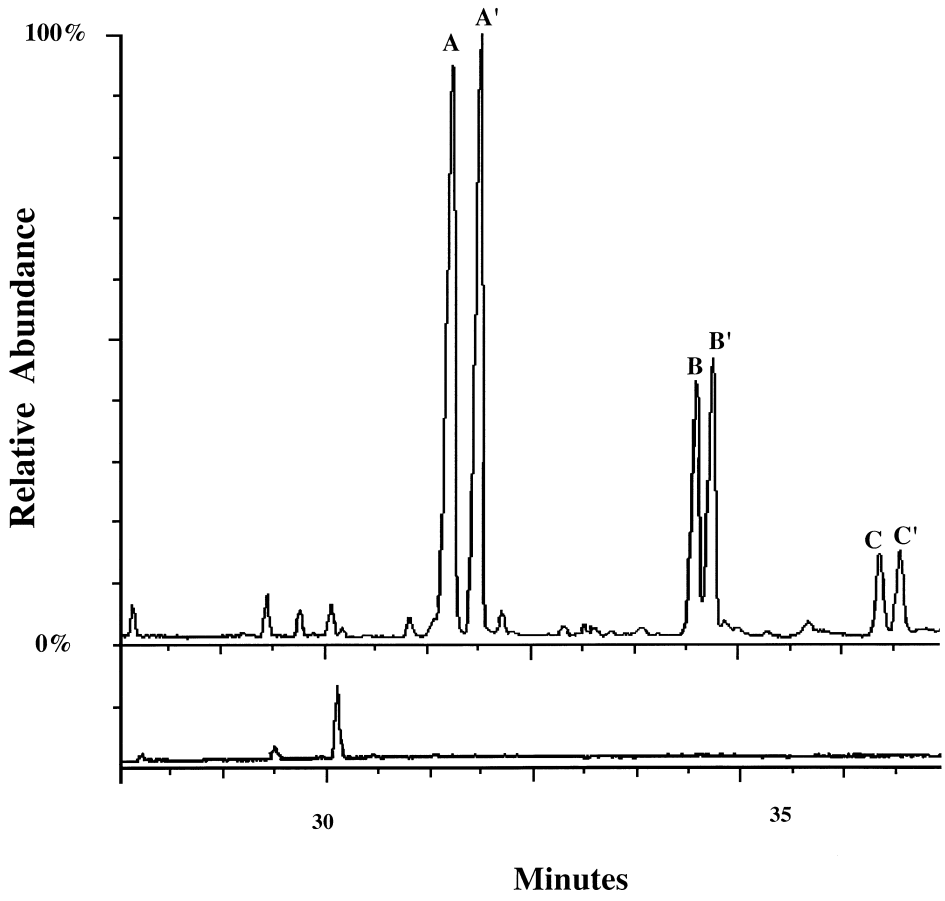

Fig. 2. Diunsaturated dimethyl disulfide methyl esters separated by gas chromatography with total ion mass spectral detection. Yeast fatty acid methyl esters were separated on silver ion columns and the diunsaturated fatty acid fraction converted to dimethyl disulfide derivatives. (Top) composition after induction of the oleoyl-PC desaturase. (Bottom) composition without induction. Peaks in the top spectra with longer retention times (not shown) correspond with rearranged dimethyl disulfide derivatives of diunsaturated fatty acids (Carballeira et al., 1994). The spectra for the pairs of peaks (AA′, BB′, CC′) are shown in Fig. 3.

10(*Z*)C19:1. If the oleoyl-PC desaturase were a Δ^{12} desaturase and referenced the ester group, the resulting doubly unsaturated product would be 10(*Z*)12(*Z*)C19:2, with conjugated double bonds. The product furnished by referencing the existing double bond and inserting the new one in a methylene-interrupted location (a Δ^{x+3} mechanism) would be 10(*Z*)13(*Z*)C19:2. These possibilities were distinguished by locating the double bonds as described below.

Mass spectroscopy was used for the identification of the location of double bonds, but direct electron impact fragmentation of the methyl esters of di-unsaturated fatty acids isomerizes and conjugates the double bond, obscuring their original location. Of the methods available (Christie, 1998), we employed the I_2 catalyzed addition of dimethyl disulfide to the double bonds of the fatty acids. Characteristic fragments result from cleavage between the vicinal methyl thioethers providing, for monoenoic fatty acids, two fragments readily identified with the two ends of the fatty acid. Dimethyl disulfide will randomly, but singly, add to one or another of the methylene-interrrupted double bonds of dienoic fatty acids after an hour of reaction at 37°C (Yamamoto et al., 1991). These dimethyl disulfide derivatives all have higher gas chromatographic retention times than the underivatized saturated fatty acid methyl esters. At higher temperatures and/or longer reaction times, thietane, tetrahydrothiophene and tetrahydrothiopyran structures are obtained from doubly unsaturated compounds (Vincenti et al., 1987; Carballeira et al., 1994). These compounds exhibit longer gas chromatographic retention times and bear a less obvious relationship to the original double bond positions.

Actively growing cultures of the engineered *S. cerevisae* and supplemented with the free fatty acid 10(*Z*)C19:1, were induced producing the oleoyl-PC desaturase. After 6 h of incubation, the fatty acyl moieties present in the yeast lipids were converted to methyl esters in situ. Note that unesterified fatty acids that have not been incorporated into lipid are not methylated by sodium methoxide. Silver ion column chromatography (Christie, 1989) was then used to resolve saturated, monoenoic and dienoic

fatty acid methyl esters. The first fraction, containing the saturated fatty acid methyl esters, was discarded and the separate fractions for monoenoic and dienoic fatty acid methyl esters retained and treated with dimethyl disulfide. The GC/MS total ion chromatograms for the monoenoic dimethyl disulfide derivatives are shown in Fig. 1 and the dienoic derivatives in Fig. 2. The mass spectra (not shown) for the three peaks in the chromatogram shown in Fig. 1 (top) and (bottom) verified their identities as dimethyl disulfide derivatives of palmitoleate, oleate, both endogenous, and *cis* Δ^9 nonadecenoate from the supplement. The amounts of monoenoic fatty acids were comparable for non-induced and induced cultures, as expected. In Fig. 2 (top), the characteristic double peaks from the fatty acids desaturated by oleoyl-PC desaturase were found. Fig. 2 (bottom) shows the absence of fatty acids in this dienoic fraction when the oleoyl-PC desaturase was not induced. The peak intensities of monoenoic fatty acid in the non-induced culture (Fig. 1, bottom) were similar to the induced culture (Fig. 1, top) implying that dienoic fatty acid derivatives would have been readily apparent if they had been present in uninduced cultures.

The mass spectra of each of the pairs of dimethyl disulfide derivative peaks from the gas chromatographic separation (Fig. 2, top) are shown in Fig. 3. The first pair of peaks (Fig, 3, A and A′) identify the product of the desaturation of endogenous palmitoleate as 9(*Z*)12(*Z*) C16:2 as has been previously observed (Covello and Reed, 1996). The second pair of peaks (Fig 3, B and B′) identify the product of desaturation of endogenous oleate as 9(*Z*)12(*Z*)C18:2 or linolenate. The third pair of peaks (Fig 3, C and C′) identify the product of the desaturation of *cis* Δ^9 nonadecenoate as 10(*Z*)13(*Z*)C19:2.

The possibilities for the specificity of the oleoyl-PC desaturase are depicted in Fig. 4. The oleoyl-PC desaturase present in developing peanut seeds and expressed in yeast was not that of a Δ^{12} desaturase because the enzyme can desaturate 10(*Z*)C19:1 to form 10(*Z*)13(*Z*)C19:2; the action of a Δ^{12} desaturase would have furnished 10(*Z*) 12(*Z*)C19:1, a conjugated fatty acid. The enzyme is not an ω-6 desaturase because it desaturated 9(*Z*)C16:1 to form 9(*Z*)12(*Z*)C16:2; ω-6 activity would have provided an allene, 9(*Z*)10(*Z*)C16:2, that was not observed. The specificity seems best to be described as Δ^{x+3} desaturase, where the key reference is the location of the existing double bond ($x=9$).

Others have previously observed that the remaining portions of the fatty acid chain, esterified to a polar lipid, are important in locating second double bonds. In intact plant systems supplemented with different fatty acids, those with a 10(*Z*) double bond and less than 19 carbon atoms were not desaturated; fatty acids with double bonds nearer than 9(*Z*) to the carboxyl group were not desaturated (Gurr, 1971; Howling et al., 1972; Heinz, 1993). Similar specificities were observed in our experiments with the oleoyl-PC desaturase expressed in yeast. Thus to locate the second double bond from the double bond system, the enzyme must be responsive both to the length of the hydrocarbon chain towards the polar portion of a complex lipid and the length of the chain towards the methyl group and the hydrophobic core of the membrane. Given the constraints, the ability of this enzyme to place a methylene-interrupted double bond so precisely in a hydrocarbon chain on the intact lipid within a membrane is extraordinary.

The regiospecificity demonstrated by using the *S. cerevisae* expression system is clearly the result of the expressed activity (compare Fig. 2, top and bottom). Results previously obtained by slices of tissue from higher plants or from other microorganisms could have been the result of one or more of the multiple desaturases present in these tissues (Gurr, 1971; Howling et al., 1972; Heinz, 1993). *S. cerevisae* contain monoenoic fatty acids in the absence of a plasmid containing *fad2*. Thus polyunsaturated fatty acids can only result from the desaturation of fatty acids by the *fad2* gene product and not from some cooperative interaction of more than one desaturase acting on a given fatty acid.

The specificity of membrane-associated desaturases from other organisms has also been explored by examining the products from feeding exogenous supplements. The enzyme from *Synechocystis* that inserts the second double bond at the Δ^{12} position has been cloned (Wada et al., 1993), and the deduced amino acid sequence differed considerably from that for oleoyl-PC desaturases of higher plants. Indeed, Southern blots using probes based on the *Synechocystis* sequence did not locate this protein in higher plants (our unpublished observations). The lipids of *Synechcystis* are primarily glycolipids, similar to plant chloroplasts lipids rather than the phospholipids of the endoplasmic reticulum where the oleoyl-PC desaturase is thought to reside. Thus the regiospecificity of this *Synechocystis* desaturase may or may not be similar to the oleoyl-PC desaturase of higher plants. When odd chain fatty acids were fed to the intact organism, the second double bond still appeared at the Δ^{12} position when the first double bond was Δ^9, suggesting that that desaturase did not count from the methyl end, i.e. it was not an ω-6 desaturase (Higashi and Murata, 1993).

The FAD6 enzyme also places double bonds at the Δ^{12} position in chloroplast lipids. This gene was cloned because of similarities in sequence to the *Synechocystis* enzyme and was successfully expressed in that organism (Hitz et al., 1994). The sequences of the FAD6 and the FAD2 (oleoyl-PC desaturase) differ markedly. Hitz et al., 1994 proposed the existence of three different desaturase families, with FAD6 and FAD2 representing two of the different families. Again one would not necessarily expect sequence-unrelated enzymes (especially those found in different compartments and acting on different

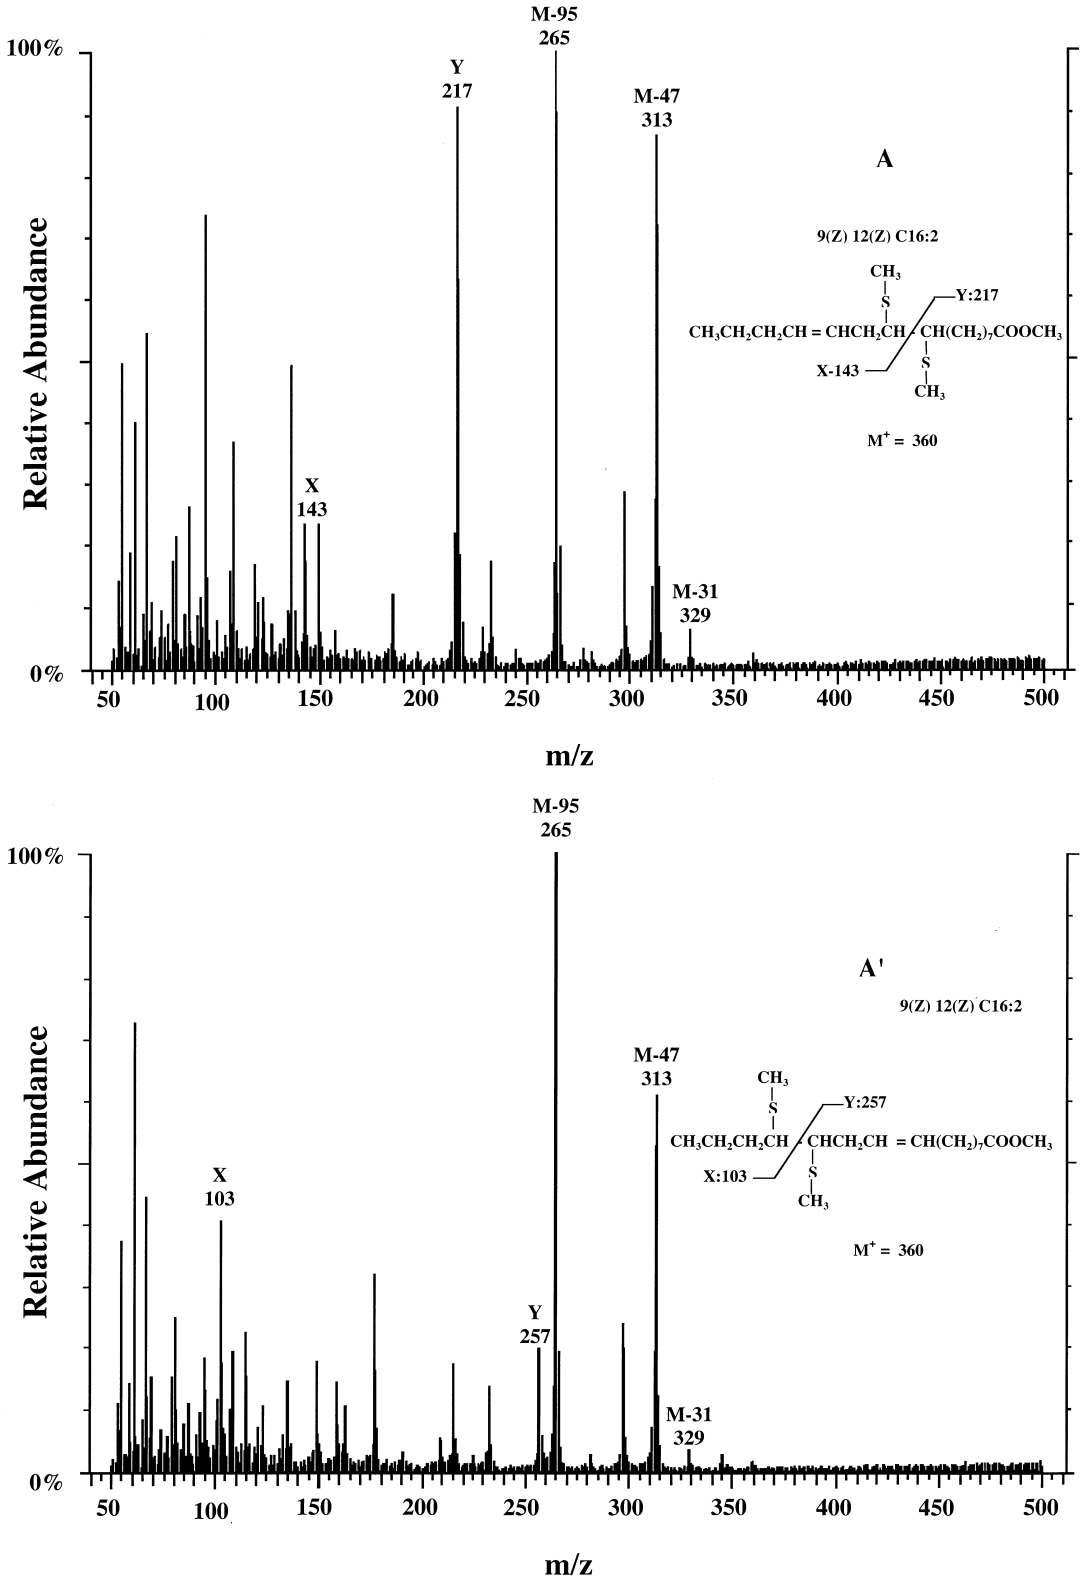

Fig. 3. Mass Spectra of the dimethyl disulfide derivatives of dienoic fatty acid methyl esters. The spectra are keyed to the labels given in Fig. 2. A and A′ identify 9(*Z*)12(*Z*)C16:2. B and B′ identify linoleic acid (9(*Z*)12(*Z*)C18:2). C and C′ identify 10(*Z*)13(*Z*)C19:2. The structures corresponding to fragments resulting from cleavage at the double bond in the location shown are provided. Sizeable molecular ions were not observed but characteristic losses of M-31 (CH_3O), M-47(CH_3S) and M-95(CH_3SSCH_3) were consistent with the calculated molecular masses (M^+) shown (*continued on next page*).

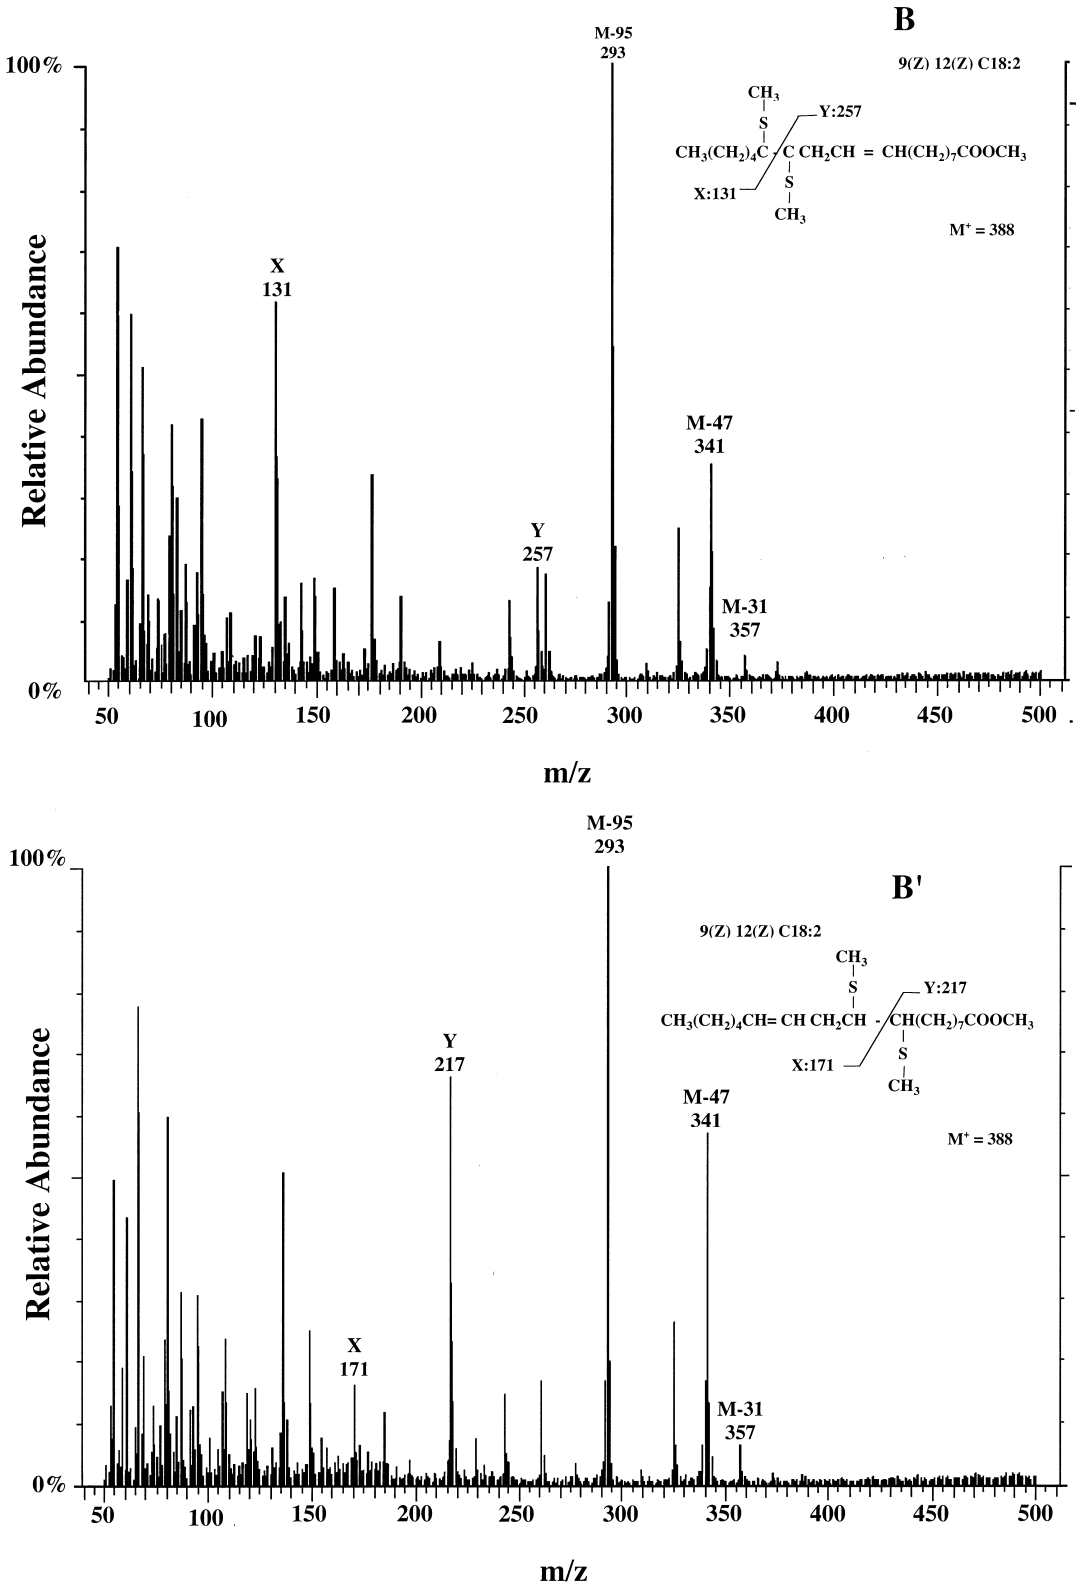

Fig. 3. (*continued*).

lipid substrates) to share similar substrate specificities. In this case, FAD6 desaturated endogenous palmitoleate to 9(*Z*)12(*Z*)C16:2 (ω-4 desaturation). Based on this desaturation, along with the desaturation of oleate to linoleate in the same construction (an ω-6 desaturation), Hitz et al., 1994 suggested that the enzyme measured from the existing double bond rather than from the methyl end.

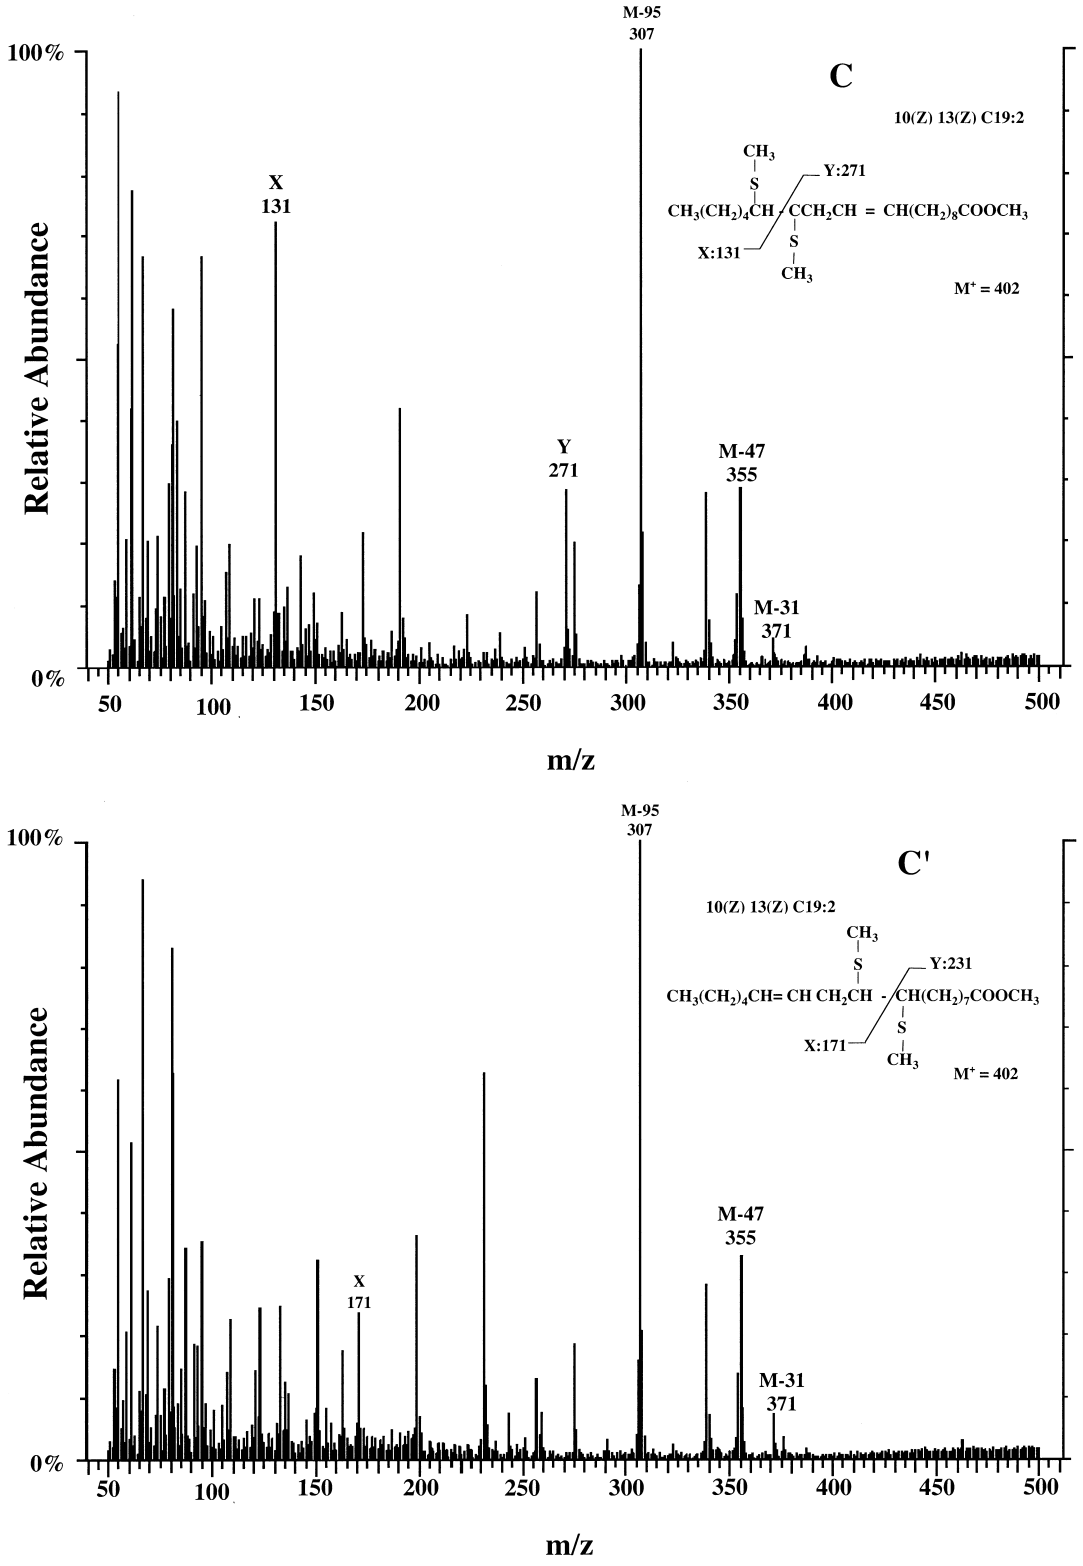

Fig. 3. (*continued*).

Although the cDNA for *fad2,* like that for the Δ^9 desaturase, encoded three conserved histidine motifs characteristic of diiron active sites (Shanklin et al., 1994), amino acid sequences of the enzymes that place the first and the second double bonds are clearly divergent. The oleoyl-PC desaturase is an intrinsic membrane enzyme and the Δ^9 desaturase is soluble; membrane-associated desaturases act on acyl groups of intact phospholipids

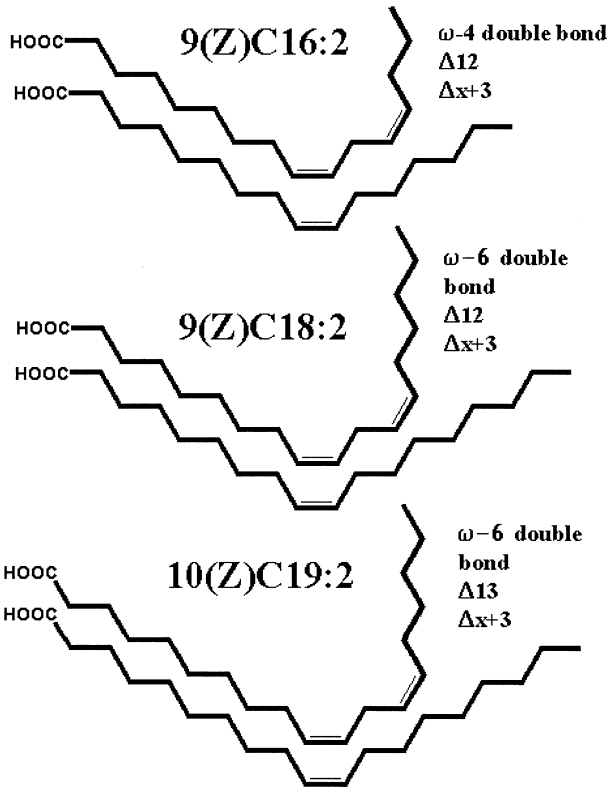

Fig. 4. Oleoyl-PC desaturase products. Three sets of fatty acids are shown. The starting monoenoic fatty acids, 9(*Z*)C16:1, 9(*Z*)C18:1 and 10(*Z*)C19:1, are the lower member of each pair. The action of oleoyl-PC desaturase provided the upper diunsaturated fatty acids. The designations on the left describe the location of the newly synthesized double bond relative to the methyl end (ω-4, ω-6 and ω-6), the ester end (Δ12, Δ12, and Δ13), and relative to the existing double bond (Δ^{x+3}).

oriented within the bilayer of the biological membrane while the soluble desaturases bind the lipoprotein acyl-ACP. The structures of the substrate binding sites for the electron carriers, cytochrome b_5 and ferredoxin, for the membrane-associated and soluble enzymes respectively, must differ as well, also accounting for some of the sequence differences between these proteins.

The most interesting information available for how double bonds are formed by desaturases comes from studies of the soluble desaturase for which a crystal structure is available (Lindqvist et al., 1996). A cavity was present that was postulated as being capable of accepting the methyl end of the acyl of the substrate. This saturated chain is bent in the vicinity of the nascent double bond. When the depth of the cavity was altered by amino acid substitution, the regiospecificity for the double bond was altered, implying that the depth of the cavity was the determinant for double bond location (Cahoon et al., 1997). In the absence of structural data for the membrane-localized oleoyl-PC desaturase, we may only speculate that a similar cavity exists. In such a model, the length of the hydrocarbon chain on either side of the existing double bond is important, regulating whether or not the unsaturated acyl chain present in the intact phospholipid can be productively accommodated within the cavity. Based on the present work, the oleoyl-PC desaturase would not place the new double bond in lipid acyl moieties relative to the methyl end (ω-6) or the ester of the intact lipid (Δ^{12}). The postulated cavity will accommodate monounsaturated acyl groups with the *cis* double bond (x) located $x+3$ from the diiron of the active site and the new double bond would be synthesized Δ^{x+3} to the existing double bond.

3. Experimental

3.1. Oleoyl-PC desaturase expression in yeast

The reading frame from the most active *fad2* from *Arachis hypogaea L.* (Jung et al., 2000; GenBank Accession Number AF03019) was directionally cloned into the pYES2 expression vector (Bruner et al., 2001). This plasmid is a centromeric expression vector containing the GAL1 promoter (Stratagene).

For expression, the cells were grown at 30°C on SC-ura liquid media containing 2% raffinose. When the A_{600} approached 0.5, 2% galactose (Acros, 99.9% purity) was added to induce the production of the *fad2* gene product. When cultures were supplemented with 1 mM 10(*Z*)C19:1 (Sigma Chemical Co.) (or other fatty acid supplements), the medium contained 0.1% Tergitol (NP-40, Sigma Chemical Co.). The cells were grown an additional six hours and were harvested by centrifugation.

3.2. Analysis of unsaturated fatty acids

The fatty acids were esterified by treatment of the cell pellets with 0.5 M sodium methoxide (Sigma Chemical Co.) in methanol for 30 min, neutralized with 125 mM H_2SO_4 and the methyl esters extracted into hexane. The methyl esters were fractionated by silver ion chromatography (Christie, 1989). The saturated fatty acid fraction was discarded. The monounsaturated and the diunsaturated fatty acid fractions were collected separately and the dimethyl disulfide derivatives (Yamamoto et al., 1991) were prepared. The fatty acid methyl esters were analyzed by gas chromatography with mass spectral detection (Varian Saturn System) using a 30 m×0.2 μ×25 mm Supelco 2380 column (Sigma/Aldrich/ Fluka/ Supelco). The temperature was programmed from 140°C (after 3 min) to 220°C at 3°C/min and the temperature held for a total run time of 50 min. The carrier gas was He with a flow rate of 20 cm/s and an injector split 100:1. GLC analysis of the fatty acid methyl esters using flame ionization detection was carried out with that column using similar conditions before and after hydrogenation of methyl esters (brief treatment in ethanol using Pd/C and H_2 gas).

Service de Pharmacognosie, Institut de Pharmacie, Université de Liège, C.H.U., Tour 4, Avenue de l'Hôpital 1, 4000 Liege 1, Belgium

Received 9 October 2000; received in revised form 16 February 2001

Abstract

The enzymatic glucose cleavage of palicoside revealed the biosynthetic pathway to akagerine, whereas the conversion of dolichantoside led to a new quaternary heteroyohimbine alkaloid named N_b-methyl-21-β-hydroxy-mayumbine. The hypothetical models of reactions occurring after the conversion of both substrates are proposed. Dolichantoside and palicoside, as well as *Strychnos mellodora* stem bark crude ethanol extract, exhibit significant antimycotic activity against human pathogens in presence of specific glucosidase. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

In our search for alkaloids in *Strychnos mellodora* S. Moore, an endemic species of East-Africa (Leeuwenberg, 1969) we isolated a wide range of gluco-alkaloids (Tits et al., 1996; Brandt et al., 1999) and particularly interesting amounts of the N_b-methylated alkaloids dolichantoside (**1**) and palicoside (**2**). Their structures are closely related to and present the same 3α configuration as strictosidine (**3**), the central intermediate in the biosynthesis of monoterpenoid indole and quinoline alkaloids (Rueffer et al., 1978; Bisset, 1980). The enzymatic cleavage of glucose in strictosidine (**3**) gives rise to a large variety of structure groups (Kisakürek et al., 1983). The intermediate isolated by Stevens (1994) after strictosidine conversion was 3α, 15α-$\Delta^{20(21)}$-didehydrocathenamine, a $\Delta^{20(21)}$-didehydro-heteroyohimbine. The amounts of dolichantoside (**1**) and palicoside (**2**) obtained from *Strychnos mellodora* gave us the opportunity to start phylogenetical studies in order to evaluate the potential biosynthetic pathway from those gluco-alkaloids. In our previous work, we mentioned the conversion of these two substrates by strictosidine glucosidase from *Catharanthus roseus* (SGD) and by a specific glucosidase isolated from *Strychnos mellodora* (SMGD) (Brandt et al., 2000). Here we present the isolation and identification of the main conversion products. An evaluation of the antimycotic activity before and after glucosidase conversion was carried out on the crude ethanol extract of *Strychnos mellodora* stem bark, as well as on dolichantoside (**1**) and palicoside (**2**).

2. Results and discussion

2.1. Identification and determination of conversion products

To check the invariability of the pattern of conversion products of dolichantoside (**1**) and palicoside (**2**), incubations were first compared in the presence of three different glucosidases: SGD, SMGD and a less specific one, the glucosidase from sweet almonds. Independent of the glucosidase used, the pattern of conversion products was the same. The kinetic parameters K_m and V_{max} were determined for the enzymes SGD and SMGD, in the presence of the substrates **1** and **2** (Brandt et al., 2000). This study clearly revealed that the conversion of substrates **1** and **2** was quicker and more complete with the enzyme SMGD (Table 1). The V_{max} or maximal

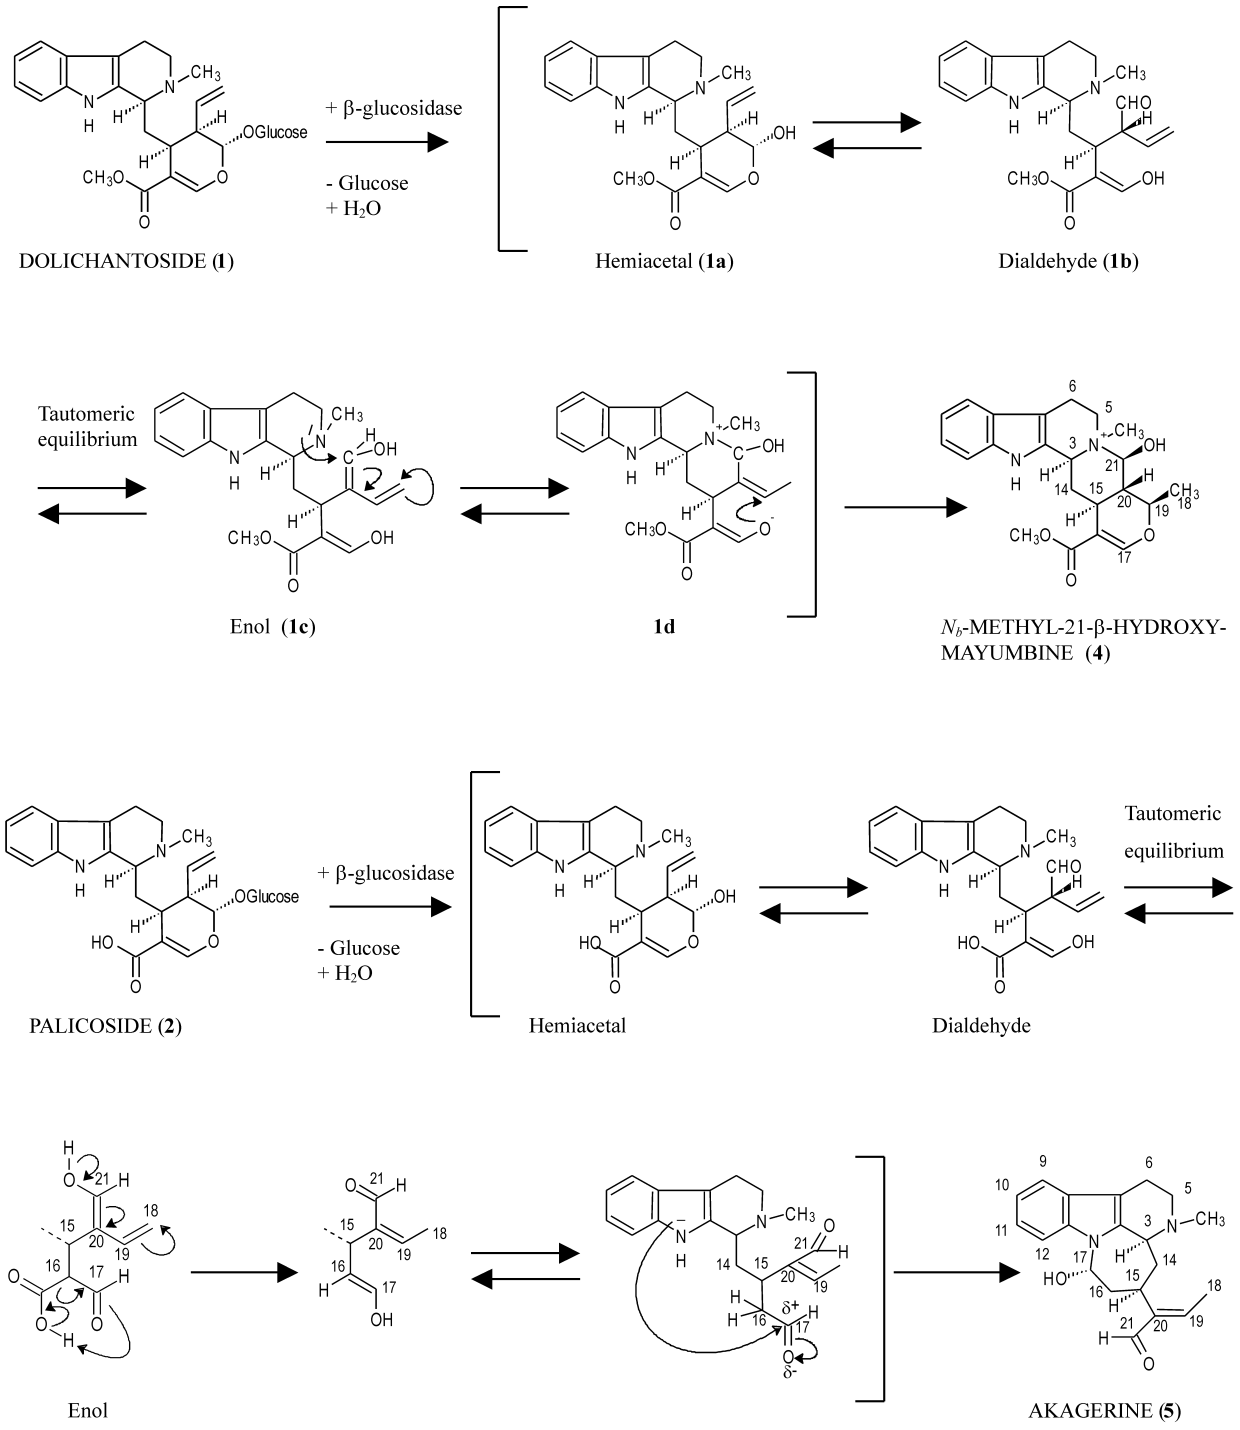

Scheme 2. Hypothetical model for the conversion of palicoside into akagerine.

conversion velocities were higher in the presence of SMGD and reached with lower substrate concentrations, as K_m represents half of the substrate concentration necessary to reach the maximal conversion velocity.

We thus incubated a larger amount of dolichantoside (**1**) in the presence of SMGD. After 72 h of incubation, dolichantoside was nearly completely converted into a main product (**4**) that was more polar. This product was compared in TLC and HPLC and stated to be identical to the one obtained after the 15 min incubation of a 1 mM dolichantoside solution. It was separated (see Experimental) from the incubation mixture and its structure determined by spectroscopic methods as N_b-methyl-21-β-hydroxy-mayumbine (**4**), a new heteroyohimbine quaternary alkaloid. Its UV spectrum revealed maxima of tetrahydro-β-carboline alkaloids. The high resolution mass spectrum exhibited a molecular peak corresponding to the molecular formula $C_{22}H_{27}N_2O_4^+$.

Table 1
Kinetic parameters of SGD and SMGD towards dolichantoside (**1**) and palicoside (**2**). Conditions used to determine these parameters are found in literature (Brandt et al., 2000)

Substrate	SGD		SMGD	
	K_m (μM)	V_{max} (nkat mg $^{-1}$ protein)	K_m (μM)	V_{max} (nkat mg $^{-1}$ protein)
(**1**)	1130	21.2	564	224
(**2**)	7015	11.1	335	39

The molecular peak also present in the ES–MS–MS spectrum at m/z 383 $(M)^+$ exactly corresponded to the loss of a glucose moiety from dolichantoside (**1**); an ion at m/z 365 suggested the easy loss of water and thus the presence of a hydroxyl function. In the ^{1}H-^{1}H NMR auto-correlation spectra, the most characteristic point for the formation of a heteroyohimbine structure was the presence of a methyl group at 1.55 ppm (d, $J_{18–19}$ = 6.7 Hz) (CH_3-18) correlated to H-19 at 3.75 ppm (q, $J_{19\text{-}20}$ = 8.6 Hz). Chemical shifts of those protons, in particular shielding of H-19, as well as high coupling constants, by comparison with the literature data concerning the eight possible diastereoisomers of heteroyohimbine type (Phillipson and Supavita, 1983), suggested α-configuration of H-19 and consequently β-configuration of the methyl group C-18 (19 *R* series). This configuration is related to 19-epiajmalicine or mayumbine (3α, 20β, *normal* diastereoisomeric type) (Uusvuori and Lounasmaa, 1981). The formation of a *normal* type alkaloid is predictable considering the initial H_3-α, H_{20}-α configuration of dolichantoside. On the other hand, the configuration α of H_{19}, characteristic of 19-epiajmalicine, is less evident but plausible if one considers the biomimetic scheme named "La Ronde" established by Lounasmaa and Hanhinen (1998). This scheme shows interconversions existing between the four $\Delta^{20(21)}$-didehydroheteroyohimbines (cathenamines), which, when combined with reduction steps, allow access to the eight basic heteroyohimbines. The option of H-19 α or β configuration takes place during the *Z–E* epimerisation of the ethylidene side chain (Lounasmaa et al., 1992; Uskoković et al., 1979). Closing of *E* ring is then achieved by a Michael addition of the enolate stereochemically exclusively possible on the β-face on the ethylidene chain (Brown, 1980). This ethylidene chain is moreover directly connected to H-20 (3.15 ppm), itself coupling with H-21 appearing in the form of a deshielded doublet at 4.45 ppm ($J_{20–21}$ = 7.5 Hz), compatible with the presence of an hydroxyl function on C-21 and the presence of an adjacent quaternary nitrogen. The coupling constant $J_{20–21}$ suggested the antiperiplanar position of H-20 and H-21, and thus the α position of H-21. H-20 is also correlated to H-15 at 2.85 ppm. The proton chemical shift of the *N*-methyl group is in accord with a C/D *cis* ring junction. Indeed, this stereochemistry is supported by the relatively low field position (^{1}H: 3.27; ^{13}C: 47.0 ppm) of the quaternary N_b-methyl, suggesting a *cis*-relationship between the N_b-methyl and the H-3 (Arata et al., 1975; Sugiura et al., 1977). The resonances of H-14a, H-14b and H-3 appear respectively at 2.45, 1.90 and 5.0 ppm. This latter deshielded value is likewise consistent with the presence of the adjacent quaternary nitrogen. All aromatic protons, including H-17 at 7.49 ppm, are detected. Carbons chemical shifts were determined on the base of HMQC spectra.

The second substrate, palicoside (**2**), was incubated with SMGD for 72 h. Its unfinished conversion gave rise to two main products. The first one, **5**, was apparently less polar than palicoside on TLC, in contrast to the second one, **6**, more polar. After a rapid chloroform extraction of **5** from the incubation mixture, its UV and MS spectra were measured. The UV spectrum exhibited maxima of an indole chromophore. The mass spectrum showed a molecular peak at m/z 325, corresponding to the molecular formula $C_{20}H_{24}N_2O_2$. We confronted this product **5** with available reference substances of identical molecular mass, and in particular to akagerine. They showed to possess the same behaviour when compared by HPLC and TLC in different systems. Moreover, the revelation of TLC plates by iodoplatinate reagent (Svendsen and Verpoorte, 1983) produced in each case a pink colour turning into red after a few minutes. We completed this identification by comparison of their 1D ^{1}H NMR spectra. The recorded resonances were identical, which confirmed that akagerine was the non-polar conversion product of palicoside (**2**). Akagerine (**5**) is a perhydroazepine alkaloid that accumulates in numerous species of *Strychnos* as *Strychnos usambarensis* (Angenot et al., 1975). It has showed convulsivant (Rolfsen et al., 1980) and antiprotozoal (Wright et al., 1991) properties on mice. Its enantioselective synthesis was proposed by Danieli et al. (1995). We completed the spectral data of this reference alkaloid by further ^{1}H and ^{13}C NMR contribution. The polar conversion product **6** could not be separated in sufficient amount to be identified and is, thus, still under studies.

2.2. Hypothetical models for the conversion reactions

For both conversions, we present hypothetical models of reactions occurring after enzymatic hydrolysis and removal of the glucose moiety. It should be noted that none of the intermediates depicted in Schemes 1 and 2 has ever been isolated as a product from any incubation mixture, or has ever been demonstrated in any other direct way. Their occurrence is described by mere theoretical organic chemistry. It has been reported that the deglucosylation of strictosidine leads also to reactive

and unstable intermediates, which may readily and quickly undergo different intra-molecular rearrangements (Hemscheidt and Zenk, 1980; Stöckigt, 1980; Stevens, 1994). The same situation is observed in our hands using systems with dolichantoside or palicoside as analogous substrates.

Reactions leading from dolichantoside (**1**) to N_b-methyl-21-β-hydroxy-mayumbine (**4**) are similar to those proposed in the conversion model of strictosidine (Stevens, 1994). They can be schematised as follows (scheme 1): removal of the glucose moiety of dolichantoside leads to an unstable hemiacetal (**1a**), which is rapidly converted into a high reactive aldehyde by opening of E ring. This aldehyde (**1b**) is in equilibrium with its enol tautomer (**1c**). This intermediate is then stabilised by a nucleophilic attack of the nitrogen N_b on C-21 to close D ring, with concomitant transformation of the vinyl chain into a *Z*-ethylidene chain (**1d**). Protonation of C-18 is ensured by the C-17 hydroxyl function, acting as proton donor. Closing of *E* ring is then achieved by a Michael addition of the enolate on the β face of the ethylidene side chain to form the quaternary alkaloid N_b-methyl-21-β-hydroxy-mayumbine (**4**).

Besides the cleavage of the glucose moiety, palicoside (**2**), during its conversion, further loses a group of 44 mass units equivalent to the carbonic gas CO_2. The conversion is thought to start by the two first steps occurring with dolichantoside (scheme 2). The loss of CO_2, happening in totally soft conditions (30°C, neutral pH), can take place at the stage of the tautomeric equilibrium between aldehyde and enol functions. This step is just characterised by the presence of a carboxylic function in β position from an aldehydic function where the start of CO_2 is favoured by a cyclic elimination process at six centres, identical to what occurs in the decarboxylation of malonic acid or β-cetonic acids (Carey and Sundberg, 1997). The double bond shift and the appearance of an ethylidene chain take place at the same time. Closing of perhydroazepine ring is then realised by the nucleophilic attack of the indole nitrogen N_a on C-17, to form a carbinolamine, akagerine (**5**). The loss of CO_2 would not be allowed in the case of dolichantoside, because of the presence of the methyl group on the carboxylic function, which prevents the six centres elimination process to take place.

2.3. Antimycotic activity of the substrates in presence of specific glucosidase

The antimycotic activity of dolichantoside (**1**) and palicoside (**2**), as well as of the crude ethanol extract of *Strychnos mellodora* stem bark (EtOH extract), was tested before and after enzymatic hydrolysis by SMGD against three standard strains of human pathogens, the yeasts *Candida albicans*, *Candida glabrata* and a filamentous fungus, *Aspergillus niger*. The substrates applied alone showed no activity at the higher tested concentrations (1.9 mg/ml of **1**; 1.8 mg/ml of **2**; 3.8 mg/ml of EtOH extract). This is in contrast with the significant antimycotic activity found against those same three pathogens when the substrates were tested in the presence of SMGD. The minimum inhibitory concentration (MIC) measured for each substrate in presence of SMGD against each strain is presented in Table 2. These products are, of course, far from competing with other antifungal agents such as miconazole that inhibits the growth of yeast strains *C. albicans* (1.6 μg/l), *C. glabrata* (0.2 μg/l) and *Aspergillus niger* (0.8 μg/l) at much lower concentrations in the same conditions (Piel et al., 1999).

Table 2
Minimal inhibitory concentration (MIC) of dolichantoside (**1**), palicoside (**2**) and the crude EtOH extract of *Strychnos mellodora* stem bark in presence of the glucosidase from *Strychnos mellodora* (SMGD) against three ATCC reference strains

	Minimum inhibitory concentration (mg/ml)		
	Candida albicans 10231	*Candida glabrata* 90030	*Aspergillus niger* 16404
Dolichantoside (**1**)/SMGD	0.38	0.76	0.38
Palicoside (**2**)/SMGD	0.14	1.48	0.74
EtOH extract /SMGD	2.28	0.38	0.76

3. Conclusion

The hypothesis formulated by Massiot and Delaude (1988) putting forward that N_b-methylated precursors lead to the formation of akagerine-type bases, monoterpenoid alkaloids with N_a–C_{17} bond, has been verified by the isolation and identification of a stable alkaloid, akagerine (**5**), after the conversion of palicoside (**2**). We have shown, moreover, that even in the presence of a methyl group, addition on N_b is possible and produces polar alkaloid, as in the case of the conversion of dolichantoside (**1**) into a new quaternary alkaloid, N_b-methyl-21-β-hydroxy-mayumbine (**4**).

We detected no presence of those conversion products in *Strychnos mellodora* organs, which may indicate that at the plant level substrates and glucosidase are contained in different cell compartments. Although the results of antimycotic activity do not concern vegetal pathogens, they may nevertheless suggest a constitutive "trigger mechanism" in the plant, in which an infection, by damage of the plant cell, results in substrate deglucosidation, thus allowing the active aglycone(s) to act against the intruder.

4. Experimental

4.1. Materials and methods

Dolichantoside (**1**) and palicoside (**2**) were isolated from *Strychnos mellodora* S. Moore stem bark according to Tits et al. (1996). Strictosidine β-glucosidase (SGD) was obtained by purification from suspension cultured cells of *Catharanthus roseus* L. G. Don according to Geerlings (1999). Strictosidine β-glucosidase from *Strychnos mellodora* (SMGD) was obtained by purification from dry leaves of *Strychnos mellodora* (Brandt et al., 2000). The β-glucosidase from sweet almonds was purchased from Merck (Germany). The reference akagerine has been isolated from *Strychnos usambarensis* and is kept in our laboratory.

The comparison of conversion products pattern was based on a HPLC method described by Pennings et al. (1989), but with a 4 × 250 mm Lichrospher 60 RP-Select B column (particle size 5 μm, cat. No. 00961; Merck). With this system the retention time of the substrates and conversion products were: **1** (18.5 min), **2** (5.4 min), **4** (24.2 min), **5** (4.3 min).

Protein concentrations were determined using the method described by Bradford (1976). UV spectra were recorded on a spectrophotometer Kontron Uvikon 922 with Hellma type 100-QS 10.00 mm thickness precision cuvettes.

^{1}H NMR and ^{13}C NMR 1D and 2D spectra of **4** were determined at 400 and 100 MHz respectively on a Bruker 400 MHz spectrometer. ^{1}H NMR and ^{1}H–^{1}H autocorrelation spectra of **5** and reference akagerine were determined at 600 MHz; ^{13}C NMR and HMQC spectra of reference akagerine were recorded at 150 MHz on a Bruker DMX 600 MHz spectrometer. Samples were run in deuterated solvents with TMS as internal standard.

HRMS was performed on a Micromass Ultima spectrometer (5.0 mDa resolution) in electrospray (MS–MS), positive ion; ES–MS–MS spectra was taken on a Micromass VG-Quattro II in electrospray, positive ion, ionisation energy 20 eV.

4.2. Conversion of dolichantoside (*1*) into N_b-methyl-21-β-hydroxy-mayumbine (*4*)

Half a milliliter of Na-Pi buffer pH 6.3 containing 50 mg dolichantoside (**1**) and 1 ml of enzymatic preparation (36.2 μg protein ml^{-1}) obtained from the leaves of *Strychnos mellodora* were mixed, homogenised and incubated in a bain-marie at 30°C until complete conversion of dolichantoside, after 72 h. The conversion was monitored by TLC analysis on silica gel with the mobile phase EtOAc–*iso*–prOH–NH_4OH 4.25% (60:25:15). In this system, dolichantoside (**1**) appears at R_f 0.43 and N_b-methyl-21-β-hydroxy-mayumbine (**4**) at R_f 0.13.

The dolichantoside (**1**) incubation mixture was then frozen and lyophilised. The dry residue was suspended in 2 ml MeOH, stirred and centrifuged 10 min at 3500 *g*. The supernatant was separated and evaporated to give a residue which was taken in 2 ml H_2O. This aq. soln was then extracted twice by *n*-BuOH and evaporated under reduced pressure. The residue dissolved in a few drops of MeOH gave by addition of Et_2O a voluminous white ppt. This latter was separated by centrifugation 10 min at 2500 *g*, dried and washed with Et_2O to obtain N_b-methyl-21-β-hydroxy-mayumbine (**4**) (27 mg) as an amorphous white powder; UV (MeOH) λ_{max} nm (log ε): 222 (4.19), 267 (3.54), 278 (3.55), 287 (3.43); ^{1}H NMR spectral data (400 MHz, CD_3OD): δ 1.55 (3H, *d*, $J=6.7$ Hz, H-18), δ 1.90 (1H, *m*, H-14b), δ 2.45 (1H, *m*, H-14a), δ 2.85 (1H, *m*, H-15), δ 3.15 (1H, *m*, $J=8.6$, 7.5 Hz, H-20), δ 3.20 (1H, H-6b), δ 3.27 (3H, *s*, N^+CH_3), δ 3.50 (1H, *d*, H-5a), δ 3.71 (3H, *s*, OCH_3), δ 3.75 (1H, *q*, $J=6.7$, 8.6 Hz, H-19), δ 4.30 (1H, H-5b), δ 4.45 (1H, *d*, $J=7.5$ Hz, H-21), δ 5.00 (1H, *d*, H-3), δ 7.07 (1H, *t*, $J=7.8$ Hz, H-0), δ 7.17 (1H, *t*, $J=8.2$ Hz, H-11), δ 7.37 (1H, *d*, $J=8.2$ Hz, H-12), δ 7.49 (1H, *s*, H-17), δ 7.50 (1H, *d*, $J=7.8$ Hz, H-9); ^{13}C NMR spectral data (100 MHz, CD_3OD): δ 10.8 (C-18), δ 17.5 (C-6), δ 25.6 (C-14), δ 32.7 (C-15), δ 47.0 (N^+CH_3), δ 51.3 (OCH_3), δ 59.5 (C-5), δ 61.7 (C-19), δ 69.0 (C-3), δ 75.0 (C-20), δ 97.0 (C-21), δ 114.4 (C-12), δ 118.2 (C-9), δ 119.6 (C-10), δ 122.4 (C-11), δ 144.0 (C-17); HRMS-MS–(EI) *m*/*z* (rel. int.): 383.1978 $[C_{22}H_{27}N_2O_4]^+$ (100), 365.2310 $[M-H_2O]^+$ (16), 352.2046 (20), 340.1962 (69), 322.1725 (41), 308.1646 (27), 144.0979 (53); Positive ES-MS-MS *m*/*z* (rel. int.): 383 $[M]^+$ (100), 365 $[M–H_2O]^+$ (13), 340 (28), 222 (30), 194 (64), 170 (50), 144 (97), 130 (42);

4.3. Conversion of palicoside (*2*) into akagerine (*5*)

Twenty milligrams of palicoside (**2**) dissolved in 200 μl of Na–Pi buffer pH 6.3 and 0.5 ml of enzymatic preparation (36.2 μg proteinml^{-1}) obtained from the leaves of *Strychnos mellodora* were mixed, homogenised and incubated in a bain-marie at 30°C. Lower specificity of the glucosidase in the presence of palicoside prevented to obtain a complete conversion of this substrate. Incubation was stopped after 72 h. In the TLC monitoring system described above palicoside (**2**) reaches a R_f of 0.09. Its conversion products, **5** and **6**, are characterised by R_f of 0.05 and 0.78 respectively. The palicoside (**2**) incubation mixture was then frozen and lyophilised. The residue was taken in 2 ml H_2O and then extracted by 2 ml CH_2Cl_2 until complete disappearance of **5** from the aq. layer. Each organic layer was separated by centrifugation 10 min at 2500 *g*. The joined organic layers were then conc. under reduced pressure and submitted to a prep. TLC in the system composed of silica gel and the mobile phase EtOAc–*iso*–prop-NH_4OH 4.25% (60:25:15). The elution was performed by CH_2Cl_2 and allowed

to obtain 7.38 mg of **5** as an amorphous white powder. UV (MeCN) λ_{max} nm (log ε): 229 (4.51), 276 (3.78), 283 (3.80), 293 (3.68); ^{1}H NMR spectral data (600 MHz, $CDCl_3$): δ 1.99 (1H, *d*, $J=12.8$ Hz, H-14b), δ 2.07 (3H, *d*, $J=7.2$ Hz, H-18), δ 2.09 (1H, *m*, H-16b), δ 2.19 (1H, *q*, $J=10.9$, 12.8 Hz, H-14a), δ 2.33 (1H, *t*, H-16a), δ 2.53 (3H, *s*, NCH_3), δ 2.72–2.78 (3H, *m*, H-5b, H-6a, H-6b), δ 3.07 (1H, *m*, H-5a), δ 3.66 (1H, *t*, $J=11.7$, 1.4 Hz, H-15), δ 3.82 (1H, *d*, $J=10.9$ Hz, H-3), δ6.24 (1H, *d*, $J=3.7$ Hz, H-17), δ 6.55 (1H, *q*, $J=7.2$ Hz, H-19), δ 7.11 (1H, *t*, $J=7.7$ Hz, H-10), δ7.18 (1H, *t*, $J=8.2$ Hz, H-11), δ 7.29 (1H, *d*, $J=8.2$ Hz, H-12), δ 7.48 (1H, *d*, $J=7.7$ Hz, H-9), δ 9.31 (1H, *d*, $J=1.4$ Hz, H-21); Positive ES–MS–MS *m*/*z* (rel. int.): 325 $[M+H]^+$ (93), 307 $[M+H\text{-}H_2O]^+$ (5), 282 (100), 264 (73), 144 (5), 130 (3); **5** has the same behaviour as reference akagerine in the TLC system described above ($R_f=0.78$), and with the mobile phases $CHCl_3$–CH_3OH (80:20) ($R_f=0.5$) and EtOAc–*iso*–prOH–NH_4OH 4.25% (45:35:5) ($R_f=0.73$); iodoplatinate reagent produces a pink color turning into red in a few minutes.

4.4. Reference akagerine

^{1}H NMR spectral data (600 MHz, $CDCl_3$) exactly match with **5** ones; ^{13}C NMR spectral data (150 MHz, $CDCl_3$): δ 15.2 (C-8), δ 19.8 (C-6), δ 29.1 (C-15), δ 36.3 (C-14), δ 37.4 (C-16), δ 42.5 (NCH_3), δ 50.4 (C-5), δ 60.8 (C-3), δ 75.7 (C-17), δ 108.3 (C-12), δ 108.8 (C-7), δ 118.3 (C-9), δ 119.4 (C-10), δ 121.3 (C-11), δ 126.7 (C-8), δ 136.0 (C-13), δ 137.0 (C-2), δ 147.9 (C-20), δ 150.5 (C-19), δ 194.9 (C-21).

4.5. Measure of antimycotic activity

The minimal inhibitory concentration (MIC) of **1**, **2** and the crude *Strychnos mellodora* EtOH extract against three ATCC® (American Type Culture Collection) reference strains were determined by using a broth microdilution method, based upon the National Committee for Clinical Laboratory Standards (NCCLS-USA) guidelines for broth microdilution technique (M-27A and M-38P) (NCCLS, 1997 and 1998). The three references strains, *Candida albicans* (ATCC 10231), *Candida glabrata* (ATCC 90030) and *Aspergillus niger* (ATCC 16404), were tested in duplicate and in parallel with the substrates alone and in presence of SMGD. Preparation of tested antifungal stock solns was not possible because of the low availability of the substrates. **1**, **2** and EtOH extract were dissolved in H_2O as acetates (by addition of the HOAc molar equivalent), filtered, frozen and then lyophilised. The residues were then weighed and dissolved in RPMI-1640 standard medium to give 7.6 mg/ml EtOH extract, 3.8 mg/ml **1** and 3.6 mg/ml **2**. These solns were incubated for 24 h in the presence of SMGD, then filtered to give solns of 6.08 mg/ml hydrolysed EtOH extract, 3.04 mg/ml hydrolysed **1** and 2.88 mg/ml hydrolysed **2**. Strains were pre-cultivated following the NCCLS guidelines. Cultures were realised in 96 wells microplates with lid. Wells 2–11 contained twofold decreasing dilutions of the different substrates. Well 1 served as sterility control with 0.1 ml RPMI 1640 medium and 0.1 ml sterile physiologic liquid while well 12 served as growing control with 0.1 ml strain suspension and 0.1 ml sterile physiologic liquid. Each well was inoculated with 0.1 ml of one of the three inoculum suspensions. The plates were then incubated at 35°C and examined on a spectrophotometer at 625 nm every 24 h until positive control reaches a optical density of 0.2. CMI is determined as the substrate concentration that allows a reduction of the strain growth to 20% of the positive control.

Acknowledgements

This research was supported by the "Fondation Léon Fredericq". We wish to thank the NMR laboratory of the Gorleaus Laboratories (University of Leiden-Netherlands) where the spectra of akagerine were measured; Mrs C. Prosperi (Physical Institute, University of Liège) for measuring the spectra of N_b-methyl-21-β-hydroxy-mayumbine; Dr. M.-P. Hayette (Department of Medical Microbiology, University of Liège) and Dr. G. Piel (Department of Pharmaceutical Technology, Institute of Pharmacy, University of Liège) who realised the antimycotic tests. The manuscript has benefited from the competence of Dr. P. DeTullio (Department of Pharmaceutical Organic Chemistry, Institute of Pharmacy, University of Liege).

Received 28 September 2000; received in revised form 13 February 2001

Abstract

The accumulation of total water-soluble carbohydrate, and specifically sucrose and fructan, by excised leaves of *Phormium tenax* and *P. cookianum* (family Phormiaceae J. G. Agardh, order Asparagales) was investigated. Total water-soluble carbohydrate content of excised leaves of *P. tenax* and *P. cookianum* increased during 48 h of continuous illumination at an average rate of 1.3 and 0.9 mg g^{-1} fresh weight leaf per hour, respectively. The sucrose content of excised leaves increased throughout the experimental period. The fructan content of excised leaves of *P. tenax* increased slightly throughout the experimental period, whilst that of *P. cookianum* was variable and showed no overall change. Chemical and spectroscopic analysis of the fructans obtained from the two *Phormium* species showed that they were similar to each other and contained mostly 1-linked and terminal fructofuranosyl (Fru*f*) residues, together with smaller amounts of 6-linked Fru*f*, 1,6-branched Fru*f*, terminal and 6-linked glucopyranosyl residues. Separation of the fructans by thin-layer and high-performance anion-exchange chromatography revealed the presence of a complex mixture of fructo-oligosaccharides and higher molecular weight fructan. The branched structure of the fructans isolated from excised leaves of *Phormium* resembles that of fructans and fructo-oligosaccharides isolated from some related species within the order Asparagales (*Agave vera cruz*, *Cordyline australis* and *Urginea maritima*), but is distinct from the linear structure of fructans from others (*Allium cepa* and *Asparagus officinalis*). The structural heterogeniety of fructans within both the order Asparagales and superorder Liliiflorae may be a useful chemotaxonomic aid. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Phormium tenax*; *Phormium cookianum*; Phormiaceae; New Zealand flax; Water-soluble carbohydrate; Fructan; Accumulation; Structure

1. Introduction

Phormium is a genus of medium to tall monocotyledonous herbs within the family Phormiaceae J. G. Agardh, order Asparagales, superorder Liliiflorae (Watson and Dallwitz, 1992 onwards). In New Zealand there are two species, *Phormium tenax* (New Zealand flax), that was once extensively cultivated for its fibre, and *Phormium cookianum* (mountain flax). The presence of fructans (polyfructosylated sucrose) in other species within the order Asparagales, such as *Agave vera cruz* (Dorland et al., 1977), *Allium cepa* (onion; Henry and Darbyshire, 1980), *Asparagus officinalis* (asparagus; Shiomi, 1993), *Cordyline australis* (New Zealand cabbage tree; Brasch et al., 1988) and *Urginea maritima* (red squill; Spies et al., 1992), suggested that *Phormium* spp. may also contain fructans.

Preliminary experiments showed that fructans were present in leaves of *P. tenax* on one occasion, but was almost absent on another occasion. To enable the potential for fructan accumulation in *Phormium* species to be evaluated, an investigation was initiated to study the accumulation of water-soluble carbohydrate (WSC) in excised leaves of both *P. tenax* and *P. cookianum*. The excised leaf has been shown to be a convenient experimental system for inducing the accumulation of WSC in temperate grasses under controlled conditions. Continuous illumination of excised leaves of *Lolium temulentum* resulted in an initial accumulation of sucrose, followed by the onset of fructan biosynthesis and stabilisation of sucrose concentration (Cairns and Pollock, 1988).

Structural variation of fructans from species within the order Poales has been used to distinguish members of the supertribes Triticodae and Poodae. Branched fructans appear to be characteristic of the Triticodae, but are absent or present in only low proportions in the Poodae (Bonnett et al., 1997). The fructans from *C. australis* (Brasch et al., 1988) and *U. maritima* (Spies et

PII: S0031-9422(01)00089-9

al., 1992), and the fructo-oligosaccharides from *A. vera cruz* (Dorland et al., 1977) are all branched to varying degrees, whereas those from *A. cepa* (Henry and Darbyshire, 1980) and *A. officinalis* (Shiomi, 1993) are linear. Thus, the structure of the fructans from members of the Asparagales may be a useful taxonomic aid.

We have now studied the accumulation of WSC in excised leaves of *P. tenax* and *P. cookianum* and in this publication we report on the characterisation of the accumulated fructan by glycosyl linkage analysis, nuclear magnetic resonance (NMR) spectroscopy, thin-layer chromatography (TLC) and high-performance anion-exchange chromatography (HPAEC). The structures of these *Phormium* fructans are compared to those from other species in the order Asparagales.

2. Results and discussion

2.1. Accumulation of water-soluble carbohydrate

Individual excised leaves of *P. tenax* and *P. cookianum* were harvested at various times during a 48 h period of continuous illumination, weighed and sequentially extracted with boiling aqueous ethanol and hot water. Total WSC and free reducing sugar contents of the extracts were estimated colorimetrically, and sucrose and fructan were determined using modifications of the Megazyme fructan assay procedure. The enzyme mixture used for the sucrose assay contained both sucrose and starch-degrading enzymes. However, starch, determined using the Megazyme total starch assay procedure, represented only 1–2% of the total WSC of the extracts at all harvest times and so was not considered separately in the determinations of sucrose content (see Experimental). The initial total WSC concentrations in leaves of *P. tenax* and *P. cookianum* were 26.1 and 32.7 mg g^{-1} fresh weight (FW) of leaf, respectively. Fig. 1 shows the changes in total WSC, sucrose and fructan extracted from excised leaves of *P. tenax* and *P. cookianum* over the 48 h illumination period.

The total WSC content of excised leaves of *P. tenax* and *P. cookianum* increased erratically. The total WSC content of leaves of *P. tenax* and *P. cookianum* generally increased throughout the 48 h experimental period at an average rate of 1.3 and 0.9 mg g^{-1} FW leaf per hour, respectively.

The initial concentrations of free reducing sugar, sucrose and fructan in excised leaves of *P. tenax* were 9.8, 7.0 and 4.6 mg g^{-1} FW leaf, respectively, and those in excised leaves of *P. cookianum* 7.1, 6.6 and 15.4 mg g^{-1} FW leaf, respectively. As the total WSC concentration in the excised and illuminated leaves increased the free reducing sugar concentrations remained almost constant. For clarity, these data are omitted from Fig. 1. The sucrose concentrations in excised leaves of *P. tenax* and *P. cookianum* increased at an overall rate of 0.7 and 0.8 mg g^{-1} FW leaf per hour, respectively. The fructan concentration of excised leaves of *P. tenax* increased at an overall rate of 0.3 mg g^{-1} FW leaf per hour. The fructan content of excised leaves of *P. cookianum* was variable and showed no overall change.

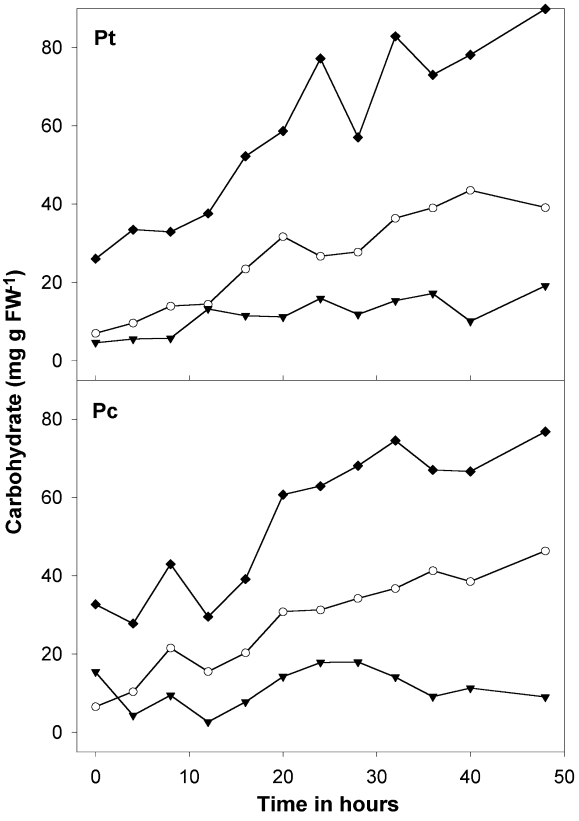

Fig. 1. Quantitative analysis of various water-soluble carbohydrate fractions from excised leaves of *Phormium tenax* (Pt) and *Phormium cookianum* (Pc) after various times of continuous illumination. Samples were assayed for total WSC (◆), sucrose (○) and fructan (▼).

2.2. Linkage composition of fructans

Fructans are a family of oligo- and polysaccharides in which one or more fructosyl-fructose linkages are present. All of the known fructans are based on three isomeric trisaccharides, 1-kestotriose (*O*-β-D-fructofuranosyl-(2 → 1)-β-D-fructofuranosyl-(2 → 1)-α-D-glucopyranoside), 6-kestotriose (*O*-β-D-fructo-furanosyl-(2→6)-β-D-fructofuranosyl-(2 → 1)-α-D-glucopyranoside) and 6_G-kestotriose (*O*-β-D-fructofuranosyl-(2 → 6)-α-D-glucopyranosyl-(1↔2)-*β*-D-fructofuranoside) (Waterhouse and Chatterton, 1993).

The linkage structures of the fructans from *Phormium* species were determined by GC–MS of partially methylated alditol acetates. Prior to derivatisation of total WSC extracts, sucrose was hydrolysed to fructose and glucose with a specific sucrase, and all monosaccharides

reduced with $NaBH_4$. Upon methylation, the resulting alditols gave highly volatile hexa-*O*-methyl derivatives which eluted much earlier than the partially methylated alditol acetate derivatives obtained from the fructans.

The linkage compositions of fructans from excised leaves of *P. tenax* and *P. cookianum* at various times after excision did not vary greatly. Table 1 shows the linkage compositions of the fructan from these two species immediately after excision and after 24 h of continuous illumination. Immediately after excision, fructan from *P. tenax* contained more terminal Fru*f* and less 1-linked Fru*f* than that from *P. cookianum*, but contained similar proportions of 6-linked Fru*f* and 1,6-branched Fru*f*. After 24 h continuous illumination the fructans from both *P. tenax* and *P. cookianum* contained similar proportions of the different fructofuranosyl linkages. Immediately after excision, the glucose residues of the fructan from leaves of *P. tenax* contained mostly terminal Glc*p* with only a small amount of 6-linked Glc*p*, while those from leaves of *P. cookianum* were mostly 6-linked Glc*p* with only a small amount of terminal Glc*p*. After 24 h continuous illumination both species contained similar amounts of both terminal and 6-linked Glc*p*.

Table 2 compares the average linkage composition of fructans extracted from excised leaves of *P. tenax* and *P. cookianum* after $t=0$, 8, 16 and 24 h of continuous illumination, with data reported for branched fructans from *C. australis* (Brasch et al., 1988), *U. maritima* (red squill; Spies et al., 1992) and the pentasaccharide fraction from *A. vera cruz* (Dorland et al., 1977). The linkage compositions of fructans from the two *Phormium* species were similar to that of fructan from the roots and stems of *C. australis* (Brasch et al., 1988), although the *Phormium* fructans contained more 6-linked Fru*f* and less 1,6-branched Fru*f*. Fructans from *Phormium* species also contained 6-linked Glc*p*, which was almost absent from *C. australis*. The fructan from *U. maritima* contained less terminal and 1-linked Fru*f*, and terminal Glc*p* than fructans from the *Phormium* species, but considerably more 6-linked and 1,6-branched Fru*f* (Spies et al., 1992). Oligosaccharide fractions from extracts of the stems of *A. vera cruz* also had similar linkage compostions to those of fructans from *Phormium* species (Dorland et al., 1977). The DP 5 oligosaccharide, for example, contained similar amounts of terminal, 1-linked and 1,6-branched Fru*f* to the *Phormium* fructans, although 6-linked Fru*f* was not present and the proportion of 6-linked Glc*p* was higher than that of fructans from *Phormium* species. *Phormium*, *Cordyline* and *Agave* have previously all been placed in the family Agavaceae (Pollard, 1978) and all contain varying proportions of different fructofuranosyl and glucopyranosyl linkages. *U. maritima* is a member of the family Hyacinthaceae and related species (e.g. *Scilla violacea*) were placed by Pollard (1978) in the Liliaceae. Therefore this species, containing branched fructans, is more closely related to *Allium* and *Asparagus* that contain linear fructans.

Table 1
Glycosyl linkage composition (mol%) of fructan in excised leaves of *Phormium tenax* and *Phormium cookianum* harvested immediately after excision and after 24 h continuous illumination

Species	Deduced glycosyl linkage	Time after excision (h)	
		0	24
P. tenax	Terminal Fru*f*	33	31
	1-Linked Fru*f*	39	46
	6-Linked Fru*f*	7	8
	1,6-Branched Fru*f*	8	5
	Terminal Glc*p*	11	6
	6-Linked Glc*p*	2	5
P. cookianum	Terminal Fru*f*	26	31
	1-Linked Fru*f*	48	44
	6-Linked Fru*f*	8	8
	1,6-Branched Fru*f*	8	7
	Terminal Glc*p*	3	6
	6-Linked Glc*p*	8	4

The detection in fructans extracted from excised leaves of *Phormium* species of both terminal and 6-linked Glc*p* suggested that oligosaccharides based on the trisaccharides 1-kestotriose and 6_G-kestotriose were present. The detection of 1-linked and 6-linked Fru*f* indicated that fructans were either a mixture of inulin (β-2,1-linked) and levan (β-2,6-linked) type fructan molecules, or mixed-linkage fructans such as those identified in the grass, *L. temulentum* (Sims et al., 1992). The existence of 1,6-branched Fru*f* indicated the presence of branched oligosaccharides such as those based on the tetrasaccharide (1 and 6)-kestotetraose (*O*-β-D-fructofuranosyl-(2 → 1)-*O*-[β-D-fructofuranosyl-(2 → 6)]-β-D-fructofuranosyl-(2 → 1)-α-D-glucopyranoside; Waterhouse and Chatterton, 1993).

2.3. ^{13}C NMR spectroscopy of fructans

Fructans from *Phormium* species, obtained after gel-permeation chromatographic fractionation of crude extracts to remove monosaccharides and sucrose, were analysed by ^{13}C NMR spectroscopy. The fructans in extracts from excised leaves of *P. tenax* and *P. cookianum* after 24 h of continuous illumination gave ^{13}C NMR spectra that were essentially the same (Fig. 2), and showed similarities to the spectra reported for fructans from *C. australis* (Brasch et al., 1988) and *U. maritima* (Spies et al., 1992).

The anomeric region contained a set of resonances at 104.7–105.6 ppm which were deduced to correspond to the C-2 of the various β-D-Fru*f* residues and a pair of resonances at 93.6 and 94.1 ppm which were deduced to correspond to the C-1 of the α-D-Glc*p* residues. The assignment of these anomeric chemical shifts shown in

Table 2
Average linkage composition (mol%) of fructans extracted from excised leaves of *Phormium tenax* and *Phormium cookianum* after $t = 0$, 8, 16 and 24 h of continuous illumination, and of fructans from *Cordyline australis* (Brasch et al., 1988), *Urginea maritima* (Spies et al., 1992) and the fructan pentasaccharide fraction from *Agave vera cruz* (Dorland et al., 1977)

Deduced	Species

Terminal Fru*f*	34	31	29	25	29
1-Linked Fru*f*	40	43	47	33	39
6-Linked Fru*f*	9	9	4	19	–
1,6-Branched Fru*f*	6	6	14	19	7
Terminal Glc*p*	8	5	5	1	5
6-Linked Glc*p*	3	6	tr	3	19

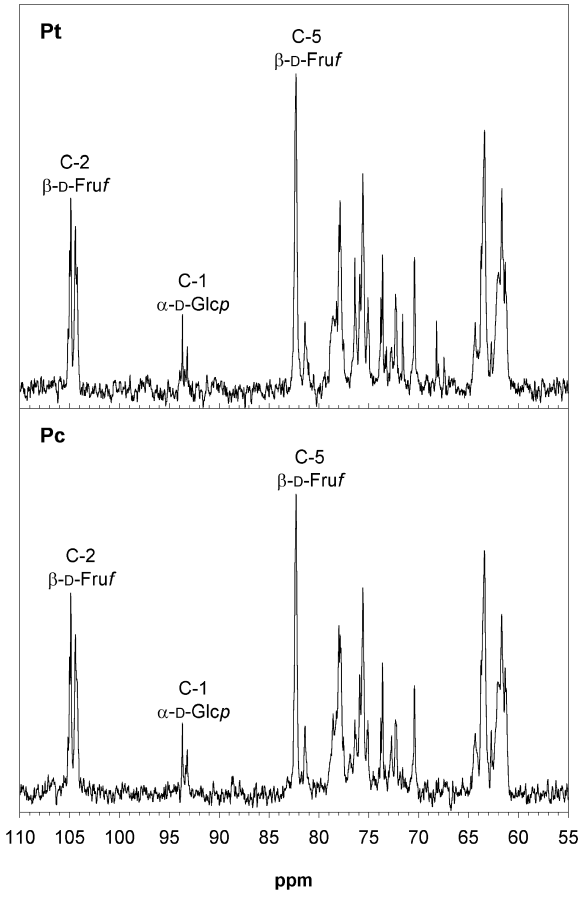

Fig. 2. ^{13}C NMR spectra of fructans from excised leaves of *Phormium tenax* (Pt) and *Phormium cookianum* (Pc), obtained after gel-permeation chromatography to remove monosaccharides and sucrose.

Table 3 was made by comparison with assignments made for the spectra for fructans from *Cichorium intybus* (chicory) and *Phleum pratense* (timothy grass), oligosaccharides from *Helianthus tuberosus* (Jerusalem artichoke) and *A. cepa* (onion), and sucrose, and by reference to published spectral data for fructans and fructo-oligosaccharides from various sources (Brasch et al., 1988; Carpita et al., 1991; Spies et al., 1992; Liu et al., 1993; Shiomi, 1993). Resonances at 104.7 and 104.9 ppm were assigned to → 1)-D-Fru*f*-β-(2→ residues and that at 105.3 ppm to D-Fru*f*-β-(2→ (Table 3). Based on the assignments of Liu et al. (1993) for chemical shifts for 1,1-kestotetraose and 1,1,1-kestopentaose, the chemical shift for →1)-D-Fru*f*-β-(2→ attached to a α-D-Glc*p* residue at O-1 was assigned at 104.9 ppm, 0.2 ppm downfield of that for →1)-D-Fru*f*-β-(2→ attached to a β-D-Fru*f* residue at O-1 (104.7 ppm).

Two resonances at 105.4 and 105.6 ppm in the spectra of fructans from *Phormium* species, downfield of that assigned to D-Fru*f*-β-(2→, did not correspond to any signals present in the spectra for fructans from *C. intybus*, *H. tuberosus* and *A. cepa*, but an intense resonance at 105.6 ppm was present in *P. pratense* fructan, which has a structure containing solely 6-linked Fru*f* with terminal Glc*p* (Cairns et al., 1999). Thus, the resonance at 105.6 ppm in spectra of fructans from *Phormium* species was assigned to →6)-D-Fru*f*-β-(2→ (Table 3). This assignment was supported by similar assignments for this residue in fructans from *C. australis* (Brasch et al., 1988), *F. arundinaceae* and *T. aestivum* (Carptia et al., 1991), and *Agropyron repens*, *Pucinella peisonis* and *U. maritima* (Spies et al., 1992) as being 0.4 ppm downfield of that for terminal β-D-Fru*f*. A resonance 0.1 ppm downfield of that for terminal β-D-Fru*f* has been assigned to the branched → 1,6)-D-Fru*f*-β-(2→ residue in fructans from *C. australis* (Brasch et al., 1988) and *U. maritima* (Spies et al., 1992), and thus, the chemical shift at 105.4 ppm in spectra of fructans from *Phormium* species was assigned to this residue. Interestingly, the chemical shift of →1,6)-D-Fru*f*-β-(2 → in fructans from *T. aestivum* (Carpita et al., 1991) and *A. repens* (Spies et al., 1992) has been assigned at 0.2 ppm upfield of that for D-Fru*f*-β-(2→, although no similar chemical shift could be detected in spectra of fructans from *Phormium* species.

The ^{13}C NMR spectra of fructans from *Phormium* species showed chemical shifts at 81.8 and 82.7 ppm which were deduced to be due to C-5 of β-D-Fru*f* residues carrying a substituent at O-6 or lacking a substituent at O-6, respectively, based on spectra for the predominantly 2,6-linked fructan from *P. pratense* and the predominantly 2,1-linked fructan from *C. intybus*. An

Table 3
Anomeric ^{13}C NMR chemical shifts (δ, ppm) of fructans extracted from excised leaves of *Phormium tenax* and *Phormium cookianum* after 24 h of continuous illumination, and of fructans from *Cichorium intybus, Phleum pratense* and *Allium cepa*, fructo-oligosaccharides from *Helianthus tuberosus* and sucrose

Residue	Chemical shifts (ppm)						
	P. tenax	*P. cookianum*	*C. intybus*	*Phleum pratense*	*A. cepa*	*H. tuberosus*	Sucrose
C-2							
D-Fru*f*-β-(2→	105.3	105.3	105.3	105.3	105.3	105.3	105.3
→1)-D-Fru*f*-β-(2→	104.7–104.9	104.6–104.8	104.9	–	104.7–104.9	104.7–104.9	–
→6)-D-Fru*f*-β-(2→	105.6	105.6	–	105.6		–	–
→1,6)-D-Fru*f*-β-(2→	105.4	105.4	–	–		–	–
C-1							
D-Glc*p*-α-(1→ (sucrose)	–	–	–	–	93.8	93.8	93.8
D-Glc*p*-α-(1→ (fructan)	94.1	94.1	94.1	94.1	94.1	94.1	–
→6)-D-Glc*p*-α-(1→	93.6	93.6	–	–	93.6	–	–

upfield shift of 0.9 ppm for the C-5 resonance of β-D-Fru*f* residues upon substitution at O-6 has been shown for purified 6-kestotriose in comparison to the resonance for C-5 of β-D-Fru*f* residues not substituted at O-6 (Liu et al. 1991). Although ^{13}C NMR spectroscopy is not entirely quantitative, the area ratio of the resonances at 82.7 and 81.8 ppm in spectra of fructans from both *P. tenax* and *P. cookianum* was ~4.5:1, close to the ~6:1 ratio of [terminal + 1-linked Fru*f*] to [6-linked + 1,6-branched Fru*f*] determined by linkage analysis.

The part of the anomeric region of the ^{13}C-NMR spectra of the *Phormium* fructans corresponding to the C-1 of the α-D-Glc*p* residues showed resonances at 93.6 and 94.1 ppm. The D-Glc*p*-α-(1 → residue from sucrose gave a resonance at 93.8 ppm, while a similar residue from *C. intybus* fructan gave a resonance at 94.1 ppm (Table 3). Fructo-oligosaccharides from *H. tuberosus* also contained resonances at both 93.8 and 94.1 ppm that were assigned to D-Glc*p*-α-(1 → from sucrose and fructan, respectively. In addition to these two signals, the spectrum of fructo-oligosaccharides from *A. cepa* gave a third signal at 93.6 ppm which was deduced to correspond to → 6)-D-Glc*p*-α-(1 →, based on the presence of oligosaccharides in the 6_G-kestotriose series in this species (Henry and Darbyshire, 1980). The signals at 93.6 and 94.1 ppm in ^{13}C NMR spectra of fructans from *Phormium* species were thus deduced to correspond to →6)-D-Glc*p*-α-(1 → and D-Glc*p*-α-(1 →, respectively (Table 3).

2.4. TLC and HPAEC of fructans

The linkage compositions and ^{13}C NMR spectra of the fructans extracted from excised leaves of *P. tenax* and *P. cookianum* suggested a complex mixture of isomeric oligosaccharides. To investigate this structural complexity, fructans obtained by gel-permeation chromatography were fractionated further by TLC and HPAEC.

Separation of *Phormium* fructans by TLC on silica gel plates revealed a complex pattern of oligosaccharides up to DP 7 and a smear of unresolved higher oligomers. Fig. 3 compares the oligosaccharides in extracts from excised leaves of *P. tenax* and *P. cookianum* after 24 h of continuous illumination with those from tubers of *H. tuberosus* and bulbs of *A. cepa*. *H. tuberosus* contains a series of linear β-2,1 linked fructo-oligosaccharides with terminal glucose, based on the trisaccharide 1-kestotriose (Bonnett et al., 1997). *A. cepa* accumulates two trisaccharides, 1-kestotriose and 6_G-kestotriose and their higher homologues (Henry and Darbyshire, 1980). The leaves of both *P. tenax* and *P. cookianum* contained two trisaccharides, with similar staining intensities,

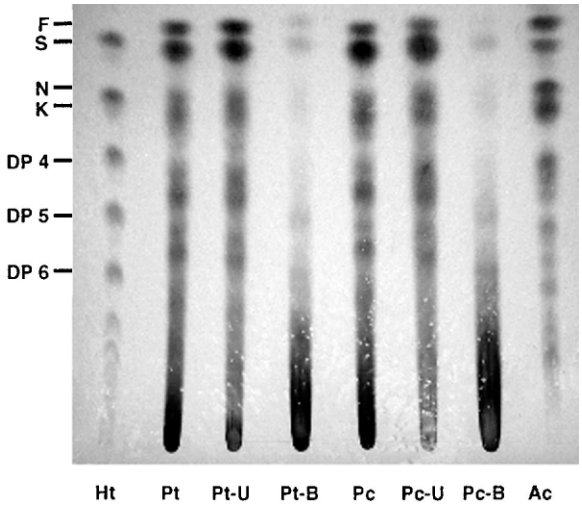

Fig. 3. Thin-layer chromatography of fructans extracted from excised leaves of *Phormium tenax* (Pt) and *Phormium cookianum* (Pc), compared with fructans extracted from tubers *Helianthus tuberosus* (Ht) and bulbs *Allium cepa* (Ac). Pt-U and Pc-U represent fructans not bound to C-18 cartridges and Pt-B and Pc-B represent fructans eluted from C-18 cartridges with methanol. Markers represent the mobilities of fructose (F), sucrose (S), 6_G-kestotriose (N), 1-kestotriose (K), and inulin tetrasaccharide (DP 4), pentasaccharide (DP 5) and hexasaccharide (DP 6).

which co-chromatographed with the deduced 1-kestotriose and 6_G-kestotriose. The trisaccharide fraction from *A. vera cruz* also contained these two trisaccharides (Dorland et al., 1977). The pattern of oligosaccharides > DP 3 from the *Phormium* species resembled the complex pattern of oligosaccharides from *A. cepa* rather than the simple series from *H. tuberosus* and added to the evidence from glycosyl linkage analysis (Table 1) which indicated that *Phormium* fructans contained oligosaccharides based on both 1-kestotriose and 6_G-kestotriose.

Separation of fructans in extracts from excised leaves of *P. tenax* and *P. cookianum* after 24 h of continuous illumination by HPAEC showed a complex pattern of oligosaccharides compared with the linear β-2,1 linked series of *H. tuberosus* and the linear β-2,6 linked series of *P. pratense* (Fig. 4). A large peak in both *P. tenax* (Fig. 4A) and *P. cookianum* (Fig. 4B) that eluted at about 13.7 min co-chromatographed with the trisaccharide from *H. tuberosus* and was thus identified as 1-kestotriose (K). The second trisaccharide, 6_G-kestoriose observed by TLC, could not be positively identified by HPAEC. This trisaccharide elutes from HPAEC between 1-kestotriose (K) and 1,1-kestotetraose (DP4, 17.6 min; Fig. 4C; Bancal et al., 1993). However, there was no peak in this region with a similar size to that of 1-kestotriose that would reflect their similar staining intensities on TLC, and unequivocal identification of this peak would require further chromatographic separation and characterisation. The complex mixture of oligosaccharides that eluted between 15 and 22 min ranged in size from DP 3 to DP7/8 as judged from the elution times of oligosaccharides of this size present in *H. tuberosus* (Fig. 4C) and *Phleum pratense* (Fig. 4D) extracts but could not be identified by their retention times. Material that was eluted from 22 to 33 min was not resolved into individual peaks and was assumed to contain a mixture of multiple isomeric fructans from DP 8 to > DP 30.

Fructans from both *P. tenax* and *P. cookianum* were passed through reverse-phase cartridges to remove hydrophobic material, giving unbound fractions (Pt-U and Pc-U) and bound fractions that was eluted with methanol (Pt-B and Pc-B). TLC showed that the distribution of oligosaccharides present in the unbound fractions, Pt-U and Pc-U, resembled that of the unfractionated material, but with less intense staining on the lower third of the plate and on the origin (Fig. 3). The bound fractions, Pt-B and Pc-B, contained material that was mostly > DP 6, with intense staining on the lower third of the plate and on the origin. Analysis of the reverse-phase unbound and bound fractions by HPAEC (not shown) gave a similar distribution of material to that observed on TLC. Reverse phase cartridges have been used previously in the preparation of fructan extracts to remove hydrophobic materials (Smouter and Simpson, 1989; Bonnett et al., 1997; St. John et al., 1997a,b), but this present study clearly shows that this results in the loss of higher molecular weight fructans, which can only be eluted with organic solvents.

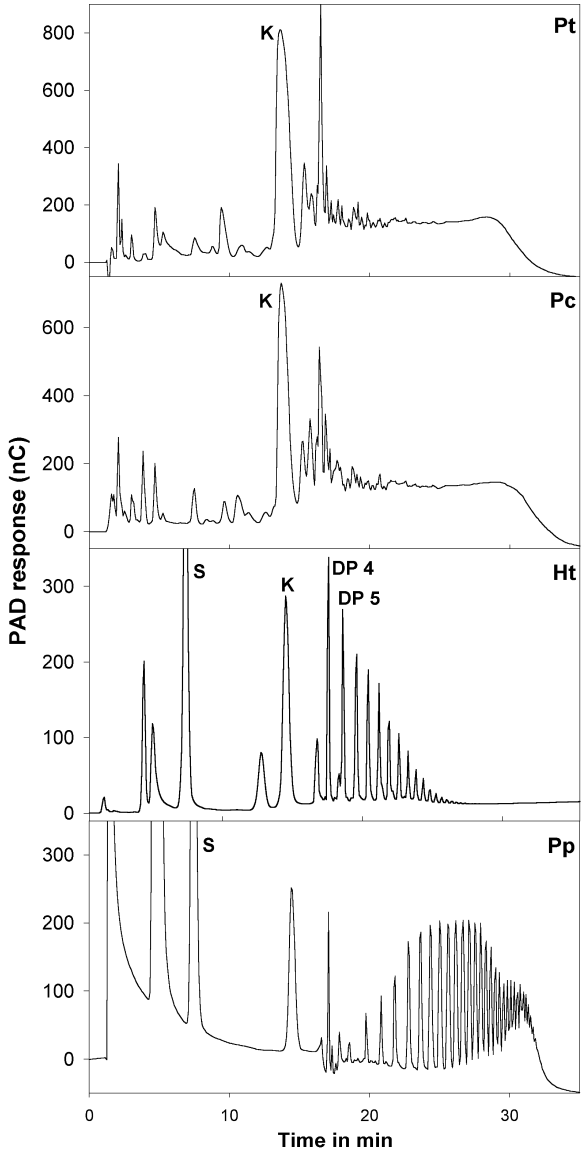

Fig. 4. HPAEC analysis of fructans extracted from excised leaves of *Phormium tenax* (Pt) and *Phormium cookianum* (Pc), compared with fructans extracted from tubers of *Helianthus tuberosus* (Ht) and leaves of *Phleum pratense* (Pp). Markers represent the mobilities of sucrose (S), 1-kestotriose (K), and inulin tetrasaccharide (DP 4) and pentasaccharide (DP 5).

2.5. Conclusions

The WSC accumulated by excised leaved of *Phormium* comprises mostly of sucrose with lesser amounts of fructan. The data indicate that there may be slight differences in the accumulation of fructan by leaves of *P. tenax* and *P. cookianum*, although more work is needed to confirm this. The fructans are based on the two trisacharides, 1-kestotriose and 6_G-kestotriose, and the

branched tetrasaccharide, (1 and 6)-kestotetraose, and have a complex distribution of oligosaccharides. The branched structure of the fructans isolated from excised leaves of *Phormium* resembles that of fructans and fructo-oligosaccharides isolated from the closely related species, *A. vera cruz* and *C. australis* and the less closely related *U. maritima*, but is distinct from the linear structure of fructans from *A. cepa* and *A. officinalis*. The detailed linkage analysis data for the branched fructans was able to separate the four species, but was not able to distinguish between the two *Phormium* species. The significance of this structural complexity is obscure, but it would be of considerable interest to use such structural heterogeniety as a chemotaxonomic aid within both the order Asparagales and superorder Liliiflorae.

3. Experimental

3.1. Fructans standards

Fructans were extracted from bulbs of *A. cepa* (obtained from a local market, UK) and tubers of *H. tuberosus* (obtained from a local market, UK) stored at 2–4°C for 6 weeks as described by Sims et al. (1991). Fructan was extracted from excised leaves of *P. pratense* as described by Cairns et al. (1999). Fructan from *C. intybus* was from Aldrich.

3.2. Plant material and induction of carbohydrate accumulation

Plants of *P. tenax* were to read and *P. cookianum* were obtained from a local nursery, NZ. Leaves approximately 50 cm long were excised and carbohydrate accumulation induced by immersing the cut ends in H_2O and illuminating at about 350 μmol m^{-2} s^{-1} photosynthetic photon flux density for up to 48 h.

3.3. Extraction of water-soluble carbohydrate

At various times after excision, individual leaves of *P. tenax* and *P. cookianum* were harvested and weighed. The leaves were cut into small pieces, killed in boiling 80% v/v EtOH (approx. 50 ml g^{-1} FW leaf), and the water-soluble carbohydrate extracted twice with H_2O (approx. 50 ml g^{-1} FW leaf, 70°C, 60 min). The pooled extracts were concentrated, filtered under vacuum (Whatman 541 filter paper), deionised by sequential passage through anion (Amberlite IR 120, Na^+ form) and cation (Amberlite IR 401, Cl^- form) exchange resins and freeze-dried.

3.4. Analyses of water-soluble carbohydrate

Total WSC was determined by the phenol-sulphuric acid method using fructose as a standard (Dubois et al., 1956). Total starch was determined using the Meagzyme Total Starch Assay Kit, Procedure B (Megazyme International Ireland Ltd.). Free reducing sugars (mostly fructose and glucose) were determined using the *p*-hydroxybenzoic acid hydrazide (PAHBAH) reducing-sugar assay (Lever, 1972). Sucrose and fructan were determined using the Megazyme Fructan Assay kit. For the determination of sucrose, the sucrase/β-amylase/pullulanase/maltase mixture was used to hydrolyse sucrose (assuming that the starch contents of the leaf extracts were negligible; see results) to glucose and fructose, and the increase in reducing-sugar content compared to unhydrolysed samples was used to calculate the sucrose content. Fructan was determined using the full Megazyme fructan assay procedure.

3.5. Fractionation of water-soluble carbohydrates

WSCs from excised leaves of *P. tenax* and *P. cookianum* illuminated continuously for 24 h were fractionated by gel-permeation chromatography on a column (90× 1.6 cm) of Fractogel TSK HW-40 (fine, Merck) in order to separate monosaccharides and sucrose from fructans. Samples (approx. 200 mg) dissolved distilled H_2O (2 ml) were loaded onto the column and eluted with distilled H_2O at 7 ml h^{-1} at room temperature. Fractions (4 ml) were collected and assayed for total carbohydrate using the phenol-sulphuric acid method (Dubois et al., 1956). Those corresponding to (A) fructans and (B) sucrose and monosaccharide were pooled and freeze-dried.

Fructans obtained following gel-permeation chromatography (20 mg) were dissolved in distilled water (1 ml). The samples were applied to reverse-phase cartridges (C-18 Sep-Pak, Waters Corporation, USA) and unbound material eluted with 5 ml distilled water. Bound material was then eluted with 5 ml MeOH, and both the bound and unbound fractions were freeze-dried.

3.6. Chromatographic analyses of fructans

Samples containing about 50 μg of fructan were applied to the origin of a 20 × 20 cm silica gel TLC plate (Schleicher & Schuell, Germany). Plates were developed three times in butan-1-ol/propan-2-ol/water (3:12:4, v/v/v) at room temperature (Kanaya et al., 1978). Compounds were visualised by spraying with the ketose-specific, urea-phosphoric acid stain (Wise et al., 1955).

Samples containing 100 μg of fructan dissolved in distilled H_2O (5 μg μl^{-1}) were separated by HPAEC at a flow rate of 1 ml min^{-1} on a Dionex BioLC using a CarboPac PA-100 column (4×250 mm; Dionex Corp., Sunnyvale, CA, USA) equilibrated in 100 mM NaOH. WSC was eluted with a gradient of NaOAc (0–0.4 M) starting 10 min after injection and ending 50 min after injection. Eluted material was monitored using pulsed amperometric detection (Dionex).

3.7. Glycosyl linkage analysis

Prior to derivatisation, sucrose was hydrolysed to fructose and glucose with a specific sucrase, and all monosaccharides were reduced to their respective alditols with $NaBH_4$. Samples of total WSC containing ~100 μg fructan were dissolved in 100 μl distilled water, 100 μl of sucrase (0.23 units) in Na-maleate (0.1 M, pH 6.5, Megazyme fructan assay kit) was added and incubated at 40°C for 1 h. $NaBH_4$ (100 μl, 10 mg ml^{-1}) was then added and the samples were incubated at 40°C for 1 h to reduce free reducing sugars to their respective alditols. Reduction was stopped by the addition of acetic acid (20 μl) and borate removed by repeated evaporation with 5% AcOH in MeOH (3×) and MeOH (3×). The samples were then dried and derivatised to partially methylated alditol acetates as described by Bonnett et al. (1994). The derivatives were separated by GC on a Hewlett Packard Ultra 2 capillary column (50 m×0.20 mm i.d., 0.33 μm film thickness) with the GC oven programmed from 130°C (held for 1 min) to 230°C at a rate of 3°C min^{-1} and analysed by MS using a HP 5970 MSD.

3.8. ^{13}C NMR spectroscopy

Fructans (~50 mg) were dissovled in 0.8 ml D_2O (99.96 atom%) in 5-mm tubes and spectra recorded at 30°C on a Brüker WM-300 spectometer (75 MHz). Chemical shifts were measured relative to internal DMSO at δ 40.4 ppm.

Acknowledgements

We are grateful to Dr. H. Wong for recording the ^{13}C NMR spectra and to Dr. R. Falshaw for critical assessment of the manuscript. This research was supported by the New Zealand Foundation for Research, Science and Technology and by the Biotechnology and Biological Sciences Research Council (UK). We are grateful to the ISAT Linkages Fund of the Royal Society of New Zealand for the provision of travel funds to I.M.S.

Received 15 August 2000; received in revised form 23 January 2001

Abstract

Biotransformation of (+)- and (−)-camphorquinones with suspension plant cultured cells of *Nicotiana tabacum* and *Catharanthus roseus* was investigated. It was found that the plant cultured cells of *N. tabacum* and *C. roseus* reduce stereoselectively the carbonyl group of (+)- and (−)-camphorquinones to the corresponding α-keto alcohols. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Nicotiana tabacum*; Solanaceae; *Catharanthus roseus*; Apocynaceae reduction; Biotransformation; (+)-Camphorquinone; (−)-Camphorquinone; 2-*exo*-Hydroxyepicamphor; 2-*endo*-Hydroxyepicamphor; 3-*exo*-Hydroxycamphor; 3-*endo*-Hydroxycamphor

1. Introduction

Asymmetric reductions of ketones by biocatalysts are useful preparative methods to obtain chiral alcohols (Sih and Chen, 1984). Chiral α-keto alcohols are useful and important intermediates for the synthesis of optically active natural products having stereodirecting groups. In previous work, microbes such as baker's yeast have been used widely to reduce camphorquinone. (Pfrunder and Tamm, 1969; Chenevert and Thiboutot, 1988; Rebolledo et al., 1991; Miyazawa et al., 1995). In the report of Miyazawa, (+)-camphorquinone (**1a**) was stereoselectivity reduced by *Glemerella cingulata* to give (−)-3*S*-*exo*-hydroxycamphor (**4a**).

On the other hand, plant cultured cells have been studied for the ability to transform foreign substrates into useful substances (Suga and Hirata, 1990). However, hitherto known biochemical reduction of the carbonyl group by plant culture cells is only NADH-dependent reduction of the C–C double bond of α,β-unsaturated ketones (Hirata et al., 1982; Shimoda et al., 1998). There is very little information on the biotransformation of diketones by plant cultured cells. Here, we report that the biotransformation of (+)- and (−)-camphorquinones (**1a** and **1b**) by *N. tabacum* and *C. roseus* yields the corresponding α-keto alcohols.

2. Results and discussion

2.1. Biotransformation of (+)-camphorquinone (*1a*) and (−)-camphorquinone (*1b*) by N. tabacum

It was found that cultured cells of *N. tabacum* reduce substrates **1a** and **1b** into α-keto alcohols. (−)-Camphorquinone (**1b**) afforded a mixture of diastereomeric isomers of four α-keto alcohols: (−)-2*S*-*exo*-hydroxy epicamphor (**3b**); (+)-3*R*-*exo*-hydroxycamphor (**2b**); (−)-3*S*-*endo*-hydroxycamphor (**4b**) and (+)-2*R*-*endo*-hydroxyepicamphor (**5b**). (+)-Camphorquinone (**1a**) was bioselectively transformed to give three corresponding enantiomers: (+)-2*R*-*exo*-hydroxyepicamphor (**3a**); (−)-3*S*-*exo*-hydroxycamphor (**4a**) and (+)-3*R*-*endo*-hydroxycamphor (**5a**). However, (−)-2*S*-*endo*-hydroxyepicamphor (**2a**) could not be formed from **1a** in this work (Schemes 1 and 2). Table 1 shows results of time-course experiments. (+)-Camphorquinone (**1a**) was easily reduced to obtain (−)-3*S*-*exo*-hydroxycamphor (**4a**, 57%) and (+)-2*R*-*exo*-hydroxyepicamphor (**3a**, 37%) as the major products after 10 h incubation. Substrate **1b** was transformed to (−)-2*S*-*exo*-hydroxy

Table 1
Biotransformation of camphorquinone by plant cultured cells

Substrate	Plant cultured cells	T/h[a]	Total yield/%[b]	Product ratio/%			
(+)-Camphorquinone (**1a**)				**2a**	**3a**	**4a**	**5a**
	C. roseus	3	96	/	11	66	23
	N. tabacum	10	82	/	37	57	6
(−)-Camphorquinone (**1b**)				**2b**	**3b**	**4b**	**5b**
	C. roseus	10	93	25	5	29	41
	N. tabacum	18	98	8	49	37	6

[a] T is reaction time.
[b] Total yield is the yield of product isolated.

epicamphor (**3b**, 49%) and (−)-3*S*-*endo*-hydroxycamphor (**4b**, 37%) after 18 h. (Figs. 1 and 2).

2.2. Biotransformation of (+)-camphorquinone (*1a*) and (−)-camphorquinone (*1b*) by C. roseus

Incubation of substrates **1a** and **1b** with cultured cells of *C. roseus*, also gave the corresponding α-keto alcohols. Compound **1a** rapidly disappeared and was undetectable after 3 h incubation. Compound **1a** was converted to (−)-3*S*-*exo*-hydroxy-camphor (**4a**, 66%) as the major product. Compound **1b** was transformated to (+)-2*R*-*endo*-hydroxyepicamphor (**5b**, 41%) as the major product at the end of 10 h.

2.3. Discussion

After incubation, the column mixtures of α-keto alcohols were applied to a silica gel. Elution with *n*-hexane–Et_2O (3:1) gave two products: 2β-hydroxycamphor (**3**) and 3β-hydroxycamphor (**4**) were identified by their IR, GC–MS and NMR spectral data. In addition, the ^1H NMR spectral data of the proton at C_2 or C_3 position of products **3** and **4** agreed with those of the authentic samples (Thoren, 1970). From the ^1H NMR spectral data of the reaction mixtures, the presence of 2α-hydroxycamphor (**2**) and 3α-hydroxycamphor (**5**) has been shown (Table 2). Then, the structures and relative yields of the products were determined on the basis of the ^1H NMR spectral peak areas of the proton at C_2 or C_3 position. The transformation products and their yields are shown in Table 1.

In this paper, we have used plant suspension cells to transform camphorquinone. (+)-Camphorquinone (**1a**) was stereoselectively reduced by *C. roseus* and *N. tabacum* to give (−)-3*S*-*exo*-hydroxycamphor (**4a**) over a short time period (3–10 h). It was found that it is more rapid than the reduction of **1a** by *Glemerella cingulata* and *Mucor mucedo* (Miyazawa et al., 1995) with the same stereoselectivity (9–24 h).

(1*S*)-(+)-Camphorquinone was purchased from Aldrich Chem. Co. (mp 200–202°C, $[\alpha]_D^{25}$ +100° (C_6H_5 CH_3; c 1.9)). (1*R*)-(−)-Camphorquinone was purchased from Tokyo Kasei Kogyo Co., Ltd (mp 200°C).

3.2. Cultivation of suspension cells of *N. tabacum* and *C. roseus*

The callus tissues of *N. tabacum* were transferred to freshly prepared MS medium (Murashige and Skoog, 1962) containing 1 ppm of 2,4-dichlorophenoxyacetic acid as auxin and 3% sucrose, and then were grown with continuous shaking (110 rpm) for 8 days at 25°C under the light. The callus tissues of *C. roseus* were transferred to freshly prepared SH medium (Schenk and Hildebrandt, 1976) containing 2 ppm of 2,4-dichlorophenoxyacetic acid as auxin and 3% sucrose, and then were grown with continuous shaking (110 rpm) for 8 days at 25°C under the light.

3.3. Time-course experiment

The details are described below using **1a** as an example. A part of the callus tissues (15 g) was transferred to 50 ml culture medium in a 200 ml Erlenmeyer flask and grown with continuous shaking for 8 days at 25°C under light (about 2000 Lux). The substrate **1a** (20 mg) was administered to the suspension cells and the cultures were incubated at 25°C in a rotary shaker (110 rpm) under light. At regular intervals, one of the flasks was taken out and the incubation mixture was filtered and extracted with EtOAc–Et_2O (1:1). The extract so obtained was then subjected to ^{1}H NMR spectral analysis. The yields of the products were determined on the basis of the peak area from ^{1}H NMR spectra and expressed as a relative percentage to the total amount of the total reaction mixture extracted.

3.4. Isolation of the metabolic products

After incubation, the culture medium was filtered. The supernatent was then saturated with NaCl and extracted with EtOAc–Et_2O (1:1). The resulting residue was applied to a silica gel column, that was eluted with *n*-hexane–Et_2O (3:1) to give: 2β-hydroxycamphor (**3**), (IR (KBr): ν 3448, 1751 and 1098 cm^{-1}; CI–MS *m*/*z*: $[M+H]^+$ 169; ^{1}H NMR ($CDCl_3$): δ (ppm) 0.94 (*s*, 3H), 1.03 (*s*, 3H), 1.04 (*s*, 3H), 1.18–1.94 (*m*, 4H), 2.18 (*d*, *J* = 7 Hz, 1H), 2.65 (*s*, *b*, 1H) and 3.54 (*s*, 1H); ^{13}C NMR ($CDCl_3$): δ (ppm) 10.3, 18.9, 20.3, 21.2, 33.9, 46.6, 49.2, 58.6, 79.5 and 218.7) and 3β-hydroxycamphor (**4**), (IR (KBr): ν 3448, 1751 and 1123 cm^{-1}; CI–MS *m*/*z*: $[M+H]^+$ 169; ^{1}H NMR($CDCl_3$): δ (ppm) 0.94 (*s*, 3H), 0.95 (*s*, 3H), 1.00 (*s*, 3H), 1.20–2.00 (*m*, 4H), 2.10 (*d*, *J* = 5 Hz, 1H), 2.59 (*s*, *b*, 1H) and 3.75 (*s*, 1H); ^{13}C NMR($CDCl_3$): δ (ppm) 9.03, 20.1, 21.0, 25.2, 28.6, 48.2, 49.2, 57.0, 77.4 and 220.0) (Thoren, 1970)

The ratios of the isomers were calculated from the peak areas of ^{1}H NMR spectral data: δ 3.86 (*s*, *b*, 1H for **2**), 3.54 (*s*, 1H for **3**), 3.75 (*s*, 1H for **4**) and 4.21 (*d*, *J* = 5 Hz, 1H for **5**).

Biotransformation of geranyl acetate to geraniol during palmarosa (*Cymbopogon martinii*, Roxb. wats. var. *motia*) inflorescence development

Vinod Shanker Dubey, Rajesh Luthra*

Biochemistry Division, Central Institute of Medicinal and Aromatic Plants, Lucknow- 226015 (U.P.), India

Received 24 May 2000; received in revised form 29 November 2000

Abstract

Only immature palmarosa (*Cymbopogon martinii*, Roxb. wats. var. *motia*) inflorescence with unopened spikelets accumulated essential oil substantially. Geraniol and geranyl acetate together constituted about 90% of the palmarosa oil. The proportion of geranyl acetate in the oil decreased significantly with a corresponding increase of geraniol, during inflorescence development. An esterase enzyme activity, involved in the transformation of geranyl acetate to geraniol, was detected from the immature inflorescence using a gas chromatographic procedure. The enzyme, termed as geranyl acetate cleaving esterase (GAE), was found to be active in the alkaline pH range with the optimum at pH 8.5. The catalysis of geranyl acetate was linear up to 6 h, and after 24 h of incubation, 75% of the geranyl acetate incubated was hydrolyzed. The GAE enzymic preparation, when stored at 4°C for a week, was quite stable with only 40% loss of activity. The physiological role of GAE in the production of geraniol during palmarosa inflorescence development has been discussed. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Palmarosa; Cymbopogon; Essential oil; Geraniol; Geranyl acetate; Esterase; Biotransformation

1. Introduction

Cymbopogon martinii, Roxb. wats. var. *motia*, commonly known as palmarosa, is a wild perennial undershrub, whose flowering tops and leaves yield an essential oil rich in the acyclic monoterpenoid geraniol. Palmarosa oil is used for imparting rose like aroma to a wide range of perfumes, soaps, cosmetics, toiletry and tobacco products. The antiseptic, mosquito repellent and pain relieving properties of the oil makes it of considerable pharmaceutical significance as well. The characteristic odour of palmarosa oil lies in its high content of total alcohol mainly geraniol and a small but varying amount of esters, particularly geranyl acetate (Husain, 1994). Monoterpenoids, the major constituents of the essential oils, are derived from geranyl pyrophosphate (GPP), synthesized through head to tail fusion of isopentenyl pyrophosphate (IPP) with dimethylallyl pyrophosphate (DMAPP) (Singh et al., 1989b). IPP is in turn derived from the conventional mevalonate-isoprenoid pathway or the newly discovered non-mevalonate (pyruvate/triose-phosphate) pathway (McCaskill and Croteau, 1998; Lichtenthaler, 1999; Luthra et al., 1999; Rohmer, 1999). GPP may undergo cyclization, coupling, hydroxylation and/or rearrangement to produce the parent monoterpene carbon skeleton, followed by a variety of secondary chemical transformations viz. oxidation, reduction, acetylation, isomerization and hydration etc. to produce the myriad of monoterpenoids encountered in plants (Singh et al., 1989b). The biotransformation of monoterpenyl acetate to monoterpenol is of great interest as the monoterpenol–monoterpenyl acetate pair occur widely in aromatic plants. Furthermore they influence the quality of the essential oil distilled from such plants.

Geraniol which constitutes about 80% of the palmarosa oil is derived from pyrophosphorylysis of GPP. Our studies with developing palmarosa inflorescence have shown that in immature inflorescence, a substantial amount of geraniol undergoes acetylation to form geranyl acetate,

PII: S0031-9422(01)00122-4

which gets hydrolyzed to produce geraniol, as the inflorescence matures. Thus, developing palmarosa inflorescence seems to be an ideal system to study the metabolism of acyclic monoterpenols. The interconversion of geraniol and geranyl acetate is presumably dependent on a complex interplay of different regulatory controls operating at the organ, cellular, subcellular and enzyme levels. There is, however, limited experimental support for these mechanisms. There are several reports with respect to chemical composition of the palmarosa oil (Saxena and Maheshwari, 1980; Akhila et al., 1984; Boelens, 1994), reproductive and breeding behaviour (Srivastava, 1987), mutational studies for crop improvement (Srivastava et al., 1998; Srivastava and Satpute, 1998), and plant tissue culture work in relation to salt tolerance (Patnaik and Debata, 1997). The present study was undertaken to understand the metabolism of geraniol and geranyl acetate during palmarosa inflorescence development. Emphasis has been presented to demonstrate the enzyme activity involved in the transformation of geranyl acetate into geraniol, the major secondary reaction occuring during palmarosa inflorescence development. The identification of an esterase enzyme activity involved in catalysis of acyclic monoterpenyl acetate is reported for the first time.

2. Results and discussion

2.1. Ontogenic changes in essential oil content and composition

Palmarosa (*Cymbopogon martinii*) inflorescence (flowering top), consisting of partially opened spikelets, contained a higher percentage of essential oil than the leaf (Table 1). Though geraniol was the major constituent of the inflorescence and leaf oil, the inflorescence oil contained a relatively higher percentage of geranyl acetate than the leaf oil (Luthra et al., 1995). The fresh weight (g/100 spikelets) of the inflorescence decreased appreciably as the spikelets opened (Fig. 1).

Table 1
Relative percentage of geraniol and geranyl acetate in leaf and inflorescence oil of palmarosa

Plant part[a]	Essential oil (% V/FW)	Relative % in essential oil[b]		
		Geraniol	Geranyl acetate	Unknown
Leaf	1.10	80.9	7.9	11.2
Inflorescence	1.30	53.5	34.0	12.5

[a] The leaf and the inflorescence sample was collected at partially opened spikelet stage.

[b] The leaf and inflorescence essential oil values significantly differ from each other by Student's *t*-test at $P < 0.05$.

The dry weight (g/100 spikelets) of the inflorescence, however, increased until the fully-opened spikelets (III) stage and then decreased (Fig. 1). An appreciable decrease in dry weight after the fully opened spikelets (III) stage suggests that the palmarosa inflorescence undergoes maturation after the spikelets were fully opened. Since fr. wt and dry wt of the spikelets vary with inflorescence development, the representation of the oil content on a unit weight basis (data not given) creates ambiguity with respect to the pattern of essential oil accumulation. The expression of results on spikelet development warrants more interest. Therefore, to avoid ambiguity, essential oil content, composition and other related parameters have been discussed only on spikelet basis during the inflorescence maturation.

The essential oil content exhibited phasic changes during palmarosa inflorescence development (Fig. 2). The essential oil content was maximum at the unopened spikelets (I) stage, and decreased significantly with their development. Since the observed levels of essential oil, accumulated during inflorescence development, are the net result of the anabolic and catabolic processes, the results suggest that only the immature inflorescence with unopened spikelets is biogenetically active to substantially accumulate essential oil (Fig. 2). One of the most important characteristics of essential oil accumulation is its dependence on the developmental stage of the concerned organ/plant part (Singh et al., 1989a,b). The concentration of volatile extracts has been, for example, reported to be highest in large buds prior to anthesis in *Boronia* flower (Mactavish and Menary, 1997), whereas in the rose flower, the essential oil content increased till open flower stage and then declined as

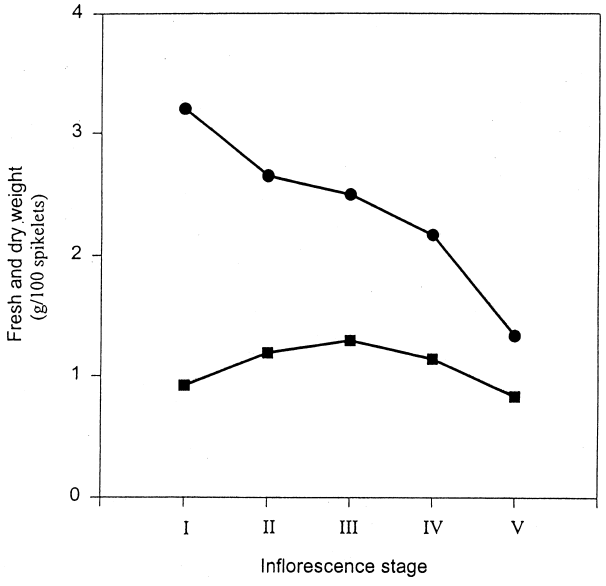

Fig. 1. Changes in fr. (●) and dry (■) wt of the spikelets during inflorescence development.

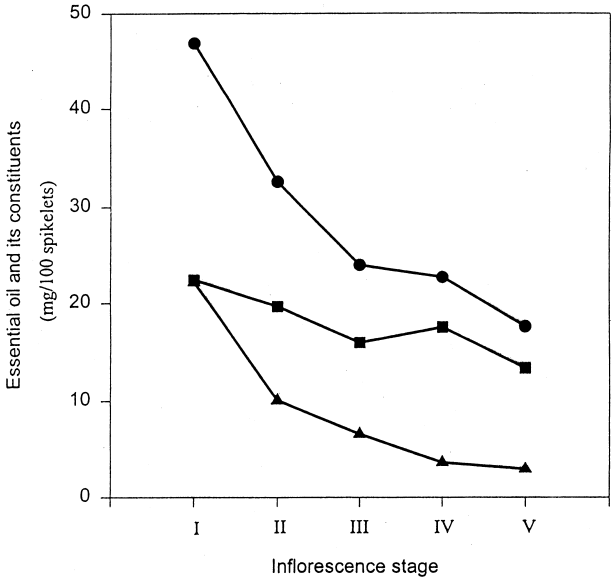

Fig. 2. Changes in essential oil content (●) and its major constituents, geraniol (■) and geranyl acetate (▲), during inflorescence development.

the flower became visibly senescent (Pogorel'skaya et al., 1980).

Gas chromatographic (GC) analysis of the essential oil from various developmental stages indicated that the geranyl acetate percentage in the oil decreased significantly from the unopened spikelets (I) stage (48%) to the partially mature spikelets (IV) stage (16%) with a corresponding increase in geraniol percentage (Fig. 3). These results suggest the role of an esterase enzyme in producing geraniol during this period. Geraniol% in the leaf oil increased from 81 to 86% with maturity, and is accompanied by a corresponding decrease in geranyl acetate (Luthra et al., 1995). The menthyl acetate content of the volatile oil in flowering peppermint, however, increased with maturity and resulted in an altered flavour characteristic of the essence distilled from flowering plants (Croteau and Hooper, 1978). Similar studies in lemongrass (*Cymbopogon flexuosus*) and citronella Java (*C. winterianus*) leaves indicated that the developmental phase influences the expression of monoterpene metabolism (Singh and Luthra, 1988; Singh et al., 1989a, 1990, 1991; Luthra et al., 1991). The relative percentage of geraniol and citronellol in the oil from immature citronella leaf increased with the tissue age along the leaf blade, and was accompanied by a corresponding decrease in geranyl acetate and citronellyl acetate (Luthra et al., 1991). The geraniol content in the palmarosa oil increases from the vegetative stage to the full flowering stage and is accompanied by a decrease in geranyl acetate content (Saxena and Maheshwari, 1980; Akhila et al., 1984). Though the geraniol percentage in the palmarosa inflorescence essential oil increased with inflorescence development, the absolute amount of geraniol decreased (Figs. 2 and 3). Since geraniol is the major constituent of the palmarosa oil at all the stages of inflorescence development, it is expected that the decrease in the essential oil content, as the inflorescence matured, shall be governed largely by the geraniol pool. Monoterpenyl glycosides have been implicated in terpene catabolism which involves their transport to the roots, where they are converted to primary metabolites (Croteau, 1987). Therefore, the decrease in geraniol content with maturity might be due to its glycosylation to form geranyl-D-glycosides for use in catabolic processes. Work in this direction needs to be carried out to determine the exact mechanism of catabolism.

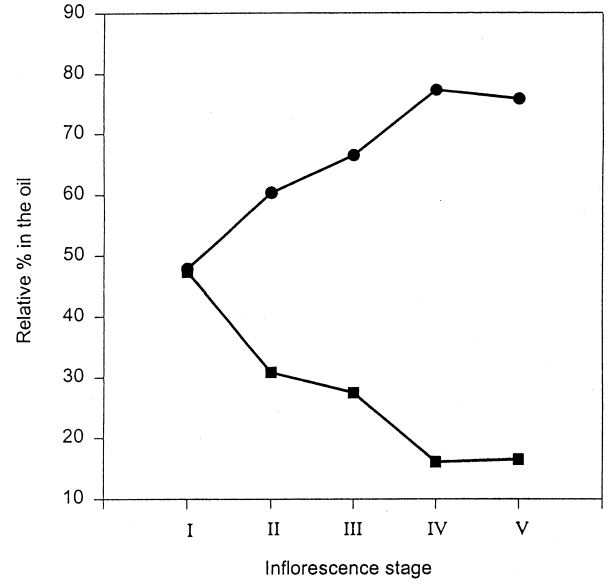

Fig. 3. Relative percentage of geraniol (●) and geranyl acetate (■) in the oil during inflorescence development.

2.2. Detection of geranyl acetate cleaving esterase activity

The enzyme which converts geranyl acetate to geraniol is named, after the reaction it catalyzes, as geranyl acetate cleaving esterase (GAE) (Dubey and Luthra, 1999). GAE activity was detected in palmarosa inflorescence using a gas chromatographic (GC) procedure. Geranyl acetate was incubated under defined conditions with respect to pH, temperature, substrate and enzyme concentration for a particular time and the amount of geraniol produced was used as an indicator of GAE activity (Fig. 4). Saturating levels (2 μmol/ml) of the substrate geranyl acetate and 0.5–1.0 mg of the enzyme protein were used in each assay. The enzyme GAE was most active in the pH range 8.0–9.0 and showed maximal activity at pH 8.5 (0.05 M Tris–HCl) and temperature 30°C. Preiss et al. (1988) have reported maximum esterase activity at pH 8.0 from tomato cell cultures hydrolyzing pyrethroid insecticide cyfluthrin, whereas, cell wall bound lanatoside 15′-*o*-acetyl esterase (LAE) from

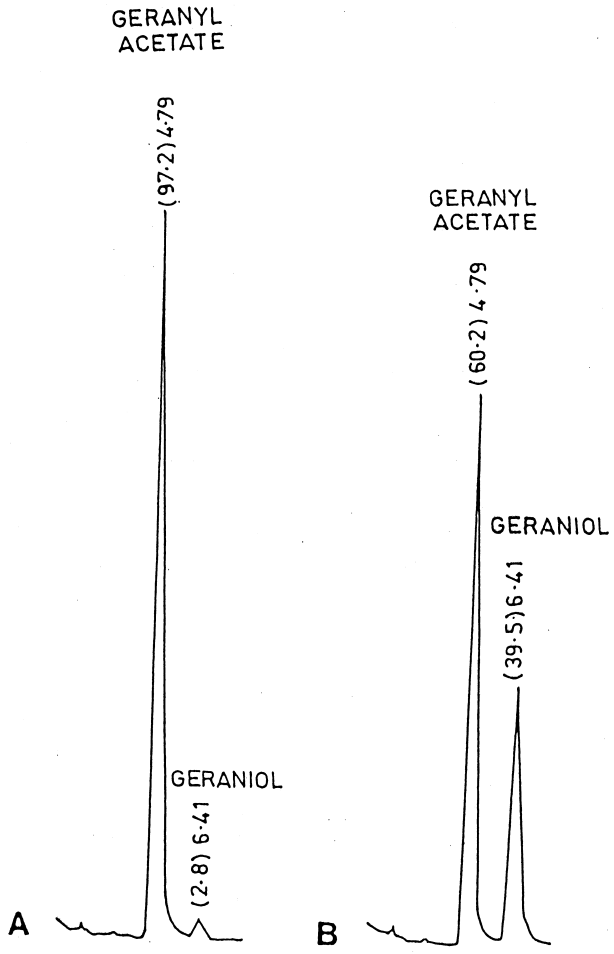

Fig. 4. Gas chromatograms (GC) of the geranyl acetate esterase (GAE) catalyzed reaction (A = control, B = assay) depicting hydrolysis of geranyl acetate (GA) to produce geraniol (G). The substrate GA was incubated with the enzymic preparation from palmarosa inflorescence for 4 h under defined conditions. The values in parentheses represent the relative% of G and GA, whereas the values outside parentheses represent the retention time.

Digitalis lanata cell suspension cultures (involved in cardenolides transformation) was found to be most active in the acidic range at pH 5.5 (Sutor and Kreis, 1996; Kandzia et al., 1998). A cyclic monoterpenyl acetate esterase from *Mentha piperita* leaves, which catalyzes transformation of menthyl acetate to menthol, also showed maximum activity at pH 8.0 (Croteau and Hooper, 1978). Thus esterases in plant system exhibited a wide pH range. The GAE activity increased linearly with protein concentration up to 1.0 mg per assay (data not given). The technical difficulty usually encountered in solubilization of geranyl acetate (substrate) was overcome by its dispersion in assay buffer containing Tween-20 (10 μg/μmol of substrate). Tween-20 had no adverse effect on the GAE activity even at concentrations much higher than that present in the assay system.

A time course experiment was performed to study the linearity of the hydrolysis of geranyl acetate during the incubation period. A linear catalytic rate was found up to 6 h of incubation at 30°C using 1 mg of enzyme protein. Almost 75% of the geranyl acetate was hydrolyzed after 24 h of incubation (Fig. 5). No geraniol was produced in the control using boiled enzyme. The enzyme in the crude preparation, when stored at 4°C, was quite stable for one week with 40% loss of activity. This is unlike other secondary metabolic enzymes, which are normally unstable in the crude preparations (Croteau, 1987; Singh et al., 1989b). The enzyme is being purified to study its kinetic attributes.

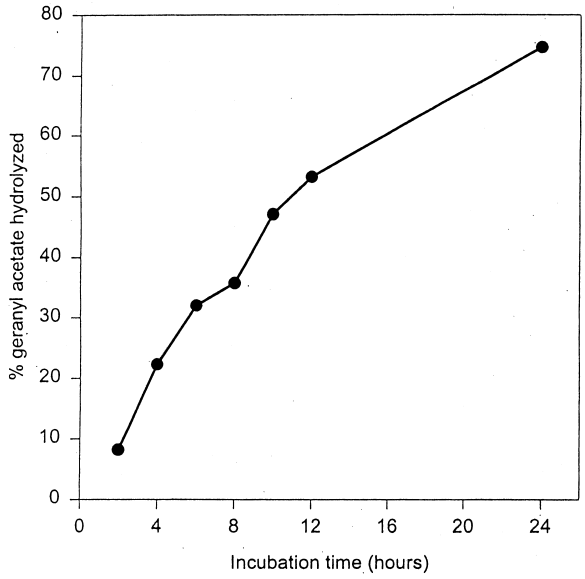

Fig. 5. Time course of hydrolysis of geranyl acetate by enzymic preparation from palmarosa inflorescence.

3. Conclusion

The geranyl acetate proportion in the oil decreased substantially with concomitant increase in geraniol during palmarosa inflorescence development, suggesting the role of an esterase in producing geraniol. A geranyl acetate hydrolyzing activity, referred to as geranyl acetate esterase (GAE), could be detected using a gas chromatographic procedure.

4. Experimental

4.1. Plant material and chemicals

Palmarosa (*Cymbopogon martinii*, Roxb. Wats. var. *motia*) plants were raised from seedlings at the experimental farm of the Central Institute of Medicinal and Aromatic Plants (CIMAP), Lucknow, by following the standard agronomic practices. The inflorescence (flowering top consisting of spikelets), was tagged at the time

of emergence. The samples were taken at 8 days interval, representing five developmental stages viz. stage I — unopened spikelets, stage II — partially opened spikelets (anthers partially visible), stage III — fully opened spikelets (yellow anthers fully visible), stage IV — partially mature spikelets (anthers brown and yellow), stage V — fully mature spikelets (brown inflorescence). The spikelets were removed from the inflorescence at each developmental stage and used for various studies. The leaf sample was collected at partially opened spikelet stage.

Geraniol and geranyl acetate were purchased from Sarsynthase (France) and the biochemicals from Sigma Chemical Co. (USA). Solvents and other chemicals used were of high purity (analytical reagent grade) and were obtained from E. Merck and Spectrochem (India).

4.2. Isolation and gas chromatographic analysis of essential oil

The essential oil was extracted from the freshly harvested spikelets (100 g) by steam distillation technique using a mini-Clevenger apparatus as described earlier (Luthra et al., 1991). The essential oil was collected in small stoppered tubes containing anhydrous sodium sulphate to remove moisture. The oil density was determined to convert the volume yields into their respective weights. The essential oil samples were analyzed for their major constituents viz. geraniol and geranyl acetate, using gas chromatography (GC). The GC analysis was performed using a Perkin Elmer (model 3920 B) apparatus equipped with FID (flame ionization detector) and a stainless steel column (2 m×3 mm i.d.) packed with 10% FFAP (free fatty acid phase) on chromosorb WAW (80–100 mesh). The operating conditions were: column temperature isothermal at 165°C, injector and detector temperatures 200 and 250°C, respectively. Nitrogen and hydrogen flow rates were adjusted to 30 and 28 ml/min., respectively. The geraniol and geranyl acetate peaks were identified by coinjecting authentic standards and quantified using a Varian integrator (model 4400). The quantitative values of the various oil constituents were computed from the relative percentage data and the amount of oil per 100 spikelets.

4.3. Enzyme extraction and assay

All the operations of enzyme isolation were carried out at 0–4°C unless specified. The extraction of the enzyme was optimized with respect to buffer, pH, protecting and stabilizing agents to obtain maximum extractable activity. Preliminary enzyme assays were done to standardize the assay conditions, and linearity of the reaction rate with time as well as protein concentration. The extraction medium consisted of 0.1 M NaPi buffer (pH 6.5) containing 50 mM sodium metabisulphite, 10 mM-mercaptoethanol, 10 mM ascorbic acid, 0.25 M sucrose and 1 mM EDTA-Na_2. The spikelets (partially opened stage) were homogenized in cold extraction medium (1 g tissue/ 3 ml) in the presence of 50% (w/w) insoluble PVPP (polyvinyl polypyrrolidone). The slurry was squeezed through four layers of muslin cloth and centrifuged at 15,000×g for 60 min. Purified amberlite XAD-4 resin (50% of the tissue weight) was added to the supernatant and kept for 5 min at 4°C to remove the endogenous terpenes of the tissue. The slurry thus formed was filtered through muslin cloth and the clear supernatant obtained was used to determine geranyl acetate cleaving esterase activity using geranyl acetate as substrate.

The terpenoid substrate geranyl acetate was solubilized by dispersion in the solution of Tween-20 (10 μg/μmol of the substrate) in assay buffer. The geranyl acetate cleaving esterase activity was determined by gas chromatographic (GC) monitoring of geraniol produced by the hydrolysis of geranyl acetate. The assay system consisted of 0.05 M Tris–HCl buffer (pH 8.5), 5 mM $MgCl_2$, 1 mM DTE, 2 mM geranyl acetate and the enzyme extract (0.5–1.0 mg protein), in a total volume of 0.5 ml. The reaction mixture was incubated at 30°C in a sealed capped tube for varying intervals (2–24 h). The geraniol produced and leftover geranyl acetate was then extracted with ether and subjected to GC analysis. The appearance of geraniol peak indicated the presence of geranyl acetate esterase activity. A blank with the boiled enzyme was also run simultaneously. The time course experiment was repeated three times to confirm the results.

4.4. Other determinations

For the determination of fr. wt and dry wt, a known number of spikelets (200) were weighed immediately after harvesting, and then oven dried at 65°C till a constant weight. Total soluble proteins were estimated by the Bradford (1976) method.

Abstract

Emission rates of monoterpenes released by apple (*Malus domestica* Borkh) and cherry (*Prunus avium* L.) were estimated at different phenological stages. These measurements employed a dynamic flow-through Teflon chamber, sample collection onto cartridges filled with graphitized carbon and thermal desorption gas chromatography–mass spectrometry (GC–MS) for identification and quantification of the emitted volatiles. At full bloom the release of monoterpene hydrocarbons from cherry flowers was 1213 ng g^{-1} dry weight (DW) h^{-1}, exceeding by approximately three-fold the emission rate of apple flowers (366 ng g^{-1} DW h^{-1}). Observed seasonal variations in biogenic volatile organic compound (VOC) emissions ranged over several order of magnitudes. At fruit-set and ripening stages, in fact, the hydrocarbon emission dramatically decreased reaching the lowest values at harvest time when leaves were fully mature (3–9 ng g^{-1} DW h^{-1}). Wide diversity in the composition of compounds from the species studied was also recorded. At blooming, linalool contributed significantly to the monoterpene emission from apple (94% of the emitted carbon) while α-pinene and camphene represented on average more than 60% of the total emitted volatiles from cherry flowers. Among the monoterpenes identified in flowers, α-pinene, camphene and limonene were also found in the foliage emission of both species. Fruit trees are relevant monoterpene emitters only at blooming and thus for a short period of the vegetative cycle. When leaves are fully developed, the carbon loss due to monoterpene emissions related to the photosynthetically carbon gain is negligible. © 2001 Published by Elsevier Science Ltd. 1. Introduction

It is well recognized that vegetation emits a wide range of photochemically reactive hydrocarbons in the atmosphere (Fehsenfeld et al., 1992; Hewitt et al., 1995), exceeding the anthropogenic emission of non-methane hydrocarbons by approximately one order of magnitude (Singh and Zimmerman, 1992). Isoprene and monoterpenes are the dominant classes of biogenic compounds released by terrestrial vegetation into the atmosphere (Guenther et al., 1995). In the last decade, a lot of attention has been given to characterizing volatile organic compounds (VOC) emission from plants (Benjamin et al., 1996; Kesselmeier and Staudt,1999) and to estimate the emission rates of these compounds from vegetable cover for a better understanding of the role of natural VOC in relation to the tropospheric air chemistry and to global change. Several inventories of biogenic hydrocarbons on regional and global scale have been published which focus on isoprene and monoterpene emissions (Guenther et al., 1995; Simpson et al., 1995). Terpenoids emitted from vegetation are in fact involved in processes regulating the oxidative capacity of the atmosphere and the formation of tropospheric ozone. Moreover, the emission of hydrocarbons represents a loss of carbon that was photosynthetically assimilated. According to the literature, this carbon loss ranges between a few thousands and some percent (Harley, 1994; Hansen et al., 1997; Kesselmeier et al., 1997, 1998).

A large surface of several European countries is covered by orchards, which represent an economically important resource in the Mediterranean area. To investigate the possible contribution of fruit trees to biogenic emissions from this area, the terpenoid emission pattern of several fruit species was determined during a preliminary study which was conducted in controlled condition on entire fruit plantlets at full bloom (Baraldi et al., 1999). This

screening indicated that fruit trees are monoterpene emitters and that the amount and composition of flower emission varies mainly between pome and stone fruits.

Since seasonal variation has been observed in many cases (Lerdau et al., 1995; Street et al., 1996; Guenther, 1997; Staudt et al., 1997), it should always be considered for an accurate estimation of the annual VOC release from vegetation. The changes of seasonal emissions are in some cases linked to plant growth and phenological events such as budding, flowering, leaf development, fruiting etc (Robertson et al., 1995; Hakola et al., 1998).

The objective of this study was to follow the whole canopy emissions during the vegetation cycles of young cherry and apple trees, as representative of stone and pome fruit plants respectively, in order to better understand the potential contribution of fruit trees to the tropospheric air chemistry and to the global carbon cycle. The experiments were conducted in controlled chamber during different phenological stages: at blooming, when leaves are not yet developed, at fruit-set, when leaves are young, and at fruit ripening, when leaves are mature.

2. Results and discussion

Typical reconstructed chromatograms of air samples from flowers and leaves of fruit trees are illustrated in Fig. 1. At blooming stage (Fig. 2) the total monoterpene emission rate calculated on a flower dry weight (DW) basis was 1213 ng g^{-1} DW h^{-1} in cherry, about three times greater than that recorded in apple (366 ng g^{-1} DW h^{-1}). Thus, according to Guenther et al. (1996) who considered plant species to be high emitters if the total emissions exceed about 0.5 μg g^{-1} h^{-1}, cherry can be considered a high monoterpene emitter while, on the contrary, apple emitted negligible amounts of hydrocarbons. The different emissions were accompanied by characteristic differences in the emission composition. A higher number of monoterpene compounds were identified in cherry compared to apple (Table 1) but, as generally reported in the literature, only few predominating components characterized flower fragrance, accompanied by a larger number of minor compounds (Pellmyr et al., 1987; Matile and Altenburger, 1988). Indeed, the main portion of emitted monoterpenes was α-pinene and camphene, which on average counted for over 60% of the emitted carbon from cherry flowers. β-Myrcene alone represented 15% of the emitted volatiles while limonene, β-pinene, linalool and camphor, together constituted about 17% of the total hydrocarbon rates.

Linalool is by far the most abundant volatile of apple flowers accounting for 94% of the total emission. This result confirms the findings obtained in the previous screening which evidenced differences in monoterpene emission mainly between stone and pome fruit plants, being these last the highest emitters of linalool (Baraldi et al., 1999). On the other hand, an important ecophysiological functions of this alcohol is generally recognized since is a typical components of flowering fragrance attracting pollinators (Loughrin et al., 1990; Bergström, 1991; Knudsen and Tollsten, 1993). Among the other monoterpenes, Δ^3-carene, limonene and α-terpinolene were also reported as headspace constituents emitted in traces from living apple flowers by Buckbauer et al. (1993).

Similar rates of volatile emission were also observed when the blooming trees were kept in the dark (data not shown) as also reported in apple by Loughrin et al., (1990). Although different experimental approaches are needed to confirm these results, it is not surprising that these species are not vesperescent taking into account the biological significance of the flower fragrance emission in attracting insect pollinators and since fruit trees are primarily bee pollinated (Faust, 1989).

Despite of the larger biomass of the emitting organs, at fruit-set and ripening the release of monoterpenes from the leaves dramatically decreased in the tested species. In fact, average VOC emission rates calculated per gram dry weight of leaves, varied from 12 to 18 ng g^{-1} DW h^{-1} at fruit-set to 3–8 ng g^{-1}DW h^{-1} at ripening (Fig. 3).

Among the monoterpene hydrocarbons identified in flowers, α-pinene, camphene and limonene were also found in the foliar emission of both species. Limonene was always the major compound released by apple leaves. Δ^3-carene and α-phellandrene were characteristic compounds of apple and cherry emission, respectively, since they were released at all the phenological stages.

In our experimental condition (PPFD = 800 μmol m^{-2} s^{-1}; $T = 28°C$), CO_2 assimilation ranged on average from 15 to 20 μmol m^{-2} s^{-1}, values comparable to the data reported in the literature (Flore and Lakso, 1989; DeJong, 1983), and that corresponded to 540–720 μmol g^{-1} DW h^{-1} in apple and cherry, respectively. By consequence, the carbon loss as foliar emission by both species was irrelevant compared to the C-fixed during the photosynthetic activity.

In conclusion, this investigation confirmed a genotypic effect on the composition and total emission of biogenic volatiles released by fruit trees, and evidenced the existence of significant seasonal fluctuations in monoterpene emissions. Indeed, as observed for other species, the temporal variations of VOC emitted by fruit trees ranged from several order of magnitudes, suggesting that the developmental stages and the phenological status of the plant play a significant role on volatile production (Robertson et al., 1995; Guenther, 1997; Hakola et al., 1998).

The biological significance of fragrance emission by flowers for these entomophilic plants, which need to interact with their impollinators, is well known. Due to this ecological function, orchards represent a substantial source of reactive hydrocarbons only for a short period

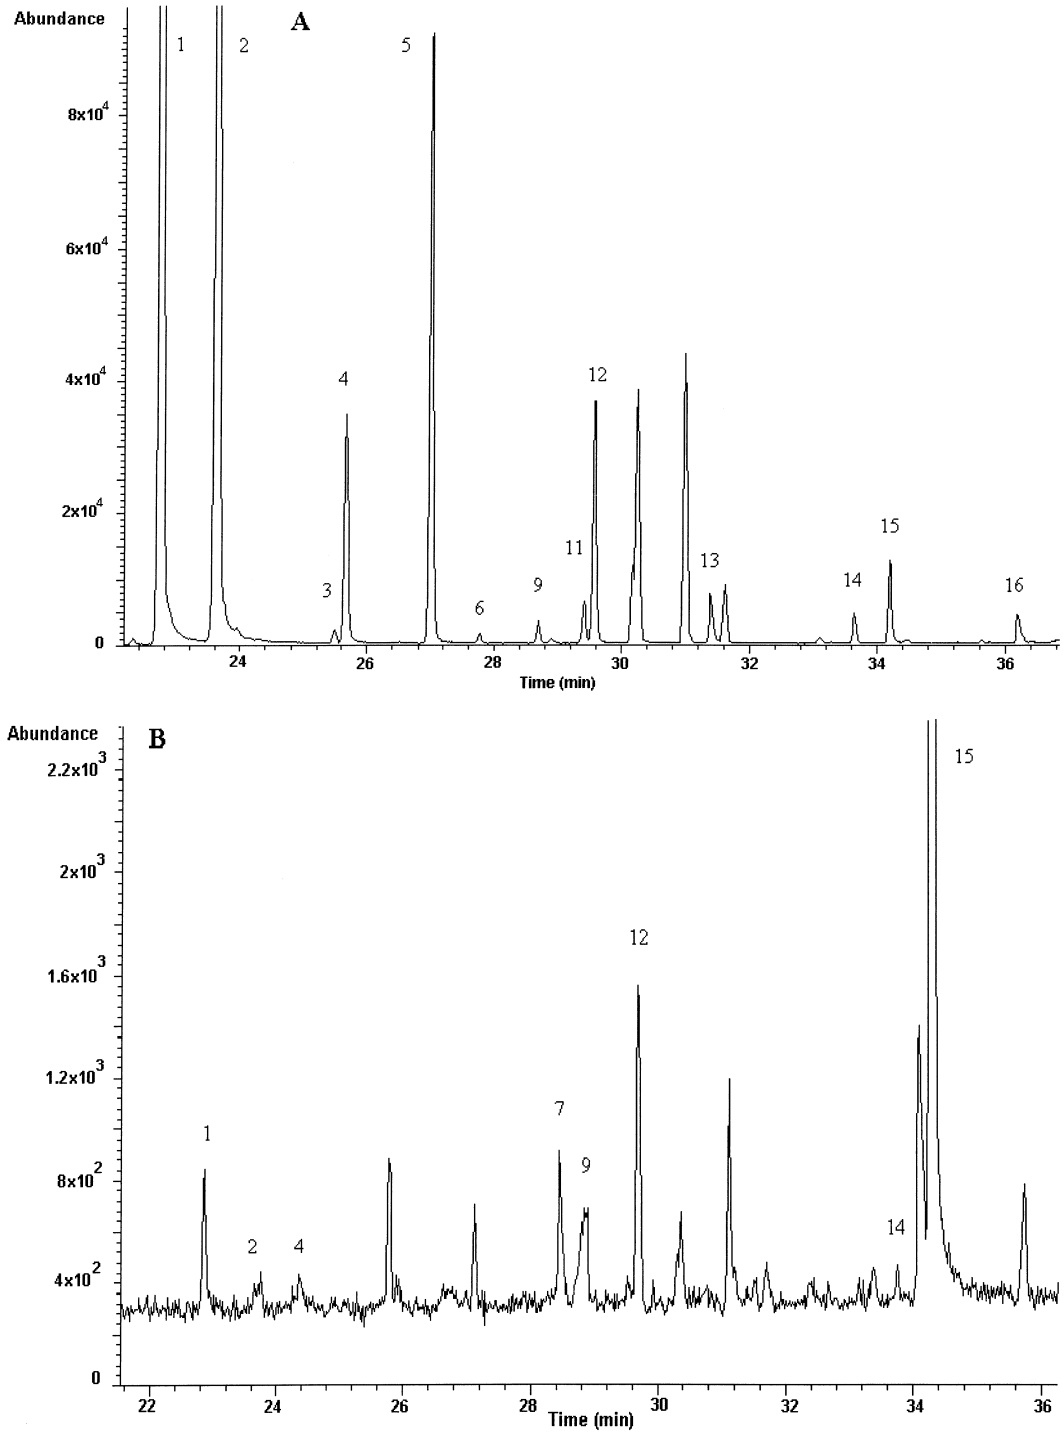

Fig. 1. Reconstructed mass chromatogram (m/z) obtained from GC–MS analysis of cherry (A) and apple (B) flower emission showing the profile of monoterpene hydrocarbons.

of the vegetation cycle, in spring, when the flowers are open and ready to be impollinated and the carbon sequestration by the not yet developed foliage is irrelevant. Later on in the season, when leaves develop or when they become mature, the total monoterpene emission rates become very low and the resulting carbon loss due to hydrocarbon emission is negligible compared to the carbon gain through the photosynthetic activity.

3. Experimental

3.1. Plant material

Three year-old plants of apple (*Malus domestica* Borkh. cv Earligold) and sweet cherry (*Prunus avium* L. cv Sunburst) were grown outdoors in 6 l pots in commercial soil under natural light conditions. Plants were

regularly watered until the beginning of the laboratory experiments, which were carried out at times corresponding to full bloom, fruit-set and fruit ripening.

3.2. Volatile collection

Three plants of each species were individually transferred 24 h before the experiments to a 300 l flow-through Teflon growth chamber at 26–28°C under natural daylight conditions. A constant flow of filtered air (9 l min^{-1}) was maintained inside the chamber which was equipped with a ventilator to ensure a rapid mixing of the air. Attention was focused on minimizing physical damage to the plants. Plants were then adapted to the following experimental conditions: constant temperature (28°C), constant relative humidity (60%) and constant photosynthetic photon flux density (PPFD = 800 μmol m^{-2} s^{-1}). After 4 h, gas samples of 3 l were taken from the outlet of the chamber and collected at a flow rate of 50 ml min^{-1} onto carbonaceous traps

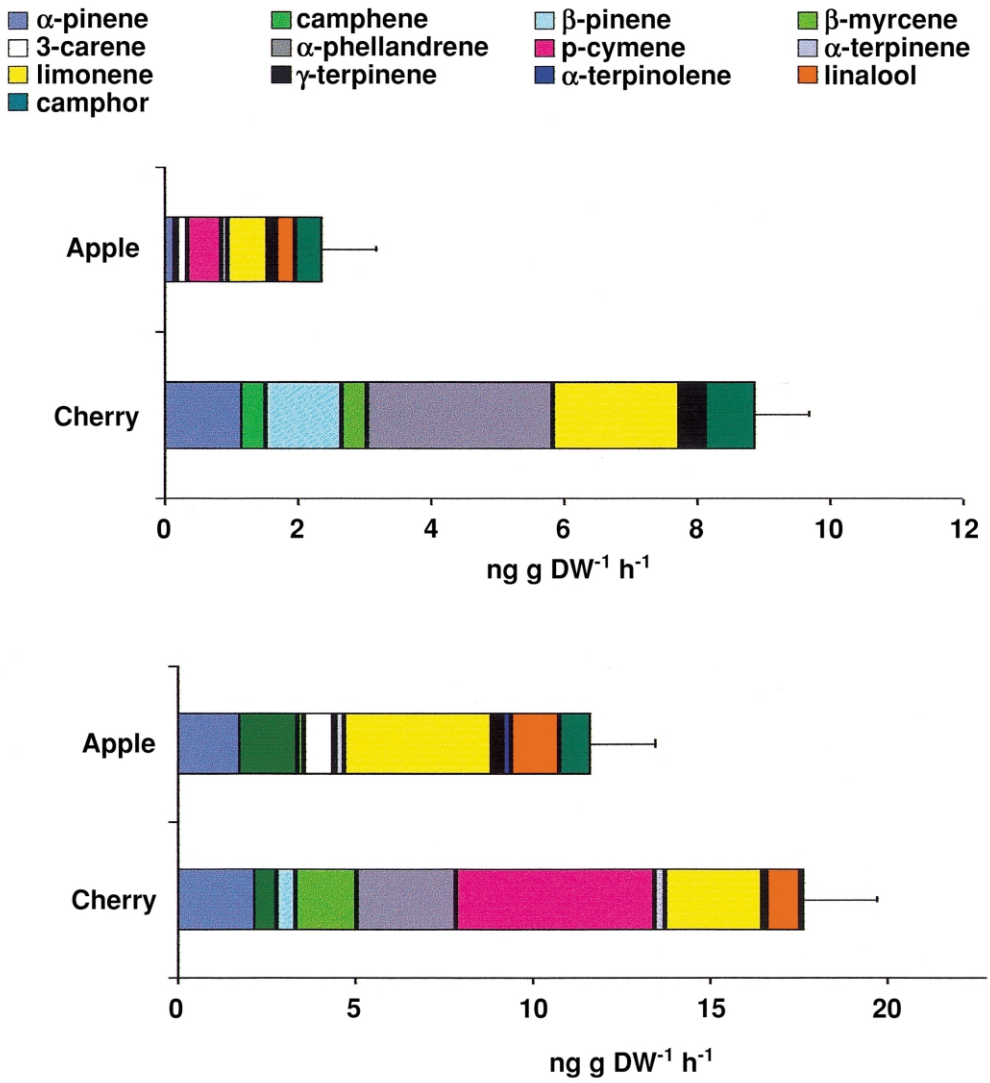

Fig. 3. Monoterpene emission rates given on a leaf dry weight basis of apple and cherry at fruit set (above) and ripening (below). The error bars note the standard deviation of the mean sum of the monoterpene emissions at PPFD = 800 μmol m^{-2} s^{-1}.

(Carbograph 1 and Carbograph 2, LARA, Rome, Italy) packed in glass tubes (Ciccioli et al., 1993). Two VOC samplings for each plant were taken simultaneously. The airflow rates were controlled with a mass-flow controller. The photon flux density in the photosynthetically active wavelength range was measured using a Li-Cor (NE, USA) 1800 spectroradiometer and the air temperature with copper constantan thermocouples (RS components, Vimodrone, Milan, Italy)

3.3. Biomass

In order to assess the biomass of the enclosed plants the dry weight of individual flowers and leaves was determined after drying the plant materials for 48 h at 70° C. The projected leaf area was determined using an image analysis method.

3.4. Analysis of volatiles and CO_2

The trapped compounds were thermodesorbed at 250°C and cryofocused at −150°C on a fused silica liner using a Thermal Desorption Cold Trap Injector (Chrompack, Middleburg, The Netherlands) connected to a Hewlett Packard 5890 gas chromatograph (GC) using a 5970 quadrupole mass spectrometer (MS) as detection system (Hewlett Packard, Palo Alto, CA, USA). The desorbed sample, enriched on the cryofocusing unit, was transferred to the capillary column (60 m × 0.25 mm I.D.; 0.25 μm film of polymethylsiloxane; HP-1, Hewlett Packard) by heating the fused silica liner to 230°C. The separation of terpenes was achieved maintaining the oven temperature at 40°C for 10 min and programming to 220°C at 5°C min^{-1}. Mass spectra and the reconstructed chromatogram were obtained by

automatically scanning in the mass range m/z from 20 to 200 a.m.u. Comparison of retention time and mass spectra of authentic standards achieved identification. Quantification of monoterpenes was performed after calculation of standard curves and response factors for each compound, and using d_{14}-cymene as internal standards (ISTD). The comparison of the response for the m/z 93 ion was generally used for quantification. Exceptions are reported in Table 1. The biogenic VOC emission rates were calculated by multiplying the concentration difference between chamber inlet and outlet air with the air flow through the chamber divided by the total biomass dry weight of the plant material (flowers or leaves).

Concurrently with the monoterpene emission measurements, CO_2 analyses were conducted using an infra-red gas analyzer (ADC 2250, Scientific Ltd Hoddesdon, Herts, UK) operating in a closed mode. The relationship between carbon loss due to monoterpene emissions and photosynthetically carbon uptake was then estimated.

Received 28 September 2000; received in revised form 14 February 2001

Abstract

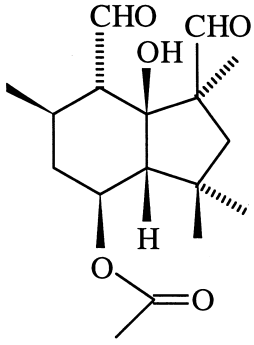
The fungal metabolite botrydial was detected for the first time in ripe fruits of sweet pepper (*Capsicum annuum*) wound-inoculated with conidial suspensions of *Botrytis cinerea* and also in leaves of *Phaseolus vulgaris* and *Arabidopsis thaliana* inoculated without wounding. This phytotoxin was produced in soft rot regions of the infection. In *C. annuum*, the most aggressive isolate produced the highest botrydial concentrations *in planta*. The levels of botrydial produced by this isolate did not correlate with the reported relative susceptibilities of four *P. vulgaris* genotypes. The results suggest that botrydial is a pathogenicity factor for this fungus, but not a primary determinant of pathogenicity. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Botrytis cinerea*; Fungal metabolites; Phytotoxicity; *Capsicum annuum*; *Phaseolus vulgaris*; *Arabidopsis thaliana*

1. Introduction

A number of factors have been suggested as the primary causes of lesion development in grey mould disease caused by *Botrytis cinerea*, a ubiquitous necrotrophic pathogen affecting more than 200 crops, especially the leaves, flowers and fruits of plants of horticultural importance (Coley-Smith et al., 1980). The pathogen secretes numerous enzymes and other low molecular weight compounds that have been implicated in pathogenicity. These include cutinases (van Kan et al., 1997), cell wall degrading enzymes (Leone and van den Heuvel, 1987; Johnston and Williamson, 1992; Elad and Evensen, 1995; ten Have et al., 1998), aspartic proteases (Movahedi and Heale, 1990), oxidative enzymes and oxalic acid involved in production of active oxygen species (Edlich et al., 1989; von Tiedemann, 1997; Deighton et al., 1999; Muckenschnabel et al., 2001).

The pathogen also produces a number of toxic bicyclic sesquiterpenes with the botrydial skeleton in static liquid culture (Collado et al., 1995, 1996; Rebordinos et al., 1996; Durán-Patrón et al., 1999, 2000). In bioassays with floating tobacco leaf disks and attached leaves, purified botrydial (**1**) applied to the adaxial leaf surface was phytotoxic (Rebordinos et al., 1996). However,



(1)

botrydial and these other metabolites have never been identified in plant tissues infected with isolates of *B. cinerea*. A greater understanding of the processes leading to disease onset and lesion expansion would be gained if this metabolite could be detected in infected whole plant tissues, at concentrations known to be phytotoxic in leaf disk assays (Rebordinos et al., 1996).

This paper describes experiments designed to determine whether botrydial has a role in pathogenicity of the grey mould pathogen. Sweet pepper (*Capsicum annuum*) fruits can be severely affected by the disease in glasshouse production and *B. cinerea* consistently produces

large spreading soft rot lesions in the pericarp of these fruits that are amenable to chemical analysis when inoculated with the pathogen (Deighton et al., 1999). Therefore peppers were inoculated with three different fungal isolates and analysed for botrydial. Analyses were also made from leaves of French bean (*Phaseolus vulgaris*) and *Arabidopsis thaliana* inoculated with a single aggressive isolate.

2. Results and discussion

All three isolates produced substantial soft rot lesions in *C. annuum* after wound inoculation, the largest lesions forming within 6 days in attached fruits inoculated with isolate B05.10. Botrydial (**1**) was detected in peppers, but its appearance and concentration was isolate-dependent and varied considerably between individual fruits (Table 1). A typical chromatogram from a soft rot lesion of a pepper inoculated with isolate B05.10 is shown in Fig. 1A, and that from a non-inoculated pepper in Fig. 1B. The internal standard (DNP-FBz) elutes at ca. 22 min (m/z 303), the 2,4- dinitrophenylhydrazone of botrydial (DNP_2-bot) elutes at ca. 26 min (m/z 669).

In attached leaves of *P. vulgaris* inoculated with the most aggressive *B. cinerea* isolate, B05.10, all leaves in the experiment became infected and botrydial was detected in all lesions (Table 1). In *A. thaliana*, the compound was detected in only three of the eight infected leaves examined and at lower levels than in the other two host tissues.

This is the first evidence that botrydial can be produced *in planta*. The fact that the same aggressive isolate released the compound in attached tissues of members of the Solanaceae, Leguminoseae and Brassicaeae grown under controlled conditions suggests that botrydial has some role in pathogenicity. However, although large soft rot lesions were always produced, the compound was detectable only in 50% of peppers inoculated with one isolate (B1.19), and was never detected in these experiments with another (B1.4). It is possible that botrydial was present in these samples, but at concentrations lower than the current detection limit (0.04 nmol g^{-1}).

Table 1
Occurrence of botrydial in tissues of *Capsicum annuum*, *Phaseolus vulgaris* and *Arabidopsis thaliana* infected by *Botrytis cinerea*

Host[a]	Genotype	Isolate	No. positive samples	Botrydial conc. (range nmol g^{-1})
Capsicum annuum	Bendigo	B05.10	7/7	0.44–12.0 **2.8**[b]
	Bendigo	B1.19	4/8[c]	0.080–0.34 **0.17**[b]
	Bendigo	B1.4	0/8[c]	nd
Phaseolus vulgaris	Huron	B05.10	18/18	7.6–260 **140**[b]
	164214	B05.10	9/9	0.23–18 **7.7**[b]
	N90598	B05.10	18/18	5.8–120 **38**[b]
	416664	B05.10	14/14	4.0–35 **11**[b]
Arabidopsis thaliana	CS2360	B05.10	3/8[c]	0.097–0.48 **0.28**[b]

[a] Four days post inoculation (*C. annuum, P. vulgaris*), 6 days (*A. thaliana*).

[b] Mean value in tissues where detected; nd, not detected.

[c] Limit of detection = 0.04 nmol g^{-1} (fresh weight), therefore botrydial may be present at < 0.04 nmol g^{-1}.

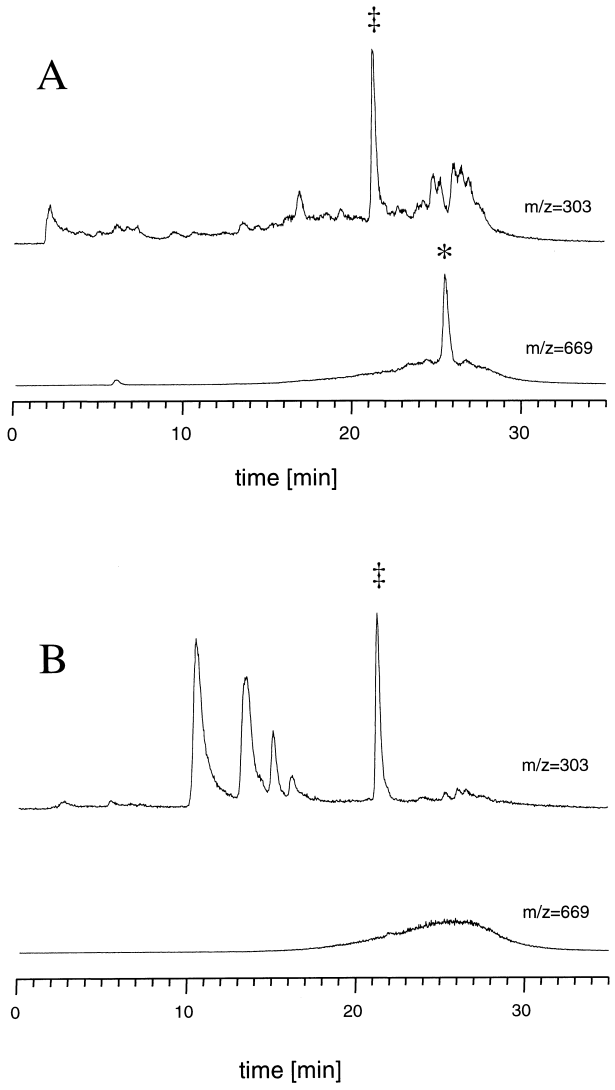

Fig. 1. Typical chromatograms from A: a soft rot lesion in the pericarp of a *Capsicum annuum* fruit inoculated with *Botrytis cinerea* isolate B05.10, and B: a non-inoculated control. Upper panels: m/z 303 ion trace. Lower panels: m/z 669 ion trace. Internal standard (DNP-FBz, ‡) elutes at ~22 min (m/z 303), botrydial derivative (DNP_2-bot, *) elutes at ~26 min (m/z 669).

