Received 23 January 2001

Abstract

The function and properties of heterologously expressed full-length cDNA clones, isolated from a *Taxus* cDNA library and specific to Taxol biosynthesis, are summarized. Recombinant enzymes are described that catalyze early steps of the pathway, including taxadiene synthase, taxadien-5α-ol-*O*-acetyltransferase and taxadien-5α-yl acetate 10β-hydroxylase, and that catalyze late steps, including 10-deacetylbaccatin III-10β-*O*-acetyltransferase and taxane 2α-*O*-benzoyltransferase. The properties of *Taxus* geranylgeranyl diphosphate synthase are also described; although this synthase does not mediate a committed step of Taxol biosynthesis, it does provide the universal plastidial diterpenoid precursor, geranylgeranyl diphosphate, for initiating Taxol biosynthesis. © 2001 Elsevier Science Ltd. Keywords: *Taxus*; Taxol biosynthesis; Taxadiene synthase; Taxadien-5α-ol-*O*-acetyltransferase; Taxadien-5α-yl acetate 10β-hydroxylase; 10-Deacetylbaccatin III-10β-*O*-acetyltransferase; Taxane 2α-*O*-benzoyltransferase

1. Introduction

The projected increase in the use of Taxol (paclitaxel) for basic research and cancer chemotherapy (Herdeg et al., 2000; Miyake et al., 2000; Reinecke et al., 2000) warrants effort to improve existing production processes for this important plant natural product. The total synthesis of the drug (Holton et al., 1995b; Nicolaou et al., 1995), while a major accomplishment, is costly and low yielding, and thus is an unrealistic alternative for commercial supply. Semisynthesis is currently the major route for the production of Taxol and related taxoids (Guénard et al., 1993; Kingston et al., 1993; Georg et al., 1994; Commerçon et al., 1995; Holton et al., 1995a); this process involves a limited number of synthetic steps (e.g. C13-side chain attachment) to convert abundant, advanced Taxol pathway intermediates (e.g. baccatin III isolated from *Taxus* needles) to the target compound. Although semisynthesis procedures are efficient, the purification of semisynthesis precursors from plant tissue requires substantial effort in the separation of the desired intermediate(s) from abundant phenolics, lipids, and other contaminants occurring in planta. The isolation of Taxol and other useful taxoids from *Taxus* cell cultures requires fewer steps than purification from intact tissue because the quantities of interfering substances are lower; however, the production yields of taxoids in cell culture are too low at present for this to be commercially viable (Ketchum and Croteau, 1998).

For the foreseeable future, Taxol and its precursors for semisynthesis will continue to be produced by biological means. The few organisms that produce Taxol include a diverse group of endophytic fungi of *Taxus* species (*Taxomyces andreanae*, *Pestalotiopsis*, *Fusarium*, and *Alternaria*) but these microbial systems have not yet achieved sustainable production of the drug (Stierle et al., 1993; Strobel et al., 1996; Kim et al., 1999; Mu et al., 1999). A most promising biological production system is *Taxus* cell cultures which respond to methyl jasmonate elicitation with increased synthesis of Taxol (Ketchum et al., 1999; Furmanowa and Syklowska-Baranek, 2000; Shin et al., 2000; Yukimune et al., 2000). Taxoid production levels in cell culture are substantially higher than that of microbial systems, but, as indicated, not sufficiently high or reliable as yet to serve as a commercial source.

Induced *Taxus* suspension cultures also provide an excellent experimental tool for in vivo and in vitro elucidation of the complex biosynthetic pathway leading to Taxol by affording elevated titers of the relevant enzymes (and nucleic acids) and intermediates for structural

PII: S0031-9422(01)00160-1

analysis. Additionally, novel taxane metabolites and derivatives can potentially be generated in culture by genetic manipulation (Han et al., 1994) and/or by altering growth conditions (Ketchum et al., 1999; Ma et al., 1994).

As biological methods comprise the only viable means of taxoid production, it is increasingly important to understand the pathway and enzymatic reactions involved in Taxol biosynthesis, since manipulation of the slow steps can provide the means for improved production of taxoids. The biosynthesis of Taxol, following diversion of primary plant metabolism, requires a dozen steps; the improved flux through slow steps by overexpression of the corresponding genes in transgenic cells would be expected to raise the production titers of these medicinally useful taxane diterpenoids to commercially significant levels. Genetic manipulation of transcription factors for the global up-regulation of the pathway, and improved efficiency of the intracellular metabolite trafficking and extracellular secretion machinery, can also be anticipated to improve production yields and the ease of drug isolation from the medium.

Over the past 5 years, major advances have been made in the identification of genes responsible for Taxol biosynthesis, a process requiring an estimated dozen enzymatic reactions involving the construction of the tetracyclic skeleton and the addition of the various oxygen and acyl functional groupings (Fig. 1). Presently, five cDNAs encoding pathway enzymes have been isolated from a *Taxus* cDNA library and functionally expressed from an appropriate vector in bacteria or yeast as host. The properties of the cDNA clones and the catalytic function of the corresponding recombinant enzymes are summarized; these include the first committed pathway enzyme, taxadiene synthase, which constructs the taxane skeleton, a cytochrome P450 taxane hydroxylase and three taxoid *O*-acyltransferases. Also, since the provision of geranylgeranyl diphosphate as the taxoid precursor is necessary, the *Taxus* geranylgeranyl diphosphate synthase is described, as are several important enzymatic steps for which the corresponding genes have not yet been isolated.

2. Geranylgeranyl diphosphate synthase: provision of the essential precursor

The tricyclic carbon skeleton of Taxol is derived by cyclizaton of the universal diterpenoid precursor (*E*,*E*,*E*)-geranylgeranyl diphosphate (GGPP; Fig. 1); the heterocyclic oxetane ring (D-ring) is formed later by a separate

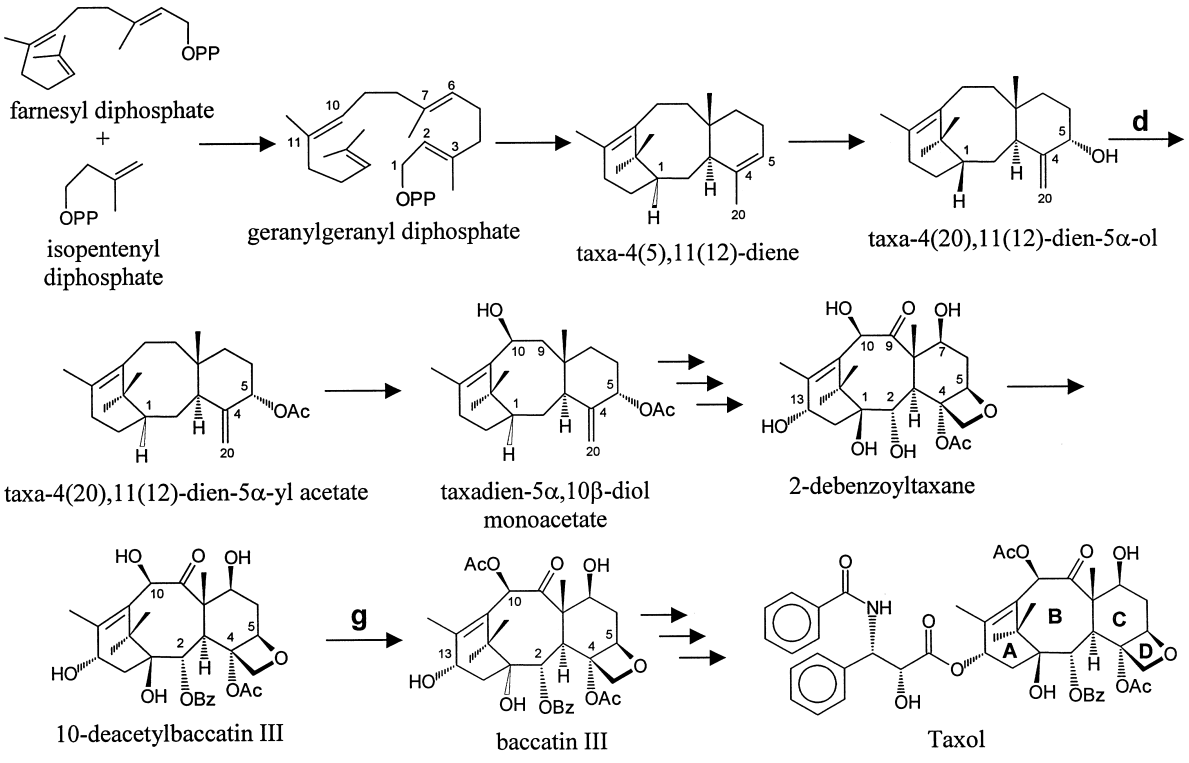

Fig. 1. Outline of early steps of the Taxol biosynthetic pathway. (a) The coupling of isopentenyl diphosphate and farnesyl diphosphate to geranylgeranyl diphosphate by geranylgeranyl diphosphate synthase, (b) the cyclization of geranylgeranyl diphosphate to taxadiene by taxadiene synthase, (c) the hydroxylation to taxadien-5α-ol by cytochrome P450 taxadiene 5α-hydroxylase, (d) the acetylation of taxadien-5α-ol by taxa-4(20),11(12)-dien-5α-ol-*O*-acetyltransferase, (e) the hydroxylation of taxadien-5α-yl acetate by cytochrome P450 taxane 10β-hydroxylase, (f) the benzoylation of a 2-*O*-debenzoyl taxane by a taxane 2α-*O*-benzoyltransferase, (g) and the acetylation of 10-deacetyl baccatin III to baccatin III by a 10-deacetyl baccatin III-10-*O*-acetyltransferase are illustrated. Multiple arrows indicate several as yet undefined steps.

and distinct reaction sequence (Fig. 2). The acyclic precursor is biosynthesized by GGPP synthase, a prenyltransferase that catalyzes the electrophilic coupling of farnesyl diphosphate (FPP) and isopentenyl diphosphate (IPP) as the terminal step (Fig. 1). Genes encoding this prenyltransferase are of considerable interest because the enzyme produces the branch-point progenitor of a variety of diterpenoids and tetraterpenoids (Schultz et al., 1985; Kleinig, 1989; Rilling et al., 1989; Clarke, 1992), several of which are relevant to the process of photosynthesis.

Since Taxol biosynthesis occurs in non-photosynthetic, terminally differentiated stem tissue *in planta*, or in non-photosynthetic, undifferentiated cells in culture, the molecular regulation of GGPP synthase is of interest, particularly in the context of flux control in the formation of this branch point precursor in an instance where high level production to drive essential primary metabolic processes is absent.

Isolation of the gene coding for this prenyltransferase has been achieved and the sequence determined (Hefner et al., 1998). A hybridization probe with significant homology to an angiosperm GGPP synthase yielded a cDNA encoding the GGPP synthase from a *Taxus canadensis* library, and the clone was confirmed by functional expression in yeast. The cDNA has an open reading frame of 1179 nucleotides and encodes a deduced protein of 393 residues (42.6 kDa) containing a presumptive N-terminal transit peptide (Hefner et al., 1998) that likely directs this nuclear gene product to the plastids for proteolytic processing to the mature form (Russell et al., 1993). The presence of a plastid-specific targeting sequence in GGPP synthase (and taxadiene synthase as described later) is consistent with the observation that diterpenes, monoterpenes and tetraterpenes, as well as their corresponding precursor prenyl diphosphates, are biosynthesized in plastids (McCaskill and Croteau, 1999a,b; Turner et al., 1999). The encoded GGPP synthase protein shares significant amino acid identity (62–75%) with other GGPP synthases of plant origin and with the large subunit of the heterodimeric geranyl diphosphate synthase from mint (Burke et al., 1999). RNA blot analysis showed that the steady state mRNA levels for GGPP synthase in methyl jasmonate-induced *Taxus* cells were discernibly higher than in non-induced control cells (Hefner et al., 1998) suggesting that methyl jasmonate modulates the production of this synthase at least at the level of transcription.

3. Taxadiene synthase: the first committed enzyme of Taxol biosynthesis

Taxadiene synthase, another plastidial enzyme, catalyzes the cyclization of geranylgeranyl diphosphate to taxa-4(5),11(12)-diene (Koepp et al., 1995), and, in constructing the unique taxane skeleton, constitutes the committed step in the biosynthesis of Taxol and related taxoids (Fig. 1). Taxadiene synthase activity was first observed in cell-free extracts of *Taxus brevifolia* stems, and the enzyme was purified by a series of traditional chromatographic steps (Hezari et al., 1995). The native, operationally soluble enzyme is monomeric (~79 kDa), exhibits a pH optimum at 8.5, a requirement for a divalent metal ion (Mg^{2+} preferred), and a K_m value of 3 μM for the prenyl substrate (Hezari et al., 1995). A homology-based PCR cloning strategy, based on conserved sequence elements of terpenoid synthases from angiosperms, was applied to acquire a hybridization probe for this gymnosperm cyclase. The subsequent screen of a cDNA library from *T. brevifolia* stems (initially employed as the PCR template) yielded a full-length clone that was functionally expressed in *E. coli* (Wildung and Croteau, 1996). The cDNA sequence specifies an open reading frame of 2586 nucleotides, and the deduced full-length preprotein (862 residues, ~98.3 kDa) includes a long N-terminal targeting sequence for localization to and processing in the plastids, and the typical terpene synthase DDXXD divalent metal ion-substrate complex binding motif (Wildung and Croteau, 1996; Davis and Croteau, 2000). Comparison of the translated taxadiene synthase sequence to other terpene synthase sequences shows significant homology to abietadiene synthase (46% identity, 67% similarity) from grand fir (Wildung and Croteau, 1996).

The protein has been heterologously overexpressed as a thioredoxin fusion which resembles the native enzyme in general properties (Huang et al., 1998); however, a pseudomature form of taxadiene synthase having 60 amino acids deleted from the N-terminus of the preprotein was found to be superior with respect to the level of expression, ease of purification, solubility, sta-

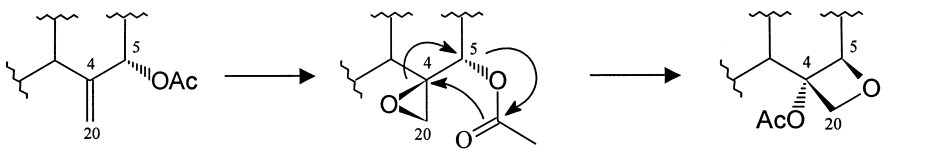

Fig. 2. Postulated biosynthetic scheme for the formation of the oxetane D-ring of Taxol and related late-stage taxoids, in which the 5α-acetoxy-4(20)-ene functional grouping is converted by epoxidation to the 5α-acetoxy-4β(20)-oxirane followed by intramolecular rearrangement to the 4α-acetoxy oxetane moiety.

bility, and catalytic efficiency with kinetics comparable to the native enzyme (Williams et al., 2000b). During the course of the N-terminal truncation studies, it was found that, in addition to the major product, taxa-4(5),11(12)-diene (94%), this synthase (both native and recombinant) produces a small amount of taxadiene isomers (~6%; Williams et al., 2000b). The stereochemistry of the taxadiene synthase reaction has been defined, and the enzyme shown to mediate a unique intramolecular hydrogen migration in the B/C-ring closure step of the catalytic cycle (Williams et al., 2000a).

4. Hydroxylation of the taxadiene nucleus by cytochrome P450 oxygenases

The oxygenation patterns of the various taxoid intermediates found in *Taxus* are established by hydroxylations of the taxane skeleton which have been shown directly to be mediated by cytochrome P450 monooxygenases (Hezari and Croteau, 1997). This conclusion is independently supported by $^{18}O_2$-feeding studies and NMR-based survey of oxygen labeling in taxayunnanine C (a taxadien-2α,5α,10β,14β-tetraol derivative) isolated from *Taxus yunnanesis* cell cultures (Eisenreich et al., 1998).

4.1. Taxadiene 5α-hydroxylase

Taxol biosynthesis from taxa-4(5),11(12)-diene continues with the oxidative modifications of this progenitor olefin. The first of these oxygenations constitutes the second specific step of Taxol biosynthesis and leads to the formation of taxa-4(20),11(12)-dien-5α-ol, which has been identified as a metabolite in *Taxus* cell cultures and confirmed as a pathway intermediate (Hefner et al., 1996). The responsible enzyme has been established as a *Taxus* microsomal cytochrome P450 mixed-function monooxygenase (Hefner et al., 1996); however, a cDNA encoding this regiospecific heme-thiolate protein has not yet been isolated. This unusual P450 catalyzes not only the regio- and stereospecific insertion of oxygen at C5α of the taxane nucleus but also the migration of the 4(5)-double bond to the 4(20)-position, a characteristic structural feature of many intermediate taxoids.

The order of subsequent oxygenations can be formulated based on consideration of the relative abundances of oxygen functional groupings present at the various carbons of the taxane ring of the now over 350 identified naturally occurring taxoids (Baloglu and Kingston, 1999). Based on such frequency of occurrence in defined taxane metabolites, the suggested order of oxygenation (after C5) is C10, followed by C2 and C9 (sequence uncertain), then C13, while oxygenations at C1 and C7 are considered to occur late in the biosynthetic pathway (Floss and Mocek, 1995; Walker and Croteau, 1999).

4.2. Taxane 10β-hydroxylase

By comparing transcripts from elicited (methyl jasmonate) and nonelicited *Taxus* cells, a set of related full-length cytochrome P450 cDNA clones was obtained by a differential display of mRNA-reverse transcription-PCR method, followed by traditional library screening. Selected clones, based on homology to other plant cytochrome P450s, were used to individually transform yeast (*Saccharomyces cerevisiae*) and the transformants were screened for oxygenase function with a series of taxoid substrates. One such clone yielded a functional enzyme that catalyzed the conversion of taxadien-5α-yl acetate to a single product which was subsequently identified as 10β-hydroxy taxadien-5α-yl acetate by combined radio-HPLC, GC-MS and 2D-NMR methods. The cDNA encoding the taxane 10β-hydroxylase has an open reading frame of 1494 base pairs corresponding to a deduced protein of 498 residues with a calculated molecular weight of 56,690, and the sequence bears all of the structural motifs anticipated for a cytochrome P450 monooxygenase (Schoendorf et al., 2001). The recombinant protein produces the same taxadien-5α,10β-diol monoacetate as the native, microsomal cytochrome P450 from *Taxus* cells (Lovy-Wheeler et al., 2001). Preliminary specificity studies with the recombinant enzyme (such experiments are not possible with the native microsomal enzyme because of the presence of competing cytochrome P450s) indicate this hydroxylase to be highly regio- and stereospecific.

5. Acylation of the taxane nucleus by CoA-dependent acyltransferases

When compared to taxadienol, taxadienyl acetate is a more efficient substrate for subsequent cytochrome P450-mediated hydroxylations by *Taxus* microsomes from cell cultures (Hezari and Croteau, 1997), and the acetate ester yields more highly functionalized products (Lovy-Wheeler et al., 2001). Therefore, taxa-4(5),11(12)-dien-5α-yl acetate likely represents the third specific intermediate in the Taxol biosynthetic pathway (Fig. 1). Taxanes bearing this 5α-acetoxy-4(20)-ene functional grouping are also considered to be the immediate precursors (via the 5α-acetoxy-4(20)-epoxy intermediate) of the late-stage 4α-acetoxy-4β,5β-oxetane compounds, including Taxol (Fig. 2).

5.1. Taxadien-5α-ol-*O*-acetyltransferase

Acetyl CoA:taxadien-5α-ol-*O*-acetyltransferase activity was readily demonstrated in soluble enzyme extracts of induced *Taxus* cells (Walker et al., 1999). Purification of this enzyme and internal microsequencing led to a reverse genetic approach for isolating a full-length cDNA

encoding taxa-4(20),11(12)-dien-5α-ol-*O*-acetyltransferase from an induced *Taxus* cell cDNA library (Walker et al., 2000). Expression of this clone in *E. coli* yielded a functional enzyme as determined by radiochemical assay and combined gas chromatographic-mass spectrometric verification of the acetylated product derived from taxadienol and acetyl coenzyme A as co-substrates. The open reading frame of 1317 nucleotides corresponds to a deduced amino acid sequence of 439 residues (Walker et al., 2000). Consistent with the size of the operationally soluble native enzyme (Walker et al., 1999), the DNA appears to encode a monomeric protein of molecular weight 49,079 that bears no N-terminal organellar targeting information (Walker et al., 2000). The recombinant and native enzymes exhibit a pH optimum at 9.0 and K_m values for co-substrates of 4.2 μM and 5.5 μM for taxadienol and acetyl CoA, respectively (Walker et al., 1999; Walker et al., 2000), and both enzymes were incapable of *O*-acetylating the advanced Taxol precursor 10-deacetylbaccatin III (possessing free hydroxyls at C1, C7, C10 and C13), suggesting that the 5α-acetyltransferase is highly specific towards the C5 hydroxyl position (Walker et al., 1999).

5.2. 10-Deacetylbaccatin III-10β-O-acetyltransferase

In addition to the first acetylation at the C5 hydroxyl of the taxane nucleus, the Taxol pathway involves another transacetylation reaction at the C10 hydroxyl of 10-deacetylbaccatin III (a late-stage Taxol pathway intermediate). A full-length cDNA clone for 10-deacetylbaccatin III-10β-*O*-acetyltransferase, which catalyzes formation of the last diterpene intermediate, baccatin III, on the Taxol biosynthetic pathway (Fig. 1), has been isolated from *Taxus cuspidata* (Walker and Croteau, 2000a). Thus, a homology-based PCR cloning strategy was employed to amplify a probe that ultimately identified a full-length putative 10-deacetylbaccatin III-10β-*O*-acetyltransferase by library screening. The gene was expressed in *E. coli* to afford the functional enzyme, as determined by ^{1}H NMR and MS verification of the product, baccatin III, derived from 10-deacetylbaccatin III and acetyl coenzyme-A as co-substrates. The full-length cDNA has an open reading frame of 1320 base pairs corresponding to a deduced protein of 440 residues with a calculated molecular weight of 49,052, consistent with the size of the operationally soluble, monomeric native acetyltransferase demonstrated in *Taxus* cell extracts (Walker and Croteau, 2000a). The recombinant acetyltransferase has a pH optimum at 7.5, K_m values of 10 and 8 μM for 10-deacetylbaccatin III and acetyl coenzyme A, respectively, and is seemingly regiospecific towards the 10β-hydroxyl group of the taxane ring (Walker and Croteau, 2000a).

5.3. Taxane 2α-O-benzoyltransferase

The homology-based PCR cloning strategy employed to isolate the 10-deacetylbaccatin III-10β-*O*-acetyltransferase gene from the methyl jasmonate-induced *Taxus* cell library provided a set of related full-length cDNA clones, one of which encoded a taxane 2α-*O*-benzoyltransferase (Walker and Croteau, 2000b). Expression of this aroyltransferase in *E. coli* yielded a recombinant enzyme that catalyzed the conversion of 2-debenzoyl-7,13-diacetylbaccatin III, a semisynthetic substrate, to 7,13-diacetylbaccatin III. Thus, this transferase appears to function at a late-stage acylation step of the Taxol biosynthetic pathway. The functionally expressed benzoyltransferase was confirmed by radio-HPLC, ^{1}H-NMR and combined HPLC-MS verification of the product, 7,13-diacetylbaccatin III, derived from 2-debenzoyl-7,13-diacetylbaccatin III and benzoyl CoA as cosubstrates in the corresponding cell-free extract of the transformed bacteria. The full-length cDNA has an open reading frame of 1320 base pairs and encodes a deduced protein of 440 residues with a calculated molecular weight of 50,089. The recombinant benzoyltransferase has a pH optimum of 8.0, K_m values of 0.64 and 0.30 mM for 2-debenzoyl-7,13-diacetylbaccatin III and benzoyl coenzyme A, respectively, and is apparently regiospecific for acylation of the 2α-hydroxyl group of the functionalized taxane nucleus. Kinetic evaluation of the selectivity of the aroyltransferase revealed that acetyl-CoA is a significantly less efficient donor than benzoyl-CoA at saturation (Walker and Croteau, 2000b).

The three acyltransferases described contain a highly conserved HXXXDG sequence motif found in other transacylases. Site-directed mutagenesis and chemical modification studies have shown that the histidine residue of this element is essential for catalytic activity of these enzymes, and it has been suggested that the histidine may function as a general base in catalyzing the transfer of the acyl group from acyl/aroyl-CoA to the alcohol substrate (Carbini and Hersh, 1993; Brown et al., 1994).

6. Conclusion

Of the dozen genes involved specifically in Taxol biosynthesis, those encoding taxadiene synthase, taxadien-5α-ol-*O*-acetyltransferase, cytochrome P450 taxadienyl acetate 10β-hydroxylase, 10-deacetylbaccatin III-10β-*O*-acetyltransferase, and taxane 2α-*O*-benzoyltransferase have been isolated, expressed, and characterized. The remaining pathway genes include at least seven additional hydroxylases for oxygenation of the taxane ring (at C1, C2, C5, C7, C9 and C13) and of the phenylpropanoid side chain, an oxidase for the formation of the C9 carbonyl function, the C13-*O*-phenylisoserinyl acyl-

transferase, and the side chain *N*-benzoyltransferase, as well as those genes responsible for the catalysts that construct the oxetane D-ring of Taxol. With the corresponding enzymes demonstrated and assays developed, the contribution of each step to pathway flux can be assessed by in vivo and in vitro studies, the slow steps identified, and suitable strategies devised to isolate and overexpress the corresponding genes in bioengineered *Taxus* cell cultures for improved production titers of Taxol. With the pathway(s) to Taxol defined and the corresponding genes made available, it should also be possible to suppress, by sense or antisense technologies, undesirable side-routes and metabolic dead-ends, or to direct the pathway toward other intermediates or, potentially, new taxoid derivatives.

Review

^{18}O Pattern and biosynthesis of natural plant products

Hanns-Ludwig Schmidt *, Roland A. Werner [1], Andreas Roßmann

Technische Universität München, Lehrstuhl für Biologische Chemie, Vöttinger Str. 40, D-85350 Freising-Weihenstephan, Germany

Received 22 September 2000; received in revised form 20 December 2000

Abstract

Oxygen atoms in plant products originate from CO_2, H_2O and O_2, precursors with quite different $\delta^{18}O$ values. Furthermore their incorporation by different reactions implies isotope effects. On this base the resulting non-statistical ^{18}O distributions in natural compounds are discussed. The $\delta^{18}O$ value of cellulose is correlated to that of the leaf water, and the observed ^{18}O enrichment ($\sim +27‰$) is generally attributed to an equilibrium isotope effect between carbonyl groups and water. However, as soluble and heterotrophically synthezised carbohydrates show other correlations, a non-statistical ^{18}O distribution — originating from individual biosynthetic reactions — is postulated for carbohydrates. Similarly, the $\delta^{18}O$ values of organic acids, carbonyl compounds, alcohols and esters indicate water-correlated, but individual ^{18}O abundances (e.g. O from acyl groups $\sim +19\%$ above water), depending upon origin and biosyntheses. Alcoholic groups introduced by monooxygenase reactions, e.g. in sterols and phenols, show $\delta^{18}O$ values near $+5‰$, in agreement with an assumed isotope fractionation factor of $\sim$1.02 on the reaction with atmospheric oxygen ($\delta^{18}O = +23.5‰$). Correspondingly, a "thermodynamically ordered isotope distribution" is only observed for oxygen in some functional groups correlated to an origin from CO_2 and H_2O, not from O_2. The individual isotopic increments of functional groups permit the prediction of global $\delta^{18}O$ values of natural compounds on the basis of their biosynthesis. © 2001 Published by Elsevier Science Ltd.

1. Introduction

Oxygen is a very important bioelement, providing functional groups for most organic compounds, thus essentially contributing to their physical and chemical properties. The element is found in nature as a mixture of three stable isotopes (mean relative natural abundance for ^{16}O: 99.7587 atom%, ^{17}O: 0.0374 atom% and ^{18}O: 0.2039 atom%); ^{17}O is the only oxygen isotope with a nuclear magnetic moment. The biosphere is in permanent contact and oxygen exchange with three virtually infinite inorganic oxygen reservoirs: Atmospheric carbon dioxide ($\delta^{18}O$:[2] +40.3 to +42.5‰, depending on geographical latitude and altitude; Francey and Tans, 1987), ground-water ($\delta^{18}O$: −10 to +2‰, leading to leaf water with −5 to +10‰) and atmospheric oxygen gas ($\delta^{18}O$ = +23.5 to +23.8‰; Kroopnick and Craig, 1972; Horibe et al., 1973). These are the primary sources for the oxygen atoms in any organic material.