These results suggest that isolates differ in their ability to produce substantial quantities of botrydial *in planta*.

Inoculation of four genotypes of *P. vulgaris* with the most aggressive *B. cinerea* isolate (B05.10) resulted in the accumulation of appreciably higher mean concentrations of botrydial than in *C. annuum*, the highest levels occurring in cv. Huron (140 nmol g^{-1}) and with very large differences between samples. There was no apparent relationship between botrydial concentration and lesion size, or the reported relative resistance of the genotypes to ozone toxicity — which in turn correlates with resistance to *B. cinerea* (von Tiedemann, 1997). In the case of the genotype Huron, botrydial was detected at concentrations 50-fold higher than those reported (Rebordinos et al., 1996) to be phytotoxic when tested in vitro on tobacco leaf disks (i.e. 1 ppm). Attempts to detect the compound at earlier stages in the infection may be difficult because of the sample size required for LC–MS. Another approach would be to take a series of samples across a leaf with a spreading soft rot lesions to indicate when production of the toxin begins in relation to appearance of lesions. Other compounds with the botryane skeleton may also be present in tissues, but the methodology applied in the present study is only applicable to aldehydic derivatives. Results therefore suggest that botrydial is associated with pathogenesis, but is not a primary determinant of the disease process.

3. Experimental

3.1. Plant material and methods of culture

Plants were grown from seeds in a standardised and quality controlled compost/sand mixture and given a minimum photoperiod of 14 h light at 20°C, with supplementary lighting provided by Hg-discharge lamps as described elsewhere (Muckenschnabel et al., 2001). Plants of *Capsicum annuum* cv. Bendigo were grown in the glasshouse to produce green fruits in excess of 10 cm in length and received no fungicide or insecticides. Seeds of *Phaseolus vulgaris* genotypes Huron (Kelly et al., 1994) and N90598 (from J.D. Kelly, Michigan State University, East Lansing, MI, USA) and 164214 and 416664 (from P.S. Benapal, Virginia State University, Petersburg, VA, USA) were grown under similar conditions to produce fully expanded primary leaves for inoculation. Seeds of *Arabidopsis thaliana* (CS2360 Wassilewskija, Ohio State University, Columbus, USA) were also grown under these conditions.

3.2. Fungal inoculum and inoculations.

Three isolates of the fungus *Botrytis cinerea* Pers.: Fr. [teleomorph *Botryotinia fuckeliana* (de Bary) Whetz.] were used in inoculations. Isolate B05.10 (Quidde et al., 1999), a haploid aggressive strain, was used on all plant hosts. Isolates B1.19 and B1.4 from *Vitis vinifera* were used only to inoculate pepper fruits. Conidial stock suspensions of all isolates remained viable in 75% glycerol at −80°C. Inoculum was obtained from 14-day-old cultures on potato dextrose agar containing an homogenate of leaves from *Phaseolus vulgaris* (50 g l^{-1} of media) and conidial suspensions at 1×10^5 conidia ml^{-1} were prepared as previously reported (Muckenschnabel et al., 2001).

In the glasshouse, attached pepper fruits were inoculated with 5 μl of the conidial suspension placed inside a tangential wound made by sterile scalpel in the proximal region. The adaxial surface of fully expanded leaves of *P. vulgaris* and *A. thaliana* (14 days old) were inoculated with two or one interveinal droplets (5 μl) of conidial suspension, respectively, and incubated in closed propagation boxes at high humidity for 4 days (*C. annuum*, and *P. vulgaris*) or 6 days (*A. thaliana*) as described by Muckenschnabel et al. (2001).

3.3. Sampling, extraction and analysis

The soft rotted areas of the fruit and leaves were excised, weighed and extracts prepared for LC–MS analyses. Briefly, leaf tissue (approx. 100 mg) was homogenised with methanol containing BHT (0.2 mM) as antioxidant (1 ml) in a MiniBead Beater (Biospec Products, Bartlesville, OK, USA) using a mixture of 0.5 g of 0.1 mm diameter and 0.5 g of 0.5 mm diameter glass beads. The methanolic extracts were then derivatised with 2,4-dinitrophenylhydrazine (35 mg 100 ml^{-1} in 1 M HCl) over a period of ca. 30 min at ca. 20°C. The dinitrophenylhydrazones (DNPHs) were extracted from the reaction mixture into dichloromethane (2×2 ml) and dried under nitrogen (40°C) in a Reacti-Therm heating module (Pierce, Rockford, IL, USA). These extracts were then made up in acetonitrile (200 μl) containing 1 μM of the DNPH-derivative of 4-fluorobenzaldehyde (DNP-FBz) as internal standard.

LC–MS analyses were carried out on a Finnigan MAT SSQ710C single quadrupole mass spectrometer with an APCI interface (ThermoQuest, Hemel Hempstead, UK) in negative ion mode with nitrogen as the reagent gas. The samples (5 μl) were eluted from a Hypersil C18 column (250×2 mm, Phenomenex, Macclesfield, UK) with a gradient from 60–90% acetonitrile in 40 mM ammonium acetate. Detection was by selected ion monitoring of the 2,4-dinitrophenylhydrazone derivatives of botrydial (DNP_2-bot, $[M\text{-}H]^-$ m/z 669) and 4-fluorobenzaldehyde (DNP-FBz, $[M\text{-}H]^-$ m/z 303). Alternate blank injections were made to ensure no carry-over from sample-to-sample. Quantification was made from a calibration curve (0.04–1250 nmol g^{-1} leaf tissue, fresh weight) prepared by injection of authentic standards (Collado et al., 1995, 1996) derivatised as above.

A second chromatographic system of different selectivity was used to ensure that the analyte from *B. cinerea*-inoculated hosts co-eluted with the authentic standard. A LUNA hexyl-phenyl (Phenomenex) column (150×2mm) was eluted with a linear gradient of 50–80% acetonitrile containing 40 mM ammonium acetate (25 min gradient, then 80% acetonitrile isocratic). With this chromatographic system, extracts from inoculated host plants gave rise to a peak (m/z 669) at approx. 28 min that co-eluted with that of DNPH-derivatised botrydial (results not shown).

Acknowledgements

This project was jointly funded by the European Union (FAIR project No. PL97-3351) and the Scottish Executive Rural Affairs Department (SERAD). We thank Professor P. Tudzynski (Münster University, Germany) for providing *B. cinerea* isolate B05.10 and Professor A. von Tiedemann (University of Rostock, Germany) for supplying isolates B1.19 and B1.4.

Abstract

Leaf-surface extracts prepared from 18 non-cultivated (wild) plant species, derived from the *Capparidaceae*, *Cruciferae*, *Resedaceae* and *Tropaeolaceae* were ranked for their ability to stimulate oviposition by the cabbage root fly, and analysed for glucosinolates. A total of 28 different glucosinolates were identified. A clear relationship was detected between the indolyl-, benzyl- and the total glucosinolate composition on the leaf surface and oviposition preference by cabbage root fly females. However, as the results are not fully explained by differences in leaf surface glucosinolates, other important oviposition deterrents and stimuli on the leaf surface of these wild crucifers must also be present. © 2001 Elsevier Science Ltd. Keywords: Leaf surface glucosinolates; *Capparidaceae*; *Cruciferae*; *Resedaceae*; *Tropaeolaceae*; Cabbage root fly; *Delia radicum*

1. Introduction

The glucosinolates are a diverse group of secondary plant products whose generalised structure is outlined in Fig. 1. These sulfur-containing compounds, over a hundred of which have been identified (Fenwick et al., 1989), have been isolated from members of at least eleven plant families, but are most commonly associated with the Cruciferae (Kjaer, 1974). These compounds, when consumed at high concentration, have been shown to have a deleterious effect on vertebrate animal performance and their effects on domesticated livestock have been frequently reviewed (Fenwick et al., 1989; Duncan, 1991; Griffiths et al., 1998). However, the consumption of brassicas has also been linked with reduced risk of cancers and this protective role has been associated with the ability of the enzyme mediated breakdown products of glucosinolates to activate protective mechanisms within the body (Heaney and Fenwick, 1995).

The ecological role(s) of glucosinolates within the plant has not been fully elucidated although their presence has been linked to plant defence mechanisms against bacteria and fungi as well as acting as deterrents to non-adapted herbivores (Chew, 1988; Louda and Mole, 1991).

In crucifer-adapted insect species, such as the cabbage (*Delia radicum)* and turnip (*D. floralis*) root flies, glucosinolates on the leaf surface (phylloplane) of host plants are important as egg laying (oviposition) stimulants. Female flies orientate towards patches of cruciferous plants following upwind odours but the key step in host acceptance or rejection for oviposition takes place after landing on the plant. Recent research has shown that plant odour apparently may play some additional role in host selection after landing (De Jong and Städler, 1999). But more importantly, on the leaf surface the female fly perceives very low concentrations of specific glucosinolates and other polar plant compounds, which trigger the post-landing behavioural sequence resulting in oviposition (Roessingh et al., 1992; Simmonds et al., 1994; Baur et al., 1996; Hopkins et al., 1997, 1999). This normally occurs in the soil at the base of the chosen plant. These insects detect chemical oviposition stimuli by the activation of chemoreceptor neurons in sensilla on the ventral side of their tarsi (Roessingh et al., 1992) and on the proboscis (Simmonds et al., 1994).

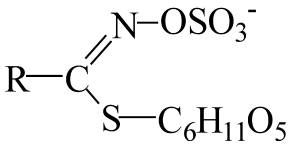

Fig. 1. Generalised glucosinolate structure.

Both field and glasshouse studies aimed at investigating the susceptibility of wild crucifers to the cabbage root fly (*D. radicum*) have indicated that several such species appear not to stimulate egg laying and do not support larval development (Finch and Ackley, 1977; Finch, 1978). Such crucifer species may therefore represent potential sources of host plant resistance to root flies, which is absent from most cultivated brassicas (Birch, 1988, 1989).

Although limited data is available on the glucosinolate composition of seeds (Kjaer, 1960; Horn and Vaughan, 1983; Daxenbichler et al., 1991) and foliage (Kjaer, 1960; Cole, 1976; Finch, 1978; Mithen et al., 1987) of wild crucifers and other closely related species, there appears to be no data regarding either the identification or quantification of glucosinolates on their leaf surfaces. Indeed, many of the earlier surveys of plant glucosinolate composition have been based on analysis of their enzymatically-derived breakdown products. Consequently these earlier studies were unable to distinguish between the various possible indolyl-based glucosinolates that are commonly present in both crucifer seeds and foliage and have been demonstrated to have an active role in some plant-insect interactions (Roessingh et al., 1992; Städler et al., 1995).

It has also been reported that the glucosinolates present in the seed and vegetative tissues may vary independently of each other (Rosa et al., 1997), with for example, the glucosinolates present in the foliage of double-low and single-low oilseed rape cultivars being similar despite the fact that those in the seed differ significantly between the two types. Similarly, foliar glucosinolate levels can vary with the developmental stage of the plant and may also be altered in response to environmental conditions (reviewed by Rosa et al., 1997). Glucosinolates on the surface of crucifer leaves have been reported to be qualitatively similar to those extracted from within the leaf, but the relative proportions of individual glucosinolates found on the phylloplane may differ from that of the leaf interior (Roessingh et al., 1992). Consequently, when evaluating the biological activity it would appear essential to both analyse and bioassay extracts simultaneously prepared from the same plants, thus ensuring that any differences seen in either insect behaviour or leaf surface chemistry can be meaningfully correlated.

The host plant preference of the cabbage root fly and other insects ovipositing on undamaged leaves of crucifers can only be understood if the leaf surface chemistry is analysed. Thus, the objective of this study was to identify and quantify the glucosinolates present in the leaf surface extracts of a range of Crucifers and other closely related plant species, which have also been ranked in order of their oviposition preference for cabbage root fly. This was performed using recently developed liquid chromatography–atmospheric pressure chemical ionisation–mass spectrometric (LC–APCI–MS) techniques for desulfo-glucosinolates (Ishida et al., 1997; Griffiths et al., 2000).

2. Results and discussion

2.1. Selection of plant material

Eighteen plant species from the Cruciferae (see Table 2) were selected on the basis of earlier published work (Finch and Ackley, 1977; Hardman and Ellis; 1978), which used development of *D. radicum* pupae after field and glasshouse exposure to egg laying females as a measure of host suitability providing a range of susceptibility to this pest. Leaf surface extracts were prepared from these 18 cruciferous plant species and sprayed onto surrogate waxed paper leaves in an oviposition choice bioasssay, as previously described (Roessingh et al., 1992; Baur et al., 1996). The percentage of the total (all plants in bioassay) eggs laid on each individual crucifer species was determined and used to rank the plants in order of increasing oviposition preference (Fig. 2).

2.2. Total glucosinolates

A total of 28 different glucosinolates (Table 1) were identified in the leaf surface extracts of the 18 plant species studied (Table 2, Fig. 2). Glucosinolates were detected on the leaf surfaces of all the species studied with the sole exception of *Capsella bursa-pastoris*. The concentration of total glucosinolates present on the leaf surfaces, expressed as μmoles/gram leaf equivalent (μmol/gle) ranged from 0.12 to 3.08 μmol/gle in *Isatis tinctoria* and *Lepidium sativum* respectively. These values were generally of the same order of magnitude as those previously reported for similarly prepared extracts from commercially available kale (0.07 μmol/gle) and swede (0.14 μmol/gle) cultivars (Hopkins et al., 1997). The absence of any detectable glucosinolates on the leaf surface of *Capsella bursa-pastoris* plants would appear to be somewhat anomalous, since earlier studies on the autolysis products released by whole plant extracts prepared from this species suggested the presence of sinigrin (prop-2-enyl glucosinolate) in the plant material (Cole, 1976). Similar studies also demonstrated the presence of sinigrin in the seeds of this species (Kjaer, 1960) whilst a more recent report concluded that *Capsella bursa-pastoris* seed contained high concentrations of methylsulfinylnonyl

[a] a = Identity based on interpretation of mass spectrum; b = identity confirmed by both retention time and comparison of mass spectrum with either synthesised or isolated desulfoglucosinolates from other plant sources (see Griffiths et al., 2000).
[b] Mass spectral data insufficient to distinguish between these two possibilities.

and methylsulfinyldecyl glucosinolates (Daxenbichler et al., 1991). However, the fact that, under field conditions, this species does not attract the cabbage root fly to lay eggs (Finch and Ackley, 1977) would appear to be consistent with the absence of leaf surface glucosinolates. Clearly more detailed studies are required to confirm the veracity of these findings and to evaluate the effects of environment, stage of plant development and within-species variation on leaf surface glucosinolate concentration.

2.3. Aliphatic glucosinolates

Aliphatic glucosinolates were detected on the leaf surfaces of all but four of the plant species studied (Table 2, Fig. 2). In many species these glucosinolates predominated with for example methyl, isopropyl and 1-methylpropyl glucosinolates accounting for 97, 65 and 82% of the total leaf surface glucosinolates in *Cleome spinosa, Sisymbrium officinale* and *Cochlearia officinalis*

Table 2
Individual glucosinolates detected on the leaf surface of plants from the Cruciferae and other closely related species

[a] All members of the Cruciferae except *Cleome spinosa* Jacq. (Capparidaceae), *Reseda luteola* L. (Resedeceae) and *Tropaeolum majus* L. (Tropaeolaceae).
[b] Abbreviated names as in Table 1.

respectively. Similarly, the only glucosinolate detected on the leaf surface of *Thlaspi arvense* was sinigrin.

Glucosinolates containing hydroxyalkene sidechains, namely progoitrin and napoliferin, were restricted to *Brassica napus napus* and *B. rapa silvestris* whilst leaf surface extracts from both *Cochlearia officinalis* and *Reseda luteola* appeared to contain a hydroxyalkane glucosinolate. Based on the presence of the diagnostic ions corresponding to $[M+H]^+$ and $[M+H\text{-}162]^+$ (Ishida et al., 1997; Griffiths et al., 2000) in the mass spectra of its desulfo analogue, this was identified as having an empirical formula equivalent to a hydroxybutyl glucosinolate. Previous studies on the seed of *Cochlearia officinalis* (Kjaer, 1960) have reported the presence of glucoconringiin (2-hydroxy-2-methylpropyl glucosinolate) which would be consistent with the empirical formulae found in the mass spectra of the leaf surface extracts. APCI mass spectra of desulfo-glucosinolates give little information regarding the exact structural nature of the glucosinolate side chain. Consequently, the possibility that this compound may be an alternative structural isomer such as glucosisautricin (2-hydroxy-1-ethylethylglucosinolate) which has also been found in the seeds of other wild crucifers (Daxenbichler et al., 1991) cannot be totally eliminated.

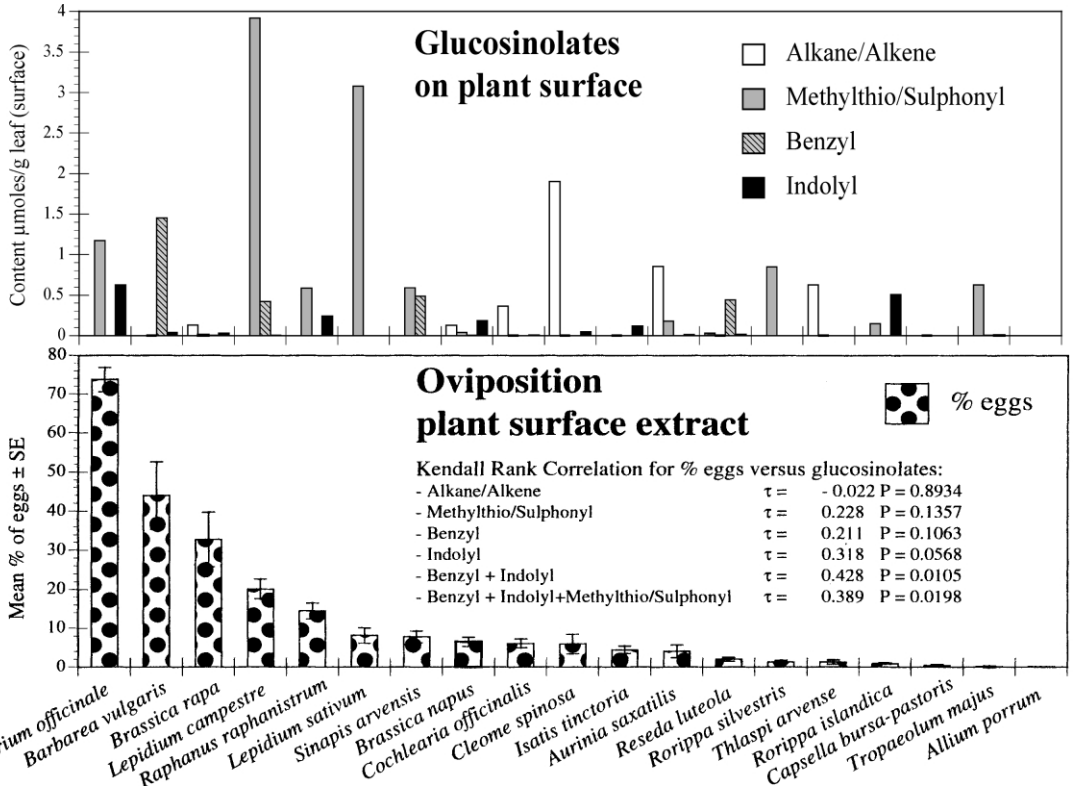

Fig. 2. The oviposition preference and glucosinolate content of leaf surface extracts prepared from a range of Cruciferae and other closely related species.

Sulfur-containing aliphatic glucosinolates were particularly common constituents of the leaf surface extracts with examples of methylthio, methylsulfinyl and methyl sulfonyl glucosinolates all being detected (Table 2). The identity of the 7-methylsulfinylheptyl, 8-methylsulfinyloctyl and 9-methylsulfinylnonyl glucosinolates in *Rorippa islandica* and *Rorippa silvestris* were based on the comparison of the mass spectra of their desulfo analogues with previously published spectra of their lower homologues (Griffiths et al., 2000). In each case, as for the lower homologues, the spectra contained, in addition to the expected ions corresponding to $[M+H]^+$ and $[M+H\text{-}162]^+$ a high intensity ion fragment with an empirical formulae equivalent to $[RCNOH]^+$. These high molecular weight methylsulfinyl glucosinolates have also been demonstrated as being the major constituents of the seed of both plant species (Daxenbichler et al., 1991).

Two methylsulfonyl containing glucosinolates, namely 8-methylsulfonyloctyl and 9-methylsulfonylnonyl glucosinolate, were detected in surface extracts from *Sinapis arvensis* and have been previously reported as major constituents of the seed of this species (Daxenbichler et al., 1991). Their identification was based on interpretation of the mass spectra of their respective desulfoglucosinolates. The mass spectra derived from both compounds contained ions with m/z values with empirical formulae weights corresponding with, and tentatively identified as: $[M+H]^+$; $[M+H\text{-}162]^+$; $[RNOH+H]^+$ (base peak) and $[ROH]^+$, all of which have been previously seen in spectra of other sulfur containing desulfo-glucosinolates (Griffiths et al., 2000). Additionally both spectra contained a fragment corresponding to $[M+H\text{-}155]^+$. This loss of neutral fragments totalling 155 mass units is difficult to reconcile, although on a purely mathematical basis, could arise by the loss of the following neutral molecules: SO_2, CH_4, HNCO and S. However, for such eliminations to occur considerable intra-molecular rearrangements would be required to produce the resultant stable fragment observed in the mass spectra of both methylsulfonyl glucosinolates.

2.4. Aromatic glucosinolates

Four aromatic glucosinolates, glucotropaeolin (benzyl glucosinolate), sinalbin (*p*-hydroxybenzyl glucosinolate) gluconasturtiin (2-phenylethyl glucosinolate) and glucobarbarin (2-hydroxy-2-phenylethyl glucosinolate), were detected. Glucobarbarin was identified as the major component on the leaf surfaces of *Barbarea vulgaris* and *Reseda luteola* and in both cases accounted for over 90% of the total leaf surface glucosinolates. This compound has been previously reported as the predominant seed glucosinolate in both these plant species (Daxenbichler et

al., 1991; Andersson et al., 1999). The mass spectrum of desulfo-glucobarbarin contained ions corresponding to $[M+H]^+$, $[M+H\text{-}18]^+$, and $[M+H\text{-}162]^+$, the last two corresponding to the loss of water and glucose respectively from the parent ion. Surprisingly, as with the methylsulfonyl-desulfoglucosinolates, the spectra from both plant sources also contained a major fragment ion equivalent to $[M+H\text{-}155]^+$. This could have arisen by the loss of C_6H_6, HNCO and H_2S but again highly complex intra-molecular rearrangements would be required.

Glucotropaeolin was the only glucosinolate detected on the leaf surface of *Lepidium sativum* plants and accounted for 99% of the leaf surface glucosinolates of *Tropaeolum majus*. Sinalbin accounted for 73% and 45% of the leaf surface glucosinolates of *Lepidium campestre* and *Sinapis arvensis* plants respectively and was also detected in quantifiable amounts on the leaves of *Tropaeolum majus*. Although gluconasturtiin was detected in three plant species (Table 2), the levels found were low and accounted in each case for less than 2% of the total leaf glucosinolates.

2.5. Indolyl glucosinolates

Indolyl containing glucosinolates were detected on the leaf surfaces of all but three of the plant species studied (Table 2, Fig. 2). The most common such glucosinolate was glucobrassicin (3-indolylmethyl glucosinolate) which was identified in extracts from eleven species and accounted for over 77% of the glucosinolates detected on the leaf surface of *Isatis tinctoria* and *Rorippa islandica* plants (Table 2). In comparison the relative concentrations of the other indolyl containing glucosinolates (4-hydroxy-, 4-methoxy- and 1-methoxy-3-indolylmethyl glucosinolates) were low, although 1-methoxy-3-indolylmethyl glucosinolate accounted for almost 20% of the total glucosinolates detected on the leaf surface of *Brassica napus* var. *napus* plants. All the indolyl glucosinolates detected have previously been reported as common constituents of cultivated brassicas (Griffiths et al., 1998).

2.6. Glucosinolate content and oviposition preference

The 18 species studied are shown in Fig. 2 in order of oviposition preference to cabbage root fly. These relative rankings were correlated with the presence or relative concentration of some, but not all, groups of glucosinolates (see Fig. 2 for significant correlations).

Significant rank correlations to the oviposition preference were found for the combined indolyl and benzyl groups and indolyl, benzyl and the sulphur-containing glucosinolate groups. This is in accordance with the findings by Roessingh et al., (1992), who found that the indolyl glucosinolate glucobrassicin and the benzyl glucosinolates glucotropaeolin and gluconasturtiin belong to compounds with the lowest threshold of activity (most stimulatory) both in the oviposition behaviour and the glucosinolate receptor neurons in the tarsal D sensilla.

But since none of the correlations were very high, this suggests that other leaf surface factors may also be responsible for the lower or higher than expected acceptability of some wild crucifers to cabbage root fly. Recently, three compounds, possibly structurally related to the brassica phytoalexins, have been isolated from cabbage leaf surface extracts and identified as potent stimulators of oviposition in cabbage root fly (Hurter et al., 1999; De Jong et al., 2000). It has been suggested that these may also be of importance in oviposition stimulation (Baur et al., 1996; Roessingh et al., 1997).

Additionally, there could be other groups of compounds present in wild crucifers that have additional positive or negative effects on the cabbage root fly's acceptance of a plant for oviposition. Indeed, some extracts have proven to inhibit the stimulation by glucosinolates (Städler et al., unpubl. results). Compounds such as the waxes, also present on the leaf surface, may affect the insect's ability to detect polar compounds already identified as oviposition stimulants (Roessingh and Städler, 1990; Spencer et al., 1999).

3. Experimental

3.1. Plant material

The seed of the plant species studied (see Table 2) were obtained from J.A.A. Renwick, Boyce Thompson Institute, Ithaca (*Aurinia saxatilis* and *Cleome spinosa*); Botanical Garden, University of Hohenheim (*Sisymbrium officinale*); Swiss Federal Research Station, Reckenholz (*Brassica napus* var. *napus* cv. Eurol, *B. rapa* var. *silvestris* cv. Hanko) and from the Botanical Garden of Zürich (all other species). The seeds were sown in mid April into compost and grown for three weeks in a glasshouse, transferred to a cold frame for acclimatisation, and then transplanted into soil. The plants were then grown under field conditions and leaf material harvested in July, prior to the onset of flowering.

3.2. Leaf surface extracts

The fresh leaf material was extracted using the method described by Städler and Roessingh (1991). After weighing, the leaves were dipped for 7–10 s into dichloromethane to remove the non-polar waxes and subsequently dipped twice for 5 s periods into methanol. The methanol fraction was filtered and evaporated under vacuum to produce a final solution containing the equivalent of between 1 and 5 g of plant material per ml of methanol (1–5gle/ml). All results are expressed in terms of gle (i.e. the

amount of a given substance extracted from the surface of 1 g of leaf material).

3.3. Oviposition bioassay

Oviposition preference tests were performed using *D. radicum* and surrogate leaves treated with leaf surface extracts of the selected wild crucifers, as previously described by Roessingh et al., (1992). In each assay about 100 female flies were given a choice of the leaf surface extracts and a methanol-treated control. The choice preference assays were performed in three partially overlapping sets of extracts and each set replicated at least 7 times, with the position of each treatment being re-randomised within the cages for each replicate. *Brassica oleracea* var "CC-Cross" was tested at two concentrations, 1 and 0.1 gle and included as a standard in all 3 sets. All the other extracts were applied at only one concentration of 1 gle. In all the three sets of extracts bioassayed, preferred, poor host plants and a non-host plant (*Allium porrum*) were included. This procedure resulted in 7–25 individual egg counts per plant species. The results (% on each treatment, of the total number of eggs laid in each assay) were averaged and the mean percent oviposition was correlated to the glucosinolate contents (μmoles / gle) using Kendall Rank Correlation statistical test (corrected for ties).

3.4. High performance liquid chromatography

The desulfo-glucosinolates were prepared using the on-column enzymatic desulfonation method of Heaney and Fenwick (1980). The resulting desulfo-glucosinolates were then separated and quantified by a reverse phase high performance liquid chromatographic method based on that of Spinks et al. (1984).

3.5. Liquid chromatography–mass spectrometry

Liquid chromatography–mass spectrometry was performed using a Finnigan MAT SSQ 710C single quadrupole instrument with an atmospheric pressure-chemical ionisation (APCI) interface (Thermo Quest, Hemel Hempstead, UK). The instrument was configured for positive chemical ionisation. Full details of instrument conditions and the gradients used have previously been published (Griffiths et al., 2000).

Received 11 February 2000; received in revised form 28 December 2000

Abstract

To investigate the antioxidant responses of radish (*Raphanus sativus* L.) to cadmium (Cd) treatment, seedlings of a tolerant variety were grown in increasing concentrations of $CdCl_2$, ranging from 0.25–1 mM, for up to 72 h in a hydroponic system. Analysis of Cd uptake indicated that most of the Cd accumulated in the roots, but some was also translocated and accumulated in the leaves, especially at the higher concentrations of Cd used in the experiments. Roots and leaves were analysed for catalase, glutathione reductase and superoxide dismutase activities. Catalase and glutathione reductase activities increased considerably in the roots and leaves after 24 h exposure to the metal, indicating a direct correlation with Cd accumulation. The analysis of native PAGE enzyme activity staining, revealed several superoxide dismutase isoenzymes in leaves, with the two predominant isoenzymes exhibiting increases in activity in response to Cd treatment. The results suggest that in radish, the activity of antioxidant enzymes responds to Cd treatment. The main response may be via the activation of the ascorbate–glutathione cycle for the removal of hydrogen peroxide, or to ensure the availability of glutathione for the synthesis of Cd-binding proteins. © 2001 Elsevier Science Ltd. 1. Introduction

Cadmium (Cd) is a toxic element that normally occurs in low concentrations in soils (Wagner, 1993). However, in areas that have been subjected to mining the concentration can be high, varying from 100–600 mg kg^{-1} dry weight (Ernst and Neilssen, 2000; Lombi et al., 2000). In addition, following the application of sewage sludge to agricultural land, Cd can accumulate in the topsoil (Lombi et al., 2000). Although Cd is not an essential nutrient for plants, the metal ion is taken up rapidly by the roots (Leita et al., 1991; Hart et al., 1998) and on most occasions causes inhibition of growth (Di Toppi et al., 1999; Sneller et al., 1999). However, a number of plants (termed hyperaccumulators) that grow on metalliferous soils, are able to translocate Cd from the roots and accumulate it in high concentrations in the shoots (Chardonnens et al., 1998). It has been suggested that such plants would be of considerable value in the remediation of soils that are heavily contaminated with heavy metals (Zhu et al., 1999).

Cd may be detoxified in plants by combination with a family of sulphur rich peptides termed phytochelatins (Leopold et al., 1999; Cobbett, 2000). The peptides are structurally related to glutathione and contain a varying number (normally 2–5) of glutamate and cysteine, linked through the γ-carboxyl group of glutamate. Synthesis of these phytochelatins can be induced very rapidly in tissue culture cells and roots, and is accompanied by a fall in the concentration of glutathione, following the addition of Cd or other heavy metals (Grill et al., 1987). Glutathione synthesis may then be stimulated by induction of enzymes involved in sulphate uptake and reduction and γ-glutamylcysteine synthetase (Haag-Kerwer et al., 1999; Heiss et al., 1999). Phytochelatin synthase which carried out the conversion of glutathione to phytochelatins is activated by Cd, but is inactive in the absence of heavy metal ions (Cobbett, 2000).

Proof that phytochelatins are synthesised from glutathione has come from an investigation into enzyme deficient mutants and overexpressing plant lines. *cad2* mutants of Arabidopsis lacking γ-glutamylcysteine

synthetase are sensitive to Cd and are unable to synthesise glutathione, whilst the *cad1* mutants lacking phytochelatin synthase are sensitive to Cd and accumulate glutathione (Howden et al., 1995; Cobbett et al., 1998). Overexpression of both γ-glutamylcysteine synthetase and glutathione synthetase in Indian mustard has been shown to increase phytochelatin synthesis and confer resistance to Cd (Yong et al., 1999; Zhu et al., 1999).

Van Assche and Clijsters (1990) have reviewed in detail the early work showing that Cd has the capacity to inhibit a range of enzyme activities in plants, in particular those of the Calvin cycle and chlorophyll biosynthesis. Research into the effects of Cd on photosynthetic CO_2 assimilation has continued (Krupa, 1999), with evidence presented that the enzymes of the Calvin cycle and RUBP carboxylase/oxygenase are particularly sensitive to Cd (Chugh and Sawhney, 1999; Di Cagno et al., 1999).

Evidence that Cd causes the production of reactive oxygen species (ROS) (Foyer et al., 1997) in plants, came from observation that new isoenzymes of peroxidase were detectable in both the root and leaves of *Phaseolus vulgaris* (Van Assche and Clijsters, 1990). Further evidence of Cd induced oxidative stress came from the detection of lipid peroxidation and chlorophyll breakdown (Somashekaraiah et al., 1992; Gallego et al., 1996a; Chaoui et al., 1997; Dalurzo et al., 1997). Due to the multiplicity of processes that produce ROS during metabolism, including photosynthesis and photorespiration, fatty acid oxidation, response to pathogen attack and senescence, plants have developed a series of detoxification reactions. Peroxide can be metabolised directly by peroxidases, particularly in the cell wall, and by catalase (CAT) in the peroxisome (Azevedo et al., 1998; Polidoros and Scandalios, 1999). In the chloroplast, superoxide is converted by superoxide dismutase (SOD) to peroxide which is then detoxified to water and oxygen via the glutathione/ascorbate cycle, which involves the operation of ascorbate peroxidase, monohydroascorbate reductase/dehydroascorbate reductase and glutathione reductase (GR) (Foyer et al., 1997; Noctor and Foyer, 1998). Three distinct types of SOD activity have been detected in plants, which can be classified according to their metal cofactor, Mn, Fe and Cu/Zn. Mn–SOD is located in the mitochondria and peroxisomes, Fe–SOD (which is not found in all plants) is associated with the chloroplasts and the abundant Cu/Zn SODs are located in the cytosol, chloroplasts and peroxisomes (Bowler et al., 1992; Del Rio et al., 1998). The occurrence of SOD activity in such a wide range of metabolic compartments suggests that enzymes of the glutathione/ascorbate cycle, as well as peroxidases, may also play an important role outside the chloroplast. The synthesis of oxalate oxidase, that is present in the cytoplasm and apoplast of germinating wheat embryos and liberates peroxide, is stimulated by the presence of Cd (Berna and Bernier, 1999).

Given the above cited mechanisms utilised by plants to detoxify ROS, it is clearly important to establish whether exposing plants to Cd causes a detrimental or stimulatory effect on the enzymes involved in this detoxification process. Somewhat surprisingly, the limited number of experiments that have been carried out on the subject have frequently produced contradictory results. CAT activity has been shown to decline in *Phaseolus vulgaris* (Somashekariah et al., 1992), *Phaseolus aureus* (Shaw, 1995), *Pisum sativum* (Dalurzo et al., 1997), *Lemna minor* (Mohan and Hossetti, 1997) and *Amaranthus lividus* (Bhattacharjee, 1998), following the application of Cd to the growth medium. However in *Phaseolus vulgaris*, although decreases in CAT activity were detected in roots and leaves, there was no effect on the stem enzyme (Chaoui et al., 1997), and in *Agropyron repens* increases in CAT activity were detected in both leaves and stems (Brej, 1998). In *Helianthus annuus* (Gallego et al., 1996b, 1999) considerable variation in CAT activity was detected over a time period up to 22 days with similar variations being also detected in tolerant varieties of *Solanum tuberosum* (Stroinski and Kozlowska, 1997).

GR activity in *S. tuberosum* increased following the application of Cd, but this was followed by a rapid and total inactivation and then a slow recovery (Stroinski et al., 1999). In two species of *Alyssum,* GR activity increased at 0.02 mM Cd but decreased at 0.05 mM Cd (Schickler and Caspi, 1999). Increases in GR activity were observed in the leaves of *Phaseolus vulgaris* (Chaoui et al., 1997), but decreases had been noted previously in germinating seedlings of the same species (Somashekariah et al., 1992). Decreases in GR activity following the application of Cd, were detected in a series of experiments employing *H. annuus* (Gallego et al., 1996a,b, 1999). Increases in total SOD activity were detected following the application of Cd in *P. sativum* (Dalurzo et al., 1997) and two *Alyssum* species (Schickler and Caspi, 1999), along with a decrease and then an increase in SOD activity in *S. tuberosum* (Stroinski and Kozlowska, 1997). SOD activity remained constant or decreased in *H. annuus* (Gallego et al., 1996a, 1999) and declined in *A. lividus* (Bhattacharjee, 1998), following the application of Cd. As far as we are aware no attempt has been made to examine the effect of Cd on the different isoenzymes of SOD in higher plants.

In this work, we report new findings showing that the activities of all three enzymes (CAT, GR and specific isoenzymes of SOD) increased in the leaves and roots of a resistant variety of radish, following exposure to increasing concentrations of Cd. Although the concentrations of Cd used (0.25 and 1 mM) are high when compared to that found in contaminated soils, they have been used recently in testes on species of *Thlaspi* that are able to accumulate high concentrations of Cd (Lombi et al., 2000).

2. Results

2.1. $CdCl_2$ effect on plant growth

Four commercial varieties of radish were grown in the presence of increasing concentrations of $CdCl_2$ concentrations for a 7 day period in Hoagland's nutrient solution. All radish varieties exhibited reduced length in the $CdCl_2$ treatments based on root growth (Fig. 1). The variety Comprido Vermelho was more sensitive to $CdCl_2$, showing some reduction in growth at 0.012 mM. At low concentration of $CdCl_2$, the inhibition of root growth was very similar for Redondo Vermelho, Scarlett Globe and Grinson Gigante (Fig. 1). However, at concentrations higher than 0.5 mM, the variety Redondo Vermelho exhibited a greater degree of tolerance to $CdCl_2$ (Fig. 2). For the other varieties, 0.5, 1 and 5 mM $CdCl_2$ proved to be lethal after 4 days of Cd treatment. The variety Redondo Vermelho was chosen for further analysis.

2.2. Cd accumulation in roots and leaves

The accumulation of Cd in Redondo Vermelho was determined in the roots and leaves after growth in 0.5 and 1 mM $CdCl_2$ for 72 h (Fig. 3). Most of the Cd that entered the plant system accumulated in the roots and only a small amount was translocated to the leaves. Furthermore, it can be seen that Cd entered the roots very rapidly, with approximately 50% of the Cd being taken up within the first 12 h of growth in the presence of the metal.

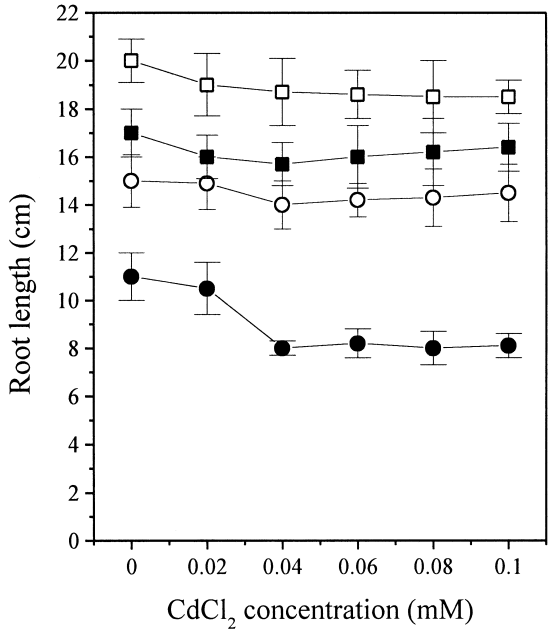

Fig. 1. Root length of four radish varieties (● Comprido Vermelho, ○ Redondo Vermelho, ■ Scarlett Globe, □ Grinson Gigante) grown in 0.02, 0.04, 0.06, 0.08 and 0.1 mM $CdCl_2$, for 7 days.

2.3. CAT activity

The specific activity of CAT expressed on a protein basis, was 2-fold higher in the leaves of the control plants, than in the roots. The CAT activity in the control plants was also shown to be very constant during the time-length of the experiment (Fig. 4). $CdCl_2$ induced an increase in CAT activity in both the roots and leaves of radish plants. A direct correlation was observed between Cd concentration and increased CAT activity in both tissues, so that higher concentrations of $CdCl_2$ produced a greater increase in CAT activity (Fig. 4). The percentage increase in CAT activity was higher in the roots than in leaves, especially at 1 mM $CdCl_2$ (Fig. 4). When $CdCl_2$ was tested on CAT activity determined by the spectrophotometric assay, no alteration in enzyme activity was observed, suggesting that $CdCl_2$ has no effect on CAT activity in vitro.

Extracts of leaves and roots treated with 0.5 mM $CdCl_2$ were applied to native PAGE gels and stained for CAT activity (Fig. 5). CAT activity staining revealed two major CAT isoenzymes in leaves (Fig. 5A), however some other minor bands were also observed in a few experiments, when much higher concentrations of protein were loaded onto the gels (data not shown). On the other hand, following electrophoresis of root extracts, one single diffuse band of CAT activity was observed (Fig. 5B), the position of which corresponded to the more electronegative band detected with leaf extracts (Fig. 5A). It can be seen in leaves exposed to 0.5 mM $CdCl_2$, that both CAT bands exhibited a major increase in activity over the 72 h time course, especially the most electropositive band (Fig. 5A). In roots, only a small increase in CAT activity was detected, after 48 h treatment with $CdCl_2$ (Fig. 5B).

Fig. 2. Radish (cv. Redondo Vermelho) seedlings grown for 7 days in 0 (A), 0.006 (B), 0.012 (C), 0.025 (D), 0.05 (E), 0.1 (F), 0.5 (G), 1.0 (H) and 5.0 (I) mM $CdCl_2$.

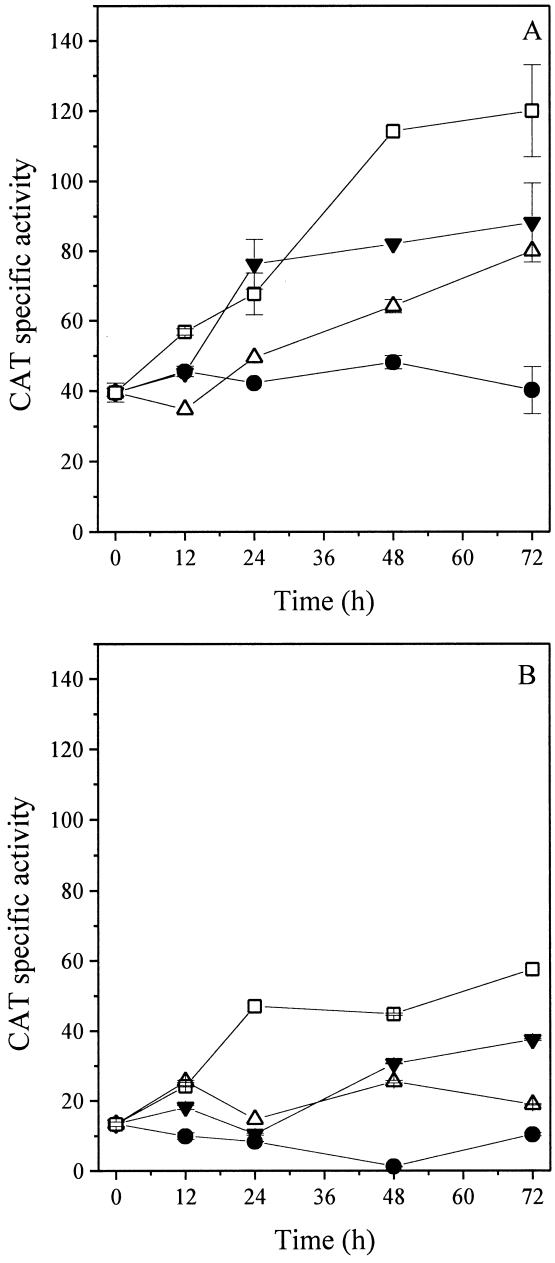

Fig. 4. The specific activity of CAT (μmol min^{-1} mg^{-1} prot) in the leaves (A) and roots (B) of radish (cv. Redondo Vermelho) seedlings grown for a 72 h period in four concentrations of $CdCl_2$. Control zero (●), 0.25 mM (△), 0.5 mM (▼) and 1.0 mM (□).

2.4. SOD activity

The same plant extracts used for CAT were also stained for SOD activity following native PAGE (Fig. 6). Several bands of SOD activity were observed in some experiments, depending on the protein concentration used in the gel. However, two major SOD bands, corresponding to ~95% of total SOD activity were observed in leaves (Fig. 6A), but only one band was present following the electrophoresis of root extracts (Fig. 6B). Both of the leaf SOD bands exhibited a continuous increase in activity after 24 h exposure to $CdCl_2$ (Fig. 6A), whereas in roots there was no significant variation in SOD activity (Fig. 6B). The incubation of gels in hydrogen peroxide and potassium cyanide was carried out to classify all the SOD isoenzymes observed in radish leaves. Two Fe–SOD (resistant to cyanide and inhibited by hydrogen peroxide) and four Cu/Zn–SOD (inactivated by both inhibitors) isoenzymes were identified, while Mn–SOD isoenzymes were not observed (data not

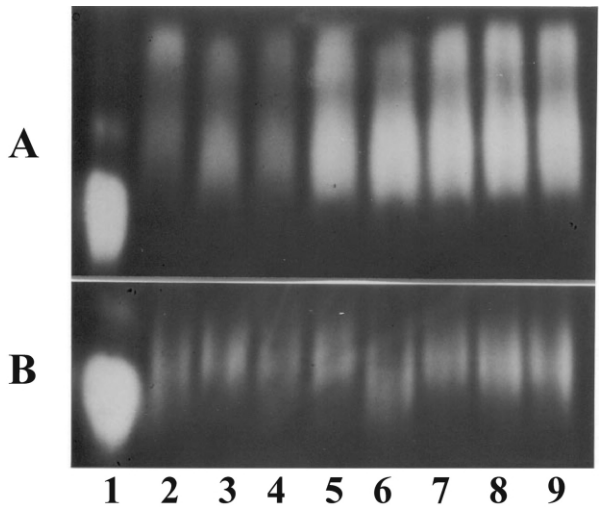

Fig. 5. Activity staining for CAT in radish (cv. Redondo Vermelho) leaves (A) and roots (B). Lane 1, CAT activity standard from bovine liver; lane 2, control (zero $CdCl_2$) after 72 h; lane 3, 3 h; lane 4, 6 h; lane 5, 9 h; lane 6, 12 h; lane 7, 24 h, lane 8, 48 h and lane 9, 72 h of growth in 0.5 mM $CdCl_2$; 60 and 15 μg of protein from leaves and roots, respectively, were loaded onto each gel lane.

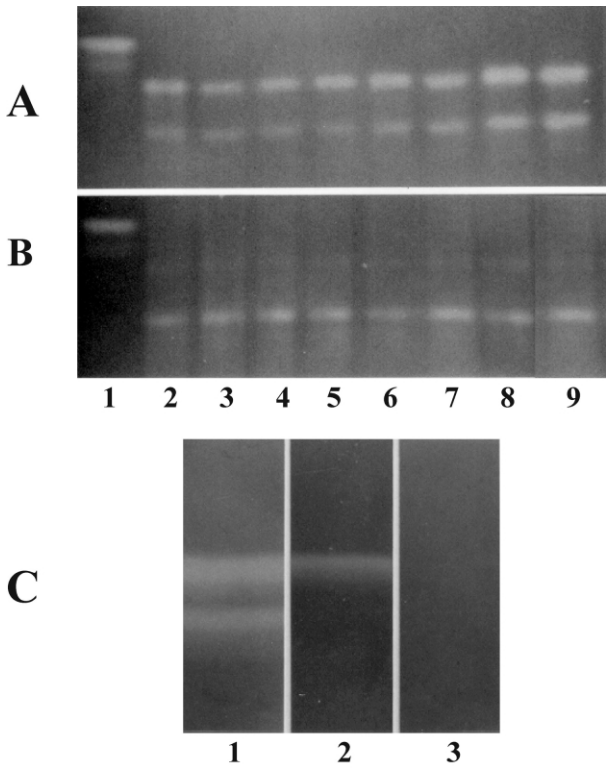

Fig. 6. Activity staining for SOD in radish (cv. Redondo Vermelho) leaves (A) and roots (B). Lane 1, Bovine SOD standard; lane 2, control (zero $CdCl_2$) after 72 h; lane 3, 3 h; lane 4, 6 h; lane 5, 9 h; lane 6, 12 h; lane 7, 24 h; lane 8, 48 h and lane 9, 72 h of growth in 0.5 mM $CdCl_2$; 30 μg of protein from leaves and roots were loaded onto each gel lane. In (C), a radish leaf protein sample (50 μg) was loaded onto the gel and stained for individual SOD isoenzymes. Lane 1, control SOD activity; lane 2, plus 2 mM potassium cyanide and lane 3, 5 mM hydrogen peroxide.

shown). Tobacco leaf SOD extracts were tested simultaneously and used as a control. The two major SOD bands of radish leaves, always present independent of the protein concentration, were classified as Fe–SOD and Cu/Zn–SOD (Fig. 6C). No other changes, such as the appearance or disappearance of bands, were detectable in the CAT and SOD isoenzyme patterns, that would suggest a specific response to $CdCl_2$ treatment.

2.5. GR activity

The activity of GR exhibited very little variation in the roots and leaves of control plants (Fig. 7A and B). However, GR activity in both tissues increased considerably with $CdCl_2$ treatment and time of exposure to the metal (Fig. 7A and B). The increase of GR activity was very rapid in roots reaching a 15-fold increase in the 1 mM $CdCl_2$ treatment, compared to the control (Fig. 7B), whereas in leaves the increase in GR activity in 1 mM $CdCl_2$ was only 7.5-fold after 72 h (Fig. 7A). In a similar manner to CAT, when $CdCl_2$ was tested in the spectrophotometric assay for GR activity, no significant alteration was observed, suggesting that $CdCl_2$ has no effect on GR activity in vitro.

3. Discussion

The impact of Cd uptake by living cells has been shown to be drastic, normally leading to cell death depending on the metal dose and time-length of exposure. Among some of the effects that heavy metals can cause is the generation of ROS. Relationship between Cd toxicity and oxidative reactions have been studied in more detail in animals and microrganisms. In mice, Cd daily administration led to inhibition of SOD activity (Patra et al., 1999). The responses of antioxidant enzymes in fish exposed to Cd have shown in general a reduction of CAT, GR and SOD activities (Zikic et al., 1997; Vaglio and Landriscina, 1999), whereas increased CAT and SOD activities were shown to be able to inhibit lipid peroxidation and Cd-induced cell injury to human fetal lung fibroblasts (Yang et al., 1997).

Increasing concentrations of $CdCl_2$ caused a decrease in the growth of the four varieties of radish under test (Fig. 1) and only one variety (Redondo Vermelho) was able to withstand 0.5 and 1 mM $CdCl_2$, albeit with a considerably reduced root growth (Fig. 2). Cd accumulated in the roots at a faster rate and to a much higher concentration than in the leaves, following the application of $CdCl_2$ (Fig. 3). In plants that are not hyperaccumulators of Cd, roots have been shown previously to be the major site of phytochelatin synthesis and hence Cd accumulation (Di Cagno et al., 1999; Zhu et al., 1999).

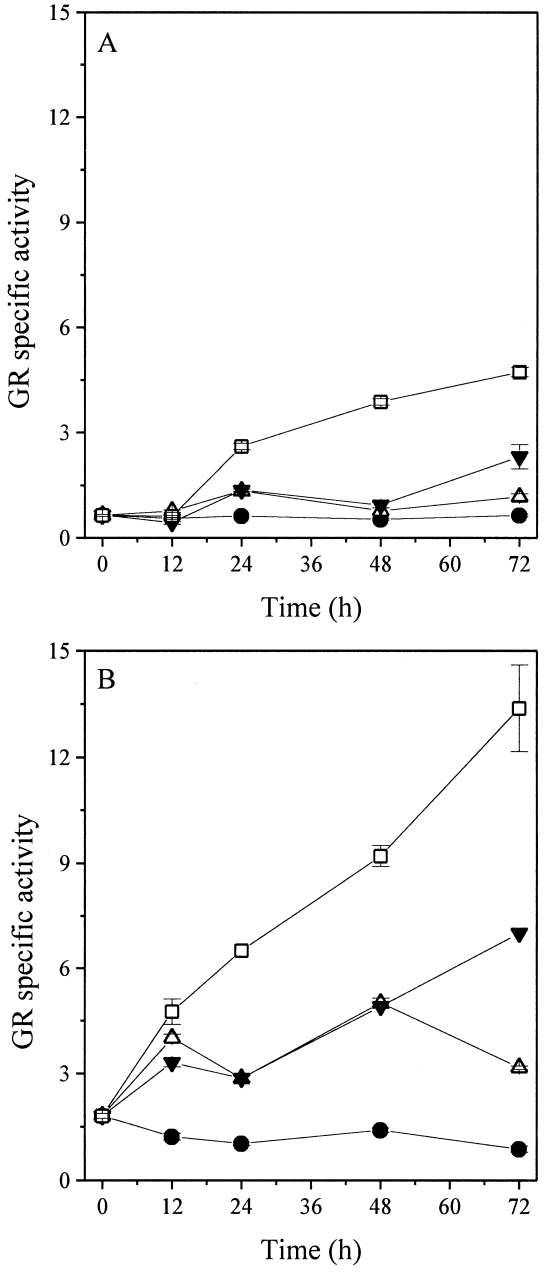

Fig. 7. The specific activity of GR (μmol min^{-1} mg^{-1} prot) in the leaves (A) and roots (B) of radish (cv. Redondo Vermelho) seedlings grown for a 72 h period in four concentrations of $CdCl_2$. Control zero (●), 0.25 mM (△), 0.5 mM (▼) and 1.0 mM (□).

As indicated in the Introduction, there have been a number of studies that have examined the effect of Cd on CAT activity in higher plants and the majority reported a decrease in activity, although there was some variation over longer time courses. Only Brej (1998), positively demonstrated a significant increase in CAT activity in the roots and leaves of some populations of *Agropyron repens* growing in highly contaminated soils. It can be clearly seen in Fig. 4, that there was a significant Cd induced increase in CAT activity in both the leaves and roots, and that the magnitude of this increase was proportional to the concentration of $CdCl_2$ in the external medium. Following the staining for CAT activity after native PAGE, two major bands were visible when leaf extracts were tested, both of which increased during the time course of exposure to 0.5 mM $CdCl_2$, although the more electropositive band seemed to respond earlier (Fig. 5A). Staining for CAT activity in root extracts was less clear and it was difficult to establish whether one or two isoenzymic bands were present. A definite increase in CAT activity was observed over the time course, although the magnitude was less than observed with leaf extracts (Fig. 5). The isoenzymic patterns for both leaves and roots in Fig. 5, are similar to those obtained by Anderson et al. (1995) in a study of chilling acclimation in maize.

A major function of CAT activity is to metabolise the peroxide liberated in the peroxisome following the conversion of glycollate to glyoxylate during photorespiration (Kendall et al., 1983). The activity of the enzyme is greatly reduced when plants are grown in elevated atmospheres of CO_2 (Azevedo et al., 1998). CAT is also important in the metabolism of peroxide liberated during the metabolism of fatty acids particularly in the germinating seed (Holtman et al., 1994). Isoenzymic forms of CAT have been studied extensively in higher plants, where there are frequently three genes encoding CAT. In *Nicotiana plumbaginofolia,* the transcription of two of the three genes was stimulated by ozone (Willekens et al., 1994), whilst the transcription of all three genes in maize has been shown to be increased by the addition of hydrogen peroxide, although the time course of the response varied between genes (Polidoros and Scandalios, 1999). The increase in CAT activity demonstrated in Figs. 4 and 5, is therefore circumstantial evidence to support the hypothesis that Cd causes the formation of ROS. The increase in CAT activity in the leaves was stimulated by much lower concentrations of Cd than in the roots, which may be due to light causing a greater formation of ROS in leaves (Noctor and Foyer, 1998; Foyer and Noctor, 1999). However there is also the possibility that there is a signal of oxidative stress transported from the roots to the leaves. Evidence that such a signalling mechanism can increase the transcription of ascorbate peroxidase has recently been reported (Karpinski et al., 1999).

Only two major bands of SOD activity were detectable following the staining of native PAGE gels for enzyme activity in the leaves (Fig. 6A). Inhibitor studies (Fig. 6C) indicated that the upper more electropositive band was a Fe–SOD, whilst the lower more electropositive band was a Cu/Zn–SOD. Although more SOD bands were visible when larger amounts of protein were loaded onto the gel, it was clear that these two isoenzymes comprised the major SOD activity in the leaves. Both activities increased in the leaves during the time course of exposure to $CdCl_2$. However, in the roots a Cu/Zn form of SOD predominated and the activity

did not vary over the time course. As indicated in the Introduction, previous work examining the effects of Cd on SOD activity in plants has produced varied results, although most have shown a decrease or no change in activity. Only in *P. sativum* (Dalurzo et al., 1997) and *Alyssum* species (Schickler and Caspi, 1999) has definite increases in SOD activity been detected, although no attempt was made to separate the different metal containing isoenzymes. However a range of different oxidative stresses have been shown to increase both the activity and expression of genes encoding SOD (Bowler et al., 1992; Willekens et al., 1994).

GR activity increased in both the leaves and roots (Fig. 7) during the time course of exposure to three different concentrations of $CdCl_2$ and as with CAT the magnitude of the response was dependent upon the concentration applied. However in contrast to the results obtained with CAT and SOD, the increase in GR activity was far greater in the roots. These data could be explained by two completely different scenarios (i) the glutathione/ascorbate cycle is operating at high rate in order to detoxify the ROS formed in the root, or (ii) it is essential to keep the glutathione in a reduced form, prior to its incorporation into phytochelatins (Cobbett, 2000). A number of previous workers have detected increases in GR activity in plants following exposure to Cd (Chaoui et al., 1997; Stroinski et al., 1999; Schickler and Caspi, 1999), although the response has often been dose dependent and variable over time. In a similar manner to CAT and SOD, oxidative stress has been shown to cause an increase in GR activity (Stevens et al., 1997). Taking into consideration data showing that ascorbate peroxidase also increases following exposure to cadmium (Shaw, 1995; Chaoui et al., 1997), the present data would indirectly suggest that the glutathione/ascorbate cycle does play a role in the detoxification of Cd-induced ROS.

In conclusion, the data presented in this paper have demonstrated that activities of the three major enzymes (CAT, SOD and GR) involved in the detoxification of ROS increase significantly following the supply of high concentrations of $CdCl_2$ to a tolerant variety of radish. However, the magnitude of these activity increases, varies with both the enzyme and the location, i.e. in the roots or leaves. It remains to be seen whether these increases in activity are due to induced gene transcriptional and de novo synthesis of protein, or are due to posttranslational modification of existing enzyme protein.

4. Experimental

4.1. Plant material

Seeds of four radish varieties (*Raphanus sativus* — cv. Redondo Vermelho, Comprido Vermelho, Grinson Gigante and Scarlett Globe) were germinated on moistened filter paper and then transferred to a glass house maintained at 25–30°C and a 16 h photoperiod at 300 μmol m^{-2} s^{-1} in a hydroponic system in pots containing 1.4 l of Hoagland's nutrient solution. Fourteen-day old plants grown in Hoagland's nutrient solution were further grown in the same solution, but containing 0.006, 0.012, 0.025, 0.05, 0.1, 0.5, 1.0 and 5.0 mM $CdCl_2$ for 12, 24, 48 and 72 h or 7 day periods. After these periods, growth was determined by measurement of root length.

Based on the growth of these varieties, Redondo Vermelho was selected and another experiment was carried out using 0.25, 0.5 and 1.0 mM $CdCl_2$ under the same conditions described above. Roots and leaves from each treatment were collected in liquid nitrogen and stored at −80°C for further analysis.

4.2. Enzyme extraction

The following steps were carried out at 4°C unless stated otherwise. The root or leaf tissue (3:1 buffer volume:-fresh weight) was homogenized in a pestle and mortar with 100 mM potassium phosphate buffer (pH 7.5) containing 1 mM EDTA, 3 mM DL-dithiothreitol and 5% (w/v) insoluble polyvynilpyrrolidone. The homogenate was centrifuged at 10,000 *g* for 30 min and the supernatant kept stored in separate aliquots at −80°C, prior to CAT, GR and SOD analysis.

4.3. CAT assay

CAT activity was determined as described by Azevedo et al. (1998), with some minor modifications. CAT activity was assayed spectrophotometrically at 25°C in a reaction mixture containing 1 ml 100 mM potassium phosphate buffer (pH 7.5), containing 2.5 μl H_2O_2 (30% solution) prepared immediately before use. The reaction was initiated by the addition of 15 μl of plant extract and activity determined by monitoring the degradation of H_2O_2 at 240 nm over 1 min against a plant extract-free blank.

4.4. GR assay

GR activity was determined as described by Barata et al. (2000). GR activity was assayed spectrophoto metrically at 30°C in a mixture consisting of 3 ml 100 mM potassium phosphate buffer (pH 7.5) containing 1 mM 5,5″-dithiobis(2-nitrobenzoic acid), 1 mM oxidized glutathione and 0.1 mM NADPH. The reaction was started by the addition of 50 μl of plant extract. The rate of reduction of oxidized glutathione was followed by monitoring the increase in absorbance at 412 nm over 2 min.

4.5. Polyacrylamide gel electrophoresis (PAGE)

Electrophoresis was carried out under native condition in 5–6% polyacrylamide gradient and 8%

polyacrylamide gels for CAT and SOD activity staining, respectively. A constant current of 20 mA/gel was applied for 8 h (gels to be stained for CAT activity) or 4 h (gels to be stained for SOD activity) and the temperature maintained at 4°C. Electrophoresis buffers and gels were prepared as described by Laemmli (1970) except that SDS was excluded. Equal amounts of protein were loaded on to each lane.

4.6. CAT activity staining

CAT activity in native PAGE gels was determined as described by Woodbury et al. (1971). Gels were incubated in 0.003% H_2O_2 for 10 min and developed in a 1% (w/v) $FeCl_3$ and 1% $K_3Fe(CN_6)$ (w/v) solution for 10 min.

4.7. SOD activity staining

After electrophoretic separation, SOD activity was determined as described by Beauchamp and Fridovich (1971) and modified by Azevedo et al. (1998). The gels were rinsed in distilled–deionized water and incubated in the dark for 30 min at room temperature in a reaction mixture containing 50 mM potassium phosphate buffer (pH 7.8), 1 mM EDTA, 0.05 mM riboflavin, 0.1 mM nitroblue tetrazolium and 0.3% (v/v) *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED). At the end of this period, the reaction mixture was poured off, the gels were rinsed with distilled–deionized water and then illuminated in water until the development of colorless bands of SOD activity in a purple-stained gel was visible. To stop the reaction, the gels were transferred to 6% (v/v) acetic acid. Bovine SOD (Sigma Chemical Co.) was applied to all gels to serve as a positive control of SOD activity. SOD isoenzymes were classified by testing a leaf sample, as described previously by Azevedo et al. (1998). Prior to SOD staining, the gel was cut into three slices; the first was stained for SOD as above; the second and third slices were incubated for 20 min in 100 mM potassium phosphate buffer (pH 7.8) containing 2 mM KCN and 100 mM potassium phosphate buffer (pH 7.8) containing 5 mM H_2O_2, respectively. At the end of this period, both slices were washed in distilled–deionized water and then stained for SOD activity. The pre-treatment of the gels in H_2O_2 and KCN before SOD staining allowed the classification of the SOD into Cu/Zn–SOD, Fe–SOD or Mn–SOD isoenzymes. Mn–SOD is resistant to both inhibitors, Fe–SOD isoenzymes is resistant to KCN and inhibited by H_2O_2, and Cu/Zn–SOD is inhibited by both inhibitors.

4.8. Determination of protein concentration

The concentration of protein was determined by the method of Bradford (1976) using BSA as a standard.

4.9. Statistical analysis

The experiments were repeated three times. Data were statistically analysed within each experiment and the results expressed as mean (±S.E.) of four independent replicates for CAT and GR activities measurements.

4.10. Cd accumulation

The accumulation of Cd in roots and leaves was analysed in a ICP–MS (inductivily coupled plasma mass spectrometer). Samples of roots and leaves of control and Cd treated plants exposed to 0.5 and 1.0 mM of $CdCl_2$, were dried at 60°C for 4 days. The samples were then digested with 2 ml concentrated HNO_3 and applied to the ICP–MS spectrophotometer and analysed exactly as described by Wu et al. (1997).

Received 22 December 2000; received in revised form 15 March 2001

Abstract

Acid hydrolysis of cell wall-rich material from young leaves of the lycophyte *Selaginella apoda* (L.) Spring yielded substantial amounts of 3-*O*-methyl-D-galactose (**1**) in addition to the usual major monosaccharides (glucose, galactose, arabinose, xylose and galacturonic acid). The yield of **1** approximately equalled that of galacturonic acid. Compound **1** was identified as 3-*O*-methylgalactose by its ^{1}H and ^{13}C NMR spectra, and shown to be the D-enantiomer by its susceptibility to D-galactose oxidase. Compound **1** was detected in acid hydrolysates of the alcohol-insoluble residues from young leaves of all lycophytes tested, both homosporous (*Lycopodium*, *Huperzia* and *Diphasiastrum*) and heterosporous (*Selaginella*). It was not detectable in the charophyte green algae *Coleochaete scutata*, *Chara coralina* or *Klebsormidium flaccidum*, any bryophytes [a hornwort (*Anthoceros*), four liverworts and three mosses], or any euphyllophytes [a psilopsid (*Psilotum*), a horsetail (*Equisetum*), eusporangiate and leptosporangiate ferns, the gymnosperm *Gnetum*, and diverse angiosperms]. A high content of **1** is thus an autapomorphy of the lycophytes. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Within dicots and non-graminaceous monocots, the primary cell wall has a relatively constant sugar composition, major monosaccharide residues being Glc, Gal, Ara, Xyl, GalA, Rha, Fuc, GlcA and Man (McNeil et al., 1984; Fry, 1988; Brett and Waldron 1996). Graminaceous primary walls contain the same monosaccharide residues but usually have more Xyl and less Gal, Ara and Fuc (Burke et al., 1974; Carpita, 1996). Gymnosperms are also similar to dicots, but tend to be richer in Man residues (Edashige and Ishii, 1996). Despite these quantitative differences, no qualitative differences in the monosaccharide composition of primary cell walls have been noted between different groups of seed plants.

Few studies have been undertaken of cell wall composition in lower land plants (Chodat and Cortesi, 1939; Edelmann et al., 1998), probably because they are not major world crops. Among bryophytes (non-vascular land plants), liverworts broadly resemble gymnosperms in their cell wall sugar residue composition, the major neutral monosaccharide residues being Glc > Gal > Man > Xyl ≈ Ara > Fuc ≈ Rha (Thomas, 1977; Thomas et al., 1984). Uronic acid residues, stated to be mannuronic acid, are also present (Das and Rao, 1967).

We have not found any reports specifically dealing with the composition of the primary cell wall of pteridophytes (non-seed vascular plants), although a few reports on their secondary walls have appeared (Timell, 1962; Bremner and Wilkie, 1971). Modern pteridophytes are the few surviving progeny of a much greater diversity of extinct taxa, representing the explosive evolutionary experimentation which occurred among land plants in the Silurian (Raven, 1993; Kenrick and Crane, 1997). Since the primary cell wall plays several essential biological roles, including the regulation of cell expansion, tissue cohesion, defence (e.g. against microbes), ion-exchange, and the production of oligosaccharins (Fry, 1988; Kaplan and Hageman, 1991; Brett and Waldron, 1996; Stübler and Buchenauer, 1996; Goldberg, 1995; Cassab, 1998), we suggest that the demands placed on it, and thus its optimal

PII: S0031-9422(01)00140-6

composition, may have changed rapidly during periods of rapid plant evolution. It is certainly the case that some green algae have cell wall compositions very different from those of seed plants (Mackie and Preston, 1974; Roberts, 1974; Domozych et al., 1980).

We are, therefore, documenting the evolution of the primary cell wall in land plants. DNA sequence data (Raubeson and Jansen, 1992; Manhart, 1994, 1995; Kranz et al., 1995; Pryer et al., 1995; Malek et al., 1996; Wolf, 1997; Duff and Nickrent, 1999, Vangerow et al., 1999) have recently confirmed the morphology-based view that the lycophytes (club-mosses) diverged very early from the ancestors of the euphyllophytes (= plants with 'true' leaves, extant euphyllophytes being all seed-plants as well as non-lycophyte pteridophytes). Indeed, the lycophytes show a relatively close relationship to the bryophytes. In the present paper we report on an unusual chemical feature in the primary cell walls of the lycophytes, which is apparently related to their isolated evolutionary position.

2. Results

2.1. An unusual sugar residue in Selaginella cell walls

Acid hydrolysis of the alcohol-insoluble residue (AIR; i.e. cell wall-rich material) from young leaves of *Selaginella apoda* followed by paper chromatography (PC) yielded an unfamiliar monosaccharide (**1**) in addition to the major monosaccharides characteristic of the cell wall polysaccharides of seed plants. In chromatography system 2, **1** migrated between Ara and Xyl. However, unlike these pentoses, **1** stained yellow-brown with aniline hydrogen-phthalate, suggesting a hexose derivative.

Larger amounts of **1** were partially purified by preparative PC (in system 2) of the acid hydrolysate obtained from 1 g of *S. apoda* AIR. Of several PC and TLC systems tested for their ability to separate **1** from the last traces of Ara and Xyl (Table 1), preparative PC in system 3 was selected, followed by gel-permeation chromatography on Bio-Gel P-2. On TLC (cellulose) in system 3, cmpd **1** exhibited an unusually high R_F, similar to that of authentic 3-*O*-methylglucose and 2-deoxygalactose; it was well resolved from the common hexoses and pentoses. R_F values (cellulose TLC, system 3) were Glc, 0.30; Gal, 0.36; Man, 0.39; Xyl, 0.37; Ara, 0.46; Rib 0.63; 6-deoxymannose (= rhamnose), 0.61; 2-deoxygalactose, 0.73; 3-*O*-methylglucose, 0.72; cmpd **1**, 0.70.

2.2. Identification of 3-O-methylgalactose by NMR spectroscopy

The standard 1D single-pulse 600-MHz proton NMR spectrum of 100 μg of purified unknown **1** in D_2O as solvent is reasonably well resolved (Fig. 1a) The doublets at 4.60δ and 5.26δ suggest the presence of the α and β anomers of a glucose or galactose derivative and the sharp signal at 3.45 suggest the presence of one methoxy group. Careful examination of this spectrum confirms the presence of the requisite number of signals and their assignment follows immediately from the 2D-COSY spectrum (Fig. 1b). Significant signal overlap occurs only for the C-6 protons. In the β-anomer the C-6 protons have different chemical shifts, and each appears as a doublet of doublets. In the α-anomer the C-6 proton signals coincide so the coupling between them is not seen resulting in a single doublet. One peak of the doublet for the C-6 of the α-anomer virtually coincides with one peak from one of the C-6 protons of the β-anomer. The coupling constants of each multiplet, measured from the 1-D spectrum (Table 2) are consistent only with a galactose derivative.

The ^{13}C chemical shifts, obtained from a 2D 1-bond carbon–proton shift (HMQC) correlation spectrum, are similar to those for the anomers of galactose with the exception of that for C-3, which is about 10 ppm higher. This is consistent with methylation of the hydroxyl at C-3. The site of methylation is confirmed by correlation between the methyl protons and C-3 of each anomer in the 2D long range carbon–proton (HMBC) shift correlation spectrum. The ^1H and ^{13}C spectral data of the individual components of **1** are given in Table 2.

In conclusion, the spectroscopic data show unambiguously that, apart from a few unidentified minor impurities, **1** was a mixture of the α and β anomers of 3-*O*-methylgalactose.

2.3. Determination of enantiomeric form

Plant cell wall polysaccharides contain both D- and L-Gal residues, which are biosynthetically derived from UDP-D-Glc (via UDP-D-Gal) and from GDP-D-Man (via GDP-L-Gal), respectively (Feingold and Avigad, 1980). The D-Gal:L-Gal ratio has been reported at ~7.3:1 in cultured sycamore cells (Roberts and Harper, 1973) and ~70:1 in cultured spinach cells (Baydoun and Fry, 1988). D-Gal, the more abundant enantiomer, is found in pectins, xyloglucans and arabinogalactan-proteins. L-Gal has been reported in the side-chains of xylans (Whistler and Corbett, 1955) and some xyloglucans (Zablakis et al., 1996; Hantus et al., 1997). It was, therefore, of interest to determine whether **1** was a derivative of D- or L-Gal.

D-Galactose oxidase uses O_2 to oxidise the $-CH_2OH$ group of D-Gal and some of its derivatives, but not of L-Gal. Derivatives of D-Gal that can be oxidised by this enzyme include the 2- and 3- but not 4-*O*-methyl monoethers (Avigad et al., 1962; Schlegel et al., 1968; Cleveland et al., 1975). D-Galactose oxidase can therefore be used to distinguish 3-*O*-methyl-D-galactose from 3-*O*-methyl-L-galactose.

Table 1
R_f values of Xyl, Ara and **1** in various solvent systems

Compound	R_F value in system[a]							
	a	*b*	*c*	*d*	*e*	*f*	*g*	*h*
Ara	0.28	0.21	0.12	0.41	0.15	0.75	0.58	0.46
Xyl	0.38	0.29	0.13	0.52	0.21	0.79	0.49	0.37
1	0.24	0.18	(s)[c]	(s)	0.12 (s)	(u)[b]	0.80	0.70

[a] Chromatographic systems used were: *a*, TLC (silica-gel) in BuOH–HOAc–H_2O (3:1:1 by vol.); *b*, TLC (silica-gel) in BuOH–HOAc–H_2O (4:1:1 by vol.); *c*, TLC (silica-gel) in MeEtCO–H_2O (85:7 by vol.); *d*, TLC (silica-gel) in EtOAc–Py–HOAc-H_2O (5:3:1:1 by vol.); *e*, TLC (silica-gel) in *i*-PrOH–NH_4OH–H_2O (8:1:1 by vol.); *f*, TLC (silica-gel) in *i*-PrOH–nitromethane–H_2O (5:2:3 by vol.); *g*, PC (Whatman No. 1) in PhOH–H_2O (4:1, w/w); *h*, TLC (cellulose) in PhOH–H_2O (4:1, w/w).
[b] (u) = Unrecordable (did not separate from Ara and Xyl).
[c] (s) = Streaked.

We confirmed that the commercial sample of galactose oxidase was able to oxidise D- but not L-Gal; it also oxidised cmpd **1**. The substrates (D-Gal and **1**) were partially destroyed within 1 h; oxidation was complete within 4 days, yielding multiple reaction products (Fig. 2). In contrast, the enzyme had no effect on L-Gal, despite the incubation continuing up to 4 days (Fig. 2). During the 4-day incubation, reaction mixtures containing D-Gal or **1** turned yellow (presumably owing to the formation of unstable aldehyde products) whereas the L-Gal reaction mixture did not change colour.

Together the results show that **1**, isolated from *S. apoda*, was 3-*O*-methyl-D-galactose.

2.4. Occurrence of 3-*O*-methylgalactose in various green plants

To ascertain the distribution of 3-*O*-methylgalactose among land plants we analysed acid hydrolysates of AIR from young shoot tissue (leaves and/or immature stems) of various pteridophytes and the thalli of various bryophytes and algae by 2D PC (exemplified by Fig. 3). 3-*O*-Methylgalactose was present in all lycophytes tested, both homosporous and heterosporous (Table 3). Typical yields (estimated from staining intensity relative to authentic 3-*O*-methylglucose) were in the order of 5–10 mg of 3-*O*-methylgalactose per g of AIR. 3-*O*-Methylgalactose was, however, undetectable in all euphyllophytes tested: a psilopsid, a horsetail, eusporangiate and leptosporangiate ferns and a gymnosperm (Table 3) and numerous angiosperms (data not shown). 3-*O*-Methylgalactose was also undetectable in all bryophytes tested: three mosses, four liverworts and a hornwort (Table 3). In addition, it was undetectable in walls of the charophytes *Coleochaete*, *Chara* and *Klebsormidium*—green algae which are thought (Kenrick and Crane, 1997) to be relatively closely related to the hypothetical, extinct, green alga from which all land plants evolved.

3. Discussion

The presence of 3-*O*-methylgalactose in both homosporous and heterosporous lycophytes supports the proposed (Bateman, 1996; Kranz and Huss, 1996) monophyly of the lycophytes. Extant lycophytes are the relicts of a much more diverse group of extinct lycophytes. Morphological features suggest that lycophytes evolved from ancestral plants between the bryophytes and the euphyllophytes. Our findings suggest that this phase of very rapid evolutionary experimentation was accompanied by the adoption of 3-*O*-methyl-D-galactose as a major component of the primary cell wall.

3-*O*-Methyl-D-galactose was not detectable in either *Equisetum* or *Psilotum*, supporting the view that these plants are more closely related to the ferns than to the lycophytes. Gene sequence data have shown *Equisetum* and *Psilotum*, but not the lycophytes, to be within the euphyllophyte clade (Robeson and Jansen, 1992; Manhart, 1994, 1995; Kranz et al., 1995; Pryer et al., 1995; Malek et al., 1996; Wolf, 1997; Duff and Nickrent, 1999; Vangerow et al., 1999).

A 3-*O*-methylgalactose (enantiomer not determined) has been detected, in trace amounts, in an extracellular polysaccharide exuded by a soil-dwelling *Cryptomonas* sp. (Paulsen et al., 1992). *Cryptomonas* is a member of the Cryptophyta, a small group of biflagellate, eukaryotic algae which frequently have red photosynthetic pigments. Most are free-swimming but one member of the Cryptophyceae has been found as an endosymbiont in a marine cilliate as a complex known as *Mesodinium rubrum*. Since the lycophytes analysed by us are not aquatic, they are unlikely to have any cryptophycean endosymbionts in their shoot tissues (Dr. D.G. Mann, RBGE, personal communication).

3-*O*-Methyl-D-galactose has also been isolated from polymers present in certain strains of the aquatic green alga *Chlorella vulgaris* (Ogawa et al., 1994). *Chlorella* spp. are primarily free-swimming and unlikely to form a symbiotic relationship with terrestrial lycophytes.

3-*O*-Methyl-D-galactose has been reported to constitute about 5% of the total neutral sugar residues in the soluble extracellular polysaccharides produced by the freshwater red alga *Porphyridium aerugineum* (Percival and Foyle, 1979). Methylgalactoses are also present in the rhodophyte genera *Geldiliella* and *Gracilaria*, from which agar is extracted. However, in agar the *O*-methyl groups are attached to galactose at position 4 and/or 6 (Matsuhiro and Urzua, 1991; Mollion, 1992; Chiovitti et al., 1995, Mollet et al., 1998; Givernaud et al., 1999). Therefore, it is highly unlikely that 3-*O*-methyl-D-galactose occurred in our lycophyte samples as a contaminant from laboratory agar. The lycophytes were collected from diverse sites (Table 3); it is, therefore, unlikely that they had a common contaminant.

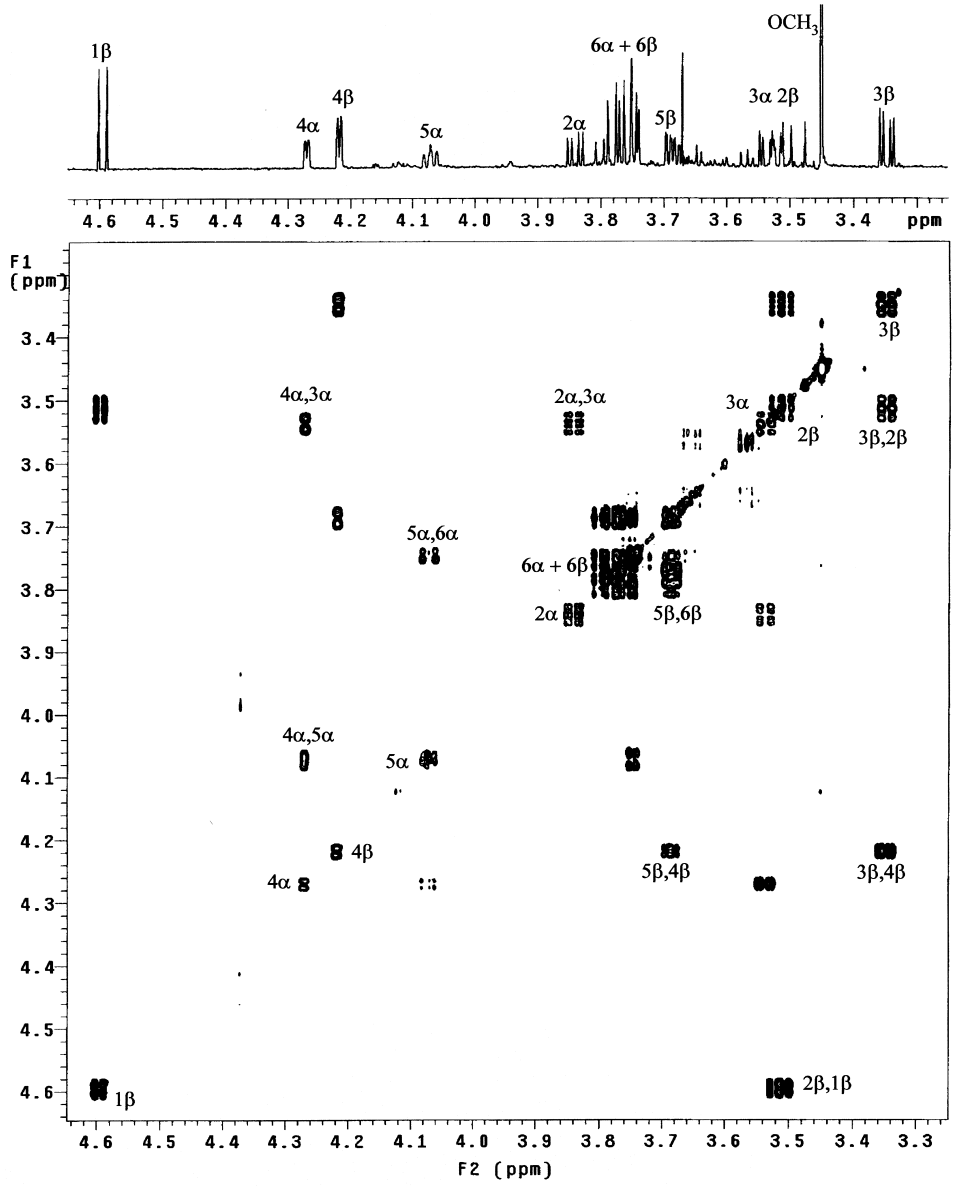

Fig. 1. NMR spectra of 3-*O*-methylgalactose (**1**): (a) 1D single-pulse 600 MHz proton NMR spectrum over the region 3.25δ–4.65δ [i.e. excluding the H-1α resonance at 5.26δ]; (b) 2D gradient selected proton COSY NMR spectrum over the same region as in (a) [i.e. excluding the H-1α diagonal resonance and the H-1α, H-2α off-diagonal resonances].

Among the fungi, 3-*O*-methyl-D-galactose has been detected as a polysaccharide component in *Armillaria mellea* (Bouveng et al., 1967) and a 3-*O*-methylgalactose (enantiomer not determined) in *Lamperomyces japonicus* (Fukuda and Hamada, 1978). 3-*O*-Methyl-D-galactose has also been reported as a component of haemocyanin, a glycoprotein from snails (Hall et al., 1977).

3-*O*-Methyl-D-galactose has been reported previously in land plants. For example, pectic polysaccharides from elm bark contain 3-*O*-methyl-D-galactose (Hirst et al., 1951; Barsett and Paulsen, 1985, 1991). These polymers have a backbone of 4-linked α-D-galacturonic acid interspersed with 2-linked α-L-rhamnose residues; some of the latter are substituted on O-4 with short side-chains containing 3-*O*-methylgalactose, galactose and/or glucuronic acid. It is possible that a similar polymer may occur in lycophytes since both rhamnose and galacturonic acid were detected in the hydrolysates of lycophyte AIRs. However, elm trees and lycophytes are not closely related and at present it is not known in which polysaccharide(s) 3-*O*-methyl-D-galactose occurs in the lycophyte cell wall.

3-*O*-Methyl-D-galactose was also detected as a component of a polysaccharide extracted from sassafras (*Sassafras albidum*) twigs (Springer et al., 1965), and a 3-*O*-methylgalactose (enantiomer not determined) was found in hydrolysates of the leaves of various dicot trees (Bacon and Cheshire, 1971). The yield from sweet-chestnut

Table 2

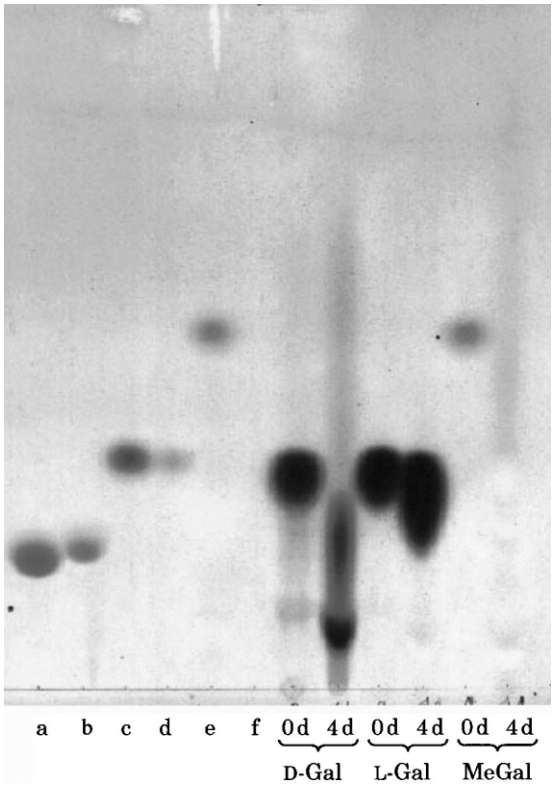

Fig. 2. Effect of D-galactose oxidase on D-Gal, L-Gal and 3-*O*-methylgalactose (**1**; MeGal) from *Selaginella apoda*. The three potential substrates were incubated with the enzyme for 0 or 4 days, as indicated, then analysed by TLC on cellulose in system 4 and stained with aniline hydrogen-phthalate. Markers used were: (a) D-GalA; (b) D-GlcA; (c) D-Gal; (d) L-Gal; (e) compound (**1**); (f) blank.

leaves was 11 mg of 3-*O*-methyl-D-galactose per 100 g AIR (Bacon and Cheshire, 1971), a very low concentration in comparison with the high levels detected in lycopod AIRs in our survey.

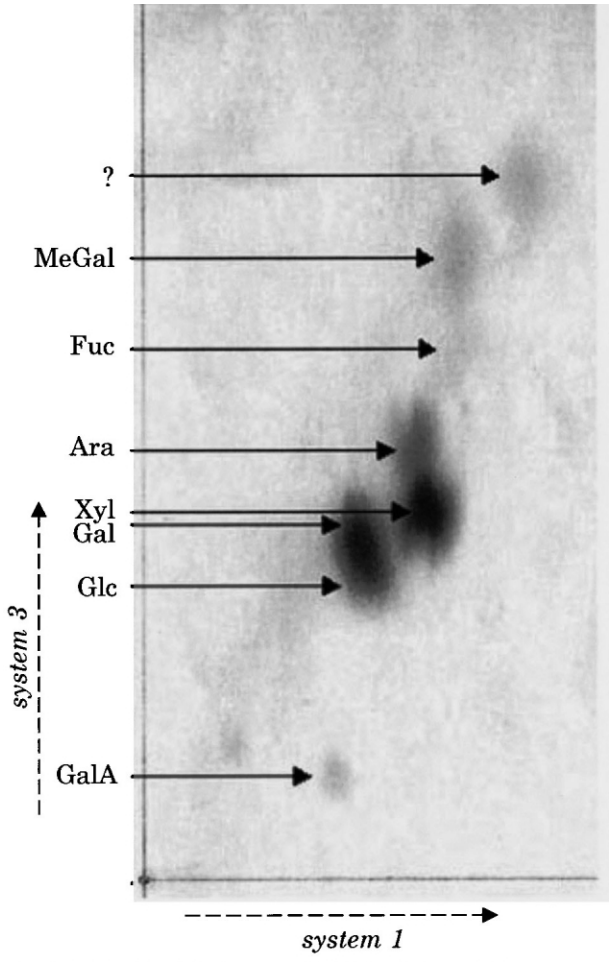

Fig. 3. Two-dimensional paper chromatogram showing 3-*O*-methylgalactose in an acid hydrolysate of AIR from *Lycopodium pinifolium* Blume. The PC was developed in system 1 (bottom to top, as photographed) followed by system 3 (left to right). Staining was with aniline hydrogen-phthalate. The spot marked '?' is unidentified: it was clearly distinguishable from rhamnose (not detectable in Fig. 3), which had an R_F higher than that of fucose in system 1 but approximately equal to that of fucose in system 3. Sugar '?' stained red with aniline hydrogen-phthalate and so is likely to have been a pentose derivative.

In conclusion, the adoption of 3-*O*-methyl-D-galactose as a quantitatively appreciable component of the primary cell wall appears to be an autapomorphy (a character which uniquely defines a taxon; Hennig, 1966) of the lycophytes that was acquired early during their evolution from hypothetical extinct ancestral land plants intermediate between the bryophytes and the euphyllophytes, and that has been retained by all extant lycophytes.

4. Experimental

4.1. Source of plant material

Sources of botanical material are listed in Table 3.

Table 3
Occurrence of 3-*O*-methylgalactose (MeGal) as a major component in acid hydrolysates of AIR from a range of lower plants

Classification		Species	MeGal[a]	Source[b]
Algae	Charophytes	*Chara coralina* (Klein ex Willd. Em. R.D.W.)	–	Culture, D. Sanders
		Coleochaete scutata Brébisson	–	CCAP 414/1
		Klebsormidium flaccidum (Kützing) Silva, Mattox et Blackwell	–	Culture, H. Sluiman
Bryophytes	Hornwort	*Anthoceros caucasicus* Spring.	–	Faial Island (R. Schumacker)
	Thalloid liverwort	*Pellia epiphylla* (L.) Corda	–	Roslin Glen
		Marsupella emarginata var *aquatica* (Lindb.) Dum.	–	Cairngorms
	Leafy liverworts	*Porella* sp.	–	Cairngorms
		Trichocolea tormentella (Ehrh.) Dum.	–	Glen Creran (D.S. Rycroft)
		Andrea rupestris Hedw. (*A. petrophila* Ehrh.)	–	Cairngorms (W.M.M. Eddie)
	Mosses	*Hypnum cupressiforme* Hedw.	–	Roslin Glen
		Sphagnum molle Sull.	–	Cairngorms

[a] + Indicates 3-*O*-methylgalactose detectable after 2-dimensional PC as shown in Fig. 3.

[b] Accession numbers followed by (E) refer to material from the Royal Botanic Garden, Edinburgh (RGBE); CCAP = Culture Collection of Algae and Protozoa, Ambleside, Cumbria; DRB = glasshouses of the Daniel Rutherford Building, The University of Edinburgh. Additional material was kindly provided by Dr. D. Long and Dr. H. Sluiman (RBGE), Dr. D.S. Rycroft (Glasgow University), Dr. R. Schumacker (University of Liege), Dr. W.M.M. Eddie (University of Texas, Austin) and Prof. D. Sanders (University of York). Other material was collected by Z.A.P. Collection sites were: Cairngorm Hills (57°05–10′ N, 3°35–45′W.), Roslin Glen (55°51′ N, 3°10′ W), Glen Creran (56°36′ N, 5°12′ W) and Faial Island (38°40′ N, 28°40′ W).

4.2. Preparation and hydrolysis of AIR

About 30 g fr. wt of (fresh or frozen) young plant material was blended (two 1-min bursts) in an MSE 'Ato-Mix' with 150 ml 70% ethanol. The suspension was filtered through Miracloth (Calbiochem) and the residue ground to a fine powder in liquid N_2 with a ceramic pestle and mortar (both pre-cooled to −80°C). The powder was transferred to a flask with 150 ml 70% ethanol and incubated at 55°C for 5 days to solubilise free sugars. The suspension was then filtered again and repeatedly washed with 70% ethanol until colourless. The residue was finally washed in acetone and dried.

A portion (20 mg) of each AIR sample was subjected to hydrolysis in 1 ml 2 M TFA at 120°C for 1 h. The hydrolysate was dried in vacuo and re-dissolved in 50 μl water, of which 2 μl was subjected to 2-dimensional PC.

4.3. Paper chromatography and TLC

Analytical PC was on Whatman No. 1 paper; preparative PC was on Whatman 3MM. One-dimensional PC was by the descending method; 2-dimensional PC was by the ascending method. Solvent systems used were (1), BuOH–HOAc–H_2O (12:3:5 by vol.); (2), as system 1 for 16 h followed, in the same dimension, by EtOAc–pyridine–H_2O (8:2:1 by vol.) for 18 h; (3), PhOH–H_2O (4:1, w/w); (4), BuOH–HOAc–H_2O (2:1:1 by vol.) followed, in the same dimension, by EtOAc–pyridine–H_2O (10:4:3 by vol.); others are indicated in Table 1. TLC was on Merck silica-gel or microcrystalline cellulose. Chromatograms were stained with aniline hydrogen-phthalate; faint spots were more readily visible by their fluorescence when viewed under a 366-nm UV lamp (Fry, 1988).

4.4. NMR methods

The NMR spectra were measured on D_2O solutions using a Varian INOVA 600-MHz spectrometer operating at 599.9 MHz for protons and 150.9 MHz for ^{13}C nuclei.

The 2D gradient selected COSY proton spectrum was obtained using the sequence (von Kienlin, 1991): D1–90°–t1–zgrd–90°–zgrd–AQ with D1 = 1.5 s, AQ = 0.646 s, zgrad = 1 gauss/cm, 0.002 s. Other parameters were SW = 1586 Hz, 2K data points, 512 increments each with 16 transients per FID. The data were processed using sine-bell squared functions in both dimensions with zero filling of the F1-data to 2K data transformation resulting in digital resolution of 1.5 Hz/pt.

The 2-D proton detected one-bond ^{1}H–^{13}C correlation (HMQC) spectrum was obtained using the sequence (Summers et al., 1986): D1–90°(^{1}H)–D2–180°^{1}H); 180°(^{13}C)–D2–90°(^{1}H)–D3–90°(^{1}H)–D2–90°(^{13}C)–$t_1/2$–180°(^{1}H)–$t_1/2$–90°(^{13}C)–D2–AQ. The delays used were D1 = 1.6 s (pre-saturation), D2 = 3.7 ms ($1/2^{1}J_{CH}$) and D3 = 600 ms (to minimise signals from protons bonded to ^{12}C nuclei). The experiment was preceded by 64 scans to establish thermal equilibrium. A 4-step phase cycle (hypercomplex acquisition) was used with ^{13}C broad band decoupling during acquisition of the proton signals. Other parameters were SW(^{1}H) = 4632 Hz, 2K data points, SW(^{13}C) = 18000 Hz, AQ = 0.408 s, 200 increments each with 4 transients per FID. The data were processed using shifted sine-bell squared functions in both dimensions with zero filling of the F_1 data from 200 to 1024 W before transformation.

The 2D proton detected gradient selected long-range ^{1}H–^{13}C correlation (HMBC-g) spectrum was obtained using the sequence (Ruiz-Cabello et al., 1992): D1–90°(^{1}H)–D2–90°(^{13}C)–D3–90°(^{13}C)–zgrd1–$t_1/2$–180°(^{1}H)–$t_1/2$–zgrad1–90°(^{13}C)–zgrd2–AQ. The delays used were D1 = 1.4 s, D2 = 3.7 ms ($1/2^{1}J_{CH}$) and D3 = 55 ms (optimised for signals from protons with couplings to carbon of ca. 9 Hz), zgrad1 = 4 gauss/cm, 0.002 s, zgrad 2 = 2 gauss/cm, 0.002 s. A 16-step phase cycle (hypercomplex acquisition) was used with no ^{13}C broad band decoupling during the acquisition of the proton signals. Other parameters were SW(^{1}H) = 2500 Hz; 2K data points; SW(^{13}C) = 15,000 Hz, AQ = 0.410 s; 128 increments each with 192 transients per FID. The data were processed using shifted sine-bell squared functions in both dimensions with zero filling of the F_1 data from 200 to 1024 W before transformation.

4.5. Oxidation with D-galactose oxidase

D-Galactose (0.5 mg), L-galactose (0.5 mg) or cmpd **1** (trace) was incubated in an open vial containing 100 μl of 100 mM P_i (K^+) buffer, pH 6.0, containing 0.5% chlorobutanol, 15 'Sigma Units' of D-galactose oxidase (EC 1.1.3.9; from *Dactylium dendroides*) and 10 Units of bovine liver catalase (both enzymes from Sigma Chemical Co., Poole, UK). The K_m of galactose oxidase for D-galactose is reported to be 0.24 M (Avigad et al., 1962). One 'Sigma Unit' of D-galactose oxidase is the activity which will produce a ΔA_{425} of 1.0 per min in a reaction volume of 3.4 ml with D-Gal as substrate in the presence of a peroxidase–*o*-tolidine system to detect the H_2O_2 generated. After incubation for 1 h to 4 days at 20°C, 20-μl samples were analysed by TLC on cellulose in system 4.

Acknowledgements

We thank Dr. D. Long (RBGE) and Dr. D.S. Rycroft (Glasgow University), who kindly assisted in the provision and identification of several bryophytes. We are very grateful to horticultural staff at the RBGE, especially Mr. Philip O. Ashby, for supply of specimens. Z.A.P. thanks the BBSRC for a Research Studentship. We thank BBSRC/EPSRC for the provision of the NMR spectrometer at the Edinburgh High Field NMR Centre.

Received 16 October 2000; received in revised form 16 January 2001

Abstract

Three dihydroxynortropanes, 2α,7β-dihydroxynortropane, 2α,3β-dihydroxynortropane, and 3α,7β-dihydroxynortropane, were isolated from calystegine-producing plants in the families Convolvulaceae and Solanaceae. 2α,7β-Dihydroxynortropane was isolated from six species in the Convolvulaceae whereas only *Calystegia soldanella* contained it and 2α,3β-dihydroxynortropane. Although neither of these were detectable in three species tested in the Solanaceae, 3α,7β-dihydroxynortropane was, however, isolated from *Duboisia leichhardtii*. © 2001 Elsevier Science Ltd. Keywords: Convolvulaceae; Solanaceae; Dihydroxynortropane; Calystegine; Swainsonine

1. Introduction

The tropane alkaloids mainly occur in the Solanaceae, but are found as well in the families Convolvulaceae, Erythroxylaceae, Proteaceae, and Rhizophoraceae, and occasionally in the Euphorbiaceae, Cruciferae, and Olacaceae (Lounasmaa, 1988; Lounasmaa and Tamminen, 1993). Nortropane alkaloids (i.e. those lacking the *N*-methyl group of tropane alkaloids) have rarely been isolated although they occasionally occur as minor constituents in plants producing tropane alkaloids. In 1988, Tepfer et al. (1988) reported the presence of a group of alkaloids in the underground organs and root exudates of *Calystegia sepium*, *Convolvulus arvensis* (both Convolvulaceae), and *Atropa belladonna* (Solanaceae). These compounds were named calystegines. Calystegines possess three structural features in common: a nortropane ring system; two to four secondary hydroxyl groups varying in position and stereochemistry; and a novel aminoketal functionality, which generates a tertiary hydroxyl group at the bicyclic ring bridgehead. The known members of the class have been subdivided into three groups on the basis of the number of hydroxyl groups present, namely calystegines A (with three hydroxyl groups), B (with four hydroxyl groups), and C (with five hydroxyl groups). Calystegines seem to be largely limited to the closely related families Solanaceae and Convolvulaceae, where they co-occur with tropane alkaloids (Asano et al., 2000). However, certain calystegines have also been found in species of *Morus* (Moraceae) (Asano, 1994a, b), which is a family not noted for the production of tropane alkaloids. In the course of isolating calystegines from species of the Solanaceae and Convolvulaceae, three dihydroxynortropane alkaloids were discovered. In the vast majority of tropane alkaloids, one or more of the hydroxyl groups on the tropane ring are esterified. However, Chinese researchers have isolated non-esterified dihydroxynortropane alkaloids, baogongten C (2β,6β-dihydroxynortropane) and erycibelline (2β,7β-dihydroxynortropane), from *Erycibe* species (Convolvulaceae) (Lu et al., 1986; Chen et al., 1986). In this report, we describe the isolation, structural determination, and the distribution of the new dihydroxynortropanes.

2. Results and discussion

A hot water extract of the dried whole plants (550 g) of *Calystegia soldanella* (Convolvulaceae) was subjected to various ion-exchange resin chromatographic procedures to give alkaloids **1** (23 mg) and **2** (7 mg), and calystegines A_3 (7 mg), B_1 (100 mg), B_2 (530 mg), and B_3 (6 mg), respectively. From the aerial parts of *Duboisia leichhardtii* (Solanaceae), calystegines B_1, B_2, B_4, C_1, and C_2 were isolated previously (Kato et al., 1997). In the present studies, we isolated alkaloid **3** (3.6 mg), together with calystegines A_5 (6 mg), B_1 (5 mg), B_2 (25 mg), B_4 (25 mg), C_1 (810 mg), and C_2 (4 mg) from the dried aerial parts (1 kg) of *D. leichardtii* (Fig. 1).

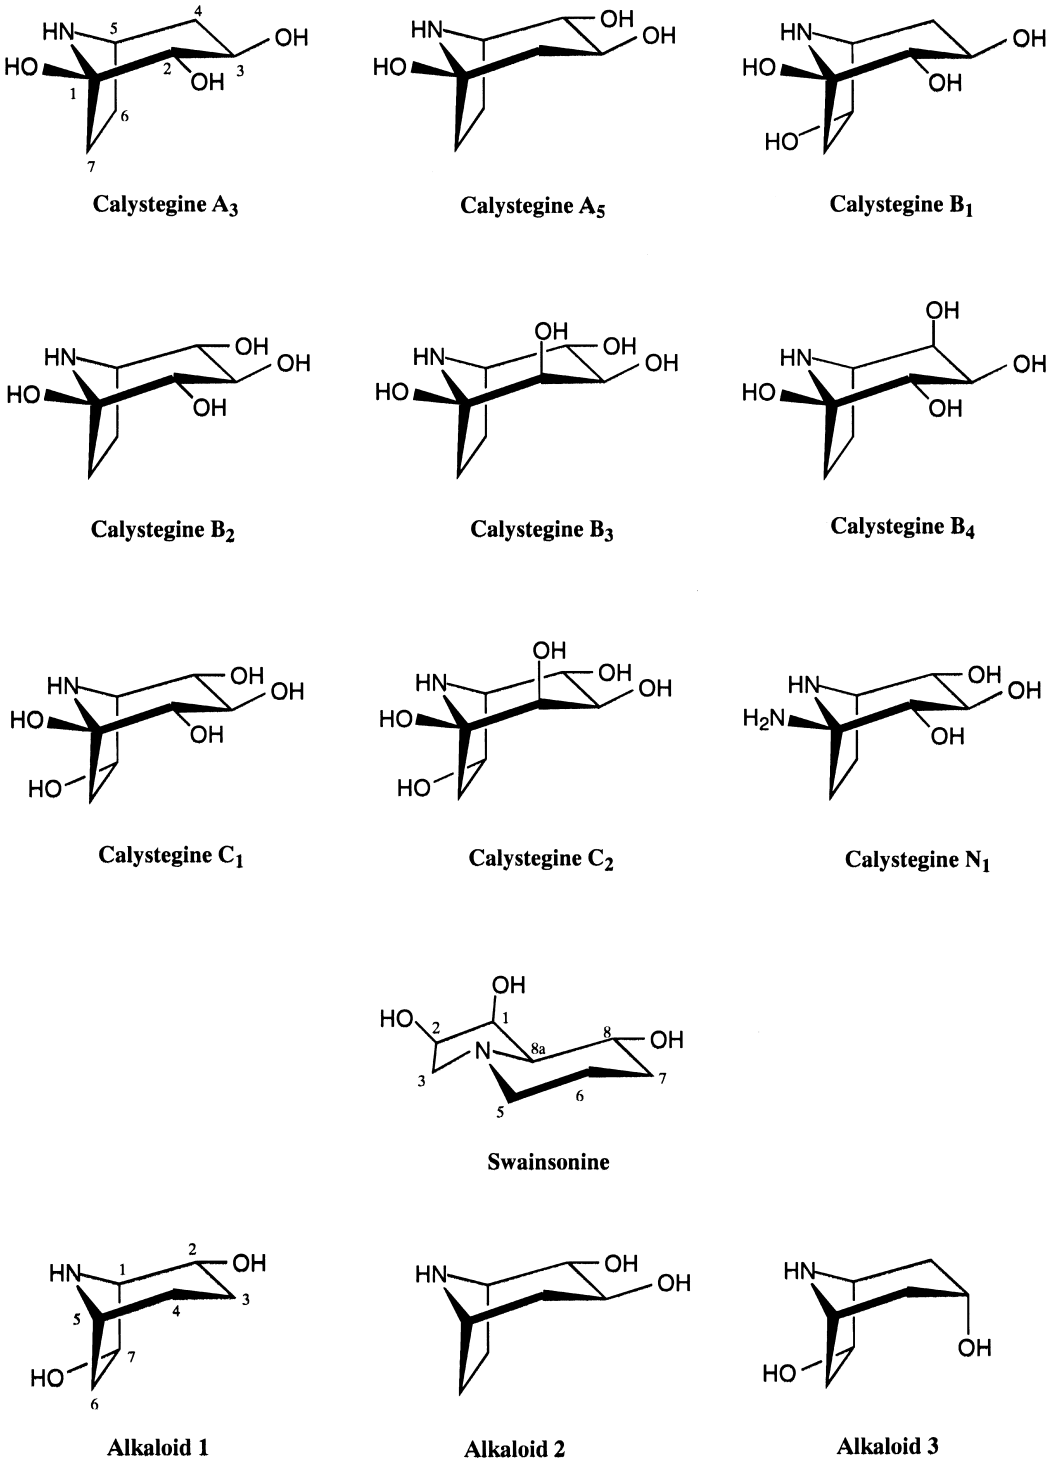

Fig. 1. Structures of the polyhydroxylated alkaloids included in this study.

The ^{13}C NMR spectrum of alkaloid **1** revealed the presence of three methylene and four methine carbon atoms. The HR–FABMS of **1** gave an $[M+H]^+$ ion at *m/z* 144.1026 ($C_7H_{14}O_2N$ requires 144.1025). The ^1H NMR spectral data, combined with extensive decoupling experiments and two-dimensional ^1H–^{13}C COSY spectral data, defined the complete connectivity of the carbon and hydrogen atoms for **1**. The methine doublets at δ 70.7 and 73.5 were assigned to C-2 and C-7, each bearing an OH group, due to the appearance in the low-field region of H-2 (δ 3.72) and H-7 (δ 4.45). The methine carbon at δ 70.1, with a doublet at δ 3.21 in the ^1H NMR spectrum, was identified as the bridgehead C-1, and the last methine at δ 57.0 was assigned to the other bridgehead C-5. There was no resolvable coupling between H-1 and H-7 in the ^1H NMR spectrum, indicating a dihedral angle close to 90° between them, and also an *endo* orientation of H-7. The strong NOE effect between H-7 and H-3ax also supports the *endo* orientation of H-7 (Fig. 2a). The coupling pattern of H-2 (*ddd*, $J_{1,2}=4.0$, $J_{2,3ax}=11.3$, $J_{2,3eq}=5.9$ Hz) and the NOE effect between H-2 and H-4ax indicate that H-2 is axial (Fig. 2a). Thus, alkaloid **1** was determined to be either 2α,7β-dihydroxynortropane or its enantiomer.

Alkaloid **2** was an isomer of **1** from HR–FABMS (*m/z* 144.1026 $[M+H]^+$) and ^{13}C NMR spectral data. The methines at δ 56.4 (C-5) and 61.0 (C-1) indicated that they must be bonded to the nitrogen of the heterocyclic ring. The coupling pattern of H-2 (δ 3.52, *dd*, $J_{1,2}=3.7$, $J_{2,3}=8.8$ Hz) indicates the *trans*-diaxial configuration of H-2 and H-3. The NOE effects between H-2 and H-4ax and between H-3 and H-6endo or H-7endo support this stereochemistry (Fig. 2b). Thus, alkaloid **2** was determined to be 2α,3β-dihydroxynortropane or its enantiomer.

Alkaloid **3** was also an isomer of **1** from HR–FABMS (*m/z* 144.1024 $[M+H]^+$) and ^{13}C NMR spectral data. The coupling pattern of H-7 (δ 4.83, *dd*, $J_{7,6endo}=7.3$, $J_{7,6exo}=2.2$ Hz), with no resolvable coupling with H-1 (δ 3.72, *t*, $J_{1,2ax}=J_{1,2eq}=4.0$ Hz), indicates an *endo* orientation for H-7. The small *J* value (4.0 Hz) between H-2ax and H-3, and the absence of an NOE effect between H-3 and H-7 or H-6endo indicate an equatorial orientation for H-3 (Fig. 2c). In addition, since alkaloid **3** was optically inactive, it was determined to be (±)-3α,7β-dihydroxynortropane.

In order to investigate the occurrence and distribution of these dihydroxynortropanes, nine species from the Convolvulaceae and three species from the Solanaceae were studied. All of the alkaloids were isolated by column chromatography using various ion-exchange resins. The known alkaloids were identified from their ^{13}C NMR chemical shifts. As shown in Table 1, 2α,7β-dihydroxynortropane (**1**) was isolated from six species in the Convolvulaceae and only *C. soldanella* produced both **1** and **2** (2α,3β-dihydroxynortropane). Although alkaloids **1** and **2** were not isolated from three species in the Solanaceae, the other alkaloid **3** (3α,7β- dihydroxynortropane) and calystegine A_5 were isolated from *D. leichhardtii*, in addition to known calystegines B_1, B_2, B_4, C_1, and C_2 (Kato et al., 1997). De Balogh et al. (1999) recently detected calystegine B_2 and swainsonine in *Ipomoea carnea* (Convolvulaceae) by GC–MS. In the present work, alkaloid **1** and calystegine B_1, in addition to calystegine B_2 and swainsonine, were isolated from the same plant. It is not known if the calystegines occur in *Erycibe* species (Convolvulaceae) (Lu et al., 1986; Chen et al., 1986), which are known to produce 2β,6β- and 2β,7β-dihydroxynortropanes. Major tropane alkaloids bear a hydroxyl group or an esterified one at C-3. Tropinone has been shown to be an intermediate on the biosynthesis of hyoscyamine and scopolamine in *Datura innoxia* (Landgrebe and Leete, 1990). Tropinone is

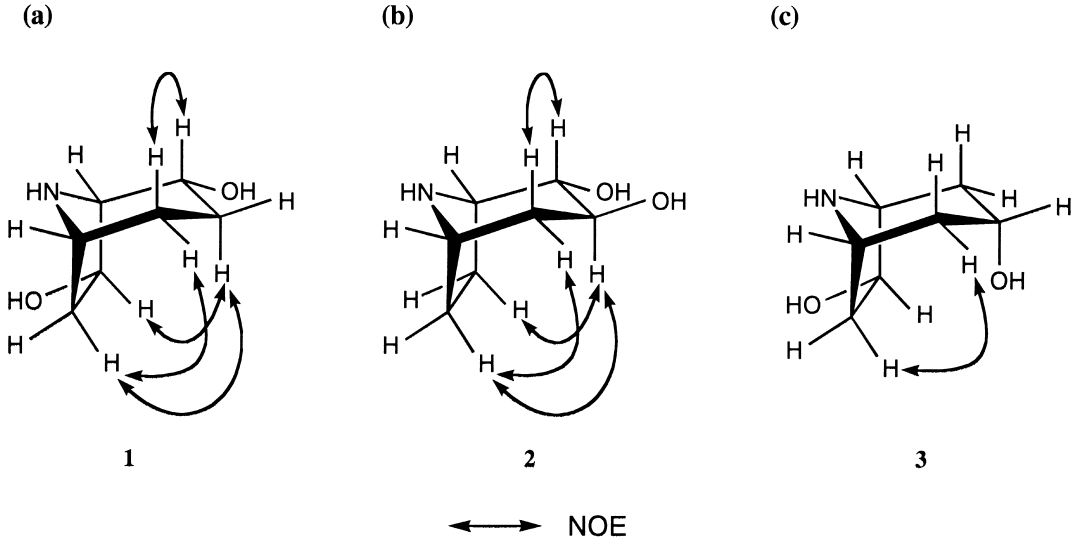

Fig. 2. NOE effects of 2α,7β-dihydroxynortropane (**1**) (a), 2α,3β-dihydroxynortropane (**2**) (b), and 3α,7β-dihydroxynortropane (**3**) (c).

reduced to specifically tropine in a cell-free system obtained from a root culture of *D. stramonium* (Koelen and Gross, 1983) or to pseudotropine as a major product in the same system of *Hyoscyamus niger* (Dräger et al., 1988). The structure of calystegines suggests that calystegines are formed by the biosynthetic pathway of tropane alkaloids. Although all of calystegines isolated from the root culture of *C. sepium* have a hydroxyl group at C-3, alkaloid **1** obtained from tha same plant does not have it. *Lycium chinense* (Solanaceae) produces calystegines A_6, A_7, and B_5 with no hydroxyl group at C-3 in addition to a lot of calystegines and *N*-methylcalystegines with a hydroxyl group at C-3 (Asano et al., 1997). The occurrence of nortropane alkaloids with no hydroxyl group at C-3 in the Convolvulaceae and Solanaceae is very interesting from the biosynthetic basis of tropane alkaloids.

3. Experimental

3.1. General

The purity of samples was checked by HPTLC on Silica Gel $60F_{254}$ (Merck) using the solvent system PrOH–AcOH–H_2O (4:1:1), and a chlorine/*o*-tolidine reagent was used for detection. Optical rotations were measured with a Jasco DIP-370 digital polarimeter. ^1H NMR (400 MHz) and ^{13}C NMR (100 MHz) spectra were recorded on a Jeol JNM-GX 400 spectrometer. Chemical shifts are expressed in ppm downfield from sodium **3**-(trimethylsilyl)propionate (TSP) in D_2O and TMS in CD_3OD as internal standards. MS were measured on a Jeol JMS-SX 102A spectrometer.

3.2. Plant material

Calystegia japonica and*C. soldanella* were collected in the wild in 1995 in Kanazawa City, Japan, and *Ipomoea obscura* and *I. pes-caprae* were collected in the wild in 1994 in Okinawa, Japan. *Quamoclit angulata* was collected in the wild in 1999 in Suwon, Korea. *I. batatas* var. *edulis*, *I. nil*, and *Solanum dulcamara* were cultivated in the field of the Medicinal Plants Garden, Hokuriku University, Japan, and *I. carnea* was grown in the greenhouse of the same facility. *Cestrum nocturnum* and *Duboisia leichhardtii* were cultivated in the greenhouse of Toyama Medical and Pharmaceutical University, Japan. Voucher specimens of all plants are deposited in the Medicinal Plants Gardens of Hokuriku University and Toyama Medical and Pharmaceutical University.

Transformed root cultures of *C. sepium* were established by transformation of leaf discs with *Agrobacterium rhizogenes* strain 8196, as described in the literature (Jung and Tepfer, 1987). Emerging roots were transferred to 25 ml of B5 liquid medium in 100 ml flasks containing 500 mg/l cefotaxim, but no phytohormones. After several subcultures, cefotaxim was omitted from the medium. For root mass production, roots were subcultured in 300 ml flasks with 70 ml of medium. Growth was typically 20–25-fold within 21 days.

3.3. Extraction and isolation

The dried whole plant (550 g) of *C. soldanella* was extracted with hot water (5 l) for 2 h. The extract (about 3 l) was applied to a column of Amberlite IR-120B (300 ml, H^+ form). The 0.5 M NH_4OH eluate was concentrated to give a brown oil (11.8 g), which was applied

to an Amberlite CG-50 column (2.5×95 cm, NH_4^+ form) with H_2O as eluant (fraction size 18 ml). The H_2O eluate was divided into five pools A (fractions 32–45, 580 mg), B (fractions 46–70, 176 mg), and C (fractions 75–100, 32 mg). The 0.5 M NH_4OH eluate from the same column was designated pool D. Pools A, B, and C were further subjected to Dowex 1-X2 (1.8×95 cm, OH^- form) column chromatorgraphy with H_2O as eluant to give calystegines B_2 (530 mg), B_1 (100 mg), and B_3 (6 mg), respectively. Pool D was applied to Dowex 1-X2 (1.8×65 cm, OH^- form) column with H_2O as eluant to give calystegine A_3 (7 mg) and a mixture of alkaloids (72 mg). The mixture was further subjected to CM-Sephadex C-25 (1.5×46 cm, NH_4^+ form) column chromatography with 0.01 M NH_4OH as eluant to give alkaloids **1** (23 mg) and **2** (7 mg).

The other plant materials were also extracted and purified in a similar manner. The yields of alkaloids from each plant are as follows.

C. japonica (300 g of dried roots): calystegines A_3 (33 mg), B_1 (42 mg), B_2 (186 mg), and alkaloid **1** (10 mg).

I. batatas var. *edulis* (2 kg of dried aerial parts): calystegines B_1 (65 mg), B_2 (95 mg), and alkaloid **1** (12 mg).

I. carnea (2 kg of dried aerial parts): swainsonine (86 mg), calystegines B_1 (39 mg) and B_2 (146 mg), and alkaloid **1** (20 mg).

I. obscura (416 g of dried whole parts): calystegines B_1 (14 mg), B_2 (88 mg), B_3 (6 mg), B_4 (10 mg), and C_1 (66 mg).

I. pes-caprae (480 g of dried aerial parts): calystegine B_2 (9 mg).

Q. angulata (330 g of dried aerial parts): calystegines B_1 (45 mg), B_2 (78 mg), and alkaloid **1** (18 mg).

Duboisia leichhardtii (1 kg of dried aerial parts): calystegines A_5 (8mg), B_1 (5 mg), B_2 (24 mg), B_4 (20 mg), C_1 (810 mg), C_2 (5 mg), and alkaloid **3** (3.6 mg).

Solanum dulcamara (250 g of dried whole parts): calystegines A_3 (34 mg), A_5 (19 mg), B_1 (6 mg), B_2 (48 mg), and N_1 (13 mg).

Fresh root cultures (1.2 kg) of *C. sepium* were extracted with 50% MeOH. The extract was concentrated and lyophilized to give a brown powder (46 g). The powder was subjected to chromatographic purification in a similar manner to give calystegines A_3 (25 mg), B_1 (32 mg), B_2 (49 mg), and alkaloid **1** (17 mg).

Fatty acid profiles and their chemotaxonomy in planktonic species of *Anabaena* (Cyanobacteria) with straight trichomes

Renhui Li*, Makoto M. Watanabe[1]

National Institute for Environmental Studies, 16-2 Onogawa, Tsukuba, Ibaraki 305-0035, Japan

Received 13 October 2000; received in revised form 23 January 2001

Abstract

Twenty-four axenic strains of planktonic *Anabaena* with straight trichomes, assigned to 7 species, were investigated by analyzing the pattern and content of their fatty acid composition and comparing their fatty acid composition with their morphological properties. In general, the fatty acids in planktonic *Anabaena* contained 14:0, 16:0, 16:1(*cis*-), 18:0, 18:1, 18:2, and 18:3(α) as their major components, and were classified as Type 2 according to the Kenyon–Murata system. These strains were further divided into 2 subtypes: 18 strains belonging to Type 2A, which contains 16:2 and 16:3, and 6 strains to Type 2B, which lacks 16:2 and 16:3. Fatty acid compositions of strains of *A. solitaria*, *A. smithii,* and *A. kisseleviana* closely corresponded to morphological properties; however, 10 strains of *A. planctonica* were divided into 4 clusters, and 3 strains of *A. affinis* into 2 clusters. These clusters should be taxonomically evaluated based on other aspects such as genetic characteristics. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Cyanobacteria; Fatty acid; Morphological characters; Planktonic *Anabaena*; Taxonomy

1. Introduction

Freshwater planktonic cyanobacteria *Anabaena* spp. are organisms that sometimes form water blooms in eutrophic lakes, reservoirs, and ponds. Like *Microcystis* species, these filamentous heterocystous cyanobacteria are also recognized as a threat to public health due to the production of toxic substances such as microcystin, anatoxin-a, and saxitoxin. (Carmichael, 1981; Skulberg et al., 1993; Humpage et al., 1994; Chorus and Bartram, 1999) and excretion of geosmin-like odor-producing substances (Izaguirre et al., 1981; Jüttner, 1987; Hayes and Burch 1989). In spite of the ecological significance of planktonic *Anabaena*, identification is problematic and often provisional (Hickel, 1982; Komárek and Anagnostidis, 1989). The current taxonomy of *Anabaena* is based mainly on morphological characteristics such as trichome form, shape of akinetes, size of cells, and relative position of the akinetes to heterocysts. According to Geitler (1942) "the determination of *Anabaena* species is very difficult and frustrating" (cf. Hickel, 1982). Some morphological criteria vary among different researchers (Fritsch, 1949; Nygaard, 1949; Komárek, 1958; Pankow, 1965; Komárková-Legenrová and Eloranta, 1992; Watanabe, 1992; Niiyama, 1996). Furthermore, taxonomic characters such as filament form and akinete cells are problematic because akinetes are occasionally absent and trichome form may be irreversibly changed by culture conditions. Recently, Castenholz and Waterbury (1989) strongly urged that bacterial approaches should be introduced to the taxonomy of cyanobacteria due to their prokaryotic properties. Therefore, it is apparent that planktonic *Anabaena* species require more taxonomic studies incorporating not only morphological characters but also physiological, chemical, and genetic features.

Fatty acid composition is a useful analytical tool in bacterial taxonomy (Welch, 1991; Embley and Wait, 1994). In the cyanobacteria, Kenyon (1972), Kenyon et al. (1972), and Murata et al. (1992) proposed that four types of fatty acid composition exist in cyanobacteria and demonstrated some correlations with morphological properties. Caudales and Wells (1992) investigated the cellular fatty acids of benthic cyanobacteria belonging to

the genera *Anabaena* and *Nostoc* and found significant differences between those genera. Krüger et al. (1995) evaluated the taxonomic importance of fatty acid composition at the genus and subgenus level by analyzing the fatty acid composition of different *Microcystis* isolates and other members of the order Chroococcales. However, there is little information about fatty acid composition and chemotaxonomy in planktonic species of *Anabaena*. According to Watanabe (1992, 1998), planktonic species of *Anabaena* are divided into two groups: species with straight trichomes and those with coiled trichomes. In the present study, we extensively examined 24 strains with straight trichomes by analyzing the pattern and content of fatty acids in these strains and established their chemotaxonomy by comparing their fatty acid composition with morphological properties.

2. Results

The 24 strains used in the present study (see Table 1) were identified as 7 species based on morphological observations: *Anabaena affinis* Lemmermann, *A. planctonica* Brunnthaler, *A. solitaria* Klenahn, *A. smithii* (Komárek) Watanabe, *A. viriguri* Denis et Fremy, *A. kisseleviana* Elenkin, *A. danica* (Nygaard) Komárková et Eloranta. The composition and content of fatty acids in these strains are shown in Table 2. The major components of fatty acids in these strains were 16:0, 16:1(*cis*-), 18:2, and 18:3(α); therefore, they are classified as Type 2 according to the Kenyon–Murata system (Kenyon, 1972; Kenyon et al., 1972; Murata et al., 1992). Our previous study indicated that Type 2 could be further divided into 2 subtypes: Type 2A (with 16:2 and 16:3), and Type 2B (without 16:2 and 16:3) (Li et al., 1998). As shown in Table 2, 18 strains belonging to *A. smithii*, *A. solitaria*, *A. planctonica* (8 strains), and *A. affinis* (2 strains) were Type 2A, and 6 strains belonging to *A. kisseleviana*, *A. danica*, *A. planctonica* (2 strains), and *A. affinis* (1 strain) were Type 2B. The simplified dendrogram created by a simplified unweighted pair-group method with arithmetic averages (UPGMA) using the NTSYS-pc program package and fatty acid data are shown in Fig. 1. In the dendrogram, the 24 strains are shown in relation to fatty acid compositions of Type 2A and 2B. In the strains of *A. smithii*, *A. solitaria,* and *A. kisseleviana*, there was a close correspondence between fatty acid composition and morphological characters; however, 10 strains of *A. planctonica* were divided into 4 separate clusters, AP 1∼4 (Fig. 1), of which 2 strains of AP-4 belonged to Type 2B and other clusters to Type 2A. In addition, 3 strains of *A. affinis* were separated into 2 clusters, AA-1 and AA-2, which belonged to Type 2A and 2B, respectively.

3. Discussion

Fatty acids of cyanobacteria have been investigated for their content, composition types, metabolism, and biotechnological application by different researchers (Cohen et al., 1987; Ahlgren et al., 1992; Murata et al., 1992; Matsunaga et al., 1995). In terms of chemotaxonomy by fatty acid composition, Cohen and Vonshak (1991) indicated that there should be a separation between freshwater and salt-tolerant strains in the genus *Spirulina* based on the difference in their fatty acid composition. Krüger et al. (1995) and Caudales and Wells (1992) also demonstrate the importance of fatty acid composition in the taxonomy of Cyanobacteria at the genus and subgenus level. Our previous study shows that fatty acid composition can be used in chemotaxonomy of cyanobacteria even at the species level based on examination of 28 strains of planktonic cyanobacteria (Li et al., 1998). In the present study, fatty acids and their chemotaxonomic values were further investigated using more strains of *Anabaena*. The results showed that both Type 2A and Type 2B are found in planktonic strains of *Anabaena* (Table 2 and Fig. 1).

Planktonic *Anabaena* species with straight trichomes were morphologically classified into *A. affinis* with bundle-

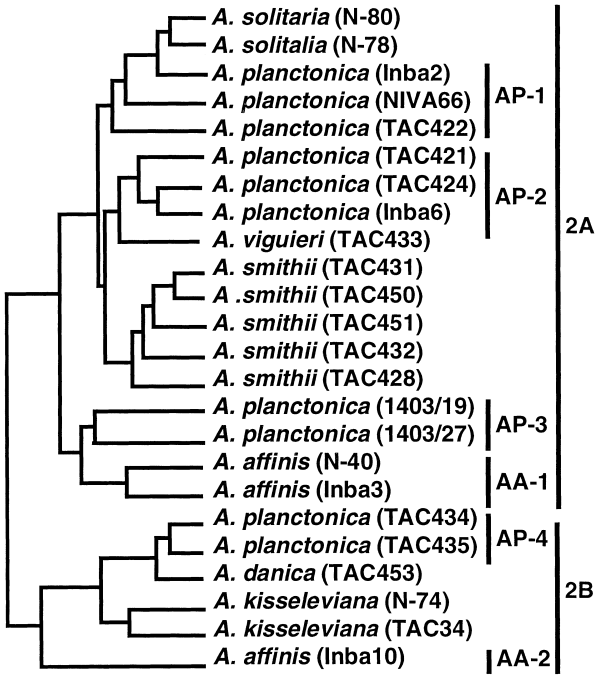

Fig. 1. Dendrogram of planktonic strains of *Anabaena* with straight trichomes based on fatty acid composition; 0.5 represents Euclidean distance. AA-1, 2 and AP-1∼4 represent clusters of *A. affinis* and *A. planctonica,* respectively.

forming trichomes and *Anabaena* spp. with solitary trichomes. The latter group was classified into *A. planctonica*, *A. solitaria*, *A. smithii*, *A. kisseleviana*, etc., based on the shape of the akinetes and their position relative to heterocysts. The results of this study indicate that the morphological classification agreed well with chemotaxonomy of fatty acids within *Anabaena* species having spherical akinetes (i.e. *A. smithii, A. kisseleviana*) and cylindrical akinetes (*A. solitaria*). However, the divergence of fatty acid composition in *A. planctonica* and *A. affinis* reflected current problems of morphological classification.

A. planctonica was established by Brunnthaler in 1903 and has many synonyms, including: *A. scheremetievi* Elenkin 1909; *A. scheremetievi* var. *recta* Elenkin f. *ovalispora* Elenkin 1938; *A. limnetica* G.M. Smith 1916; *A. solitaria* f. *solitaria* sensu Komárek 1958; *A. planctonica* f. *planctonica* (Brunnth.) Komárek 1958; *A. affinis* var. *intermedia* Griffith; *A. catenula* var. *intermedia* Geitler; and *A. affinis* var. *intermedia* f. *tenuis* Nygaard. Since it was first described, *A. planctonica* has been characterized mainly by its ellipsoidal akinetes. However, criteria for the size range of akinetes has varied among researchers (e.g. 14–18.8×21–37 μm by Watanabe, 1992, and 10–20×15–30 μm by Komárková-Legnerová and Eloranta, 1992), causing problems in classifying transient

forms and also resulting in overlap with other species, such as *A. macrospora* and *A. viguieri*. Baker (1991) suggested that there exists some variation in *A. planctonica* and described two morphotypes. To distinguish clusters of strains of *A. planctonica* by fatty acid composition, we tentatively designated them as AP-1, 2, 3, and 4. It is noteworthy that AP-4, with Type 2B fatty acids, included TAC434 and 435, which have higher salinity tolerance (up to 1.5%) than the other *A. planctonica* strains (with up to 0.78%) (Li, 1998), and they also have smaller vegetative cells and heterocysts than other clusters do (Li et al., 2001).

It is generally recognized that bundle formation in planktonic species of *Anabaena* occurs only in *A. affinis*. Akinetes of these bundle-forming *Anabaena* were occasionally absent in both field-collected and cultured specimens; consequently, the akinete shape and size were disregarded. In the genus *Aphanizomenon*, several species have been identified based on other morphological features besides bundle formation (Komárek and Kovácik, 1989). Therefore, it is possible that there are more than one species of bundle-forming *Anabaena*. Results of the fatty acid analysis in the present study suggest this possibility, which was further supported by results on growth temperature range (data not shown). Two clusters of *A. affinis* strains have been designated as AA-1 and AA-2. Clusters of *A. planctonica* and *A. affinis* should be taxonomically reevaluated based on other aspects such as genetic characteristics.

4. Experimental

4.1. Organisms and culture conditions

Axenic strains of 24 planktonic *Anabaena* with straight trichomes were used in the present study. Among these strains, 20 were obtained from different culture collections (NIES, TAC, CCAP, and NIVA; for abbreviations see Table 1), and 4 were isolated by the authors from Japan (Table 1). The unialgal strains were purified into the axenic state using the pipette washing method. Taxonomy of all the strains, based on morphological characteristics, are presented in Li et al. (2001). All the strains were cultivated in CT medium (Watanabe and Hiroki, 1997). The cultures were grown in 1 l of medium in 2-l flasks equipped with aeration by a filter with 0.22-μm pore size. All cultures were grown at 20°C under a 12:12 L/D cycle with a photon irradiance of 40 μmol m^{-2} s^{-1} provided by daylight fluorescent lamps.

4.2. Fatty acid analyses

About 5–10 mg of lyophilized cells were transmethylated with 5% HCl-methanol (TCI-SU, Japan) at 100°C for 3 h. The methylated acids were extracted with 1.5 ml hexane, washed with 0.5 ml distilled water, and filtered with quartz, then concentrated to 50 μl by nitrogen gas or by vacuum evaporation. A 1-μl portion of concentrated sample was injected into a Shimadzu GC-17A gas chromatograph equipped with a hydrogen flame ionization detector and a capillary column (25 m×0.25 mm×0.25 μm) coated with methyl silicone as a polar stationary phase (007-FFAP, Tokyo Kasei). The flow of helium gas was 40 ml min^{-1}, and column temperature was programmed to increase from 130–220°C at 5°C/min. The methyl esters were identified by co-chromatography of authentic standards (Sigma, USA) and by mass spectroscopy. The relative concentrations of fatty acids were calculated by comparing the areas under the chromatographic peaks with a data processor (C-R 6A, Shimadzu). All analyses were performed in triplicate. The quantitative fatty acid data were numerically analyzed using the NTSYS-pc program package (Applied Biostatistics, Inc., Setanket, NY), and the results are presented as dendrograms drawn using the unweighted pair-group arithmetic average (UPGMA) clustering method.

Received 2 October 2000; received in revised form 29 December 2000

Abstract

The essential oils of *Hyptis suaveolens* plants collected from 11 localities of the Brazilian Cerrado region were investigated by GC–MS. Sabinene, limonene, biclyclogermacrene, β-phellandrene and 1,8-cineole were the principal constituents. The results were submitted to principal component and chemometric cluster analysis which allowed three groups of essential oils to be distinguished with respect to the content of *p*-mentha-2,4(8)-diene, limonene/β-phellandrene/γ-terpinene and germacrene D/bicyclogermacrene. In patterns of geographic variation in essential oil composition indicated that the sesquiterpenes are mainly produced in the samples grown at lower latitudes. © 2001 Elsevier Science Ltd. 1. Introduction

Hyptis Jacq., with well over 300 species, exhibits a major morphological diversity in the Brazilian Cerrado region (Harley, 1988). Its species are quite aromatic and are frequently used for the treatment of gastrointestinal infections, cramps, and pain, as well as in the treatment of skin infections (Corrêa, 1931). The aggressive annual weedy species, *Hyptis suaveolens* (L.) Poit. is distributed in the tropics and subtropics, and it is not commonly found over 500 m. The plant is normally restricted to places where soils have been profoundly disturbed, and may be considered as a ruderal species (Wulff, 1973). Some work dealing with the composition and antifungal (Pandey et al., 1982; Singh et al., 1992; Zollo-Amvam et al., 1998), antibacterial (Iwu et al., 1990; Asekun et al., 1999), and anticonvulsant (Akah and Nwambie, 1993) activities of *H. suaveolens* leaf oil have been previously reported: these plants were obtained from various origins (Brazil, India, Malaysia, Nigeria, USA, Aruba). Although relatively few samples have been analysed, it appears from reported data that leaf or aerial parts oils of *H. suaveolens* exhibited several compositions characterised by the occurrence, as major components, of β-caryophyllene (Malaysia and Nigeria), 1,8-cineole and sabinene (USA, India and Aruba), 1,8-cineole and β-pinene (Brazilian Amazonian and Brazilian Northeast) (Craveiro et al., 1981; Gottlieb et al., 1981; Luz et al., 1984; Din et al., 1988; Iwu et al., 1990; Mallavarapu et al., 1993; Ahmed et al., 1994; Singh and Upadhyay, 1994; Asekun and Ekundayo, 2000). As part of our ongoing work on the characterisation of essential oils of aromatic plants growing wild in the Brazilian Cerrado region (Costa et al., 2000), we now report on the results obtained for the essential oil composition and variability of *H. suaveolens*. For that purpose, 11 different sampling sites (Fig. 1) were chosen, and the qualitative and quantitative analysis of the volatile oil of a representative population sample of each was performed by GC–MS. To study the chemical variability, the chemical constituents from the essential oil of samples from each locality were submitted to principal component and chemometric cluster analysis, in order to detect dome pattern distribution of samples and to identify which

constituents can differentiate between the groups of individuals.

2. Results and discussion

The essential oil of *H. suaveolens* plants collected from the eleven different sampling sites of Brazilian Cerrado (Fig. 1) gave an average yield of 0.7% (wt/wt). In total, 40 compounds were identified, accounting for 91–97% of the volatile constituents. Monoterpene hydrocarbons were the main group of constituents in most of the populations (36.89–73.40%). Nevertheless, important differences in the amounts of the major constituents were found, mainly of sabinene (2.93–31.13%) which had the highest percentage in population D, *p*-mentha-2,4(8)-diene (0.19–20.87%) as the principal constituent of populations E and G, β-phellandrene (0.92–18.17%), limonene (3.60–17.56%), γ-terpinene (0.52–17.33%) as the major components of population C. Populations A and B had the highest percentage of 1,8-cineole (0–15.08%), and populations H, J and K had bicyclogermacrene (2.38–12.68%) as the main constituent. The results showed some important differences between the populations, indicating the existence of chemical polymorphism. Results obtained from nearest neighbour complete linkage cluster analysis using Ward's technique (Ward, 1963) and principal component analysis (PCA) showed the existence of a highly chemical variability within the essential oil *H. suaveolens* (Fig. 2). First principal component separates monoterpene hydrocarbons (mean content 71.01%, S.D. = 2.39; populations C and D) from sesquiterpene samples (20.70%, S.D. = 11.40; populations B, H and I–K), and the second principal component distinguishes the populations A, E, F and G for the content of *p*-mentha-2,4(8)-diene. In Fig. 2, the strong negative correlation between sesquiterpenes and monoterpene hydrocarbons is clear. Additionally, there is a correlation between essential oil composition and geographic variation (Table 1). Sesquiterpenes were mainly produced at lower latitudes, whereas monoterpenes at higher ones. Therefore, three main types of essential oils were found: Cluster I was characterised by a high percentage of *p*-mentha-2,4(8)-diene (11.73%, S.D. 8.4); Cluster II had limonene (15.19%, S.D. = 3.35), β-phellandrene (16.48%, S.D. = 2.39) and γ-terpinene (10.65%, S.D. = 9.45) as the major compounds; and Cluster III showed substantial percentages of germacrene D (6.54%, S.D. = 2.43) and bicyclogermacrene (11.49%, S.D. = 1.22). The chemical composition of the oils from USA (Ahmed et al., 1994), India (Mallavarapu et al., 1993), Aruba (Fun and Svendsen, 1990) and Brazilian Amazonian (Gottlieb et al., 1981) are closed to the composition determined for

[b] $P < 0.01$ (Student's *t*-test).

sample of cluster I. Otherwise, the content of the β-pinene in oil from Brazilian Amazonian is much higher than that of our samples. The chemical composition of Clusters II and III are original. The chemical variability presented in this paper corresponds well with the results from both polymorphism in seed germination and differential rate of growth in plantlets of *Hyptis suaveolens* (Wulff, 1973), which may be important factors in the colonising ability of this species.

3. Experimental

3.1. Plant material

H. suaveolens plants were collected at the vegetative stage in January and March 2000 and identified by two of the authors (I.F.P.C. and H.D.F.); 3–5 individuals, representing the local population, were collected from the each locality (Fig. 1). Voucher specimens of each sample are deposited in the Herbarium of the Universidade Federal de Goiás, Goiás State, Brazil. The aerial parts were air-dried at room temp. for 7 days. Then, the total plant material from each population was pulverized and submitted to hydrodistillation (6 h) using a Clevenger apparatus.

3.2. Analysis of essential oils

Oil samples analysis were performed on a GC–MS Shimadzu QP5050A instrument employing the following conditions: Column: CBP-5 (Shimadzu) fused silica capillary column (50 m long × 0.25 mm i.d. × 0.25 μm film thickness composed of 5% phenylmethylpolysiloxane) connected to an ion trap detector operating in EI mode at 70 eV; carrier gas: He (1 ml min^{-1}); injector and ion-source temperatures were 250°C and a split ratio of 1:5. Injection volume was 1 μl (20% in CH_2Cl_2) and the oven temperature was programmed from 60°C (isothermal for 2 min), with an increase of 3°C min^{-1}, to 240°C, then 10°C min^{-1} to 280°C, ending with a 10 min isothermal at 280°C. Individual components were identified by comparing their RR_t and mass spectra with those of the authentic samples, literature (Adams, 1995) and a computerized MS-data base using NIST libraries.

3.3. Chemical variability

Principal component analysis (PCA), using SPAD.N software package (Lebart et al., 1994), was applied to examine the interrelationships between different populations and its chemical constituents. Cluster analysis was also applied to the study of similarity of samples on the basis of constituent distribution. Nearest neighbour complete linkage technique by Benzécri algorithm (Benzécri, 1980) was used as an index of similarity and hierarchical clustering was performed according to the Wards variance minimising method (Ward, 1963).

Acknowledgements

We thank Dr. A.J. Marsaioli (IQ-Unicamp) for supplying the authentic samples. Thanks are also due to CNPq, PADCT III/QEQ (Grant No. 620166/97-5) and Fundação de Apoio à Pesquisa-FUNAPE/UFG for their financial support.

Received 11 July 2000; received in revised form 20 December 2000

Abstract

Dihydrochalcone derivative, 3′,5′-di-*C*-β-glucopyranosylphloretin (**1**), is present in the genus *Fortunella*, (*F. crassifolia*, *F. japonica*, *F. margarita*, *F. polyandra* and *F. hindsii*). These species accumulate a large quantity of **1** in their fruits (peel, 6.5–15.2 mg/g in dry wt; juice sac, 1.5–10.5 mg/g) and in their leaves (21.3–60.2 mg/g). Twenty-seven Tanaka's *Citrus* species examined lack **1**, but *C. madurensis* and *C. halimii* contain **1** in large quantities in their peels (25.1 and 33.6 mg/g) and juice sacs (4.1 and 4.2 mg/g). *Poncirus* species do not contain **1**. *Fortunella*-citrus hybrids, the Orangequat [*C. unshiu*×*F. crassifolia*], the Thomasville citrangequat [*Fortunella* sp.×(*C. sinensis*×*Poncirus trifoliata*)], and seven hybrid progenies [*F. margarita*×*C. junos*], contain large amounts of **1** in their peels (17.0–7.9 mg/g) and juice sacs (2.0–9.9 mg/g). These facts suggest that accumulation of **1** is a generic trait of the genus *Fortunella* and that the inheritance of the trait among the intergeneric hybrids is controlled by a dominant allele. Thus *C. madurensis* and *C. halimii* are thought to originate from natural hybrids between the genera *Citrus* and *Fortunella*. Phloridzin, which has the same aglycon as **1**, was not detected in the citrus plants examined. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Fortunella*; *Citrus*; *Poncirus*; Rutaceae; Hybrid; Taxonomy; Dihydrochalcone; Flavonoid; 3′; 5′-Di-*C*-β-glucopyranosylphloretin

1. Introduction

The principal flavonoids of the genus *Citrus* are flavanone glycosides such as narirutin, naringin, hesperidin, and neohesperidin, and flavone aglycons such as nobiletin and tangeretin (Mizuno et al., 1991; Kanes et al., 1993; Tsuchida et al., 1997; Kawaii et al., 1999). The genus *Fortunella* is taxonomically close to the genus *Citrus*. Flavonoid compositions of *Fortunella* species, however, differ from those of *Citrus* species. While a flavanone glycoside, poncirin, has been reported, flavanones are thought to be minor constituents in plants of the *Fortunella* genus. A number of *C*-glycosylated flavones have also been identified in *F. japonica* and *F. crassifolia* (Kumamoto et al., 1985; Tsuchida et al., 1997), but quantities of flavonoids in *Fortunella* plants have been found to be rather low compared with plants of the *Citrus* genus (Kanes et al., 1993; Tsuchida et al., 1997). Our previous report demonstrated the presence and quantities of 24 flavonoid constituents in the edible portions of 66 citrus fruits (Kawaii et al., 1999). Narirutin was identified as a major constituent of plants of the *Fortunella* genus. As the result of reinvestigation, this "narirutin" is shown to be a new dihydrochalcone glucoside, 3′,5′-di-*C*-β-glucopyranosylphloretin (**1**), which was isolated from *F. margarita* as a major flavonoid. Also isolated were three flavone glycosides, 2′-*O*-α-L-rhamnopyranosylcytisoside (**2**), 2′-*O*-α-L-rhamnopyranosylisocytisoside (**3**), and acacetin 7-*O*-neohesperidoside (fortunellin, **4**), which had been isolated previously from plants of the *Fortunella* genus (Matsuno, 1958; Kumamoto et al., 1985). In this paper, we describe the structure determination of **1**. The distribution of major flavonoid species such as narirutin, naringin, hesperidin,

PII: S0031-9422(01)00132-7

and neohesperidin is applicable to the chemotaxonomy of the genus *Citrus*. Chemotaxonomy based on dihydrochalcones in citrus plants is a subject that has remained unexplored. We report the distribution and content of **1** and its related dihydrochalcone, phloridzin, in plants of the genus *Fortunella*, *Citrus*, and *Poncirus*, and moreover of the *Fortunella*-citrus hybrids. The generic relationship between the accumulation of **1** and citrus plants is discussed.

2. Results and discussion

The ^{1}H and ^{13}C NMR spectra of **1** indicated the presence of a *p*-substituted and a fully-substituted phenyl group. While the UV spectrum of **1** is similar to that of flavanones, ABX signals of H-2 and H_2-3 characteristic of flavanone were absent in the ^{1}H NMR spectrum of **1**. The presence of two methylene groups in **1** were indicated by ^{1}H (δ 3.34 and 2.85) and ^{13}C NMR signals (δ 47.8 and 31.0). These suggested that **1** had a dihydrochalcone skeleton. A partial structure of 3-(4-hydroxyphenyl)-1-propanone was deduced from the correlation of COSY, HMBC, and HMQC. The ^{13}C NMR special data indicated that the fully-substituted phenyl group consisted of three oxygenated carbons [δ 163.1 and 162.2 (2C)] and three carbons [δ 106.2 and 104.4 (2C)] having two adjacent oxygenated carbons. The presence of two pairs of equivalent carbons suggested that ring A had a symmetrical 2,4,6-trihydroxylphenyl structure. All of the NMR signals corresponding to hexapyranose moieties possessed double intensities; therefore, two equivalent hexapyranose moieties existed. The hexapyranose moieties were attached to the benzene ring in the manner of the *C*-glycosyl linkage because the anomeric carbon signals appeared at higher field (δ 76.7) compared with those of the *O*-glycosyl linkage. The fact that **1** resisted acid hydrolysis with 2 N HCl at 90°C for 3 h also indicated a *C*-glycosyl linkage. The HMBC correlation between anomeric protons and the carbons of ring A showed that the hexapyranose moieties were connected with C-3′ and C-5′. The ^{1}H NMR signals of the hexapyranose moieties at H-1, 2, 3 and 4 involve only axial-axial couplings ($J=8$ Hz). The manner of these couplings indicate that the hexapyranose moieties have a β-glucopyranose structure. The combined data suggested that the ring A had a symmetrical 2,4,6-trihydroxyl-3,5-di-*C*-β-glycopyranosylphenyl structure. Thus compound **1** was determined to be 3′,5′-di-*C*-β-glucopyranosylphloretin. Markham et al. (1976) reported phloretin-3′,5′-di-*C*-glycoside as a component of *Hymenophyton leptopodum* (Hepaticae). Its sugar structure was not determined. The spectral data described in their report are insufficient for discriminating between the two. We consider that the present paper is the first to describe and define **1**. Compounds **2**, **3**, and **4** were identified as 2′-*O*-α-L-rhamnopyranosylcytisoside (Kumamoto et al., 1985), 2′-*O*-α-L-rhamnopyranosyliso cytisoside (Kumamoto et al., 1985), and acacetin 7-*O*-neohesperioside (fortunellin) (Matsuno, 1958), respectively, as based on comparison of spectral data described in the literature and the results of hydrolysis.

Among the constituents isolated from *F. margarita* (Nagami kumquat), **1** is remarkable for the presence of the dihydrochalcone structure and for its high content. We have examined the distribution of **1** in other *Fortunella* plants. The genus *Fortunella* includes six species according to Tanaka's (1969) systematics. Five species except *F. obovata* (Changshou kumquat) were collected and analyzed as shown in Table 1. All of the *Fortunella* plants analyzed contained **1**. An HPLC profile of the peel of *F. margarita* is illustrated in Fig. 1. Compound **1** is actually a unique flavonoid glycoside, unlike more typical citrus flavanone glycosides such as narirutin, naringin, hesperidin, and neohesperidin. Tsuchida et al. (1997) reported the presence of an unidentified peak in the HPLC profile of the peel of *F. crassifolia* (Meiwa kumquat). The peak probably corresponds to **1**. The content of **1** in this fruit is as high as 6.5–15.2 mg/g (peels) in dry weight and 1.5–10.5 mg/g (juice sacs). It is notable that the leaves of the *Fortunella* species contained **1** in very large quantities (21.3–60.2 mg/g). In our previous report (Kawaii et al., 1999), we have consequently indicated the existence of narirutin instead of **1** in the edible portion of several *Fortunella species* and *C. madurensis* (Calamondin, see below) due to erroneous assignment.

Citrus species are rich sources of flavanone glycosides, but the presence of chalcones and dihydrochalcones, which are biosynthetic congeners of flavanones, is scarce in plants of the genus *Citrus*. We know of few species that contain chalcone or dihydrochalcone among the subfamily Aurantioideae: the root bark of *C. sinensis* (sweet orange) and *C. nobilis* (King mandarin) (Wu, 1989), the fruit of *Merrillia caloxylon* (Fraser and Lewis, 1974), and the apical stems and leaves of *Poncirus trifoliata* (trifoliate orange) and *C. jambhiri* (Rough lemon) (Bester and Rabe, 1996). Thus we assumed that the accumulation of **1** is a generic trait of the genus *Fortunella*, while the genera *Citrus* and *Poncirus* probably lack **1**. This was checked as mentioned below. Tanaka's systematics arranges 159 *Citrus* plants, which are divided into eight groups based upon a descriptive morphology (Tanaka, 1946, 1948, 1969 and 1980). Several species were selected from each group. Twenty-eight Tanaka's *Citrus* species and *C. halimii* were analyzed, as shown in Table 1. *C. halimii* is a recently described wild *Citrus* plant indigenous to peninsular Thailand and Malaya (Stone et al., 1973). Compound **1** was not detected in most *Citrus* species analyzed, with the exception of *C. madurensis* and *C. halimii*. These species accumulate a large quantity of **1** in their fruits. The contents of **1** in

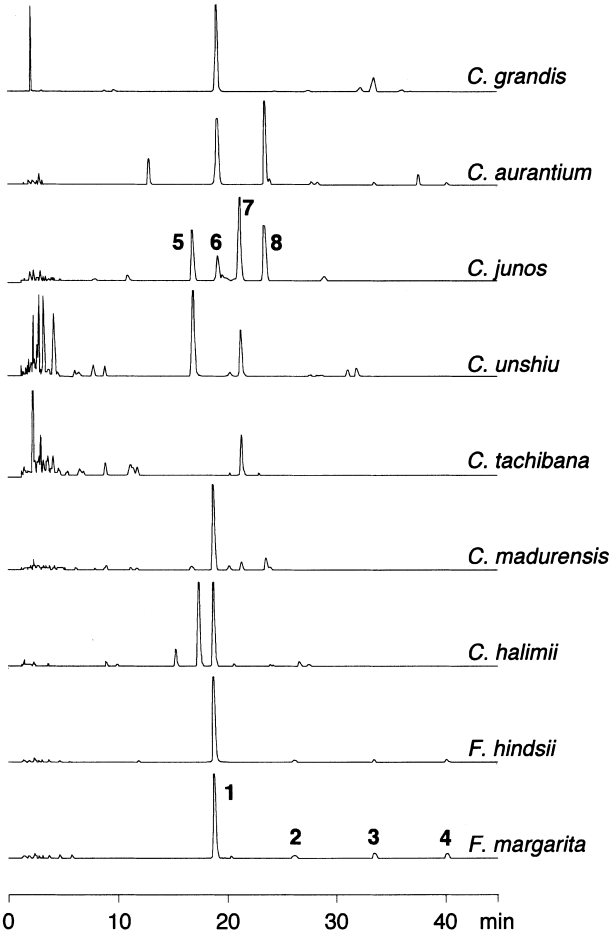

Fig. 1. HPLC profiles of the peels of some citrus plants. 1: 3′,5′-di-*C*-β-glucopyranosylphloretin; 2: 2′-*O*-α-L-rhamnopyranosylcytisoside; 3: 2′-*O*-α-L-rhamnopyranosylisocytisoside; 4: acacetin 7-*O*-neohesperioside; 5: nariruin; 6: naringin; 7: hesperidin; 8: neohesperidin.

the peels were 25.1 and 33.6 mg/g, respectively. *C. madurensis* contained the typical citrus flavanones in small quantities (Fig. 1), while *C. halimii* contained two unidentified constituents whose online-uv spectra suggested a flavone structure, instead of the typical citrus flavanones. The genus *Poncirus*, which consists of *P. trifoliata* alone, lacks **1**. Seasonal variation in the contents of **1** was not examined in the present study. The growth of the fruits generally decreases the flavonoid contents per fruit weight in *Citrus* fruits. Polymethoxylated flavones, tangeretin and heptametoxyflavone in the fruit of *C. aurantium* were seen to fall below undetectable quantities at the mature stage (Del Río et al., 1998). On the other hand, considerable amounts of flavanone diglycosides such as naringin and neohesperidin were maintained in the mature peels of several *Citrus* species (Tsuchida et al., 1996). The contents per fruit (*C. aurantium*) of naringin and neohesperidin were invariable after reaching their maximum levels (Castillo et al., 1993). These facts suggest that the diglycosides are end products of the flavonoid biosynthesis and their translo-

cation does not occur. We assume that seasonal variation in the contents of **1** is similar to that of the diglycosides. The fruits and leaves obtained from single trees growing in one area were used for the evaluation of the content of **1**. Tsuchida et al. (1996) reported that variations in the polymethoxylated flavone and coumarin contents in the fruit of *C. unshiu* (Satsuma mandarin) peels among trees growing in several individual areas were not larger than the variations among trees growing in one area. Thus we consider that constituents including **1** of citrus fruits are negligibly affected by the growing condition.

The *Citrus* species have undergone natural crossing for a long period (Hodgson, 1967). The genus *Citrus* comprises not only the true species but also many natural hybrids (Barret and Rhodes, 1976). Only *C. madurensis* belongs to the group Pseudofortunella according to Tanaka's systematics. Morphological and numerical taxonomic studies have suggested that *C. madurensis* probably originated from a natural hybrid between a *Fortunella* and a *Citrus species* (Swingle and Reece, 1967; Barret and Rhodes, 1976; Handa and Oogaki, 1985). The taxonomic position of *C. halimii* is uncertain, but this species has a leaf and fruit morphology intermediate between the genus *Fortunella* and the genus *Citrus* (Stone et al., 1973). A generic relationship deduced by analyses of isoenzymatic systems has indicated that *C. halimii* is located apart from the *Citrus* species and closer to the *Fortunella* species (Herrero et al., 1996). The accumulation of **1** in *C. madurensis* and *C. halimii* is reliable evidence that natural crosses between plants of the *Fortunella* genus and *Citrus* genus gave rise to these species.

A number of intergeneric crossbreedings between the genus *Fortunella* and related genera have been performed for the development of cold-hardy hybrids. The Orangequat and the Citrangequat are well-known hybrids that include *Fortunella* parentage. The Orangequat is a hybrid between *C. unshiu* (Satsuma mandarin) and *F. crassifolia*. Crossing between *F. margarita* and Willtis citrange, which is a hybrid of *C. sinensis* with *P. trifoliata,* yielded the Thomasville citrangequat. The fruit of the Orangequat contains a large amount of **1** (31.2 mg/g in peel and 2.0 mg/g in the juice sac), while the fruit of the Thomasville citrangequat also contains **1** in large quantities (47.9 mg/g in peel and 8.0 mg/g in juice sac). We have seven hybrid progenies produced by crossing *F. margarita* and *C. junos* (Yuzu). The fruits of these hybrid progenies showed morphologies between those of the *Fortunella* species and *C. junos*. The fruits of seven hybrids contain **1** in large quantities (peel, 17.0–28.7 mg/g; juice sac, 4.8–9.9 mg/g).

The above data indicated that the *Fortunella*-citrus hybrids certainly inherited accumulation of **1** from the *Fortunella* parent. Crossing *F. margarita* and *C. junos* has caused a unilateral accumulation of **1** in the resulting hybrids. The backcrossed hybrids do not exist, but there is a strong presumption that the accumulation of **1** in the intergeneric hybrids is controlled by a dominant allele, and that *Fortunella* species are probably homozygous for the allele. The biosynthesis of naringin has been established (Lewinsohn et al., 1989; McIntosh et al., 1990; Bar-Peled et al., 1991), while that of dihydrochalcone has not yet been clarified. Lewinsohn et al. (1989) showed that cell-free extract derived from the young fruit of*C. madurensis* possessed the capability to biosynthesize naringenin and 7-*O*-glucosylnarngenin, prunin, in the presence of the precursors, namely, *p*-coumaroyl-CoA, malonyl-CoA, and UDP-glucose. The fruit of *C. madurensis* accumulates small quantities of flavanone diglycosides such as hesperidin and neohesperidin (Kawaii et al., 1999) as shown in Fig. 1, while it did not contain naringenin. Flavanone biosynthesis occurs in the citrus plants involving the *Fortunella* parent. An immediate precursor of the aglycone of **1**, phloretin, is thought to be naringenin because phloretin is not synthesized during incubation. Phloretin 2′-*O*-glucoside, phloridzin, and **1** have a common aglycone. Bester and Rabe (1996) identified phloridzin in the leaves and stems of *P. trifoliata* and *C. jambhiri*. Our analysis did not detect its presence in the fruits and the leaves of citrus plants, regardless of whether or not they contained **1**. We assume that the *Fortunella* species possess a predominant flavonoid-biosynthetic pathway consisting of *C*-glucosylation of naringenin and the formation of phloretin and flavone structures occurring after the *C*-glucosylation, and that the true *Citrus* species lack the pathway.

Fortunella species and *Fortunella*-*Citrus* hybrids may be important plants for the elucidation of dihydrochalcone biosynthesis.

The fruits and leaves of *Fortunella* species have been used as the folk medicine in China (Jiangsu New Medical College, 1977). Phloridzin and its aglycone phloretin indicate biological and pharmacological activities; for example, they inhibit glucose transmembrane transport and tumor cell growth (Nelson and Falk, 1993). The activities of **1** have drawn a certain amount of interest. The dihydrochalcone glycosides, naringin dihydrochalcone and neohesperidin dihydrochalcone, have potential as sweetening agents (Borrego et al., 1995). The solution of **1** at a concentration of 10,000 ppm is tasteless.

3. Experimental

3.1. General

Narirutin, naringin, hesperidin, and neohesperidin were obtained from EXTRASYNTHESE (Funakoshi, Japan), and phloridzin from Sigma (St Louis, MO, USA). NMR spectra were recorded on a DPX400 spectrometer (Brüker, Japan). Mass spectra were measured

using an LC–MS apparatus (JMS 700, Jeol, Japan) equipped with FAB or APCI interfaces.

3.2. Isolation

Fresh fruits of *F. margarita* (225 g, harvested in December 1996) were extracted using EtOH at room temperature for a month. Concentrated ethanolic extract was partitioned between BuOH and water. The BuOH phase was concentrated, suspended in water, and subjected to HP-20 resin (Mitsubishi Kasei, Japan). The EtOH eluate (600 mg in dry weight) was applied to an ODS column (Tosoh ODS-Prep, 10 μm, 250 mm×22 mm i.d., Tosoh, Japan) using a MeOH–0.2%HOAc eluent (flow rate, 5.0 ml/min; gradient, 30–60% MeOH in 90 min) to afford **1** (220mg), **2** (21 mg), **3** (24 mg), and **4** (34 mg).

3.3. Identification

Compound **1**, 3′,5′-di-*C*-β-glucopyranosylphloretin. Yellow powder. $[\alpha]_D^{20}$ +83.6° (MeOH; *c* 1.0). UV λ_{max}^{MeOH} nm (log ε): 233 (4.3), 286 (4.1), 335 *sh*. Positive FABMS *m*/*z*: 599 $[M+H]^+$, 277, 249, 185. Negative FABMS *m*/*z*: 597 $[M-H]^-$, 183. Positive APCIMS (needle, 4.0 kV; orifice, 0 V; ring lens, 20 V) *m*/*z*: 599, 581, 569, 479, 461, 389, 359. 3.4. Plant material

Citrus plants, listed in Tables 1 and 2, were selected from germplasm reserved in the Department of Citriculture at the National Institute of Fruit Tree Science of Japan. Fruits in a mature or near mature stage were collected from each citrus tree in October 1998–Feburary 1999 (most of the species), in September–October 1999 (*C. ichangensis* and *C. halimii*), and in October 1999–January 2000 (Orangequat, Thomasville citrangequat, and *F. margarita–C. junos* hybrids). One-year leaves were collected from each citrus tree in February–March 2000. For all the fruit studied, the whole fruit was roughly cut. The samples were frozen at −80°C and freeze-dried. The fruits were divided into peel (epicarp and mesocarp), juice sacs, endocarp, and seeds. In this report, peel and juice sacs were analyzed. The samples were pulverized using a cutter and stored at −30°C for analysis.

3.5. Analytical procedure

Each Sample (1.000 g), which was a mixture of several fruits or leaves from single trees, was ground in MeOH–water (1:1, 15.0 ml) by using a mixer (Kinematica, Switzerland) for 3 min. The mixing generator was rinsed with MeOH–water (1:1) (5 ml×2). These solutions were combined and filtered through paper. The residue on the filter paper was washed with MeOH–water (1:1) (50 ml). The filtrate was concentrated, and then dissolved into MeOH-water (1:1), and adjusted to 5 ml in a volumetric flask. The HPLC analyses of **1** and phloridzin were carried out under the following conditions: column, YMC ODS M80 (4 μm, 150 mm×4.6 mm i.d.,

[c] na, Not analyzed.

YMC, Japan); injection volume, 5.0 μl; column temperature, 40°C; flow rate, 1.2 ml/min; elution schedule, an initial 5 min of 20% MeOH in 20 mM H_3PO_4 followed by a linear gradient with increasing concentration of MeOH from 20 to 45% in 45 min; detection, UV absorption at 286 nm. The purity of the authentic **1** was 97% as based on analysis by HPLC. The quantities of **1** were estimated using the absolute calibration method. The detection limit for determination of 1 using this procedure was 0.0002 mg/ml in sample solution. The peak for **1** was identified by its UV spectrum obtained by a diode-array detector. Since the chromatographic behavior, retention times, and UV spectrum of **1** are similar to those of the flavanone glycosides, the presence of **1** in *C. madurensis* and *C. halimii* was confirmed using an LC–MS equipped with an atmospheric pressure chemical ionization (APCI) interface. Statistical analyses of the quantitative values were not examined except in the Thomasville citrangequat (Table 2). Since each specimen was a mixture of several fruits or leaves, the quantities were practically considered to be the mean value.

Received 27 October 2000; received in revised form 30 January 2001

Abstract

Bioactivity-directed fractionation of the CH_2Cl_2/MeOH (2:1, v/v) extract of the roots of *Petiveria alliacea,* using mutant yeast strains of *Saccharomyces cerevisiae* and fungi *Cladosporium cladosporioides* and *C. sphaerospermum* led to the isolation of dipropyl disulphide (**1**), dibenzyl sulphide (**2**), dibenzyl disulphide (**3**), dibenzyl trisulphide (**4**), dibenzyl tetrasulphide (**5**), benzylhydroxymethyl sulphide (**6**) and di(benzyltrithio) methane (**7**). Of these, **5**–**7** are new compounds and this is the first report of the natural occurrence of **2** and **3**. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Petiveria alliacea*; Phytolacaceae; Antifungal polysulphides

1. Introduction

Petiveria alliacea L. (Phytolacaceae) is a shrub widely distributed in South and Central America. It grows in all regions of Brazil where it is known by many popular names. Among these, ''erva-guiné'', ''guiné'', ''pipi'' and ''tipi''; and the Tupi-Guarani ''macuracaá'' are noteworthy (Hoehne, 1939; Pio Correa, 1969). In the State of Minas Gerais the roots of this plant are used to treat rheumatism (De Sousa et al., 1987) and in other Brazilian regions, both the roots and the leaves are popularly used as stimulants and abortefacients (Da Silva, 1935). Previous work on *P. alliacea* revealed the occurrence of coumarins, triterpenes and flavonoids (Rocha and Da Silva, 1969; Delle Monache and Suarez, 1992), amino acids and trisulphide (Adegosan, 1974). In continuing our search for biologically active compounds from the Brazilian flora (Carbonezi et al., 1999), a CH_2Cl_2/MeOH (2:1 v/v) extract of the roots of this plant was selected for phytochemical investigation due to its significant activity against some mutant yeast strains of *Saccharomyces cerevisiae* (Gunatilaka et al., 1994) and inhibition of the growth of *Cladosporium cladosporioides* and *C. sphaerospermum* (Homans and Fuchs, 1970). This study led to the isolation of five new polysulphides (**2**, **3**, **5**, **6** and **7**), together with two known compounds (**1**, **4**). Among the known compounds described in this study, only compound **4** had been previously isolated from this plant species (De Sousa et al., 1990).

2. Results and discussion

The CH_2Cl_2/MeOH (2:1) extract of roots of *P. alliacea* L. inhibited strains of *Saccharomyces cerevisiae* (RS 188N, RS 52YK and RS 321) indicating strong activity of this extract towards the mutant strains of yeast. This extract was also shown to possess potent inhibitory activity against *Cladosporium cladosporioides* and *Cladosporium sphaerospermum* fungi. Solvent–solvent partitioning of the bioactive crude extract afforded hexane, $CHCl_3$ and EtOAc fractions, in which the activities were concentrated. These fractions were individually subjected to silica gel column chromatography, using CH_2Cl_2 or CH_2Cl_2/MeOH as eluents, to obtain six major bioactive fractions. The purification of these fractions was performed on silica gel preparative TLC, reversed-phase Sep Pak cartridge and HPLC affording seven bioactive polysulphide compounds.

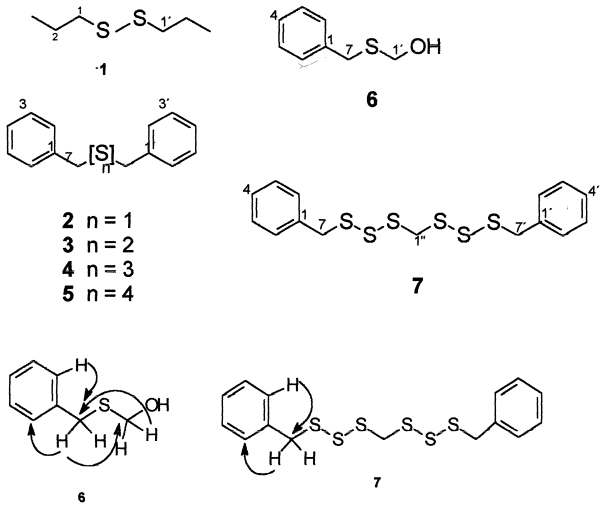

Fig. 1. Selected HMBC correlations for compounds **6** and **7**.

The molecular formula of compound **1** was determined as $C_6H_{14}S_2$, by ^1H, ^{13}C NMR, MS and elemental analysis. Three resonances at δ 2.66 *t* ($J=7.25$ Hz), δ 1.72 *dq* ($J=7.5$, 6.5) and 0.99 *t* ($J=7.26$ Hz) in the ^1H NMR spectrum were characteristic of a propyl moiety (Table 1). The ^{13}C NMR data also supported the propyl skeleton (Table 2). The proton resonance at δ 2.66, corresponding to a methylene group, was attributed to a sulfur-bearing carbon atom, which was confirmed by elemental analysis and interpretation of its mass spectrum. According to these data the structure of **1** was assigned as dipropyl disulphide, which is reported as a natural derivative in Phytolacaceae for the first time.

Compounds **2**–**5** exhibited common features in their MS, ^1H and ^{13}C NMR spectra. The presence of a significant ion peak at *m/z* 91, which is characteristic of a benzyl fragment was observed in all mass spectra of these compounds. The benzyl portion appeared to bear one, two, three and four sulfur atoms, respectively, based on the elemental analyses. The ^1H NMR spectra (Table 1) of **2**, **3**, **4** and **5** presented the same signal, around δ 7.30, compatible with a monosubstituted aromatic ring. The major differences observed in the ^1H NMR spectra of each compound was due to the chemical shift of the methylene benzylic hydrogens linked to the sulfur, which in compound **2** appeared at δ 3.66; **3** at δ 4.05; **4** at δ 4.15 (De Souza et al., 1990) and **5** at δ 4.19, respectively. The ^{13}C NMR spectral data (Table 2) of these compounds, interpreted with the aid of DEPT spectra, indicated the presence of one quaternary C and five CH's sp^2 carbons attributable to an aromatic monosubstituted ring and one sp^3 CH_2 assigned to a benzylic carbon. The elemental analysis and HRMS data of compounds **2**–**5** firmly established the number (and amount) of sulfur atoms in these polysulphides and confirmed their identities as dibenzyl sulphide (**2**), dibenzyl disulphide (**3**), dibenzyl trisulphide (**4**) and dibenzyl tetrasulphide (**5**),

[a] Spectra determined in $CDCl_3$; data reported in ppm (δ). Carbon type determined by DEPT.

respectively. Polysulphide **4** has previously been reported from this species (De Souza et al., 1990).

Compound **6**, isolated as an oil, gave IR absorption bands at 3335 (OH), 1580, and 1495 cm^{-1} (Ar). The EI MS showed a molecular ion peak $[M]^+$ at *m/z* 154 that together with ^{13}C NMR and elemental analysis established a molecular formula of $C_8H_{10}SO$. The ^1H and ^{13}C NMR spectra (Tables 1 and 2) of this compound resembled closely those of dibenzyl sulphide (**2**). Prominent differences in the ^1H and ^{13}C spectroscopic values between **2** and **6** were observed only in the aliphatic region; one extra methylene signal was observed at δ 5.03 *s* (δ 78.50, CH_2). These results allowed us to deduce that compound

6 had an hydroxymethyl group linked to the sulfur in place of the second benzylic group as in compound **2**. Interpretation of some HMBC data (Fig. 1) aided elucidation of this structure. Correlations observed between the methylene protons signal at δ 5.03 with the benzylic carbon at δ 44.27 and the methylene protons signal at δ 3.60 with the carbons at δ 78.50 and 127.42 established compound **6** as benzylhydroxymethyl monosulphide.

Polysulphide **7** is closely comparable with dibenzyl trisulphide (**4**); comparison of the ^{1}H and ^{13}C NMR spectra (Tables 1 and 2) data with those of **4** showed that the only differences observed were due to chemical shift of the benzylic hydrogens, which in **7** appeared at δ 4.20 ($\delta_C = 43.19$) and the presence of an additional singlet signal at δ 5.30, which was attributed to methylene protons by the analysis inferred by COSY, HMQC and DEPT spectral data. Analysis of ^{13}C NMR spectroscopic data recorded a methylene benzylic carbon at δ 43.19 and a second one, extremely unshielded at δ 106.32, whose chemical shift could be explained by the stereoeletronic effects of several sulfur atoms linked to methylene carbon. In fact, no correlations were observed in the spectra of the ^{1}H–^{1}H COSY and HMBC (Fig. 1) of the corresponding methylene protons with other protons or carbons, respectively in **7**. The elemental analysis, together with HRMS analysis established its molecular formula as $C_{15}H_{16}S_6$ and thus confirmed **7** to be di(benzyltrithio) methane.

Bioautography with the plant pathogenic fungi *C. cladosporioides* and *C. sphaerospermum* was employed to guide fractionation and isolation of the polysulphides **1**–**7**, these being responsible for the fungicidal activity detected in the crude extract (Table 3). Similar or higher to the reference compound Nystatin, the polysulphides **1**–**4** showed potent inhibition, while compounds **5**–**7** showed marginal activity against fungal growth (10.0 >25 and 5.0 μg, respectively), in both phytopathogenic strains tested. Furthermore, their potential anticancer activities were also tested, using a mechanism-based yeast bioassay for DNA-modifying agents (Gunatilaka et al., 1994). Compounds **1**, **3** and **5** had moderate effect on DNA, as deduced by the selective inhibition of the mutant strains RS 321 and RS 52YK, relative to the wild strain RS 188N (Table 3).

3. Experimental

3.1. Instrumentation

^{1}H NMR (300 MHz) spectra were recorded on a Bruker DPX-300 spectrometer, using TMS as an int. standard. The ^{13}C NMR (50 or 75 MHz) spectra were recorded on Bruker AC-200 and DPX-300 spectrometer. EI-MS were measured at 70 eV on a HP 5990/5988 A spectrometer and on a VG platform II spectrometer. Elemental analysis was performed on a Perkin-Elmer CHN Elemental Analyzer 2400. IR spectra were recorded on a FT-IR 1750 Perkin Elmer and FT-IR 510 Nicolet. UV spectra were recorded on a Perkin-Elmer UV/vis Hitachi U-3000.

3.2. Plant material

The species *Petiveria alliacea* L. was collected in September and October (1997) in the Instituto Butantã Reserve, in the city of São Paulo. Whole shrubs were collected and separated in their distinct parts: leaves, stems and roots. A voucher specimen was deposited in the Herbarium of the Instituto de Botânica-SMA, under the number SP112.6.84.

3.3. Biological testing

DNA-damaging assay with mutant yeast *S. cerevisiae*: Experimental screening methods utilizing mutant strains of *S. cerevisiae* have been described elsewhere (Gunatilaka et al., 1992). The IC_{12} values refer to the concentration in

[a] Results are expressed as IC_{12} (RS 188N, RS 321, RS 322YK) (μg/ml) or MIC (*C. cladosporioides* and *C. sphaerospermum*) (μg) values.

μg/ml required to produce a inhibition zone of 12 mm in diameter around a 100 μl well during a 48 h incubation period at 30°C.

TLC bioautography assay: *Cladosporium cladosporioides* Fresen de Vries SPC 140 and *Cladosporium sphaerospermum* Penzig SPC 491 were maintained at the Instituto de Botânica-SMA. Ten microliters of the solutions of crude extracts, fractions and pure compounds were prepared, in different concentrations: corresponding to 20, 10, 1, 0.1 μg for pure compounds and 100, 50, 30 and 20 μg for the crude extracts or fractions, respectively. The samples were applied to TLC plates, these being eluted with the appropriate solvent system followed by complete removal of the solvent. The chromatographic plates were sprayed with spores suspension of *C. sphaerospermum* and *C. cladosporioides* in a nutritive medium and incubated for 48 h at 37°C. After incubation, clear inhibition zones appeared against a dark background chromatogram.

3.4. Extraction and isolation of constituents

Roots, stems, and leaves of *P. alliacea* L. were dried at room temperature, powdered and extracted three times with CH_2Cl_2:MeOH (2:1, v/v), for two days, at room temperature. The resulting extracts were filtered and concentrated in vacuo to yield 7.0, 8.0 and 15 g of root, stem and leaf extracts, respectively. Due to the higher bioactivity noted, half of the root extract was suspended in MeOH:H_2O (8:2) and successively extracted with hexane, chloroform, ethyl acetate and *n*-butanol. After liquid/liquid partition, the resulting residue was concentrated in vacuo and extracted with H_2O. Bioactivity-guided fractionation of the hexane, $CHCl_3$, and EtOAc solubles, using silica gel column chromatography and hexane, CH_2Cl_2, CH_2Cl_2:EtOAc and CH_2Cl_2:MeOH (with increasing polarity) as eluants, afforded several fractions, whose bioactivities were detected only in six of them. The first hexane fraction was applied to a Si gel column eluting with a hexane:CH_2Cl_2 gradient to afford compound **1** (22 mg). The fractions eluted with CH_2Cl_2:EtOAc were further subjected to silica gel column chromatography using a MeOH:H_2O gradient. The intermediary fractions of this column, purified by HPLC using a C-18 Econosil column, 5 mm, 250×4 mm i.d., with an elution gradient of MeOH:H_2O (70:30) 7 min; MeOH:H_2O (90:10) 15 min. and MeOH (100%) 20 min with flow rate of 1 ml/min yielded the compounds **2** (7.8 mg), **3** (4.5 mg), **4** (15.0 mg) and **5** (3.6 mg). The EtOAc soluble fraction, was subjected to Si gel column chromatography using CH_2Cl_2:EtOAc with increasing polarity. The fractions obtained with CH_2Cl_2: EtOAc (7:3) afforded **6** (3.8 mg). Compound **7** (2.0 mg) was isolated from the hexane fraction, by further purification over column chromatography on Si gel eluted with CH_2Cl_2:EtOAc (8:2).

3.4.1. Dipropyl disulphide (*1*)

Colorless volatile oil with a strong odour of garlic. $C_6H_{14}S_2$ requires 47.95% C, 9.39% H, 42.66% S; found 47.80% C, 9.40% H, 42.15% S. ^{1}H NMR (300 MHz, $CDCl_3$) and ^{13}C NMR (50 MHz, $CDCl_3$) (Tables 1 and 2). IR ν_{max}^{film} cm^{-1}: 2872, 1450, 1375, 720. MS *m*/*z* (rel. int.): $[M]^+$; 150(38),$[M+2]^+$ 152(2), 149(100), 108(36), 73 (37), 74(12).

3.4.2. Dibenzyl sulphide (*2*)

Yellow oil. $C_{14}H_{14}S$ requires 78.46% C, 6.58% H, 14.96% S; found 78.28% C, 6.56% H, 15.01% S. ^{1}H NMR (300 MHz, $CDCl_3$) and ^{13}C NMR (50 MHz, $CDCl_3$) (Tables 1 and 2). UV λ_{max}^{MeOH} nm (ε): 220 (8400), 265 (450). IR ν_{max}^{film} cm^{-1}: 3085, 3060, 3030, 2930, 1600, 1495, 1455, 712. MS *m*/*z* (rel. int.): $[M]^+$ 214(78), $[M+2]^+$ 216(1), 137(57), 124(100), 91(56), 78(33), 77 (28), 65(41).

3.4.3. Dibenzyl disulphide (*3*)

Yellow amorphous solid. $C_{14}H_{14}S_2$ requires 68.25% C, 5.73% H, 26.02% S; found 68.30% C, 5.61% H, 25.89% S. ^{1}H NMR (300 MHz, $CDCl_3$) and ^{13}C NMR (50 MHz, $CDCl_3$) (Tables 1 and 2). UV λ_{max}^{MeOH} nm (ε): 239 (9200), 279 (340). IR ν_{max}^{film} cm^{-1}: 3080, 3060, 3019, 3008, 1604, 1503, 1460, 700. MS *m*/*z* (rel. int.): $[M]^+$ 246(63), $[M+2]^+$ 248(3), 170(47), 156(100), 124(48), 91 (57), 78(45), 77(31), 65(29).

3.4.4. Dibenzyl trisulphide (*4*)

Yellow amorphous solid. $C_{14}H_{14}S_3$ requires 60.39% C, 5.07% H, 34.54% S; found 60.29% C, 4.94% H, 34.40% S. ^{1}H NMR (300 MHz, $CDCl_3$) and ^{13}C NMR (50 MHz, $CDCl_3$) (Tables 1 and 2). UV λ_{max}^{MeOH} nm (ε): 215 (9800), 260(320). IR ν_{max}^{film} cm^{-1}: 3076, 3025, 2988, 1598, 1489, 1456, 722. MS *m*/*z* (rel. int.): $[M]^+$ 278(71), $[M+2]^+$ 280(2), 202(56), 188(100), 124(32), 91(63), 78 (40), 77(27), 65(32).

3.4.5. Dibenzyl tetrasulphide (*5*)

Orange amorphous solid. $C_{14}H_{14}S_4$ requires 54.16% C, 4.54% H, 41.30% S; found 53.98% C, 4.53% H, 41.2% S. ^{1}H NMR (300 MHz, $CDCl_3$) and ^{13}C NMR (50 MHz, $CDCl_3$) (Tables 1 and 2). UV λ_{max}^{MeOH} nm (ε): 235 (11100), 256 (530). IR ν_{max}^{film} cm^{-1}: 3076, 3029, 2930, 1610, 1504, 1458, 719. MS *m*/*z* (rel. int.): $[M]^+$ 310(69), $[M+2]^+$ 312(1), 234(12), 220(100), 188(45), 156(29), 124 (19), 91(54), 78(33), 77(19), 65(28).

3.4.6. Benzyl hydroxymethyl sulphide (*6*)

Colorless oil. $C_8H_{10}OS$ requires 62.33% C, 6.49% H, 10.39% O, 20.77% S; found 63.12% C, 6.30% H, 10.12% O, 19.89% S. ^{1}H NMR (300 MHz, $CDCl_3$) and ^{13}C NMR (50 MHz, $CDCl_3$) (Tables 1 and 2). UV λ_{max}^{MeOH} nm (ε): 198 (13100), 264 (489). IR ν_{max}^{film} cm^{-1}: 3335, 3050, 1580, 1495, 1468, 1227, 757, 721. MS *m*/*z*

(rel. int.): 177(49)$[M+Na]^+$, $[M+2]^+$ 156(3), 137(71), 124 (100), 91(57), 78(12), 77(21), 65(33), 31(48).

3.4.7. Di(benzyltrithio) methane (7)

Orange amorphous solid. $C_{15}H_{16}S_6$ requires 46.36% C 4.15% H, 49.49% S; found 46.10% C, 4.09% H, 49.50% S. ^{1}H NMR (300MHz, $CDCl_3$) and ^{13}C NMR (50 MHz, $CDCl_3$) (Tables 1 and 2). UV λ_{max}^{MeOH} nm (ε): 238 (7200), 276 (240). IR ν_{max}^{film} cm^{-1}: 3079, 3057, 3007, 1585, 1498, 1456, 731, 708. MS *m/z* (rel. int.): $[M]^+$ 388(29), $[M+2]^+$ 390(2), 202(71), 188(100), 124(45), 91 (61), 78(35), 77(26), 65(29).

Received in revised form 12 January 2001

Abstract

The endogenous gibberellins in immature seeds of *Prunus persica* were analyzed by gas chromatography–mass spectrometry. Eleven known gibberellins, GA_3, GA_9, GA_{17}, GA_{19}, GA_{30}, GA_{44}, GA_{61}, GA_{63}, GA_{87}, GA_{95} and GA_{97} were identified. Additionally, several hitherto unknown gibberellins were detected and their putative structures were verified by synthesis of the authentic gibberellins. These gibberellins were then assigned trivial numbers, e.g. 1α-hydroxy GA_{20} (GA_{118}), 1α-hydroxy GA_9 (GA_{119}), 1,2-didehydro GA_9 (GA_{120}), 1,2-didehydro GA_{70} (GA_{121}), 1,2-didehydro GA_{69} (GA_{122}) and 1,2-didehydro GA_{77} (GA_{126}). GA_{118} and GA_{119} were the first 1α-hydroxy gibberellins identified from higher plants. The above profile of 1,2-didehydro gibberellins suggests that 1,2-dehydrogenation might occur prior to 3β-hydroxylation in biosynthesis of GA_3, GA_{30} and GA_{87} in immature seeds of *P. persica*. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Prunus persica*; Rosaceae; Peach; Immature seeds; Identification of gibberellins; GA_{118}; GA_{119}; GA_{120}; GA_{121}; GA_{122}; GA_{126}

1. Introduction

Gibberellins possessing a 1,2- double bond as well as a 3β-hydroxyl group, such as GA_3 (**1**) and GA_7 (**2**), exhibit high biological activity in many bioassay systems (Reeve and Crozier, 1974). The metabolic conversion of GA_5 (**14**) into GA_3 (**1**) has been shown in many plant systems, e.g. seedlings of *Zea mays* (Fujioka et al., 1990), cell suspensions cultures of *Prunus persica* (Koshioka et al., 1988), cell-free systems from seeds of *Marah macrocarpus* (Albone et al., 1990; MacMillan et al., 1997) and anthers of *Oryza sativa* (Kobayashi et al., 1991). Thus, GA_3 (**1**) in higher plants is currently thought to be biosynthesized from GA_5 (**14**) by 3β-hydroxylation which is accompanied by a rearrangement of the 2,3-double bond to the 1,2-location (Fujioka et al., 1990). Furthermore it has been shown that GA_7 (**2**) is formed in a similar manner from 2,3-didehydro GA_9 (**15**) in *M. macrocarpus* (Albone et al., 1990; MacMillan et al., 1997).

While investigating the presence of endogenous gibberellins in immature seeds of *Prunus cerasus*, we noted the co-occurrence of GA_3 (**1**) and GA_{95} (1,2-didehydro GA_{20}) (**5**); however, GA_5 (**14**) could not be detected (Nakayama et al., 1996). This led us to speculate that GA_{95} (**5**) could be the direct precursor of GA_3 (**1**) by 3β-hydroxylation without an A-ring double bond rearrangement. Additionally, GA_{30} (**3**) and GA_{87} (**4**), A-ring analogues of GA_3 (**1**) that possess both a 1,2-double bond and a 3β-hydroxyl group, were identified in immature seeds of *P. cerasus* (Nakayama et al., 1996). Hence GA_{30} (**3**) and GA_{87} (**4**) could also be biosynthesized from A-ring analogues of GA_{95} (**5**) by 3β-

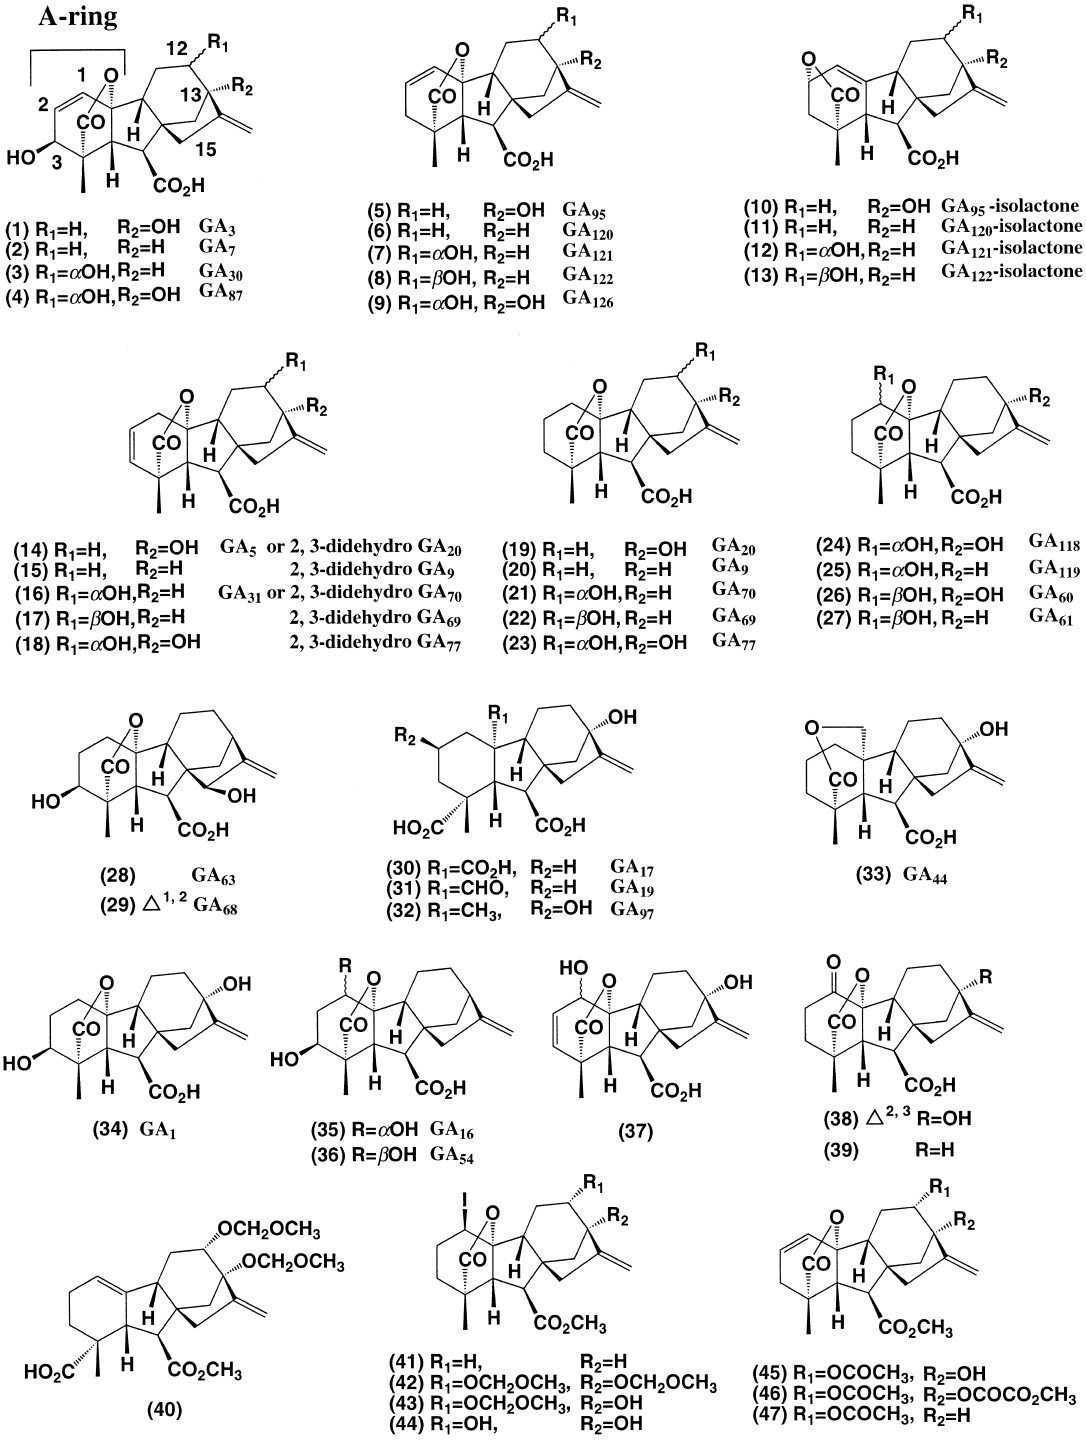

Fig. 1. Gibberellin structures.

hydroxylation without the double bond rearrangement in this plant tissue.

We analyzed the endogenous gibberellins in immature seeds of *P. persica*, with special emphasis on identifying potential precursors of GA_3 (**1**). Herein we report the co-occurrence of GA_3 (**1**) and GA_{95} (**5**) and their A-ring analogues in immature seeds of *P. persica*.

2. Results and discussion

The acidic EtOAc fraction of an extract from immature seeds of *P. persica* was analyzed by GC–MS. Based on comparisons of mass spectra and Kovats retention indices (KRIs) with methyl ester trimethylsilyl ether derivatives of authentic compounds, GA_3 (**1**), GA_9 (**20**),

GA_{17} (**30**), GA_{19} (**31**), GA_{30} (**3**), GA_{44} (**33**), GA_{63} (**28**), GA_{68} (**29**), GA_{87} (**4**), GA_{95} (**5**) and GA_{97} (**32**) were identified as endogenous gibberellins (Table 1). GA_{95} (**5**) had been found in immature seeds of *P. cerasus* (Nakayama et al, 1996). Its presence also in *P. persica* suggests that GA_{95} (**5**) may occur in a wide range of *Prunus* spp.

Several unknown gibberellin-like compounds were also detected. Mass spectra and KRIs of methyl ester trimethylsilyl ether derivatives of compounds **24** and **25** were respectively coincided with those of trimethylsilyl ether derivatives of 1α-hydroxy GA_{20} methyl ester and 1α-hydroxy GA_9 methyl ester, which had been already prepared (Tables 1 and 2). The authentic sample of compound **24** was synthesized by oxidation of the epimeric mixture of 1-hydroxy GA_5 methyl esters (**37**) obtained from the solvolysis of methyl gibberellate 3-methanesulfonate (Duri and Hanson, 1984), followed by reduction of the resulting enone of compound **38** with potassium tri-*sec*-butyl borohydride (Fortunato and Ganem, 1976) to remove the A-ring double bond and reduce the carbonyl function at C-1. An authentic sample of compound **25** was more readily obtained by oxidation of the carbinol group in GA_{61} (**27**) methyl ester (Kirkwood and MacMillan, 1982) followed by borohydride reduction. In both cases, reduction of the 1-oxo function gave the 1α-epimer as the major product.

Mass spectra of the methyl ester trimethylsilyl ether derivatives of the four remaining gibberellin-like compounds indicated that they might be either 1,2-didehydro derivatives (**6**–**9**) or 2,3-didehydro derivatives (**15**–**18**) of GA_9 (**20**), GA_{69} (**22**), GA_{70} (**21**) and GA_{77} (**23**).

[a] In text, GA_{120}, GA_{120}-isolactone and 2,3-didehydro GA_9 were analyzed as methyl ester derivatives. All other gibberellins were analyzed as methyl ester and trimethylsilyl ether derivatives.
[b] The KRI was obtained by using an HP-5 column, otherwise a DB-1 was used.

The 2,3-didehydro derivatives (**15**–**18**) had been already synthesized and were available to use as authentic samples (Willis, 1987; Chu and Mander, 1988). 1,2-Didehydro GA_9 (**6**) methyl ester was prepared by elimination of the 1β-iodo group of compound **41** by 1,8-diazabicyclo[5.4.0]undec-7-ene (Furber et al., 1995). The remaining putative structures were assembled from compound **40**, a key intermediate in the preparation of several 12-hydroxy C_{20} gibberellins (Mander and Owen, 1997). Compound **40** was converted into iodolactone (**42**) and the methoxymethyl protecting groups at C-12 and C-13 were removed to afford compound **44**. The iodide of compound **44** was eliminated with 1,8-diazabicyclo[5.4.0]undec-7-ene to afford compound **9** methyl ester. The more reactive 12-hydroxyl group of compound **9** methyl ester was masked by acetylation and 13-methyloxalate (**46**) was prepared. After treatment with tributyltin hydride (Dolan and MacMillan, 1985), careful hydrolysis afforded compound **7** methyl ester. The 12-epimer of compound **7** methyl ester, namely compound **8** methyl ester, was prepared in an analogous manner, details of which have been published elsewhere (Leitch, 2000). Using GC–MS analysis we identified these unknown gibberellin-like compounds as 1,2-didehydro GA_9 (**6**), 1,2-didehydro GA_{70} (**7**) 1,2-didehydro GA_{69} (**8**) and 1,2-didehydro GA_{77} (**9**), respectively (Tables 1 and 2). Novel gibberellins detected in this study were assigned as the trivial numbers GA_{118} (**24**), GA_{119} (**25**), GA_{120} (**6**), GA_{121} (**7**), GA_{122} (**8**) and GA_{126} (**9**) according to convention (MacMillan and Takahashi, 1968; for allocation of GA_{117}, see Wynne et al., 1998; and allocation of GA_{123}, GA_{124} and GA_{125}, see Blake et al., 2000).

Methyl esters of GA_{120}-isolactone (**11**), GA_{121}-isolactone (**12**) and GA_{122}-isolactone (**13**) were synthesized by treatment with tetrakis-(triphenylphosphine)-palladium(0) (Serebryakov, 1980) and used as authentic samples in GC–MS analysis. Thus, GA_{95}-isolactone (**10**), GA_{120}-isolactone (**11**), and GA_{122}-isolactone (**13**) were also identified from immature seeds of *P. persica* (Tables 1 and 2). Because GA_{120} (**6**) could not be isomerized under our purification conditions (data not shown), we conclude that GA_{120}-isolactone (**11**) is a naturally occurring gibberellin in these tissues. GA_{95} (**5**) and GA_{122} (**8**) were easily converted to the isolactone form under our purification conditions (data not shown). So far it could not be determined whether GA_{95}-isolactones (**10**) and GA_{122}-isolactone (**13**) are naturally occurring gibberellins in *P. persica*.

Approximate quantitative levels of the identified gibberellins were estimated based on the total ion current areas over m/z 100 (as methyl ester or methyl ester trimethylsilyl ether derivatives) relative to a known amount of GA_1 (**34**) methyl ester trimethylsilyl ether derivative (Table 3). The most abundant gibberellin was

Table 3
Approximate amounts (ng/kg fw) of gibberellins present in immature seeds of *Prunus persica*. Estimates are based on total ion current peak areas obtained by GC–MS analysis, with a known amount of GA_1 as a quantitative standard

	1,2-Didehydro gibberellins				1α-Hydroxy gibberellins		Other gibberellins	
	Possessing 3β-hydroxyl group		Lacking 3β-hydroxyl group					
C_{19}-Gibberellins	GA_3	1550	GA_{95}	350	GA_{118}	400	GA_9	50

	GA_{68}	150	GA_{120}	350				
	GA_{87}	50	GA_{120}-isolactone	450				
			GA_{121}	150				
			GA_{122}	100				
			GA_{122}-isolactone	450				
			GA_{126}	200				
C_{20}-Gibberellins							GA_{17}	2250
							GA_{19}	350
							GA_{44}	1000
							GA_{97}	500

GA_{119} (**25**) followed by GA_{17} (**30**), GA_{95}-isolactone (**10**) and GA_3 (**1**).

While 1,2-didehydro derivatives of GA_9, GA_{20}, GA_{69}, GA_{70} and GA_{77} (**5**–**9**) were identified as endogenous gibberellins, their 2,3-didehydro derivatives (**14**–**18**) could not be detected. Because 2,3-didehydro GA_9 (**15**) methyl ester and GA_{120} (**6**) methyl ester could not be sufficiently separated to allow definitive identification using the DB-1 (100% dimethyl polysiloxane) column, we subjected these two gibberellins to HP-5 (5% diphenyl-95% dimethyl polysiloxane) column chromatography. This procedure allowed us to confirm the absence of 2,3-didehydro GA_9 (**15**) (Tables 1 and 2). Yamaguchi et al. (1975) first identified GA_5 (**14**) in immature seeds of *P. persica* by GC and MS. However we could not detect GA_5 (**14**) in the current collections of immature seeds of *P. persica*. Nor could we find endogenous GA_5 (**14**) in immature seeds of *P. cerasus* (Nakayama et al., 1996).

In immature seeds of *P. persica*, GA_3 (**1**), GA_{30} (**3**) and GA_{87} (**4**) were identified with their 3-deoxy derivatives, GA_{95} (**5**), GA_{121} (**7**) and GA_{126} (**9**). These co-occurrences suggest that 1,2-dehydrogenation might occur prior to 3β-hydroxylation in biosynthesis of GA_3 (**1**), GA_{30} (**3**) and GA_{87} (**4**) in this tissue. We are proceeding administering deuterated derivatives of the relevant gibberellins to the immature seed systems with a view to elucidating the speculative gibberellin biosynthetic pathways.

While several 1β-hydroxy gibberellins have been identified in higher plants, identification of 1α-hydroxy gibberellins in higher plants has not been reported. Once the detection of 1α-hydroxy gibberellin, GA_{16} (**35**), in *Secale cereale* had been reported by Dathe et al. (1978), but their reinvestigation elucidated the structure to be 1β-epimer, GA_{54} (**36**) (Dathe et al., 1989). Therefore GA_{118} (**24**) and GA_{119} (**25**) are the first 1α-hydroxy gibberellins identified from higher plants. The occurrence of GA_{118} (**24**) and GA_{119} (**25**) implies the presence of a 1α-hydroxylase in immature seeds of *P. persica*. Interestingly, GA_{61} (1β-hydroxy GA_9) (**27**) was found in *Ornithogalum thyrsoides* along with GA_7 (**2**), GA_9 (**20**) and GA_{120} (**6**) (Koshioka et al., 1999). It was shown in *Zea mays* that one enzyme can catalyze both 2,3-dehydrogenation and 3β-hydroxylation of gibberellins (Spray et al., 1996). The enzyme that catalyzes 1,2-dehydrogenation of gibberellins may also be multifunctional and catalyze 1-hydroxylation of gibberellins. Further research on these gibberellin biosynthetic enzymes would warrant this speculation.

3. Experimental

3.1. Extraction and isolation

Fruit of *Prunus persica* cv. Kansuke-hakutou growing at Chiba University, Japan, were collected 40 days after anthesis. After freezing on dry ice, the immature seeds (290 g fr. wt) were harvested and kept frozen at −80°C until extraction and analysis. The immature seeds were extracted once with MeOH, then twice with 80% aq. MeOH. The MeOH extracts were combined and reduced to the aq. phase in vacuo. The aq. residue was adjusted to pH 7.0 with 0.5 M K–Pi buffer (pH 7.3) and partitioned with EtOAc. The aq. fraction was then adjusted to pH 3.5 with 0.5 M K–Pi buffer (pH 2.3) and extracted with EtOAc, which was taken to dryness in vacuo. The acidic EtOAc soluble fraction was dissolved in 0.5 M K–Pi buffer (pH 3.5) and passed through a PVP column (25 g). The eluate was passed through an ODS column (6 g). The ODS column was washed with 0.1% HOAc and eluted with 80% aq. MeOH containing 0.1% HOAc. This later eluate was taken to dryness, then dissolved in

MeOH and loaded onto a Bondesil DEA column (8 g). This column was eluted with MeOH, followed by 0.5% HOAc in MeOH.

The later eluate was taken to dryness, then dissolved in 30% aq. MeOH containing 0.1% acetic acid and injected onto an Inertsil-2 ODS column (25×0.46 cm i.d.) in a Hewlett Packard 1100 HPLC system. Elution conditions were as follows: solvent, 0–2 min, 0% solvent A (MeOH containing 0.1% HOAc) in solvent B (30% aq. MeOH containing 0.1% HOAc); 2–42 min, 0–100% solvent A; 42–52 min, 100% solvent A; flow rate, 0.6 ml min^{-1}; column temp., 40°C; fractionation, every 1 min. The eluates were taken to dryness, methylated with ethereal diazomethane and then passed through a Bondesil NH_2 column for further purification.

3.2. GC–MS analysis

The methylated fraction from R_t 24 to 26 min was trimethylsilylated with *N*-methyl-*N*-(trimethylsilyl)-trifluoroacetamide at 60°C for 10 min. The other methylated fractions were trimethylsilylated at 80°C for 30 min. The derivatized samples were analyzed using a HP 5989B MS-system equipped with a HP 5890 GC-system fitted with a capillary column DB-1 (30 m×0.25 mm i.d., 0.25 μm film thickness), to which a retention gap column (5 m×0.25 mm i.d.) was attached. Ionization voltage was 70 eV. Helium carrier gas flow rate was 1 ml min^{-1} in the constant flow mode. Two column temp. programs were used. Program 1 was started at 60°C for 2 min, then raised to 210°C at 30°C min^{-1}, then raised to 280°C at 2°C min^{-1} and finally held at 280°C for 5 min. Temp. of the injection port, the separator, the ion source and the analyzer were 220, 280, 250 and 100°C, respectively. Program 2 was started at 60°C for 2 min, then raised to 225°C at 30°C min^{-1}, then raised to 280°C at 0.5°C min^{-1}, and finally held at 280°C for 5 min. Temp. of the injection port, the separator, the ion source and the analyzer were 180, 280, 250 and 100°C, respectively. HPLC fractions from R_t 33 to 36 min were analyzed also by a capillary column HP-5 (30 m×0.25 mm i.d., 0.25 μm film thickness) using the column temp. program 1, to which a retention gap column (5 m×0.25 mm i.d.) was attached.

3.3. Synthesis of methyl esters of novel gibberellins

3.3.1. GA_{118} (**24**) methyl ester

An epimeric mixture of 1-hydroxy GA_5 (**37**) methyl esters (300 mg), prepared by the procedure of Duri and Hanson (1984), was dissolved in CH_2Cl_2 (15 ml) and treated with pyridinium dichromate (1.0 g). After stirring overnight, Et_2O (15 ml) was added, the mixture was filtered through celite, solvent was removed and the residue was purified by flash chromatography on silica gel (EtOAc–pentane, 1:1). 1-Oxo-GA_5 (**38**) methyl ester (210 mg) was obtained as a white solid; ^1H NMR (300 MHz, $CDCl_3$): δ 1.36 (3H, *s*, H-18), 2.86 (1H, *d*, $J=10.4$ Hz, H-6), 3.42 (1H, *d*, $J=10.4$ Hz, H-5), 3.76 (3H, *s*, OCH_3), 4.98 (1H, *br s*, H-17) and 5.29 (1H, *t*, $J=2.5$ Hz, H-17′), 6.12 (1H, *d*, $J=9.5$ Hz, H-2), 6.99 (1H, *d*, $J=9.5$ Hz, H-3). A portion of this material (108 mg) dissolved in dry THF (2 ml) at −70°C was treated with potassium tri-*sec*-butylborohydride (1 M, 0.66 ml, 2.2 equivalent) and the mixture was stirred at −70°C for 30 min. EtOH (40 ml) was added and the mixture was stirred for 15 min, then potassium tri-*sec*-butylborohydride (0.9 ml) was added and stirring continued for 30 min at −70°C. The reaction vessel was transferred to an ice bath and 10% NaH_2PO_4 (0.5 ml) was added dropwise followed by the slow addition of H_2O_2 (100 vol) until gas evolution stopped. EtOAc (20 ml) was added and the mixture was washed with H_2O twice, brine, and dried Na_2SO_4. Removal of solvent in vacuo afforded a colorless gum (124 mg) and then flash chromatography on silica gel (EtOAc–pentane, 1:1 and 2:1) furnished GA_{60} (**26**) methyl ester (55 mg) followed by 1-*epi*-GA_{60} (GA_{118}) (**24**) methyl ester (40 mg) as an oil; ^1H NMR (300 MHz, $CDCl_3$): δ 1.05 (3H, *s*, H-18), 1.30–2.20 (11H, *m*), 2.4 (2H, *m*, 2×OH), 2.54 (1H, *d*, $J=10.5$ Hz, H-5), 2.71 (1H, *d*, $J=10.5$ Hz, H-6), 3.70 (3H, *s*, OCH_3), 3.72 (1H, *m*, H-1), 4.93 (1H, *s*, H-17), 5.24 (1H, *s*, H-17′); ^{13}C NMR (75 MHz, $CDCl_3$): δ 16.3 (C-18), 19.2 (C-11), 29.9 (C-3), 33.0 (C-2), 38.6 (C-12), 43.0 (C-14), 44.5 (C-15), 48.0 (C-4), 49.7 (C-8), 51.6 (C-6), 52.2 (OCH_3), 53.0 (C-9), 56.5 (C-5), 73.8 (C-1), 78.0 (C-13), 94.0 (C-10), 107.6 (C-17), 157.0 (C-16), 172.6 (C-7), 179.1 (C-19); EIMS *m*/*z* (rel. int.): 362 $[M]^+$ (76), 344 (5), 330 (25), 313 (29), 312 (85), 303 (100), 284 (16); HRMS *m*/*z*: Calc. for $[M]^+$ $C_{20}H_{26}O_6$: 362.1729; Found: 362.1731.

3.3.2. GA_{119} (**25**) methyl ester

To a soln. of GA_{61} (1β-hydroxy GA_9) (**27**) methyl ester (680.1 mg, 1.96 mmol) (Kirkwood and MacMillan, 1982) in CH_2Cl_2 (15 ml) was added Dess-Martin reagent (916 mg, 2.16 mmol) (Dess and Martin, 1983). The mixture was stirred overnight, followed by dilution with Et_2O (15 ml) and addition of 1 M NaOH soln. (20 ml), then stirred for a further 10 min. The organic layer was washed with 1 M NaOH soln. (20 ml), H_2O (20 ml), dried over $MgSO_4$, filtered, and the solvent was removed in vacuo. The crude material was applied to a silica gel column (EtOAc–petroleum ether, 1:4) to yield 1-oxo-GA_9 (**39**) methyl ester as a white foam (61%): R_f 0.40 (silica gel, EtOAc–petrol, 1:4); IR ν_{max} cm^{-1}: 2938, 1790, 1733, 1198; ^1H NMR (300 MHz, $CDCl_3$): δ 1.19 (3H, *s*, H-18), 1.42–1.90 (7H, *m*), 1.93–2.10 (3H, *m*), 2.44–2.74 (4H, *m*), 2.86 (1H, *d*, $J=10$ Hz, H-6), 2.91 (1H, *d*, $J=10$ Hz, H-5), 3.72 (3H, *s*, OCH_3), 4.86 (1H, *s*, H-17), 4.99 (1H, *s*, H-17′); ^{13}C NMR (75 MHz, $CDCl_3$): δ 16.2 (C-18), 16.3 (C-11), 31.2 (C-12), 33.8 (C-3), 35.1

The above ketone (385.7 mg, 1.12 mmol) in EtOH (15 ml) was stirred at 0°C. Following the addition of $NaBH_4$ (850 mg, 22.5 mmol) the mixture was allowed to warm to room temp. and stirred for 15 min. H_2O was added dropwise to the solution followed by dilution with CH_2Cl_2 (20 ml). The aq. layer was extracted with CH_2Cl_2 (2×10 ml) and the combined organic extracts were dried over $MgSO_4$ and filtered, and solvent was removed in vacuo. The crude material was applied to a silica gel column (EtOAc–petroleum ether, 1:3) and appropriate fractions were combined to yield 1β-hydroxy GA_9 (GA_{61}) (**27**) methyl ester (19%) and 1α-hydroxy GA_9 (GA_{119}) (**25**) methyl ester (24%): mp 176-178°C; R_f 0.15 (silica gel, EtOAc–petroleum ether, 1:3); IR ν_{max} cm^{-1}: 3382, 1774, 1735, 1657, 1457, 1437, 1383, 1344, 1291, 1107; ^1H NMR (500 MHz, $CDCl_3$): δ1.05 (3H, *s*, H-18), 1.23–1.44 (2H, *m*), 1.52–1.58 (1H, *dt*, *J*=6,12 Hz, H-12), 1.62–1.73 (4H, *m*), 1.74–1.82 (2H, *m*), 1.93 (1H, *br s*, OH), 2.01–2.06 (3H, *m*), 2.15–2.20 (1H, *dt*, *J*=14.0, 6.2 Hz, H-11β), 2.53 (1H, *d*, *J*=11 Hz, H-5), 2.59 (1H, *br t*, *J*=8 Hz, H-13), 2.72 (1H, *d*, *J*=11, H-6), 3.69 (3H, *s*, OCH_3), 3.71–3.75 (1H, *m*, H-1β), 4.83 (1H, *s*, H-17), 4.96 (1H, *s*, H-17′); ^{13}C NMR (75 MHz, $CDCl_3$): δ 16.4 (C-18), 18.1 (C-11), 30.0 (C-2), 31.6 (C-12), 32.9 (C-3), 36.3 (C-14), 38.4 (C-13), 44.5 (C-15), 47.8 (C-8), 51.6 (C-6), 51.8 (C-4), 52.0 (OCH_3), 53.5 (C-9), 56.1 (C-5), 74.1 (C-1), 94.4 (C-10), 107.7 (C-17), 156.8 (C-16), 172.8 (C-7), 179.1 (C-19); EIMS, *m/z* (rel. int.): 346 $[M]^+$ (36), 314 (60), 286 (100), 91 (32); HRMS *m/z*: Calc. for $[M]^+$ $C_{20}H_{24}O_5$: 346.1780; Found: 346.1779.

3.3.3. GA_{120} (*6*) methyl ester

A soln. of 1β-iodo GA_9 methyl ester (**41**) (Furber et al, 1995) (100 mg, 0.219 mmol) in CH_2Cl_2 (1.0 ml) was treated with 1,8-diazabicyclo[5.4.0]undec-7-ene (0.45 ml) and the mixture heated under reflux for 6 h. CH_2Cl_2 was added, the soln. washed with 2 N HCl, then brine, and dried. Chromatography on silica gel (Et_2O–hexane, 1:4) afforded GA_{120} (**6**) methyl ester (71 mg, 99%), mp 160–162°C; IR ν_{max} cm^{-1}: 1770, 1740; ^1H NMR (300 MHz, $CDCl_3$): δ1.19 (3H, *s*, H-18), 1.22–1.40 (1H, *m*), 1.45–1.72 (4H, *m*), 1.47–1.86 (2H, *m*), 1.97–2.10 (2H, *m*), 2.25–2.30 (2H, *m*), 2.62-2.66 (1H, *m*, H-13), 2.66 (1H, *d*, *J*=10.9 Hz, H-6), 2.85 (1H, *d*, *J*=10.9 Hz, H-5), 3.64 (3H, *s*, OCH_3), 4.78 (1H, *br s*, H-17), 4.91 (1H, *br s*, H-17′), 5.78 (1H, *ddd*, $J_{1,2}$=9.3 Hz, $J_{2,3}$=3.3 Hz, $J_{2,3'}$=3.3 Hz, H-2), 6.10 (1H, *ddd*, $J_{1,2}$=9.3 Hz, $J_{1,3}$=2.2 Hz, $J_{1,3'}$=2.2 Hz, H-1); ^{13}C NMR (75 MHz, $CDCl_3$): δ 15.5 (C-11), 17.2 (C-18), 31.0 (C-12), 36.0 (C-14), 37.5 (C-3), 38.3 (C-13), 44.1 (15), 47.4 (C-4), 50.9 (C-6), 51.4 (C-9), 51.6 (OCH_3), 52.0 (C-8), 55.6 (C-5), 90.4 (C-10), 107.4 (C-17), 130.0, 130.6 (C-1, C-2), 156.8 (C-16), 173.1 (C-7), 179.8 (C-19); EIMS *m/z* (rel. int.): 328 $[M]^+$ (7), 297 (18), 296 (42), 285 (59), 268 (29), 225 (70), 224 (55), 209 (41), 183 (28), 181 (44), 156 (34), 155 (44), 143 (34), 141 (31), 129 (35), 128 (31), 115 (34), 105 (71), 93 (36), 91 (93), 81 (30), 79 (48), 77 (60), 65 (34), 55 (38), 53 (41), 51 (31), 41 (100); HRMS *m/z*: Calc. for $[M]^+$ $C_{20}H_{24}O_4$: 328.1675; Found: 328.1672.

3.3.4. GA_{126} (*9*) methyl ester

A soln. of compound **40** (Mander and Owen, 1997) (235.1 mg, 0.505 mmol) in THF (6 ml) and CH_2Cl_2 (6 ml) was treated with $NaHCO_3$ (5% aq. solution, 1 ml) followed by addition of iodine (102 mg, 0.81 mmol). The mixture was stirred overnight at room temp. Upon completion by TLC the reaction mixture was diluted with EtOAc (10 ml) and the entire soln. washed with satd. $Na_2S_2O_3$ soln. (10 ml). The organic layer was washed with brine, dried over dry $MgSO_4$, filtered and the solvent removed under reduced pressure. The crude material was applied to a silica gel column (EtOAc–petrol, 1:1 and 2:1) to afford the desired iodo lactone (**42**) (*ent*-12β, 13-bismethoxymethoxy-1α-iodogibberell-16-ene-7-oic acid 19, 10-lactone 7-methyl ester) (146.6 mg): R_f 0.8 (EtOAc–petrol, 1:1); ^1H NMR (300 MHz, $CDCl_3$): δ 1.08 (3H, *s*, H-18), 1.50–1.59 (1H, *dd*, *J*=13, 5 Hz, H-14), 1.82–2.28 (10H, *m*), 2.64 (1H, *d*, *J*=10 Hz, H-6), 3.30 (3H, *s*, $CH_2O\underline{CH_3}$), 3.34 (1H, *d*, *J*=8 Hz, H-5), 3.34 (3H, *s*, $CH_2O\underline{CH_3}$), 3.62 (1H, *t*, *J*=7 Hz, H-12), 3.71 (3H, *s*, $CO_2\underline{CH_3}$), 4.49 (1H, *d*, *J*=5 Hz, H-1), 4.56 (1H, *d*, *J*=7 Hz, $\underline{CH_2}OCH_3$), 4.63 (1H, *d*, *J*=7 Hz, $\underline{CH_2}OCH_3$), 4.68 (1H, *d*, *J*=7 Hz, $\underline{CH_2}OCH_3$), 4.86 (1H, *d*, *J*=7 Hz, $\underline{CH_2}OCH_3$), 5.17 (1H, *s*, H-17′), 5.19 (1H, *d*, *J*=2 Hz, H-17); ^{13}C NMR (75 MHz, $CDCl_3$): δ 16.8 (C-18), 25.8 (C-11), 27.2 (C-1), 30.8 (C-3), 31.6 (C-2), 37.0 (C-14), 43.2 (C-15), 47.3 (C-6), 49.3 (C-4), 50.9 (C-8), 52.0 (C-9), 54.9 ($CO_2\underline{CH_3}$), 55.1 (C-5), 55.2 [$(CH_2O\underline{CH_3})_2$], 79.5 (C-12), 84.9 (C-13), 91.9 ($\underline{CH_2}OCH_3$), 93.5 (C-10), 97.0 ($\underline{CH_2}OCH_3$), 111.5 (C-17), 150.7 (C-16), 172.3 ($\underline{CO_2}CH_3$), 177.9 (C-7); EIMS *m/z* (rel. int.): 576 $[M]^+$ (1), 531 (75), 327 (52), 283 (59), 195 (33), 149 (83), 129 (34), 91 (100); HRMS *m/z*: Calc. for $[M]^+$ $C_{24}H_{33}O_8I$: 576.1220; Found: 576.1224.

A soln. of iodo lactone (**42**) (146.6 mg, 0.254 mmol) in MeOH (10 ml) and H_2O (2 ml) containing Dowex resin (50W/H^+) was heated at reflux. After 16 h, TLC showed that all starting material had been consumed and two products were present. The reaction mixture was filtered through a plug of celite and diluted with EtOAc. The entire soln. was washed with KH_2PO_4 soln. (10%), brine, dried $MgSO_4$, filtered and the solvent removed in vacuo. The residue was applied to a silica

gel column (EtOAc–petrol, 1:1) to yield compound **43** (*ent*-13-hydroxy-1α-iodo-12β-methoxymethoxy-20-norgibberell-16-ene-7, 19-dioic acid 7-methyl ester 19, 10-lactone) (68.1 mg, 63%): R_f 0.75 (EtOAc–petrol, 2:1); IR $\nu_{max}cm^{-1}$: 3513, 2950, 1784, 1736; ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.18 (3H, *s*, H-18), 1.57-1.59 (1H, *dd*, $J=14$, 5 Hz), 1.71–2.31 (12H, *m*), 2.63 (1H, *d*, $J=10$ Hz, H-6), 3.40 (3H, *s*, $CH_2O\underline{CH_3}$), 3.40 (1H, *d*, $J=8$ Hz, H-5), 3.50 (1H, *t*, $J=8$ Hz, H-12), 3.70 (3H, *s*, $CO_2\underline{CH_3}$), 4.50 (1H, *d*, $J=5$ Hz, H-1), 4.73 (2H, *s*, $\underline{CH_2}OCH_3$), 5.14 (1H, *s*, H-17′), 5.31 (1H, *d*, $J=2$ Hz, H-17); ^{13}C NMR (75 MHz, $CDCl_3$): δ 16.9 (C-18), 26.0 (C-11), 27.6 (C-1), 30.6 (C-3), 31.7 (C-2), 41.2 (C-14), 42.5 (C-15), 48.0 (C-8), 49.2 (C-6), 49.7 (C-4), 51.0 (C-9), 52.1 ($CO_2\underline{CH_3}$), 54.6 (C-5), 56.0 ($CH_2O\underline{CH_3}$), 77.8 (C-13), 81.1 (C-12), 93.7 (C-10), 96.8 ($\underline{CH_2}OCH_3$), 111.5 (C-17), 152.4 (C-16), 172.0 ($\underline{CO_2}CH_3$), 178.1 (C-7); EIMS *m*/*z* (rel. int.): 531 $[M]^+$ (6), 504 (48), 327 (52), 469 (34), 441 (33), 409 (44), 375 (40), 343 (82), 315 (56), 297 (36), 283 (100), 269 (48), 255 (59), 237 (60), 225 (38), 211 (62), 197 (49), 185 (36), 171 (40), 155 (40), 143 (50), 135 (44), 127 (60), 115 (45), 91 (69), 77 (53), 69 (42); HRMS *m*/*z*: Calc. for $[M]^+$ $C_{22}H_{29}O_7I$: 532.0958; Found: 532.0951, followed by compound **44** (*ent*-12β, 13-dihydroxy-1α-iodo-20-norgibberell-16-ene-7, 19-dioic acid 7-methyl ester 19, 10-lactone) (39.5 mg, 37%): R_f 0.6 (EtOAc–petrol, 2:1); IR $\nu_{max}cm^{-1}$: 3407, 2938, 1782, 1735; ^{1}H NMR (300 MHz, $CDCl_3$); δ 1.11 (3H, *s*, H-18), 1.57–2.37 (13H, *m*), 2.66 (1H, *d*, $J=10$ Hz, H-6),3.42 (1H, *d*, $J=10$ Hz, H-5), 3.63 (1H, *t*, $J=7$ Hz, H-12), 3.73 (3H, *s*, $CO_2\underline{CH_3}$), 4.52 (1H, *d*, $J=5$ Hz, H-1), 5.13 (1H, *s*, H-17′), 5.30 (1H, *d*, $J=2$ Hz, H-17); ^{13}C NMR (75 MHz, $CDCl_3$): δ 16.9 (C-18), 27.1 (C-11), 27.2 (C-1), 30.8 (C-3), 31.6 (C-2), 40.6 (C-14), 42.5 (C-15), 47.8 (C-6), 49.6 (C-8), 49.7 (C-4), 50.9 (C-9), 52.2 ($CO_2\underline{CH_3}$), 54.8 (C-5), 74.5 (C-12), 78.6 (C-13), 93.7 (C-10), 110.8 (C-17), 152.6 (C-16), 172.2 ($\underline{CO_2}CH_3$), 178.1 (C-7); EIMS *m*/*z* (rel. int.): 488 $[M]^+$ (38), 470 (50), 417 (70), 361 (48), 343 (51), 329 (70), 311 (50), 301 (82), 265 (32), 257 (88), 237 (70), 229 (48), 211 (64), 197 (46), 181 (30), 171 (34), 155 (36), 143 (44) 129 (52), 115 (46), 91 (70). Compound **44** (39.4 mg, 0.081 mmol) was dissolved in CH_2Cl_2 (4 ml) and 1,8-diazabicyclo[5.4.0]undec-7-ene (400 ml, mmol) was added. The mixture was heated until reflux began, this being maintained overnight and until the reaction was judged complete by TLC. After cooling, the mixture was diluted with EtOAc (10 ml) and washed with HCl (2 M, 2×20 ml), H_2O (10 ml) and brine (10 ml). The organic layer was dried $MgSO_4$, filtered and the solvent was removed under reduced pressure. The residue was subjected to silica gel column chromatography (EtOAc–petrol, 1:1) to afford GA_{126} (**9**) methyl ester (22.0 mg, 75%): R_f 0.4 (EtOAc–petrol, 2:1); IR ν_{max} cm^{-1}: 3348, 2925, 1773, 1734; ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.19 (3H, *s*, H-18), 1.72 (1H, *d*, $J=11$ Hz), 1.82 (3H, *m*), 2.07 (1H, *br s*, OH), 2.12 (1H, *m*), 2.24 (2H, *m*), 2.34 (2H, *m*), 2.60–2.85 (1H, *br s*, OH), 2.76 (1H, *d*, $J=11$ Hz, H-6), 2.93 (1H, *d*, $J=11$ Hz, H-5), 3.66 (1H, *t*, $J=10$ Hz, H-12), 3.73 (3H, *s*, $CO_2\underline{CH_3}$), 5.11 (1H, *s*, H-17′), 5.31 (1H, *d*, $J=5$ Hz, H-17), 5.87 (1H, *dt*, $J=9$, 3 Hz, H-2), 6.14 (1H, *dt*, $J=9$, 2 Hz, H-1); ^{13}C NMR (75 MHz, $CDCl_3$): δ 17.6 (C-18), 27.5 (C-1), 37.8 (C-3), 40.7 (C-14), 43.3 (C-15), 48.0 (C-8), 48.3 (C-6), 50.6 (C-9), 51.0 (C-4), 52.2 ($CO_2\underline{CH_3}$), 56.2 (C-5), 74.8 (C-2), 78.6 (C-13), 89.7 (C-10), 110.8 (C-17), 129.4 (C-2), 131.2 (C-1), 152.9 (C-16), 172.6 (C-7), 179.2 (C-19); EIMS *m*/*z* (rel. int.): 360 $[M]^+$ (13), 342 (16), 329 (27), 316 (100), 284 (99), 271 (35), 256 (51), 238 (48), 211 (92), 195 (65), 183 (38), 167 (76), 155 (42), 143 (58), 121 (64), 105 (74), 91 (77), 77 (60); HRMS *m*/*z*: Calc. for $[M]^+$ $C_{20}H_{24}O_6$: 360.1573; Found: 360.1569.

3.3.5. GA_{121} (7) methyl ester

A soln. of GA_{126} (**9**) methyl ester (6.6 mg, 0.018 mmol) in CH_2Cl_2 (2 ml) was cooled to 0°C and triethylamine (6.4 ml, 0.046 mmol) was added, followed by addition of Ac_2O (4.31 ml, 0.046 mmol). The mixture was stirred overnight at room temp. Starting material was still present by TLC thus a further two equivalents of triethylamine and Ac_2O were added by the above method. Two h later all starting material was consumed. Ice was added and the reaction mixture stirred for 15 min, followed by dilution with EtOAc. The entire mixture was washed with HCl (1 M, 5 ml) and the aq. layer back extracted with EtOAc (2×10 ml). The combined organic layers were washed with brine (5 ml), dried $MgSO_4$, filtered and the solvent was removed under reduced pressure to give compound **45** (*ent*-12β-acetoxy-13-hydroxy-20-norgibberell-1, 16-ene-7, 19-dioic acid 7-methyl ester 19, 10-lactone) in quantitative yield (7.2 mg): R_f 0.6 (EtOAc–petrol, 2:1); ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.19 (3H, *s*, H-18), 1.85 (3H, *m*), 2.12 (3H, *m*), 2.13 (3H, *s*, $OCO\underline{CH_3}$), 2.33 (3H, *m*), 2.67 (1H, *s*, O<u>H</u>), 2.77 (1H, *d*, $J=10$ Hz, H-6), 2.95 (1H, *d*, $J=6$ Hz, H-5), 3.74 (3H, *s*, $CO_2\underline{CH_3}$), 4.74 (1H, *t*, $J=7$ Hz, H-12), 5.22 (1H, *s*, H-17′), 5.40 (1H, *s*, H-17), 5.87 (1H, *dd*, $J=9$, 3 Hz, H-2), 6.12 (1H, *d*, $J=9$ Hz, H-1); ^{13}C NMR (75 MHz, $CDCl_3$): δ 17.6 (C-18), 21.3 ($OCO\underline{CH_3}$), 25.0 (C-11), 37.8 (C-14), 41.4 (C-15), 43.3 (C-3), 48.0, 48.1 (C-8, C-6), 50.6 (C-4), 51.0 (C-9), 52.2 ($CO_2\underline{CH_3}$), 56.2 (C-5), 76.4 (C-12), 77.8 (C-13), 89.6 (C-10), 112.4 (C-17), 129.3 (C-2), 131.3 (C-1), 152.0 (C-16), 171.0 ($O\underline{CO}CH_3$), 172.4 (C-7), 179.1 (C-19); EIMS *m*/*z* (rel. int.): 402 $[M]^+$ (36), 371 (27), 342 (78), 298 (72), 282 (100), 254 (35), 237 (60), 211 (72), 195 (43), 167 (47), 143 (40), 129 (30), 105 (44), 91 (83), 77 (34); HRMS *m*/*z*: Calc. for $[M]^+$ $C_{22}H_{26}O_7$: 402.1679; Found: 402.1668.

A soln. of compound **45** (7.3 mg, 0.018 mmol) in CH_2Cl_2 (2 ml) was treated with *N*,*N*-dimethyl-4-aminopyridine (small spatula amount) and pyridine (6.6 ml, 0.081 mmol) followed by addition of methyl oxalyl

chloride (7.47 ml, 0.081 mmol). After 2 h the reaction was complete by TLC. The reaction mixture was diluted with EtOAc (5 ml), washed with HCl (2M, 5 ml), sat. $NaHCO_3$ (5 ml), H_2O (5 ml) and brine (5 ml) and dried over $MgSO_4$, filtered and the solvent removed under reduced pressure. The residue was applied to a silica gel (EtOAc–petrol, 1:2) to afford compound **46** (*ent*-12β-acetoxy-13-methyloxalyloxy-20-norgibberell-1, 16-ene-7, 19-dioic acid 7-methyl ester 19, 10-lactone) (3.1 mg, 35%): R_f 0.6 (EtOAc–petrol, 1:1); ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.21 (3H, *s*, H-18), 1.85 (1H, *dd*, $J=12$, 6 Hz), 1.98 (1H, *m*), 2.04 (1H, *dd*, $J=12$, 5 Hz), 2.12 (3H, *s*, $OCO\underline{CH_3}$), 2.13 (1H, *m*), 2.26 (2H, *m*), 2.34 (2H, *m*), 2.62 (1H, *d*, $J=10$ Hz), 2.79 (1H, *d*, $J=11$ Hz, H-6), 2.96 (1H, *d*, $J=11$ Hz, H-5), 3.76 (3H, *s*, $CO_2\underline{CH_3}$), 3.87 (3H, *s*, $OCOCO_2\underline{CH_3}$), 5.17 (1H, *t*, $J=8$ Hz, H-12), 5.23 (1H, *bs*, H-17′), 5.37 (1H, *d*, $J=2$ Hz, H-17), 5.89 (1H, *dt*, $J=9$, 3 Hz, H-2), 6.11 (1H, *d*, $J=9$ Hz, H-1); EIMS *m*/*z* (rel. int.): 488 $[M]^+$ (3), 457 (25), 428 (100), 401 (55), 384 (92), 341 (40), 297 (58), 280 (30), 237 (66), 193 (31); HRMS *m*/*z*: Calc. for $[M]^+$ $C_{25}H_{28}O_{10}$: 488.1682; Found: 488.1684.

A soln. of compound **46** (3.1 mg, 6.3 mmol) and azo-bisisobutyronitrile (0.5 mg, 3.2 mmol) in toluene (2 ml) was degassed and re-filled with N_2. Subsequent addition of tributyltin hydride (5.1 ml, 0.019 mmol) followed by gentle reflux for 15 min yielded a mixture of product and starting material (Dolan and MacMillan, 1985). After cooling the reaction mixture EtOAc (5 ml) was added. The solvent was removed under reduced pressure and the residue taken up in CH_3CN (5 ml) and layered with petrol (5 ml). The CH_3CN layer was washed with KF solution (1 M, 5 ml), and solvent removed under reduced pressure. The residue was applied to a silica gel column (EtOAc–petrol, 1:3) to yield the title compound **47** (*ent*-12β-acetoxy-20-norgibberell-1, 16-ene-7, 19-dioic acid 7-methyl ester 19, 10-lactone) (1.8 mg) and recovered starting material (1.3 mg): ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.19 (3H, *s*, H-18), 2.05 (3H, *s*, $OCO\underline{CH_3}$), 1.85–2.16 (5H, *m*), 2.36 (1H, *dt*, $J=5$, 3 Hz), 2.70 (1H, *m*, H-13), 2.78 (1H, *d*, $J=11$ Hz, H-6), 2.96 (1H, *d*, $J=11$ Hz, H-5), 3.73 (3H, *s*, $CO_2\underline{CH_3}$), 4.69 (1H, *t*, $J=8$ Hz, H-12), 5.06 (1H, *s*, H-17′), 5.24 (1H, *s*, H-17), 5.86 (1H, *dd*, $J=9$, 3 Hz, H-2), 6.14 (1H, *d*, $J=9$ Hz, H-1).

Compound **47** (1.8 mg, 0.0047 mmol) was dissolved in MeOH, and K_2CO_3 (1 mg, 0.0072 mmol) was added. The resulting suspension was stirred for 30 min then more K_2CO_3 (1 mg, 0.0072 mmol) was added and stirred for 3 h by which time the reaction was judged complete by TLC. The mixture was diluted with EtOAc (5 ml) and washed with HCl (1 M, 5 ml). The organic layer was washed with $NaHCO_3$ (satd. soln., 5 ml), H_2O (5 ml) and brine and subsequently dried over $MgSO_4$, filtered and the solvent was removed under reduced pressure. The residue was washed with CH_3CN–hexane and the CH_3CN layer was condensed under reduced pressure. The residue was then taken up in EtOAc (5 ml) and washed with KF soln. (1 M, 5 ml). The organic layer was condensed under reduced pressure and the residue was applied to a silica gel column (progressive elution: 1% EtOAc to 100% EtOAc) to yield GA_{121} (**7**) methyl ester (0.4 mg, 27%): R_f 0.2 (EtOAc–petrol, 1:2) or 0.1 (EtOAc–petrol, 1:3); ^{1}H NMR (600 MHz, $CDCl_3$): δ 1.19 (3H, *s*, H-18), 1.53–1.74 (3H, *m*), 1.89 (2H, *dt*, $J=13$, 2 Hz), 1.95 (1H, *dd*, $J=11$, 2 Hz, H-14), 2.01-2.05 (2H, *m*), 2.09–2.14 (2H, *qt*, $J=19$, 2 Hz), 2.63 (1H, *d*, $J=5$ Hz, H-13), 2.78 (1H, *d*, $J=11$ Hz, H-6), 2.96 (1H, *d*, $J=11$ Hz, H-5), 3.73 (3H, *s*, $CO_2\underline{CH_3}$), 3.77 (1H, *t*, $J=8$ Hz, H-12), 5.00 (1H, *s*, H-17′), 5.11 (1H, *s*, H-17), 5.86 (1H, *dt*, $J=10$, 3 Hz, H-2), 6.15 (1H, *d*, $J=10$ Hz, H-1); ^{13}C NMR (600 MHz, $CDCl_3$): δ 17.6 (C-18), 27.1 (C-11), 33.8 (C-3), 37.8 (C-14), 44.7 (C-15), 47.9 (C-8), 48.2 (C-6), 49.3 (C-9), 50.7 (C-5), 52.1 ($CO_2\underline{CH_3}$), 52.5 (C-4), 56.3 (C-13), 75.1 (C-12), 89.9 (C-10), 110.1 (C-17), 129.7 (C-2), 131.0 (C-1), 151.1 (C-16), 172.8 (C-7), 179.3 (C-19); EIMS *m*/*z* (rel. int.): 344 $[M]^+$ (32), 326 (47), 312 (52), 294 (50), 239 (50), 221 (86), 195 (100), 181 (55), 167 (30), 155 (38), 143 (42), 119 (42), 105 (57), 91 (71); HRMS *m*/*z*: Calc. for $[M]^+$ $C_{20}H_{24}O_5$: 344.1624; Found: 344.1627.

3.3.6. Other novel gibberellins

The synthesis of 2,3-didehydro GA_9 (**15**) has been described in Willis (1987). The syntheses of 2,3-didehydro GA_{69} (**17**), 2,3-didehydro GA_{70} (GA_{31}) (**16**) and 2,3-didehydro GA_{77} (**18**) have been described in Chu and Mander (1988). GA_{122} (**8**) methyl ester was prepared in an analogous fashion to GA_{121} (**7**) methyl ester; detail will be published elsewhere (Leitch, 2000). GA_{120}-isolactone (**11**) methyl ester, GA_{121}-isolactone (**12**) methyl ester, and GA_{122}-isolactone (**13**) methyl ester were prepared from GA_{120} (**6**) methyl ester, GA_{121} (**7**) methyl ester and GA_{122} (**8**) methyl ester, respectively, as 3:2 mixtures with the parent gibberellins by treatment with tetrakis-(triphenylphosphine)-palladium(0) (Serebryakov, 1980).

Received 28 November 2000; received in revised form 26 January 2001

Abstract

The polyamine, cadaverine, was detected in transformed root cultures of *Brugmansia candida* (syn. *Datura candida*), a Solanaceae which produces the tropane alkaloids scopolamine and hyoscyamine. To the best of our knowledge, this is the first time that the existence of this uncommon polyamine has been detected in a *Datura* species. Cadaverine, however, could not be found in the whole plant. The occurrence of cadaverine in hairy roots could be a consequence of either the transformation or a response to stress. Also, cadaverine could be participating in other secondary pathways rather than to the tropane alkaloids. The common polyamines, putrescine, spermidine and spermine were also observed. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Brugmansia candida* (syn. *Datura candida*); Solanaceae; Cadaverine; *Agrobacterium rhizogenes*; Hairy roots; Polyamines

1. Introduction

Brugmansia candida (syn. *Datura candida*), a member of the Solanaceae, is a South American plant that produces the tropane alkaloids scopolamine and hyoscyamine (Roses et al., 1988). These alkaloids are extensively employed in medicine as anticholinergic agents. In our laboratory, we have worked with transformed (hairy) roots of *B. candida* in order to obtain these alkaloids (Pitta-Alvarez and Giulietti, 1995, 1997). The biosynthesis of these secondary metabolites uses the polyamine putrescine (Put) as a precursor (Scheme 1), a compound which can also diverge into the metabolic route leading to two other polyamines, spermidine (Spd) and spermine (Spm), both linked mainly to primary metabolism in this plant.

The common aliphatic polyamines Put, Spd and Spm, are ubiquitous in all types of organisms, and are considered to participate in a variety of events related to plant growth and development (Bagni and Torrigiani, 1992; Galston and Kaur Sawhney, 1995). However, besides these common polyamines, there are also some uncommon ones, such as 1,3-diaminopropane, cadaverine (Cad), norspermidine and homospermidine, which have been associated with the capacity of some biological systems to grow or function under extreme environments (Slocum and Flores, 1991). Cad (1,5-diaminopentane), is the penta homologue of Put, and it is present in many biological tissues. However, the existence of this diamine in plants is sporadic and less common than its homologue Put. Cad has been found in several genera of the Leguminosae, such as *Pisum*, *Glycine*, *Lathyrus*, *Trifolium*, *Lupinus* and *Vicia*; in *Hordeum* and *Oryza* (Gramineae), in *Zantedeschia* (Araceae), and in *Sedum* (Crassulaceae). In the Solanaceae, however, it has only been detected in *Nicotiana* and *Lycopersicon* (Slocum and Flores, 1991; Wink 1997).

The objective of our work was to evaluate the polyamine (Put, Spd and Spm) levels in hairy roots of *B. candida*. Unexpectedly, Cad was also found.

Abbreviations: Cad, Cadaverine; Put, putrescine; Spd, spermidine; Spm, spermine

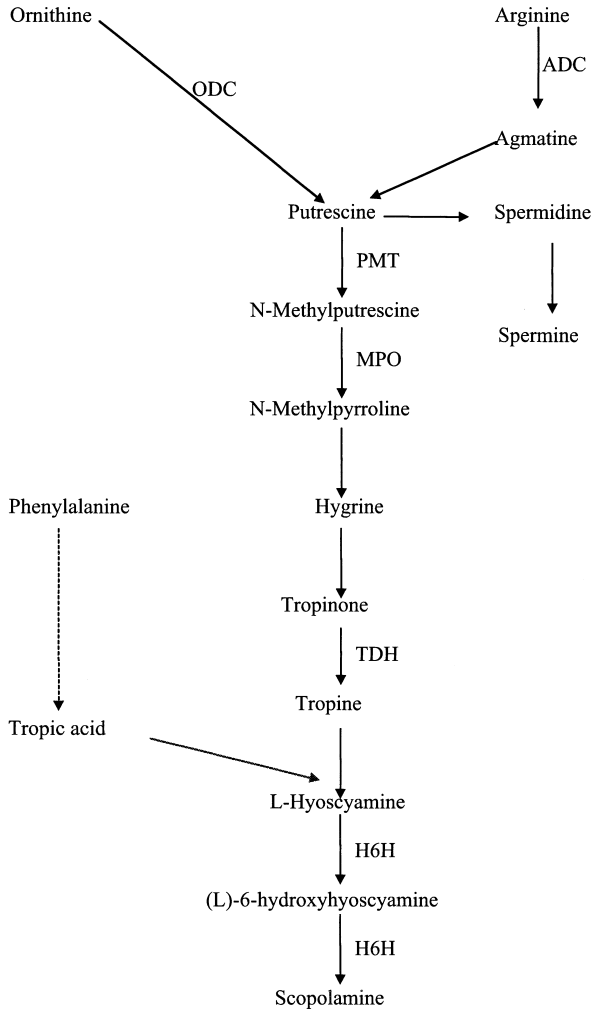
2. Results and discussion

2.1. Time-course of growth and polyamine biosynthesis

Table 1 and Fig. 1 show the time course of growth of hairy root cultures of *B. candida* and the corresponding Put, Spd and Spm contents, respectively. The values obtained were similar to those observed by Robins et al. (1991) in hairy roots of *Datura stramonium*. The levels of the three polyamines decrease when the cultures enter into an exponential phase. This depletion could suggest that they are being used actively for cell division and growth.



Scheme 1. Biosynthesis of hyoscyamine and scopolamine. ODC: ornithine-decarboxylase; ADC: arginine-decarboxylase; PMT: putrescine-methyltransferase; MPO: methylputrescine-oxidase; TDH: tropinone dehydrogenase; H6H: hyoscyamine 6-β-hydroxylase.

Table 1
Time course of growth of *Brugmarsia candida* hairy roots[a]

Time (days)	Fresh wt (g)
5	0.22±0.02
10	0.51±0.05
15	0.47±0.05
20	1.02±0.01
25	1.7±0.12
30	1.61±0.11

[a] Data are mean values of two independent experiments±S.E. Each point represents six replicates.

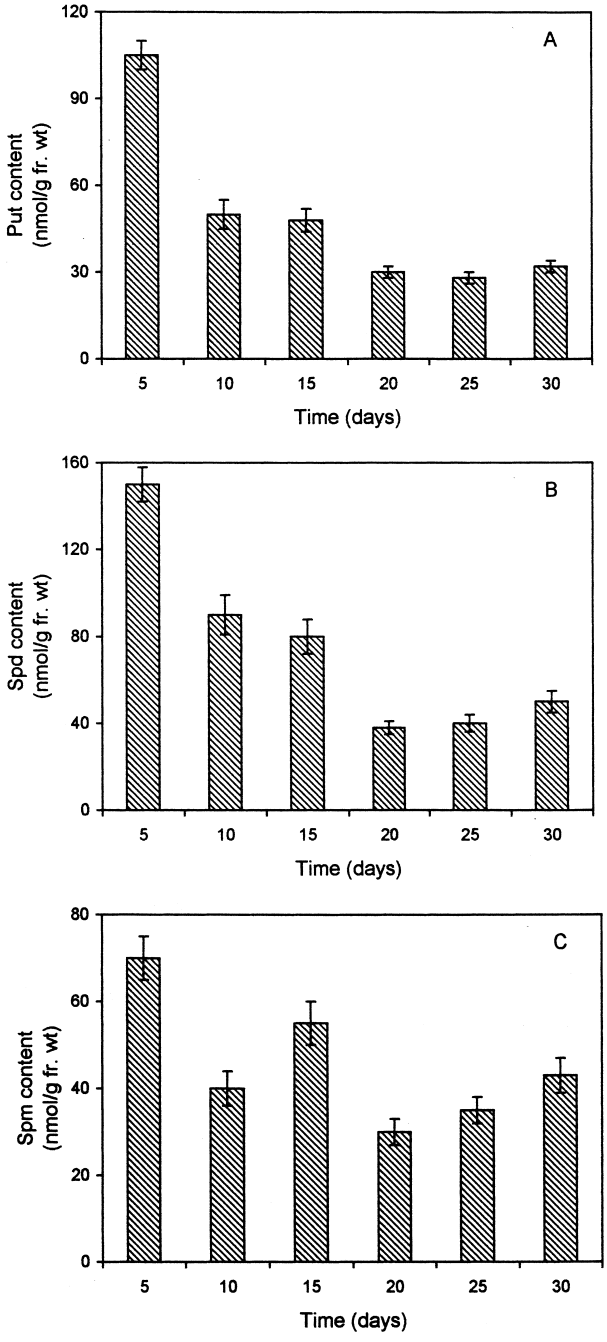


Fig. 1. Time course of accumulation of polyamines: (A) putrescine, (B) spermidine and (C) spermine in hairy roots of *Brugmarsia candida*. Values are the mean of two different experiments with three replicated measurements, and bars indicate S.E.

2.2. Cadaverine detection

When the TLCs of the perchloric extracts obtained from the cultures were examined, an additional band, which had the same R_f (in chloroform:triethylamine) as Cad, was detected. Moreover, this compound showed the same R_f as Cad in *n*-hexane:ethyl acetate. To confirm the identity of this compound, the FAB MS (positive ion mode) for the unknown compound and a Cad standard were performed. The presence of the characteristic ions, $[M+H]^+$ (m/z: 569) and $[(M+H)-C_{12}H_{10}N]^+$ (m/z: 399), were observed in both spectra coming from the two different solvent systems.

Data obtained from both TLC and mass spectrometric analyses clearly demonstrated that the unknown compound was Cad.

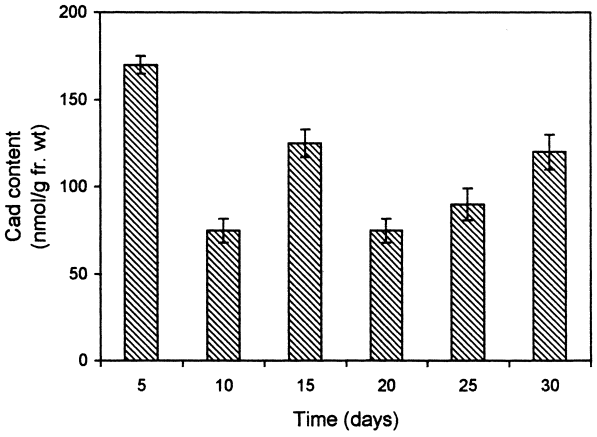

Fig. 2. Time course of accumulation of cadaverine in hairy roots of *Brugmansia candida*. Values are the mean of two different experiments with three replicated measurements, and bars indicate S.E.

2.3. Time-course of growth and cadaverine content

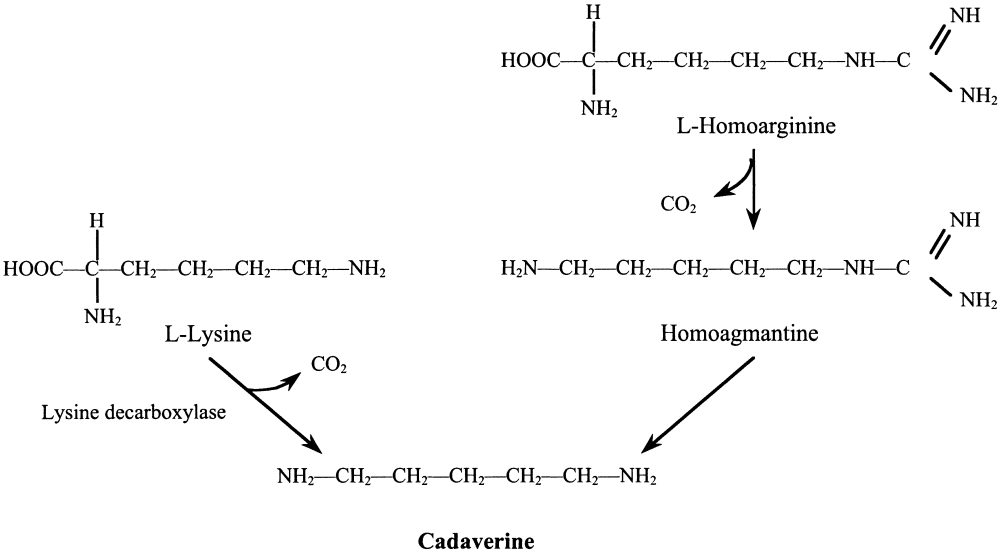
Table 1 and Fig. 2 show the time course of growth of hairy root cultures of *B. candida* and the corresponding Cad content, respectively. In comparison to the other three polyamines (Fig. 1), Cad was found in slightly higher quantities. However, the same phenomena of reduction of polyamine content concomitant with the exponential growth period, was observed. These results are in agreement with those found by Gamarnik and Frydman (1991) in soybean roots.

2.4. Occurrence of Cad in whole non-transformed plants

In view of the fact that the occurrence of Cad had not been described previously in *B. candida*, or to the best of our knowledge in any other *Datura* species, we decided to investigate whether it accumulated in different parts of the whole plant. No Cad was found either in leaves or roots of the plant. In contrast, there are reports of the presence of Cad in soybean radicles (Tajima et al., 1983) and in *Glycine max* cotyledons, embryonic axes and roots (Gamarnik and Frydman, 1991).

It is important to emphasize that the plant examined was the one whose explants had originated the transformed roots, and therefore shared with the latter the same genetic background.

The surprising finding of Cad in *B. candida* generates multiple hypotheses, whose robustness must be put to trial in the future. Several studies have indicated that *Agrobacterium rhizogenes* affects the levels of polyamines in transformed plants (Altabella et al., 1995; Martin-Tanguy et al., 1996). Also, the appearance of uncommon polyamines has been linked to stress (Tiburcio et al., 1997). In vitro cultures can be considered a stressful



Scheme 2. Biosynthesis of cadaverine.

situation for plants, and the expression of the gene coding for the enzyme that synthesizes Cad could be triggered by it (Flores, 1991) either for transforming lysine into Cad in a reaction catalyzed by lysine decarboxylase or via an alternative route that involves L-homoarginine and homoagmatine (Wink, 1997) (Scheme 2).

Finally, the main question that remains unanswered is what is the role of Cad in hairy roots. As was mentioned previously, it could be part of the roots response to stress. Also, their participation in secondary routes, not necessarily to tropane alkaloids, might be possible.

3. Conclusions

Cadaverine (Cad), an uncommon polyamine, was detected for the first time in hairy roots of *Brugmansia candida*, and in comparison to the other three polyamines (Put, Spd and Spm), Cad was found in higher quantities. Cad levels decreased when the cultures entered into an exponential phase. This depletion could suggest that it is being used actively in cell division and growth.

Further studies will be necessary in order to assess more precisely the role of Cad in transformed roots of *Daturas* species.

4. Experimental

4.1. General experimental procedures

TLC was performed on high resolution silica gel plated (Merck, silica gel 60 F-254 plates). The silica gel used in column chromatography was Kieselgel DG (Riedel de Haen). All the chemical used were of analytical grade. Solvents were distilled before use. FAB MS spectra were obtained using a ZAB SEK (VG, Fisons) spectrometer.

4.2. Establishment and maintenance of axenic hairy root cultures

Transformed roots were obtained by infection of sterile leaves of *B. candida* with *A. rhizogenes* LBA 9402 according to the method described by Pitta-Alvarez and Giulietti (1995). The root tips were transferred to hormone-free Gamborg (Gamborg et al., 1969) medium, with half concentration of vitamin and minerals nutrients ($B5_{1/2}$) and with the addition of 15 g/l sucrose (Pitta-Alvarez and Giuletti, 1995). Cefotaxime 0.05% was added until axenic cultures were obtained. The transformation was confirmed according to the procedure described by Hamill et al. (1991). The roots that were used in the experiments were maintained in an hormone-free $B5_{1/2}$ medium, supplemented with 15 g/l sucrose and subcultured every 15–20 days. They were incubated at $24\pm2^{\circ}C$, in gyratory shakers at 100 rpm with a 16-h photoperiod using cool white fluorescent lamps, at a light intensity of approximately 1.8 W m^{-2}.

4.3. Time course of growth and polyamine content

Inocula of fresh weight (0.5 g) of 20-day-old hairy roots were inoculated in 50 ml of $B5_{1/2}$ (with 15 g/l sucrose) contained in 250 ml Erlenmeyers. The cultures were incubated as described above and samples were taken every 5 days during 30 days and fresh wt and free polyamines were determined in each one of them.

4.4. Analytical methods

Plant material (400 mg fresh wt of hairy roots, leaves and normal roots) was homogenized with 5% perchloric acid, kept 30 min on ice and centrifuged at 5000 rpm for 10 min. The supernatants (15 ml) were derivatized using the dansylation method described by Smith and Meeuse (1966) and 1,6 hexanediamine was used as internal standard. Standards of Put, Spd, Spm were dansylated simultaneously. The dansylated derivatives were extracted with 1 ml ethyl acetate. Polyamines (200 μl) were separated and identified by TLC with both chloroform–triethylamine (9:1) and *n*-hexane–ethyl acetate (2:1) solvent systems. Dansylated polyamines were identified by comparing the R_f values of dansylated standards. Silica plates were observed under UV light and the bands corresponding to polyamines in the samples and standards were scraped off the plates and eluted with EtOAc (1 ml). Their fluorescence was measured in a spectrofluorometer using an excitation wavelength of 365 nm and an emission wavelength of 510 nm.

For confirmation of the identity of Cad, the band with the same R_f as Cad was scraped from the plate and eluted off using chloroform–methanol (9:1). The solvent was evaporated and the residue was filtered through a small column of silica gel (2×1 cm) using the above-mentioned solvent. The fractions containing the product were evaporated in vacuum and afforded a white yellowish solid. FAB MS spectrometry was obtained using glycerol as a matrix: *m/z*: 569 $[M+H^+]$, 399$[(M+H)-C_{12}H_{10}N]^+$.

For fresh wt determinations, root tissues were separated from the medium by filtration and weighed.

Abstract

Maize bran heteroxylan samples were extracted in various conditions of severity. Their ferulate and diferulate content was investigated by GC–MS of methyl ester-TMSi derivatives. When extracted by 0.5 M NaOH in mild conditions, the heteroxylan sample contained a low level of ferulic acid (0.032% by wt.) and the main diferulate surviving alkaline extraction was found to be the 8–8′ diferulate. On peroxidase treatment, this sample nevertheless produced a firm and brittle gel without any change in the diferulate profile. Typical lignin structures, mainly comprising syringyl units interconnected through β-*O*-4, β-1 and β-β interunit bonds, were evidenced in the maize bran sample. More importantly, these lignin structures were found to be tightly associated with the alkali-extracted heteroxylans. Thioacidolysis revealed the occurrence of 0.1–0.5% (by wt.) lignin structures in heteroxylan fractions extracted in mild or severe conditions, before and after purification of the polysaccharides. The gelling potential of the heteroxylan fractions was not only dependent on their ferulate level, but also influenced by associated lignin structures. These results argue for the occurrence of covalent linkages between heteroxylan chains and lignin structures which could participate in the peroxidase-driven gelation of feruloylated polysaccharides. They demonstrate the role of low lignin levels in the organization of native or reconstructed polysaccharide networks. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Maize bran is an important by-product of the maize industry. This cell wall fraction, mainly composed of matrix polysaccharides and cellulose, originates from the pericarp tissues. The matrix polysaccharides, which represent more than 50% of the wall, are heteroxylans made primarily of xylose and arabinose units with minor amounts of galactose and glucuronic acid (Saulnier et al., 1995a). In addition, cinnamic acids represent up to 4–5% by weight of the destarched maize bran (Saulnier et al., 1999; Saulnier and Thibault, 1999). These acids, mainly ferulic acid (3-methoxy-4-hydroxycinnamic acid) together with a lower amount of *p*-coumaric acid (4-hydroxycinnamic acid), are esterified to the wall polymers (Kato and Nevins, 1985; Mueller-Harvey et al., 1986; Saulnier et al., 1995b). Many studies with grass cell walls or appropriate ferulate model compounds have demonstrated that ferulate esters can participate in peroxidase-mediated oxidative coupling (Ralph et al., 1994; Wallace and Fry, 1995; Grabber et al., 1995). Such coupling results in the cross-linking of polysaccharide chains, thereby decreasing the wall extensibility (Kamisaka et al., 1990; Sanchez et al., 1996; Wakabayashi et al., 1997) and enzymatic degradability (Grabber et al., 1998). In addition, during lignification, the oxidative coupling between lignin units and ferulate esters anchors lignins to polysaccharides and further strengthens grass cell walls (Jacquet et al., 1995). In contrast to ferulic acid, *p*-coumaric acid is not prone to peroxidase-mediated coupling (Russel et al., 1996; Wallace and Fry, 1999), but participates in photodimerization reactions (Ford and Hartley, 1988). In addition to the biological importance of the ferulate-based cross-linking, the oxidative gelation of feruloylated pectins isolated from sugar beet (Thibault, 1986; Oosteveld et al., 1997) or of feruloylated heteroxylans isolated from

maize or wheat bran (Ng et al, 1997; Figueroa-Espinoza and Rouau, 1998; Schooneveld-Bergmans et al., 1998) has an interesting technological potential.

Because of the localization of maize heteroxylans in the secondary cell walls of pericarp tissues, their isolation requires alkaline conditions and their recovery yield varies with the severity of the treatment (Chanliaud et al., 1995). Accordingly, their gelling capacity depends on the ferulate content which can survive the extraction process (Ng et al., 1997). With the objective of further delineating the role of ferulate esters in the gelation of maize heteroxylans, we have examined herein the ferulate content of various heteroxylan fractions in relation to their gelling properties. Moreover and for the first time, we have examined the possibility that grass lignin structures remain associated to the alkali-extracted heteroxylans and thereby participate in the peroxidase gelation of these polysaccharides.

2. Results and discussion

2.1. Isolation and purification of maize bran heteroxylan fractions

Various heteroxylan samples were isolated from destarched maize bran, under mild (samples AX and AXP, Table 1) or more severe (samples HX and HXO, Table 1) conditions of alkaline extraction. The various heteroxylan fractions were purified by ion exchange chromatography. Crude polysaccharide fractions were yellowish in color and this colored material was retained on the column during the purification step. Glucose arising from residual starch was also eliminated from the purified fractions (see fractions AX and AXP in Table 1).

The sugar composition of purified fractions was similar, although HXO was slightly depleted in galactose compared to other samples. Size-exclusion chromatograms of the different fractions are presented in Fig. 1. Polysaccharides eluted as a main peak which presented a shoulder on the leading edge, indicating some heterogeneity in molar mass distribution. Weight average molar mass was about the same for AXP and HX, but was about two times lower for HXO (Table 1), which was extracted in the presence of hydrogen peroxide. Hydrogen peroxide did not improve the extraction yield, but might have catalyzed the cleavage of linkages labile in oxidative conditions. Heteroxylans with a similar low molar mass have been previously extracted from maize bran using acidic hypochlorite (Saulnier et al., 1995a).

2.2. Ferulate content of destarched maize bran and corresponding heteroxylan samples

The alkali-released ferulic and *p*-coumaric acids of destarched maize bran and of the corresponding heteroxylan fraction AX were analyzed by HPLC. Ferulic acid represented 2.82% (by weight) of the maize bran sample, versus 0.33% for *p*-coumaric acid (Table 2). A very small proportion of ester-linked ferulic acid (about 1% versus 18% for *p*-coumaric acid) survived the alkaline extraction used for the isolation of AX (Table 2). This alkali-releasable ferulic acid essentially resisted the purification step of the AX sample performed by ion exchange chromatography (data not shown). This result confirms that ferulic acid units surviving in the AX sample are covalently linked to the heteroxylan chains. Conversely, heteroxylans (HX and HXO) extracted in severe alkaline conditions did not contain ferulic acid.

The analysis of diferulates was performed by GC–MS in order to unambiguously identify the dimers from their mass fragmentation patterns. In addition, we observed that the 8–8′ diferulate could not be satisfactorily analyzed by HPLC, in agreement with recently reported results (Saulnier et al., 1999). The diferulates were analyzed by GC–MS of their methyl ester-TMSi derivatives after esterification with BF_3 methanol, then trimethylsilylation. This two-step derivatization mode was preferred to trimethylsilylation as TMSi derivatives of phenolic acids have been repeatedly reported to be somehow unstable during GC analyses (for review, see Wittkowski, 1985). Exhaustive methylation with diazomethane led to unsatisfactory results because of the formation of pyrazoline derivatives when the cinnamic compounds were subjected to a prolonged CH_2N_2 exposure. The diferulate derivatives obtained by the esterification/silylation procedure are outlined in Fig. 2. The corresponding GC trace and mass spectra are provided in Fig. 3 and Table 3. According to these results, we could observe that acyclic 8–5′ and 5–5′ diferulates (dimers **3** and **7**, in Fig. 2) were completely methylated at COOH,

Table 2
Content of *p*-coumaric acid, ferulic acid and ferulic acid dehydrodimers for destarched maize bran and for the corresponding heteroxylan fraction AX isolated in mild conditions[a]

Hydroxycinnamic derivative (g/100 g)	Destarched maize bran	AX heteroxylan fraction
p-Coumaric acid	0.33	0.062
Ferulic acid	2.82	0.032
8–8′ diFA (**1** and **2**)	0.09	0.06
8–5′ diFA (**3** and **6**)	0.23	tr
8-*O*-4′ di FA (**4** and **5**)	0.13	tr
5–5′ diFA (**7**)	0.23	tr

[a] *p*-Coumaric and ferulic acid are analyzed by HPLC; dehydrodimers are analyzed by CPG–SM of their methyl ester-TMSi derivatives (structures outlined in Fig. 2) and by setting their response factor as 1.0; tr: trace amount.

similar to the case of ferulic and *p*-coumaric acid. In contrast, the cyclic 8–8′ and 8-*O*-4′ diferulates yielded two derivatives differing in their methylation degree (compounds **1** and **2**; compounds **4** and **5**, Fig. 2) and the cyclic 8-5′ diferulate provided only one derivative with one COOTMSi and one COOMe group (compound **6**, Fig. 2). More drastic methylation conditions were not attempted in order to avoid any diferulate degradation. Moreover, the recovery of partially methylated compounds did not hinder analysis of the reaction mixture (Fig. 3). The mass spectral fragmentation patterns of the methyl ester-TMSi derivatives of diferulates (Table 3) displayed some similarities with the ones of their fully trimethylsilylated analogues (data not shown). The common observed features were loss of formic acid (methylated or silylated) in 8–8′ and 8-*O*-4′ diferulates and of HOTMSi groups in diferulates **2** and **6** (giving rise to the fragment at *m*/*z* 467 from the ion at *m*/*z* 557 in **2** and to the *m*/*z* 454 base peak in **6**). However, an important attribute of the methyl ester-TMSi derivatives, relative to their fully trimethylsilylated analogues, was their abundant molecular ion (Table 3). The quantitative evaluation of the diferulates was carried out by setting their response factor as 1.0, due to the lack of appropriate standards in pure form. However, the data reported in Table 2 can be nevertheless comparatively discussed as follows. The only diferulate recovered from the AX sample in substantial amount was the cyclic 8–8′ diferulate (Table 2 and Fig. 3). In addition, the GC profile of AX displayed an additional compound (peak 8 in Fig. 3): its mass spectrum (M^+ at *m*/*z* 498 as the base peak) suggested that this compound originated from the decarboxylation of the 8–5′ diferulate **3**. The other diferulates could be detected only as trace components. The diferulate ester type which was, therefore, the less easily released from maize bran cell walls was the 8–8′ diferulate one. A similar conclusion has been recently reported in the case of maize coleoptile (Pena et al., 1998).

In contrast to similar studies carried out with maize bran heteroxylan (Ng et al., 1997), the diferulate profile of the maize heteroxylan AX fraction was not altered by the peroxidase gelation of the sample (GAX in Fig. 3). The amount of alkali-released 8–8′ diferulate was found similarly low (0.06% by weight) in AX and in GAX. Moreover, the GAX chromatographic profile did not reveal any increased amount of other diferulates (Fig. 3). In contrast, the amount of alkali-released ferulic acid was about two times lower in GAX than in the initial sample AX (data not shown). This result argues for the effective participation of ferulic units in cross-linking structures that cannot be released by mild alkaline hydrolysis, a phenomenon reminiscent of the situation met for lignified cell walls. Recent studies have established the propensity of ferulate esters to copolymerize with lignin units and demonstrated that most of the resulting cross-links are not measurable by solvolytic techniques (Grabber et al., 1995, 1998). Accordingly, the occurrence of lignin structures in the heteroxylan fractions isolated from maize bran was explored in order to tentatively account for the peroxidase-promoted disappearance of ferulic units without the concomitant formation of alkali-releasable diferulates.

2.3. Evidence for lignin structures in maize bran and in the corresponding heteroxylan samples

In order to unambiguously detect the occurrence of lignin structures that could putatively participate in the peroxidase cross-linking of maize heteroxylans, we subjected the heteroxylan fractions isolated in various conditions and the destarched maize bran to thioacidolysis. Thioacidolysis, that is solvolysis in dioxane-ethanethiol with boron trifluoride etherate, is an analytical degradation procedure which results in the depolymerization of lignins (Lapierre, 1993). The key reaction of thioacidolysis is the cleavage of the labile β-*O*-4 bonds which are the major interunit bonds in native lignins. The

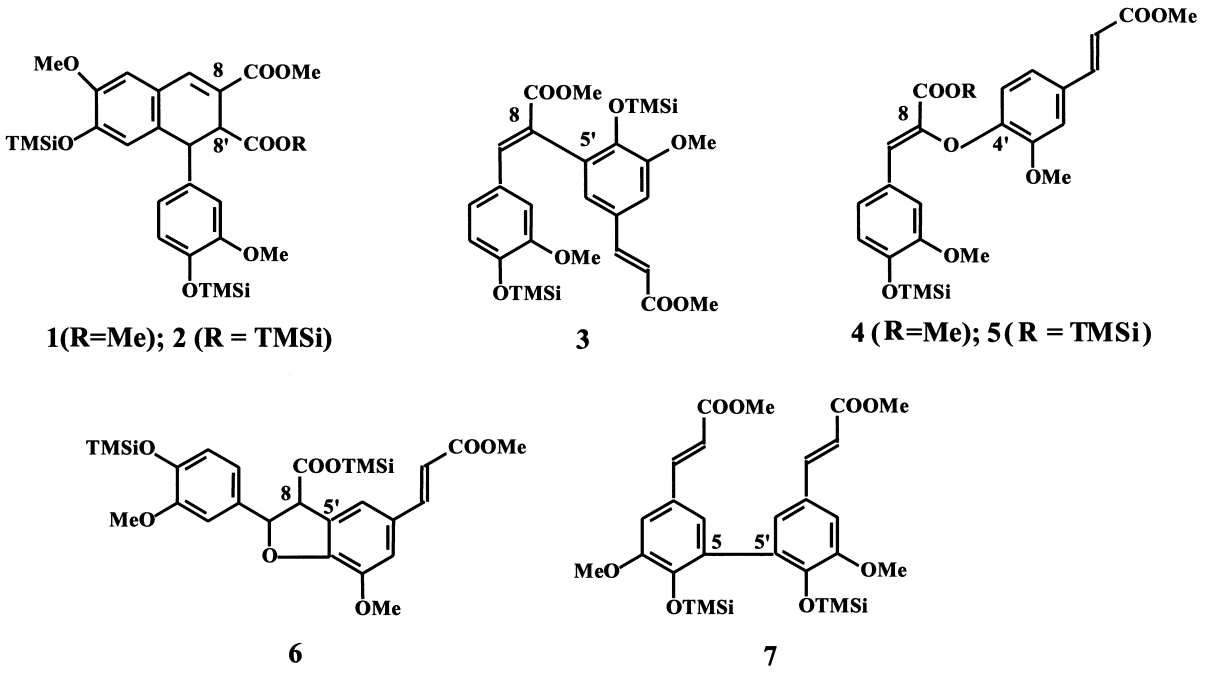

Fig. 2. Main diferulates recovered from maize bran and analyzed as methyl ester-TMSi derivatives. The compound numbers correspond to the peak quotation of the GC–MS profile shown in Fig. 3.

guaiacyl (G) and syringyl (S) lignin units only involved in β-*O*-4 bonds specifically and respectively give rise to thioethylated G and S monomers (Fig. 4), with a high reaction yield. In contrast, ferulic ester bonds are only partially cleaved, which give rise to free ferulic acid and to the corresponding product formed by addition of EtSH on the double bond (Lapierre, 1993). On this basis, thioacidolysis may be viewed as a diagnostic test for the presence of lignins in ferulic-containing samples.

Noticeable amounts of G and S thioethylated monomers were released from destarched maize bran (Table 4). The recovery yield was approximately one tenth of the yield obtained from mature maize internodes with 16–17% lignin content (Méchin et al., 2000), which suggests that the lignin content of destarched maize bran is in the 1–2% range (wt.%). Thioacidolysis revealed that the heteroxylan fractions extracted from maize bran by alkali in mild or in severe conditions were associated with β-*O*-4 structures, the most diagnostic lignin structures. The amount of β-*O*-4 lignin structures occurring in these maize heteroxylan fractions was only four times lower than that of the maize bran samples. According to the S/G proportion reported in Table 4, the β-*O*-4 linked lignin structures evidenced in maize bran and in corresponding heteroxylan fractions were particularly enriched in S units relative to the level observed for internode lignins (Table 4 and more comprehensive data in Méchin et al., 2000). In addition and as revealed by thioacidolysis of permethylated samples (Lapierre, 1993), maize bran lignins differed from maize stem lignins by the observation that ca. 12% of the β-*O*-4 linked S units were terminal units with a free phenolic group (versus 2% in maize stem lignins). This difference may support the hypothesis that lignin structures associated with maize bran are lower molecular weight phenolics relative to their maize stem analogues. About 75% of the lignin structures evidenced in the crude AX sample were lost

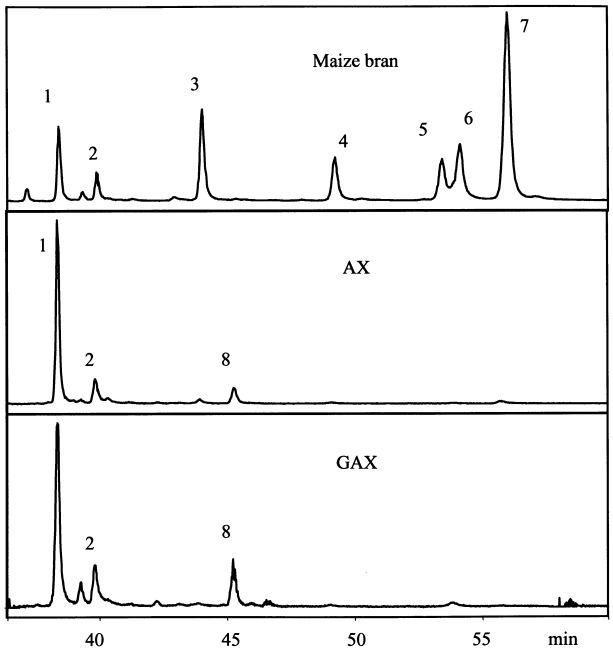

Fig. 3. Partial GC–MS trace of the various diferulates recovered from maize bran (upper trace) and from corresponding heteroxylan sample before (AX) and after (GAX) peroxidase gelation. On each trace, the y-scale (total ion current, arbitrary unit) is normalized on the highest peak. Numbers 1–8 on trace refer to specific diferulates (see Table 3).

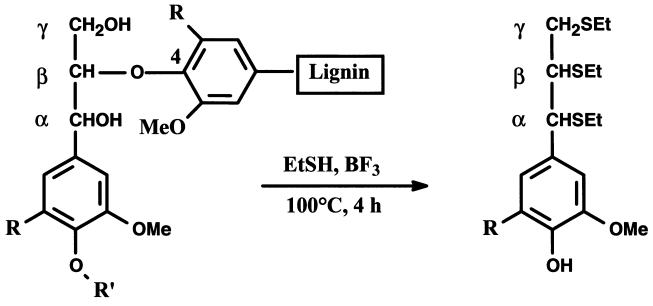

Fig. 4. Principle of the thioacidolysis analytical degradation. Thioethylated guaiacyl (R = H) and syringyl (R = OMe) monomers are specifically released from the typical β-*O*-4 lignin structures (R′ = H or side chain of lignin unit).

during the purification step (AXP, Table 4) which is in agreement with the decolorizing effect of ion-exchange chromatography. Taken together, the data of Table 4 argue for the tight association between alkali-extracted maize heteroxylans and a small percentage of lignin structures. Such associations which resist purification steps might involve alkali-resistant covalent linkages. With the assumption that these lignin structures give rise to thioacidolysis G and S monomers with reaction yields that approximate those of maize internode lignins and from the data of Table 4, we can evaluate the content of lignin structures in maize heteroxylan samples ranging between 0.1 and 0.5% by weight.

Further structural investigation of the lignin moiety associated with maize bran heteroxylans confirmed the occurrence of genuine lignin structures in these samples. The analysis of lignin-derived dimers recovered after thioacidolysis and Raney nickel desulfurization was carried out according to Lapierre (1993). The main lignin-derived dimers recovered from AX and HX samples were syringyl dimers representatives of the β-1 diarylpropane and of the syringaresinol bonding patterns (data not shown), which confirms the occurrence of typical lignin structures in maize heteroxylan samples before and after extensive purification.

Table 4
Yield of lignin-derived thioacidolysis G and S monomers recovered from destarched maize bran and the corresponding heteroxylan fractions obtained in various conditions (Table 1). The yield observed for an extractive-free maize internode sample (F292 line harvested at maturity) with 16.4% lignin (wt.%) content is given for comparison purpose

Sample	S + G (μmol per gram dry sample)	Molar proportion S/G
Maize internode (extractive-free) F292	129	59/41
Destarched maize bran	13.2	80/20
AX fraction	3.9	93/7
AXP fraction (= purified AX)	0.8	94/6
HX fraction (purified)	2.9	92/8
HXO fraction (purified)	4.4	90/10

When the various maize heteroxylan samples studied herein were subjected to peroxidase treatment, the very rapid formation of a firm and britlle gel was observed

only for the AX sample. In contrast, heteroxylan samples isolated in severe conditions did not yield any gel. When the peroxidase treatment was applied to the purified AXP sample, gelling was obtained, but very slowly and the resulting gel was soft and unstable. While the content in ferulate and diferulate units was not affected by the purification procedure, the content in lignin structures was four-fold reduced in AXP and relative to the unpurified AX sample. Taken together, these observations strongly support the hypothesis that lignin structures associated with maize heteroxylan samples may synergistically participate in the gelation phenomenon, at least when the amount of ferulic units available for cross-linking is very low. The fact that gelation induces a decrease in ester-linked ferulic acid without any correlated increase in alkali-releasable diferulates is compatible with the hypothesis that the cross-linking of maize heteroxylan chains may not exclusively involve ferulic units, but also lignin units.

3. Conclusions

The present work has provided the first evidence that typical lignin structures are tightly associated with maize bran heteroxylan extracted by alkali and extensively purified. The amount of lignin structures, as evaluated by thioacidolysis, ranged between 0.1 and 0.5% (wt.%) of the sample. These results argue for the occurrence of covalent linkages between heteroxylan chains and lignin structures. At this point, we cannot determine whether these linkages exist ab initio and/or are formed during the alkaline extraction of heteroxylan. The lignin structures evidenced in maize bran and in the heteroxylan fractions display the typical β-*O*-4, β-1 and β-β bonding patterns met in stem lignins. They differ from stem lignin by their high content in S units, including an unusually high level of S units with free phenolic groups.

In spite of a very low ferulate level, maize bran heteroxylan fractions could efficiently gel upon peroxidase treatment except when the lignin content was reduced to 0.1%. This point further supports a role for lignins, even when present in low amount, in the organization of native or reconstructed polysaccharide networks.

4. Experimental

4.1. Extraction of maize bran heteroxylan samples

Maize bran provided by ULICE (France) was destarched and deproteinized as previously reported (Saulnier et al., 1995b). Heteroxylan fractions were isolated from maize bran under mild or severe alkaline conditions as follows. Purified bran (25 g) was suspended in 500 ml of an alkaline solution (see precise conditions in the following). Solids were separated from solution by centrifugation (5000 *g*, 15 min) and the residue was rinsed with 500 ml of distilled water, centrifuged and rinsed again with 2×250 ml of distilled water. The extract and washings were pooled, acidified to pH 3–4, concentrated in a rotary evaporator at 40°C, dialyzed against distilled water. The pH was adjusted to 3.5 with conc. HOAc and polysaccharides were isolated by EtOH precipitation (4 vol, overnight at 4°C) as previously reported (Saulnier et al., 1995a). The heteroxylan fractions AX, HX and HXO were prepared using the following extraction conditions 0.5 M NaOH, 30°C, 2 h; 1.5 M KOH, 100°C, 2 h and 1.5 M KOH, 1% H_2O_2, 100°C, 2 h, respectively. Recovery yields of 19.1, 55.6 and 56.3% (wt.%) were observed for AX, HX and HXO, respectively.

4.2. Sugar analyses

Individual neutral sugars were determined after hydrolysis (1.5 h in 1 M H_2SO_4 at 100°C for extracted polysaccharides; 1 h in 72% H_2SO_4 at 25°C, then 2 h in 1 M H_2SO_4 at 100°C for the bran) by GC as their alditol acetates derivatives (Englyst and Cummings, 1988). Uronic acids were assayed by the automated *m*-hydroxydiphenyl method (Thibault, 1979) (after pre-hydrolysis for 1 h in 72% H_2SO_4 at 25°C for the bran), using glucuronic acid as standard

4.3. HPLC and GC–MS analyses of alkali-released hydroxycinnamic acid derivatives

Ferulic and diferulic acids were determined after alkaline treatment run according to Saulnier et al. (1999) and to Jacquet et al. (1995). The monomers were determined by HPLC analyses (Saulnier et al., 1999). The dimer fraction was analyzed after derivatization with BF_3 methanol (14% by wt., Supelco) at 80°C and for 30 min. The methylated reaction mixture was diluted with water, the pH adjusted to 3–4 (0.4 M aq. $NaHCO_3$) and the methyl ester derivatives were extracted with EtOAc–CH_2Cl_2 (1:1). Trimethylsilylation of the methylated compounds and subsequent GC–MS analysis of the methyl ester-TMSi derivatives were run according to Jacquet et al. (1995).

The quantitative determinations of diferulates by GC–MS were done relative to 5–5′ dieugenol added as internal standard and according to Jacquet (1997). A diferulate 8–5′ model compound, prepared by $FeCl_3$ oxidation of ferulate methyl ester in THF (data not shown), allowed us to check that the response factor of the 8–5′ dimer relative to dieugenol was 1 (relative concentration/relative surface). The other dimers were quantitatively determined using the same response factor, but without carrying out any precise calibration. Standard errors between duplicate experiments were in the 10–15% range.

4.4. Thioacidolysis experiments

Thioacidolyses were carried out from 10 to 50 mg of maize bran and corresponding heteroxylan fractions. The GC–MS analyses of the lignin-derived monomers and dimers were performed according to Lapierre et al. (1995). Standard errors between duplicate experiments were in the 5–10% range.

4.5. Ion-exchange chromatography

Ion-exchange chromatography was performed on a DEAE-Sepharose CL-6B column (2.6×28 cm) equilibrated with 0.05 M NaOAc buffer, pH 4.5. Heteroxylans (50 ml of a solution at 20 g/l) were loaded onto the column and the gel was washed with 400 ml of 0.05 M NaOAc buffer, pH 4.5. The bound material was eluted with 400 ml of 0.5 M NaOAc buffer, pH 4.5. Fractions (5 ml) were collected and analyzed for their contents of neutral sugars and uronic acids by the automated orcinol (Tollier and Robin, 1979) and *m*-hydroxydiphenyl (Thibault, 1979) assays, respectively. The bound fractions eluted with 0.5 M buffer were pooled, concentrated, extensively dialyzed against distilled water and freeze-dried to give purified heteroxylan fractions (AXP, HX or HXO, Table 1).

4.6. Gelation experiments

Heteroxylan fractions were dissolved in distilled water (ca. 30 mg/ml). One milliliter of the solution was put in a test tube together with 0.1 ml of 0.01 M aq. H_2O_2 and 0.1 ml of horseradish peroxidase aq. solution (110 U/ml, Type I, Sigma). The tube was left at room temperature for 2 h and then returned upside down to check gelation.

4.7. Molar mass determination

Heteroxylan samples were gently dispersed into 0.05 M aq. $NaNO_3$ containing 0.02% NaN_3 (by wt.) and left for dissolution overnight under magnetic stirring. The solutions (ca. 3 mg/ml) were centrifuged in a bench top centrifuge and filtered on 0.10 μm Minisart RC15 Sartorius membranes. Samples were then injected on a high-performance size exclusion chromatography (HPSEC) system constituted of a Shodex OH SB-G pre-column followed by two Shodex OH-pack 804 and 805 columns used in series. The elution was performed at room temperature with 0.05 M aq. $NaNO_3$, containing 0.02% NaN_3 as preservative, at a constant 0.7 ml/min flow rate. On-line molar mass determinations were performed using a multiangle laser light scattering (MALLS) detector (mini-Dawn, Wyatt, Santa Barbara, CA) operating at three angles (41°, 90° and 138) and a differential refractometer (ERC 7517 A) ($dn/dc = 0.146$ ml/g).

Received 2 November 2000; received in revised form 15 February 2001

Abstract

Five triterpene glycosides were isolated from the MeOH extract of *Sanguisorba officinalis* (Rosaceae) roots, as confirmed by detailed analysis of their ^{1}H, ^{13}C, and two-dimensional NMR data, and by the results of hydrolytic cleavage. Three known triterpenes and six known triterpene glycosides were also isolated and identified. The isolated compounds were evaluated for their cytotoxic activities against HSC-2 cells and HGF. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Sanguisorba officinalis*; Rosaceae; Triterpene glycosides; Cytotoxic activity; HSC-2 cells

1. Introduction

Sanguisorba officinalis L. (Rosaceae) is a perennial plant that occurs in the northern districts in China. Its roots have hemostatic, analgesic, and astringent properties, and have been used in traditional Chinese medicine for the treatment of burns, scalds, and internal hemorrhage (Cheng and Cao, 1992). A series of hydrolysable tannins were reported as characteristic constituents of *S. officinalis* roots and are considered to be partially responsible for the therapeutic effects of this crude drug (Tanaka et al., 1985). Apart from medicinal folklore background of *S. officinalis* as mentioned above, the discovery of a cytotoxic activity associated with inhibition of DNA topoisomerases of sanguiin H-6, a dimeric ellagitannin from *S. officinalis*, is noteworthy (Bastow et al., 1993). A communication dealing with the nitric oxide production-suppressing activity of sanguiin H-6 and H-11 has recently been published (Yokozawa et al., 2000). Furthermore, *S. officinalis* is known to contain a triterpene glycoside, ziyu-glycoside I, and its derivatives, including their corresponding aglycones (Cheng and Cao, 1992; Yosioka et al., 1971). However, triterpene constituents of *S. officinalis* seemed not to be completely known and thus deserved further study. We systematically examined the triterpene glycosides components of *S. officinalis* and isolated five new triterpene glycosides, along with three known triterpenes and six known triterpene glycosides. This paper deals with the structural elucidation of the new triterpene glycosides on the basis of spectroscopic analysis, including two-dimensional (2D) NMR spectroscopic techniques, and of the results of hydrolytic cleavage. The cytotoxic activities of the isolated triterpenes against human oral squamous cell carcinoma (HSC-2) cells and normal human gingival fibroblasts (HGF) are also reported.

2. Results and discussion

A concentrated MeOH extract of *S. officinalis* roots was passed through a polystyrene resin (Diaion HP-20) column, and the MeOH eluate fraction, in which triterpenes and triterpene glycosides were enriched, was subjected to column chromatography using silica gel and octadecylsilanized (ODS) silica gel, as well as preparative HPLC, to yield a total of 14 triterpenes and triterpene glycosides (compounds **1**–**14**). Compounds **6**–**14** are known constituents and identified as 3β,19α-dihydroxyurs-12-en-28-oic acid (**6**) (Cheng and Cao, 1992), 2α,3α,19α-trihydroxyurs-12-en-28-oic acid (**7**) (Cheng and Cao, 1992), 1β,2α,3α,19α-tetrahydroxyurs-12-en-28-oic acid

(**8**) (Guang-Yi et al., 1989), 3β,19α-dihydroxyurs-12-en-28-oic acid 28-β-D-glucopyranosyl ester (**9**) (Cheng and Cao, 1992), 2α,3β,19α-trihydroxyurs-12-en-28-oic acid 28-β-D-glucopyranosyl ester (**10**) (Jia et al., 1993), 2α,3α,19α-trihydroxyurs-12-en-28-oic acid 28-β-D-glucopyranosyl ester (**11**) (Jia et al., 1993), 3β-[(α-L-arabinopyranosyl)oxy]-19α-hydroxyurs-12-en-28-oic acid (**12**) (Cheng and Cao, 1992), 3β-[(α-L-arabinopyranosyl)oxy]-19α-hydroxyurs-12-en-28-oic acid 28-β-D-glucopyranosyl ester (**13**) (Cheng and Cao, 1992), 3β-[(α-L-arabinopyranosyl)oxy]-23-hydroxyolean-12-en-28-oic acid 28-β-D-glucopyranosyl ester (**14**) (Kizu et al., 1985), respectively. The physical and spectral data were consistent with the literature values.

Compound **1** was isolated as an amorphous solid with a molecular formula, $C_{41}H_{66}O_{13}$, as determined by elemental analysis combined with data of the positive-ion FABMS exhibiting an $[M+Na]^+$ ion at *m/z* 789. The IR spectrum showed a characteristic absorption attributable to an ester carbonyl group at 1731 cm^{-1}, as well as a broad absorption due to hydroxyl groups near 3418 cm^{-1}. The ^1H NMR spectrum of **1** (C_5D_5N) exhibited signals for seven tertiary methyl groups at δ 1.65, 1.27, 1.16×2, 1.00, 0.97, and 0.91 (each *s*), and an olefinic proton at δ 5.52 (*t*-like, $J=3.2$ Hz), which were characteristic of the oleanolic acid skeleton. Furthermore, two anomeric proton signals were identified at δ 6.39 (*d*, $J=8.1$ Hz) and 4.78 (*d*, $J=7.0$ Hz). Acid hydrolysis of **1** with 1 M HCl in dioxane–H_2O (1:1) gave a triterpene ($C_{30}H_{48}O_4$) (**1a**), and D-glucose and L-arabinose as the carbohydrate components. The monosaccharides, including their absolute configurations, were identified by direct HPLC analysis of the hydrolysate, with detection being carried out by using an optical rotation (OR) detector. Comparison of the ^1H and ^{13}C NMR spectroscopic assignments of **1a** with those of oleanolic acid (Kizu et al., 1995), taking into account the molecular formula of **1a**, suggested that **1a** was an oleanolic acid derivative with a hydroxyl group at the ring E portion. The proton signal at δ 3.66 showed long-range correlations with C-13 (δ 144.9), C-17 (δ 46.1), and C-28 (δ 180.9) in the HMBC spectrum, and was assigned to H-18. This proton had a proton spin-coupling correlation with the signal at δ 3.64, which was associated with the carbon signal at δ 81.3 (CH) in the HMQC spectrum. Thus, the presence of a hydroxyl group at C-19 was evident. The $^3J_{H,H}$ value of 2.8 Hz between H-18 and H-19, and NOE correlations from H-19 to Me-29 (δ 1.21) and Me-30 (δ 1.13) gave evidence for the C-19α hydroxy configuration. The ^1H and ^{13}C NMR signals of the glycoside moieties were readily assigned by interpretation of the ^1H–^1H COSY and HMQC spectra. Proton multiplet patterns and coupling constants, as well as the proton and carbon chemical shifts revealed that **1** contained that an α-L-arabinopyranosyl unit and a β-D-glucopyranosyl unit, which were directly linked to the aglycone. In the HMBC spectrum of **1**, correlation peaks were observed from δ 4.78 (anomer of arabinosyl) to δ 88.7 (C-3 of aglycone), and δ 6.39 (anomer of glucosyl) to δ 177.2 (C-28 of aglycone). Accordingly, the structure of **1** was characterized as 3β-[(α-L-arabinopyranosyl)oxy]-19α-hydroxyolean-12-en-28-oic acid 28-β-D-glucopyranosyl ester.

Compound **2** was obtained as an amorphous solid, and its molecular formula, $C_{41}H_{64}O_{12}$, was deduced from the positive-ion FABMS (*m/z* 771 $[M+Na]^+$) and the result of elemental analysis. The ^1H NMR spectrum of **2** (C_5D_5N) contained signals for five tertiary methyl groups at δ 1.29×2, 1.14, 0.97, and 0.89 (each *s*), a secondary methyl group at δ 1.07 (*d*, $J=6.4$ Hz), an exomethylene group at δ 5.21 and 5.06 (each *br s*), an olefinic proton at δ 5.55 (*t*-like, $J=3.3$ Hz), and two anomeric protons at δ 6.34 (*d*, $J=8.1$ Hz) and 4.79 (*d*, $J=7.1$ Hz). These data and the ^{13}C NMR spectral feature suggested that **2** was a triterpene bisdesmoside based upon ursolic acid. In the HMBC spectrum, the exomethylene protons showed long-range correlations with the carbons due to C-18 (δ 52.2) and C-20 (δ 37.5), indicating the location of the exomethylene group at C-19(29). Based on an NOE correlation between the protons of Me-30 and H-21α, Me-30 was assigned as α-configuration. Acid

hydrolysis of **2** with 1 M HCl resulted in the production of two artifactual triterpenes (**2a**, **2b**), together with D-glucose and L-arabinose. The ^{1}H NMR spectrum of **2a** showed seven three-proton singlet signals, and two of them were assigned as being located on a double bond. The UV spectrum of **2b** showed a λ_{max} at 226 nm (log ε 3.65), which implied the presence of a conjugated diene group, and the ^{1}H NMR spectrum included signals for five tertiary methyl groups, a secondary methyl group, and a methyl group on a double bond. These spectral properties combined with information from the MS, ^{13}C NMR, and various 2D NMR spectra allowed the identification of **2a** and **2b** as 3β-hydroxyurs-12,19(20)-dien-28-oic acid and 3β-hydroxyurs-12,18-dien-28-oic acid, respectively (Ahmad and Basha, 2000). These compounds were considered to be produced through migration of the C-19(29) double bond under acidic conditions. The ^{1}H, ^{13}C, and 2D NMR spectral data of **2** indicated that it had an α-L-arabinopyranosyl unit at C-3 and a β-D-glucopyranosyl unit at C-28 in the molecule, as in **1**. The structure of **2** was characterized as 3β-[(α-L-arabinopyranosyl)oxy]urs-12,19(29)-dien-28-oic acid 28-β-D-glucopyranosyl ester.

Compound **3** was shown to have the molecular formula, $C_{41}H_{64}O_{13}$, by the positive-ion FABMS (*m*/*z* 787 $[M+Na]^+$) and elemental analysis. The spectral properties of **3** were very similar to those of **2**. However, the molecular formula of **3** differed from **2** by containing an additional oxygen atom. When the ^{1}H NMR spectrum of **3** was compared with that of **2**, the signal for Me-23, which was observed at δ 1.29 in **2**, disappeared in **3**, and instead signals for an hydroxymethyl group were detected at δ 4.30 and 3.70 (AB*q*, $J=10.6$ Hz). The ^{13}C NMR spectrum of **3**, in which a signal at δ 64.5 was observed for an hydroxymethyl group rather than a tertiary methyl group, and an NOE correlation between the hydroxymethyl protons and H-6α equatorial proton (δ 1.67), also supported this structural modification. The structure of **3** was shown to be 3β-[(α-L-arabinopyranosyl)oxy]-23-hydroxyurs-12,19(29)-dien-28-oic acid 28-β-D-glucopyranosyl ester.

Compound **4** had the molecular formula $C_{35}H_{54}O_7$ on the basis of the positive-ion FABMS (*m*/*z* 609 $[M+Na]^+$) and elemental analysis. The ^{1}H NMR spectrum showed signals for six tertiary methyl groups at δ 1.89, 1.31, 1.18, 1.04, 0.97, and 0.89 (each *s*), a secondary methyl group at δ 1.13 (*d*, $J=6.9$ Hz), an olefinic proton at δ 5.73 (*t*-like, $J=2.8$ Hz), and an anomeric proton at δ 4.80 (*d*, $J=7.1$ Hz). The UV absorption at λ_{max} 226 (log ε 3.79) were attributable to a conjugated diene system. Acid hydrolysis of **4** gave **2b** and L-arabinose. The ^{13}C NMR spectrum of **4** showed data consistent with an arabinose moiety, and it was found to be attached at C-3 of the aglycone by an HMBC correlation from δ 4.80 to δ 88.7 (C-3 of aglycone). The structure of **4** was determined to be 3β-[(α-L-arabinopyranosyl)oxy]urs-12,18-dien-28-oic acid.

Compound **5** was obtained as a pale-yellow solid. Its molecular formula was determined as $C_{48}H_{70}O_{17}$ on the basis of the positive-ion FABMS (*m*/*z* 941 $[M+Na]^+$) and elemental analysis. The ^{1}H NMR spectrum included signals for seven triterpene methyls at δ 1.68 (*s*), 1.33 (*s*), 1.25 (*s*), 1.19 (*s*), 1.02 (*d*, $J=6.7$ Hz), 0.99 (*s*), and 0.93 (*s*), an olefinic proton at δ 5.53 (*t*-like, $J=3.3$ Hz), and two anomeric protons at δ 6.30 (*d*, $J=8.0$ Hz) and 4.76 (*d*, $J=7.0$ Hz). In addition, the presence of a galloyl ester group was suggested by the UV [λ_{max} 278 nm (log ε 3.75)], ^{1}H NMR [δ 7.87 (2H, s)], and ^{13}C NMR [δ 167.4 (C=O), 147.4 (C×2), 140.8 (C), 121.1 (C), 110.3 (CH×2)]. Alkaline treatment of **5** with 10% NH_3aq yielded **13** and gallic acid. When the ^{1}H and ^{13}C NMR spectra of **5** were compared with those of **13**, downfield shifts by *O*-acylation were detected at the H_2-6 signal at δ 5.01 (2H, *d*, $J=9.2$ Hz) and the C-6 signal at δ 64.6 of the glucosyl residue. Furthermore, an HMBC correlation was observed from δ 5.01 to the carbonyl carbon resonance of the galloyl group at δ 167.4. All of these data for **5** were consistent with the structure 3β-[(α-L-arabinopyranosyl)oxy]-19α-hydroxyurs-12-en-28-oic acid 28-(6-*O*-galloyl-β-D-glucopyranosyl) ester.

Compounds **1**–**5** are new triterpene glycosides, and this is the first report on the isolation of **8**, **10**, **11**, and **14** from *S. officinalis*.

The isolated compounds were evaluated for their cytotoxic activities against HSC-2 cells and HGF (Table 2). Compounds **3** and **14**, which are bisdesmosidic triterpenes with the oleanane or ursane skeleton bearing a hydroxyl group at C-23, showed cytotoxic activity against HSC-2 cells with the respective IC_{50} values of 15 and 18 μg/ml, although they were not cytotoxic against HGF at all ($IC_{50} > 200$ μg/ml).

3. Experimental

3.1. General

FABMS: Finnigan MAT TSQ-700 (San Jose, CA, USA) (matrix: Magic Bullet, a mixture of dithiothreitol and dithioerythritol, 3:1; Tokyo-Kasei, Tokyo, Japan). NMR (ppm, *J* Hz): Bruker DPX-400 (400 MHz for ^{1}H NMR, Karlsruhe, Germany) or Bruker AM-500 (500 MHz for ^{1}H NMR). CC: Diaion HP-20 (Mitsubishi-Kasei, Tokyo, Japan); silica gel (Fuji-Silysia Chemical, Aichi, Japan); ODS silica gel (Nacalai Tesque, Kyoto, Japan); Sephadex LH-20 (Pharmacia, Freiburg, Germany). TLC: precoated Kieselgel 60 F_{254} (0.25 mm thick, Merck, Darmstadt, Germany) and RP-18 $F_{254}S$ (0.25 mm thick, Merck). Preparative HPLC: a Tosoh HPLC system (pump, CCPM; controller, CCP controller PX-8010) equipped with an RI detector (Tosoh RI-8010, Tokyo, Japan) and a Capcell Pak C_{18} UG80 column (10 mm i.d.×250 mm, ODS, 5 μm, Shiseido,

Tokyo, Japan). Cell culture and assay for cytotoxic activity: Dulbecco's modified Eagle medium (DMEM) (Gibco, Grand Island, NY, USA); fetal bovine serum (FBS) (JRH Biosciences, Lenexa, KS, USA); penicillin, streptomycin, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT), and α-minimum essential medium (α-MEM) (Sigma, St. Louis, MO, USA). All other chemicals used were of biochemical reagent grade.

3.2. Plant material

Sanguisorba officinalis was purchased from a wholesale firm in Uchida-Wakanyaku, Tokyo Japan in 1997. One of the authors, Y. Sashida., identified it by its morphological characters. A voucher specimen has been deposited in the laboratory of Y. Sashida (voucher No. SO-97-7, Laboratory of Medicinal Plant Science).

3.3. Extraction and isolation

The dessicated roots of the plant material (3 kg) were extracted with hot MeOH. The MeOH extract was concentrated under reduced pressure, and the viscous concentrate (320 g) was passed through a Diaion HP-20 column eluting with increased amounts of MeOH in H_2O (30% MeOH, 50% MeOH, and 80% MeOH), MeOH, EtOH, and EtOAc. Preliminary TLC analysis of these fractions suggested that the MeOH eluate portion contained a variety of triterpene and triterpene glycosides, on which further fractionation was carried out. CC of the MeOH eluate portion on silica gel and elution with a stepwise gradient mixture of $CHCl_3$–MeOH (9:1; 4:1; 2:1), and finally with MeOH alone, gave five fractions (I–V). Fraction I was applied to a silica gel column this being eluted with hexane–Me_2CO (1:1) and $CHCl_3$–MeOH (19:1) and ODS silica gel with MeOH–H_2O (4:1) to give **4** (9.0 mg), **6** (43.2 mg), **7** (7.5 mg), and **8** (5.5 mg). Fraction II was subjected to CC on silica gel eluting with $CHCl_3$–MeOH–H_2O (80:10:1; 50:10:1) and ODS silica gel with MeOH–H_2O (3:1) and MeCN–H_2O (2:3; 1:2) to yield **9** (7.0 mg), **11** (115 mg), and **12** (104 mg). Fraction III was subjected to a silica gel column eluting with $CHCl_3$–MeOH–H_2O (80:10:1; 50:10:1) and an ODS silica gel column with MeOH–H_2O (2:1) and MeCN–H_2O (1:2) to give **10** (3.2 mg). Fraction IV was applied to a silica gel column which was eluted with $CHCl_3$–MeOH–H_2O (50:10:1) and ODS silica gel with MeOH–H_2O (2:1) to give a mixture of **1** and **13**, and **2** with a few impurities. The mixture was separated by preparative HPLC using MeOH–H_2O (3:2) into **1** (40.2 mg) and **13** (180 mg). Compound **2** was completely refined by preparative HPLC using MeOH–H_2O (4:1) to furnish **2** (140 mg) as a pure compound. Fraction V was applied to a silica gel column eluted with $CHCl_3$–MeOH–H_2O (40:10:1) and ODS silica gel with MeOH–H_2O (2:1) and MeCN–H_2O (1:2) to give **3** (21.4 mg) and **5** (23.8 mg), and **14** with a few impurities. Compound **14** was purified by preparative HPLC using using MeOH–H_2O (2:1) to afford **14** (9.4 mg) as a pure compound.

3.4. Compound *1*

An amorphous solid. $[\alpha]_D^{25}$ +14.0° (MeOH: *c* 0.10). FABMS (positive mode) *m/z* 789 $[M+Na]^+$. (Found: C, 60.68; H, 8.64. Calc. for $C_{41}H_{66}O_{13}\cdot 5/2H_2O$: C, 60.66; H, 8.81%). IR ν_{max} (film) cm^{-1}: 3418 (OH), 2927 (CH), 1731 (C=O), 1455, 1388, 1260, 1190, 1071, 1028, 866. ^1H NMR (pyridine-d_5): δ; 6.39 (1H, *d*, *J* = 8.1 Hz, H-1″), 5.52 (1H, *t*-like, *J* = 3.2 Hz, H-12), 4.78 (1H, *d*, *J* = 7.0 Hz, H-1′), 3.59 (1H, *d*, *J* = 2.8 Hz, H-19), 3.34 (1H, *dd*, *J* = 11.7, 4.3 Hz, H-3), 1.65 (3H, *s*, Me-27), 1.27 (3H, *s*, Me-23), 1.16 (3H×2, *s*, Me-26 and Me-29), 1.00 (3H, s, Me-30), 0.97 (3H, *s*, Me-24), 0.91 (3H, *s*, Me-25). ^{13}C NMR: Table 1.

3.5. Acid hydrolysis of *1*

A solution of **1** (25 mg) in 1 M HCl (dioxane–H_2O, 1:1, 4 ml) was heated at 95° for 2 h under an Ar atmosphere. After cooling, the reaction mixture was neutralized by passage through an Amberlite IRA-93ZU (Organo, Tokyo, Japan) column and subjected to silica gel chromatography using a gradient mixture of $CHCl_3$–MeOH (19:1; 9:1; 1:1) to give an aglycone fraction and a sugar fraction (5.9 mg). The aglycone fraction was purified by silica gel CC eluting with hexane–Me_2CO (4:1) to give an aglycone (**1a**) (3.2 mg). HPLC analysis of the sugar fraction under the following conditions showed the presence of D-glucose and L-arabinose. Column: Capcell Pak NH_2 UG80 (4.6 mm i.d.×250 mm, 5 μm, Shiseido); detector: Shodex OR-2 (Showa-Denko, Tokyo, Japan); solvent: MeCN–H_2O (17:3); flow rate: 1.0 ml/min. R_t (min): 8.27 (L-arabinose, positive optical rotation); 13.39 (D-glucose, positive optical rotation).

3.6. Compound *1a*

An amorphous solid. $[\alpha]_D^{25}$ +20.0° (MeOH: *c* 0.10). EIMS *m/z* 472 $[M]^+$. IR ν_{max} (film) cm^{-1}: 3449 (OH), 2927 (CH), 1688 (C=O), 1455, 1388, 1260, 1071, 1028, 866. ^1H NMR (pyridine-d_5): δ 5.60 (1H, *t*-like, *J* = 3.3 Hz, H-12), 3.66 (1H, *d*, *J* = 2.8 Hz, H-18), 3.64 (1H, *d*, *J* = 2.8 Hz, H-19), 3.46 (1H, *dd*, *J* = 11.7, 4.3 Hz, H-3), 1.67 (3H, *s*, Me-27), 1.26 (3H, *s*, Me-23), 1.21 (3H, *s*, Me-29), 1.13 (3H, *s*, Me-30), 1.10 (3H, s, Me-26), 1.05 (3H, s, Me-24), 0.95 (3H, s, Me-25). ^{13}C NMR: Table 2.

3.7. Compound *2*

An amorphous solid. $[\alpha]_D^{25}$ +12.0° (MeOH: *c* 0.10). FABMS (positive mode) *m/z* 771 $[M+Na]^+$. (Found:

3.8. Acid hydrolysis of **2**

Compound **2** (20 mg) was subjected to acid hydrolysis as described for **1** to give **2a** (4.8 mg) and **2b** (3.5 mg), and a sugar fraction (4.1 mg). HPLC analysis of the sugar fraction under the same conditions as in the case of that of **1** showed the presence of D-glucose and L-arabinose.

3.9. Compound **2a**

An amorphous solid. $[\alpha]_D^{25}$ +4.0° (MeOH: *c* 0.10). EIMS *m*/*z* 454 $[M]^+$. IR ν_{max} (film) cm^{-1}: 3383 (OH), 2927 (CH), 1689 (C=O), 1449, 1378, 1256, 1091, 1025, 866. ^{1}H NMR (pyridine-d_5): δ 5.71 (1H, *t*-like, $J=3.5$ Hz, H-12), 3.64 (1H, *br s*, H-18), 3.46 (1H, *dd*, $J=11.3$, 4.3 Hz, H-3), 1.71 (3H, *s*, Me-29), 1.64 (3H, *s*, Me-30), 1.23 (3H, *s*, Me-23), 1.15 (3H, *s*, Me-27), 1.04 (3H, *s*, Me-26), 1.03 (3H, *s*, Me-25), 0.92 (3H, *s*, Me-24). ^{13}C NMR: Table 2.

3.10. Compound **2b**

An amorphous solid. $[\alpha]_D^{25}$ +166° (MeOH: *c* 0.10). EIMS *m*/*z* 454 $[M]^+$. UV λ_{max} (MeOH) nm: 226 (log ε 3.65). IR ν_{max} (film) cm^{-1}: 3412 (OH), 2927 (CH), 1689 (C=O), 1460, 1376, 1258, 1096, 1034. ^{1}H NMR (pyridine-d_5): δ 5.74 (1H, *t*-like, $J=2.8$ Hz, H-12), 3.48 (1H, *dd*, $J=11.3$, 4.3 Hz, H-3), 1.88 (3H, *s*, Me-29), 1.25 (3H, *s*, Me-23), 1.15 (3H, *s*, Me-27), 1.12 (3H, *d*, $J=6.9$ Hz, Me-30), 1.06 (3H, *s*, Me-26), 1.04 (3H, *s*, Me-24), 0.93 (3H, *s*, Me-25). ^{13}C NMR: Table 2.

3.11. Compound **3**

An amorphous solid. $[\alpha]_D^{25}$ +24.0° (MeOH: *c* 0.10). FABMS (positive mode) *m*/*z* 787 $[M+Na]^+$. (Found:

C, 63.28; H, 8.75. Calc. for $C_{41}H_{64}O_{13}\cdot 1/2H_2O$: C, 63.63; H, 8.47%). IR ν_{max} (film) cm^{-1}: 3376 (OH), 2935 (CH), 1733 (C=O), 1455, 1388, 1260, 1198, 1136, 1073. ^1H NMR (pyridine-d_5): δ 6.32 (1H, *d*, $J=8.2$ Hz, H-1″), 5.54 (1H, *t*-like, $J=3.1$ Hz, H-12), 5.18 and 5.03 (each 1H, AB*q*, $J=1.4$ Hz, CH_2-29), 4.79 (1H, *d*, $J=7.2$ Hz, H-1′), 4.31 (1H, overlapping, H-3), 4.30 and 3.70 (each 1H, AB*q*, $J=10.6$ Hz, CH_2-23), 1.19 (3H, *s*, Me-27), 1.16 (3H, *s*, Me-25), 1.06 (3H, *d*, $J=6.4$ Hz, Me-30), 0.99 (3H, *s*, Me-26), 0.93 (3H, *s*, Me-24). ^{13}C NMR: Table 2.

3.12. Compound **4**

An amorphous solid. $[\alpha]_D^{25}$ +112° (MeOH: *c* 0.10). FABMS (positive mode) *m/z* 609 $[M+Na]^+$. (Found: C, 63.86; H, 9.20. Calc. for $C_{35}H_{54}O_7\cdot 4H_2O$: C, 63.80; H, 9.48%). UV λ_{max} (MeOH) nm: 226 (log ε 3.79). IR ν_{max} (film) cm^{-1}: 3367 (OH), 2929 (CH), 1688 (C=O), 1449, 1388, 1367, 1256, 1136, 1083, 998. ^1H NMR (pyridine-d_5): δ 5.73 (1H, *t*-like, $J=2.8$ Hz, H-12), 4.80 (1H, *d*, $J=7.1$ Hz, H-1′), 3.40 (1H, *dd*, $J=12.0$, 4.1 Hz, H-3), 1.89 (3H, *s*, Me-29), 1.31 (3H, *s*, Me-23), 1.18 (3H, *s*, Me-27), 1.13 (3H, *d*, $J=6.9$ Hz, Me-30), 1.04 (3H, *s*, Me-26), 0.97 (3H, *s*, Me-24), 0.89 (3H, *s*, Me-25). ^{13}C NMR: Table 2.

3.13. Acid hydrolysis of **4**

Compound **4** (5 mg) was subjected to acid hydrolysis as described for **1** to give **2b** (2.7 mg) and a sugar fraction (0.7 mg). HPLC analysis of the sugar fraction under the same conditions as in the case of that of **1** showed the presence of L-arabinose.

3.14. Compound **5**

A pale-yellow amorphous solid. $[\alpha]_D^{25}$ +10.0° (MeOH: *c* 0.10). FABMS (positive mode) *m/z* 941 $[M+Na]^+$. (Found: C, 55.65; H, 7.74. Calc. for $C_{48}H_{70}O_{17}\cdot 13/2H_2O$: C, 55.63; H, 8.07%). UV λ_{max} (MeOH) nm: 278 (log ε 3.75). IR ν_{max} (film) cm^{-1}: 3418 (OH), 2931 and 2878 (CH), 1723 and 1714 (C=O), 1614 and 1538 (aromatic ring), 1455, 1350, 1228, 1137, 1078, 938, 870. ^1H NMR (pyridine-d_5): δ 7.87 (2H, *s*, H-2‴ and H-6‴), 6.30 (1H, *d*, $J=8.0$ Hz, H-1″), 5.53 (1H, *t*-like, $J=3.3$ Hz, H-12), 5.01 (2H, *d*, $J=9.2$ Hz, H_2-6″), 4.76 (1H, *d*, $J=7.0$ Hz, H-1′), 3.32 (1H, *dd*, $J=11.7$, 4.2 Hz, H-3), 1.68 (3H, *s*, Me-27), 1.33 (3H, *s*, Me-29), 1.25 (3H, *s*, Me-23), 1.19 (3H, *s*, Me-26), 1.02 (3H, *d*, $J=6.7$ Hz, Me-30), 0.99 (3H, *s*, Me-25), 0.93 (3H, *s*, Me-24). ^{13}C NMR: Table 2.

3.15. Alkaline hydrolysis of **5**

Compound **5** (8 mg) was treated with 10% NH_3aq (1 ml) at room temperature for 30 min. After evaporation of solvent, the reaction mixture was chromatographed on Sephadex LH-20 eluting with MeOH to furnish **13** (6.3 mg) and gallic acid (1.2 mg).

3.16. Cell culture

HSC-2 cells were maintained as monolayer cultures at 37° in DMEM medium supplemented with 10% heat-inactivated FBS in a humidified 5% CO_2 atmosphere. HGF were isolated, as described previously (Ito et al., 2000). Briefly, gingival tissues were obtained from healthy gingival biopsies from a 10-year-old girl, undergoing periodontal surgery. The tissue were cut into 1 to 2 mm^3 pieces, washed twice with phosphate-buffered saline (PBS, 0.01 M phosphate buffer, 0.15 M NaCl, pH 7.4) supplemented with 100 U/ml penicillin and 100 μg/ml streptomycin, and placed into 25 cm^2 tissue culture flasks. The explants were incubated in α-MEM supplemented with 30% FBS and antibiotics. When outgrowth of the cells was observed, the medium was replaced twice until the cells reached confluence. The cells were detached from the monolayer by trypsinization and recultured in 100 cm^2 tissue culture flasks until confluent monolayers were again obtained. Cells between the fifth and seventh passages were used.

3.17. Assay for cytotoxic activity

Cells were trypsinized and inoculated at 6×10^3 per each 96-microwell plate (Falcon, flat bottom, treated polystyrene, Becton Dickinson, San Jose, CA, USA), and incubated for 24 h. After washing once with PBS, they were treated with 24 h without or with test compounds. They were washed once with PBS and incubated for 4 h with 0.2 mg/ml MTT in DMEM medium supplemented with 10% FBS. After the medium was removed, the cells were lysed with 0.1 ml DMSO and the relative viable cell number was determined by measuring the absorbance at 540 nm of the cell lysate, using Labsystems Multiskan^R (Biochromatic, Helsinki, Finland) connected to a Star/DOT Matrix printer JL-10. The LD_{50} value, which reduces the viable cell number by 50%, was determined from the dose-response curve.

Received 17 October 2000; received in revised form 23 January 2001

Abstract

The C-8-(*S*) isomer of deoxyloganic acid (7-deoxyloganic acid), together with β-sitosteryl glucoside, five known stereoisomeric pentacyclic oxindole alkaloids and the tetracyclic oxindole isorhyncophylline, were isolated from the inner bark of *Uncaria tomentosa*. Structures of the isolated compounds were based on ^{1}H and ^{13}C NMR data, mainly 2D NMR experiments, including ^{1}H–^{13}C HMBC and ^{1}H–^{1}H NOESY correlation. Furthermore, the hitherto unreported ^{15}N chemical shifts of the isomeric oxindole alkaloids, using ^{1}H–^{15}N HMBC experiments, were utilized to facilitate their characterization. Uncarine D showed weak cytotoxic activity against SK-MEL, KB, BT-549 and SK-OV-3 cell lines with IC_{50} values between 30 and 40 μg/ml, while uncarine C exhibited weak cytotoxicity only against ovarian carcinoma (IC_{50} at 37 μg/ml). © 2001 Elsevier Science Ltd. 1. Introduction

Uncaria tomentosa (Wild.) DC. (Uña de Gato; Cat's Claw) is considered one of the most valuable botanicals in the rainforest and is widely used in traditional medicine by native people of Peru for numerous ailments (Jones, 1995). This plant displays a diverse range of bioactive secondary metabolites, including tetracyclic and pentacyclic oxindole alkaloids, triterpenes, glycosides, flavonoids and procyanidins (Aquino et al., 1990, 1991, 1997; Jones, 1995; Van Ginkel, 1996; Wirth and Wagner, 1997). The pentacyclic oxindole alkaloids are considered to be biochemical markers of cat's claw and are responsible, in part, for immunomodulatory, cytotoxic, anti-AIDS and anti-amyloidosis (Alzheimer's disease) activities (Wagner et al., 1985; Keplinger et al., 1986; Keplinger and Keplinger, 1994; Jones, 1995; Lemaire et al., 1999; Castillo and Snow, 2000). To date, nine natural heteroyohimbine-type pentacyclic oxindole isomers have been isolated from *Uncaria* species and six of them are restricted to *U. tomentosa* inner bark (Shamma et al., 1967; Seki et al., 1993).

As part of our continuing program to isolate marker compounds from traditional medicines and evaluate their biological activity, the present study deals with the isolation and characterization of a new constituent, 7-deoxyloganic acid (**1**) from the inner bark of *U. tomentosa*. In addition, the ^{15}N NMR spectral assignments of the stereoisomeric oxindoles (uncarines C, D and E, mitraphylline and isomitraphylline) is described and cytotoxicity of the isolated compounds evaluated.

2. Results and discussion

Column chromatography of the ethanolic extract, using 1–5% MeOH in $CHCl_3$ mixture as eluent (see

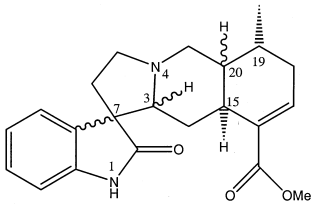
2 R=Glc(Ac)$_4$



Uncarine C (**3**) 3*S*, 7*R*, 15*S*, 19*S*, 20*S*
Uncarine D (**4**) 3*R*, 7*S*, 15*S*, 19*S*, 20*S*
Uncarine E (**5**) 3*S*, 7*S*, 15*S*, 19*S*, 20*S*
Mitraphylline (**6**) 3*S*, 7*R*, 15*S*, 19*S*, 20*R*
Isomitraphylline (**7**) 3*S*, 7*S*, 15*S*, 19*S*, 20*R*

Experimental), resulted in the isolation of five known stereoisomeric oxindoles [namely, uncarines C, D and E, mitraphylline and isomitraphylline (**3**–**7**) (Shamma et al., 1967; Seki et al., 1993)], the tetracyclic oxindole isorhyncophylline (**8**) (Phillipson and Hemingway, 1973; Yu et al., 1989), as well as 7-deoxyloganic acid (**1**).

Compound **1**, $C_{16}H_{24}O_9$, was obtained as colorless amorphous granules: mp. 94–96°; $[\alpha]_D^{27}$ −81.9°; which exhibited the presence of carboxylic acid (ν_{max} 1680 cm^{-1}; δ_C 170.1) and β-D-glucose [$\delta_{C\text{-}1'}$ 99.1, $\delta_{C\text{-}2'}$ 73.8, $\delta_{C\text{-}3'}$ 77.0, $\delta_{C\text{-}4'}$ 70.6, $\delta_{C\text{-}5'}$ 77.3, $\delta_{C\text{-}6'}$ 61.9; δ 4.65, 1H, *d* (J=7.9 Hz, H-1′) (Murai et al., 1984)] substituents. The ^{13}C NMR spectrum of **1** (Table 1) was found to be similar to those reported for 8-(*S*) isomer of 7-deoxyloganic acid tetraacetate (**2**) (Tagawa and Murai, 1983), save for the differences associated with the presence of the β-D-glucose moiety at C-1. Furthermore, a close comparison of the ^{13}C NMR spectrum of **1** with those of other deoxyloganic acid isomers, such as 8-*epi*deoxyloganic acid [8-(*R*) isomer of 7-deoxyloganic acid], 1,5,9-*epi*deoxyloganic acid and 5-*epi*deoxyloganic acid, isolated from *Nepeta cataria* (Tagawa and Murai, 1983; Murai et al., 1984), led to the conclusion that indeed **1** was the C-8-(*S*)-isomer of deoxyloganic acid, which has not been reported previously as a natural product. Thus, the structure and stereochemistry of **1** was unambiguously established by detailed 2D NMR spectroscopic studies, including ^{1}H–^{13}C HMQC, ^{1}H–^{13}C HMBC and ^{1}H–^{1}H NOESY experiments. The ^{1}H–^{13}C HMBC experiment on **1** showed the key three-bond correlation between $\delta_{C\text{-}1'}$ 99.2 and δ 5.17 (H-1); $\delta_{C\text{-}11}$ 170.1 and δ 7.40 (H-3); $\delta_{C\text{-}9}$ 48.2 and δ 1.05 (H-10), confirming the placement of COOH, β-D-glucose and methyl substituents at C-1, C-4 and C-8, respectively.

The stereochemical assignment at the carbon centers C-1, C-5, C-8 and C-9 was inferred from 2D NMR ^{1}H–^{1}H NOESY experiments, which showed correlations between H-5 (δ 2.85), H-9 (δ 1.70) and H-10 (δ 1.05), indicating that they are *cis* (α-face) to each other. As a result, fusion between the five and six-member rings was also *cis* in **1**. Furthermore, the NOESY showed a *cis* (β-face) relationship between the protons H-1 (δ 5.17) and H-8 (δ 1.95), thereby confirming the assignment of β-D-glucose moiety at the α-face of the molecule. Compound **2** was previously reported as a catalytic hydrogenation product of asperuloside tetraacetate and its absolute configuration at C-8 was established as (*S*) (Inouye and Arai, 1964; Murai and Tagawa, 1980). Based on foregoing data compound **1** was established as the C-8 (*S*)-isomer of deoxyloganic acid.

The initial identity and purity of the isolated five stereoisomeric pentacyclic oxindoles (**3**–**7**) and the tetracyclic isorhyncophylline (**8**) were evaluated by HPLC (Ganzera et al., 2001), as well as by their optical purity ($[\alpha]_D$ values). All the oxindoles were found to be 99-99.5% pure by HPLC, except for isomitraphylline, which could only be purified up to 84.5%. The structures and relative stereochemistries of **3**–**7** were determined rigorously using high field 2D NMR spectroscopic studies, including ^{1}H–^{1}H NOESY and ^{1}H–^{13}C HMBC experiments and were found to be in agreement with those reported by Seki et al. (1993). In addition, the absolute stereochemistry of uncarine C (**3**) and uncarine E (**5**) were determined by single crystal X-ray crystallography,[1] which will be reported elsewhere. The pentacyclic oxindole isomers (**3**–**7**) are difficult and tedious to distinguish by simply comparing the ^{1}H or ^{13}C NMR spectral data. Therefore, the 2D ^{1}H–^{15}N NMR HMBC spectra were acquired to obtain ^{15}N chemical shifts that help to distinguish between most of the isomers (Table 2). The chemical shift of N-1 ranges from δ 136.9 to δ 135.1 and N-4 ranges from δ 54.6 to δ 64.8. The *allo*-type isomers (3*S*, 20*S*) uncarine C (**3**) and E (**5**) exhibited a drastic chemical shift differences at N-4 nitrogen (8-10 ppm) compared to those observed for *epiallo*-type (3*R*, 20*S*) uncarine D (**4**) and *normal*-type (3*S*, 20*R*) mitraphylline (**6**) and isomitraphylline (**7**). Although, the ^{15}N chemical shift differences between **4** and **6** are negligible, they can be very conveniently distinguished by their $[\alpha]_D^{27}$ values (+91° for **4** vs −8.6° for **6**). The ^{1}H–^{15}N HMBC experiment on uncarine C (**3**) demonstrated the correlation between the signals at δ_N 136.85 (N-1), $\delta_{N\text{–}H}$ 9.07 and $\delta_{H\text{-}12}$ 6.85; and δ_N 56.9 (N-4) and $\delta_{H\text{-}5}$ 1.95, $\delta_{H\text{-}6,14}$ 1.69, $\delta_{H\text{-}20}$ 1.53 and $\delta_{H\text{-}21}$ 3.29. All the correlated protons from ^{1}H–^{15}N HMBC data of five isomers studied (Table 2) were in good agreement with their original ^{1}H NMR spectroscopic assignments. Therefore, the ^{15}N chemical shifts and specific rotation values can be used as a valuable tool to distinguish quickly and conveniently all the five stereoisomers **3**–**7**. To our knowledge, this is the first report of ^{15}N NMR chemical shifts for *Uncaria* oxindole alkaloids.

All six oxindole alkaloids, as well as compound **1** and β-sitosteryl glucoside, were evaluated for cytotoxic activ-

[1] Fronczek, F.R., Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803-1804, USA, pers. commun.

ity, using a microplate assay (Dou et al., 1996) against human cancer cell lines of malignant melanoma (SK-MEL), epidermoid carcinoma (KB), ductal carcinoma (BT-549) and ovarian carcinoma (SK-OV-3). The *epiallo*-type C-3(*R*)-isomer uncarine D (**3**) showed weak cytotoxic activity against all the cell lines with IC_{50} values at 30, 35, 34 and 30 μg/ml, respectively, while *allo*-type C-3(*S*-)-epimer uncarine C demonstrated weak cytotoxicitiy only towards SK-OV-3 at 37 μg/ml (Table 3). The other three isomers, *allo*-type uncarine E, *normal*-type mitraphylline and isomitraphylline as well as isorhyncophylline, compound **1** and β-sitosteryl glucoside were found to be inactive. Interestingly, uncarine C and uncarine E had previously been reported from *U. guianensis* to possess weak but selective DNA damaging activities (Lee et al., 1999).

Spray Ionization (ESI); Optical rotation measurements were taken on a JASCO DIP-370 digital polarimeter at 27°C; HPLC: was performed using a Waters 2690 alliance separation module with 996 PDA photodiode detector and a 3 μm Luna C-18 (Phenomenex) column; TLC: silica gel 60 F254 plates; solvent: hexane–EtOAc (4:6) and MeOH–$CHCl_3$(5:95); CC: flash-silica gel G (J.T. Baker, 40 μm); centrifugal preparative TLC (CPTLC, using Chromatotron®, Harrison Research Inc. Model 8924): 2 mm silica gel GF Chromatotron™ rotors (Analtech, Inc.), at a N_2 flow rate of 4 ml/min. The isolated compounds were visualized by observing under UV at 254 nm, followed by development in an iodine chamber or spraying with Dragendorff's reagent (Sigma Chemical Co.) and spraying with anisaldehyde–H_2SO_4 spray reagent.

3.2. Plant material

The inner stem bark of *Uncaria tomentosa* (Fam. Rubiaceae) was collected in April 2000 near Lima, Peru. A voucher specimen was deposited at the herbarium of University of Mississippi.

3.3. Extraction and isolation

The powdered inner stem bark of *U. tomentosa* (2.5 kg) was extracted by percolation with EtOH (3 × 2L). The combined extract was evaporated under reduced pressure and then freeze dried (yield 223 g). A portion of the crude extract (150g) was subjected to flash-CC over silica gel G (40 μm, 4.5 kg). Using 1% MeOH–$CHCl_3$ as solvent yielded uncarine E (**5**; needles, 500 mg), followed by mixture A, that was separated by a short flash-CC, using 25% EtOAc in *n*-hexane to afford uncarine C (**3**, plates, 225 mg) and isomitraphylline (**7**, amorphous powder, 180 mg). Further elution of the CC with 3–5% MeOH–$CHCl_3$ yielded mitraphylline (**6**, granules, 500 mg), followed by mixture B, which was purified by CPTLC (2 mm disc; solvent: 3% MeOH–$CHCl_3$) to give uncarine D (**4**, needles, 80 mg), followed by isorhyncophylline (**8**, needles, 100 mg; mp 138°, $[\alpha]_D^{27}$ +15°, lit.[2] mp 144°, $[\alpha]_D^{27}$ +8.3 ↔ +13°). Finally, elution with 6% MeOH in $CHCl_3$ yielded mixture C, which was separated and purified by CPTLC using 5% MeOH–$CHCl_3$ as eluent in a 2 mm disc to give **1** (80mg, R_f 0.30, solvent: 5% MeOH–$CHCl_3$) and β-sitosteryl glucoside (150 mg, R_f 0.25). The identity of β-sitosteryl glucoside was confirmed by the direct comparison with an authentic sample. The purity of the oxindoles was evaluated by an in-house HPLC method. The physical[2] and spectral data (Phillipson and Hemingway, 1975; Seki et al., 1993) of the oxindoles **3**–**7** were in agreement with those reported in literature.

3.4. 7-Deoxyloganic acid (*1*)

Obtained as colorless amorphous granules from $CHCl_3$, mp 94–96°; $[\alpha]_D^{27}$ −81.9° (MeOH, *c* 1.0); UV λ_{max}^{EtoH} nm (log ε): 220 sh (3.60), 238 (3.85) and 262 (3.88); IR ν_{max}^{KBr} cm^{-1}: 3357 (OH), 2952, 2870, 1680(COOH), 1630, 1548, 1071; ^1H and ^{13}C NMR: Table 1; HRMS (*m*/*z*): 361.1485 ($[MH]^+$, $C_{16}H_{24}O_9$.H); calculated for 361.1493.

3.5. Cytotoxicity assay

The in vitro cytotoxic activity was determined against four human cancer cell lines, SK-MEL, KB, BT-549, and SK-OV-3 (Table 3), obtained from American Type Culture Collection (ATCC, Rockville, MD). A primary assay for the oxindoles was conducted at a single concentration (100 μg/ml), followed by a secondary assay at three to six concentrations (between 50 and 1.56 μg/ml), using a culture-treated 96-well microplate (Dou et al., 1996). The level of toxicity of each sample was also determined by measuring their effect on fibroblast cell line from African green monkey kidney (VERO; non-transformed). The assay is based on the accumulation of neutral red dye in the lysosomes of viable cells. A subsequent addition of 2-propanol will lyse the cells releasing the dye into solution and the absorbance is measured at 490 and 630 nm. Corresponding growth inhibition was calculated and graphed. For secondary assays, IC_{50}s were determined from logarithmic graphs of growth inhibition values. The cytotoxic agents doxorubicin and 5-fluorouracil were used as positive controls, while the DMSO vehicle was used as negative control.

[2] The literature physical data (melting point and optical rotation values) were obtained from the Dictionary of Natural Products on CD ROM. 1999. Chapman and Hall, CR Cnet Base, Version 8:1, Chapman and Hall Numbers: CCG99-V, CCH03-T, CCH06-W, CGL89-T, CGL93-Q and CHF57-L.

Sterol composition of *Aureoumbra lagunensis*, the Texas brown tide alga

José-Luis Giner*, Xiaoyong Li, Gregory L. Boyer

Department of Chemistry, SUNY-ESF, Syracuse NY 13210, USA

Received 15 August 2000; received in revised form 31 October 2000

Abstract

Aureoumbra lagunensis, the alga responsible for the ''Texas brown tide'', contains (*E*)-24-propylidenecholesterol (35.7% of total sterols) as its dominant sterol, in common with other members of the Pelagophyceae. Other major sterols are stigmasterol (22.2%), sitosterol (19.2%), cholesterol (14.1%), and (24*R*)-24-propylcholesterol (5.2%). Trace amounts of 24-methylenecholesterol, crinosterol, clerosterol, campesterol, dihydrobrassicasterol, and 24-isopropylcholesterol were also detected. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Texas brown tide; *Aureoumbra lagunensis*; Pelagophyceae; Chemotaxonomy; Algal sterols

1. Introduction

Aureoumbra lagunensis is a golden-brown picoplanktonic alga responsible for ''brown tides'' in lagoons along the Texas coast of the Gulf of Mexico (Stockwell et al., 1993; De Yoe et al., 1997). This organism is similar to *Aureococcus anophagefferens*, the alga responsible for the ''brown tide'' of the New York and Southern New England coasts (Cosper et al., 1987, 1989; Sieburth et al., 1988). Based on 18S rRNA analysis, ultrastructure, and pigmentation, these algae have recently been classified together with several other chrysophytic algae as members of a new taxon, the Pelagophyceae (DeYoe et al., 1997; Andersen et al., 1993; Saunders et al., 1997, 1995). The sterol composition of all members of this group examined to date is dominated by the unusual marine sterol (24*E*)-24-propylidenecholesterol (**1**) (Rohmer et al., 1980; Raederstorff and Rohmer, 1984; Giner and Djerassi, 1991). We have recently reported the sterol composition of *Aureococcus anophagefferens*, and have proposed that (24*Z*)-24-propylidenecholesterol may serve as a unique biomarker for this organism (Giner and Boyer, 1998). We hereby report the sterol composition of *Aureoumbra lagunensis*, the Texas brown tide alga.