Most organic compounds contain only one or a few oxygen atoms with the exception of carbohydrates. The $^{18}O/^{16}O$ ratio of cellulose has been the target of many investigations, in particular since the observation of Libby and Pandolfi (1974) that the $\delta^{18}O$ value of tree rings is correlated to the $\delta^{18}O$ value of the leaf water and thus can be used as a climate indicator (tree ring thermometer). Corresponding measurements unequivocally prove a defined correlation between the $\delta^{18}O$ values of cellulose and leaf water (Epstein et al., 1977; Sternberg et al., 1986; Yakir and DeNiro, 1990); they are compiled and discussed in a recent review by Farquhar et al. (1998) (see also Sternberg, 1989).

The generally accepted ^{18}O enrichment in cellulose of trees relative to the water present during its biosynthesis is +27±4‰ (Sternberg, 1989). As this corresponds numerically to an equilibrium oxygen isotope effect between a carbonyl group and water as measured for acetone (1.027; Sternberg and DeNiro, 1983), it is generally assumed that the $\delta^{18}O$ value of cellulose is an expression of the oxygen isotope equilibration between water and carbonyl groups (DeNiro and Epstein, 1979), which can occur in any position of the molecule during the biosynthesis of carbohydrates. However, because there are examples for cellulose from other plants than trees and also for carbohydrates from animal origin (see later), which do not show this "equilibrium" enrichment, and because the slopes of the most correlation lines for tree cellulose and water do never attain the value 1.0 (Yakir and DeNiro, 1990), we believe that the numerical coincidence of the 27‰ enrichment and the equilibrium isotope effect may be at least partially accidental. Saurer et al. (1997) for instance found evidence that there is a dependence of the cellulose $\delta^{18}O$ value upon plant species and actual metabolic status. Therefore, as already outlined in former contributions (Schmidt et al., 1995; Schmidt and Gleixner, 1998a,b) we think that several effects contribute to the $\delta^{18}O$ value of cellulose, that for example after the first step of the photosynthetic carboxylation reaction, the $\delta^{18}O$ value of carbon dioxide (...+41‰...) is primarily contributing to the $\delta^{18}O$ value of carbohydrates, that the thus attained

[2] $\delta^{18}O[‰]_{V\text{-}SMOW} = \left[\frac{(^{18}O/^{16}O)_{sample}}{(^{18}O/^{16}O)_{V\text{-}SMOW}} - 1\right] \times 1000$

Stable isotope abundances of bioelements are generally expressed as the relative difference of the isotope ratio of a compound to that of an international standard in ‰. This standard for oxygen isotope ratio measurements is: V-SMOW = Vienna Standard Mean Ocean Water with an $^{18}O/^{16}O$ ratio of $(2005.20 \pm 0.45) \times 10^{-6}$, according to international agreement (Gonfiantini et al., 1995). $\delta^{18}O$ values measured by us are normalized according to Coplen (1988). Procedure and problems with oxygen isotope standardization are reported elsewhere (Kornexl et al., 1999a). $\delta^{13}C$ and $\delta^{2}H$ represent the corresponding stable carbon and stable hydrogen isotope ratios with the respective international isotope ratio standards V-PDB and V-SMOW.

primary high enrichment is partially lost later by oxygen isotope exchanges from carbonyl groups. On the other side, reactions implying kinetic isotope effects directly introduce oxygen atoms from H_2O into organic intermediates. From here, we suppose that in carbohydrates a distinct non-statistical ^{18}O pattern like that found in glucose for ^{13}C (Rossmann et al., 1991) and ^{2}H (Zhang et al., 1994a) must exist, with individual relative ^{18}O enrichments and ^{18}O depletions, and that the summation of these individual positional ^{18}O abundances will finally lead to the reported global mean ^{18}O enrichment of $+27\pm4$‰ of the carbohydrate relative to the water from the same source.

While this global $\delta^{18}O$ value of carbohydrates is in line with predictions and theoretical considerations for "thermodynamically ordered positional isotope abundances" (Galimov, 1985), this is not the case with $\delta^{18}O$ values of lignin and other aromatic compounds. Oxygen in these products must originate from O_2, introduced by monooxygenase reactions. Furthermore, the $\delta^{18}O$ value of lignin around $+13.5\pm1.5$‰ (Gray and Thompson, 1977), suggests a kinetic isotope effect on these oxygenase reactions.

Except for carbohydrates, no systematic investigation aiming on the explanation of global and positional $\delta^{18}O$ values of organic, mainly natural compounds has been performed so far. $\delta^{18}O$ Values from various secondary products are available from the literature, however, not always in connection with those of their precursors, mainly water from the same source. We have therefore systematically analysed representatives of the main biosynthetic pathways in higher plants in order to fill the gaps of experimental data not available in the literature for the demonstration of the global correlations of ^{18}O abundances and biosynthetic pathways. Probably due to experimental difficulties and the danger of artifacts implied in degradations methods, so far very few oxygen isotope patterns in organic molecules were available (see, for example, Fronza et al., 1999). We have recently succeeded in measuring ^{17}O patterns of esters by semi-quantitative ^{17}O NMR (Schramm et al., 1998); the data correspond to the ^{18}O pattern obtained by degradation (Werner, 1998; Schmidt et al., 1999).

In the present contribution, we have compiled $\delta^{18}O$ values (and partial ^{18}O patterns) of many types of natural products and of their synthetic counterparts, if available, and we correlate them to the corresponding primary oxygen sources, to (bio)synthetic reactions and possible oxygen isotope exchanges, and to the equilibrium and kinetic isotope effects accompanying these processes. We aim at a general view and explanation of the origin of intermolecular oxygen isotope distributions and intramolecular isotope patterns, and at their prediction as a contribution to the elucidation of biosyntheses and to the discrimination between natural and synthetic organic compounds.

2. Results and discussion

2.1. Carbohydrates and related compounds — oxygen atoms from carbon dioxide and/or water

As already pointed out, the mean global $\delta^{18}O$ value of autotrophically synthesized cellulose is obviously correlated in a defined manner to that of the leaf water present during its biosynthesis (Sternberg et al., 1986; Yakir and DeNiro, 1990). This defined correlation is a

"Furaneol®" from strawberry (*Fragraria*)[c]	$\delta^{18}O = +31\pm1.5$	Hilkert (pers. commun., this work)
"Furaneol®", synthetic[c]	$\delta^{18}O = +8$ to $+12$	Hilkert (pers. commun., this work)

[a] $\alpha = \left(\delta^{18}O_{compound} + 1000\right)/\left(\delta^{18}O_{water} + 1000\right)$.
[b] $\delta^{18}O$ Value predicted from biosynthesis $+25.6$‰; see Section 2.3.
[c] "Furaneol®" = 2,5-dimethyl-4-hydroxy-3(2H)-furanone.

well known fact, irrespective of the question if this is really the expression of a complete intramolecular oxygen isotope randomization, or the result of an overlap of many reactions and isotope effects in the course of the biosynthesis, leading to a non-statistical intramolecular oxygen isotope distribution. According to Table 1 soluble carbohydrates reflect the physiological characteristics of the plant in question and the climate and precipitation of their origin as does cellulose (Table 2), and this is meanwhile routinely used, e.g. for fruit juice geographical origin assignment and/or the proof of its adulteration with sugar from other sources (Houerou et al., 1999). It is furthermore quite obvious that the $\delta^{18}O$ value of immediate descendants of carbohydrates, e.g. glycerol, is dominated by that of the precursor; as outlined later, even for glycerol from fermentations the $\delta^{18}O$ value is more influenced by that of the precursor carbohydrate than by that of the water in contact during the fermentation.

Also very convincing in this context is the $\delta^{18}O$ value of quinic acid, a reduction product of dehydroquinic acid, an early intermediate of the shikimic acid pathway (see Section 2.3). Assuming a mean $\delta^{18}O$ value of +30‰ for three oxygen atoms originating from erythrose-4-phosphate as one of the precursors and the same for one from the phosphoenolpyruvate moiety, and . . . + 19‰. . . for the two from the carboxyl group (see Section 2.2), a mean $\delta^{18}O$ value of +25.6‰ is to be expected, which will, like the $\delta^{18}O$ value of the precursors, individually depend on the $^{18}O/^{16}O$ ratio of the leaf water in question. The $\delta^{18}O$ value found for the sample investigated (Table 1) confirms exactly this expectation.

Another immediate descendant from carbohydrates is "furaneol®". This natural product is a flavour compound from strawberry (*Fragraria*) and pineapple (*Ananas sativus*). Roscher et al. (1997) and Schwab (1998) have shown that it is derived from fructose-1,6-biphosphate by a kind of "Natural Maillard Reaction". In accordance with this

[a] The water in these measurements is the water in the potato tubers; correlation $\delta^{18}O_{Cellulose} = 1.15\times\delta^{18}O_{Starch} - 7.5$.

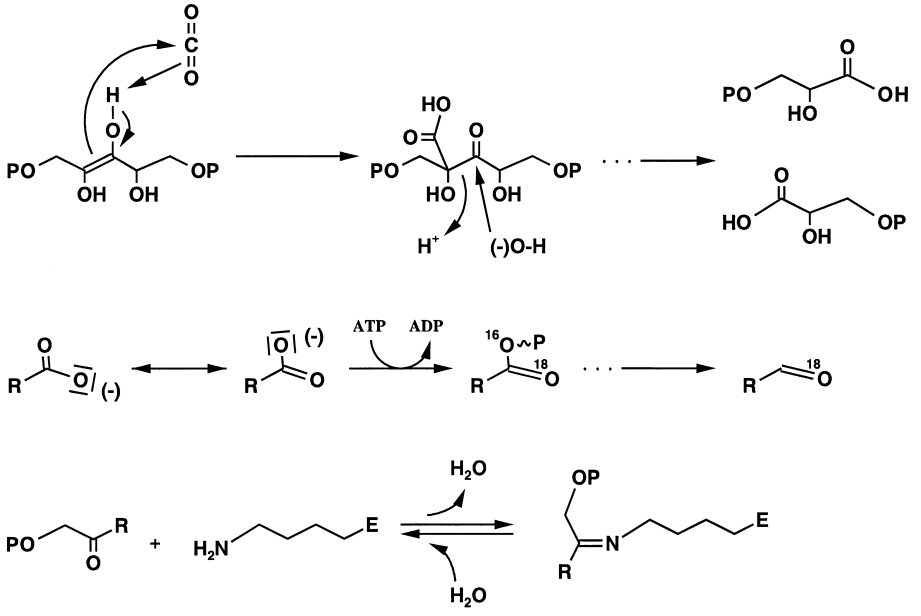

Fig. 1. Mechanisms of some reactions in the Calvin cycle and/or glycolysis involving introduction or elimination of O atoms: oxygen isotope exchange or equilibration of carbonyl groups is not indicated. First row: ribulosebiphosphate-carboxylase reaction; second row: biochemical activation of an acid; third row: binding of fructose-1,6-biphosphate and dihydroxiacetone-phosphate to aldolase (E).

biosynthesis, the $\delta^{18}O$ value found for the natural compound was $+31 \pm 1.5$‰, while that of synthetic counterparts, synthesized from different other precursors (for chemical synthesis reactions see, e.g. Bauer et al., 1990), was near $+10$‰, as expected from their corresponding synthesis reactions (Werner, 1998).

The $\delta^{18}O$ value of these compounds is thus indirectly correlated, probably via their precursors, to that of the water present during their biosynthesis. Systematically, this correlation has been investigated for carbohydrates, mainly cellulose. The numerical correlations reported for the $\delta^{18}O$ value of these compounds to that of the water in contact during their biosynthesis are compiled in Table 2. In most cases the ^{18}O enrichments for autotrophically synthezised cellulose are by $+30$‰ as compared to the water, however, the slopes of the correlation lines are quite different and practically never attain the value 1.0. Very recently, Roden and Ehleringer (1999) even proved that, although the correlation between cellulose and water exists, the oxygen isotope exchange between them can be incomplete. In the case of heterotrophic carbohydrate synthesis, the correlation seems to be even more complex. Therefore, one can assume that, as postulated, the equilibration of carbonyl groups with an isotopic shift of $+27$‰ is not exclusively responsible for the ^{18}O enrichment of the carbohydrates, even though this fits numerically very well with the corresponding isotope effect. A definite proof will only be possible on the base of carbohydrate isotope pattern elucidations and on the study of individual reactions of the carbohydrate metabolism, their mechanisms of oxygen incorporation and the possible isotope effects accompanying these reactions.

One can start from the premise that in plants a real isotope equilibrium certainly exists between water and CO_2. The equilibrium isotope effect for the system CO_2/H_2O provides carbon dioxide enriched in ^{18}O by about 41‰ against the water [O'Neil et al. (1975); see also Brenninkmeijer et al. (1983) and literature cited therein], and this equilibrium is rapidly attained in living systems under the influence of carbonic anhydrase (Silverman, 1982; Farquhar et al., 1998), although recent results indicate that in C_4 monocotyl plants this equilibrium may not always be complete (Gillon and Yakir, 2000). On the other hand, the possible isotopic equilibration of carbonyl groups with water under non-catalyzed conditions and at surrounding temperatures is relatively slow (order of hours; Rittenberg and Graff, 1958; Samuel and Silver, 1965), but can be very fast in the presence of enzymes (Hamilton and Westheimer, 1959; Model et al., 1968; Sternberg et al., 1986). In non enzyme-catalyzed reactions, oxygen isotope exchange occurs most rapidly with aldehydes, followed by ketones and acids, depending on their substituents and reaction conditions applied (Byrn and Calvin, 1966; Wedeking and Hayes, 1983). It is therefore unlikely that a non-catalyzed isotope exchange under the conditions of metabolism (pH 7–8, moderate temperatures, rapid turnover of intermediates) will always lead to a complete isotopic equilibration of any carbonyl group of short-lived intermediates with water. On the other hand, it is very likely that enzymes do not only catalyze such equilibrations but also introduce oxygen atoms directly from water with individual ^{18}O enrichments or depletions, depending on the mechanism and the degree of reversibility of the reaction. This will be discussed for the following reactions involved in the biosynthesis of carbohydrates (Fig. 1): The ribulosebiphosphate–carboxylase reaction proceeds by binding "equilibrated" CO_2 (as explained above) to the enediol intermediate, while a kinetic oxygen isotope effect will accompany the OH^--binding to position C-3. Two molecules of 3-PGA (3-phosphoglyceric acid) will arise, one with high ^{18}O enrichment in both O-atoms of the carboxyl group, the other with a relative ^{18}O depletion on at least one of these two oxygen atoms. The next step is an activation of the carboxyl group.

The oxygen atoms in a dissociated carboxyl group are equivalent, due to a mesomeric dissipation of the negative charge. Therefore, one can assume that a substitution of one of them implies an intramolecular IE (isotope effect); the phosphoglycerate-kinase will probably prefer the "light" oxygen of the carboxylate for the substitution with phosphate (intramolecular IE), and the subsequent reduction of the 1,3-bisphosphoglycerate will eliminate this oxygen atom with the phosphate. Hence the product glyceralphosphate [glycerol aldehyde phosphate (GAP)] will be highly enriched in ^{18}O, independent from the fact that the compound itself implies the possibility of a secondary oxygen isotope exchange with water, depending on its lifetime. In the next step of the Calvin cycle, the triosephosphate–isomerase reaction, there will probably be no oxygen isotope exchange from the diol intermediate, however, both trioses themselves will certainly be submitted to an oxygen isotope exchange in their carbonyl groups, even though probably not attaining an equilibrium under the condition of metabolism.

More dramatic is the oxygen isotope exchange in the subsequent step, the aldolase reaction. Aldolase type I enzymes completely replace the oxygen atom of the keto groups in both directions, because the enzyme–substrate complex is a Schiff base, which is hydrolyzed with water from the medium; it is not known whether this is accompanied by a kinetic isotope effect. However, it is well-known that aldolase catalyzes the oxygen isotope exchange of the substrates with water (Model et al., 1968), and hence the final state of the oxygen isotope introduction by aldolase will depend on the velocities of substrate binding and turnover.

On the base of these processes and other reactions of the Calvin cycle, an oxygen isotope pattern will result in hexoses which will probably be different from ^{18}O equilibrium concentrations for some positions. There is even one oxygen atom which will virtually never be touched by

exchange reactions after its very primary incorporation (either from CO_2 or H_2O), namely that in position C-6 (hexoses) or C-5 (pentoses), because it remains phosphorylated from the beginning. We have already pointed out in our interpretation of the ^{13}C pattern of glucose (Rossmann et al., 1991) that this position is probably the only "isotopically normal" and constant one.

The following observations may serve as an indirect proof for the individual history of the oxygen atoms in certain positions of carbohydrates. As indicated (Fig. 2, Table 2) lactose from cattle milk has a $\delta^{18}O$ value between +15 and +20‰, while that of the water of the milk is −10 to −2‰; slope and enrichment in the corresponding correlation line (0.59 and 20.6‰) are different from that for plant sugars and better corresponding to that for cellulose synthezised under heterotrophic conditions (Table 2). In parallel we found that the ethanol from a yeast fermentation of this lactose is relatively enriched in ^{13}C by 1.4‰ (Versini and Roßmann, unpublished), in contrast to a ^{13}C depletion by 1.7‰ generally observed for ethanol from plant carbohydrates (Roßmann et al., 1996). This finding is in complete agreement with data from Vallet et al. (1998) and from Masud et al. (1999), who found the same ^{13}C enrichment especially for ethanol from animal, mainly ruminant lactose, and in addition a ^{2}H pattern in galactose from animal origin different from that of plant origin, especially for the hydrogen atoms bound to position C-6 (Zhang et al., 1994b). All these results suggest an unusual isotopic pattern for all three elements in lactose (galactose and glucose moiety), different from that of plant carbohydrates, at least in position C-6.

The observations have to be discussed on the base of the biosynthesis of carbohydrates in ruminants (Fig. 3): In these animals glucose and galactose, hence also lactose, are synthesized from propionate, leading via methylmalonate, succinate, fumarate, malate and oxaloacetate to phosphoenolpyruvate and finally to 3-phosphoglycerate (3-PGA). In this sequence, which is probably unidirectional, hence irreversible, two molecules of H_2O are introduced by lyase reactions, namely by the fumarase and by the enolase reaction, respectively. The reverse of both reactions is accompanied by large kinetic ^{18}O isotope effects (Anderson, 1991) and one can postulate the same for the water addition (equilibrium ^{18}O isotope effect at pH 5.5 for the fumarase reaction: 1.033; Blanchard and Cleland, 1980). As the oxygen atom introduced by the enolase reaction is immediately protected from oxygen isotope exchange with water by phosphorylation (phosphoglyceromutase reaction), it remains the same until the final product lactose.

Starting from the observed mean $\delta^{18}O$ value of the water in milk (−6‰) and assuming an in vivo kinetic isotope effect of 1.02 for the enolase reaction, a $\delta^{18}O$ value of −25.5‰ will result in the position C-6 of lactose. If we use the correlation formula for orange sugars as a base for the calculation of the ^{18}O enrichment in the other positions (Table 2: $\delta^{18}O = 0.79 \times -6 + 30.7 = +25.96$), a $\delta^{18}O$ value of +26‰ has to be assumed for these (beginning from 3-phosphoglycerate any other reaction is identical to those in plants), and a global $\delta^{18}O$ value for lactose can be calculated according to $(9 \times 26 - 2 \times 25.5)/11 = +16.6$‰, which is very close to the observed mean one (+17.5‰). This has to be verified by the degradation of lactose.

The reactions in Fig. 3 will probably also be a base for a satisfactory explanation of the unusual deuterium enrichment at the hydrogen atom bound in position C-6 observed as mentioned above, and even for the unusual ^{13}C pattern postulated from the ^{13}C enrichment in the ethanol from lactose fermentation: In the course of the carbohydrate resynthesis from propionate, and probably already during the propionic acid fermentation, symmetrical intermediates (succinic and fumaric acid)

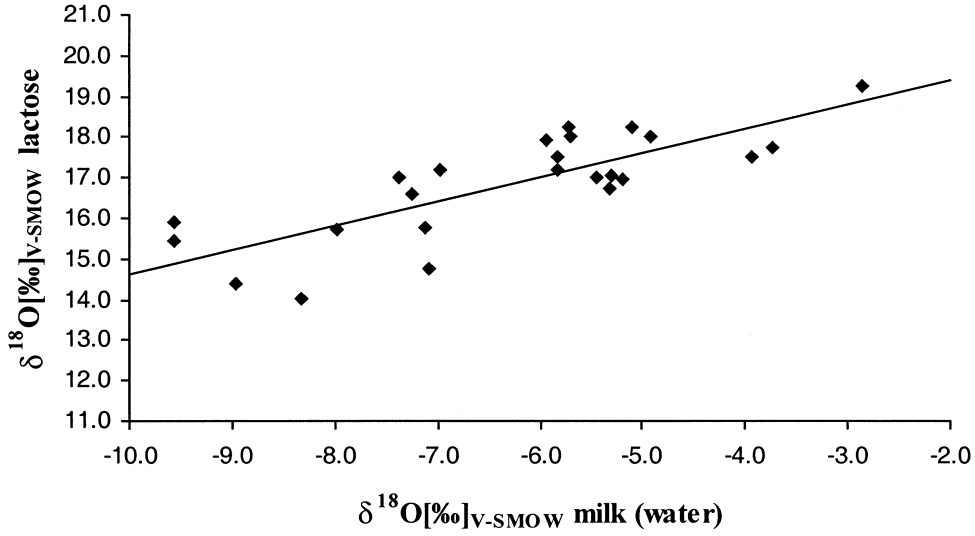

Fig. 2. Correlation between $\delta^{18}O$ values of water and lactose from cattle milk. $\delta^{18}O = 0.59 \times \delta^{18}O_{H_2O} + 20.6$‰, correlation coefficient $r = 0.80$.

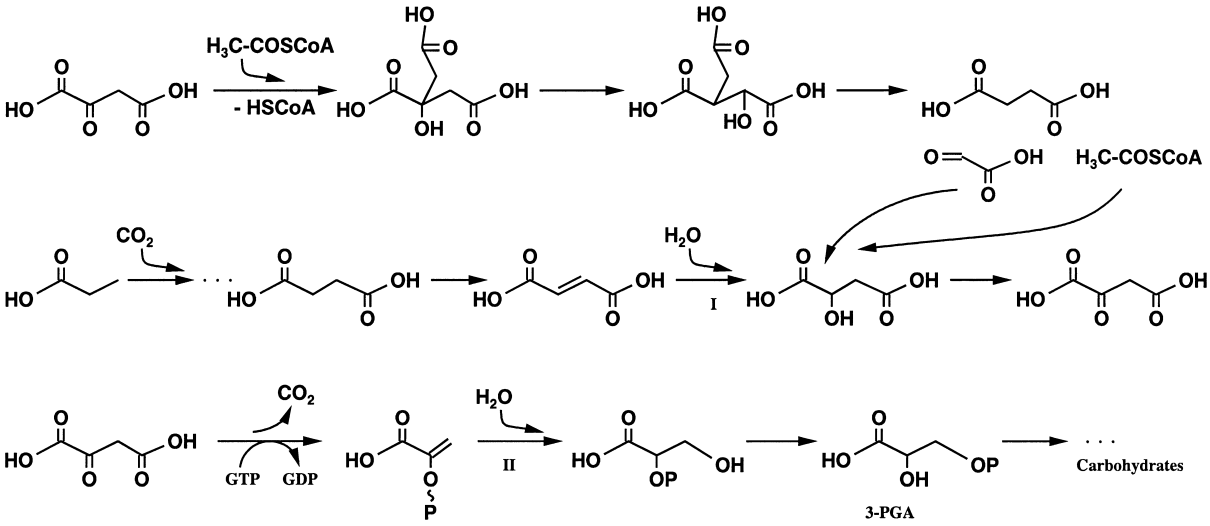

Fig. 3. Synthesis of 3-PGA in ruminants (second and third row) and in germinating oil seeds (first and third row). The O-atom introduced by the fumarase reaction (I) may exchange with water in oxaloacetate, however, the one introduced by the enolase reaction (II) will be preserved until the carbohydrates. The fumarase reaction prefers OH^- binding to ^{13}C.

occur, in which the original positions C-2 and C-3 of pyruvate from the fermented carbohydrates (here positions C-2/C-5 and C-1/C-6) are scrambled; we know from the ^{13}C pattern of malic acid synthezised from fumaric acid under the influence of fumarase that the water addition implies an intramolecular ^{13}C isotope effect leading to a relative ^{13}C enrichment on the C atom with the OH group (Schmidt et al., 2000), the same one which becomes C-1 in ethanol.

One would expect similar results for cellulose from *Ricinus communis* germs grown in the dark (Sternberg et al., 1986), because this cellulose should originate from fats via the glyoxylate pathway and meet that described for propionic acid (Fig. 3); however, its $^{18}O/^{16}O$ ratio was correlated to that of the surrounding water like in photosynthesizing plants (Table 2). Nevertheless, heterotrophic cellulose synthesis (Luo and Sternberg, 1992; Terwilliger and DeNiro, 1995) generally ends in products, which definitely indicate the influence of gluconeogenesis on their $^2H/^1H$ and $^{18}O/^{16}O$ ratio. Investigations on ^{18}O patterns of carbohydrates will allow a deeper insight into this matter.

2.2. Aliphatic acids, esters, carbonyl compounds and alcohols — oxygen from water by addition or equilibration

Carbonyl compounds and organic acids can exchange oxygen atoms with water; the velocity of this reaction is dependent on pH (O'Neal et al., 1983) and temperature. So, Wedeking and Hayes (1983) found for the equilibration of benzoic acid with water a rate constant 1.4×10^{-3} min^{-1} at 80°C and pH 1.0; the equilibration factor was $1.0172 + 0.0009$. Other equilibration factors reported (Rishavy and Cleland, 1999) range from 1.016 (acetaldehyde) to 1.035 (formic acid), indicating an important influence of the substituents of the CO group (cf. also 1.027 for acetone; Sternberg and DeNiro, 1983).

The facts given above suggest that under the conditions prevailing in biological systems, a complete equilibration will not always be attained, especially not with short-lived intermediates. However, this must be completely different, when the CO group is implied in the mechanism of an enzyme catalyzed reaction. So, for example, asparaginase catalysed the rapid oxygen isotope exchange of the carbonamide group in position C-4 of its substrate, while that of the carboxyl group in position C-1 remained completely unaffected (Röhm and Van Etten, 1986). For practical reasons in the present context we will use a mean empirical equilibration factor 1.019 for carboxyl and some carbonyl groups, corresponding to a relative enrichment of these groups to the water in contact of $\geqslant 19‰$ in case of complete equilibration.

In cases where water is an immediate reactant or a participant of the reaction in question, the introduction or elimination of an oxygen atom may be accompanied by a kinetic isotope effect. As outlined before (phosphoglycerate-kinase reaction), the activation of carboxyl groups by ATP/CoASH (coenzyme A) may even lead to a higher ^{18}O enrichment, independent whether or not aldehydes produced from these activated acids may partially exchange oxygen atoms with H_2O molecules before their further reduction to alcohols, depending on their chemical structure and the relative velocity of these competing reactions.

As already pointed out, the $\delta^{18}O$ value of glycerol is correlated to that of water, but on a "higher" level, in that it preserves the oxygen atoms from sugars (Table 3), and this is even true for fermentations; correspondingly, the correlation factor for $\delta^{18}O$ values of glycerol and

[a] These alcohols were by-products in olive oil indicated in Table 4; they showed local differences in ^{18}O, which were, however not so obviously correlated to the local precipitation water as the whole oil.
[b] As expected for O from O_2 (see Section 2.3), the $\delta^{18}O$ values were absolutely independent from the harvest area and its water characteristics.
[c] Contained approximately 20 mol% (crystal?) water.

water in wine is quite low ($\sigma = 0.68$), and a fermentation in ^{18}O enriched water is accompanied by only 15% oxygen isotope exchange between water and glycerol. The $\delta^{18}O$ value of glycerol from animal fat is lower as compared to that from plant fat. Like already outlined for lactose, the biosynthesis of glycerol in ruminants may be different from that in plants, and this may be responsible for the relatively smaller ^{18}O enrichment of glycerol, at least from ruminant fats. In parallel to the situation with lactose, we have to expect that the relative ^{18}O depletion is probably concentrated to position C-3, however, the experimental proof of this will be a task of future work.

It is in line with the fast irreversible conversion of glucose to ethanol by yeast that also for this product only a partial oxygen isotope equilibration of the intermediates with water takes place, and that ethanol thus preserves a quite high ^{18}O enrichment from the precursor; correspondingly, fermentations in ^{18}O enriched water indicate an only partial oxygen isotope exchange. One can assume that the rate of isotope exchange is the lower the larger is the reduction velocity of acetaldehyde. This is confirmed by the observation that also the $\delta^{2}H$ value of the –CH_2OH–group of ethanol is depending on the fermentation conditions (Vallet et al., 1996). On the other hand the low $\delta^{18}O$ value of synthetic ethanol results from the addition of water to ethylene. Water is also the source of oxygen functions in open chained isoprenoids (citral), introduced by the addition of OH^- to the intermediate carbenium ion.