2. Results and discussion

The sterols (Table 1) of cultured *Aureoumbra lagunensis* were separated by HPLC, and identified from their ^{1}H NMR spectra. The major sterol was (24*E*)-24-propylidenecholesterol (**1**) (35.7%), followed by stigmasterol (22.2%), sitosterol (**2**) (19.2%), cholesterol (14.1%), and (24*R*)-24-propylcholesterol (**3**) (5.2%). The configuration of the latter compound was determined by stereospecific synthesis (Giner and Li, 2000). Also isolated as minor sterols were 24-methylenecholesterol, crinosterol, clerosterol, campesterol, dihydrobrassicasterol, and 24-isopropylcholesterol. The 24-methylcholesterols (campesterol and dihydrobrassicasterol) were present in nearly equal amounts, with dihydrobrassicasterol predominating slightly.

We previously identified (24*Z*)-24-propylidenecholesterol as a sterol (12.4%) of the brown tide alga *Aureococcus anophagefferens*, and we proposed that it may be useful as a specific biomarker for this organism (Giner and Boyer, 1998). This sterol was not detected in the Texas brown tide alga *Aureoumbra lagunensis*. On the other hand, the (24*E*)-isomer (**1**), which represents a biomarker specific to pelagophyte algae, was found as

Table 1
Sterols of *Aureoumbra lagunensis*

Sterol	HPLC retention time	Total sterols (%)
24-Methylenecholesterol	42.6 min	0.4
Epibrassicasterol	44.8 min	0.9
Clerosterol	46.6 min	1.1
Cholesterol	49.8 min	14.1
(*E*)-24-Propylidenecholesterol (**1**)	51.9 min	35.7
Stigmasterol	53.3 min	22.2
24-Methylcholesterols	55.0 min	0.7
Sitosterol (**2**)	60.1 min	19.2
(24*R*)-24-Propylcholesterol (**3**)	65.7 min	5.2
24-Isopropylcholesterol	68.4 min	0.4
Sterol content: 0.16% wet wt		

35.7% of the total sterols. When compared with the sterol compositions of other pelagophyte algae (Rohmer et al., 1980; Raederstorff and Rohmer, 1984; Giner and Boyer, 1998), the sterol composition of *Aureoumbra* most closely resembles that reported for *Nematochrysopsis roscoffensis*, which also has a relatively high percentage of the stigmasterol (25%) and sitosterol (**2**) (6%), as well as cholesterol (12%) (Raederstorff and Rohmer, 1984). The use of stigmasterol and sitosterol (**2**) as biomarkers for terrestrial plant input in the marine environment should therefore be interpreted with caution (Volkman, 1986). It is interesting to note that 24-propylcholesterol (**3**, which also occurs in *Nematochrysopsis roscoffensis*, 9%) is found with the same configuration at C24 as the 24-ethyl sterols, stigmasterol and sitosterol (**2**). This suggests that the same sterol $\Delta^{24(28)}$-reductase may be involved in their biosynthesis (Fig. 1).

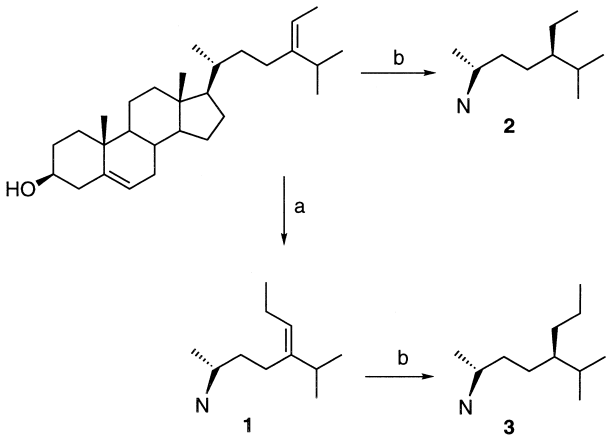

Fig. 1. Biosynthesis of *Aureoumbra lagunensis* sterols. (a) sterol methyltransferase; (b) sterol $\Delta^{24(28)}$-reductase.

3. Experimental

3.1. General procedures

NMR spectra were acquired using Brüker Avance-300 and Brüker Avance-600 instruments using $CDCl_3$ as the solvent and referenced to residual $CHCl_3$ signals (^1H: 7.26 ppm, ^{13}C: 77.0 ppm). GC–MS data was obtained using a Hewlett-Packard 5890 series II gas chromatograph with a Hewlett-Packard 5989B mass spectrometer. TLC was performed on glass backed plates coated with a 0.25 mm layer of Si gel 60 F254. HPLC was carried out using a Waters 6000A pump, Waters 410 differential refractometer, and two Altex Ultrasphere ODS 5-μm 10x250 mm columns in series, at a flow rate of 3 ml/min MeOH.

3.2. Culture conditions

Cultures of *Aureoumbra lagunensis* CCMP-1681 were grown at 18°C with aeration in 12 l glass carboys containing artificial seawater (Golmand and McCarthy, 1978) supplemented with F/2 trace metals (Guillard and Ryther, 1962) using a 14:10 h light/dark cycle (160 μE m^{-2} s^{-1}). Cell growth was measured using in vivo fluorescence and by visual cell counts under phase contrast. Cells were harvested in stationary phase by centrifugation (14,000 × *g*) and lyophilized. 2.7 g (wet wt) of cells were obtained from 8 l containing 3.7×10^6 cells ml^{-1}.

3.3. Sterol analysis

The cells were extracted at room temp. with 12 ml EtOAc overnight, then a second time for 3 h. The extracts were concentrated under reduced pressure and fractionated by TLC on silica gel (hexanes–EtOAc 2:1). The sterol band was further purified from contaminating pigments by chromatography on a small column of Florisil (hexanes–EtOAc 9:1 followed by 4:1). The sterols (4.4 mg) were separated by reversed phase HPLC. The relative proportions of sterols were determined from integration of the HPLC trace. The sterol fractions were evaporated with a stream of N_2 and characterized by ^1H NMR (300 MHz, $CDCl_3$). The NMR spectra matched those of known samples: (E)-24-propylidenecholesterol (**1**) (Rohmer et al., 1980); 24-methylenecholesterol (Hetzel et al., 1994); 24-methylcholesterols (dihydrobrassicasterol and campesterol) (Rubinstein et al., 1976); crinosterol (Rubinstein et al., 1976); clerosterol (Akihisa et al., 1991); 24-isopropylcholesterol (Hofheinz and Oesterhelt, 1979; Kokke et al., 1979).

3.4. (24*R*)-24-Propylcholesterol (*3*)

Abstract

The recently isolated pigments from *Petunia integrifolia* and *Triteleia bridgesii* present a distinct feature that sheds new light on the understanding of intramolecular copigmentation of anthocyanins. These are among the infrequent anthocyanins that naturally present a coumaric acid substituent in both *cis* and *trans* forms. As a consequence, the two isomers demonstrate substantial variations of their thermodynamic and kinetic constants and also colour properties. A possible explanation for these characteristics is presented, making use of molecular modelling and taking into account the three-dimensional structures of the pigments. © 2001 Elsevier Science Ltd. 1. Introduction

Progress on extraction and purification techniques has afforded details of several forms of acylated anthocyanins (Toki et al., 1994a,b; Saito et al., 1995; Tatsuzawa et al., 1997). These recently discovered pigments possess, as a common trait, one or more aromatic acyl residues. Depending on the length of the "chains" that link them to the central chromophore, they may fold over the 2-benzopyrylium system and strongly influence its properties as a colourant (Brouillard and Dangles, 1994). A pattern is common to most of these recently discovered pigments: the hydroxycinnamic acid units occur in a *trans* configuration (Saito and Harborne, 1992; Strack and Wray, 1994). To our knowledge, only eight papers report the isolation and characterization of hydroxycinnamic acid residues present in a *cis* configuration, one on the Labiatae (Yoshida et al., 1990), one on the Commelinaceae (Kondo et al., 1991), three on Liliaceae (Hosokawa et al., 1995a,b; Toki et al., 1998) and three on the Solanaceae (Ando et al., 1999a,b; Slimestad et al., 1999) flowers. In all of the above-cited works, the *trans* isomer always predominates in vivo.

The present paper reports, for the first time, on the colour stabilisation and intensity changes brought about by the isomerisation of the coumaroyl residue. The results concern two pairs of acylated anthocyanins (Scheme 1): malvidin 3-*O*-[6-*O*-(4-*O*-(*trans-p*-coumaroyl) -α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-(β-D-glucopyranoside) (**1**) and malvidin 3-*O*-[6-*O*-(4-*O*-(*cis-p*-coumaroyl)-α-L-rhamnopyranosyl)-β-D-glucopyranoside]- 5-*O*-(β-D-glucopyranoside) (**2**) isolated from the red-purple flowers of *Petunia integrifolia* (Ando et al., 1999a,b) and delphinidin 3-*O*-[6-*O*-(*trans-p*-coumaroyl)-β-D-glucopyranoside]-5-*O*-[6-*O*-(malonyl)-β-D-glucopyranoside] (**3**) and

delphinidin 3-*O*-[6-*O*-(*cis*-*p*-coumaroyl)-β-D-glucopyranoside]-5-*O*-[6-*O*-(malonyl)-β-D-glucopyranoside] (**4**) extracted from the blue-purple flowers of *Triteleia bridgeseii* (Toki et al., 1998).

The thermodynamic and kinetic results gathered from the two pairs of natural pigments allowed the interpretation of intramolecular copigmentation from a new perspective, even supporting the hypothesis that such *cis*-hydroxycinnamic isomers may be more prolific in nature than has previously been thought, due to their aptitude to positively influence flower colour.

2. Results and discussion

Flower colour is, to a large extent, the consequence of the expression of the colouring properties of anthocyanins, the pigments residing in the vacuoles of plant cells. These pigments are, according to their chemical structure, capable of displaying an immense variety of tints and hues. In particular, acylated anthocyanins were shown to exhibit some of the more astonishing and stable colour capabilities ever found in plant pigments (Brouillard, 1981; Dangles et al., 1993a,b; Figueiredo et al., 1996a,b,1999). In this paper, we look at the changes brought about by the isomerisation around a coumaroyl residue on two sets of acylated anthocyanins (Scheme 1). In the vast majority of acylated anthocyanins extracted from plant material, the hydroxycinnamic acid units commonly appear as *trans* isomers, *cis* isomers being very rare. The two pairs of isomers presented in this work do not undergo isomerisation in aqueous solution, due to the high activation energy needed to convert between *trans* and *cis* forms. However, conversion between the two isomers was shown to take place in vitro, both with artificial (366 nm) and natural (sun) irradiation, for another set of structurally comparable anthocyanins (Yoshida et al., 1990).

The simple change from a *trans* to a *cis* configuration of the terminal coumaric acid on the molecules here studied produced some appreciable modifications both at the level of colour expression and colour stability. Table 1 reports those properties. Although the maximum absorbance wavelength in the visible, for the flavylium cation forms, does not greatly change among the four pigments concerned, their molar extinction coefficients do so (Fig. 1). In fact, *cis* isomers exhibit ε values about 1.5 times greater than *trans* ones, in both pairs of molecules. This increase in colour intensity may be due to differences in co-planarity between the central chromophore and the acyl residue. Computed structures for the two isomers **3** and **4** (Fig. 2), performed both in vacuo, in the AM1 (Dewar et al., 1985) parametrization, and in a simulated water container, with the MM+ (Allinger, 1977) force field, suggest that **4** has the coumaroyl residue almost parallel to the central anthocyanidin moiety, while **3** presents a quasi-perpendicular conformation.

The computed structures for anthocyanins **1**–**4** showed their ability to form folded structures (intramolecular copigmentation) that protect the pigments against the colour damaging hydration reaction. This is particularly true with the *cis* isomers (Fig. 2). The distance of the acyl residue in the *cis* isomer **4** to anthocyanidin moiety is smaller than in the *trans* isomer **3** (Fig. 2).

The hydration reaction is the primary cause of a marked colour loss in non-acylated anthocyanins, due to the formation of colourless equilibrium forms, in aqueous solution. This property is also affected by the change in configuration of the coumaroyl moiety from *trans* to *cis*. Calculated pK'_h values (Table 1) reveal that the *cis* isomers are less prone to undergo hydration than their *trans* counterparts. A closer look at the values obtained for the kinetic constants k_1 (hydration) and k_2 (reverse reaction) helps to understand this behaviour. While k_1 is of the same order of magnitude for both isomers, k_2 is always greater for the *cis* forms. This means that although

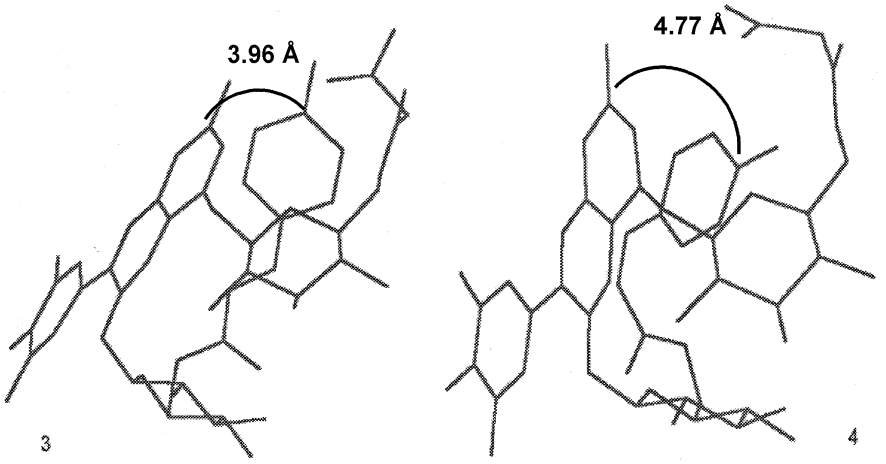

Fig. 2. Conformations of **3** and **4**, optimised by MM+. The arrows point to the coumaroyl moieties.

both forms have the same susceptibility to water addition to the charge deficient positions (C_2 and C_4), the *cis* isomer has a faster back reaction to reform the coloured flavylium cation. This may be due to a more favourable spatial arrangement of the molecules, conferred by *cis* isomerisation around the coumaroyl moiety. The computed (MM+) differences in formation energies between BH_2 (colourless hemiacetal) and AH_2^+ (coloured flavylium) indicate a more pronounced gap for anthocyanin **3** than for pigment **4**, which may account for the faster back reaction of **4**.

The present set of acylated anthocyanins presents pK_a values, for the proton transfer reaction transforming the coloured flavylium form in the also coloured quinonoidal base, within the characteristic range previously estimated for similar molecules (Dangles et al., 1993a,b; Figueiredo et al., 1996a, 1999). The influence of the *trans-cis* isomerisation seems not to be relevant in this particular case (Table 1). There is, however, a small variation in both pairs of anthocyanins, with *trans* isomers exhibiting slightly lower values in pK_a. The AM1 computed electronic charge densities for the atoms on C-7 and C-4' may account for such a difference. In all four molecules, the charge is more positive for C-7 than for C-4', in accordance with previously reported results (Figueiredo et al., 1999), indicating that the hydroxyl in position 7 of the aglycone is always the first to undergo proton transfer. Furthermore, in the present work, *trans* isomers yielded more positive values for the computed C-7 charges than their *cis* counterparts. However, no data clearly indicate that this feature is a consequence of structural variations caused by isomerisation about the coumaroyl moieties of the anthocyanins.

The results here reported once more stress the importance of the nature of substituents on colour stability of the anthocyanins. It is demonstrated, for the first time,

that one of the rarest features found in these pigments play an important role in preventing colour loss by nucleophilic water attack. In effect, the change from the common *trans* coumaroyl substituents to the unusual *cis* isomers confers an additional protection against hydration, reflected on an increase in pK'_h values. The more co-planar arrangement allowed by *cis* isomers is postulated as the rationale supporting the enhanced colour stability.

Knowing that *trans-cis* photoisomerisation may take place in vivo (Yoshida et al., 1990), we propose this mechanism as an additional means for preservation of flower colour, but one should bear in mind that the conversion between the two isomers in vivo is certainly rare due to low amounts of the *cis* configuration.

3. Experimental

3.1. Materials

Pigments were extracted according to published procedures and had their purity (always $\geqslant 98\%$) checked by ^{1}H NMR spectroscopy (Toki et al., 1998; Ando et al., 1999a). 3-*O*-[6-*O*-(4-*O*-(*trans*-*p*-coumaryl)-α-L-rhamnopyranosyl)-β-D-glucopyranosyl]-5-*O*-(β-D-glucopyranosyl) malvidin chloride (**1**) and 3-*O*-[6-*O*-(4-*O*-(*cis*-*p*-coumaryl)-α-L-rhamnopyranosyl)-β-D-glucopyranosyl]-5-*O*-(β-D-glucopyranosyl) malvidin chloride (**2**) were isolated from the red-purple flowers of *Petunia integrifolia* and 3-*O*-[6-*O*-(*trans*-*p*-coumaroyl)-β-D-glucopyranosyl]-5-*O*-[6-*O*-(malonyl)-β-D-glucopyranosyl] delphinidin chloride (**3**) and 3-*O*-[6-*O*-(*cis*-*p*-coumaryl)-β-D-glucopyranosyl]-5-*O*-[6-*O*-(malonyl)-β-D-glucopyranosyl] delphinidin chloride (**4**) were obtained from the blue-purple flowers of *Triteleia bridgeseii* and used without further purification. All other chemicals used were of analytical grade.

3.2. Absorption spectra

Absorption spectra were recorded with a Hewlett Packard diode-array spectrophotometer fitted with a quartz cell ($d = 1$ cm) equipped with a stirring magnet. A constant temperature of 25 ± 0.1°C, measured with a Comark thermocouple, was maintained in the spectrometer sample cell by use of a Bioblock water-thermostated external bath. Water used in sample preparations was bidistilled.

3.3. Data analysis

UV–visible absorption data were recorded on a Pentium P200 PC using the Hewlett Packard UV–visible Chemstation Programme. Mathematical treatments applied to the data were carried out with the Microsoft Excel 98 programme running on a PowerMacintosh G3/300 machine.

3.4. Thermodynamic measurements

Stock solns ranging from 6.6×10^{-5} M to 1.1×10^{-4} M of the 4 pigments were prepared in 0.1 M HCl and left to equilibrate in the dark for about 3 h. Then, for each pigment, 16 solns were prepared by 1:10 dilutions of the stock solns with different volumes of NaOH 0.1 M soln and H_2O so that the final pH covered a range of 1–3.5. After equilibration in the dark, the UV–vis spectra of these solns were recorded. The values of the global equilibrium constants ($K' = K'_h + K_a$) are gained from measuring the relative hyperchromic shift at the visible absorption maxima of the flavylium cation, for all the pigments studied, as a function of pH.

3.5. Kinetic measurements

One milliliter of each equilibrated aq. soln of anthocyanin, at different pH values (from 1.0 to 3.0, depending on the pigment) was magnetically stirred in the spectrophotometer cell. The concentrations of pigments **1**–**4** were respectively 8.54×10^{-6} M, 6.61×10^{-6} M, 1.07×10^{-5} M and 7.82×10^{-6} M. To these solns, 1 ml of acetate buffer solns, ranging in pH from 3.0 to 5.0, was quickly added and the visible absorbance at ca. 530 nm (near the visible absorption maxima for all the pigments) was immediately recorded every second over 120 s to guarantee that the hydration equilibrium is attained. The final pH was then measured and ranged from 2.4 to 4.6. The spectrophotometer software automatically computes the first order apparent rate constant of the hydration reaction (k).

3.6. Molecular modelling

Molecular mechanics [MM+ (Allinger, 1977)], inside a simulated periodic box of ca. 350 water molecules and semi-empirical quantum mechanical calculations [AM1 (Dewar et al., 1985)] were performed on a Pentium P350 PC using the Hyperchem programme (version 4, Hypercube, Inc., Ont., Canada).

Book reviews

Bioactive Compounds from Natural Sources: Isolation, Characterisation and Biological Properties
Edited by C. Tringali; Taylor & Francis, London and New York, 2001, 693 pp., ISBN 0-7484-0890-8, £65

There is a renewed interest in obtaining natural products for evaluation in high throughput screens and also a need to better understand the chemistry of herbal medicinal products and foods. This multi-author book is aimed at advanced students and research scientists from various disciplines working in areas related to natural products. This volume aims to focus on the modern approach to the isolation of biologically active natural products in general but there are also some very detailed research reviews by experts in the fields such as on limonoids, flavonoids, other potential anti-tumour compounds and marine natural products.

The book includes chapters on general modern methods of identifying and purifying natural products such as on-line identification of plant metabolites by LC–UV, LC–MS and LC–NMR and also NMR methods in structural elucidation (by the editor). An ethnobotanical approach is described using Mexican plants used to treat gastrointestinal disorders as an example and how cytotoxins and chemicals with activities as herbicides and insecticides were found. The other chapters deal with particular classes of compounds such as flavonoids in cancer prevention, anti-cancer drugs from higher plants, anti-HIV aromatic compounds, antioxidants from plants, antimalarial and anti-inflammatory compounds (affecting cyclo-oxygenase-2) and three chapters on marine metabolites including glycolipids as immunomodulators.

There is also an unusual chapter on phytotoxins from fungi which are pathogenic to agrarian, forestal and weedy plants. The taxoid chapter gives an interesting review of natural sources and the limonoid chapter has considerable detail of their biosynthesis, chemistry and anti-feedant properties to insects.

The title of the book gives a good description of the chapters, which are very detailed and interesting in their multi-disciplinary content of biology, biochemistry and chemistry. Since Professor Tringali is the editor, it is not surprising that the chapters tend to include useful details of NMR data. All of the chapters have a good literature reference list. This book is recommended to all natural products researchers.

Molecular and Supramolecular Chemistry of Natural Products and Their Model Compounds
J.-H. Fuhrhop and C. Endisch, Marcel Dekker, New York, Basel, 1999, 602 pp., ISBN: 0-8247-8201-1, $195

Molecular and Supramolecular Chemistry of Natural Products and Their Model Compounds is primarily targeted at Masters and Doctoral students in chemistry and biochemistry who are interested in the basic structural properties and reactivity of common natural products. This book should provide an invaluable reference to researchers in this developing and exciting field and, perhaps, is the only book of its kind offering remarkable depth to each chapter. The book is logically presented covering all major natural compounds as well as extensively covering the properties of natural compounds in synkinetics (i.e. the reversible synthesis of complex molecular structures). The book is divided into nine chapters of which the first is essentially a review of the basic concepts covering the isolation and structure of natural compounds, the synthesis of natural compounds, their reactivity and finally synkinesis. The remaining eight chapters are organised systematically beginning with lipids and membranes, steroids, carbohydrates,

carotenes, porphyrins, vitamins, DNA and finally proteins. Of particular interest was the lipids and membranes chapter where applications relevant to monolayer technology were generously covered including atomic force microscopy of monolayers, two physical methods for measuring ion flow in black lipid membranes, large vesicular, and cell membranes as well as a method that works with a large population of vesicles using entrapped fluorescence dyes. The section on carbohydrates is focused on organic chemists who are working with cellulose and the structures of all known forms of cellulose are covered. The DNA and protein chapters will be of interest to molecular biologists who are familiar with manipulating DNA but not aware of the chemistry! The protein chapter covers a number of interesting examples of synkinesis with proteins. For example the assembly of peptide pores in membranes using bee venom melittin and gramicidine A as classical examples. Also discussed are examples of protein interactions with steroids (progesterone), carbohydrates, carotenes and porphyrins (using the heme pocket in myoglobin as an example). Finally, the most interesting section of the protein chapter is the section on the assemblies of proteins covering, zinc-finger proteins, leucine zippers and the formation of immunoglobulins.

One useful aspect of this book is that it covers new and emerging technologies such as cryo-electron, atomic force microscopy and scanning force microscopy as well as including established techniques such as black film methodology. One surprise for a book of this nature was the extensive illustrations with over 500 figures, almost equalling one per page. Perhaps, due to the large number of figures used some of the figures are very small and in places difficult to discern (this is particulary true of the DNA chapter). In addition, *Molecular and Supramolecular Chemistry of Natural Products and Their Model Compounds* is extensively referenced with over 900 references making this an ideal sourcebook for further study. The price of the book ($195) seems appropriate for an advanced reference book of this nature.

Editorial

Special Issues Devoted to the Biosynthesis of Woody Plant Biopolymers and Related Substances

These Special Issues (Vol. 57/6 and 57/7) are largely derived from the presentation of papers given at the Millennium Symposium of the American Chemical Society (ACS) entitled, "Biosynthesis of Woody Plant Biopolymers and Related Substances", held in San Francisco from the 26–29 March 2000. It was organized by G.P. Bolwell and N.G. Lewis, under the auspices of the ACS Cellulose, Paper and Textile Division. The meeting was devoted to fundamental research on the biosynthesis, assembly and properties of plant cell walls which underpin their use as industrial feedstocks and other aspects that impinge on daily life such as dietary fiber. Of special interest was the way in which chemistry is being augmented with genomic, proteomic and metabolic studies to unravel the complex processes involved in plant cell wall assembly, and in combination with molecular breeding to improve fiber properties.

The rationale of the gathering was directed at integrating the present knowledge of the synthesis and assembly of carbohydrate and phenolic biopolymers in woody tissues. That notwithstanding, additional communications were given on those components that have been rather neglected in the past but which are important in preserving and enhancing both the integrity and function of specialized cell walls. These contributions focus upon specialized phenolics and lipids of secretory, cuticular, suberized and heartwood tissues.

We have organized these issues in several thematic sections, which mainly reflect the range of topics covered at the meeting. Authors were encouraged to update their contributions in the time since the meeting. The first section primarily deals with structural and anatomical aspects but contain protein and gene expression data that help understand the complexity of individual cell types within woody tissues. Four papers (McCann, Haigler and Lewis) largely relate to polysaccharide biosynthesis and cell wall assembly at the cellular level, while within the second group, two (Donaldson and Ruel) summarize spatial aspects of lignin biosynthesis and others (Lewis and Gross) describe the processes involving specialized depositions of lignins/lignans and tannins, in woody tissues, respectively.

The next section has an emphasis on chemical aspects and plant component analysis. The first begins with a comprehensive review on pectins (Mohnen) and is presented together with a research paper describing novel linkages between heterogeneous pectins (Ishii). Another contribution (Murray) describes an intriguing occurrence of oligosaccharides which might be related to glucan biosynthesis. A second chemistry section has two papers (Iiyama and Ralph) which describe some observations that they believe affect lignin assembly and a third by Stange indicates that the lignin formed by the wounding of cucumber is actually largely *p*-coumaraldehyde. Marton and Ferreira describe additional complex flavonoid derived structures found within specialized cell walls containing phenolic polymers, including that of heartwood. The final paper in this section (Stark) summarizes our knowledge of the lipid components associated with phenolics in cuticular structures.

The next sections address progress made on the biochemistry and molecular biology of carbohydrate and phenolic polymers. We begin with protein biochemistry and metabolism of wall carbohydrate synthesis. Further characterization of the synthesis of polysaccharides in vitro is described in two contributions (Carpita and Bolwell). This is followed by a study on metabolism of monosaccharides (Magel) which is also related to the provision of phenolic precursors for heartwood deposition. The biosynthesis of monolignols is reviewed with respect to metabolic channeling of individual monolignol pathways (Dixon) with three other papers following on coniferyl alcohol metabolism (Savidge and Ros Barcelo). Bernards and Cornish summarize the important advances being made in suberin and rubber biosynthesis, respectively. In the year in which the Arabidopsis genome was completed, molecular genetics have not been left out. It is apt that as we strive to identify the genes responsible for cell wall polysaccharide biosynthesis that we present a review that is germane to such studies (Brown). Five articles describe results on the regulation and manipulation of lignin biosynthesis, and these complete the two special issues (Kawaoka, Legrand, Ye, Grima-Pettenati and Bolwell). Such study represents the immediate take-off point for present commercially oriented work.

As Editors of this Special Issue, we are extremely grateful for the timely preparation and updating of

these articles by the authors. We hope that they and the readers will find these an important and stimulating series of articles on the present status of our yet very incomplete understanding of the biosynthesis of woody plant biopolymers and related substances. In this respect, we have strived in these two volumes to compile a range of views, which sometimes differ on the same topic.

Following this editorial, we provide a summary on our understanding of the remarkable processes involved in wood evolution. It would be remiss if we did not wholeheartedly thank financial support provided by a number of organizations without whose help neither symposium nor special issues would have been possible. These include, Applied Phytologics, Inc., American Chemical Society, Elsevier Science Ltd., the S.R. Noble foundation, Waters Corporation and the Weyerhaeuser Company.

Editorial comment

The Holy Grail of wood evolution — from wood anatomy to tissue-specific gene expression: to what extent do molecular studies of biosynthesis of cell wall biopolymers help the understanding of the evolution of woody species?

1. Introduction

During the assembly of these two Special Issues, we have been prompted in the review of the contributions to reflect on two main threads of study pursued for woody species. The first is the assessment of the current knowledge of how wood evolution occurred, drawing as far as we can at present upon the fields of genomics, proteomics, wood anatomy, plant chemistry and plant biology. The second is in the identification of the outstanding questions and opportunities that challenge us both now and in the future as regards strategic manipulations and optimization of wood and fiber quality. Thus, we attempt to highlight the progress made over nearly three centuries and apologize in advance for any omissions that may have occurred.

Woody vascular and herbaceous plant evolution was arguably the single most important development for sustenance of life in a terrestrial habitat. Moreover vascular plant life in general markedly defines and characterizes our terrestrial ecosystems, and their conquest of land has led to all of our modern soils and the varied life forms therein, as well as in providing the means to support the explosion of all terrestrial (metazoan) groups as they emerged (Graham et al., 2000). Vascular plant life has also markedly impacted the atmospheric chemistry and climate including the levels of gaseous CO_2. Humanity, of course, has long used woody plants for sundry purposes as a source of fiber, solid wood products, foods, medicines, intermediate chemicals, flavors and fragrances.

From its very early beginnings, phytochemistry has made many great advances into the chemical compositions and constituents of plant life, which in turn have set the foundation for the modern fields of plant chemotaxonomy, plant biochemistry and even genomics. However, phytochemistry now assumes perhaps its most compelling challenge, namely its integration with morphological and molecular studies, in order to comprehensively define how a plant both forms and compartmentalizes its various metabolic products. In this regard, what greater opportunity is there in defining how development of this heterogeneous tissue that we describe collectively as wood occurs? Arguably it represents one of nature's greatest engineering feats.

In this post-genomic age and with the ability to carry out molecular breeding at our disposal, we are now in a position to consider a technologically driven evolution of woody species with benefits for industrial processes including their impact on the environment. At this juncture, though, it is worth reflecting upon the course of evolution that has led to present day species. This is because the work presented at the meeting that has given rise to these Special Issues, and communications also published elsewhere recently, are adding to the insights into the evolution of woody species already developed in paleobotanical studies. Molecular analysis of the biochemistry and differential gene expression shown by present day plants is a culmination of 200 million years of evolution and carries the imprint of the early colonizers of terrestrial habitats. If woody species represent an evolutionary pinnacle from the point of view of mechanical success and as a bulk resource, then they are a product of many attempts to develop the vascular habit.

In terms of dicots, the advent of the vessel is thought to be significant in the evolution of woody species (Bailey, 1953; Cheadle, 1953). However, this and other genetic remnants of evolution ultimately led to the inherent variability found in the 250,000–350,000 plant species in existence today. This natural variability is observed not only in terms of both chemical compositions but also morphological patterns both between and within species.

Put in another way, while common biochemical themes clearly exist for cell wall assembly, individual species, nevertheless, generate specific patterns of formation of their extracellular matrices, e.g. through modulation of their biochemical pathways to the cell wall biopolymers. We simply do not know the limits to this variability at present, and one goal is to determine this and use it to humanity's benefit in a manner that is environmentally, societally and ethically responsible. Some of the questions to be asked include what are the desirable targets for change and is it really as simple as less lignin and more cellulose? Indeed the fundamental question may simply reside in defining the actual limits to cell wall variability. First impressions are that this variability is considerable and we review this in the context of these Special Issues.

Work of this type has, however, a number of ethical, societal and environmental ramifications, as noted from the ongoing GMO debates and related concerns. It is important that these aspects are not ignored by the scientific community during the period of research that will follow. This will require that we reach out to our communities and help explain both natural variability and the benefits that can accrue from such investigations, whether for new fiber sources, human health protection, and so forth.

2. What are the limits to structural variation?

Even without engineering mutations, wood development shows considerable variability in response to mechanical and environmental factors. One of the most common and widespread forms of this variability is in the generation of reaction wood, as is seen by compression wood in gymnosperms and tension wood in angiosperms. These serve to realign the stem when it is dislodged from its vertical alignment and restore the photosynthetic canopy, as well as being involved in determining the branching patterns and orientations. These effects arise by strategic synthesis of new wall material in the requisite areas of the developing stem or branch. In compression wood this takes the form of having a rounded phenotype and having a higher lignin content. Tension wood in contrast arises in the uppermost part of the leaning stem in the form of a gelatinous layer reflecting a higher cellulosic and lower lignin content than compression wood. Two papers Kwon et al. (2001a) and Levine et al. (2001) tackle the influence of mechanical factors from another angle by observing whether the effects of microgravity can override these programmable changes, and discovered that — in contrast to many reports in the literature-they do not.

Water status is also a factor. Besides the familiar effects of adverse conditions on ring growth the reciprocal effect of high water levels gives rise to the vesselless phenotype in willow and pea, as was recognized in the nineteenth century (Böhm, 1879; Vesque and Viet, 1881). It is, therefore, apparent that the study of xylem development needs to occur with the recognition that within the plant genome exists a flexibility that leads to different cell wall types and their constituents in order to maintain the particular biomechanical properties necessary for the tissue being formed. How plants perceive these needs and how the corrective actions are taken will be the focus of much research in the future.

3. Can wall polysaccharides be favorably altered?

Although cellulose is found universally there is considerable variation in its molecular weight ranges and extent of crystallinity both within and between species; this again presumably reflects the changes that this biopolymer has for individual cell types and subcellular layers.

There is also considerable variation in the associated polysaccharides which is found in its extreme in the dicots and monocots. The dicot primary wall contains three major pectin types and xyloglucan as the main hemicellulose. It is often overlooked that the middle lamella and primary wall, albeit subsequently lignified, is preserved in tracheids but the adjacent secondary wall that is laid down has a very different composition. There is little pectin and the major hemicellulose is xylan. In terms of composition this resembles the monocot primary wall, where the hemicellulose is mainly arabinoxylan together with *beta* $1\rightarrow3$; $1\rightarrow4$ mixed-linkage glucan. Indeed callose has been reported in secondary walls on occasion using histological staining (Currier, 1957) and can be detected using immunolocalization (M.E. Kerry and G.P. Bolwell, unpublished). Already there are reports that alteration in lignin in woody species brings about favorable increases in cellulose content (Hu et al., 1999). This has not yet been approached through direct manipulation of polysaccharide synthases due to the lack of genes available with the exception of cellulose synthase.

The paper by Saxena et al. (2001) illustrates how understanding the cellulose synthase may allow identification of further polysaccharide synthases in the genomic databases. Alternatively two papers [Buckeridge et al. (2001); Kerry et al. (2001)] describe the types of biochemical studies that are striving to identify the enzymes in order to lead to identification of new target genes. Already there are enough indications that these will be good targets to further explore the limits to wall variability. However, the differences between primary and secondary walls indicate that more sophisticated microscopic analysis, rather than chemical analyses of whole material, will be needed to understand the consequences of such manipulation such as those described by Ruel et al. (2001).

4. The pathway to lignin biosynthesis and polymerization; is there one pathway to lignification?

Understanding of the lignin pathway is truly in a state of flux at present! It is constantly being redrawn with revision of the functionality of some of the enzymes. Multiplicity of the number of genes coding for individual steps is adding a new complexity. This is described in a review (Dixon et al., 2001) which also introduces the concept of metabolic channeling.

5. Differential gene expression: do different cell types in wood express the same genes?

Differential gene expression in this context relates to the temporal and spatial activity of genes in the various vascular cell types. Several papers (Kwon et al., 2001b; Ye et al., 2001) together with work elsewhere suggest that different cell types express different genes and that this can give rise to micro-heterogeneity for both lignin biosynthesis and related substances in vessels and tracheids at least. In the paper by Ye et al. (2001) expression of CCOMT seemed to be confined to tracheids and fibers; there was a lack of a signal in the vessels. Does this reflect problems with detection limits, or is the lignin pathway in vessels lacking CCOMT? How also are the other pathways in woody plant cells using monolignols (not for lignification) kept separate. Clearly, as shown by Kwon et al. (2001b) and Burlat et al. (2001), we are just beginning to scratch the surface in unraveling the organizational frameworks of these complex biochemical machineries.

Structural genes in the lignin pathway are mainly regulated through transcriptional control (Kawaoka and Ebinuma, 2001). Cell-specific expression then resides in the regulatory sequences. If there is compelling evidence for considerable differential gene expression in tracheids and vessels then it does indeed support separate origins for the two cell types in primitive dicots. In addition to suppression of vessels by high humidity (Section 2) some species of dicot never form vessels particularly amongst the aquatic plants, saprophytes, parasites and succulents which have been considered to arise through a loss of the vessel habit (Bailey, 1953; Cheadle, 1953). There are also ten genera of dicots which are vessel-less and considered primitive. There does not seem to be any examples of tracheid-less dicots, although monocots and herbaceous dicots resemble vessel-type primitive land plants in the persistence of distinct vessel-rich vascular bundles rather than a continuous vasculature seen in woody plants. Since the presence of vessels would seem to be an advantage it is entirely feasible that it was selected for. In addition any crossing that introduced both cell types into a new hybrid would have conferred an enormous evolutionary advantage and would have been selected for.

6. Implications for understanding the evolution of woody species

This distinction between vessels and tracheids is important since the occurrence of vessels has been a focus of much of the work aimed at understanding the evolution of woody species (Bailey, 1953; Cheadle, 1953; Wheeler and Baas, 1991). As incomplete as the fossil records are, they provide evidence for migration of complex photosynthetic life forms, presumably derived from algal forerunners, to a land base some 470 million years ago (Edwards, 2000) (Fig. 1). This ultimately led to the development of tracheary elements as defined as imperforated cells with bordered pits, which following autolysis form reinforced water conducting cells. This pivotal progression ultimately led to complex multicellular plant forms and hence to the enormous proliferation of plant species in existence today.

Initially it has been proposed, based on the fossil record that three major classes of primitive plants then evolved, each possessing a characteristic tracheid type. All three differ markedly from the typical seed plant tracheids in existence today, and these differences shed important evolutionary insight into the success of land colonizing seed plants. Fig. 2 shows the three types of tracheary elements present in the S, G and P-type tracheids of early but now extinct land plants (Friedman and Cook, 2000). All three types contain a degradation-resistant layer adjacent to the cell lumen and a degradation-prone layer in the outer confines of the secondary wall thickening. In modern seed plant secondary thickenings there is no comparable degradable layer. In the S-type tracheids, present in the extinct Rhynia (Rhyniopsida), there are annular or helical wall thickenings as well as a lateral (degradation-prone layer) possessing spongy or reticulate material. In the G-type tracheids, present in the extinct Zosterophyllum (Lycophytina), there are again two layers — a resistant layer adjacent to the cell lumen and a degradation-prone layer in the external regions. Fossil evidence also suggests the presence of perforations in the primary wall and small pits in the decay-resistant secondary wall. The P-type tracheids present in *Psilophyton* (Euphyllophytina), resemble those of the G-type variants except for having bordered pits. It has been speculated that these early primitive land plants contained phenolics (lignin?) in their degradation resistant zones but lacked them in their degradation prone regions. This would reveal a situation at variance with present day gymno- and angio-sperms where essentially the whole wall is lignified in vascular cells. However, can the primitive condition be mimicked by altering patterns of micro-heterogeneity of lignification and loosening of wall structures (degradation-prone?). Interestingly, in a CCR down-regulated line this occurred, albeit in the reverse orientation (Ruel et al., 2001).

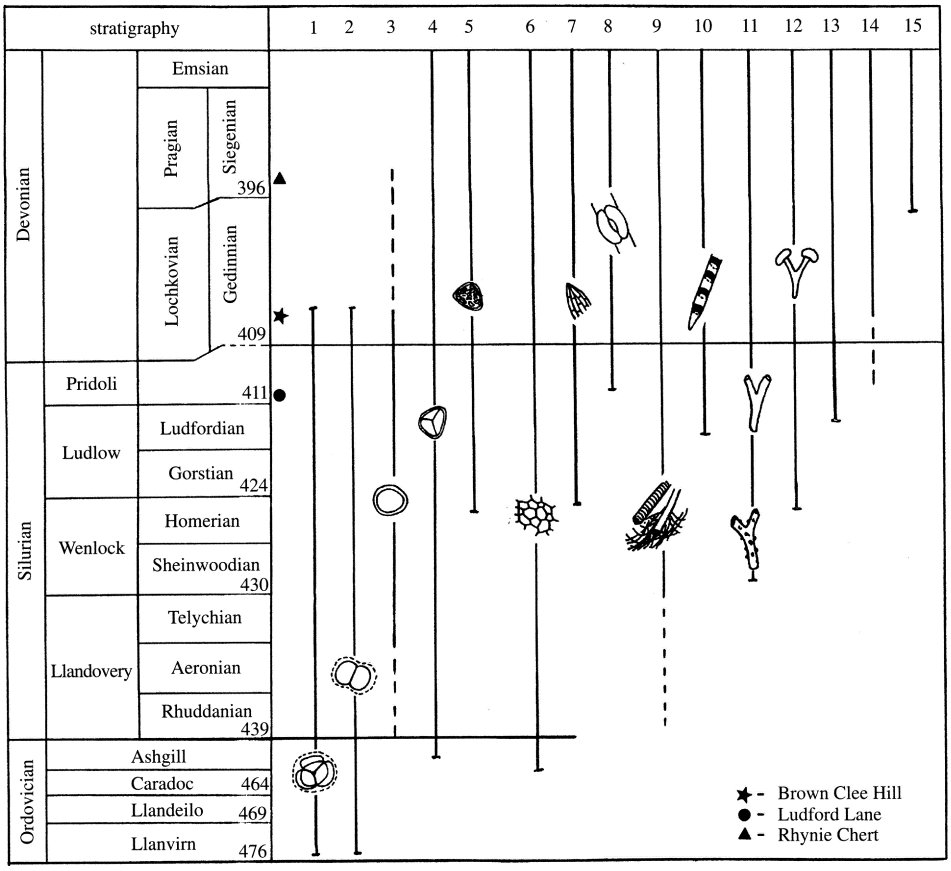

Fig. 1. Stratigraphic ranges of fossils. (1) Permanent (obligate) tetrads±envelope; (2) permanent dyads±envelopes; (3) hilate monads; (4) trilete laevigate monads; (5) ornamented trilete monads; (6) cuticular sheets (cf. *Nematothallus*); (7) sporangial cuticles; (8) stomata; (9) associations of tubes, solid line only indicates presence of banded tubes; (10) tracheids; (11) bifurcating axes of tracheophyte type; (12) *Cooksonia*/ Rhyniopsida; (13) Lycophytina sensu lato; (14) zosterophylls; (15) Trimerophytina. Redrawn from Edwards (2000) with permission.

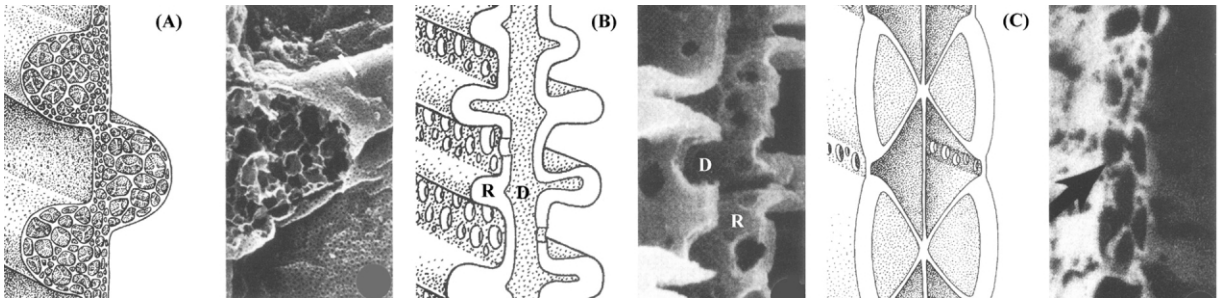

Fig. 2. The three major types of early tracheids. (A) Left: drawing of the wall of an S-type water-conducting cell showing the wall thickenings with a spongy (alveolate) structure and a thin microporate surface on the lumen face of the tracheid; right: SEM of a single gyre from a S-type cell of *Sennicaulis*, a member of the Rhyniopsida. (B) Left: drawing of the wall of a G-type water-conducting cell showing the wall thickenings that lack material in the core and holes in the surface of the lumen face of the tracheid; right: SEM of a portion of a G-type cell of *Gosslingia*, a member of the Lycophytina. (C) Left: drawing of the wall of a P-type water-conducting cell showing the wall thickenings that lack material in the core and continuity of the wall material that overlies the pits and has holes; right: SEM of a portion of a P-type cell of *Psilophyton*, a member of the Euphyllophytina. R = resistant, D = degradation prone. Reproduced from Friedman and Cook (2000) with permission.

Present day vascular cryptograms, of course, resemble the G, P and S type tracheids in that they possess only a very faintly lignified core at the base of their secondary wall thickenings (Bierhorst, 1958, 1960). Indeed, Friedman and Cook (Cook and Friedman, 1998; Friedman and Cook, 2000) have compared the cell walls of the extant lycopod Huperzia with those of the early fossil tracheids. Following deposition of the primary wall in Huperzia, a secondary wall is laid down as a "template" followed by a (lignified?) degradation-resistant layer. Although much remains to be established regarding secondary cell wall formation in primitive vascular plants it

is clear that the basic cell type, the tracheary elements, have been substantially modified through vascular plant evolution and coincided with the emergence of other vascular cell types.

Realization of the heterogeneity of cell types in vascular tissues dates from Antoni van Leeuwenhoek's (1673-1696) initial observations and led to the recognition of vessels in addition to tracheids and fiber cells. A large body of work resulted in the identification of "Baileyan trends". In this analysis, cryptograms are regarded as the most primitive with long tracheary elements with gymnosperms of an intermediate length. By contrast, angiosperms with their shorter tracheids and vessels are regarded as the most advanced. Germane to this advance must be the presence of vessels, currently defined as cells with pit perforations at the end walls.

In summary the evolution of woody plants occurred through stages of vesselless long tracheids, through intermediate stages of scalariform perforated and pitted vessels to arrive at woody plants with short, simply perforated, alternatively pitted vessels and libriform fibers. Vessels conferred the advantage in being more efficient conductors of water. These changes are summarized in Table 1 which shows the changes in wood anatomical features from the Cretaceous to the present. The vessel is thought to have appeared about 140 million years ago (Aloni et al., 2000). According to Bailey (1953) and Cheadle (1953), two lines of evolution occurred towards fibers or vessels. Vessels were thought to have arisen independently in lycopods, ferns, gymnosperms, monocotyledons and dicotyledons and arose several times independently in some of these groups, particularly the dicots. This is supported by more recent analysis of the fossil record (Wheeler and Baas, 1991) which concludes vessel evolution occurred in marked changes especially between the Cretaceous and Tertiary, whereas evolution in ray composition, storied structure and parenchymal patterns occurred very gradually.

7. Conclusions

It is obvious that considerations of evolution can tell us much about modern wood as it is a product of the

Table 1
Incidence (in percentages) of various wood anatomical features in extant families of different geological age according to their fossil pollen record, compared with character frequency in the extant woody flora of the world by families and genera (Baas, 1982)

process. However, it also teaches us that there is a variability to be explored in woody species but warns us that our analysis of the effects of manipulation cannot be simple chemical analysis to show what has been changed. It must take into account cell types and the structure of the cell wall layers as exemplified by the study of Ruel et al. (2001).

Abstract

Cell wall polysaccharides are some of the most complex biopolymers known, and yet their functions remain largely mysterious. Advances in imaging methods permit direct visualisation of the molecular architecture of cell walls and the modifications that occur to polymers during growth and development. To address the structural and functional relationships of individual cell wall components, we need to better characterise a broad range of structural and architectural alterations in cell walls, appearing as a consequence of developmental regulation, environmental adaptation or genetic modification. We have developed a rapid method to screen large numbers of plants for a broad range of cell wall phenotypes using Fourier transform infrared microspectroscopy and Principal Component Analysis. We are using model systems to uncover the genes that encode some of the cell-wall-related biosynthetic and hydrolytic enzymes, and structural proteins. © 2001 Elsevier Science Ltd. 1. Introduction

The plant cell wall is a highly organized composite of many different polysaccharides, proteins, and aromatic substances that undergo dynamic changes during cell division, expansion and differentiation (McCann and Roberts, 1991, Carpita and Gibeaut, 1993). However, it has been difficult to ascribe specific functions to these molecules. Molecules of the cell wall must provide mechanical strength, regulate porosity, and control cell-cell adhesion. The functions of the wall are not only mechanical, but also biological. Like the animal extracellular matrix, plant cell walls are a source of signalling molecules that elicit a range of cell behaviours, such as in response to pathogen invasion. Built largely from polysaccharides, the components of the wall are subject to many modifications between the processes of gene expression and assembly in the apoplast. Glycoproteins and polysaccharides are assembled in the Golgi apparatus, enter the secretory pathway in vesicles that release their contents into the apoplast, where cell–wall enzymes act upon their substrates and incorporate them into precise architectures. The current field of cell wall research must encompass the signal transduction mechanisms that result in up- or down-regulation of the

genes that encode biosynthetic and wall-modifying enzymes, the transcription and translation of those genes, the synthesis of wall polysaccharides by those gene products, and the assembly of the components of the wall into a functional architecture that responds during growth and differentiation to the changing needs of the cell and transmits information back to the protoplast. Such a goal requires both broad and directed views to address the specifics of function. In this paper, we discuss three approaches to characterising cell wall architecture: imaging techniques that probe the location of specific molecules; screening for variation in architecture using IR spectroscopy, and identifying differentially-expressed genes in a model system in which wall synthesis and deposition are the key events.

2. Results and discussion

2.1. Imaging the compositional diversity of walls at the single cell level

The fast-freeze rotary-shadow replica technique has previously been used to directly visualise cell-wall architecture of dicotyledonous species (McCann et al., 1990; Fujino et al., 2000). The images obtained are thought to preserve the native architecture of cell walls, and many thin cross-linking fibres are visible as well as cellulosic microfibrils. In dicots, these cross-linking glycans are xyloglucans — they have a glucan backbone that can hydrogen bond to the surface of cellulose microfibrils and are decorated with xylose-containing side-chains. Xyloglucans are long enough to link two or more microfibrils together to form a network. This network is embedded in a second independent but coextensive network of pectins, the most variable and complex component of the wall. Pectins are loosely defined as polymers rich in galacturonic acid and their associated side-chains, and comprise 20–50% of the wall. Homogalacturonans (HGAs) are long polymers of galacturonic acids that can be methyl-esterified. If methyl groups are removed, then calcium can bind to the carboxylate ions of the galacturonic acid to cross-link them (Goldberg et al., 1996). Some pectins called rhamnogalacturonan I (RGI) are built from a backbone of alternating rhamnose and galacturonic acid residues and carry side-chains of arabinans and galactans.

Dissection of a particular cell type at a specific developmental stage is seldom practical for chemical analysis, which requires microgram to milligram quantities of material. Thus, traditional methods of biochemistry average out the intrinsic heterogeneity of plant tissues (McCann et al., 1997). Two approaches offer the opportunity to analyse wall composition at the single cell level — the use of probes such as antibodies (Knox, 1997), and Fourier transform infrared (FTIR) microspectroscopy (McCann et al., 1997).

Longitudinal and transverse sections of plant stems, roots, or leaves, provide a developmental snapshot of cell growth and differentiation. In the light microscope, the use of probes, such as monoclonal antibodies coupled to fluorescent markers, has revealed the tissue-specific distributions of particular cell components in transverse sections of plant materials (Knox, 1997), whilst longitudinal sections reveal developmental regulation of those components. This is illustrated in Fig. 1 using monoclonal antibodies as designer stains for molecules of the pectin network in potato tubers. Reflectance confocal laser scanning microscopy (RCLSM) allows pectins to be localised to different domains within a wall, even at the light microscope level, by silver enhancement of immuno-gold-labelled tissue and imaging in the confocal microscope (Bush and McCann, 1999). Methyl-esterified pectin is present throughout the walls of parenchymal cells, the galactan side-chains of RGI are next to the plasma membrane but excluded from the middle lamella region that sticks two cells together, and the calcium cross-linked junction zones are localised to the cell corners (Fig. 1a–c). Different tissues contain combinations of different pectic epitopes. Fig. 1d and e shows that parenchymal cells contain both arabinans and galactans, whilst the vascular cells contain arabinans but very little galactan. In the potato stolon, developmental patterns rather than tissue specificity is marked by the presence of arabinan in all of the tissues from the tip to the hook of the stolon, and then calcium pectate and also galactans in all of the tissues beyond the hook (Bush et al., 2001).

Although antibodies are powerful tools, their availability is confined to a small number of wall epitopes and is not comprehensive of the structural complexity of the wall. An alternative technology, called chemical imaging, is becoming available, which combines spatial information with chemical information deduced from relative IR absorbances. In the IR spectrometer, a source emits radiation with a range of frequencies which is then passed through the sample. Particular chemical bonds in the sample absorb radiation of specific frequencies from the beam, and this is plotted as an absorbance spectrum against frequency. IR spectroscopy simultaneously reveals the type, distribution and relative abundances of chemical components within a particular system. However, a single IR spectrum also contains information about the molecular structure and intermolecular interactions among the individual sample components (McCann et al., 1992, 1997). A microscope accessory can be attached such that the infrared beam from the spectrometer is diverted to pass through a sample placed on the microscope stage. The sample can be imaged with visible light and apertures used to restrict the area of sample from which IR spectroscopic data are to be obtained. Therefore, determining the presence and distribution of the chemical constituents within a sample

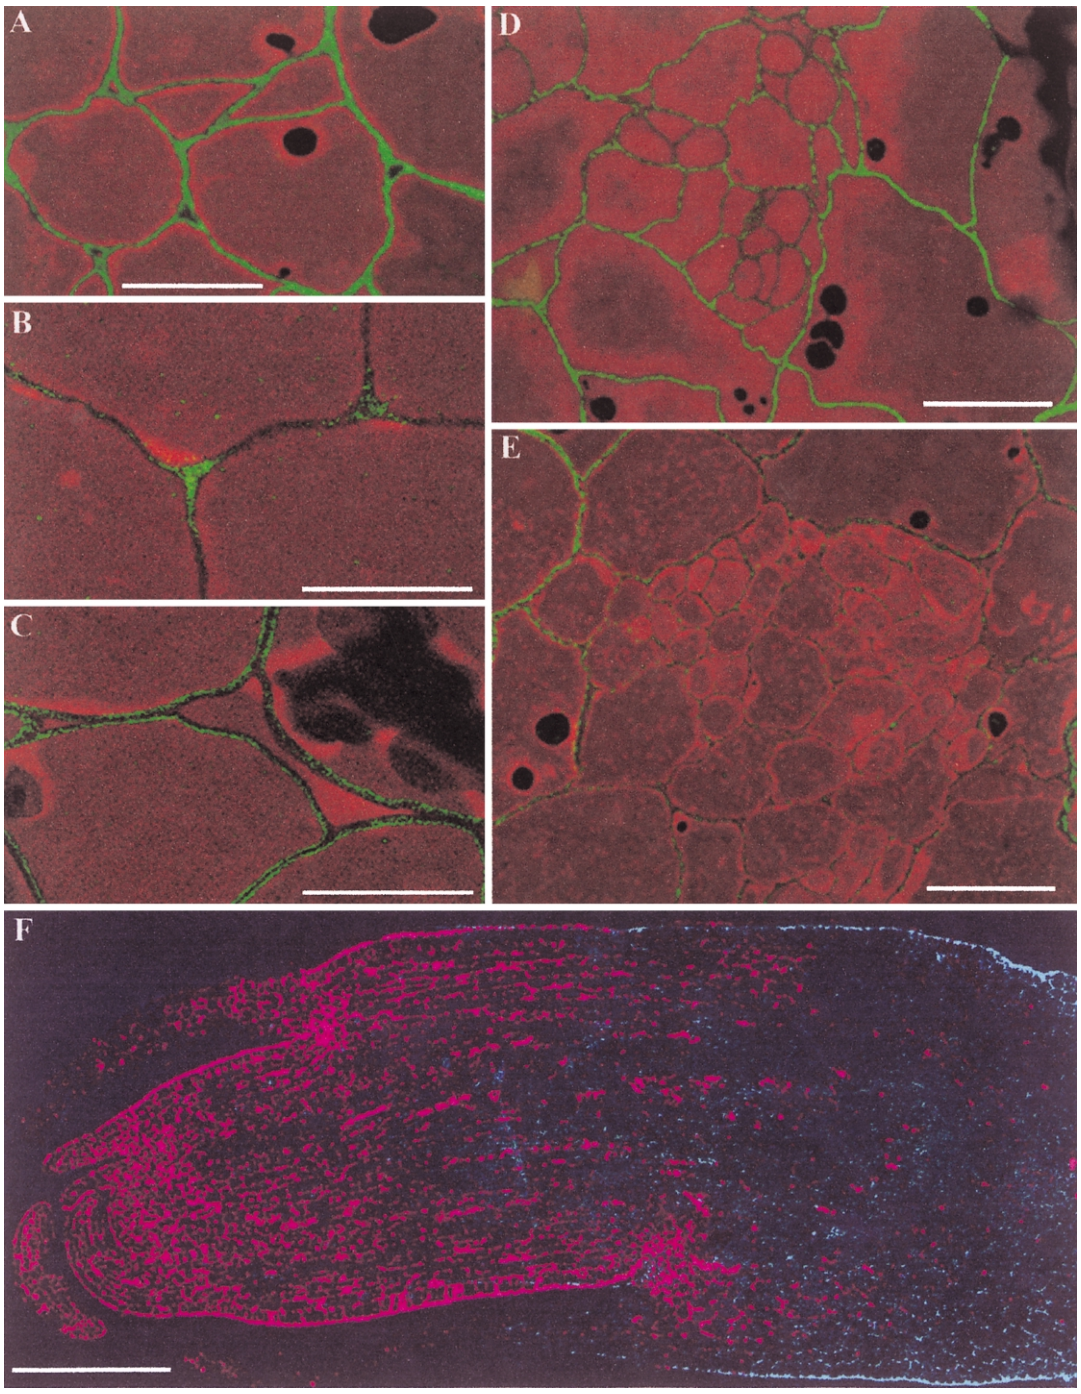

Fig. 1. Potato tuber sections of perimedullary tissue gold-labelled with mAbs (A) JIM 7, (B) 2F4 and (C) LM5 then silver-enhanced and viewed by reflectance confocal microscopy. (A) Methyl-esterified pectic epitopes are throughout the wall, (B) calcium pectate is localised to cell corners, and (C) galactans are present in a region close to the plasma membrane but excluded from the cell corners and middle lamellae. Vascular tissues are labelled with mAb LM6 (D) but label lightly with mAb LM5 (E), indicating the presence of arabinan but very few galactan side-chains of RG1 in these tissues. (F) Longitudinal section of a stolon tip labelled with mAbs 2F4 (blue) and LM6 (pink). The 2F4 epitope is only detected in walls from more proximal regions of the stolon, where it is concentrated in the epidermal and cortical walls. In contrast the LM6 arabinan epitope is localised to walls of young cells at the stolon tip. Scale bars for A, B, C, D, and E represent 20 μm, bar F is 0.5 mm.

depends only on the intrinsic spectral characteristics of the sample, and not on the addition of fluorescent tags or stains. The synergy of what have traditionally been two distinct methods for studying the chemistry and morphology of a sample, IR spectroscopy and optical microscopy, is called chemical imaging.

Current IR microscopes work in two modes. The first mode is single spectrum collection in which data are

collected from a region of the sample as small as 10×10 μm. This is accomplished by limiting the area of a sample illuminated by adjusting an aperture located at a remote image plane. During this process the size of the IR beam focus remains fixed as does the detector area. The maximum size from which a spectrum can be collected is 100×100 μm, which is the size of the detector area. When the smallest usable aperture of 10×10 μm is employed only a fraction of the detector area is illuminated. This small fraction of the detector generates the signal whilst the entire detector area generates noise. Consequently the spectroscopic performance falls dramatically with the size of aperture used.

The second mode of operation is mapping (McCann et al., 1997). In this mode the sample is moved under computer control such that different areas of the sample are measured in turn. Eventually an array of spectra is generated. These spectra can be correlated with visual images of the sample so that optically observed features can be associated with functional groups. While contrast in MRI images is determined by differences in the NMR spectrum of the sample components, contrast in IR spectroscopic imaging is determined by differences in the vibrational spectral response. It is possible to generate a contour plot (map) of the distribution of functional groups within a sample, using colour to represent absorbance intensities.

A 3-day-old maize coleoptile was sectioned transversely by hand, cleared of its soluble material and mounted on a barium fluoride window for chemical imaging. Mapping software allowed the collection of 273 individual FTIR spectra with an aperture size of 25×25 μm in an array encompassing epidermal, vascular and mesophyll cells from a transverse section of one-quarter of the coleoptile (Fig. 2a). The spectra in the data set were first area-normalised to compensate for any changes in thickness across the section. Peaks corresponding to phenolic esters (1720 cm^{-1}) or to methyl esters (1740 cm^{-1}) were enriched in the vascular bundle, and slightly enhanced in the outer epidermis (Fig. 2b, c). A peak corresponding to phenolic ring absorbance (1515 cm^{-1}) is enriched in the vascular tissue, and is decreased in the inner epidermis (Fig. 2d). The chemical images thus indicate some differences between the inner and outer epidermis. Absorbances at 1000 and 1020 cm^{-1} are enriched in the mesophyll layer (Fig. 2e, f), whilst absorbances at 1090 and 1034 cm^{-1} are enriched in the epidermal tissues (Fig. 2g, h). These latter two absorbances are potentially diagnostic for the presence of glucomannans (Kacuràková et al., 2000). These data demonstrate the ability of chemical imaging to localise different chemical species to specific cell types and the large heterogeneities in wall composition within the maize coleoptile. A new generation of instruments are becoming available that combine an IR microscope with focal plane array detector. These devices collect spectra simultaneously from all points in a field of view, reducing collection times for equivalent samples from a few hours to a few minutes.

2.2. Detecting cell walls of altered composition

Why cell walls are structurally complex seems obvious — cell walls must function in cell–cell adhesion, signal transduction both cell-to-cell and environment-to-cell, cell division, growth and differentiation, but how the molecular machinery of the wall is assembled and later modified to carry out those functions is still unknown. By studying cell walls with altered compositions, either as a consequence of developmental regulation, environmental adaptation, or genetic modification, we can assess the effect of such modifications on cell wall properties and on plant development. The selection of mutant plants with altered cell wall compositions and architectures is particularly useful because of the wide range of potential modifications and the possibility of uncovering novel genes that encode enzymes that participate in biosynthetic pathways, wall assembly, or in modifications to polymers in muro (Reiter, 1998). Mutants with altered cellulose deposition have been identified directly by birefringence (Potikha and Delmer, 1995). Other cell-wall mutations have appeared serendipitously in the course of screens for developmental phenotypes, such as a temperature-sensitive radial cell swelling mutant that was cellulose-deficient (Baskin et al., 1992, Arioli et al., 1998) or a collapsed xylem phenotype (Turner and Somerville, 1997).

Mutations in non-cellulosic polysaccharides may not always have visually abnormal or otherwise predictable phenotypes, and, hence, a general method is necessary to select for a broad range of potential modifications. One method that has been successfully applied is to screen directly for neutral sugars of cell-wall polymers that are over- or under-represented when compared with their distribution in the walls of a wild-type population (Reiter et al., 1997). This screen employs derivatisation of the cell-wall non-cellulosic sugars from leaves to alditol acetates, with subsequent quantitation by gas–liquid chromatography. Sugar composition can be assayed with great precision by this method, but the large numbers of plants involved in a mutant screen make it labour-intensive. FTIR microspectroscopy is an extremely rapid, non-invasive vibrational spectroscopic method that can quantitatively detect a range of functional groups including carboxylic esters, phenolic esters, protein amides and carboxylic acids, and can provide a complex "fingerprint" of carbohydrate constituents and their organization (McCann et al., 1992, 1997; Séné et al., 1994). The time taken to acquire a spectrum of a sample is roughly 30 s. It is non-destructive and does not require derivatization of the sample, so further assays can be applied to the same sample once potential mutants are identified.

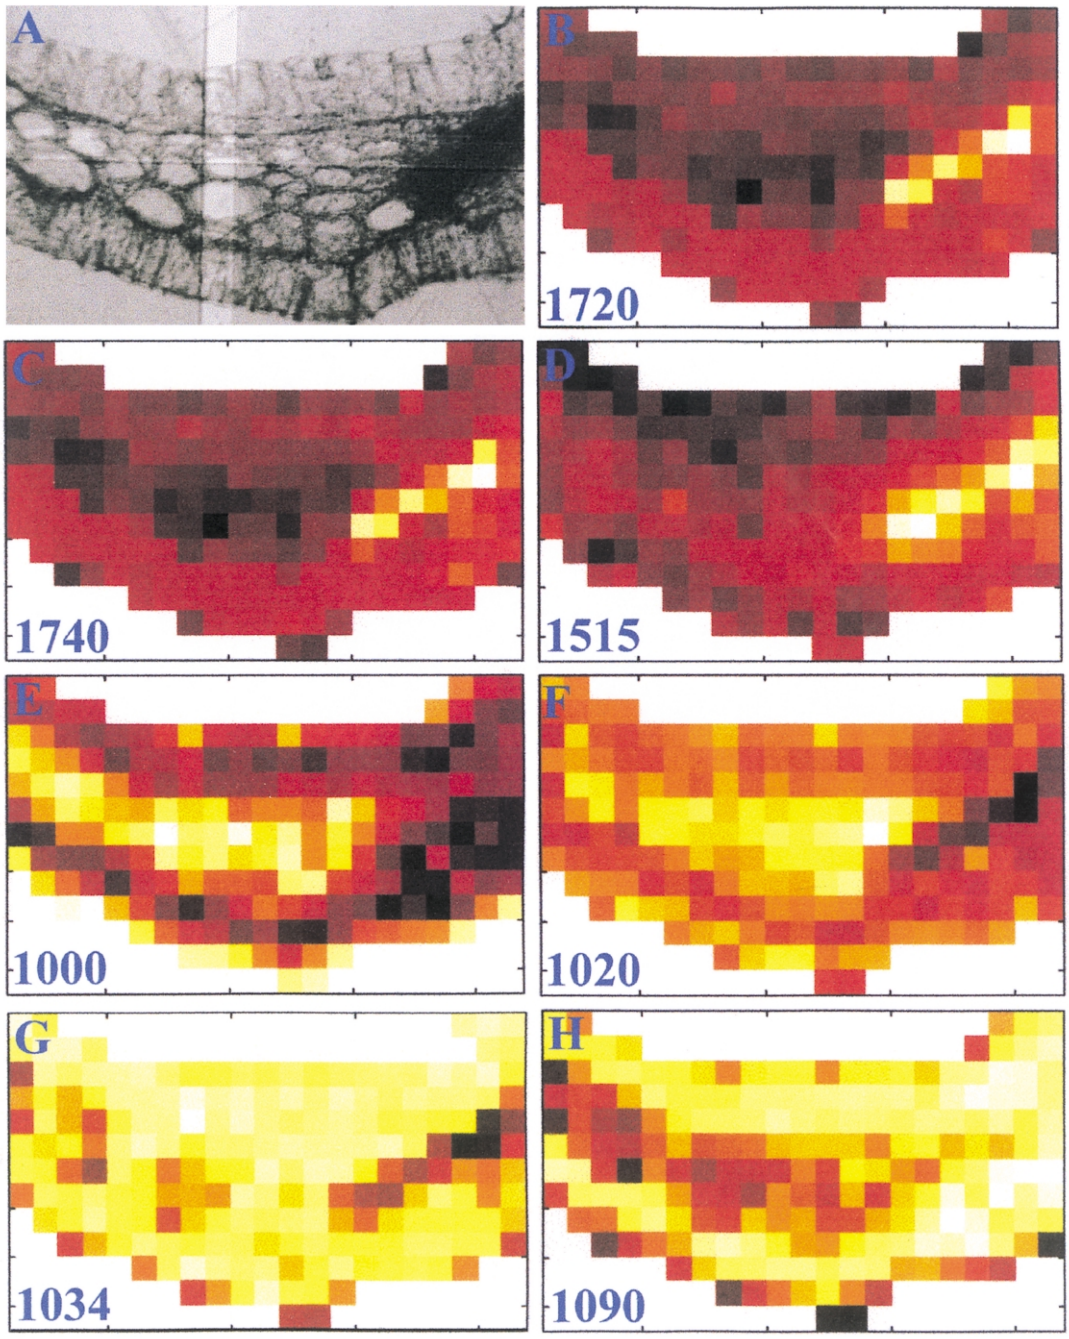

Fig. 2. Chemical images of a transverse section of 3-day-old maize coleoptile derived from FTIR spectra sampled with a 25×25 μm window. (A) Brightfield micrograph of the coleoptile section using mirror optics in the IR microscope. An example of the area from which IR data is sampled is delimited by a pair of transparent double-bladed apertures. (B) Phenolic esters of uronic acids sampled at 1720 cm^{-1}. (C) Carboxyl esters sampled at 1740 cm^{-1}. (D) Aromatic substances sampled at 1515 cm^{-1}. (E) Absorbance intensity at 1000 cm^{-1}. (F) Absorbance intensity at 1020 cm^{-1}. (G, H) Absorbances at 1034 and 1090 cm^{-1}, respectively, characteristic of glucomannan.

The effective analysis of large data sets of spectra is complex and the use of multivariate data reduction techniques (Massart et al., 1988) is now standard practice for many applications. Spectra are not analog, but are constructed from data points collected at intervals of 8 cm^{-1}. Principal component analysis (PCA) is a widely-used mathematical technique that is used to reduce the dimensionality of the data from the several hundred data points in the original spectra to a fewer number of dimensions (Kemsley, 1998). The variability in each individual spectrum relative to the mean of the population can then be represented as a smaller set of values (axes) termed principal components (see Fig. 3). The effect of this process is to concentrate the sources of

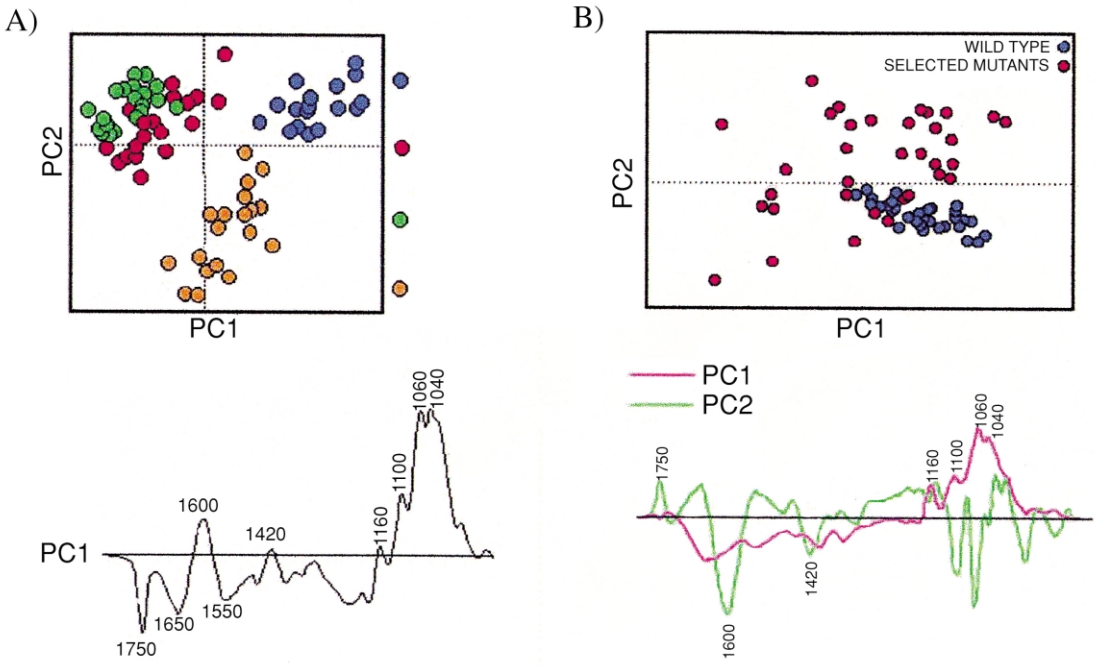

Fig. 3. Exploratory PCA of IR spectra sampled from populations of *Arabidopsis* hypocotyls. (A) Relative cellulose content of populations can be estimated from their scores on PC1, a loading with characteristic features of cellulose (Liang and Marchessault, 1959). Peaks associated with pectin are negatively correlated in the loading. The *rsw1* mutants discriminate on PC2 probably because they are in a different ecotype background. (B) Some dwarf hypocotyl mutants can be discriminated from wild-type on the basis of two principal components, PC1 has features of cellulose (Liang and Marchessault, 1959) whilst PC2 shows features of pectin (Sene et al., 1994).

variability in the data into the first few PCs. Plots of the so-called PC scores (projection on to PC axes) against one another can reveal clustering or structure in the data set.

We established and validated a model that can discriminate between the leaves of wild-type and a previously defined set of cell-wall mutants of *Arabidopsis*. Exploratory PCA indicated that mutants deficient in different cell-wall sugars are distinguished from each other (Chen et al., 1998). We have also used IR microspectroscopy to screen a population of hypocotyl mutants for alterations in their cell walls. The *Arabidopsis* hypocotyl mutants were selected from seedlings that are dwarf when dark-grown, and thus affected in cell elongation (Gendreau et al., 1997). The hypocotyl is laid down by a set of programmed cell divisions during early embryogenesis. Post-embryogenic growth of this organ involves no further cell divisions and so separates the events of cell division from those of cell expansion.

From a pre-selected sample of 40 dwarf mutants, PCA shows that both pectic (Sene et al., 1994) and cellulosic (Liang and Marchessault, 1959) features in the FTIR spectra can be used to discriminate mutants from a population of wild-type (Fig. 3). The wild-type population shows that a tight ratio exists under normal growth conditions, but this proportionality is disrupted in the mutants. PCA also revealed a dose-dependent reduction in cellulose content within hypocotyls treated with increasing concentrations of dichlorobenzonitrile (DCB), an inhibitor of cellulose synthesis. Cellulose deficiency was also detected in hypocotyl cell walls of *rsw1*, a temperature-sensitive mutant when grown at the restrictive temperature for a gene encoding the catalytic subunit of cellulose synthase (Arioli et al., 1998). The *kor* mutation (*korrigan*) is a mutation in a gene encoding an endo-glucanase (Nicol et al., 1998). Analysis of FTIR spectra of *rsw1*, *kor*, and DCB-treated seedlings showed that cellulose deficiency was invariably associated with an increased pectin content (Fig. 3). These observations are consistent with earlier results using suspension-cultured cells of tomato adapted to growth on DCB which make a pectin-rich wall that virtually lacks a cellulose-xyloglucan network (Shedletzky et al., 1990). The formation of one network has been prevented, while the other is still able to provide a cell wall with at least some of its usual functions.

Transgenic materials in which cell-wall-related genes have been up- or down-regulated provide a useful complement to mutants. We are also studying transgenic potato tubers in which fungal cell-wall enzymes have been over-expressed in a tuber-specific manner as a means to valorise the waste from starch production (Vincken et al., 2000). Removal of galactans by apoplastic expression of a fungal galactanase resulted in normal tuber development (Oxenbøll-Sørensen et al., 2000). We used PCA of IR spectra to screen a number

of transgenic lines, and selected one line that can be distinguished from the relevant control because of changes in pectic characteristics (Fig. 4a). Immuno-gold labelling confirmed that this line indeed had a greatly reduced galactan content (Fig. 4b–e).

2.3. Expression profiling — a molecular approach to identify genes that encode cell-wall related proteins

The wall contains structural proteins as well as hundreds of different cell-wall enzymes, and polysaccharides are the

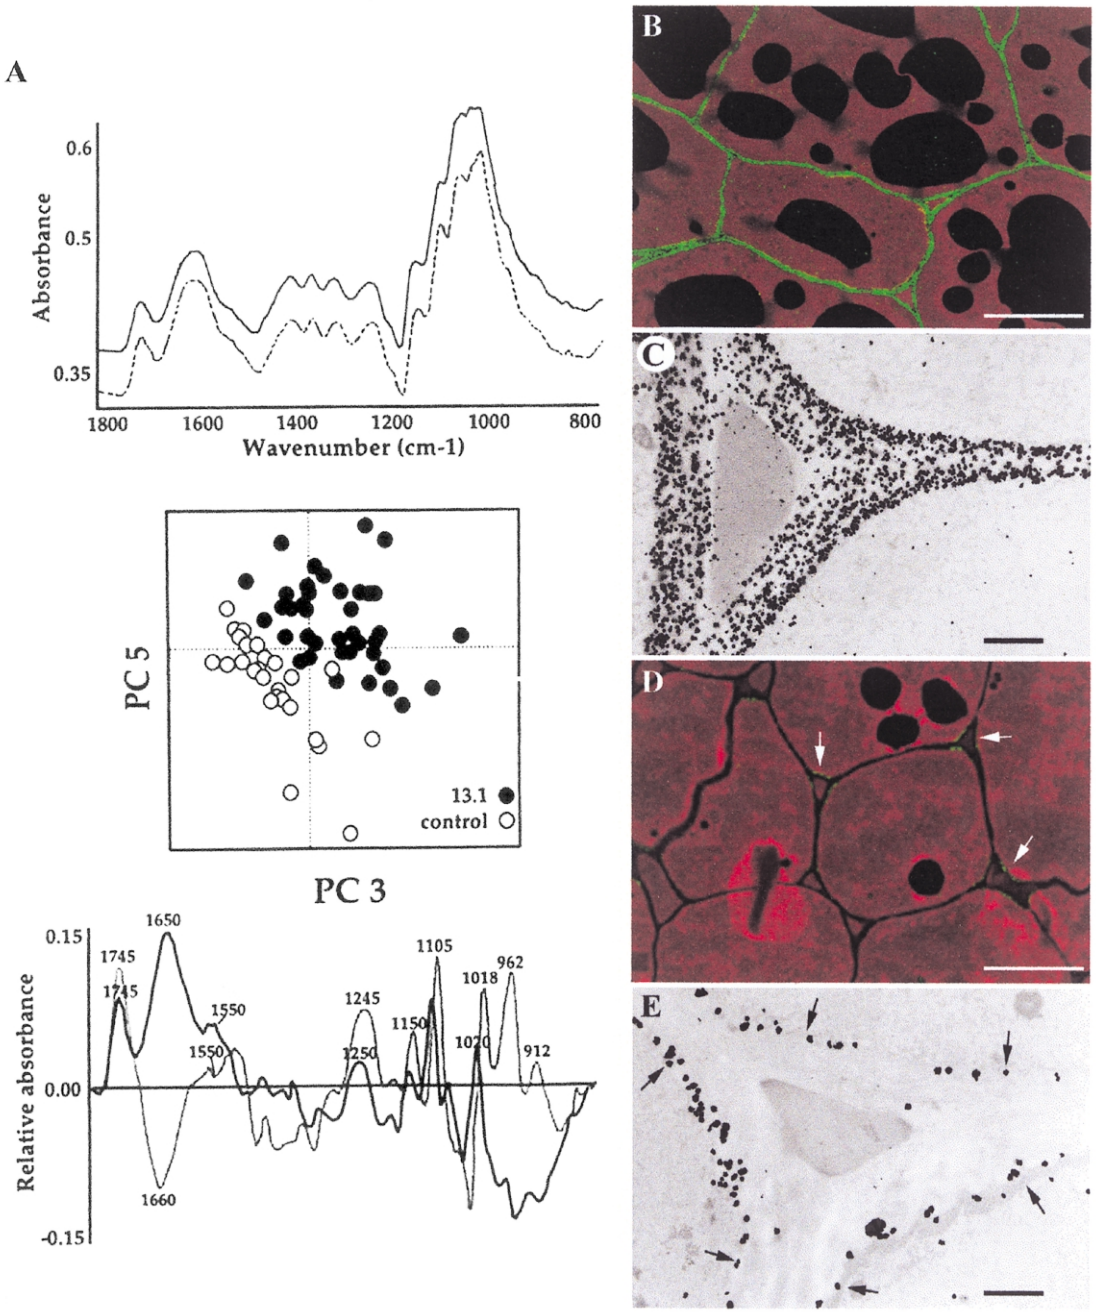

Fig. 4. (A) Top: averaged FTIR spectra of potato tuber cortex from 20 wild-type tubers (solid line) and 20 transgenic tubers (dashed line) over-expressing a fungal galactanase targetted to the apoplast. Middle. Exploratory PCA discriminates the transgenic population from the wild type, using the third and fifth PC scores. The loadings for PC3 (black line) and PC5 (gray line) show features characteristic of pectins at 1745, 1250, 1150, 1105 and 1018 cm^{-1}. Sections of wild-type tuber gold-labeled with mAb LM5, that recognises a galactan epitope, and imaged by RCLSM (B) and in the TEM (C), and equivalent of the galactanase transformant (D, E). The walls of wild-type parenchymal cells are strongly labelled (green in A, black particles in B) whereas in the transformant, the labelling density is greatly reduced and localised only to some cell corners (arrows) close to the plasma membrane. Scale bars represent 100 μm for RCLSM images and 2 μm for electron micrographs.

products of biosynthetic enzymes. The genes that encode these classes of cell-wall-related proteins belong to large multi-gene families. Much work remains to be done to elucidate the functions of the different family members, and to identify cell-wall-related genes without sequence identities. We are using a model system in which synthesis and deposition of cell wall is the main event, to identify cell-wall-related genes involved specifically in xylogenesis.

The construction of a tracheid or xylem element involves deposition of thick reinforcing hoops of secondary cell wall, waterproofing it with lignin followed by autolysis of the cell contents. In a plant, only a few cells are in the process of forming xylem, but we can study this entire developmental pathway in vitro using the *Zinnia* mesophyll cell system originally developed by Fukuda and Komamine (1980). In our laboratory, the *Zinnia* system consists of mesophyll and palisade cells isolated from the leaves of *Zinnia elegans* cv. Envy that are put into liquid culture and supplied with two plant growth factors, auxin and cytokinin, after 48 h (McCann et al., 2000). In a further 48 h, over half of the living cells have synchronously undergone trans-differentiation, making it possible to precisely stage the events involved in building a TE. Thus, one cell type can be reproducibly and synchronously switched, with known external signals, into a different cell type.

We have recently applied a novel RNA finger-printing technology, cDNA-AFLP (Bachem et al., 1996, Durrant et al., 2000), that allowed the detection of differentially-regulated genes across the time-course of xylo genesis. cDNAs are synthesized from mRNA populations isolated from the *Zinnia* cultures at five time-points, digested with a pair of restriction enzymes, adaptor-ligated and amplified by PCR to produce the primary template. A subset of this population of fragments is selectively amplified using primers with two selective nucleotides, and then analysed on polyacrylamide gels. Over 600 genes, whose transcription show overt changes in abundance over time, have been selected and partial sequences obtained. These sequences were then compared with databases from the plant and animal genome sequencing projects, allowing an identity to be assigned to about half of the predicted gene products, including about 10% that encode cell wall biosynthetic enzymes, hydrolytic enzymes or structural proteins (manuscript in preparation).

The deposition of hoops of secondary wall material occurs at 90–96 h of culture (between 42 and 48 h after

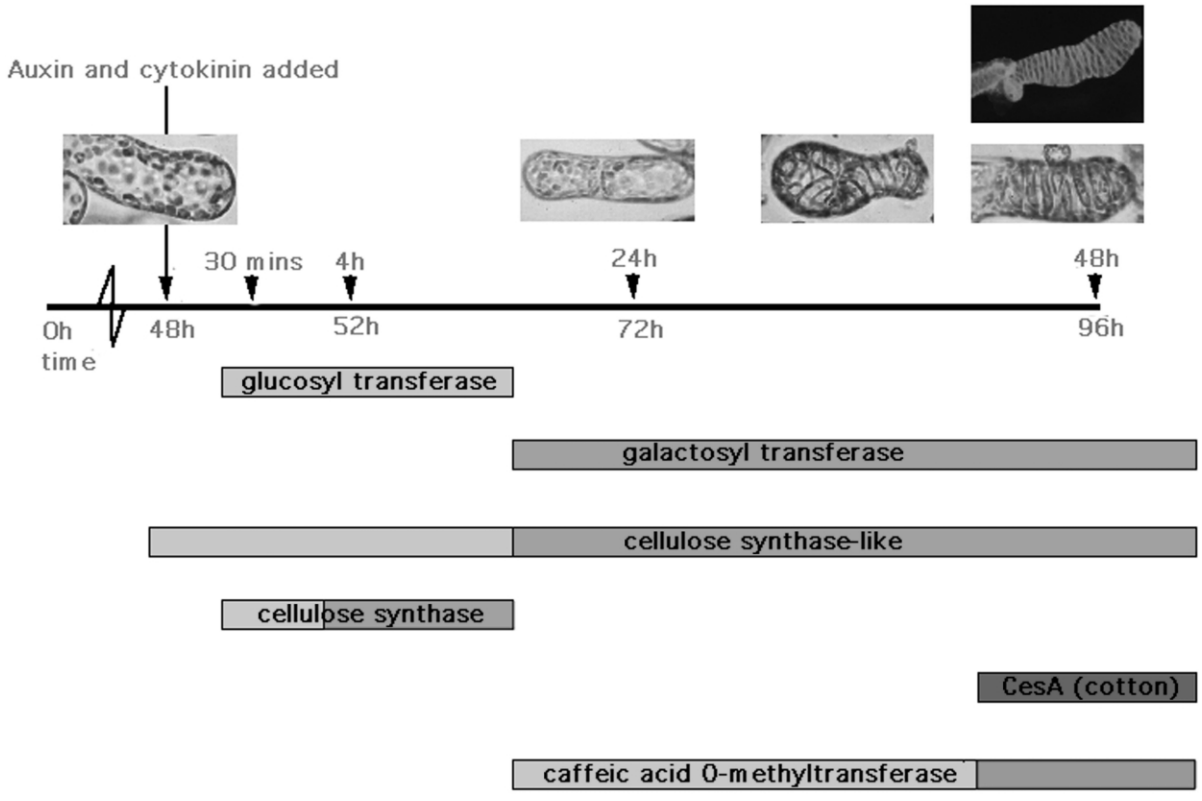

Fig. 5. Time course of the trans-differentiation of isolated *Zinnia* mesophyll cells to tracheary elements and the expression patterns of six cell wall biosynthetic genes identified so far by the cDNA-AFLP screen. Micrographs, left to right. (1) A palisade parenchyma cell appears unchanged after 48 h in liquid culture without TE-inducing growth factors. Auxin and cytokinin are added at 48 h, and RNA is extracted at this time and then 30 min, 4 h, 24 h and 48 h later. (2) At the 16 h point after induction, the chloroplasts move to the cell edges, and most of the cells have divided. (3) By 42 h after induction, the secondary wall thickenings have been deposited. (4) By 48 h after induction, the thickenings become lignified, and can be stained with phloroglucinol (above). Shading intensities of the bars indicate relative abundance of the cDNA-AFLP fragment in the gel.

addition of auxin and cytokinin). We have over 50 partial sequences of cell-wall related genes, many of which are hydrolytic enzymes (Milioni et al., 2001). Fig. 5 shows the expression patterns of six of the sequences that encode biosynthetic enzymes. A cellulose synthase is up-regulated early, perhaps simply induced by auxin, and a late-expressed cellulose synthase has high sequence identities with an Arabidopsis sequence (AB006703), the cotton cellulose synthase that is expressed in differentiating cotton fibers (Holland et al., 2000), and with a xylem-specific cellulose synthase gene from aspen (Wu et al., 2000). There are two sugar transferases for adding sugars to non-cellulosic polymers and a cellulose-synthase-like gene, which may encode a biosynthetic enzyme making a different polymer backbone. The enzyme caffeic acid *O*-methyltransferase from the lignin biosynthetic pathway is also expressed. About 40% of our sequences are unknowns — either hypothetical proteins in the *Arabidopsis* database or not represented in any of the plant or animal databases. As known genes encoding cell wall-related proteins comprise about 10% of our 600 sequences, then there may be further 30 sequences that represent cell-wall-related proteins of totally unknown function.

3. Conclusion

Genetically-defined variation through mutant approaches or transgenic technologies offers the best opportunity to identify a broad range of structural and architectural alterations in cell walls, leading to improved understanding of plant cell growth and differentiation. Gene discovery in the *Zinnia* system will have relevance for many commercially important tree species. By defining the key structural components in *Arabidopsis*, there is the opportunity to define wall properties in which variation is economically desirable include the length, substitution, and cross-linking of pectic polysaccharides, the relative levels of cellulose, the length and mechanical properties of fibres, the relative allocation of carbon to wall biomass, the regulation of cell–cell adhesion, wall-based growth control, and lignin composition, architecture, distribution and amount.

4. Experimental

4.1. Tissue preparation for immunocytochemistry

Elongating stolons and mature tubers were cut from mature *Solanum tuberosum* (L.) plants (cv. Karnico) and immersed in 2.5% (v/v) glutaraldehyde (EM grade) in 0.05 M sodium cacodylate containing 0.05% (v/v) NP-40 (Sigma, Poole, UK). All of the samples were processed for low temperature L.R. White resin embedding as described previously (Bush and McCann, 1999).

4.2. Immunogold labelling

Blocks of tissue were sectioned: 0.5-μm thick resin sections were collected on multi-well glass slides for light microscopy and ultrathin sections for electron microscopy were collected on Formvar-carbon coated gold grids. The sections were labelled as described previously (Bush and McCann, 1999), with mAbs that recognise the following pectic epitopes; JIM 7, $\geqslant$35% methyl-esterified homogalacturonan (Knox et al., 1990); 2F4, a calcium-dependent conformational epitope of at least nine contiguous galacturonic acid residues (Liners et al., 1989); LM5, (1→4)-β-D-galactan (Jones et al., 1997); LM6, (1→5)-α-L-arabinan (Willats et al., 1998). After three 10 min washes in phosphate-buffered saline (PBS) the sections were incubated with 5 nm gold conjugates (British BioCell International) overnight at 4°C. Sections were washed in PBS again, fixed in 1% (v/v) glutaraldehyde, and finally rinsed thoroughly with distilled water prior to silver enhancement. Control sections were treated in parallel but with the omission of the primary mAb. Silver enhancement of 5 nm gold probes was performed for 2 min at 20°C for electron microscopy, but this was extended to 10–15 min for light microscopy; the BioCell silver enhancement kit (British BioCell International) was used according to the manufacturer's instructions.

4.3. Reflectance confocal laser scanning microsopy (RCLSM)

Gold-labelled and silver-enhanced 0.5 μm-thick resin sections were counter-stained with basic fuchsin and examined with a Leica TCS NT laser scanning confocal microscope, using an RT 30/70 mirror and excitation and emission wavelengths of 488 and $>$515 nm, respectively. Images of autofluorescence and epi-reflectance were recorded separately, and merged and processed with Adobe Photoshop 4.0. Ultrathin sections counter-stained with uranyl acetate and lead citrate were examined in a Jeol 1200EX transmission electron microscope.

4.4. FTIR microspectroscopy and chemical imaging

The Arabidopsis hypocotyls were placed on 2-mm thick×13-mm diameter barium fluoride windows, and the materials were air-dried at 37°C for about 1 h. The windows were supported on the stage of a UMA500 microscope accessory of a Bio-Rad FTS175c FTIR spectrometer equipped with a liquid nitrogen-cooled mercury cadmium telluride detector. An area of wall (100×100 μm) was selected for spectral collection in

transmission mode. One hundred and twenty-eight interferograms were collected with 8 cm^{-1} resolution and co-added to improve the signal-to-noise ratio for each sample. Three spectra were collected from different areas of each hypocotyl, avoiding the stele and then averaged and baseline-corrected.

For chemical imaging, transverse sections were hand-cut from 3-day-old maize coleoptiles that were frozen in a cryosectioning medium (Tissue-Tek, Agar UK). Sections about 50 μm thick were picked up onto barium fluoride windows. The sections adhering to the surface were then washed extensively with water to remove all traces of the sectioning medium. A small amount of the sectioning medium was also streaked across a barium fluoride window as a control. FTIR spectra were acquired with an aperture size of 25×25 μm from an array encompassing epidermal, vascular and mesophyll cells from transverse sections comprising about 25% of the coleoptile area.

4.5. Preparation of cell cultures

Seeds of *Zinnia elegans* c. Envy (Chiltern Seeds Ltd, UK) were germinated in a peat/sand potting compost in a controlled environment room at 20°C with a 16 h day. The first true leaves of 14-day-old plants were removed, surface-sterilised in 5% commercial NaOCl, and rinsed three times in sterile distilled water. Single cells were isolated by gently grinding the leaves in 0.2 M mannitol in a mortar and pestle. The suspension was filtered through two layers of muslin and washed three times in 0.2 M mannitol by spinning at 800 rpm for 2 min. Cells were resuspended in culture medium (Fukuda and Komamine, 1980) with no hormones (maintenance medium), or 1 mg l^{-1} BAP and 1 mg l^{-1} NAA (inductive medium). Cultures were maintained at 27°C in the dark, shaking at 80 rpm, with 3 ml of cell suspension per well in six-well plates (Sterilin, UK) at a density of 10^6 cells ml^{-1}. At 48 h, cells were transferred by pipetting media and cells from the wells in the six-well plates into 30-ml screw-cap tubes (Sterilin, UK), spinning the tubes at 800 rpm for 2 min, pouring off the supernatant and re-suspending the cells in new medium at the same cell density of 10^6 cells ml^{-1}.

4.6. cDNA-AFLP

Total RNA was extracted from *Zinnia* cells at different stages of in vitro TE formation, according to Shirzadegan et al. (1991). Poly(A^+) RNA was obtained by using magnetic oligo(dT)25 Dynabeads, according to the manufacturer's (DYNAL, UK) instructions. Synthesis of the first strand of cDNA was carried out with Expand Reverse Transcriptase (Boehringer Mannheim), as described by the manufacturer. The second strand cDNA synthesis was performed according to Gubler et al. (1983). cDNA-AFLP was performed according to Bachem et al. (1996) and Durrant et al. (2000). The AFLP products were analyzed on a 6% polyacrylamide denaturing gel, at constant power (90 W) until the bromophenol blue dye reached the bottom. Gels were dried under vacuum at 80°C and exposed to X-ray films (KODAK X-OMAT AR) for autoradiography.

4.7. Isolation of cDNA clones and sequence data analysis

The cDNA bands of interest were marked and the X-ray films were repositioned on the radioactive gels. The segments of interest were cut out with a surgical blade, eluted and re-amplified with the same primer set as used for the initial amplification. The re-amplified cDNAs were subcloned using the pGEM-T easy vector system (PROMEGA). For each re-amplified fragment, several independent *E. coli* colonies were selected and the inserted fragments were sequenced on an automated sequencer using the BigDye Terminator kit (Applied Biosystems). Each sequence was analyzed against the sequences in Genbank non-redundant and expressed sequence tag (EST) databases using the BlastN programme for nucleic acids and the BlastX programme for proteins at the NCBI web server (Altschul et al., 1997). Default parameters of the programmes were used in both cases.

Acknowledgements

We are grateful to Drs. J.P. Knox and P. Van Cutsem for their kind gifts of mAbs. We would like to thank Kate Kemsley for advice on using PCA and LDA, Grant Calder for assistance with the Leica confocal microscope, Sue Bunnewell for photographic assistance, and Dr. Jonathon Jones and Dr. Wendy Durrant for assistance and advice with the cDNA-AFLP screen. NJS, MD, GC, RHW and KR gratefully acknowledge the financial support of the BBSRC. DM is funded by an EU Marie Curie Fellowship, MB is funded by an EU network grant, PS is funded by a BBSRC special studentship, NCC is funded by a grant from the US National Science Foundation Genome Research Program, and MCM is funded by a Royal Society University Research Fellowship.

Received 10 July 2000; received in revised form 17 October 2000

Abstract

The synthesis of crystalline cellulose microfibrils in plants is a highly coordinated process that occurs at the interface of the cortex, plasma membrane, and cell wall. There is evidence that cellulose biogenesis is facilitated by the interaction of several proteins, but the details are just beginning to be understood. In particular, sucrose synthase, microtubules, and actin have been proposed to possibly associate with cellulose synthases (microfibril terminal complexes) in the plasma membrane. Differentiating tracheary elements of *Zinnia elegans* L. were used as a model system to determine the localization of sucrose synthase and actin in relation to the plasma membrane and its underlying microtubules during the deposition of patterned, cellulose-rich secondary walls. Cortical actin occurs with similar density both between and under secondary wall thickenings. In contrast, sucrose synthase is highly enriched near the plasma membrane and the microtubules under the secondary wall thickenings. Both actin and sucrose synthase lie closer to the plasma membrane than the microtubules. These results show that the preferential localization of sucrose synthase at sites of high-rate cellulose synthesis can be generalized beyond cotton fibers, and they establish a spatial context for further work on a multi-protein complex that may facilitate secondary wall cellulose synthesis. © 2001 Elsevier Science Ltd. 1. Introduction

The change of the millennium is paralleled by a change to the post-genomics era. For example, the genomes of *Arabidopsis* and rice have been completely sequenced, and the technology exists to obtain many cDNA sequences from any plant relatively quickly. Similarly, microarray technology will allow suites of genes that are expressed in particular developmental or physiological states to be analyzed and compared. Even for genes with known homology, the challenge will then be to elucidate how the cognate proteins cooperate in biochemical pathways and which enzymes exert most control within pathways. Genes with no or weak homology will be even harder to correlate with cellular functions. Analysis of mutant plants (in species where this is practical) and biochemistry will be important tools in functional genomics, and fluorescence and electron microscopy are also re-emerging as essential tools. This paper provides an example of the use of cryogenic immunoelectron microscopy to establish spatial relationships between structural proteins and enzymes that may facilitate cellulose synthesis.

Based on biochemical, molecular, and immunofluorescence evidence in secondary-wall-stage cotton fibers, a novel membrane-associated form of sucrose synthase (SuSy; EC 2.4.1.13) was proposed to channel UDP-glucose to cellulose synthase in a closely coupled reaction (Amor et al., 1995). When acting degradatively, SuSy degrades sucrose (with input of UDP) to release fructose and UDP-glucose. UDP-glucose is thought to be the immediate substrate for cellulose polymerization in higher plants, and direct channeling of UDP-glucose to cellulose synthase from SuSy may promote high-rate cellulose synthesis (Delmer and Amor, 1995). However, the previous immunofluorescence localization of SuSy

PII: S0031-9422(01)00045-0

in cotton fibers (Amor et al., 1995) had insufficient resolution to establish clearly the spatial relationship of SuSy to the plasma membrane where cellulose synthases are located (Kimura et al., 1999). Also, there were no data to establish the generality of this model in other secondary-wall-stage, cellulose-synthesizing cells.

Biochemical evidence also indicated that SuSy is an actin-binding protein, but it did not establish a role for SuSy/actin in any particular process. Furthermore, it was suggested that soluble SuSy, not membrane-associated SuSy, was associated with F-actin (Winter et al., 1998). Cortical F-actin has frequently been discussed as a possible participant in cellulose synthesis (Heath and Seagull, 1982). When actin antagonists are applied to differentiating cotton fibers and differentiating TEs, both microtubules and newly deposited secondary wall thickenings occur in abnormal orientations relative to the cell axis (Kobayashi et al., 1988; Seagull, 1990). In addition, cortical actin networks have been visualized by immunofluorescence in both of these cell types during secondary wall deposition with a questionable degree of accuracy [(Kobayashi et al., 1987; Seagull, 1990); see also below and the discussion of Frost and Roberts, 1996)].

We set out to clarify the relationship of SuSy and actin to patterned secondary wall deposition using a cryogenic electron microscopic immunolocalization methods that greatly reduces artefacts (Nicolas and Bassot, 1993) and differentiating TEs as a model system (Fukuda and Komamine, 1980). Tracheary element differentiation is characterized by the deposition of cellulose-rich secondary walls in precise patterns. Proteins associated with cellulose synthesis accumulate within the plasma membrane in this pattern, as evidenced by the localization of protein aggregates called rosettes than contain the cellulose synthase (Herth, 1985; Kimura et al., 1999). Bands of cortical microtubules also underlie and help determine the secondary wall pattern of tracheary elements (Hepler, 1981). The specific, patterned, association of rosettes (cellulose synthases) and microtubules with the secondary wall thickenings of tracheary elements of *Zinnia elegans* differentiating in culture (the cell system used here) has been shown previously (Falconer and Seagull, 1985; Haigler and Brown, 1986). Therefore, we set out to test whether other proteins that might facilitate high-rate secondary wall cellulose synthesis, specifically sucrose synthase and actin, would also accumulate in the same pattern.

Cellulose synthesis is well-known to be easily disturbed. For example, from exogenous UDP-glucose, isolated membrane preparations of higher plants tend to synthesize callose (β-1,3 glucan) much more readily than cellulose (β-1,4 glucan) (Delmer and Amor, 1995), and rosettes of cellulose synthases are not detected after even low-speed centrifugation (Herth and Weber, 1984). Therefore, this research required immunolocalization methods that would not allow perturbation of molecules associated with cellulose synthesis in vivo. This was emphasized by our preliminary immunofluorescence studies that failed to show repeatable enrichment of SuSy over the thickenings (see below). Localization at the electron microscope level after freeze substitution was a preferred method, but the initial step of ultra-rapid freezing limited the depth of freezing that could be obtained without destructive ice crystal formation. This technical difficulty was overcome by use of TEs differentiating semi-synchronously in culture from isolated mesophyll cells of *Zinnia elegans L.* (Fukuda and Komamine, 1980). These single cells could be frozen without substantial ice crystal formation and processed for electron microscopy using techniques that should greatly hinder molecular movement (Echlin, 1992).

2. Results

2.1. Western blotting established antibody specificity in Zinnia elegans

Both antibodies used have been well-characterized in other systems. The rabbit polyclonal antibody to SuSy was raised against gel-purified cotton fiber SuSy (Amor et al., 1995). The mouse monoclonal antibody to actin (ICN, Costa Mesa, CA; clone C4) was raised against chicken gizzard actin, and it recognizes a conserved epitope in the N-terminal region of all actin monomers (Lessard, 1988). Western blots showed that both anti-SuSy and anti-actin each recognized one main band near the predicted size in whole cell protein extracts of differentiating *Zinnia* cultures (Fig. 1a and b). Thus, in *Zinnia* the band recognized by anti-SuSy ran below the 97 kDa marker, which is close to the 91 kDa molecular weight of cotton SuSy. The band recognized in *Zinnia* by anti-actin ran below the 50 kDa marker, which is consistent with the 41.8 kDa molecular weight of monomeric actin.

2.2. Immunofluorescence studies to detect SuSy yielded variable results

Immunofluorescence studies using anti-SuSy antibody revealed variable patterns in differentiating TEs, and SuSy was only rarely observed over thickenings. The cell in Fig. 2 was a differentiating TE as shown by birefringence of the thickenings in polarized light microscopy (Fig. 2a). Note that the secondary wall at the top of the cell is pitted, as shown by the horizontal white thickenings and the vertical black thickenings. The pitted wall, combined with the location of chloroplasts between thickenings, makes it appear that SuSy surrounds chloroplasts (Fig. 2b and c), but this is coincidental. Fig. 2b and c shows the fluorescence of

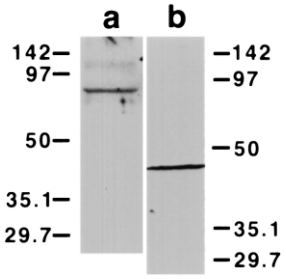

Fig. 1. Western blots against *Zinnia* protein: (a) anti-SuSy; (b) anti-actin. The location of the molecular weight standards run with each gel are indicated to the side.

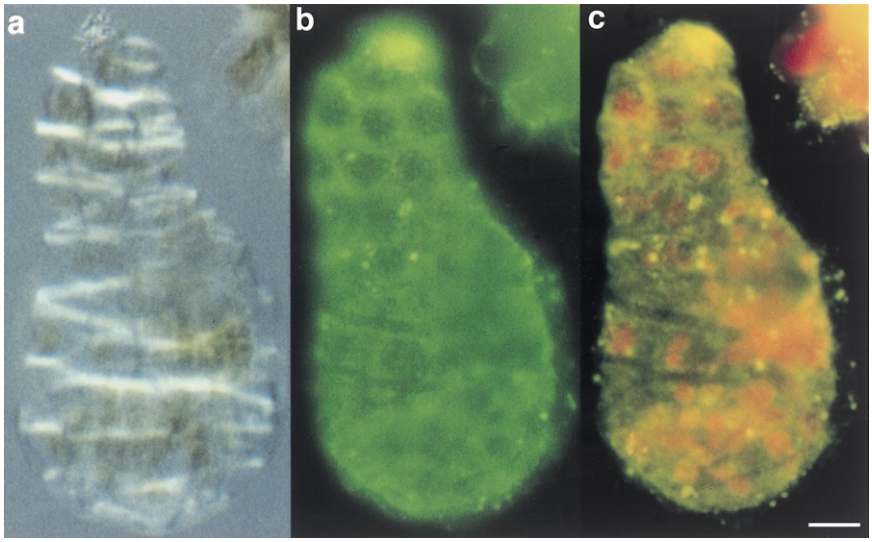
FITC-labeled SuSy with (Fig. 2b; SuSy appears green) and without (Fig. 2c; SuSy appears yellow) a filter blocking chlorophyll autofluorescence. Without the chlorophyll-blocking filter, the chloroplasts were seen as orange spheres. Comparing the images in Fig. 2, FITC/SuSy was enriched over the thickenings at the top of the cell where chloroplasts remained normally placed for mesophyll cells (arrayed in a single layer of the cell cortex). However, SuSy was enriched between thickenings (leaving a "negative" image of thickenings) at the bottom of the cell where chloroplasts apparently moved from their normal location. This suggests that preparative methods for immunofluorescence caused variable and artefactual results. For example, since chloroplasts (and/or SuSy) might be tethered by actin, one possibility is that variable results arise due to inability to preserve actin structure and location during immunofluorescence protocols (see Section 3). We also observed that SuSy/FITC mainly retracted with the plasma membrane in an area of slight plasmolysis on the lower right side of the cell. Cells treated with the pre-immune serum at the same concentration showed only very dim, dull green fluorescence (data not shown).

2.3. Electron microscopic immunolocalization of SuSy and actin after freeze substitution established their pattern relative to secondary wall thickening

In contrast to the immunofluorescence results, using the superior technique of freeze substitution, SuSy was consistently highly-enriched close to the plasma membrane underlying secondary wall thickenings (Fig. 3a and b) and much less abundant between thickenings (Fig. 3a). Grazing sections that revealed longitudinal cross-sections of microtubules underneath a secondary cell thickening clarified that SuSy lies above the cortical microtubules and near the plasma membrane (Fig. 3c). No labeling was observed when similar sections were incubated with the same concentration of the pre-immune serum from the rabbit used to produce the antibody to SuSy (Fig. 3d). Equivalent results were obtained with a second polyclonal antibody raised against SuSy from Vicia faba (data not shown).

In differentiating TEs during active cellulose synthesis, labeling of SuSy over the cytoplasm or any organelle was rare (Fig. 3a–c). This low-frequency cytoplasmic labeling could well be background, non-specific, labeling. Therefore, these data showed that active secondary cell wall cellulose synthesis was characterized by the



(Colour)

Fig. 2. Immunofluorescence of SuSy in a differentiating TE. (a) Polarization microscopy of the differentiating TE showed the birefringence of patterned cellulose. (The background was unusually bright for polarization microscopy because of the planapochromatic lens used to optimize fluorescence); (b) FITC labeling of SuSy was visualized as green with the chlorophyll blocking filter in place. SuSy was observed to be enriched over thickenings or between thickenings in the upper and lower parts of the cell, respectively; (c) FITC labeling of SuSy was visualized as yellow and chloroplasts were visualized as orange spheres with the chlorophyll blocking filter removed. Here, the "negative" images of thickenings in the lower left of the cell were enhanced. Note that different SuSy patterns correlate with different placement of the chloroplasts at the top and bottom of the cell. Bar is 5 μm.

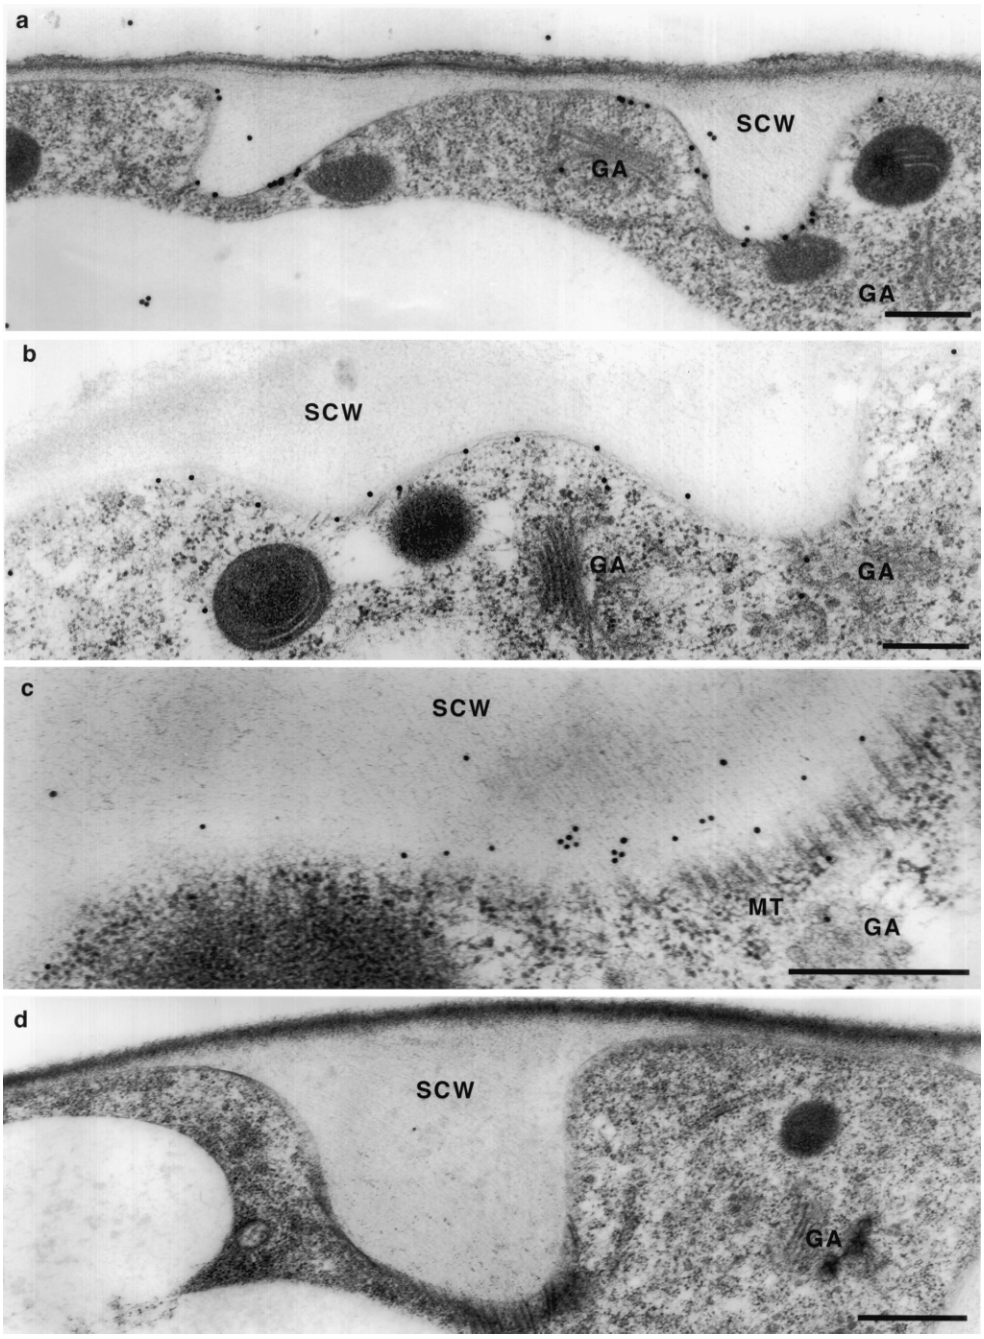


Fig. 3. Electron microscopic immunolocalization of SuSy in differentiating TEs. (a, b, c) Labeling occurred near the plasma membrane underneath secondary cell wall thickenings (SCW) and above the microtubules (MT), which are clearly shown in c. The Golgi apparatus (GA) was generally not labeled; (d) no labeling was observed after treatment of similar sections with the pre-immune serum. Bars are 0.2, 0.2, 0.5, and 1 μm in a, b, c and d, respectively.

preferential localization of SuSy at the plasma membrane.

Actin occurred in the vicinity of the plasma membrane all along the cortex of differentiating TEs, both between and over secondary wall thickenings (Fig. 4a). Labeling deep in the cytoplasm was also sometimes observed, and the labeling of a microfilament there confirmed the specificity of this monoclonal antibody (Fig. 4b).

Quantitative analysis of labeling of differentiating TEs (Fig. 5) was performed on cross-sections so that the difference between secondary wall thickenings and regions between thickenings was clearly apparent. Prior to patterned secondary wall deposition, the mesophyll cells thicken their primary wall uniformly (Burgess and Linstead, 1984), but cell walls between thickenings typically did not exceed 0.25 μm and patterned thickenings exceeded 0.5 μm. The label for SuSy was denser

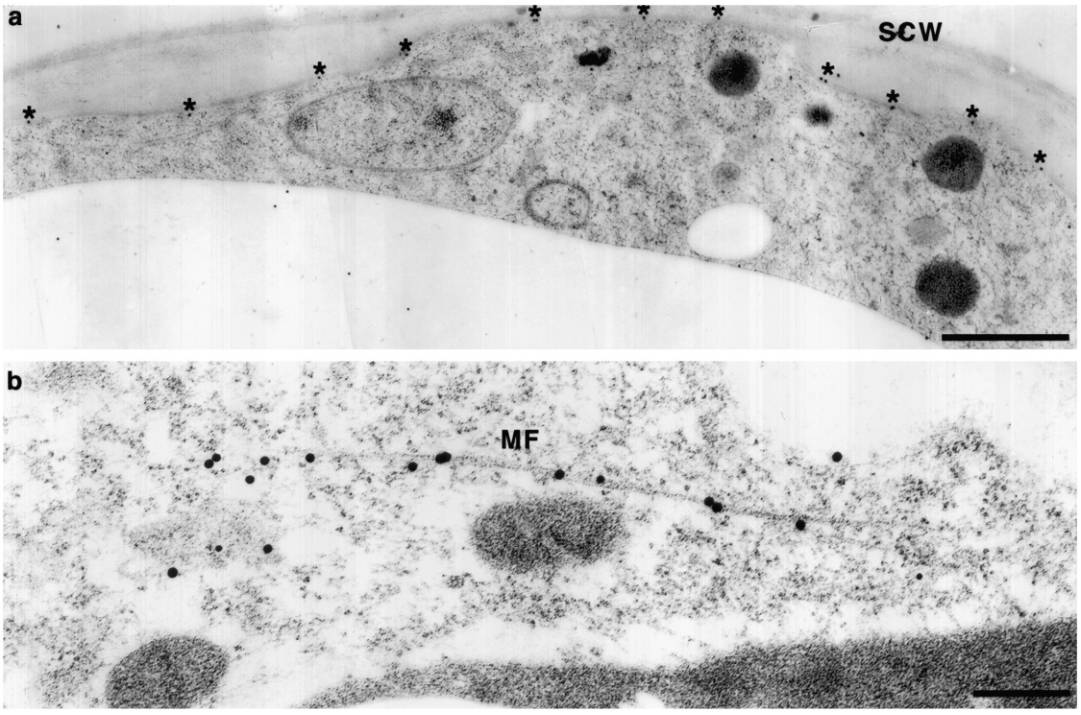

Fig. 4. Electron microscopic immunolocalization of actin in differentiating TEs. (a) Labeling of actin (as highlighted by asterisks) occurred near the plasma membrane both between and under secondary wall thickenings (SCW); (b) Labeling of a single microfilament (MF) deep in the cytoplasm. Bars are 1 and 0.2 μm in a and b, respectively.

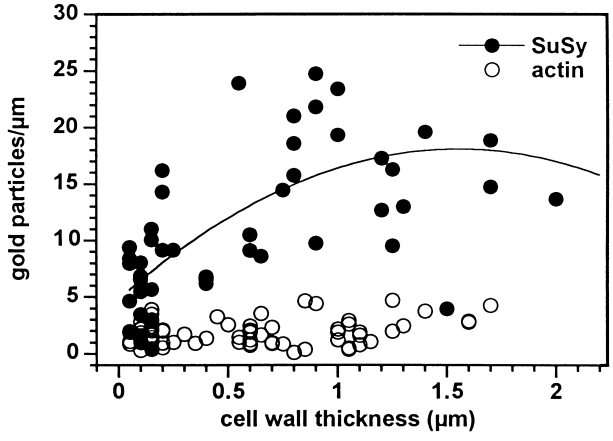

Fig. 5. Quantity of SuSy (●) and actin (○) labeling near the plasma membrane in relation to the thickness of the adjacent cell wall. Correlating observations and measurements, primary walls between thickenings typically did not exceed 0.25 μm and secondary wall thickenings exceeded 0.5 μm. The SuSy data were fitted with a second order polynomial equation ($R^2 = 0.44$).

over thickenings, whereas the label for actin had the same density regardless of cell wall thickness (Fig. 5). The best fit for the SuSy distribution data was obtained with a second order polynomial equation (coefficient of determination, $R^2 = 0.44$), whereas no type of line fitted the actin distribution data. Only cell walls that labeled are represented in the graph, which therefore over-represents the tendency of SuSy to label between thickenings. For both SuSy and actin, all the thickenings used for quantitation (25–26 in each case) had some associated label. In contrast, the areas between thickenings had more tendency not to label for SuSy (27% clean or 58% clean/sparsely labeled) than for actin (12% clean).

2.4. Double labeling of tangential sections established the spatial relationship of microtubules, SuSy, and actin relative to each other and the plasma membrane

Tangential sections that grazed between secondary cell wall and cytoplasm (Fig. 6a) clearly established the spatial relationships of molecules at the cell cortex. Little SuSy or actin label was observed when long lengths of longitudinally sectioned microtubules were revealed, a zone lying within the microtubule array below each secondary wall thickening (Fig. 6b, upper left). Instead, SuSy and actin labeled when the section traversed the region near the plasma membrane between the microtubules and the cell wall, indicating that SuSy and actin lie just above the microtubules. The area of the unlabeled microtubule array between the arrowheads in Fig. 6b does label in the next serial section outward toward the cell surface; the label is just above the microtubules (Fig. 6c). Actin labeled slightly closer to the microtubules than SuSy, as shown by these (Fig. 6b, lower right, and Fig. 6c; note the different placement of asterisks and arrows relative to the microtubules) and other micrographs (data not shown). In contrast to cross-sections (Figs. 4 and 5), actin

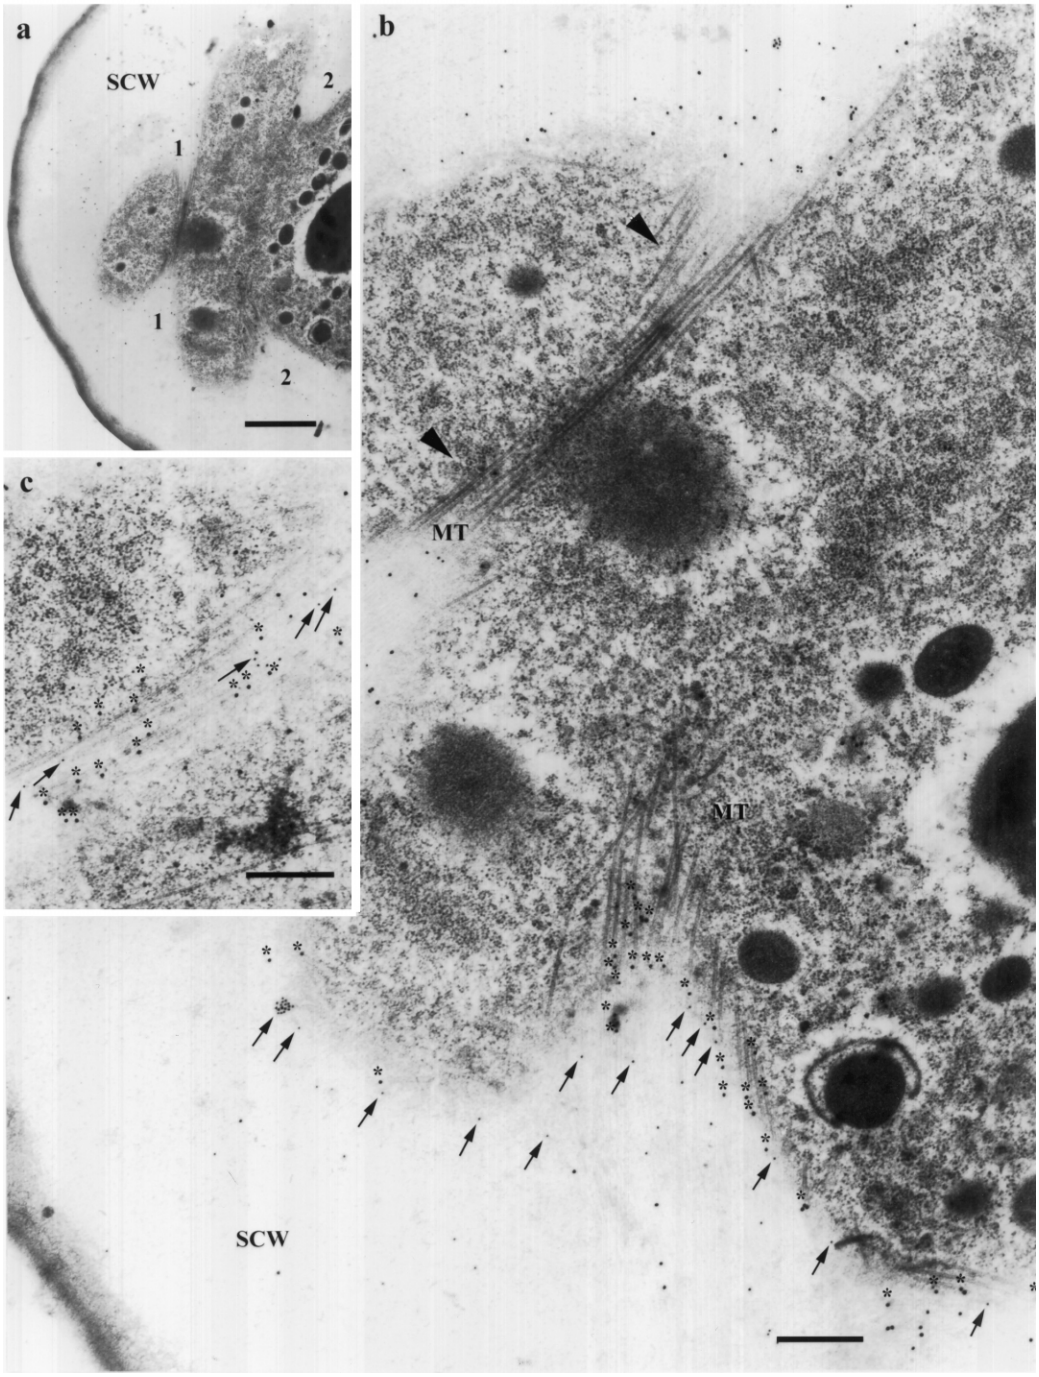

Fig. 6. Double labeling of SuSy (10 nm gold) and actin (20 nm gold) in a differentiating TE. To aid clarity in (b) and (c), sometimes the 10 nm gold labeling of SuSy is indicated by arrows and the 20 nm gold labeling of actin is indicated by asterisks. (a) A tangential section that includes secondary cell wall (SCW), deep cytoplasm, and all the intervening layers. The plane of section has just entered the zone of cytoplasm below the two secondary wall thickenings. (Opposite sides of each of the two thickenings — labeled 1 and 2 — point to each other at the top and bottom of the TE.); (b) high magnification view of one part of the section in (a) that grades between secondary cell wall (SCW) and cortical microtubules (MT). Note in the region between the arrowheads that neither SuSy nor actin occurs in the plane where the microtubule bundle under a thickening is visible along much of its length. However, the lower part of the micrograph shows that both SuSy and actin label in a plane between the microtubules and the cell wall. There is a tendency for actin to label more abundantly closer to the microtubules than SuSy (compare location of asterisks and arrows); (c) high magnification view of the next section outward toward the cell surface of the microtubule area between the arrowheads in (b). Note that the density of SuSy and actin labeling greatly increases in this plane above the microtubule bundle and below the thickening wall (beginning to appear as an unstained area devoid of organelles), which is consistent with close proximity to the plasma membrane. Bars are 2, 0.5, and 0.5 μm in a, b, and c, respectively.

labeled with a density ca. equal to SuSy in tangential sections (Fig. 6b), probably because longer regions of microfilaments are exposed in the section plane.

3. Discussion

The enrichment of SuSy underneath the patterned secondary wall thickenings of differentiating TEs is consistent with plasma membrane-associated SuSy being specifically related to high-rate cellulose synthesis. Organized cellulose synthases, rosettes, are specifically enriched over the thickenings (Haigler and Brown, 1986; Kimura et al., 1999). The rare labeling of SuSy in the cytoplasm could be partially explained by dilution in a large volume, but the data suggest that SuSy is strongly recruited to the plasma membrane during secondary wall deposition. Future biochemical experiments designed to discriminate between soluble and membrane-associated SuSy are planned to test this differential distribution, although it is possible that these cryogenic microscopic results are more definitive than extraction procedures that necessarily disrupt normal cellular organization.

SuSy is positioned so that it could interact with the inner bilayer of the plasma membrane and/or the cytoplasmic portion of the secondary wall cellulose synthase and/or actin (Fig. 7). Therefore, SuSy may channel UDP-glucose to cellulose synthase in diverse species and cell types, not only in cotton fibers that have unusual secondary walls composed of almost pure cellulose. In contrast to previous biochemical results that supported an interaction between soluble SuSy and F-actin (Winter et al., 1998), at least during active cellulose synthesis there is a possibility that membrane-associated SuSy is also interacting with F-actin. Membrane-associated SuSy extracted by EGTA from cotton fibers during secondary wall cellulose synthesis re-precipitated upon Ca^{2+} addition, along with other proteins including Ca^{2+}-independent kinase, tubulin, actin, and annexins (D. Delmer and M. Datcheva, unpublished). However, other methods such as fluorescence resonance energy transfer between GFP/BFP-tagged proteins (Mahajan et al., 1998) will be required to prove that direct binding between SuSy and other proteins exists in vivo.

In addition to cotton fibers, biochemical evidence of membrane-associated SuSy has been shown in maize endosperm and growing organs of maize and soybean (Carlson et al. 1996; Winter et al., 1998; Buckeridge et al., 1999). However, further work will be required to show that SuSy participates directly in primary wall cellulose synthesis or other endo- or plasma membrane-associated processes in these tissues. The Golgi apparatus of differentiating TEs did not commonly label for SuSy even though they are probably synthesizing abundant xylan, the predominant hemicellulose in *Zinnia*

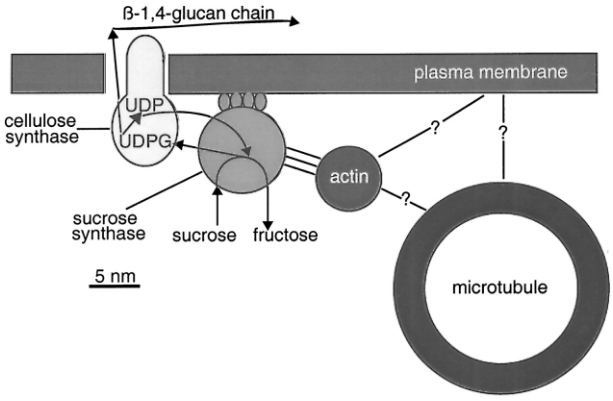

Fig. 7. Model depicting how cellulose synthase, SuSy, actin, and microtubules are positioned relative to each other in the cortex below secondary wall thickenings of differentiating tracheary elements and how they might interact to facilitate cellulose synthesis. The model takes into account the new data presented here and previously published findings. Sucrose synthase and actin are shown closer to the plasma membrane than microtubules, with SuSy being closest, as suggested by our data. Cellulose synthase is shown as a transmembrane protein that is enriched beneath secondary wall thickenings (Delmer, 1999; Haigler and Brown, 1986). The loops between SuSy and the plasma membrane indicate a hydrophobic region of the protein that may facilitate its membrane interaction (Carlson and Chourey, 1996), and the hatch marks between SuSy and actin indicate a peptide in SuSy that is homologous to known F-actin-binding amino acid sequences (Winter and Huber, 2000). The suggested channeling of UDP-glucose between SuSy and cellulose synthase is adapted from a previously published diagram (Delmer and Amor, 1995). The question marks indicate other possible binding interactions not addressed by our data. A gap remains in the plasma membrane to the left of the cellulose synthase to indicate that there is a still-undefined mechanism by which glucan chains reach the cell wall space. The scale of the drawing is approximately as indicated by the scale bar in the lower left (see Section 3).

secondary cell wall thickenings (Ingold et al., 1988). Therefore, membrane-associated SuSy might not be an obligatory part of xylan synthesis, which would require UDP-xylose rather than UDP-glucose as immediate substrate, whereas it has been proposed to participate in Golgi-associated β 1->3, 1->4 glucan synthesis in maize but not xyloglucan synthesis in soybean (Buckeridge et al., 1999). One possible explanation for this difference is that, among the UDP-glucose-requiring hemicellulose synthases, only the β 1->3, 1->4 glucan synthase may have a cellulose synthase ancestor (Buckeridge et al., 1999).

Multi-protein interactions highly related to cell structure and under complex cellular control may explain why cellulose has been difficult to synthesize reproducibly in vitro at high rates and in its native crystalline form (Blanton and Haigler, 1996). For example, related to the data presented here, the binding of SuSy to the plasma membrane, cellulose synthase, and/or actin in secondary wall synthesizing cells might be modulated very precisely by calcium. Elevated calcium hinders cellulose synthesis in vitro and in semi-permeablized cotton fibers (Amor et al., 1995; Delmer and Amor,

1995). F-actin can be degraded under elevated calcium (Frost and Roberts, 1996), which could destabilize an integrated cellulose synthase complex. However, uptake of extracellular calcium is required for tracheary element differentiation (Roberts and Haigler, 1990), microsomal SuSy remained in cotton fibers extracted with 200 nM free Ca^{2+}, and microsomal SuSy was released from cotton fibers by EGTA washing (D. Delmer and M. Ivanova-Datcheva, submitted). Elevated sucrose could also enhance the formation of a multi-protein cellulose synthesizing complex, as preliminarily suggested for actin/SuSy binding (Winter and Huber, 2000). In this case, secondary wall, cellulose synthesis would occur only when carbon was plentiful. The preference of cellulose synthesis for exogenous sucrose in semi-permeabilized cotton fibers (Amor et al., 1995) could be at least partially explained by promotion of the formation of such a multi-protein complex.

Only freeze substitution gave reproducible information about SuSy localization. Immunofluorescence techniques may have led to inconsistent and artefactual results for at least two reasons. First, aldehyde fixatives, which are usually used alone (without OsO_4) in order to preserve protein antigenicity, cross-link proteins but not lipids (Bozzola and Russell, 1999). Therefore, membrane flow might continue, carrying peripheral membrane proteins like SuSy to artefactual locations. Also, aldehyde fixatives and their buffers can degrade actin filaments (Frost and Roberts, 1996), possibly causing SuSy delocalization. Second, cellulases and/or pectinases that permeabilize the cell wall to antibodies in immunofluorescence protocols could disrupt cell wall/cytoskeleton linkages that stabilize localized plasma membrane domains and cortical organelles (Fowler and Quatrano, 1997). Similar reasons may explain why our electron microscope immunolocalization supports uniform distribution of cortical actin in differentiating TEs, whereas previous immunofluorescence supported its localization between thickenings (Kobayashi et al., 1988). In that paper, Fig. 1k shows actin only between thickenings in an image that is strikingly similar to the "negative" image of SuSy at thickenings in the bottom half of the cell in Fig. 2b and c. Therefore, immunofluorescence preparative procedures may disturb and allow secondary reorganization (Frost and Roberts, 1996) of specialized actin filaments (and bound SuSy) that normally underlie the thickenings. Protoplast undulations that occur due to continued, localized, plasma membrane/cell wall attachment after plasmolysis in TEs of several species (Seagull, 1991), including *Zinnia* (Roberts and Haigler, 1989), suggest that patterned cell wall/cortical interactions do exist in TEs.

This research provides a spatial context to guide further research on multi-protein interactions that may facilitate cellulose synthesis. A working model based on current knowledge is shown in Fig. 7, which is drawn with an approximately realistic scale and shows metabolic channeling between SuSy and cellulose synthase. The cellulose synthase is shown as an integral plasma membrane protein because of its eight predicted transmembrane helices and its identification there by freeze fracture labeling (Kimura et al., 1999). Its size and shape are predicted from the known molecular structure of membrane ATPases (Auer et al., 1998; Zhang et al., 1998), which have a molecular weight and topology similar to that known or predicted for cellulose synthase (Delmer, 1999). An approximate size for globular SuSy was derived from the relationship of its molecular weight (91 kDa for cotton) to cellulose synthase (110 kDa for cotton) (Kawagoe and Delmer, 1997). The gap beside cellulose synthase indicates that glucan chains must reach the cell wall space, which could occur through a pore formed by the trans-membrane helices (Delmer, 1999) or by the aggregation of multiple cellulose synthase proteins into rosettes (Emons, 1991). In Fig. 7, SuSy is shown to interact with the plasma membrane as a peripheral membrane protein through an identified hydrophobic region and with actin through a peptide identified in SuSy that has homology to known actin-binding peptides (Winter and Huber, 2000). Since we have no specific information about whether SuSy and cellulose synthase might be directly bound to each other, the diagram only shows them adjacent. However, cotton cellulose synthase has a LIM-like domain that could facilitate protein/protein interactions (Kawagoe and Delmer, 1997). Microtubules are shown furthest below the plasma membrane, but closest to cortical actin, as indicated by our data. The relationship of microtubules to a possible interaction between SuSy, actin, and cellulose synthase cannot be minimized. Unlike the actin that is distributed over the whole cortex, microtubules, SuSy, and cellulose synthases are specifically restricted to the sites of secondary wall deposition in differentiating tracheary elements. Therefore, the location of a possible complex between SuSy, cellulose synthase, actin, and other unidentified proteins may ultimately depend on the microtubules or microtubule-associate proteins underlying the thickenings. This possibility is consistent with the well-known effects of microtubule antagonists in disrupting secondary wall patterns, including in *Zinnia* tracheary elements (Falconer and Seagull, 1986). The question marks in the diagram indicate other possible linkages and/or sites for other interacting proteins not yet identified.

4. Concluding remarks

The diagram in Fig. 7 shows only one cellulose synthase and associated proteins, whereas many (about 24–36) of them are proposed to aggregate into one rosette to facilitate the crystallization of cellulose I microfibrils.

The rosettes are also proposed to move through the plasma membrane in prescribed patterns, spinning cellulose microfibrils behind them (Blanton and Haigler, 1996). This seems challenging enough for one rosette about 30 nm across (Kimura et al., 1999). If SuSy were directly linked to the rosette would this movement be hindered, or might SuSy linked to actin and microtubules serve only to saturate the cortex with UDP-glucose to be used by the moving cellulose synthases? Arguing against the latter possibility and for direct coupling, semi-permeabilized cotton fibers use sucrose for cellulose synthase much more readily than exogenous UDP-glucose (Amor et al., 1995). Another interesting question is what network of protein binding is required to cause SuSy to prefer the sites of secondary wall thickening? Might a different macromolecular organization of actin mediate this specific localization, or do the microtubules alone cause this? Is SuSy phosphorylation related or not to its recruitment to the cortex for cellulose synthesis? Questions like these will be answered as perturbed systems are analyzed and as more candidate proteins are discovered that may participate in a multi-protein complex regulating cellulose synthesis. Accurate placement of such proteins in their cellular context, as we have shown here, will be an essential part of future research.

5. Experimental

5.1. Cell cultures

Tracheary elements were induced to differentiate from isolated mesophyll cells of *Zinnia elegans* L. var. Envy as previously described (Fukuda and Komamine, 1980). Simplified medium (Roberts et al., 1992) was used to minimize salt crystals that hindered cell selection and sectioning. Cultures were frozen early in differentiation when about 20% of all cells were depositing cellulose in patterned secondary walls, but before extensive autolysis or lignification of TEs occurred.

5.2. Western blotting

Cells at the same stage of differentiation as described above were: pelleted by gentle centrifugation; suspended in 1× SDS sample buffer by addition of 5×buffer to the pellet; broken by sonication (Tekmar Sonic Disruptor Model TM300, Cincinnati OH, microtip, 2×10 s, duty 50, microlimit 5, pulse on, on ice, without foaming); boiled 3 min; and spun at 13,000 rpm to pellet debris. Samples were run in 10% SDS gels (10 μg protein/lane), and they were processed for Western blotting by standard methods with anti-SuSy (1:3000 in TBS/5% milk) or anti-actin (1:1000 in TBS/5% milk) and secondary antibodies for chemiluminescent detection on film (ECL kit; Amersham Pharmacia Biotech, Piscataway, NJ).

5.3. Sample preparation

For immunofluorescence, differentiating TEs were concentrated in medium without centrifugation by briefly slowing the rate of flask rotation to about 72 rpm so that cells clumped toward the middle. Using a wide-tip pipet, 0.5 ml cells in medium were removed and added to 1 ml fixative. After 10 min, cells were pelleted by low speed centrifugation and resuspended in fresh fixative for 1 h (RT). Fixatives used with equivalent results were: (a) Histochoice®, an acidic, buffered soln. containing glyoxal, a derivative of formaldehyde, and no chelators (Amresco, Solon, OH); or (b) 3.7% formaldehyde, 1 mM $MgSO_4$, and 5 mM EGTA in 50 mM PIPES, pH 6.9 (closely related to a previously-described buffer optimized for microtubules; Doonan and Clayton, 1986).

For immunoelectron microscopy, differentiating TEs concentrated as described above were placed in a microcentrifuge tube, and sprayed with an artist's air brush (Echlin, 1992) into resolidifying propane (near −168°C) cooled by liquid nitrogen within 3 min of removal from the incubator. [We also observed the same results in cells frozen on agar-coated loops (Lancelle et al., 1986), but the spray method resulted in a higher percentage of well-frozen cells.]

Cells were collected in the propane by a 10 μm nylon mesh funnel attached to a microcentrifuge tube "basket" then transferred to acetone at −80°C in 10 ml polypropylene vials contained within a pre-chilled, home-made, drilled brass block with cover (3.3 kg total mass to cause gradual temperature changes; design of Mark Grimson). Substitution at −80°C continued for 4 days and fixation (with acetone acting as a mild aldehyde; Newman and Hobot, 1993) occurred overnight at −40°C. Cells were washed in −40°C acetone, then infiltrated with gradually increasing percentages of resin (a 1:1 mix of Lowicryl K4M and HM20 acrylic resins, Electron Microscopy Sciences, Ft. Washington, PA; the resin was added in successive drops) for 2–3 days at −40°C followed by 3 changes of 100% resin (during a total period of 2 days) before embedding. The prolonged infiltration was necessary to optimize embedding of these thick-walled cells.

Cells were flat embedded between two slides treated with Paramount® release agent (#70880, Electron Microscopy Sciences, Ft. Washington, PA) using #1 thickness cover slips as spacers (Reymond and Pickett-Heaps, 1983). Polymerization proceeded with indirect 360 nm UV irradiation for 2 days at −20°C (light on within a −40°C freezer) and 1 day at 4°C. The upper slide was removed and differentiating TEs were selected by polarization microscopy (to detect patterned cellulose in secondary walls) and marked with a diamond "objective" (Leitz Optometric Inc., Richardson TX). Resin squares containing selected TEs were excised with

a razor blade and mounted with cyanoacrylate glue onto blank resin blocks. Ultrathin sections were taken (LKB Ultramicrotome III, Stockholm, Sweden) with a diamond knife (Diatome, Ft. Washington, PA) and mounted on Formvar-coated grids.

5.4. Immunolabeling

TBS and TBST refer to Tris-buffered saline (20 mM Tris–HCl, 150 mM NaCl, 0.02% azide, pH 7.5) minus or plus 0.05% (w/w) Tween 20, respectively. TB refers to 20 mM Tris, pH 8.2, 0.02% azide, used without salt for washing to minimize gold aggregation and background.

For immunofluorescence, after fixation cells were washed 2×10 min in TBS, 10 min in 0.05 M $C_2H_3NaO_2$ buffer, pH 5.0 and cells were permeabilized by 30 min digestion (RT) in 2.5 mg/ml pectinase (Sigma P2401), 2.5 mg/ml pectolyase (Sigma P3026), 2.5 mg/ml saponin (Sigma S2149), 0.25% (w/v) gelatin (Sigma G8150) in 0.05 M $C_2H_3NaO_2$ buffer, pH 5.0 plus protease inhibitors (0.57 mM PMSF, 2 mM N-CBZ-L-phenylalanine, and 5 mM 1,10-phenanthroline). After brief water washes (×3), cells were air-dried to poly-L-lysine-coated, multi-well slides, and autofluorescence was minimized by 10 min immersion in 0.1% $NaBH_4$ followed by 10 min washes (×2) in TBS. Cells were pre-blocked in 1% BSA in TBS (15 min, RT), and anti-SuSy was applied at 1:200 in TBS/BSA (overnight, 4°C). After 10 min washes in TBS (×3), goat anti-rabbit FITC (Organon Teknika, Durham, NC) was applied at 1:200 in TBS/BSA (1 h, RT). After 10 min washes in TBS (×3), an anti-fade mountant was applied [0.1% phenylenediamine in 90% glycerol/10% TBS (v/v), pH 8.6 adjusted with 0.5 M $CNa_2O_3/CHNaO_3$ buffer], and the edge of the coverslip was sealed with fingernail polish. As a control, the pre-immune serum was applied at the same concentration as anti-SuSy in the same protocol.

For immunoelectron microscopy, thin sections on nickel grids were: (a) blocked (15 min, RT, high humidity chamber) in TBST plus 5% normal goat serum (Sigma S-2007); (b) incubated in primary antibody (1–1.5 h, RT; anti-SuSy, 1:100 and/or anti-actin, 1:20 in TBST/5% normal goat serum); (c) washed in TB (×3); (d) incubated in secondary antibody [1–1.5 h, RT; 1:50 goat anti-rabbit and/or goat anti-mouse coupled to 10, 15, or 20 nm colloidal gold (Amersham Pharmacia Biotech, Piscataway, NJ) in TB plus 0.06% BSA]; and (e) washed in TB and dH_20. Grids were then stained for 15 min with 2% (w/v, aq.) uranyl acetate and 1.5 min with Reynold's lead citrate (Bozzola and Russell, 1999) before examination in the electron microscope. The pre-immune serum for polyclonal anti-SuSy was applied at the same dilution as the antibody as a control. For double labeling, the primary and secondary antibodies were applied together with each secondary antibody tagged with a different size of colloidal gold.

5.5. Microscopic observations

For immunofluorescence, samples were observed in an Olympus BH2 epi-fluorescence microscope equipped with polarization optics, a blue filter package for FITC (BP 490 with additional EY-455 excitation filter), an optional KP560 barrier filter (Carl Zeiss, Inc. Thornwood NY) to block chlorophyll autofluorescence, and a planapochromatic 40× lens with iris. Micrographs were recorded using an Olympus PM-10ADS automatic exposure device on Ektachrome 400 slide film. Images of cells for which pre-immune serum was substituted for the primary antibody in the same labeling protocol (not shown) were recorded at a manually set exposure time representing the average of several cells treated with anti-SuSy.

For immunoelectron microscopy, sections were observed and photographed in a transmission electron microscope (Hitachi HS-9 or Jeol 1200 EX).

5.6. Quantitation of immunoelectron microscopic labeling

We analyzed cross-sections near the middle of TEs so that thickenings and areas between thickenings were clearly revealed. For SuSy, 5 cells were analyzed and for actin, 8 cells were analyzed over about 1/2 or their circumference. The maximum width of the cell wall in a thickening or between thickenings was measured and the length of that segment of the plasma membrane was determined with a hand-operated measuring device (Map Mate; National Geographic Society). The number of gold particles lying not more than 0.1 μm from the membrane was counted and divided by the membrane length to determine density of labeling in each plasma membrane region. This value was plotted against cell wall thickness.

Acknowledgements

We thank: (a) James Lessard and Heather Ross, respectively, for gifts of monoclonal anti-actin (initial supply) and anti-SuSy (*Vicia faba*); (b) Marina Salnikova for assistance with ultramicrotomy and immunocytochemistry; (c) Trina Muehring for testing freeze substitution protocols for *Zinnia*; (d) Alison Roberts for development of the immunofluorescence digestion mixture; (e) Brett Kiedaisch for preparation of *Zinnia* cultures; (f) Larry Blanton for assistance in drawing Fig. 7; (g) the Electron Microscope Laboratory of Texas Tech University for access to instruments; and (h) NSF Plant Genomics grant R98RA1829 to D.P.D., C.H.H., and A.S.

Abstract

The microgravity environment encountered during space-flight has long been considered to affect plant growth and developmental processes, including cell wall biopolymer composition and content. As a prelude to studying how microgravity is perceived — and acted upon — by plants, it was first instructive to investigate what gross effects on plant growth and development occurred in microgravity. Thus, wheat seedlings were exposed to microgravity on board the space shuttle *Discovery* (STS-51) for a 10 day duration, and these specimens were compared with their counterparts grown on Earth under the same conditions (e.g. controls). First, the primary roots of the wheat that developed under both microgravity and 1 *g* on Earth were examined to assess the role of gravity on cellulose microfibril (CMF) organization and secondary wall thickening patterns. Using a quick freeze/deep etch technique, this revealed that the cell wall CMFs of the space-grown wheat maintained the same organization as their 1 *g*-grown counterparts. That is, in all instances, CMFs were randomly interwoven with each other in the outermost layers (farthest removed from the plasma membrane), and parallel to each other within the individual strata immediately adjacent to the plasma membranes. The CMF angle in the innermost stratum relative to the immediately adjacent stratum was ca 80° in both the space and Earth-grown plants. Second, all plants grown in microgravity had roots that grew downwards into the agar; they did not display "wandering" and upward growth as previously reported by others. Third, the space-grown wheat also developed normal protoxylem and metaxylem vessel elements with secondary thickening patterns ranging from spiral to regular pit to reticulate thickenings. Fourthly, both the space- and Earth-grown plants were essentially of the same size and height, and their lignin analyses revealed no substantial differences in their amounts and composition regardless of the gravitational field experienced, i.e. for the purposes of this study, all plants were essentially identical. These results suggest that the microgravity environment itself at best only slightly affected either cell wall biopolymer synthesis or the deposition of CMFs, in contrast to previous assertions. © 2001 Published by Elsevier Science Ltd. 1. Introduction

Plant cell walls perform critical functions in plant development and survival (Taylor et al., 1992). Although the underlying reasons are poorly understood, the phenomena of differential syntheses of the various polymeric cell wall components and their concomitant organization into cell walls of distinct types are fundamental to plant morphogenesis and differentiation (Cosgrove, 1997; Hable et al., 1998; Lewis et al., 1999; Croteau et al., 2000). The cell wall helps control the direction of cell expansion through orientation of cellulose microfibrils (CMF), and also provides mechanical reinforcement through deposition of an additional layer of cellulose onto the primary wall. Then, depending upon the cell type being sculptured, subsequent impregnation and reinforcement by hemicelluloses and lignins can occur. For example, in tracheary and vessel elements, the

PII: S0031-9422(01)00148-0

secondary thickenings arise in cell-specific patterns and ultimately allow effective water transportation upward against the gravitational force vector. Therefore, the investigation of cell wall formation and structure in an environment where the gravitational force is essentially absent or greatly diminished could be anticipated to yield important insight into how gravity impacts upon these processes. In early space-flight experiments, it was reported that cell wall assembly processes, including cellulose microfibril orientation and lignin composition and amount, were adversely affected in the microgravity environment (reviewed in Halstead and Dutcher, 1987) Additionally, the reports therein also indicated that various root tissues became disoriented, with all of these observations being related to the direct effect of microgravity.

Many environmental factors and chemical perturbations have been shown to alter the ultrastructure of the cell wall (Hogetsu and Shibaoka, 1978a; Lang et al., 1982; Roberts et al., 1985; Pritchard et al., 1993; Sauter et al., 1993). However, the effect of gravity on cell wall morphology is poorly understood due to the fact that gravitational forces cannot typically be eliminated (for extended durations) on Earth. A few qualitative observations concerning cell wall formation indicate that the cell wall was thinner and the cellulose microfibril organization was disturbed in the absence of gravity (Halstead and Dutcher, 1987; Claassen and Spooner, 1994). A recent study also demonstrated that a clinostat-based simulation of weightlessness decreased the percentage of *Brassica* protoplasts with cortical microtubules organized in parallel (Skagen and Iversen, 1999). However, the evidence of these growth patterns after exposure to microgravity is far from conclusive, and it was thus deemed important to ascertain the effects of the microgravity environment on the growth of wheat (*Triticum aestivum*) seedlings.

This paper thus presents the results of a space-flight experiment relevant to these cell wall-related questions: (i) Does greatly diminishing the gravitation vector (e.g. in microgravity in space) alter CMF organization and cell wall (including lignin) composition? (ii) Is the secondary wall thickening pattern modified in microgravity? Clarification to both questions is fundamental not just in delineating how gravity affects plant growth and development (e.g. cell wall formation and structure), but also in determining the suitability of plant growth in the microgravity environment during space exploration and utilization.

2. Results and discussion

2.1. *T. aestivum* plant growth and development

The growth in space (microgravity) of vascular plants and their subsequent study on Earth resulted in numerous reports claiming an enormous number of aberrations in various plant species, e.g. in terms of effects on the overall growth, the root orientation(s), the cell wall assembly processes and the biopolymer compositions — including lignin content reduction — as well as alterations in metabolic profiles (Cowles et al., 1984; reviewed in Halstead and Dutcher, 1987). However, these experiments were carried out during the initial stages of space exploration, and questions regarding the effects of nutrient and water transport were then unknown.

For this study, we considered it essential to devise a growth system whereby continual provision of water and nutrients could be assured for experimentation in a microgravity environment and for the corresponding 1 *g* controls. This was because of a growing concern that we had regarding some of the changes being claimed for the microgravity environment, which we rationalized might be due to stresses introduced as a consequence of an inadequate water/nutrient supply delivery while in microgravity (space-flight).

NASA utilizes a so-called plant growth unit (PGU) for growing plants in space, but which has no effective mechanism for adding water/nutrients as needed. We, therefore, designed a so-called nutrient pack (Fig. 1A) for continual growth of wheat (*T. aestivum*) from seed to seed. In this way, during a so-called pre-flight payload verification test (PVT), it was established that for the duration of the proposed space-flight (10 days), the plants grew "normally" following seed germination. That is, the sterilized germinated seeds were placed in the nutrient packs within the PGU and grew without provision of additional water and/or nutrients.

In the corresponding space-flight conditions, the plants (at the germinating stage) were placed in the PGU which was then loaded onto the space shuttle *Discovery*, and following lift-off were permitted to grow for 10 days, when the plants returned to Earth for analysis. A corresponding control experiment, carried out on Earth under identical growth conditions experienced during space-flight except for the gravitational vector, was started 1-h later.

As can be seen in Fig. 1B and C, both sets of plants grew "normally," and there were no obvious or significant differences in either the volume or mass of biomass produced (see Table 1). Additionally, the roots grew downwards (relative to the photosynthetic canopy) within either the agar medium (see Fig. 1D for an example) or alternately on nitex-foam. Consequently, these results contrasted markedly with other plant growth experiments, one of whose main differences was that previous studies had been conducted under conditions where no reliable provision of water/nutrients in microgravity had occurred. Thus, having observed no significant differences in vegetative growth profiles, it was next of interest to establish whether cell wall architecture or lignin contents were adversely affected or not.

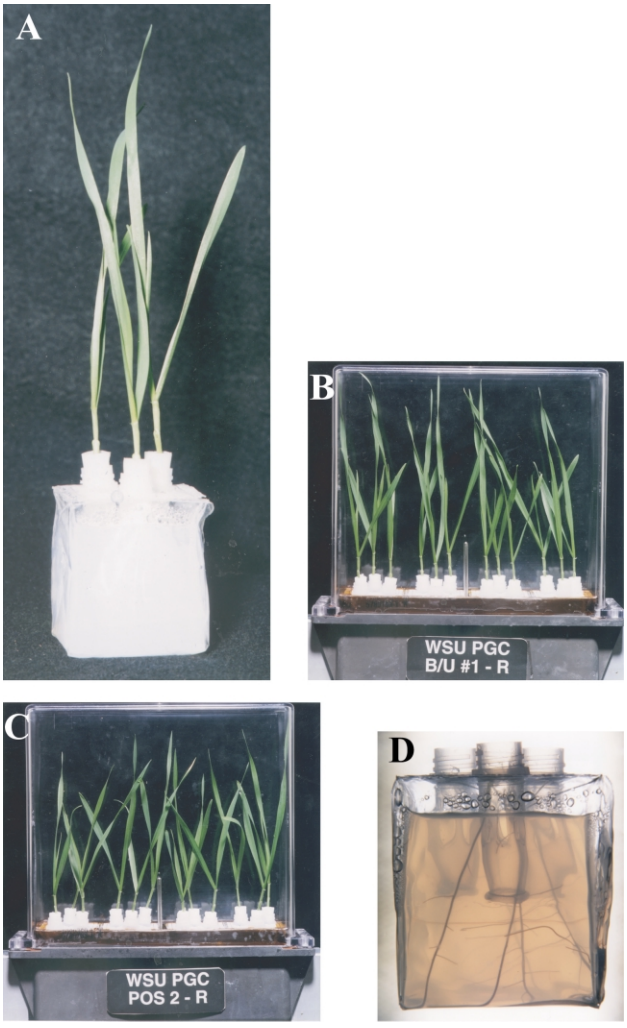

Fig. 1. Nutrient pack (A). Wheat grown (B) on Earth (1 *g* control) and (C) in microgravity aboard the space shuttle *Discovery* during the STS51 mission, as well as (D) the root sections that were also grown in space.

2.2. Cellulose microfibril (CMF) organization in cortical parenchyma cell walls of T. aestivum

The freeze-fracture/deep-etch technique (Hawes and Martin, 1986) was employed in order to visualize orientation patterns of CMFs in different strata of wheat plant cell walls. As described in the Experimental section, the tissues were pretreated with methylamine before freeze-fracture to remove non-cellulosic carbohydrates: Figs. 2 and 3 show representative electron micrographs of platinum/carbon replicates of the outer and inner surfaces of cortical parenchyma cell walls. The samples of the outer strata of the cortical parenchyma cell walls taken from the microgravity-exposed wheat primary roots were selected in such a way as to ensure that they came from tissue completely developed in space. Nevertheless, these tissues were essentially identical to those from the 1 *g*-developed cell wall controls (Fig. 2A and B), i.e. the microfibrils had no predominant orientation, and were interwoven with each other. It is well known that there are disordered microfibrils in the outer strata of the cell wall, as well as cell walls of isodiametric cells such as in suspension cultures of Earth-grown plants (Hogetsu and Shibaoka, 1978b; Satiat-Jeunemaitre et al., 1992; Carpita and Gibeaut, 1993). The same applies to wheat cell walls grown in space (microgravity).

In contrast to the outer layers, a higher order of cellulose microfibril organization was observed within the cell wall layers adjacent to the plasma membrane in both the Earth-grown and microgravity (space-flight) wheat (Fig. 3A and B). Microfibrils within any one layer were parallel to each other and regularly spaced, although their orientation underwent an abrupt change relative to the adjacent layers. Although the mechanism by which CMF orientation shifts from one layer to another is still worthy of debate, this arrangement is a typical feature of the helicoidal wall (Lang et al., 1982; Roland et al., 1987), and was not disrupted by the microgravity environment. Examination of the plants grown in both agar-based and nitex-foam media under microgravity gave essentially the same result. This contrasts markedly to previous reports (Sytnik et al., cited in Halstead and Dutcher, 1987).

Furthermore, the tissue before methylamine treatment was also examined to ensure the treatment does not induce any artifacts. Successful fracture and replication of the inner surfaces of cortical parenchyma cells gave rise to the same ordered arrangement of the CMFs (Fig. 4) as that of the treated tissue. However, under these conditions, the individual microfibril bundles were less distinct: i.e. they were flatter due to the presence of non-cellulosic embedding materials. Notably, as expected, the untreated tissue did not give large fracture surfaces, especially between cells.

In an effort to quantify the offset of CMF orientation between adjacent strata, electron microscopic images were next digitized and analyzed. Cell walls of primary roots grown in the agar-nutrient pack exhibited statistically indistinguishable relative microfibril angles of 82 ± 4.87 and 76 ± 11.06 for microgravity and 1 *g* grown plants respectively (data not shown). The result for the

Control	15.13 ± 1.61	0.20 ± 0.03	11.99 ± 3.71	0.23 ± 0.08

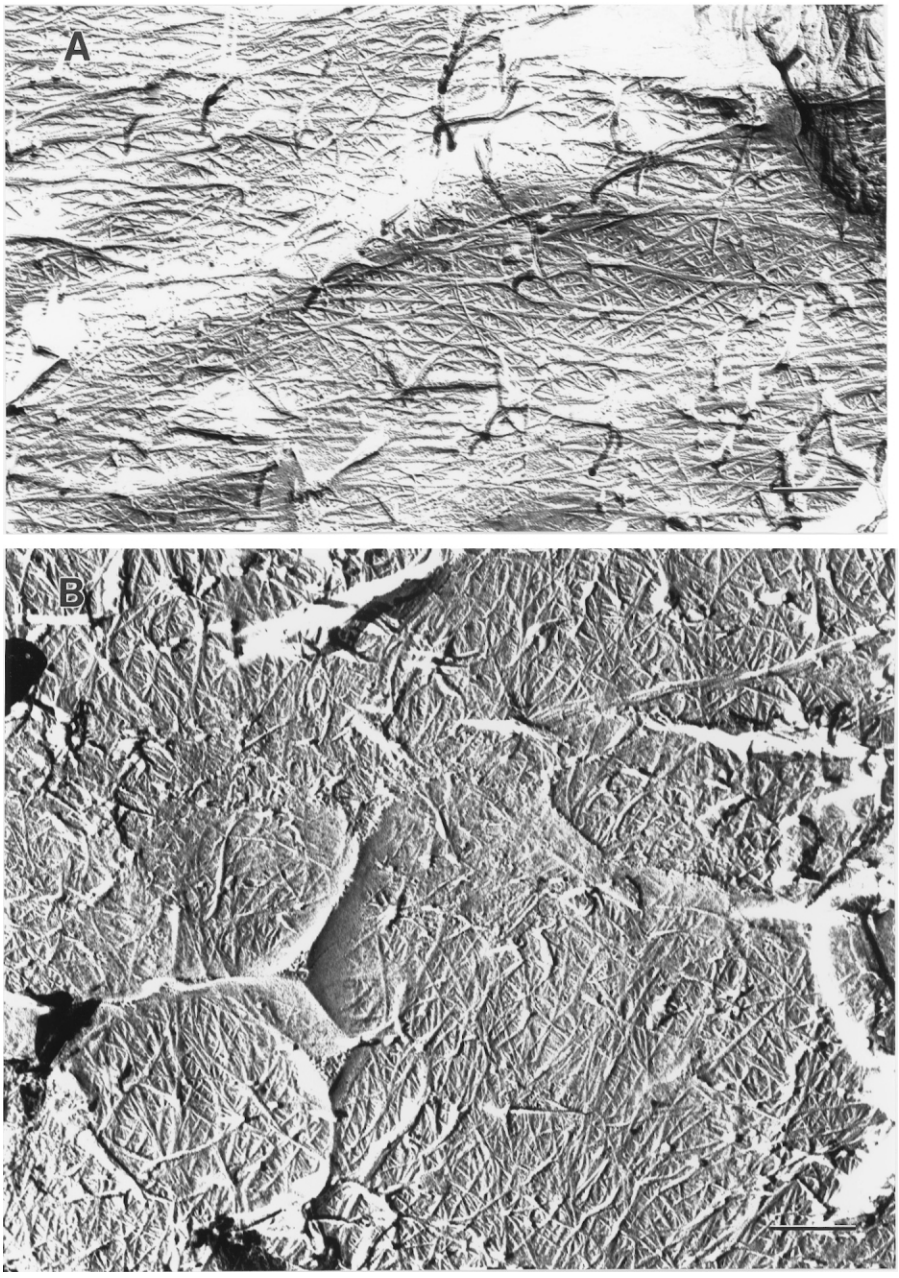

Fig. 2. Cellulose microfibril organization in the outer strata of cortical parenchyma cells of wheat primary roots developed under 1 *g* on Earth (A) and in microgravity (B), scale bar: 0.25 μm.

foam-nitex grown wheat was similar. Although no attempt was made to determine the absolute orientation of CMFs relative to the cell axis, one can assume that the microfibrils on those load-bearing (innermost) layers had a helical pattern, i.e. this offset suggests an oblique (within a ca 40 degree angle) orientation of the CMFs. These results imply that microgravity and its associated conditions do not perturb the deposition of ordered CMFs in the primary walls of wheat. This is contrary to the observation of Sytnik et al. (cited in Halstead and Dutcher, 1987) in which cellulose microfibrils were claimed to be randomized in relation to the longitudinal axis of cells developed under microgravity conditions.