The primary oxygen source for certain positions of cyclic isoprenoids (menthol, pulegone) is O_2, from where one oxygen atom is introduced into the substrate by hydroxylation (e.g. by limonene-3-hydroxylase; Richter, 1996; see also Fuchs et al., 1999). The resulting $\delta^{18}O$ value is quite low (+5 to +6‰), but may raise because of (partial) secondary oxygen exchange with water at the stage of biosynthetic intermediates with carbonyl groups. This is not possible for the 3-position of sterols, and therefore here the primary, not water-correlated ^{18}O abundance is preserved. The $\delta^{18}O$ value of oxygen atoms introduced by hydroxylations will extensively be discussed in Section 2.3 of this paper in context with aromatic compounds.

A slight ^{18}O enrichment is found in alcohols from olive oil. As they are probably reduction products of fatty acids, their $\delta^{18}O$ values are primarily going back to these precursors, which may be submitted to partial secondary oxygen isotope exchange with water. Citric acid from orange juice is ^{18}O enriched relative to the water between +17.6 and +21‰ in excellent agreement with the expected mean $\delta^{18}O$ value ~+19‰ (see first paragraph of this section). In conclusion, there is an oxygen isotopic correlation between carboxyl/carbonyl groups and water, but it is not as distinctly expressed as between carbohydrates and water, probably due to partially incomplete equilibrations.

The situation must be more complicated with higher fermentation alcohols, some of which are originating from amino acids or intermediates of their biosynthesis (e.g. *i*-butanol and *i*-pentanol; Fig. 4). Their precursors, α-keto acids, can be products of transamination reactions, and their keto group must therefore contain oxygen atoms from water introduced by the hydrolysis of a Schiff-base with pyridoxalphosphate (PLP). As discussed for the aldolase, the corresponding introduction of oxygen atoms from H_2O may imply a kinetic isotope effect (KIE), and the enzyme may even catalyze an oxygen isotope exchange; thus the final degree of equilibration will depend on the relative velocity of substrate binding and transformation. The subsequent oxidative decarboxylation of the α-keto carbonic acid will probably not alter this situation, and therefore the $\delta^{18}O$ value of the aldehydes and alcohols should be close to the level of the surrounding water. Corresponding experiments are in progress in our laboratory.

The logic continues with natural esters (Table 4). Once synthezised, they do no longer exchange oxygen atoms with water under the conditions in biological systems, hence preserve the $\delta^{18}O$ values of their precursors and the isotope fractionations implied by the isotope effects in the course of their formation.

The alcohols from natural esters show $\delta^{18}O$ values as already found and discussed for the corresponding (non equilibrated) free alcohols (+4 to +8‰, Table 3), while the acid moieties, obtained from difference calculations, show very high ^{18}O enrichments. These are probably due to an intramolecular ^{18}O isotope effect on their activation during esterification, as already outlined before (Fig. 4). This may not be the case with fatty acids, because they are directly transfered to CoASH from the

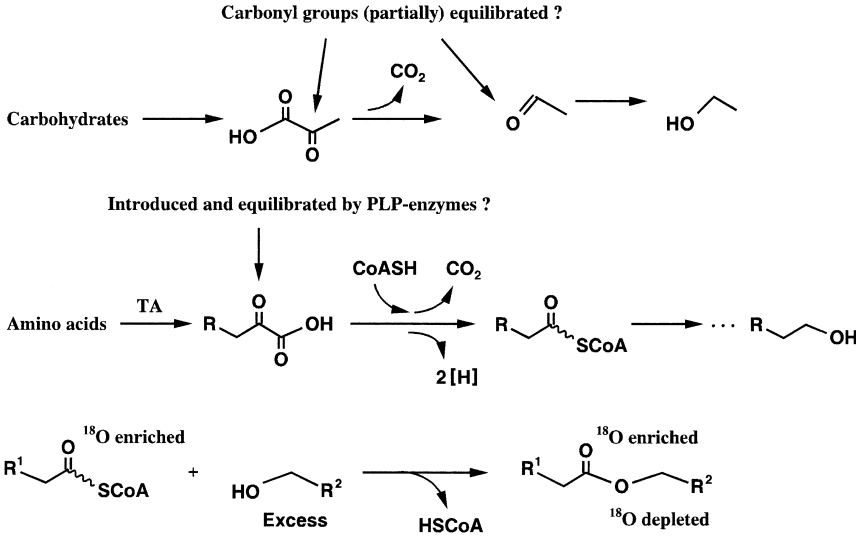

Fig. 4. Oxygen origin in alcohols and esters. In the course of the fast alcoholic fermentation to ethanol, the oxygen atoms from positions C-2 and C-5 may partially be preserved. Oxygen in higher alcohols originating from amino acids, may originate from water. The formation of esters is accompanied by isotope effects. TA = transamination, PLP = pyridoxalphosphate.

Olive oil (Mediterranean)	+20.7 to +28.5 [+22 to +28] [+16 to +22]						Angerosa et al. (1999)

[a] After hydrolysis only the $\delta^{18}O$ value of the alcohol has been determined, that of the acid is calculated from the difference to the ester.
[b] Values in parentheses are calculated from mean $\delta^{18}O$ values of glycerol (Table 3).

multienzyme complex of fatty acid biosynthesis. In this context it has to be mentioned that the incorporation of ^{18}O from labelled acetate into fatty acids is less than the 50%, which are to be expected from the loss of one O atom by the activation reaction (Pollard and Ohlrogge, 1999). As a possible reason the authors discuss a kinetic isotope effect on this reaction, although they admit that they are "unaware of its magnitude and direction". We believe that such an isotope effect would more probably lead even to ^{18}O enriched acetyl-CoA and that therefore the observed ^{18}O depletion must be due to an overlap of a partial oxygen isotope exchange of the precursor with water before its activation.

Anyway, the $\delta^{18}O$ values of triglycerides from various plants suggest their ^{18}O enrichment of approximately +17‰ above the plant water. A more reliable indirect calculation can be made for (the triglycerides from) olive oil (Angerosa et al., 1999): Independent of the extreme abundance range of their $\delta^{18}O$ values (+19 to +31‰), the mean $\delta^{18}O$ values for olive oils from the same region are more constant (e.g. Italy $+20.7\pm1.5$‰, Morocco $+28.5\pm1.2$‰) and they correspond to the $\delta^{18}O$ values of the precipitation in these areas (−8.8 to 0‰; Förstel et al., 1975). If we assume from here that the mean $\delta^{18}O$ values of the leaf water are in the range of −2 to +7‰, an ^{18}O enrichment of the triglycerides relative to water of approximately +22‰ results. As the enrichment observed for glycerol is approximately +25‰ (Table 3), the enrichment for the fatty acid moiety must be near +19‰. Again this $\delta^{18}O$ value is as observed for free fatty acids (Table 3) and is as expected (Wedeking and Hayes, 1983). On the base of a $\delta^{18}O$ value range for water in plants between −5 and +8‰ (different organs), a range of +14 to +26‰ has to be assumed for equilibrated fatty acids and their descendants; carbonyl compounds may be more enriched in ^{18}O.

The ^{18}O pattern of synthetic esters (sometimes produced from natural precursors) is similar to that of natural ones. This is in line with the mechanisms and isotope effects on the corresponding synthesis reactions (Fig. 5). For example, the acid-catalyzed esterification of *n*-butyric acid with *n*-hexanol was accompanied by a large intramolecular isotope effect on the oxygen elimination from the carboxyl moiety [$k_{16}/k_{18} = 1.058$] leading to a high ^{18}O enrichment in this moiety, and a kinetic isotope effect on the oxygen atom of the alcohol moiety [$k_{16}/k_{18} = 1.014$] which has for consequence a ^{18}O depletion in the corresponding position (Werner, 1998). The actual $\delta^{18}O$ values were depending on the individual conditions of the esterification, especially on the relative ratio of the reactants used for esterification. Furthermore, it has to be pointed out, that the use of carbonic acid anhydrides for esterification implies additionally a large intramolecular carbon isotope effect, because the preferred transfer of the "light" acyl group results in a remarkable ^{13}C depletion at the CO position of the acyl moiety (Werner, 1998; Schmidt et al., 1999).

Like the enolase and the fumarase reaction, other lyase reactions, isomerisations (e.g. by aconitase) and epimerisations (glucose/galactose) as well as any hydrolase reaction will introduce OH^- from water into their products (Mayer and Larner, 1959), and all of them probably imply kinetic isotope effects. Finally, one has to keep in mind that also most synthase reactions basing on phosphorylations with ATP deal in some way with participation of OH groups of the reactants and water.

2.3. Aromatic compounds — oxygen functions from O_2

It has been known for a long time (Gray and Thompson, 1977) that the $\delta^{18}O$ value of aromatic compounds, mainly lignin, shows an ^{18}O depletion in comparison to primary compounds, such as cellulose, attaining $\delta^{18}O$ values around +12‰. The fundamental structural element of these compounds is the phenylpropane unit, synthesized via the shikimic acid pathway (Haslam, 1993a) from erythrose-4-phosphate and phosphoenolpyruvate (PEP; Fig. 6). Some aromatic compounds are thought to

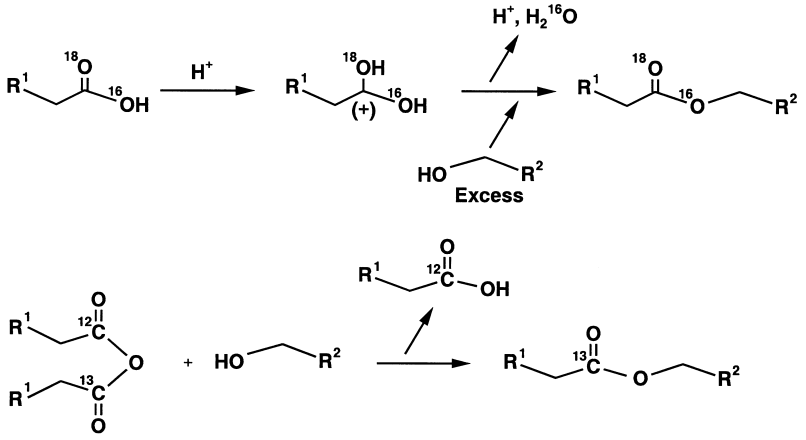

Fig. 5. Intramolecular ^{13}C- and ^{18}O-isotope effects on the acid moiety, and kinetic ^{18}O-isotope effects on the alcoholic component in the course of an acid catalyzed esterification.

be synthezised directly from shikimic acid, which would imply the origin of their phenolic hydroxyl group from this precursor, and therefore a high ^{18}O abundance (corresponding to quinic acid; Table 1). In the synthesis of phenylpropanes by plants the last non-aromatic intermediate is arogenic acid, yielding tyrosine by dehydrogenation, phenylalanine by dehydratation. As plants cannot hydroxylate phenylalanine, here any tyrosine and its descendants, like some alkaloids, preserve the highly ^{18}O enriched oxygen function from erythrose in the *p*-position. Tyrosine can also be converted to *p*-coumaric acid, however, a remarkable tyrosine-ammonia-lyase activity has so far only been observed in *Gramineae* (or *Poacea*, grasses, cereals; Kindl, 1991; Richter, 1996). The predominant pathway in plants to *p*-coumaric acid is the hydroxylation of cinnamic acid, hence by introduction of oxygen from O_2. Correspondingly, most further oxygen bound to the aromatic ring originates from O_2, and is introduced through hydroxylations by monooxygenases, mainly of the P-450-type (Haslam, 1993b; Bolwell et al., 1994; Richter, 1996). Plant dioxygenases (Prescott and John, 1996) introduce both oxygen atoms from O_2 into their substrates; however, very often one of the primarily bound O atoms is rapidly lost as H_2O or transferred to an acceptor, the other one can, after a secondary conversion of the oxygen function to an sp^2 structure, be exchanged with the surrounding water (synthesis of jasmonic acid, initiated by a lipoxygenase). This is also the case for the oxygen atoms introduced in the course of photorespiration (Berry et al., 1978; Cooper and DeNiro, 1989). Dioxygenases are for example involved in the biosynthesis of tropolones and some alkaloids; here they may lead to non-exchangeable oxygen functions, which should, however, in the present context, not much differ from those introduced by P-450-type monooxygenases.

It is very probable that all these reactions imply (kinetic) isotope effects. However, as no corresponding data are available for the oxygenated products, we have to deduce them from measured isotope effects on O_2, obtained in context with the production, reduction and activation of this molecule by biological systems: Molecular oxygen in the atmosphere has a constant $\delta^{18}O$ value of about +23.5‰ and is thus largely enriched relative to sea water [''Dole effect''; Dole (1935); Morita (1935); for a recent review see, e.g. Keeling (1995)]. Already Lane and Dole (1956) showed that an important contribution to this enrichment is due to isotope discriminations by respiration (see also, e.g. Wagener, 1974). While oxygen from the photosynthetic water fission is not ^{18}O enriched, dissolved oxygen in the ocean can be enriched in ^{18}O up to 14‰, and this enrichment is inversely correlated with the O_2 content of the water; this effect is attributed to bacterial respiration processes (Kroopnick and Craig, 1976). It has generally been observed that the photosynthetically evolved O_2 originates from the water in the chloroplasts (Guy et al., 1993; Keeling, 1995). Climate and transpiration may indirectly contribute to a small variation of the absolute $\delta^{18}O$ value via the enrichment of the leaf water (Dongman et al., 1972; Wagener, 1974); so Schleser (1979) observed the formation of O_2 with +4.5‰ from land plants. Stevens et al. (1975)

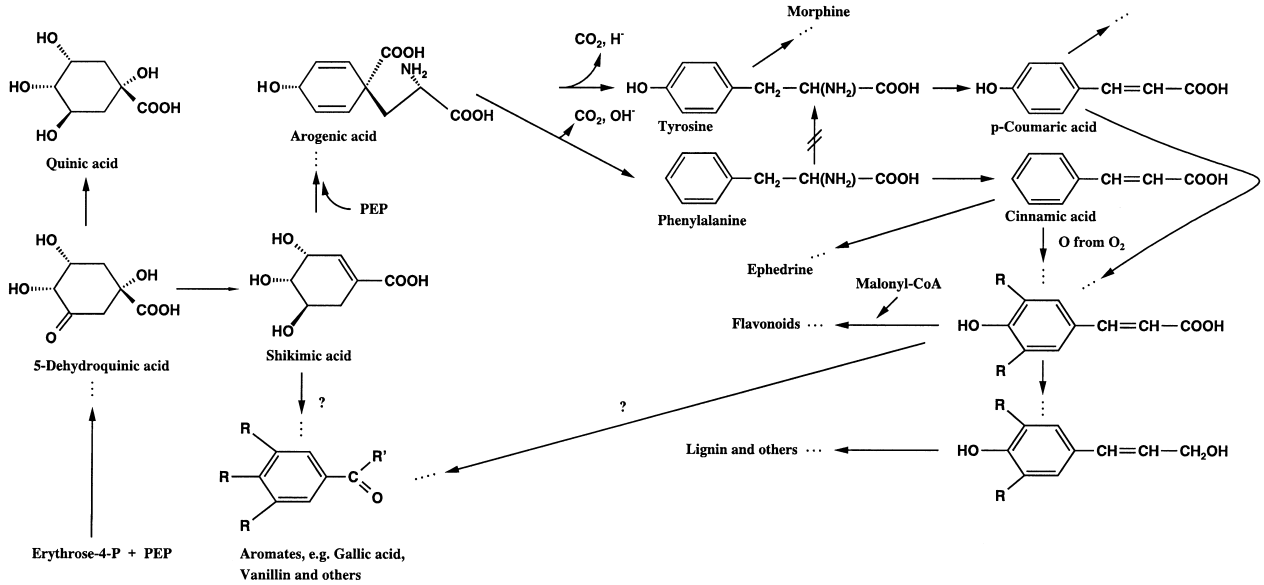

Fig. 6. Oxygen sources in aromatic compounds originating from the shikimic acid pathway. Indication of the different origin of the oxygen atom in *p*-position depending on the dehydrogenation or dehydratation of arogenate, respectively. Correspondingly, the alternative possibilities of the biosynthesis of vanillin are shown. In case of the direct origin of oxygen from shikimic acid the phenolic oxygen in *p*-position would be highly ^{18}O enriched. The synthesis via cinnamic acid implies hydroxylation, hence a $\delta^{18}O$ value near +6‰. The latter pathway is confirmed by the $\delta^{18}O$ values of vanillin (Table 6). PEP = phosphoenolpyruvate, R = –H,–OH or –O–CH_3; R′ = –H or –OH.

showed that photosynthetically produced O_2 by blue-green and green algae has nearly the same $\delta^{18}O$-value as the surrounding water ($\Delta\delta^{18}O$: −0.5‰). A certain contribution to the ^{18}O enrichment of atmospheric O_2 can also be due to photorespiration (Berry et al., 1978; Guy et al., 1987), the kinetic oxygen isotope effect on the ribulosebiphosphate–oxygenase reaction itself being near 1.03 (Kreckl et al., 1989). A further small contribution may also originate from the ''Mehler reaction'', the production of H_2O_2 by O_2 reduction in the case of a lack of another electron acceptor (Kreckl, 1988). However, in total the Dole effect is due to isotope effects on oxidation reactions.

Any electron transfer to O_2 by proteins is preceded by a (reversible?) binding of O_2, which by itself could already imply an equilibrium isotope effect. In Table 5, observed equilibrium and kinetic constants for oxygen binding, reduction and activation are compiled. The following conclusions can be derived from this table: Isotope discriminations are implied in O_2 binding, reduction and activation; the discrimination connected to a hydroxylation seems to depend on the enzyme system involved. So, for example, the isotope effects on the cytochrome oxidase and on spinach mitochondria reactions correspond to that between the binding isotope effect by a porphyrin and a copper protein, respectively, while, on the other hand, the discrimination observed for the Mehler reaction (probably flavoprotein catalyzed) exceeds that calculated for the H_2O_2 formation. In total, all oxygenase and oxidase reactions obviously imply oxygen isotope fractionations; these seem to be partially due to equilibrium isotope effects on the binding of O_2, however, may be overlapped by isotope effects on oxygen activation and transfer. In addition, in living plants, isotope effects on oxygen diffusion processes may contribute to the in-vivo oxygen isotope discrimination (Zanconato et al., 1992; Aggarwal and Dillon, 1998).

Any data reported in Table 5 deal with the ^{18}O enrichment of the non-converted dioxygen. The stoichiometry of a monooxygenase reaction ($R–H + O_2 + NADPH + H^+ \rightarrow R–O–H + H_2O + NADP^+$; Sono et al., 1996) and the isotope balance demand a corresponding ^{18}O depletion in both products, R–O–H and H_2O, independent on the relative influence or contribution of the above mentioned oxygen isotope effects. Assuming in an first approach a statistical transfer of the two oxygen atoms from O_2 to R–O–H and H_2O, respectively, one can postulate, on the base of the data in Table 5, as a mean value of a discrimination factor for the hydroxylation reaction $\alpha = 1.02 \pm 0.003$, where $\alpha = 1023.5/\left(\delta^{18}O_{Prod.} + 1000\right)$. Starting from the infinite O_2 pool with $\delta^{18}O = +23.5‰$, one has to expect $\delta^{18}O$ values for R–O–H between 0 and +7‰; the $\delta^{18}O$ values found for sterols ($+5.5 \pm 2.4‰$, Table 3) confirm very well this expectation. Deviations

[a] n. = natural; n.i. = nature identical.
[b] Calculation of most expected $\delta^{18}O$ values are based on the mean $\delta^{18}O$ values for molecule parts or functional groups: phenolic OH = +6‰; carbonyl and carboxyl O = +19‰ above water.
[c] Probably guajacol of natural origin as precursor.

from this $\delta^{18}O$ range may occur from partial incorporation of intrinsic oxygen from photosynthesis with a very low $\delta^{18}O$ value, and from differences in the ^{18}O discrimination by individual enzymes.

In order to arrive at a uniform discussion of the available experimental results, we have assumed a mean $\delta^{18}O$ value of +6‰ for the non-exchanging oxygen functions in aromates originating from O_2. By inclusion of the former outlined $\delta^{18}O$ values of other oxygen containing functional groups, mean $\delta^{18}O$ values of natural compounds can be deduced from the increments (Table 6).

Thus the $\delta^{18}O$ values of anethol, eugenol and safrole, respectively, as representatives for aromatic compounds containing only phenolic oxygen from O_2, fit very well with those expected from the preceding considerations. The same is true for the $\delta^{18}O$ values of natural benzaldehyde and cinnamic aldehyde, representing aromatic compounds with a carbonyl group as oxygen function, provided this is not caused by an artifact in the course of the isolation procedure. The calculated $\delta^{18}O$ value of raspberry ketone as a representative for both groups is identical to that found experimentally by Fronza et al. (1999), while the $\delta^{18}O$ value found for the corresponding alcohol from the same source, betuligenol, is only +9.2‰ (expected $\delta^{18}O$ value +14.0‰). The reductive elimination of the phenolic hydroxyl group leads to 4-phenyl-butanol-(2) with a $\delta^{18}O$ value of +19.2‰ (correct carbonyl $\delta^{18}O$ value !), from where a $\delta^{18}O$ value for the phenolic group of −0.8‰ results. The oxygen isotope pattern of raspberry ketone from lindleyin, a glycoside from a succulent, is quite similar (total $\delta^{18}O$ value +12.4‰, phenolic OH group +0.6‰, from where a $\delta^{18}O$ of +24.2‰ results for the carbonyl group. (Fuganti, personal communication). Thus, the $\delta^{18}O$ value of the OH group of this compound is at the lower edge of the $\delta^{18}O$ range assumed for products of monooxygenase reactions (0 to +7‰). This is not the case with the $\delta^{18}O$ value of the *p*-hydroxyl group of the phenylpropane unit of naringenin, a flavonoid from citrus fruits, which was found to be +12‰ (Fuganti, personal communication); a tentative explanation for this unexpected finding could be that the molecule moiety in question is *partially* originating from tyrosine, thus preserving in part the oxygen atom from shikimic acid (Fig. 6).

Investigations so far available on the biosynthesis of natural vanillin did not permit a decision between two alternative pathways (Funk and Brodelius, 1994; Schmidt and Gleixner, 1998b; Werner, 1998; Fig. 6); the ^{18}O data could help to solve this problem. One of them, the immediate origin from shikimic acid, would imply the preservation of one of the oxygen functions of this precursor in the aromatic nucleus ($\delta^{18}O$ value expected +30‰; see quinic acid, Table 1). This would have for consequence a mean $\delta^{18}O$ value of vanillin of (+30‰ +6‰ +24‰)/3 = +20‰. The experimentally found $\delta^{18}O$ value of approximately +12‰ confirms that the

aldehyde is synthezised via β-oxidation of ferulic acid, which demands a $\delta^{18}O$ value $(2\times6‰ + 24‰)/3 = +12‰$. Recent experimental data of the ^{18}O pattern of natural vanillin (Fronza et al., 2001) showed $\delta^{18}O$ values of $+5.8‰$ for the phenolic oxygen, $+2.7‰$ for the methoxyl oxygen (probably due to the introduction of the second oxygen atom by a copper containing monooxygenase with slightly higher isotope discrimination), and $+26.2‰$ for the carbonyl oxygen (corresponding to an enrichment $> +19‰$), and a mean global $\delta^{18}O$ value $+11.5‰$.

If we apply our theoretical increments to the oxygen atoms from the different functional groups of other aromates (Fig. 7), in most cases a perfect agreement results with their experimental $\delta^{18}O$ values. The somewhat too low $\delta^{18}O$ values as calculated for hesperidin and hesperetin may result from a wrong $\delta^{18}O$ value assumed for citrus water (however, compare discussion above on naringin). In the case of lignin a prediction is quite difficult: The monomers contain 1, 2 or 3 phenolic O–R groups, and one oxygen from the alcoholic function in the side chain, for which at least the mean $\delta^{18}O$ value of $+19‰$ may be assumed. Furthermore, we have to take into account that in the course of the oxidative polymerisation some additional oxygen functions from O_2 are introduced into the polymer. Hence, approximately 2–3 phenolic oxygen atoms will come on one alcoholic one; the resulting $\delta^{18}O$ value $(2.5\times6‰ + 19‰)/3.5 = +9.7‰$ fits quite satisfactorily into the scheme.

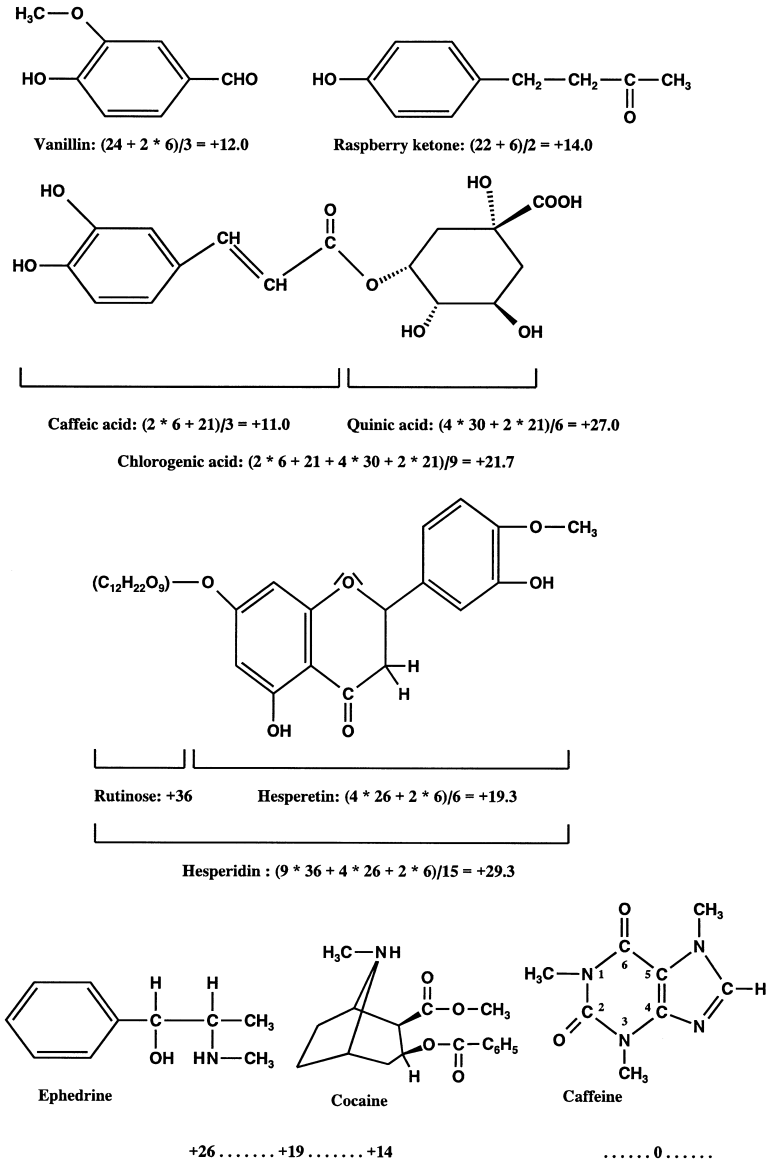

Fig. 7. Structures and calculated global mean $\delta^{18}O$ values of some natural aromatic compounds. The following $\delta^{18}O$ increments are used for calculation of $\delta^{18}O$ values of the different molecule parts (functional groups): Sugars: $+30$ to $+36‰$ (Tables 1 and 2); immediate carbohydrate descendents: $\ldots+30\ldots$ (Table 1); carbonyl and carboxyl groups: $\ldots+19\ldots$, lower limit $+13$, upper limit $+26‰$ above water; phenolic hydroxyl groups from O_2: $\ldots+6\ldots$ (corresponding limits 0 and 7‰).