Further interpretation of these observations requires consideration of the hypothetical mechanism by which CMF orientation is governed, and of the roles of CMFs in controlling cell growth and cell anisotropy. CMFs are precisely deposited onto cell walls through the guidance of underlying cortical microtubules (MTs) (Cyr, 1994; Wymer and Lloyd, 1996; Hable et al., 1998), and hence provide the mechanical strength to withstand isotropic turgor pressure and to permit preferential cell expansion in one direction (growth anisotropy). Thus, the ability of CMFs to control anisotropic growth lies in their mechanically anisotropic behavior, i.e. the cellulose macromolecules have higher tensile moduli and greater

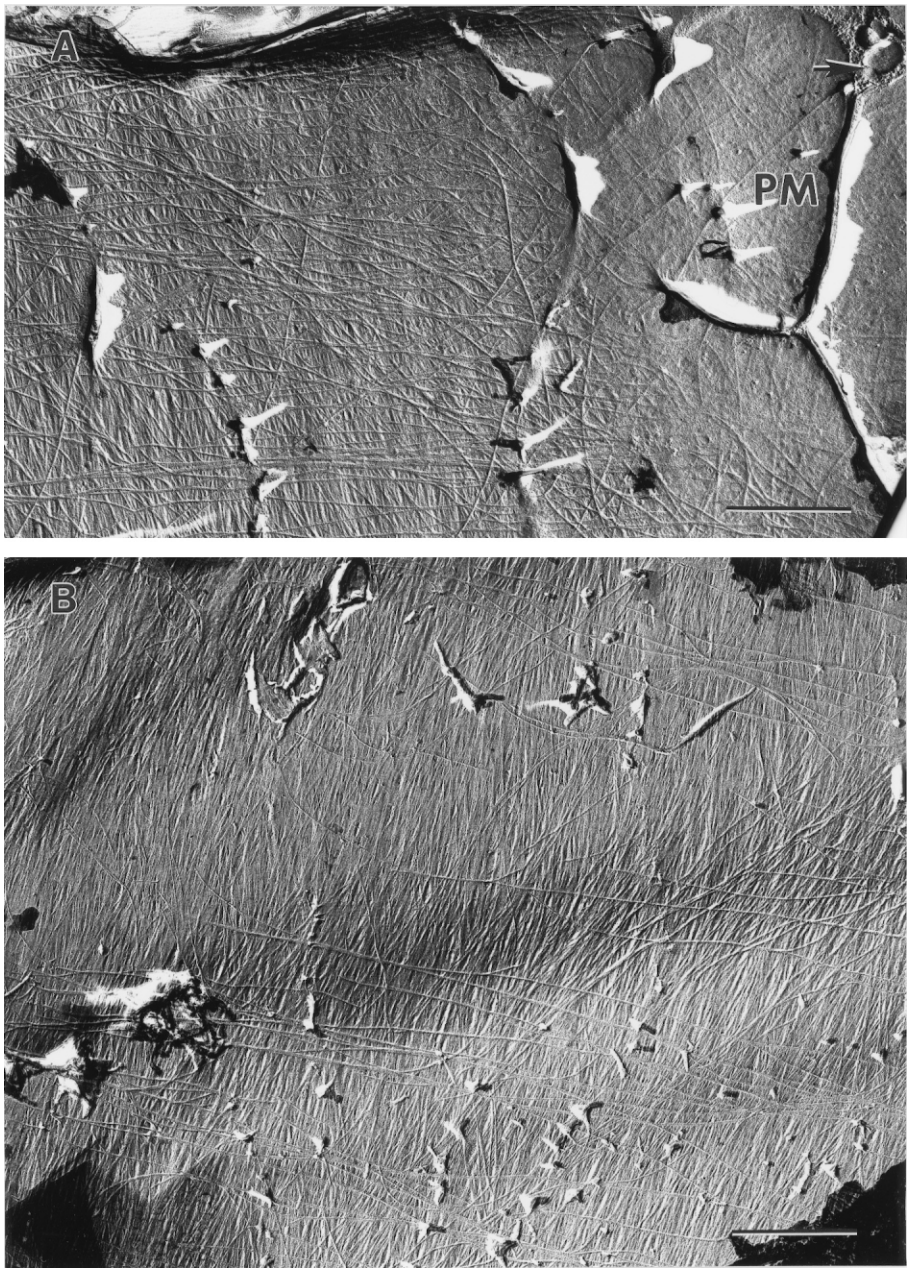

Fig. 3. Cellulose microfibril organization in the inner strata (facing the plasma membrane, PM) of cortical parenchyma cells of wheat primary roots developed under 1 *g* on Earth (A) and microgravity (B), scale bar: 0.5 μm.

tensile strength when stressed along their longitudinal axes than when stressed along the transverse axis (Niklas, 1992). Anisotropic expansion is also characterized by the direction in which maximal expansion rate occurs and in the degree to which this exceeds the minimal rate. The preponderance of evidence, therefore, suggests that the direction of maximal expansion is dictated by the mean orientation of the CMFs (Baskin et al., 1999 and references cited within), whereas the randomly oriented CMFs physically restrict directional expansion. Ordered cellulose microfibrils are also essential for directional expansion and proper differentiation. The fact that mature cells in space-grown wheat were properly elongated (Fig. 6) also supports the observation of well-organized CMFs with a preferred orientation.

Yet, previous studies under microgravity had suggested that mitotic activity in the root meristem following space flight was reduced (Krikorian et al., 1992; Claassen and Spooner, 1994). However, given that plant growth principally relies upon cell division and cell expansion, then if cellulose synthesis and CMF organization were dramatically disrupted by microgravity, it would be anticipated that cell elongation would have correspondingly been inhibited and the primary roots would have been shorter than their Earth-grown counterparts. On the contrary, the roots of the space-grown

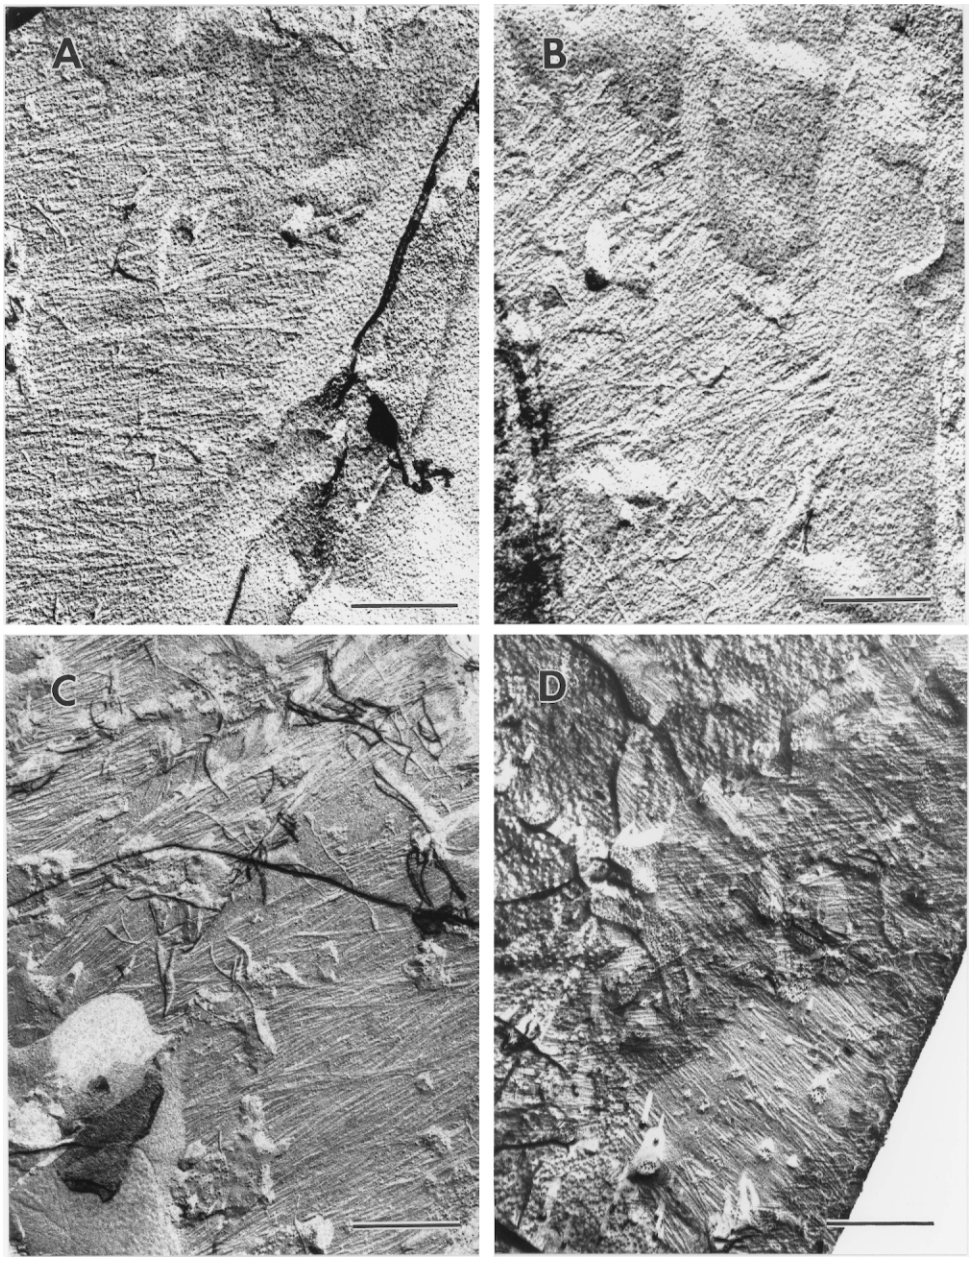

Fig. 4. Replicas of CMF arrangement on the innermost layer of untreated primary walls of cortical parenchyma cells in wheat primary roots developed under 1 *g* on Earth (A and B) and in microgravity (C and D), scale bar: 0.5 μm.

wheat were not significantly different from their Earth-grown controls (13.18 cm±4.26 vs. 11.99 cm±3.71, respectively). Furthermore, instances of even longer root lengths being formed under space-flight conditions, relative to the 1 *g* controls, have been reported (Levine et al., 1991, 2000; Levine and Krikorian, 1992).

2.3. *T. aestivum* secondary wall thickening patterns in water-conducting elements

Fig. 5A and B present transmission electron microscopy views of the cross-section of a vessel element and an adjacent parenchyma cell wall from ground and space-grown wheat roots, respectively. There is extensive thickening of the secondary wall (SW) in both vessel elements. The SW is slightly thinner in the space-developed vessel element in the micrographs shown, but the inherent variability in thickening over the entire surface of the primary walls negates any ability to claim significance in this respect. Serial longitudinal sections (Fig. 6) also revealed uneven secondary thickenings (as indicated by arrows) for both Earth- (1 *g*) and microgravity-grown plants. Three distinct types of thickenings were observed in both the space- and Earth-grown plants (Fig. 6), i.e. ring or spiral, regularly pitted and reticulate patterns. It seems that a single protoxylem

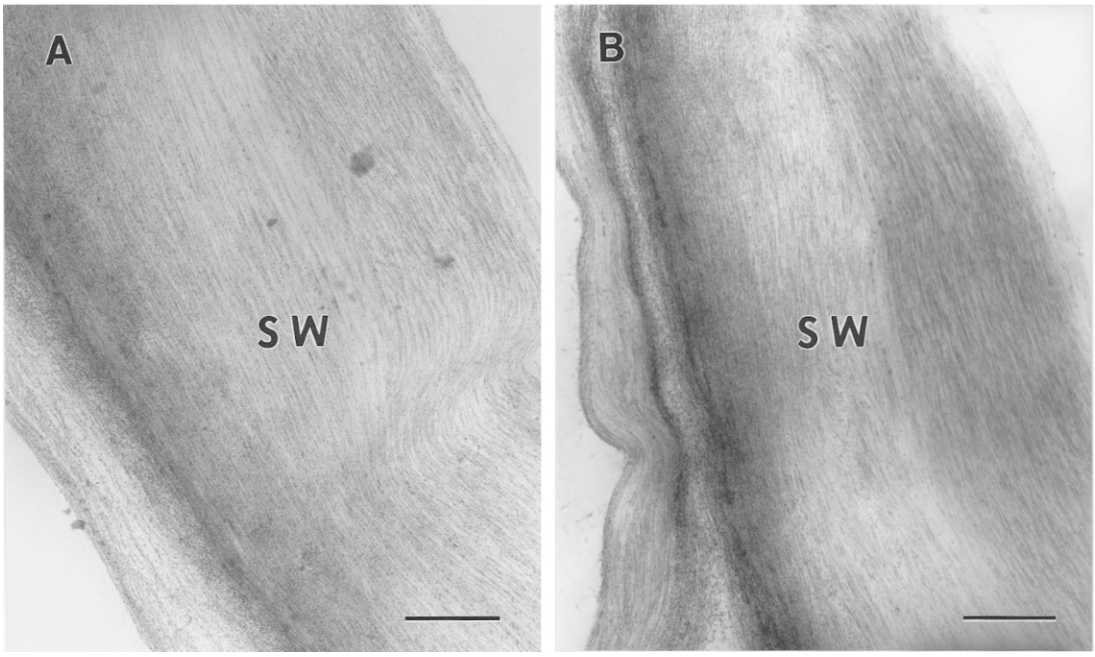

Fig. 5. Cross-sections of a vessel element and an adjacent parenchyma cell wall of wheat primary roots developed under 1 *g* on Earth (A) and in microgravity (B), scale bar: 0.5 μm.

vessel element has different patterns from one end to another (Fig. 6C), a feature commonly noted in plants (Hogetsu, 1991).

Next, a three-dimensional visualization of the secondary wall thickenings of both Earth- (1 *g*) and microgravity-grown wheat plants, was obtained by tissue maceration of the primary roots followed by staining with a fluorescent dye (see Experimental Section and Fig. 7). This method verified not only the thickenings in the protoxylem, but also allowed the examination of a broad range of distinctive vessel elements. Metaxylem vessels of larger diameter exhibited reticulate thickenings in the lateral walls (Fig. 7A and D), whereas medium sized vessel elements had both regularly arranged pits and randomly distributed pits (Fig. 7B and E). The protoxylem vessels, by contrast, had lattice thickenings (Fig. 7C and F) in addition to spiral thickenings (data not shown). Importantly, no twisted, deformed or mutated patterns of cell wall assembly were found in space-developed cell walls relative to those from ground control plants. However, the intensity of the fluorescent stain on the space-developed cell walls was less intense, as indicated by lower levels of contrast in the micrographs (Fig. 7D, E and F). This may be an indication of reduced cellulose deposition and thinner secondary walls in the space-grown wheat.

The secondary wall is an additional layer of cellulose deposited onto the primary wall with impregnation by hemicellulose and lignin to reinforce a specific group of cells (such as vessel elements). Carbohydrate synthesis is a key component in secondary wall formation. Previous studies demonstrated that the treatment of differentiating *Zinnia* cells with a cellulose synthesis inhibitor (2,6-dichlorobenzonitrile, DCB) results in less significant and less regular secondary thickenings (Suzuki et al., 1992; Taylor et al., 1992). Furthermore, the presence of the microtubule-disrupting agent, amiprophosmethyl, disrupted the deposition of cellulose and hemicellulose, resulting in deformed secondary thickening patterns in tracheary elements of *Pisum* roots and epicotyl and *Commelina* roots (Hogetsu, 1991). Therefore, the finding of normal thickenings in the water conducting elements of space-grown primary roots could be an indication that neither cell wall biopolymer synthesis nor microtubule assembly and functions involved in secondary thickenings were adversely affected by the microgravity environment to any appreciable extent. These results also imply that cells grown under microgravity conditions undergo successful differentiation according to their predetermined functions.

2.4. Lignin analyses of *T. aestivum* leaves and roots

It was next deemed instructive to ascertain the lignin content, determined as % acetyl bromide lignin (Iiyama and Wallis, 1990), and the lignin monomeric composition, using the thioacidolysis procedure (Lapierre et al., 1985), to determine relative amounts of guaiacyl and syringyl moieties (Table 2). The results obtained for removal of extractives, gave higher yields for flight-grown shoots and roots relative to Earth-grown plants. By contrast, acetyl bromide lignin determinations of the flight grown tissues were very slightly lower (~7%) than that of the Earth-grown counterparts, and not statistically

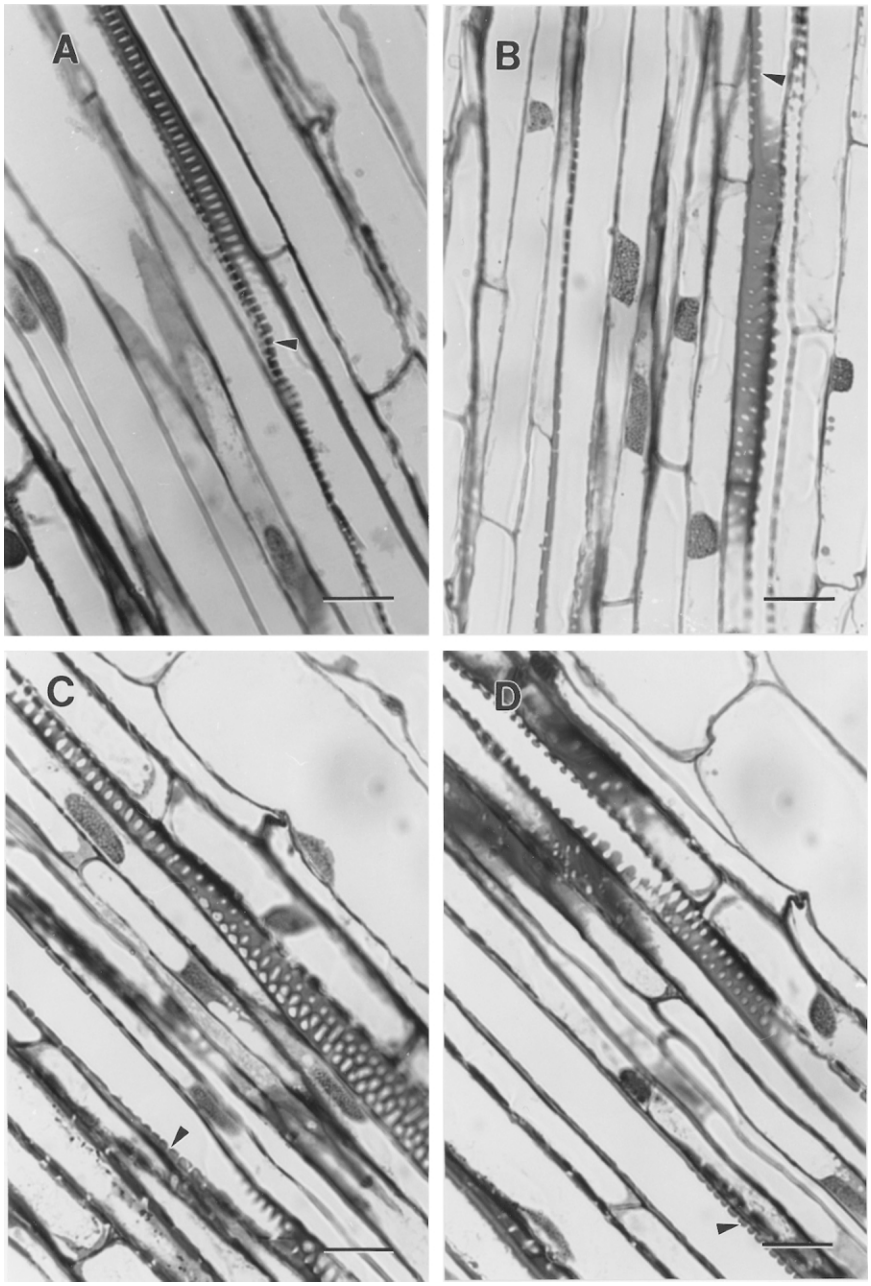

Fig. 6. Longitudinal sections of wheat primary roots revealing secondary thickening patterns developed under 1 *g* on Earth (A and B) and in microgravity (C and D), scale bar: 20 μm.

very different. Thioacidolysis also revealed that the *S*/*G* ratio for both shoots and roots were essentially the same. In conclusion, there were no substantial differences in either lignin contents or composition.

2.5. Concluding remarks

We report herein on several aspects of cell wall formation under microgravity conditions. Primary roots of wheat developed under space-flight conditions possessed normal primary and secondary wall frameworks, i.e. equivalent to those noted at 1 *g*, with lignin contents and compositions only slightly changed relative to the 1 *g* counterparts. It is possible, that while seedlings initiated on Earth did not exhibit any microgravity effects during the course of these relatively short space shuttle missions, a different result might be obtained for either seedlings actually initiated in space and/or grown for much longer duration. In addition, there may be multiple gravisensing thresholds which come into effect for different graviresponses. Note also that while the convention is to refer to the gravitational environment on a space shuttle as a microgravity (10^{-6} *g*) environment, in reality the term milligravity (10^{-3}–10^{-4} *g*) may be more appropriate (Krikorian and Levine, 1991). Thus, we cannot eliminate the possibility that more striking

Fig. 7. Fluorescence-stained whole cell mounts demonstrating reticulate, regular pits and latticed secondary thickenings of metaxylem, medium-sized and protoxylem vessel elements from wheat primary roots grown under 1g (A–C) and microgravity conditions (D–F), scale bar: 40 μm.

Table 2
Lignin content and compositional analyses of wheat (*Triticum aestivum*) plants grown in space aboard space shuttle *Discovery* and on Earth

	Extractives (%)	Lignin content (%)	*S*/*G* ratio
Flight			
Shoots	63.6	9.15±0.18	0.145
Roots	75.8	11.72±0.28	0.380
Control (1 g)			
Shoots	41.0	10.32±0.33	0.150
Roots	70.2	12.04±0.26	0.430

responses would have been evident under conditions closer to a zero *g* environment. Finally, metabolic and morphological responses may differ based upon the physiological state of the plant when the critical stimulus is exerted. Given these variable factors, this may in part explain some of the conflicting results obtained from previous space flight experiments which were conducted using different species at different life stages and using different protocols and hardware. Clearly, more studies are required in order to dissect and explain the role that gravity has in plant growth and development. However, a growth and development system has now been developed to study these processes, and to help identify what effects the microgravity environment has.

3. Experimental

3.1. Plant material

Dwarf wheat (*Triticum aestivum*, var. Super Dwarf) seeds obtained as a gift from Dr. Bruce Bugbee (Crop

Physiology laboratory, Utah State University, Logan) were planted in Washington State University greenhouse facilities, grown to maturation and the seeds harvested. The corresponding seeds were then used in all further experiments.

3.2. Plant growth unit (PGU)

The plant growth unit (PGU) used in this experiment is as described in Kwon et al. (2001).

3.3. "Nutrient pack" for support of T. aestivum growth and development

A nutrient support system was designed in order to immobilize the nutrients and water in a gel matrix, and this configuration was named "nutrient pack" (see Fig. 1A).

The non-media components of the "nutrient pack" consist of the medium enclosure membranes, prepared from 55 μm gauge autoclavable polypropylene film, fused with a 24 mm 0.02 μm-disc gas diffusion membrane (Sun bags, Sigma). This material was sectioned and heat sealed to form square packs (4.2×4.5×6.5 cm; L×W×H), with the diffusion membrane positioned in the upper face of the pack. The upper face was also used to incorporate three open ended columns (3.0 cm in length; prepared from 1.5 ml polypropylene Eppendorf tubes). Each column was sectioned with 8 longitudinal slits (15×1.0 mm) to provide mechanical support for the germination media plug on which the seeds are originally planted.

Four empty packs were autoclaved in each PGC. Under aseptic conditions, 50 ml of enriched medium (see composition below) were added to each pack and allowed to set before a further addition of normal strength medium (50–60 ml, see composition below) leaving an air phase of ca 1.0 cm in depth. Columns prepared with solidified germination medium (see composition below) were finally secured to the upper face of the nutrient pack and partially submerged to a depth of 1.0–1.5 cm into the normal strength medium.

3.4. Nutrient media

3.4.1. Normal strength medium

Macroelements: $CaNO_3$ (4 mM), KNO_3 (6 mM), $MgSO_4$ (2.0 mM), KCl (0.32 mM), NaH_2PO_4 (0.81 mM), and KH_2PO_4 (0.93 mM).

Microelements: H_3BO_3 (24.25 μM), $MnSO_4$ (13.24 μM), $ZnSO_4$ (13.92 μM), Na_2MoO_4 (1.03 μM), $CuSO_4$ (0.4 μM), $CoCl_2$ (0.105 μM), KI (4.52 μM), NaFe-EDTA (2.7 μM), and $FeSO_4$ (5.0 μM).

The pH of the medium was adjusted to 5.6 (NaOH, 100 mM) and 1.0% (w/v) agar was added prior to autoclaving for 20 min.

3.4.2. Enriched medium

This medium was prepared as above but with KNO_3 (9.0 mM), NaFe-EDTA (5.4 μM) and $FeSO_4$ (10.0 μM).

3.4.3. Germination medium

This medium consisted of 0.7% agar only.

3.5. T. aestivum seed germination and transfer of germinated seeds to the plant growth chamber (PGC)

Seeds were sterilized in a 25% (v/v) aqueous solution of bleach (6.25% sodium hypochlorite) containing 2% (v/v) Triton X100 for 10 min then washed with sterile distilled water (5 times). The seeds were next transferred to Petri dishes (24 seeds/dish) containing the normal strength medium diluted 1:1 with H_2O and these were placed in an incubator at 25° in the dark. After 2 days, the germinated seeds were individually transferred to "nutrient agar plugs", with the emerging shoot placed in a vertical position. Two days later the nutrient agar plugs were inserted into the support column of the nutrient bag. The PGC was then closed and transferred to the PGU.

3.6. Payload verification test

The PGU was placed in the orbiter environmental simulator (OES) which uses space shuttle calibrated ancillary data (CAS) to mimic the middeck environment. Following a 9-day mission the PGU was removed from the OES, photographs were taken, and the plants were harvested and fixed as described in Section 3.8.

3.7. Flight experiment

On day 1 (11:00 am), the nutrient agar plugs were inserted into the support columns of the nutrient packs. Two PGCs were prepared under these conditions. Wheat plants were also grown in a foam-nitex matrix (2 other PGC's) as described in Tripathy et al. (1996). The PGCs were closed, photographs were taken, and then transferred to the PGU. The PGU was stored in the orbiter environmental simulator until 4:30 PM where it was taken and stowed in the space shuttle *Discovery*. *Discovery* took off on day 2 at 7:45 am EDT at Cape Canaveral, FL, and returned to Earth after 9 days, 20 h, 11 min, 11 s. Seedlings were allowed to grow under continuous light, with an intensity of 30–60 μmol sec^{-1} m^{-2}, and at a temperature range of 22–26°C.

3.8. Space-grown T. aestivum tissue fixation

Plants were harvested within 3–4 h following landing at Kennedy Space Center. Four representative wheat plants grown in the "nutrient pack" and 6 in the foam-nitex matrix were chosen. Segments (2–3 mm long) of

primary roots were dissected from a point one centimeter basal to the root tips, thereby assuring that growth had occurred during the space flight. The segments were immediately immersed in fixative containing 3% glutaraldehyde and 2% paraformaldehyde in PIPES buffer (1,4-piperazinediethanesulfonic acid, 100 mM, pH 7.4) and placed at 4°C until further processing.

3.9. Postfixation and embedding

Chemically fixed plant tissues were rinsed with 0.1 M PIPES buffer and postfixed in 1% osmium tetraoxide overnight at 4°C. Specimens were thoroughly rinsed and dehydrated with an alcohol series (30, 50, 70, 80, 95 and 100% × 2). The dehydrated specimens were infiltrated with Spurr's resin and embedded by heating the resin at 70°C overnight. Longitudinal sections (1 μm thick) of the wheat roots were prepared and stained with methylene-blue. Sections were observed using an Olympus BH2 microscope, and micrographs were recorded on Technical pan 100 black-white film.

3.10. Freeze-fracture/transmission electron microscopy

Prefixed root tissues were further cut into short segments (1–2 mm) and treated with methylamine for 18 h. The root segments were next placed onto a Balzers specimen holder using starch paste (1 g/1.5 ml), then quickly immersed into liquid nitrogen cooled Cryokwik (dichlorodifluoromethane, CCl_2F_2) slurry for 30 sec. Frozen specimens were carefully but rapidly transferred to a precooled (−140°C) Balzers specimen stage in a freeze-etch unit (BA-360 M), fractured at −120°C, and etched for 15 min at −110°C under 10^{-6} Torr. Exposed etched surfaces were replicated by shadowing with platinum/carbon at an angle of 30–40° and backed with deposition of carbon at an angle of 90°. The replicas were floated onto distilled water and subsequently transferred to 30% chromic acid (v/v) to digest away tissue remnants. These were then thoroughly washed with distilled water and loaded onto formvar-coated 200-mesh grids (Ted Pella, Inc.). The platinum/carbon cell wall replicas were observed with a Hitachi H-600 at 100 kV and photographed with Kodak film 4489.

3.11. Measurement of microfibril angle

Digitized versions of micrographs were analyzed for the relative angle of the cellulose microfibrils in adjacent cell wall layers using the NIH Image 1.54 image processing program in a manner similar to that described by Seagull (1992). Micrographs of 3–5 replicates were measured. The mean microfibrillar angles for both layers within each micrograph were then used to calculate the angular offset between the two layers. Thus each micrograph yielded one final value reflecting the degree to which the two microfibril layers were offset from one another.

3.12. Whole cell mounts and fluorescence microscopy

Excised wheat root segments were macerated in a solution of HCl-95% ethanol (1:3) at room temperature for 24 h followed by an additional 2 h treatment at 70°C. The tissue was then rinsed with distilled water thoroughly and stained with 0.01% (wt/v) Fluorescent brightener 28 (Sigma) for 30 s. Samples were placed onto a microscope slide in a drop of 50% glycerol and squashed gently with a coverslip. Observations were made with an Olympus BH 2 microscope equipped with epifluorescence optics and using a blue-filter package. Micrographs were recorded using an Olympus PM 20 automatic exposure unit on TMAX 400 film.

3.13. Lignin analyses

Aerial portions and roots of plants grown both in space and on Earth (control) were freeze dried and reduced to a powder by means of a ball-mill. Aerial portions (~200 mg) and roots (~50–60 mg) were sequentially extracted with water, ethanol, and toluene/ethanol (1:1) as described in Yahiaoui et al. (1998). The resulting extracted residue was dried and subjected to both acetyl bromide (Iiyama and Wallis, 1990) and thioacidolysis (Lapierre et al., 1985; Blee et al., 2001) analyses, respectively.

Abstract

In the microgravity environment of the Space Shuttle Columbia (Life and Microgravity Mission STS-78), were grown 1-year-old Douglas fir and loblolly pine plants in a NASA plant growth facility. Several plants were harnessed (at 45°) to establish if compression wood biosynthesis, involving altered cellulose and lignin deposition and cell wall structure would occur under those conditions of induced mechanical stress. Selected plants were harnessed at day 2 in orbit, with stem sections of specific plants harvested and fixed for subsequent microscopic analyses on days 8, 10 and 15. At the end of the total space mission period (17 days), the remaining healthy harnessed plants and their vertical (upright) controls were harvested and fixed on earth. All harnessed (at 45°) plant specimens, whether grown at 1 *g* or in microgravity, formed compression wood. Moreover, not only the cambial cells but also the developing tracheid cells underwent significant morphological changes. This indicated that the developing tracheids from the primary cell wall expansion stage to the fully lignified maturation stage are involved in the perception and transduction of the stimuli stipulating the need for alteration of cell wall architecture. It is thus apparent that, even in a microgravity environment, woody plants can make appropriate corrections to compensate for stress gradients introduced by mechanical bending, thereby enabling compression wood to be formed. The evolutionary implications of these findings are discussed in terms of "variability" in cell wall biosynthesis. © 2001 Published by Elsevier Science Ltd. All rights reserved.

1. Introduction

Douglas fir (*Pseudotsuga menziesii*) and loblolly pine (*Pinus taeda*) represent two important gymnospermous tree species used today for pulp and paper manufacture, and for other solid wood products. Understanding how to optimize both the quality and the texture of such woody (secondary xylem) tissue is an important biotechnological goal, particularly with current trends towards "fast-growing" plantations as sources of both fiber and wood (Lewis and Davin, 1994). A highly deleterious feature in terms of wood properties for such applications arises when their stems form reaction wood. This specialized tissue is manifested as "compression" wood in the Coniferales, Ginkgoales and Taxales, and as "tension" wood in the woody angiosperms.

The physiological function of such specialized reaction wood tissues (and corresponding cell types) provides woody stems with a mechanism by which they can realign their orientations when displaced away from the vertical axis. Branches also form such tissues in a way whereby this provides the means for continually orientating (or reorientating) branching angles. Compression wood is formed on the underside of leaning stems and branches, and manifests its effect by slowly buttressing (pushing) the stem or branches until the requisite (re)orientation is achieved. Tension wood, on the other hand, is formed on the upper side of woody angiosperm branches and leaning stems, and functions by "pulling" the branches and stems to the needed orientation (Westing, 1965; Scurfield, 1973; Timell, 1986; Lewis et al., 1999; Croteau et al., 2000).

The formation of compression/tension wood is an inducible process (Cronshaw and Morey, 1965; Wilson and Archer, 1977; Fisher, 1985; Baba et al., 1995), although how this is achieved is not understood in terms of: the nature of the stimulus (gravity, "stress", and/or other factors); how the signal(s) is (are) perceived by the plant(s); how signal transduction occurs resulting in activation of cascades of various biochemical pathways, and, thus, which ultimately affords these specialized cell wall structures. Fig. 1a shows the effect of prolonged compression wood deposition in a sequoia (*Sequoia sempervirens*), a gymnosperm, which unsuccessfully attempted to restore its vertical alignment over several centuries. There are two distinct regions observable in the transverse section, namely that of compression wood on the underside and so-called opposite wood on the upperside. For comparative purposes, Fig. 1b displays a transverse section of "normal" wood tissues in a gymnosperm. Clearly, these corrective processes when induced can be sustained over extremely long periods if the required effect is not achieved.

In gymnosperms, the wood opposite to compression wood has "normal" tracheids of a squared or rectangular shape, with apparently no significant differences to those of "normal" xylem (Timell, 1986). In "opposite" wood, the relative proportions of the plant cell wall biopolymers (lignin, cellulose and hemicelluloses) appear to be essentially identical to that of "normal" wood (Timell, 1986). However, compression wood tracheids are markedly different from "normal" tracheids. For example, in loblolly pine (*P. taeda*), the compression wood tracheids are 10–40% shorter than normal (Yoshizawa and Idei, 1987) with frequently distorted tips (Wardrop and Dadswell, 1952). Fig. 2 shows a Douglas fir cross-section of normal wood (Fig. 2a) and compression wood (Fig. 2b), where the tracheids of the latter (Fig. 2b) have a rounded outline with large intercellular spaces in the cell corner regions, with three or four tracheids in contact with each other; the "normal" tracheids by contrast have a rectangular shaped outline with no intercellular spaces (Fig. 2a). Anatomically, compression wood tracheids differ from those of normal wood as follows: the S1 and S2 layers of compression wood secondary cell walls are thicker (Fig. 2d) than those of "normal" wood (Fig. 2c), with the S2 layer deeply fissured along the direction of the cellulose microfibrils (Wardrop and Dadswell, 1950; Wardrop and Davies, 1964); there is no S3 layer (Westing, 1965, 1968; Yoshizawa and Idei, 1987).

In general, compression wood cellulose has a lower degree of polymerization, is less crystalline (Lee, 1961) and has an altered cellulose microfibril orientation in the secondary cell wall (Timell, 1986). In "normal" tracheids (Fig. 2c), the cellulose microfibrils are relatively flat (70° to 50° to the cell length) in the Sl and S3 sublayers, while in the S2 sublayers they are relatively steep (45° to 10° to the cell length; Scurfield, 1973). By contrast, compression wood tracheids are aligned more or less transversely in the S1 sublayer, whereas in the S2 sublayer they are, for the most part, at an angle of 30–45° to the longitudinal axis of the cell (Fig. 2d; Scurfield, 1973). This suggests that microtubular assembly/orientation is greatly affected during compression wood cell wall assembly.

Woody angiosperms biosynthesize a different kind of reaction wood tissue known as tension wood. In this

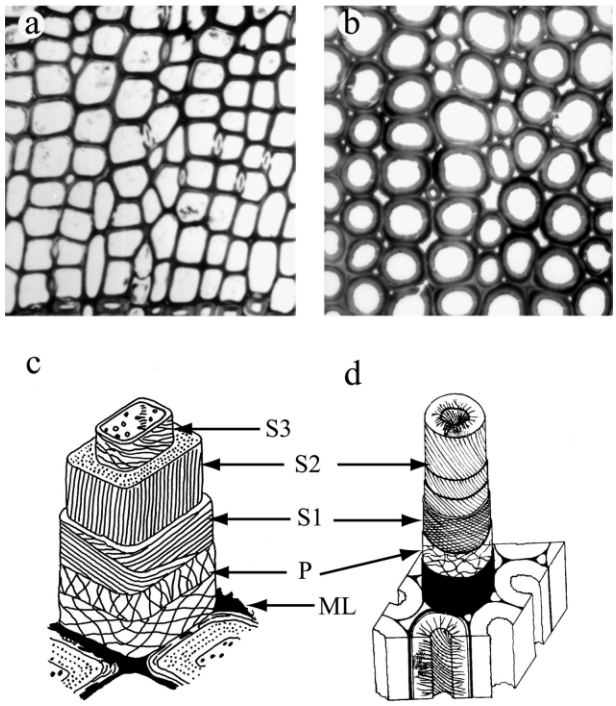

Fig. 2. Cross-section of Douglas fir seedling stems displaying (a) "normal" wood and (b) compression wood, as well as idealized schematic models for the cell wall structures of xylary cells (tracheid and libriform fibers) in (c) "normal" wood and (d) compression wood secondary xylem. Solid lines approximate the cellulose microfibril orientations. Abbreviations: ML: middle lamella; P: primary cell wall; S1: outermost layer of secondary wall; S2: middle layer of secondary cell wall; S3: innermost layer of secondary cell wall [c and d: redrawn from Fengel and Wegener (1984) and Timell (1986), respectively].

case, the accentuated growth is generated on the upper side of the branches and leaning stems as they attempt to (re)gain a particular alignment or orientation (Scurfield, 1973). Relative to "normal" wood (Fig. 3a), the most characteristic feature of tension wood is in the deposition of a new cell wall layer, the so-called gelatinous (G) layer (see Fig. 3b–d). "Tension" wood contains conspicuously thickened inner cell wall layers (i.e. non-lignified G-layers; Scurfield, 1964), which are composed almost entirely of cellulose (Norberg and Meier, 1966). Moreover, three distinct types of secondary walls in tension wood fibers have been reported; these include cells which either have not formed the S2 and S3 sublayers (Fig. 3b), and the S3 sublayer (Fig. 3c), or those which also contain an additional G layer (Fig. 3d), respectively. Interestingly, the microfibrils in the G layer are oriented (nearly) parallel to the longitudinal axis and have a high degree of crystallinity (Mia, 1968; Côté et al., 1969; Scurfield, 1973).

Another important distinction between both forms of reaction wood is in the differences in their cell wall polymeric constituents. In compression wood, for example, the lignin content is significantly higher, with a large increase in the amount of *p*-coumaryl alcohol present relative to that of coniferyl alcohol (Bland, 1961; Nimz et al., 1981; Timell, 1986; Lapierre and Rolando, 1988; Lapierre et al., 1988). Indeed, the darker color of compression wood might be attributed in part to this increase in the amount of lignin (e.g. from ca 25% in "normal" wood to ca 34% in compression wood of *Abies balsamea*; Westing, 1965). Tension wood, by contrast, may have lower lignin contents although this is still somewhat controversial (Timell, 1986).

Although both the content and monomeric composition of compression wood lignins are quite different from that of "opposite" wood, essentially nothing is known yet about how each is formed. In compression wood of *Thuja orientalis* and *Metasequoia glyptostroboides,* the activities of certain enzymes involved in lignin precursor biosynthesis were marginally higher than that of "normal" wood, i.e. phenylalanine ammonia lyase (PAL), 3-*O*-methyltransferase (OMT), *p*-hydroxycinnamate:CoA ligase (4CL) and cinnamyl alcohol dehydrogenase (CAD) (Kutsuki and Higuchi, 1981).

More recently, an important clue as to how monolignol composition and content is controlled was obtained through the study of monolignol biosynthesis in *P. taeda* cell suspension cultures (Anterola et al., 1999). By provision of increasing amounts of phenylalanine, a differential induction of formation of its monolignols was observed, i.e. the formation of coniferyl and *p*-coumaryl alcohols was differentially induced, with their ratios changing from ca 8:1 to 1:1, respectively (Anterola et al., 1999). This observation may provide an

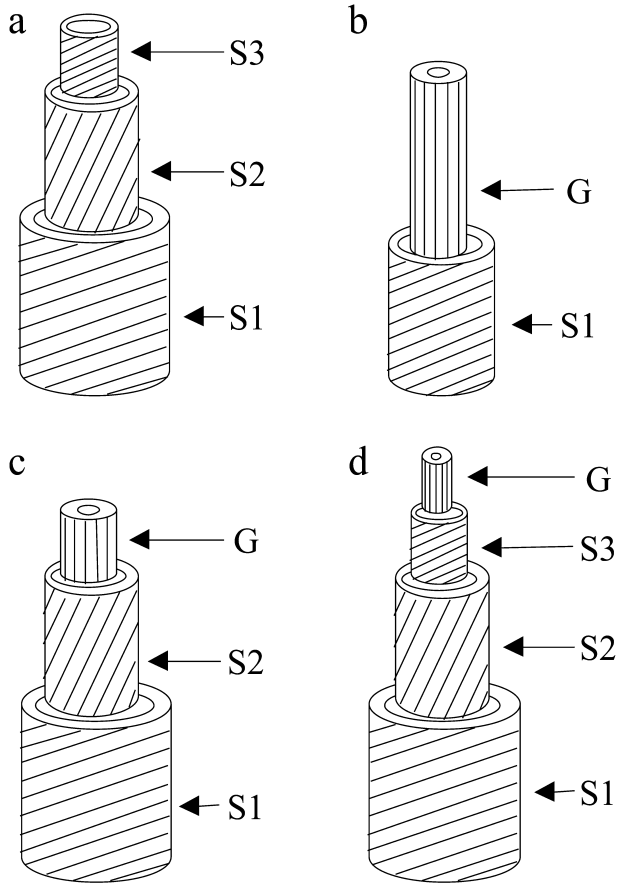

Fig. 3. Idealized diagrammatic representation of the organization of normal angiosperm wood (a), and three types of secondary walls observed in tension wood formation (b, c, and d). Solid lines indicate the cellulose microfibril orientation [redrawn from Wardrop and Dadswell (1955)].

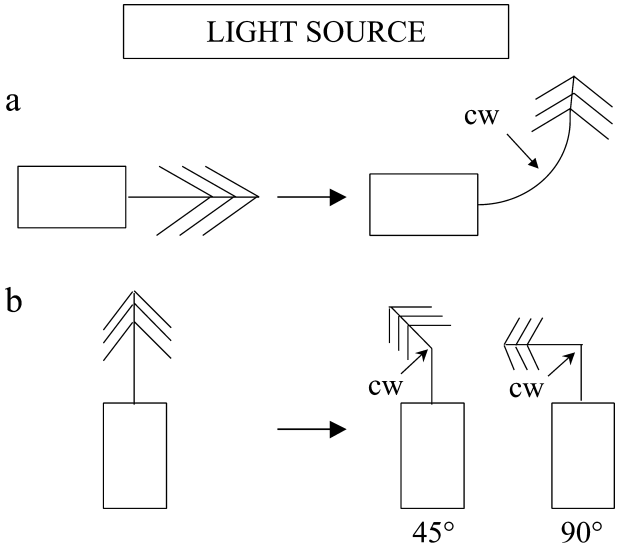

Fig. 4. Preferred plant configuration for studying compression wood formation in microgravity (a) and the configuration adopted for this study to induce compression wood formation of Douglas fir (*Pseudotsuga menziesii*) and loblolly pine (*Pinus taeda*) seedlings by mechanical bending at 45 and 90° (b).

explanation for the noted increases in the *p*-coumaryl alcohol content of compression wood lignins.

In this study, 1-year-old Douglas fir (*P. menziesii*) and loblolly pine (*P. taeda*) plants were placed under mechanical strain (harnessed at 45°) in a microgravity environment, aboard the Space Shuttle, Columbia (STS-78 mission), in order to determine whether compression wood formation would still occur. Because of the time constraints of the flight experiment (~17 days), the plant stems were oriented (bent) to a 45° angle from the vertical axis by mechanical stimulation. This procedure was initiated after 48 h in flight. This study describes the results from this research, i.e. as a first step to establishing how regulation of reaction wood formation occurs, and how the processes of both compression and tension wood have differentially evolved.

2. Results and discussion

The STS-78 mission objective was to establish whether compression wood formation could be engendered in a true microgravity environment when the plant species of interest were placed under mechanical strain. In order to investigate this question, various experimental protocols needed to be developed prior to embarking upon space-flight. These included: (1) verifying that compression wood was formed within the duration of the proposed space-flight and then (2) adapting an experimental protocol for space-flight that would result in compression wood being biosynthesized under normal gravitational loads (at 1 *g*).

Eventually, in order to test whether compression wood formation is manifested in microgravity, the preferred experimental design would be growth of the woody plants in space in an horizontal orientation relative to the light source (Fig. 4a). Following unassisted phototropic mediated reorientation of the stem and the photosynthetic canopy over an extended duration of time (weeks, months), the resulting xylem formed could then be analyzed to establish if compression wood resulted. Under such conditions, there would presumably be no external stresses imposed (e.g. by mechanical bending) on the plants, and hence this would represent the most ideal growth conditions to investigate the effects of a greatly diminished gravitational load (microgravity). Such an experiment is not yet possible since the duration of space-flight experiments on the space shuttle cannot be extended to the lengthy timeframes required. This study, therefore, must await scientific utilization of the International Space Station research platform in the future.

As a preliminary experiment, it was instructive to first ascertain whether compression wood formation might result by mechanical stimulation in microgravity. This involved the harnessing (bending) of woody plants aboard the 17 day STS-78 space shuttle mission.

Conditions for compression wood formation and its detection at normal gravitational loads (1 *g*) were first verified as follows: soil-grown Douglas fir and loblolly pine seedlings (four each) were mechanically bent at 45° and 90° (Fig. 4b), for different time intervals (9 and 15 days). The plants were then restored to a vertical alignment, and at the end of 17 days, were harvested and analyzed. All plants when bent at 45° and 90° to the vertical axis had formed compression wood, i.e. as evidenced by the presence of the characteristic compression wood round-shaped tracheids and intercellular spaces (see Fig. 5a and b which show only the results for Douglas fir). Since progression of compression wood development could be observed when plants were mechanically bent at a 45° angle, this particular orientation was adopted for all subsequent experiments.

With a timeframe suitable for the study of possible compression wood development on the space shuttle flight, the next technical development was to identify

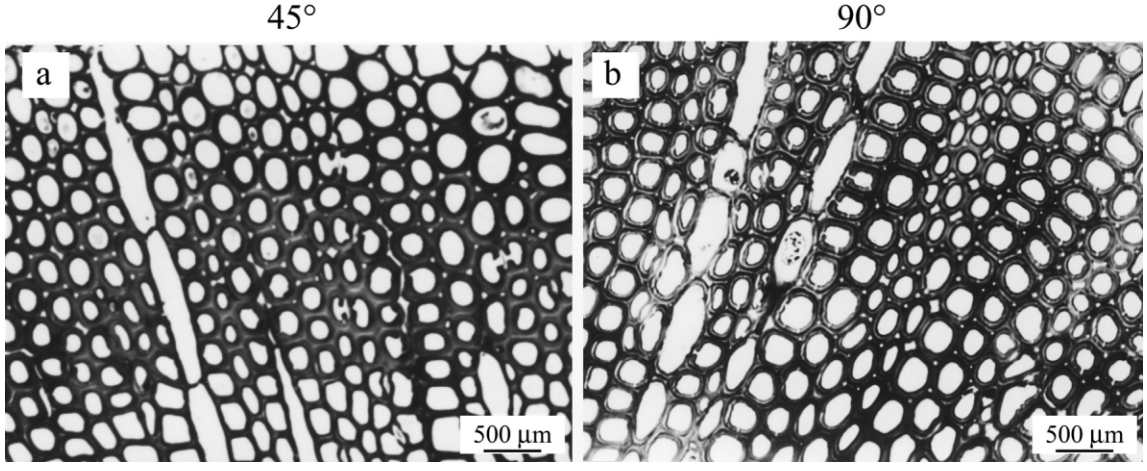

Fig. 5. Partial cross-sections of Douglas fir seedlings grown for 9 days at (a) 45° and (b) 90° configuration, respectively, then allowed to further grow for an additional 8 days in an upright (vertical) orientation.

suitable plant growth conditions using the NASA supplied plant growth chambers (PGCs). Plant growth in space in general has long been problematic, mainly because applied liquids (water) in space tend to ball up and not diffuse (spread) throughout the solid root supporting system(s). Additionally, the NASA plant growth unit (PGU), which can house up to six PGCs, has no ability to readily add water and nutrients to plants on an ongoing basis during space-flight. Moreover, although lighting is provided, the temperature regimen experienced cannot be controlled, i.e. the plant growth temperature is dictated by, as a minimum value, the ambient temperature of the space shuttle cabin.

Nutrient packs (agar gels containing the requisite amount of water and nutrients required for the duration of the Space-Shuttle flight, see Section 4) were next developed, and these were adapted for growth of both Douglas fir and loblolly pine seedlings (Fig. 6a, showing only loblolly pine). The overall dimensions of the PGCs necessitated trimming of the plants at the crown (via decapitation) in order for them to fit snugly into the growth chamber (Fig. 6b, showing only loblolly pine). In earlier studies (Wardrop, 1957; Westing, 1961), both girdling of trees and decapitation had no noticeable effect on the ability to form reaction wood. Decapitation of the Douglas fir and loblolly pine plants in our studies also had no deleterious effect on compression wood formation (data not shown). Thus, with the various experimental parameters [light levels, temperatures, orientation and use of trimmed (decapitated) plants] so defined, attention was next directed to establishing the precise protocol to be employed for space-flight.

Space shuttle flight experiments must undergo rigorous pre-flight controls at Kennedy Space Center at Cape Canaveral [so-called payload verification tests (PVTs)] in order to verify conditions necessary for successful space-flight experimentation, and thus to ensure that reliable scientific data is collected on the effects of the microgravity environment proper. The PVT thus established that (1) decapitated Douglas fir and loblolly pine seedlings grew ''normally'' in the nutrient pack within the plant growth chambers (of the PGU) for the duration of the proposed flight(s); (2) that compression wood was formed in the plants used, when their stems were bent at a 45° angle to the vertical axis, while housed in the nutrient packs in the PGC for periods of 8, 10 and 15 days, respectively; and (3) that plant tissues were well preserved when fixed at room temperature in 2% paraformaldehyde/2.5% glutaraldehyde, using a specially designed fixation kit suitable for handling and containing liquid samples in space (microgravity; see Fig. 6c and d, respectively).

To summarize, the decapitated Douglas fir and loblolly pine seedlings, when placed in the nutrient packs housed in the PGC, grew either normally (upright) or developed compression wood (45° harnessing) during the time-frame examined (see Fig. 7a–e and 7b–d, respectively).

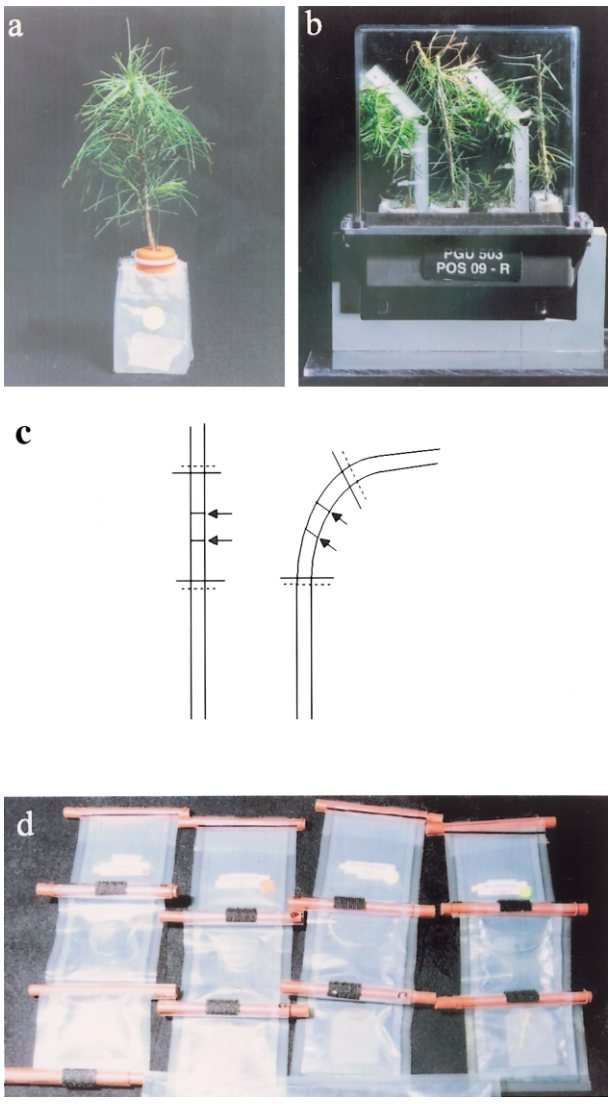

Fig. 6. Loblolly pine seedling inserted in a nutrient pack (a) and a plant growth chamber (PGC) containing decapitated loblolly pine seedlings which were grown in an upright (vertical) position and at a 45° configuration, respectively (b); a comparable system was used for Douglas fir seedlings. Diagram showing the regions of plant stem samples that were selected and harvested for fixation and microscopic analysis (c) and the fixative bags designed for plant tissue fixation in space (d). The dotted lines approximate the sites of initial sectioning with wire cutters, and the second solid line shows the region subsequently sectioned using mechanical clippers. The plant tissue segment between the two arrows was subsequently fixed and utilized for microscopic analyses.

By contrast, the corresponding opposite wood (Fig. 7f–h) only developed ''normal'' secondary xylem with rectangular shaped tracheids and no intercellular spaces.

It was possible to identify cells designated to become compression wood tracheids as early as at the beginning of primary wall differentiation, i.e. when the cells undergo expansion just after cell division has occurred

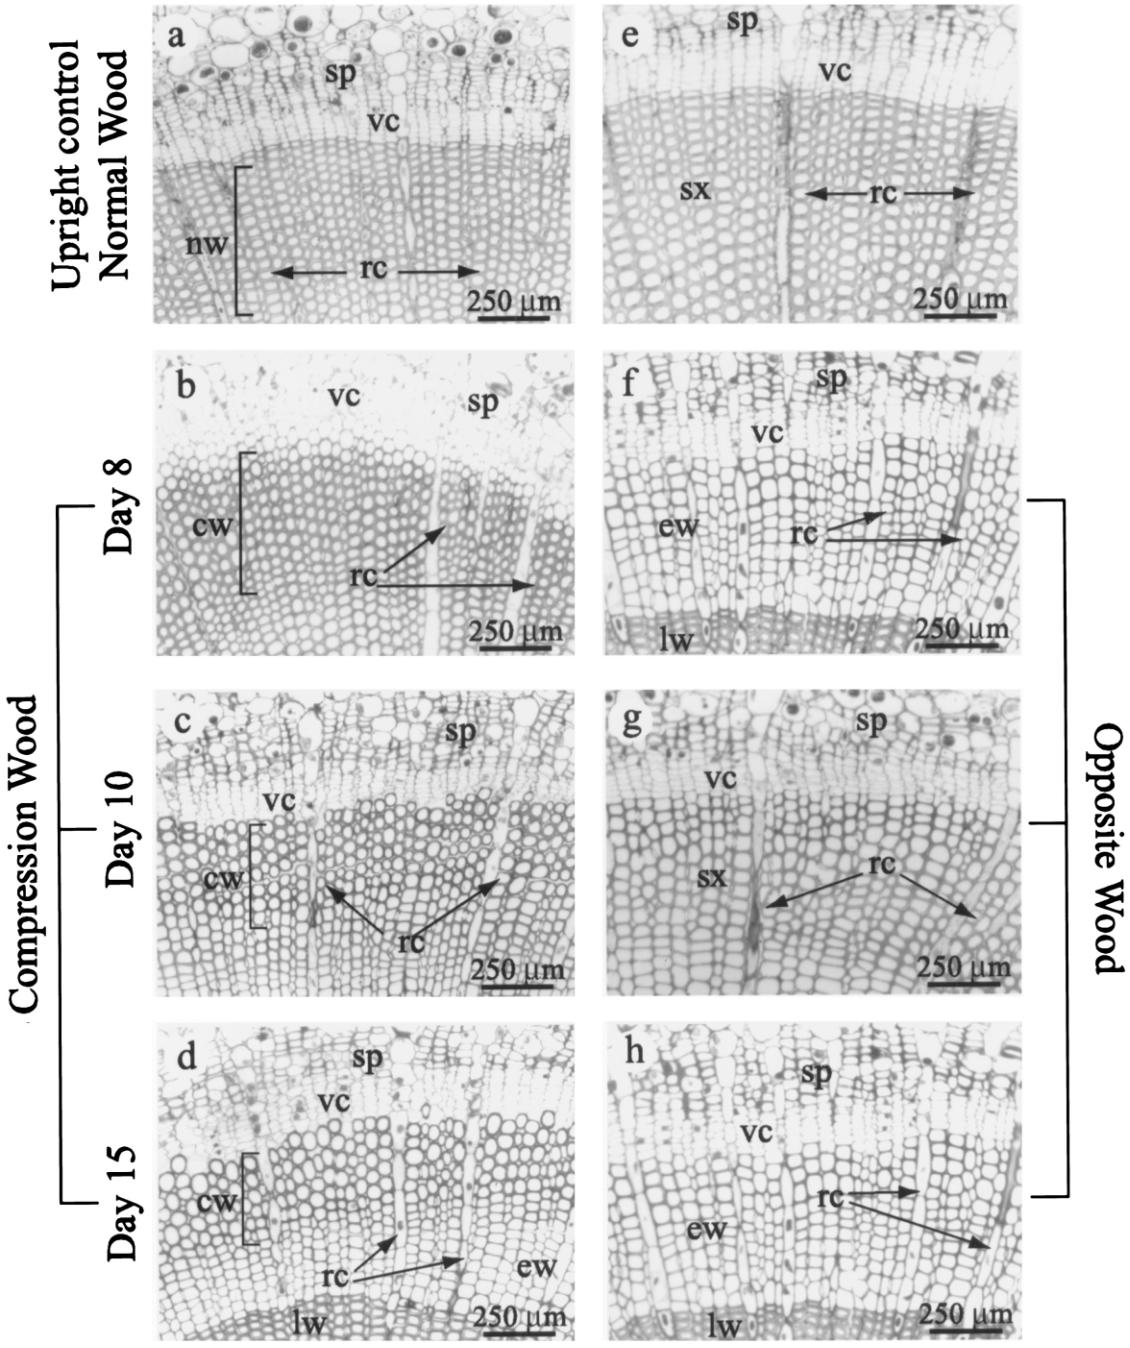

Fig. 7. Cross-sections of Douglas fir seedlings grown in an upright vertical position for 17 days (a, e) and at a 45° orientation for 8 (b and f), 10 (c and g) and 15 (d and h) days in nutrient packs within the PGC during the Payload Verification Test (PVT). Abbreviations: cw: compression wood; ew: early wood; lw: late wood; nw: normal wood; rc: ray cells; sp: secondary phloem; sx: secondary xylem; vc: vascular cambium.

in the vascular cambium region. This suggests that the perception and transduction of the external signal(s) stipulating compression-wood formation is perceived by cambial-derived tracheid initials in the cambial zone, as proposed earlier by Sinnott and Westing (Sinnott, 1952; Westing, 1965). However, maturing tracheids were also able to undergo dramatic morphological changes during secondary cell wall formation and lignification. This additionally suggests that developing xylem (i.e. from initial primary cell expansion to secondary maturation) is influenced by the stimulus of the stresses/strains perceived as a consequence of the mechanical load and/or gravitational force experienced. Indeed, the compound middle lamella region of the cell corners of the compression wood so formed undergoes major morphological modifications relative to that of "normal" tracheids, i.e. as evidenced by development of large intercellular spaces. Furthermore, these regions generally undergo

the initial stages of lignin deposition (Bland, 1961; Donaldson, 1994). Accordingly, it will be of considerable interest to ascertain at the molecular level how the changes in a stress/strain gradient ultimately result in a different form of cell wall being sculptured for the particular cells "sacrificed" for buttressing.

Space Shuttle Columbia (STS-78) carried 16 Douglas fir and 4 loblolly pine plants. Following 48 h in orbit in space, the PGU was opened with the sterilized PGCs having their casings removed. The mechanical harnessing devices in the PGCs were then adjusted to place two plants per PGC at 45° to the vertical axis (i.e. to the light source of the PGC; Fig. 6b). The PGCs were then reassembled, placed back into the PGU, which was powered as before. After ten days in orbit, a plant retrieval protocol was employed whereby the PGU was again opened. All plants (both upright vertical controls and those harnessed at 45° for 8 days, two each) were removed from one PGC, and harvested in space by clipping stem regions adjacent to the area undergoing bending (see Fig. 6c). The plant sections obtained were immediately fixed in 2% paraformaldehyde/2.5% glutaraldehyde, using a device designed to give three levels of containment (against liquid/vapor leakage; Fig. 6d). Comparable sections were collected for the same anatomical regions for the stems of "vertical" controls (see Fig. 6c). Additional sampling was made at day 12 (2 days upright and 10 days harnessed at 45°, as well as the corresponding vertical controls). Remaining plant specimens in the PGU/PGCs were returned at the end of the space flight (2 days upright and 15 days harnessed at 45° and their corresponding controls) on earth, harvested

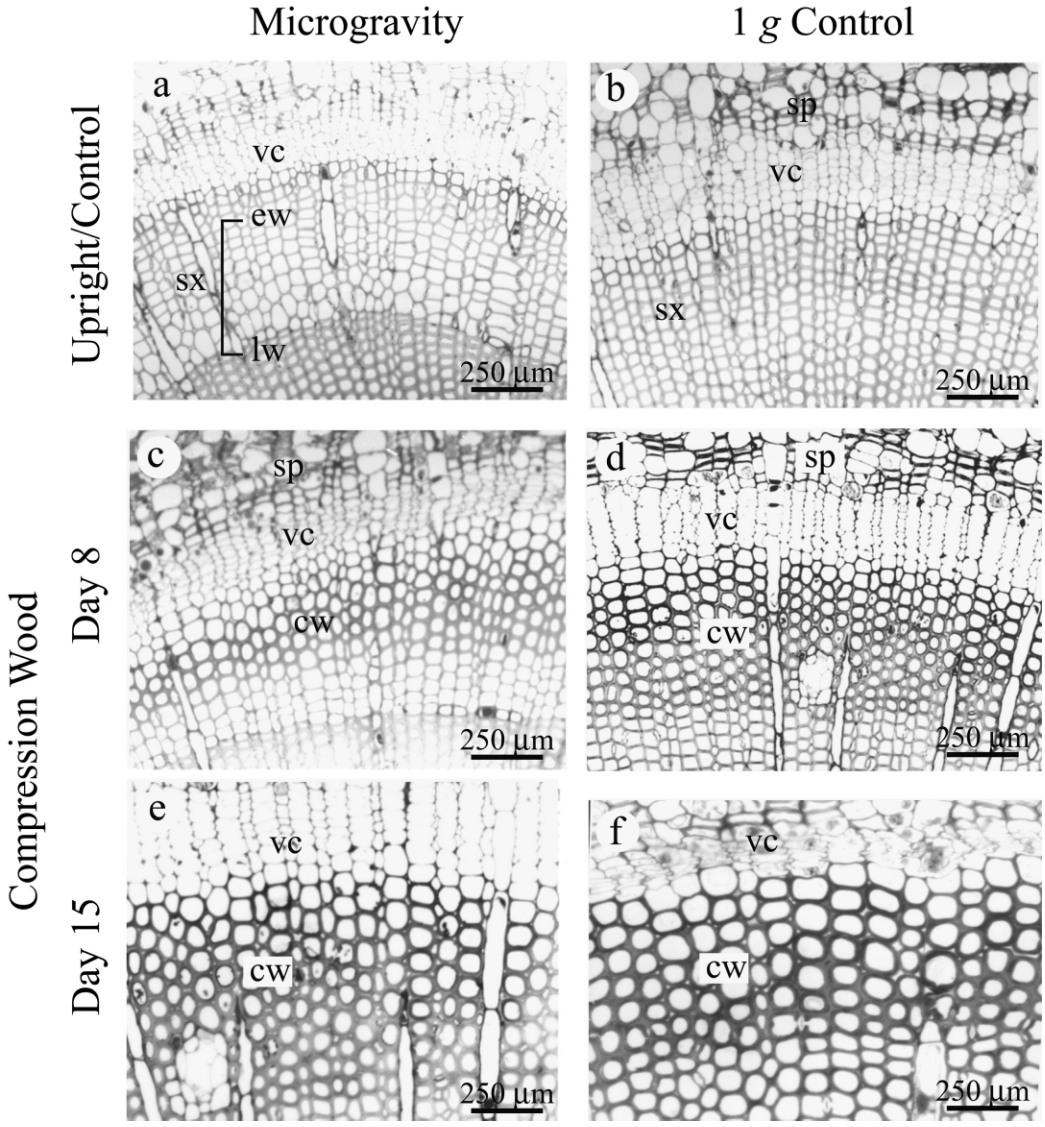

Fig. 8. Cross-sections of Douglas fir seedlings grown in microgravity (a, c, and e) and at 1 *g* (b, d, and f). Specimens were either placed in an upright vertical orientation for 17 days (a and b) or at a 45° orientation for 8 (c and d) and 15 (e and f) days. Abbreviations: cw, compression wood; ew, early wood; 1w, late wood; sp, secondary phloem; sx, secondary xylem; vc, vascular cambium.

and fixed as above. Additionally, a flight simulation experiment, except for being conducted at 1 *g*, was initiated 48 h after launch, with plant processing protocols following those used for space-flight.

The space-flight experiment established that compression wood development was able to occur in the near absence of gravity, provided that the stems were harnessed (at 45°). However, the study was not without technical difficulty, this resulting from high temperatures (>29°) due to an extremely warm space shuttle cabin environment, which was significantly higher than any other previous mission. This had a deleterious effect on the growth and survival of several plant specimens, particularly the loblolly pine, with only about 20% returning healthy (i.e. still containing new growth).

Nevertheless, the (healthy) plant specimens, whether grown under microgravity conditions or at 1 *g* gave essentially identical results, i.e. they all formed compression wood when oriented at a 45° angle (Fig. 8), and "normal" wood when grown in a vertical orientation, i.e. the Douglas fir seedlings grown in a vertical (upright) orientation for 17 days, under either microgravity or 1 *g* conditions, only developed normal secondary xylem as expected (Fig. 8a and b). On the other hand, those harnessed at a 45° configuration for 8 days developed compression wood in their developing secondary xylem region (Fig. 8c), and its formation was even more pronounced with samples harnessed for 15 days (Fig. 8e). As expected, Douglas fir seedlings harnessed at 45° under the 1 *g* controls displayed similar patterns of compression wood development (Fig. 8d and f), with no significant differences compared to those grown in microgravity (Fig. 8c and e).

3. Concluding remarks

To account for compression wood formation in space, two possibilities can be considered: First, the greatly reduced gravitational forces of the microgravity environment are still sufficient that the plants can still respond to this stimulus. Second, and more likely, the effect of induced stress through mechanical loading (harnessing at 45°) overrides the gravitactic responses (due to overlapping signal transduction, perception and response mechanisms). The plants then compensate to limit the effect of the mechanical stresses and strains imposed through certain cells undergoing compression wood formation. That is, even in microgravity, the woody plants can make appropriate corrections to alleviate stress gradients introduced by mechanical bending.

Given that compression wood induction can occur in a microgravity environment, studies will be conducted in the future to ascertain whether it is still formed when plants restore their "vertical" alignment unassisted relative to tracking of the lighting source in microgravity, i.e. when placed in a configuration (horizontal) parallel to the light source (see Fig. 4a).

The results obtained have important evolutionary implications. They raise questions as to which point during the evolution of land plant growth and development did the cambial cells initiate secondary thickening processes leading to woody tissue development? At what point did the earliest plant forms evolve these complex biological systems whereby reaction wood tissues were generated in order to both maintain stem orientation (relative to the vertical axis) and to regulate branching patterns? The gymnosperms have perhaps deployed buttressing of woody tissue by compression wood formation for up to the ~360 million years that they have been in existence. It is intriguing to contemplate what advantages were conferred, if any, by changing this buttressing mechanism in gymnosperms to the generation of tension wood tissues (both spatially and chemically) in the angiosperms. How did such different processes achieving comparable physiological functions differentially evolve? Much remains to be learned about these fascinating biochemical systems at the molecular, biochemical, chemical and anatomical levels and which ultimately lead to these remarkable morphologies. This will be the subject of additional study in the future.

4. Experimental

4.1. Plant material

One-year-old Douglas fir (*Pseudotsuga menziesii* (Mirb.) Franco), obtained from the University of Idaho Forest Experimental Station, and 1-year-old loblolly pine (*Pinus taeda*,) grown from seeds, were maintained in Washington State University greenhouse facilities. Plant specimens for the payload verification test (PVT), the space shuttle flight and simulation experiments were transported by air while being maintained throughout in a vertical position. Plants were transferred into walk-in growth chambers (23°C, 16 h light and 8 h dark) at NASA (Kennedy Space Center, Cape Canaveral, FL) until needed. Payload verification tests and flight simulations were conducted in walk-in growth chambers under temperature and lighting conditions used for the flight experiment.

4.2. Mechanical harnessing and tip decapitation of Douglas fir and loblolly pine seedlings

In order to establish the effects of bending and decapitation on compression wood formation, soil grown one year old Douglas fir and loblolly pine seedlings were decapitated by removing the tips of their stems. The decapitated stems were then harnessed at 45° or 90° for 9 and 15 days, respectively, then harvested as

described in Section 4.8 and processed as described in Section 4.9.

4.3. Plant growth unit

The NASA plant growth unit (PGU) has overall dimensions of 51×45×26 cm (L×W×H) and fits in a middeck locker on the space shuttle. It includes housing controls for electronic regulation of light, temperature and aeration. Lighting was provided by a bank of three fluorescent lamps containing Duratest Vitalite phosphor lenses, a reflector and an aluminium housing. Each PGU has a cavity region able to hold up to five plant growth chambers (PGC) as well as an Atmospheric Exchange System which circulates filtered cabin air through four of the PGCs, with the fifth serving as a control with no air flow. Temperature was controlled by heat from the lamps, one 20 W strip heater and the flow of middeck cabin air through the PGU: in order to be controlled, the temperature has to be above the middeck temperature. The PGU also contains a Data Acquisition System to record data such as day/night cycles and temperature. (A fuller description of the PGU/PGC can be found at http://lsda.ksc.nasa.gov/payload/payload_web/hdw_home.htm.) Inside each PGC was installed a mechanical device to either mechanically bend each of the Douglas fir/loblolly pine plants to an angle of 45° from the vertical axis or to maintain them in an upright position.

4.4. Plant "nutrient" packs

Plant nutrient packs were prepared as described in Levine et al. (2001) with the following modifications: the overall dimensions of the pack were 3.5×1.5×6.5 cm (L×W×H). To each pack was added a sterile (autoclaved) solution, which consisted of 5% (v/v) modified Brown and Lawrence medium (Eberhardt et al., 1993) containing 1% (v/v) antibiotic solution [antimycotic lyophilized powder: 10,000 U penicillin, 10 mg streptomycin and 25 μg amphotericin B per ml in 0.9% NaCl (Sigma)], 3.0% (w/v) thiabendazole (Sigma) in DMF (N, N-dimethylformamide, Sigma) and 1% (w/v) phytoagar (Gibco BRL Life Technology). Prior to the medium gelling, a conical tube (15 ml, Corning), filled with glass beads (2 mm in diameter), was inserted into the center of each nutrient pack, and following gelling through cooling, each conical tube was removed. Into the void created by the tube was inserted the upper part (2.5 cm) of a 15 ml-Corning tube through which four holes (6 mm in diameter) had previously been drilled equidistant from each other to facilitate subsequent root growth. One-year-old Douglas fir/loblolly pine plants, freshly depotted and with root systems individually washed successively with tap and distilled water, were soaked for 10 min in a 10% (v/v) bleach (Clorox) solution and then for 2 min in the 1% (v/v) antibiotic solution (see earlier) containing 0.9% (w/v) thiabendazole in DMF. The plants were individually inserted into nutrient packs, with roots placed through the 2.5 cm-long Corning tube, in the void originally housing the conical tube. Freshly prepared liquid growth medium at ca 50°C with 1% (w/v) low melting point agar (Gibco BRL Life Technology), instead of 1% phytoagar, was slowly added to the root tissue compartment of the nutrient pack until filled. The screw cap of the Corning tube which had a hole drilled through the middle (6 mm in diameter) as well as an opening (slit) at the side, was inserted around the Douglas fir/loblolly pine stem and loosely tightened. Following gelling through cooling, the screw cap was removed, the empty space around the Douglas fir/loblolly pine plant was packed with sterilized (autoclaved) cotton wool (see Fig. 6a) and the cap again tightened loosely. Four nutrient packs were placed inside each PGC and these were kept in an incubator (23°C; 16 h light and 8 h dark) until needed.

4.5. Payload verification test

A payload verification test (PVT) was conducted during which all phases of the pre/post and in-flight operations were performed using flight hardware. Two PGU's were prepared containing 20 plants each (four plants/PGC) as described in Section 4.4 with the trees secured along the mechanical devices of the PGC's with 4-inch cable tie. The regions of the stems stipulated to undergo either mechanical bending, or for the vertical controls corresponding to the same anatomical regions, were marked with red (top) and blue (bottom) lines by means of permanent markers to facilitate harvesting (see Fig. 6c). Both PGUs were placed in the Orbiter Environmental Simulator (OES) which uses space shuttle calibrated ancillary data to mimic the middeck environment. Ten of the plants (2/PGC) in both PGUs had their stems reorientated at 45° to the vertical axis by activating the mechanical device (see Fig. 6b) 48 h after transfer to the OES. At day 8 after bending, two vertical and two specimens at 45° were harvested from one PGC (from both PGUs) and fixed as described in Section 4.8; this procedure was repeated at day 10 after bending with another PGC. The stem segments were held in fixative bags at the temperature of the OES until the end of PVT; these were further processed as described in Section 4.9. The remaining plants from one PGU were harvested on day 17 and from the other on day 19 (17-day mission plus 2 contingency days). Trees were photographed at the time of harvest for record-keeping purposes.

4.6. Flight experiment

Sixteen Douglas fir and four loblolly pine seedlings were transferred to "nutrient packs", respectively, as before, these being placed inside five PGC's. After

securing the trees along the mechanical device with 4-inch cable tie, they were marked as described in Section 4.5. The PGC's were next stored in an incubator (23°C, 16 h light, 8 h dark). Two days prior to flight (13:00 to 15:00 EDT), the PGCs were transferred to the PGU. Photographs of each PGC were taken during the transfer, and the PGU was stored in the OES. The next day 17:00 EDT, the PGU was taken from the Life Science Support Facility and stowed in the middeck of the Columbia Space Shuttle. Columbia (STS-78 mission) lifted-off at 10:49:00 EDT on June 20, 1996 at Cape Canaveral, FL, and climbed to a 278 km-high orbit with a 39° inclination to the earth's equator. Following 48 h of growth in orbit, the astronauts placed two Douglas fir/loblolly pine plants from each PGC in a 45° orientation through activation of the mechanical device shown in Fig. 6b; the remaining two plants in each PGC were left in an upright (vertical) orientation. Plants (vertical controls and 45° oriented specimens from one PGC) were harvested, sectioned, and fixed in flight on day 10 and again at day 12 (2 days upright and 8 and 10 days harnessed at 45°, respectively, as well as the corresponding controls) as described in Section 4.8. The stem segments were held in the fixative bag at the Shuttle ambient temperature until the end of the mission. Photographs of the plants were also taken during bending and harvesting. Space Shuttle Columbia returned to Kennedy Space Center at 8:36:45 EDT on July 7, 1996, giving a total mission elapsed time of 16 days 21 h 47 mm 45 s. The PGU was returned to the Life Science Support Facility approximately at 12:00 EDT. Photographs were next taken with the remainder of the plants then being harvested, sectioned, and fixed as described in Section 4.8. All the specimens in fixative bags were processed as described in Section 4.9. PGC temperatures were recorded during the flight, and these ranged in average from 23.5°C to 30.5°C. Note that all loblolly pine plants died during the space flight experiment due to shuttle cabin overheating.

4.7. Flight simulation experiment (2 days after launch)

An additional control experiment was carried out under identical conditions to that of the space flight experiment except for being conducted at 1 *g*. This was initiated 2 days following lift-off, with a time-lapse being employed in order to download temperature data from the shuttle to Kennedy Space Center; these conditions were then used for flight simulation. Thus, plants were transferred to the PGC/PGU exactly as described for the flight experiment (Section 4.6), albeit 48 h later. Growth conditions (temperature and lighting) were maintained exactly as for that of the flight experiment, since the control PGU was located in the OES. Douglas fir (two per PGC) and loblolly pine plants were placed in a 45° orientation at the same flight times as for the microgravity-grown plants. At days 8 and 10 (same overall time period as the flight specimens), the plants from two PGCs were sectioned and fixed as described Section 4.8. The fixative bags were held at the same temperature as the samples harvested in space, until the end of the simulation (16 days 21 h 47 mm 45 s) at which time the remaining plants were sectioned and fixed as described in Section 4.8. All specimens were processed as described in Section 4.9. Photographs were taken at time of bending and harvesting.

4.8. Sample harvest and fixation in space and on Earth

Douglas fir and loblolly pine plants were harvested during the PVT, space flight, and flight simulation experiment, as follows: stem segments (3 cm in length) were collected from the marked-up areas flanking the region of the stem that had undergone either mechanical bending, or were from vertical controls corresponding to the same anatomical region (3 cm in length). Coarse stem sections were initially harvested above the red and below the blue marks with a wire cutter, and then more precisely trimmed by means of a mechanical clipper at both sides of the marked up zones (Fig. 6c). Any plant debris was collected by means of a small hand held vacuum cleaner for the operation in space aboard the space shuttle. Harvested stem segments were immediately placed into fixative bags (Fig. 6d) containing 2% paraformaldehyde/2.5% glutaraldehyde in 0.05 M phosphate buffer (pH 7.2). All fixation procedures were carried out inside a glove-box in order to achieve four levels of containment as required by NASA for occupational exposure.

4.9. Microscopy analyses offlight and control (1 g) plant tissue stein sections

Stem segments stored in the fixative bags were briefly washed three times in 0.05 M phosphate buffer (pH 7.2) and then further dissected into smaller pieces (0.5 cm in length) and dehydrated gradually in 30, 50, 70, 90, 95, and 100% ethanol (10 min each). After dehydrating two more times in 100% EtOH, the samples were transferred gradually to solutions of EtOH–acetone 1:3, 1:2, 1:1, and 0:1. After infiltration in Spurr's resin in acetone (10, 30 50, 70, 90 and 100%, four times each) at room temperature, the stem segments were finally embedded overnight in fresh Spurr's resin in a 70°C oven. Thick sections (800 nm) were obtained by means of a glass knife using an ultramicrotome (Reichert). Sections were next mounted on microscopic slides (VWR Scientific Inc.) and stained with Stevanels' blue for morphological observation. The anatomy of sections was recorded using an Olympus BH2 photomicroscope housing Tech pan film (Kodak). Photographs were developed and scanned using a ScanMaker III (Microtek).

Acknowledgements

The authors thank NASA (NAG 10-0164) for generous financial support of this study, and Deborah Vordermark-Wells, Rina Thompson and Chung Wang (for designing the mechanical device to bend the trees in a 45° configuration), the Bionetics Corporation, Kennedy Space Center, for excellent technical assistance. Special thanks are also expressed to astronauts, Jean-Jacques Favier and Susan Helms, for their participation in this study.

Review

Lignification and lignin topochemistry — an ultrastructural view

Lloyd A. Donaldson *

Forest Research, Private Bag 3020, Rotorua, New Zealand

Received 27 June 2000; received in revised form 26 October 2000

Abstract

This review discuses the ultrastructural aspects of cell wall lignification and lignin topochemistry. Lignification results from the enzyme mediated polymerization of monolignols initiated by unknown factors (initiation sites) located at the corners of cells and in the middle lamella. Lignification results in the filling of pores within the carbohydrate matrix following a sequence from the outer regions of the wall towards the lumen. The amount and chemical characteristics of lignin vary across the cell wall, with the presence of reaction wood, and among cell types. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Lignin is a complex 3-dimensional polymer that occurs predominantly in the xylem of most land plants, forming about 1/3 of the terrestrial woody biomass. As a major component of the cell wall of tracheids, vessels and fibers, lignin contributes to the compression strength of woody stems, and to the water proofing of conductive elements within the xylem. Lignification has allowed the evolution of large arborescent land plants capable of survival in relatively arid environments. As a major component of wood lignin is of major technological significance, particularly in the pulp and paper industry

where lignin removal is often a major processing step. Because the distribution of lignin, or its topochemistry, influences commercial utilization of wood for both pulp and paper, and solid wood (although the latter is often not considered), this has been a topic of considerable interest since the early 1950s.

2. Ultrastructure of lignifying xylem

Lignification is one of the final stages of xylem cell differentiation, where lignin is deposited within the carbohydrate matrix of the cell wall by infilling of interlamellar voids, and at the same time, formation of chemical bonds with the non-cellulosic carbohydrates. The process of lignification has been studied by a variety of microscopy techniques including microautoradiography, histochemistry, UV absorbance, interference microscopy, fluorescence microscopy, and transmission electron microscopy. Lignification begins at the cell corners in the middle lamella and S1 regions, eventually spreading across the secondary wall towards the lumen. Lignification of the middle lamella and primary wall typically begins after the start of secondary wall formation, while lignification of the secondary wall usually begins when secondary wall formation is complete, as judged by the presence of an S3 layer (Wardrop, 1957, 1976; Hepler et al., 1970; Kutscha and Schwarzmann, 1975; Imagawa et al., 1976; Takabe et al., 1981, 1986; Saka and Thomas, 1982; Donaldson 1991, 1992).

2.1. Lignin formation

Lignin biosynthesis has recently been reviewed by Higuchi (1990) and Boudet (2000). Lignin monomers (coniferyl alcohol, sinapyl alcohol, *p*-coumaryl alcohol) are synthesized in the cytoplasm (golgi or endoplasmic reticulum), and are released into the cell wall from vesicles as monolignols or monolignol glucosides (Freudenberg et al., 1955; Wardrop, 1965; Pickett-Heaps, 1968; Hepler et al., 1970; Fujita et al., 1978b). Enzymes located within the cell wall during lignification, in either the free or bound state, including various types of peroxidase and oxidase (including laccase), have been shown to have a role in monolignol polymerization, both in vivo and in vitro (Goldberg et al., 1985; Nakashima et al., 1992; Terashima et al., 1995, 1996; Tsutsumi et al., 1998; Deighton et al., 1999). Oxidase activity may be associated with the earliest stages of lignification and peroxidase with the later stages so that the phytotoxic effects of H_2O_2 are avoided until apoptosis has commenced (Sterjiades et al., 1993). Both oxidase and peroxidase with specific activity against coniferyl or sinapyl alcohol have been identified (Tsutsumi et al., 1998; Deighton et al., 1999).

Because lignification starts in the region furthest from the protoplast, it has been suggested that there are initiation sites bound to specific regions of the cell wall, which begin the polymerization process as shown diagrammatically in Fig. 1 (Donaldson, 1994). Enzymes bound to specific locations in the cell wall could act as initiating sites. However, the observation that oxidase and peroxidase activities are restricted to lignifying cells during xylem formation (Hepler et al., 1972; Fukuda and Komamine, 1982; Goldberg et al., 1985; Yoshizawa et al., 1991; Czaninski et al., 1993; Nose et al., 1995; Deighton et al., 1999), suggests that these enzymes are not initiating sites. Ideally, initiating sites should be built into the wall during its formation (and thus be present in differentiating xylem prior to the onset of lignification), rather than relying on diffusion of enzymes to secondary binding sites in the primary wall or middle lamella. Although these enzymes are known to be present in cell walls undergoing lignification, little or no information is available on their exact location within the cell wall and how their distribution changes during the lignification process. For example it is not known if the complement of enzymes within the cell wall changes in relation to the type of lignin being formed, or if it is the substrate that changes, or both. Ultrastructural localization of both enzymes and substrates is needed to confirm their relative roles in controlling lignin topochemistry. This is no easy task given the nature of the substrates, which would readily diffuse

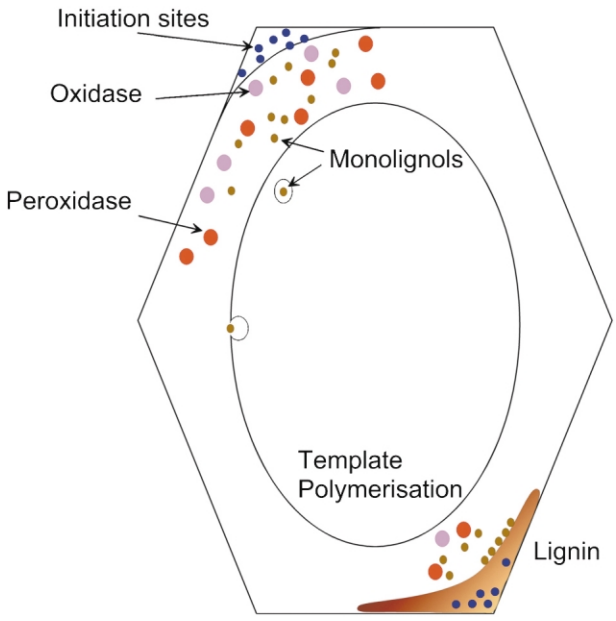

Fig. 1. A tentative scheme for the lignification process in xylem cell walls. Monolignols are released into the cell wall from the protoplast and diffuse towards initiation sites where the polymerisation process begins. Lignification is mediated by a range of free and bound enzymes and occurs by addition of monolignols to the expanding lignin polymer in a process known as template polymerisation. The nature of initiating sites and the way in which the amount and type of lignin formation is controlled across the cell wall are poorly understood.

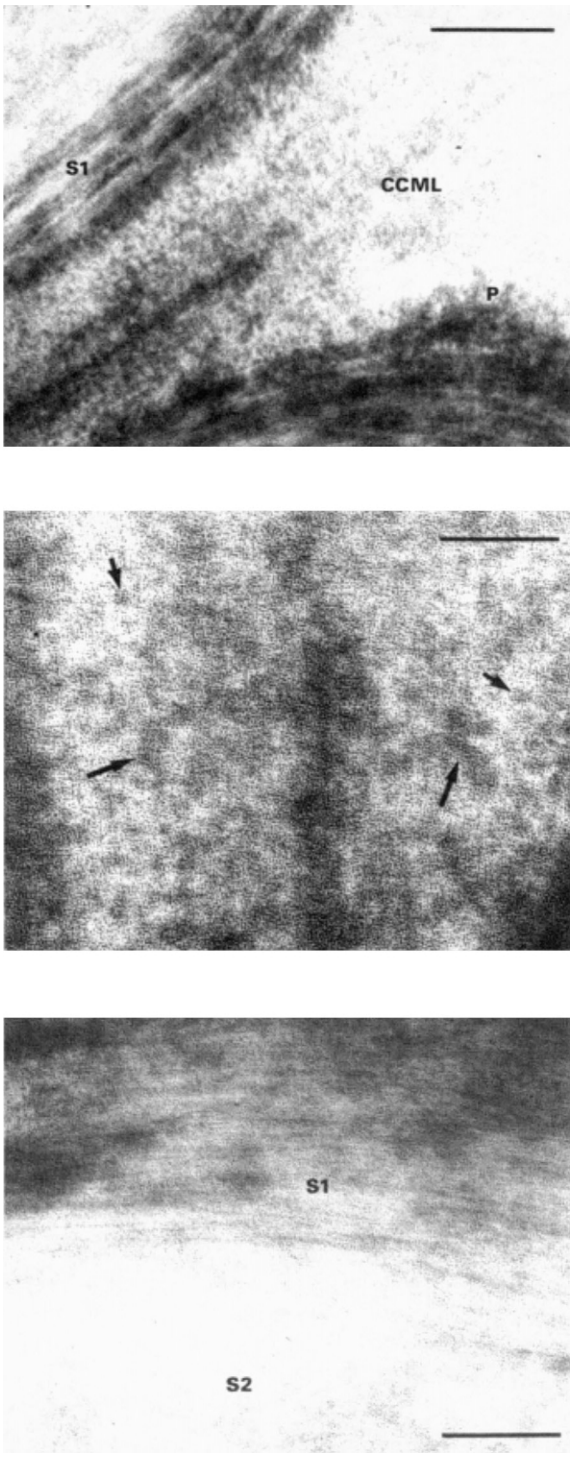

Fig. 2. Transmission electron microscopy of lignifying cell corner middle lamella (ccml), primary wall (P) and S1 regions in *Pinus radiata* after permanganate staining for lignin. Lignification is initiated in the central zone of the middle lamella and in the S1 region of the secondary wall. Arrows indicate small particles of lignin associated with initiation sites. The particles eventually coalesce (long arrows) to form a continuous matrix. Particles are rounded in the middle lamella region but form greatly elongated structures in the S1 region because of the orienting effect of the cellulose microfibrils. Scalebars top 440 nm, middle 170 nm, bottom 250 nm. (Reproduced with permission from Donaldson, 1994.)

out of the sample during most types of preparation for microscopy. The use of some form of cryo-microscopy may prove effective at fixing the substrates within the cell wall although localization remains a problem.

Initiating sites may be rich in calcium, thought to be needed for H_2O_2 formation via enzymatically produced superoxide radicals, a prerequisite for polymerization of coniferyl alcohol in the absence of laccase or oxidase activity (Wardrop, 1976; Westermark, 1982; Westermark et al., 1986). Other candidates for initiating sites include arrays of dirigent sites (proline-rich proteins, extensins) (Nose et al., 1995; Müsel et al., 1997; Davin et al., 1997; Devin and Lewis, 2000), and cell wall polysaccharides (Terashima et al. 1995, 1996). Little is known about the nature and distribution of cell wall proteins in differentiating xylem, especially in relation to lignification (Westermark et al., 1986; Bao et al., 1992; Ryser and Keller 1992). Bao et al. (1992) describe an extensin-like protein from differentiating xylem and mature wood of loblolly pine (*Pinus taeda* L.). Müsel et al. (1997) studied lignification in primary xylem and showed that proline-rich proteins were localized in secondary wall thickenings prior to lignification. Because primary and secondary xylem lignify differently (typically only the secondary wall lignifies in primary xylem), a comparison of these two tissues may provide useful insight in to the problem of initiation. Dirigent (non-enzymatic) proteins are known to have a role in lignan biosynthesis (Davin et al., 1997) but their involvement in lignification [proposed as arrays of dirigent (monomer binding) sites] remains a controversial issue (Davin and Lewis, 2000). It is thought that the lignin macromolecules themselves act as templates for further lignification once the process has been initiated (Sarkanen, 1998).

Lignification is influenced by the carbohydrate matrix in which it occurs. Donaldson (1994) studied the early stages of lignification in radiata pine by transmission electron microscopy. Growing lignin particles in the middle lamella and primary wall form roughly spherical structures within the randomly arranged matrix, while in the secondary wall, lignin lamellae form greatly elongated structures, following the orientation of microfibrils in this region of the cell wall (Fig. 2). It was concluded that the carbohydrate components of the cell wall exert a mechanical influence on the expanding lignin lamellae during lignification. Using a Raman microprobe, Atalla and Agarwal (1985) have shown that the aromatic rings of lignin are often oriented within the plane of the cell wall, possibly also as a result of the mechanical or chemical influence of the carbohydrate wall components. At the same time, lignin is forming chemical bonds with the hemicellulose component of the cell wall, which acts as a bridge or adhesive, ensuring coherence between the matrix phase and the cellulose microfibrils (Meshitsuka et al., 1982; Minor, 1986; Iversen et al., 1987; Tanabe and Kobayashi 1988; Hansen and Björkman 1998;

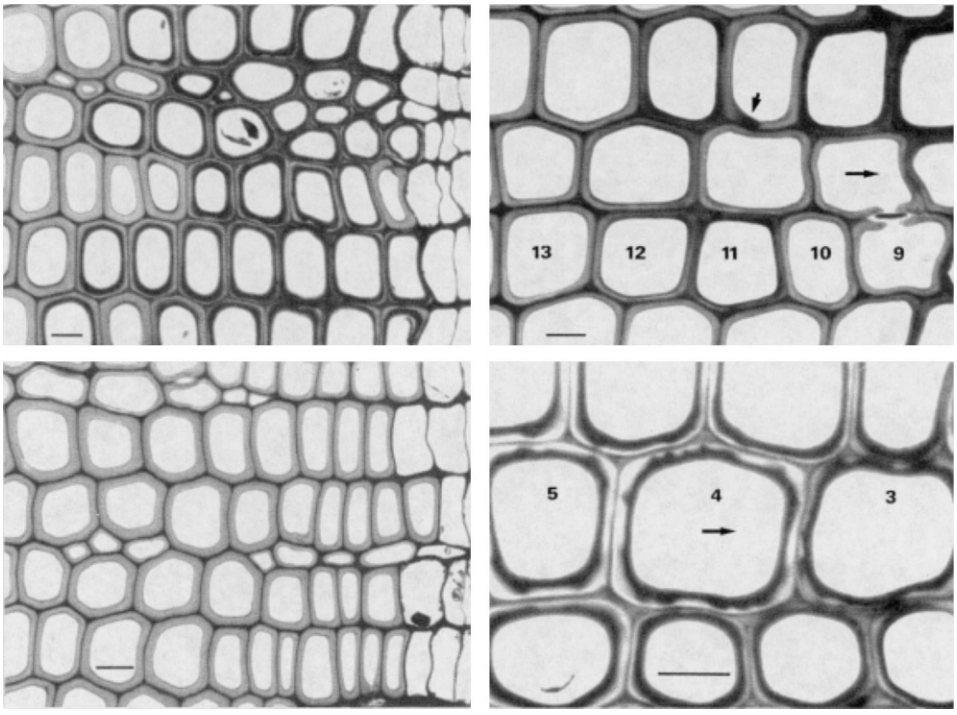

Fig. 3. Lignifying earlywood and latewood tracheids stained with toluidine blue in *Pinus radiata*. The numbers indicate the distance (cell number) from the cambium. The long arrows indicate the direction of the cambium while the short arrow indicates non-uniform lignification. The two images on the left show normal latewood, one sample showing partial lignification, the other showing full lignification. Both trees were sampled during the winter. The two images on the right show lignifying normal earlywood cells. Scalebars are all 10 μm. (Reproduced with permission from Donaldson, 1992.)

Salmén and Olsson 1998). The chemical nature of the carbohydrate environment in which lignin forms also has a recognized role in controlling the properties of the resulting polymer (Roussel and Lim, 1995; Terashima et al., 1995, 1996).

2.2. Topochemistry of lignification

In normal wood of Balsam fir (*Abies balsamea* (L.) Mill.) lignification starts in the middle lamella between pit borders, extending into the initial pit borders and cell corners, and then into the secondary wall (Kutscha and Schwarzmann, 1975). Similar patterns have been observed in *Pinus radiata* D. Don (Wardrop and Bland, 1959), *Larix leptolepis* Gord. (Imagawa et al., 1976), *Pinus thunbergii* Parl. (Takabe et al., 1981), and *Cryptomeria japonica* D. Don (Takabe et al., 1986). Cell corners adjacent to rays may lignify earlier than those more distant from the rays. All regions of the cell wall undergo continuing lignification until cell death and loss of the protoplast.

Lignification in loblolly pine was studied using bromination/EDXA by Saka and Thomas (1982). The middle lamella lignin concentration reached approximately 50% of its maximum before lignification of the secondary wall commenced. An S3 layer was detected prior to the start of secondary wall lignification, which was a more gradual process than the relatively rapid lignification of the middle lamella.

In lignifying xylem of *Picea glauca* (Moench) Voss, Yumoto et al. (1982) observed groups of tangentially arranged cells that differed from the surrounding lignifying cells when stained with hematoxylin-orange G, indicating these cells had not yet begun to lignify. Donaldson (1992) also observed differences in the state of lignification among adjacent cells (Fig. 3) suggesting that the lignification process is controlled to a significant extent by individual tracheids.

Lignification of secondary xylem has been studied by incorporation of radioactive precursors of lignin and subsequent microautoradiography. Saleh et al. (1967) treated cuttings of poplar, Douglas fir and wheat with tritiated ferulic acid[1] and demonstrated labeling of lignin, first in the primary wall at the cell corners, and subsequently in the middle lamella of radial and then tangential walls. Fujita and Harada (1979) later observed labeling of lignin in the secondary wall, also using tritiated ferulic acid as a precursor. Further studies by Terashima and coworkers demonstrated the formation and localization of *p*-hydroxyphenyl, guaiacyl, and syringyl lignins using a variety of labeled precursors including monolignol glucosides in pine, *Ginkgo*, sugarcane, *Magnolia*, *Syringa*, poplar, lilac, beech, rice, bamboo grass and orchid. In pine (Terashima and Fukushima, 1988; Terashima et al.,

[1] Ferulic acid is no longer considered a significant precursor for syringyl lignin (Li et al., 2000).

1988) and *Ginkgo* (Fukushima and Terashima, 1991a), *p*-hydroxyphenyl lignin is formed in the compound middle lamella and cell corner at an early stage of the lignification process. Guaiacyl lignins are first deposited in the middle lamella region and later in the secondary wall, while syringyl lignins are deposited in trace amounts during the late stages of secondary wall lignification. In pine, lignification was found to proceed in three stages (Terashima et al., 1988), lignification of the cell corner and middle lamella after S1 formation, slow lignification during secondary wall formation, and the main lignification after S3 formation. In magnolia (*Magnolia kobus* DC.) and poplar (*Populus maximowiczii* A. Henry *x berolinensis* C. Koch) (Terashima et al., 1986a,b), lignification was first observed in the vessel wall, cell corner and middle lamella, with formation of guaiacyl lignin, followed at a later stage by lignification of the fiber walls with a mixed guaiacyl-syringyl lignin. Deposition of *p*-hydroxyphenyl lignin occurred in the compound middle lamella of vessel and fiber cell walls during the early stages of secondary wall formation (Fukushima and Terashima, 1990).

Similar patterns of lignification are found in monocotyledons, with the additional formation of phenolic acids among all cell types. Ferulic acid is deposited in the middle lamella and cell corners during early lignification, while *p*-coumaric and sinapic acids are deposited in the secondary walls (He and Terashima, 1989a,b, 1990). The polylamelate walls of monocotyledonous fibers such as palms and bamboo show concentric variations in lignification corresponding to each wall layer (Itoh, 1990; Weiner et al., 1996). Such fibers remain living for extended periods and continue to develop new lamellae, which then undergo lignification.

During latewood formation in Japanese oak (*Quercus mongolica* Fisch.) (Yoshinaga et al., 1997a, b), guaiacyl lignin is deposited in vessel elements and vasicentric tracheids at all stages of lignification, while syringyl lignins are deposited in the later stages of lignification in fibers. Similar results were found in *Betula grossa* Sieb. et. Zucc., and *Aesculus turbinata* Blume (Yoshinaga et al., 2000). By comparing the rates of cell wall formation and lignification these authors conclude that cell walls rich in guaiacyl lignin are thickened rapidly and lignify slowly, while walls rich in syringyl lignin both thicken and lignify slowly.

Fujino and Itoh (1998) studied the lignification process in *Eucalyptus tereticornis* Sm. using rapid-freeze deep-etching electron microscopy to provide a 3D perspective on lignin deposition. This study clearly demonstrates the loss of wall porosity as lignin deposition proceeds, illustrating the likely reason for differences in lignin concentration among wall regions in mature wood. The highly porous carbohydrate matrix in the middle lamella and primary wall allows greater lignin deposition by space filling than the more densely packed secondary cell wall. Whether the uneven distribution of lignin in mature wood results entirely from differences in porosity of the carbohydrate matrix, or is a more actively controlled process, requires further investigation. For example there is evidence that the lignification of the middle lamella is reduced when the middle lamella and secondary wall lignify concurrently, presumably as a result of restricted access by monolignols due to blockage of diffusion pathways (Donaldson, 1991).

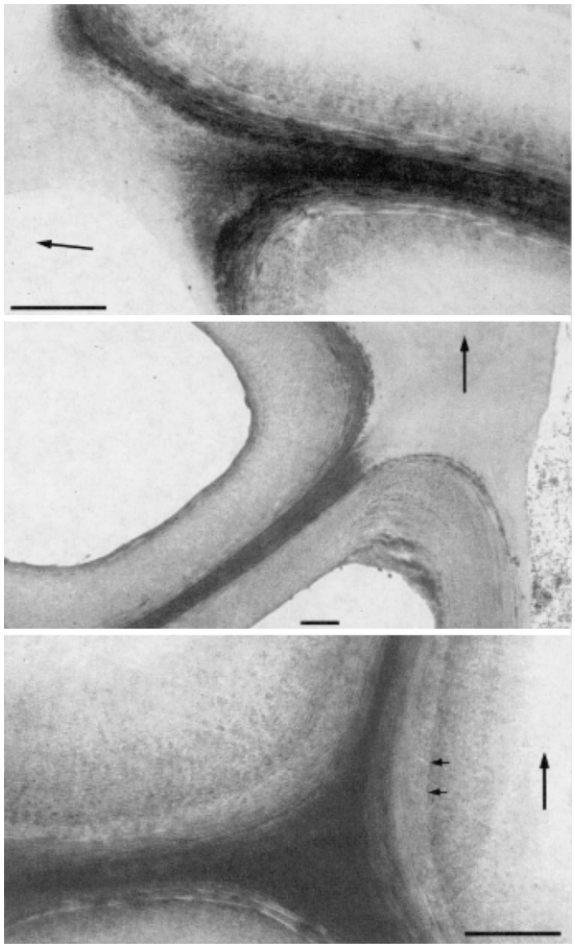

Fig. 4. Lignifying latewood tracheids stained with potassium permanganate and imaged by transmission electron microscopy in *Pinus radiata*. The three micrographs indicate different stages of secondary wall lignification. The top image shows an early stage of lignification, the middle image an almost complete state of lignification, and the bottom image an intermediate stage. The long arrows indicate the direction of the cambium. The short arrows indicate a lignification boundary within the S2 region. Scalebars are all 1 μm. (Reproduced with permission from Donaldson, 1992.)

The only known case of a lignification sequence markedly different to what is considered typical, is described by Engels and Jung (1998) in the primary phloem fibers of alfalfa stems. The primary phloem fibers show a 3-step pattern of cell wall development including a localized thickening of the primary wall, lignification of a thin region of primary wall at the lumen boundary,

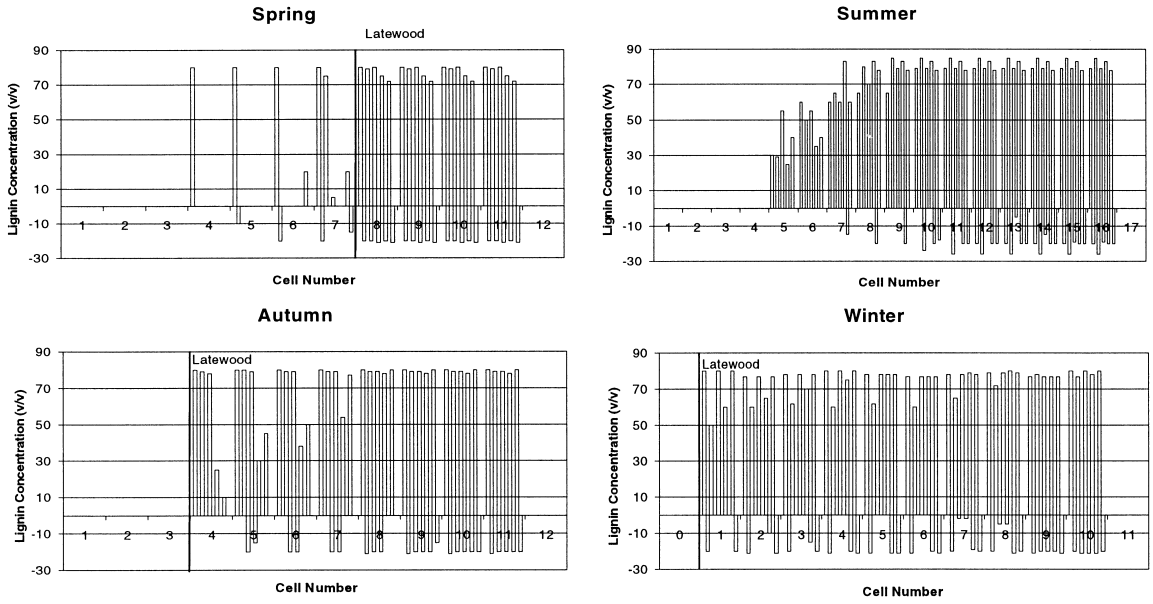

Fig. 5. Variations in lignification of the middle lamella and secondary wall during one growth season comparing 5 trees at each sample time. The upper values in each graph are for the cell corner middle lamella, while the lower values are for the S2 region. The cell numbers refer to the cells that were measured and not to the distance from the cambium as in previous figures. Varying numbers of cells were measured as required to cover the range from unlignified to fully lignified. In the case of spring and summer, the cambium is located beyond the left margin of each figure. In the case of autumn and winter, the cambium is located immediately to the left of the latewood boundary (Reproduced with permission from Donaldson 1991, 1992.)

and subsequent deposition of a thick unlignified secondary wall. These authors conclude that the lignified "ring" forms as a result of polymerization of monolignols at the lumen surface, thus preventing diffusion of monolignols into the middle lamella, which remains unlignified. This study is significant because it appears to describe a pattern of lignification that would be expected in the absence of initiating sites, i.e. where lignin forms adjacent to the protoplast rather than at some more remote location in the cell wall.

2.3. Seasonal and environmental effects on lignification

Donaldson (1991) studied the seasonal variations in lignification during one growth season in radiata pine. Although the pattern of lignification remained the same, the number of lignifying cells reached a maximum during the summer. Lignification of the secondary wall of latewood tracheids was often incomplete at the onset of winter (Figs. 3–5), with secondary walls remaining in a partially lignified state until early the following spring, suggesting that lignification is quite sensitive to environmental conditions such as temperature. Winter is thus the ideal time for microscopic study of lignification when the rapid early stages are well represented. Similarly Grand et al. (1979) found that light is necessary for incorporation of guaiacyl but not syringyl residues from radioactively labeled phenylalanine in poplar stems.

In one of the trees examined by Donaldson (1991) lignification occurred concurrently in both the middle lamella and secondary wall, and as a result, the middle lamella of mature wood showed below average lignin concentrations. Reduced lignification, especially in the middle lamella, has been reported for Cu deficient trees of *P. radiata* although the change in lignification was not directly attributed to the physiological effects of Cu deficiency (Downes et al. 1991).

3. Lignification of reaction wood

In view of the significant differences in lignin distribution between compression wood and normal wood, with the presence of a highly lignified S2L layer, it is surprising that many studies of the lignification process in compression wood describe a lignification sequence largely the same as in normal wood. The first investigation of lignification in any tree was a study of compression wood in *Pinus sylvestris* L. (Sanio, 1873). Sanio found that lignification started at the cell corners and progressed through the secondary wall towards the lumen. In radiata pine compression wood, the S1 region may show a reduction in lignification (Wardrop and Bland, 1961). Scurfield (1967) found that lignin was first deposited at the apex of intercellular spaces and subsequently spread into the secondary wall in radiata pine compression wood. The lignification process in compression wood of *Abies balsamea* has been studied by Kutscha (1968) using permanganate fixation and transmission electron microscopy, showing that the lignifica-

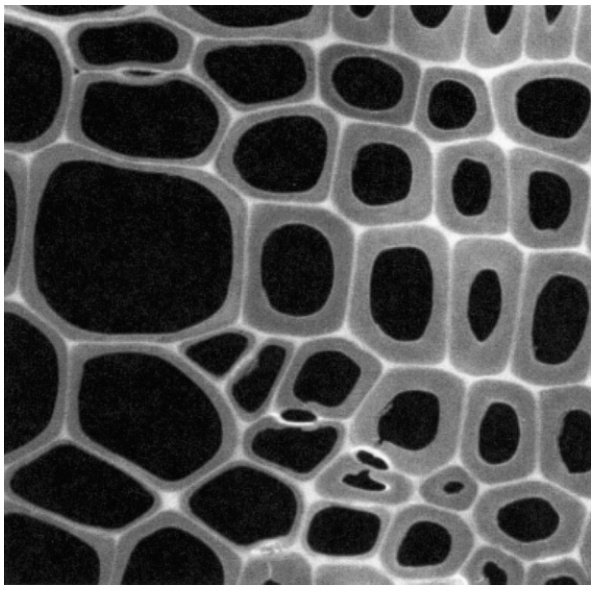

Fig. 6. Confocal fluorescence micrograph of *Pinus radiata* wood showing lignin autofluorescence at 530 nm. Increased brightness reflects higher lignin concentration. This image shows a growth ring boundary with thick walled latewood tracheids on the right. The image is 160 × 160 μm.

tion process was similar to that in normal wood. Fujita et al. (1978a,b) studied lignification in compression wood of *Cryptomeria japonica* and also observed a process similar to that of normal wood.

Fujita et al. (1978a,b) indicate that the lignification of the middle lamella is more distinctly separate from lignification of the secondary wall in compression wood compared to normal wood. These results were later confirmed by Fujita and Harada (1979) using autoradiography, indicating that lignification of the S2L region where most of the lignin is deposited, takes place after completion of secondary wall formation.

In a significant study, Fukushima and Terashima (1991b) used microautoradiography to study lignification of compression wood in *Pinus thunbergii*. Lignin was deposited in the order *p*-hydroxyphenyl, guaiacyl, and syringyl, which is the same sequence as normal wood. However *p*-hydroxyphenyl units were deposited in both the compound middle lamella and the S2 region in compression wood, in contrast to normal wood, where these units are deposited only in the compound middle lamella. Lignification of the secondary wall took place for an extended period in compression wood while S2 formation was still taking place, the most active lignification occurring in the outer S2 (S2L) region. In contrast, S2 lignification in normal wood became active only after S3 formation was complete. This study is one of the few to show distinct differences in the lignification process of normal and compression wood.

It is important to note that intercellular spaces present in severe compression wood do not lignify. If initiating sites are usually located in the cell corner region they must obviously be located elsewhere in this type of material, thus potentially accounting for the altered lignin distribution of compression wood. In mild compression wood the reduced lignification of the middle lamella may be due to an effect of the highly lignified S2L region on diffusion pathways into the middle lamella in the event of concurrent lignification in these two regions (Fukushima and Terashima, 1991b; Donaldson et al., 1999).

4. Lignin distribution in gymnosperms

Two distinct approaches have been used to study the distribution of lignin across the cell wall. Cell walls can be thin sectioned and examined by histochemistry or by other microscopy techniques such as UV absorbance. Alternatively, wood material can be finely ground to form minute cell wall fragments, which can subsequently be separated, purified according to their origin in the cell wall, and chemically analyzed.

A number of early investigations established that the compound middle lamella is more highly lignified than the secondary wall in typical softwood tracheids (Crocker, 1921; Ritter, 1925; Kerr and Bailey, 1934; Bailey, 1936; Bailey and Kerr, 1937; Staudinger, 1942; Lange, 1944, 1950; Lange and Kjaer, 1957; Jayme and Fengel, 1961; Hepler and Newcomb, 1963; Sachs et al., 1963; Meier, 1964; Côté et al., 1966, 1968; Bucher, 1968; Côté and Day, 1969; Norberg, 1969; Hepler et al., 1970; Parham and Côté, 1971; Kutscha and Gray, 1972; Parham, 1974). Some inference was also made from comparison of lignin content with the morphological variability of the tracheid walls (Ritter and Fleck, 1926; Hale and Clermont, 1963; Berlyn and Mark, 1965; Larson, 1966; Stamm and Sanders, 1966; Siddiqui, 1976). However, detailed quantitative information on the distribution of lignin in the tracheid wall was not available until the development of quantitative methods such as UV microscopy (Scott et al., 1969; Scott and Goring, 1970b; Wood and Goring, 1974).

The compound middle lamella region of the cell wall typically contains more than 50% lignin concentration (w/w) while the S2 region contains about 20% (Fig. 6). However, because the secondary wall represents a much greater volume than the relatively thin middle lamella, most of the lignin in wood is located in the secondary wall, a point which caused much confusion in the early literature. It is thus important to differentiate between lignin concentration (within a cell wall region) and lignin content (a measure of lignin in bulk samples which is thus dependent on variations in anatomy such as cell wall thickness and earlywood/latewood proportion). The cell corner middle lamella is often more highly lignified than the compound middle lamella with reported values above 70% lignin concentration (Fergus et al., 1969;

Wood and Goring, 1971; Boutelje, 1972; Fukazawa and Imagawa, 1981; Saka et al., 1981; Boutelje and Eriksson, 1982, 1984; Takano et al., 1983; Donaldson, 1985, 1986, 1993; Donaldson et al., 1997; Westermark et al., 1988). Comparisons of earlywood and latewood tracheids indicate little if any difference in lignin distribution as is the case for juvenile and mature wood (Fergus et al., 1969; Wood and Goring, 1971; Fukazawa and Imagawa, 1981; Takano et al., 1983; Donaldson, 1985; Gindl et al., 2000). Differences in the lignin content of earlywood and latewood probably arise almost entirely from variations in cell wall morphology within the growth ring. A thicker secondary wall in latewood tracheids reduces the contribution of the high middle lamella lignin concentration, resulting in a slightly lower lignin content for latewood (Siddiqui, 1976). However Gindl et al. (2000) using *Picea abies* (L.) Karst. and UV microscopy, have reported a reduction in the lignin concentration of the S2 region of the terminal latewood cells. The lignin concentration of these cells was found to be correlated with autumn temperature under alpine growing conditions.

Values determined by microscopy seem to agree quite well with those determined by analysis of cell wall fractions (Hardell et al., 1980a; Whiting et al., 1981; Whiting and Goring, 1982a; Sorvari et al., 1983, 1986).

Significant variation among trees in lignin concentration, especially in the cell corner middle lamella, has been reported for radiata pine using interference microscopy (Donaldson, 1985, 1986). Later studies with clones confirmed that this between tree variation is genetic in origin (Donaldson, 1993; Donaldson et al., 1997).

Although the S2 layer in normal wood is typically uniformly lignified it may occasionally show concentric variations in lignification (Daniel and Nilsson, 1984).

Lignification of the S1 region is variously described as similar to the middle lamella, intermediate between the middle lamella and S2 region, or similar to the S2 region, depending on species and technique used (Sachs et al., 1963; Bland et al., 1971; Parham and Côté, 1971; Timell, 1973; Saka et al., 1979, 1981). Maurer and Fengel (1991) describe lignin distribution in the S1 region as being in two distinct parts, high in the outer and low in the inner regions for *Picea abies*. Donaldson (1995) describes the lignification of the S1 region in *P. radiata* as patchy and generally lower than that of the S2 layer, especially at the S1/S2 boundary. This reduced lignification has been ascribed to the occurrence of cell wall fracturing at the S1/S2 boundary during processing in radiata pine.

The S3 layer has often been reported to be more highly lignified than the adjacent S2 layer (Jayme and Fengel, 1961; Sachs et al., 1963, 1965; Wergin, 1965; Côté et al., 1966; Scott and Goring, 1970a; Bland et al., 1971; Parham and Côté, 1971; Timell, 1973; Saka et al., 1981; Donaldson, 1987). Quantitative studies indicate values intermediate between the S2 and compound middle lamella but the general opinion is that the lignification state of the S3 layer is a variable feature (Scott and Goring, 1970a). Lignin concentration in the S3 layer is similar to that in the S2 region in both Douglas fir and Larch. Little information is available on species outside of the Pinaceae.

Initial pit borders (part of the primary cell wall) are more lignified than adjacent parts of the pit border (Singh, 1997). Pit membranes including the torus of bordered pits, are unlignified, although in heartwood, impregnation with extractives may be confused with lignification (Bamber, 1961; Bauch et al., 1968; Bauch and Berndt, 1973).

Analysis of cell wall fractions has indicated that secondary wall lignin of *Picea abies*, *Picea mariana* (Mill.) B.S.P., and *Pseudotsuga menziesii* (Mirb.) Franco, contains about twice as many phenolic-OH groups as lignin from the middle lamella (Sorvari et al., 1983, 1986; Whiting and Goring, 1982a,b; Hardell et al., 1980a; Yang and Goring, 1978, 1980). Middle lamella lignin has a higher molecular weight and a higher oxygen content compared to secondary wall lignin (Sorvari et al., 1983, 1986).

Using microautoradiography, Terashima and Fukushima (1988) found high levels of *p*-hydroxyphenyl lignin in the compound middle lamella in *Pinus thunbergii*. Condensed guaiacyl units were also higher in the middle lamella compared to the secondary wall. Traces of syringyl lignin were found in the inner secondary wall. In contrast, Westermark (1985) found that normal wood of *Picea abies* contains low levels of *p*-hydroxyphenyl units in the middle lamella.

Little information is available on the lignification of ray cells, which probably varies with cell type and species. Harada and Wardrop (1960) examined the lignification of ray parenchyma in *Cryptomeria japonica* using UV microscopy and interference microscopy, indicating a relatively high lignin concentration (44%) with lignin distributed evenly across the cell wall. A high lignin concentration in ray cells was also reported in spruce by Westermark et al. (1988). In pines, thick-walled ray parenchyma and ray tracheids are lignified, while thin walled parenchyma are unlignified (both types may be present within a species). Thick-walled ray parenchyma cells and axial tracheids are lignified to a similar extent in larch (Côté et al., 1968). Bamber and Davies (1969) suggest that thin walled ray parenchyma cells may become lignified during heartwood formation in radiata pine.

Resin canal epithelial cells are unlignified while associated strand tracheids are lignified to the same extent as axial tracheids (Bamber, 1972).

5. Lignin distribution in angiosperms

In contrast to gymnosperms where lignin is predominantly made up of guaiacyl units, angiosperm lig-

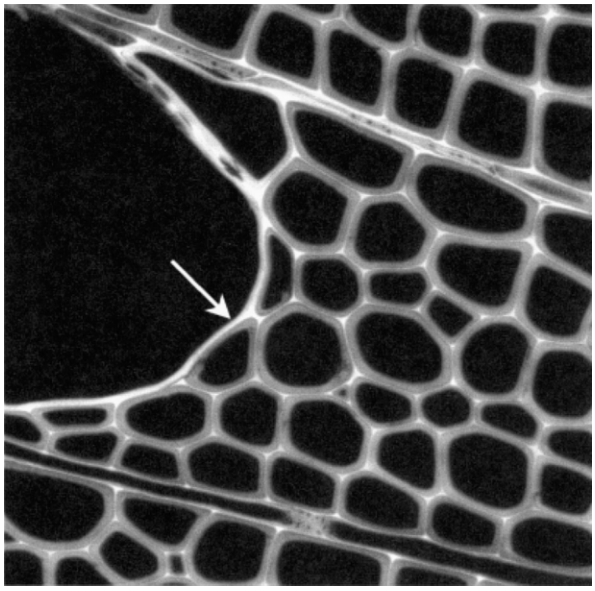

Fig. 7. Confocal fluorescence micrograph of *Populus nigra* Du Roi, stained with acriflavine to show lignin distribution. Increased brightness reflects higher lignin concentration. Note the more highly lignified vessel cell wall (arrow). The image is 160×160 μm.

nin contains a mixture of guaiacyl and syringyl units. The vessel secondary wall and middle lamella of typical hardwoods contains guaiacyl units while the secondary walls of fibers and the cell walls of parenchyma cells contains a mixture of guaiacyl and syringyl units with the latter predominating (Fergus and Goring, 1970a,b; Musha and Goring, 1975a,b; Hardell et al., 1980b; Kolar et al., 1982; Saka and Goring, 1988; Wu et al., 1990, 1992; Takabe et al., 1992; Yoshinaga et al., 1992; Peng and Westermark, 1997; Ruel et al., 1999). In white birch the G/S ratio of vessel secondary walls was found to be 88:12 while in fiber walls the ratio was 12:88, and in parenchyma walls 49:51 (Saka and Goring, 1988). However, these ratio's may vary significantly among species (Fujii et al., 1987). Wu et al. (1992) in a survey of 25 hardwood species from China, found that the monomeric composition of lignin was influenced by cell type, location within a growth ring, vessel arrangement and tree habitat. Three major patterns were found including:

1. All elements rich in guaiacyl lignin represented by vessel-less hardwoods and some tropical diffuse porous woods.
2. Vessels with guaiacyl lignin and fibers with guaiacyl/syringyl lignin, represented by diffuse porous woods.
3. Vessels with guaiacyl/syringyl lignin in variable ratios, represented by ring-porous and radial porous woods.

Vessel secondary walls may be more highly lignified in some species (Fig. 7). Vessel cell walls must withstand the large compressive forces resulting from the transpiration stream in plants and hence an increased lignification of the cell wall would be expected to increase the compression strength of the vessel and reduce its susceptibility to collapse (Yoshinaga et al., 1992). Takabe et al. (1992) examined lignin distribution in secondary xylem of *Fagus crenata* Blume, using UV microscopy. Their micrographs clearly show increased lignification of vessel secondary walls in earlywood, but not in latewood. Yoshizawa et al. (1993a, b) studied lignin distribution in normal and "compression wood" of *Buxus microphylla* Nakai, using UV microscopy and fluorescence microscopy, both techniques showing vessel secondary walls to be more highly lignified than adjacent fibers. Using mercurisation combined with EDXA, Eriksson et al. (1988) found the cell wall of vessels and ray cells had a lignin concentration 1.5–1.6× that of the fiber secondary wall.

The lignin distribution between secondary wall and middle lamella in hardwood fibers is similar to that in softwoods, however the secondary wall of hardwood fibers is often less lignified than the secondary wall of softwood tracheids. Fergus and Goring (1970b) examined lignin distribution in white birch using UV microscopy and found values for lignin concentration of 16–19% for the secondary wall of fibers, and 72–85% for the middle lamella. Saka and Goring (1988) determined the lignin concentration in the S2 and middle lamella regions of fibers and vessels of white birch using bromination combined with TEM/EDS. The average value for the S2 region of fiber walls was 16% (w/w) while for vessels the comparable value was 22%. The average value for the middle lamella region was 72%.

Cho et al. (1980) examined the chemical characteristics of middle lamella lignin isolated from birch (*Betula ermanii* (Nakai) T. Shimizu). The lignin content of this fraction was found to be 44% with a lower syringaldehyde/vanillin molar ratio among the nitrobenzene oxidation products and fewer methoxyl groups compared to the secondary wall fraction.

Variability in lignification within the middle lamella region has been reported in several studies. Singh and Schmitt (2000) studied lignin distribution in *Hevea brasiliensis* Engl. (rubber wood) with transmission electron microscopy and permanganate staining. They describe poorly lignified areas within the otherwise highly lignified cell corner regions between fibers, later confirmed by UV absorbance measurements on the same material. Similar observations have been made by Daniel et al. (1991) and by Tirumalai et al (1996), in birch.

6. Lignin distribution in reaction wood

Several studies of lignin distribution in compression wood have shown that the middle lamella region is less lignified than in normal wood (Côté et al., 1968; Wood

and Goring, 1971; Fukazawa, 1974; Donaldson, 1991; Donaldson et al., 1999). The presence of intercellular spaces at the cell corners, reduces the contribution of middle lamella lignin to the lignin content of compression wood. Lignin content is generally much higher than normal wood as a result of the more highly lignified secondary wall (Watson and Dadswell, 1957; Bland, 1958; Young et al., 1970). The highly lignified S2L layer (Fig. 8) (Lange, 1950; Wardrop and Davies, 1964; Wood and Goring, 1971; Fukazawa, 1974; Donaldson et al., 1999; Singh and Donaldson, 1999; Wi et al., 2000) is characteristic of both mild and severe forms of compression wood, not only in the Coniferales but also in the Ginkgoales and Taxales (Timell, 1978a,b; Yumoto et al., 1983; Yoshizawa et al., 1992; Wi et al., 2000). The increased lignification of the outer secondary wall in compression wood is thought to contribute to the formation of helical checking and the resulting longitudinal swelling is the mechanism by which compression wood achieves the correction of stem lean in standing trees (Boyd, 1973).

Lignin distribution may be highly variable within a single sample of compression wood. Donaldson et al. (1999) found concentrations of 26, 46, and 57% (v/v) for the S2, S2L, and cell corner middle lamella regions respectively in mild compression wood of *Pinus radiata*, with significant variation among adjacent cells. The inner S2 region of compression wood tracheids often shows radial lignin striations parallel to, and associated with, helical checking (Singh et al., 1998). The distribution of lignin subunits also varies in compression wood. *p*-Hydroxyphenyl units occur in both the compound middle lamella and in the secondary wall especially in the S2L region (Fukushima and Terashima, 1991b).

Lignin distribution in reaction wood of the more primitive angiosperms is similar to that in the compression wood of gymnosperms. Yoshizawa et al. (1993a,b, 1999) studied lignin distribution in the "compression wood" of *Buxus microphylla* using UV microscopy and fluorescence microscopy, both techniques showing vessel secondary walls to be more highly lignified than adjacent fibers. A highly lignified S2L region was observed in both vessel and fiber-tracheid cell walls. While normal wood of this species contains a mixture of guaiacyl and syringyl lignins, compression wood showed an increased content of guaiacyl lignin (Yoshizawa et al., 1993a,b, 1999).

Very few studies of lignin distribution in tension wood have been completed, especially using modern techniques (Fig. 8). Tension wood is characterized by the presence of a gelatinous layer forming part of the secondary wall in fibers. This gelatinous layer is considered to be unlignified and to consist of highly crystalline cellulose (Lange, 1950; Wardrop and Dadswell, 1955; Norberg and Meier, 1966; Robards, 1966, 1967; Robards and Purvis, 1967). The lignification of the S2 and S3 layers if present may be variable. Ruel et al. (1999) studied the distribution of lignin subunits in *Eucalyptus gunnii* Hook.f. tension wood, indicating a low proportion of condensed guaiacyl-syringyl subunits in the S2 region of the fiber walls. Distribution of lignin in tension wood of *Acer rubrum* L., *Fagus grandifolia* Ehrh., *Populus tremuloides* Michx., and *Ulmus americana* L., has been studied using the lignin skeleton method (Bentum et al., 1969). Normal and tension wood in these species showed a similar lignin distribution except for the unlignified G layer. The ultrastructure of tension wood in *Populus tremuloides* and *Acer rubrum* has been examined by Blanchette et al. (1994) who found a complete lack of

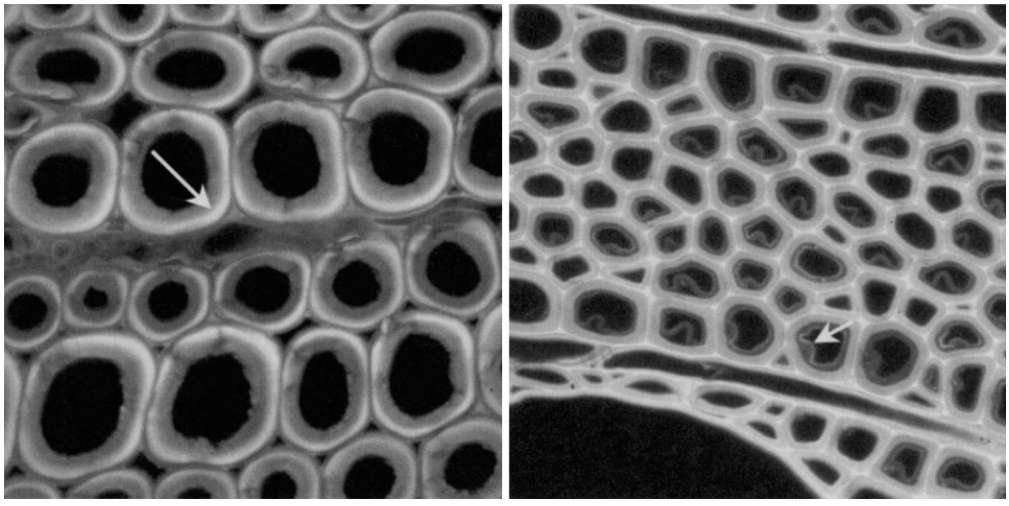

Fig. 8. Confocal fluorescence micrographs of compression wood (*Pinus radiata* left) and tension wood (*Populus nigra* right) stained with acriflavine showing lignin distribution. Increased brightness reflects higher lignin concentration. Note the presence of a highly lignified S2L region in the secondary wall (long arrow) The poplar micrograph has been overexposed to enable visualization of the unlignified G layer (short arrow) adjacent to the fiber lumen. In this case the G layer is unstained and is visualized by its extremely weak autofluorescence. Each image is 160×160 μm.

lignin in the G layer but normal lignin distribution in the rest of the secondary wall.

7. Conclusions

The process of lignin deposition within the cell wall during xylem formation appears to be highly controlled, requiring initiation sites and a complement of cell wall localized enzymes. The process of lignin deposition is thought to be an example of template polymerization and is still poorly understood. Further research is needed to understand the role of initiating sites including identifying the nature of such sites, and to understand the roles of enzymes and the cell wall matrix during lignin deposition. The involvement of peroxidase, laccase and oxidase enzymes, and arrays of dirigent (monomer binding) sites in the lignification process remain controversial. There is ample scope for immunolocalisation of these proteins in order to understand their spatial relationship to the lignification process. There is a need for novel histochemical techniques to localize specific monolignols or their glucosides within the cell walls of lignifying cells. Similarly there is a need to localize both enzymes and substrates involved in monolignol biosynthesis within the cytoplasm. It is anticipated that molecular biology will play an increasing role in the understanding of the lignification process.

Lignin shows a variety of qualitative and quantitative differences in its distribution. Typically there is a highly lignified middle lamella containing a predominance of guaiacyl units, and a less lignified secondary wall containing guaiacyl units in gymnosperms, or a mixture of guaiacyl and syringyl units in angiosperms. The type of lignin structural units in angiosperm xylem can often be distinguished on the basis of cell function (structural support versus water conduction — the former favoring a less highly lignified secondary wall containing syringyl units, the latter favoring a more highly lignified secondary wall containing guaiacyl units). Work continues to explore the natural diversity of lignified cell walls. More studies are needed on the influence of environment on lignification and its interaction with genotype.

Abstract

In tobacco plants the effect of antisense down-regulation of various genes encoding enzymes of the monolignol biosynthetic pathway resulted in quantitative and qualitative changes in lignin distribution and in diverse alterations of the secondary wall assembly of modified tobacco plants. Total lignin content, composition in syringyl and guaiacyl units, and absolute proportions of condensed and non-condensed substructures occurring in the cell walls, were differentially modified according to the repressed gene. Immunocytochemical characterisation and visualisation of the distribution of condensed and non-condensed lignin substructure epitopes in transmission electron microscopy (TEM) revealed that some transformations entailed profound and specific alterations in the secondary wall biogenesis. Correlation between micro-morphological cell wall alterations and semi-quantitative immunoanalysis of the topochemical distribution of lignin sub-units suggests that the mode of polymerisation of monolignols into non-condensed units, favoured by the microfibril matrix of the secondary wall, plays an important part in the lignified cell wall assembly.

1. Introduction

Lignin has long been recognised as essential in the cell wall architecture of land plant vascular tissues. However, the sequence of events that relate lignin monomer biosynthesis and their insertion and polymerisation within the pre-existing extracellular carbohydrate matrix is far from being known. Genetically modified plants, aside from their potential economical interest, constitute versatile tools for the study of plant physiology and biochemistry (Reiter, 1998). Tobacco plants have been modified by down-regulating various lignin biosynthetic genes leading to transformed lines differentially modified in their lignin content as well as their lignin monomer composition. These plants may be regarded as potential models towards the understanding of the role of lignin in plant cell wall assembly. Lignin monomer biosynthesis is derived from the shikimic acid pathway (Higuchi, 1990) and consists of a multistep process (Whetten and Sederoff, 1995) which offers various possibilities for selective targeting of genes that control the flux of monolignol production. There are still several unclear points regarding alternative enzymatic steps and the extent of inter-relationships between enzymes. Because of that it is still impossible to predict the exact impact of gene down regulation upon lignin content and composition in the derived transgenic plants, as well as the consequence of such modification on the plant cell wall assembly.

To assess the structural changes arising after lignin biosynthesis modification, chemical analysis has been the principal way to estimate the monomeric composition and the nature of the inter-unit linkages. Lignins from genetically modified plants have been analysed principally by thioacidolysis (Lapierre et al., 1999) and

PII: S0031-9422(01)00118-2

by nuclear magnetic resonance (NMR) (Ralph et al., 1998). The thioacidolysis method provides information on the relative proportions of syringyl and guaiacyl nuclei and on the proportion of non-condensed linkages in a lignin fraction. Similarly, NMR spectroscopy gives qualitative and quantitative indications about the monomer composition of lignins. Thus, ^{13}C–^{1}H NMR spectroscopy provided evidence for unusual and new aldehyde units, suggesting that other phenols than the usual monolignols may be utilised through redirected pathways (Ralph et al., 1998). Thioacidolysis analysis and NMR spectroscopy clearly identify differences between the lignins from control and transgenic plants. However, the compositional and structural information provided by these methods are limited to a certain fraction of lignin and it could be misleading to extend the results provided by these methods to the whole lignin present in cell walls.

In this paper, in order to partly overcome these limitations in view of the assessment of lignification following genetic transformation, we have used a non-invasive in situ immunocytochemical characterisation of lignin structural features by transmission electron microscopy (TEM). This approach allows the visualisation and characterisation of the diversity of lignin types in all the different parts of a cell wall, and in the various cell types. The antibodies used in this study were directed against condensed and non-condensed inter-unit linkages, respectively, as described in Ruel et al. (1994). Immuno-gold labelling in TEM allowed identification and ultrastructural localisation of specific lignin subunit epitopes in a comparative way between control and transgenic plants. Semi-quantitative results regarding the most typical lignin features synthesised in the different tissues of transformed tobacco could thus be obtained. Tobacco plants respectively down-regulated on the enzymes caffeic acid/5-OH-ferulic *O*-methyl transferase (COMT1), cinnamyl CoA reductase (CCR), and cinnamyl alcohol deshydrogenase (CAD) were used for the study together with a double transformed plant (CADxCCR) (Halpin et al., 1994; Atanassova et al.,1995; Piquemal et al., 1998; Chabannes et al., 2001).

The aim of this study was to investigate how changes in the content and/or the composition and molecular structure of lignin had influenced cell wall assembly and microstructure.

2. Results and discussion

The impact of modifications of lignin composition and structure on cell wall assembly was investigated at the ultrastructural level on a series of genetically engineered tobacco lines. Immunocytochemical identification and distribution of lignin sub-units was studied on ultra-thin sections from the stem of three simple transformants respectively down-regulated in expression of CAD, CCR and COMT1, and the double transformant resulting from the sexual crossing between CAD and CCR single transformants. These lines were selected according to previously obtained analytical data (Halpin et al., 1994; Atanassova et al., 1995; Piquemal et al., 1998; Chabannes et al., 2001; Pinçon et al., 2001) indicating that two of the transformed plants, CAD and COMT1, had almost no change in their lignin content, whereas the two other lines, CCR and CAD x CCR had considerable reduction of their lignin contents. Down-regulation of genes encoding key-step enzymes in the lignin biosynthetic pathway is also known to modify lignin composition and structure. Thus, examination of the respective amounts of lignin subunits in terms of non-condensed linkages versus condensed linkages (Lapierre et al., 1995) and recalculation of their respective amounts relative to total lignin content and to total cell wall material showed that the amount of condensed sub-units were always largely predominant in all tobacco lines (Table 1). Interestingly, the lignin of the double transformant, whose content had been lowered, had almost the same proportion of non-condensed linkages as the wild type plant. In spite of that, the monomer composition of the non-condensed subunits (S/G ratio) were very different between the control (S/G, 0.9) and the double transformant (S/G, 2.5). This observation can be extended to the CAD and CCR single transformants which had dramatically different total lignin contents, whose lignin showed very close proportions of non-condensed substructures (84.2 and 82.4%, respectively) in spite of their highly different composition in syringyl and guaiacyl monomers (S/G 0.4 and 3.2, respectively). This suggests that the strict guaiacyl and syringyl composition may not have a direct influence on the type of inter-unit linkages in the final lignin polymer and that other factors may be considered. Among those, the role of the environment in which the coupling reaction between monolignols occurs may be taken into account. In fact, the polymer matrix constituted by the pre-deposited cell wall polymers has been considered a determinant in the control of the course of the polymerisation of monolignols (Siegel, 1957). Of particular importance are the effects induced by different types of polysaccharides localised in different zones of the cell wall (Yoshida et al., 1994; Houtman and Atalla, 1995; Terashima et al., 1995). The calculation of absolute amounts of non-condensed and condensed lignins occurring in the cell walls (Table 1) show that the wild type plant harbours the highest amounts of both lignin types, whereas the CCR transformant had the lowest amounts of both. Interestingly, it appears that the cell walls of the parent CCR and of the double transformant CADxCCR had in common the same content of condensed subunits (ca 9% of the wall material) but markedly differed in the amount of non-condensed subunits (1.7 vs 2.8%, respectively).

Table 1
Respective amounts of non-condensed and condensed subunits in normal and transformed tobacco plants

Plant	Lignin %[b]	Non-condensed subunits[a]		Condensed subunits[a]		S/G in non-condensed subunits
		% of lignin	% in cell wall	% of lignin	% in cell wall	
Normal plant (wt)[c]	22.2	23.4	5.2	76.6	17	0.9
CCR (−)	10.7	15.8	1.7	84.2	9	3.2
CAD(−)	21.05	17.6	3.7	82.4	17.3	0.4
$COMT_1$ (−)	21.2	–	–	–	–	–
CAD^- x CCR^-	11.82	23.7	2.80	76.3	9	2.51

[a] The respective amounts of lignin subunits were recalculated from Halpin et al., 1994 Atanassova et al., 1995; Piquemal et al., 1998; Pinçon et al., 2000; Chabannes et al., 2001.
[b] As Klason lignin.
[c] Abbreviations: wt; wild type, CCR, cinnamoyl CoA reductase; CAD, cinnamyl alcohol dehydrogenase; COMT., caffeic acid *O*-methoyl transferase.

The effects of CCR anti-sense inhibition on the micromorphology of the secondary xylem elements, as observed in TEM, were characterised by a dramatic loosening between cellulose microfibrils, and a perturbation in their orientation, occurring in most of the S2 layer of vessels and fibres [Fig. 1(B)]. Interestingly, in both cell types, the S1 layer was not affected by the loosening. This suggests that there is a clear and distinct control in the assembly of lignin in the S1 and S2 layers. Further evidence of the spatio-temporal and cell specific regulation of lignification in secondary walls was shown by the fact that the ultrastructural alteration of S2 concerned only fibres and vessels of the metaxylem but not vessels of the protoxylem (data not shown). This shows that cell types and even sublayers of cell walls are differently and specifically affected when one of the genes of the pathway leading to lignin monomers is down-regulated.

The fact that the high reduction in the total lignin content resulting from the inhibition of CCR activity (Piquemal et al., 1998) is accompanied by an intense wall loosening shows the global importance of lignin in cell wall cohesion. However, in spite of a similar reduction of lignin content, the double transformant CADxCCR was not affected in the formation of secondary walls which did not show ultrastructural loosening and exhibited the same cohesion as the normal plant [Fig. 1 (E)]. This indicates that other factors besides the total amount of lignin must prevail for maintaining cohesion between cellulose micro-fibrils during cell wall assembly. It is indeed worth noting that the nature of the lignin varies between the normal plant and the different transformants. The variations which were found at the level of the relative proportions of syringyl and guaiacyl units and at the level of the nature of the inter-unit linkages (i.e. condensed and non-condensed) (Table 1) may have different effects on the process of cell wall assembly. To verify whether the type of lignin deposited in the cellulose–hemicellulose matrix of the secondary walls could have a specific impact on the wall cohesion, the ultrathin sections were assayed with our immunospecific probes respectively directed against condensed and non-condensed guaiacyl–syringyl subunits (Joseleau and Ruel, 1997). This allowed us to establish the topochemistry of lignin structural epitopes in each transformant. The results are illustrated in Fig. 1 with the labelling of non-condensed subunits. In view of comparing the respective intensities of the labelling, all the transformants and the normal plants were treated in parallel with the same antiserum at the optimal dilution. This insured that semi-quantitative evaluation of the labelling could be done for each antibody assayed. It is important to recall here that one cannot compare quantitatively the intensities of labelling given by two antibodies of different specificity. Therefore, semi-quantitative results are expressed separately for each antibody. The figures reported in Tables 2–5 were calculated from the number of gold particles per μm^2 in the three sub-layers of fibre and vessel walls, respectively, and are expressed relative to the highest concentration of gold particles found in any one of the sub-layers of the normal plant taken as control. Thus, comparative intensities of labelling between normal plant and transformants could be evaluated for each antibody.

As expected from the strongly altered ultrastructure of fibres and vessels of the CCR down-regulated transformant, striking variations in the labelling of fibres and vessels were observed. The strong loosening of S2 and S3 coincides with a very weak concentration of non-condensed GS epitopes in these regions of the walls, both in fibres and vessels (Tables 2 and 4). Conversely, the condensed GS epitopes appear relatively well represented in the less disorganised outer part of the S2 in the walls of the CCR plant (Tables 3 and 5) and do not show dramatic variations of concentration compared to the normal plant. This indicates that the overall 50% diminution of total lignin brought about by the anti-sense inhibition of CCR activity had repercussions

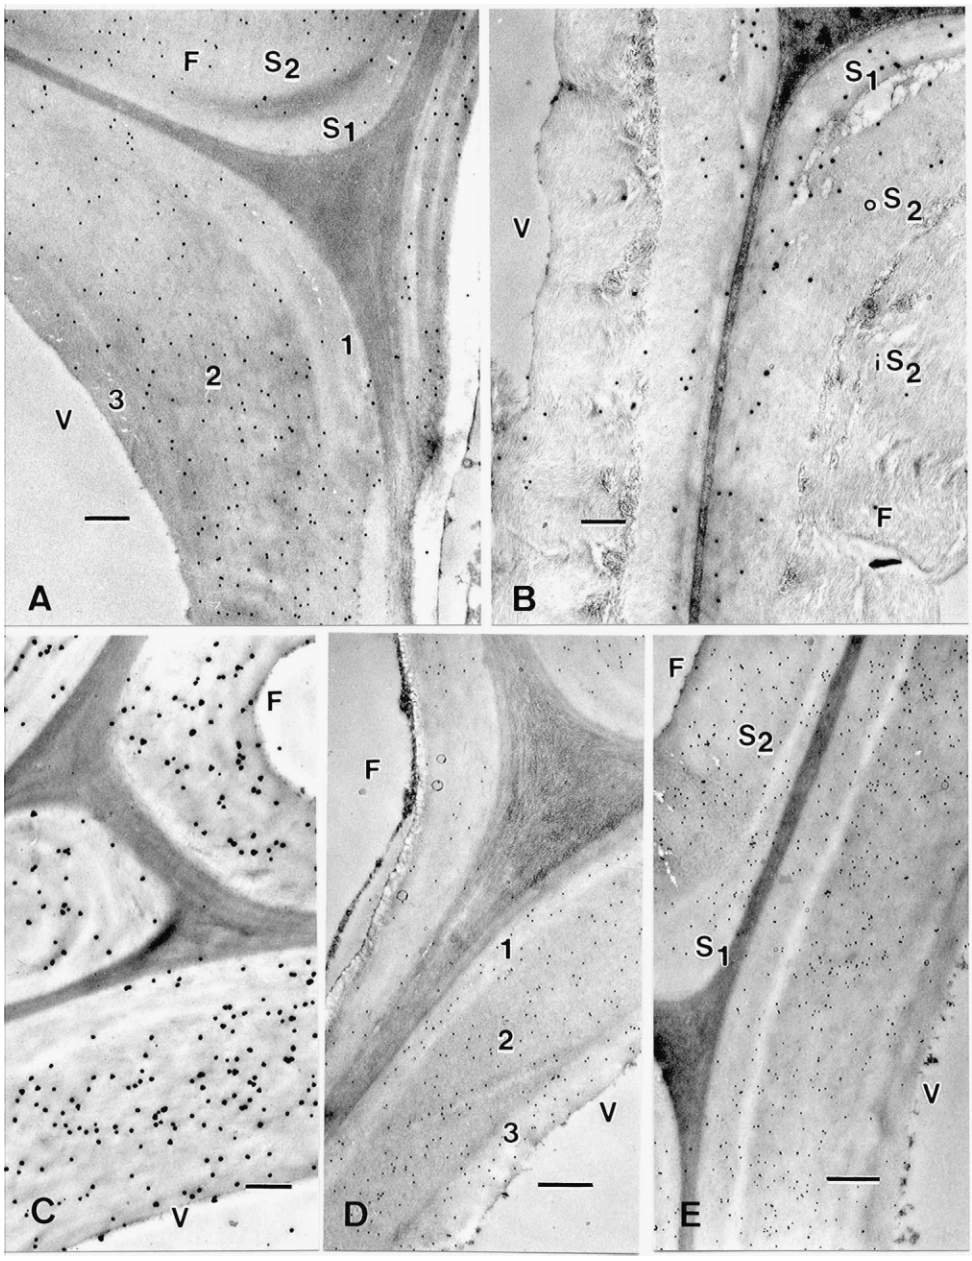

Fig. 1. Immunocytochemical localisation of non-condensed mixed guaiacyl–syringyl lignin sub-units in lignified tissues of wild type tabacco, CCR down-regulated, CAD down-regulated, COMT I down-regulated and CADxCCR double transformant lines. N.B.: The gold particles (5 nm in diameter) were silver enhanced. As a result, the size of silver grains may vary from one preparation to the other due to temperature and time. However, the actual number of grains remains unchanged. Bar = 0.5 μm; V = vessel; F = fibre; S1, S2, S3, and 1, 2, 3 = sub-layers in fibres and vessels, respectively; iS, oS = inner and outer parts of S2 layers. (A) In wild type plants, gold particles cover the three sub-layers of fibre walls with a lower labelling in the part of S1 adjacent to cell corners. In vessels, gold particles are essentially concentrated in S2. Middle lamellae and cell corners do not contain these subunits. (B) In CCR down-regulated line, gold particles have become mostly localised in S1, in fibres and vessels. An extensive loosening of the cellulose framework is visible in S2 of both fibres and vessels. Cellulose microfibrils appear irregularly oriented. (C) In CAD down-regulated line, the distribution of the gold particles is similar to that the wild type plant. (D) In the COMT I down-regulated line, the fibre presents an immature aspect. The distribution of gold particles seems to be weak. In vessel walls, gold grains are homogeneously distributed in the three sub-layers. (E) In the double transformant (CADxCCR), the distribution of gold particles in fibres and vessels is abundant in S1 and S2 where it predominates. However, in vessels, the newly formed S3 is only weakly labelled.

mostly on the formation of non-condensed sub-structures. These results are consistent with the general trends given by chemical analyses (Table 1), indicating that the lignin of CCR down-regulated lines was more severely depressed in non-condensed (ca. three times less than in a normal plant) rather than in condensed sub-units.

On the basis of analytical results (Table 1), one could expect the respective labelling in the double transformant CADxCCR to be stronger for the non-condensed

Table 2
Semi-quantitative distribution of non-condensed GS epitopes in fibres of transformants relative to wild type[a]

subunits, whose relative abundance is higher than in the single CCR transformant, and the labelling of condensed units to be of comparable intensities since both the single (CCR) and double transformants harbour the same amount of these subunits in their cell walls. The results of semi-quantitative evaluation of the immunological labelling (Tables 2 and 4) confirm that the double transformant was richer in non-condensed sub-units than the CCR transformant, mostly in vessels. The TEM images showed also that the ultrastructural distribution of non-condensed GS epitopes had not been significantly modified in the double transformant, as compared to the normal plant [Fig. 1(A) and (E)]. Contrarily, the ultrastructural distribution of the condensed epitopes (Tables 3 and 5), particularly in the outer S2 of fibres, was significantly modified. Also, the pattern of condensed epitopes in vessels, concentrated almost exclusively in S1, was much different from that of the normal plant and of the CCR parent. However, according to analysis and calculations (Table 1), the global amount of condensed forms in the cell walls are expected to be similar between the CCR parent and the double transformant. Added to the fact that the double transformant did not display the strong loosening observed in the CCR simple transformant, these results support the conclusion that the non-condensed moiety of lignin could have a preferential structural participation in the cohesion of the micro-fibril matrix of the secondary walls. This seems particularly significant in the case of fibres. This view is further supported by the results obtained with the anti-sense CAD and anti-sense COMT down-regulated lines which showed the non-condensed GS epitopes to be distributed in significant amounts in the S2 of both fibres and vessels without signs of loosening of the micro-fibril matrix. A peculiar feature of CAD modified plants is the accumulation of 4-hydroxy-3methoxycinnamaldehyde whose coupling would be similar to the corresponding alcohol, with the possibility of increasing the number of 8-*O*-4′ linkages (Russel et al., 2000). This could explain the high value of non-condensed sub-units in CAD cell walls (Table 1), and the rather large distribution of non-condensed epitopes observed in all sub-layers of fibres and vessels. On the other hand, the condensed GS epitopes were present in highly variable amounts in these two lines (Tables 3 and 5) without noticeable consequence on the ultrastructural wall assembly in S2. It seems thus that condensed substructures might be less implicated in secondary wall cohesion than their non-condensed counter part.

3. Conclusions

The effect of anti-sense down-regulation of various genes encoding enzymes of the monolignols biosynthetic pathway resulted in diverse alterations of the secondary wall assembly. Immunological characterisation showed that the topochemical distribution of lignin substructure epitopes was also modified (already described, Ruel et al., 2000; Chabannes et al., 2001). Inhibition of CCR activity resulted in an important loosening of the microfibrillar cellulose-hemicellulose matrix, together with a perturbation in the microfibrils orientation. Taken together with the reduction of 50% in total lignin content, it might be deduced that a minimum amount of lignin is necessary to insure cohesion between microfibrils in the secondary wall. However, with the same reduction in total lignin content, the double transformant resulting from the cross between individual homozygous CCR and CAD down-regulated lines (Chabannes et al., 2001), did not show loosening of its xylem walls. This constitutes a clear evidence that the global amount is not sufficient to explain the participation of lignin in the maintaining of cohesion in secondary wall assembly.

The deposition of lignin during the formation of the composite secondary wall has been suggested to be a highly regulated phenomenon (Lewis et al., 1999). This view is further supported by in vitro model of lignin biosynthesis suggesting that in the natural microenvironment lignin polymerisation would involve an alternating sequence of radical and ionic steps leading to an ordered structure with repeating units (De Angelis et al., 1999). Our results show that the condensed and non-condensed GS substructure epitopes underwent modifications in their repartition that depended on the genetic transformation. The alteration of ultrastructure in CCR transformant coinciding with a dramatic depletion in non-condensed GS epitopes suggests that this type of lignin substructure must be implicated in the morphogenesis of the secondary wall. The fact that it is the non-condensed form rather than the condensed form of lignin that has a special role in secondary wall assembly agrees with the view that the restricted space (ca. 30 Å) between the cellulose-hemicellulose microfibrillar template favours the extended macromolecule conformation of the non-condensed lignin molecule over the bulky one of condensed lignin (Terashima and Fukushima, 1989; Higuchi, 1990; Roussel and Lim, 1995; Joseleau and Ruel, 1997). The occurrence of the extended non-condensed lignin between microfibrils is further supported by the results of calculation of lignin morphology by computer modelling, predicting in the secondary wall a high degree of orientation of the phenylpropane sub-units parallel with cellulose microfibrils (Agarwal and Atalla, 1986; Jurasek, 1996, 1998).

Our results of immuno-labelling show that variations in the ultrastructural distribution of lignin substructures were observed whenever lignin composition and structure had been modified. This must be related to the metabolic flux and availability of the precursor monolignols, on the one hand (Roussel and Lim, 1995), and to the influence of the polysaccharide matrix on lignin polymerisation, on the other hand. This is also in favour of a fast and irreversible coupling of monolignols within the microfibril template placed under kinetic control suggested by Houtman (1999). The question of the implication of stereo-specific proteins (Davin et al., 1997) in the control of orientation of the coupling reactions of monolignols still remains unresolved. The variability in lignin ultrastructural distribution would therefore depend on the respective rate of synthesis of the monolignols and the fact that the different saccharides of the secondary wall interact differently with the different lignin precursors (Houtman and Atalla, 1995). These views are consistent with the irregular and within-wall specific distribution of the different types of lignins in the secondary walls depicted in all cell walls with the immunological probes. They are also consistent with a spatially-controlled organisation of lignification.

The increasing availability of engineered plant cell walls should help in uncovering the complex biochemical and physicochemical machinery underlying secondary wall assembly.

4. Experimental

4.1. Plant materials

The transgenic tobacco lines used in this work have been described previously. They consisted of three single transformants, a CAD down-regulated line (Halpin et al., 1994), a CCR down-regulated line (Piquemal et al., 1998) a COMT I down-regulated line (Atanassova et al., 1995), and a double transformant originating from cross-pollination between CAD and CCR transformants (Chabannes et al., 2001).

The chemical and microscopy analyses were performed on the basis of the stems of mature plants grown in a culture room.

4.2. Immunocytochemistry

Two specific polyclonal antibodies prepared and characterised as described in Ruel et al. (1994); Joseleau and Ruel (1997) were used as anti-sera. They were directed respectively against: mixed guaiacyl/syringyl (GS) lignin polymer containing non-condensed inter-unit linkages (8-*O*-4), and, mixed guaiacyl/syringyl lignin polymer containing condensed inter-units.

Small slices (1 mm in thickness) obtained by free hand sectioning with a razor blade were fixed in a freshly prepared mixture of 0.1% glutaraldehyde (v/v), 2%

paraformaldehyde (w/v) in 0.05 M phosphate buffer (pH 7–7.2). After rinsing in phosphate buffer, they were dehydrated through a graded ethanol series up to 80% (v/v), then infiltrated and embedded in LR White resin (hard mixture, TAAB) and polymerised 24 h at 50°C as described earlier (Ruel et al., 1994).

In TEM, immunolabelling was done on ultra-thin transverse sections (500 Å) floating downward in plastic rings passed on 50 µl drops of reagents deposited on parafilm. The sections were first treated with 0.15 M glycine in Tris–HCL buffer 0.01 M, pH 7.6, containing 500 mM NaCl, for blocking remaining aldehyde functions. This was followed by 2 min rinse (×5) on TBS500. Protein-protein interactions were blocked for 30 min by incubating on 5% (w/v) non-fat dried milk in TBS500. The sections were then incubated on each antiserum diluted 1/50–1/100 in the blocking buffer. Incubation time was 3 h at room temperature followed by one night at 4°C. After 4 washes (2 min each) in TBS500 followed by 3 rinses in Tris–HCl buffer (0.01 M Tris–HCl, pH 7.4–7.6), the sections were floated on the secondary marker [protein A-gold (pA 5), (Amersham)] diluted 1/25 in Tris–HCl buffer containing 0.2% fish gelatin for 90 min at room temperature. They were washed 5 times (2 min each) in Tris–HCl buffer and 3 times in H_2O. The sections were then post-fixed in 2.5% glutaraldehyde in H_2O and washed 3 times in H_2O. At this stage, the diameter of the 5 nm gold particles was further enhanced using a silver enhancing kit from Amersham. Finally, thin sections were transferred on carbon-coated copper grids and post-stained in 2.5% aqueous uranyl acetate. Observations were performed at 80 kV with a Philips CM 200 Cryo-electron microscope.

All comparative immunolabelling experiments were carried out in parallel in order to keep the same experimental conditions (dilutions of antibodies, times of contact et) and pre-immune serum for each antibody was assayed on the different tobacco lines, in the same conditions as described for the immuno-gold labelling.

Quantitative estimation of the labelling was carried out by counting the gold particles per μm^2. In each case, a section of the wild type plant was used as control for immunolabelling. Value 1.00 was assigned to the highest labelled sub-layer in the control. The labelling in the transformed samples are expressed relative to the normal plant.

Dirigent proteins and dirigent sites in lignifying tissues

Vincent Burlat, Mi Kwon, Laurence B. Davin, Norman G. Lewis*

Institute of Biological Chemistry, Washington State University, Pullman, WA 99164-6340, USA

Received in revised form 18 January 2001

Abstract

Tissue-specific dirigent protein gene expression and associated dirigent (site) localization were examined in various organs of *Forsythia intermedia* using tissue printing, in situ mRNA hybridization and immunolabeling techniques, respectively. Dirigent protein gene expression was primarily noted in the undifferentiated cambial regions of stem sections, whereas dirigent protein sites were detected mainly in the vascular cambium and ray parenchyma cell initials. Immunolocalization also revealed cross-reactivity with particular regions of the lignified cell walls, these being coincident with the known sites of initiation of lignin deposition. These latter regions are considered to harbor contiguous arrays of dirigent (monomer binding) sites for initiation of lignin biopolymer assembly. Dirigent protein mRNA expression was also localized in the vascular regions of roots and petioles, whereas in leaves the dirigent sites were primarily associated with the palisade layers and the vascular bundle. That is, dirigent protein mediated lignan biosynthesis was initiated primarily in the cambium and ray cell initial regions of stems as well as in the leaf palisade layers, this being in accordance with the occurrence of the lignans for defense purposes. Within lignified secondary xylem cell walls, however, dirigent sites were primarily localized in the S_1 sublayer and compound middle lamella, these being coincident with previously established sites for initiation of macromolecular lignin biosynthesis. Once initiation occurs, lignification is proposed to continue through template polymerization. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

The biochemical processes involved in stipulating the outcome of monolignol coupling to afford vascular plant lignin biopolymers and (oligomeric) lignans, nature's second most abundant substances, are only now beginning to yield to inquiry (Davin et al., 1997; Lewis and Davin, 1998, 1999; Sarkanen, 1998; Gang et al., 1999; Lewis, 1999; Lewis et al., 1999). The lignins are heterogenous structural biopolymers mainly laid down within cell-walls of primary and secondary xylem, as well as phloem fibers (Lewis et al., 1999). Their compositions can vary both between and within plant species according to the type of monolignols present (i.e. *p*-coumaryl, coniferyl and sinapyl alcohols, Fig. 1A), as well as by the various intermonomeric linkages involved (Lewis and Yamamoto, 1990; Brunow et al., 1998). Lignin heterogeneity results from predetermined differences in the *organized* distribution of individual monolignols in lignins within different cell types and even within distinct cell wall layers of the same cell type (Fergus and Goring, 1970; Hardell et al., 1980; Saka et al., 1982; Tollier et al., 1986; Lewis and Yamamoto, 1990; Fukushima and Terashima, 1991; Burlat et al., 1997; Joseleau and Ruel, 1997).

It has long been known that lignin formation begins at so-called lignin initiation sites located at the furthermost outer reaches within the preformed wall (Wardrop and Bland, 1959; Donaldson, 1994). That is, lignification is initiated at the outermost regions and then works its way back towards the plasma membrane/lumen after which the cell dies. The evolution of this remarkable biochemical system thus provided the means for not only ensuring that lignification occurs throughout the entire plant cell wall, but also affords the means for the cytoplasm to control both lignin assembly and monomer composition throughout the wall. However, we still have a very incomplete understanding of how the monomers are transported to the lignin initiation sites and their precise interactions with the lignin forming proteins and

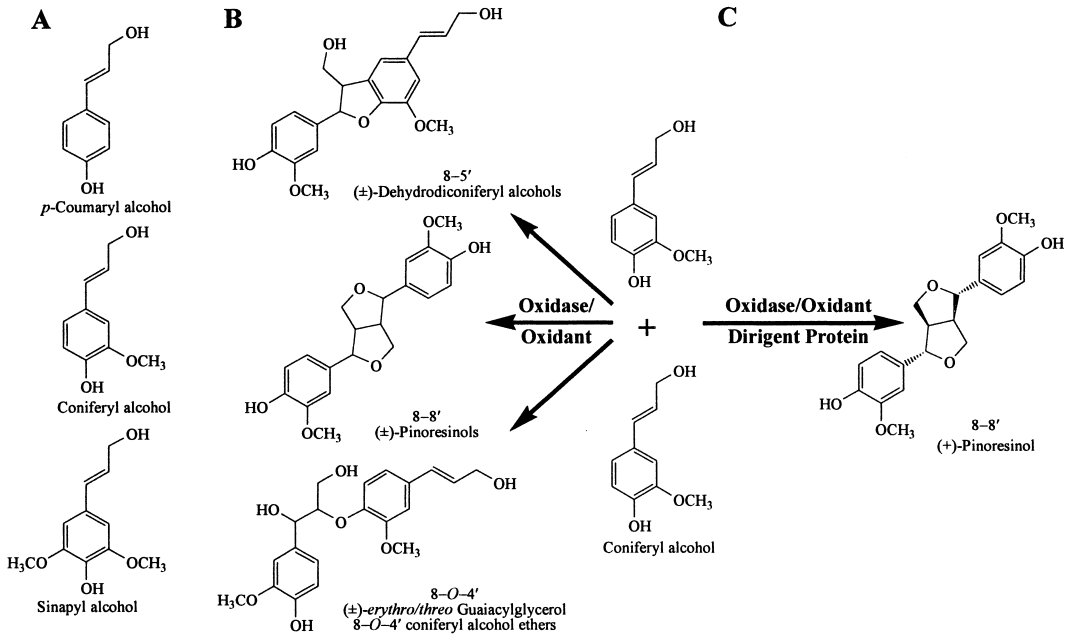

Fig. 1. Monolignols and oxidative coupling. (A) Chemical structures of monolignols, (B) non-specific, racemic phenoxy-radical coupling of *E*-coniferyl alcohol in presence of an oxidant/oxidase, and (C) an example of stereoselective phenoxy-radical coupling of *E*-coniferyl alcohol, in this case, in the presence of an oxidant/oxidase and the *Forsythia intermedia* dirigent protein (psd-Fi1).

enzymes in the wall. Nevertheless, the regiospecificity of coupling affords a polymer typically having 50–70% of 8-*O*-4′ linkages (Adler, 1977), with this perhaps even being as much as 80% in transgenic *Arabidopsis* (Meyer et al., 1998; Marita et al., 1999). Following lignin initiation, it has been proposed that subsequent lignification occurs back toward the plasma membrane through a template polymerization process (Guan et al., 1997; Sarkanen, 1998).

Lignification has been temporally and spatially correlated with secretion from the Golgi apparatus of specific glycine-rich proteins (GRPs) (Keller et al., 1988; Ye et al., 1991; Ye and Varner, 1991; Ryser et al., 1997) and proline-rich proteins (PRPs) (Marcus et al., 1991; Ye et al., 1991; Müsel et al., 1997). Although these ultimately become an integral part of the maturing cell wall architecture, no explicit biochemical function was demonstrated in vitro for either class of proteins.

The lignans are a widespread class of related, but biochemically distinct, metabolites, which are frequently found as 8-8′ linked dimers, although other interunit linkages abound (e.g. 8-5′, 8-*O*-4′) (for reviews, see Lewis and Davin, 1994, 1998, 1999). They are found in *all* plant tissues examined thus far. Many lignans are optically active; they can exist as higher molecular weight oligomeric entities, such as major heartwood constituents in western red cedar (*Thuja plicata*) (Beatson et al., 1998; Fujita et al., 1999). Their roles appear to be primarily in plant defense, with their formation being either under constitutive or inducible control (Lewis and Davin, 1994, 1999); their deposition can have important positive contributions to plant tissue durability, color and quality. Various lignans have been demonstrated to have antioxidant (Osawa et al., 1985; Harper et al., 1999), antiviral (Gnabre et al., 1995; Asano et al., 1996), bactericidal (Nitao et al., 1991), antifungal (Atta-ur-Rahman et al., 1995; Miyazawa et al., 1996), and cytotoxic (Kupchan et al., 1978; Day et al., 1999) properties.

A new perspective on control of monolignol coupling was obtained with the discovery of dirigent proteins (Latin: *dirigere*, to guide or to align) (Davin et al., 1997; Gang et al., 1999). Discovered first in *Forsythia intermedia*, the dirigent glycoprotein stipulates, at both the regio- and stereochemical levels, the outcome of coupling of two molecules of *E*-coniferyl alcohol to give the lignan, (+)-pinoresinol, as shown in Fig. 1C rather than racemic products (Fig. 1B) (Davin et al., 1997). A requirement of the protein is, however, provision of one-electron oxidation through an auxiliary source (e.g. laccase, peroxidase, cytochrome P-450, and ammonium peroxydisulfate). Significantly, only *E*-coniferyl alcohol derived substrates were utilized by this protein, and not *p*-coumaryl or sinapyl alcohols which differ only in the degree of methoxylation (see Fig. 1A).

The discovery of dirigent proteins established the long anticipated existence of *specific* monolignol (radical) binding proteins. The gene encoding the ~18 kDa dirigent protein subunit was cloned, with the fully functional glycosylated recombinant form (~26 kDa subunit) obtained using a *Spodoptera*/baculovirus expression system (Gang et al., 1999). It had no significant level of similarity or identity to any other protein of known function. Thus far, dirigent proteins and their homologues have only been reported in vascular plants (Davin and Lewis, 2000).

This discovery led to the central question of whether or not arrays of dirigent (monomer binding) sites might be the means for initiating the onset of lignification at the so-called lignin initiation sites. This does not, however, imply that the dirigent proteins and arrays of dirigent (monomer) binding sites are synonymous. Indeed they could not be, as the former are required for optically active lignan biosynthesis. A dual deployment of dirigent proteins for lignan biosynthesis and dirigent (monomer binding) sites in other proteins for lignin biosynthesis initiation would place this main branch of metabolism in alignment with all other major branches of plant metabolism. That is, in terpenoid, carbohydrate and lipid metabolism, there are recurring biochemical (enzymological) processes which account for dimer, oligomer and biopolymer biosyntheses in each metabolic class, e.g. glycosyl transferases and prenyl transferases. It is therefore tempting to consider that there are recurring themes in free-radical coupling also, and which would control lignan and lignin biosynthesis assembly processes. Furthermore, a mechanism employing template polymerization could explain how lignins proper have relatively few cross-links and types of inter-unit linkages, and lack any apparent optical activity.

This study undertook the objectives of establishing, at the ultrastructural level, the specificity of both dirigent protein gene expression (i.e. mRNA localization) and dirigent site localization, in different tissues and subcellular compartments of the angiosperm *F. intermedia*. Polyclonal antibodies were employed not only to localize the dirigent protein involved in (+)-pinoresinol biosynthesis, but also to ascertain whether related proteins harboring (arrays of) dirigent (monomer binding) sites were co-localized with the established initiation sites of lignin formation (Donaldson, 1994). The results described below provide further evidence for the involvement of dirigent proteins and dirigent sites in lignan and lignin biosynthesis, respectively.

2. Results and discussion

The morphology of cross-sections of different tissues of *F. intermedia* is conveniently revealed (Fig. 2) by toluidine blue staining. Fig. 2A and D [1st, young, and 10th, more mature, internodes, respectively] show stem morphology at two developmental stages, whereas Fig. 2G, J and M display the relative morphologies of petiole, root and leaf tissues. Three broad tissue categories are observed in the stem sections (Fig. 2A and D): the cortex, the differentiating cambial layers, and the lignified developing xylem. With increased maturity (Fig. 2D), the vascular cambium cells are readily distinguished from the secondary phloem located beneath the phloem fibers, and the pith progressively collapses to give the central hollow. In petioles (Fig. 2G), the crescent-shaped vascular bundle embodying the vascular cambium is flanked by secondary phloem and the lignified developing xylem/ground parenchyma. In the roots (Fig. 2J), the meristematic cambial region is constituted by the pericycle, with vascular lignified tissues forming the stele, whereas in leaves (Fig. 2M), the bundle sheath cells are embodied within the paraveinal mesophyll, these cells being flanked by the palisade parenchyma above and the spongy mesophyll below.

Using phloroglucinol-HCl histochemical staining (Johansen, 1940), patterns of lignin deposition are readily visualized within the stem xylem cell walls, phloem fibers and sclerified pith parenchyma (Fig. 2B and E). Patterns of lignin deposition are also observed inside the developing xylem of the petiole (Fig. 2H), the stele of the root (Fig. 2K), and the bundle sheath cells of the leaves (Fig. 2N). The application of autofluorescence (Franceschi et al., 1998) permits an assessment of the gross localization of phenolics in the various lignin and lignan containing tissues of *Forsythia*; this revealed that beside the lignified cell walls (and the cutinized and/or suberized epidermis), additional light blue signals were present in both the cortex and the vascular cambium-secondary phloem region of stems (Fig. 2C and F). Similar observations were made in the cambium-secondary phloem region and ground parenchyma of the petiole (Fig. 2I), as well as in the pericycle and cortex regions of the root (Fig. 2L). Finally, in leaf tissues (Fig. 2O), where lignins are scarcely present but where lignans accumulate (Rahman et al., 1990), an intense phenolic autofluorescence was observed in the palisade parenchyma and the paraveinal spongy mesophyll, as well as the vascular bundles. Thus, beside the lignin patterning in the cell walls of vascular tissues, other populations of phenolics, which typically include lignans, are present in various different cell types. Lignans are also present in all of the other *Forsythia* tissues (Chiba et al., 1979; Kitagawa et al., 1988; Rahman et al., 1990).

2.1. Tissue specific expression of dirigent transcripts

The expression patterns of the dirigent protein gene psd-Fi1 was examined in *F. intermedia* stem, root and petiole tissues, using tissue print mRNA hybridization (McClure and Guilfoyle, 1989; Ye et al., 1991; Ye and Varner, 1991) and in situ hybridization (Bochenek and Hirsch, 1990) techniques; this dirigent protein gene is from a multigene family with at least three members in the *Forsythia* species (Gang et al., 1999, Jeon and Lewis, unpublished data).

Physical prints onto sobo glue (polyvinyl acetate) first revealed the gross morphology of the different tissues (Fig. 3A, D, G, J and M). Tissue-print blotting was next used to define patterns of dirigent protein mRNA accumulation. Hybridization with the radiolabeled antisense probe (Fig. 3B, E, H, K and N) revealed specific

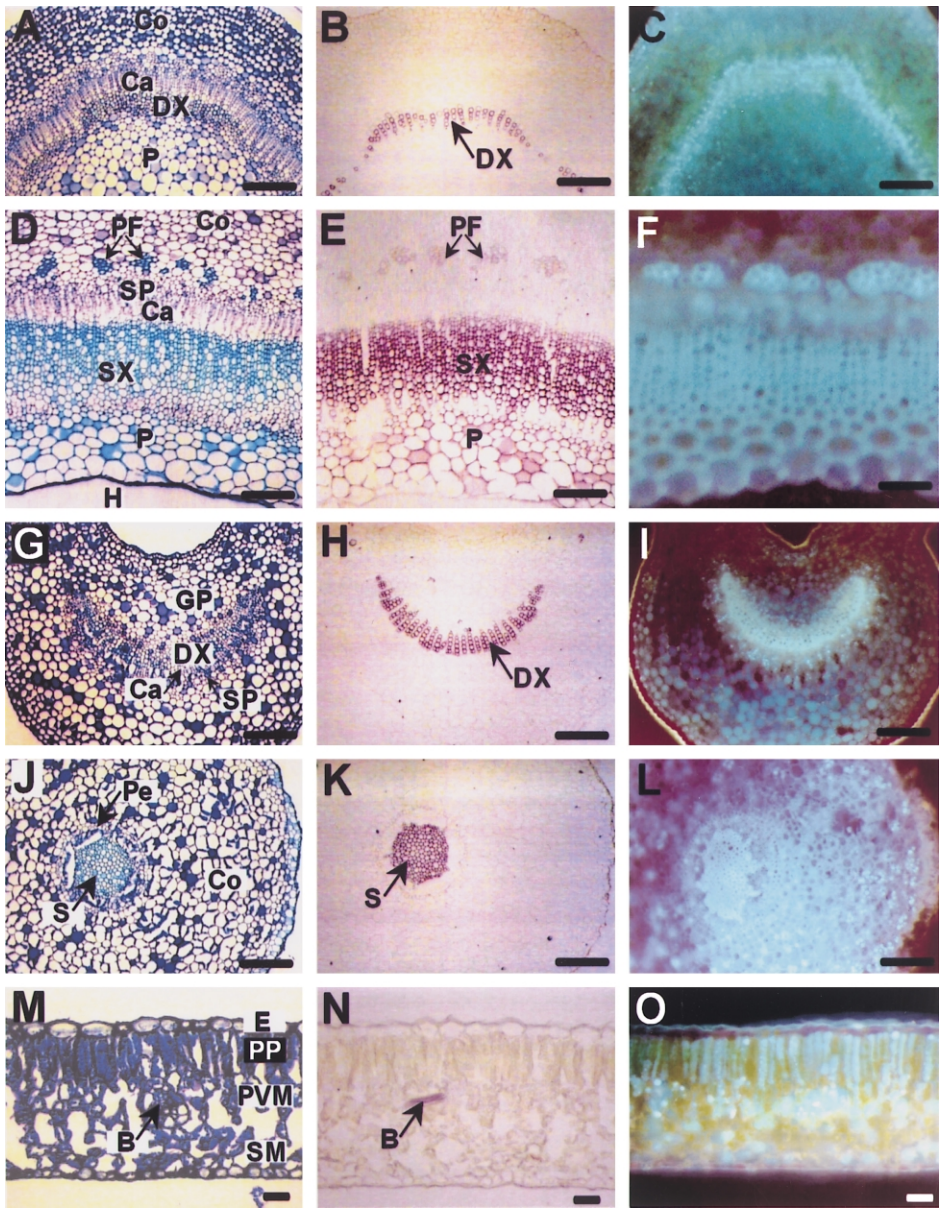

Fig. 2. Distribution of lignin and other phenolics (i.e. lignans) within cross-sections of *Forsythia intermedia* tissues. (A)–(C) Stem 1st developing internode, (D)–(F) stem 10th mature internode, (G)–(I) mature petiole, (J)–(L) root and (M)–(O) leaf, respectively. Morphological features are revealed with toluidine blue staining (A), (D), (G), (J), and (M), whereas histochemical aspects of lignin deposition are displayed by phloroglucinol-HCl staining (B), (E), (H), (K), and (N), and the phenolics are exposed via light blue autofluorescence (C), (F), (I), (L), and (O). Note in addition to the lignin deposition detected in vascular tissues with both phloroglucinol-HCl and phenolic autofluorescence, the additional phenolic populations detected as autofluorescence in different cell types/tissues. B, bundle sheath; Ca, cambium; Co, cortex; DX, developing xylem; E, epidermis; GP, ground parenchyma; H, hollow; P, pith; Pe, pericycle; PF, phloem fibers; PP, palisade parenchyma; PVM, paraveinal mesophyll; S, stele; SM, spongy mesophyll; SP, secondary phloem; SX, secondary xylem. Bars: 50 μm.

and intense signals in all cases examined, as compared to the corresponding sense controls (Fig. 3C, F, I, L and O). In stem cross-sections, the dirigent protein mRNA signals were predominantly present in the cambial region in all three developmental stages examined [young (1st, Fig. 3B), intermediate (10th, Fig. 3E) and oldest (20th, Fig. 3H) internode, respectively]. Additional signals were detected at the youngest (1st internode) developmental stage in the cortex, developing xylem and pith tissues (Fig. 3B). The intensity of this particular labeling pattern decreased with maturation, with the signal becoming essentially restricted to the cambial region (Fig. 3H). Petiole cross-sections (Fig. 3K) also displayed a specific, albeit weaker, signal, this being in the cambial tissue adjacent to the differentiating lignified vascular region. A similar observation was made with root cross-sections (Fig. 3N), where a relatively weak but specific signal was noted with the anti-sense probe in the pericycle surrounding the central vascular tissues (stele). Thus, the tissue printing hybridization technique established that

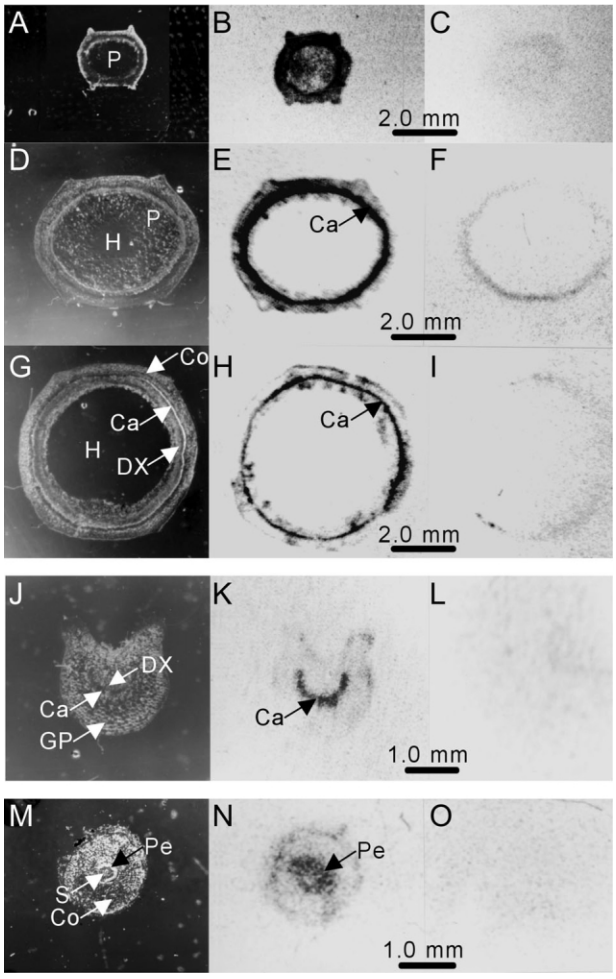

Fig. 3. Dirigent protein mRNA localization via tissue-print hybridization of fresh cross-sections of *Forsythia intermedia* tissues. (A)–(C) Stem 1st developing internode, (D)–(F) stem 10th mature internode, (G)–(I) stem 20th mature internode, (J)–(L) petiole, and (M)–(O) root, respectively. (A), (D), (G), (J) and (M) Physical prints of cross-sections displaying gross tissue morphology. Each of the blots from adjacent cross-sections within the same tissue were hybridized in parallel with the ^{35}S-thio UTP-labeled anti-sense (B), (E), (H), (K) and (N) and sense (C), (F), (I), (L) and (O) probes for dirigent protein mRNA labeling and for negative controls, respectively. Note: (i) the intense dark signals (anti-sense experiments) due to localization of dirigent protein mRNA in the differentiating cambial region of the stems and petiole, and in the pericycle of root; (ii) the fainter signal observed in the outer cortex of the young differentiating internodes that disappeared during maturation of the stem, with the mRNA localization subsequently becoming restricted to the cambial region. Ca, vascular cambial region; Co, cortex; DX, developing xylem; GP, ground parenchyma; H, hollow; P, pith; Pe, pericycle; S, stele.

gross localization of the dirigent mRNA was mainly associated with the cambial regions (Burlat et al., 1999; Kwon et al., 1999); it should be noted that historically the cambial region/differentiating xylem has hitherto been viewed by many researchers as exclusively restricted to lignin biosynthesis (Freudenberg, 1968; Bao et al., 1993).

In situ hybridization experiments were conducted using 1st and 10th internode stem cross-sections as a means to obtain resolution at the cellular level (Fig. 4). These particular samples were chosen for the relatively high dirigent gene expression level as noted from both tissue print hybridization (Fig. 3B and E) and northern analysis (Kwon et al., 1999). These experiments confirmed the observations with tissue printing hybridization, with the main signal again being present in the cambial regions of the 1st internode (Fig. 4A and C) and 10th internode (Fig. 4E and G), respectively. At the youngest stage of development, dirigent protein expression was also observed in the cortex and the pith (Fig. 4A); however, the strongest signals were restricted to the cambial region and ray parenchyma cell initials (Fig. 4C). Interestingly, the latter cells are *adjacent* to the lignified tracheary elements which, by comparison, only display a weak signal, especially in the oldest lignified tracheary elements adjacent to the pith. The more mature stem, in contrast, showed a relatively weaker signal, which was specifically localized along the vascular cambium, and, to a lesser extent, the secondary phloem (Fig. 4E and G). Negative controls with the sense probe gave essentially no background signals (Fig. 4B, D, F and H).

Both methods thus gave complementary results illustrating that among the tissues studied, dirigent gene expression was mainly associated with the vascular cambium region, in the cambium and secondary phloem of mature stem and petiole tissues, i.e. regions previously described as the exclusive domain of lignification (Freudenberg, 1968; Bao et al., 1993).

2.2. Tissue specific and sub-cellular localization of dirigent protein and proposed arrays of dirigent (monomer binding) sites

The next objective was to localize the dirigent protein (and/or related dirigent sites) at the tissue and subcellular levels. For this purpose, polyclonal antibodies were specifically employed with the rationale that they would not only immunolocalize dirigent proteins involved in lignan biosynthesis, but would perhaps display an antigenic response with related dirigent binding sites (for coniferyl alcohol derived substrate) involved in the initiation of lignin deposition. Thus, the glycosylated dirigent protein obtained in functional recombinant form through heterologous expression of psd-Fi1 in a *Spodoptera*/baculovirus expression system (Gang et al., 1999) was used to raise polyclonal antibodies in two rabbits.

The titers of both rabbit sera (raised against the dirigent protein and the pre-immune serum controls, respectively) were first evaluated using the indirect ELISA technique. It was found that neither of the two pre-immune sera bound the antigen, even at the lowest dilutions tested, i.e. 1:100 (data not shown). The best titer (highest dilution to obtain an $\frac{1}{2}$ OD 490 nm max reading) was observed after 7 weeks for the first rabbit ($\sim$1:2500), and 11 weeks for the second ($\sim$1:2500), in harmony

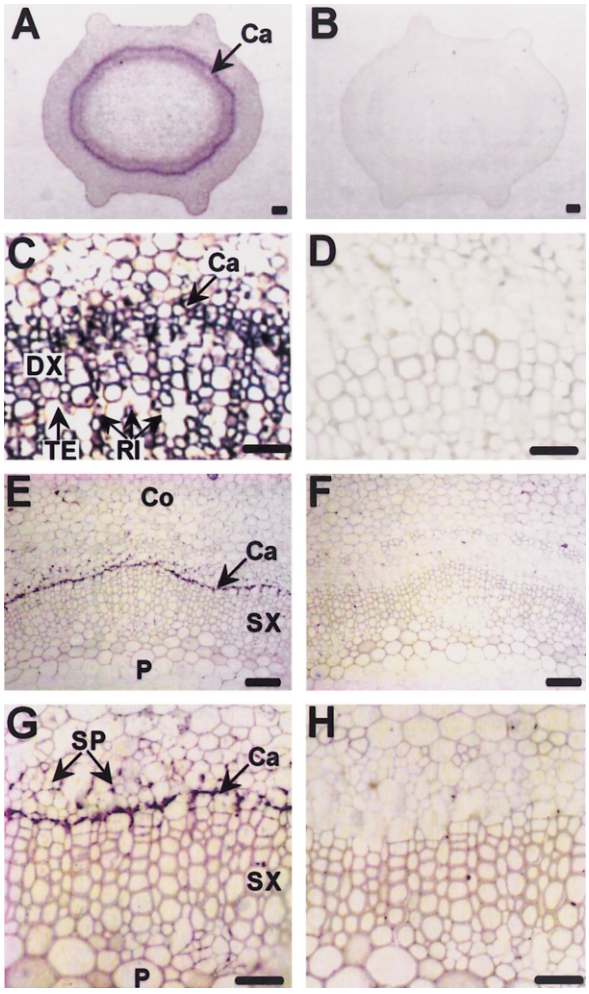

Fig. 4. In situ hybridization of *Forsythia intermedia* dirigent protein mRNA with digoxigenin-labeled riboprobes. (A), (C), (E), and (G) Labeling with anti-sense probe, and (B), (D), (F), and (H) controls using the sense probe. The data shown are for the *F. intermedia* stem differentiating 1st internode (A)–(D) and mature 10th internode (E)–(H), and are given at two different enlargements in each case. Note the evolution of the dark purple signal with maturation of the stem. This became restricted to the cambium and secondary phloem in the differentiated 10th internode, whereas it was also present, to a lesser extent, in the cortex of the young differentiating 1st internode. Ca, cambium; Co, cortex; DX, developing xylem; P, pith; RI, ray initials; SP, secondary phloem; SX, secondary xylem; TE, tracheary elements. Bars: 50 μm (A), (B), (E) and (F), 25 μm (C), (D), (G) and (H).

with previous observations using the whiffle-ball technique to raise antibodies (Hillam et al., 1974; Ried et al., 1992). The 7-week immune serum of the first rabbit and its corresponding pre-immune serum were chosen for subsequent experiments.

Note, however, that SDS–PAGE followed by western blot analysis had previously demonstrated that the dirigent protein immune serum specifically recognized the recombinant *Forsythia* dirigent protein (even after deglycosylation), as well as both the dirigent in a crude protein extract from *Forsythia* stems and the purified native *Forsythia* dirigent (Gang et al., 1999). The same specific band (~26 kDa for the glycosylated subunit) was also observed on western blots of crude protein extracts from petioles, roots and leaves (data not shown).

Antiserum specificity was further confirmed by indirect competitive ELISA experiments. These demonstrated that, among the pre-adsorbed competitors tested, only the dirigent protein inhibited antiserum binding of the pure recombinant dirigent (Fig. 5A). This clearly established the specificity of the antiserum for both recombinant and native dirigent forms, as compared to other *F. intermedia* proteins (e.g. pinoresinol/lariciresinol reductase and laccase). Furthermore, none of the plant cell-wall polymers tested (xylan, cellulose, and three types of pectins) or other related preparations (i.e. synthetic lignins) displayed any significant competitive inhibitory properties. Additionally, the total crude protein extract from *F. intermedia* stems functioned in an analogous manner (Fig. 5B). Therefore, the antiserum appeared to be very useful for the study of the localization of dirigent and/or dirigent sites in vascular (lignifying) tissues.

Using thick sections of paraffin embedded samples, immunolabeling of different *F. intermedia* anatomical tissues revealed intense specific signals with the dirigent immune protein serum (Fig. 6A, C, E, G, I, K and M), as compared to the pre-immune serum control of serial sections (Fig. 6B, D, F, H, J, L and N). Essentially, the 1st internode stem cross-sections displayed a strong dark signal in both the vascular cambium region and young developing xylem, together with labeling in the outer layers of the cortex (Fig. 6A). With stem maturation the signal became primarily restricted to the vascular cambium region (cambium and secondary phloem), and the lignified cells of the secondary xylem, sclerified pith parenchyma, and phloem fibers (Fig. 6C and E). Dirigent protein immune serum also gave a very intense signal in all tissues of young developing leaves and their central veins (Fig. 6G). Interestingly, fully mature leaves displayed the strongest immunolabeling response within the palisade parenchyma layers, and to a somewhat lesser extent in the paraveinal and spongy mesophyll (Fig. 6I). The labeling pattern observed in young differentiating petioles was also identical to those of the central vein extension (data not shown). In a similar manner, as observed during stem maturation, the signal observed in mature petioles was mainly restricted to the cambial layers and secondary phloem, as well as in the developing xylem (Fig. 6K). Roots displayed an uniform labeling pattern in the pericycle layers together with the vascular tissues of the stele at all maturation stages observed (see Fig. 6M for example).

These findings were generally consistent with observations made for dirigent protein gene expression in the cambial regions of stem, petiole and, to a lesser extent, root sections (Figs. 3 and 4). Moreover, during stem maturation, development of the patterns of both gene expression and protein accumulation also displayed

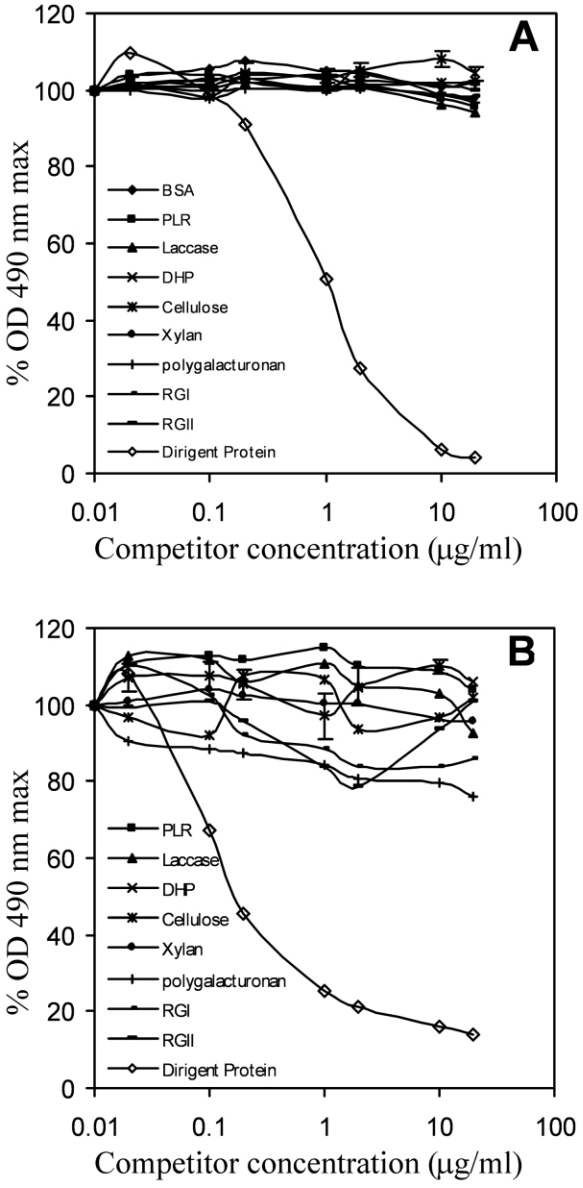

Fig. 5. Specificity of the *Forsythia intermedia* dirigent protein antiserum as revealed by indirect competitive ELISA. (A) Pure recombinant dirigent protein and (B) a crude extract of total protein from *F. intermedia* young stems were used as antigens to coat 96-well ELISA plates. Different competitors were pre-incubated with the antiserum at different concentrations as described in the Experimental. Abbreviations: BSA, bovine serum albumin; DHP, dehydrogenative polymer (synthetic lignin); PLR, pinoresinol/lariciresinol reductase; RGI, rhamnogalacturonan I; RGII, rhamnogalacturonan II. Note that, among the competitors tested, only the dirigent protein itself was able to significantly reduce the cross-reaction of the dirigent protein immune serum with the pure recombinant dirigent protein, as well as with a crude protein extract from *Forsythia* stems.

striking similarities, namely decrease of the signal in the outer cortex and restriction to the cambial region. It was interesting to note that immunolabeling experiments revealed the presence of a population of dirigent sites within the lignified tissues, which had not been detected at the gene expression level. Even though the secondary xylem has originated from cambial cells, the dirigent protein gene expression observed in these cells is unlikely to be the forerunners of dirigent sites detected in the developed secondary xylem. This is because it is highly unlikely that the dirigent proteins are incorporated into developing cell walls — particularly at the sites of lignin initiation; instead they are considered to be involved in lignan deposition within the cell itself. It is much more likely that the epitopes detected are from related proteins having [arrays of] lignin monomer binding sites (coniferyl alcohol derived), and which are involved in initiation of lignin biosynthesis proper. However, much remains to be done to characterize these sites, the mechanism of lignin monomer transport, the interactions between lignin monomers and the arrays of dirigent sites, as well as determination of the placement and catalytic functions of the various oxidases involved in lignin assembly(ies).

Immunolabeling experiments were next conducted on resin embedded sections in order to obtain better resolution. A strong signal was again detected in the lignified cell walls of secondary xylem cells, sclerified pith parenchyma, and phloem fibers but not in either the cambial region or young cortex tissues (data not shown) (Gang et al., 1999); this was true for all developmental stages and different tissues examined. A comparable observation had been made for glycine-rich proteins in both tobacco (*Nicotiana tabacum*) and petunia (*Petunia hybrida*) stems (Ye et al., 1991). That is, while the encoding gene was specifically expressed in the cambial region as determined by tissue printing hybridization, the corresponding protein was only observed in the cell walls of vascular tissues with resin embedded sections. The differences in detection and relative intensity between the two procedures (paraffin and resin sections, respectively), are thus attributed to one or more of the following *three* reasons: Firstly, the resin fixation method (i.e. using paraformaldehyde/glutaraldehyde) is employed *primarily* for ultrastructural preservation; however, this can be anticipated to result in a higher loss of antigenicity of dirigent protein epitopes in the cytoplasmic rich regions such as the cambial region and the young cortex tissues, i.e. as compared to those within fully lignified secondary cell walls where the cross-linking agent is not as readily accessible. This could result in either differences in relative solubility/extractability of the two populations of dirigent (epitope)s, and/or to differences in aldehyde resin accessibility in both regions. Secondly, since thick (8 μm) paraffin sections were deparaffinized prior to immunolabeling, this might result in an overestimation of the antigenicity of the more soluble dirigent protein epitopes in the cambial region relative to those dirigent sites less accessible in the immobilized lignified cell wall regions. Thirdly, with resin-embedded sections, a more representative surface reaction is anticipated, even with the

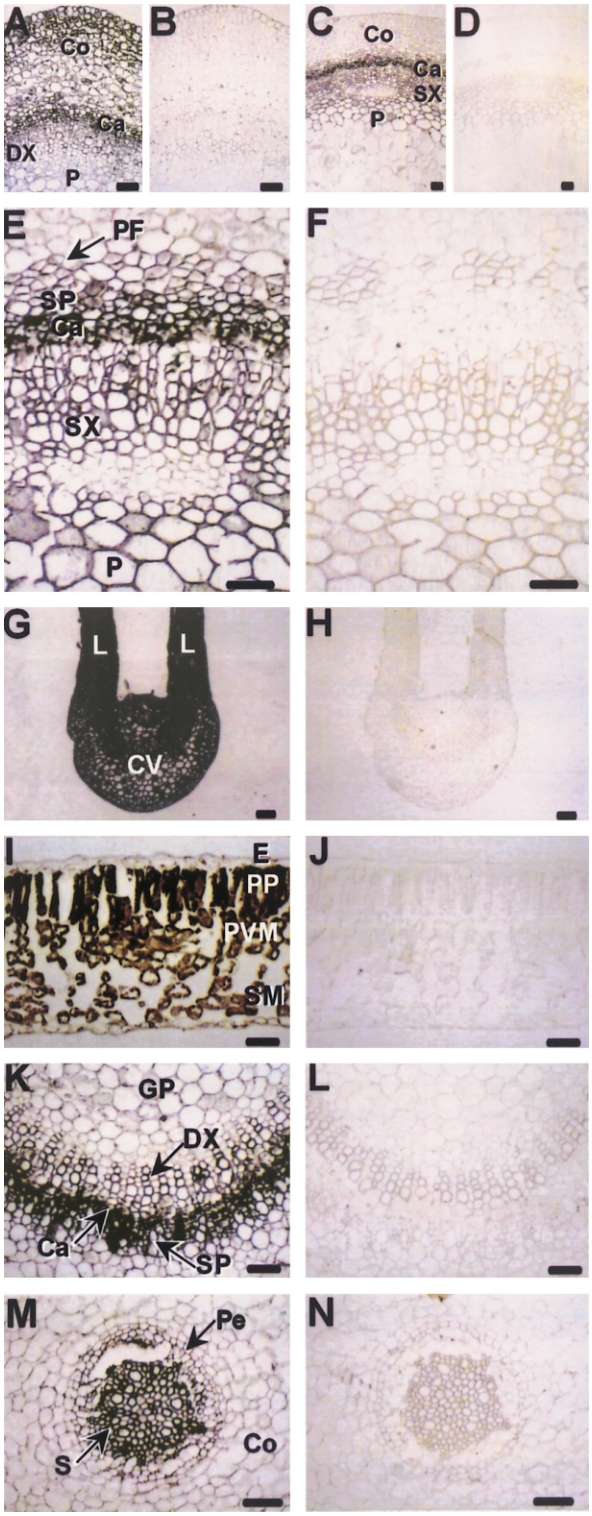

Fig. 6. Tissue-specific immunolocalization of dirigent protein and dirigent site epitopes on cross-sections of paraffin-embedded tissues of *Forsythia intermedia*. (A), (C), (E), (G), (I), (K), and (M) Dirigent protein immune serum and (B), (D), (F), (H), (J), (L), and (N) corresponding pre-immune serum negative control were applied to serial cross-sections of the following: differentiating 1st internode (A) and (B), more mature 10th internode (C)–(F), differentiating leaf with its central vein (G) and (H), mature leaf (I) and (J), mature petiole (K) and (L) and root (M) and (N). The localization of the major dirigent protein epitopes (dark black signal) was in the same tissues where the dirigent protein gene was expressed, i.e. vascular cambium and secondary phloem of the stem and petiole, as well as in the cortex of young differentiating stem and root pericycle. Additional strong specific signals were also observed in the lignified regions of stem, petiole and root tissues, whereas the strong dark signal in the differentiating leaves became mainly restricted to the palisade parenchyma layers at maturation. Ca, vascular cambium region; Co, cortex; CV, central vein; DX, developing xylem; E, epidermis; L, leaf; P, pith; Pe, pericycle; PP, palisade parenchyma; PF, phloem fibers; PVM, paraveinal mesophyll; S, stele; SM, spongy mesophyll; SP, secondary phloem; SX, secondary xylem; X, xylem. Bars: 50 μm.

different levels of epitope conservation and accessibility in various tissues. Furthermore, even when other fixation protocols, such as with cryofixation (Fisher and Housley, 1972) and microwave-curing (Turner et al., 1999), were evaluated for resin embedding using different mixtures of aldehydes, the same labeling pattern restricted to the lignified cell walls, albeit with poorer ultrastructural preservation, was obtained (data not shown).

Thus, there are two main regions of dirigent proteins (or dirigent sites), namely in the cambial region for lignan formation and in the lignified elements of mature stem, petiole and root tissues for lignification, respectively. Interestingly, downstream lignan metabolic processes involving expression of the genes encoding pinoresinol-lariciresinol reductases are also localized in the cambial regions as well (Kwon et al., 2001), as evidenced by in situ hybridization. This again demonstrates that this region can no longer be viewed as the exclusive domain of lignin biosynthesis. Mature leaves also gave a very tissue specific localization of dirigent protein (site)s, with a stronger signal in the palisade parenchyma layers (lignans), relative to that of the lignified bundle sheath and the spongy mesophyll cells.

High-resolution transmission electron microscopy was next employed to estimate the sub-cellular locations of dirigent sites within different *types* of lignified cell walls of stems. In this way, distinct, but specific, patterns of labeling (see Fig. 7) were clearly observed with the various cell types present in *F. intermedia* serial sections. In all cases, in order to provide a comparative analysis of a particular anatomical region, experiments were conducted with both immune and pre-immune (control) sera; these controls gave, as expected, no labeling (Gang et al., 1999).

An examination of the immunolabeling patterns in fully developed vessels (Fig. 7A) and in developing ray cells (Fig. 7B) was first undertaken. This revealed that immunolabeling was predominantly in the S_1 sub-layer and the compound middle lamella, as well as, to a lesser extent, in the S_3 sub-layer — with the latter only being detected when the S_3 layer was completed. No significant degree of labeling was noted in either the S_2 sub-layer or the cell corners. These immunolabeled regions are consistent with the placement of lignin initiation sites.

The patterns of dirigent sites were also examined in lignified phloem at two stages of fiber cell development, namely at an early stage of development (Fig. 7C) and when more fully mature (Fig. 7D). As can be seen, the labeling of the phloem fiber cells was again essentially only associated with the S_1 sub-layer, as previously noted for vessels (Fig. 7A), possessing layered cell walls. Thus, in summary, the patterns of labeling in the ray cells, vessels and fibers were essentially the same, despite the ray cells having much thinner cell walls.

It was next of interest to establish whether immunolabeling patterns were similar in both secondary xylem and primary xylem (in this case, metaxylem), with the latter lacking any distinctive secondary cell wall layering, i.e. the metaxylem has an uniform cell wall thickening (Fig. 8A), in contrast, for example, to the layered vessels of the secondary xylem (Fig. 8C).

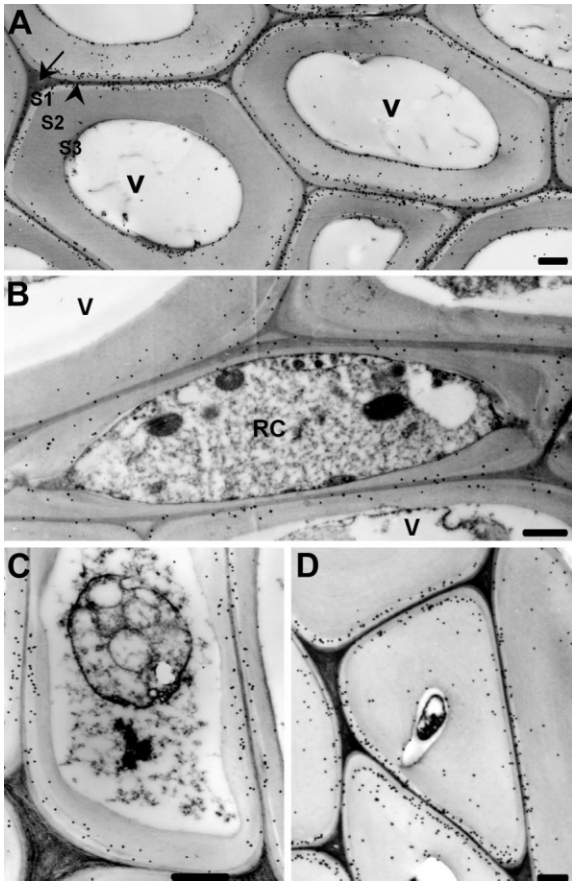

Fig. 7. Sub-cellular immunolocalization of dirigent protein epitopes (or dirigent sites) in various cell types present in *Forsythia intermedi*a young stem cross-sections using transmission electron microscopy. Representative immunolabeling of the S_1 sub-layer and compound middle lamella, and to a lesser extent of the S_3 sub-layer, observed in fully developed vessels (A), ray cells (B) as well as in young (C) and mature (D) phloem fibers. Arrow, cell corner; arrowhead, compound middle lamella (middle lamella with very thin primary walls on each side); RC, ray cell; S_1; S_2; S_3, successive sub-layers of secondary walls with numerical labeling of each moving inward from the outer to the inner part; SW, secondary wall; V, vessel. Bars: 1 μm.

In Fig. 8A and C, the patterns of both secondary cell wall layering and lignin distribution in the different cell types were revealed using the $KMnO_4$ lignin staining technique (Donaldson, 1994); as noted, the *secondary* cell walls of both metaxylem (Fig. 8A) and vessels (Fig. 8C) were stained uniformly, indicative of the presence of lignins throughout both wall types. Next, the patterning of dirigent sites was investigated and found to differ markedly: these were now uniformly distributed throughout the metaxylem secondary wall (Fig. 8B), in sharp contrast to that of lignified vessels (Fig. 7A) where they predominated in the S_1 sublayer. This is most

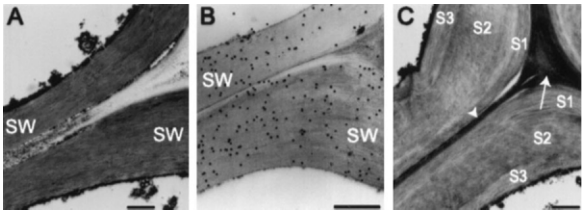

Fig. 8. $KMnO_4$ histochemical lignin staining of single-layered secondary wall metaxylem vessels (A) and dirigent site immunolocalization (B). For comparison, $KMnO_4$ lignin staining of triple-layered (S_1, S_2, S_3) secondary wall vessels is shown (C). For legend see Fig. 7.

interesting since it suggests a different pattern of arrays of dirigent site distribution during lignin macromolecular assembly in cell walls lacking distinct layers.

Overall, the main pattern of sub-cellular localization of dirigent sites was associated with the S_1 sub-layer and compound middle lamella of lignified secondary xylem cells, and to a lesser extent inside the corresponding S_3 sublayers, whereas in the primary (meta)xylem tissue it was uniformly distributed throughout the entire wall. It must again be emphasized, however, that none of the other cell wall polymers examined cross-reacted in any detectable manner with dirigent immune serum, e.g. xylan (4-*O*-methyl-D-glucurono-D-xylan). The latter polymer was of particular interest for two reasons: it contained sugar residues common to the glycosylated portion of the dirigent protein (data not shown), and these xylans are known to be present in the S_1 sub-layer of xylem cells of dicotyledonous woody plants, such as *Betula verrucosa* (Meier, 1964).

Taken together, these data provided compelling evidence that dirigent mediated lignan biosynthesis occurs within all of the cell and tissue types previously associated with lignification. However, given that control over one form of monolignol coupling was occurring to afford the lignans, this raised the central question of whether an analogous level of control was being exercised over lignification in the same tissues.

In this regard, it should be recognized that the first stage of plant wall development is that of expansion, which, in essence, establishes the nature of the cell (vessel, tracheid, ray cells, etc.) and its overall dimensions; during this phase, the primary wall has been laid down. The plasma membrane then gradually contracts inwards, sculpturing in its wake the various layers (S_1, S_2, S_3, etc.) of the secondary xylem cell wall. During this developmental phase, the carbohydrates (celluloses, hemicelluloses) are deposited in a defined temporal and spatial manner, as well as that of various proteins and oxidative enzymes (e.g. those containing the proteins proposed as harboring arrays of dirigent sites, glycine and proline-rich proteins, peroxidases and laccases). That is, such proteins and enzymes are *strategically* incorporated into specific regions of the growing cell wall in a manner whereby the cytoplasm can maintain control over subsequent cell wall developmental events.

In this way, the living part of the cell establishes not only the overall architecture of the developing wall, but it can also subsequently target the monolignol-derived radicals to (specific) dirigent binding sites where lignification is initiated. The evidence for such a viewpoint now seems to be quite compelling: secondary xylem cell wall lignification indeed begins at lignin initiation sites in regions farthest from the plasma membrane, such as in the S_1 sublayer and the compound middle lamella (Wardrop and Bland, 1959; Donaldson, 1994). That the presumed arrays of dirigent (coniferyl alcohol derived monomer binding) sites are immuno-detected in those very regions (Fig. 7A–D) provides a facile explanation as to why lignification is indeed initiated at these key sites. If such a control mechanism were *not* in place, the monomers would then presumably undergo oxidation and coupling following immediate passage through the plasma membrane, and lignification might inevitably be restricted to regions directly adjacent to the plasma membrane and not throughout the wall. Furthermore, following the initiation of lignin biosynthesis at these initiation sites far removed from the plasma membrane, the lignifying regions begin to expand gradually inward until the entire wall is reinforced, and the cell then dies (Donaldson, 1994). Sarkanen (Guan et al., 1997; Sarkanen, 1998) has proposed that this expansion phase of lignification occurs through an iterative process of lignin assembly (following primary chain formation) in a template guided manner. Overall, this process is presumed to favor the observed 8-*O*-4′-linked regiospecificity observed in native lignins.

These results, however, only serve to illustrate how much we still have to learn about lignification: for example, how are the monolignol-derived monomers differentially translocated from the plasma membrane to specific cell wall regions? How are the proposed arrays of dirigent sites oriented in such a way as to promote regiospecific linkage formation of the incoming monomers? Or are they just involved in initial binding and more than one protein is involved in dictating lignin assembly? What are the precise roles of each of the various oxidative enzymes in the cell wall, and what are their precise subcellular localizations and in which cell types? Why are the lignin chains [apparently] formed in mirror image form? Why is it that within primary xylem (e.g. metaxylem cells), which lack any distinctive cell wall layering (Fig. 8A), the proposed arrays of dirigent protein epitopes appear to be uniformly distributed throughout the wall (Fig. 8B)? Each of these aspects require full explanation, and these must be the subject of future investigation. It must be emphasized, however, that we are in the infancy of understanding how cell wall macromolecular assemblies are controlled, not just lignification. It is likely that cell wall ''organelles'' utilize tens — if not hundreds — of different proteins to ensure biopolymer orientation, ''self-assembly'' and control of lignification. Certainly, the

recent advances in genomics and proteomics and the vast number of presumed cell wall proteins of unknown function so identified underscore how little we yet understand about cell wall biosynthesis and its control.

3. Experimental

3.1. Plant materials

Forsythia intermedia plants, grown in Washington State University greenhouse facilities, were harvested in Spring 1998 and 1999.

3.2. Tissue preparation for light microscopy (LM) and histochemical detection of lignin

F. intermedia stems, petioles, leaves and roots were fixed in FAA solution (10% formalin, 5% glacial acetic acid, 50% ethanol, v/v) at 4°C overnight. Tissues were processed under vacuum using an histomatic tissue processor 166A (Fisher Scientific) as follows: sequential dehydration at room temperature in 70, 80, 95 and 100% (3 times) ethanol (20 min each). Tissues were infiltrated and embedded in paraffin at room temperature using hemo-De (Fisher Scientific) (Ruzin, 1999). Thick sections (~8 μm), obtained using a rotary microtome (Jung Biocut, Leica), were subsequently mounted on silane (3-aminopropylsilane) coated microscopic slides. Paraffin was solubilized by immersion of the slides in hemo-De for 10 min, and then 100% ethanol. Sections were re-hydrated (5 min each) in 90 and 70% (v/v) ethanol and finally H_2O (twice), and allowed to dry. For morphological observations and lignin histochemistry, the sections were stained with toluidine blue (0.05% aqueous solution) and phloroglucinol-HCl (Johansen, 1940), respectively.

3.3. Autofluorescence of phenolics

Hand-cut cross-sections of fresh *F. intermedia* tissues were mounted in water and directly observed using a Leitz Aristoplan photomicroscope operated in an epifluore scence mode (Franceschi et al., 1998). UV light (340–380 nm) was used as the excitation wavelength with a long bandpass filter (440 nm and above) being employed for visualization of the light blue induced fluorescence. Images were captured on Kodak Gold 100 film.

3.4. Tissue print hybridization

Tissue print mRNA hybridization was performed with fresh *F. intermedia* stems, roots and petioles, using the protocol of Ye et al. (1991) which was modified as follows. Freshly cut cross-sections of tissues of interest were pressed onto nylon membranes (Genescreen, NEN Research Products, Boston), air dried, and UV cross-linked. pBluescript plasmids, containing the psd-Fi1 cDNA insert (Gang et al., 1999), were linearized by either *Bam* HI or *Xho* I and ^{35}S-thio-UTP was incorporated using T7 or T3 RNA polymerase in order to obtain the antisense and sense probes, respectively. Membranes were prehybridized at 68°C for 4 h in 1.5×SSPE, 1% SDS, 1% BSA, 100 mM DTT and then hybridized at 68°C for 16 h in the same solution containing ^{15}S-thio-UTP labeled probe. Membranes were washed successively in 4×SSPE, 2×SSPE and 1×SSPE, for 30 min each, at room temperature and finally in 0.1×SSPE, for 1 h at 68°. For image evaluation, membranes were exposed for 5 days at room temperature to Kodak scientific imaging film. Additionally, the corresponding tissue prints showing anatomical features were obtained by pressing the surface of freshly cut cross-sections onto sobo glue (polyvinyl acetate) coated microscopic slides. Physical prints and membranes were photographed using Kodak Technical Pan film with a stereomicroscope (Wild Heerbrugg) and then scanned (ScanMaker III, Microtek).

3.5. In situ hybridization

Stem tissues were harvested at various stages of development and fixed in paraffin as above. Deparaffinized and rehydrated tissue sections were treated with proteinase K (2 μg/ml) (Boehringer Mannheim). Digoxigenin-labeled antisense and sense riboprobes were synthesized as above but with digoxigenin-11-dUTP (Boehringer Mannheim) instead of ^{35}S-thio-UTP. RNA transcripts were fragmented into 150 bp by alkaline hydrolysis prior to hybridization (Duck, 1994). Slides were prehybridized for 2 h at room temperature in 50% formamide, 30 mM NaCl, 10 mM Tris–HCl (pH 7.5), 1 mM EDTA, 1×Denhardt's solution, 10% dextran sulfate, 100 mM DTT, 500 μg/ml denatured salmon sperm DNA (Sigma) and 150 μg/ml yeast tRNA (Sigma). Tissue sections were hybridized in the same solution containing 0.05 μg/ml digoxigenin-labeled probe for 16 h at 38°C, then washed at room temperature in 2×SSC, 1×SSC, 0.5× SSC, for 30 min each, and finally at 38°C, in 0.1×SSC, for 1 h. Hybridization of riboprobes was detected with anti-digoxigenin antibodies conjugated to alkaline phosphatase (Boehringer Mannheim) and visualized by color development according to the manufacturer's instructions.

3.6. Antigen and immunization

Dirigent protein, heterologously expressed in a *Spodoptera frugiperda*/*Autographa californica* system (Gang et al., 1999) and purified to apparent homogeneity (Davin et al., 1997; Gang et al., 1999), was used for immunization of two male New Zealand rabbits in facilities of the Laboratory Animal Resource Center at Washington State University. Immunization used the

subcutaneous implanted-ball (whiffle ball) technique which permits introduction of microgram quantities of immunizing antigen without adjuvant, and subsequent removal of large amounts of antibody-containing fluid from the implanted-ball (Hillam et al., 1974; Ried et al., 1992). Initially, a 45 μg-injection of dirigent protein was followed by two 22 μg-booster injections after 5 and 7 weeks, respectively. Prior to each injection, serum (10–20 ml) was withdrawn from the whiffle ball, this being centrifuged for 30 min at 1000 *g* at 4°C, and stored in aliquots (0.5 ml) at −20°C until needed. The titer of the resulting polyclonal antibodies was monitored using the indirect ELISA technique as described below.

3.7. Indirect ELISA

Unless otherwise stated, all steps were performed at room temperature. Each well of Immulon 2 ELISA plates (Dynatech Laboratories, Inc., Chantilly, VA) was coated with recombinant dirigent (100 μl, 1 μg/ml in 0.05 M carbonate buffer, pH 9.6) for 16 h at 4°C. After washing 3 times with PBS-Tween 20 [150 μl, 0.1 M phosphate buffer (pH 7.4), 150 mM NaCl, containing 0.05% (wt/v) Tween 20] for 2 min each, the wells were blocked for 1 h with 0.5% (wt/v) gelatin (fish skin gelatin, Sigma) in PBS-Tween 20. Then, 100 μl of a two-fold serial dilution (from 1:100 to 1:102,400) of the sera (whether pre-immune or immune-sera, for each rabbit), in the same blocking buffer was added and further incubated for 2 h. After washing with PBS-Tween 20 (4×150 μl) for 2 min, the secondary antibody (goat anti-rabbit-horse radish peroxidase; Pierce, Rockford, IL), diluted 1:10,000 in PBS-Tween 20 containing 0.25% (wt/v) gelatin, was added and incubated for 2 h. The wells were then washed 3 times as before, and incubated with 100 μl of chromogenic substrate (*O*-phenylenediamine dihydrochloride, Sigma) as directed by the manufacturer. The reaction was terminated by addition of H_2SO_4 (50 μl, 10% aqueous solution), with the absorbance (A_{490}) measured using an ELISA plate reader (Spectra Max 250, Molecular Devices). Serum giving the best titer, expressed as the dilution giving A_{490} max/2, together with the corresponding rabbit pre-immune serum, were used as outlined below.

3.8. Crude protein extraction

Crude protein extracts from *F. intermedia* stems were obtained using the TRI Reagent™ Kit (Molecular Research Center, Cincinnati, OH) (Chomczynski, 1993), according to the manufacturer's instructions.

3.9. Indirect competitive ELISA

Purified recombinant dirigent protein and crude total protein extracts from *F. intermedia* stems were coated in the wells as described above. The same protocol, previously employed for indirect ELISA experiments, was also used, except that the dirigent immune-serum (50 μl, diluted 1:250 in the blocking buffer) was first mixed with solutions of potential competitors in blocking buffer (50 μl) at different concentrations. That is, each potential competitor was diluted to eight different concentrations (0.01 to 20 μg/ml) in blocking buffer (1:500 final dilution of the antiserum) for testing, with each sample individually incubated under mild agitation for 16 h at 4°C before being applied to the coated wells. Bovine serum albumin (Sigma), recombinant *F. intermedia* pinoresinol-lariciresinol reductase (PLR) (Dinkova-Kostova et al., 1996), purified native *F. intermedia* laccase, guaiacyl-dehydrogenative polymeric (DHP) synthetic lignin obtained using the Zutropf method (G-DHPzt) (Lewis et al., 1987), cellulose powder (Whatman, Fairfield, NJ), 4-*O*-methyl-D-glucurono-D-xylan (Sigma), polygalacturonic acid methyl ester (Sigma), rhamnogalacturonan I (gift from Dr. M. Vignon, CERMAV, CNRS, France), rhamnogalacturonan II (gift from Pr. J.P. Joseleau, CERMAV, CNRS, France), and purified recombinant dirigent protein from *F. intermedia*, were used as potential competitors. In the case of the DHP, five different samples were solubilized in DMSO (10 μg/μl stock solutions) before further use in the same buffer as the other competitors. This resulted in a 2% (v/v) maximum concentration of DMSO in the pre-adsorbed antibody solutions, with no effect on the antibody-antigen interaction being observed (data not shown). The average of these five DHP samples ± standard deviation is displayed in Fig. 5A and B. Optical density values were corrected by subtracting the very low pre-immune serum background, and results were expressed as percentages of the maximal reaction (immune-serum pre-incubated with buffer only).

3.10. Preparation of resin embedded samples for light microscopy (LM) and transmission electron microscopy (TEM)

Several protocols (i.e. cryofixation (Fisher and Housley, 1972), microwave fixation (Turner et al., 1999) and different fixative mixtures) were evaluated in order to optimize both antigenicity conservation and ultrastructural preservation; conditions adapted from Klauer et al. (1991) were finally utilized. Freshly cut samples were dissected into small pieces in fresh fixative solution (1.25% glutaraldehyde/2% paraformaldehyde in 50 mM Pipes buffer, pH 7.2), these being placed under gentle vacuum (1 atm, few seconds), then fixed for 2 h at room temperature in this solution under mild agitation. Samples were individually rinsed in 50 mM Pipes (3×20 min) at room temperature, and dehydrated (30, 50, 70, 95 and 100% ethanol; 20 min each). Subsequent infiltration used a mixture of L. R. White acrylic

resin (hard mixture, Ted Pella, Inc.) and 100% ethanol (3:1, v/v) for 20 min, with subsequent pure L. R. White resin changes (4–5) within one week at 4°C. Sample embedding in L. R. White resin was performed in 0.2 ml gelatin capsules with a 24 h polymerization at 50°C.

3.11. Immunolabeling for light microscopy (LM)

Semi-thin sections (800 nm) were obtained using an ultramicrotome (Reichert) with glass knives. Floating sections were collected using plastic rings as previously described (Burlat et al., 1997). Immunolabeling was attained by floating the plastic rings, containing the semi-thin sections, on 50 μl drops of either the different incubation or washing solutions. These solutions were distributed in plastic molds (Pelco) and placed in a moist chamber to prevent evaporation. For dirigent protein immune serum the labeling steps were as for Klauer et al. (1991), with the following modifications. Experiments were carried out at room temperature, except for the washing steps following primary antibody incubation, which were conducted at 37°C for background reduction. Quenching of residual aldehydic functionalities was carried out by incubation with 0.15 M glycine in TBS_{500} (0.01 M Tris–HCl, 500 mM NaCl, pH 7.6) for 30 min, with resulting sections washed with TBS_{500} (4×5 min) and blocked for 1 h with 1% (wt/v) BSA in TBS_{500} (TBS-BSA). Sections were incubated for 3 h with dirigent protein immune serum diluted 1:50 to 1:100 in TBS-BSA, then washed at 37°C with TBS-BSA (6×5 and 2×15 min) and incubated for 3 h with the secondary antibody (Goat anti-rabbit-1nm gold particle, Auro Probe One; Amersham-Pharmacia Biotech Inc.) diluted 1:50 in TBS-BSA containing 0.1% gelatin (Amersham-Pharmacia Biotech Inc.). Sections were sequentially washed with TBS-BSA (3×10 min), TBS_{500} (3×10 min) and H_2O (3×5 min), then post-fixed with 2.5% (v/v) glutaraldehyde for 5 min and rinsed with H_2O (3×2 min). Silver enhancement was carried out for 15 min at 20°C with intenSE M (Amersham-Pharmacia Biotech Inc.), in accordance with the manufacturer's instructions. Sections were finally deposited onto gelatin-coated slides and dried before counter-staining for 30 s with 0.5% (wt/v) *O*-Safranin with mounting under a cover slip in immersion oil.

The same protocol was used for immunolabeling of paraffin sections (prepared as described above for in situ hybridization) except that they were immobilized on gelatin coated slides covered with 1 ml of the different incubating and washing solutions containing 0.3% (wt/v) Tween 20 under gentle shaking (30–50 rpm). Sections were analyzed without counterstaining under a Olympus BH2 microscope equipped with a Pulnix TM-7 CN color CDD camera.

3.12. Immunolabeling for transmission electron microscopy (TEM)

The same protocol as for LM was used, with the following modifications. Ultrathin sections (100 nm), precisely obtained using an ultramicrotome (Reichert) and a diamond knife (Delaware Diamond Knifes, Wilmington, DE), were positioned on uncoated 300 mesh nickel grids so that both sides of the ultrathin section were accessible to the incubation and washing solutions. Labeling was attained by immersing grids in 50 μl drops of the different solutions contained in plastic molds as before and gently agitating them by means of a magnetic stirrer. The resulting steps employed were as for the LM protocol, except that 0.3% (wt/v) Tween 20 was added to the TBS and TBS-BSA buffers. Pre-immune or immune sera were diluted from 1:10 to 1:25; the grids were incubated for 1 h with secondary marker (protein A conjugated to 10 nm gold particles; Amersham-Pharmacia Biotech Inc.), with silver enhancement performed for a 3–5 min duration as above. Post-staining employed 2% (wt/v) uranyl acetate, and grids were observed at 80 kV using a Jeol 1200 EX transmission electron microscope.

3.13. Immunolabeling controls

Pre-immune sera were employed under the same conditions and dilutions as for immune sera. Negative controls, with omission of immune serum, and pre-adsorption of the antiserum by the antigen (competitive inhibition) were also performed. As an additional control, it is emphasized that the pattern of immunolocalization of dirigent protein epitopes was exactly the same when polyvinyl pyrolidone (PVP) was used during the labeling protocol, this being carried out to quench the different phenolic sites (Franceschi et al., 1998).

Acknowledgements

The authors thank Professor Vincent R. Franceschi (Director of the Electron Microscopy Center, Washington State University) for use of the facilities, helpful technical assistance and critical reading of the paper. Thanks are extended to Christine M. Davitt and Valerie J. Lynch-Holm (EM Center, Washington State University), as well as to Jean-Paul Joseleau and Michel Vignon (CERMAV, CNRS, Grenoble, France) for the gift of RGII and RGI samples, respectively. We gratefully acknowledge the United States Department of Energy (DE-FG03-97ER20259), the National Science Foundation (MCB-9976684), the National Aeronautics and Space Administration (NAG 21198), the United States Department of Agriculture (99-35103-8037), McIntire-Stennis, the Arthur M. and Kate Eisig Tode Foundation and

the Lewis B. and Dorothy Cullman and G. Thomas Hargrove Center for Land Plant Adaptation Studies for generous support of this and related studies.

In situ hybridization and immunolocalization of lignan reductases in woody tissues: implications for heartwood formation and other forms of vascular tissue preservation

Mi Kwon, Laurence B. Davin, Norman G. Lewis*

Institute of Biological Chemistry, Washington State University, Pullman, WA, 99164-6340, USA

Received 6 October 2000; received in revised form 29 November 2000

Abstract

Vascular plants have evolved with remarkable ways to form and protect the vasculature apparatus. In certain woody shrubs, the secondary xylem can have within its center a hollowed pith surrounded by secondary xylem, whereas in most trees there is a solid core of heartwood. Both types of woody systems have, however, the commonality of accumulating so-called 'secondary' metabolites, albeit to different extents, whose roles are to protect and preserve the vascular (lignified) tissues. This investigation had as its purpose establishing the nature of the cells involved in the biosynthesis of these specialized 'secondary' metabolites in plants forming heartwood and hollow piths, respectively. This was achieved by determining the tissue-specific expression of two lignan biosynthetic pathway enzymes: pinoresinol-lariciresinol reductase (PLR) and phenylcoumaran benzylic ether reductase (PCBER), soluble enzymes which catalyze analogous benzylic ether reductions of 8–8′ and 8–5′ linked lignans, respectively. Using *Forsythia intermedia*, reverse transcription-PCR (RT–PCR) and northern blots revealed that PLR mRNA accumulated mainly in young stems, as well as in young roots and petioles. Furthermore, PLR-specific DIG-labeled riboprobes established that in the stems its mRNA accumulated in the radial parenchyma cells [and to a lesser extent in the developing vessels], as well as in the cambial cells of developing secondary xylem. In addition, immunocytochemical localization of PCBER in *Pinus taeda* established that it was in the axial and radial parenchyma cells of secondary xylem of stems. That is, irrespective of whether the woody plants formed hollowed piths or heartwood, the 'secondary' metabolite pathways leading to the protective lignans predominantly involved axial and radial parenchyma cells. This is in contrast to monolignol coupling (i.e. the entry point to both the lignans and lignins), which appears to be more restricted to the vascular cambial regions. © 2001 Elsevier Science Ltd. 1. Introduction

Vascular woody plants represent some of the most successful life forms to have evolved, in terms of longevity and durability through self-protective (preservation) mechanisms, as well as in relative orders of magnitude (size). Certain conifers, for example, such as California redwood (*Sequoia sempervirens*), western red cedar (*Thuja plicata*) and bristlecone pine (*Pinus longaeva*) can have life spans of 2000–5000 years (Lewis and Davin, 1999). Indeed, in general, the longevity, durability and relatively large sizes of woody plants are very much a consequence of an extraordinary ability to form highly specialized (vascularized) secondary bodies, such as lignified stems and bark (cork layers). However, the precise form of vascularization conferred can differ substantially, and the pattern of metabolites deposited is quite species-specific. Differences in vascularization can include both the type and amounts of bark and heartwood formed, and in their relative chemical compositions. Some species do not, for example, form heartwood but instead have discontinuous (pigmented) secondary xylem tissues, and others have hollow piths within the vascular apparatus. While these variations are all presumably consequences of differences in evolutionary adaptation, the biochemical processes associated with such developments are only now beginning to yield to enquiry (Magel et al., 1997; Gang et al., 1998;

PII: S0031-9422(01)00108-X

Hauch and Magel, 1998; Fujita et al., 1999; Burlat et al., 2001).

Another fascinating aspect of overall woody plant growth and development is that such plants apparently must continually replace their water and nutrient conducting elements. That is, the original elements designated for this purpose are gradually converted into non-conducting tissues, such as in the heartwood of secondary xylem. In this way, plants have evolved systems which permit growth to enormous heights, and for the management of massive weights including the accompanying associated stresses and strains so encountered. Accordingly, it can be considered that this continual replacement of water/nutrient conducting cells has evolved as a fail-safe mechanism, i.e. before the individual cells designated for this purpose became unable to fulfill their functions due to deterioration through aging.

Concomitant with the continual displacement/renewal of conducting cells is the often massive accumulation of distinctive 'secondary' metabolites, whose deposition helps impart desirable properties to specific woody tissues. Examples of this include the black colored phlobaphene metabolites in the highly valued ebony (*Diospyros ebenum* Koenig) (Hillis and Soenardi, 1994) and the orange-red lignan-derived substances in highly durable western red cedar (Swan et al., 1969) heartwoods. Furthermore, the longevity of such plant species may also be positively impacted by the deposition of these complex 'secondary metabolite' mixtures, since they frequently contain bioactive plant products and thus help protect against opportunistic pathogens and other encroachers. Interestingly, the precise composition of such secondary constituents is often species specific, and hence their individual metabolic profiles frequently provide characteristic chemical 'fingerprints' for a particular species. For example, western red cedar heartwood contains nearly 20% of its weight as highly colored, but distinctive lignans, derived from plicatic acid (Swan et al., 1969), whereas in Douglas fir (*Pseudotsuga menziesii*) characteristic flavonoids and other lignans, such as α-conidendrin, accumulate (Hemingway and Hillis, 1970). Another example is in the heartwood of *Eucalyptus sideroxylon*, which contains, amongst other metabolites, a variety of stilbenes (Hart and Hillis, 1974) important in resisting fungal decay (Scheffer and Cowling, 1966).

In spite of their enormous importance, the accompanying biochemical and molecular processes involved in vascularization leading to, for example, heartwood and secondary phloem formation, are essentially unknown (Gang et al., 1998). In the case of heartwood, Chattaway had proposed that its formation is largely a consequence of accumulation of heartwood-forming metabolites (or the corresponding precursors) in the ray parenchyma cells, these being exuded into adjacent tracheary elements during heartwood maturation (Chattaway, 1952). Recently, using western red cedar, the first specific genes and enzymes involved in the biochemical pathways leading to its heartwood metabolites were reported (Gang et al., 1998; Fujita et al., 1999), although no specific cell types were identified at that point. Other studies, using black locust (*Robinia pseudoacacia*), have suggested a complex range of biochemical processes as being operative during heartwood formation, these occurring between the cambial cells and the so-called heartwood-sapwood transition zone (Hauch and Magel, 1998). In that study, various conversions of carbohydrates into heartwood flavonoids were reported to occur between the cambium cells and the heartwood-sapwood transition zone, although no specific cell types were implicated.

Not all woody plant species, however, produce heartwood such as with western red cedar and black locust. For example, the sapwood of several species including alder (*Alnus glutinosa*), British sycamore (*Acer pseudoplatanus*), quaking aspen (*Populus tremuloides*) and Norway maple (*Acer platanoides*) has a different mechanism involved in the further maturation of its secondary xylem (Magel et al., 1997). That is, under 'normal' growing conditions, these species still contain living parenchyma cells at the pith of the stem even after considerable trunk cambial expansion/growth (Bosshard, 1966; Magel et al., 1997). It is believed that in such species changes characteristic of heartwood formation are considerably delayed or are absent (Bosshard, 1966). Yet when, for example, species such as European ash (*Fraxinus excelsior*), European beech (*Fagus sylvatica*), and quaking aspen are injured by pathogen attack, they can also form discolored wood (Sucoff et al., 1967) similar in appearance to normal heartwood, albeit discontinuous in its occurrence in secondary xylem (Farkas and Király, 1962; Shigo and Hillis, 1973). This irregular discolored wood is formed by deposition of phenols and other substances (Gagnon, 1967), these appearing as inclusions in parenchyma cells; however, interestingly, the cell walls of fibers and vessels apparently typically remain unpigmented in such cases (Bosshard, 1968).

Other species, such as *Forsythia*, have evolved additional means for preservation/protection of their vascular apparatus. Rather than forming heartwood tissue, the parenchyma cells within the pith collapse as the stem matures (ages) to give a hollow pith (Kwon et al., 1999). However, the lignified secondary xylem in *Forsythia* contains significant levels of lignan-derived metabolites which provide both color and protection to the mature secondary xylem tissues. Thus, these three different examples [i.e. (a) heartwood-forming conifers, (b) formation of discontinuous pigmented wood upon injury in poplar and related species, and (c) others, such as *Forsythia*, having a hollow pith] illustrate some of the different forms of successful vascularization that have evolved in woody plants. Significantly, however, each type of woody tissue is linked through a common process

of enhanced protection and preservation via deposition of complex 'secondary' metabolic products.

The purpose of this particular study was thus to begin to define the cellular processes involved during both the formation and deposition of these important protective 'secondary' metabolites. Lignan biosynthesis was selected for this study using *F. intermedia* and *P. taeda*. Both species are intimately involved in 'secondary' metabolite deposition processes and they form a hollow pith and heartwood, respectively. The approaches utilized in this investigation involved both in situ hybridization and immunolocalization, these being carried out in order to define the specific cells and tissues involved.

In this regard, the lignans, primarily derived from the monolignols, *E*-coniferyl, *E*-sinapyl and *E*-*p*-coumaryl alcohols, are typically dimeric substances — although higher oligomers exist as well (Lewis and Davin, 1999). While mainly present in heartwood and bark tissues, lignans can also accumulate in other organs and tissues including sapwood, leaves, fruits, seeds and roots; (MacRae and Tower, 1984; Ayres and Loike, 1990; San Feliciano et al., 1992). Lignans have broad roles in defense based on their profound biological activities which include antioxidant (Osawa et al., 1985; Fauré et al., 1990), antifungal (Belmares et al., 1979), antibacterial (Hattori et al., 1986), antiviral (Gnabre et al., 1996), insect antifeedant (Harmatha and Nawrot, 1984), phytotoxic (Elakovich and Stevens, 1985) and cytotoxic properties (Binns et al., 1987).

F. intermedia was chosen for study since its lignan biosynthetic pathway has been fully delineated from *E*-coniferyl alcohol (**1**) to the 8–8′ linked lignan, (−)-matairesinol (**2**) (Fig. 1) (Umezawa et al., 1991; Chu et al., 1993; Dinkova-Kostova et al., 1996; Davin et al., 1997) and the genes for each transformation are now available (Dinkova-Kostova et al., 1996; Gang et al., 1999a; Xia et al., 2001). Significantly, (−)-matairesinol (**2**) is a precursor of heartwood lignans, such as plicatic acid (**3**) and α-conidendrin (**4**), in *T. plicata* and *T. heterophylla*, respectively (Lewis and Davin, 1999), and some of the genes involved in the biochemical pathway to matairesinol (**2**) have been characterized in both species (Gang et al., 1998; Gang et al., 1999a). Moreover, even though *F. intermedia* itself does not form heartwood, it was, nevertheless, considered to be able to provide meaningful information regarding sites (cells and tissues) involved in 8–8′-linked lignan biosynthesis, and thus important insight into the processes likely involved during heartwood formation in *T. plicata* and *T. heterophylla*. The first objective therefore addresses defining the tissue specific expression of the (+)-pinoresinol/(+)-lariciresinol reductase gene in *F. intermedia*; this enzyme catalyzes the first step in 8–8′-lignan biosynthesis, en route to (−)-matairesinol (**2**).

(+)-Pinoresinol/(+)-lariciresinol reductase was purified from *F. intermedia* stem tissue (Dinkova-Kostova et al., 1996); this soluble, 35 kDa, NADPH dependent, bifunctional enzyme catalyzes the sequential enantiospecific conversions of (+)-pinoresinol (**5**) into (+)-lariciresinol (**6**), and (+)-lariciresinol (**6**) into (−)-secoiso lariciresinol (**7**), respectively (see Fig. 1): the corresponding antipodes do not serve as substrates. The gene encoding PLR (*plr-Fi1*) was also obtained and cloned, this having considerable homology (~50% identity, ~ 65% similarity) to both isoflavone reductases (IFRs) and PLR/IFR homologs (Gang et al., 1997). The IFRs catalyze analogous reductions of α, β unsaturated ketones during isoflavonoid phytoalexin formation, and appear to be evolutionarily related to the PLRs in plant defense (Gang et al., 1997). The PLR/IFR homologs, however, appear to be mainly involved in phenylcoumaran benzylic ether reductions (Gang et al., 1999b) in lignan (8–5′-linked) biosynthesis.

Pinus taeda was also chosen for study, since it largely accumulates the 8–5′-linked lignans, dehydrodiconiferyl alcohol (**8**) and its derivatives in its heartwood (Fig. 2) (Gang et al., 1999b). Interestingly, formation of such metabolites is apparently inducible in the Pinaceae, given the increase in their amounts during gall formation in *Picea glauca*, resulting from attack by the gall-forming aphid *Adelges abietis* (Kraus and Spiteller, 1997). In this regard, one of the first 8–5′-lignan post-coupling transformations in *P. taeda* and *Cryptomeria japonica* (Lewis and Davin, 1999) involves benzylic ether reductions (Fig. 2) (Gang et al., 1999b). The presumed enzyme catalyzing this conversion, phenylcoumaran benzylic ether reductase (PCBER), has been obtained from both species, with the encoding genes cloned and functional proteins over-expressed in recombinant form (Gang et al., 1999b). The second objective of this investigation was thus directed toward employing immunocytochemistry to ascertain the tissue localization of PCBER. The results described below were presented at the 219th American Chemical Society National Meeting in San Francisco, March 2000 (Lewis et al., 2000).

2. Results

Using primers designed from the *plr-Fi1* sequence (GeneBank accession number U81158), the cDNAs for two PLR/IFR homologs and two other PLRs were isolated from different species, i.e. from *F. intermedia* was obtained the PLR/IFR homolog, *plrh-Fi1* (Dinkova-Kostova et al., 1996), and from *T. plicata* were genes encoding the PLR isoforms, *plr-Tp1* (GeneBank accession number AF242503) and *plr-Tp2* (GeneBank accession number AF242504) (Fujita et al., 1999). A comparable screening of a *P. taeda* cDNA library afforded the PLR/IFR homolog, the phenylcoumaran benzylic ether reductase (PCBER, *plrh-Pt1*, GeneBank accession number AF242490) (Gang et al., 1999b): The latter has rather

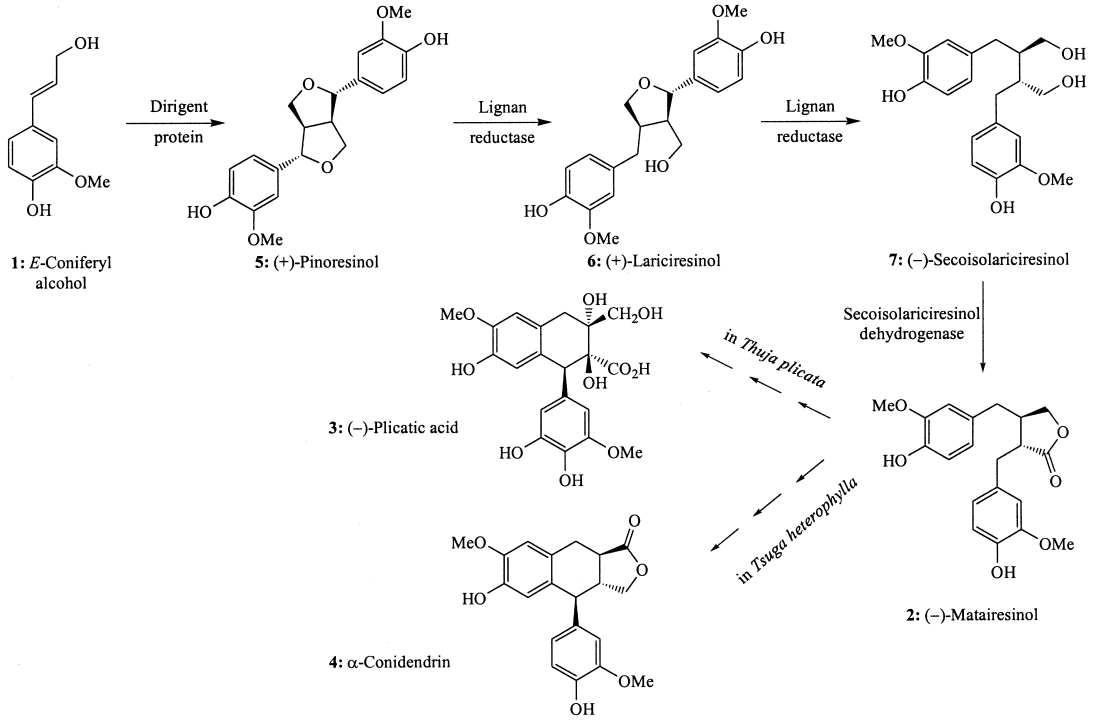

Fig. 1. The biosynthetic pathway to various 8–8′-linked lignans in *Forsythia intermedia*, *Thuja plicata* and *Tsuga heterophylla*. Two molecules of *E*-coniferyl alcohol (**1**) are stereoselectively coupled to afford (+)-pinoresinol (**5**) via dirigent protein mediation, which then undergoes sequential enantiospecific reduction to first give (+)-lariciresinol (**6**) and then (−)-secoisolariciresinol (**7**). (−)-Matairesinol (**2**) is subsequently formed via dehydrogenation of (−)-secoisolariciresinol (**7**), the further metabolism of which affords lignans, such as (−)-plicatic acid (**3**) and (−)-α-conidendrin (**4**), which accumulate in large amount in the heartwood of *T. plicata* and *T. heterophylla*, respectively.

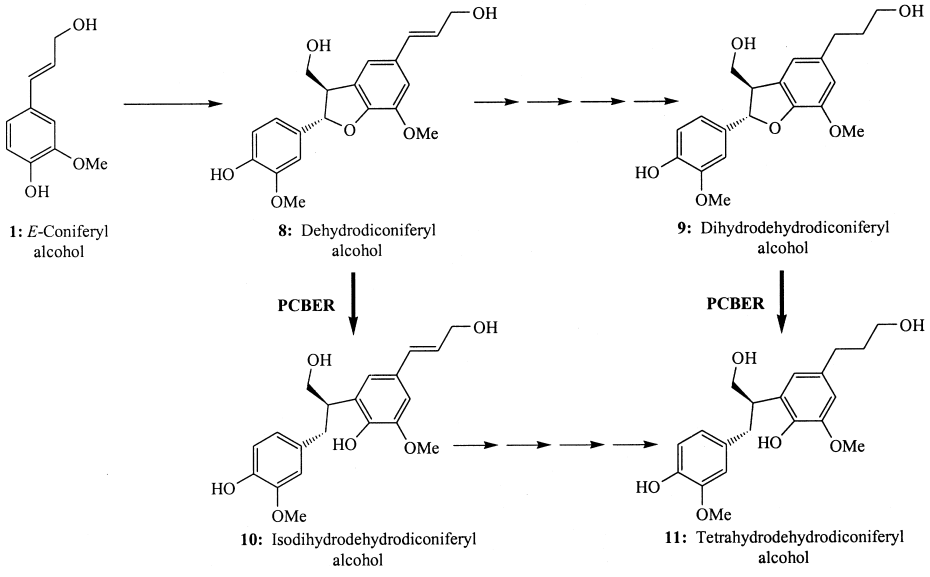

Fig. 2. The biosynthetic pathway to the 8–5′-linked lignans of *Pinus taeda* and *Cryptomeria japonica*. NADPH-dependent allylic double bond reduction of dehydrodiconiferyl alcohol (**8**) to its analog, dihydrodehydrodiconiferyl alcohol (**9**), occurs in several steps (Kasahara et al., manuscript in preparation), with a similar conversion also occurring for isodihydrodehydrodiconiferyl alcohol (**10**) and tetrahydrodehydrodiconiferyl alcohol (**11**). PCBER catalyzes the NADPH-dependent conversion of either dehydrodiconiferyl alcohol (**8**) or dihydrodehydrodiconiferyl alcohol (**9**) leading to the benzylic ether cleavage products isodihydrodehydrodiconiferyl alcohol (**10**) and tetrahydrodehydrodiconiferyl alcohol (**11**), respectively.

low enzymatic activity; nevertheless, it catalyzes the regiospecific, NADPH dependent, reduction of both dehydrodiconiferyl alcohol (**8**) and dihydrodehydrodiconiferyl alcohol (**9**) into isodihydrodehydrodiconiferyl alcohol (**10**) and tetrahydrodehydrodiconiferyl alcohol (**11**), respectively, in *P. taeda* (Fig. 2), with a

slightly higher affinity for dehydrodiconiferyl alcohol (**8**) based on the K_m and V_{max} determinations (Gang et al., 1999b). Interestingly, 8–5′-lignan dehydrodiconiferyl alcohol (**8**) derived substances are widespread throughout the Pinaceae, and mainly result from allylic double bond reductions, demethylations, and phenylcoumaran ring cleavage (Suga et al., 1993; Pan and Lundgren, 1995; Su et al., 1995; Lewis and Davin, 1999). Such substances and their higher oligomeric forms are present in both sapwood and heartwood of the Pinaceae, although they are typically 10-fold higher or so in the latter (Kraus and Spiteller, 1997).

2.1. PLR gene expression/mRNA accumulation are organ specific and developmentally regulated in F. intermedia

In order to initially establish the organ specificity of PLR (*plr-Fi1*) gene expression in *F. intermedia*, both RNA gel blot (Fig. 3a) and RT–PCR (Fig. 3b) analyses were conducted. For RNA gel blot analysis, a ^{32}P-labeled DNA probe was first obtained from the purified PCR product amplified from a near full-length *plr-Fi1* cDNA (28–936 bp) inserted in the pBluescript vector (SK$^-$) using T7 DNA polymerase (see Experimental). Subsequent RNA gel blot analyses (Fig. 3a) indicated that *plr-Fi1* mRNA accumulation was highest in the stems as compared to the roots and petioles (Fig. 3a, lower panel), this assumption being based on comparison of accumulation levels relative to that of ribosomal RNA from each tissue (Fig. 3a, upper panel).

RT–PCR analysis was next carried out in order to compare the levels of PLR mRNA accumulation at different stages of stem development. cDNA libraries, individually constructed from RNA samples from both young (first to second internodes) and mature stems (tenth to twentieth internodes), respectively, were amplified using primers designed from the 3′ region of the *plr-Fi1* cDNA (from 808 to 955 bp). The resulting amplified PCR products were then examined by gel electrophoresis as before whereby only the one expected band (circa 140 bp) (Fig. 3b, lower panel, lanes 1 and 2) was observed in each case. However, relative to similar amounts of 5.8S rRNA (Fig. 3b, upper panel), the PLR mRNA accumulation was highest in the young stems as compared to that of more mature stem tissue (Fig. 3b, lower panel, lanes 1 and 2). A similar trend was also noted for young roots relative to the more mature root tissues (data not shown). Finally, cDNA libraries were constructed from total RNA, isolated from both stem xylem and bark (first to twentieth internodes) regions, respectively, with the corresponding cDNA pools subsequently amplified using the same primers and PCR conditions as before. This revealed that PLR gene expression/mRNA accumulation were essentially only in the xylem tissues and not bark (Fig. 3b, lower panel, lanes 3 and 4).

2.2. PLR gene expression/mRNA accumulation in the cambium tissues of F. intermedia

With the gross tissue/organ specificity of the PLR gene having been demonstrated, it was next of interest to examine which cell types were associated with its specific mRNA accumulation. However, given the considerable level of homology (55.8% similarity, 55.8% identity), between PLR (*plr-Fi1*) and its homolog (*plrh-Fi1*), a *plr-Fi1* specific riboprobe was first designed in order to reduce and/or eliminate the potential for unwanted cross-reactivity and nonspecific binding (see Experimental). The specificity of both antisense and sense riboprobes was next evaluated by hybridizing each riboprobe (circa 210 nt, Fig. 4b and c) with the cDNAs encoding the *F. intermedia* PLR (*plr-Fi1*) and its homolog (*plrh-Fi1*) (see Fig. 4a). As an additional control, a PLR cDNA from *T. plicata* (*plr-Tp1*) was also examined for cross-reactivity. Thus, following employment of the anti-DIG antibodies conjugated to alkaline phosphatase with a chemiluminescent substrate both antisense (Fig. 4b) and sense (Fig. 4c) riboprobes were found to be only specifically hybridized to the *plr-Fi1* cDNA (1060 bp) but not to either the *plrh-Fi1* (954 bp) or the *plr-Tp1* (1190 bp).

However, prior to discussing the results obtained for in situ hybridization, it is first necessary to briefly

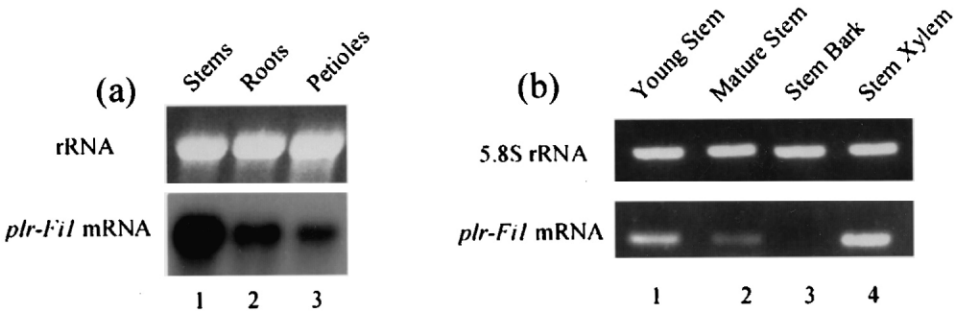

Fig. 3. Relative abundance of *plr-Fi1* mRNA in various *Forsythia intermedia* organs, and at different stem developmental stages. (a) RNA gel blot analysis using full-length *plr-Fi1* cDNA as template for synthesis of ^{32}P-labeled DNA probes using T7 DNA polymerase. (b) RT-PCR using gene specific primers for cDNA library amplification.

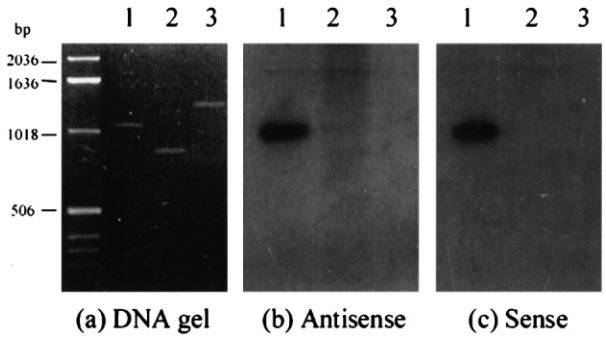

Fig. 4. Antisense and sense riboprobe specificity of *plr-Fi1* cDNA and reductase homologs, *plrh-Fi1* and *plr-Tp1*. (a). Gel fractionation of double digested fragments released following *Eco*RI and *Kpn*I restriction enzyme digestion. This released double-stranded full length cDNA coding for *plr-Fi1* (1060 nt, lane 1), *plrh-Fi1* (954 nt, lane 2) and *plr-Tp1* (1190 nt, lane 3), respectively, from their individual cDNAs cloned into the pBluescript vector (SK^-). (b) and (c). Probe specificity of *plr-Fi1* (lane 1) versus that of *plrh-Fi1* and *plr-Tp1* (lanes 2 and 3, respectively) using antisense (b) and sense (c) probes from *plr-Fi1*, respectively. Note: antisense (b) and sense (c) specifically bind to the *plr-Fi1* cDNA and not to the homologs *plrh-Fi1* and *plr-Tp1*.

describe the morphology of the tissues that were examined. Thus, in Fig. 5, the panels on the left column reveal the gross morphology as described following Saffranin-O staining of thick sections (8 μm) of the different organs selected for study. These were obtained from stems e.g. the first (Fig. 5a), second (Fig. 5d), tenth (Fig. 5g), and twentieth (Fig. 5j) internodes as well as from the young roots (Fig. 5m), the petioles (Fig. 5p) and the leaves (Fig. 5s). With the first internode (Fig. 5a), the vascular cambium (vc), the pith (p) and the cortex (co) are readily visible, as is the secondary xylem (sx) which has begun to develop from the vascular cambium (vc). As the stem grows and matures further (Fig. 5d,g and j), the stem diameter increases mainly as a consequence of secondary xylem development, as clearly visible from the second internode (Fig. 5d) onwards. By development of the tenth internode (Fig. 5g), the pith (p) has partially collapsed as evidenced by the hollow developing in the center, and it has completely collapsed by the twentieth internode (Fig. 5j), which contains highly lignified secondary xylem (sx) tissues. In the cross-sections of the young roots (Fig. 5m), both the cortex (co) and the stele (st) are clearly visible, as are the cortex (co), the midrib (mr) and the vascular bundles (vb) of the petioles (Fig. 5p) and leaf (Fig. 5s) tissues.

Accordingly, with the gene specific riboprobes in hand, in situ hybridization of PLR mRNA was next carried out using these *F. intermedia* stems, roots, petioles and leaves. Initially, serial sections were prepared from paraffin-embedded tissues and subjected to in situ hybridization using antisense and sense (negative controls) riboprobes described above.

In this way, in situ hybridization revealed that the strongest signal was detected in the stems (Fig. 5b,e,h and k) when compared to other organs such as the roots (Fig. 5n), the petioles (Fig. 5q) and the leaves (Fig. 5t). In the stem sections, the PLR gene expression/mRNA accumulation were mainly associated with the vascular cambium/differentiating xylem region (Fig. 5b,e,h and k), together with faint signal in the cortex in the early stages of maturation (Fig. 5b and e). However, as maturation proceeded, the levels of detectable PLR mRNA decreased (Fig. 5h and k), this being in agreement with the previous RT-PCR analysis (Fig. 3b). The negative controls, on the other hand, using the sense probe gave essentially only background signals in each case (Fig. 5c,f,i and l). Accumulation levels were also lower in the roots (Fig. 5n), the petioles (Fig. 5q) and the leaves (Fig. 5t), as predicted from the previous RNA gel blot analyses (Fig. 3a). It is noteworthy, however, that in each case, PLR gene expression was only associated with the meristematic tissues. For example, in the young root section (Fig. 5n), which contains both cortex and a centralized vascular network, the PLR mRNA accumulation was associated only with the pericycle (pe), the outermost layer of the stele (st); no signal was detected in the negative control (Fig. 5o). In the petioles, it was mainly in the cambium (ca), vascular bundles (vb) and the midrib (mr) (Fig. 5q), with again no signal being observed with the negative control (Fig. 5r). Lastly, in the leaf tissues, PLR mRNA accumulation was observed in the leaf blade as well as in the midrib cambium (ca) region (Fig. 5t), and the sense probe also gave essentially no signal as expected (Fig. 5u). Thus, taken together, PLR gene expression/mRNA accumulation in each case were broadly confined to the cambium regions typically associated with the onset of vascularization. Similar results were obtained with tissue printing (data not shown).

2.3. PLR mRNA accumulation in radial parenchyma cells, vessels, and the vascular cambium of F. intermedia stems

Fig. 6 displays the differences encountered in stem morphology, secondary xylem development and PLR mRNA accumulation during stem maturation at the 1st, 2nd and 20th internodes, respectively. Saffranin-O staining reveals the anatomical features at both lower (see Fig. 6a, d and g) and higher magnification (Fig. 6b, e and h), with the latter focusing on the vascular cambium and developing secondary xylem regions. In the cross-section of the shoot apex of the first internode (Fig. 6a and b), the vascular cambium (vc) has clearly developed from the interfascicular (ifc) and procambium-derived fascicular (fc) cambium. That is, the meristematic vascular cambium (vc), the cortex (co) and the pith (p) (Fig. 6a) consist of essentially only parenchyma cells, with the vascular cambium containing phloem- and xylem-parent cells and their undifferentiated daughter cells. At higher magnification

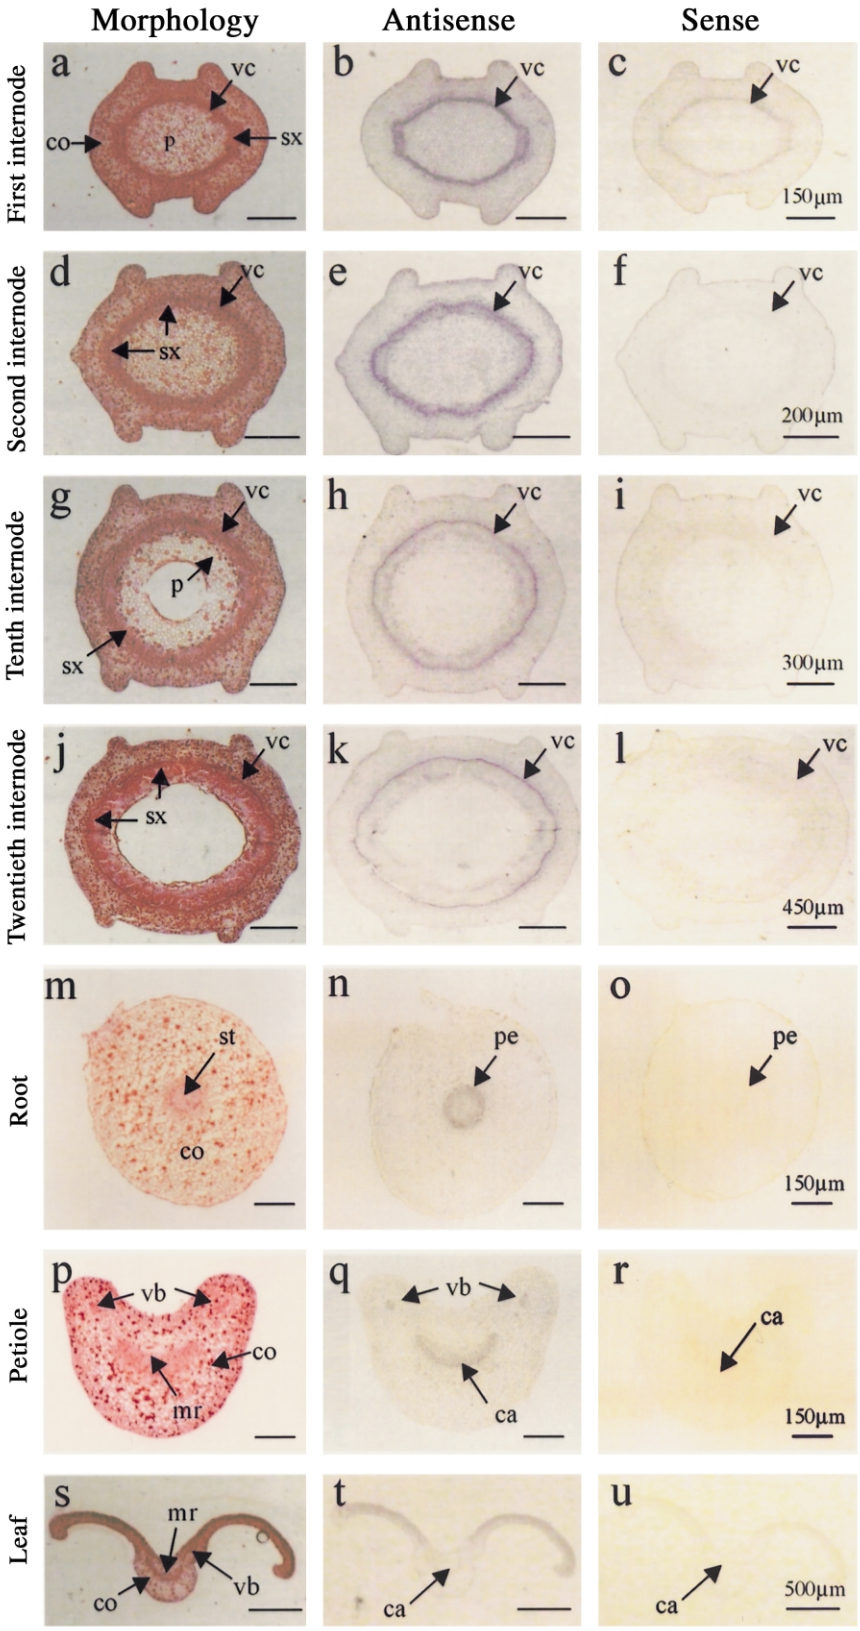

Fig. 5. Morphology of different *Forsythia intermedia* organs and the in situ hybridization of *plr-Fi1* mRNA expression. For morphology, tissue sections were stained with Saffranin-O (red-color). Serial sections of various tissues were used for direct comparisons between antisense and sense experiments. Antisense probes to *plr-Fi1* were specifically detected in the stem, root, petiole and leaf sections, whereas negative controls gave no signal. Abbreviations: ca, cambium; co, cortex; mr, midrib; p, pith; pe, pericycle; sx, secondary xylem; st, stele; vb, vascular bundle; vc, vascular cambium.

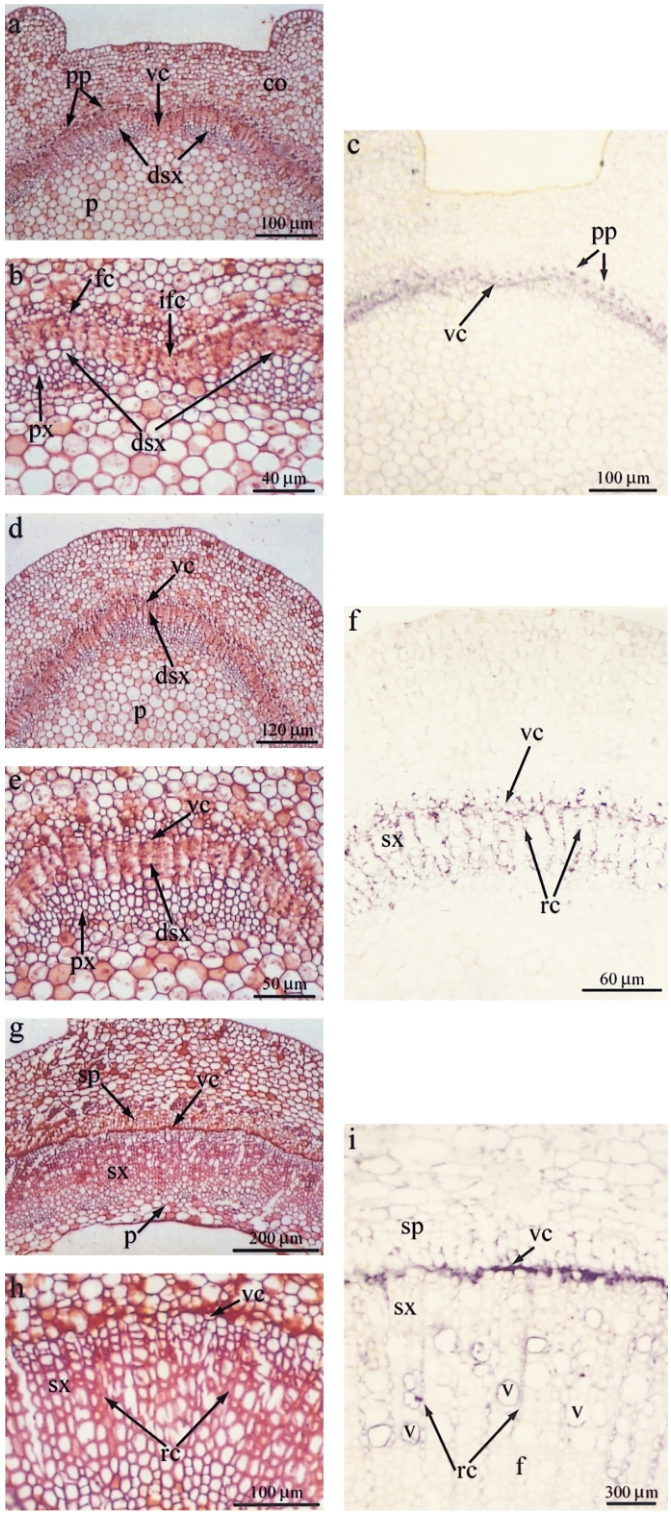

Fig. 6. Stem morphology, secondary xylem differentiation and PLR mRNA accumulation in the secondary xylem of *Forsythia intermedia* stems at different developmental stages. (a) through (c): first internode; (d) through (f): second internode; (g) through (i): twentieth internode. Partial cross sections revealed stages of secondary xylem development (a, d and g). Higher magnification of the vascular cambium region show development of the different cell and tissue types of interest (b, e and h). Sections were incubated with the antisense probe to *plr-Fi1* (c, f and i). PLR mRNA strongly accumulated in the vascular cambium regions (vc), and in the primary phloem (pp). As the stem matures and in the second and twentieth internodes, the *plr-Fi1* mRNA expression was in the vascular cambium, and in the ray parenchyma cells (rc). In the twentieth stem internode, the *plr-Fi1* mRNA was mainly expressed in the vascular cambium, as well as in the vessels (v) adjacent to the radial parenchyma cells, but not in the fibers (f) of secondary xylem. Abbreviations: co, cortex; dsx, developing secondary xylem; f, fiber; fc, fascicular cambium; ifc, interfascicular cambium; p, pith; pp, primary phloem; px, primary xylem; rc, radial parenchyma cells (or ray cells); sp, secondary phloem; sx, secondary xylem; v, vessel; vb, vascular bundle; vc, vascular cambium.

(Fig. 6b), the differentiating secondary xylem (dsx) is more clearly visible and the primary xylem (px), formed during primary growth, has separated away from the vascular cambium as secondary xylem development has proceeded. By development of the second internode (Fig. 6d and e), the differentiating secondary xylem (dsx) is more clearly detectable on the interior relative to that of the vascular cambium (vc). That is, the vascular cambium derived daughter cells have begun to differentiate into either lignifying cells (vessels and fibers) or into parenchyma cells. At this stage, cell wall lignin deposition in the secondary xylem is clearly detectable (Kwon et al., 1999). As the stems grow and mature further (Fig. 6g and h), both the secondary phloem (sp) and the secondary xylem (sx) were clearly distinguishable, with the latter being more highly lignified. At the twentieth internode stage (Fig. 6g and h), the conducting vessels, fibers, ray parenchyma cells and the collapsed pith tissues in the secondary xylem are now essentially fully developed. As noted earlier by the tenth internode (Fig. 5g), the *F. intermedia* stem had partially developed a hollow pith (Fig. 6g).

With these developmental observations, the differential patterns of PLR mRNA accumulation noted were instructive. At the first internode developmental stage, which lacks both developed secondary phloem and xylem formation, the PLR gene was strongly expressed in the vascular cambium (vc), together with a very faint level of mRNA accumulation in the primary phloem (pp) (Fig. 6c). However, at the second internodal developmental stage, where both the differentiating secondary xylem (sx) and vascular cambium (vc) are readily visible, the PLR mRNA clearly accumulated in both the vascular cambium and the differentiating radial parenchyma cells (rc) (Fig. 6f). As maturation continued (e.g. by development of the 20th internode), the strongest signal was detected in the vascular cambium and to a lesser extent, in the fully differentiated radial parenchyma cells (rc) of the secondary xylem (Fig. 6i). In addition, PLR mRNA accumulation was also faintly detectable in the vessels (v) adjacent to the ray parenchyma cells, but not in the xylem fibers (Fig. 6i). In summary, therefore, PLR gene expression/mRNA accumulation were not only mainly associated with the vascular cambium, but also to a lesser extent with radial parenchyma cells and vessels of the secondary xylem.

2.4. PCBER localization in P. taeda stems

The next objective was to localize the 8–5′-lignan reductase, the phenylcoumaran benzylic ether reductase (PCBER), at the cell and tissue levels. For this purpose, polyclonal antibodies were first raised in rabbits against the purified recombinant 35 kDa PCBER, with both the 35-week immune and the corresponding pre-immune serum chosen for subsequent experimentation. The

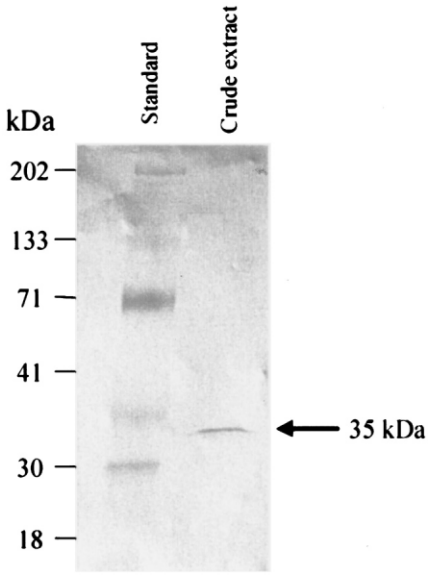

Fig. 7. Western blot analysis of a crude protein extract from *Pinus taeda* using PCBER polyclonal antibodies for detection. Polyclonal antibodies against purified functional recombinant PCBER specifically binds to PCBER (35 kDa) in *Pinus taeda* crude extract. Lane 1: standards; Lane 2: *P. taeda* stem crude extract.

polyclonal PCBER antibodies were found only to cross-react with the purified recombinant PCBER but not to its homologs, the PLR's from *F. intermedia* and *T. plicata* (data not shown). Next, western blot analysis of the total crude protein extract from *P. taeda* seedling stem tissues revealed that the polyclonal antibodies raised against PCBER specifically cross-reacted with PCBER, to give the expected band of circa 35 kDa molecular size (Fig. 7). With the specificity of the PCBER polyclonal antibodies thus established, *P. taeda* seedlings stem sections (1 year old) were next examined in order to define the cell and tissue specificities of PCBER. Two tissue sections were evaluated, namely that of both the green shoot (newly growing tissue) and the basal woody stem. For the green shoot section (Fig. 8a and b), although the secondary xylem has begun to develop, cells and tissues had not yet fully differentiated. By contrast, at the basal part of the more mature stem (Fig. 8c and d), the vascular cambium derived secondary xylem cells are now differentiated into specific cell types, such as tracheid (t), and radial (rc)/axial (ap) parenchyma cells. Characteristic brown spots in both the green shoot and woody stem are due to the presence of resinous material, some of which may also be phenolic.

At the green shoot developmental stage, PCBER was found to be localized in the differentiating secondary xylem regions, i.e. in the regions containing undifferentiated tracheids, undifferentiated fibers and the initials of both axial and radial parenchyma cells (Fig. 8a). As expected, the pre-immune control gave essentially no signals (Fig. 8b). In the more mature woody stem

(Fig. 8c), however, PCBER was now specifically localized in the fully differentiated axial (ap) and radial (rc) parenchyma cells, and, by contrast, to a much lesser extent in the vascular cambium (vc). Indeed, the latter observation in the vascular cambium might correspond to either axial or radial parenchyma cell initials. Again, the pre-immune controls gave background signals (Fig. 8d). Thus these findings clearly established that the PCBER was mainly localized in the radial and axial parenchyma cells of *P. taeda*. [Note added in proof: Somewhat analogous findings for PCBER have been reported also for poplar (Vander Mijnsbrugge et al., 2000).]

3. Discussion

These results are beginning to reveal how different species have evolved their distinctive mechanisms for long-term survival, i.e. where the monolignols are differentially deployed for both protective and structural roles as in *F. intermedia* secondary xylem and *P. taeda* heartwood formation. In the case of *F. intermedia*, the central parenchyma-rich pith tissues partially collapse and this part of the stem hollows out over time with the protective lignans being deposited in the remaining lignified secondary xylem. In *P. taeda*, on the other hand, the heartwood forming substances, including lignans, are synthesized and/or transported along axial and radial parenchyma cells; these are presumably converted subsequently into the corresponding heartwood-characteristic metabolites at the sapwood and heartwood boundary zone, where they are later infused into adjacent pre-lignified tracheary elements.

In earlier studies (Chattaway, 1952; Gang et al., 1998), the ray cells (radial parenchyma cells) had been proposed as possible sites for specialized secondary metabolite biosynthesis and thus for the formation of heartwood metabolites (e.g., such as lignans). According to this model, heartwood metabolites were biosynthesized and/or translocated along the ray cells, with these then being infused through the pits in the so-called transition zone, between the heartwood and sapwood, and into adjacent cell lumens. Indeed, this presumably explains why lignans often accumulate in lignified tissues as non-structural components, even when originating from axial and radial parenchyma cells (Hillis, 1971). It is also very significant that during heartwood formation, lignan biosynthetic and deposition processes are also clearly highly controlled: for example, in western hemlock (*T. heterophylla*) heartwood, the lumen of some tracheid cells can contain 7′-hydroxymatairesinol, whereas adjacent cells can accumulate α-conidendrin (**4**) (Krahmer et al., 1970). Moreover, the lignans can also have quite marked variations in molecular sizes: in western red cedar (*T. plicata*) heartwood, for example, the 8–8′-lignans derived from plicatic acid (**3**) can range in size from dimers up to oligomers of at least MW∼10,000 (Beatson et al., 1998). Furthermore, since a portion of these are also solubilized under conditions required for lignin removal, their presence had originally led to the erroneous consideration that they were formed through the 'aging' of lignin (Li and Sarkanen, 1971).

The discovery of lignan-specific biosynthetic enzymes thus provided not only a means to localize the cellular sites involved in lignan heartwood metabolite formation, but also that of related processes in non-heartwood

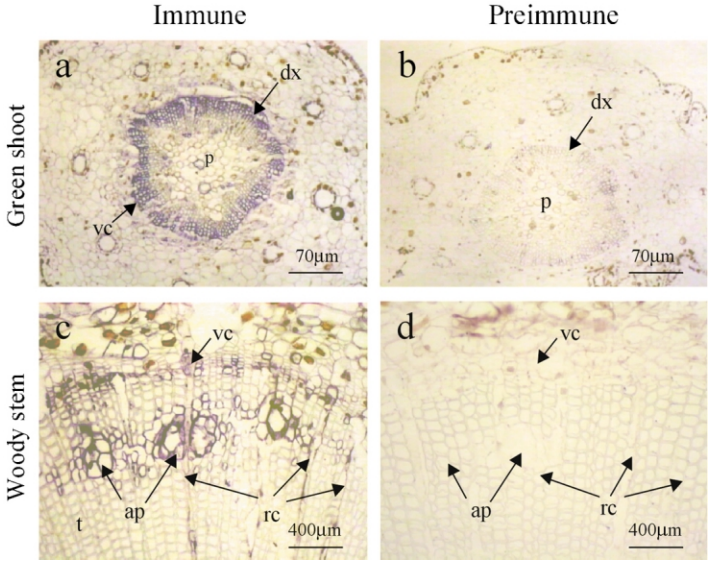

Fig. 8. PCBER localization in *P. taeda* (1 year old) seedlings. PCBER was in the developing xylem regions (dx) of young green shoots. In the basal stem section, PCBER was present in the axial (ap) and radial (rc) parenchyma cells, and to a lesser extent in the vascular cambium regions (vc). Abbreviations: ap, axial parenchyma cells; dx, developing xylem; p, pith; rc, radial parenchyma cells; t, tracheid; vc, vascular cambium.

forming species, e.g. during secondary xylem/hollow pith generation. Interestingly, the initial steps of the lignan and lignin pathways, namely that of monolignol coupling, were previously noted to occur mainly in the vascular cambial cells at all stages of stem development in *F. intermedia* as demonstrated by dirigent protein mRNA accumulation (Kwon et al., 1999; Davin and Lewis, 2000; Burlat et al., 2001). To a lesser extent, dirigent gene expression was also noted in the developing secondary xylem and in undifferentiated ray parenchyma cells as shown by in situ hybridization (Kwon et al., 1999; Burlat et al., 2001), but, importantly, not in the fully differentiated radial parenchyma cells of mature secondary xylem. This, in turn, suggests that monolignol partitioning into the lignan and lignin biosynthetic pathways occurs predominantly in the cambial regions.

On the other hand, while the *F. intermedia* PLR gene was expressed in the vascular cambium region of young stems, significant levels of mRNA accumulation were also noted along the ray parenchyma cells of mature secondary xylem (Fig. 6i). Furthermore, another downstream lignan-forming enzyme, secoisolariciresinol dehydrogenase, is also largely localized in the ray parenchyma cells of mature stem secondary xylem of *F. intermedia* (Pélissier, Franceschi, Davin and Lewis, unpublished results). Therefore, based on expression of several enzymes involved in the early stages of 8–8′-lignan biosynthesis (Kwon et al., 1999; Davin and Lewis, 2000; Burlat et al., 2001), it appears that monolignol coupling occurs mainly in the vascular cambium whereas post-coupling transformations are manifested along the radial parenchyma cells in addition to the vascular cambium.

A low level of PLR mRNA accumulation was also specifically noted in the developing vessels adjacent to radial parenchyma cells in the secondary xylem of mature *F. intermedia* stems, but not in the fibers. However, since vessels have relatively well developed pit systems which link adjacent axial/radial parenchyma cells, this finding also supports the possibility of lignan metabolite infusion into these tracheary elements. On the other hand, it is also possible that the PLR gene is expressed at lower levels in the vessels prior to programmed cell death. Whatever case holds, this may further explain the presence of heartwood (lignan) metabolites in heartwood tracheary elements.

The involvement of both radial and axial parenchyma cells was also supported further by the immunolocalization of PCBER, presumed to be involved in the post-coupling modification of 8–5′-lignans in *P. taeda*. Since PCBER was localized mainly in the axial/radial parenchyma cells of secondary xylem of maturing stem sections, this gave additional evidence at the molecular level for the involvement of these cells in the biosynthesis of the heartwood characteristic substances. Therefore, it can be considered that the involvement of axial/radial parenchyma cells is important in generating the properties of lignan-rich woody tissues (including that of heartwood). However, for heartwood formation, the precise metabolic function of the sapwood-heartwood transition zone still remains to be fully established; i.e. as to the precise nature of the specific metabolic events occurring in this region whereby the transition from sapwood to heartwood occurs. Nevertheless, it is clear that the axial and ray parenchyma cells are involved in this process, and it will be of considerable importance to ultimately define the precise metabolic processes operative, and how they differ between species.

Until this study, the co-occurrence of lignans and lignins in secondary xylem was not well understood. For example, for secondary xylem formation to occur, the vascular cambium derived cells need to undergo active expansion and elongation in order to differentiate into the specific cell types, such as xylary cells (tracheary elements and fibers) as well as in generating axial/radial parenchyma cells (Bosshard, 1965). These xylary cells (tracheary elements and fibers) then undergo a process involving massive monolignol deposition, these being mainly directed to the secondary cell wall regions prior to cell death; however, by the stage where monolignol infusion for lignification occurs, the cell walls already contain other constituents such as cellulose microfibrils, the hemicelluloses, cell wall structural proteins (e.g. glycine and proline-rich proteins), and various oxidative enzymes (apoplastic peroxidase and laccases). Hitherto, the enzymes localized in the radial parenchyma cells of secondary xylem were considered only in terms of lignin biosynthesis, even though these cells were not (immediately) lignified in contrast to the tracheary elements and fibers. Accordingly, the radial/axial parenchyma cell expression/localization of PLR and PCBER now establishes an involvement in lignan biosynthesis, with lignification being — at least initially — restricted to other cell types, such as the tracheary elements and fibers.

In conclusion, there are significant spatial and temporal differences emerging between lignan and lignin biosynthesis, even though both are formed via monolignol coupling; these observations are in harmony with their distinct physiological roles and functions.

4. Experimental procedures

4.1. Plant materials

F. intermedia (var. Lynwood Gold) and *P. taeda*, obtained from Bailey's Nursery (St. Paul, MN) and Gulf States Nursery (Tuscaloosa, AL), respectively, were maintained in greenhouse facilities at Washington State University. In this study, *Forsythia* plant tissues were harvested in the spring of 1998 and 1999, whereas *P. taeda* tissues from one year old specimens were collected during the summer of 1999.

4.2. RNA isolation from F. intermedia

Total RNA samples were extracted and utilized for gene expression analysis as follows. Tissues (3 g, fresh weight) from different organs were individually pulverized in liquid nitrogen in a mortar with a pestle. Each was homogenized in 5 volumes of extraction buffer [50 mM Tris–HCl, pH 8.0, 300 mM NaCl, 5 mM EDTA, 2% SDS, 0.5% (w/v) soluble polyvinylpyrrolidone (PVP), 0.5 mM aurintricarboxylic acid and 10 mM dithiothreitol (DTT)] for 10 min at 65°C. Each homogenate was next filtered through a single layer of miracloth (Calbiochem, La Jolla, CA) and centrifuged for 10 min at 4°C at 10,000× *g*. Potassium acetate solution (0.42 ml, 5 M, pH 4.8) was added to each supernatant with the resulting suspension centrifuged at 10,000 *g* (30 min, 4°C) and further incubated on ice for 30 min. Next, a lithium chloride solution (5 ml, 8 M) was added to each supernatant with the corresponding mixture incubated overnight at 4°C. The nucleic acids were recovered by centrifugation at 2000× *g* (20 min, 4°C), resuspended in 5 ml DEPC (diethylpyrocarbonate)-treated distilled H_2O, and extracted with 2 volumes of phenol-chloroform-isoamyl alcohol (24:23:1) mixture, and finally with 2 volumes of chloroform. Following addition of 0.1 volume of sodium acetate (500 μl, 3 M) to the recovered aqueous phase, the nucleic acids were precipitated overnight at −20°C in ethanol [final concentration 33% (v/v)] and recovered by centrifugation at 10,000× *g* (10 min, 4°C). Each RNA pellet was resuspended in DEPC-treated distilled H_2O and stored at −80°C until needed.

4.3. RNA gel blot analysis

A DNA probe was prepared from *plr-Fi1* cDNA (50 ng, GeneBank accession number U81158) which had previously been isolated and cloned into pBluescript (SK$^-$) vector (Dinkova-Kostova et al., 1996). The probe was labeled from the purified PCR product amplified from the near full-length *plr-Fi1* cDNA (from 28 to 936 bp) with 50 μCi of [α-^{32}P] dCTP (3000 Ci/mmol) at 37°C for 15 min using T7 DNA polymerase (6 units, T7 Quick Prime Kit), according to the manufacturer's instructions (Amersham Pharmacia Biotech, Inc., Piscataway, NJ). The ^{32}P-labeled DNA probe was next purified by centrifugation using Micro Bio-Spin Chromatography Columns (Bio-Rad, Hercules, CA) in order to remove unincorporated nucleic acids.

Total RNA samples (15 μg) were individually denatured at 70°C, and resolved in 1.2% formaldehyde-containing gels (Sambrook et al., 1989). Each RNA gel was blotted onto a Hybond^{TM}-N$^+$ nylon membrane (Amersham Pharmacia Biotech, Inc.) in 10×SSPE (1.8 M NaCl, 0.1 M sodium phosphate, 0.01 M EDTA) overnight, with each blot irradiated under UV light (1.2×10^5 μJ cm^{-2}) for 30 s (UV Stratalinker^{TM} 2400, Stratagene, La Jolla, CA). The blots were then prehybridized for 4 h at 68°C in 5×SSPE, 5×Denhardt's solution, 1% SDS, 10% dextran sulfate and subsequently hybridized in the same solution containing the ^{32}P-labeled DNA probe which had previously been denatured by boiling for 10 min. Hybridization was carried out for 16 h at 68°C, with the blots next washed at high stringency (final wash 0.1×SSPE and 0.1% SDS) at 68°C and finally subjected to autoradiography at −80°C using intensifying screens.

4.4. Reverse transcription polymerase chain reaction (RT–PCR) analysis

First-strand cDNAs were synthesized by incubating *F. intermedia* total RNA (4 μg), previously heat-denatured at 70°C for 10 min, with reaction buffer [50 mM Tris–HCl (pH 8.3), 75 mM KCl, 3 mM $MgCl_2$ and 10 mM DTT], 0.5 mM each deoxyribonucleoside triphosphate (dNTP), 1 mM random hexamer (Amersham Pharmacia Biotech, Inc.) and 200 units of Superscript II (Life Technologies, Rockville, MD) in a total volume of 20 μl for 50 min at 42°C. Following incubation, the resulting first-strand cDNAs (1 μl) were individually amplified by PCR. PCR conditions were as follows: 35 cycles, each consisting of 30 s denaturation at 95°C, 30 s annealing at 60°C, 1 min extension at 72°C with an additional 7 min extension after the final cycle. Amplification was carried out in reaction buffer [10 mM Tris–HCl (pH 7.5), 50 mM KCl, 0.5 mM DTT, 7.5 mM $MgCl_2$, 0.05 mM EDTA, 0.25% Tween 20 (v/v), 100 μM each dNTP] with 2.6 units of enzyme mixture consisting of *Taq* DNA and *Pwo* DNA polymerases (total volume of 50 μl) using the Expand^{TM} High Fidelity PCR system (Boehringer Mannheim, Indianapolis, IN) and gene specific primers (0.5 μM each). The sequences of the primers used in this amplification were 5′-CTCGAGTATGCTCAGCAAGTGGG-3′ (from 808 to 830 bp) and 5′-GCTTGAGGTACTCTTCCACAC-3′ (from 935 to 955 bp). For a positive control, *F. intermedia* rRNA was amplified under the same conditions as above, but with the following primers 5′-TCG GCAACGGATATCTCGGCTCT-3′ and 5′-GCGTGA CGCCCAGGCAGACGT-3′ designed from the tobacco (*Nicotiana tabacum*) 5.8S rRNA (GeneBank accession number AJ012367). RT-PCR products were analyzed on 1.2% agarose gel with UV visualization after ethidium bromide staining.

4.5. Run-off transcription and RNA probe preparation

Because of the considerable homology of *plr-Fi1* to a pinoresinol/lariciresinol reductase homolog in *F. intermedia* (*plrh-Fi1*, GeneBank accession number AF242491, 55.8% similarity, 55.8% identity), efforts were made to synthesize gene-specific probes for the detection of *plr-Fi1*

mRNA as follows. First, a 210 bp *Pst* I/*Hind* III fragment, located at 761/971 bp in the *plr-Fi1* cDNA, was subcloned into the corresponding sites of pBluescript vector (SK^-). Digoxigenin (DIG)-labeled antisense and sense RNA probes were next synthesized by an in vitro transcription reaction from the pBluescript SK^- template containing the partial sequence of *plr-Fi1* cDNA using the DIG-RNA Labeling Kit (Boehringer Mannheim): plasmids were linearized by cleavage using either *Pst* I or *Hind* III, and digoxigenin-11-dUTP (Boehringer Mannheim) was incorporated using either T7 or T3 polymerase for the antisense or sense probes, respectively. These were then individually fragmented to about 150 nt in size by alkaline hydrolysis prior to hybridization according to Duck (Duck, 1994). The specific activities of both sense and antisense riboprobes were determined using DIG-Quantitation Teststrips (Boehringer Mannheim) according to the manufacturer's instructions.

4.6. Riboprobe specificity

cDNA inserts from the *Forsythia* PLR homolog (*plrh-Fi1*), and as an additional control from an authentic PLR from *T. plicata* (*plr-Tp1*), were cross-hybridized with a riboprobe specifically designed for *plr-Fi1* mRNA detection in order to test for its specificity. That is, both the *F. intermedia* pinoresinol/lariciresinol reductase homolog (*plrh-Fi1*, GeneBank accession number AF242491) and the *T. plicata* pinoresinol/lariciresinol reductase (*plr-Tp1*, GeneBank accession number AF242503), were individually tested to verify the specificity of the *plr-Fi1* RNA probe as well as the specificity to *plr-Fi1* itself. Each cDNA (*plr-Fi1*, *plrh-Fi1*, *plr-Tp1*) sample was digested with *Eco*RI/*Kpn*I, with 15 ng of each fragment subjected to agarose gel electrophoresis (Fig. 3a). The gels were next blotted onto Hybond^{TM}-N^+ nylon membranes (Amersham Pharmacia Biotech Inc.) in alkaline solution (0.4 M NaOH) overnight, with each blot cross-linked under UV light (1.2×10^5 μJ cm^{-2}) for 30 s to immobilize the DNA. The blots were then prehybridized for 1 h at 65°C in prehybridization buffer containing 5×SSPE, 5×Denhardt's solution, 10% SDS, and denatured salmon sperm DNA (0.5 mg ml^{-1}). These were next individually hybridized for 16 h at 65°C in fresh prehybridization buffer containing either DIG-labeled antisense or sense RNA probes (0.05 μg ml^{-1}) which had been hydrolyzed and denatured prior to hybridization as described previously. The blots were rinsed in 2×SSPE, 0.1% (w/v) SDS at room temperature, and finally in 1×SSPE, 0.1% (w/v) SDS at 65°C. These were then incubated for 30 min at room temperature, with sheep anti-DIG-alkaline phosphatase antibodies diluted (1:25,000) in maleic acid buffer (0.1 M, pH 7.5) containing 0.15 M NaCl and 10×blocking reagent (Boehringer Mannheim). After washing in maleic acid buffer (0.1 M, pH 7.5) containing 0.15 M NaCl and 0.3% (v/v) Tween 20, the blots were next incubated with CSPD (disodium 3-(4-methoxyspiro{1,2-dioxetane-3,2′-(5′-chloro)tricyclo[3.3.1.$1^{3,7}$]decan}-4-yl) phenyl phosphate, 25 mM), a chemiluminescent substrate for alkaline phosphatase, diluted (1:100) in Tris buffer (0.1 M Tris–HCl, pH 9.5), containing 0.1 M NaCl according to the manufacturer's instructions (Boehringer Mannheim). After 15 min at 37°C, the blots were exposed to a Hyper film ECL^{TM} (Amersham Pharmacia Biotech Inc.) for 5 min and the films were then developed.

4.7. Tissue preparation and RNA in situ hybridization of PLR in F. intermedia

To protect samples from the effects of exogenous RNase during experimentation, each solution was treated with DEPC and autoclaved. In addition, all glassware, metal items, microscopic slides and cover slips were baked at 180°C.

Stems at various developmental stages, as well as roots, petioles and leaves were harvested from *F. intermedia* and immediately fixed in FAA solution (10% formaldehyde, 5% glacial acetic acid, 50% ethanol, v/v) overnight at 4°C. Tissues were next dehydrated gradually in 50, 70, 80, 95 and 100% ethanol solutions and transferred to a histomatic tissue processor (166A, Fisher Scientific) for infiltration and paraffin embedding. Thick sections (8 μm) were then obtained and directly mounted onto silane (3-aminopropylsilane) coated microscopic slides (Fisher Scientific), with the paraffin being removed by immersion of the slides in a hemo-D (Fisher Scientific) solution. The sections were subsequently rehydrated in 100, 95, 80, 50 and 30% ethanol and distilled water and finally air dried. Several treatments, prior to prehybridization, were applied to increase the accessibility of each probe to the target mRNA as well as to minimize nonspecific binding as follows: First, tissue sections were incubated with protease K solution (1 μg ml^{-1}) in TE buffer (50 mM Tris–HCl, 5 mM EDTA, pH 7.4) for 30 min at 37°C. After washing with TE buffer and then water, sections were sequentially incubated in a solution of aqueous soluble PVP (1%, w/v) at room temperature for 20 min in order to quench any background reaction caused by phenolics. Tissue sections were next prehybridized in a prehybridization solution containing 50% formamide (v/v), 30 mM NaCl, 10 mM Tris–HCl (pH 7.5), 1 mM EDTA, 1×Denhardt's solution, 10% dextran sulfate, 100 mM DTT and 150 μg ml^{-1} yeast tRNA (Sigma) for 2 h at room temperature. Tissue sections were hybridized overnight at 38°C in the same solution but which also contained the denatured digoxigenin-labeled probe (0.1 μg ml^{-1}), which had previously been hydrolyzed into 150 nt segments as described above. Following hybridization, sections were washed in 2×SSC, 1×SSC, and 0.5×SSC at room temperature for 30 min each, then in 0.1×SSC for 1 h at 38°C and finally

with Tris-buffered saline–Tween (TBST; 10 mM Tris–HCl, 500 mM NaCl, 0.3% Tween 20, pH 8.2). Sections were first incubated in TBST solution containing 1% (w/v) BSA, 0.1% (w/v) PVP and 0.5% whole sheep serum (Ted Pella, Inc., Redding, CA), for 1 h at room temperature and then in sheep anti-DIG-antibodies conjugated with alkaline phosphatase (Boehringer Mannheim) [(1:1000 in TBST containing 1% w/v BSA (TBST + BSA)] for 2 h at room temperature. After three washes (10 min each) in TBST, PLR mRNA was detected by incubating the slides with the chromogenic substrates, nitroblue tetrazolium chloride (NBT) and 5-bromo-4-chloro-3-indolyl-phosphate, 4-toluidine salt (BCIP) in 100 mM Tris–HCl (pH 9.2) containing 100 mM NaCl and 50 mM $MgCl_2$. Incubation was carried out in the dark, for up to 10 min, at room temperature according to the manufacturer's instructions (Boehringer Mannheim). In order to remove endogenous alkaline phosphatase activity in the tissue sections, levamisol (Sigma, 0.24 mg ml^{-1}) was additionally added to the color developing solution as described in Bochenek and Hirsch (1990). Progression of the color reaction was terminated by washing the slides for 5 min in H_2O, followed by air drying in the dark at room temperature. Slides were next covered with cover-slips for microscopy analyses using a Permount (Fisher Scientific) as a mounting media without counter-staining.

4.8. Western blot analysis using PCBER antibodies

P. taeda stems were ground in liquid N_2 to a powder by means of a mortar and pestle. The powder was next homogenized in potassium phosphate buffer (0.1 M, pH 7.9). The resulting slurry was passed through one layer of miracloth, then centrifuged (10,000 *g* for 5 min) and the total crude protein extract so obtained was used for western blot analysis. Total proteins [4 μg, based on absorbance at 595 nm with the Bradford reagent (Bradford, 1976)] were next loaded onto a polyacrylamide gel (4–15% acrylamide) (Bio-Rad) and subjected to electrophoresis (20 mA) according to Laemmli (1970), using Kaleidoscope prestained standards (Bio-Rad). The resulting gel was then blotted onto a PVDF membrane (Bio-Rad), presoaked in transfer buffer containing 20% MeOH, and 80% [25 mM Tris buffer, and 192 mM glycine]. This was then blotted at 150 mA for 1 h using the corresponding transfer apparatus, with the resulting membrane washed briefly in distilled water and blocked in TBS (20 mM Tris–HCl, pH 7.5, 500 mM NaCl) buffer containing 5% powdered milk for 30 min at room temperature. After briefly washing the membrane in 20 mM Tris–HCl buffer (pH 7.5) containing 500 mM NaCl and 0.05% Tween 20 (TBST), it was next incubated with PCBER antibodies, diluted (1:5000) in TBST buffer containing 5% powdered milk. After washing with TBST twice for 10 min each, the membrane was incubated with goat anti-rabbit antibody conjugated to horseradish peroxidase (Pierce, Rocklord, IL) diluted (1:10,000) in TBST containing 5% powdered milk, for 2 h at room temperature. After washing the membrane three times in TBST for 5 min each, and then twice in TBS for 5 min each, the antibody binding was visualized using 4-chloro-1-naphthol and hydrogen peroxide in TBS.

4.9. Immunocytochemistry of PCBER in Pinus taeda

Stems of 1 year old *Pinus taeda* seedlings were harvested and embedded in paraffin after FAA fixation as described above. Thick sections (10 μm) were obtained using a rotary microtome (Jung Biocut, Leica) and mounted on silane coated-microscopic slides (Fisher Scientific). The paraffin was removed by immersion of the slides in a hemo-D (Fisher Scientific) solution and subsequently rehydrated in 100, 95, 80, 50 and 30% EtOH, and finally in distilled water. After air drying, sections were blocked for 1 h in TBST containing 1% (w/v) BSA, 0.1% (w/v) PVP, 0.5% whole rabbit serum (Ted Pella, Inc). All incubations were carried out at room temperature with gentle shaking. Sections were next transferred to a solution containing either rabbit polyclonal antibodies raised against purified recombinant PCBER protein expressed in *E. coli* or the preimmune serum as a control, each of which had been diluted 1:10 in TBST containing 1% (w/v) BSA (TBST + BSA). After incubation for 4 h, sections were immersed and rinsed in TBST + BSA for four times 15 min, then finally transferred to and incubated in blocking solution (TBST + BSA containing 0.5% (v/v) whole sheep serum) for 30 min. Sections were next incubated for 2 h with sheep anti-rabbit antibody conjugated to alkaline phosphatase (Boehringer Mannheim) (1:50, in TBST + BSA). Tissue sections were washed with TBST + BSA, TBST and with distilled water (3 times each), successively, and then each was incubated with chromogenic substrates, NBT and BCIP as described above (Bochenek and Hirsch, 1990). Color development was carried out at room temperature for 10 min in the dark according to manufacturer's instructions (Boehringer Mannheim). Slides were treated as described above for microscopy analyses.

4.10. Image processing

Photographs of sections were archived using a Stereomicroscope (Wild Heerbrugg) and an Olympus BH2 microscope equipped with a Pulnix TM-7 CN color CDD camera.

Received 29 June 2000; received in revised form 29 August 2000

Abstract

Pathways to complex gallotannins have been elucidated by enzyme studies, indicating that β-glucogallin is required as principal acyl donor. Evidence for the in vitro oxidation of pentagalloylglucose, the pivotal metabolite in this sequence, to ellagitannins, is presented. Immunohistochemical studies with antibodies raised against pentagalloylglucose and the galloyltransferase catalyzing the formation of this ester revealed that leaf mesophyll cell walls were a typical site of origin and deposition of hydrolyzable tannins. Seasonal changes of these compounds were studied with extracts from cell walls and intracellular space of oak leaves. © 2001 Published by Elsevier Science Ltd. All rights reserved.

1. Introduction

Vegetable tannins, nowadays often called 'plant polyphenols' as an attempt to describe their heterogenous chemical structures and manifold reactions more adequately (cf. Haslam, 1989, 1999), have exerted a strong impact on human life for millenia. As common components of food and beverages of plant origin, they influenced their taste by providing a more or less appreciated astringency (which must not necessarily be negative if one considers the recently intensively discussed 'French paradox' (cf. Carando and Teissedre, 1999), i.e. reduced incidence of coronary artery disease supposed to be caused by ingestion of red wine tannins). They were later recognized as valuable chemicals for technical processes (e.g. in tannery to convert raw hides to durable leather or for the production of dyes and inks) and as versatile medicinal agents that have been widely used in traditional folk medicine to cure a variety of physical disorders (cf. Haslam et al., 1989; Haslam, 1996) and that appear to experience now a renaissance as potent antioxidant, antimicrobial, antiviral and antitumor agents (for recent reviews related to these topics, see Gross et al., 1999). It is, thus, not surprising that chemists started studies on the structure of tannins already more than a century ago. These efforts were, however, awarded by significant progress only during the past decades when the problems that arose from the complexity of these substances and that prevented their facile isolation and unequivocal characterization had been solved by the introduction of modern chromatographic and analytical techniques, like high-performance liquid chromatography (HPLC), mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy. The rich body of different tannin structures isolated from many plant species that became available by such investigations stimulated subsequent considerations on the then completely unknown biosynthesis of these compounds. Experiments on this latter challenging question, focussed on the biogenetic routes to the class of hydrolyzable tannins, were performed in the authors' laboratory by enzyme studies with cell-free extracts from leaves of staghorn sumac (*Rhus typhina*), pedunculate oak (*Quercus pedunculata*, syn. *Q. robur*) and the weed *Tellima grandiflora* (Saxifragaceae). [According to the already classical definition proposed by Freudenberg (1920), plant tannins are divided into hydrolyzable tannins and flavonoid derived condensed tannins, *syn.* proanthocyanidins, which are not the subject of this contribution]. In close connection with this research project it became

increasingly interesting to investigate the subcellular localization of the enzymes involved in the biosynthesis of hydrolyzable tannins and also to determine the compartments for the deposition of their reaction products. Results of biochemical and histochemical studies related to these topics, including recent unpublished findings, are summarized in this article.

2. Biosynthesis of hydrolyzable tannins

The biogenetic pathways to hydrolyzable tannins can be logically divided into three smaller sections that reflect typical structural features of the intermediates involved in these conversions. A starting sequence comprises the reactions from free gallic acid (**1**) to 1,2,3,4,6-penta-*O*-galloyl-β-D-glucopyranose (**6**) (Fig. 1). The compounds of this route are often referred to as 'simple galloylglucose esters', primarily to differentiate them unequivocally from higher substituted polygalloylglucoses (gallotannins sensu strictu, for clarity referred to as 'complex gallotannins' here) and neglecting the fact that tetra- and pentagalloylglucoses are very potent tanning agents. Many details of this reaction sequence have recently been described in comprehensive review articles (Gross, 1999a,b; Niemetz et al., 1999); consequently, only the most prominent features of this pathway will be discussed here. As theorized already decades ago (e.g. Haslam, 1989), the end-product of this first sequence, pentagalloylglucose (**6**), has a pivotal role as immediate precursor of two subsequent routes, one leading to (complex) gallotannins which are characterized by additional galloyl residues bound to the pentagalloylglucose core. In an alternative pathway, ellagitannins are formed by oxidative processes that yield C–C linkages between adjacent galloyl groups of pentagalloylglucose and that often lead to the subsequent formation of dimeric and oligomeric derivatives.

2.1. The pathway from gallic acid to pentagalloylglucose

In recent experiments on the still not completely clarified origin of gallic acid (Fig. 1, **1**), the principal phenolic unit of hydrolyzable tannins, [^{13}C]glucose was administered to the fungus *Phycomyces blakesleeanus* and to the dicotyloneous plant *R. typhina,* followed by NMR spectroscopical determination of the isotope distribution of gallic acid and aromatic amino acids isolated from these species. Interpretation of the isotopomer patterns of these metabolites by a retrobiosynthetic approach showed that gallic acid was derived from an early intermediate of the shikimate pathway, most likely 5-dehydroshikimic acid, suggesting that dehydrogenation of this compound was the predominant pathway to gallic acid (Werner et al., 1999). However, alternative routes cannot be excluded.

For thermodynamic reasons, esterification of gallic acid and glucose to yield β-glucogallin (1-*O*-galloyl-β-D-glucose, **2**), the often proposed primary specific metabolite in the route to hydrolyzable tannins, depends on the participation of an 'activated' intermediate with a high group-transfer potential. Enzyme studies revealed that this requirement was met by a common metabolite, UDP-glucose, which was utilized by a glucosyltransferase from oak leaves for the (reversible) synthesis of β-glucogallin (cf. Fig. 1) and of related 1-*O*-acyl-β-D-glucoses

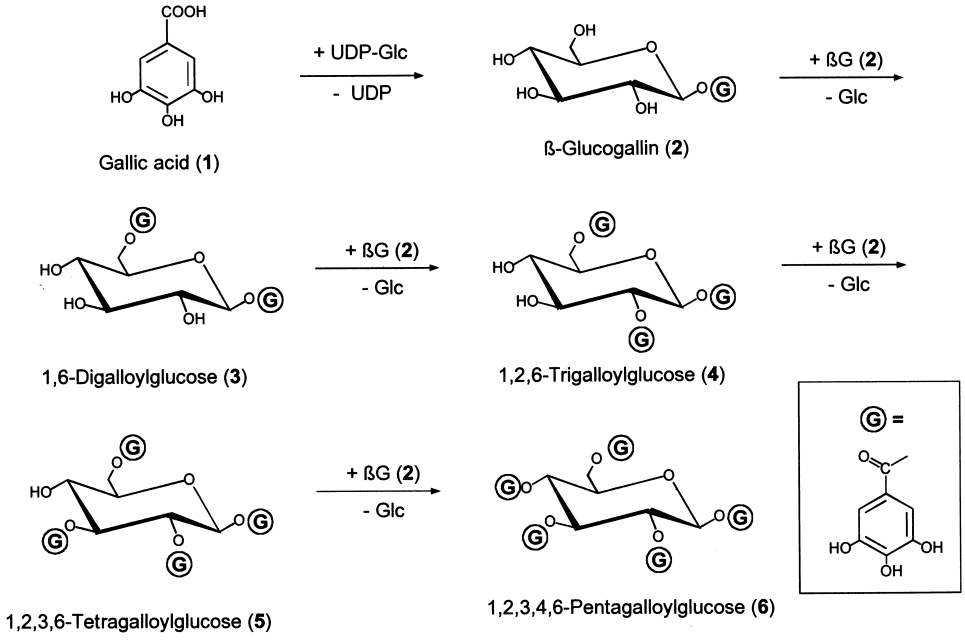

Fig. 1. Enzyme reactions catalyzing the biosynthesis of 1,2,3,4,6-pentagalloylglucose (**6**).

(Gross, 1983a). Cell-free extracts from this plant were also found to catalyze the subsequent transformation of β-glucogallin to di- and trigalloylglucoses, a reaction that surprisingly ocurred in the absence of any other cofactors and which could be explained only by the assumption that β-glucogallin exerted a dual role, functioning not only as acyl acceptor, but also as an efficient acyl donor (Gross, 1983b). Such a behavior would necessarily require that β-glucogallin had the then unexpected characteristic of an energy-rich 'activated' compound. This question was answered by the discovery of Mock and Strack (1993) that a related ester, 1-*O*-sinapoyl-β-D-glucose, had an unexpectedly high $\Delta G_o'$ of 35.7 kJ mol^{-1}, i.e. a value that is comparable to the well-known data for acyl-CoA thioesters. Numerous examples for the reactivity of such acetal esters have been reported meanwhile (for references, see Gross, 1999a,b; Niemetz et al., 1999). It is evident now that phenolic 1-*O*-acylglucose esters, often regarded in the past as metabolically inert compounds, have acquired a prominent position in the secondary metabolism of higher plants.

Further studies with enzymes isolated from oak or sumac revealed that this mechanism applied to the entire route from β-glucogallin (**2**) to pentagalloylglucose (**6**). As depicted in Fig. 1, substitution of glucose hydroxyls was not randomly distributed in these conversions but displayed extreme specificity, thus constituting the metabolic sequence β-glucogallin (**2**)→1,6-digalloylglucose (**3**, Schmidt et al., 1987)→1,2,6-trigalloylglucose (**4**, Gross and Denzel, 1991)→1,2,3,6-tetragalloylglucose (**5**, Hagenah and Gross, 1993)→1,2,3,4,6-pentagalloyl glucose (**6**, Cammann et al., 1989). Interestingly, an identical pattern has been reported for the chemical substitution of glucose hydroxyls in experiments with 1-benzyl or 1-methyl-β-D-glucopyranose which was explained as a combination of reactivity differences according to variations in chemical nature (primary vs secondary hydroxyls), neighboring group activation effects and steric hindrance (Williams and Richardson, 1967; Reinefeld and Ahrens, 1971).

These enzyme studies gave the impression of a straight, forward-directed pathway that depended on β-glucogallin as sole and general acyl donor. However, the existence of other enzymes was encountered that led to side-reactions and ramifications of the main pathway. An acyltransferase was isolated from oak leaves that catalyzed an unusual galloyl exchange between β-glucogallin and free glucose, a reaction that was detectable only by the use of labeled substrates and whose physiological significance is still obscure (Gross et al., 1986). Another enzyme that had been isolated from sumac leaves interfered with the acylation of 1,6-digalloylglucose (**3**) to 1,2,6-trigalloylglucose (**4**) by promoting this reaction without any requirement of the established acyl donor, β-glucogallin (**2**). It was recognized that this enzyme catalyzed a 'disproportionation' reaction in which two molecules 1,6-digalloylglucose were converted to 1,2,6-trigalloylglucose and anomeric 6-*O*-galloylglucose as partially deacylated byproduct (Denzel and Gross, 1991). This latter finding stimulated ideas that, besides β-glucogallin, also higher substituted galloylglucoses could act as acyl donors, provided that they possessed the energetically indispensable 1-*O*-galloyl group. This interpretation was corroborated by substrate specificity studies which, however, revealed that the reactivity of higher substituted analogs was drastically diminished, most likely because of steric hindrance due to excessive bulkiness of these molecules, thus leaving 1-mono- and, within certain limits, 1,6-di-esters as predominating galloyl donors (Denzel and Gross, 1991).

The pathway to pentagalloylglucose, as summarized in Fig. 1, has long been assumed to be unique. However, striking similarities have been reported for the biosynthesis of isobutyroyl-β-D-glucoses in wild tomato (*Lycopersicon penellii*) leaves. A UDP-glucose dependent glucosyltransferase catalyzed the formation of 1-*O*-isobutyroyl-β-D-glucose. This ester, in turn, was utilized as activated acyl donor in a series of substitution reactions that afforded 1,3-di-, 1,2,3-tri- and 1,2,3,4-tetra-*O*-isobutyroyl derivatives, and was also involved in an acyl exchange reaction with free glucose as an analogy to the above mentioned galloyl exchange reaction (Ghangas and Steffens, 1993, 1995; Kuai et al., 1997).

2.2. Biosynthesis of gallotannins

Formally, 'simple' galloylglucoses are converted to complex gallotannins by the addition of further galloyl residues to 1,2,3,4,6-pentagalloylglucose (**6**) to yield the *meta*-depside groups that characterize this class of

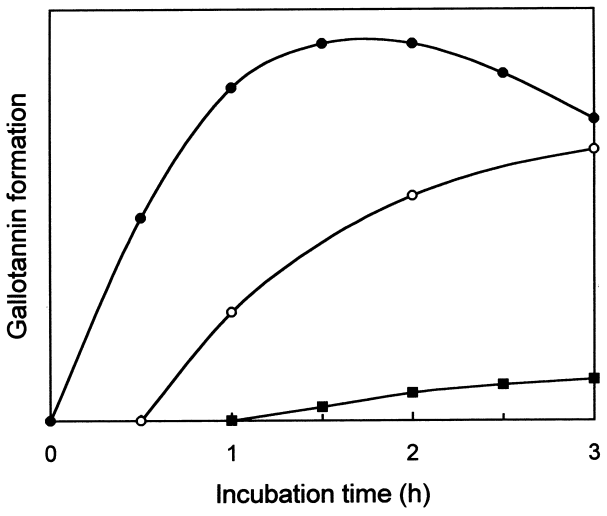

Fig. 2. Enzymatic synthesis of complex gallotannins by galloylation of 1,2,3,4,6-pentagalloylglucose (**6**) in the presence of β-glucogallin with crude enzyme extracts from leaves of *Rhus typhina*. (●), Hexa-, (○), hepta-, (■), octagalloylglucoses (from Gross, 1999a).

phenolic plant constituents (cf. Ⓖ▸Ⓖ in Fig. 3). It must be emphasized that this process is not a mere continuation of the esterification reactions of the preceding steps because the newly introduced galloyl moieties now combine with phenolic hydroxyls whose chemical properties differ significantly from those of the aliphatic OH-groups of glucose. It was thus surprising to discover that crude enzyme preparations from sumac (*R. typhina*) leaves catalyzed the sequential transformation of pentagalloylglucose to complex gallotannins according to the same reaction mechanism as above, i.e. by utilizing β-glucogallin (**2**) as specific galloyl donor (Fig. 2). Such assays afforded a mixture of hexa-, hepta-, octa- and nonagalloylglucoses, together with traces of decagalloyl glucoses, and eventually even of undecagalloylglucoses, as shown by HPLC with normal-phase (Si 60) and reversed-phase (RP-18) columns (Hofmann and Gross, 1990). Evidence for the presumed gallotannin nature of the most abundant enzyme reaction products, hexa- to octagalloylglucoses that had been purified from scaled-up in vitro assays, was obtained by hydrolysis with fungal tannase, leaving gallic acid (**1**) as sole phenolic component. Upon methanolysis, known to exclusively cleave *meta*-depside bonds, these compounds were degraded to 1,2,3,4,6-pentagalloylglucose (**6**) and methyl gallate in the expected molar ratios of 1:1, 1:2, and 1:3, respectively. Structural proof of hexa- and hepta-galloylglucoses was obtained by ^{1}H and ^{13}C NMR spectroscopic analyses and comparison with previously published data on the components of Chinese gallotannin from the related species *R. semialata* (Nishizawa et al., 1982; cf. Fig. 3).

Recent enzyme studies revealed the existence of numerous isoenzymes in sumac (*R. typhina*) leaves that participated in the in vitro acylation of pentagalloylglucose (**6**) to higher substituted derivatives. Among these, four galloyltransferases (transferases A–D) have been isolated and characterized to date. The general properties of these enzymes were found to vary significantly, particularly with respect to the enormous band-width of their molecular weights. It was also apparent that their substrate and product specificities were rather low, a feature that, however, is not uncommon to enzymes of secondary plant metabolism. Accordingly, in order to maintain a clear overall view of the major biogenetic interrelationships, only the most prominent reactions of the pathways from penta- to heptagalloylglucoses (higher substituted gallotannins of defined structure were not available) are reported below (cf. Fig. 3).

Galloyltransferase A has been purified to apparent homogeneity. It had a molecular weight (M_r) of 360,000 and was found to preferentially acylate pentagalloyl glucose (**6**) in the 4-position, followed by substitution of the 2-position, yielding the hexagalloylglucose, 4-*O*-digalloyl-1,2,3,6-tetra-*O*-galloylglucose (**7**), and the hepta galloylglucose, 2,4-bis-*O*-digalloyl-1,3,6-tri-*O*-galloyl-glucose (**10**). Compound (**7**) was the preferred substrate (Niemetz and Gross, 1999). Transferase B (M_r 260,000) also catalyzed the sequence (**6**)→(**7**)→(**10**) but was more effective in the formation of the hexagalloylglucose, 3-*O*-digalloyl-1,2,4,6-tetra-*O*-galloylglucose (**9**), and particularly of the heptagalloylglucose, 3-*O*-trigalloyl-1,2,4,6-tetra-*O*-galloylglucose (**12**) (Niemetz and Gross, unpublished results). Transferase C could also be purified to

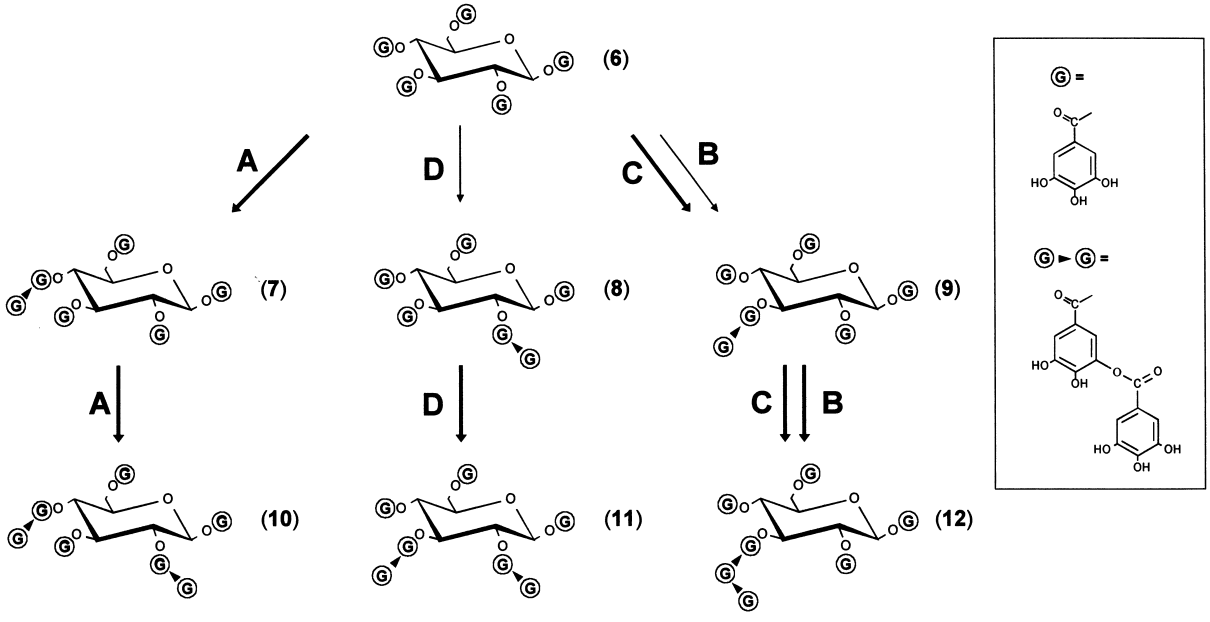

Fig. 3. Major routes in the transformation of pentagalloylglucose (**6**) to hexagalloylglucoses (**7**–**9**) and heptagalloylglucoses (**10**–**12**), catalyzed by galloyltransferases **A**–**D** from sumac (*Rhus typhina*) leaves. Main reactions are symbolized by bold arrows, minor reactions by thin arrows.

apparent homogeneity; it had an M_r of 170,000 and was found to be composed of four identical subunits of M_r 42,000. The preferred substrate for this enzyme was pentagalloylglucose (**6**) which was preferentially acylated to hexagalloylglucose (**9**) and heptagalloylglucose (**12**) (Niemetz and Gross, 1998). Transferase D (M_r 300,000) was detected in a different screening experiment in which hexagalloylglucose (**8**) replaced the standard acceptor substrate of the above investigations, pentagalloylglucose (**6**). This enzyme displayed rather low affinity toward pentagalloylglucose, which was preferentially acylated to the hexagalloylglucose, 2-*O*-digalloyl-1,3,4,6-tetra-*O*-galloylglucose (**8**), but was very effective in acylating this latter compound to the heptagalloylglucose, 2,3-bis-*O*-digalloyl-1,4,6-tri-*O*-galloylglucose (**11**) (Fröhlich and Gross, unpublished results). In summary, the specificities of these enzymes support earlier findings that the C-1 and C-6 positions of 'Chinese gallotannin' from *Rhus semialata* generally remain free of depsidic substituents (Nishizawa et al., 1982), in contrast to the gallotannins from *Quercus infectoria* ('Turkish gallotannin'; Nishizawa et al., 1983a) or *Paeonia lactiflora* (Nishizawa et al., 1980, 1983b) where depside bonds occur also at C-6 of the glucose core.

It should finally be mentioned that the reported reactions bear the risk of interference with nonenzymatic, chemical acyl migrations. We observed, for instance, a significant translocation of the distal, *meta*-depsidically bound galloyl group of hexagalloylglucose (**9**) from the 3-position to the adjacent 4-position to yield hexagalloylglucose (**7**) under slightly acidic conditions (Bayer and Gross, unpublished results).

2.3. Biosynthesis of ellagitannins

In contrast to the rather limited distribution of gallotannins in nature, ellagitannins are typical constituents of many plant families. These compounds display an enormous structural variability that results from the manifold possible sites for the linkage of HHDP (**14**) residues with the glucose moiety (which, in turn, can adopt several conformations that control the range of possible spatial arrangements of reactive ligands), and particularly by their strong tendency to form a multitude of dimeric and oligomeric derivatives being interconnected by C–C and C–O–C linkages (recently reviewed by Haslam, 1998). This structural diversity of ellagitannins, together with their recently recognized role as promising chemotherapeutic agents (e.g. Yoshida et al., 1999; Miyamoto et al., 1999), have attracted the interest of chemists for decades, culminating in recent successful efforts on the extreme challenge of synthesizing ellagitannins by chemical means (Feldman et al., 1999).

Progress in the study of the biosynthesis of ellagitannins was significantly slower (cf. Helm et al., 1999). It has been postulated very early that the HHDP residues of ellagitannins should originate from the dehydrogenation of neighboring galloyl groups of 1,2,3,4,6-pentagalloylglucose (**6**) (reviewed by Haslam, 1989). In the case of the preferred $^4C_1$ configuration of pentagalloylglucose, for instance, the two galloyl groups at C-4 and C-6 were thought to be interconnected to form one HHDP group, thus yielding tellimagrandin II (**13**) as a primary ellagitannin metabolite that can be subjected to further oxidation reactions. Hydrolysis of (**13**) would afford both free gallic acid (**1**) and hexahydroxydiphenic acid (**14**), the latter possessing a strong tendency to spontaneously undergo lactonization to give ellagic acid (**15**) (Fig. 4).

Many attempts to unravel the mechanism of ellagitannin biosynthesis have been carried out by experiments with chemical oxidants (e.g. O_2, Fe^{3+}) or by studies with the enzymes laccase and peroxidase, using gallic acid, methyl gallate, β-glucogallin, 3,6-digalloylglucose or pentagalloylglucose as substrates (references in Gross, 1999b). Only free ellagic acid (**15**), however, was detected as a typical product in these experiments, while the formation of true ellagitannins, characterized by glucose-bound HHDP residues, was never observed.

Considering these negative results, it was apparent that new strategies were required that combined both increased specificity and higher sensitivity to tackle the question of ellagitannin biosynthesis. A common way to eliminate such problems is the use of radioactively labeled compounds, which in this specific case also would provide an excellent tool to discriminate between true in vitro enzyme reaction products and any contaminating ellagitannins that had been formed in vivo and were transferred to the assays by unspecific binding to proteins due to their tannin nature. We therefore synthesized [U–^{14}C]pentagalloylglucose by photoassimilation of $^{14}CO_2$ in leaves of *R. typhina* (Rausch and Gross, 1996). Using this compound as standard substrate in an extended screening program, based on the considerations depicted in Fig. 4 and aiming at the detection of in vitro formed [^{14}C]ellagic acid-liberating products, we were finally able to isolate and partially purify a soluble enzyme fraction from leaves of *Tellima grandiflora* (saxifragaceae) that catalyzed the conversion of [U–^{14}C]pentagalloylglucose to several radioactively labeled products (Fig. 5A). Major components among these products were purified by semipreparative HPLC and subsequently hydrolyzed, releasing [^{14}C]glucose, [^{14}C]gallic acid (**1**) and [^{14}C]ellagic acid (**15**) as labeled degradation products (cf. Fig. 5B), thus indicating the preceding in vitro formation of true ellagitannins (Niemetz et al., 2001). ^{1}H NMR spectroscopy (500 MHz) of one of the most prominent enzyme reaction products obtained in these experiments showed signals that were analogous to those of an authentic sample of tellimagrandin II (**13**), i.e. the compound that traditionally

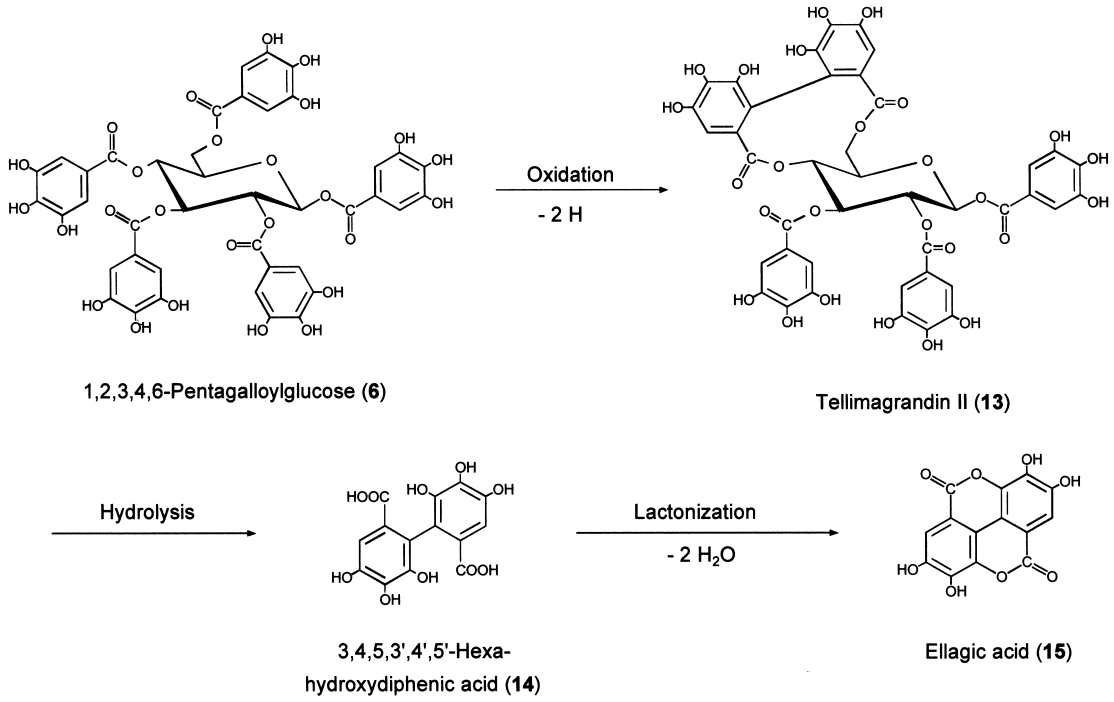

Fig. 4. Oxidation of pentagalloylglucose to the ellagitannin, tellimagrandin II (**13**), and formation of ellagic acid (**15**) via hydrolytically released hexahydroxydiphenic acid (**14**) as characteristic degradation product of ellagitannins.

has been proposed as primary metabolite in the oxidation of pentagalloylglucose to ellagitannins. In particular, three prominent singlets at δ ppm (TMS) 7.04 (2H), 6.94 (2H) and 6.92 (2H) were detected in methanol-d_4 that corresponded to the aryl-2,6 hydrogens at C-1, C-2 and C-3 of tellimagrandin II (**13**), respectively, while the singlets at δ 6.60 (1H) and 6.47 (1H) were due to the 2- and 2′-hydrogens of diphenic acid at C-4,6. Furthermore, also the chemical shifts for the glucose moiety were in full agreement with those of the authentic sample of (**13**). Additional signals were observed that were interpreted to result from a C-2,3 linked HHDP unit, suggesting the eventual in vitro formation also of compounds like casuarictin (**16**) or pedunculagin (**17**) (Fig. 6). Summarizing these data, it is evident that the evasive clue to clarify the mechanism of ellagitannin biosynthesis has been found in these investigations.

3. Subcellular sites of biosynthesis and deposition of hydrolyzable tannins

In the course of the above reported biochemical investigations it became increasingly evident that only limited reliable data was available on all aspects related to the histology of hydolyzable tannins, and tannins in general. This was not really surprising with respect to considerations on their biogenesis, an aspect that has been investigated only recently in the case of hydrolyzable tannins while the routes to condensed tannins are still a matter of speculation. However, also reports on

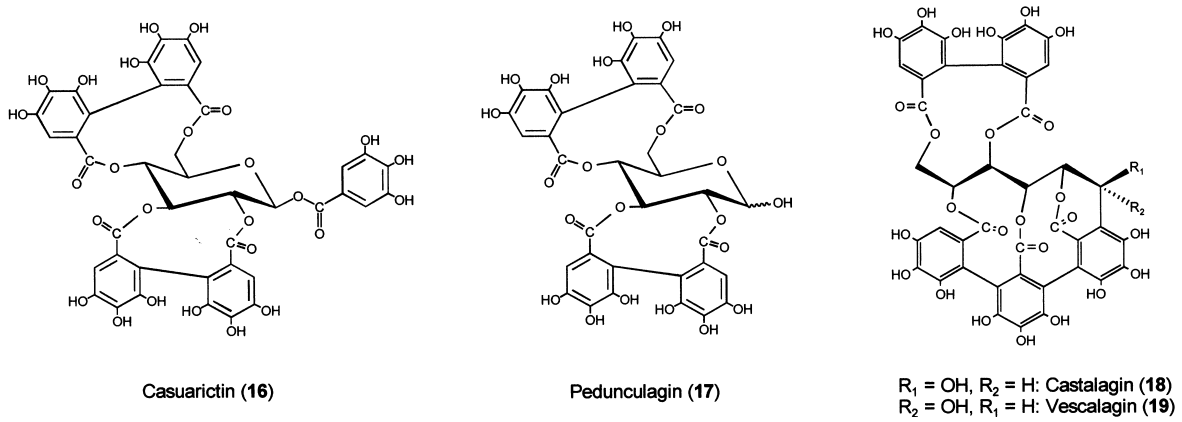

Fig. 6. Structures of prominent ellagitannins (**16**–**19**) from oak.

the localization of tannins are characterized by remarkable ambiguity, despite abundant knowledge of the structures and properties of these compounds that should have facilitated studies in this area. Consequently, such different epitopes like plastids, dictyosomes, smooth or rough endoplasmatic reticulum and vacuoles (including 'tannin vacuoles') have been proposed as subcellular compartments of polyphenolic compounds (references in Kaspar et al., 1998).

It must be emphasized that all these histological studies had been performed with common but rather unspecific staining reagents (e.g. Fe^{3+} or Fe^{2+} ions, $Cr_2O_7^{2-}$, vanillin/HCl, neutral red, methylene blue, toluidine/molybdate, etc.), thus preventing their unequivocal identification and discrimination from other phenolic plant constituents. When closer identification of tannins had been attempted in a few cases, they were classified as proanthocyanidins on the mere basis of the above unspecific criteria.

A well established method that avoids such problems is the use of immunocytochemical techniques that combine both specificity and sensitivity. Besides their traditional application to localize macromolecules they have also gained increasing importance in the detection of low-molecular weight compounds. Considering the essential role of 1,2,3,4,6-pentagalloylglucose (**6**) in the biosynthesis of gallotannins and ellagitannins, and hence also of the acyltransferase catalyzing the synthesis of this pivotal metabolite, we decided to use this representative metabolic step as a specific marker to detect the sites of synthesis and cellular localization of hydrolyzable tannins (Fig. 7). For this purpose, we produced two antibodies, one raised against pentagalloylglucose as antigen, and a second one which was directed against

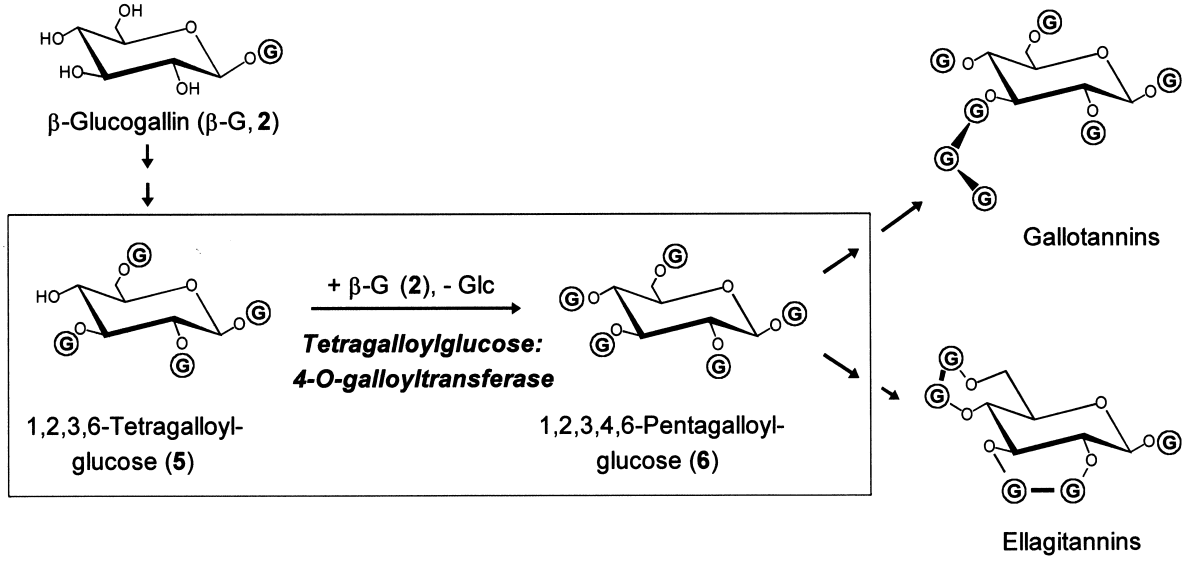

Fig. 7. Key function of the enzyme, β-glucogallin: 1,2,3,6-tetra-*O*-galloyl-β-D-glucose 4-*O*-galloyltransferase, in the pathway from β-glucogallin to gallotannins (example: heptagalloylglucose **12**) and ellagitannins (example: casuarictin 16) via 1,2,3,4,6-penta-*O*-galloyl-β-D-glucose as immediate common precursor. the enzyme, β-glucogallin: 1,2,3,6-tetragalloylglucose 4-*O*-galloyltransferase, for immunohistochemical studies.