The $\delta^{18}O$ values of some alkaloids with well-known origin and biosynthesis are included in Table 6. Ephedrine is a sympathicomimetic drug from *Ephedra vulgaris* or *Ephedra distachys*, shrubs growing in dry areas of Asia and America and around the Mediterranean Sea. The main precursor of the alkaloid is phenylalanine (Grue-Sørensen and Spenser, 1988); this is degraded to benzaldehyde, which is then condensed with "active acetaldehyde" to phenylacetylcarbinol. The alcoholic oxygen atom remaining in the side chain at the end of the biosynthesis is originating from the intermediate benzaldehyde; it is obvious that the $\delta^{18}O$ value (+33‰) is due to a large ^{18}O-enrichment of the plant water in an aride climate, simultaneously, it is the expression of an exceptional equilibrium isotope effect. The source of (−)-cocaine is *Erythroxylon coca*, a bush growing originally in the higher areas of Peru and Bolivia. The precursors of the alkaloid are ornithine, acetoacetate and benzoate. The oxygen carriers are therefore exclusively carbonyl/carboxyl groups, and the $\delta^{18}O$ value is — with regard to the altitude of the growth area — to be placed at the lower edge of the abundance limits, namely near +14‰ (recent tracer studies on the biosynthesis of tropane alkaloids with ^{18}O labelled precursors proved a complete oxygen isotope exchange with water; Duran-Patron et al., 2000). Again the $\delta^{18}O$ value found ($+13.9 \pm 1$‰, $n=7$) is in absolute agreement with this prediction. The precursors of natural papaverine and morphine are two moles of tyrosine in both cases, hence introducing oxygen from erythrose. In papaverine these are supplemented by two oxygen atoms from O_2; the expected $\delta^{18}O$ value is therefore $(2\times 26‰ + 2\times 6‰)/4 = +16‰$. The quite satisfactory agreement of the experimental $\delta^{18}O$ value ($+14.7 \pm 0.3$‰) may nevertheless be by chance, because most commercially available papaverine samples are said to be synthetic. In the case of the biosynthesis of morphine from tyrosine (Amann and Zenk, 1996), the primary introduced oxygen atoms are partially equilibrated with those from water. Even if one takes this into account, the experimental global $\delta^{18}O$ value (-2.2 ± 1‰) is far away from that as expected (+17.0‰). Easier to know and understand is the origin of the oxygen atoms in caffeine. One of them is introduced in the course of the incorporation of HCO_3^- into position 6 of the purine nucleus, the other by the addition of H_2O to the double bond between positions 2 and 3. One has to assume that the first oxygen function is probably heavily enriched towards water (for HCO_3^-/H_2O, $K=1.033$ at 0°C), while the second one is probably depleted due to a kinetic isotope effect on the addition reaction. Furthermore, both positions should be submitted to a secondary partial oxygen isotope exchange with water. This complicated situation implies a correlation of the $\delta^{18}O$ value of caffeine to the leaf water, however, in a way very sensitive to the individual conditions of plant cultivation and climate. This is exactly what has been found by Dunbar and Wilson (1982); the $\delta^{18}O$ value of caffeine varies between large limits, and it depends from the plant and the individual climate conditions of its cultivation.

Therefore, the systematic determination and observation of $\delta^{18}O$ values of natural compounds does not only help with the confirmation and explanation of biosynthetic pathways; the results also underline the general importance of the present considerations for the authenticity assignments e.g. of flavour, aroma compounds and drugs.

3. Concluding remarks

Our first successful systematic attempt to correlate $\delta^{18}O$ values of a compound to its precursors and (bio)-synthesis dealt with nitrate; on the basis of this result it became possible to assign the origin of this important ion to bacterial nitrification, chemical synthesis and atmospheric events (Amberger and Schmidt, 1987; Voerkelius and Schmidt, 1990). The present compilation of ^{18}O abundances of natural compounds and their interpretation on the base of biosynthetic reactions and their mechanisms confirms our earlier postulation (Schmidt et al., 1995; Schmidt and Gleixner, 1998a,b) that oxygen atoms in these molecules are originating from three different primary sources, namely H_2O, CO_2 and O_2, and that they are introduced by different mechanisms with different isotope effects and are submitted to different degrees of equilibration with water.

As summarized in Fig. 8, leaf water in plants is the most important oxygen source, either directly (addition or exchange) or indirectly via CO_2 or as the source of photosynthetic O_2. So far, it has generally been assumed that carbohydrates in photosynthesizing plants are in isotopic equilibrium with the surrounding water in any position. This is obviously not always the case (Roden and Ehleringer, 1999), and therefore we believe that carbohydrates have a distinct ^{18}O pattern, and that their global $\delta^{18}O$ value, which is correlated to that of the water, is only a mean of this pattern. Our opinion is supported by the fact that the expected correlation slope near unity has been reported only once (DeNiro and Cooper, 1989). Furthermore, differences between the $\delta^{18}O$ values of cellulose and reserve carbohydrates from the same source are observed: The latter are explained on the base of the partial degradation of these precursors to trioses before resynthesis of hexoses (Hill et al., 1995). Correspondingly, variations observed in the $\delta^{18}O$ values of monosaccharides and glycerol from different species are discussed on the base of physiological differences and variations of time for oxygen isotope equilibration (Fogel and Cifuentes, 1993). Finally, there is evidence that the postulated oxygen isotope equilibrium is not attained in the case of heterotrophically synthesized carbohydrates.

Fig. 8. Correlations between the $\delta^{18}O$ values of organic compounds or functional groups and that of the primary oxygen sources in plant metabolism (modified after Schmidt and Gleixner, 1998b; Werner, 1998). [1]O from acyl groups; O from carbonyl groups may exceed this value by 7‰.

Our data prove that also carbonyl and carboxyl groups from other compounds exchange oxygen atoms with water, however, the equilibrium may not always be attained and the enrichment is not as high as in carbohydrates. Distinct $\delta^{18}O$ values are observed for alcohols, depending on wether they are synthezised by addition of OH^- or H_2O, by reduction of carbonyl compounds or by hydroxylation. The latter is the case for sterols and aromatic compounds; and the monooxygenase reactions imply an isotope fractionation factor near 1.02. In total, on the base of these explanations the $\delta^{18}O$ value of a corresponding position and the global $\delta^{18}O$ value of a given compound can be predicted, and this is not only of fundamental importance for the understanding and elucidation of biochemical pathways but also for the origin and authenticity assignment of flavour and fragrance compounds.

If we apply Galimov's theory of the "thermodynamically ordered isotope distribution" to oxygen isotope abundances, a good correlation between $\delta^{18}O$ values and β_Σ-factors (Galimov, 1985) is found for H_2O, CO_2, and some plant products like carbohydrates (by chance?) and related compounds (Fig. 9); in these cases, small deviations from the thermodynamic equilibrium line may indicate that the equilibration with water has not completely been attained. Larger shifts, as observed for aliphatic acids and esters, may be due to the fact that only "basic" β_i increments have been available. They are expressions of binding enthalpies, and for a given bond, they are modulated by the type of other substituents of the same carbon atom (Galimov, 1985). This must also be true for oxygen–carbon bonds found in different functional groups, as unequivocally demonstrated by the substituent influence on oxygen equilibrium isotope effects on acids, esters and carbonyl compounds (Rishavy and Cleland, 1999). Thus, in the present case the applied β_i increments do have only preliminary character. The reason for the large deviation from the equilibrium line for all compounds, to which oxygen had been introduced by hydroxylation reactions (sterols, phenols) must be quite different. These substances are products of an irreversible unidirectional process, hence far away from equilibration with water. Therefore, their $\delta^{18}O$ value is kinetically determined, while the prerequisite for a thermodynamically dominated introduction of oxygen is that the biological system in question is close to steady-state conditions. A global view and critical general discussion of this aspect is the topic of a forthcoming paper by H.-L. Schmidt and E.M. Galimov.

4. Experimental

4.1. General experimental procedures

For the determination of the $\delta^{18}O$ value of soluble sugars, cellulose, glycerol, lactose and furaneol the coupled elemental analyser–IRMS system described elsewhere (Werner et al., 1996; Werner, 1998) was used. A sample amount corresponding to 80 μmol O was wrapped into silver capsules, put into the autosampler and pyrolysed at 1080°C over an inert glassy carbon grit. The pyrolysis gases were swept by the He carrier gas (He 5.0, 60 ml min^{-1}) through ascarite, magnesium perchlorate and active charcoal traps to remove residual traces of CO_2 and H_2O and to adsorb other unwanted

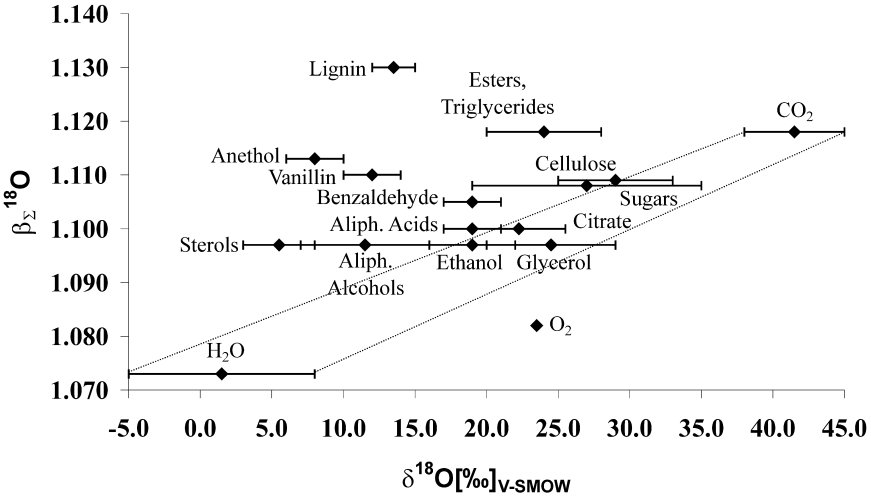

Fig. 9. $\delta^{18}O$ Values of H_2O, CO_2 and O_2 in mean natural abundance and $\delta^{18}O$ of natural products as compared with β_Σ ^{18}O factors calculated after Galimov (1985): The β_Σ factors are theoretical relative ^{18}O enrichments of the molecules in the state of "thermodynamical order". They are for H_2O: 1.0734, O_2: 1.0818 and for CO_2: 1.1086. The β_i increments for atoms in given positions are for ≡C–O–H: 1.097, =C=O: 1.105 and for ≡C–O–C≡: 1.130; from these results $\beta_\Sigma = 1/n\sum_i^n \beta_i$.

pyrolysis by-products. The pyrolysis gases then passed through a GC column packed with a molecular sieve 5 Å to separate the isobaric decomposition products N_2 (in case N-containing samples were pyrolyzed) and CO. Ergosterol, (–)-quinic acid, citral, anethol, emodin, hesperetin, hesperidin and chlorogenic acid were pyrolysed with the apparatus and method described by Kornexl et al. (1999b). At 1400°C, the samples (also wrapped in Ag capsules) were quantitatively converted to CO, H_2 and C (with traces of CH_4). The gases passed an ascarite trap and were separated on a GC column as described above. The minimum sample amount was 50 μmol O. Esters, corresponding alcohols and vanillin were pyrolysed using a "carbon reduction" irm–GCMS system (for details, see Werner, 1998). This carbon reduction coupling is analogous to that of the conventional GC combustion (and reduction) technique (Brand et al., 1994) with some modifications (Werner, 1998). The reduction furnace of the irm–GCMS system (freshly prepared, no CuO) was inactivated (120°C in order to avoid condensing and other unwanted reactions of water and other less volatile substances on/with the copper and to avoid possible isotope exchange reaction between copper oxide and CO). The alumina tube (320×1.0 mm i.d.) of the pyrolysis reactor contained a Ni tube (0.8 mm, ending in the heated area of the furnace). The transfer capillary to the reactor was adjusted into the Ni tube; additionally, a make-up or reaction gas flow enters the alumina tube in the GC furnace (outside the Ni tube). This "tube in tube" system was operated at 1250–1300°C. At this temperature the yield of CO from the conversion of H_2O and CO_2 with excess carbon was higher than 99.9%. The analyte mixture was separated on a GC column preceeding the pyrolysis reactor.

4.2. Origin of purchased natural compounds

Hesperidin from citrus, hesperetin (4-methoxy-3′, 5, 7-trihydroxy-flavanone), origin unknown, and emodin from *Frangula* roots were from Lancaster, 63155 Mülheim, Germany; chlorogenic acid and ergosterol, both of unknown origin, were purchased from Sigma-Aldrich Chemie GmbH, Deisenhofen, Germany; and (−)-quinic acid from *Cinchona ledgeriana* was from Roth, Karlsruhe, Germany. (L)-Ephedrine was a kind gift from Professor W. Steglich, München, Germany; (−)-cocaine and papaverine were kindly provided by Dr. R. Dahlenburg, Bundeskriminalamt, Wiesbaden, Germany. Natural and nature-identical furaneol® (2,5-dimethyl-4-hydroxy-3(2H)-furanone) was a gift from Dr. K. Kempe, Silesia, Neuss, Germany, and Professor A. Mosandl, Frankfurt, Germany. Most natural and nature-identical flavour and aroma compounds (anethol, benzaldehyde, cinnamic aldehyde, citral, various esters, vanillin from several sources) were also kindly provided by Dr. K. Kempe.

4.3. Isolation of natural compounds from various sources

4.3.1. Cellulose from beet leaves and roots

Sugar beet plants were separated in leaves and tubers, which were frozen in liquid N_2; the plant material was ground, freeze-dried and stored at −18°C.

Methods described by Brugnoli et al. (1988) and by Garnier-Dardart et al. (1976) were adapted for the isolation of different fractions from the plant material. 5 g ground leaf or tuber material were extracted three times with 150 ml boiling water. After centrifugation at 1200 *g* for 20 min the supernatant was collected for the isolation of soluble compounds. Dowex-50 (H^+) and Dowex 1X8 (Cl^-) resins were used to separate the ionic fractions

from the non-ionic soluble sugar fraction. This fraction was freeze-dried and stored in dry form at −18°C. The insoluble pellet was suspended several times in a boiling mixture of 80% ethanol/aceton (80:20), until after centrifugation both supernatant and pellet were colourless. Transitory starch was twice extracted with 20% HCl (w/w), and the solution was discarded. The residual plant material (1 g) was rinsed with water and then heated to 90°C for 1 h in 300 ml water containing 10 g $NaClO_2$ and 3 ml acetic acid (Green, 1963). Another 10 g sodium chlorite and 3 ml of acetic acid were added and heating was continued; this procedure was repeated twice. The solution was discarded and the residual fraction was washed with hot and several times with cold water. The residual holocellulose fraction was treated with 17% NaOH under continous stirring for 40 min. The cellulose was washed with 17% NaOH followed by several washings with 10% acetic acid and then distillated water. The product was dried after solvent exchange with acetone. A further drying for 72 h in vacuo followed. The isolated α-cellulose was stored in dry form at −18°C. The $\delta^{18}O$ value of the soluble sugar fraction and the cellulose was determined with EA–pyrolysis–IRMS as described above.

4.3.2. Sugars from fruit juices

The isolation was as described by Houerou et al. (1999).

4.3.3. Glycerol from milk and wine

The procedure was adapted from Kornexl et al. (1997) and Weber et al. (1997), respectively. The lipids from 1 l raw milk were separated by centrifugation at 3000 *g* for 10 min. The lipid phase obtained was dried in vacuo. 12.5 g of the dry lipids were heated with 100 ml 2 N NaOH for 1 h to 60°C under continuous stirring. After that the solution was acidified by 100 ml 2 N HCl, and the fatty acids were extracted with 100 ml diethylether/petroleum ether (1:1) in three portions. The aqueous phase was concentrated under reduced pressure, and the remainder was extracted with ethanol (1×20 ml, 3×10 ml). The combined extracts were filtered, the solvent was removed under reduced pressure, and the glycerol was purified by vacuum distillation (0.1 torr, 200°C). About 800 mg product were thus obtained. Animal fats were treated correspondingly. The isolation of glycerol from wine was performed as described by Roßmann et al. (1998).

4.3.4. Lactose from cattle milk

0.1 N HCl was added to 100 ml skim milk (Section 4.3.3) until the pH was 4.3. The casein was separated by centrifugation (1000 *g*, 10 min) and the precipitate washed twice with water. The first two supernatants were combined, filtered and then evaporated to dryness by lyophylisation. 1.1 g of the residue were redissolved in 30 ml water, the solution was heated for 10 min to 80°C. The precipitated whey proteins were separated by filtration. The filtrate and the first washing were lyophilized to yield approx. 1 g lactose.

4.3.5. Pretreatment of alkaloids

L-(−)ephedrine and papaverine were analyzed as received, (−)-cocaine was precipitated from an aqueous solution of the hydrochloride by 3.5% solution of NH_3, isolated by filtration and dehydrated over night at 65°C.

4.4. Hydrolysis of aliphatic esters

The hydrolysis of the esters and the separation of the products for isotope ratio analysis was as described under Section 4.5.3.

4.5. Estimation of the kinetic ^{18}O isotope effects on the H^+-catalyzed esterification of n-hexanol and butyric acid

4.5.1. Esterification with excess of n-hexanol

In order to obtain a 20% turnover of the alcohol and a complete consumption of the acid, 1 g (11.4 mmol) butyric acid, 5.8 g (56.9 mmol) *n*-hexanol and 0.23 g H_2SO_4 were heated for 5 h to 150°C (reflux). The excess *n*-hexanol was then eliminated by distillation. The remainder was treated with a 5-fold amount of ice water, and the ester was twice extracted with diethylether. The combined organic phases were neutralized by washing with Na_2CO_3 solution, then dried over Na_2SO_4 and concentrated in vacuo. The crude *n*-hexylbutyrate was purified by MPLC on kieselgel 60, using as eluent 10 ml *n*-pentane/methanol (99:1), then dichloromethane as solvent. The ester was detected via its absorption at 255 nm, its purity was controlled by GC. The ester containing fractions were combined, the solvent eliminated in vacuo.

4.5.2. Esterification with excess of butyric acid

The complete consumption of *n*-hexanol and a 20% turnover of butyric acid was attained by reacting 5 g (56.9 mmol) butyric acid, 1.16 g (11.4 mmol) *n*-hexanol and 0.23 g H_2SO_4. Reaction conditions and product isolation were as described before.

4.5.3. Ester hydrolysis

0.1 ml ester, 1.0 ml 0.1 N methanolic KOH and 0.25 ml 15% aqueous KOH were heated to the boiling point in a tightly closed test tube for 10 min. After cooling 1 ml diethyl ether and 0.5 ml saturated NaCl-solution were added, and the solution was acidified by dropwise addition of conc. HCl. After separation of the phases by centrifugation, the organic phase was washed with 0.5 ml saturated NaCl solution, and adjusted to pH 5.0 by the addition of a few drops of a 10% Na_2CO_3 solution. Then the organic phase was dried over Na_2SO_4.

4.5.4. Isotope abundance measurements and calculations

The $\delta^{13}C$ and the $\delta^{18}O$ values of the reactants and products were measured simultaneously by irm–GCMS as described under 4.1; the $\delta^{18}O$ value of acids from ester hydrolyses had to be calculated from the difference ester/alcohol.

The calculation of the intramolecular ^{18}O isotope effect on the acid during the esterification after O'Leary (1980) based on the δ value shift between acid and ester under the conditions of total alcohol consumption; it was $k_{16}/k_{18} = 1.058$ [k_{16}/k_{18} kinetic ^{18}O isotope effect]. Using this value and determining the $\delta^{18}O$ shift between starting materials and ester and/or conditions of partial alcohol but total acid turnover, the intermolecular oxygen isotope effect on the alcohol could be calculated $k_{16}/k_{18} = 1.014$ (for details see Werner, 1998).

Acknowledgements

The authors thank: Fabiano Reniero (JRC, Ispra, Italy) for valuable discussions and the provision of unpublished data on sterols, Claudio Fuganti (Centro CNR, Milano, Italy) and Fabiano Reniero and their colleagues for the permission to use data from their unpublished manuscripts on raspberry ketone and naringin, and on vanillin, respectively, Claude Hillaire-Marcel (Montreal, Quebec, Canada) for providing valuable references, Judith P. Klinman (Berkeley, CA, USA) for discussion on oxygen isotope effects and providing unpublished data, M.H. Zenk (LMU, München, Germany) for discussions on the tyrosine metabolism in plants, Willi A. Brand (MPI für Biogeochemie, Jena, Germany) for helpful discussions, Andreas Hilkert (Finnigan MAT, Bremen, Germany) for providing unpublished data, Barbara E. Kornexl (UFZ GmbH, Leipzig, Germany) for making available unpublished data and for the performance of some $\delta^{18}O$ value measurements, Harigh Avak (Finnigan MAT, Bremen, Germany) as well as Elke Sada (JRC, Ispra, Italy) for the performance of some $\delta^{18}O$ value measurements. Klaus Kempe (Silesia, Neuss, Germany) for supply of flavourings and performance of esterification and ester hydrolysis, A. Mosandl (Johann Wolfgang Goethe Universität, Frankfurt, Germany) for supply of strawberry flavourings and R. Dahlenburg, BKA Wiesbaden for providing some alkaloids.

Note added in proof

While this paper was in press, some additional data on polyketids and on flavonoids, natural products with oxygen functions from acyl groups, became available, which permitted to confirm and generalise the empirically assumed ^{18}O-enrichment of these oxygen atoms by $\sim +19$‰ above plant water. According to Burk and Stuiver (1981) the $\delta^{18}O$-value of precipitation water ($\delta^{18}O_{prec}$) in the northern hemisphere is correlated to the latitude ($\delta^{18}O_{prec} = -0.31^{*\circ}N + 5.76$), from where the oxygen isotope abundance of this precipitation water can be calculated in cases, where the $\delta^{18}O$-value of the plant water is not known. For corresponding calculations in the present context the following mean geographical latitudes have been assumed: Israel, Morocco, Tunisia 31°N; Cyprus, Spain, Turkey 35°N; Greece 38°N; (Central-)Italy 41°N; Central Germany 50°N.

Plant water is always enriched in the heavy isotopes ^{18}O and ^{2}H relative to the precipitation or ground water, and this enrichment depends on plant transpiration as a function of assimilation type (C_3-, C_4- or CAM-plant), plant species and organ, and on local conditions of climate (microenvironment and water availability). Thus, it can be assumed that the plant water ^{18}O-enrichment relative to precipitation water decreases with increasing northern latitude. So Houerou et al. (1999) give $\delta^{18}O$-values of the water from orange juices from Israel and Morocco +5.65‰, from Cyprus and Turkey +1.85‰; the calculated $\delta^{18}O$-values for the precipitate water of these areas (−3.85 and −5.09‰, respectively) indicate an ^{18}O-enrichment of +9.50 and +6.94‰ by the plant. The ^{18}O-enrichment of the citric acid from these juices relative to plant water is $+19 \pm 0.5$‰.

On the base of this knowledge it is now possible to exploit other data for a systematic correlation of oxygen from acyl groups to plant water: the mean $\delta^{18}O$-values given by Angerosa et al. (1999) for olive oil from Morocco/Tunisia are +27.30‰, from Spain/Turkey +25.04‰, from Greece +23.15‰ and from Italy +20.70‰. If one assumes for the plant water in these areas an ^{18}O-enrichment of +8.0, +6.5, +5.5, and +4.5‰ relative to the corresponding precipitation water, as calculated from the above equation ($\delta^{18}O$: −3.85, −5.09, −6.02 and −6.95‰), an identical ^{18}O-enrichment of $+23.5 \pm 0.5$ ‰ above plant water results for the triglycerides from all areas. Taking into account that half of the oxygen atoms in these triglycerides is originating from glycerol, which is enriched by +28‰ ($+27 \pm 2$‰, see Table 3 of review), a coresponding enrichment for the acyl moiety of $\sim +19$‰ results, identical to the experimental $\delta^{18}O$-value for citric acid mentioned before (Houerou et al., 1999).

The application of these results now permits to compare measured bulk global $\delta^{18}O$-values of natural compounds with those of their estimated patterns (Fig. 10). Assuming that hesperidine (Table 6 and Fig. 7 of review) is originating from oranges from Israel, the $\delta^{18}O$-values of its carbohydrate and its polyketid moieties can be calculated from the corresponding mean $\delta^{18}O$-value of orange juice water (+5.65‰); for the latter results +24.65‰, in case of the highest $\delta^{18}O$-value for this orange juice water (+6.50‰) +25.40‰, more

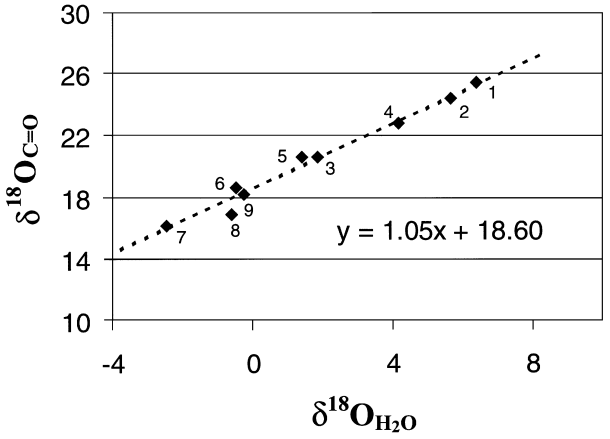

Fig. 10. Correlation between the $\delta^{18}O$ values of oxygen atoms in natural compounds originating from acyl groups ($\delta^{18}O_{C=O}$) and those of plant water ($\delta^{18}O_{H_2O}$). In cases where the latter was not directly available, it was estimated from the precipitate water as calculated after Burk and Stuiver (1981). Samples 2 and 3, citric acid from orange juice; samples 4 to 7 acid moiety of olive oil from Morocco/Tunisia, Spain/Turkey, Greece, and Italy, respectively; samples 1, 8 and 9 polyketid moieties from hesperidine (Israel?) and malvidine glucosides from Germany, respectively.

or less identical to the empirically assumed $\delta^{18}O$-value (+26.0‰). The reverse calculation for two malvidine glucosides from Palatine wines (Degenhardt et al., 2000) with global $\delta^{18}O$-values +18.10±0.45 and +18.56±0.24‰ for the organic compound and −0.62 and −0.25 ‰ for the corresponding water yields (on the base of an ^{18}O-enrichment of the oxygen atoms in the sugar moiety by 0.8* $\delta^{18}O_{H_2O}$ +29‰ and the $\delta^{18}O$-value +6‰ for the oxygen atoms introduced by hydroxylation) a $\delta^{18}O$-value +16.89 and +18.24 ‰ for the polyketid originating oxygen atoms, corresponding to their ^{18}O-enrichment of +17.51 and +18.49‰ above the water of the wines.

A calculation of the $\delta^{18}O$-values of the acyl originating oxygen atoms of two polyketids from the fungus *Cortinarius sanguineus Fr*. (Steglich and Austel, 1966: emodine, 4 acyl oxygen atoms, 1 from O_2, $\delta^{18}O = +17.8 \pm 0.2$‰ and dermocybine, 4 acyl oxygen atoms, 3 from O_2, $\delta^{18}O = +14.7 \pm 0.2$‰) yielded the identical $\delta^{18}O$-values +21.0±0.2‰ for the acyl oxygen atoms. This would correspond to a fungus cell water of +2‰, hence a quite high ^{18}O-enrichment of this water above the ground water from the origin area near München $\delta^{18}O$: ∼−10‰). Although it is known that these fungi are capable of remarkably enriching ^{2}H in their cell water relative to that of the host (H. Ziegler, private communication), a total ^{18}O-enrichment of +12‰ is quite improbable, and therefore an explanation of the result must be left to future discussions.

This is not the case with a contribution to the elucidation of an open question from the biosynthesis of gallic acid (Wolfgang Eisenreich and Adelbert Bacher, Technische Universität München, Germany, we are grateful for the permission to use these data), where the origin of the phenolic hydroxyl groups had to be elucidated. A product obtained by acid hydrolysis of a gallotannine from *Rhus* sp. in water ($\delta^{18}O = -10.7$‰) had a $\delta^{18}O$-value +21.2±0.7‰. The calculation [2*(19–10.7) +3*X]/5 = +21.2‰ yielded +29.8‰ for all phenolic OH-groups, hence their unequivocal immediate origin from shikimic acid; the alternative with one oxygen atom originating from O_2 would have demanded a global $\delta^{18}O$-value of +16.5‰.

We are highly obliged to Wolfgang Steglich (LMU München, Germany) for kindly providing the polyketid and to Peter Winterhalter (Technische Universität Braunschweig, Germany) for the malvidine glucoside samples. We thank Heike Geilmann (MPI für Biogeochemie Jena, Germany) for the $\delta^{18}O$ measurements.

Received 13 September 2000; received in revised form 15 January 2001; accepted 6 April 2001

Abstract

The hypersensitive response (HR), elicited when resistant hosts are infected by incompatible races of biotrophic fungi, has been researched extensively. New studies on host responses to necrotrophic fungi are beginning to show that when the HR occurs in hosts colonized by necrotrophs, fungal growth is accelerated rather than retarded. We review current knowledge about how necrotrophs survive in host plants in which the HR is expressed. We discuss how necrotrophs cope with the environmental factors formed as a result of the HR. Necrotrophs contain an array of enzymes, which can help in exploiting the hostile environment in order to colonize the host and to remove or inactivate active oxygen species (AOS). Among this array of enzymes are superoxide dismutase (SOD), peroxidases, catalase, and perhaps laccases and polyphenol oxidases. Of these, only SOD and catalase have been studied in any detail. The precise significance of SOD and catalase in host invasion and fungal resistance is still not adequately known. The importance of different peroxidases is also still far from clear. We speculate that AOS species may trigger the response of necrotrophs to the host environment. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

It is has been shown that various species of active oxygen (AOS), which are produced from dioxygen, i.e. the superoxide ion, O_2^-, the hydroxyl radical, $^{\bullet}OH$, and hydrogen peroxide, H_2O_2, are deleterious to cellular growth and development of many, if not all, living organisms (Halliwell and Gutteridge, 1998). Such active oxygen species, also termed "ROI, reactive oxygen intermediates" (Govrin and Levine, 2000), "ROS, reactive oxygen species" (Emri et al., 1999), or "active oxygen" (Greenberg, 1997), can disrupt cellular membranes, induce oxidative changes in DNA, and disrupt cellular metabolism (Halliwell and Gutteridge, 1998).

Nitrogen oxide (nitric oxide, $NO^{\bullet}$) is also involved in the host-pathogen interaction, and can modify the HR reaction. Nitric oxide is known to be formed readily by plants (Leshem, 1996; Leshem et al., 1998), and its production is induced as part of the host response to pathogens (Delledonne et al., 1998; Durner et al., 1998).

Lamb and Dixon (1997) describe the chemistry of active oxygen and give details of the reactions leading to their formation: the so-called "oxidative burst" i.e. the generation of active oxygen species in response to pathogens. Their review discusses the importance of this oxidative burst to disease resistance in higher plants. We also employ their terminology for the superoxide ion, O_2^-, and the hydroxyl radical, $^{\bullet}OH$.

Two classes of fungal plant pathogens are relevant to the discussion in this review:*necrotrophic fungi,* which kill host tissue and *biotrophic fungi,* which grow on living hosts. In this review we will stress aspects of the behaviour of necrotrophic fungi, e.g. *Botrytis cinerea*.

Necrotrophic fungi are able to exploit the host defense mechanism, enlarge the infection court and colonise the host (Govrin and Levine, 2000). Necrotrophic fungi are apparently not deterred by the hypersensitive reaction of the host, and stimulation of the HR facilitates host infection by *Botrytis cinerea*. In their work, Govrin and Levine do not discuss the enzymatic mechanisms by which the fungus protects itself from the host response and the formation of AOS. We suggest that in order to inactivate or remove the AOS species formed and to exploit the environment created by the hypersensitive reaction, necroptrophic fungi utilise an array of enzymes.

In this review, we pose the question: how does a necrotrophic fungal pathogen survive on a host expressing the HR, while a biotrophic pathogen does not? We analyse current knowledge of this aspect of the behaviour of necrotrophic fungal pathogens of plants (and probably all fungal pathogens). We also discuss how such pathogens protect themselves from the toxic or destructive effects of AOS during colonization of a host's tissue, and stress the importance of the enzyme systems, which may be involved. Disease resistance mechanisms other than the HR also have a role in defense against fungal pathogens (Yu et al., 1998), but we focus here on the HR of the host and the fungal response to it.

2. The host environment

In order to define the conditions that a necrotroph encounters when it colonizes a host plant, the HR environment is briefly described below.

2.1. The hypersensitive response

Fungal infection of a host resistant to a fungal plant pathogen leads to the "hypersensitive reaction", a term coined by Stakman (1915). The hypersensitive reaction includes a localized tissue collapse and cell death at the infection site. This is an active process triggered by fungal elicitors and orchestrated by an oxidative burst, which occurs rapidly, often within hours of the attack by avirulent pathogens (Levine et al., 1994; Lamb and Dixon, 1997).

The oxidative burst is one of the earliest responses of plants to an attack either by a non-pathogen, an avirulent race of a biotrophic pathogen (Lapinskas et al.,

1993; Lu and Higgins 1999), or by a necrotroph (Govrin and Levine, 2000). There is visible necrosis of the host tissue, and the necrotic region, which arises as a result of very complex events in the host, constitutes a defensive barrier. While this barrier prevents the spread of biotrophic fungi (Lamb and Dixon, 1997; Lu and Higgins, 1999), it does not prevent the subsequent spread of necrotrophic fungi. However, AOS alone may not always be sufficient to cause programmed cell death in the HR response, and additional factors such as iron availability or production of nitric oxide may be required.

In plants, the effects of the AOS can apparently be reversed or inhibited by NO, and it may act as a scavenger of AOS (Beligni and Lamattina, 1999). Yeast strains deficient in catalase or SOD showed increased sensitivity to peroxynitrite and nitric oxide (Jakubowski et al., 1999). These authors suggest that secondary AOS species are involved in the peroxynitrite induced cell death. Free radical scavengers were able to protect against the cytotoxicity of peroxynitrite. A regulatory role of NO in the interaction of plants and microorganisms has been discussed by Wojtaszek (2000) and by Bollwell (1999). Thus, NO formation by the host is part of the signalling process during the oxidative burst. Whether *Botrytis* or other necrotrophs are capable of removing NO or whether they can interfere in its formation remains to be determined.

Toxins produced by the pathogen may also contribute to host cell death (Duran-Patron et al., 1999).

2.2. Sources of active oxygen species (AOS)

AOS can be formed both by the host plant and by the invading fungal pathogen, and it is often difficult to distinguish experimentally between the actual sources of the AOS.

2.2.1. Reactions leading to AOS production in plants

The chief source of AOS in plants is the NADPH-oxidase catalyzed reaction between NADPH and O_2 leading to O_2^- formation, followed by a number of additional reactions including dismutation, which in turn lead to H_2O_2 production. There is some evidence for additional sources of AOS in plants, including their formation by oxalate oxidase and lipoxygenase, although these have not yet been described adequately (Lamb and Dixon, 1997). Hutcheson (1998) has extensively reviewed the oxidative burst in plant defense.

2.2.2. Reactions leading to AOS production in fungi

Fungi are themselves able to produce AOS using a number of mechanisms (Deighton et al., 1999; Von Goenner et al., 1993; Von Tiedemann, 1997). The precise mechanism that is operating in any given set of conditions probably depends to a large extent on the nutritional status of the fungus. The level of different enzymes that can breakdown or utilize hydrogen peroxide is also clearly affected by the conditions of growth of the fungus (Gil-ad and Mayer, 1999). Some of the possible reactions leading to AOS formation by fungi are briefly discussed below.

NAD(P)H-oxidases are enzymes that catalyze a widely described reaction that forms AOS as a by-product of mitochondrial electron transport and flavin dehydrogenase reactions. The O_2^- produced can be converted into other active oxygen species of which $^{\bullet}OH$ is the most reactive. The NAD(P)H-oxidases have been shown to produce superoxide in animals, higher plants, and fungi (Luttik et al., 1998). Apparently, they have not been studied in fungal pathogens, but they may be important in all aspects of host–parasite relations.

Sugar oxidases are a group of flavin, iron, and/or copper-containing proteins that oxidize their substrates while reducing dioxygen to hydrogen peroxide. For example, one of the major sugar oxidases is glucose oxidase, which is present in many fungal species. This enzyme is a FAD-containing protein that catalyzes the conversion of glucose to delta-gluconolactone and hydrogen peroxide. A glucose oxidase from *Botrytis cinerea* was characterized as a non-glycosylated tetrameric protein with a native molecular weight of about 160 kDa (Liu et al., 1998). The expression of glucose oxidase in *B. cinerea* and *Phanerochaete chrysosporium* was induced by low glucose concentrations in the culture medium (Kelly and Reddy, 1986; Liu et al., 1998).

Fungi usually contain a wide variety of sugar oxidases. Their many forms, whose activities result in formation of H_2O_2, suggest their potential importance in fungal metabolism and the infection process. However, since sugars are easily inter-convertible in fungi it would probably be difficult to show by gene-deletion analysis that a specific sugar is essential for the pathogenicity process

Xanthine oxidase catalyzes the formation of O_2^-, and often is used to generate free-radicals in assay protocols (Jocelyn, 1970; Zeng et al., 1997). Lipoxygenase activity, at least in plants, can also result in the formation of free radicals (Brash, 1999). Xanthine oxidase and lipoxygenase have been studied far less in plant and fungal systems than the sugar oxidases. Thus the list of enzymatic reactions, which are the basis for the HR is probably still incomplete.

3. Survival of necrotrophic fungi in the host environment

3.1. Effects of AOS on fungi

Studies on the yeast, *Saccharomyces cerevisiae*, provide an instructive view of the deleterious effects of AOS on fungal growth. Mutants of *Saccharomyces cerevisiae*,

null for both *SOD1* and *SOD2*, are defective in sporulation, have a high rate of mutation, and are unable to biosynthesize lysine and methionine (Liu et al., 1992). Yeast suppressors, which have bypassed the SOD defect ("bsd" strains), e.g. cells which lack SOD but which are resistant to oxygen toxicity, suppress a variety of biological defects associated with *sod1* and *sod2* null mutants. Thus, a single gene mutation can alleviate the requirement for SOD in cell growth. Both "bsd" complementation groups isolated by Liu et al. (1992) were unable to utilize many non-fermentable carbon sources, suggesting a possible suppressor-linked defect in electron transport.

3.2. Necrotrophs in the HR environment

How might necrotrophs protect themselves in the HR environment? Fungal parasites do have the ability to secrete enzymes in order to protect themselves from a hostile chemical in the environment. For example, *Botrytis cinerea* can protect itself against fungicides using some of the enzymes present in the fungus. Changed enzyme activities have been shown to occur in fungicide-resistant strains of *B. cinerea*. Choi et al. (1997) reported that Vinclozolin-resistant strains of *B. cinerea* had enhanced activities of both catalase and Cu,Zn-SOD. They suggested that both enzymes appear to be involved in protecting strains of *B. cinerea* resistant to the dicarboximide fungicide, Vinclozolin. In addition, catalase and SOD activities were considerably enhanced one hour after fungicide treatment in Vinclozolin-resistant isolates compared with the susceptible isolate.

Do necrotrophs secrete enzymes that would protect them against AOS in the environment of a host expressing the HR? There is an interesting correlation between AOS, resistance to fungicides, and infection that suggests how necrotrophs can survive in an AOS-rich host environment. It has been shown that AOS might be instrumental in killing host tissue during the initial stages of infection (Levine et al., 1994; Lamb and Dixon, 1997). In fact, Govrin and Levine (2000) have shown from detailed studies that the HR response by plants to pathogens facilitated the rapid growth and spread of *Botrytis cinerea* and probably also *Sclerotium sclerotiorum*. The hypersensitive response induced by other pathogens or elicited by fungi themselves restricted the spread of biotrophic pathogens, but accelerated the growth of necrotrophs. Their evidence has also suggested that the bulk of the hydrogen peroxide produced during an attack by *B. cinerea* originates from host metabolism.

3.3. Fungal enzymes capable of inactivating AOS

What enzymes, then, might fungal pathogens employ to protect themselves in an AOS-rich environment? Staples and Mayer (1995) considered the enzymes present in fungi that are able to breakdown cell walls and complex phenolics, as part of the attack mechanism. Here, we focus on fungal enzymes that may be active in protecting the fungus against the adverse environment created by the elicitation of the HR (Fig. 1).

3.3.1. Superoxide dismutases (SOD)

Superoxide dismutases (SODs) rapidly convert O_2^- and $^{\bullet}OH$ to O_2 and H_2O_2. SODs are metalloproteins found in all aerobic organisms. The enzymes prevent damage to cellular membranes caused by oxygen toxicity and photo-oxidation, and they are the primary

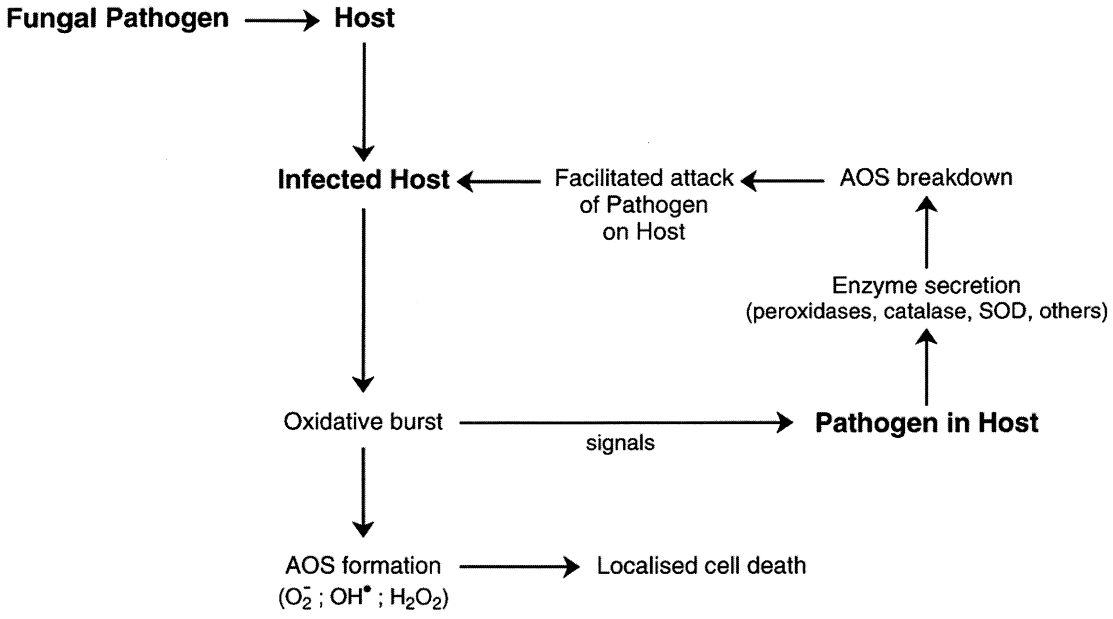

Fig. 1. Schematic presentation of some of the interactions between a plant host and a necrotrophic pathogenic fungus.

defense against the cellular damage that can be caused by the superoxide ion O_2^- (Fridovich, 1997). Fungal tissues, which lack the enzyme or in which it has been inactivated, exhibit a variety of defects.

There are at least three forms of SOD in eukaryotes: a cytosolic Cu,Zn-SOD, a mitochondrial Mn-SOD, and an extracellular Cu,Zn-SOD (Fridovich, 1997; Halliwell and Gutteridge, 1998). In addition, there is perhaps an iron-containing SOD. A wide variety of fungi have been shown to contain at least two of the three forms of SOD. Besides the earlier demonstration of SODs in yeast and *Neurospora*, the Cu,Zn-form of SODs have been found in various fungi that are pathogenic on plants and animals, including *Botrytis cinerea* (Choi et al., 1997), *Candida albicans* (Hwang et al.,1999; Rhie et al., 1999), *Cryptococcus neoformans* (Chaturvedi et al., 1999), and *Aspergillus japonicus* (Lin et al., 1994).

Fungal Cu,Zn-SODs appear to be rather closely related in terms of both structure and function. For example, the native Cu,Zn-SOD from *Candida albicans* (Hwang et al., 1999) has a mass of 39.4 kDa and is composed of two identical subunits with a molecular mass of 19.6 kDa. The gene *SOD1*, predicted a protein with 154 amino acids and a molecular mass of 16,143 Da, was found to be 79 and 69% similar to SOD genes from *Neurospora crassa* and *Saccharomyces cerevisiae*, respectively. The cloned *SOD1* contained an intron of 245 nucleotides. The gene for a cell-wall associated/excreted SOD was cloned recently from *Botrytis cinerea* (*BCSOD1*) by T. Quidde, K.-M. Weltring, and B. Tudzynski (pers. comm.). The gene has high homology to *CPSOD1* from *Claviceps purpurea* and to *SOD1* from *N. crassa*. A 21-kDa monomer of a tetrameric 85-kDa Cu,Zn-SOD was also isolated from *Uromyces appendiculatus* (Lamboy et al., 1995). A cell-wall associated, excreted Cu,Zn-SOD, which was cloned recently from *C. purpurea* (Moore and Tudzynski, pers. comm.) might be of the EC-SOD type; if proved, it would be new for pathogenic fungi.

A manganese-containing SOD from *Candida albicans* (Rhie et al., 1999) was a 106-kDa-protein composed of identical subunits with molecular masses of 26 kDa each. The gene *SOD2*, predicted a manganese-containing SOD, which contained 234 amino acid residues with a molecular mass of 26,173 Da, displayed 57% sequence identity to the homologue of *Saccharomyces cerevisiae*.

3.3.2. Activities of SOD in fungal pathogens

Vegetative hyphae of the phytopathogen *Fusarium oxysporum* differentiate into chlamydospores when triggered by growth on low-carbon media (Kono et al., 1995). In vegetative hyphae, three isozymes of SOD were present, none of which were inhibited by hydrogen peroxide and cyanide, whereas in chlamydospores, an isozyme was present and was inhibited by hydrogen peroxide but not by cyanide. Kono et al. (1995) concluded that as differentiation proceeded the Mn-type of SOD disappeared while an Fe-type of SOD appeared, and suggested that the Fe-type SOD is specifically expressed during chlamydospore formation. Direct evidence confirming the presence of an Fe-type SOD in *F. oxysporum*, which would be unusual for a fungus, was not provided.

3.4. Destruction of hydrogen peroxide

3.4.1. Catalase

This iron-containing enzyme catalyzes the rapid conversion of hydrogen peroxide to dioxygen and water. However, the enzyme appears to degrade hydrogen peroxide external to the fungal mycelia rather than the hydrogen peroxide produced internally by metabolism. Catalase is itself vulnerable to hydrogen peroxide as demonstrated by DeLuca et al. (1995).

Catalase is thought to play a key role as an antioxidant, protecting aerobic organisms from the toxic effects of hydrogen peroxide. For example, the filamentous penicillin-producing fungus, *Penicillium chrysogenum*, is especially resistant to the oxidative stress caused by high concentrations of H_2O_2 (Emri et al., 1997). Emri et al. (1997) claimed that the majority of the exogenous peroxide was likely removed by the high levels of catalase in the fungus, but that peroxide generated endogenously was removed by glutathione-pathway related enzymes. This could be taken as a hint that glutathione peroxidase also functions to reduce endogenous levels of peroxide in fungi. Thus, catalase appears to be involved only in protecting the fungus from exogenous hydrogen peroxide. However, the results reported by Gil-ad and Mayer (1999) do not support this conclusion as being general. Gil-ad and Mayer suggested that the involvement of catalase in breakdown of hydrogen peroxide seemed to be ruled out because the very specific inhibitor of catalase, 3-aminotriazole, had no effect on hydrogen peroxide breakdown. This is supported by the fact that SOD (but not catalase activities) responded when *P. chrysogenum* was treated with menadione, a drug that caused significant increases in the intracellular peroxide concentration of the fungus (Emri et al., 1999).

Wysong et al. (1998) cloned the *CAT-1* gene from the animal pathogen *Candida alibcans,* which coded for a protein of 487 amino acid residues and developed *CAT-1*-deficient mutants. These mutants exhibited normal morphology and comparable growth rates of both yeast and mycelial forms of the fungus. Enzymatic analyses revealed an abundance of catalase in the wild-type strain, decreasing catalase activity in heterologous mutants, and no detectable catalase in a homozygous null mutant. Mutant strains were more sensitive to damage by concentrations of exogenous peroxide that were sublethal for the parental strain, and the homozygous null mutant was far less virulent for mice. The authors suggested that catalase may be a pathogenicity

factor of *C. albicans* by protecting the fungus from the deleterious effects of hydrogen peroxide during host colonization.

Van der Vlugt-Bergmans et al. (1997) have proposed that the release of hydrogen peroxide by fungal oxidase activity served to facilitate host penetration by *Botrytis cinerea*, and they proposed that catalase activity might play a role in protecting the fungus against the damaging effects of hydrogen peroxide. They were able to show that *B. cinerea* contains a single-copy intracellular catalase gene, *CAT-A*, that codes for a 480-amino acid protein that most closely resembles the peroxisomal catalases. However, when *B. cinerea* colonized broad bean, *Vicia faba*, no *CAT-A* expression was detected by RNA blot analyses. From studies using tomato as the host plant, van der Vlugt-Bergmans et al. (1997) were able to confirm that there was no expression of *CAT-A* during host colonization by *Botrytis cinerea*, although hydrogen peroxide induced gene expression in an in vitro system of the fungus. It is known that hydrogen peroxide is produced during fungal colonization of the host plant, tomato, from the time of fungal penetration onwards. This hydrogen peroxide production therefore induced the tomato *cat1* gene, but not the fungal *CAT-A* gene. It is possible either that *B. cinerea* does not experience oxidative stress to the same extent as the plant host does, or that the fungitoxic effects of plant defense compounds accumulated around the necrotic lesion abolish *de novo* gene expression (Van der Vlugt-Bergmans et al., 1997). It is also possible that additional catalases other than *CAT-A* are present in *B. cinerea*, which may serve as pathogenicity factors.

More recent studies strongly suggest that indeed there are additional genes coding for catalase in *Botrytis* besides *CAT-A*. Evidence for at least one gene encoding an extracellular catalase in *B. cinerea* has now been obtained (Schouten and van Kan, pers. comm.), and the activities of these genes may account for the residual catalase activity demonstrated by Gil-ad and Mayer (unpublished data). Knowledge of the role of catalase in protecting fungal necrotrophs during host colonization awaits cloning and analysis of the additional genes.

Two catalase genes, *CPCAT1* and *CPCAT2* have been cloned from the fungal plant pathogen *Claviceps purpurea* (S. Moore and P. Tudzynski, pers. comm.). The role of these enzymes in the virulence of the pathogen is not known yet.

Two very divergent catalase genes, *CAT1* and *CAT2* have been described *in Cladosporium fulvum* (Bussink and Oliver, 2001). *CAT1* codes for a catalase subunit corresponding to peroxisome-localised catalases of yeasts and animal tissues. However, *CAT2* codes for a subunit of catalase similar to those found in filamentous fungi and bacteria. These two genes were differentially expressed, the product of expression of *CAT1* appearing in spores, while the *CAT2* gene was expressed in the mycelium. Neither of these catalases had an obvious secretory signal, nor could an extracellular catalase be detected. The catalase system of *Cladosporium fulvum* is clearly very complex and differs from that of yeast and of *Claviceps* and*Botrytis*.

Hydrogen peroxide diffuses readily into tissues, and it would therefore be difficult to determine whether an intracellular catalase or a secreted, extracellular catalase is acting on the substrate. The existence of a concentration gradient of peroxide between the medium and the mycelium would result in the disappearance of extracellular hydrogen peroxide by the action of either of these enzymes (Gil-ad et al., 2000; Gil-ad and Mayer, 1999). It has recently been shown that horseradish peroxidase can act as a scavenger of H_2O_2. (Baker et al., 2000). Thus, it is not impossible that some of the anomalous results on the function of catalase are due to a similar activity of fungal peroxidases.

3.4.2. Peroxidases

These are haem-containing proteins that catalyze the reduction of hydroperoxides, especially hydrogen peroxide to water. In addition, vanadium-dependent peroxidases are known (Van Schijndel al., 1993), and a haem-less peroxidase was reported as occurring in *Streptomyces* (Picard et al., 1997). A large number of peroxidases have been reported from fungi (Nakayama and Amachi, 1999), and elevated levels of peroxidase activity in host tissue have been repeatedly reported (Eshdat et al., 1997). But the origin of the increased activity is by no means clear, and may arise either from the host or from the pathogen.

Peroxidases have been found in almost all fungi studied. Among the fungal plant pathogens, *Botrytis cinerea* stands out as being very resistant to hydrogen peroxide (Gil-ad and Mayer. 1999). Spores of *B. cinerea* can germinate in the presence of up to 180 mM hydrogen peroxide, and mycelia are even more resistant (Gil-ad and Mayer, 1999). The breakdown is not inhibited by inhibitors of catalase, but is considerably reduced by inhibitors of peroxidase. The peroxidases in *Botrytis* and other pathogens have not been adequately characterized. Assay of a general peroxidase activity (guaiacol peroxidase) may not be an adequate measure of the ability of pathogens to remove hydrogen peroxide. Additional peroxidases, such as glutathione peroxidase and ascorbic peroxidase may well have a central function. Thus, while the level of guaiacol peroxidase activity showed great fluctuation depending on conditions of culture, ascorbic peroxidase and glutathione peroxidase levels were far more steady (Gil-ad et al., 2000).

There has not yet been a convincing demonstration that peroxidase protects a fungal pathogen from AOS encountered during colonization of its host plant. However, Gil-ad and Mayer (1999) concluded on the

basis of studies with inhibitors that the necrotrophic fungus *Botrytis cinerea* could protect itself from harmful peroxides by breaking them down with peroxidase. This conclusion is supported by the finding that *B. cinerea* forms intra- and extracellular peroxidases, including ascorbate peroxidase (Gil-ad et al., 2000).

Other peroxidases include the haloperoxidases, which have been described in the pathogenic fungi *Curvularia inaequalis* (Van Schijndel et al., 1993) and *Caldariomyces fumago* (Hager et al., 1966; Morris and Hager, 1966) and *Botrytis cinerea* (Bar-Nun and Mayer, unpublished). While the function of glutathione peroxidase, which inactivates hydrogen peroxide in animal tissues (Halliwell and Gutteridge, 1998), has not yet been investigated in fungi, its presence in plants has recently been demonstrated (Eshdat et al., 1997; Gil-ad et al., 2000).

3.4.3. Host-produced oxidases

While host-produced peroxidases might also serve as scavengers of AOS in the infection court (Gil-ad and Mayer, 1999; Von Tiedemann 1997), a direct demonstration has not been possible yet. However, consider, for example, that a versatile peroxidase able to oxidise Mn^{+2} as well as phenolic and non-phenolic aromatic compounds was isolated from *Pleurotus eryngii*, as well as the gene, *mmp1*, coding for it (Ruiz-Dueñas et al., 1999). Strong induction of *MMP1* expression was caused when the fungus was exposed to exogenous hydrogen peroxide, probably by a stress-response mechanism.

3.4.4. Laccases and polyphenol oxidases

An additional group of enzymes universally present in fungi (Mayer, 1987) include the polyphenol oxidases and laccases. An intermediary reaction product of the activity of laccases is a free radical, which could then easily interact with a variety of other radicals (Ferrari et al., 1997). While such reactions could lead to the initiation of complex reactions, including those with hydrogen peroxide or with other free radicals, little is known yet about the actual participation of these enzymes in protecting fungi in plant hosts expressing the hypersensitive response.

3.4.5. Alternative oxidase

Recently, a number of reports have indicated that plants deficient in the cyanide-sensitive alternative oxidase (AOX) had increased levels of AOS (Maxwell et al., 1999), while plants with reduced ability to detoxify AOS were hypersensitive to pathogen infection (Mittler et al., 1999). These results raise the possibility that fungal parasites could induce an increase in the level or activity of AOX in the host, for example by activating it, thereby reducing the levels of AOS. The activity of AOX is normally very tightly regulated. In either case, the hypersensitive reaction of the host would be reduced, thus facilitating pathogen development. At present, there is no evidence that fungal plant pathogens modify the levels of AOX in their hosts. However, it is also worth noting that fungi, including *Botrytis cinerea* contain an AOX, whose regulation differs from that of the plant enzyme (Tamura et al., 1999; Umbach and Siedow, 2000). The fungal AOX activity is not regulated by dimerisation. It is conceivable that such AOX could divert electrons from a host pool of ubiquinol following damage to the host cells.

4. Discussion and perspectives

When fungal plant pathogens colonize their hosts, they usually encounter a host resistance response, the generation of an environment around the pathogen rich in AOS, and death of host cells surrounding the infection site (Fig. 2). The dead host cells become a defensive layer that deprives the biotroph of a food supply. This layer also acts as a mechanical barrier, which the pathogen finds difficult to breach (Lamb and Dixon, 1997; Gilchrist, 1998). However, necrotrophs can exploit this host defense mechanism and enlarge the infection court to colonize the host (Govrin and Levine, 2000). In order to protect themselves and exploit this hostile environment, necrotrophic fungi contain an array of enzymes useful for infection of hosts, i.e. an assortment of enzymes capable of removing or inactivating toxic AOS. The mechanisms by which the production of some of these enzymes are controlled, either

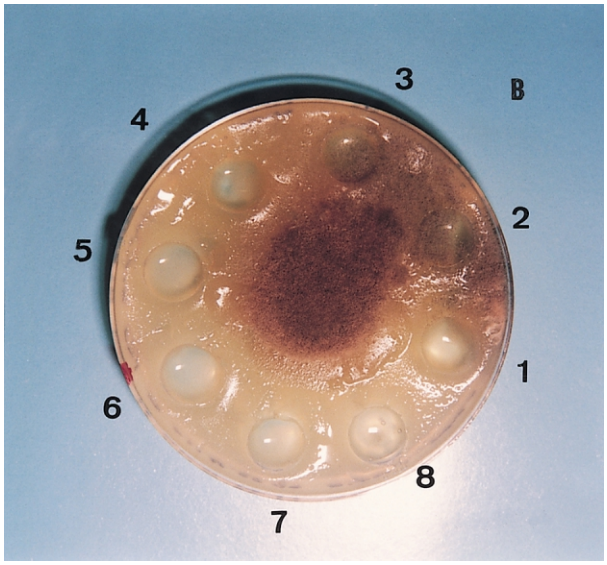

Fig. 2. Growth of *Botrytis cinerea* for 13 days on agar plates in the presence of hydrogen peroxide: 1 = 0.1 M; 2 = 0.2 M; 3 = 0.5 M; 4 = 1.0 M; 5 = 1.5 M; 6 = 2 M; 7. = 4 M; 8 = 6,4 M. The figure shows the ability of the fungus to cope with the presence of high hydrogen peroxide concentrations.

by internal or external factors, are far from clear at present, and measured enzyme activities can be expected to show great variability (Gil-ad et al., 2000).