3.1. Preparation and characterization of antibodies

As a preriquisite for the production of antibodies against 1,2,3,4,6-penta-*O*-galloyl-β-D-glucose (**6**) it was necessary to bind this low-molecular compound (M_r 940) on a macromolecule, preferentially a protein, to give it immunogenic properties. Bovine serum albumin or keyhole limpet hemocyanin were therefore substituted with *p*-aminohippuric acid, followed by diazotation of this linking unit and final coupling with the hapten, pentagalloylglucose. Crude antisera obtained by immunization of rabbits with these antigens were purified by affinity chromatography on Sepharose-coupled pentagalloylglucose (Kaspar et al., 1998). Cross reactivities of this pure antibody were analyzed in a heterogenous competitive ELISA (Weiler et al., 1981) with solid-phase adsorbed anti-pentagalloylglucose IgG and chemically synthesized antigen-peroxidase conjugate. Not unexpectedly owing to the polyphenolic nature of the antigen, high reactivities were observed with penta- to nonagalloylglucoses and with structurally related ellagitannins, pedunculagin (**18**) and vescalagin (**19**). In contrast, insignificant cross-reactivity, or none at all, was displayed with biogenetic precursors or degradation products of hydrolyzable tannins, i.e. glucose, gallic acid (**1**), β-glucogallin (**2**) and ellagic acid (**15**), as well as with numerous low-molecular phenolics, including coniferyl alcohol as the principal monomeric unit of the polyphenolic cell wall constituent lignin. In contrast to the highly cross-reactive hydrolyzable tannins, condensed tannins (procyanidin B-3 and B-4) and their monomeric precursors, e.g. catechin and structurally related flavanoids, were inactive. Monomeric, dimeric and polymeric carbohydrates, including high-molecular plant cell wall components (pectin, polygalacturonic acid, xylan), exhibited no affinity toward the antibody. In summary, this pentagalloylglucose-derived polyclonal antibody (referred to as 'anti-tannin' serum below) provided a reliable tool for the specific detection of hydrolyzable tannins (i.e. gallotannins and ellagitannins) without interference with proanthocyanidins, low-molecular polyphenolic substances or aliphatic polyhydroxylated compounds.

For the preparation of anti-galloyltransferase, rabbits were vaccinated with pure denatured 4-*O*-galloyltransferase from oak leaves. Crude antisera were purified by ammonium sulfate precipitation, chromatography on protein-A and gel filtration and a final affinity complexation step (Olmsted, 1981), affording pure polyclonal antibodies that showed no cross-reactivity with cell-free extracts from staghorn sumac (*Rhus typhina*), known to produce high concentrations of gallotannins via a metabolic pathway identical to that in oak, nor with extracts from leaves of *Tellima grandiflora*, a rich source of pentagalloylglucose-derived ellagitannins, nor with spinach (*Spinacia oleracea*) leaves being devoid of tannins (Grundhöfer and Gross, 2000).

3.2. Immunohistochemical studies

Tannin and galloyltransferase epitopes were analyzed by light-microscopical examination of semi-thin cross sections (0.5 μm) from pedunculate oak (*Q. robur*) leaves. After specifically blocking endogenous peroxidase with trypsin/H_2O_2, sections were successively treated with anti-tannin or anti-transferase serum (replaced by corresponding pre-immune sera in controls), respectively, followed by goat anti-rabbit IgG-peroxidase complex and diaminobenzidine (DAB) which resulted in significant staining of chloroplasts and cell walls (Fig. 8). Similar staining patterns were obtained with anti-rabbit IgG-alkaline phosphatase complex as secondary antibody. Analogous experiments with sumac (*R. typhina*) revealed an identical staining of chloroplasts and cell walls upon treatment with anti-tannin serum, while no reaction occurred with anti-galloyltransferase IgG, thus demonstrating the high specificity of this antibody that had been raised against enzyme from oak (Grundhöfer and Gross, 2000). Cross sections from (tannin-free) spinach, used as control in these experiments, were inactive with both antisera.

More conclusive information was obtained by transmission electron microscopy of ultra-thin sections (0.1 μm) from oak leaves that had been treated with anti-galloyltransferase and anti-rabbit immunogold IgG, revealing that the enzyme occurred in the undifferentiated cytosol and in the intercellular space, displayed more pronounced affinity to chloroplasts (particularly to starch grains), and was preferentially associated with cell walls, as depicted in Fig. 9A. Parallel experiments with anti-tannin IgG applied to ultra-thin sections from caffeine-pretreated tissues (to prevent leaching of phenolics into the cytoplasm; Mueller and Greenwood, 1978) revealed that immunogold labeling was primarily associated with cell walls (Fig. 9B), while the cytoplasmatic regions beetwen cell walls and chloroplasts showed only traces of gold particles. In both cases, no reaction was observed in controls with pre-immune serum (Fig. 9D and E). Of particular interest were results from double-labeling experiments with both antibodies which revealed a close association of 4-*O*-galloyltransferase and hydrolyzable tannins to form characteristic 'clusters' that were preferentially located in the cell walls, but also occurred in the intracellular space and the cytoplasm (Fig. 9C). Similar tannin deposition patterns were observed with ultra-thin sections from leaves of sumac (*R. typhina*) and *T. grandiflora* which, however, displayed no affinity toward the antibody directed against the 4-*O*-galloyltransferase from oak. As above, controls with spinach leaves where inactive throughout.

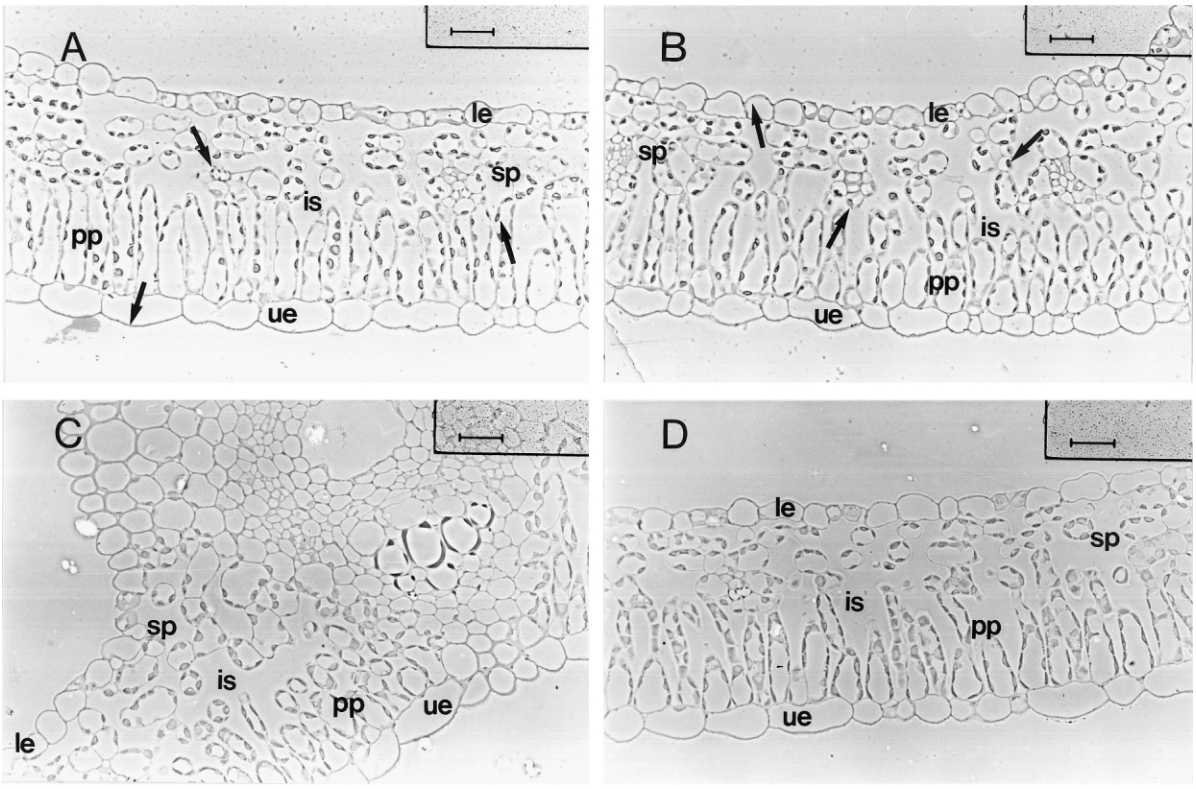

Fig. 8. Light microscopical determination of 4-*O*-galloyltransferase and hydrolyzable tannin epitopes in semi-thin cross-sections from leaves of *Quercus robur* by treatment with anti-galloyltransferase (A) and anti-tannin IgG (B), respectively, and subsequent peroxidase-diaminobenzidine staining; (C, D), controls with pre-immune sera. Arrows point to characteristic color reactions of cell walls and chloroplasts. is, Intercellular space; le, lower epidermis; pp, palisade parenchyma; sp, spongy parenchyma; ue, upper epidermis. Bars represent 15 μm (A, C; ×40) and 25 μm (B, D; ×60).

The logical assumption of a largely apoplasmatic origin and deposition site of hydrolyzable tannins, comprising both cell walls and intracellular space, was confirmed by analyzing these compartments for the occurrence of 4-*O*-galloyltransferase and galloylglucose esters. For this purpose, we used an unpublished washing method (G. Hrazdina, Cornell University) in which young oak leaves were infiltrated with water under slight vacuum (200 mbar). After slowly releasing the vacuum to avoid cell rupture, the leaves were centrifuged at 3000 *g* to yield cell wall extracts that contained gallic acid and mono- to hexagalloylglucoses esters, together with activity of the marker enzyme, 4-*O*-galloyltransferase, as shown by HPLC, enzyme assays and immuno dot blot tests (unpublished results). Similar results were obtained with extracts from *R. typhina* and *Q. robur* leaves.

Summarizing these data, it is evident that walls of leaf mesophyll cells represent a major site for the formation and deposition of hydrolyzable tannins. This conclusion is in clear contrast to numerous earlier reports on 'tannin vacuoles' (e.g. Chafe and Durzan, 1973; Diers et al., 1973; Zobel, 1986; Lees et al., 1993). Considering the rather unspecific staining procedures employed in these studies, however, it is uncertain what phenolic plant metabolites have actually been detected in these investigations. On the other hand, our data are consistent with observations on the immunocytochemically determined accumulation of flavonoids in cell walls of *Chrysosplenium americanum* (Charest et al., 1986; Marchand et al., 1987) and they are further supported by recent considerations on chemical interactions between lignins and hydrolyzable tannins in wood (Helm et al., 1997). An obvious explanation for the currently available data is that cytotoxic hydrolyzable tannins are rapidly excreted into the apoplast or, more efficiently, that they are directly produced and deposited in this compartment where they can exert their protecting potential without harming cytoplasmatic components.

4. Seasonal turnover of hydrolyzable tannins in cell walls

It was apparent that the above cell wall extraction method provided an excellent tool to study the concentrations of hydrolyzable tannins in this compartment without requiring abundant quantities of plant material. We thus determined the amounts of gallic acid and mono- to hexagalloylglucoses (the occurrence of higher substituted derivatives and ellagitannins was not analyzed in these experiments) in 3-month-old leaves of *Q. robur*, i.e. at a developmental stage in which the activity

A: Anti-galloyltransferase treated mesophyll cells (10 nm gold particles; ×11,000); B: anti-tannin treated mesophyll (20 nm gold particles; ×30,000); C: double labeling with anti-galloyltransferase and anti-tannin IgG (particle sizes as above; ×34,000); D: control to A with pre-immune serum (×30 000): E: control to B (×5,000). Arows indicate typical epitopes of enzyme and hydrolyzable tannins. cp, Chloroplast; cw, cell wall; cy, cytoplasm; er, endoplasmatic reticulum; is, intercellular space; m, mitochondrium; ml, middle lamella; sg, starch grain; v, vacuole.

of the marker enzyme, 4-*O*-galloyltransferase, had reached its maximum as shown by immuno dot blot tests. Tetra- and particularly pentagalloylglucose were found to be the most prominent metabolites, while the concentration of hexagalloylglucoses was significantly lower. A similar pattern was determined with extracts from *T. grandiflora*, in contrast to *R. typhina* where hexagalloylglucoses represented the predominant galloylglucose fraction. It is feasible to assume that these data reflect the marked biogenetic differences between these plants, according to which complex gallotannins are exclusively formed from pentagalloylglucose in *R. typhina*, while *Q. robur* and *T. grandiflora* oxidize this intermediate to ellagitannins.

These observations stimulated experiments in which the seasonal changes of hydrolyzable tannins and their precursors in oak leaves were analyzed. As depicted in Fig. 10, the concentrations of gallic acid (**1**) and of monogalloylglucoses, in particular β-glucogallin (**2**), were constantly rather low but nevertheless displayed a maximum in the third month. The tetragalloylglucose fraction had a first maximum in the second month that corresponded to 1,2,3,6-tetragalloylglucose (**5**), and a second peak late in the year with high concentrations of

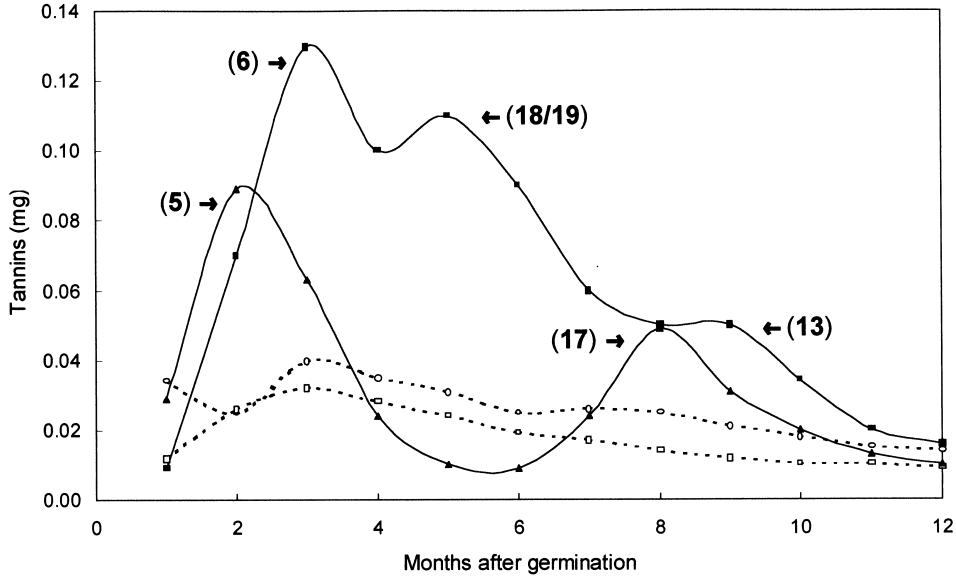

Fig. 10. Seasonal changes of hydrolyzable tannins and their precursors in extracts from cell walls and intercellular space of greenhouse-grown *Quercus robur* leaves. ○, Gallic acid (**1**); □, monogalloylglucoses, e.g. β-glucogallin (**2**); ▲, tetragalloylated derivatives; ■, pentagalloylated derivatives. The following tannin metabolites were identified: 1,2,3,6-tetragalloylglucose (**5**), 1,2,3,4,6-pentagalloylglucose (**6**), tellimagrandin II (**13**), pedunculagin (**17**), castalagin/vescalagin (**18**, **19**).

an ellagitannin, pedunculagin (**17**). Pentagalloylglucoses displayed a first maximum after three months, with 1,2,3,4,6-pentagalloylglucose (**6**) as characteristic metabolite which was transformed to ellagitannins like castalagin/vescalagin (**18**, **19**) accumulating in the fifth month, and tellimagrandin II (**13**) that appeared in late fall. It is evident from these results that 'simple' galloylglucoses were preferentially formed in spring, followed by oxidation to ellagitannins in summer and eventual degradation reactions in fall. Similar observations have been reported for the hydrolyzable tannins from leaves of *Liquidambar formosana* (Hamamelidaceae) by Hatano et al. (1986).

5. Conclusions

The above reported enzyme studies describe the intermediates and reaction principles involved in an extended biochemical pathway that ranges from a simple phenolic plant constituent, gallic acid, to highly substituted complex gallotannins. This laborious but highly evidential technique has also provided first insights into the transition of pentagalloylglucose, often regarded as the pivotal metabolite in the biosynthesis of hydrolyzable tannins, to ellagitannins, thus superseding critical statements that have still been formulated only one year ago (Gross, 1999a; Niemetz et al., 1999). It is hoped that the mechanism(s) of these oxidative processes will be understood in the near future to solve the old enigma of ellagitannin biosynthesis.

An unexpected result was obtained in the above described immunohistochemical studies on the origin and intracellular deposition of hydrolyzable tannins. In clear contrast to numerous reports describing the existence of tannin vacuoles, we were unable to find evidence supporting this view in experiments with specific antibodies. Instead, we observed pronounced affinities to leaf mesophyll cell walls, giving this apoplasmatic compartment a characteristic role as deposition site of hydrolyzable tannins (in addition to established cell wall polyphenols like lignins or suberin-associated aromatic derivatives), while the contents of tannin vacuoles must be considered now as (poly)phenolic compounds of uncertain nature that were detected by unspecific color reactions. We are confident that the *bon mot* of R. H. Davis (cited from Hrazdina, 1992) that *"the subcellular localization of small molecules is easy to believe, but difficult to prove"* does not apply to our studies related to hydrolyzable tannins.

Acknowledgements

We thank Angelika Müller (Ulm) for excellent technical assistence, and Professor Geza Hrazdina (Cornell University, Geneva) for valuable suggestions and making available unpublished methods. Generous financial support from the Deutsche Forschungsgemeinschaft (Bonn), the Fonds der Chemischen Industrie (Frankfurt/M.) and from research grants of the University of Ulm are gratefully acknowledged.

Review

Pectins: structure, biosynthesis, and oligogalacturonide-related signaling

Brent L. Ridley, Malcolm A. O'Neill, Debra Mohnen*

Complex Carbohydrate Research Center and Department of Biochemistry and Molecular Biology, University of Georgia, 220 Riverbend Road, Athens, GA 30602-4712, USA

Received 2 October 2000; received in revised form 11 December 2000

Abstract

Pectin is a family of complex polysaccharides present in all plant primary cell walls. The complicated structure of the pectic polysaccharides, and the retention by plants of the large number of genes required to synthesize pectin, suggests that pectins have multiple functions in plant growth and development. In this review we summarize the current level of understanding of pectin primary and tertiary structure, and describe new methods that may be useful to study localized pectin structure in the plant cell wall. We also discuss progress in our understanding of how pectin is biosynthesized and review the biological activities and possible modes of action of pectic oligosaccharides referred to as oligogalacturonides. We present our view of critical questions regarding pectin structure, biosynthesis, and function that need to be addressed in the coming decade. As the plant community works towards understanding the functions of the tens of thousands of genes expressed by plants, a large number of those genes are likely to be involved in the synthesis, turnover, biological activity, and restructuring of pectin. A combination of genetic, molecular, biochemical and chemical approaches will be necessary to fully understand the function and biosynthesis of pectin. © 2001 Elsevier Science Ltd. 1. Structure

1.1. Introduction

A generally accepted primary structure of pectin has emerged from cumulative studies spanning the last 70 years. The pectins used in these studies were typically isolated from plants of economic importance (e.g. citrus, tomato, sugar beet, apple) or from suspension-cultured cells (e.g. sycamore, carrot, spinach, and rose). However, these plants represent only a small fraction of the total number of known flowering plants (~235,000 species), and little is known about the pectin of green algae, liverworts, mosses, and ferns. The characterization of pectin from lower plants, from cell wall mutants, and from plants that grow in extreme environments may reveal hitherto unknown pectin structures and provide further insight into the origins and functions of these complex polysaccharides.

In this section we briefly describe what is currently known about the chemical structures of pectin. We also provide an overview of some new approaches to studying localized pectin structure that may increase our knowledge of the biological functions of pectin.

1.2. The chemical structure of primary cell wall pectins

Pectins are a family of complex polysaccharides that contain 1,4-linked α-D-galactosyluronic acid (Gal*p*A) residues. Three pectic polysaccharides (homogalacturonan, rhamnogalacturonan-I, and substituted galacturonans) have been isolated from primary cell walls and structurally characterized (O'Neill et al., 1990; Visser and Voragen, 1996).

Homogalacturonan (HG) is a linear chain of 1,4-linked α-D-galactopyranosyluronic acid (Gal*p*A) residues in which some of the carboxyl groups are methyl esterified (Fig. 1). HGs may, depending on the plant

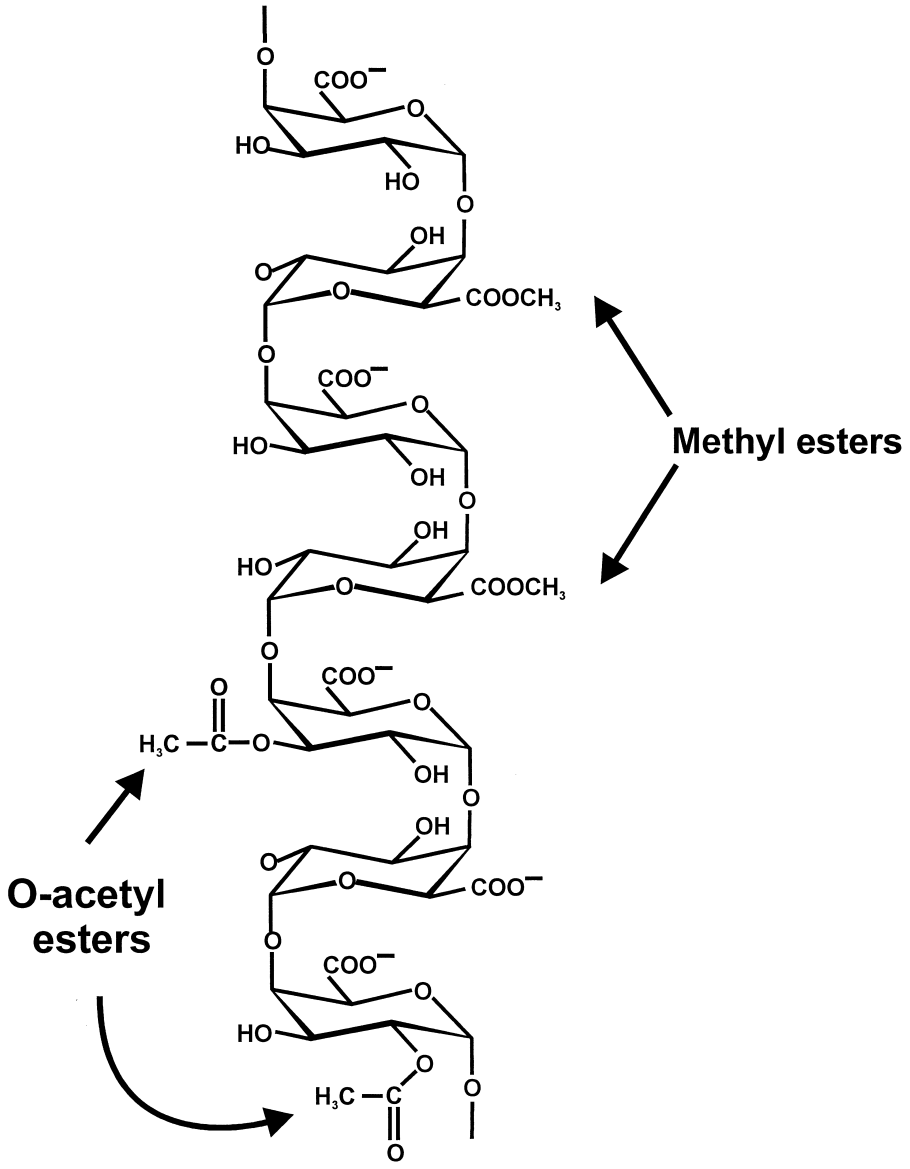

Fig. 1. The primary structure of homogalacturonan. Homogalacturonan is a linear polymer of 1→4 linked α-D-Gal*p*A residues. Some of the carboxylates of the Gal*p*A residues are esterified with methanol. The Gal*p*A residues may also be esterified with acetic acid at C2 and C3. At least three enzymes homgalacturonan galacturonosyltransferase, homogalacturonan methyltransferase, and homogalacturonan acetyltransferase are required for the synthesis of HG (see Table 1 for details).

source, also be partially O-acetylated at C-3 or C-2 (Ishii, 1995, 1997a).

Rhamnogalacturonan-I (RG-I) is a family of pectic polysaccharides that contain a backbone of the repeating disaccharide [→4)-α-D-Gal*p*A-(1→2)-α-L-Rhap-(1→] (Fig. 2). The backbone Gal*p*A residues may be *O*-acetylated on C-2 and/or C-3 (Komalavilas and Mort, 1989). There is no conclusive chemical evidence that the Gal*p*A residues are methyl esterified, however, an enriched RG-I-like wall fraction from flax has been reported to contain methyl esters (Rihouey et al., 1995). The Gal*p*A residues typically are not substituted with mono- or oligosaccharide side chains, although a recent study reported that a single β-D-Glc*p*A residue is linked to C-3 of ~2% of the Gal*p*A in the backbone of sugar beet RG-I (Renard et al., 1999). In contrast, 20–80% of the rhamnosyl (Rha*p*) residues are, depending on the plant source and method of isolation, substituted at C-4 with neutral and acidic oligosaccharide side chains (O'Neill et al., 1990). The predominant side chains contain linear and branched α-L-arabinofuranosyl (Ara*f*), and/or β-D-galactopyranosyl (Gal*p*) residues (Fig. 2), although their relative proportions and chain lengths may differ depending on the plant source (Lerouge et al., 1993). The glycosyl residues α-L-fucosyl (Fucp), β-D-glucuronosyl (Glc*p*A), and 4-*O*-methyl β-D-glucuronosyl (4-*O*-Me GlcpA) may also be present (O'Neill et al., 1990), as may ferulic and coumaric acid (Saulnier and Thibault, 1999).

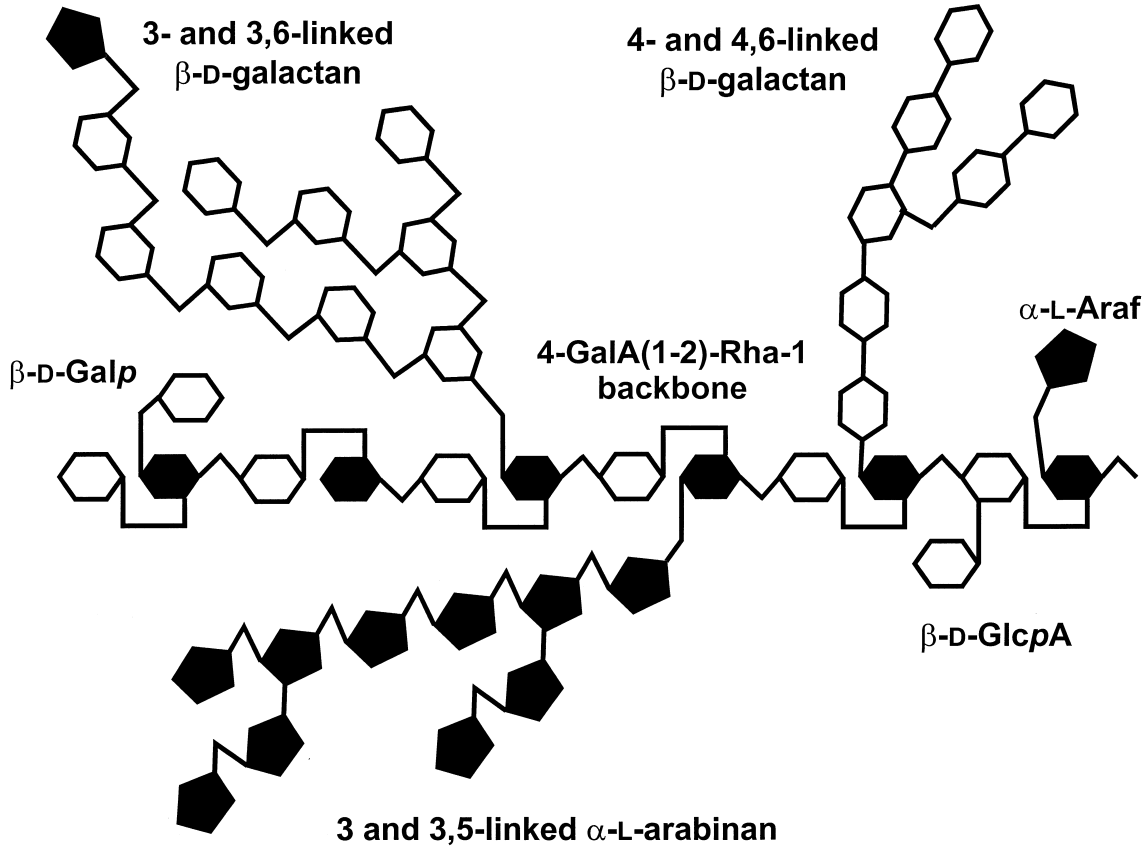

Fig. 2. A model showing the major structural features of rhamnogalacturonan I. The backbone is composed of the disaccharide repeating unit [→4-α-D-Gal*p*A-(→2)-α-L-Rhap-(1→]. Branched and linear oligosaccharides composed predominantly of α-L-Ara*f* and β-D-Gal*p* residues are linked to C4 of some of the Rha*p* residues. Some of the Rha*p* residue may also be *O*-acetylated at C2 and/or C3. More than ten glycosyltransferase activities are required for the biosynthesis of RG-I (see Table 2 for details).

Substituted galacturonans (SG) are a diverse group of polysaccharides that contain a backbone of linear 1,4-linked α-D-Gal*p*A residues (O'Neill et al., 1990). The substituted galacturonan referred to as rhamnogalacturonan II (RG-II) is present in all higher plant primary walls analyzed to date (O'Neill et al., 1990). The demonstration that wine and other fruit juices contain relatively high amounts (20–150 mg/l) of RG-II (Doco et al., 1997), that RG-II binds heavy-metals (Pellerin et al., 1997, Pellerin and O'Neill, 1998; Szpunar et al., 1999; Tahiri et al., 2000), and that RG-II has immunomodulating activities (Shin et al., 1998) has led to a greater interest in the structure of RG-II and to the role of this enigmatic pectic polysaccharide in human nutrition and health.

RG-II is *not* structurally related to RG-I since its backbone is composed of 1,4-linked α-D-Gal*p*A residues rather than the repeating disaccharide [→4)-α-D-Gal*p*A-(1→2)-α-L-Rhap-(1→] (O'Neill et al., 1990). A nonasaccharide (side chain B) and an octasaccharide (side chain A) are attached to C-2 of some of the backbone GalA residues and two structurally different disaccharides (side chains C and D) are attached to C-3 of the backbone (Fig. 3). The locations on the backbone of the side chains with respect to one another have not been established with certainty.

Other substituted galacturonans have been described that are present in the walls of a restricted number of plants. For example, xylogalacturonans (XGA), which contain β-D-xylosyl (Xylp) residues attached to C-3 of the backbone (Kikuchi et al., 1996; Yu and Mort, 1996; Schols et al., 1995; O'Neill et al., 1990; Aspinall, 1980), are present in the walls of reproductive plant tissues (e.g. apple, carrot, cotton, and pine). Apiogalacturonans, which are present in the walls of some aquatic monocotyledons (e.g. *Lemna* and *Zostera*), contain β-D-apiofuranosyl (Api*f*) residues attached to C-2 and C-3 of the backbone either as a single Api*f* residue or as the disaccharide β-D-Api*f*-(1→3′)- β-D-Apif-(1→(Hart and Kindel, 1970a,b; Cheng and Kindel, 1997).

1.3. Advances in the structural analysis of cell wall pectic polysaccharides

1.3.1. Homogalacturonan and rhamnogalacturonan I

The availability of exo- and endoglycanases, and endolyases that fragment HG and RG-I has led to a greater understanding of the structure of these pectic

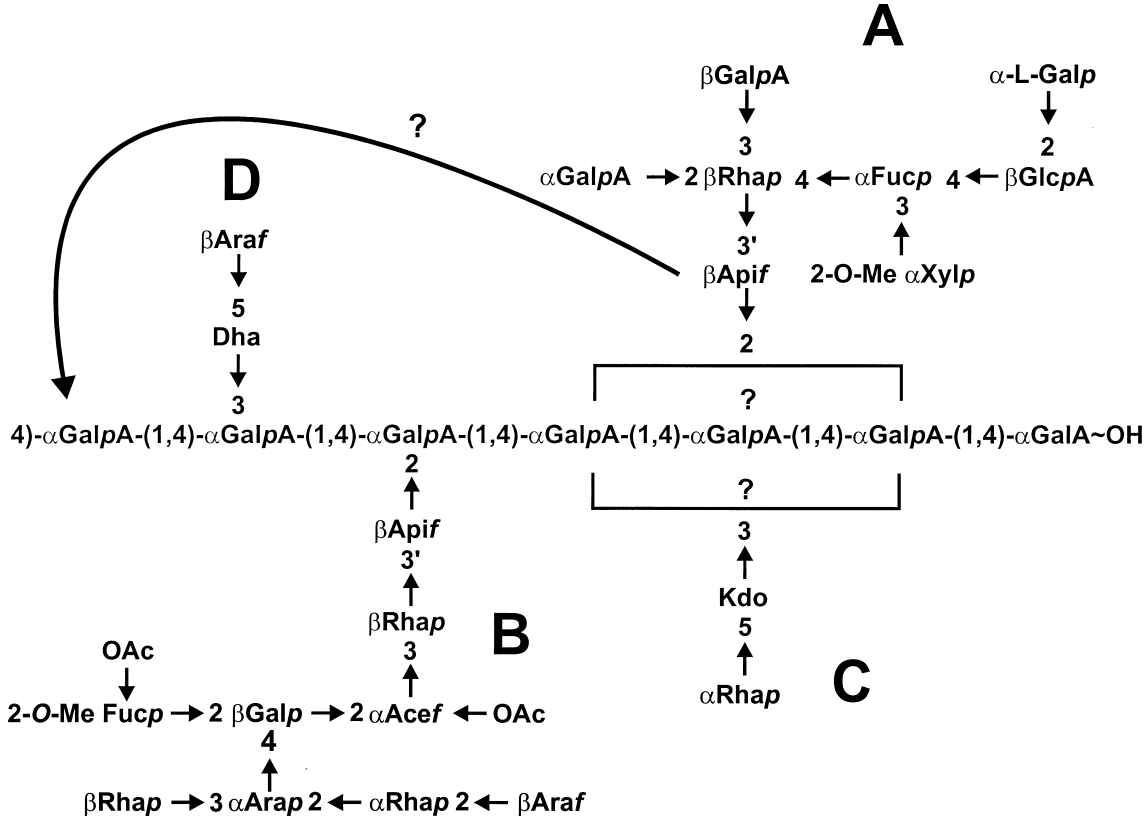

Fig. 3. The primary structure of rhamnogalacturonan II. The backbone of RG-II is composed of at least seven 1→4 linked α-D-Gal*p*A residues. Four structurally different oligosaccharide side chains (A–D) are linked to the RG-II backbone. The anomeric configurations of the glycosyl residues present in side chain B have been determined by high resolution NMR spectroscopy. The anomeric configurations of the glycosyl residues in side chain A are taken from Melton et al., 1986, but have not been confirmed by high resolution NMR spectroscopy. The order of the side-chains has not been unambiguously determined. At least 20 glycosyltransferase activities are required for the biosynthesis of RG-II (see Table 3 for details).

polysaccharides (Prade et al., 1999). For example, rhamnogalacturonase, rhamnogalacturonan lyase, rhamnogalacturonan-rhamnohydrolase, rhamnogalacturonan-galacturonohydrolase, and exo- and endogalacturonases, arabinanases and galactanases have been used to refine the structural features of RG-I (Prade et al., 1999). These enzymes, which have been isolated from fungi and bacteria, also provide insight into the wide range of enzymes that microorganisms secrete to fragment HG and RG-I (De Vries et al., 2000).

The distribution of methyl esters in HG has been investigated using chemical methods (Mort et al., 1993) and by treating walls, or isolated pectin, with pectin methylesterase (PME), endopolygalacturonase (EPGase), and endopectin lyase (PL) in combination with NMR spectroscopy (Grasdalen et al., 1988) and mass spectrometry (Daas et al., 1998; Limberg et al., 2000a). The results of such studies have demonstrated that commercially prepared pectin typically has a less regular pattern of methyl esterification than HGs isolated from cell walls, presumably due to the methods used to extract the pectin from the plant material. Mass spectrometry and anion-exchange chromatography, in combination with EPGase and PL fragmentation, have been used to show that plant PMEs cause blockwise de-esterification of pectin, whereas microbial PMEs typically cause random de-esterification (Limberg et al., 2000b).

1.3.2. Rhamnogalacturonan II

RG-II is present in primary walls predominantly as a dimer that is cross-linked by a 1:2 borate-diol ester (Kobayashi et al, 1996; Ishii et al., 1999). This cross-link is formed between OH-2 and OH-3 of the apiosyl residues in each monomeric RG-II subunit. Two diastereoisomers are formed (see Fig. 4) when methyl β-D-apiofuranoside is reacted with borate at pH 8 (Ishii and Ono, 1999). It is not known whether the naturally occurring dimer contains one or both of the diastereoisomers (O'Neill et al., 1996). Chemical analysis of naturally occurring and in vitro formed dimer suggests that the apiosyl residue of each side chain A, but not those of side chain B (see Fig. 3), are cross-linked by borate (Ishii et al., 1999). However, the possibility cannot be discounted that borate esters may cross-link the apiosyl residues of side chains A and B (Matoh et al., 2000).

RG-II dimer formation is a self-assembly process since it occurs in vitro in the absence of a catalytic protein. The anionic nature and chemical structure of RG-II

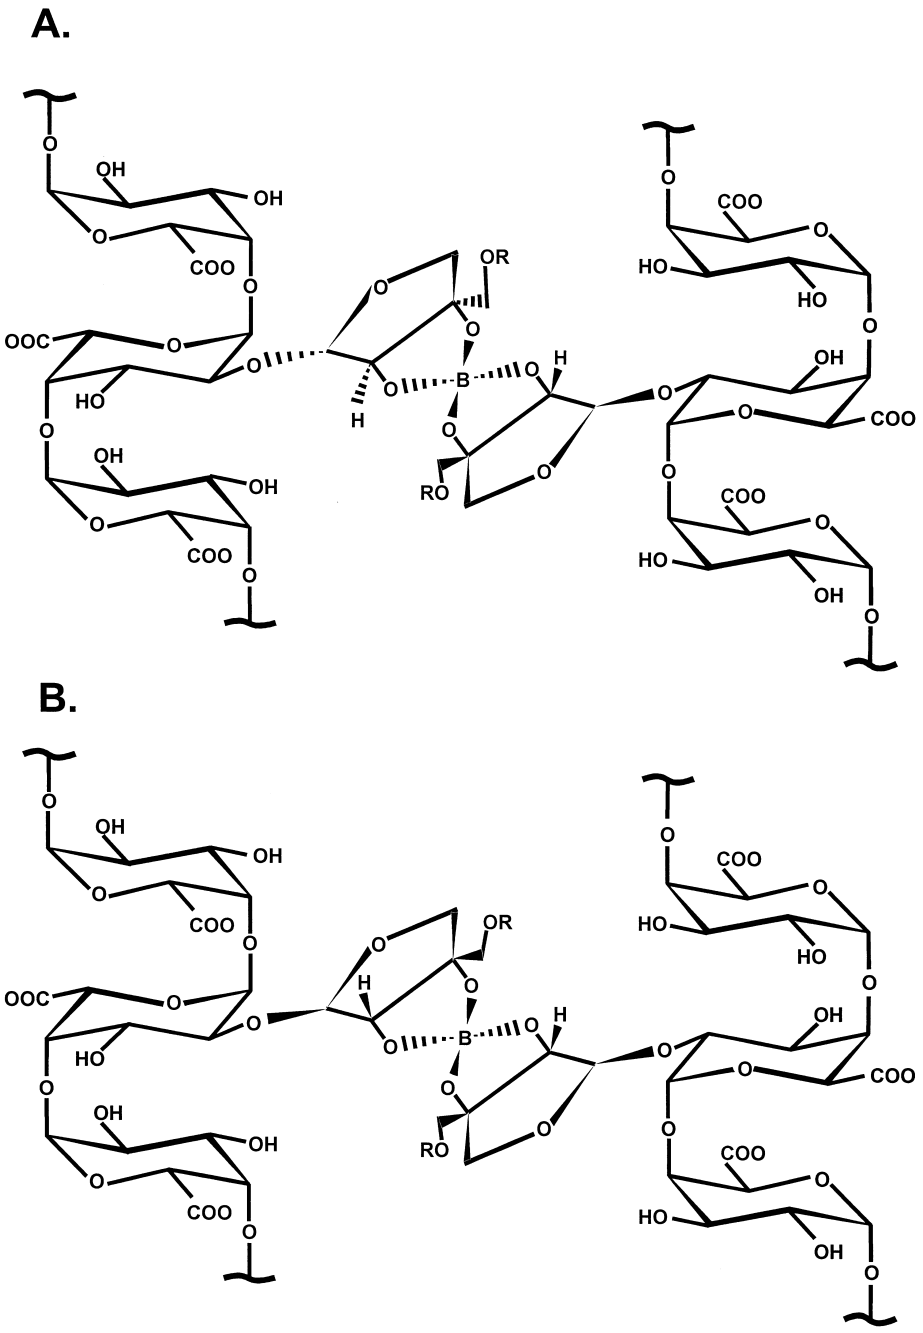

Fig. 4. The borate 1:2 diol ester that cross links two monomeric units of RG-II. The borate ester is formed between OH-2 and OH-3 of the 3′ linked apiosyl residues. "R" represents the oligoglycose that is linked to 3′ of the apiosyl residues. The ester can exist in either of two diastereomeric forms. In A one "R" group is pointing upward and the other is pointing downward. In B both "R" groups are pointing upward.

are likely to be major factors in determining the optimum pH (pH 3.0–4.0) for dimer formation in vitro (O'Neill et al., 1996) since 1:2 borate-diol esters of methyl β-D-apiofuranoside do not form below pH 5 (Ishii and Ono, 1999). The rate and extent of RG-II dimer formation in vitro are increased in the presence of di- and trivalent cations with ionic radii >1.0 Å (Ishii et al., 1999). Calcium at low concentrations (1 mM) is less effective than the larger cations (Ishii et al, 1999). However, higher concentrations (10 mM) of calcium and boric acid do increase the rate of dimer formation in vitro (Matoh and Kobayashi, 1998). The role of Ca^{2+} in dimer formation in vivo is not fully understood but there is evidence that it increases the stability of the RG-II dimer (Fleischer et al., 1999; Kobayashi et al., 1999).

The chemical structure of RG-II has been increasingly refined using high-field NMR spectroscopy in combination with electrospray and matrix-assisted laser desorption mass spectrometry. As a result, some of the previously published structures (Spellman et al., 1983) have been

revised (Vidal et al., 2000). The aceric acid-containing side chain (B in Fig. 3) is most likely a nonasaccharide (Whitcombe et al., 1995; Shin et al 1998; Terrell, M. and Prestegard, J., personal communication) and not a heptasaccharide as had previously been reported (Spellman et al., 1983). Side chain B is linked to *O*2 of the fifth Gal*p*A residue from the reducing end of the backbone, whereas side chain D [β-L-Araf-(1→5)-α-D-Dha-(1→] is most likely linked to *O*3 of the sixth Gal*p*A residue from the reducing end (Vidal et al., 2000). This study also provided evidence that the aceryl acid residue is α linked and that the galactosyl residue is β-linked, thus reversing the previously published anomeric configurations of these residues (Spellman et al., 1983). Somewhat unexpectedly, the terminal Gal*p* residue on side chain A (see Fig. 3) has been shown to have the L rather than the D configuration (Reuhs et al., submitted) thereby confirming that L-galactose is a minor component of primary walls (Baydoun and Fry, 1988).

A preliminary assignment of the ^{1}H and ^{13}C resonances in the NMR spectra of the $NaBH_4$-reduced RG-II monomer have been made and used to propose an NMR solution structure for RG-II (Du Penhoat et al., 1999). The ^{1}H and ^{13}C resonance assignments appear to be based in part on the published, and in some cases incorrectly assigned, anomeric configurations of the glycosyl residues present in RG-II. Inter-glycosidic NOEs and long-range NOEs were measured and interpreted on the basis of these assignments. The specific attachment site of each side-chain was not determined, although the authors suggest that only two arrangements of the side-chains (A, C, B, D or A, D, B, C) are consistent with the NMR spectroscopic data (Du Penhoat et al., 1999). Additional data are required before the validity of this conclusion can be assessed since the unambiguous assignment of all the resonances and the interpretation of NOE data for RG-II is a challenging endeavor. This is largely due to the considerable signal overlap and degeneracy that result from the relatively narrow spectral dispersion of complex carbohydrates (Van Halbeek, 1994). Complete assignment of the resonances in crowded regions of the NMR spectra of RG-II may be achieved by using selective excitation techniques (Freeman, 1992) or by 3D NMR spectroscopy. 3D NMR techniques were developed to facilitate the assignment of resonances in NMR spectra of isotopically-enriched proteins (Marion et al., 1989; Zuiderweg and Fesik, 1989) and have also been used to analyze ^{13}C-labeled complex carbohydrates (Van Halbeek, 1994; Bush et al., 1999). The availability of ^{13}C-enriched RG-II (York, W.S., O'Neill, M.A., Terrell, M., Prestegard, J., unpublished results) now makes 3D NMR spectroscopic analysis of this polysaccharide possible.

Molecular modeling procedures have been used to generate several possible three-dimensional structures for the side-chains of RG-II (Mazeau and Perez, 1998; Perez et al., 2000). The reader should consult Woods (1998) for a concise discussion of the computational methods that are used to model complex carbohydrates. The validity of the RG-II side chain models remain to be established, particularly in light of the evidence showing that in side-chain B the Ace*f*A residue is α- rather than β-linked, and that the 2,4-linked Gal*p* residue is β- and not α-linked. The computer-generated conformations of side-chain A need to be reexamined since they were obtained by assuming that the previously published anomeric configurations of the glycosyl residues (Melton et al., 1986) were correct and that the galactosyl residue was D rather than L.

1.4. The macromolecular organization of HG, RG-I, and RG-II in the primary wall

1.4.1. Are homogalacturonan, rhamnogalacturonan I, and RG-II linked together covalently?

Homogalacturonan, RG-I, and RG-II are solubilized from insoluble walls by treating the walls with aqueous buffers or calcium chelators. The polysaccharides, however, are not separated from each other by size-exclusion chromatography (e.g. Superose 6 and 12) since they elute in the column void volume (molecular masses >200 kDa). Fractions enriched in RG-I, RG-II, and oligogalacturonides are generated by treating the high molecular weight material with EPGase (O'Neill et al., 1990). Thus, it is often assumed that in primary walls HG, RG-I, and RG-II are covalently linked to one another and models have been proposed for the distribution of RG-I and HG in pectin (Matsuhashi et al., 1993).

Homogalacturonan and RG-II are likely to be covalently linked since they both have backbones composed of 1→4-linked α-D-Gal*p*A residues and they are both solubilized by treating walls with EPGase. The backbone of EPGase-solubilized RG-II contains up to 15 1,4-linked α-D-Gal*p*A residues, providing indirect evidence that RG-II is linked to HG (Whitcombe et al., 1995). RG-I is also solubilized by treating walls with EPGase even though there are no glycosyl residues in RG-I that are susceptible to EPGase. However, no oligosaccharides composed of the RG-I backbone disaccharide repeating unit covalently linked to fragments of HG have been isolated, nor is there evidence that HG is glycosidically linked to the side-chains of RG-I. The notion that HG chains are interrupted by the insertion of a single Rhap residue between regions containing 20–30 Gal*p*A residues is almost certainly incorrect (Zhan et al., 1998).

1.4.2. Is pectin cross-linked to other wall components?

Early models of the primary cell wall postulated that xyloglucans and pectic polysaccharides, as well as structural glycoproteins, are covalently linked together

to form a continuous macromolecular network (Keegstra et al., 1973). This view has gradually changed and current models emphasize the predominance of non-covalent linkages between wall polymers (Carpita and Gibeaut, 1993). Nevertheless, there is a substantial body of data showing that RG-II molecules are covalently cross-linked by borate esters.

1.4.3. Borate-ester cross-linked pectin

There is accumulating evidence that borate ester cross-linking of RG-II is required for the formation of a macromolecular pectic network within the plant cell wall (Matoh and Kobayashi, 1998). The function of this network is not understood, although it may have a role in controlling the mechanical properties of the primary wall (Loomis and Durst, 1992; Flesicher et al., 1998, 1999). For example, boron-mediated cross-linking of RG-II in the walls of living plant cells generates a pectin network with a decreased size-exclusion limit for polymers (Fleischer et al., 1999). Such results are consistent with previous studies showing that the size of molecules able to diffuse through the wall is increased by enzymic and chemical fragmentation of wall-bound pectin (Baron-Epel et al., 1988; Ehwald et al., 1992).

Chenopodium album cells divide and grow in the absence of added boron (Fleischer et al., 1998) and their walls contain monomeric RG-II, but no discernible amounts of dimeric RG-II. Thus, borate ester cross-linking of RG-II is unlikely to be required for cell division and growth in these cells. Boron-deficient *C. album* cells, in contrast to their boron-grown counterparts, are unable to reduce their wall pore size and thereby undergo excessive cell enlargement and experience wall rupture during their transition to the stationary phase (Fleischer et al., 1998). Thus, it appears that the size-exclusion or cross-linking effects of the pectic network may become essential for the stability of *C. album* cells only when growth has ceased. In contrast, tobacco cells do not grow in a boron-free medium but do grow in media containing a low amount (10 μg/l) of added boric acid (Matoh et al., 2000). Most (~60%) of the RG-II is present as the monomer in the boron-deficient cells and the walls are swollen suggesting that the cross-linking and organization of the pectin network has been altered (Matoh et al., 2000). The inability to form a borate ester cross-linked pectic network may influence physiologically important processes including the incorporation of polymers into the wall, the access of wall modifying enzymes or proteins to their substrates or ligands, and the transport of polymers from the protoplast into the wall.

Kobayashi et al. (1999) have provided evidence that cyclohexanediaminetetraacetic acid (CDTA) promotes the hydrolysis of the RG-II dimer and that the release of the most tightly bound wall calcium is correlated with the solubilization of wall-bound RG-II. Divalent cations promote soluble dimer formation in vitro (O'Neill et al., 1996; Matoh and Kobayashi, 1998) and together with boric acid prevent the low-pH mediated increase in wall pore size (Fleischer et al., 1999). These results, when taken together with the ability of calcium to stabilize borate complexes in root tips (Wimmer and Goldbach, 1999), suggest that in muro calcium has a role at specific, but as yet unidentified, sites close to the borate ester cross-link.

1.4.4. Anionic cross-links

Pectins are the predominant anionic polymer in the primary walls of dicots and non-graminaceous monocots and thus many of their properties are believed to be determined by ionic interactions. The properties of pectin gels and the mechanism of gelation have been the subject of numerous studies (Grant et al., 1973; Powell et al., 1982; Morris et al., 1982; Thibault and Rinaudo, 1986; Thakur et al., 1997). The pectins used for many of the gelation experiments, however, were often solubilized from plant tissue by degradative treatments (e.g. hot aqueous acid). Thus, the relevance of such studies for the macromolecular properties of cell wall-bound pectin has been questioned (MacDougall et al., 1996).

Pectin gels have also been studied using pectin isolated from cell walls by nondegradative conditions. For example, CDTA treatment of unripe tomato fruits has been shown to result in cell separation and the solubilization of a high methoxy pectin (DM 68%). This pectin is believed to originate from the middle lamella and may have an important role in maintaining cell adhesion (MacDougall et al., 1996). The CDTA-soluble pectin forms elastic gels in the presence of calcium. These gels have a higher affinity for calcium than aqueous solutions of the same polysaccharide (Tibbits et al., 1998). A fraction of the Gal*p*A residues in the gel does not participate in ionic cross-linking but may contribute to gel swelling particularly at low ionic strength (Tibbits et al., 1998). The maximum swelling of the gel and the minimum shear modulus (strength of the gel) occur at pH 3 which is close to the pK_a of the carboxyl group of galacturonic acid (Tibbits et al., 1998). This pH value is also similar to the optimum pH required for borate ester cross-linking of RG-II in vitro (O'Neill et al., 1996). The question of what role RG-II cross-linking has on the properties of CDTA-soluble pectin gels has not yet been addressed.

1.4.5. Other cross-links

A portion of primary wall pectin is not solubilized by treatment with aqueous buffers, calcium chelators, or EPGase, but is solubilized by aqueous base (Bauer et al., 1973; Selvendran, 1985). Thus, the existence of esters that form between the carboxyl group of a 4-linked Gal*p*A residue and a hydroxyl group of another glycosyl residue has been hypothesized (Fry, 1986). The presence of

non-methyl galacturonosyl esters has been implied from chemical analysis of maize cell walls (Kim and Carpita, 1992) and by chemical and infra-red spectroscopic analysis of tobacco cell walls (McCann et al., 1994). Non-methyl esters have also been reported to be present in the walls of spinach (Brown and Fry, 1993) and carrot (Needs et al., 1998), although no fragments of HG containing unusual esters have been isolated and structurally characterized. The trans-esterification of pectin has been reported to be catalyzed by pectin methyl esterase (Hou and Chang, 1996), but additional structural evidence is required to substantiate this claim.

In the walls of the *Chenopodiaceae* (e.g. sugar beet and spinach) some of the pectic arabinosyl and galactosyl residues are esterified with ferulic or coumaric acid and these phenolic residues are potential sites for cross-linking via oxidative coupling (Ishii, 1997b; Saulnier and Thibault, 1999). However, the existence in muro of intermolecular dehydrodiferuloyl cross-linked pectin has not been demonstrated. Hemicellulose-pectin complexes that may be cross-linked by as yet unidentified phenolic material have been reported to be present in the walls of cauliflower (Femenia et al., 1999), asparagus stems (Waldron and Selvendran, 1992), and olive seed hulls (Coimbra et al., 1995).

Pectin and xyloglucan are both solubilized by treating primary walls with alkali (Bauer et al., 1973; Selvendran, 1985; Thompson and Fry, 2000). A portion of the xyloglucan and pectin is assumed to be covalently cross-linked since these polymers co-elute from anion-exchange columns and xyloglucans themselves contain no acidic glycosyl residues (Thompson and Fry, 2000). However, the nature of the covalent linkage between xyloglucan and pectin, if it exists, has not been established. The wall material remaining after 4M KOH treatment is rich in cellulose but may also contain Rhap and Gal*p*A residues and Hyp-rich glycoprotein. Linkages between pectin and wall glycoprotein have been inferred from chemical analysis (Qi et al., 1995; Fu and Mort, 1996; Peronne et al., 1998) and from solid state NMR spectroscopic studies (Pan, 1992) but compelling evidence for these cross-links is lacking.

Although numerous studies have reported cross-linking between pectic and hemicellulosic polysaccharides and between pectin and wall glycoprotein, conclusive evidence for their existence is lacking. Future research should be directed towards the isolation and structural characterization of these putative cross-links.

1.4.6. Biophysical methods for determining the properties and functions of primary wall pectin

The current lack of understanding of the macromolecular organization of pectin in the primary wall is largely due to a paucity of evidence for all but a few of the postulated cross-links and ionic interactions. One interpretation of the available, albeit inadequate, data is that primary wall pectin exists as a continuous three-dimensional cross-linked network. The functional characteristics of this network depend on the chemical structures, the conformations, and the interactions of the individual macromolecules. Thus, techniques are required that can examine primary walls in their native state. Such techniques include solid state NMR spectroscopy, Fourier transform infra-red spectroscopy, and atomic force microscopy.

Solid state ^{13}C NMR spectroscopy is a useful tool for the characterization of synthetic polymers (Andrew and Szczesniak, 1995), biological solids (McDowell and Schaefer, 1996), and plant cell walls (Jarvis and McCann, 2000). Chemical shift data provide information on the local chemical environment and structure whereas local dynamics, including the thermal motion of polymers in the solid state, are derived from various relaxation measurements (Jarvis and McCann, 2000). Such relaxation experiments have led to the general conclusion that pectic galacturonans have a range of thermal mobilities and that highly methyl esterified pectins are more mobile than low esterified pectins (Ha et al., 1997; Jarvis and McCann, 2000; Tang et al., 2000). The most mobile portions of pectin are the galactan and arabinan side chains of RG-I which are suggested to behave as "tethered liquids" (Jarvis and McCann, 2000).

Conventional solid state ^{13}C NMR spectra are typically interpreted primarily in terms of a single polymer chain. Thus, the relationship between the microscopic structure of a polymer, the mobility of a polymer, and its macroscopic properties can only be inferred indirectly. However, an accurate and direct characterization of inter-chain packing is required to understand the mechanical properties of the cell wall. The inter-nuclear distances (10–15 Å) between packed chains can be determined from long-range, weak dipolar couplings using rotational echo double resonance (REDOR) and transferred echo double resonance (TEDOR) NMR (McDowell and Schaefer, 1996; Schaefer, 1998). These technically challenging experiments are complicated because observation of the appropriate dipolar couplings necessitates selective enrichment of the polymers with isotopes (e.g. ^{13}C–^{15}N, ^{13}C–^{2}H, ^{19}F–^{31}P), whose abundance is low in naturally occurring samples. REDOR NMR has been used to investigate the structure and dynamics of cross-links in *Staphylococcus aureus* cell walls (Tong et al., 1997), in mussel byssal plaques (McDowell et al., 1999), in insect cuticle (Merritt et al., 1996), and in the binding sites of several proteins (Schaefer, 1998). REDOR ^{15}N NMR analysis, in combination with double cross-polarization magic angle spinning ^{13}C NMR analysis, of ^{15}N- and ^{13}C-enriched tomato cell walls have provided evidence that some carbonyl carbons, presumably from pectin, are cross-linked to histidine (Pan, 1992). However, additional experimental evidence is required to support this conclusion.

Fourier transform infra-red (FTIR) spectroscopy is a valuable tool for determining the bulk structural features of polysaccharides and cell walls (Jarvis and McCann, 2000; Kacurakova et al., 2000). The IR beam is focused onto a small ($\geqslant$10 μm) sample area using a FTIR microscope and information is obtained for the distribution of wall polysaccharides within a tissue. Information on the mean orientation of pectin and cellulose in the wall can be obtained using polarized IR beams (Jarvis and McCann, 2000).

The IR spectra of polysaccharides are complex. The major classes of cell wall polysaccharide (HG, RG-I, arabinan, galactan, arabinogalactan, xyloglucan, arabinoglucuronoxylan, glucomannan, and galactoglucomannan) each have distinctive absorption bands (Kacurakova et al., 2000). Nevertheless, partial overlap of the absorption bands in the 1200–800 cm^{-1} region of the spectra complicates determining the polysaccharide composition of a wall by IR spectroscopy. The carboxylate and ester bands of pectin at 1607 and 1740 cm^{-1}, respectively, are reasonably well resolved from other absorption bands and their relative intensities provide information on the degree of esterification of HG (Bociek and Welti, 1975). However, the IR spectra of walls containing a large amount of protein are likely to contain a significant amide band (1650 cm^{-1}) and this may overlap with the carboxylate band (Bociek and Welti, 1975).

Scanning probe microscopy encompasses several distinct techniques that have been used to characterize cell surfaces and cell wall polysaccharides (Brant, 1999; Morris et al., 1999). Atomic force microscopy (AFM) is an imaging technique that has been used to visualize plant cell walls (Morris et al., 1997), cellulose (Baker et al., 1997) and pectin (Round et al., 1997). The polysaccharides are imaged directly under butanol and the images are likely to contain less artifacts than electron microscope images which are obtained from rotary-shadowed replicas of polysaccharides (Seymour and Harding, 1987).

AFM images of a sodium carbonate-soluble pectin from tomato show the presence of a mixed population of single chains and aggregates (Round et al., 1997). Somewhat unexpectedly, the AFM images revealed branched structures that have been interpreted as evidence that HG chains are covalently linked to one another or that the neutral-sugar side chains of pectin are considerably longer than previously believed (Round et al., 1997).

Single-molecule force spectroscopy is a technique that has been used to measure the mechanical properties of proteins (Leckband, 2000) and polysaccharides (Brant, 1999). A single polymer chain is tethered at one point to a fixed substrate and at another point to an AFM tip. The application of a stretching force elastically deforms the molecule and may also induce conformational transitions (Marszalek et al., 1998, 1999). The force-extension curves for citrus pectin show two reversible yield domains that correspond to abrupt increases in the length of the polysaccharide chain (Marszalek et al., 1999). The yield domains may result from the conversion of D-Gal*p*A residues in the $^4C_1$ chair to an intermediate boat/skew-boat conformer and then to the $^1C_4$ chair. Such conformational changes are suggested to result in a increase in chain length since the distance spanned by the $^1C_4$ ring conformer is larger than the $^4C_1$ ring conformer (Marszalek et al., 1999). The force-extension curves of cellulose contain no yield domains since the virtual bond length of the glucosyl residues is not increased by a change in ring conformation (Marszalek et al., 1999). Thus, differences in the extensibility of pectin and cellulose may allow plant cells to finely control the extensibility of their walls (Marszalek et al., 1998).

1.4.7. Are there pectin-membrane-cytoskeleton connections?

There is an increasing awareness that the mechanical and biochemical properties of the primary wall influence the growth and development of plant cells and tissues, although the mechanisms by which a cell perceives and responds to changes in wall properties are not understood (Roberts, 1990; Wyatt and Carpita, 1993). The limited available data suggest that the primary wall and the cytoskeleton are connected by membrane associated proteins, although the nature of the connecting proteins and the wall components they interact with are largely unidentified (Miller et al., 1997; He et al., 1996). In contrast, the role of the extracellular matrix in the growth and development of animal cells has been studied in detail (Chothia and Jones, 1997; Deller and Jones, 2000) and models have been proposed to explain how mechanical forces affect the behavior of animal cells (Ingber, 1998).

Homologs of animal cell adhesion molecules (integrins, proteoglycans, vitronectin, and fibronectin) have been detected in plant cell walls and membranes using antibodies and synthetic peptides (Miller et al., 1997). *A. thaliana* plasma membranes contain proteins with homology to animal β-integrins (Laval et al., 1999). Purified plasma membranes from *Arabidopsis* cells have also been reported to contain two types of high-affinity binding sites for the RGD (Arg–Gly–Asp) peptide, a sequence typically required for binding to integrin receptors (Canut et al., 1998). A heptapeptide containing the RGD motif has been reported to cause a loss of wall-membrane attachments (Hechtian threads) in plasmolyzed onion epidermal cells and suspension-cultured *arabidopsis* cells (Canut et al., 1998). However, it was not shown whether the effects of the RGD motif result from an interaction with the cell wall or plasma membrane. RGD peptides have been reported to enhance cell division in soybean (Schindler et al., 1989), to inhibit gravity perception in Chara (Wayne et al., 1992), and to disrupt protoplast adhesion in NaCl-adapted tobacco cells (Zhu et al., 1993), although the mechanisms of action remain unidentified.

Fibronectin-like molecules and wall-associated kinases have been identified in plants and these proteins may bind directly or indirectly to pectic polysaccharides (He et al., 1996; Miller et al., 1997). No direct evidence has been obtained to show that pectic polysaccharides are linked to the plasma membrane, although a narrow zone of the wall adjacent to the plasma membrane is often enriched with unesterified HG (Knox et al., 1990), RG-II (Williams et al., 1996; Matoh et al., 1998), β1→4 linked galactan and β1→6 linked galactans (Jauneau et al., 1998; Sorensen et al., 2000). Such labeling patterns must be interpreted with caution since the pectin located in the region of the wall adjacent to the plasma membrane is likely to be the most recently deposited wall material and may be more accessible to the antibodies than pectin in the rest of the wall.

1.5. The distribution of pectic polysaccharides in the primary wall

Antibodies that recognize specific structural features of primary cell wall pectin are powerful tools for determining the location and distribution of these polysaccharides within a single wall and for following changes in pectin structure during cell and tissue development (Knox, 1997; Vicre et al., 1998; Willats et al., 2000b). Antibodies have been described that are believed to recognize HG with different degrees of esterification including JIM 5 (VandenBosch et al., 1989; Knox et al., 1990); Jim 7 (Knox et al., 1990) and PAM1 (Willats et al., 1999a). Other anti-pectin antibodies are 2F4 that recognizes calcium cross-linked pectin (Liners et al. 1989), and LM5 and LM6 that recognize, respectively, 1→4-linked β-D-galactan (Jones et al., 1997) and 1→5-linked α-L-arabinan (Willats et al., 1998) in the side chains of RG-I. Another series of antibodies includes CCRC-M1 that recognizes polysaccharides containing a terminal non-reducing α-L-fucosyl residue (Puhlmann et al., 1994), CCRC-M2 that recognizes RG-I (Puhlmann et al., 1994), CCRC-M7 that recognizes arabinosylated 1→6-linked β-D-galactan (Steffan et al., 1995), and CCRC-R1 that recognizes RG-II (Williams et al., 1996).

The epitopes recognized by LM5 and LM6 are known with some certainty since these antibodies were generated against specific oligosaccharides coupled to proteins (Jones et al., 1997; Willats et al., 1998). The epitope recognized by CCRC-M1 has been shown, using a series of structurally related oligosaccharides, to contain a terminal 1→2 linked α-L-fucosyl residue (Puhlman et al., 1994). The binding characteristics of PAM1, JIM5, and JIM7 have been compared using pectin of varying degrees and patterns of methyl esterification (Willats et al., 1999a, 2000a). PAM1 binds most effectively to fully de-esterified pectin whereas JIM5 and JIM7 bind to pectin with a wide range of degrees of methyl esterification. Some published studies, however, have been interpreted based on the assumption that JIM5 recognizes deesterified HG and JIM7 recognizes methylesterified HG. Thus, the results of immunolocalization studies using JIM5 and JIM7 must be interpreted with caution (Willats et al., 2000a).

Immunolocalization studies have provided evidence that the localization and structure of pectin may have an impact on plant cell growth and development. For example, the presence of a pectin sheath on the primary walls of developing cotton fibers is correlated with the ability of epidermal cells to differentiate into elongating fiber cells (Vaughn and Turley, 1999), while epidermal cells that do not have a pectin sheath do not elongate. The role of the external pectin-rich layer in cell elongation, however, remains to be determined since epidermal cells in maize coleoptiles (Schindler et al., 1995), flax (Jauneau et al., 1997), and pea stems (Fujino and Itoh, 1998) have an asymmetric distribution of pectin but do not elongate.

Differences in the distribution of pectic epitopes in different cell and tissue types have also been reported in pea cotyledons (McCartney et al., 2000), tomato pericarp (Roy, 1994; Steele et al., 1997; Orfila and Knox, 2000); flax roots and hypocotyls (Jauneau et al., 1997, 1998), potato tubers (Bush and McCann, 1999), Arabidopsis roots (Freshour et al., 1996; Dolan et al., 1997), aspen cambium (Ermel et al., 2000), poplar cambium (Guglielmino, 1997), pollen (Geitmann et al., 1995; Juah and Lord, 1996), *Zinnia* cells (Stacey et al., 1995), suspension-cultured cells (McCann et al., 1994; Williams et al., 1996; Matoh et al., 1998), and cauliflower stems (Femenia et al., 1998). The results of these studies, when taken together, lead to the general conclusion that unesterified HG is localized to the middle lamella, to cell corners, and around air spaces whereas esterified HG is typically present throughout the wall. The immunocytochemistry results also suggest that the presence and location of the arabinan and galactan side chains of RG-I are often correlated with stages of cell and/or tissue development. The appearance of 1→4-linked β-D-galactan and a decrease of 1→5-linked α-L-arabinan in carrot cell walls has been correlated with the transition from cell division to cell elongation (Willats et al., 1999b). The α1,5-arabinan epitopes are also expressed specifically in the central meristem of carrot roots and in proliferating carrot suspension-cultured cells, while the 1,4-galactan epitopes are not expressed in these cells but rather in the root cap and differentiating stele and cortical cells of the carrot root and in non-proliferating induced carrot suspension cultures (Willats et al., 1999a,b). The expression of the arabinan and galactan side chains of RG-I also appears to be developmentally regulated in other plants and tissues. HG and α1,5-arabinan epitopes are present in the pea cotyledon throughout development while the β1,4-galactan-epitope is restricted to a specific stage of cotyledon development

(26–30 days after anthesis) and is present in a thin layer at the plasma membrane face of the cell wall (McCartney et al., 2000). The HG, α1,5-arabinan and β1,4-galactan epitopes in the wall surrounding pit fields in the tomato pericarp are also spatially regulated, with HG present in the pit fields, α1,5-arabinan surrounding the pit fields, and β1,4-galactan absent from the pit field (Orfila and Knox, 2000).

The results of immunocytochemical studies showing the differential labeling of a particular wall epitope may suggest that the synthesis of the epitope is regulated, however, additional experiments are required to determine if the lack of binding of an antibody to a tissue section is due to the absence of the epitope or to the masking of an epitope. For example, Masuda et al. (1984) reported that in elongating carrot walls the ratio of 3,5- to 5-linked arabinosyl residues increased. Thus, increased branching of the 1,5-linked arabinan may account for the reduced labeling of elongating cell walls by the 1→5-linked α-L-arabinan antibody (Willats et al., 1999b). Evidence that the antibody labeling pattern of the tissues is due to the differential expression of arabinan, rather than to the masking of the epitope(s) recognized by the antibody, is not easily obtained by independent methods since it is difficult to excise discrete cell populations and prepare their walls in amounts sufficient for conventional chemical or biochemical analyses.

Another example of a differentially labeled cell wall epitope is an RG-II epitope recognized by polyclonal anti-RG-II antibodies (Matoh et al., 1998). The RG-II epitope is present in dicot and monocot walls, but is not detected in the middle lamella (Matoh et al., 1998). This epitope, however, may be masked by a base-labile component since alkali treatment of the walls typically results in a dramatic increase in the density of labeling (Williams et al., 1996; Matoh et al., 1998). This example again illustrates that care must be taken in interpreting the results of immunolabeling studies. Furthermore, it is difficult to determine whether the changes in the ability of specific antibodies to bind to tissue sections results from a change in the glycosyl residue composition of the wall or to changes in the physical properties of the wall (e.g. permeability). Additional antibodies with well defined epitopes and methods to structurally analyze the walls surrounding single cells are required to address this issue.

The differential expression of a wall carbohydrate epitope may, or may not, indicate that the specific epitope plays a role in plant growth or development. For example, despite the differential expression of the β-D-galactan epitope, the role of 1→4-linked β-D-galactan in plant growth is unclear since the walls of potato tubers transformed with a fungal endo-1,4-β-D-galactanase contain ~30% of the normal amount of galactose and yet the plants have no apparent change in phenotype (Sorensen et al., 2000).

1.6. Probing the structure and function of pectin with cell wall mutants

Our knowledge of the primary structure of wall pectin, its distribution within the wall, and some of its interactions with itself and other wall components has increased dramatically over the last 10 years. In contrast, our understanding of the biological functions of pectic polysaccharides remains inadequate. The increasing availability of cell wall mutants provides new opportunities to study pectin structure and function (Fagard et al., 2000).

Many of the cell wall mutants currently available have been generated using Arabidopsis, although only a limited number of them have been shown to have altered pectin structure or metabolism (Fagard et al., 2000). Arabidopsis mutants (*Mur1–Mur11*) have been described that have reduced levels of Fuc, Ara, Gal, or Rha in their walls (Reiter et al., 1997). These glycosyl residues are typically present in RG-I and RG-II, although Fuc, Ara, and Gal are also components of xyloglucan and arabinogalactan proteins. Thus, some of these mutants are likely to have structural changes in more than one wall component.

Mur1 and *Mur4* have each been shown to be defective in a single gene that is required for the biosynthesis of a specific monosaccharide. For example, the aerial portions of *Mur1* plants are defective in an isoform of GDP-mannose-4,6-dehydratase and thus their walls contain ~5% of the wild type fucose (Bonin et al., 1997). The reduced fucose content is reflected in the almost total absence of fucosyl residues in *Mur1* xyloglucan (Zablackis et al., 1996) and RG-II (Reuhs et al., submitted). Somewhat unexpectedly, ~30% of the β-D-galactosyl residues that would normally be substituted with a L-fucosyl residue are substituted with an α-L-galactosyl residue (Zablackis et al., 1996). Similarly, the 2-*O*-Me α-L-fucosyl and α-L-fucosyl residues in *Mur1* RG-II are replaced with terminal 2-*O*-Me α-L-galactosyl and α-L-galactosyl residues (Reuhs et al., submitted). L-galactosyl residues are believed to be generated from GDP-mannose by GDP-mannose-3,5-epimerase, a enzyme required for the biosynthesis of vitamin C (Wheeler et al. 1998). *Mur4* plants are defective in a membrane-bound UDP-D-xylose 4-epimerase and thus have reduced levels of arabinose in their walls (Burget and Reiter, 1999). *Mur4* plants have no visible phenotype, although the double mutant *Mur4*/*Mur1* has been reported to have an extreme dwarf phenotype (Reiter et al., 1997). The walls of *Mur4*/*Mur1* plants are likely to contain structurally modified RG-II, xyloglucan, and possibly RG-I, although no structural analysis of the individual polysaccharides has been reported.

Mutant plant populations are generated by random mutagenesis of seeds with ethylmethanesulfonate or through T-DNA or transposon-mutagenesis. Typically,

this results in many thousands of M2 lines that must be screened. The identification of wall mutants is labor-intensive since no rapid screening procedures are currently available, although sample throughput may be increased using FTIR spectroscopy (Chen et al., 1998) and immunocytochemical methods (Willats et al., 2000b). Thus, more direct methods for generating transgenic plants with altered pectin structure and/or metabolism are now being exploited.

Antisense mRNA technology has been used to investigate the role of EPGase in the ripening and softening of tomato fruit. Transgenic tomato fruits containing $<1\%$ of the normal EPGase activity ripen normally showing that EPGases are not responsible for ripening-associated softening (Tieman and Handa, 1994). Nevertheless, these fruits have improved storage characteristics since tissue integrity is maintained during fruit senescence. Normal ripening also occurs in transgenic tomato plants with reduced PME activity but there is a significant decrease in tissue integrity during fruit senescence, and the fruits are more susceptible to microbial attack (Tieman and Handa, 1994). Antisense mRNA has also been used to show that in pea root tips the PME-catalyzed de-esterification of pectin has a role in border cell release and in root growth (Wen et al., 1999).

An alternative approach to antisense mRNA approaches to modify the wall is to transform plants with glycanases that are known to fragment cell wall polysaccharides. For example, the walls of transgenic potato tubers expressing a fungal endo-β1,4-galactanase contain reduced amounts of galactose, although plant growth is not affected (Sorensen et al., 2000).

Virus-induced gene silencing of a putative cellulose synthase gene has been used to generate transiently dwarf tobacco plants (Burton et al., 2000). The walls of the infected leaves have a reduced cellulose content, the HG content is increased, and the HG is reported to be less esterified than the HG in the walls of control plants. Pectin also accounts for a greater proportion of the walls of plant cells grown in the presence of the cellulose synthesis inhibitor dichlorobenzonitrile (Shedletzky et al., 1992). Thus, a plant may compensate for reduced cellulose production by increasing the amount of HG in its wall (Burton et al., 2000).

Several Arabidopsis mutants that may yield insights into pectin function have been generated in studies not directly related to primary cell walls. For example, transgenic arabidopsis plants expressing a fungal cutinase exhibit postgenital organ fusion in epidermal tissue that lacks an intact cuticle. These fusions are due in part to pectin-mediated cell-cell adhesion and have been observed in the leaves, stems, and flowers but not in the roots (Sieber et al., 2000). Fusions occur in epidermal cells only early in organ development when the organs are close together and often results in the formation of cell bridges (Sieber et al., 2000). The material in the junctions of the fusions and cell bridges is rich in pectin with low and high degrees of esterification. Thus, in the absence of an intact cuticle, the walls of closely appressed epidermal cells partially fuse by co-polymerization of pectin (Sieber et al., 2000). A second example of abnormal pectin-mediated cell-cell adhesion has been observed in the *Qrt* mutant of arabidopsis. In wild type plants, the pollen mother cell wall consists of an inner callose layer and an outer pectin-rich layer. These layers are both removed during pollen maturation and the four microspores separate before deposition of the exine. Callose is fragmented normally in *Qrt* mutants but the pectin layer persists and the microspores remain attached to one another. The exine is then deposited simultaneously on all four microspores. The nature of the QRT gene product is not known but it is likely to have a role in pectin metabolism (Rhee and Somerville, 1998).

A vitamin C deficient mutant (*Vtc1*) has recently been shown to be partially defective in GDP-mannose pyrophosphorylase (Conklin et al., 1999). This mutation may affect the fucosyl, mannosyl, and L-galactosyl contents of the wall since these glycosyl residues are derived from GDP-mannose (Conklin et al., 1999). The arabidopsis mutant *Cyt1-2* is believed to contain a completely defective GDP-mannose pyrophosphorylase (Conklin et al., 1999). *Cyt1-2* is an embryo-lethal mutant with severely deformed walls, although it has not been shown that the wall defects themselves are directly responsible for the observed phenotype.

The identification of cell wall-related genes in arabidopsis via sequence similarities to *Acetobacter xylinum* and *Agrobacterium tumefaciens* genes involved in cellulose synthesis has met with considerable success (Delmer, 1999; Pear et al., 1996). This approach also has the potential to identify genes involved in the biosynthesis of pectic polysaccharides (Bonin and Reiter, 2000). No bacteria are known that synthesize HG, RG-I, or RG-II. Nevertheless, the glycosyl residues present in pectin are, with the exception of apiose and aceric acid, also present in various bacterial polysaccharides. For example, a 4-linked α-D-Gal*p*A residue and a 2-linked α-L-Rha*p* are present in the hexasaccharide repeating unit of the extracellular polysaccharide synthesized by *Erwinia chrysanthemi* A350 (Gray et al., 2000). The ability to selectively mutate genes involved in cell wall formation and metabolism clearly presents new opportunities for determining the function of pectic polysaccharides in plant growth and development.

2. Biosynthesis

2.1. Introduction

The study of pectin biosynthesis is challenging and progress in this area has been slow. The complex structure

of pectin requires the action of at least 53 different enzymatic activities (Mohnen, 1999). Some of the nucleotide sugar substrates for the pectin biosynthetic enzymes are unknown, most are not commercially available, and the oligo/polysaccharide acceptors required to assay the enzymes must be generated by chemical or enzymatic cleavage of pectin and then purified. In order to understand how the activity of the 53 distinct enzymatic activities required for pectin synthesis (see Tables 1–3) are coordinated, and how that process is regulated, the pectin biosynthetic enzymes must be identified and the corresponding genes cloned. No pectin biosynthetic enzyme has yet been purified to homogeneity, and no pectin biosynthetic glycosyl-, methyl- or acetyltransferase has been cloned. Nevertheless, recent progress in the area of pectin biosynthesis, including the partial purification of some of the pectin biosynthetic enzymes, make it likely that the first genes for pectin biosynthetic enzymes will be identified in the near future. The published literature on pectin biosynthesis has recently been reviewed (Mohnen, 1999), thus only recent developments in our understanding of pectin biosynthesis will be presented here.

2.2. Setting the stage for pectin synthesis

The synthesis of pectin must be regulated in a temporally, spatially, and developmentally specific manner since the pectic polysaccharides are largely absent from many secondary walls while they show cell type and developmental expression in primary walls. A discussion of pectin synthesis must first address where synthesis occurs. Immunocytochemistry using antibodies directed against cell wall carbohydrate epitopes (Hoson, 1991; Moore et al., 1991; Knox, 1992; Staehelin and Moore, 1995) showed that HG and RG-I-like epitopes are present in both the *cis*- and medial-Golgi. Thus, it is likely that the synthesis of these epitopes begins in *cis* Golgi (Lynch and Staehelin, 1992; Zhang and Staehelin, 1992) and continues into the medial Golgi (Moore et al., 1991; Zhang and Staehelin, 1992; Staehelin and Moore, 1995). The esterification of HG appears to occur in the medial and trans Golgi (Vian and Roland, 1991; Liners and Van Cutsem, 1992; Zhang and Staehelin, 1992; Sherrier and VandenBosch, 1994; Staehelin and Moore, 1995), while more extensive branching of pectin occurs in the trans Golgi cisternae (Zhang and Staehelin, 1992; Staehelin and Moore, 1995). Final pectin assembly may occur as the Golgi vesicles are transported to the plasma membrane and the pectin is inserted into the wall, often as a highly methyl esterified polymer (Carpita and Gibeaut, 1993; Liners et al., 1994; Dolan et al., 1997). Some cell types, however, appear to secrete relatively unesterified pectin in the wall. For example, melon callus cells (Vian and Roland, 1991) and slime-secreting clover root epidermal cells (Lynch and Staehelin, 1992) contain unesterified HG in the trans Golgi. Also, unesterified HG epitopes have been found at the plasma membrane-cell wall interface by immunocytochemistry, suggesting that HG can also be inserted into the wall in a relatively unesterified form and that HG is not necessarily synthesized in a highly esterified form (Knox et al., 1990; Casero and Knox, 1995). The extent to which HG is esterified during synthesis thus remains an open question.

Table 1
List of glycosyltransferase activities required for homogalacturonan (HG) biosynthesis

Type of transferase	Working[a] number	Enzyme[b]		Ref.[c] for structure
		Acceptor substrate	Enzyme activity

Methyl- RG-I: GlcA-4-*O*-methyltransferase	–	RG-I	GlcAβ1,6-Gal		(An et al., 1994)
Acetyl- RG-I: GalA-3-O/2-*O*-acetyltransferase	–	RG-I	GalAα1,2-L-Rhaα1,4$_{(n)}$		(Lerouge et al., 1993; Ishii, 1997a; O'Neill et al., 1990; Bacic et al., 1988; Komalavilas and Mort, 1989)

[a] Enzymes that transfer the same type of glycosyl residue to different acceptors are given numbers to facilitate identification of the specific glycosyltransferase activities. Note that the numbers are different from those in (Mohnen, 1999) since the glycosyltransferases have been grouped according to the type of pectic polysaccharide they synthesize.

[b] All sugars are D sugars and have pyranose rings unless otherwise indicated. Glycosyltranferases add to the glycosyl residue on the left* of the indicated acceptor.

[c] Refs. for the structure.

[d] Enzyme that may be required to make an HG/RG-I junction.

[e] This enzymatic activity would also be required to synthesize arabinogalactan proteins (AGPs).

Data from biochemical and structural studies of the pectic polysaccharides suggest that HG and RG-II are covalently linked in the wall. It is likely that HG serves as the backbone for RG-II synthesis. It is also possible that HG and RG-I are linked in the wall, however, definitive chemical evidence for that linkage has not been reported.

2.3. Nucleotide sugars, transporters, and a general model for the topology of pectin biosynthesis

The pectin biosynthetic glycosyltranferases studied to date all use nucleotide-sugars as substrates for in vitro enzymatic reactions and it is believed that nucleotide sugars are the immediate substrates for the reactions in

Table 3
List of glycosyltransferase activities required for RG-II biosynthesis

[d] GalAT-I may be the same as GalAT-I for HG synthesis if RG-II is synthesized onto an existing HG backbone.

vivo (Mohnen, 1999). The nucleotide sugars required for pectin biosynthesis and progress towards understanding the biochemical pathways by which they are synthesized has recently been reviewed (Mohnen, 1999). The nucleotide sugars are, for the most part (see Hayashi et al., 1988, for a possible exception) believed to be synthesized on the cytosolic side of the Golgi. However, the transferase reactions that catalyze the synthesis and modification of the polysaccharide backbone and side chains are believed to occur in the Golgi. Thus, mechanisms are required to transport the nucleotide sugars across the Golgi membrane. Data from animal systems (Capasso and Hirschberg, 1984) and plants (Munoz et al., 1996; Wang et al., 1997; Neckelmann and Orellana, 1998) suggest that this transport is achieved by nucleotide-sugar:nucleoside monophosphate antiporters. The availability of nucleotide-sugars differentially labeled on both the nucleotide and sugar moieties will facilitate the study of Golgi-localized transporters involved in pectin biosynthesis (Orellana and Mohnen, 1999).

A working model for the topology of pectin synthesis is shown in Fig. 5. It is proposed that the nucleotide-sugars are synthesized on the cytosolic side of the Golgi

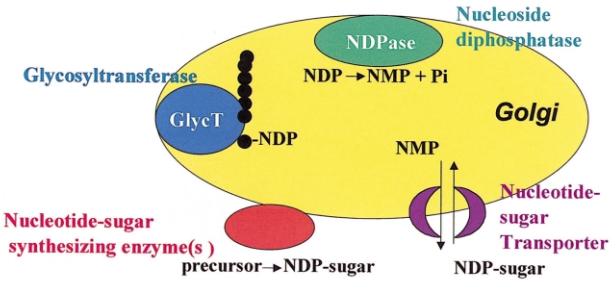

Fig. 5. A model for pectin biosynthesis. The model predicts that pectin biosynthesis is dependent upon the formation of the required nucleotide-sugars by nucleotide-sugar transformation reactions that occur on the cytosyolic side of the Golgi. The nucleotide-sugars are transported into the Golgi by specific nucleotide-sugar:nucleoside monophosphate antiporters. Once inside the Golgi, the nucleotide-sugar is used as a substrate by glycosyltransferases that are specific for the type of nucleotide sugar, the type of oligo/polysaccharide acceptor, and the nature of the anomeric configuration and linkage of the glycosyl linkage formed. The released nucleoside monophosphate is hydrolyzed by a Golgi-localized nucleoside diphosphatase and the nucleoside monophosphate and the inorganic phosphate are transported out of the Golgi by separate transporters (Munoz et al., 1996; Wang et al., 1997; Neckelmann and Orellana, 1998; Sterling et al., submitted).

and transported into the Golgi lumen by specific nucleotide-sugar:nucleoside monophosphate antiporters. The nucleotide-sugar is used as a substrate by the glycosyltransferase and the glycosyl residue is transferred onto a growing polysaccharide chain. The released nucleoside diphosphate (NDP) is hydrolyzed by a Golgi-localized nucleoside-5′-diphosphatase (Orellana et al., 1997) into NMP and inorganic phosphate, making available the nucleoside monophosphate for the nucleotide-sugar:nucleoside monophosphate antiporter. The regulation of pectin biosynthesis could occur during the formation of the nucleotide-sugar, the transport of the nucleotide-sugar into the Golgi, or at the level of the glycosyltransferase or other polymer modifying enzymes. One challenge for the next decade is to identify the molecular components required for each step of pectin biosynthesis. Many questions need to be addressed including: Does the proposed model hold for all of the glycosyl residues found in pectin? Are nucleotide-sugars the immediate glycosyl donors for all the pectin biosynthetic glycosyltransferases or are lipid-linked donors involved? Are all the required nucleotide-sugars made outside the Golgi, or are some made in the Golgi as has been suggested for UDP-Xyl (Hayashi et al., 1988)? Do the levels of nucleotide-sugars in the Golgi fluctuate and, if so, does this level regulate the relative activity of different types of glycosyltransferases? What is the organization of the different glycosyltransferases in the Golgi? How is this organization made and maintained? How is the inorganic phosphate generated by the nucleoside diphosphatase transported out of the Golgi? Does the transport of phosphate establish or maintain an ion gradient in the Golgi that is required for pectin synthesis?

2.4. Synthesis of homogalacturonan

Most effort towards understanding pectin biosynthesis has been directed towards two enzymes believed to be involved in the synthesis of homogalacturonan (HG) in planta: a homogalacturonan-α1,4galacturonosyltransferase (also referred to as polygalacturonate:α1,4-galacturonosyltranferase) and homogalacturonan-methyltransferase (also referred to as pectin methyltransferase) (see Table 1).

2.4.1. α1,4Galacturonosyltransferase (GalAT)

A membrane-bound α1,4galacturonosyltransferase (GalAT) has previously been identified and partially characterized in mung bean (Kauss and Swanson. 1969; Villemez et al., 1966), tomato (Lin et al., 1966), turnip (Lin et al., 1966), and sycamore (Bolwell et al., 1985), and more recently in suspension cultured tobacco cells (Doong et al., 1995), radish roots (H.F. Quigley, and D. Mohnen, unpublished results), enriched Golgi from elongating pea epicotyls (Sterling et al., submitted) and arabidopsis (J. Sterling and D. Mohnen, unpublished results). The GalAT from tobacco has been most extensively characterized. GalAT adds [^{14}C]GalA from UDP-[^{14}C]GalA (Liljebjelke et al., 1995) onto endogenous acceptors in membrane preparations to produce a radiolabeled product of large M_r (i.e. ~105 kDa in tobacco microsomal membranes (Doong et al., 1995) and ⩾500 kDa in pea Golgi (Sterling et al., submitted). The cleavage of up to 89% of the radiolabeled tobacco product into GalA, diGalA and triGalA upon exhaustive hydrolysis with a purified endopolygalacturonase confirmed that the product synthesized was largely HG. Since approximately 90% of the GalA in the primary wall is present in HG (Mohnen et al., 1996), these results suggest that the identified activity may be the GalAT responsible for the elongation of HG. The enzyme was thus named polygalacturonate α-4-galacturonosyltransferase (EC 2.4.1.43) (PGA-GalAT) in accordance with the nomenclature for a comparable enzyme activity in mung bean microsomes (Villemez et al., 1965, 1966; Lin et al., 1966; Kauss and Swanson, 1969). The product synthesized in vitro in tobacco microsomes is ~ 50% esterified and at least 40% of the ester is a C-6 methylester (Doong et al., 1995). These results are consistent with a model of pectin biosynthesis in which the newly synthesized HG is directly, or somewhat belatedly, esterified during synthesis.

Fractionated membranes from pea were recently used to localize GalAT to the Golgi and to demonstrate that the catalytic site of GalAT is on the lumenal side of the Golgi (Sterling et al., submitted). These results provide the first direct enzymatic evidence that a pectin biosynthetic glycosyltransferase (i.e. GalAT) resides in the Golgi.

GalAT was solubilized from membranes and shown to add GalA onto the non-reducing end (Scheller et al.,

1999) of exogenous HG acceptors (oligogalacturonides; OGAs) of a degree of polymerization $\geqslant 10$ (Doong and Mohnen, 1998). Surprisingly, the bulk of the HG is elongated by a single GalA residue in vitro using either solubilized GalAT from tobacco membranes (Doong and Mohnen, 1998) or detergent-permeabilized Golgi from pea (Sterling et al., submitted). Thus, the solubilized GalAT does not express the processivity expected for a polymer synthase. The lack of processivity of the solubilized GalAT may be due to the dissociation of an enzyme complex during solubilization, to the loss of a factor/activator required for processivity, or to the absence of a required substrate(s). Alternatively, the GalAT may not be a processive GalAT but rather a GalAT involved in a priming reaction for HG or in some other pectin biosynthetic reaction. One question that needs to be resolved is: How many contiguous GalA residues are added onto the endogenous acceptor in Golgi or microsomal preparations? In other words, how processive is the membrane-bound GalAT?

The possibility that an acceptor other than oligogalacturonides (OGAs) of DP 10-23 is required to convert the solubilized GalAT into a processive enzyme has been investigated. Specific oligosaccharide acceptor structures have been shown to be required for the processivity of other types of glycosyltransferases (Kojima et al., 1996). For example, a mammalian α2,8-polysialic acid synthase acts processively only when its protein acceptor has a specific α-1,6-linked fucose in its N-linked glycans (Kojima et al., 1996). In this case only one, or a few, sialic acid residues are added to structurally related acceptors without the α-1,6-linked fucose. Studies with GalAT suggest that neither polygalacturonic acid nor pectins of various degrees of esterification (31–90%) stimulate GalAT activity above the rate achieved with OGAs (R.L. Doong and D. Mohnen, unpublished results). GalAT activity is also not stimulated by GalA, diGalA or triGalA as individual acceptors. A question that must still be addressed is: Is endogenous HG in Golgi and in microsomal membranes a better substrate to promote processivity of GalAT in vitro than HG oligomers or commercially available PGA or pectin?

The possibility that high (>1 mM) concentrations of the substrate UDP-GalA might convert solubilized GalAT into a processive mode of action has also been tested. An effect of substrate concentration on the structure of a polymer synthesized by a glycosyltransferase has been reported for the in vitro synthesis of (1→3),(1→4) β-glucan in which the ratio of cellotriosyl to cellotetraosyl sequences increases from 1.5 to 11 as the concentration of UDP-Glc is increased from 5 μM to 30 mM (Buckeridge et al., 1999). The results of preliminary studies with GalAT, however, suggest that high concentrations (>1 mM) of UDP-GalA do not convert in vitro GalAT into a processive mode of action (H.F. Quigley and D. Mohnen, unpublished results).

HG isolated from the wall is partially methyl esterified and acetylated. Thus, it is possible that processivity of GalAT requires the simultaneous action of GalAT, HG-methyltransferase and/or HG-acetyltransferase. The in vitro synthesis of HG by GalAT in microsomal membranes, however, is not stimulated by the methyl donor S-adenosylmethionine (Kauss and Swanson, 1969; Doong et al., 1995) and/or the acetyl donor acetylCoA (D. Mohnen, unpublished results). Thus, no evidence has been obtained to support the idea that in vitro synthesis of HG by membrane bound GalAT requires concurrent methylation and/or acetylation of HG.

An obstacle to the study of GalAT is the time and expense required to synthesize UDP-[^{14}C]GalA. Radiolabeled UDP-GalA can be produced by the enzymatic epimerization of UDP-[^{14}C]GlcA to UDP-[^{14}C]GalA (Liljebjelke et al., 1995). Recently, a procedure for the one step production of UDP-[^{14}C]GalA has been reported (Basu et al., 2000). The procedure is based on the enzymatic oxidation of UDP-[^{14}C]Gal to UDP-[^{14}C]GalA (Rao and Mendicino, 1976; Kelleher and Bhavanandan, 1986). Basu et al. (2000) report a yield of $>90\%$ UDP-[^{14}C]GalA using a polyethyleneimine (PEI-cellulose) column chromatography purification step. We have found, using a slightly modified verison of this procedure, that it is necessary to purify the synthesized UDP-[^{14}C]GalA by HPLC in order to remove contaminants that inhibit GalAT activity. Under these conditions our final yield of UDP-[^{14}C]GalA was 32% (J. Sterling, and D. Mohnen, unpublished results). Further work is required to establish whether the epimerization procedure (approximately 20% yield) or the oxidation procedure (Basu et al., 2000) will prove more useful for the routine synthesis of the radiolabeled UDP-GalA required for studies of pectin biosynthesis.

The purification of GalAT has not yet been reported. Progress towards understanding the role of GalAT in HG synthesis requires that the enzyme be purified and its gene identified.

2.4.2. HG-methyltransferase (HG-MT)

HG-methyltransferase (HG-MT) [the term HG-MT is used in preference to pectin methyltransferase to specify the enzyme that methylates HG rather than RG-I or RG-II] has been identified in microsomal membranes from mung bean (Kauss et al., 1967, 1969; Crombie and Reid, 1998), flax (Vannier et al., 1992; Schaumann et al., 1993), tobacco (Goubet et al., 1998) and soybean hypocotyls (Ishikawa et al., 2000) (see Table 4). The membrane-bound HG-MTs from flax (Bruyant-Vannier et al., 1996; Bourlard et al., 1997a) and from tobacco (Goubet and Mohnen, 1999a) have been solubilized in an active form and the flax enzyme(s) has been partially purified (Bruyant-Vannier et al., 1996). The HG-MT from detergent-treated etiolated soybean hypocotyls is significantly more active (1360 pmol mg^{-1} min^{-1}) than the HG-MT

Table 4
Comparison of catalytic constants and pH optima for HG-methyltransferases involved in, or potentially involved in, pectin biosynthesis[a]

Enzyme[b]	Plant source	Apparent K_m for SAM[c]	pH optimum	V_{max}[d]	Ref
HG-MT[b]	Mung bean	59 μM	6.6–7.0	2.7[e]	(Kauss and Hassid, 1967; Kauss et al., 1969; Kauss et al., 1967)
PMT	Flax	10–30 μM	6.8	n.d.[g]	(Schaumann et al., 1993; Vannier et al., 1992)
PMT (sol)[f]	Flax	0.5 μM	7.1[h] or 5.5[i]	n.d.	(Bourlard et al., 1997a,b; Bruyant-Vannier et al., 1996)
HG-MT	Tobacco	38 μM	7.8	49	(Goubet et al., 1998)
HG-MT (sol)	Tobacco	18 μM	7.8	7.3	(Goubet and Mohnen, 1999a)
PMT-MT	Soybean	230 μM	6.8	1360	(Ishikawa et al., 2000)

[a] Unless indicated, all enzymes are measured in particulate preparations.
[b] All enzymes are thought to be HG-MT. However, since some authors use the previous name, pectin methyltransferase, it is included for clarity.
[c] Apparent K_m for *S*-adenosylmethionine.
[d] V_{max} in pmol min^{-1} mg^{-1} protein.
[e] The V_{max} is our calculation using data from Kauss et al. (1969).
[f] (sol): Detergent-solublized enzyme.
[g] n.d.: Not determined.
[h] From Bruyant-Vannier et al. (1996).
[i] From Bourlard et al. (1997a,b).

from mung bean, flax and tobacco (i.e. 3–49 pmol mg^{-1} min^{-1}, reviewed in Goubet et al., 1998). The apparent K_m of 0.23 mM for *S*-adenosylmethionine (SAM) reported for the soybean enzyme (Ishikawa et al., 2000) is much higher than the values reported for the other HG-MTs, 30–59 μM for membrane-bound HG-MTs (see Table 4 and Goubet et al., 1998) and 0.5–18 μM for solubilized HG-MT.

The low HG-MT activity recovered has hampered the purification of HG-MT or other pectin methyltransferases (Bourlard et al., 1997a). Thus, the increased activity recovered from soybean is noteworthy. The HG-MT from soybean (Ishikawa et al., 2000) was assayed by spotting the radiolabeled product onto paper, followed by paper chromatography to remove the unincorporated radiolabeled SAM. The product immobilized at the base of the paper chromatogram strip was analyzed by scintillation counting. Most other studies of HG-MT have employed a precipitation method to recover synthesized product. The precipitation method may not recover all of the methylated product (Pauly and Scheller, 2000). Alternatively, differences in the recovered HG-MT activity may depend on the plant species, on the amount and type of exogenous pectic acceptors used, or on whether intact membranes, detergent permeabilized membranes, or solubilized enzyme are used.

A question regarding the synthesis and methylation of HG is: How are the activities of GalAT and HG-MT coordinated during the synthesis of HG? The methylesterification of HG in membranes from mung bean (Kauss and Swanson, 1969) and tobacco (Goubet et al., 1998) is increased by the addition of UDP-GalA, a substrate for HG synthesis. The stimulation of HG-MT activity by UDP-GalA would be expected if either HG synthesis, or HG substrate, was required for endogenous methylation of HG. Evidence from studies with intact membranes in which UDP-GalA stimulates HG-MT activity (Kauss and Swanson, 1969; Goubet et al., 1998), and from studies using detergent-permeabilized membranes and solubilized HG-MT in which polygalacturonic acid or partially methylesterified pectin serve as acceptors of HG-MT, support the hypothesis that at least a small stretch of HG is synthesized prior to its methylation by HG-MT in the Golgi. However, the available results regarding the relationship between the action of GalAT and HG-MT need to be confirmed by reconstitution experiments using cloned and/or purified enzymes, and by using plants transgenically modified in the pectin biosynthetic genes.

Tobacco membrane-bound HG-MT has been localized to the Golgi and its catalytic site shown to face the Golgi lumen (Goubet and Mohnen, 1999b). These observations are consistent with earlier reports that mung bean HG-MT resides in a membrane compartment (Kauss and Swanson, 1969), and that a pectin methyltransferase from pea epicotyls is located in the Golgi (Baydoun et al., 1999). Similarly, about half of the pectin methyltransferase activity from flax co-fractionates with Golgi vesicles (Vannier et al., 1992; Bourlard et al., 1997b). The co-localization of the catalytic sites of GalAT and HG-MT in lumen of the Golgi support the notion that these enzymes act together, either sequentially or as a complex, during the synthesis of HG. Two questions that must be addressed are: How many different HG-MTs are required for HG synthesis?, and What is the substrate specificity of the HG-MT(s)? The fact that at least one HG-MT in detergent-permeabilized membranes from flax and soybean shows a preference for partially esterified pectin over polygalacturonic acid (Bourlard et al., 1997b; Ishikawa et al., 2000), suggests

that multiple HG-MTs may exist that either initiate the methylation of HG or enhance the further methylation of HG. Different HG-MTs may also exist that recognize other structural differences in HG (e.g. degree of acetylation or other modifications).

2.4.3. HG-acetyltransferase (HG-AT)

A pectin *O*-acetyltransferase activity has been identified in microsomes from suspension-cultured potato cells (Pauly and Scheller, 2000). Incubation of potato microsomes with [^{14}C]acetyl-CoA resulted in the recovery of a NaCl/ethanol precipitable product. Approximately 8% of the radiolabeled product was specifically solubilized by treatment EPGase and PME indicating that [^{14}C]acetate had been transferred either to HG, or to RG-II or RG-I that was covalently attached to HG. Further work is required to establish whether the described activity is an HG-AT or an acetyltransferase that acetylates one of the other pectic polysaccharides that is covalently linked to HG.

2.5. Synthesis of rhamnogalacturonan-I (RG-I)

2.5.1. RG-I-galactosyltransferase (RG-I-GalT)

Galactosyltransferase activity has been identified in particulate cell free homogenates from mung bean (McNab et al., 1968; Panayotatos and Villemez, 1973). It is possible that RG-I biosynthetic galactosyltransferases (see Table 2) were among those present in the homogenate since the synthesized product contained some β-1,4-galactan and a lesser amount of β-1,3-galactan (Panayotatos and Villemez, 1973). More recently, a β-1,4-galactosyltransferase activity with a pH of optimum of 6.5 has been identified in membrane preparations from mung bean hypocotyls based on sensitivity of the product to fragmentation by endo-β-1,4-galactanase (Brickell and Reid, 1996). Such results are consistent with an RG-I biosynthetic β-1,4-galactosyltransfserase in mung bean microsomal membranes. Galactosyltransferases have also been studied in particulate homogenates (Goubet and Morvan, 1993, 1994) and solubilized enzymes (Goubet, 1994) from flax. The chemical properties of some of the products synthesized in flax are consistent with those expected for GalTs involved in RG-I or arabinogalactan protein synthesis. However, glycosyl-linkage composition analysis of the synthesized product, or proof that the products are cleaved with RG-I-specific enzymes, is required to confirm this interpretation.

An RG-I:β-1,4-galactosyltransferase in suspension-cultured potato cells transfers [^{14}C]Gal from UDP-[^{14}C]Gal onto endogenous acceptor(s) in the membranes (Geshi et al., 2000). The synthesized product was fragmented by a purified endo-β-1,4-galactanase and rhamnogalacturonase A (an endohydrolase that cleaves the glycosidic linkage between the GalA and the Rha in the backbone of RG-I; Azadi et al., 1995), showing that the GalT catalyzed the transfer of galactose to RG-I. The β-1,4-galactosyltransferase had a pH optimum of 6.0–6.5 and required Mn^{2+} for maximum activity. The intact [^{14}C]Gal-labeled product synthesized in potato membranes had an estimated size of >500 kDa. Fragmentation of the intact product using endo-β-1,4-galactanase yielded [^{14}C]Gal and [^{14}C]galactobiose as the primary radiolabeled products. Cleavage of the intact and de-esterified (to remove methyl and acetyl groups from the RG-I backbone) product with rhamnogalacturonase A fragmented the product into material between 50 and 180 kDa in size. Subsequent treatment of the [^{14}C]Gal-labeled fragments with endo-β-1,4-galactanase yielded [^{14}C]Gal and slightly larger fragments that themselves could be cleaved to [^{14}C]Gal by a purified β-galactosidase. Taken together, these results support the conclusion that potato microsomal membranes contain enzymes that both initiate, and elongate, β-1,4-galactan side chains of RG-I.

2.5.2. RG-I-arabinosyltransferase

Arabinosyltransferases putatively involved in the synthesis of RG-I side chains have been recently reviewed (Mohnen, 1999). One advance in this area is the description of an improved procedure for the synthesis and purification of non-radiolabeled and radiolabeled UDP-β-L-arabinopyranose (Pauly et al., 2000). The UDP-Ara is produced by the enzymatic 4-epimerization of UDP-Xyl to UDP-Ara using a partially purified UDP-xylose-4-epimerase from wheat germ (Fan and Feingold, 1970; Feingold and Avigad, 1980). The UDP-Ara is purified by high performance anion exchange chromatography (HPAEC), a method that also allows quantitation of the product (Pauly et al., 2000).

2.5.3. RG-I-methyltransferase (RG-I-MT)

Detergent-solubilized pectin methyltransferase (PMT) from suspension-cultured flax cells uses an RG-I-enriched fraction from flax fibers as an exogenous acceptor (Bourlard et al., 1997a). In the presence of the RG-I fraction, methyltransferase activity was stimulated 1.5- to 1.7-fold above the endogenous acceptor activity and the radiolabeled product recovered had a size similar to the RG-I fraction. While these results suggest that an RG-I methyltransferase activity may have been identified, it has not yet been shown where in RG-I the methylation occurred. Methylation may have occurred on HG tails covalently linked to RG-I. Thus, the identified activity may result from methylesterification of HG rather than methylesterification of the galacturonic acid in the RG-I backbone. Alternatively, the methylation could have occurred on a non-galacturonic substituent. Some of the side chains of RG-I contain 4-*O*-methylGlcA (An et al., 1994). Further work is required to determine the site(s) of methylation and thus, the identity of the enzyme reported.

2.5.4. RG-I-acetyltransferase (RG-I-AT)

An RG-I acetyltransferase has been identified in microsomes from suspension-cultured potato cells (Pauly and Scheller, 2000). Incubation of potato microsomes with [^{14}C]acetyl-CoA resulted in the recovery of a NaCl/ethanol precipitable product that consisted of at least 19% acetylated RG-I based on the release of [^{14}C]acetate by treatment with a purified rhamnogalacturonan *O*-acetyl esterase (Pauly and Scheller, 2000). The product recovered from the microsomes had a mass >500 kDa and was partially fragmented by treatment with rhamnogalacturonan lyase (RGase B). An assay for RG-I-AT was developed based on specific solubilization of the product with RGase B. RG-I-AT has a pH optimum of 7.0 with 80% of activity retained from pH 6.5 to 8.0. The potato RG-I-AT has an apparent K_m for acetyl-CoA of 35 μM and an apparent V_{max} of 54 pmol min^{-1} mg^{-1} protein.

2.6. Synthesis of rhamnogalacturonan-II (RG-II)

2.6.1. RG-II-methyltransferase (RG-II-MT)

Detergent-solubilized pectin methyltransferase (PMT) from suspension-cultured flax cells is able to use RG-II isolated from wine as an exogenous acceptor (Bourlard et al., 1997a). In the presence of RG-II, the methyltransferase activity was stimulated 7-fold above the endogenous acceptor activity and the radiolabeled product had a size similar to RG-II monomers and RG-II dimers. While these results suggest that an RG-II-MT activity (see Table 3) may have been identified, it has not yet been shown where in RG-II the methylation occurred. Methylation of the HG "tails" covalently linked to RG-II, would represent methylesterification of HG rather than methylesterification of RG-II. Alternatively, the activity may represent methyletherification of side chain residues since RG-II side chains contain 2-*O*-methyl xylose and 2-*O*-methyl fucose (Darvill et al., 1978). Further research is required to determine the location of methylation and thus, the identity of the potentially novel enzyme activity.

2.6.2. Pressing needs in pectin biosynthesis research

Progress in understanding how pectin is synthesized requires that genes that encode the biosynthetic enzymes be identified. The genes are essential to generate the tools (e.g. antibodies against the biosynthetic enzymes and transgenic plants modified in pectin biosynthesis) needed to elucidate the structure and function of each enzyme and to determine how the enzymes work together to synthesize the structurally complex pectic polysaccharides. Furthermore, a study of the regulation of the pectin biosynthetic genes may indicate how the fine structure of pectin is altered during plant growth and development. The production of transgenic plants modified in the synthesis of pectin will allow the testing of hypotheses, the establishment of models of pectin biosynthesis, and the elucidation of the function(s) of pectin in the plant.

As noted above, the identification of pectin biosynthetic genes will undoubtedly come, in part, through the purification of the biosynthetic enzymes and the use of amino acid sequences to identify the genes in plant DNA databases. It is also likely that putative pectin mutants will be useful for identifying candidate genes, as will DNA sequence/motif similarity computer searches. Gene families for some of the hemicellulose biosynthetic enzymes such as xyloglucan:α1,2-fucosyltranferase (Perrin et al., 1999) and galactomannan: α1,6-galactosyltransferase (Edwards et al., 1999) have been identified. Some of the putative fucosyltransferase and galactosyltransferase genes may encode enzymes involved in RG-II and/or RG-I synthesis. Once the first genes for pectin biosynthetic enzymes are cloned, it is likely that web-based sequence analysis sites, such as the "carbohydrate active enzyme server (CAZY)" established by Bernard Henrissat (http://afmb.cnrs-mrs.fr/~pedro/CAZY/db.html), will be useful aids for the identification of genes for other pectin biosynthetic enzymes. For example, the section of the CAZY site devoted to glycosyltransferases currently contains 51 sequence-based families that are expected to have similar tertiary structure. Thus, once the first pectin galacturonosyltransferase gene (for example) is identified, such sequence/structure-based databases may allow the rapid identification of other putative pectin galacturonosyltransferases. The definitive identification of pectin biosynthetic genes, however, will require proof of enzymatic activity. Thus, one major area of need is the generation of the required nucleotide-sugar and oligo/polysaccharide substrates for the biosynthetic enzymes. This is a challenging problem since many of the chemical or enzymatic methods required to generate the specific fragments needed for use as acceptors for the enzymes are not available. Thus, progress in identifying pectin biosynthetic genes, and in studying the biosynthetic enzymes, will require the combined use of carbohydrate chemistry, biochemistry, molecular biology and genetics.

3. Biological activities of oligogalacturonides

3.1. Introduction

Biologically active carbohydrates that act as signal molecules are called oligosaccharins (reviewed by Côté and Hahn, 1994; Côté et al., 1998). Oligogalacturonides (OGAs), which are linear molecules of two to about twenty α-1,4-D-galactopyranoslyuronic acid (GalA) residues, were the first plant oligosaccharins to be discovered (Bishop et al., 1981; Hahn et al., 1981). OGAs are released upon fragmentation of homogalacturonan (HG) from the plant primary cell wall (reviewed by Côté

et al., 1998). Biological responses to OGAs occur in at least five of the six subclasses of dicotyledonous plants; Magnoliidae, Hamamelidae, Asteridae, Rosidae, Dilleniidae (Côté and Hahn, 1994; Reymond, et al., 1996); in a monocot (Moerschbacher et al., 1999); and a gymnosperm (Asiegbu et al., 1994). A number of different biological responses to OGAs have been reported, and the particular response observed depends on the plant species, the bioassay, and the chemical structure of the OGA used (Côté et al., 1998). A spectrum of modified and unmodified OGAs of various lengths are active in different systems (reviewed by Côté and Hahn, 1994; for recent examples see Reymond et al., 1996; Weber et al., 1996; Simpson et al., 1998; Spiro et al., 1998; Moerschbacher et al., 1999). The biological responses of plants to OGAs can be divided into two broad categories: plant defense, and plant growth and development (Côté and Hahn, 1994).

3.2. Oligogalacturonide-induced responses involved in plant defense

Pathogens enter plant tissues in at least three ways: digesting cell walls, entering through wounds, and invading through natural openings such as stomata. Pectins are one of the first targets of digestion by invading pathogens (Pagel and Heitifuss, 1990). OGAs are released when endopolygalacturonases (EPGases) and endopectate lyases (ePLases) secreted from the pathogen degrade the homogalacturonan in the cell wall (Côté et al., 1998). The OGAs released are a carbon source for the pathogens, but can also be detected by plants as signals to initiate defense responses. A plant may attempt to limit introgression by the pathogen in several ways. For example, the plant may strengthen its cell walls, close its stomata, synthesize phytoalexins and other antibiotic compounds, synthesize pathogenesis-related (PR) proteins and toxic peptides, contain the infection by means of localized cell death resulting from the hypersensitive response (HR), and produce cytotoxic active oxygen species (Low and Merida, 1996; Côté et al., 1998; Bolwell, 1999). Exogenously added OGAs inhibit the light-induced opening of stomata in tomato and *Commelina communis* L. leaves (Lee et al., 1999). Stomatal openings provide access to inner leaf tissues required by many plant pathogens (Agrios, 1997), suggesting that the constriction of stomatal apertures is beneficial for plant defense.

The first response observed after the addition of OGAs that is clearly involved in plant defense is the production of active oxygen species, including H_2O_2, and O_2^- (Low and Merida, 1996). This response, termed the oxidative burst, occurs within a few minutes after the addition of OGAs to suspension-cultured soybean (Legendre et al., 1993a), tobacco (Rout-Mayer et al., 1997; Binet et al., 1998), and tomato (Stennis et al., 1998) cells. Protein synthesis was not required for tomato suspension-cultures to initiate an oxidative burst, suggesting that changes in gene expression are not required (Stennis et al., 1998). Intact tomato leaves have been reported to produce active oxygen species in response to systemically (Orozco-Cardenas and Ryan, 1999) or locally (Lee et al., 1999) applied OGAs.

The oxidative burst is an immediate and localized reaction that is believed to have several roles in plant defense (Low and Merida, 1996; Bolwell, 1999). The quantities of reactive oxygen species produced can be cytotoxic and thus are expected to be antimicrobial. Reactive oxygen species are thought to have direct (through cytotoxicity) and indirect (through signaling) roles in the plant cell death required for the HR. Reactive oxygen species induce the expression of defense related genes (Lamb and Dixon, 1997), and are implicated as second messengers that elicit other defense responses, including systemic acquired resistance (SAR) and the HR (Bolwell, 1999). SAR is the induction of defense mechanisms at locations remote from the original wound or infection site that serve to prepare the plant to defend itself against new attacks by pathogens (Sticher et al., 1997). In addition, reactive oxygen species drive the rapid peroxidase-mediated oxidative cross-linking of cell wall lignins, proteins, and carbohydrates, thereby reinforcing the wall against enzymatic maceration by the pathogen (Côté and Hahn, 1994).

OGAs initiate signaling cascades that activate a plant's defense responses and many examples of OGA-elicited induction of defense related genes and proteins have been reported (Côté and Hahn, 1994). The exogenous application of OGAs elicit the expression of proteinase inhibitors (PIs) in tomato plants (Bishop et al., 1984; Moloshok et al., 1992). These PIs inhibit insect proteases and thereby decrease the digestability of plant proteins and reduce the nutrients available to feeding insects (Orozco-Cardenas et al., 1993). OGAs have been shown to induce phenylalanine ammonia-lyase (PAL), the activity of the first enzyme in the phenylpropanoid pathway, in suspension-cultured carrot (Messiaen and VanCutsem, 1994) and tobacco (Lapous, et al., 1998) cells, and in bean cotyledons (Dixon et al., 1989; Tepper and Anderson, 1990). This biochemical pathway leads to the production of phytoalexins and lignin. The activity of chalcone synthase (CHS), which is part of a branch in the phenylpropanoid pathway leading to the production of flavonoids including some phytoalexins, is induced by OGAs in bean cotyledons (Tepper and Anderson, 1990; Rose et al., 1999). The activity of casbene synthetase, an enzyme required for the synthesis of the phytoalexin casbene, is induced by OGAs in castor bean seedlings (Walker-Simmons et al., 1984). Accordingly, OGA-induced phytoalexin accumulation has been observed in soybean cotyledons (Davis et al., 1986a; Komae et al., 1990), bean cotyledons (Dixon et al., 1989; Tepper and Anderson, 1990), castor bean seedlings (Walker-Simmons

et al., 1984), pea pods (Walker-Simmons et al., 1984), and parsley suspension-cultured cells (Davis and Hahlbrock, 1987).

OGAs have a role in the induction of cell wall strengthening in response to pathogenic infection (Côté and Hahn, 1994). OGAs induce a series of cell wall peroxidase isoenzymes in suspension-cultured castor bean cells (Bruce and West, 1989). In the presence of active oxygen species, such peroxidases catalyze the free-radical mediated cross-linking of lignins, proteins, and carbohydrates, thereby strengthening the wall. OGA treatment of bean seedlings induced the accumulation of hydroxyproline-rich glycoproteins (HRGPs) which may also reinforce the cell wall after free-radical mediated cross-linking (Boudart et al., 1995). In addition, OGAs have been shown to induce lignin deposition in suspension-cultured castor bean cells (Bruce and West, 1989), cucumber hypocotyls (Robertson, 1986), and bean cotyledons (Tepper and Anderson, 1990).

Exogenously added OGAs regulate the expression of some enzymes and polypeptides that are involved in extracellular polysaccharide metabolism. For example, OGAs induce β-1,3 glucanase in suspension-cultured parsley cells (Davis and Hahlbrock, 1987), and chitinase in tobacco leaves (Broekaert and Peumans, 1988). Both of these enzymes fragment fungal cell wall polysaccharides. OGAs also elicit the expression of the mRNA and activity of an endogenous EPGase and of endopolygalacturonase-inhibiting protein (PGIP); two proteins involved in the metabolism of homogalacturonans in the cell wall. The elicited EPGase is present in tomato leaves and may have a role in the SAR response to insect feeding (Orozco-Cardenas and Ryan, 1999). PGIP, which was shown to be elicited by OGAs in suspension-cultured bean cells, binds to fungal EPGases in vitro and slows the rates of their enzymatic reactions (Bergmann et al., 1994). Thus PGIP is thought to expedite the plant's defense response by prolonging the life of the elicitor active OGAs in the apoplasm, and slowing the degradation of cell wall pectins (Cervone et al., 1993).

OGAs have been implicated in HR, but their role is unclear. OGAs may have a role in protecting potato tubers from maceration by the bacterial pathogen *Erwinia carotovora*, which causes potato soft rot (Weber et al., 1996). The protection may be mediated by OGA-induced cell death, but more work is needed to confirm this. Indeed, injection of OGAs into tobacco leaves prior to their inoculation with the pathogenic bacteria *Pseudomanas syringae* pv. syringae, completely inhibited the expected hypersensitive reaction (Baker et al., 1990). In contrast, the hypersensitive reaction is only partially inhibited when wheat leaves are injected with OGAs prior to their inoculation with the wheat rust fungus *Puccina graminis* Pers. f. sp. tritici (Moerschbacher et al., 1999).

3.3. Biological responses involved in plant growth and development

Exogenously added OGAs influence the growth and development of plant tissues (Côté and Hahn, 1994). OGAs inhibit auxin-induced pea stem elongation (Branca et al., 1988) and are also active in the tobacco thin-cell layer (TCL) (Tran Thanh Van et al., 1985; Mohnen et al., 1990), and the tobacco leaf explant (Bellincampi et al., 1993) bioassays. When biologically active OGAs are added to media containing specific phytohormone concentrations, TCLs that would normally form few or no organs form flowers, while TCLs that normally form roots form significantly fewer roots (Eberhard et al., 1989; Marfà et al., 1991). Biologically active OGAs inhibit root formation (Bellincampi et al., 1993) and increase stomata formation (Altamura et al., 1998) on tobacco leaf explants incubated in media with specific phytohormone concentrations. All of the affects OGAs have on tobacco explant morphogenesis could be mimicked if the explants were cultured on media containing a lower auxin concentration (Branca et al., 1988; Eberhard et al., 1989; Altamura et al., 1998).

OGAs are involved in fruit ripening. They have been shown to induce ethylene production in the fruits of tomato (Brecht and Huber, 1988; Campbell and Labavitch, 1991) and citrus (Baldwin and Biggs, 1988). Pectic fragments that elicit ethylene production have been extracted from tomato fruit at the breaker stage of ripeness. This suggests that OGAs, presumably released by EPGase, could be involved in initiating the ripening process (Melotto et al., 1994), since exogenous ethylene initiates the ripening process and the production of ethylene is required for ripening (Theologis et al., 1993; Giovannoni, 1997). The role of OGAs in fruit ripening, however, seems to be complex and is not understood. Tomato fruits expressing antisense EPGase mRNA exhibited a 99% reduction in EPGase activity and a substantial reduction in pectin depolymerization, but were unaffected in their ethylene production and overall ripening (Smith et al., 1990). Moreover, the increase in ethylene production during ripening is detected prior to the increase in EPGase production (Grierson and Tucker, 1983), and elevated ethylene levels can induce the accumulation of EPGase mRNA (Sitrit and Bennett, 1998). The addition of trigalacturonide to ripening tomato fruit tissue inhibits the increase in EPGase mRNA and enzyme activity, as well as fruit ripening (Mignani, et al., 1995). These data indicate that although OGAs are involved in tomato fruit ripening, their role in the process is not clear (discussed in Rose et al., 1998).

In every case reported to date where OGAs regulate the growth and development of plant tissues, with the exception of fruit ripening, their effect is the opposite of the effect of added auxin (Branca et al., 1988; Eberhard et al., 1989; Altamura et al., 1998). Accordingly, OGAs

inhibit the auxin-induced expression of the plant oncogene rolB (Bellincampi et al., 1996), and the auxin-induced division of phloem parenchyma cells (Altamura et al., 1998) in tobacco leaf disk explants. OGAs also induce the tobacco leaf explants to produce extracellular H_2O_2 (Bellincampi et al., 2000). However, the H_2O_2 does not appear to have a role in the OGA induced signal transduction pathway leading to the inhibition of rolB expression (Bellincampi et al., 2000). The mechanism by which OGAs act in opposition to the action of auxin is presently unknown.

3.4. The structural requirements for the biological activity of oligogalacturonides

Many studies attributing biological responses to OGAs have used impure mixtures of OGA oligomers that often contain sugars other than galacturonic acid (Côté and Hahn, 1994). The results of such studies must be considered carefully, since molecules other than OGAs may be responsible for the observed biological activities. Furthermore, studies using mixtures of different sizes of OGA oligomers reveal little about the OGA structure that is required for biological activity. Homogeneous, size-fractionated OGAs are relatively easy to prepare, and have been used in some studies (Spiro et al., 1993, 1998). Thus, only studies using size fractionated OGAs will be discussed in this section.

Most biological responses have been attributed to OGAs with a degree of polymerization (DP) from 10 to 16, with the most active sizes being around DP 12 (Côté and Hahn, 1994). These responses include: the induction of phytoalexins in soybean (Davis et al., 1986a; Komae, et al., 1990), the induction of casbene synthetase in castor bean (Jin and West, 1984), the induction of PAL in suspension-cultured carrot cells (Messiaen and Van Cutsem, 1994), the induction of rolB expression in tobacco leaf explants (Bellincampi et al., 1993), the induction of Ca^{2+} influx in suspension-cultured tobacco cells (Mathieu et al., 1991), and the regulation of organogenesis in tobacco TCL and leaf explants (Marfà et al., 1991; Bellincampi et al., 1993). The same size range of OGAs (i.e. DP ~10-16) having a GalA or a Δ-4,5 unsaturated GalA residue at the non-reducing terminus induce the production of phytoalexins in soybean cotyledons, indicating that 4,5-unsaturation of the non-reducing terminal GalA does not greatly influence the biological activity of the OGAs (Hahn et al., 1981; Davis et al., 1986b; Komae et al., 1990). In contrast, modifications of the reducing terminus including biotinylation, tyramination, C_1 reduction, and C_1 oxidation decrease the biological activity of OGAs 2–6 fold in the tobacco TCL bioassay and 2–32 fold in suspension-cultured tobacco cell extracellular alkalinization bioassays (Spiro et al., 1998). Chemical esterification of the C_6 carboxylates of OGAs greatly diminishes their ability to elicit casbene synthetase in castor bean, whereas subsequent deesterification restores their biological activity (Jin and West, 1984). This shows that, at least in the case of induction of casbene synthetase, free carboxylates are necessary for activity.

The minimum size of OGAs required for most of the biological activities reported, and the minimum size requirement for the formation of a Ca^{2+}-dependent conformation often called the "egg-box" conformation, coincide at a DP of approximately 10 (Kohn, 1975; Côté and Hahn, 1994; Messiaen and Van Cutsem, 1994; Thakur et al., 1997). Millimolar Ca^{2+} is required for biological activity of OGAs in carrot and tobacco cell suspensions (Mathieu et al., 1991; Messiaen and Van-Cutsem, 1994) which suggests that a Ca^{2+}-dependent conformation formed by OGAs with DPs $\geqslant 10$ is required for biological activity in certain bioassays (Côté and Hahn, 1994; Messiaen and VanCutsem, 1994). The polyamines spermidine and spermine are believed to selectively prevent OGAs from adopting the Ca^{2+}-dependent conformation (Messiaen and Van Cutsem, 1999). Physiological concentrations of these polyamines inhibit the biological activity of OGAs in carrot cell suspensions, suggesting that they modulate the biological activity of OGAs by preventing the Ca^{2+}-dependent formation of an active conformation (Messiaen and VanCutsem, 1999).

There are several reports showing that OGAs other than those with DPs from 10 to 17 are biologically active (Côté and Hahn, 1994). For example, OGAs from DP 2 to 30 elicit the expression of proteinase inhibitors (PIs) in tomato seedlings, with the disaccharide being the most active (Farmer et al., 1990; Moloshok et al., 1992). In this system, di- and tri-GalA with Δ-4,5 unsaturated GalA at the non-reducing terminus are active, whereas C_1 reduced oligomers are not. OGAs with a DP from two to six induce ethylene biosynthesis in tomato plants, with the pentasaccharide being the most active (Simpson et al., 1998). Trigalacturonide is active in inhibiting the production of EPGase in ripening tomato fruit tissue (Mignani et al., 1995). Di- and tri- GalA elicit the accumulation of HGRPs in the cell walls of bean seedlings (Boudart et al., 1995). Di- and tri- GalA also suppress the induction of PAL and the hypersensitive response to a fungal pathogen in wheat leaves (Moerschbacher et al., 1999). Nonreducing-end Δ-4,5 unsaturated di-GalA is active in inhibiting tissue maceration in potato tuber tissue infected with the bacterial soft rot pathogen Erwinia carotovora (Weber et al., 1996).

3.5. Presence and fate of biologically active oligogalacturonides in plant tissues

Plant cells and plant pathogens secrete endo- and exo-polygalacturonases into their extracellular matrix.

EPGases are often found at sites where the application of exogenous OGAs elicit a biological response and thus, the EPGases are present at those locations where the release of biologically active OGAs would be expected (Côté et al., 1998; Hadfield and Bennett, 1998). However, a conclusive demonstration that EPGases release biologically active OGAs from a plant's cell wall at physiologically relevant locations and times is lacking. The best evidence to date comes from studies of ripening tomato fruit. Polygalacturonase activity is known to increase during tomato ripening, and pectic oligomers that elicit ethylene have been extracted from tomato fruits at the breaker stage of ripening (Melotto et al., 1994). Purified OGAs with a DP greater than eight initiate ethylene biosynthesis in tomato fruits (Brecht and Huber, 1988; Campbell and Labavitch, 1991). The OGA-enriched material isolated from ripening tomato fruit, and EPGase-generated OGAs have similar chromatographic profiles, suggesting that the active components in the fruit extracts are OGAs. However, the individual OGA oligomers isolated from the fruit cell wall material are contaminated with the neutral sugars present in RG I and RG II.

There have been conflicting reports concerning the movement of OGAs in plants. When crude ^{3}H-labeled pectic fragments (Bishop et al., 1981) or ^{3}H-labeled OGAs (MacDougall et al., 1992) are introduced into the xylem of tomato plants through cut stems, the radiolabel moves through the plant with the transpiration stream. Ninety minutes after being introduced, the label was found throughout the plant (MacDougall et al., 1992). Labeled OGAs recovered from the plants had been fragmented into smaller oligomers, and some were esterified with an unidentified alcohol. In contrast, ^{14}C-labeled pectin and ^{3}H-labeled pectic fragments were immobile when applied to wounds on the leaves of tomato plants (Baydoun and Fry, 1985). The label would have needed to move out of the leaves via the phloem, since xylem flow is transpiration driven and normally flows into leaves. The immobility of the label indicates that OGAs do not move in the phloem, and that biologically active OGAs generated in infected leaves cannot move through the plant and induce SAR. In contrast, OGAs released during infection of the roots or stems could move throughout the plant's xylem and induce SAR (MacDougall et al., 1992).

To function as signal molecules, biologically active OGAs must be present when the physiological responses they induce are required and are likely to be absent when the responses are not required. Therefore, it is likely that OGA signal molecules are removed or inactivated following the activation of a physiological response. Endogenous EPGases are often found in plant tissues where the exogenous application of OGAs would elicit physiological responses. For example, polygalacturonase activity has been found in suspension-cultured tobacco (Mathieu et al., 1998), carrot (Konno et al., 1989) and rose (García-Romera and Fry, 1995) cells, as well as in cotton cotyledons (Zhang et al., 1996). In the tobacco and rose cells, the enzymes do not release biologically active concentrations of OGAs from the plant cell walls, suggesting that the enzymes are maintained in an inactive state or that their substrates are inaccessible (Mathieu et al., 1998; García-Romera and Fry, 1995). On the other hand, exogenously added OGAs are rapidly sequestered into the cell wall or degraded in tobacco (Mathieu et al., 1998) and rose (García-Romera and Fry, 1997) suspension-cultured cells. These findings indicate that endogenous endo- and exo- polygalacturonases capable of degrading biologically active OGAs after initiation of a physiological response are present in suspension-cultured cells (Mathieu et al., 1998; García-Romera and Fry, 1997).

3.6. Oligogalacturonide receptors

Considering the diversity of biologically active OGA structures, and the range of biological activities attributed to these structures, it would not be surprising to find that OGAs are perceived through multiple mechanisms (Côté and Hahn, 1994; Spiro et al., 1998). It is generally believed that biologically active macromolecules are recognized by receptor proteins and that this recognition event elicits a biological response via a signal transduction cascade (Hahn, 1996). The widely variable concentrations of OGAs required for bioactivity (from 10^{-4} to 10^{-7} M) supports the notion that OGAs are recognized by a number of receptors with different affinities (Côté and Hahn, 1994). However, OGAs can bind to each other and to other homogalacturonans in the cell wall. A significant portion of the OGAs added to suspension-cultured tobacco cells was found to be ionically bound to the cell wall (Mathieu et al., 1998). Thus, OGAs may saturate binding sites in the wall before they can be perceived at the plasma membrane. If this is the case, the concentration required for biological activity would not reflect the affinity of the receptor.

The possibility that the cell wall itself could be the 'receptor' for OGAs has been discussed (Mohnen and Hahn, 1993). OGAs may intercalate into the junction zones formed by the self-association of homogalacturonans, thereby releasing some of the tension in the wall (Carpita and Gibeaut, 1993; Rose et al., 1999). Changes in the tension of cell wall polymers may be transmitted to the cytoskeleton and initiate signaling cascades through transmembrane proteins similar to integrins (Schwartz et al., 1995; Miller et al., 1997; Faik et al., 1998).

Suspension-cultured soybean cells have been reported to respond to OGAs in a process of receptor mediated endocytosis in (Horn et al., 1989). An OGA of DP 14,

derivatized with fluorescein via a thiosemicarbazone linkage, bound to the surface of soybean suspension-cultured cells and was internalized. The fluorescence traveled from the plasma membrane to the vacuole over the course of two hours. OGAs labeled with I^{125} after derivatization with tyrosine via a hydrazone linkage were used to measure the binding kinetics. The binding was competitively inhibited by an excess of non-labeled OGA (Horn et al., 1989), and was saturated at a concentration about five times higher than that required for maximum biological activity (Low et al., 1993). To date, no connection has been made between this binding and a biological response elicited by OGAs. It should be noted that the thiosemicarbazone and hydrazone linkages used in these derivatives are chemically unstable (Ridley et al., 1997). Thus, it is not certain whether OGA was covalently linked to all the fluorescence or iodinated signals observed.

A 34 kilodalton (kd) plasma membrane protein that is phosphorylated in response to OGAs with a DP from 13 to 30 has been cloned from potato (Farmer et al., 1991; Reymond et al., 1996). This protein, called remorin, binds to, and is phosphorylated in vitro in response to, OGAs of the same size range (Reymond et al., 1995, 1996). Immunologically similar proteins that are phosphorylated in response to OGAs were found in several widely divergent species of dicots. The OGA size requirement for phosphorylation of remorin does not match the size requirement for any of the known OGA-induced biological responses and remorin has not been implicated in any of the known biological responses elicited by OGAs. Remorin does not have homology to any known receptor proteins, although it does share properties such as plasma membrane-association, binding to polyanions, and phosphorylation, with the 30-kd cell-to-cell movement protein of tobacco mosaic virus (Reymond et al., 1996). Interestingly, viral cell movement proteins bind pectin methylesterase in the wall (Dorokhov et al., 1999) and deletion of the PME-binding region of the movement protein inhibits cell-to-cell viral movement through plasmodesmata (Chen et al., 2000). The hypothesis that remorin plays a role in plant driven transport or signaling through plasmodesmata has been prosposed (Reymond et al., 1996).

3.7. Oligogalacturonide induced signaling cascades

Much information is available concerning the signaling events underlying a plant's responses to OGAs and a coherent picture of these events is now beginning to emerge. Selected elements of the signaling cascades have been studied in suspension-cultured soybean, tobacco, and carrot cells, and in tomato plants, but in no case have all elements been studied in one system. Several potential limitations of these studies should be considered when general conclusions are made. The OGAs used in many of these studies were not size-fractionated or completely pure. Since differently-sized OGAs can elicit unique sets of responses, the responses obtained using mixtures of differently-sized OGAs could result from multiple receptors and/or the induction of multiple signal transduction pathways. Furthermore, cultured plant cells are in vitro systems that are subject to genetic and epigenetic variation and extrapolating results obtained with such cells to the physiology of whole plants can be difficult. Finally, much of the information available is based on the use of pharmacologic inhibitors whose specificity and affects are not well characterized in plants.

3.7.1. Suspension-cultured soybean cells: early signaling events

Cultured soybean cells produce H_2O_2 within seconds to a few minutes after the addition of partially purified pectic fragments (Legendre et al., 1992, 1993a). OGA elicited H_2O_2 production appears to be tightly regulated since the quantity and duration of H_2O_2 production are limited, and are relatively consistent between experiments (Legendre et al., 1993a,b). Furthermore, the cells become desensitized to an additional dose of OGAs for a defined period (refractory period). It is noteworthy that OGA-elicited H_2O_2 production in suspension-cultured soybean cell is not accompanied by transient extracellular alkalinization (Horn et al., 1992), as it is in suspension-cultured carrot and tobacco cells (Messiaen and VanCutsem, 1994; Matheiu et al., 1996b).

Signaling events that require protein phosphorylation and GTP binding proteins (G-proteins) may be required for H_2O_2 production (Fig. 6). The protein kinase inhibitors, K252a and staurosporine block the OGA-induced oxidative burst in a concentration dependent manner, whereas the phosphatase inhibitors, okadaic acid and calyculin A elicit an oxidative burst in the absence of OGAs (Chandra and Low, 1995). This suggests that kinase activity is required for the oxidative burst, and that in the absence of phosphatase activity a basal level of kinase activity can activate the signaling cascades leading to H_2O_2 production in the absence OGAs. The G-protein activator, mastoparan, also elicits an oxidative burst in soybean cells, suggesting that G-protein activation is required for the oxidative burst (Legendre et al., 1992). However, direct G-protein involvement in OGA-elicited oxidative burst has not been demonstrated, and more than one signal transduction pathway leading to oxidative burst is likely to exist in plants (Low and Merida, 1996; Bolwell, 1999). Phospholipase C activation resulting in the release of inositol triphosphate (IP_3) may be part of OGA activated signaling in suspension-cultured soybean cells (Legendre et al., 1993b). OGAs promote a transient increase in the intracellular level of IP_3 prior to the biosynthesis of H_2O_2. Furthermore neomycin sulfate, an inhibitor of

The dashed arrows indicate hypothetical interactions/pathways that are implied from experimental evidence. The arrows are not meant to suggest that a particular number of biochemical steps are involved in any of the interactions.

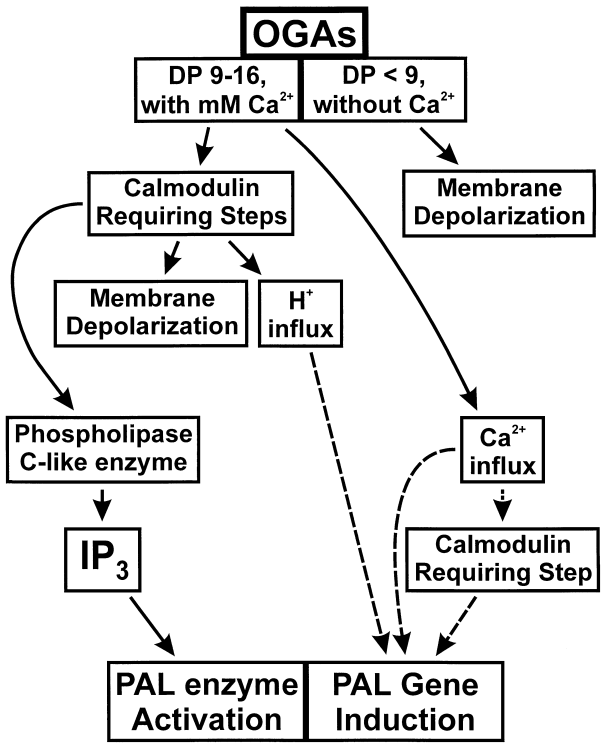

Fig. 7. A working model of OGA-induced signaling in suspension-cultured carrot cells. The solid arrows indicate potential pathways whose existence is supported by experimental evidence. The dashed arrows indicate hypothetical interactions/pathways that are implied from experimental evidence. The arrows are not meant to suggest that a particular number of biochemical steps are involved in any of the interactions.

polyphosphoinositide hydrolysis, partially inhibits the OGA induced biosynthesis of H_2O_2, suggesting that IP_3-independent signaling may also exist.

3.7.2. Suspension-cultured carrot cells: the role of calcium

OGAs with a DP from 9 to 16 induce a transient cytosolic Ca^{2+} mobilization, cytosolic acidification, and plasma membrane depolarization accompanied by an induction of PAL mRNA and enzyme activity in carrot cells (Fig. 7; Messiaen and VanCutsem, 1994). The most active size of OGA is DP 11. Externally supplied Ca^{2+} is required for all of these responses except for membrane depolarization. OGAs with a DP <9 elicit plasma membrane depolarization irregardless of the presence of Ca^{2+}, but do not elicit any of the other responses measured (Messiaen and VanCutsem, 1994). This is a particularly significant result since it suggests that the two different size classes of OGAs interact with the same cells to activate distinct signal transduction pathways.

The calcium channel blockers, verapamil and nifedipine, block OGA (DP 9–16) elicited cytosolic Ca^{2+} mobilization and PAL mRNA induction, but do not block cytosolic acidification or membrane depolarization (Fig. 7, Messiaen and VanCutsem, 1994). Furthermore, when the calcium ionophore A23187 is used to increase the cytosolic free Ca^{2+}, PAL mRNA is induced but cytosolic acidification and membrane depolarization are not. The inhibitor of the ATP-dependent plasma membrane proton-pump, vanadate, causes membrane depolarization and cytosolic acidification, but not PAL induction (Fig. 7; Messiaen and VanCutsem, 1994). Conversely, the activator of the ATP-dependent plasma membrane proton-pump, fusicoccin, causes a slight cytosolic alkalinization and inhibits OGA-elicited cytosolic acidification, membrane depolarization, and PAL mRNA induction. Together, these data suggest that transient cytosolic Ca^{2+} mobilization is required for induction of PAL mRNA induction, whereas transient cytosolic acidification and membrane depolarization do not require Ca^{2+} mobilization and may or may not be involved in PAL mRNA induction (Fig. 7; Messiaen and VanCutsem, 1994).

Neomycin sulfate, an inhibitor of polyphosphoinositide hydrolysis, inhibits the OGA-elicited induction of PAL enzyme activity by about 50%, suggesting that phospholipase C- mediated IP_3 turnover is involved in activation of the enzyme (Messiaen and VanCutsem, 1994). Neomycin sulfate has a small quantitative affect on OGA induced cytosolic Ca^{2+} mobilization, but does not affect cytosolic acidification, plasma membrane depolarization or PAL mRNA induction. The calmodulin inhibitor, calmidazolium, does not affect cytosolic Ca^{2+} mobilization, but blocks OGA elicited induction of cytosolic acidification, membrane depolarization, and PAL mRNA and enzyme activity (Messiaen and VanCutsem, 1994). This suggests that calmodulin is required for

steps affecting all of these responses except cytosolic Ca^{2+} mobilization (Fig. 7).

3.7.3. Suspension-cultured tobacco cells: a role for cytosolic acidification

OGAs with a DP from 10 to 15 (DP 12 is most active) induce a transient K^+ efflux, Cl^- efflux, cytosolic acidification, cytosolic Ca^{2+} mobilization, oxidative burst, plasma membrane depolarization, and induction of PAL mRNA accumulation in suspension-cultured tobacco cells (Fig. 8; Mathieu et al., 1991; Lapous et al., 1998; Spiro et al., 1998). Degradation of the OGA elicitor molecules is not responsible for the transient nature of the responses (Mathieu et al., 1998). The protein kinase inhibitors, staurosporine and 6-dimethylaminopurine, block OGA elicited oxidative burst, cytosolic acidification, and induction of PAL, whereas the protein phosphatase inhibitors, calyculin A and cantharidin induce these responses in the absence of OGAs (Mathieu et al., 1996a,b). Furthermore, OGA-induced changes in the phosphorylation of membrane-associated proteins from suspension-cultured tobacco cells have been detected (Droillard et al., 1997). As with soybean cells, protein kinase activity seems to be required, and in the absence of phosphatase activity a basal level of kinase activity may activate the signaling cascades in the absence of added OGAs.

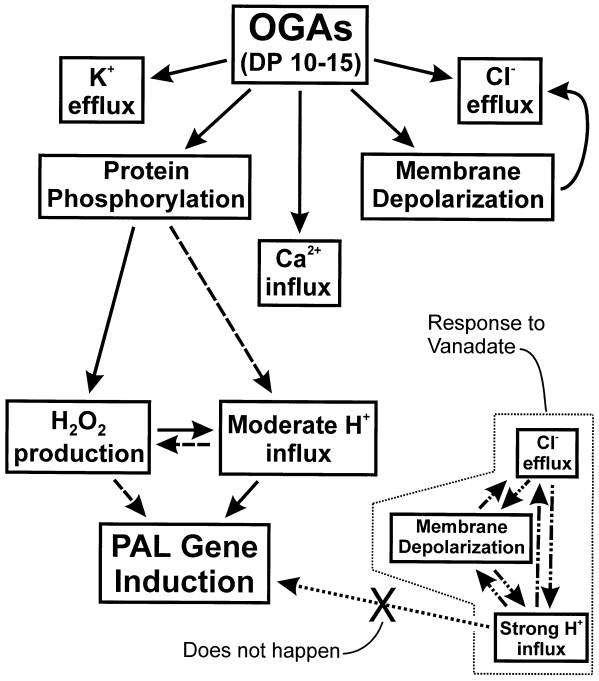

Fig. 8. A working model of OGA-induced signaling in suspension-cultured tobacco cells. The solid arrows indicate potential pathways whose existence is supported by experimental evidence. The dashed arrows indicate hypothetical interactions/pathways that are implied from the experimental evidence. The dot-dashed arrows indicate hypothetical interactions that potentially interconnect the responses induced by vanadate in the absence of OGA's. The arrows are not meant to suggest that a particular number of biochemical steps are involved in any of the interactions.

The inhibitors of the ATP dependent plasma membrane proton pump, vanadate and erythrosine B, cause plasma membrane depolarization, cytosolic acidification, and Cl^- efflux (Fig. 8; Zimmermann et al., 1998). Patch clamp experiments suggest that activation of a voltage-gated anion channel is responsible for the Cl^- efflux. Treatment of tobacco cells with the hydrophobic acid propionate, which moves protons across the plasma membrane with the proton gradient to cause cytosolic acidification, elicits PAL mRNA production. On the other hand, the cytosolic acidification caused by the proton pump inhibitor erythrosin B does not induce PAL mRNA (Lapous et al., 1998). It is suggested that the moderate cytosolic acidification induced by propionate stimulates production of PAL mRNA, while the strong cytosolic acidification induced by vanadate or erythrosine B is inhibitory (Fig. 8). In light of these results, the role of OGA-induced cytosolic acidification in the induction of PAL in carrot suspension-cultured cells merits reexamination.

The oxidative burst inhibitor, iodonium diphenyl, completely inhibited the OGA induced oxidative burst in suspension-cultured tobacco cells and inhibited cytosolic acidification (Rout-Mayer et al., 1997). This suggests that H_2O_2 may induce cytosolic acidification, although inverse experiments involving the addition of exogenous H_2O_2 were not reported.

3.7.4. Tomato wound response: oligogalacturonide signaling in intact plant tissues

When tomato seedlings with their roots excised are placed in a solution containing OGAs, these elicitors travel through the xylem and induce the expression of PIs, EPGase, and oxidative burst throughout the plant (MacDougall et al., 1992; Moloshok et al., 1992; Bergey et al., 1999; Orozco-Cardenas and Ryan, 1999). OGAs from DP 2 to 30 induce the expression of PIs, and other systemic wound response proteins (SWRPs) in these plants (Fig. 9; Moloshok et al., 1992; Bergey et al., 1996, 1999). PIs and SWRPs have been shown to help protect the plant from insect damage by reducing the nutrients available to feeding insects (Orozco-Cardenas et al., 1993). Xylem transport of OGAs is, however, thought to be physiologically insignificant in the normal tomato systemic wound response (SWR) to herbivore attack. Herbivores normally feed on leaves, and OGAs released in leaves are not transported in the phloem and do not move from the leaves to initiate a systemic reaction (Baydoun and Fry, 1985). For this reason, OGAs are thought to constitute a localized signal in the induction of SWR. The peptide hormone, systemin, is transported throughout the plant via the phloem and the xylem after its proteolytic release from its precursor in response to wounding or insect feeding (Doares et al., 1995; Narvaez-

Vasquez et al., 1995; Bergey et al., 1996; Ryan and Pearce, 1998). The signal from systemin propagates very rapidly, perhaps by means of rapid pressure changes in the xylem that are perceived throughout the plant (Malone, 1996; Stratmann and Ryan, 1997). Like OGAs, systemin and wounding induce the expression of PIs, SWRPs, EPGase, and H_2O_2 (Stratmann and Ryan, 1997; Bergey et al., 1999; Orozco-Cardenas and Ryan, 1999). Tomato plants expressing an antisense prosystemin gene respond to OGAs and systemin normally, but do not produce PIs, SWRPs, EPGase, or H_2O_2 in response to wounding, indicating that the activation of systemin is not required for the response to OGAs (Orozco-Cardenas and Ryan, 1999).

Jasmonic acid is required for the induction of H_2O_2, EPGase, PIs, and SWRPs by either OGAs or systemin (Fig. 9; Doares et al., 1995; Howe et al., 1996). Jasmonic acid is synthesized via the octadecanoid pathway from linolenic acid which, presumably, is released from phospholipids by phospholipase A activity (Howe et al., 1996). Tomato plants with a mutation in the octadecanoid pathway do not make jasmonic acid and do not produce PIs in response to OGAs, systemin, or wounding (Howe et al., 1996). Two inhibitors of the octadecanoid pathway, salicylic acid and diethylthiocarbamic acid, severely inhibit the induction of PIs by OGAs, systemin, and wounding (Doares et al., 1995). Wounding, OGAs, systemin, and jasmonic acid all induce tomato plants to produce ethylene and PIs (O'Donnell et al., 1996; Simpson et al., 1998). The induction of PIs is blocked by the ethylene biosynthesis inhibitors, silver thiosulphate and norbornadiene (O'Donnell et al., 1996), suggesting that ethylene is required as a second messenger when wounding, or treatment with OGAs, systemin, or jasmonic acid induce PIs. The ethylene requirement was not readily apparent because the addition of jasmonic acid induces the ethylene biosynthesis required for elicitation (Farmer and Ryan, 1992; O'Donnell et al., 1996; Orozco-Cardenas and Ryan, 1999). Taken together these results indicate that both ethylene and jasmonic acid are required for the induction of PIs by OGAs, systemin or wounding.

A 48 kd myelin basic protein kinase is activated in response to wounding, systemin, and OGAs (Stratmann and Ryan, 1997). The kinase is also activated by the same signals in plants that have a genetic defect in the octadecanoid pathway blocking the normal induction of PIs and SWRPs (Howe et al., 1996) (see Fig. 9). A synthetic analogue of the peptide hormone systemin strongly inhibits activation of the kinase and the induction of SWRPs by systemin (Stratmann and Ryan, 1997). This suggests that the 48 kd myelin basic protein kinase functions between these primary signals and the octadecanoid biosynthetic pathway as part of the signaling cascade leading to the SWR (Stratmann and Ryan, 1997).

Systemin elicits the systemic production of an endogenous EPGase in the leaves of tomato plants (Orozco-Cardenas and Ryan, 1999). This EPGase could generate biologically active OGAs, which act locally in concert with systemin to augment the SWR (Fig. 9; Bergey et al., 1999). Accordingly, the simultaneous addition of OGAs and systemin to suspension-cultured tomato cells produces an oxidative burst at least an order of magnitude larger than when OGAs are added alone (Stennis et al., 1998). This suggests that the two signals could act synergistically in the induction of the SWR in whole plants. Systemin is inactive in eliciting an oxidative burst in the suspension-cultured cells, suggesting that intact plant tissues are required (Stennis et al., 1998). Comparison of the timing and location of EPGase mRNA accumulation with H_2O_2 biosynthesis in whole plants treated with systemin suggests that OGAs

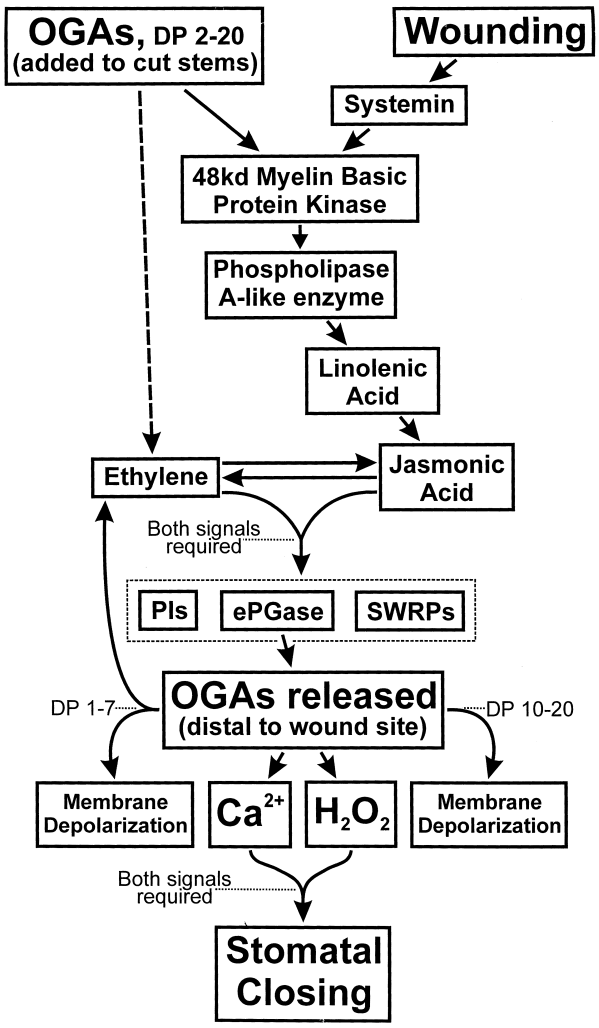

Fig. 9. A working model of OGA-induced signaling in tomato plants. As indicated in the text, the potential existence of some of the interactions shown is based on experiments using tomato tissues other than whole plants. The solid arrows indicate potential pathways whose existence is supported by experimental evidence. The dashed arrows indicate hypothetical interactions/pathways that are implied from experimental evidence. The arrows are not meant to suggest that a particular number of biochemical steps are involved in any of the interactions.

released by this enzyme could be responsible for the systemically induced oxidative burst associated with the SWR (Orozco-Cardenas and Ryan, 1999).

Another response that may be involved in the SWR is the OGA-induced closing of stomata (Fig. 9; Agrios, 1997; Lee et al., 1999). The Ca^{2+} chelater, EGTA, as well as the H_2O_2 scavengers, catalase and ascorbate, completely inhibit OGA induced stomatal closing in tomato leaf epidermal peels (Lee et al., 1999). This suggests that both Ca^{2+} and H_2O_2 signals are required for OGA-induced stomatal closing (Fig. 9).

A unique feature of the induction of SWR by OGAs in tomato plants is that a broad range of OGA sizes are biologically active (Farmer et al., 1990). OGAs with a DP from 1 to 7, as well as those with a DP from 10 to 20 are active in inducing membrane depolarization in tomato leaf mesophyll cells and in inducing PI activity in tomato plants (Thain et al., 1990). However, the membrane depolarization responses elicited by the two size ranges of OGAs are quantitatively and kinetically different. Furthermore, OGAs with a DP from 4 to 6 induce ethylene biosynthesis in tomato plants, whereas other sizes do not (Simpson et al., 1998). In light of these findings, it seems likely that tomato plants recognize OGAs by at least two different mechanisms.

3.7.5. Conclusions and relevance to future work

Oligogalacturonides participate in an information network of branched and interconnecting signal transduction pathways that lead to the more integrated tissue level responses. Plants are able to respond adaptively to changing environmental conditions by means of such information networks. It is of great importance to understand how plants accomplish this remarkable feat. Our understanding of OGA signal transduction is sketchy, and in some cases, conflicting. A variety of OGA signaling elements have been implicated in different plant species, but the role of each element has not been investigated in a single species. A major limitation has been the difficulty of isolating and directly characterizing the components of the OGA signaling cascades, including the receptors. In similar research with animals, the isolation of receptors and other signaling components has allowed interacting signaling elements to be identified.

Abstract

A borate-containing pectin was solubilized from sugar beet (*Beta vulgaris* L.) cell walls by treatment with 0.5 M imidazole, pH 7. The molecular weight of the pectin was reduced when the borate ester was hydrolyzed by treatment with 1 N HCl. Treatment of the acid-treated pectin with boric acid in the presence of Pb^{2+} gave a product whose molecular weight distribution was similar to the imidazole-soluble pectin. The imidazole-soluble pectin was saponified and then digested with *endo*- and *exo*-polygalacturonases. These treatments shifted the boron peak at the high molecular weight region to the low molecular weight (10 kDa), which corresponds to rhamnogalacturonan II-borate ester cross-linked dimer (dRG-II-B). The treatment also generated rhamnogalacturonan I (RG-I), dRG-II-B, monomeric rhamnogalacturonan II and galacturonic acid. These results show that imidazole solubilizes a high molecular weight borate-containing pectic complex composed of homogalacturonan-rhamnogalacturonan II and RG-I. Our data suggest that borate esters formed between rhamnogalacturonan II molecules cross-link the macromolecular pectin. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Pectin consists of three structurally well characterized polysaccharides: homogalacturonan (HG), rhamnogalacturonan I (RG-I) and rhamnogalacturonan II (RG-II) (O'Neill et al., 1990). These polysaccharides are believed to be covalently linked to one another because they are all solubilized by *endo*-polygalacturonase (EPG) treatment of primary cell walls. As far as we are aware there is no compelling evidence showing that HG, RG-I and RG-II are covalently linked to each other to form a macromolecular pectin complex.

Recent studies have shown that RG-II is present in the primary cell wall predominantly as a dimer (dRG-II-B) that is cross-linked by a borate diol diester (Ishii and Matsunaga, 1996; Kobayashi et al., 1996; O'Neill et al., 1996). RG-II is the only known borate-binding polysaccharide in the primary cell wall (Ishii and Matsunaga, 1996; Kobayashi et al., 1996; O'Neill et al., 1996). These results provide support for the hypothesis that one of the physiological functions of boron (B) in the normal cell growth and development of higher plants is to cross-link cell wall pectins. Nevertheless, the effects on the macromolecular organization of pectin and on the structure of the cell wall that result from borate ester cross-linking of pectin are poorly understood (Fliescher et al., 1999). In this report we show that a high molecular weight boron-containing pectin is solubilized by treating sugar beet walls with 0.5 M imidazole, pH 7, and that this pectin is composed of HG, RG-I and borate ester cross-linked RG-II. The molecular weight distribution of the pectin is decreased after hydrolysis of the borate ester cross-link and is increased when the ester cross-link is reformed in vitro. Our data provide evidence that RG-II and HG are covalently linked together.

2. Results

2.1. Isolation of a borate-containing pectin from sugar beet cell walls

Imidazole, 0.5 M, pH 7.0 (Mort et al., 1991; Marry et al., 2000) was used to solubilize pectin from sugar beet

cell walls rather than the chelating reagent cyclohexanediamine tetraacetate (CDTA) (Selvendran and O'Neill, 1986) since CDTA converts dRG-II-B to mRG-II (Kobayashi et al., 1999). In our study we found that ~70% of dRG-II-B was converted to mRG-II by treatment for 16 h at room temperature with 50 mM CDTA, pH 6.5. In contrast, dRG-II-B was stable in 0.5 M imidazole-HCl, pH 7.

Approximately 12% of the weight of the sugar beet cell walls was solubilized by 0.5 M imidazole, pH 7. The soluble material was subjected to ion-exchange chromatography to give Fraction I (Fig. 1a), which was subsequently subjected to size-exclusion chromatography (SEC) to give Fraction II (Fig. 1b). Fraction II was further characterized and appeared to be a boron-containing macromolecule. The pectin was shown to be a boron-containing macromole (69 μgB/g dry wt) with an apparent molecular mass of 200–150 kDa by SEC with a refractive index detector (SEC/RI, Fig. 2a) and by SEC with inductively coupled mass spectrometry SEC/(ICP-MS) (Fig. 2d). The ^{11}B NMR spectrum of the pectin contained a single signal at δ-9.5, thereby establishing the presence of a borate diol diester (van Duin et al., 1985).

2.2. Hydrolysis of the borate ester reduces the molecular weight distribution of the borate-containing pectin

The borate ester in the imidazole-soluble pectin was completely hydrolyzed by treatment for 1 h with 1 N HCl, which was confirmed by SEC/ICP–MS that the acid-treated pectin contained no B (data not shown). Moreover, the molecular weight distribution of the native (Fig. 3, curve 1) and acid-treated pectin (Fig. 3, curve 2) were not the same. The acid treatment had broadened the molecular weight distribution and increased the amount of material eluting in the lower molecular weight region (compare curves 1 and 2 in Fig. 3). To obtain evidence that borate ester formation alters the molecular weight distribution of pectin, the acid-treated pectin was kept for 16 h in K hydrogen phthalate/HCl, pH 3.7, containing

(---) The elution profile of the pectin after treatment for 1h at 30°C with 1 N HCl. 3. (- - - -) The elution profile after the acid-treated pectin was kept for 16 with boric acid and lead acetate at pH 3.7. Pullulan P-800 (854 kDa, V_0) and glucose (V_i) eluted at 13.3 and 32.3 min, respectively. The chromatograms were normalized.

boric acid (6 mM) and lead acetate (4 mM). These conditions have been known to completely convert mRG-II to dRG-II-B in vitro (O'Neill et al., 1996). The molecular weight distribution of the acid-treated pectin that had been treated with boric acid and Pb^{2+} and the original pectin are similar (Fig. 3, curves 1 and 3). The reconstructed pectin contained 79 μgB/g dry wt and its ^{11}B NMR spectrum contained a signal at δ −9.5 that corresponds to a borate diol diester. These results suggest that borate ester cross-links in part determine the molecular size of the pectin.

2.3. The imidazole-soluble pectin is composed of HG, RG-I and RG-II

The glycosyl composition and linkage analyses of the borate-containing pectin (Tables 1 and 3, Fr. A) indicate that it contained RG-I, RG-II and HG. Additional evidence for the presence of these polysaccharides was obtained by saponifying the pectin and treating the resulting material with a mixture of *endo*- and *exo*-polygalacturonase. Approximately 50% of the material was recovered after enzymatic treatment and dialysis. This material was shown by SEC to contain four major components (Fig. 2b). The boron eluted as a sharp peak in the region corresponding to dRG-II-B (~10 kDa) (Fig. 2e) rather than as a broad, high molecular weight boron-containing peak in the native pectin (Fig. 2d). The results show that dRG-II-B is linked to HG in the pectin. A free boric acid peak eluted at the lower molecular weight region was partly due to the degradation of the borate complex during the sample preparation

1990). Fraction B4 was shown by high pH anion-exchange chromatography with pulsed amperometic detection (HPAEC-PAD) to contain di- and trigalacturonides, in addition to galacturonic acid. These are the expected products resulting from *endo*- and *exo*-polygalacturonase treatment of HG. Taken together these results establish that the imidazole-soluble pectin contains HG, RG-I and borate ester cross-linked RG-II. These results provide evidence that dRG-II-B is covalently inserted with HG chains.

To characterize the high molecular weight fraction and to determine the content of RG-I in the pectin, the pectin was treated with EPG together with arabinanase and α-L-arabinofuranosidase since Fraction B1 (see Fig. 2b) contained a high level of arabinosyl residues (Table 1). Approximately 15% of the material was recovered after enzyme treatment and dialysis. This treatment resulted in a decrease in the amount of the high molecular weight peak (Fraction B1, see Fig. 2b) and the appearance of a broad, lower molecular weight fraction (Fig. 2c, Fractions C1 and C2). As expected the arabinosyl residue content of Fraction B1 was decreased by the enzyme treatment. Fractions C1 and C2 most likely contain RG-I since they are enriched with terminal non-reducing Ara_f and Gal, 2-Rha, 2, 4-Rha, 5-Ara_f, 4-Gal and 4-linked GalA residues (Table 3) (Ishii et al., 1989). These fractions may also contain xylogalacturonan since small amounts of terminal non reducing-Xyl and 3, 4-linked GalA residues were also detected (Schols and Voragen, 1996). The molecular weight distribution of the original pectin and Fractions C1 and C2 was similar, indicating that RG-I and xylogalacturonan in the pectin were likely to be a contaminant. Glycosyl-residue composition (Table 2) and glycosyl-linkage composition analyses (Table 3) confirmed that Fraction C-3 contained RG-II. Fraction C4 was shown by HPEAC-PAD to contain galacturonic acid and arabinose.

3. Discussion

A high molecular weight pectin containing HG, RG-I and RG-II was solubilized by treating sugar beet cell walls with imidazole-HCl. The pectin contained 69 μg B/g and had a molecular weight of 150–200 kDa. Previous results showed that dRG-II-B having a molecular weight 10 kDa contained one mole boron (Ishii and Matsunaga, 1996; Kobayashi et al., 1996; O'Neill et al., 1996). It can be estimated that approximately one mole of dRG-II-B/mol pectin was present. *Endo*-polygalacturonase treatment of the pectin fragmented the homogalacturonan region of the molecule and generated RG-II with an apparent molecular mass of 5–10 kDa. Thus, it is likely that the pectin contains RG-II covalently linked within homogalacturonan chains. *Endo*-polygalacturonase, arabinanase and α-L-arabinofuranosidase treatment fragmented some of the arabinosyl-containing side chains of RG-I, in addition to homogalacturonan. Nevertheless, a portion of this material still eluted in the high molecular weight region of the column (Fig. 2c, C1 and C2). This material contained RG-I with short side chains and xylogalacturonan. If the pectin contains RG-I and xylogalacturonan as a contaminant, their content is less than 10%. It is uncertain from the present results that RG-I is linked to HG and that RG-I, RG-II and HG are on the same molecule. Isolation and characterization of oligogalacturonides carrying oligosaccharides derived from RG-I is essential for providing evidence for the above notion.

The molecular weight distribution of the imidazole-soluble pectin decreased after hydrolysis of the borate ester. The in vitro reformation of the borate ester gave a pectin that had a molecular weight distribution pattern similar to native pectin (Fig. 3, curves 1 and 3). Such a result indicates that RG-II being covalently linked to

HG can itself assemble into a borate ester cross-linked dimer and that the formation of this cross-link increases the molecular size of the pectin. Sugar beet pectin contains ferulic and diferulic acids ester-linked to arabinan and galactan side chains of RG-I (Ishii, 1997a). Ferulate and diferulate esters are stable under acid treatment used to cleave borate esters (Ishii, unpublished results). These results exclude the possibility of the involvement in diferulate cross-linking of pectin. In previous studies, dRG-II-B has been isolated as a low molecular weight component (10 kDa) from *endo*-polygalacturonase digests of plant cell walls (Ishii and Matsunaga, 1996; Kobayashi et al., 1996; O'Neill et al., 1996). RG-II has also been solubilized as a high molecular weight pectin (>25 kDa) by 0.5 M phosphate-buffer treatment of *Chenopodium album* (Fleischer et al., 1999). The RG-II in these macromolecules is converted to a low molecular weight (5–10 kDa) component by *endo*-polygalacturonase treatment. The results of the present study have established that borate ester cross-linking of RG-II determines the macromolecular properties of pectin.