Hydrogen peroxide is a stress factor in fungi, which acts as a trigger controlling their reaction to the environment. Consider, for example, that yeast cells have a major yeast stress-response regulon controlled by the H_2O_2-inducible *Yap1* transcription factor (Lee et al., 2000). Over all, yeasts respond to H_2O_2 by inducing the formation of some 115 proteins and the repression of 52 others (Godon et al., 1998). In contrast, the superoxide ion seems to stimulate defense gene activation in higher plants (Nuernberger et al., 1997; Durrant et al., 2000). We suggest that host-produced AOS may control the enzymatic responses of necrotrophic pathogens that enables them to survive in the AOS-rich environment of the infected host plant. Thus, H_2O_2 formation correlated positively with growth of *B. cinerea* (Govrin and Levine, 2000). In contrast, the growth of a virulent form of *Pseudomonas syringae* was inhibited in the same system when the HR was induced with an avirulent strain of the pathogen. At present, there are few tools for addressing these speculations, or for assigning a definite task for the depletion of AOS to any one of the enzymes we have discussed.

Abstract

A cDNA encoding flavone synthase I was amplified by RT-PCR from leaflets of *Petroselinum crispum* cv. Italian Giant seedlings and functionally expressed in yeast cells. The identity of the recombinant, 2-oxoglutarate-dependent enzyme was verified in assays converting (2*S*)-naringenin to apigenin. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Petroselinum crispum*; Apiaceae; Flavonoid biosynthesis; Flavone synthase I cloning; 2-Oxoglutarate-dependent dioxygenase; Heterologous expression

During the last decade considerable progress has been achieved towards elucidating the mode of action and molecular architecture of 2-oxoglutarate-dependent dioxygenases. These enzymes catalyze diverse reactions, such as the hydroxylation, desaturation, epoxidation or cyclization of substrates, and the activities depend on ferrous iron and molecular oxygen which is reduced during catalysis by two electrons provided by decarboxylation of the cosubstrate (Prescott, 1993; DeCarolis and DeLuca, 1994; Prescott and John, 1996). Although 2-oxoglutarate is the common cosubstrate, some closely related dioxygenases mobilize the electrons from decarboxylation of the substrate itself, e.g. isopenicillin *N*-synthase (Baldwin and Abraham, 1988) and 4-hydroxyphenylpyruvate dioxygenase (Bradley et al., 1986; Rüetschi et al., 1992), or by the oxidation of ascorbate as in ethylene biosynthesis (Zhang et al., 1995; Lay et al., 1996). These latter enzymes may nevertheless classify with the 2-oxoglutarate-dependent dioxygenases stricto sensu in one category of intermolecular dioxygenases. Intermolecular dioxygenases fulfill a variety of pivotal functions in primary and secondary metabolism in bacteria (Omura et al., 1984; Salowe et al., 1990) and fungi, including the cyclization and ring expansion reactions in penicillin/cephalosporin biosynthesis (Baldwin and Abraham, 1988), as well as in mammalian tissues (Lindstedt et al., 1977; Kivirikko et al., 1989; Stenflo et al., 1989). Furthermore, these enzymes catalyze numerous reactions in plants, e.g. in the formation of hydroxyproline-rich glycoproteins (Tanaka et al., 1980), of gibberellins (Hedden and Graebe, 1982) and the secondary metabolites scopolamine (Hashimoto and Yamada, 1986), vindoline (DeCarolis et al., 1990) or of various flavonoids (Forkmann et al., 1980; Britsch et al., 1981; Lukačin and Britsch, 1997; Lukačin et al., 2000 a,b,c).

Five 2-oxoglutarate-dependent dioxygenases have been identified so far from flavonoid biosynthesis, which include the widely distributed anthocyanidin synthase (Menssen et al., 1990), flavanone 3β-hydroxylase (Forkmann et al., 1980; Britsch et al., 1981; Lukačin and Britsch, 1997; Lukačin et al., 2000 a,b,c) and flavonol synthase (Britsch et al., 1981; Holton et al., 1993). Another dioxygenase, catalyzing the 6-hydroxylation of partially methylated flavonols, was reported recently from *Chrysosplenium americanum* (Anzelotti and Ibrahim, 2000), while flavone synthase I, FNS I, appears to be confined to species of the Apiaceae (Britsch, 1990). FNS I had been characterized in 1981 as a soluble enzyme from parsley, in contrast to the microsomal flavone synthase II, FNS II, from other plants (Kochs and Grisebach, 1987; Martens and Forkmann, 1998), and was partially purified through six-steps of fractionation from irradiated cell cultures (Britsch, 1990). This

enzyme was then employed in kinetic studies aiming at the reaction mechanism, which revealed that synthetic 2-hydroxynaringenin did not compete with flavanone substrates. Accordingly, the 2,3-desaturation of flavanones by FNS I was postulated to proceed by direct abstraction of the vicinal hydrogen atoms (Britsch, 1990), which would assign FNS I to a distinct desaturase subgroup among the 2-oxoglutarate-dependent dioxygenases. An analogous reaction mechanism, exluding the successive hydroxylation and dehydratation, was proposed for the desaturation of alkanes to olefines suggesting a reaction *via* radical intermediates (Mansuy, 1998). The exact course of FNS I catalysis requires further experimental support, but appears to proceed analogous to that of the cytochrome P450-dependent FNS II expressed in many plants except for the Apiaceae. The first full size FNS II cDNAs were recently cloned from *Gerbera hybrida* (Martens and Forkmann, 1999), *Antirrhinum majus* and *Torenia hybrida* (Akashi et al., 1999) by differential display PCR and expressed in yeast cells. As anticipated for a P450-dependent monoxygenase, this FNS II converted labelled flavanones to the corresponding flavones apparently without any intermediate (Martens and Forkmann, 1999).

The common mode of oxygen activation by intermolecular dioxygenases, particularly among the 2-oxoglutarate-dependent enzymes, seems to predict a high degree of homology at the DNA and polypeptide levels. However, only 30% similarity was observed in the polypeptide sequences of, for example, flavanone 3β-hydroxylase from *Petunia hybrida* and hyoscyamine 6β-hydroxylase from *Hyoscyamus niger* (Britsch et al., 1992), and the similarity of prolyl 4-hydroxylase with lysyl hydroxylase from chicken (Myllylä et al., 1991) or of fungal isopenicillin *N*-synthase with desacetoxycephalosporin C synthase ranged only at approx. 20% (Britsch et al., 1993). Nevertheless, superimposing the structural models of the penicillin and cephalosporin synthases revealed an almost identical architecture for these two enzymes (Lloyd et al., 1999), and comparison of the CD spectra of *Petunia* flavanone 3β-hydroxylase and isopenicillin *N*-synthase suggested the same pattern of helical, non-helical and β-sheet motifs for the *Petunia* dioxygenase (Lukačin et al., 2000b). Flavanone 3β-hydroxylase and FNS I both use 2-oxoglutarate as the cosubstrate and depend on the same flavanone substrates (Fig. 1). Accordingly, a thorough examination of the sequential and spatial differences of these two enzymes, together with in vitro mutagenesis studies, might be rather helpful to pinpoint the putative substrate binding sites and to explain the formation of flavones and flavonols, respectively.

Based on alignments of fourteen intermolecular dioxygenase polypeptides from public data bases two conserved sequence motifs were chosen, and, similar to the previous cloning of flavonol synthase (Fig. 1) from *Petunia hybrida* (Holton et al., 1993), degenerate oligonucleotide primers were designed for the cloning of FNS I. In combination with oligo(dT), the primers were employed for RT-PCR amplification of cDNAs from total RNA that had been extracted from young leaflets at four stages of development of flavone-producing *Petroselinum crispum* cv. Italian Giant plants (Martens and Forkmann, 1999). A whole set of intermolecular dioxygenase cDNAs was amplified, and the full-size

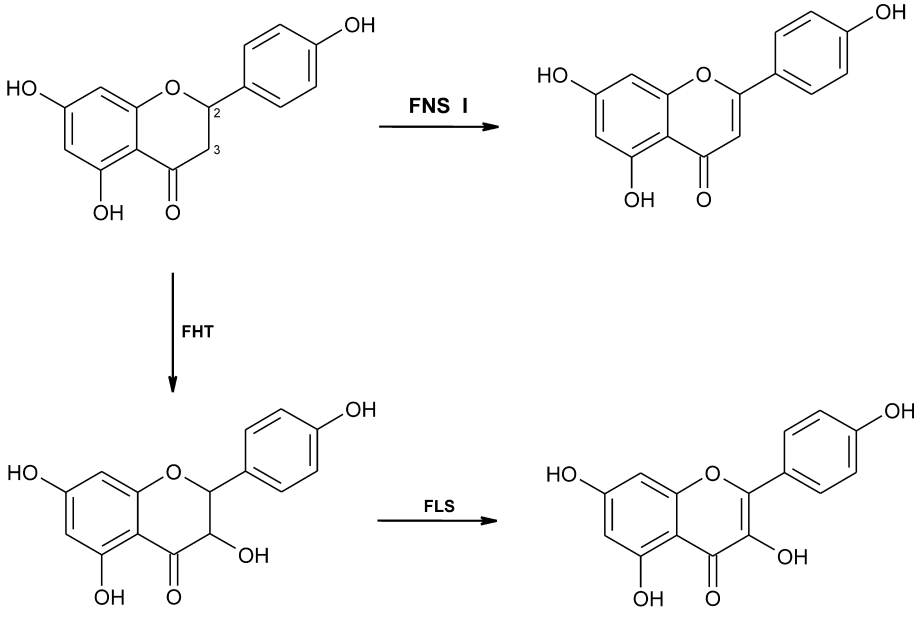

Fig. 1. Reaction catalyzed by flavone synthase I (FNS I), converting (2*S*)-naringenin to apigenin, in comparison to the activities of flavanone 3β-hydroxylase (FHT) and flavonol synthase (FLS), which sequentially convert (2*S*)-naringenin to dihydrokaempferol and kaempferol.

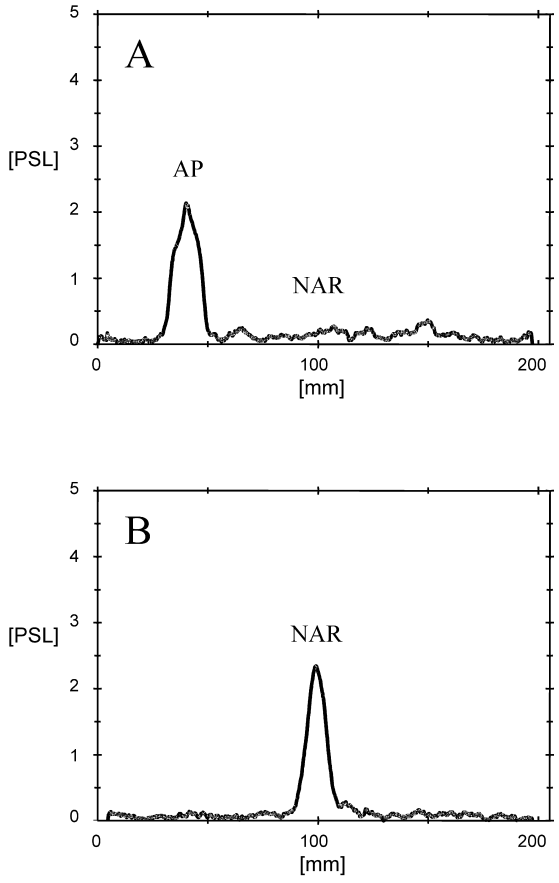

Fig. 2. Catalytic activity of parsley FNS I expressed in yeast cells. Crude extracts from yeast cells expressing the FNS I from the cDNA inserted in the pYES2 expression vector (A) or harbouring the FNS I cDNA in the inverse orientation (B) were incubated with (2*S*)-[4a,6-8-^{14}C]naringenin (NAR) as described for the native plant enzyme (Britsch, 1990). Subsequently, the incubations were extracted with ethyl acetate, the extracts were separated by thin-layer chromatograpy on cellulose in 30% aqueous acetic acid (v/v), and the radioactivity was spotted by a phosphorimager (Martens and Forkmann, 1998). The product was identified by cochromatography with authentic apigenin (AP).

clones were generated by the 5′-RACE technique. In addition to flavanone 3β-hydroxylase, flavonol synthase, 1-aminocyclopropane-1-carboxylate oxidase and two not yet fully characterized 2-oxoglutarate-dependent dioxygenases, FNS I was also recognized among the cDNA clones. The FNS I cDNA was unequivocally identified by expression in yeast strain INVSc1, using the expression vector pYES2 (Invitrogen, Groningen, The Netherlands), and the efficient conversion of naringenin to apigenin by the recombinant enzyme (Fig. 2 A). The identity of the reaction product was confirmed by direct comparison of the retention time on reversed phase HPLC in water/acetonitrile 7:3 and the ESI–MS spectrum with the mobility and fragmentation pattern of authentic apigenin (data not shown). The FNS I polypeptide was also recognized in Western blots by a FNS I polyclonal rabbit antiserum (Lukačin et al., unpublished). Moreover, the yeast strain transfected with the pYES2 vector hosting the FNS I cDNA in the inverse orientation did not express flavone synthase activity (Fig. 2 B). Recombinant FNS I lacked flavonol synthase activity (Fig. 1), and the sequences of these two enzymes differ considerably. Thus, soluble FNS I prevailing in the Apiaceae was cloned for the first time and has become available in quantity for mechanistic studies as well as for the convenient preparative synthesis of radiolabeled flavones which enable further biosynthetic and biotechnological studies. The evolutionary context for the expression of the soluble synthase exclusively in the Apiaceae remains to be established. In addition, the recombinant enzyme may be of value for the production of flavone-nutraceuticals due to their antioxidant and anticancer potentials (Harborne and Williams, 2000).

Acknowledgements

We are indebted to Dr. L. Britsch, Dr. R. Zimmermann and Dr. H. Müller (Merck KGaA, Darmstadt) for the ESI–MS analysis of apigenin as the product of the recombinant parsley FNS I.

Abstract

Hypa A, a novel macrocyclic polypeptide containing 30 amino acid residues, has been isolated from the *n*-butanol extract of the Argentine plant *Hybanthus parviflorus*. The sequence, cyclo-(SCVYIPCTITALLGCSCKNKVCYNGIPCAE), was determined by automated Edman degradation, quantitative amino acid analysis and nanospray MS/MS^2. Three intramolecular disulfide bridges stabilize the cyclic peptide backbone of hypa A. Using these structural features to classify the peptide as a cyclotide, we extended the distribution of that substance class to a new genus, and now propose a uniform nomenclature for cyclotides. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Hybanthus parviflorus* (Mutis ex L. F.) Baill.; Violaceae; Violetilla; Isolation; Primary structure; Cyclotides; Macrocyclic polypeptides; Hypa A; LCQ

1. Introduction

The generic name 'cyclotides' (cyclic peptides) has been given to a rapidly emerging family of macrocyclic polypeptides, which are approximately 30 amino acid residues in length and are cyclized via the amide bonds of the peptide backbone (Craik et al., 1999). Their known taxonomic distribution has been limited to genera of Violaceae and Rubiaceae (Table 1). Recently, the characteristic cyclic cystine knot has also been found in peptides isolated from the family Cucurbitaceae (Hernandez et al., 2000). To further investigate the occurrence of cyclotides within Violaceae, we examined *Hybanthus parviflorus* (Mutis ex L. F.) Baill.

H. parviflorus is a perennial shrub, widely distributed in the tropical and subtropical regions of America from Colombia to Argentina (Correa, 1988). In annual cultivations, it is a weed that grows on stubble, walls, rubble and wasteland (Zuloaga and Morrone, 1999). In several South American countries, including Colombia, Chile, Peru and Argentina, it is used as an emetic and purgative drug, and has substituted for ipecacuanha in medicine (Soukup, 1986; Murillo, 1889; Rutter, 1990; García Barriga, 1992; Mazorca, 1997). In Argentina, it is known under the name 'violetilla'.

In this study, we report the occurrence of the cyclotide hypa A in *H. parviflorus*, together with a modified sample clean-up and capture procedure. We also propose a principle for uniform naming of new members of this growing family of peptides.

2. Results and discussion

In our previous work on cyclotides from the Violaceae (Claeson et al., 1998; Göransson et al., 1999), we have used a fractionation protocol originally developed for polypeptides in general from plant biomass (Claeson et al., 1998). Here we utilise the pronounced lipophilic nature of the cyclotides by exchanging two steps in the original protocol, gel filtration on Sephadex G-10 and solid phase extraction on RP-18 silica, for a simple solvent–solvent partitioning between water and butanol. The butanolic fraction is then directly amenable to high-performance chromatography techniques (i.e. RP–HPLC).

Table 1
The taxonomic distribution of known cyclotides

Family	Taxa	Reference
Violaceae	*Hybanthus parviflorus*	This work
	Leonia cymosa C. Martius	(Hallock et al., 2000)
	Viola arvensis Murray	(Göransson et al., 1999; Claeson et al., 1998)
	V. odorata Linn.	(Craik et al., 1999)
	V. hederacea Labill.	(Craik et al., 1999)
Rubiaceae	*Chassalia parvifolia* K. Schum.	(Gustafson et al., 2000; Gustafson et al., 1994)
	Oldenlandia affinis DC.	(Craik et al., 1999; Gran, 1973a,b; Sletten and Gran, 1973)
	Palicourea condensate Standl.	(Bokesch et al., 2001)
	Psychotria longipes Muell. Arg.	(Witherup et al., 1994)
Cucurbitaceae	*Momordica chinensis* Hort.	(Hernandez et al., 2000)

Thus, in this investigation of *H. parviflorus*, the plant material was first defatted with CH_2Cl_2 and then extracted with EtOH:H_2O 1:1. The acidified extract was filtered through polyamide to remove tannins before being partitioned between H_2O and *n*-BuOH. The *n*-BuOH extractives were subjected to repeated RP-HPLC to yield a homogeneous substance with an experimentally determined molecular mass of 3143 Da [M]. In comparison to the calculated theoretical mass given by the quantitative amino acid and Edman sequencing analyses (Table 2), a difference of 24 Da was observed. This agrees with previously isolated cyclotides, and is readily explained by the macrocyclic structure. Ring closure of the N- and C-terminals and the six cysteines engaged in three disulfide bridges corresponds to a mass loss of 24 Da.

The peptide was then reduced and alkylated with 4-vinylpyridine to yield the *S*-(ß-4-pyridylethyl) cysteine (PEC) derivative. The experimentally determined mass was 3780 Da [M], which agrees with the theoretical mass (3780 Da [M]) of a derivative with all six cysteines alkylated by 4-vinylpyridine. Subsequent digestion with endoproteinase Glu-C provided a single linear alkylated peptide (observed [M], 3798 Da; calculated [M], 3798 Da). The complete sequence of this derivative was then determined by automated Edman degradation and verified by MS^2. The results are shown in Table 2 and in Figs. 1 and 2.

Overall, this novel peptide exhibited a high degree of sequence similarity with the previously known cyclotides from Rubiaceae and Violaceae (Craik et al., 2001), and was 90% identical with the closest homologue, cycloviolacin O1, isolated from *V. odorata*. The disulfide arrangement in hypa A is most probably identical with the one reported from the NMR-structure of cycloviolacin O1 (Craik et al., 1999), i.e. C2–C17, C7–C22 and C15–C28. Moreover, the alignment placed the peptide in subfamily 1, the bracelet cyclotides, distinguished from the Moebius subfamily 2 by the lack of a *cis*-amide bond in a Trp-Pro sequence (Craik et al., 1999).

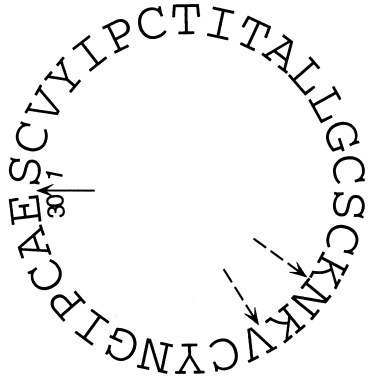

Fig. 1. The amino acid sequence of the cyclotide hypa A. The cleavage site of endoproteinase Glu-C, marked with an arrow, was chosen as an arbitrary starting point of the numbering of the amino acids (trypsin cleavage sites are marked with dashed arrows).

Cyclotides have hitherto been found in *Leonia* and *Viola* of the Violaceae family. This identification (the first) of a member of this substance class in *Hybanthus* supports chemotaxonomically the placing of *H. parviflorus* in Violaceae.

The total number of known cyclotides now exceeds 40, and that figure will no doubt grow. With the principles for naming them having varied considerably, we propose that the trivial name should be constructed as an indicative and pronounceable acronym of the Latin binomial of the plant from which the cyclotide was first isolated, followed by a letter indicating the order of appearance. By these principles, this first cyclotide from *Hybanthus parviflorus* is named hypa A.

3. Experimental

For HPLC, a Shimadzu LC-10 system was used, equipped with a SPD-M10Avp photodiode array detector. UV data were collected between 200 and 300 nm, 250×4.6 (id) and 250×10 (id) mm Rainin Dynamax (C_{18}, 5 μm, 300 Å) columns were used for analytical and

preparative RP–HPLC. For MS and MS^2, a nanospray-ion trap MS (Protana's NanoES source mounted on a Finnigan LCQ MS) was used. All samples were sprayed in 50% MeOH, 1% HOAc, the capillary temperature was set to 230°C and the spray voltage to 0.8 kV. Average isotopic masses were used for all calculated molecular weights.

3.1. Plant material

Aerial parts of *H. parviflorus* [syn. *Ionidium glutinosum* Ventetat, *Viola parvifolia* Roemer & Schultes (Ballard and Jorgensen, 1997)] were collected along the road No.12 and its intersection with Arroyo Feliciano, Department La Paz, Entre Ríos Province, Argentina, during October 1998. A voucher specimen, identified by Dr. Juan de Dios Muñoz, is deposited at the herbarium of the Facultad de Ciencias Agrarias, Universidad Nacional de Entre Ríos, Paraná, Argentina with the collection number Muñoz 1514 (ERA). After sun and oven drying at a temperature no more than 60°C, the plant material was ground to a fine powder.

3.2. Extraction and isolation

Powdered aerial plant material (30.9 g) was extracted by maceration for 1 h with 300 ml of CH_2Cl_2 in a beaker mounted on a shaking table. This procedure was

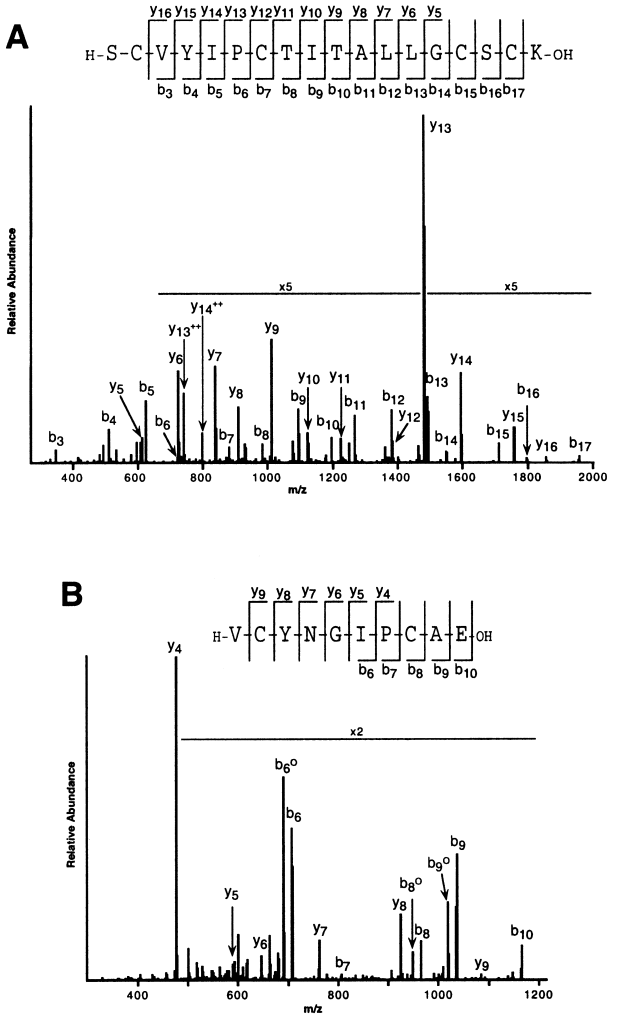

Fig. 2. MS^2-confirmation of the amino acid sequence after digestion with trypsin and endoproteinase Glu-C. Enzymatic peptides were isolated by RP-HPLC and analysed with nanospray-ion trap MS^2 (35% CID; observed fragment masses are listed in the Experimental section). The two peptides sequenced here cover 28 out of 30 amino acids. The remaining dipeptide, N19-K20, was confirmed in MS^2 fragmentation of a 30 amino acid linear peptide produced by partial digestion with trypsin (N19–K18, data not shown). (A) The fragmentation spectra of the ion 1052.5 $[M+2H]^{2+}$. Assignment of the b (N-terminal fragments) and y series (C-terminal fragments) verifies 18 amino acids, S1 to K18. (B) Fragmentation of the ion 1183.3 $[M+H]^+$, verifies the 10 amino acids before the cleavage point of GluC, V21 to E30 (b^O is b-H_2O). The assignment of this peptide is not as straightforward as in (A), due to the lack of basic amino acids.

repeated 7 times, and the CH_2Cl_2-soluble extractives were discarded. The plant residue was dried overnight at room temperature and macerated 3 times in an analogous manner with 400 ml of EtOH:H_2O 1:1.

The combined alcoholic extracts were evaporated to dryness in vacuo, then tannins were removed by dissolving the extract in 2% AcOH and passing it through 31 g of polyamide gel (Polyamide 6S Riedel-de Haën, Seelze, Germany) as described previously (Claeson et al., 1998). The yield was 4.5 g of lyophilized powder. A portion, 42 mg, of the tannin-free extract was dissolved

in H_2O (10 ml) and partitioned 3 times against *n*-BuOH (10 ml). The butanolic phases were combined to yield 0.84 mg of extractives after removal of the solvent, which was then subjected to preparative RP-HPLC using a 250×10 (i.d.) mm column eluted with a linear gradient from 25% CH_3CN, 0.1% TFA to 60% CH_3CN/0.1%TFA (v/v) over 30 min at a flow rate of 4 ml/min.

For final purification by RP–HPLC, we used a 250×4.6 (i.d.) mm column eluted with a gradient of 45–48% organic modifier (CH_3CH/*i*-PrOH, 6/4), 0.1% TFA, over 40 min at a flow rate of 1 ml/min. The yield of hypa A was 0.2 mg, as determined by quantitative amino acid analysis.

3.3. Determination of primary structure

Quantitative amino acid analysis was done at the Amino Acid Analysis Centre, Department of Biochemistry, Uppsala University. The peptide was hydrolysed for 24 h at 110°C with 6 N HCl containing 2 mg/ml phenol; the hydrolysates were analysed with an amino acid analyser using ninhydrin detection.

For the sequence analysis, the peptide was reduced with dithioerythritol in 0.25 M Tris–HCl containing 1 mM EDTA and 6 M guanidine-HCl (pH 8.5; 24°C; 2 h). The reduced peptide was subsequently alkylated to its PEC derivative by adding 4-vinylpyridine to the solution (37°C; 1 h). Desalting and isolation of the alkylated peptide was done using gel filtration on a Superdex Peptide HR 10/30 column (Amersham Pharmacia Biotech, Uppsala, Sweden) in 40% CH_3CN in 0.1% aqueous TFA.