4. Experimental

4.1. Plant material

Sugar beet pulp was a gift from Hokkaido Prefecture Konsen Agricultural Experimental Station (Nakashibetsu, Hokkaido). The pulp was ground with a hammer mill, refluxed with MeOH for 16 h, and the alcohol-insoluble residue (AIR) (B content 37 μg/g dry AIR) was used as the cell wall material.

4.2. Isolation of a borate-containing pectin

Sugar beet cell walls (10 g) were stirred for 16 h at room temperature in 0.5 M imidazole-HCl, pH 7.0, (1 l). The suspension was centrifuged for 10 min at 5000 g. The insoluble residue was suspended in 500 ml of 0.5 M imidazole, pH 7 and extracted for 4 h at room temperature, and then centrifuged. The supernatants were combined and dialyzed against deionized H_2O with 12 kDa cutoff dialysis tube. The retentate was applied to a column (2.5×30 cm) of DEAE-Sepharose Fast Flow that had been equilibrated with 50 mM $HCOONH_4$, pH 5.3. The column was washed with equilibration buffer (500 ml) to remove unbound material and then eluted with a linear gradient from 50 mM to 1 M $HCOONH_4$, pH 5.3 (total volume 800 ml). Fractions (10 ml) were collected and assayed for their B, total sugars and uronic acid contents. Fraction I (Fraction Nos. 21–28 in Fig. 1a) was pooled, dialyzed (12 kDa cutoff), and freeze-dried. A solution of Fraction I in 50 mM $HCOONH_4$, pH 5.3 (5 ml) was loaded onto a column (2.5×90 cm) of Sepharose CL-6B, equilibrated with 50 mM $HCOONH_4$, pH 5.3, and eluted with the same buffer. Fractions (2 ml) were collected and assayed for their B, uronic acid and total sugar contents. Fraction II (Fraction Nos. 41–52 in Fig. 1b) was pooled, dialyzed (12 kDa cutoff), and freeze-dried.

4.3. Acid treatment of the borate-containing pectin and reformation of the borate ester in the acid-treated pectin

The pectin (2 mg) was treated for 1 h at 30°C with 1 N HCL solution (0.5 ml). The acid-treated pectin was dialyzed (1 kDa cutoff) and freeze-dried. The acid-treated pectin (1 mg) was kept for 16 h in K^+ hydrogen phthalate/HCl, pH 3.7, (200 μl) containing boric acid (6 mM) and lead acetate (4 mM) (O'Neill et al., 1996). This solution was then dialyzed (1 kDa cutoff) and freeze-dried.

4.4. Enzymic treatments of the borate-containing pectin

The borate-containing pectin (5 mg) was saponified to remove ester bonds by treatment for 4 h at 4°C with 0.1 N NaOH (0.2 ml). The solution was then adjusted to pH 5.0 with 10% AcOH . The saponified pectin was treated for 16 h at 30°C with homogeneous preparations of recombinant *endo*-polygalacturonase (3 units) and *exo*-polygalacturonase (2 units). The recombinant *endo*-polygalacturonase (EPG-II) from *Aspergillus niger* and *exo*-polygalacturonase (ExoPG) from *A. tubingensis* (Biely et al., 1996) were over-expressed in *A. niger* and then purified to apparent homogeneity; these were a gift of J. Visser (Wageningen, The Netherlands). One unit of EPG and one unit ExoPG, respectively, releases 1 μmol of reducing sugar/min from polygalacturonic acid at pH 5. The solution was dialyzed (1 kDa cutoff) and freeze-dried. In a second experiment, the saponified pectin was digested for 16 h at 30°C with a mixture of *endo*- and *exo*-polygalacturonase, arabinanase (2 units) and α-L-arabinofuranosidase (2 units) from *A. niger* (Megazyme, Ireland), dialyzed (1 kDa cutoff), and freeze-dried. The arabinanase preparation contained arabinanase, arabinofuranosidase, and α-D-galacturonase activities, but it did not degrade RG-I (Lerouge et al., 1993).

4.5. Analytical methods

The enzymatic digests were separated by HPLC using a Shimadzu LC6A liquid chromatograph with a Superose 12 HR 10/30 column (Pharmacia, Uppsala) and a refractive index detector (Shimadzu model RID-6A) eluted with 50 mM $HCOONH_4$, pH 5. 3 at 0.6 ml/min. SEC/ICP–MS was performed with the same column using a JASCO PU-1580i pump and a SII SPQ9000 ICP mass spectrometer. The column elution conditions were the same as above. The pectin solution (2 mg/ml) was prepared and 100 and 20 μl were injected for SEC-HPLC and SEC/ICP-MS, respectively. The monosaccharides

released by enzymatic treatment were determined by HPAEC-PAD with a Dionex BioLC as described (Ishii, 1997b).

The boron concentrations in each fraction (Fig. 1) were determined by ICP–MS (Ishii and Matsunaga, 1996). ^{11}B NMR spectra were recorded with a Jeol Alpha 500 NMR spectrometer (Ishii and Matsunaga, 1996).

Uronic acids and total sugars were determined by the *m*-hydroxybiphenyl method (Blumenkrantz and Asboe-Hansen, 1973), and phenol-sulfuric acid methods (Hodge and Hotreiter, 1962), respectively. The neutral and acidic glycosyl residue compositions of the pectin were determined by GC–MS analysis of the alditol acetate derivatives and trimethylsilyl methyl glycoside derivatives, respectively (York et al., 1985). The glycosyl linkage compositions were determined by a modified Hakomori procedure method (Ishii et al., 1999).

Abstract

A series of oligomeric glycans can be extracted from the cell walls of developing cotton fibers with weak acid. Glycans that produce similar profiles on high pH anion chromatography with pulsed amperometric detection (HPAEC-PAD) are also found in a protein complex extracted from developing fibers and in amorphous aggregates found in association with immature fibers in developing, but not in mature cotton bolls. The quantity and composition of the glycans recovered from the carbohydrate–protein complex varies significantly with the time of day when the bolls are harvested. This diurnal variation is consistent with the hypothesis that secondary cell walls are deposited primarily at night. Incubation of re-hydrated cotton fibers in the presence of exogenous oligosaccharides, *myo*-inositol and glycerol substantially alters the apparent quantity of the oligomers extracted from the fibers. The same and similar glycans have also been extracted from cotton fabric, marine algae, various paper products and wood. While many of the oligomers isolated from the various cellulose sources display the same peaks by HPAEC-PAD, the specific number of oligomers and their relative quantities appear unique for each source of cellulosic material. Oligomeric glycans, as described in the preceding, are present in all cellulose sources that have been investigated. Their relative abundance changes in response to source, stage of development and other physiological variables. We hypothesize that the glycans are intermediates in the biological assembly of cellulose, and that their incorporation in cellulose is mediated by physicochemical and enzymatic mechanisms. © 2001 Elsevier Science Ltd. 1. Introduction

Cell wall biosynthesis is a highly complex process which involves soluble substrates being converted to insoluble products at the surface of the cell membrane or external to it. This is complicated by the synthesis of a primary wall followed by the synthesis of the secondary wall often with overlap of the synthesis of both. The products include polysaccharides, glycoproteins, proteins and enzymes which may exist in complexes or be covalently linked to each other. Correlations between cell growth and substrate concentrations and the activities of several enzymes have been made (Murray and Bandurski, 1975; Murray and Brown, 1997). The fact that hydrolysis of sucrose to glucose and fructose is an integral part of fiber wall synthesis (Basra et al., 1990) is consistent with observations in this laboratory. A direct relationship between cell growth and acid invertase activity has been demonstrated in several plant tissues (Morris and Arthur, 1985; Sturm and Chrispeels, 1990; Basra et al., 1990; Sturm et al., 1995; Buchala, 1987). The increased invertase activity is the result of transcription of messenger RNA, rather than simply an enzyme kinetic effect, therefore, the invertase response is specific and induced (Sturm and Chrispeels, 1990; Sturm et al., 1995).

The secondary cell wall of cotton fibers consists almost entirely of cellulose which directs interest to cellulose biosynthesis. The potential role of sucrose synthase with the cellulose synthetic apparatus has been proposed (Amor et al., 1995; Delmer, 1999). The possible role of the invertase mentioned above, the possible role of

lipid-bound intermediates (Matthysse et al., 1995; Brett, 2000) and the suggestion of self-assembly mechanisms (Brett, 2000) remain observations in search of explanations.

Our interest is in understanding the dynamics of carbohydrate metabolism during cotton fiber development. Since a plant cell must synthesize cell wall material in order to grow and develop, knowledge of the events in cell wall biosynthesis can be used to monitor plant growth and to detect aberrations in growth due to environmental influences (Murray, 1998, 2000). The cotton fiber is unique in its development since it is a plant cell that usually does not divide or store starch. During the period of fiber elongation, it is generally synthesizing primary cell wall (Graves and Stewart, 1988). Following the period of cell elongation, the fiber cell thickens as it synthesizes secondary cell wall, which consists almost entirely of cellulose. The period of cotton lint development, from pollination to dry, mature fiber extends only about 45 days. The rates of cellulose deposition, on a per mm fiber length basis, vary with one maximum at 16 days post anthesis (DPA) and a greater maximum at 28DPA (Meinert and Delmer, 1977). Prior to 21 DPA well-defined fibers are usually not present in developing bolls. However, only after the first 21 days have elapsed, can fibers be excised from developing bolls.

The present work shows that several carbohydrates and the carbohydrate–protein complex vary in a manner that is consistent with known characteristics of cell wall development in plants. We have identified a series of glucose containing oligomers, which are ubiquitous in all plant tissues investigated to date including monocots, dicots, and marine algae. The quantitative distribution and presence of specific oligomers appears to be unique to each plant and tissue as well as to the developmental stage. These glycans constitute another piece of the cell wall biosynthetic process. Since they can be extracted from developing cotton fibers, mature cotton fibers and aging cotton fibers in fabric, they may be subunits of the cotton fiber. Since they have been extracted from every sample of plant cell wall material examined suggests that they are fundamental elements, which occur with cellulose.

2. Results

2.1. Effects of physiological factors on oligomers in fibers

A practical way to investigate cotton fiber development is to freeze bolls in the field, and subsequently lyophilize them. Fractionation of the re-hydrated, developing fibers yields mono- and oligosaccharides, oligomers, an oligomer–protein complex, as well as insoluble fiber material as shown in Fig. 1. The oligomers can be extracted using weak acid from developing cotton fibers, mature cotton fibers, cotton dust and cotton fabric at various stages of processing as well as from old fabric, paper and wood.

Chromatograms of the carbohydrate oligomers show that many of the peaks appear in a pattern of slightly decreasing retention time increments. Such increments suggest a series of oligomers differing in length by a repeating unit. Fig. 2 shows this pattern for oligomers extracted from first position cotton bolls collected from sequential fruiting branches on the same plant at the same time from 15 to 39 days post anthesis (DPA). Extracts of the older bolls contain the same oligomers, but less material is extracted on a dry weight basis. The relative abundance of the oligomers in extracts from developing cotton fibers correlates with the deposition of secondary cell wall and changes in the content of soluble oligosaccharides (Murray and Brown, 1997). The oligomers extracted are most abundant at about 21 DPA, which is the time when secondary cell wall synthesis is rapidly occurring. The quantitative decrease in the oligomers extracted with age corresponds to decreased synthesis, and probable incorporation of these glycans into linkages that are not cleaved by the weak acid extraction. The pattern of oligomers extracted from a plant stunted due to periodic drought stress is shown in Fig. 3. The relative abundance of the oligomers changes particularly with those eluting at 15–20 minutes of retention time. Changes in the number and relative quantities of oligomers are a sensitive detector of stress. As seen in this case, the first oligomer in the sequence is present in a large quantity, but it appears that the sequential oligomers, observed in the boll of a plant developing under favorable growing conditions are not present. In addition to the correlation of oligomers with developmental age the oligomers extracted from 24DPA fibers change with the time of day as shown in Fig. 4. They are more abundant in the early morning and evening. This difference correlates with the diurnal variation in soluble oligosaccharide content as well (data not shown).

Each chromatogram shows PAD response and A_{280} which is likely protein but could include other phenolic compounds. It appears that certain of the oligomers are associated with A_{280} absorbing material. Further, the nature of the A_{280} absorbing material also changes with the time of day. The chromatograms of extracts from bolls collected early and late in the day show an A_{280} triplet peak between 20 and 25 min, while the midday chromatogram shows a prominent A_{280} peak at about 35 min.

2.2. Characterization of oligomers

The glycans reported in this paper have been extracted at 100°C in 0.1 N HCl which has then been neutralized with an equivalent amount of 1 N NaOH. If these oligomers are allowed to stand in the refrigerator

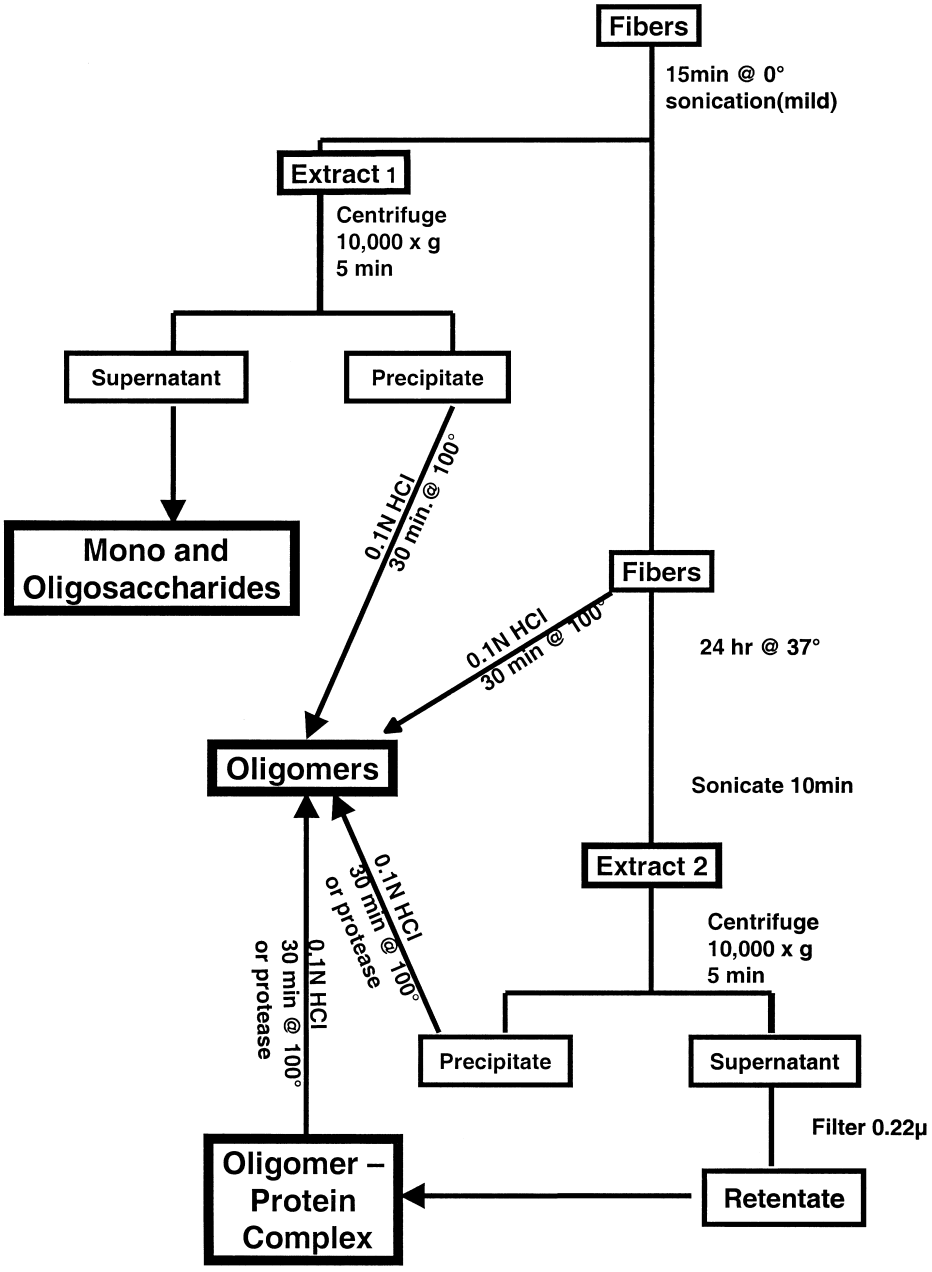

Fig. 1. Extraction procedures for cotton fibers.

at 4°C for a few days, they precipitate out of solution. If the solution of the oligomers is desalted by passage over ion exchange resins the oligomers precipitate out immediately and will plug up the filter (0.2 μm). Once precipitated out of solution, the material can be resolublized by boiling in 0.1 N HCl. The oligomers are reducing sugars as evidenced by the fact that they are susceptible to mild alkaline degradation, 0.1 N NaOH, boiling for 5–10 min (Whistler and BeMiller, 1958). Incubation with cellulase, in this case from *Trichoderma reesii* (Sigma), results in the degradation of the oligomers with retention times greater than 16 min, with a concomitant increase in the oligomers with retention times of approximately 14 and 16 min as shown in Fig. 5. In this system cellobiose elutes at about 10.5 min.

Treatment of the oligomers with ß-glucosidase, almond emulsin, results in a chromatogram with peaks quantitatively greater than the control. Presumably this is due to trimming of the longer oligomers which either are not resolved on the column or have a reduced detector response or both. A similar observation has been made in other work in which the oligomers with longer retention times, greater than 20 min, can be precipitated with alcohol. Subsequently, the precipitated oligomers can be dissolved and treated with a highly purified cellulase (endoß-1,4-glucanase, Megazyme, Ireland) which

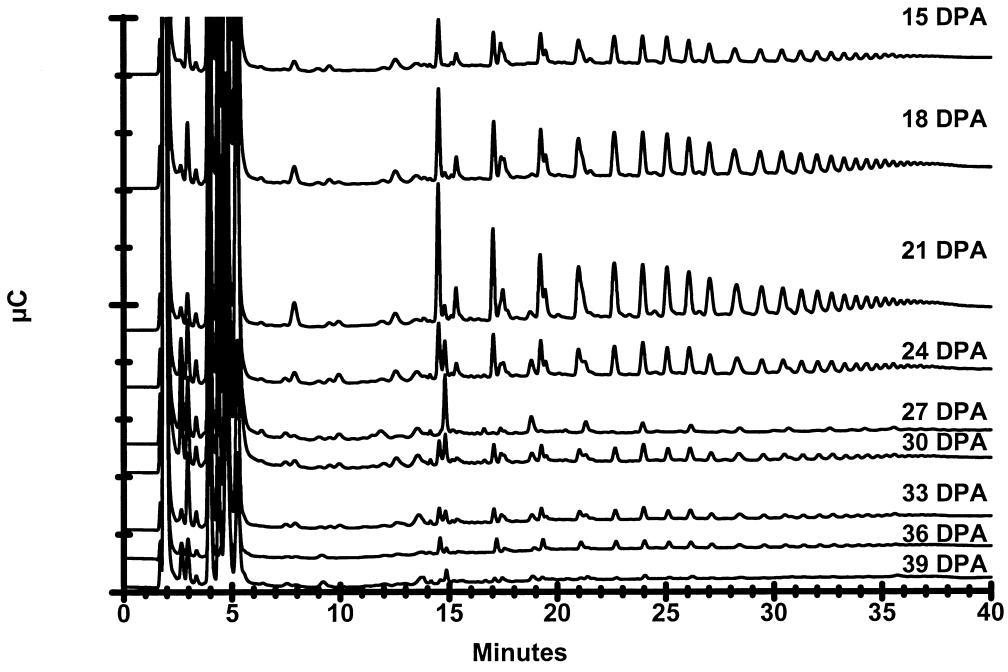

Fig. 2. Oligomers extracted from fibers from sequential first position bolls on a normal plant. In all cases essentially the same amount of fiber was extracted within 10%. Plots of detector response usually within 10%.

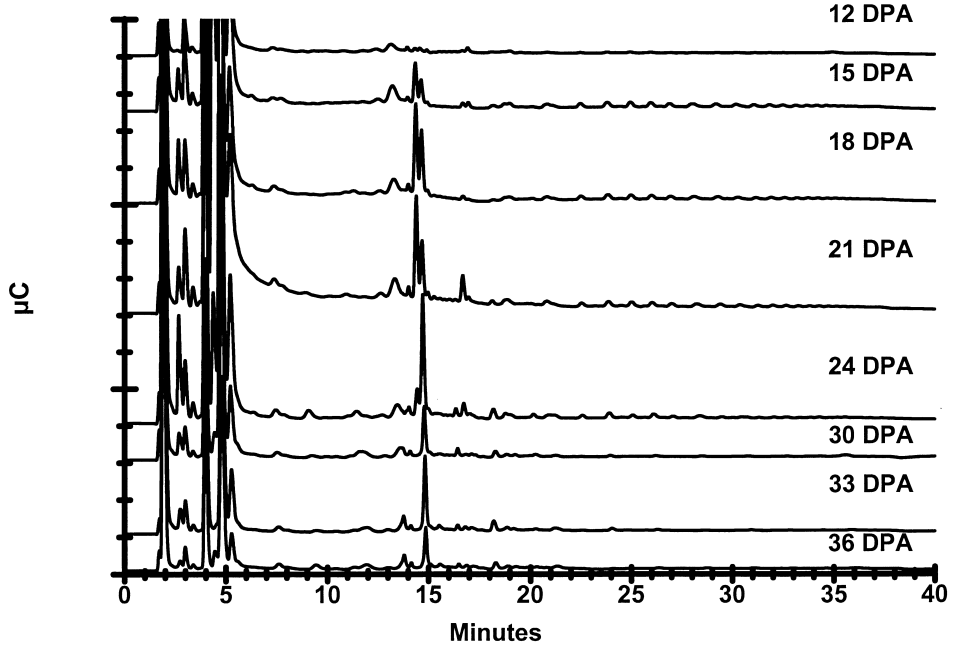

Fig. 3. Oligomers extracted from fibers from sequential first position bolls on a stunted plant. The amount of fiber extracted was the same as in Fig. 2.

then trims them back to the peaks with shorter retention times. The only monosaccharide released by this cellulase treatment is glucose. A preliminary investigation of the monosaccharide composition of the oligomers extracted from 21 DPA fibers has shown that the most prevalent monosaccharide is glucose, but that they also contain galactose, mannose, *m*-inositol and glycerol.

The major difference between successive oligomers from normal fibers is in the relative glucose content. That is, successive oligomers in a series have comparable amounts of galactose and mannose but different amounts of glucose. It is not yet known whether the apparently suppressed production of oligomers in the drought stressed plants follows this pattern. However, many of these

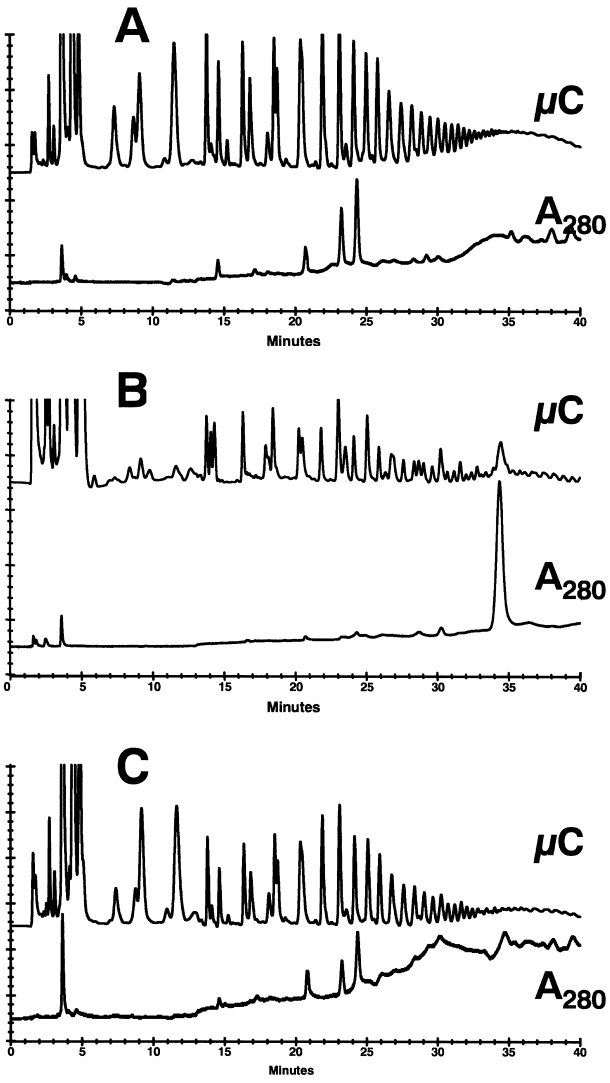

Fig. 4. Oligomers extracted from 24DPA fibers from bolls collected at 7 am (A), noon (B) and 7 pm (C).

same oligomers are found in a variety of cell walls although the data are not presented here.

2.3. Effect of incubation temperature, substrates, and tunicamycin on oligomers released

Fibers were rehydrated for 15–30 min prior to the beginning of the incubation with substrates. Oligomers were extracted from fibers, incubated for 24 h at 37°C under toluene with the substrates glycerol, *m*-inositol, sucrose, raffinose and cellobiose: control fibers had no exogenous substrates added. The control treatment resulted in oligomers as extracted from unamended fibers. The important point is that the addition of certain substrate combinations appear to reduce the quantities of oligomers which are extracted. Presumably such combinations of putative substrates affect the association of the oligomers with insoluble cell wall components. We hypothesize that these data suggest association of the oligomers with insoluble cellulosic structures, resulting in reduced extraction of oligomers by the weak acid procedure. The substrates were chosen due to their presence in aqueous extracts or hydrolyzates of fibers with the exception of cellobiose. However, the concentrations used are much higher than found in the aqueous extracts.

The effect of tunicamycin during incubation on the oligomers extracted from cotton fibers was investigated. Fibers were extracted with cold water to remove endogenous substrates and then incubated for 24 h with or without tunicamycin (10 μg/ml) both with and without added substrates 25 mM raffinose and 25 mM cellobiose. Tunicamycin specifically inhibits the formation of the bond between asparagine and *N*-acetylglucosamine in *N*-linked glycoproteins (Elbein, 1979) and it has been shown to inhibit other glycolipid mediated carbohydrate transfer reactions (Elbein, 1979; Barr et al., 1989; Müller et al., 1981). Without added substrates, tunicamycin had no appreciable effect, but with added substrates such as cellobiose and raffinose, the effect was substantial as the tunicamycin inhibited the relative quantities of oligomers extracted as shown in Fig. 6. In other experiments, not shown here, the tunicamycin effect was variable if the endogenous substrates were not removed by cold water extraction prior to addition of tunicamycin.

Incubation of developing fibers in water for up to 72 h at various temperatures results in the release of a white material to the medium, resulting in turbidity which can be precipitated by centrifugation. Cotton fibers (25 DPA) were extracted with water at three different temperatures, 37, 25 and 4°C for up to 30 days. The extraction tubes were sonicated for 15 min, and extracts were removed each day and centrifuged to yield a white particulate pellet. Microbial growth was retarded by a layer of toluene on the surface of the water in the tube. Following removal of the extracts fresh water was added back with the toluene layer on top. From 3 to 9 days of extraction, the fibers extracted at 4°C were characterized by one obvious difference. Before sonication all tubes were clear, but following sonication the extract in the tubes incubated at 4°C became turbid. The turbidily appeared as a very fine particulate suspension. Yet on centrifugation, the pellets obtained from all of the tubes were similar in the quantity of precipitate, and in the relative quantities of oligomers obtained. This result is indicative of a temperature dependent, and thus probably an enzymatic process which produces larger particles at the warmer temperatures. This precipitate material, when subjected to the 0.1 N HCl treatment, is completely dissolved, and is a rich source of the oligomers. The chromatograms of the oligomers obtained from this source appear to be more uniform with a smoother baseline between the peaks than from intact fibers.

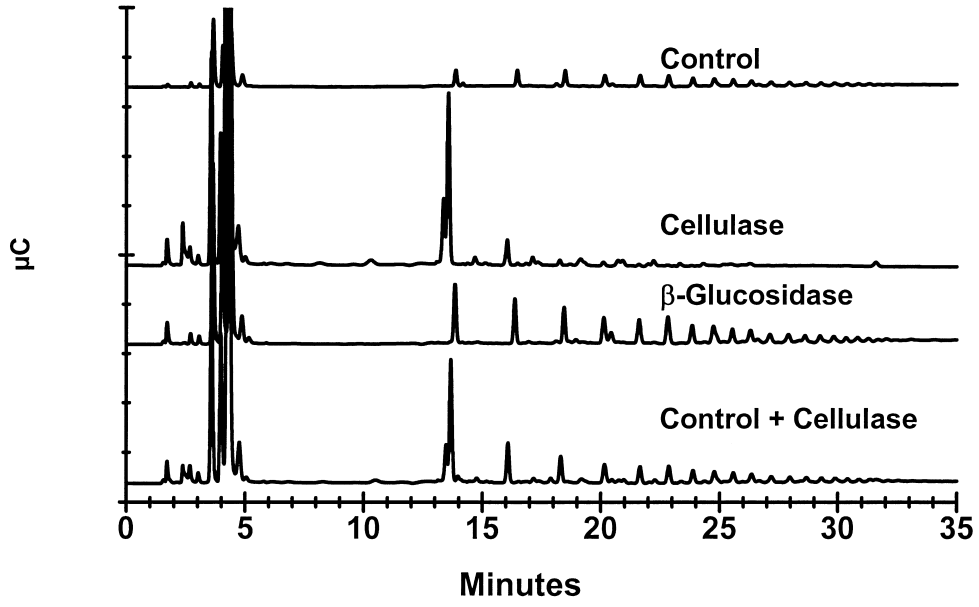

Fig. 5. Oligomers following treatment with cellulase or ß-glucosidase and the control without treatment. The bottom plot is a mixture of equal parts of the samples from the control oligomers and those treated with cellulase. This was done to determine if there were shifts in retention time of any of the peaks.

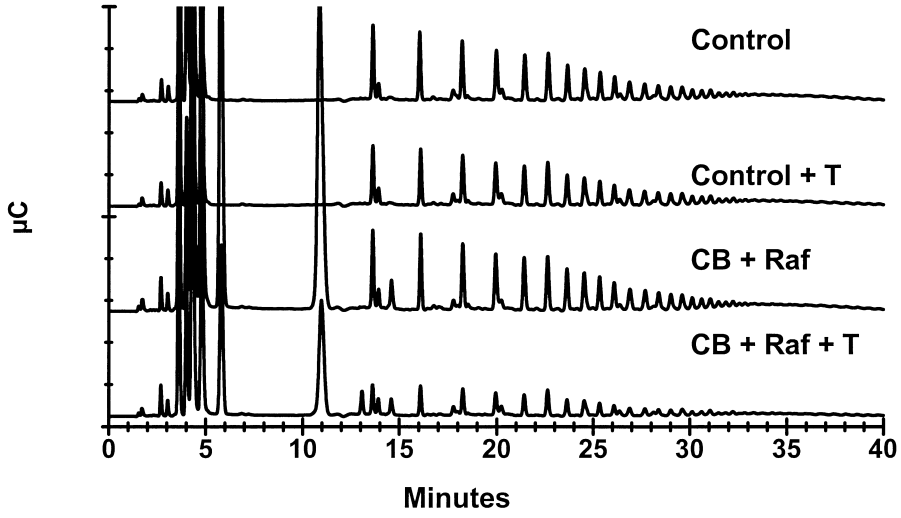

Fig. 6. Effect of tunicamycin on oligomers released following incubation. (CB: cellobiose; Raf: raffinose; T: tunicamycin).

2.4. An oligomer-protein colloid

In addition to the precipitate, another material remaining in solution, has been isolated by filtration on 0.22 μm filters. This material may be subjected to the weak acid treatment to yield the oligomers. Treatment with proteases also releases the oligomers from this carbohydrate-protein complex, after which it does pass through the 0.22 μm filter. Of four proteases investigated (proteinase K, trypsin, chymotrypsin and Pronase®), chymotrypsin is the most efficient in releasing the oligomers, being some 500-fold more active than trypsin on a molar basis. Proteases will also dissolve the white precipitate material and release the oligomers.

The carbohydrate-protein complex extracted from developing fibers varies with the time of day when the bolls were picked. If the fibers are boiled for 10 min prior to the extraction of the carbohydrate-protein complex , differences in the oligomers released are observed. The oligomer pattern of the carbohydrate-protein complex from boiled fibers and fibers that were not boiled is characterized by the absence of one peak in fibers from bolls harvested at 7 am, as shown in Fig. 7A , but the difference is very large in fibers from bolls harvested at noon, with most of the peaks being absent as shown in Fig. 7B.

While cotton fibers are still immature, external agglo merations appear as white flakes on the lyophilized fibers and in freshly opened bolls, until at least 39PDA.

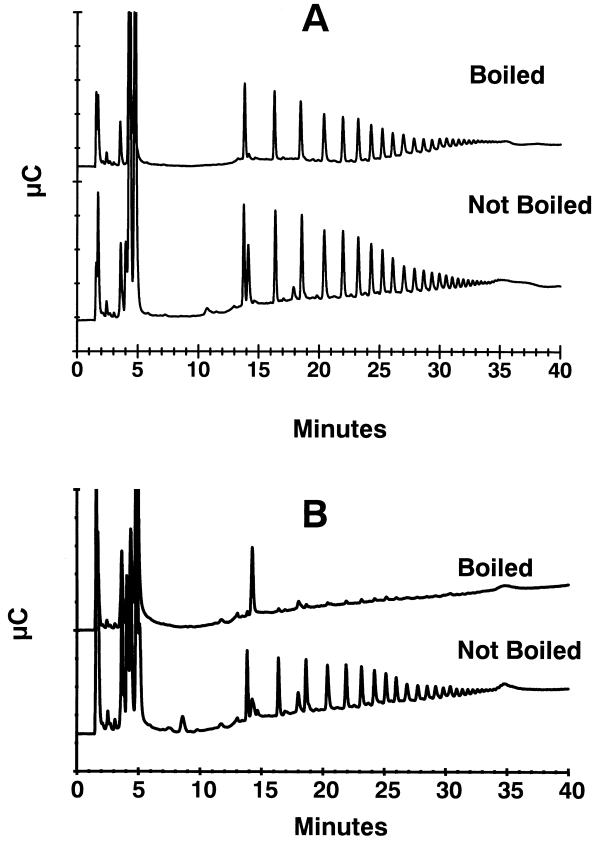

Fig. 7. Oligomers released from carbohydrate-protein complex from fibers from bolls collected at 7 am (A) and noon (B), which were boiled or not boiled before extraction.

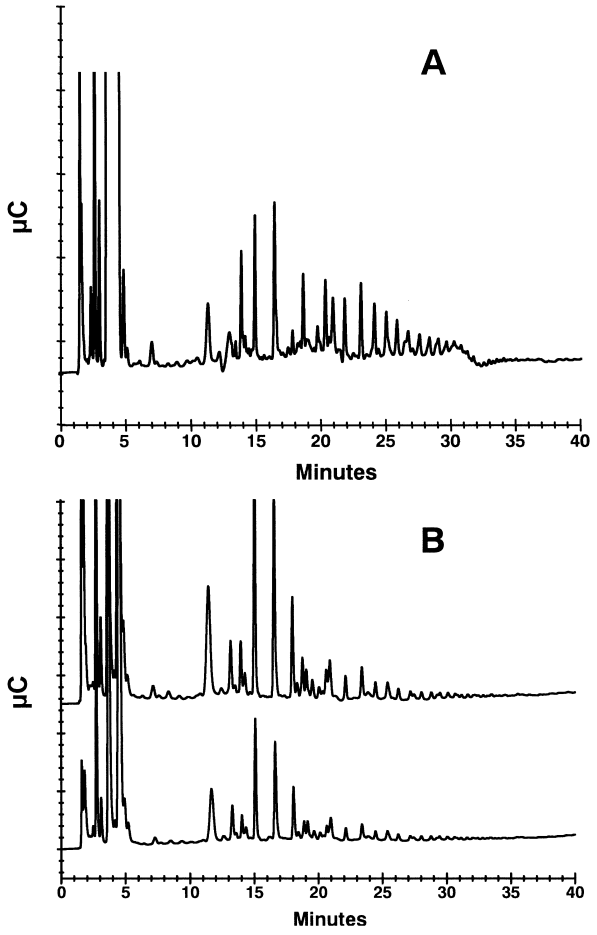

Fig. 8. Oligomers extracted from old denim fabric (A) and a towel dyed ivory in color (B). In (B) the upper plot is a newly manufactured towel and the lower plot is the same towel after one washing.

Such flakes have not been observed in later stages of development, nor in mature bolls. Although several investigators have mentioned observing the white flakes, we find no detailed characterization of them in the literature. Dissection of white flakes from the fibers, followed by both the cold water and weak acid extractions, demonstrated that they were rich sources of the same soluble oligosaccharides and oligomers as found in the fibers. On a dry weight basis, white flakes release at least 5-10 times the quantity of oligomers as do the fibers. Since these white flakes contain oligomers, that we hypothesize are incorporated into the fibers, we also infer that the white flakes contain materials that will be precursors of the fiber wall. If this is the case, then all of the developing fiber wall material does not reside within the cylindrical interior of the individual fiber during cellulose synthesis. However, the origin and role of such extra-fibril oligomers are not known at this time.

2.5. Oligosaccharides and oligomers in cotton textiles, wood, and paper products

Not only are oligosaccharides and oligomers found in extracts of fibers sampled directly from cotton bolls, but extracts of cotton textiles produce peaks having the same retention times, relative to know compounds, as do the extracts of fibers from plant material (Fig. 9, see also Fig. 2). Moreover, the same oligosaccharides and oligomers can be recovered from cotton textiles, e.g. denim, sheets and towels after prolonged wear and washings (data not shown). The effect of washing is to reduce the quantity of the oligosaccharides and oligomers extracted, relative to those found in newly-manufactured textile products or cotton fibers sampled from bolls (Fig. 8).

Similar oligosaccharides and oligomers may also be extracted from woods (Fig. 9). Twenty-two different woods have been extracted. While many of the same oligosaccharides and oligomers are found in the woods and in cotton, no two species of wood have been found to be display identical chromatograms. Thus each species of wood has a distinct signature. For example, birch and pine vary in peaks eluting between approximately 15 and 20 min; while balsa, a very low density wood has lower levels overall. (Note that in Fig. 9 the scale for balsa is expanded 5×). As with the new and old cotton products, there appears to be an effect of washing and aging

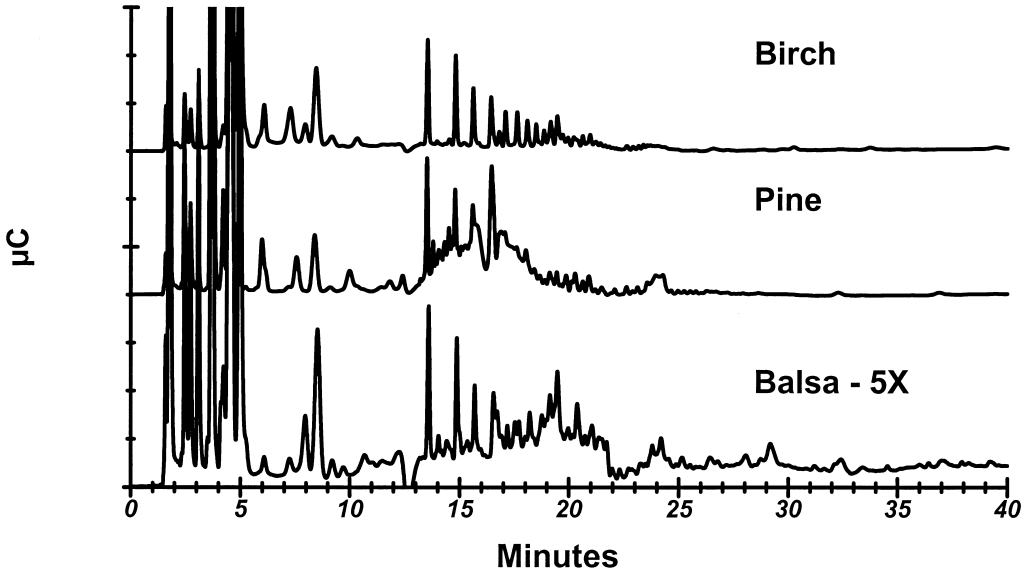

Fig. 9. Oligomers extracted from three different woods, birch, pine and balsa.

with woods as well. Note that the chromatograms of teak that has been part of the deck of a sea-going vessel for nineteen years is almost indistinguishable from that of recently-harvested teak, except that the scale of the weathered teak must be expanded 4× for the chromatographs to appear congruent (Fig. 10) for both the cotton and the wood, a probable hypothesis is that fractions of oligosaccharides and oligomers have leached out of the cellulose with successive exposure to water and salts. Loss of the oligosaccharides and oligomers may indicate, and may in fact constitute, wear and loss of integrity of the fabric and wood fibers.

Various paper products also display oligosaccharides and oligomers similar to those found in cotton and wood (Fig. 11) As with woods, every paper product tested to date has produced a unique chromatograph. Whereas the difference among the woods are probably due to differences in biochemistry and patterns of growth, the differences among the paper products illustrate differences in both cellulose source and in processing, such as type and degree of bleaching, coloring, and surface finishing.

3. Discussion

The relative amounts of oligomers extracted from the developing fibers vary with age of the tissues. The period of greatest abundance of the lower molecular weight oligomers coincides with the time considered to be the

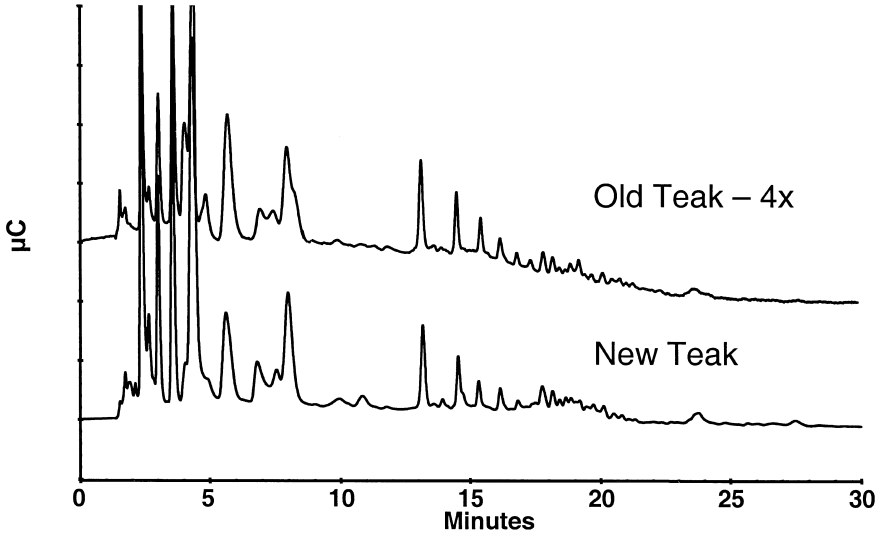

Fig. 10. Oligomers extracted from new teak and old teak which was weathered on a boat deck for 19 years.

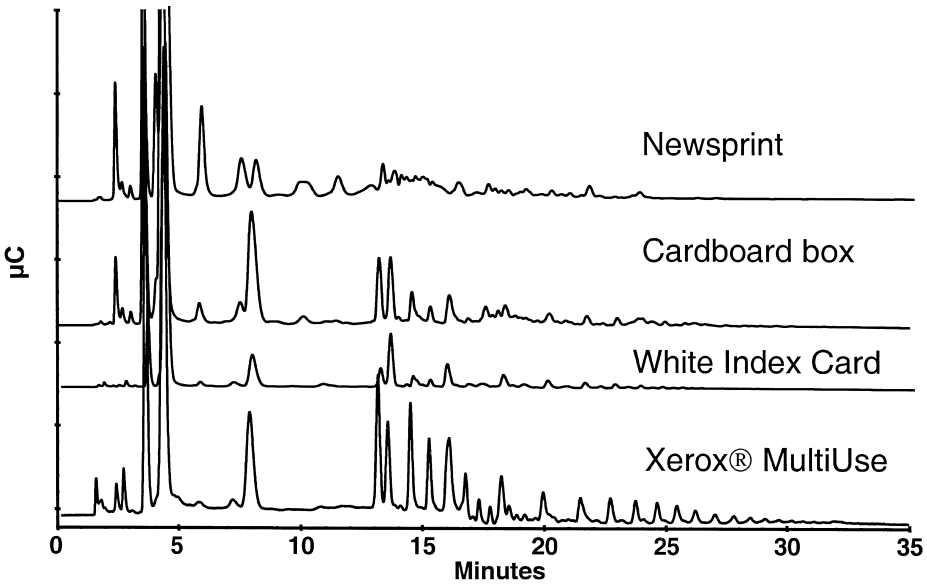

Fig. 11. Oligomers extracted from newsprint, cardboard, m indexcard and Xerox® MultiUse paper.

onset of secondary cell wall synthesis. This correspondence suggests a role of the oligomers in the biosynthetic process. Such a role is also supported by the skewed distribution of the oligomers in the sequential bolls from the a plant stunted due to periodic drought stress. The roles of UDPG, sucrose and sucrose synthase have been well described (Delmer, 1999). Correlation between the levels of sucrose and the sucrosyl oligosaccharides and the cyclical changes in the relative quantities of the oligomers with the time of day is suggestive of a role for these sugars in the synthesis of the oligomers. The influence of the concentrations of *myo*-inositol, sucrose, raffinose, cellobiose and glycerol on the oligomers extracted from fibers following incubation also supports the notion that a number of these sugars may function as substrates. The prospect of substrates originating external to the fiber being incorporated into the cellulose of the fiber wall was first raised by Delmer et al. (1974).

The extraction of the carbohydrate–protein complex containing the oligomers is also suggestive of a biosynthetic role for the oligomers. The fact that this material can be isolated by filtration, but that it appears to be incorporated into a larger material which precipitates with increased incubation time, is consistent with such a role. A likely scenario is that the rehydrated fibers are capable of carrying out some but not all of the enzymatic steps involved in the biosynthetic pathway.

The inhibition of the production of extractable oligomers by tunicamycin is very suggestive of a role of lipid linked intermediates (Elbein, 1979; Barr et al., 1989; Müller et al., 1981). In our case, incubation of fibers with tunicamycin results in a significant decrease in the oligomers which can be extracted if exogenous substrate is added (Fig. 6). Without exogenous substrate tunicamycin did not greatly decrease the oligomers which could be extracted. In contrast, experiments by Pillonel and Meier (1985) showed that fibers incubated with tunicamycin, at the same concentration, did not result in the reduction of ^{14}C incorporated into either ß-1,3 or ß-1,4 glucans using sucrose as the substrate. In fact, the incorporation was increased slightly. This apparent discrepancy may be explained by the different extraction methods used in the work of Pillonel and Meier, which utilized hot ethanol followed by precipitation of insoluble material. This procedure very likely included higher molecular weight glycans than have been extracted by the methods used herein (Fig. 1.) Also extraction with hot ethanol would very likely have destroyed the functionality of any associated proteins, such as that associated with the carbohyrdrate-protein complex isolated by the procedures used in this work. In ovule culture experiments the inclusion of tunicamycin in the culture medium resulted in the inhibition of secondary cell wall biosynthesis (Davidonis, 1993). An effect of tunicamycin similar to the ovule culture experiment and to what we report here has also been observed for the inhibition of cellulose biosynthesis in cell walls of *Arabidopsis* by tunicamycin (C. Somerville, personal communications).

The diurnal cycling of the carbohydrate-protein complex extracted from fibers harvested at different times of day coincides with the documented biosynthetic pattern of plant metabolism (Kehr et al., 1998). Although the the structure of the carbohydrate–protein complex has not been completely determined, the fact that the oligomers are released by weak acid suggests that they might have been released from a glycolipid. The possible role of intermediates other than glycolipids must also be kept open with the description of an *N*-glucosylated protein intermediate in the biosynthesis of a cell wall ß-1,6-glucan in *Saccharomyces cerevisiae* (Shahinian et al., 1998) and

an autoglycosylated protein implicated in plant cell wall biosynthesis (Delgado et al., 1998). The differences in the monosaccharide composition of oligomers subjected to differing conditions, as illustrated by those between oligomers extracted from fibers immediately following the cold water treatment versus those extracted from fibers following a 2 h incubation at 37°C also suggests biosynthetic activity. Such differences could be due to metabolic incorporation of the non-glucose components during the incubation, the addition of glucose to the oligomers, or differences in binding by other components of the system. A rigorous study employing thorough washing of the fibers prior to extraction with weak HCl following hydration or hydration and incubation is required to address these issues. The release by proteases suggests that the oligomers may be bound by a protein complex, also suggesting the possibility of a biosynthetic process. Invertase activity is present in the carbohydrate–protein complex, but the possibility of the presence of other enzyme activities remains open.

Clearly, biosynthesis of a polymer as large as cellulose may involve carbohydrates larger than sucrose. That such intermediates have not been described may be attributable to the complexity of carbohydrate biochemistry, and the relative fragility of glycoprotein associations, in the presence of rigorous extraction procedures. In this work, the use of mild extraction procedures, together with HPAEC-PAD, has revealed a number of, as yet not fully-characterized, oligomers. Such oligomers have been found in a number of cellulosic materials. The relative abundance of these oligomers varies with source and with developmental variables within a source. Moreover, the oligomers have been found in association with protein and, in certain experimental incubations, have behaved as if their solubility, acid-liability, and associated soluble products were affected by temperature and by amendment with biologically active saccharides. In short, they have behaved as if they were components of a biosynthetic apparatus. It is probable that the process of cellulose synthesis involves as yet un-described enzymatic activity, and that such activity is energetically favored by the conformation of glycan and glycoprotein conformations that are amenable to low-energy and possibly low-bioenergetic interconversion. We propose that the oligomers herein described are a fertile area for further research in elucidation of a model of cellulose biosynthesis.

4. Experimental

4.1. General experimental procedures

All water extractions were done using 18.3 megohm water from a Barnstead Nanopure water system. Enzymes used were obtained from Sigma Chemical Company. Chromatography was performed on a Dionex Bio-LC.

4.1.1. Plant material

Cotton, *Gossypium hirsutum* var. DP-50, was grown in the Mississippi Delta region for the time of day samples which were collected at 7 am, noon and 7 pm at 25 DPA. Plants for the sequential bolls were also *G. hirsutum* var. DP-50 grown in the Sacramento Valley of California. Sequential bolls were taken at the same time on the same plant. Bolls were placed on ice and frozen on dry ice as soon as possible following collection.

4.2. Extraction of fibers

The lyophilized fibers were first extracted with water at 0°C to remove soluble oligosaccharides and monosaccharides (Murray, 1998) (Fig. 1.). Typically, a 20 mg sample of fibers was placed in a 1.7 ml screw cap plastic tub to 0.5 ml water was added, the tube shaken, then placed in a Branson 85 W sonicator filled with ice water. Following removal of the cold water extract with a Pasteur pipette, 0.5 ml of 0.1 N HCl was added and the tube was placed in a boiling water bath for 30 min to extract the glucose containing oliogmers (Murray, 2000). The mono- and oligosaccharides extracted by the cold water procedure include *myo*-inositol, galactinol, arabinose, glucose, fructose, melibiose, sucrose, manninotriose, verbascotetraose, raffinose, stachyose, verbascose and, tentatively, ajugose which can be used as indicators of fiber development (Murray, 1998, 2000). The oligosaccharides extracted by the 0.1 N HCl procedure can also be used as indicators of cell wall biosynthesis and fiber development (Murray, 2000). The HCl extracts were neutralized with an equivalent amount of 1 N NaOH prior to HPAEC-PAD. In the case of fabric, wood or paper products typically 40–60 mg of material was extracted in a volume of 1.0 ml.

4.3. Isolation of oligomer–protein colloid

To obtain the oligomer–protein colloid, the cold water extract was removed and 0.5 ml of water was added, with 50 μl of toluene layered on top to prevent microbial growth, the cap was screwed on tightly and the tube was placed in a 37°C water bath for 24 h. Following the incubation, the oligomer–protein colloid was isolated by first centrifugation at 15,000 × *g* for 5 min after which the supernatant was filtered through a 0.22 μm Z-Spin filter (Gelman) with the oligomer–protein colloid being retained by the filter. The oligomers were released from the oligomer–protein colloid by either chymotrypsin or by the weak acid extraction.

4.4. Enzyme treatments

Extracted multimers were subjected to incubation with a cellulase (*Trichoderma reesei*) or a β-glucosidase (almond emulsin) both obtained from Sigma Chemical

Company. The enzymes were used at a concentration of 1 mg/ml in 50 mM sodium acetate buffer, pH 4.8. The effect of the β-glucosidase appeared to be to increase the heights of the multimer peaks significantly and to generate one additional small peak with a retention time slightly greater than 20 min. Presumably this is the result of removing terminal glucose unit(s) that results in a compound with an increased detector response. The cellulase gave a very different result since it resulted in the near elimination of many peaks and great reductions in many peak heights with a great increase in the peak height of the first peak in the series of multimers as shown in Fig. 5. Protease treatments of the carbohydrate-protein colloid were performed using a protein concentration of 1 mg/ml in water.

4.5. Chromatography

HPAEC-PAD was performed using a CarboPac PA-1 column. The eluent was 150 mM sodium hydroxide, isocratic from 0 to 5 min then a linear sodium acetate gradient from 5 to 40 min going from 0 to 500 mM in 150 mM NaOH at a flow rate of 1 ml/min. The detector wave form was the following: 0–0.50 s, 0.1 V; 0.51–0.59 s, 0.6 V; 0.60–0.65 s, −0.6 V; integration 0.30–0.50 sec. For monosaccharide composition, oliogomers were obtained by collecting fractions of the HPAEC-PAD eluent, which was passed through a Dionex ASRS-II anion suppressor to remove salt. Fractions were then lyophilized and taken up in 200 μl of water, made up to 2N trifluoroacetic acid (TFA)(Manzi and Varki, 1993). flushed with argon and sealed in screw cap plastic vials with O-rings. The samples were then placed in a heating block at 100°C for 2–4 h. Following hydrolysis, the samples were taken to dryness in a Speed-Vac overnight and then taken up in 200 μl of water for HPAEC-PAD on a Dionex CarboPac-PA10 column under isocratic conditions in 15 mM NaOH.

Acknowledgements

The authors would like to thank Judy Brown, Finch Ranch, Orland, CA, for collecting the sequential boll samples. Supported in part by Cotton Incorporated, 98-638. A portion of the work was performed under USDA CRADA No. 58-3K95-M415.

Bonding of hydroxycinnamic acids to lignin: ferulic and *p*-coumaric acids are predominantly linked at the benzyl position of lignin, not the β-position, in grass cell walls

Received 10 September 1999; received in revised form 2 October 2000

Abstract

A suspension in dichloromethane–water (18:1, v/v) of various fractions containing hydroxycinnamic acid ester–ether bridges between lignin and polysaccharides prepared from cell walls of matured oat (*Avena sativa* L.) internodes, and a solution of their acetates in the same solvent, were treated with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). This reagent selectively cleaves benzyl ether and ester linkages of negatively charged aromatic nuclei. The sample treated with DDQ was directly hydrolysed either under mild (1 M NaOH, overnight at 37°C) or severe (4 M NaOH, for 2 h at 170°C) conditions. The hydroxycinnamic acids released in the hydrolysate were methylated with diazomethane and analysed quantitatively using gas chromatography. Significant portions of ether linkages between hydroxycinnamic acids and lignin were cleaved with DDQ, which suggests that most of the hydroxycinnamic acids were ether-linked at the benzyl position, and not the β-position, of the lignin side chain as previously claimed. © 2001 Elsevier Science Ltd. 1. Introduction

The presence of both ether- and ester-linked hydroxycinnamic acids in cell walls of wheat (*Triticum aestivum* L.) straw and rice (*Oryza sativa* L.) straw has been reported by Scalbert et al. (1985, 1986), and Sharma et al. (1986), respectively. It has been suggested that ether-linked hydroxycinnamic acids, especially ferulic acid, form bridges between lignin and polysaccharides in cell walls of wheat internodes (Iiyama et al., 1990). By using the specific techniques of hydrogenation followed by borohydride reduction, Lam et al. (1992, 1994b) found that in wheat and phalaris internodes, most of the ferulic acid ether-linked to lignin (excluding *p*-coumaric acid) was also ester-linked to polysaccharides. We have also proposed that during primary cell wall formation, ferulic acid is esterified to polysaccharides and the ferulate is then linked to the benzyl position of a lignin side chain through a nucleophilic addition reaction to quinonemethide intermediates of lignin during lignification (Iiyama et al., 1990; Lam et al., 1994b).

Ralph et al. (1992) and Ralph and Helm (1993), using ^{13}C NMR spectroscopy of a lignin preparation of maize (*Zea mays*) which had been administered ^{13}C enriched ferulic acid, have suggested that ferulate is ether-linked to the β-position of a lignin side chain through a radical coupling reaction between ferulate and monolignol radicals, which are presumably produced by the action of peroxidase. They also suggested that ferulate radicals are coupled with monolignol radicals to form various inter-unit linkage types such as β-5 (phenylcoumaran type), β-β (pinoresinol type), 5-5 (biphenyl type) etc, i.e. that ferulate acts as a monolignol. Jacquet et al. (1995) also isolated a ferulic acid-coniferyl alcohol dimer as the β-ether linked dimer, in a reaction mixture recovered from mild alkaline hydrolysis (2 M NaOH for 2 h at

PII: S0031-9422(01)00052-8

37°C) of mature wheat and oat samples. Under these conditions, only ester linkages are cleaved. So the fragment of coniferyl alcohol should be a monomer, not a polymer. Lignin, on the other hand, is polymeric. Isolation of the ferulic acid-coniferyl alcohol dimer, therefore, has no relationship to the existence of β-ether linkages between lignin and ferulic acid. Terashima et al. (1993) and Morrison et al. (1998) have also suggested that ferulic acid is ester-linked to cell wall polysaccharides and thus is an anchor of lignification.

The cell walls of grasses release significant amounts of ferulic acid upon alkaline hydrolysis under various conditions, but there are few species of dicotyledonous plants which have detectable amounts of ferulic acid (Hartley and Harris, 1981; Kim et al., 1995). In order to understand the biosynthetic pathway of hydroxycinnamic acid bridges as well as the biosynthesis of lignin, it is important to identify the positions at which the hydroxycinnamic acids are ether-linked to lignin.

In this paper, internode walls of oat (*Avena saliva* L.) and various fractions containing lignin-polysaccharide associations through ferulic acid prepared from internode cell walls of oat were treated with 2,3-dichloro-5,6-dicyano-l,4-benzoquinone (DDQ). This reagent is well known as an oxidant, which selectively cleaves benzyl ester and ether linkages through charge transfer intermediates with negatively charged aromatic nuclei (Oikawa et al., 1982, 1983). DDQ has been applied to investigate the linkage position of polysaccharides to lignin (Koshijima et al., 1984; Watanabe et al., 1986, 1989). The results described here clearly suggest that most of the hydroxycinnamic acids, ferulic and *p*-coumaric acids, are etherlinked to the benzylic and not the β-position.

2. Results and discussion

The total recovery of fractions containing lignin-associated polysaccharides was ca. 90% of the extract-free cell walls of oat internodes (Table 1). About 10% of the walls were lost during ball milling and centrifugation. A significant amount of xylan was soluble in aqueous dioxane and DMSO; the DMSO-residue (DMR) was mostly composed of cellulose (Table 1). The total yield of products released by alkaline nitrobenzene oxidation was slightly higher in both 90 and 50% dioxane-soluble fractions than in other fractions (Table 2).

We tried to identify the position of the ether linkage of ferulate using DDQ. It has been reported that DDQ is a specific oxidant used to cleave benzyl ether and ester linkages by the formation of charge transfer complexes with reactants (Fig. 1) (Oikawa et al., 1982, 1983). Benzyl ether and ester linkages attached to aromatic nuclei of lignin (which is negatively charged), can be selectively cleaved by DDQ treatment. This reagent has been applied to the identification of the linkage position of polysaccharides to lignin in a fraction containing lignin–carbohydrate complexes isolated from wood meal (Koshijima et al., 1984; Watanabe et al., 1986, 1989). These results showed that sugar residues are linked to the lignin side chain at the benzyl position.

As the reaction of DDQ to cleave benzyl linkages is due to formation of charge transfer complexes with lignin aromatic nuclei, dichloromethane–H_2O (19:1, v/v) was used as solvent for the reaction. However, because the samples were not completely soluble in this solvent system, a homogeneous reaction using acetylated samples was also tested. The DDQ treatment for the heterogeneous system was carried out at 37°C for 24 h and 2 h for the homogeneous system. After DDQ treatment, dichloromethane was removed by evaporation and the samples were directly hydrolysed under mild (1 M NaOH, overnight at 37°C) and severe (4 M NaOH, for 2 h at 170°C) conditions. The hydroxycinnamic acids released by hydrolysis were derivatised with *N,O*-bis(-trimethylsily1)acetamide (BSA) and analysed by gas chromatography (GC) as previously described (Lam et al., 1994a). However, trimethylsilylated ferulic acid could not be separated from 2,3-dichloro-5,6-dicyano-l,4-hydroquinone, so the DDQ products were methylated with freshly prepared diazomethane and analysed by GC under the same conditions used for the trimethylsilyl derivatives (Lam et al., 1994a) (Fig. 2).

Hydroxycinnamic acids ether-linked to the benzyl position of the lignin side chain could be hydrolysed

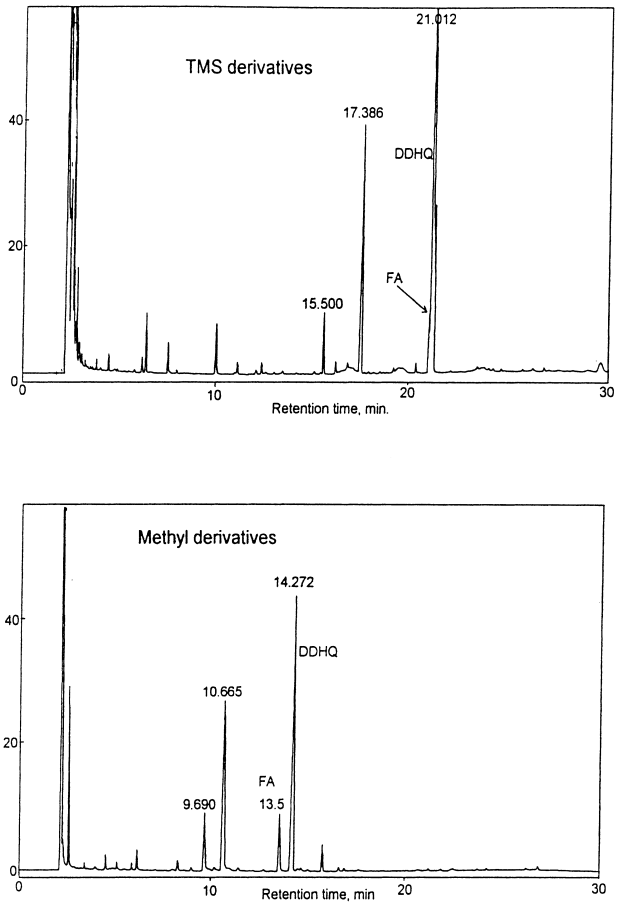

Fig. 2. Gas chromatograms of TMS derivatives and methyl derivatives of the products of alkaline hydrolysates.

using mild alkaline treatment. While the overall quantities of *p*-coumaric and ferulic acids liberated through mild and severe alkaline hydrolysis of each particular wall fraction (or its acetylated derivative) remained approximately constant, the amounts of both of the hydroxycinnamic acids released by mild alkaline hydrolysis alone increased substantially as a result of prior treatment with DDQ (Table 3). Thus, the results clearly showed that a significant portion of ether-linked hydroxycinnamic acids were cleaved by DDQ treatment. The data suggested that more than 80% of ether-linked hydroxycinnamic acids (both *p*-coumaric and ferulic acids) were linked to the benzyl position [Fig. 3(a)], and not to the β-position [Fig. 3(b)]. Therefore, the hypotheses of Ralph et al. (1992) and Ralph and Helm (1993), Terashima et al. (1993), Jacquet et al. (1995) and Morrison et al. (1998) that ferulate radicals produced by the action of peroxidase might be an anchor of lignification, should be reconsidered.

3. Experimental

3.1. Plant material and fractionation

Internodes of oat (*Avena saliva* L.) were harvested on 4 June, 1996 from the experimental field at the University of Tokyo, the Graduate School of Agricultural and Life Sciences, immediately frozen at −20°C, then freeze-dried. The dry internodes were ground in a Wiley mill and passed through a 420 μm sieve, then extracted successively with boiling Et_2O for 1 h (×3), boiling 80% (v/v) aqueous EtOH for 1 h (×3), and H_2O at 37°C overnight on a shaker. Solid material remaining following extraction was washed with $(CH_3)_2CO$ then dried in a vacuum oven at 40°C. The dried sample was finely ground for a further 96 h with water cooling (<25°C) using a stainless steel vibratory ball mill without solvent (Koshijima et al., 1972). The finely ground sample was extracted with 90% (v/v) aqueous dioxane at 37°C overnight on a shaker. The soluble sample was separated by filtration, and the residue was extracted again with 90% (v/v) aqueous dioxane. The extraction was performed in triplicate. The combined organic solution was

concentrated in vacuo (45°C), then freeze-dried to give a 90% dioxane soluble fraction (90S).

The residue was further extracted with 50% (v/v) aqueous dioxane as described above, and the 50% aqueous dioxane soluble fraction (SOS) was recovered by freeze-drying. A dimethylsulfoxide (DMSO) soluble fraction was obtained by extraction of the residue of 50% aqueous dioxane extraction with DMSO at 37°C overnight with shaking. The extract was added dropwise into five volumes of MeOH with stirring, and the precipitate was collected by centrifugation (DMSO soluble fraction: DMS). The residue was washed several times with $(CH_3)_2CO$ and Et_2O, then dried in a vacuum oven at 40°C to give a DMSO insoluble fraction (DMR) (Fig. 4).

3.2. Chemical analysis

Hydroxycinnamic acids covalently bound to internode walls of oat and its fractions containing lignin-polysaccharide complex, were quantified as described by Lam et al. (1994a) using *m*-coumaric acid as an internal standard. Lignin content was determined using the acetyl bromide procedure (Iiyama and Wallis, 1990). Neutral sugar compositions of samples were determined by an alditol acetate procedure (Blakeney et al., 1983) which included some minor modifications. Digestion was carried out in 4% H_2SO_4 at 121°C for 60 min. Inositol was used as an internal standard, and a TC- 17 capillary column was used for gas chromatography (GC). The aromatic composition of lignin was analysed by alkaline nitrobenzene oxidation, and yields of products were corrected for products from *p*-coumaric and ferulic acids (Iiyama and Lam, 1990). All chemical analyses were carried out in duplicate.

3.3. Oxidation with 2,3-dichloro-5,6-dicyano-1, 4-benzoquinone (DDQ)

The samples (finely ground internode walls and fractions: 50 mg each) were suspended in CH_2Cl_2–H_2O (18:1, v/v, 25ml); DDQ (25 mg) was then added. The

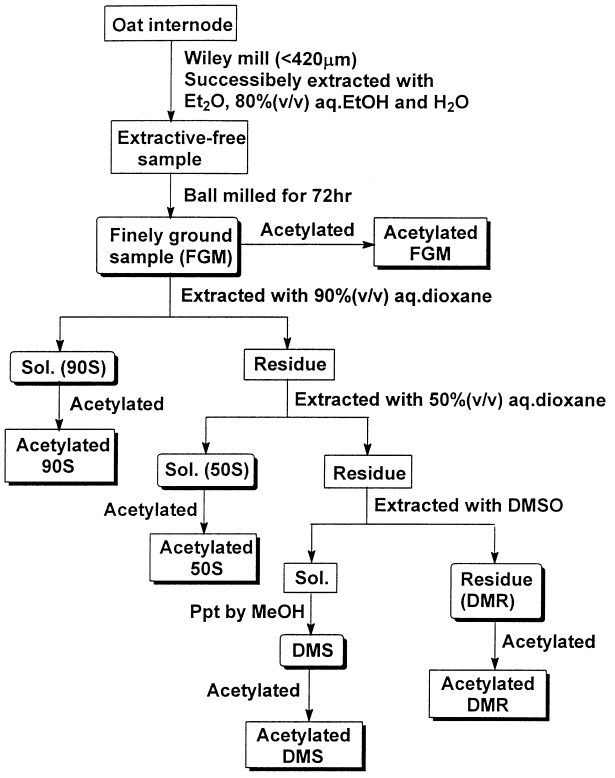

Fig. 4. Preparation of fractions containing lignins and polysaccharides.

suspension was stirred at room temperature for 24 h. Acetylated samples (50 mg) (except acetylated walls and DMSO-insoluble fraction) were dissolved in CH_2Cl_2–H_2O (18:1, v/v, 25 ml), then treated with DDQ for 2 h at room temperature with stirring. After DDQ oxidation, the solvent was removed by evaporation, and the reaction mixture was hydrolysed with 1 M NaOH (10 ml) at 37°C overnight on a shaker or with 4 M NaOH (5 ml) for 2 h at 170°C (Lam et al., 1994a). Products were extracted sequentially with CH_2Cl_2 (twice) and Et_2O, then dried (Na_2SO_4). The products were methylated with freshly prepared diazomethane, then analysed using GC under the same conditions with trimethylsilyl derivatives (Lam et al., 1994a).

Abstract

Studying lignin-biosynthetic-pathway mutants and transgenics provides insights into plant responses to perturbations of the lignification system, and enhances our understanding of normal lignification. When enzymes late in the pathway are downregulated, significant changes in the composition and structure of lignin may result. NMR spectroscopy provides powerful diagnostic tools for elucidating structures in the difficult lignin polymer, hinting at the chemical and biochemical changes that have occurred. COMT (caffeic acid *O*-methyl transferase) downregulation in poplar results in the incorporation of 5-hydroxyconiferyl alcohol into lignins via typical radical coupling reactions, but post-coupling quinone methide internal trapping reactions produce novel benzodioxane units in the lignin. CAD (cinnamyl alcohol dehydrogenase) downregulation results in the incorporation of the hydroxycinnamyl aldehyde monolignol precursors intimately into the polymer. Sinapyl aldehyde cross-couples 8–O–4 with both guaiacyl and syringyl units in the growing polymer, whereas coniferyl aldehyde cross-couples 8–O–4 only with syringyl units, reflecting simple chemical cross-coupling propensities. The incorporation of hydroxycinnamyl aldehyde and 5-hydroxyconiferyl alcohol monomers indicates that these monolignol intermediates are secreted to the cell wall for lignification. The recognition that novel units can incorporate into lignins portends significantly expanded opportunities for engineering the composition and consequent properties of lignin for improved utilization of valuable plant resources. © 2001 Elsevier Science Ltd. 1. Introduction

NMR continues to become increasingly valuable as a tool for lignin structural elucidation. A number of powerful experiments stand out as being exceptionally useful. An extensively illustrated overview of solution-state NMR of lignins was recently published (Ralph et al., 1999c), so experimental details will not be given here. This paper will instead present recent NMR applications elucidating the structures of novel units in lignins from plants deficient in two monolignol biosynthetic pathway genes/enzymes.

Lignins are traditionally described as plant polymers resulting from dehydrogenative polymerization (via radical coupling reactions) of three primary phenylpropanoid monomers, *p*-coumaryl (4-hydroxy-cinnamyl), coniferyl (4-hydroxy-3-methoxy-cinnamyl), and sinapyl (3,5-dimethoxy-4-hydroxy-cinnamyl) alcohols, analogs varying in their degrees of methoxylation (Harkin, 1967; Freudenberg and Neish, 1968). They represent a class of complex polymeric natural products present in large quantities in the cell walls of terrestrial plants. The strict definition has, however, been long recognized as too narrow (Sarkanen and Ludwig, 1971). Other phenolic components, such as acylated hydroxycinnamyl alcohols and hydroxycinnamate esters may also intimately incorporate into lignins (Boudet, 1998; Sederoff et al., 1999; Ralph et al., 1999c). There has been considerable debate over what constitutes a "real" lignin (Lewis, 1999; Sederoff et al., 1999). We do not wish to revisit those issues here. We shall simply make the following observation. If a phenolic phenylpropanoid that is likely derived from the basic monolignol biosynthetic pathway couples (via radicals), as a monomer, with a growing oligomer/polymer of phenylpropanoids, and is further integrated into the polymer by endwise coupling with a new monolignol (or monomer), then we shall call this product lignin here. Ideally, histochemical studies should also be done to demonstrate that the polymer incorporating these units is in the cell wall.

Recent advances in genetic engineering have allowed researchers to perturb the monolignol biosynthetic pathway (Dixon and Ni, 1996; Baucher et al., 1998; Boudet, 1998; Whetten et al., 1998), allowing the abundance of normally minor components to be substantially enhanced and therefore structurally analyzed (Van Doorsselaere et al., 1995; Ralph et al., 1997, 1998, 1999b; Lapierre et al., 1999; Kim et al., 2000; Jouanin et al., 2000). This approach provides valuable insights into the control of lignification and into the remarkable biochemical flexibility of the lignification system.

The monolignol biosynthetic pathway in angiosperms has undergone considerable reevaluation recently. Fig. 1 derives from recent clarifications of the primary pathways, as deduced by Chiang's and Chapple's groups (Humphreys et al., 1999; Osakabe et al., 1999; Li et al., 2000). Studies to date indicate that downregulating any of the enzymes of the major pathways can affect the course and/or extent of lignification. General down-regulation of lignification (producing plants with reduced lignin levels) is possible. For example, NMR and other methods showed that the lignins from plants deficient in either a CoA ligase, Pt4CL1 (Hu et al., 1999) or an *O*-methyl transferase, CCoAOMT (Meyermans et al., 2000), were essentially normal in their composition and structure, despite having significantly lower than normal lignin levels. In both cases however, the levels of *p*-hydroxybenzoates on the lignins increased suggesting that the pathways to the monolignol esters might not be fully coupled to general monolignol synthesis (Li et al., 2000).

The most striking example of compositional flexibility in the normal monolignols came from the F5H (ferulate 5-hydroxylase) Arabidopsis mutants and transgenics produced by Chapple's group; F5H is sometimes now referred to as CAld5H to implicate coniferaldehyde as the preferred substrate for that enzyme (Humphreys et al., 1999; Osakabe et al., 1999). As shown by NMR (Marita et al., 1999) and other methods (Meyer et al., 1998), a chemical mutagenesis mutant of Arabidopsis had lignins devoid of syringyl units. More strikingly, when a suitably promoted *F5H* gene was introduced into the F5H-deficient mutant, up-regulation of sinapyl alcohol production was at such a high level that the lignin became extremely syringyl-rich. With an approximately 3% guaiacyl component, these plants' lignins have a far lower guaiacyl content than any plant reported to date (Marita et al., 1999). The up-regulation of F5H is therefore strikingly effective at diverting the monolignol pool toward sinapyl alcohol. In these examples massive compositional shifts in the traditional lignin components are apparent. As will be seen, compositional shifts can range considerably wider.

Here we present NMR data from recent studies on mutants and transgenics deficient in two of the later pathway enzymes, CAD (cinnamyl alcohol dehydrogenase) and COMT (caffeic acid *O*-methyl transferase, the favored substrate for which now appears to be 5-hydroxyconiferyl aldehyde (Li et al., 2000) although 5-hydroxyconiferyl alcohol must also be a viable substrate (Matsui et al., 1994; Chen et al., 1999; Humphreys et al., 1999; Maury et al., 1999). Downregulating these enzymes dramatically affects the composition of lignins and the structures contained in those lignins. We also reexamine the F5H-upregulated Arabidopsis transgenics where the methylation apparently can't keep pace with the increased hydroxylation rate.

2. CAD-deficient tobacco: aldehyde incorporation

CAD is the last enzyme on the pathway to the monolignols coniferyl and sinapyl alcohols **2**G and **2**S, from which lignins are normally derived, Figs. 1 and 2. When CAD is downregulated, the hydroxycinnamyl aldehyde precursors to the monolignols, coniferyl aldehyde **1**G and sinapyl aldehyde **1**S, build up and may be incorporated into the polymer by radical coupling (Halpin et al., 1994, 1998; Higuchi et al., 1994; Provan et al., 1997; Ralph et al., 1997, 1998; Stewart et al., 1997; Yahiaoui et al., 1998; Vailhe et al., 1998). Indeed, coniferyl aldehyde readily incorporated into synthetic lignins under biomimetic conditions (Higuchi et al., 1994). Recent studies have begun to elucidate the propensity for the mono-

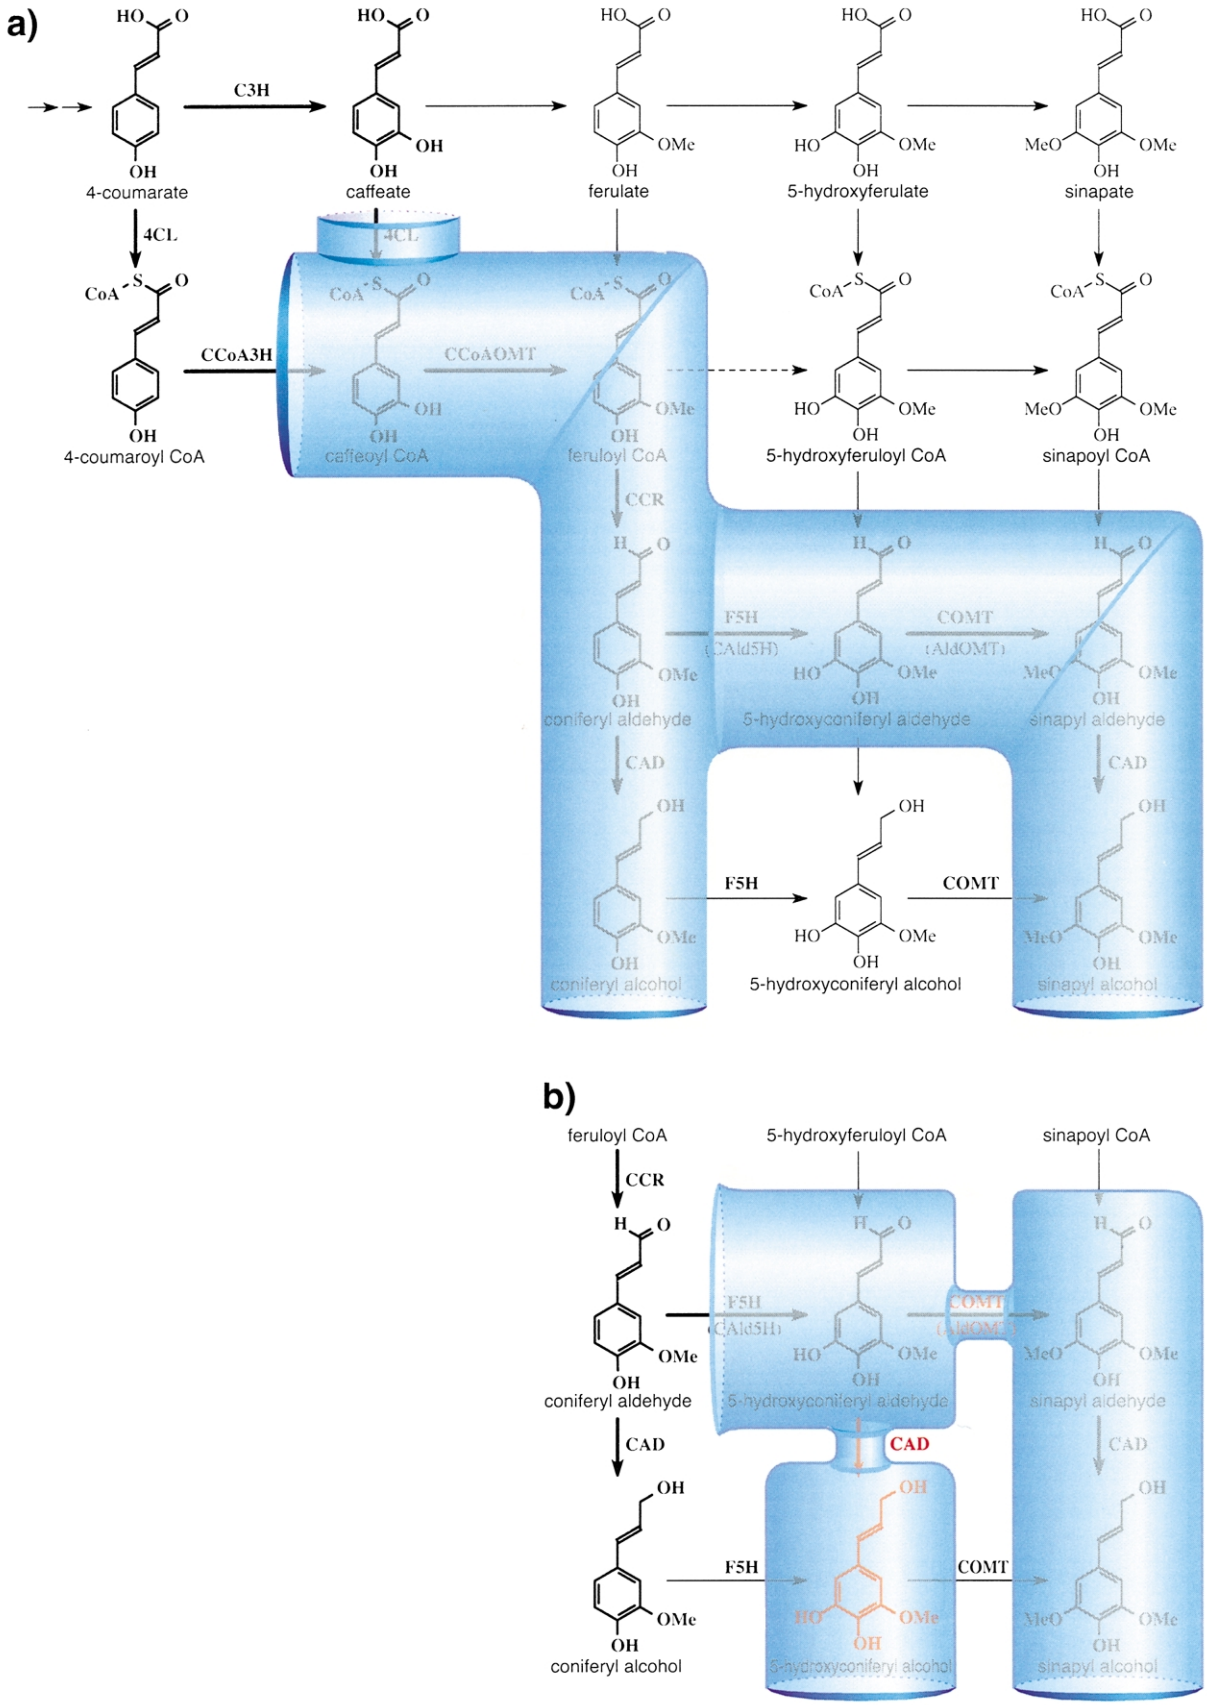

Fig. 1. (a) The monolignol biosynthetic pathway in angiosperms. Bolder structures and arrows (with large-diameter pipes) represent preferred pathways as recently clarified (Humphreys et al., 1999; Osakabe et al., 1999; Li et al., 2000). (b) When COMT activity is deficient, sinapyl alcohol production backs up the 5-hydroxyconiferyl aldehyde intermediate which can apparently be reduced by CAD; 5-hydroxyconiferyl alcohol then becomes a significant monomer in lignin biosynthesis.

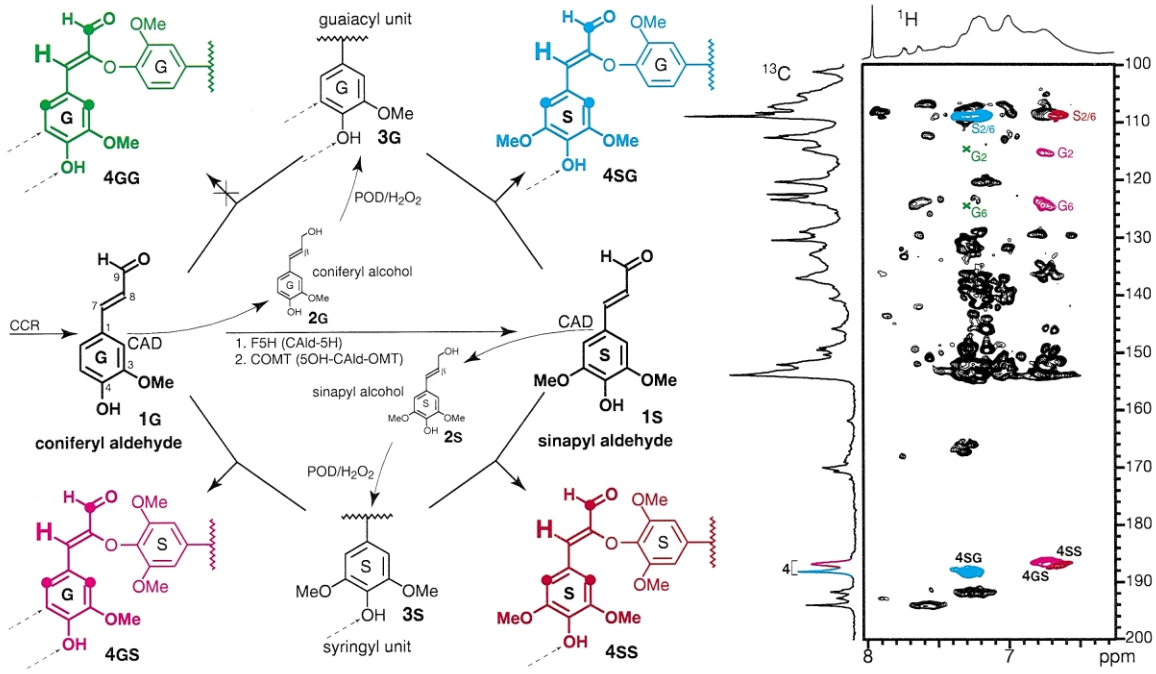

Fig. 2. Cross-coupling of hydroxycinnamyl aldehydes **1**G and **1**S with guaiacyl and syringyl lignin units **3**G and **3**S can potentially produce four 8–O–4-cross-coupled structures **4**. Only three of the four cross-products (**4**GS, **4**SG and **4**SS but not **4**GG) are significantly represented, as determined by analysis of the gradient-HMBC partial spectrum to the right. The HMBC section shows, in a lignin isolated from CAD-deficient tobacco stems, correlations from the aldehyde carbonyl carbons (185–195 ppm) to the H7 protons within three-bonds in structures **4** that have been further incorporated into lignin at positions indicated by the dashed arrows. These H7 protons diagnostically correlate with the 2- and 6-carbons of the cinnamyl aldehyde ring; the G2 and G6 carbons for guaiacyl units, and the higher-field equivalent S2/6 (syringyl) carbons are identified and colored correspondingly. Colored dots on the structures indicate the carbons correlated by $^{3}J_{C-H}$ to the H7-protons (which are shown in a larger font size) shown in the HMBC spectrum. The aldehydes at ~188.1 ppm, with their corresponding H7s at ~7.3 ppm result from hydroxycinnamyl aldehydes **1** 8–O–4-coupled to guaiacyl units **3**G in lignin; correlations from H7 indicate, however, that sinapyl aldehyde **1**S, but not coniferyl aldehyde **1**G, couples with guaiacyl units **3**G — the green X's show where correlations are present in a model for **4**GG. The aldehydes at ~186.7 ppm, with their corresponding H7s at ~6.7 ppm result from hydroxycinnamyl aldehydes **1** 8–O–4-coupled to syringyl units **3**S in lignin; correlations from H7 indicate that sinapyl aldehyde **1**S and coniferyl aldehyde **1**G each couple with syringyl units **3**S. S = syringyl, G = guaiacyl, CCR = cinnamoyl-CoA reductase, CAD = cinnamyl alcohol dehydrogenase, F5H = ferulate 5-hydroxylase which has recently also been termed CAld5H = coniferyl aldehyde 5-hydroxylase, to reflect the preferred in vivo substrate (Osakabe et al., 1999; Humphreys et al., 1999), COMT = caffeoyl *O*-methyl transferase (for which the preferred substrate appears to be 5-hydroxyconiferyl aldehyde, Li et al., 2000), POD = peroxidase. Convention for compound numbering: e.g. **4**GS = a guaiacyl aldehyde (coniferyl aldehyde **1**G) coupled 8–O–4 to a syringyl lignin unit (**3**S).

lignols to cross-couple with (free-phenolic) guaiacyl and syringyl units in lignins (Syrjanen and Brunow, 1998, 2000). With the availability of a ^{13}C-enriched lignin from a CAD-deficient tobacco transgenic (Ralph et al., 1998) and a series of model compounds (Kim et al., 2000), NMR methods can be used to ascertain hydroxycinnamyl aldehyde in vivo cross-coupling propensities. Data revealing such details of plant lignification are rarely obtained.

Radical cross-coupling of monolignols **2**, Fig. 2, with the growing lignin oligomer/polymer **3** is the major reaction occurring during lignification. Thus, the hydroxycinnamyl alcohol **2** (primarily at its β-position) couples with phenolic units **3** (at the 4–O- or 5-position for guaiacyl units **3**G, and almost exclusively at the 4–O-position for syringyl units **3**S) to form a chain-extended oligomer/polymer, also with the general formula **3**. Fig. 2 (right) shows a selected region of a long-range ^{13}C–^{1}H correlation (gradient-HMBC) spectrum from a CAD-deficient tobacco lignin, with peaks in the ^{13}C-projection and the resultant contours in the HMBC spectrum colored to match structures on the left for easy identification. In fact, the aldehyde structures in the lignins likely have been further incorporated into the polymer by primarily 4–O-coupling with the next monolignol, so they are not strictly the phenolic compounds **4** shown. Available coupling sites are indicated in Fig. 2 by the dashed arrows.

As the caption to Fig. 2 describes, correlation of the aldehyde carbonyl carbons in cross-products **4** to the H7-protons three-bonds away identifies the type of lignin units involved. Protons H7 resonate at ~7.3 ppm for hydroxycinnamyl aldehydes (either **1**G or **1**S) coupled 8–O–4 to guaiacyl units **3**G (compounds **4**GG and **4**SG, δ_C = 188.1 ppm), whereas they resonate considerably upfield, at ~6.7 ppm when coupled 8–O–4 to syringyl units **3**S (compounds **4**GS and **4**SS, δ_C = 186.8 ppm). Correlations from these H7 protons into the ring

identify the hydroxycinnamyl aldehyde involved in the coupling; three-bond correlations identify equivalent S2/6 carbons derived from sinapyl aldehyde **1**S units at higher field than the non-equivalent G2 and G6 carbons from units derived from coniferyl aldehyde **1**G. Therefore, for 8–O–4 cross-coupled units **4** in lignins, the G/S nature of both the hydroxycinnamyl aldehyde component (coupled 8-) and the lignin unit (coupled 4–O-) are diagnostically revealed. Other aromatic protons in the complex lignin polymer resonate in the H7 regions so correlations that are not of interest here will result; an absence of correlations is therefore more diagnostic, revealing the absence of a component.

Of the four possible aldehyde 8–O–4 incorporation products **4**, Fig. 2, only three can be detected in the antisense-CAD tobacco lignin by NMR methods. Product **4**GG is conspicuously absent. The data imply that sinapyl aldehyde **1**S cross-couples 8–O–4 with both guaiacyl and syringyl units (to form cross-coupled structures **4**SG and **4**SS), but that coniferyl aldehyde **1**G cross-couples 8–O–4 *only* with syringyl units **3**S and not with guaiacyl units **3**G. Thus, cross-coupling product **4**GS is readily detected, whereas **4**GG cannot be detected even when spectra are viewed at close to the baseplane noise level. This cross-coupling propensity is presumably the reason why 8–O–4-coupled structures are not found to be prominent in CAD-deficient softwood lignins (Ralph et al., 1997).

Attempting to prepare compounds modeling **4**GG by biomimetically cross-coupling coniferaldehyde **1**G (at the eight-position) with coniferyl alcohol **2**G or with a simple guaiacyl model 1-(4-hydroxy-3-methoxy)-ethanol (at the 4–O-position), also failed to produce 8–O–4-coupled cross-products. Apparently the same factors that promote cross-coupling in vitro apply in vivo, suggesting that these radical coupling reactions and those involved in "normal" lignification are likely to be under simple chemical control in the plant (Sederoff et al., 1999). In the cross-products, the chemical shifts match those in model compounds synthesized by traditional means (Kim et al., 2000). Also available from the HMBC spectrum in Fig. 2 is some information regarding the incorporation of the hydroxycinnamyl aldehydes **1** and their derived hydroxybenzyl aldehydes at ring 4–O-positions, as described elsewhere (Kim et al., 2000).

Examination of the spectra also provides significant information regarding the incorporation of hydroxycinnamyl aldehydes into "bulk" vs. "endwise" polymers (Sarkanen, 1971). "Bulk" lignins are characterized by frequent dimerization reactions, whereas endwise polymerization, the normal process occurring during lignification in the secondary cell wall, is from cross-coupling of monomers with the growing polymer. Dimerization of coniferaldehyde produces the 8–O–4-coupled dimer (analogous to **4**GG, Fig. 2), along with the other anticipated 8–8- and 8–5-coupled dimers (Connors et al., 1970). The absence of signals for coniferaldehyde coupled with G-units (of which the coniferaldehyde dimer **4**GG is an example), is evidence that coniferaldehyde does not dimerize at an appreciable level and therefore is not significantly involved in "bulk" lignification.

In summary, in 8–O–4-coupling reactions, coniferyl aldehyde cross-couples only with syringyl units, whereas sinapyl aldehyde cross-couples with both guaiacyl and syringyl units. These observations require no departure from the existing theory of radical coupling of phenols into polymeric lignins since they appear to reflect simple chemical coupling propensities.

3. CAD-deficient pine: incorporation of dihydroconiferyl alcohol and guaiacylpropane-1,3-diol

Preliminary observations (Ralph et al., 1997) on the novel lignins from a CAD-deficient pine (*Pinus taeda*) mutant are being strengthened as more diverse evidence accumulates (Dimmel et al., 1999; Ralph et al., 1999a; Lapierre et al., 2000). The plant, despite a reduction in CAD levels to $< 1\%$ of normal levels (MacKay et al., 1997), appeared to be producing normal levels of lignin (Klason lignin values were almost identical). A possible interpretation is that the CAD-deficiency is not sufficient to change the system and that there is still sufficient flux through the residual enzyme levels that normal lignification can proceed. The lignin in the CAD-deficient pine mutant however was highly colored and stained strongly with phloroglucinol, suggesting a higher aldehyde component. From NMR studies on isolated lignins, aldehydes and dihydroconiferyl alcohol were substantial components of that lignin (Ralph et al., 1997, 1999c).

New aldehyde components were misidentified originally (Ralph et al., 1997), but corrected in subsequent publications (Ralph et al., 1998, 1999b,c). A book chapter on NMR details how the incorrect assignment was made (Ralph et al., 1999c). The aldehyde components all stem from incorporation into the lignin of more significant quantities of coniferyl aldehyde (and its product vanillin) than in normal pine. The low aldehyde levels seen in normal lignins could possibly result from post-lignification oxidation, but the levels seen in this and other CAD-deficient plants suggest that incorporation of hydroxycinnamyl (and hydroxybenzyl) aldehydes into lignins is a normal process that becomes more significant when the pathway to the final monolignols is downregulated.

The CAD-deficient pine lignin had another feature that may or may not be attributable directly to the CAD-deficiency. Since this was a natural mutant other unknown enzymes may have also been impacted by the mutation(s); however, this is unlikely because the genetic determinant of the modified wood colocalized with the coding

sequence for the enzyme CAD (MacKay et al., 1997). Substantial levels of an unexpected unit derived from dihydroconiferyl alcohol (DHCA, **5**, Fig. 3) were identified in the mutant's lignin (Ralph et al., 1997, 1999c; Sederoff et al., 1999). DHCA is found at lower levels in normal plant lignins (Lundquist and Stern, 1989; Fukagawa et al., 1991; Brunow et al., 1998; Ralph et al., 1999c) but its derivation is not completely clear. Claims that the unit could only arise as a modified metabolic product *following* dimerization of traditional lignin monomers (Gang et al., 1998; Lewis et al., 1998) were incorrect; there is ample evidence that DHCA is formed as a monomer in the CAD-deficient pine and that the monomer is incorporated into the lignin via radical coupling processes (Ralph et al., 1997, 1999c; Sederoff et al., 1999; Lapierre et al., 2000). NMR showed that about half of the DHCA units in the soluble lignin fractions were involved in 5–5-coupled structures (Ralph et al., 1997, 1999c); coniferyl alcohol has never been shown to 5-5-dimerize. We were able to dissolve the (dioxane-water insoluble) residual lignin in acetyl or propionyl bromide. These reagents acylate and α-brominate the lignin, and cause some other structural changes, but in no way (other than acylation) affect the saturated aryl propanol sidechain. HMQC and COSY NMR experiments then unambiguously determined that DHCA was a component of that residual lignin although quantification was not possible (Ralph et al., 1999c).

More recently, guaiacylpropane-1,3-diols (GPDs) were also identified in lignins isolated from the CAD-deficient pine mutant, Fig. 3. This helped to unravel the nature of weak correlations often seen in pine lignin ^{13}C–^{1}H correlation NMR spectra; smaller amounts of GPDs are now recognized to be present in lignins from normal pines and presumably other softwoods. The structures in the complex lignin polymers are readily proven by NMR of isolated lignins.

Fig. 3a shows a subplot of the sidechain region from a 2D HMQC-TOCSY NMR experiment on an acetylated lignin isolated from the mutant pine, highlighting the new (acetylated) guaiacylpropane-1,3-diols **6** (red) along with the DHCA **5** units (green). Data from a model compound, 1,3-diacetoxy-1-(4–O-benzyl-3-methoxyphenyl)-propane (Ralph et al., 1999b), are at the center of the yellow circles and obviously match well.

As with other novel units found in lignins from transgenic or mutant plants, traces of the same components can be found in lignins from control plants. Fig. 3b shows the α-C/H region of an HSQC spectrum of the mutant's lignin, where the β-aryl ether units (blue) and the strong new GPD unit (red) appear most cleanly. Fig. 3c shows the same region in lignin from a

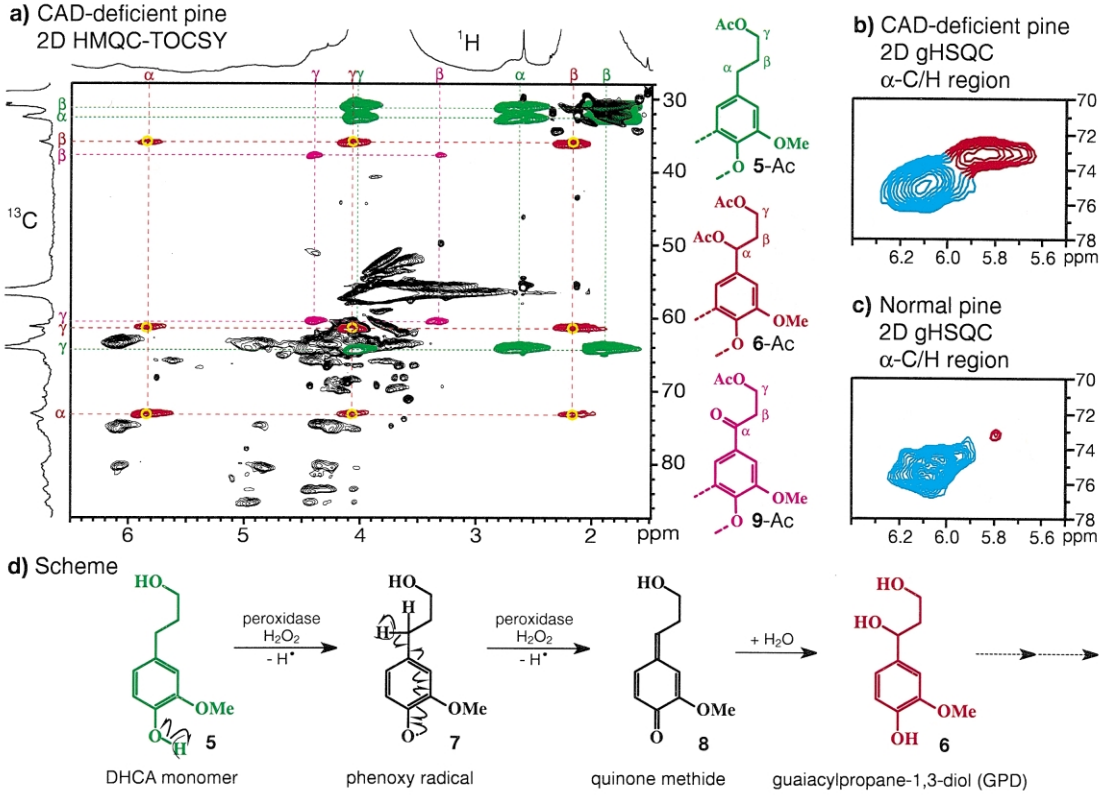

Fig. 3. NMR spectra showing new GPD **6** structures (red) and derived benzylic ketone analogs **9** (magenta), along with DHCA **5** units (green); data from acetylated model **6**–Ac are at the centers of the yellow circles; some β-aryl ether units are also shown (blue) in the HSQC spectra in b and c. The mechanism for producing GPD **6** from DHCA is shown in d.

normal pine control. Although the GPD peak is weak, it is diagnostic and, with other correlations evident (not shown), well authenticated.

GPD monomeric units derive from DHCA monomer **5** via the action of peroxidase and hydrogen peroxide, Fig. 3d. The mechanism, via a vinylogous quinone methide **8**, involves two H-radical abstractions. Abstraction from a benzylic CH_2 to produce quinone methides from phenoxy radicals has been noted previously (Zanarotti, 1982). When DHCA is subjected to peroxidase-H_2O_2, monomeric GPD **6** as well as the range of homo- and crossed-dimers involving DHCA and GPD are found (Peng and Ralph, unpublished).

Also evident in the HMQC-TOCSY spectrum, Fig. 3a, are (acetylated) ketones **9** (magenta contours). Products of benzylic alcohol oxidation are seen in various isolated lignins, notably from syringyl (3,5-dimethoxy-4-hydroxy-phenyl) units; they may arise during lignin isolation (particularly in the ball-milling step). Ketones **9** provide additional confirmatory evidence for the GPD structures **6** described earlier.

In summary, another previously unidentified unit present in small quantities in normal lignins is a major component of the hydroxyphenylpropanoid polymeric component of a pine mutant deficient in CAD. Those units, guaiacylpropane-1,3-diols, arise from conversion of dihydroconiferyl alcohol monomers by radical reactions and also incorporate into lignins as monomers. Like DHCA however, GPD **6**, which does not possess an unsaturated sidechain, is limited to coupling on the ring 4–O-, 5-, and possibly 1-positions, necessarily forming terminal units in lignin (except via 5–O–4-coupling). High MW polymers cannot be created without the incorporation of authentic hydroxycinnamyl alcohols (or other cinnamyl derivatives) as well. The CAD-deficient pine lignin is more soluble in alkali and has reduced molecular weight (Dimmel et al., 1999).

4. COMT-deficient poplar: benzodioxanes from incorporation of 5-hydroxyconiferyl alcohol

COMT is one of two enzymes required to 5-methoxylate guaiacyl monomeric units to produce sinapyl alcohol and eventually produce syringyl units in angiosperm lignins, Fig. 1. If COMT is downregulated, 5-hydroxyconiferyl aldehyde might build up and might be expected to be reduced to 5-hydroxyconiferyl alcohol if the next enzyme, CAD, is sufficiently non-specific. In fact, as illustrated in Fig. 1b, it appears that 5-hydroxyconiferyl alcohol is indeed formed, shipped out to the wall, and incorporated into lignin analogously to other lignin monomers (although it produces some novel structures in the final lignin).

NMR provides beautiful evidence that benzodioxane structures are produced in lignins which incorporate 5-hydroxyconiferyl alcohol. Fig. 4b shows the sidechain region of an HMQC spectrum from an (acetylated) isolated lignin from a COMT-deficient poplar (*Populus tremula* × *Populus alba*) described recently (Jouanin et al., 2000). The transgenic was actually the result of an attempt to up-regulate COMT by sense-methods that instead resulted in gene silencing. The degree of COMT suppression was higher than in other trials using antisense suppression (Van Doorsselaere et al., 1995; Lapierre et al., 1999). As with the dibenzodioxocins **D** (Karhunen et al., 1995a,b), the benzodioxanes **H** are readily apparent in short-range ^{13}C–^{1}H correlation spectra (HMQC or HSQC) of acetylated isolated lignins. Well separated contours at δ_C/δ_H of 76.8/4.98 (α), and 75.9/4.39 (β) are diagnostic for the benzodioxanes **H**; the γ-correlations overlap with those in other lignin units. Anticipated shifts occur following acetylation; in the unacetylated lignins (not shown), the correlations are centered at δ_C/δ_H of 76.5/4.87 (α), and 78.9/4.06 (β). As seen in Fig. 4b and d, the sidechain correlations are consistent with those in a model compound for the *trans*-benzodioxane **10**–Ac, synthesized by biomimetic cross-coupling reactions between coniferyl alcohol and a 5-hydroxyguaiacyl unit (Ralph et al., 2000). The α-proton shift deviated the most presumably since this is an acetylated (and therefore originally free-phenolic) model, rather than a phenol-etherified structure which would correspond to most of the units in the lignin polymer. Lignins from COMT antisense poplars also contain benzodioxane units (Ralph et al., 2000).

A reasonable quantification of this unit can be done by measuring volume integrals in the 2D spectra (Zhang et al., 2000), particularly if the similar Cα–Hα correlations are used. The ratios in the transgenic (and in the wild-type control in parentheses) are 53% (88%) aliphatic-sidechain β–O–4-units **A**, 13% (3%) phenylcoumarans **B**, 5% (7%) resinols **C**, 6% (0%) dibenzodioxocins **D**, 5% (2%) coniferyl alcohol endgroups **X**, and 18% (0%) of the new benzodioxane units **H**. The 5-hydroxyconiferyl alcohol-derived benzodioxane **H** units are therefore the second most abundant interunit type in this sample. Since the lignins analyzed by NMR represent 65% of the total lignin in this transgenic, it is logical that the benzodioxane structures would remain a significant component even if the lignins were drastically partitioned by the isolation process. The total β-ether frequency (normal β-ether **A** plus dibenzodioxocins **D** plus benzodioxanes **H**) in the transgenic is around 77%, lower than in the control because of the higher guaiacyl content. However, there are a few units not covered by these percentages since they have no resonances in the aliphatic sidechain region of the NMR spectra (cinnamaldehyde endgroups, β–1-structures). Although the data are limited at present, it appears that 5-hydroxyconiferyl alcohol may quantitatively make up for the sinapyl alcohol deficiency.

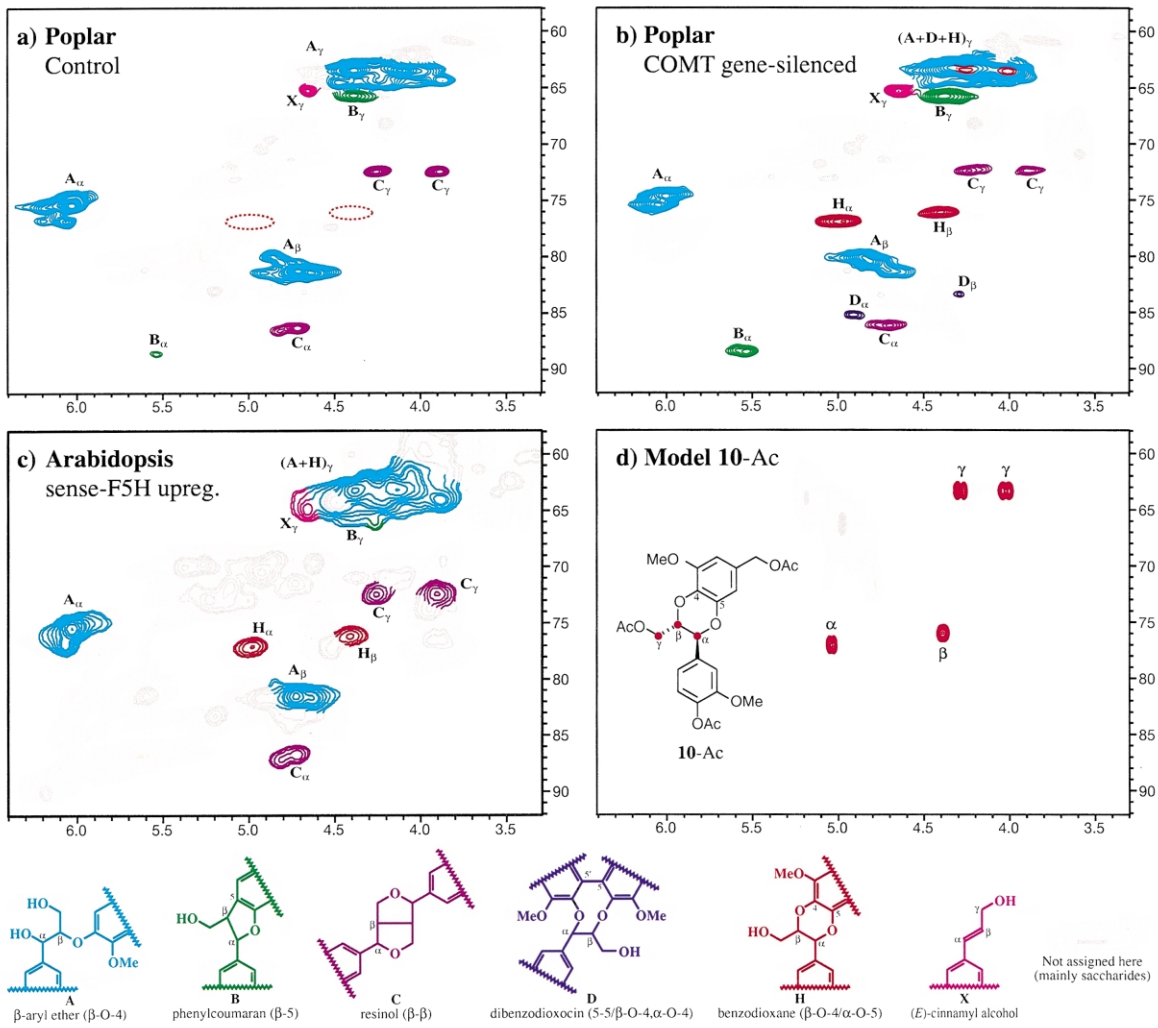

Fig. 4. Partial spectra from gradient HMQC NMR experiments highlighting new peaks for benzodioxane units **H**. Lignins were from (a) a control poplar, (b) a COMT-downregulated transgenic, (c) an F5H-upregulated Arabidopsis, and (d) similar correlations from a benzodioxane model **10**–Ac. The major unit coding is the same as that used in Ralph et al., 1999c and other references; it is suggested that **H** be reserved for 5-hydroxyguaiacyl benzodioxane units in lignin NMR spectra.

The incorporation of 5-hydroxyconiferyl alcohol into lignins has been documented several times (Hwang and Sakakibara, 1981; Lapierre et al., 1988; Jacquet, 1997; Suzuki et al., 1997). Benzodioxanes have been proposed to be in lignins previously (Hwang and Sakakibara, 1981; Jacquet, 1997; Jouanin et al., 2000), and analogous structures occur in lignans (Ishikawa et al., 1995; Su et al., 1997), but until now the occurrence of benzodioxanes in lignins has not been observed directly. The likely mechanism for formation of the novel benzodioxane units is shown in Fig. 5, as described in the caption.

There is another sample in which benzodioxanes are evident, an interesting variant in the COMT-deficiency class. Arabidopsis transgenics with upregulated F5H have previously been shown to have only a minor guaiacyl component (Meyer et al., 1998; Marita et al., 1999). Contours previously unidentified in the 2D NMR spectra of their lignins (Marita et al., 1999) now obviously result from benzodioxane structures, Fig. 4c. The observations here imply that, whereas syringyl production was enormously up-regulated in these transgenics, the methylation could apparently not keep pace with the accelerated production of 5-hydroxy units (e.g. 5-hydroxyconiferyl aldehyde and 5-hydroxyconiferyl alcohol). The result is a significant incorporation of 5-hydroxyconiferyl alcohol into the monolignol pool for the most heavily F5H-upregulated transgenics, ~10% as measured from contour volumes in the HMQC spectrum in Fig. 4c.

As further evidence accumulates from degradative and NMR methods that coniferyl and sinapyl alcohols couple with the new terminus created by incorporation of 5-hydroxyconiferyl alcohol monomers into the growing polymer (e.g. Jouanin et al., 2000), it becomes clear that 5-hydroxyconiferyl alcohol can be used as a

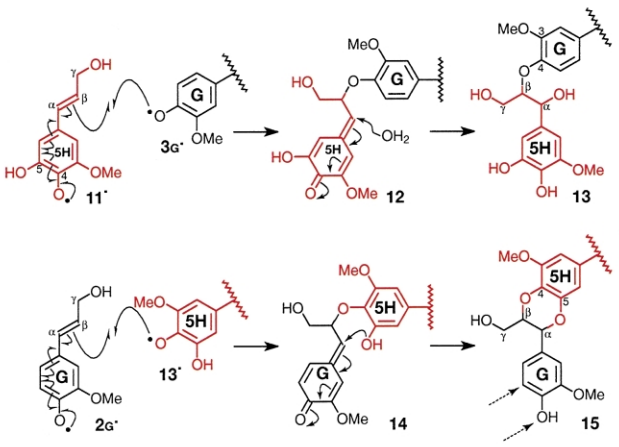

Fig. 5. Production of benzodioxanes **15** in lignins via incorporation of 5-hydroxyconiferyl alcohol **11** into a guaiacyl lignin. Only the pathways producing β-ether units are shown, but β–5-(phenylcoumaran) units are also possible. Cross-coupling with syringyl units is also possible but must be less pronounced in lignins which have a low syringyl content due to strong COMT downregulation. Cross-coupling of 5-hydroxyconiferyl alcohol **11**, via its radical **11·**, with a guaiacyl lignin unit **3**G, via its radical **3**G**·**, produces a quinone methide intermediate **12** which re-aromatizes by water addition to give the β-ether structure **13** (possessing a 5-hydroxyguaiacyl end-unit). This unit is capable of further incorporation into the lignin polymer via radical coupling reactions of radical **13·**. Reaction with the monolignol coniferyl alcohol **2**G, via its radical **2**G**·**, produces a quinone methide intermediate **14**. This time, however, quinone methide **14** can be internally trapped by the 5-OH phenol, forming a new 5–O–α-bond, and creating the benzodioxane ring system in **15**. The presence of structures **15** in COMT-deficient transgenic plants is diagnostically revealed by NMR, units **H** in Fig. 4.

lignin monomer by plants to offset the deficiency in sinapyl alcohol monomers. The recent statement that "There is, however, no known precedent for the free interchange of monomeric units in any biopolymer assembly, then or now, and no biochemical evidence..." (Lewis, 1999) needs to be revisited. In fact, plants and other organisms have long used loosely ordered chemistry to enhance their viability and resistance, as eloquently stated in a letter to Science (Denton, 1998).

5. Conclusions

Recent studies have shown that manipulating specific lignin-biosynthetic-pathway genes produces profound alterations in plant lignins. Although the lignins in mutant and transgenic plants may appear to be strikingly different from normal lignins, they often represent merely broad compositional shifts; most of the novel units that have been found to date appear to be (often previously unidentified) minor units in lignins from 'normal' plants. A salient observation is that the process of lignification appears to be flexible enough to readily incorporate phenolic phenylpropanoids other than the traditional monolignols. The incorporation of hydroxycinnamyl aldehyde monomers as well as 5-hydroxyconiferyl alcohol also implies that the plant is sending these products of incomplete monolignol biosynthesis out to the cell wall for incorporation. The resultant modified lignins apparently have properties sufficient to accommodate the water transport and mechanical strengthening roles of lignin and to allow the plant to be viable. Whether such plants will be able to confront the rigors of a natural environment replete with a variety of pathogens remains to be determined. However, the plants' flexible approach toward lignification, i.e. polymerizing monolignol precursors and derivatives along with the traditional monolignols, is a testament to their flexible strategy; in a single generation, these plants have circumvented genetic obstacles to remain viable. The recognition that novel units can incorporate into lignin provides significantly expanded opportunities for engineering the composition and consequent properties of lignin for improved utilization of valuable plant resources.

6. Experimental

6.1. Plant materials and lignin isolation

Isolation of the lignins for which NMR spectra are reported here were all previously described. All isolations follow the basic scheme: solvent extraction to remove major extractives and protein, ball milling, crude cellulases digestion to remove the bulk of the polysaccharides, dioxane–water (96:4) extraction to remove soluble lignin fractions, and some clean up of this lignin fraction by EDTA washing to remove some saccharide impurities and metal contaminants which can otherwise reduce the quality of the NMR data. All of the isolated lignins described here were acetylated and dissolved in acetone-d_6 (~60–100 mg in 0.4 ml) for NMR. In some cases, the proportion of the lignin that could be extracted and solubilized for NMR studies was as low as 17%; in poplar samples it is more typically 65%. Criticisms that these lignins are therefore not representative, or are contaminated by non-lignin extractives are slowly being dispelled as the results of more diverse studies, primarily using degradative methods, emerge. It is nevertheless important that this potential sample limitation be known, so the yields are reproduced here. Our comments on what constitutes a lignin for this study are delineated in the second paragraph of Section 1.

The sense-F5H-upregulated (C4H-promoted) Arabidopsis lignin (Fig. 4c) was obtained in 27.5% yield (Marita et al., 1999). The CAD-deficient (antisense downregulated) tobacco lignin (Fig. 2) was isolated in 24% yield (Ralph et al., 1998). Lignin from the CAD-deficient loblolly pine mutant (Fig. 3) was isolated in 17% yield (Ralph et al., 1997). Poplar lignins in Fig. 4a, b were isolated in 65% yields (Ralph et al., 2000).

6.2. NMR experiments

NMR spectra were acquired on a Bruker DRX-360 instrument fitted with a 5-mm ^{1}H/broadband gradient probe with inverse geometry (proton coils closest to the sample). The central acetone solvent peak was used as internal reference (δ_C 29.80, δ_H 2.04). We used the standard Bruker implementation (inv4gstp) of the gradient-selected inverse (^{1}H-detected) HMQC experiment for the spectra in Fig. 4, the standard (inv4gslplrnd) gradient-selected inverse-detected HMBC experiment with a 100 ms long-range coupling delay for the spectrum in Fig. 2, and a (non-gradient) HMQC-TOCSY (invbmltp) with a 100 ms mixing time for the spectrum in Fig. 3a. These experiments and their applications to lignins are detailed in a recent book chapter on "Solution-state NMR of Lignins" (Ralph et al., 1999c).

Abstract

Accumulation of "lignin-like" material (L-LM) by plant tissues in response to injury or disease has been observed in a wide variety of plant taxa. The most intensively studied L-LM is that produced by members of the Cucurbitaceae; this material is thought to be an unusual lignin rich in *p*-coumaryl alcohol derived subunits. Employing acidolysis we found the primary degradation product of L-LM from squash fruit was *p*-coumaryl aldehyde. These findings conflict with the current concept of L-LM, but would be consistent with L-LM being a polymer derived directly from *p*-coumaryl aldehyde or a gum containing this compound. Results of hot water extraction support the latter possibility. Further, we report on a simple TLC method useful for rapid qualitative characterization of acidolysis degradation products. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Cucurbita maxima*; Cucurbitaceae; Squash; Composition of induced lignin; *p*-Coumaryl alcohol; *p*-Coumaryl aldehyde

1. Introduction

The lignin-like material (L-LM) produced by many plants in response to injury or disease has been studied by numerous investigators and is frequently associated with resistance to fungal or bacterial pathogens (Ride, 1975; Vance et al., 1980; Nicholson and Hammerschmidt, 1992). Lignins are a complex class of compounds derived via the free radical polymerization of the three primary lignols (Fig. 1), *p*-coumaryl **1b**, coniferyl **2b** and sinapyl **3b** alcohols (Harkin, 1967; Freudenberg and Neish, 1968; Whetten et al., 1998). Lignins are classified based on the ratio of the different lignols present. Because of their high molecular weight and insolubility, precise knowledge of the composition of lignins cannot be obtained directly, but must be gained indirectly by NMR of soluble lignin fractions or by identification of lignin degradation products (Lewis and Yamamoto, 1990). Degradation methods used include pyrolysis-GC–MS, hydrolysis, and oxidation (Tanahashi and Higuchi, 1988; Ralph and Hatfield, 1991). In addition to providing subunit composition, a portion of the products from the first two methods retain their C-3 side chains, providing information about the interunit linkages in the parent lignin (Lundquist, 1992; Ralph and Hatfield, 1991). However, the sheer number of possible products complicates routine analysis of lignins by these methods. In contrast, oxidative methods degrade lignins to the benzaldehyde or benzoic acid analogues of their parent lignols. Because there are only three primary products, analyses of oxidative degradation products are relatively simple, (Tanahashi and Higuchi, 1988), but information on the nature of the sidechains is lost.

Deposition of L-LM has been reported in a wide variety of plant taxa (Vance et al., 1980; Rittinger et al., 1987). However, only in a relatively small number of plants has the composition of the L-LM been examined. The L-LM from members of the Cucurbitaceae is perhaps the best characterized, having been studied by four independent research groups using alkaline cupric oxide or nitrobenzene oxidization methods. L-LM induced by fungal infection in five species of cucurbits was

PII: S0031-9422(01)00096-6

characterized by Hammerschmidt et al. (1985) and in muskmelon by Grand and Rossignol (1982). L-LM in cucumber, induced by wounding of fruit (Walter et al., 1990) or by an elicitation of hypocotyls with a pectic elicitor (Robertsen and Svalheim, 1990) has also been characterized. In all these studies, degradation products of tissues containing L-LM contained an abundance of *p*-hydroxybenzaldehyde, with increases of up to 61-fold over control tissues (Grand and Rossignol, 1982; Hammerschmidt et al., 1985; Robertsen and Svalheim, 1990; Walter et al., 1990). Similar results have been reported in other plant taxa. Compared to controls, degradation products of L-LM-containing tissues of radish roots, wheat leaves, soybean cotyledons, and parsley suspension cells had 2.5, 6.7, 2.9, or 8.6 fold more *p*-hydroxybenzaldehyde (Asada and Matsumoto, 1972; Ride, 1975; Graham and Graham, 1991; Kauss et al., 1993). Thus, our current concept about L-LM is of a lignin that is unusually rich in *p*-coumaryl alcohol derived subunits. Consistent with their role in defense, lignins rich in this lignol may yield highly condensed lignins that are resistant to degradation (Hammerschmidt et al., 1985). Some lignins of unique function, such as compression wood lignin, also have unique compositions (Nimz et al., 1981; Timell, 1982, 1986).

Although there is a consensus that the function of L-LM is protective, investigators earlier in this century had a much different concept of its chemical nature. While these earlier investigators did not have a precise chemical model, the intense reaction with phloroglucinol-HCl (PG-HCl) was attributed to the presence of aromatic aldehydes held within a water insoluble gum, termed wound gum (Bloch, 1937; Rawlins and Takahashi, 1952). Both wound gum and lignin become strikingly colored in PG-HCl; however, on the basis of other histological, anatomical and developmental criteria, wound gum was thought to be biochemically distinct from lignin (Hewitt, 1938; Schneider, 1980).

We recently reported that squash tissue elicited with pectinase synthesizes and accumulates the antifungal compound *p*-coumaryl aldehyde **1a** (Stange et al., 1999). The appearance of this compound is coincidental with the deposition of L-LM (unpublished data). This compound is also the immediate biosynthetic precursor of *p*-coumaryl alcohol that is presumed to be the primary component of L-LM in cucurbits (Lewis and Yamamoto, 1990). Recent studies of novel lignins, formed by plants with reduced cinnamyl alcohol dehydrogenase activity, have dramatically expanded our concept of lignins (Whetten et al., 1998). In these plants, conversion of coniferyl aldehyde **2b** to coniferyl alcohol **2a** is partly or completely blocked and their lignins are synthesized, in part, from coniferyl aldehyde (Higuchi et al., 1994; Baucher et al., 1996; Ralph et al., 1997). Thus, aldehyde analogs of lignols can be directly polymerized into lignins or lignin-like materials. The oxidation methods used by earlier investigators to characterize the L-LM from cucurbits would not have differentiated between lignins derived from *p*-coumaryl aldehyde or alcohol (Grand and Rossignol, 1982; Hammerschmidt et al., 1985; Robertsen and Svalheim, 1990; Walter et al., 1990). Distinguishing the identity of L-LM's parent compounds requires use of methods which do not destroy the C3 side chain.

The close association between *p*-coumaryl aldehyde and L-LM accumulation in squash, together with the general doubts of earlier researchers that L-LM is even lignin at all, poses several fundamental questions. Is the L-LM an unusual lignin derived from *p*-coumaryl alcohol or aldehyde? Or, in fact, is the material a lignin at all? We attempt to begin to address these questions by using acidolysis to analyze tissues containing L-LM. In addition, we report on a TLC method for separation of the acidolysis degradation products which greatly simplifies the analyses of the hydrolysates of L-LM.

2. Results and discussion

Identification of components unique to L-LM depends on comparing degradation products of tissues having low lignin content with or without L-LM being present. Further, comparison of degradation products from L-LM containing tissue with highly lignified tissues would assist in the characterization of L-LM acidolysis products and provide confirmation of the methodology. Our experimental scheme utilized extractive-free cell wall preparations from squash fruit tissue elicited with pectinase and cured 24 h to promote accumulation of L-LM (Stange and McDonald, 1999), from unelicited freshly sliced fruit tissue, and from tissue of the highly lignified stem of the fruit.

Histochemical tests were performed to confirm the composition of these cell wall preparations. When the Mäule test was performed, the abundant, heavily sclerified cell walls in the stem tissue gave an intense reaction,

		R	R′
1a/b	*p*-coumaryl aldehyde/alcohol	H	H
2a/b	coniferyl aldehyde/alcohol	OMe	H
3a/b	sinapyl aldehyde/alcohol	OMe	OMe

Fig. 1. Primary lignols and their corresponding aldehydes.

turning a dark purple-red (Fig. 2, Mäule). However, microscopic examination revealed that remnants of xylem elements in the stem tissue gave no reaction with the Mäule test. Similarly, positively testing xylem components were observed in neither fresh nor elicited-cured fruit tissue preparations. The Mäule (-) reaction of the xylem is consistent with the observations of Walter et al. (1990) and with the results of Robertsen and Svalheim (1990), who reported finding no syringaldehyde in the CuO oxidation products of cucumber hypocotyls. Syringaldehyde is indicative of sinapyl alcohol **3b** derived constituents in lignin, which in turn, form colored products in the Mäule test (Iiyama and Plant, 1988). However, the xylem content of the stem tissue was low, relative to the abundant sclerified cells, which composed most of the sample.

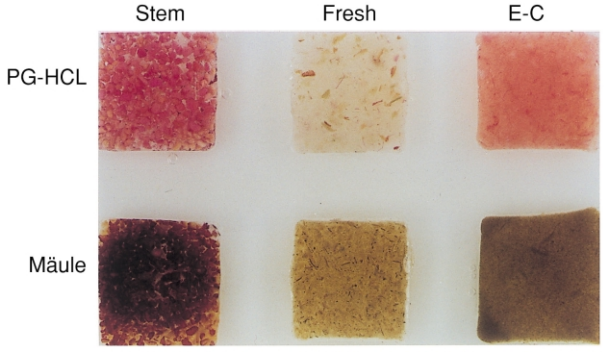

Fig. 2. Histochemical reactions of cell wall preparations. Each well contains similar volumes of extractive-free cell wall preparations from stem (Stem), fresh fruit (Fresh) and elicited-cured (E–C) fruit tissues. Cell wall preparations were subjected to the phloroglucinol-HCl test (PG-HCl) for aldehydes (upper) and the Mäule test for syringyl groups (lower). Wells are 1 cm^2.

Both sclerified cells and xylem remnants in the stem tissue sample reacted positively with PG-HCl, turning a purple-red color (Fig. 2, PG-HCl). The sclerifed tissue in the stem sample reacted positively with both reagents; this set of reactions is typical of angiosperm lignins (Towers and Gibbs, 1953; Lewis and Yamamoto, 1990). In fresh fruit cell wall preparations, only xylem elements reacted positively with PG-HCl. In contrast, a large portion of the elicited-cured fruit tissue reacted with the PG-HCl reagent, L-LM turned red while the xylem elements turned a purple-red color. The abundance of xylem in both fresh and elicited-cured fruit samples was quite low (Fig. 2, PG-HCl). The PG-HCl (+) and Mäule (-) histochemical reactions of L-LM are consistent with those reported by previous workers in cucurbits (Walter et al., 1990) and other crops (Schneider, 1980). Thus, the fruit tissue preparations provide samples with a low abundance of vascular lignin, with L-LM being either abundant in elicited cured tissue, or absent in fresh tissue. The stem sample has no L-LM, but contains an abundance of typical lignin.

Acid hydrolysis products of these three types of samples were obtained by the standard method, refluxing in dioxane-HCl (Tanahshi and Higuchi, 1988; Lundquist, 1992) and by mild acid hydrolysis [2 N HCl at 90°C]. Degradation products from both methods were separated by TLC and visualized with PG-HCl or Folin–Ciocalteu's phenol reagent. PG-HCl gives red to purple products with aromatic aldehydes and yellow to orange spots with furfurals (Feigl and Anger, 1966). Several compounds giving red to purple hued spots were observed in the stem tissue sample (Fig. 3). Two of these spots corresponded in mobility and color to the magenta spot of coniferyl aldehyde **2a** and the purple-brown spot of sinapyl aldehyde **3a**. Large quantities of staining material were

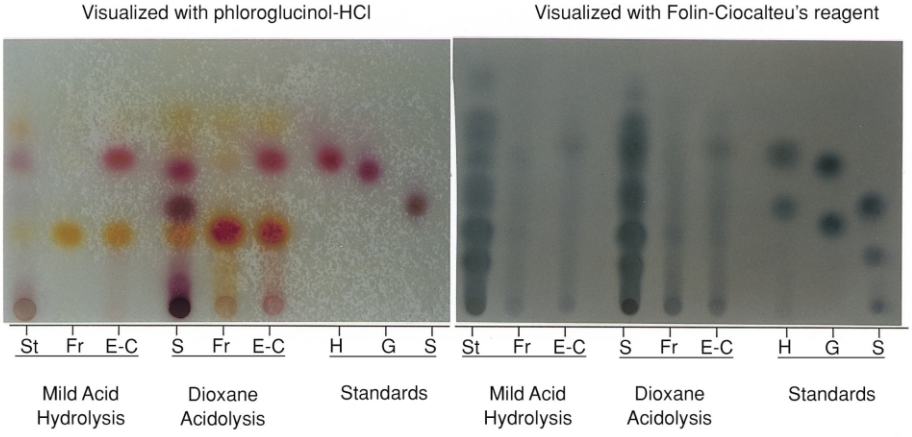

Fig. 3. Comparison of mild acid hydrolysis and dioxane acidolysis products from stem (St), fresh fruit (Fr) and elicited-cured fruit (E-C) extractive-free cell wall preparations. Standards are mixtures of *p*-coumaryl (H) **1**, coniferyl (G) **2** or sinapyl (S) **3** alcohol and aldehyde; 0.5 μg of each compound spotted. Plates were developed in hexane–EtOAc (1:1); solvent fronts travelled 90 mm, 60 mm of travel shown. TLC plate on left visualized with phloroglucinol-HCl to reveal aromatic aldehydes (red to purple colors) and furfurals (orange to yellow colors). Loading of hydrolysates equivalent to 1.5 mg cell wall preparation. TLC plate on right visualized with Folin–Ciocalteu's reagent to reveal phenolics. Loadings of hydrolysates equivalent to 0.5 mg cell wall preparation.

present at the origin, indicating that component(s) of the sample were of higher molecular weight or highly polar. No red hued spots were evident from the fresh fruit samples; this would be expected given the low abundance of lignin in the sample. The elicited-cured tissue yielded a single red spot, unique to this sample. This compound had similar color and mobility to *p*-coumaryl aldehyde **1a**. When plates were visualized for phenolics with Folin-Ciocalteu's reagent, similar patterns were observed. Products of the stem tissue sample were abundant and numerous (Fig. 3). By contrast, in fresh and elicited-cured fruit tissue samples products were far less abundant, indicating that very few phenolic components were present. The exception to this was *p*-coumaryl aldehyde **1a** in the elicited-cure sample, which produced a distinct spot with Folin–Ciocalteu's reagent. Both acid hydrolysis methods yielded similar products from fresh and elicited-cured fruit samples, but for the stem sample mild acid hydrolysis yielded fewer products and gave lower yields than dioxane acidolysis.

Hot water and mild acid hydrolysis of elicited tissue yielded 161 ± 25 ($n = 4$) and 303 ± 19 ($n = 4$) μg *p*-coumaryl aldehyde **1a** per gram cell wall material, respectively. When residues from hot water hydrolysis were subjected to mild acid hydrolysis, additional *p*-coumaryl aldehyde (130 ± 25 μg/g cell wall) was recovered. Because the hot water suspension was slightly acidic (initial pH, 5.7; final pH, 5.2), one possibility is that the *p*-coumaryl aldehyde recovered by this treatment was held by relatively easily hydrolyzed covalent bonds, such as ester linkages. However, the more probable interpretation is that the compound was contained within a gum which was dissolved by the hot water. We are attempting to address this technically difficult question presently.

A single furfural predominated in both fruit samples (orange spots, Fig. 3, PG-HCl), but furfurals were rare or lacking in the stem tissue sample. The abundance of furfurals in fruit samples was much greater with the dioxane acidolysis method than with mild acid hydrolysis.

GC–MS analysis of the stem tissue sample acidolysis products identified six guaiacyl and two syringyl derivatives. The presence of syringyl units is consistent with the positive Mäule reaction of the tissue (Iiyama and Plant, 1988). In the fresh fruit sample, no lignin related degradation products were found by GC–MS, again indicating the low abundance of lignified xylem in the fresh fruit samples. The identity of the compound giving a red colored spot in TLCs of the elicited-cured samples was confirmed by GC–MS and by NMR following separation by TLC. As suspected, the compound was *p*-coumaryl aldehyde **1a**. Further, this was the only lignin related product detectable by GC–MS.

The predominant furfurfal in both the fruit samples was 5-(hydroxymethyl)-2-furaldehyde. In addition, the elicited-cured sample contained 2-hydroxymethyl furan. Presence of this compound in the mixture interfered with the identification of *p*-coumaryl aldehyde **1a** by GC–MS. We are uncertain of the significance of this compound, but it may indicate differences in the carbohydrate composition between fresh and elicited-cured samples.

Our results confirm that the stem tissue contained a typical angiosperm lignin, composed primarily of guaiacyl and syringyl units. The fresh fruit tissue had a very low abundance of lignin. These results could be anticipated based on histochemical tests and microscopic observations. The colors developed by hydrolysates when TLC plates were visualized with PG-HCl corresponded very well to the colors of cell wall residues treated with this reagent. The elicited-cured tissue developed the same pure red color developed by *p*-coumaryl aldehyde **1a**. The stem tissue's more purple color suggests the magenta to purple colors developed by coniferyl **2a** and sinapyl **3a** aldehydes.

Finding *p*-coumaryl aldehyde as the sole acidolysis product of L-LM was unexpected. This result is strong evidence that L-LM is not derived from *p*-coumaryl alcohol **1b**. The exact nature of L-LM is, however, much less clear. If it were a lignin-like material derived from *p*-coumaryl aldehyde, we would have expected more related products, similar to the numerous products yielded from stem tissue. Because a *p*-coumaryl aldehyde based lignin might be highly condensed, these products could be quite rare, and more exhaustive are studies needed to determine if they exist. Attempts to dissolve the L-LM in acetyl bromide and subsequent application of the 'derivatization followed by reductive cleavage' method (Lu and Ralph, 1997a,b,1998) were unsuccessful, even with extended treatment periods. Only minor amounts of the fraction, mainly saccharide components, dissolved. We (Lu and Ralph, 1999, unpublished) have previously encountered difficulty in dissolving aldehyde-rich fractions in acetyl bromide. While our results do fit well with the concept of the material being a water-insoluble gum imbedded with *p*-coumaryl aldehyde, they do not rule out the possibility that a portion of this compound is covalently bound. Whatever it is, this material certainly differs from a lignin derived from *p*-coumaryl alcohol **1b**. More fundamental research, utilizing a wider variety of approaches based on the above models, is needed to determine the actual composition and structure of the so-called "lignin-like" material from elicited cured squash.

3. Experimental

3.1. Plant material, elicitation and isolation of lignin-like material

Green acorn squash, *Cucurbita maxima*, were purchased from retail outlets. Only recently harvested fruits

with green living stems were selected. Stems were air dried and ground through a #20 mesh screen using a Wylie® mill. Fresh fruit tissue was diced finely. Elicited-cured tissue was prepared as described earlier from squash sliced 5 mm thick (Stange et al., 1999). Extractive-free cell wall preparations were made by first homogenizing tissues 1 min in 10 mM phosphate buffer, pH 6 (25 ml per g dry wt). Cell wall material was pelleted by centrifugation (6000×*g*) and washed with two changes of buffer. The water-insoluble residue was further extracted with two changes over 24+ h of the following sequence of solvents: ethanol–water (4:1) (25 ml per g dry wt); chloroform–methanol–water (5:10:4); methanol; acetone (12 ml per g dry wt). Extractive-free cell wall preparations were stored at −20°C.

3.2. Chemicals

Coniferyl and sinapyl alcohols and aldehydes were purchased from commercial sources. *p*-Coumaryl alcohol **1b** was synthesized according to Quideau and Ralph (1992) and *p*-coumaryl aldehyde was prepared from **1b** by oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

3.3. Histochemical tests

PG-HCl and Mäule tests were performed on cell wall preparations using standard methods (Rawlins and Takahashi, 1952). Microscopic examination of samples was done under bright and dark field illumination using a Nikon Optiphot microscope at 40 and 100× magnification.

3.4. Hydrolysis of extractive-free cell wall samples

A modification of the procedure of Tanahashi and Higuchi (1988) was used for acidolysis (Lundquist, 1992). Tissue, 400 mg, was refluxed under N_2 in 20 ml dioxane–2 M HCl (9:1) for 3 h. The suspension was filtered, and the residue washed with dioxane. The filtrate was adjusted to pH 3 with 0.4 M $NaHCO_3$ and stirred for 30 min. This solution was extracted with methylene chloride, and the organic phase was dried over Na_2SO_4, filtered, and evaporated under vacuum. Acidolysis products were dissolved in EtOAc–EtOH (3:1) and stored at −20°C.

For mild acid hydrolysis, 400 mg extractive-free cell wall residue was placed in a 100-ml volumetric flask with 40 ml 2 N HCl. The flask was purged with N_2, capped with a marble, and placed in a 90°C water bath for 3 h. The suspension was cooled, 40 ml 2-propanol added, and then filtered. The residue was washed with 20 ml 2-propanol. Combined filtrates were reduced to aqueous under vacuum, extracted 2× with methylene chloride, and the organic phase was dried over Na_2SO_4. This solution was filtered, dried, and the products dissolved and stored as the acidolysis samples above. Hot water hydrolysis products of elicited-cured tissue were also obtained using this procedure by substituting distilled water for 2 M HCl.

3.5. Analyses of hydrolysis products by TLC

Samples and standards were spotted onto polyester backed silica gel TLC plates (250 μm) and developed in hexane–EtOAc (1:1). Phenolics were visualized using Folin Ciocalteu's reagent as described by Fry (1988). Aromatic aldehydes and furfurals were visualized by first spraying with 1% phloroglucinol in ethanol–water (7:3), air drying, and spraying with conc HCl (Feigl and Anger, 1966). The quantity of *p*-coumaryl aldehyde present in mild acid and hot water hydrolysates was determined as follows. Samples and standards of *p*-coumaryl aldehyde were separated by TLC, spots corresponding to the compound were located under long-wave UV, scraped off, and dissolved in 1 ml 95% ethanol. Abundance of *p*-coumaryl aldehyde was quantified by A_{325}.

3.6. Analyses of hydrolysates by GC–MS

GC was run on a Hewlett-Packard (Atlanta, GA) 5980 gas chromatograph; column 0.2 μm film, 0.2 mm × 30 m SPB-5 (Supelco); He carrier gas, 1 ml/min; 30:1 split ratio; injector 220°C, initial column temperature 150°C, ramped at 10°C/min to 310°C, hold for 10 min, total running time 34 min. Mass spectra (EI, 70 eV) were collected on a Hewlett-Packard 5970 MS Detector connected directly to a similar column in the same GC.

Three samples were chosen for GC–MS analysis: mild acid hydrolysate of stem tissue, and dioxane acidolysis hydrolysates of fresh and elicited-cured fruit tissues. For trimethylsilylation hydrolysates (0.5 mg) were silylated using BSTFA {N,*O*-bis(trimethylsilyltrifluoroacetamide)} (80 μl) plus pyridine (20 μl) at 50°C for 15 min. For acetylation, hydrolysates (1 mg) were acetylated with 1:1 acetic anhydride:pyridine (0.5 ml) at RT for 4 h. Solvents were removed by co-evaporation with ethanol on a rotary evaporator. The acetylated products were dissolved in methylene chloride (0.2 ml) for GC.

3.6.1. GC–MS

Acetylated or trimethylsilylated samples (2 μl) were injected into the GC. Trimethylsilylated *p*-coumaraldehyde eluted at 6.01 min; acetylated *p*-coumaryl aldehyde at 5.76 min. Mass spectra were identical with those derived from authentic *p*-coumaryl aldehyde (Aldrich): trimethylsilyl *p*-coumaryl aldehyde 220 (M+, 66), 205 (47), 73 (100); 4-acetoxycinnamaldehyde 190 (M+, 14), 148 (100).

3.7. Confirmation of p-coumaryl aldehyde by NMR

The dioxane acidolysis hydrolysate of elicited fruit tissue (37 mg) was applied to a preparative TLC plate (2 mm thickness, Macherey-Nagel Products, Germany), and eluted with 10:2 CH_2Cl_2:EtOAc. The band at R_f 0.6 was isolated (2.5 mg) and shown by NMR (^{1}H, COSY) to be identical to authentic *p*-coumaryl aldehyde **1a** — NMR data were the same as for compound number 152 in the "NMR Database of Lignin and Cell Wall Model Compounds" (Ralph et al., 1998). The acetylated TLC fraction had spectra identical to acetylated *p*-coumaryl aldehyde, compound number 223 in the same database.

Acknowledgements

We thank anonymous reviewers, D. Akin, N.G. Lewis, W. Walter and C. West for their helpful suggestions on improving this manuscript and Hoon Kim for preparation of the *p*-coumaryl aldehyde. Henry Schneider's efforts in educating the first author on wound gum are greatly appreciated.

A heartwood pigment in *Dalbergia* cell cultures

Mihály Czakó*, László Márton

Department of Biological Sciences, University of South Carolina, 700 Sumter Street, Columbia, SC 29208, USA

Received 18 October 1999; received in revised form 11 January 2000

Abstract

In an extensive survey of the genera *Baphia, Caesalpinia, Dalbergia, Haematoxylon,* and *Pterocarpus*, we have identified a number of species whose cell cultures accumulated pigments similar to those in heartwood. Thirteen rosewood (*Dalbergia*) species produced a purple quinonemethide pigment in the callus that was apparently identical between the species. The pigment was first purified from *D. retusa* cell culture and its structure was elucidated by mass, infrared, and detailed ^{1}H and ^{13}C NMR and NOE spectroscopic studies including 2D experiments (COSY, NOESY, HMQC, and HMBC). Retusapurpurin A (**1a**) is a C_{30} isoflavan of novel skeleton whose formation can be rationalized to occur via regioselective oxidative coupling of an isoflavan to 4,4′-dihydroxy-2′-methoxychalcone. Retusapurpurin A was also isolated from *D. parviflora* heartwood and cell culture indicating that stress metabolism pathways that are shared with heartwood-type secondary metabolism subpathways are initiated in *Dalbergia* cell cultures. Therefore, *Dalbergia* cell cultures afford a good model system for studying heartwood-type metabolic differentiation. © 2001 Published by Elsevier Science Ltd. All rights reserved.

Keywords: *Baphia*; *Caesalpinia*; *Dalbergia*; *Haematoxylon*; *Pterocarpus*; Leguminosae; Cell culture; Heartwood pigment; Isoflavan; Quinonemethide

1. Introduction

Despite the importance of wood as the depository of a large fraction of the fixed carbon stored in the global ecosystem and as a raw material for major global industries, we know little of the genes involved in the formation of wood. While there has been great progress in the understanding of the biology of xylem/sapwood formation (Fukuda, 1996; Whetten et al., 1998; Gang et al., 1999; Lewis, 1999), information on gene expression during heartwood formation is not available.

Wood (xylem), a tissue unique to higher plants, is a highly ordered arrangement of living, dying, and dead cells. Meristem cells of the vascular cambium differentiate into water-conducting and supportive fiber (and vessels for hardwoods) and intercalating parenchyma cells for food storage. Terminal differentiation of the fibers and vessels quickly ends with programmed cell death while there remain live parenchyma cells, sometimes deep in the no-longer-conducting sapwood (Allen and Hiatt, 1994); parenchyma cells can live for over a hundred years (Shigo, 1994) in certain trees.

Programmed cell death occurring during the terminal differentiation of ray and axial parenchyma is a developmental process probably under strict control since it occurs only within no-longer-conducting sapwood, spreading from the tree's center. Ray parenchyma's final function is the synthesis of secondary metabolites that impregnate the wood, and this wood is called heartwood (Higuchi, 1997). Ray parenchyma cells in the intermediate (or transition) wood, the sapwood adjacent to heartwood, undergo physiological differentiation and alter their metabolism. The similarity of the spectrum of substances found in heartwood to those in pathogen- or pest-challenged or stressed plants (Harborne, 1994) suggests that some heartwood- and active defense-related secondary metabolism (phytoalexin) pathways may be common.

Only a few of the enzymes of secondary metabolism have been characterized in wood. Phenylalanine ammonia-lyase (PAL) is active across the sapwood, while

chalcone synthase is active exclusively in the vicinity of the heartwood boundary (Magel et al., 1991, 1995; Magel and Huebner, 1997). PAL is involved both in the formation of lignin and flavonoid biosynthesis; an inhibitor of the enzyme fed to the sapwood prevented the formation of phenylpropanoid metabolites (Ohashi et al., 1991). The flavonoids in the heartwood thus are formed in situ; they are not transported to the heartwood via the phloem and the ray cells (Magel et al., 1991, 1995).

The characterization of novel genes involved in the biosynthesis of heartwood-specific secondary metabolites in intermediate wood should lead to a better understanding of mechanisms controlling this important differentiation pathway. Heartwood does not lend itself to biosynthetic studies or mRNA extraction because it does not contain living cells, and access to the transition zone or intermediate wood is limited. To overcome this difficulty, we sought a system of lower complexity where some aspect of heartwood-type metabolic differentiation is recreated in cell cultures. Cell cultures of gymnosperm trees (Campbell and Ellis, 1992; Eberhardt et al., 1993; Nose et al., 1995; Yamaguchi et al., 1997; Gang et al., 1999) and two angiosperm trees (Paré et al., 1994; Davin et al., 1997; Zhentian et al., 1999) have been utilized to study biochemical processes related to the formation of wood, but for heartwood formation the optimal indicator metabolite would be colored, easy to assay, not far off the charted biosynthetic pathways, yet specialized enough not to occur outside heartwood. These criteria narrowed the choices to relatively very few candidates including the quinonemethide pigments in angiosperm plants derived from precursors originating from the well studied isoflavonoid and flavonoid pathways in leguminous plants (Harborne, 1994; Dixon et al., 1998). In an extensive survey of leguminous woody plants, we have identified several species of *Dalbergia* that produce brilliantly colored pigments in cell cultures under controlled conditions. We describe herein the isolation and structural elucidation of a novel isoflavan-derived quinonemethide pigment, retusapurpurin A, from cell cultures and heartwood. The structure has been established by spectral analysis, mainly based on detailed ^{1}H and ^{13}C NMR and NOE studies including 2D experiments (COSY, NOESY, HMQC, and HMBC).

2. Results and discussion

As part of our ongoing research on heartwood development, cell cultures of a great number of leguminous plants were established in order to find species whose cell cultures undergo metabolic differentiation to produce heartwood secondary metabolites. This is the first report of in vitro culture of all the species listed under 'seeds and live plants' in the experimental procedures except for *C. pulcherrima* (Rahman et al., 1993), *P. indicus* (Lee and Rao, 1980), *D. latifolia,* and *D. sissoo* (Mandal et al., 1994).

Quinonemethide pigments were detected on the basis of their intensive color and electrophoretic mobility towards the cathode on paper after conversion into pyrylium ions by protonation in an acidic buffer. Species of *Caesalpinia* and *Haematoxylon* are well known for the intense colored brazilein and hematein heartwood pigments (Robinson, 1985) which, however, were not detectable in tissue cultures of 12 *Caesalpinia* and 2 *Haematoxylon* species despite the dark pigmentation in certain species. Similarly, tissue cultures of *Baphia nitida* and seven *Pterocarpus* species did not contain the santarubins and/or santalins characteristic for the heartwood (Arnone et al., 1975, 1977a,b, 1981). Heartwood extracts were used as references where available.

Since a quinonemethide pigment was also reported from a *Dalbergia* species (Hamburger et al., 1988), we tested callus cultures of numerous *Dalbergia* species for pigment production (Table 1). Several species of *Dalbergia* proved especially prone to pigment production in vitro. Pigmentation in most species was localized and most intense in the cells that were in contact with the medium and in adjacent cells, and the callus left a colored 'footprint' in the medium. The emergent portion of the callus usually was free of red, orange, brown, and purple pigments, with the exception of certain species where systemic coloration developed (Table 1).

Besides the apparently water insoluble immobile pigments in the 'footprint' and basal cell layers, diffusible pigments were also produced in certain species. Paper electrophoresis revealed a common major component in the pigment extracts of thirteen *Dalbergia* species (Table 1). It was a barely diffusible pigment located in the basal cell layers and the 'footprint'. It appeared orange-yellow in the acidic buffer, and turned purple with ammonia fumes. It showed strong fluorescence under UV. This component was easily extractable with ethanol. On silica thin layer chromatograms, it was the largest spot common to all the above thirteen species. It was conveniently detected by its yellow/orange fluorescence under UV, and by its pink fluorescence in ammonia fumes. The major component was accompanied by several similar fluorescent, as well as non-fluorescent, purple pigments. Since we first discovered pigment production in *D. retusa,* the major pigment was named retusapurpurin A. Pigmentation in cell cultures of other *Dalbergia* species was either not observed under the conditions tested, or the above purple pigment was not present and the color and solubility of the pigments were different (Table 1).

Rapid pigment accumulation can be induced by transferring the emergent portion of *D. retusa* callus on DM-2, and in *D. parviflora* callus upon transfer to DM-10 medium. Coloration started within 24 h and pigment accumulation continued thereafter. An orange to deep

[a] Normal callus color is a light to dark, chlorophyllous green.
[b] Composition of media is given in the text.
[c] Coloration on maintenance medium unless indicated otherwise. Explanation of color codes: *L*: Localized to the tissue in contact with the medium and some of it is secreted into the medium but not very diffusible ('footprint'); *S*: systemic, expressed in nearly all cells; D: diffusible in the medium; b: bright; d: dark; l: light; Bl: black; Br: Brown; Gy: grey; Or: orange; P: purplish; Pu: purple; R: reddish; Re: red.

blood red stain, occasionally intensifying to black, was deposited at the foot and in the core of the compact callus.

Retusapurpurin A and the accompanying pigments were not soluble in water but were readily extractable by polar organic solvents. Retusapurpurin A (**1a**) was recovered from a methanol eluate of preparative TLC separated band as an amorphous deep reddish purple powder. It exhibited interesting physicochemical properties. The color was pH sensitive. The UV/vis spectrum of a fresh ethanol solution (red) retusapurpurin A dried in vacuo was close to what could be measured under pH controlled conditions in ethanol (pH 5.0). A bathochromic shift on addition of $NaHCO_3$ (purple red) suggested the presence of free phenolic hydroxyl groups. Identical UV spectra were obtained with addition of $AlCl_3$ and HCl or with HCl alone, indicating that the hypsochromic shift (orange solution) was solely caused by the acidity of $AlCl_3$. Retusapurpurin A also showed a pronounced solvatochromism: it dissolved in dimethylsulfoxide (DMSO) with a deep blue color. Color in DMSO was moisture dependent; unsealed solutions gradually turned the same color as can be obtained by addition of traces of water. Retusapurpurin A also displayed phase transition induced chromism in DMSO solution: it turned red upon freezing. The solution in acidified DMSO was dark orange that turned red on freezing.

The characteristic fluorescence, color, and electrophoretic mobility of retusapurpurin A facilitated identification of the cell culture-produced pigment in heartwood extracts. We searched for retusapurpurin A in heartwood containing samples of 50 *Dalbergia* species from both the Old and the New World tropics. *D. parviflora* was identified as the only species whose heartwood appeared to contain retusapurpurin A accompanied by similar UV fluorescent purple pigments in smaller amounts. Retusapurpurin A was also found in a sample of *Dalbergia* wood which was reported to be *D. candenatensis* (Hamburger et al., 1988; courtesy of the authors) and from which the quinonemethide pigment candenatone (**3**) was isolated. Comparison of the pigment profile of authentic *D. parviflora* wood (supported by a herbarium

voucher) and that of '*D. candenatensis*' (Hamburger et al., 1988), as well as a wood of identical appearance from a commercial source, suggested that these samples represent the same species, while a specimen of authentic *D. candenatensis* shoot containing traumatic wood near a split (also supported by a herbarium voucher) was very different in color and pigment composition. *D. parviflora* wood is dark reddish brown to blood red while the wood of *D. candenatensis* is blackish violet. *D. candenatensis* was not one of the species that produced retusapurpurin A in wood or in cell cultures under the conditions tested so far, while *D. parviflora* callus does produce it (Table 1).

Retusapurpurin A was most conveniently purified in a quantity sufficient for structure elucidation from *D. retusa* callus because of the high concentration and relative purity. The structure of retusapurpurin A (**1a**, Fig. 1) was determined on the basis of MS and IR spectroscopy as well as detailed ^{1}H and ^{13}C NMR and NOE studies including 2D experiments (COSY, NOESY, HMQC, and

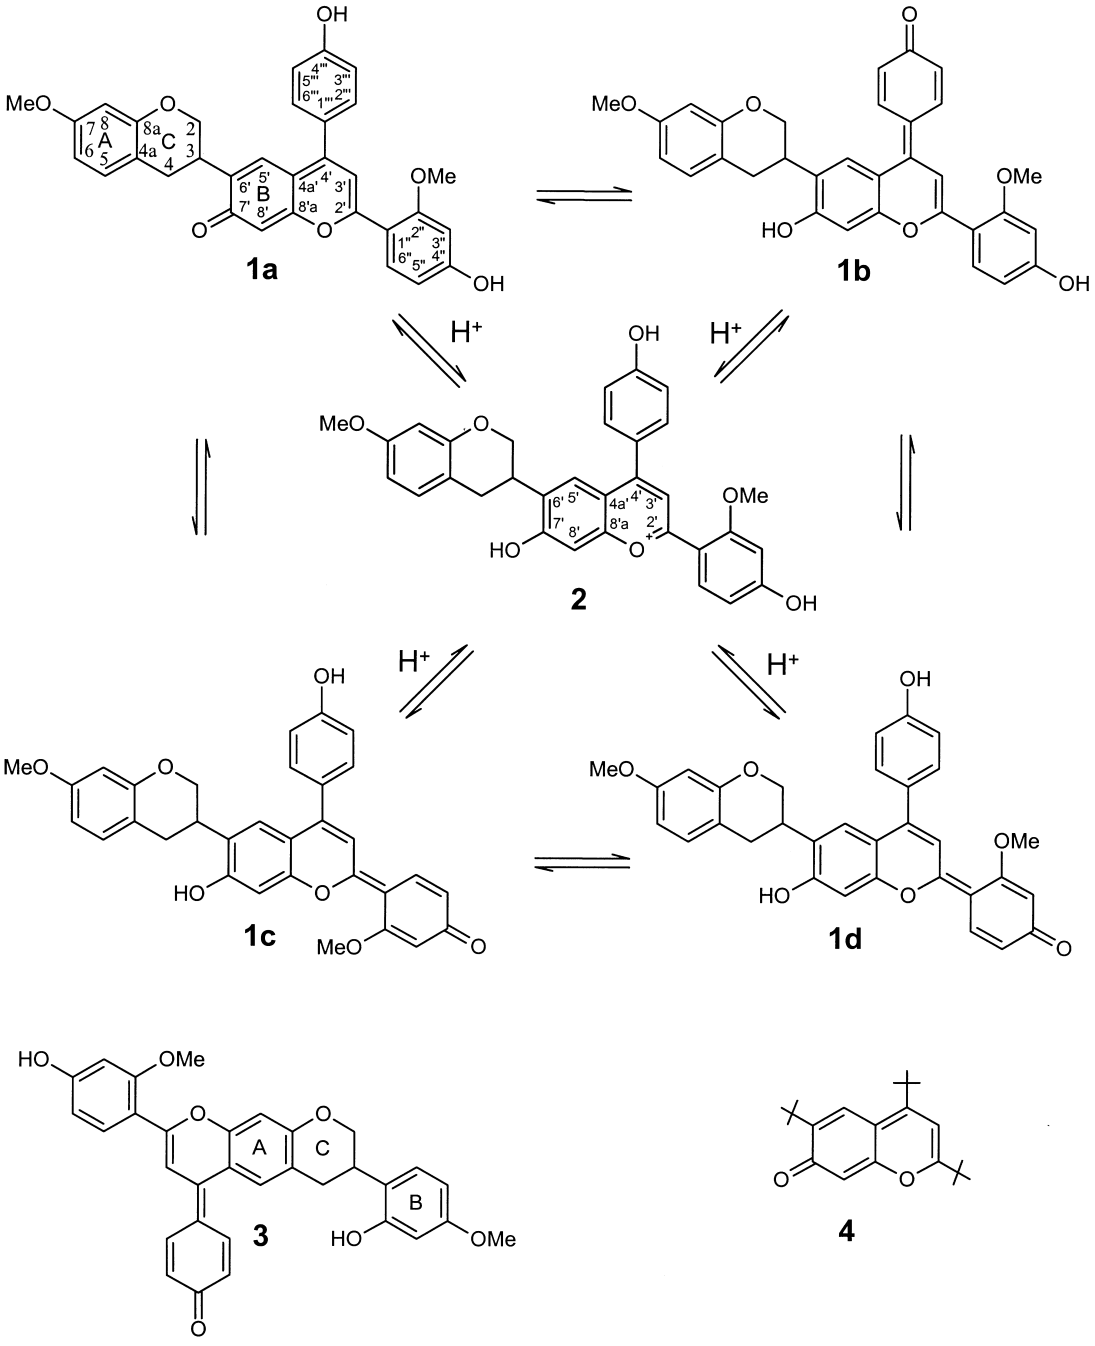

Fig. 1. Retusapurpurin A (**1a**), three of its possible tautomers (**1b–1d**), their protonated form (**2**), the partial structure (**4**), and the related pigment, candenatone (**3**).

HMBC) leading to complete assignment of the proton and carbon chemical shifts. Its molecular formula $C_{32}H_{26}O_7$ was deduced from the pseudo-molecular ion $[M+H]^+$ peak at m/z 523 in the ESI and APCI MS spectra. In the upfield region of the ^{1}H NMR spectrum of **1a** two pairs of methylene protons were observed (Table 2, at δ 2.71 and 2.89 and 4.02 and 4.19, respectively). The COSY spectrum revealed a methine proton hidden under the HDO peak at δ 3.43. The coupling patterns of the five aliphatic protons were typical for the C-ring of isoflavans (Kurosawa et al., 1978; Hamburger et al., 1988). This partial structure was further supported by the COSY cross-peaks (between H-2/H-3 and H-3/H-4), ^{13}C NMR (Table 2), and 2D NMR spectral data, which provided an overdetermined system of correlations.

Partially overlapping signals for 13 protons belonging to three aromatic rings were also observed in the ^{1}H NMR spectrum, in addition to two aromatic methoxy signals (Table 2). H-5 (*d*, δ 6.93) showed three-bond HMBC correlations with C-4 and C-8a (Fig. 2), in addition to COSY correlations with two protons (δ 6.31 (*d*) and 6.43 (*dd*)). The signal at δ 6.43 was assigned to H-6 since it was a double doublet and showed a three-bond interaction with C-4a and C-8, the latter also presenting an interaction with C-4a. These observations, also supported by the NOE between H-5 (*peri* position) and the methylene on C-4 NOE (Fig. 2 all NOEs were positive), confirmed (Hamburger et al., 1988) that **1a** had an isoflavan A/C-ring partial structure. C-7 showed correlation to a methoxy group (δ 3.70) (HMBC), and so did H-6 and H-8 (NOESY) (Fig. 2). From these observations it was concluded that **1a** has a 7-methoxy-substituted A-ring, similar to that of neovestitol (7-methoxy-2′,4-dihydroxyisoflavan; Ingham, 1979).

Three singlet signals were observed downfield in the ^{1}H spectrum of **1a** and they appeared to belong to a fifth ring or moiety because all other aromatic protons could be assigned to two additional aromatic rings. The proton signals at δ 6.38, 6.42, and 7.82 (Table 2) suggested a 1,2,4-tri-substituted ring. Their coupling was also confirmed by DQF-COSY. These chemical shifts were in good agreement with those obtained for

[a] Assignments were confirmed by HMBC and HMQC.
[b] Interchangeable.

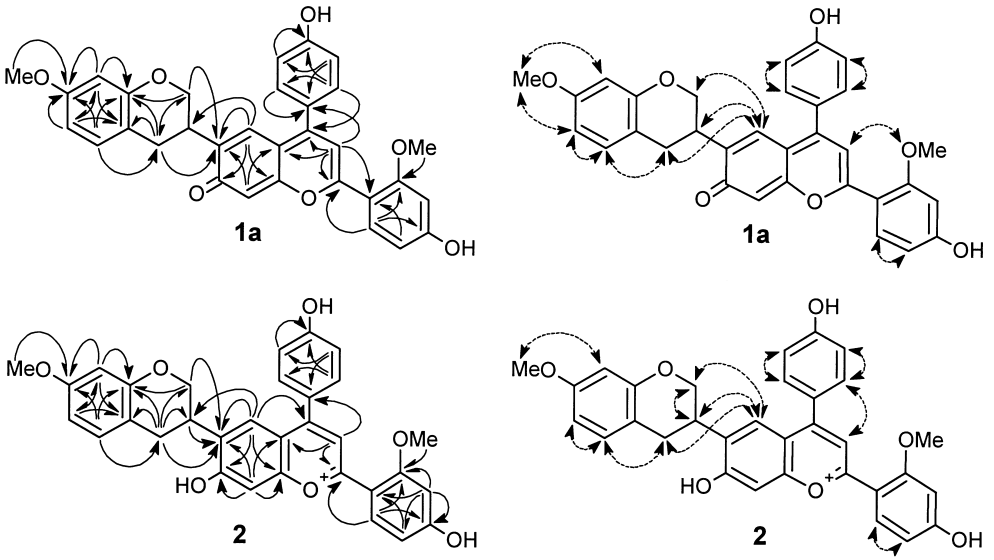

Fig. 2. Diagnostic HMBC (—) and NOE (- - - -) interactions in compounds **1a** and **2**.

the 2-methoxy-4-hydroxy substituted phenyl ring of candenatone (**3**), an isoflavan-chalcone dimer isolated from *Dalbergia* wood (Hamburger et al., 1988). The *ortho* position of the methoxy group (δ 3.83) was confirmed by HMBC. The doublets (showing the characteristic second order effects typical for an AA'XX' system) at δ 6.87 and 7.25 were assigned to a *para* substituted ring. Their coupling was confirmed in a DQF-COSY experiment. The signals for protons belonging to hydroxyl groups predicted by the molecular formula were apparently missing.