The cyclic PEC derivative was digested with endoproteinase Glu-C (sequencing grade, Promega Co., WI, USA) in 50 mM ammonium bicarbonate (pH 7.8; 37°C; 4 h). The linear peptide was isolated using gradient RP-HPLC [250×4.6 (i.d.) mm, H_2O/CH_3CN in 0.1% TFA], and its amino acid sequence was determined by automated Edman degradation using a protein sequencer.

We then verified the sequence by MS^2 analyses of endoproteinase Glu-C and tryptic fragments (sequencing grade modified trypsin, Promega Co., WI, USA; 50 mM NH_4HCO_3 pH 7.8; 37°C; 4 h) of the cyclic peptide alkylated with iodoacetamide. Experimental masses $[M+H]^+$ of assigned MS^2-fragments (nomenclature according to Biemann, 1990): Fig. 2A, b-series: 1958.0 (b_{17}), 1796.7 (b_{16}), 1710.7 (b_{15}), 1549.5 (b_{14}), 1492.5 (b_{13}), 1379.5 (b_{12}), 1266.5 (b_{11}), 1195.4 (b_{10}), 1094.3 (b_9), 981.1 (b_8), 878.7 (b_7), 720.3 (b_6), 623.1 (b_5), 510.0 (b_4), 346.9 (b_3), y-series: 1855.9 (y_{16}), 1758.9 (y_{15}), 1594.7 (y_{14}), 1480.7 (y_{13}), 1384.8 (y_{12}), 1223.5 (y_{11}), 1122.4 (y_{10}), 1009.5 (y_9), 908.4 (y_8), 837.3 (y_7), 724.1 (y_6), 611.2 (y_5); Fig. 2B, b-series: 1165.4 (b_{10}), 1036.3 (b_9), 965.3 (b_8), 805.3 (b_7), 707.1 (b_6), y-series: 1084.3 (y_9), 923.1 (y_8), 760.2 (y_7), 646.1 (y_6), 589.5 (y_5), 476.1 (y_4).

Acknowledgements

We thank Dr. Juan de Dios Muñoz at the herbarium of the Facultad de Ciencias Agrarias, Universidad Nacional de Entre Ríos, Paraná for identifying the voucher specimen, Prof. Ernst Oliw, Dept. of Pharmaceutical Biosciences, Uppsala University, for technical advice concerning LCQ MS, and Dr. Åke Engström in the Dept. of Medical Biochemistry and Microbiology, Uppsala University for assistance with Edman sequencing. We also thank the Swedish Institute, Stockholm, for a scholarship that enabled one of us (A.M.B.) to spend a sabbatical leave from the University of Buenos Aires at Uppsala University.

Received 3 January 2001; received in revised form 30 March 2001

Abstract

The activity of 7-deoxyloganin 7-hydroxylase, an enzyme catalyzing the conversion of 7-deoxyloganin into loganin, was detected in a microsomal preparation from the cell suspension cultures of *Lonicera japonica*. It was dependent on NADPH and molecular oxygen. The enzymatic reaction was inhibited by carbon monoxide as well as by several cytochrome P450 inhibitors, especially ketoconazole, indicating that the reaction was mediated by cytochrome P450. The enzyme showed substrate specificity for 7-deoxyloganin. The K_m values for 7-deoxyloganin and NADPH were estimated as 170 and 18 μM, respectively, from Lineweaver–Burk plots. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Lonicera japonica*; Caprifoliaceae; Cell suspension cultures; Loganin; 7-Deoxyloganin; Iridoid glucoside; 7-Deoxyloganin 7-hydroxylase; Cytochrome P450; Enzyme; Biosynthesis

1. Introduction

Secologanin, a secoiridoid glucoside, is a pivotal terpenoid intermediate in the biosynthesis of monoterpenoid indole alkaloids such as reserpine, ajmaline, ajmalicine, vincristine and vinblastine, which are biosynthesized via strictosidine, an alkaloidal glucoside, formed from secologanin and tryptamine (Zenk, 1977, 1980). *Lonicera japonica* (Caprifoliaceae) is known to contain loganin, an iridoid glucoside, as the main constituent as well as other derivatives of secologanin (Kawai et al., 1988). Our earlier studies demonstrated that the cell suspension cultures of *L. japonica* lacked the capability of secologanin biosynthesis but had the ability to convert 7-deoxyloganin and loganin into secologanin (Yamamoto et al., 1999). In our subsequent paper (Yamamoto et al., 2000), secologanin synthase, the enzyme catalyzing the conversion of loganin into secologanin was characterized as a cytochrome P450 dependent monooxygenase. Some possible radical-initiating mechanisms for this conversion were also proposed instead of the ionic ring-fission process proposed by Battersby (1967), which remained unsolved through many years in spite of several efforts (Battersby et al., 1981; Inoue et al., 1981, 1989).

As mentioned above, loganin is a biosynthetic intermediate just preceding secologanin. It is presumed that hydroxylation at the 7-position of the iridoid, which leads to loganin or loganic acid, takes place at either 7-deoxyloganin or deoxyloganic acid. Uesato et al. (1986) reported that hydroxylation proceeded at the stage of 7-deoxyloganic acid on the basis of administering various labeled compounds to *Galium* species, which contain both iridoid and secoiridoid glucosides (Bock et al., 1976; Bianco et al., 1978; Uesato et al., 1984). On the other hand, the conversion of 7-deoxyloganin into loganin was observed in cell suspension cultures of *L. japonica* (Yamamoto et al., 1999), suggesting that hydroxylation takes place at 7-deoxyloganin. The same result was also obtained in monoterpenoid indole alkaloid biosynthesis by Battersby et al. (1970). In the present paper, we describe the characterization of 7-deoxyloganin 7-hydroxylase from *L. japonica* cultured cells.

2. Results and discussion

2.1. Detection and preparation of 7-deoxyloganin 7-hydroxylase from Lonicera japonica cell suspension cultures

It is known that in plants, hydroxylation reactions at saturated carbons are catalyzed by either cytochrome

PII: S0031-9422(01)00181-9

P450 dependent-mono-oxygenases, P450 dependent-peroxygenases (Bolwell et al., 1994) or 2-oxoglutarate-utilizing dioxygenases (Hashimoto and Yamada, 1986; De Carolis and De Luca, 1994). In order to investigate the properties of 7-deoxyloganin 7-hydroxylase, we first examined the cofactor requirement of the hydroxylase by using the cell-free extract prepared as described in the ''Experimental''. NADPH, NADH, FAD, FMN and H_2O_2 were used as potential cofactors for mono-oxygenase and peroxygenase, and $FeSO_4$ + Na ascorbate + 2-oxoglutarate as cofactors for dioxygenase. The enzymatic reaction proceeded only in the assay system containing NADPH or NADH and the specific activity (1.66 pkat/mg protein) was higher with NADPH. The enzymatic product detected by HPLC was identified by comparison of its UV absorption spectrum and LC–MS to those of loganin. No conversion was observed with the cell-free extract denatured by heating (data not shown).

2.2. Localization and reaction parameters of 7-deoxyloganin 7-hydroxylase

The subcellular localization of 7-deoxyloganin 7-hydroxylase in *L. japonica* cells was investigated. The cell-free extract was centrifuged at 100,000 × *g*. The precipitate was washed twice by homogenization in the same buffer followed by centrifugation at 100,000 × *g*. Even after washing twice, the hydroxylase activity still remained in the microsomal fraction, indicating that 7-deoxyloganin 7-hydroxylase was tightly associated with the membrane fraction. At the same time, secologanin synthase activity was also measured because this enzyme, a cytochrome P450 monooxygenase, was known to be included in the same fraction (Yamamoto et al., 2000). Secologanin, however, was not detectable because the amounts of secologanin formed from 7-deoxyloganin through loganin by two enzymes would still be beyond the limits of detection.

The hydroxylase activity of the microsomal fraction was stable upon storage at −84°C for at least 6 months.

The requirement of cofactors for 7-hydroxylase activity was studied in some detail using a microsomal preparation. Of the five cofactors used in this study, NADPH, NADH, NADP, NAD and FAD, NADPH was essential for enzymatic activity. As compared to NADPH, ca. 45% of the activity was detected with NADH and only ca. 10% with NADP or NAD (data not shown).

The optimal pH for the activity of 7-deoxyloganin 7-hydroxylase was 7.5 (in Tris–HCl buffer) with half-maximal values at 7.1 (in phosphate buffer) and 9.4 (in glycine–NaOH buffer). The pH optimum found was similar to those reported for cytochrome P450-dependent monoterpenoid hydroxylases such as sabinene hydroxylase (pH 7.4; Karp et al., 1987) and (−)-limonene C-3 and C-6 hydroxylase (pH 7.4; Karp et al., 1990), camphor hydroxylase (pH 7.0; Funk and Croteau, 1993) and (+)-limonene-6-hydroxylases (pH 7.2–7.4; Bouwmeester et al., 1999).

In the time-course of the amounts of loganin formed by 7-deoxyloganin 7-hydroxylase, the reaction proceeded linearly for ca. 10 min and then with a slow upward hyperbolic shaped-curve until after 1 h (data not shown).

2.3. Characterization of 7-deoxyloganin 7-hydroxylase

The effect of molecular oxygen on 7-hydroxylase activity was examined (Table 1). The substitution of nitrogen for air reduced the enzymatic activity by ca. 50%. An absolute requirement for oxygen was demonstrated by the removal of oxygen from the assay system by addition of the glucose oxidase/catalase system (Kochs and Grisebach, 1987), where the activity was reduced to ca. 6% of the control. This inhibition was not observed when glucose oxidase was denatured by heating. These results suggest that the hydroxylation is catalyzed by cytochrome P450.

To confirm this assumption, the effects of carbon monoxide (Omura and Sato, 1964) and several cytochrome P450 inhibitors (Fujita et al., 1982; Rossi, 1983; Wendorff and Matern, 1986; Lamberts et al., 1987) on the enzyme activity were investigated. As shown in Table 1, the reaction was inhibited by ca. 60% by CO/O_2 gas mixture in the dark and this inhibition was partially reversible upon illumination with white light. Six well-known cytochrome P450 inhibitors were also examined. Of these, ketoconazole had the strongest inhibitory effect (93% inhibition at the concentration of 0.01 mM and complete at 0.1 mM). In addition, miconazole, metyrapone, ancymidol and cytochrome c at concentrations of 0.01 and 0.1 mM inhibited 7-hydroxylation by 78.5 and 26.2, 92.4 and 73.6, 77.0 and 58.4, as well as 59.6 and 44.9%, respectively. The 7-hydroxylation activity was not inhibited by potassium cyanide, a potent inhibitor of peroxidases (Fujita et al., 1982). These results demonstrated that 7-deoxyloganin

Table 1
Influence of different treatments on 7-deoxyloganin 7-hydroxylase activity from *Lonicera japonica* cell suspension cultures

Treatment	Relative activity (%)
Air (dark)	100[a]
Air (light[b])	93.4
N_2 (dark)	50.9
N_2 (light[b])	42.0
Air + glucose + glucose oxidase + catalase	6.2
Air + glucose + boiled glucose oxidase + catalase	101.6
$CO/O_2 = 9/1$ (dark)	41.8
$CO/O_2 = 9/1$ (light[b])	59.4

[a] The enzyme activity of the control was 5.28 pkat/mg protein.
[b] White light (20,000 lx).

7-hydroxylase was a microsomal cytochrome P-450 mono-oxygenase.

2.4. Kinetic parameters of 7-deoxyloganin 7-hydroxylase

Kinetic parameters of 7-deoxyloganin 7-hydroxylase for 7-deoxyloganin and NADPH were determined by Lineweaver–Burk plots. The K_m values for 7-deoxyloganin and NADPH were 170 μM and 18 μM, respectively. The K_m value for 7-deoxyloganin was ten-fold higher than those reported for other terpenoid hydroxylases such as geraniol-10-hydroxylase (15 μM) (Hallahan et al., 1992) and (-)-limonene C-3, C-6 and C-7 hydroxylases (18, 20 and 21 μM) (Karp et al., 1990), indicative of the low affinity of 7-deoxyloganin for 7-deoxyloganin 7-hydroxylase.

2.5. Substrate specificity of 7-deoxyloganin 7-hydroxylase

The substrate specificity of the 7-hydroxylase was studied. The following substrates were used: the 11-carbomethoxy-type substrates, 7-deoxyloganin, 8-epi-7-deoxyloganin, 10-deoxygeniposide, mussaenoside and adoxoside; the 11-carboxyl-type substrates, 7-deoxyloganic acid, 8-epi-7-deoxyloganic acid, 10-deoxygenipo sidic acid, mussaenosidic acid and adoxosidic acid; the 11-aldehyde-type substrates, 5-deoxystansioside and boschnaloside; the 11-alcohol-type substrates, 7,8-dehydro-11-hydroxy-iridodial glucoside, 11-hydroxyiridodial glucoside; the 11-methyl-type substrates, iridodial glucoside (Fig. 1 for their structures). Of these 7-deoxy compounds, only two compounds, 7-deoxyloganin and 7-deoxyloganic acid, were hydroxylated and the production of loganic acid from 7-deoxyloganic acid was only ca. 50% of that of loganin from 7-deoxyloganin.

The conversion of 7-deoxyloganin into loganin, previously observed from administration experiments to *L. japonica* cultured cells (Yamamoto et al., 1999), was also confirmed in the present study at the enzyme level. 7-Deoxyloganic acid is presumed to be an intermediate just before 7-deoxyloganin. However, our above results, coupled with those of administration experiments to *Galium mollugo* (Uesato et al., 1986), suggest that *L. japonica* cells might include the following two biosynthetic pathways; one is the pathway in which methylation of deoxyloganic acid precedes hydroxylation of the resulting ester leading to loganin (not via loganic acid). The other is the pathway via loganic acid formed by 7-hydroxylation of 7-deoxyloganic acid leading to loganin. Madyastha et al. (1973) reported that the methyltransferase from *Catharanthus roseus* plant catalyzed the conversion of loganic acid into loganin but not that of deoxyloganic acid into deoxyloganin. Thus, the biosynthetic pathway to loganin remains unclear. Further information on loganin biosynthesis in *L. japonica* cultured cells requires detailed studies involving the administration of several substrates into the cultured cells, the purification and substrate specificity of the methyltransferase as well as the separation of cytochrome P450 dependent mono-oxygenases; this work is now in progress.

3. Experimental

3.1. Plant material and culture method

The origin and subculturing of cell suspension cultures of *Lonicera japonica* were described in our previous paper (Yamamoto et al., 1999). Fresh cells (1.5 g) were transferred to 20 ml of Murashige-Skoog liquid medium (Murashige and Skoog, 1962) containing 10 μM naphthaleneacetic acid and 10 μM 6-benzylaminopurine, and were agitated on a rotary shaker at a speed of 100 rpm at 23°C in the dark and subcultured every 2 weeks.

3.2. Enzyme preparation

All enzyme preparation operations were carried out at 4°C. Nine-day-old cultured *L. japonica* cells (20 g) were homogenized in 20 ml of 100 mM potassium phosphate buffer (pH 6.5) containing 10 mM DTT and 2 g PVPP with a teflon homogenizer. The homogenate was centrifuged at 12,000 × *g* for 20 min. The supernatant was applied to a PD-10 column (Amersham Pharmacia Biotech, UK) previously equilibrated with 100 mM Tris–HCl buffer (pH 7.5) containing 10 mM DTT and then the enzyme preparation was eluted with 3.5 ml of the same buffer. The eluted solution was used as the cell-free extract.

For the microsomal preparation, the above 12,000 × *g* supernatant was centrifuged at 100,000 × *g* for 30 min. The pellet was washed twice with 100 mM Tris–HCl buffer (pH 7.5) containing 10 mM DTT and then resuspended in 4 ml of the same buffer containing 10 mM DTT. This suspension was used as the microsomal fraction and was either used directly for assays, or frozen in liquid nitrogen after an addition of 10% (v/v) glycerol to the suspension and stored at −84°C.

Protein contents were determined according to the method of Bradford (1976), using bovine serum albumin as standard (Sigma, USA).

3.3. Enzyme assay for cofactor requirement

The incubation mixture contained 250 nmol 7-deoxyloganin, 200 μl cell-free extract (1.42 pkat/mg protein), various cofactors and was adjusted to a total volume of 250 μl with 100 mM Tris–HCl buffer (pH 7.5) containing 10 mM DTT. The cofactors used in this experiment were 250 nmol NADPH, 250 nmol NADH, 250 nmol

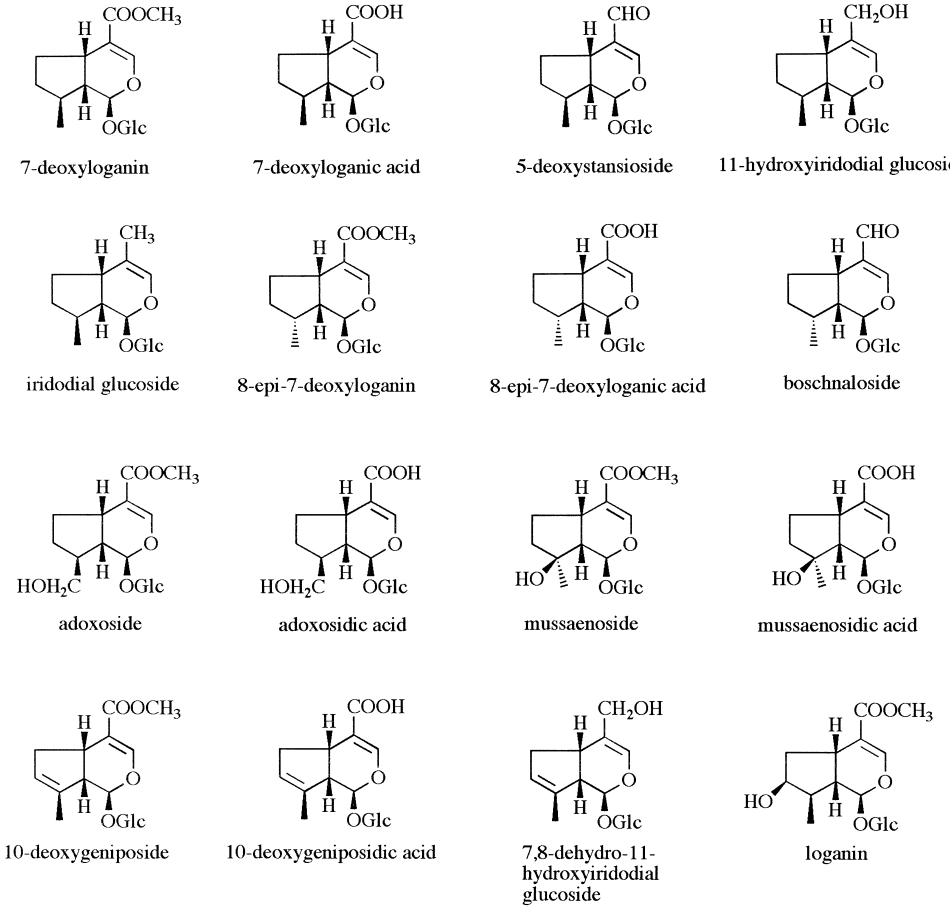

Fig. 1. Structures of substrates used for the experiments on substrate-specificity for 7-deoxyloganin 7-hydroxylase.

FAD, 250 nmol FMN, 250 nmol NADPH + 2.5 nmol FAD, 250 nmol NADPH + 2.5 nmol FMN, 250 nmol NADH + 2.5 nmol FAD, 250 nmol NADH + 2.5 nmol FMN, 40 nmol $FeSO_4$ + 400 nmol sodium ascorbate + 100 nmol 2-oxoglutarate or 250 nmol H_2O_2. The reaction was initiated by the addition of each cofactor to the mixture and after the incubation for 30 min at 30°C, terminated by boiling the reaction mixture on a water bath for 5 min. The mixture was centrifuged at 15,000 × *g* for 5 min and the supernatant was analyzed by reversed phase HPLC. The assays were performed in duplicate.

3.4. Standard enzyme assay

The incubation mixture contained the same components as described above except for the use of 200 µl of the microsomal fraction as the enzyme and 250 nmol NADPH as cofactor. After incubation for 10 min at 30°C, the mixture was treated and analyzed as described above. The assays were performed in duplicate.

3.5. pH-Optimum determination

Determination of the pH-optimum was carried out as described for the standard assay, but using the following three buffers: 200 mM potassium phosphate buffer (pH 5.0–7.5), 200 mM Tris–HCl buffer (pH 7.0–9.0) and 200 mM glycine–NaOH buffer (pH 8.5–10.0).

3.6. Oxygen dependence

The 20 ml test tubes containing all the reaction components of the standard enzyme assay except for NADPH were sealed with septum caps, and 60 ml of N_2, CO/O_2 (9:1) mixture or air were slowly bubbled into the mixture on ice, respectively.

The reaction was initiated by the addition of 250 nmol NADPH, treated and analyzed as described above. The assays were performed in duplicate. To examine the effect of the light on the inhibition by CO, the tubes were kept in the System Biotron (20,000 lx of fluorescent lights) for 10 min at 30°C. Tubes covered with aluminium foil were also kept in the same chamber as the dark condition. Additionally, to examine the photochemical effect on the enzyme activities under air or under nitrogen, the tubes containing the standard incubation mixture were kept in the same chamber.

For the oxygen consumption experiments, an enzyme assay lacking NADPH was preincubated at 30°C with 10 nmol glucose, 10 unit glucose oxidase (Nacalai Tesque,

Japan) and 20 unit catalase (Sigma, USA) (Kochs and Grisebach, 1987). After 5 min, the incubation was initiated by addition of 250 nmol NADPH and continued as described above. As a comparative experiment, heat-inactivated glucose oxidase was used.

3.7. Inhibition experiments

The P450 inhibitors, ketoconazole, miconazole, metyrapone, ancymidol and cytochrome c were tested. Metyrapone and cytochrome c were dissolved in H_2O and others were dissolved in DMSO. KCN was dissolved in 100 mM Tris–HCl buffer (pH 7.5). The concentrations of inhibitors were adjusted to 1 or 0.1 mM with each solvent. The incubation mixture contained 250 nmol 7-deoxyloganin, 250 nmol NADPH, 175 μl enzyme (24.95 pkat/mg protein) and 25 μl the solution of each inhibitor in total volume of 250 μl and continued as described above.

3.8. HPLC analysis

The amount of loganin was determined by reversed phase HPLC using Bio-Sil C18 HL 90-5 S column (5 μm, 4.6×250 mm, Bio-Rad, USA) in an oven at 40°C, with a CH_3CN/H_2O linear gradient solvent system, from 10% MeCN to 30% MeCN in 40 min at a flow rate of 1.0 ml/min, monitoring the absorption at 240 nm. The quantities were calculated from the peak area at 240 nm recorded by Chromatopac C-RA4 (Shimadzu, Japan). Rt. of loganin, 12.8 min, Rt. of 7-deoxyloganin, 32.8 min.

3.9. Identification of the reaction product

The identification of the product was carried out on the basis of UV and MS spectra obtained with Shimadzu SPDM-6A HPLC-photodiode array system (Shimadzu, Japan) as well as Shimadzu high performance liquid chromatograph–mass spectrometer LCMS-QP8000. The HPLC condition for the LC–MS system were as follows: column, Shim-pack VP-ODS (5 μm, 2.0×150 mm); solvent, CH_3CN/H_2O; linear gradient solvent system, from 10% MeCN to 30% MeCN in 30 min at a flow rate of 0.2 ml/min, monitoring the absorption at 240 nm oven temp., 40°C, Rt. of loganin, 9.5 min. Negative FAB–MS m/z; 389 ($[M-H]^-$).

3.10. Determination of kinetic parameters

The apparent Michaelis constant (K_m) and maximal reaction velocity (V_{max}) for 7-deoxyloganin was determined by Lineweaver–Burk plots at 0.04, 0.08, 0.16, 0.32 mM, using 250 nmol NADPH and those for NADPH at 0.02, 0.04, 0.08, 0.16 mM, using 250 nmol 7-deoxyloganin. K_m and V_{max} values for 7-deoxyloganin were 170 μM and 12.47 pkat/mg protein and for NADPH 18 μM and 8.33 pkat/mg protein, respectively.

Received 16 November 2000; received in revised form 2 March 2001

Abstract

Two proteinaceous α-amylase inhibitors termed αAI-Pa1 and αAI-Pa2 were purified from seeds of a cultivated tepary bean (*Phaseolus acutifolius* A. Gray, cv. PI311897). The two inhibitors differed in their specificity towards α-amylases of insect pests such as bruchids, although neither showed any inhibitory activity against α-amylases of mammalian, bacterial or fungal origin. αAI-Pa2 resembles two common bean inhibitors, αAI-1 and αAI-2, in several characteristics such as N-terminal amino acid sequences and oligomeric structure being composed of α and β subunits. In contrast αAI-Pa1 is composed of a single glycopolypeptide with a molecular mass of 35 kDa, and its N-terminal amino acid sequence resembled that of seed lectins in tepary bean and common bean. The information on the two tepary bean α-amylase inhibitors may be useful not only for providing insight into critical structure for the specificity towards different α-amylase enzymes but also for enhancing insect resistance in crops. © 2001 Elsevier Science Ltd. Keywords: *Phaseolus acutifolius*; Leguminosae; α-Amylase inhibitor; Lectin; Insect resistance; Bean weevil; Bruchid

1. Introduction

Seeds of common bean (*Phaseolus vulgaris* L.) contain proteinaceous inhibitors of the digestive enzyme α-amylase. The common bean α-amylase inhibitor (αAI) does not inhibit the activity of plant, fungal and bacterial α-amylase, but inhibits the activity in mammals and some insects (Powers and Whitaker, 1977a; Powers and Culbertson, 1983; Freis and Rupmnow, 1984). Due to its inhibitory specificity, αAI has drawn attention as an insecticidal protein (Chrispeels and Raikhel, 1991) and as an antinutritional factor for humans and livestock (Layer et al., 1985). In conventional and molecular breeding, bean αAI is a powerful tool to control insect pests, such as bean weevils (bruchids). The inhibitor prevents insect growth through the inhibition of starch digestion in the gut. As a result, insect larvae starve to death. This insecticidal effect has been confirmed by the bioassay of bruchids on artificial bean containing purified αAI and by the expression of the cDNA encoding αAI in the pea (*Pisum sativum*) and azuki bean (*Vigna anguralis*) (Ishimoto and Kitamura, 1988; Huesing et al., 1991; Shade et al., 1994; Schroeder et al., 1995; Ishimoto et al., 1996). Transgenic crops accumulating αAI became resistant to several species of bruchids such as pea weevil (*Bruchus pisorum*) and azuki bean weevil (*Callosobruchus chinensis*).

Two allelic variants of αAI are found in common bean. αAI-1, which is found in most common beans, has been purified and characterized comprehensively from several bean varieties (Marshall and Lauda, 1975; Powers and Whitaker, 1977b; Lajolo and Finardi Filho, 1985). αAI-1 inhibits larval gut α-amylase of azuki bean weevil and cowpea weevil (*C. maculatus*) as well as mammalian α-amylase (Ishimoto and Kitamura, 1989). The second variant, αAI-2, has initially been found in some wild common beans resistant to Mexican bean weevil (*Zabrotes subfasciatus*), which is a storage pest of common beans, and specifically inhibits the larval α-amylase of *Z. subfasciatus* (Minney et al., 1990; Ishimoto and Kitamura, 1993). The cDNAs of the two inhibitors have been isolated and were shown to share 78% amino acid sequence identity (Hoffman et al., 1982; Mirkov et al., 1994; Suzuki et al., 1994).

In addition to common bean, αAI is distributed in some other legumes of the genus *Phaseolus* such as scarlet runner bean (*P. coccineus*) and tepary bean (*P. acutifolius*) (Pueyo et al., 1993; Ishimoto and Chrispeels, 1996; Pueyo and Delgado-Salinas, 1997). In inhibitory specificity to α-amylase enzymes, scarlet runner bean αAI resembles αAI-1, while tepary bean αAI is different from the other bean inhibitors (Ishimoto and Chrispeels, 1996). The seed extract of tepary bean inhibited α-amylase of both *C. chinensis* and *Z. subfasciatus* but not mammalian α-amylases. An α-amylase inhibitor protein was purified from a tepary bean cultivar and its primary characteristics reported (Blanco-Labra et al., 1996), indicating that αAI was active against a large number of insect α-amylases, as compared with the other inhibitors purified from common beans. Because of its wide specificity toward insect enzymes, tepary bean αAI may be a source of factors important to the production of insect-resistant plants by conventional breeding and genetic engineering and may provide new information on the structure of αAI as it relates to the specificity and insecticidal activity. In contrast to αAI-1 and αAI-2, there is little information on the biochemical properties of tepary bean αAI. In the present paper, we describe the purification, characterization, and primary structure of tepary bean αAI.

2. Results and discussion

Tepary bean seed extracts showed a specificity for α-amylase inhibitory activity different from that of well-known common bean inhibitors, αAI-1 and αAI-2 (Table 1). αAI-1 inactivates the α-amylases of *C. chinensis*, *C. maculatus* and mammals, while αAI-2 shows specific inhibition towards the larval α-amylase of *Z. subfasciatus*. The specificity of the seed extracts from tepary beans suggested genetic variation in the α-amylase inhibitor as in common bean, and we classified the tepary bean accessions into two genotypes, αAI-Pa1 and αAI-Pa2. αAI-Pa1 inhibited the α-amylase activity of *C. chinensis*, but not porcine pancreatic α-amylase, while αAI-Pa2 inhibited the α-amylase activity of *Z. subfasciatus* in addition to *C. chinensis*.

The α-amylase inhibitor in common bean seeds can be visualized by immunoblotting with antibodies raised against αAI-1. Subunits of αAI-1 and αAI-2 were detected at around 14–20 kDa (Fig. 1, lanes 1, 2 and 4). The anitibodies cross-reacted with other α-amylase inhibitor-related proteins (around 29 kDa) such as arcelin in a breeding line, TAr4 (lane 2), and α-amylase inhibitor-like protein (AIL) in a breeding line, TO (lane 3), and Shiro-kinugasa (lane 4), while no seed extracts of tepary bean had proteins that intensely cross-reacted with the antibodies. Only a few faint polypeptide bands were detected at around 29 kDa. It is not clear whether the less-intense bands in tepary bean reflect the lower abundance in their seeds or the structural difference of the tepary bean α-amylase inhibitor from common bean inhibitors. Among tepary bean accessions used here, cultivar PI311897 classified as αAI-Pa2 type showed inhibitory activity against both *C. chinensis* and *Z. subfasciatus*. Therefore, we purified α-amylase inhibitor protein from seeds of PI311897.

We initially tried to purify the α-amylase inhibitor protein from tepary bean seeds by the method used for purifying αAI-1 and αAI-2 (Suzuki et al., 1993). The inhibitor protein in tepary bean, however, did not bind

[a] Two independent experiments were performed. Inhibitory activity (%) shows the relative value against activity of α-amylase preparations without preincubation with any inhibitor.
[b] Bold indicates more than 30% inhibition.

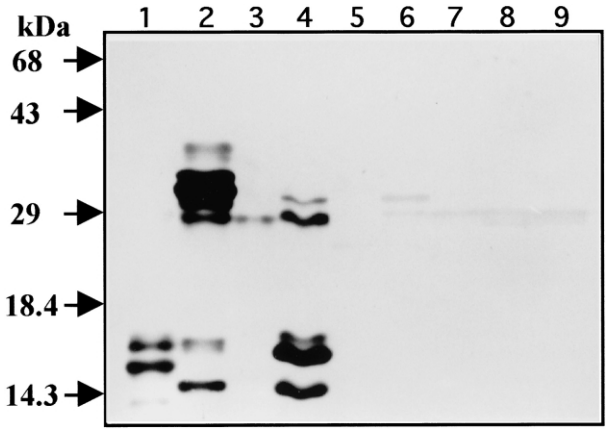

Fig. 1. Immunoblot analysis of α-amylase inhibitor (αAI)-related proteins in bean seed extracts. Polypeptides were separated by SDS-PAGE and detected by antibodies against αAI-1. Lanes 1–4: common bean (*Phaseolus vulgaris*), 1: Taisho-kintoki; 2: TAr4; 3: TO; 4: Shiro-kinugasa. Lanes 5–9: tepary bean (*Phaseolus acutifolius*), 5: G40072; 6: G40074; 7: PI311897; 8: PI321437; 9: Nayarit. Molecular weight markers are indicated on the left.

to a column of DEAE-Sephacel equilibrated with 20 mM PBS, pH 6.7. Therefore, the unadsorbed fraction was applied to a column of Concanavalin A (ConA)-Sepharose. The inhibitory activity against larval α-amylase of *C. chinensis* and *Z. subfasciatus* was detected in the fraction obtained by elution with 0.1 M α-methyl-D-mannopyranoside from the immobilized lectin. This fraction was dialyzed against a 50 mM acetate buffer (pH 3.6) and then applied to a CM-Sepharose column equilibrated with the same buffer. Three peaks were eluted with a linear gradient of NaCl, when proteins were monitored at 280 nm (Fig. 2A). The inhibitory activity against *Z. subfasciatus* was observed in the second peak while the inhibitory activity against *C. chinensis* was mainly observed in the third peak (Fig. 2B). On the SDS–PAGE gel, the protein in the second peak gave three polypeptides in the range of 14–18 kDa (Fig. 3, lane 4), and the protein in the third peak was composed of a single polypeptide band at 35 kDa (Fig. 3, lane 3). Thus, we identified two different α-amylase inhibitors coexisting in seeds of a tepary bean, cv. PI311897, classified as αAI-Pa2 type and re-designated the purified inhibitor proteins as αAI-Pa1 (active against *C. chinensis* α-amylase) and αAI-Pa2 (active against *Z. subfasciatus* α-amylase). Molecular weight of αAI-Pa1 was determined as 39.6 kDa by gel filtration chromatography, while molecular weight of αAI-Pa2 was esitimated as 28.1 kDa. Blanco-Labra et al. (1996) isolated tepary bean αAI from a different cultivar. The tepary bean αAI seems to be similar to αAI-Pa1 in primary structure, being a single glycopolypeptide with a molecular mass of 35 or 38 kDa and a monomer of about 39 kDa.

The two purified α-amylase inhibitors were analyzed for inhibitory activity against three α-amylase preparations, those of *C. chinensis*, *Z. subfasciatus* and porcine

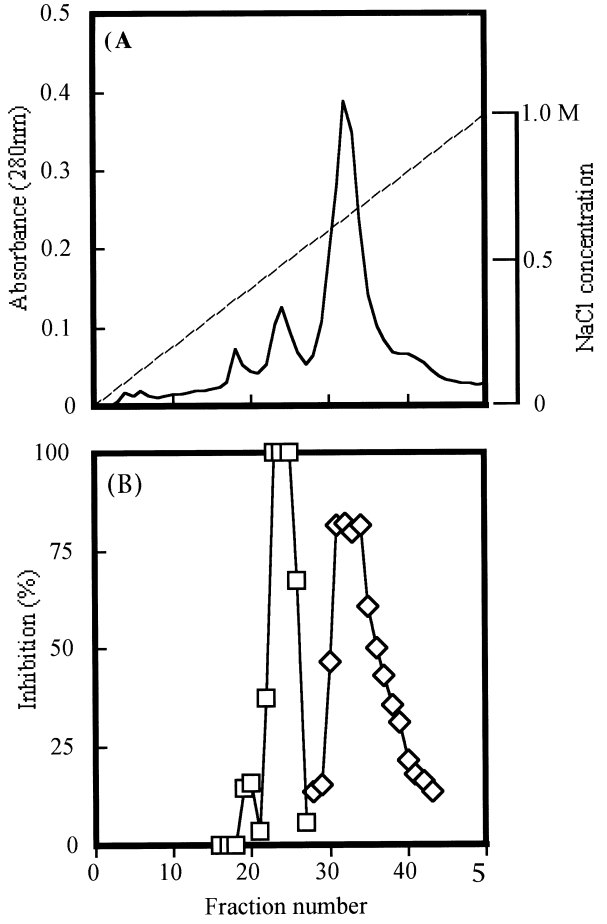

Fig. 2. Separation of two fractions showing α-amylase inhibitory activity on a column of CM-Sepharose. Column chromatography was performed with a linear gradient from 0 to 1.0 M NaCl. (A) Eluted protein was monitored at 280 nm. (B) Each fraction (10 ml) was pooled and measured for inhibitory activity against the larval α-amylases of *Callosobruchus chinensis* (◇) and *Zabrotes subfasciatus* (□). Inhibition (%) shows the relative value against one unit of each α-amylase activity without pre-incubation with any fraction.

pancreas (Fig. 4). αAI-Pa1 only inhibited *C. chinensis* α-amylase, which lost approximately 80% of its activity on addition of more than 3μg of αAI-Pa1 (Fig. 4A). αAI-Pa2 was highly active against *Z. subfasciatus* α-amylase (Fig. 4B), which was nearly completely inhibited on pre-incubation with not less than 1 μg of αAI-Pa2. αAI-Pa2 also inhibited *C. chinensis* α-amylase activity. Three micrograms of αAI-Pa2 inhibited nearly half of the activity of *C. chinensis* α-amylase, although the inhibitory effect was not increased even after incubation with an excess amount (5 μg) of the inhibitor (Fig. 4B).

The specificity of the two tepary bean α-amylase inhibitors, αAI-1 and αAI-2 was analyzed in detail using 9 α-amylase preparations (Table 2). There was no effect on fungal and bacterial α-amylases by the inhibitors. And while αAI-1 inhibited mammalian and coleopteran α-amylases, it did not inhibit the α-amylase activity of *Z. subfasciatus*, which is known to be a storage pest of the common bean. The other three αAIs did not inhibit

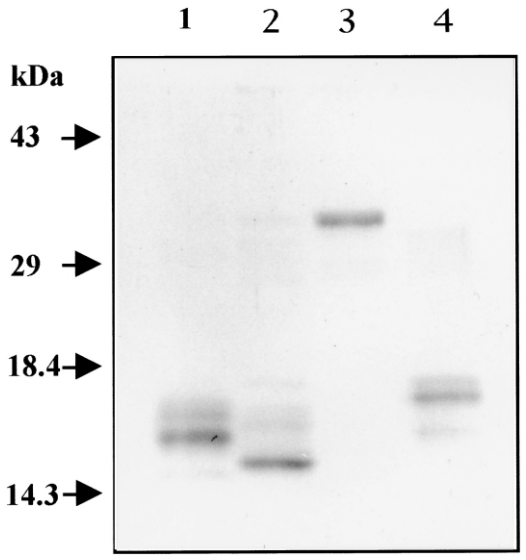

Fig. 3. SDS–PAGE analysis of purified α-amylase inhibitor proteins. Five micrograms of each protein was applied to a 13.5% polyacrylamide gel. Lane 1: αAI-1; 2: αAI-2; 3: αAI-Pa1; 4: αAI-Pa2. Molecular weight markers are indicated on the left.

the mammalian α-amylases. αAI-2 showed no evident inhibitory activity against the α-amylases except *Z. subfasciatus* α-amylase. αAI-Pa1 inhibited the α-amylase activity of *C. chinensis*, *C. maculatus*, *T. molitor*, and *T. confusum* but not *Z. subfasciatus*. On the other hand, the tepary bean αAI purified by Blanco-Labra et al. (1996) showed strong inhibitory activity against the α-amylase of *Z. subfasciatus* In spite of the molecular weight similarity between the tepary bean αAI and αAI-Pa1, they differ from each other on the inhibitory specificity to α-amylase enzymes. It appears more likely that at least three variants of αAI are found in tepary bean. αAI-Pa2 was active against all insect α-amylases tested, but its inhibition of the *C. chinensis* or *C. maculatus* α-amylase was less than 50%. *C. maculatus* larvae have at least four isozymes of α-amylase in the gut, and αAI-1 and wheat α-amylase inhibitor inhibited only some of these isozymes (Campos et al., 1989). αAI-Pa2 may inhibit a part of α-amylase isozymes of *C. maculatus* and *C. chinensis*, resulting in half of the original activity even after incubation with an excess amount of αAI-Pa2.

The purified αAI-Pa2 yielded three polypeptide bands on a SDS-PAGE gel (Fig. 3, lane 4). The two polypeptides with a higher molecular mass had an identical N-terminal amino acid sequence, showing high homology with the α-subunits of αAI-1 and αAI-2, while the lowest molecular mass polypeptide had high similarity to the β-subunits (Fig. 5B). In the case of αAI-1, post-translational maturation of the αAI precursor is essential to the development of an active form composed of two subunits, α- and β-subunits. (Altabella and Chrispeels, 1990; Santino et al., 1992; Pueyo et al., 1993). A

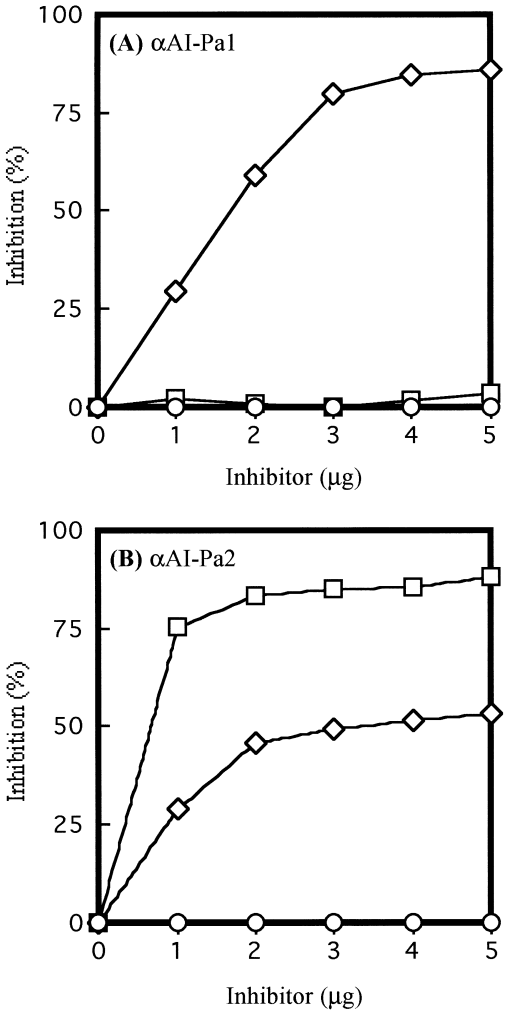

Fig. 4. α-Amylase inhibitory activity of αAI-Pa1 (A) and αAI-Pa2 (B) against α-amylase preparations from *Callosobruchus chinensis* (◇), *Zabrotes subfasciatus* (□) and porcine pancreas (○). Inhibition (%) shows the relative value against one unit of each α-amylase activity without pre-incubation with any fraction.

conformational change during the processing results in the creation of an active site filling the whole-substrate docking region of the α-amylase enzyme (Bompard-Golles et al., 1996). αAI-Pa2 is also composed of two subunits whose N-terminal amino acid sequences were similar to the α- or β-subunit of αAI-1 and αAI-2, suggesting that αAI-Pa2 is also proteolyticaly processed.

In contrast to αAI-Pa2, αAI-Pa1 is a single glycopolypeptide with a molecular mass of about 35 kDa. A similar α-amylase inhibitor was isolated from a different tepary bean cultivar (Blanco-Labra et al., 1996). These results indicate that αAI-Pa1 and an analogous inhibitor seem not to need the processing for the activation and the new group of αAI is widespread in tepary bean. The N-terminal amino acid sequence of αAI-Pa1 had high homology with seed lectin in tepary bean (TEPL) and common bean (PHA-L) (Fig. 5A) (Hoffman and Donaldson, 1985; Pratt et al., 1990), although αAI-Pa1

Table 2
Inhibitory activity of purified α-amylase inhibitor proteins against each α-amylase preparation[a]

Source of α-amylase preparations	α-Amylase inhibitor protein

Fig. 5. Comparison of N-terminal amino acid sequences of two α-amylase inhibitors (αAI-Pa1 and αAI-Pa2) purified from a tepary bean (PI311897) and other αAI-related proteins. αAI-1 (Hoffman et al., 1982); αAI-2 (Mirkov et al., 1994; Suzuki et al., 1994); PHA-E: erythroagglutinating PHA subunit (Hoffman and Donaldson, 1985); PHA-L: leucoagglutinating PHA subunit (Hoffman and Donaldson, 1985) and Arc1: arcelin1 in the common bean (Osborn et al., 1988); TEPL: tepary bean lectin (Pratt et al., 1990). Identical amino acids to those of αAI-Pa2 are indicated in bold.

showed no agglutination of rabbit erythrocytes at any dilution. The lectin-related defense proteins, αAI and arcelin, isolated from common bean and tepary bean share a high degree of sequence identity in amino acid sequence (Mirkov et al., 1994). In common bean, the genes for lectin, αAI, and arcelin are encoded at a single locus (Nodari et al., 1993), suggesting that these homologous genes have evolved through duplication and divergence of an ancestral gene. αAI-Pa1 and αAI-Pa2 may have arisen through a similar evolutional process, and αAI-Pa1 may provide new information on the essential structure and evolution of αAI, because αAI-Pa1 is an unprocessed αAI.

The introduction of cDNA encoding αAI-1 into pea and azuki bean protected the seeds from attack by bruchid larvae, indicating the usefulness of bean αAI in pest management (Schroeder et al., 1993, 1995; Ishimoto et al., 1996; Morton et al., 2000). Because of the antinutrient effect of the common bean α-amylase inhibitor in mammals (Pusztai et al., 1995), however, consumers would likely be apprehensive of transgenic crops expressing αAI-1. Recently, Pusztai et al. (1999) reported that diets containing transgenic peas expressing αAI-1 at a moderate level (~300 g/kg) did not have major harmful effects on growth, metabolism, and health in rats, suggesting that it would be safe to use them in the diets of mammals, including farm animals. αAI-Pa1 and αAI-Pa2 are only active against insect α-amylases, having broad specificity towards storage pest α-amylases. Therefore, tepary bean αAIs have potential for crop protection from seed-eating insects by genetic engineering. Further studies on novel types of bean inhibitors such as αAI-Pa1 should elucidate the relationship between specificity and structure.

3. Experimental

3.1. Materials

Two wild accessions (G40072 and G40074) and 3 cultivated accessions (PI311897, PI321437 and Nayarit) of tepary bean were obtained from the Centro International de Agricultura Tropical (CIAT) in Cali, Columbia. Two common bean cultivars, Taisho-kintoki (containing αAI-1) and Shiro-kinugasa (containing αAI-1) were obtained from Hokkaido Prefectural Tokachi Agricultural Experiment Station in Memuro, Japan. Each near isogenic line, TO line (lacking αAI) or TAr4 line (containing αAI-2), was developed by backcrossing five times Taisho-kintoki into either an αAI-lacking cultivar (Ofuku-5) or a wild common bean accession (G12953). A laboratory colony of *C. chinensis* was obtained from the National Institute of Agro-Environmental Sciences, Tsukuba, Japan. Colonies of *C. maculatus* and *Z. subfasciatus* were obtained from the University of Tsukuba, Tsukuba, Japan. Larvae of yellow mealworm (*Tenebrio molitor*) and confused flour beetle (*Tribolium confusum*) were provided by the National Food Research Institute, Tsukuba, Japan. Porcine pancreatic α-amylase (Type I-A), human salivary α-amylase (type IX-A), fungal α-amylase from *Aspergillus oryzae*, and bacterial α-amylase from *Bacillus licheniformis* were purchased from Sigma

(St. Louis, MO). Phytohemagglutanin-P (PHA-P) from *Phaseolus vulgaris* was purchased from Wako Pure Chem. (Kyoto, Japan). DEAE-Sephacel, ConA-Sepharose, CM-Sepharose CL-6B, Superose 12, Superdex 200 were purchased from Amersham Pharmacia Biotech (Buckinghamshire, England). BCA protein assay kit was purchased from Pierce (Rockford, IL). Polyvinylidene difluoride (PVDF) membrane was from Bio-Rad (Hercules, CA). All other chemicals and reagent used were of analytical grade.

3.2. Seed protein extraction

The distal portion (50 mg) of individual dry seeds was ground with a mortar and pestle in 500 μl of 20 mM sodium phosphate buffer (PBS) pH 6.8. The supernatant was obtained by centrifugation at 15,000×*g* for 5 min at 4°C. The protein content in each seed extract was determined with a BCA protein assay kit, and then diluted to an adequate concentration for the analysis of inhibitory activity or immunoblotting.

3.3. α-Amylase inhibition assay

The α-amylases of three bruchid species, *C. chinensis*, *C. maculatus* and *Z. subfasciatus*, were prepared by homogenization of dissected larval guts as described previously (Ishimoto and Chrispeels, 1996), except for the use of 20 mM PBS buffer (pH 5.8). The larval α-amylases of *T. molitor* and *T. confusum* were prepared by homogenization of whole larvae with the above buffer. α-Amylase activity was measured with a modification of the Bernfeld method (Bernfeld, 1955) at pH 5.8 for insect α-amylases or at pH 6.8 for mammal, fungal and bacterial α-amylases. One unit of α-amylase activity is defined as the amount of enzyme that liberates 1 μmol of maltose at 37°C in 5 min under the assay condition. To analyze the inhibitory activity, seed extract or purified α-amylase inhibitor was pre-incubated with one unit of each α-amylase preparation prior to the addition of substrate solution.

3.4. Hemagglutination assay

Hemagglutination activity was measured using a serial dilution of rabbit erythrocytes. Five millilitres of rabbit blood was centrifuged at 1,500 *g* and 4°C for 10 min to remove the plasma. The erythrocytes were suspended in 5 ml of 50 mM sodium phosphate buffer, pH 6.7, containing 0.15 M NaCl, centrifuged at 1000 *g* and 4°C for 10 min, and washed three times with the same buffer. Finally, erythrocytes were resuspended to 3% (v/v) in the same buffer. The hemagglutination activity of each purified inhibitor was measured in microtiter plates. Each protein sample was serially diluted from the original concentration, 28 μg in 40 μl, and then mixed well with an equal volume of erythrocyte suspension. After 2 h at room temperature, agglutination was observed. PHA-P was used as a standard.

3.5. Electrophoresis and immunoblotting

Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) (13.5% acrylamide) was performed according to the method of Laemmli (Laemmli, 1970). After separation by SDS-PAGE, polypeptides were transferred onto a PVDF membrane, and reacted with polyclonal antibodies against αAI-1 (Ishimoto et al., 1996). Goat anti-rabbit IgG coupled to horseradish peroxidase (Cappel) was used as secondary antibody for the detection of the products obtained with αAI-1 antibodies.

3.6. Purification of α-amylase inhibitor protein

α-Amylase inhibitor was purified from seeds of a tepary bean cultivar PI311897. Seed flour (20 g) was extracted with 200 ml of 20 mM sodium phosphate buffer (PBS), pH 6.7 at 4°C for 3 h. After centrifugation, the supernatant was fractionated by ammonium sulfate precipitation with 20–60% saturation. The precipitate was collected by centrifugation, dissolved with 50 ml of 20 mM PBS and dialyzed against the same buffer for 24 h. This material was applied to a column of DEAE-Sephacel equilibrated with 20 mM PBS (pH 6.7). The unadsorbed fraction was pooled and applied to a column of ConA-Sepharose equilibrated with 20 mM PBS (pH 6.7) containing 0.5 M NaCl. The adsorbed fraction was eluted with the same buffer containing 0.1 M α-methyl-D-mannopyranoside. The eluate was dialyzed against a 50 mM acetate buffer (pH 3.6), and this material was applied to a column of CM-Sepharose CL-6B equilibrated with the same buffer. The adsorbed material was eluted with a linear gradient from 0 to 1.0 M NaCl in the same buffer. The fractions showing αAI activity were dialyzed against distilled water, and lyophilized. The lyophilized material was dissolved in 50 mM PBS (pH 6.7) containing 0.15 M NaCl and was purified by gel filtration on a column of Superose 12 equilibrated with the same buffer.

αAI-1 and αAI-2 were purified from common bean cultivars, Taisho-kintoki and TAr4, according to the method of Suzuki et al. (1993).

3.7. Estimation of molecular weight

Molecular weight of αAI-Pa1 and αAI-Pa2 were estimated by gel filtration chromatography of a Superdex 200 column (1×30 cm). Proteins were eluted with 50 mM PBS (pH 6.7) containing 0.15 M NaCl at a flow rate of 0.5 ml/min, and monitored by absorbance at 280 nm. The following proteins were used as standard samples,

bovine serum albumin (67 kDa), ovalbumin (43 kDa), chymotrypsinogen A (25 kDa), myoglobin equine (17.8 kDa), and ribonuclease A (12.3 kDa). Blue dextran was used to measure the void volume.

3.8. N-terminal amino acid sequencing

After separation of the purified αAIs by SDS-PAGE, the polypeptides were transferred onto a PVDF membrane and detected by Coomassie brilliant blue staining. The bands corresponding to the αAI subunits were cut out and the N-terminal amino acid sequences were determined with a gas-phase protein sequencer 492 (Applied Biosystems).

Acknowledgements

We thank Dr. K. Fujii, University of Tsukuba, for providing us with colonies of *C. maculatus* and *Z. subfasciatus*.

Abstract

Raffinose oligosaccharides (RO) are the major factors responsible for flatulence following ingestion of soybean derived products. Removal of RO from seeds or soymilk would then have a positive impact on the acceptance of soy-based foods. Enzymic hydrolysis of the RO is accomplished by α-galactosidase. While the content of RO decreases during seed germination, the activity of α-galactosidase increases substantially. Two α-galactosidases were isolated from germinating seeds by partition in an aqueous two-phase system followed by ion-exchange and affinity chromatography. One of the enzyme preparations (P1) showed a single protein with M_r of 33 kDa, and the second (P2) had two proteins with M_r of 31 and 33 kDa. Maximal activities against the synthetic substrate ρ-nitrophenyl-α-D-galactopyranoside (ρNPGal) were detected at pH 5.0–5.5 and 45–50°C. Both enzymes were fairly stable at 40°C, but lost most of their activities after 30 min at 50°C. The K_m values for hydrolysis of ρNPGal by the P1 and P2 enzymes were 1.55 and 0.76 mM, respectively. The K_m values determined for hydrolysis of raffinose and melibiose by the P2 enzyme were 5.53 and 5.34 mM, respectively and galactose was a competitive inhibitor ($K_i = 0.65$ mM). To different extents, both enzymes were sensitive to inhibition by galactose, melibiose, $CuSO_4$, and SDS. Sucrose and β-mercaptoethanol showed discrete inhibitory effects on both enzymes. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Soybean (*Glycine max* L.) is an excellent source of proteins for human and animal use. Nevertheless, due to its raffinose oligosaccharides (RO) content, mainly raffinose [α-D-galactopyranosyl-(1,6)-α-D-glucopyranosyl-β-D-fructofuranoside] and stachyose [α-D-galactopyranosyl-(1,6)-α-D-galactopyranosyl-(1,6)-α-D-glucopyranosyl-β-D-fructofuranoside], the legume has not been used to its full potential. Since humans and other monogastric animals lack the enzyme α-galactosidase (E.C. 3.2.1.22, α-D-galactoside galactohydrolase), necessary for hydrolysis of the α-1,6 linkages present in RO (Gitzelmann and Auricchio, 1965), these sugars pass intact into the large intestine where anaerobic micro-organisms ferment then and cause flatulence. It is suggested that blocking the expression of the galactinol synthase gene which codes for the key enzyme on the synthetic route of the RO in the seeds, could decrease RO content and reduce flatulence caused by legumes (De Lumen, 1992). On the other hand, enzymic conversion of these RO in soymilk may be a rational alternative to improve the nutritional quality of this low-cost, high-quality protein supplement for humans and animals (Cruz and Park, 1982; De Rezende and Felix, 1997; Sanni et al., 1997). Hydrolysis of RO may be achieved either by α-galactosidase, invertase or both. While α-galactosidase hydrolyses the α-1,6 linkage of raffinose producing galactose and sucrose, the invertase hydrolyses the α-1,2 linkage producing melibiose and fructose. α-Galactosidase enzymes are widely distributed in microorganisms (De Rezende and Felix, 1999), plants and animals (Dey and Pridham, 1972). However, no economically efficient enzymic process using either indigenous or recombinant soybean α-galactosidase to reduce RO in soymilk has yet been

proposed. Here we report on the characterization of α-galactosidases from germinating soybean seeds, and on the possibility of using these enzymes for hydrolysis of the RO present in soymilk.

2. Results and discussion

The RO content in germinating soybean seeds decreased during germination (Fig. 1). Consistently, the activity against the synthetic substrate (*ρ*-nitrophenyl-α-D-galactopyranoside) *ρ*NPGal (Fig. 1), and the content of soluble fructose (not shown) increased confirming hydrolysis of the fructose-containing oligosaccharides. The results confirm previous reports that RO are used as an energy source during seed germination (Porter et al., 1990; Avigad and Dey, 1997).

Most of the α-galactosidase activity (80%) present in the seed crude extract partitioned into the upper phase of an aqueous two-phase system (ATPS), which contained 12% NaCl. Chromatography of the resulting ATPS enzyme sample on a CM-Sepharose column (Fig. 2) resulted in the separation of two protein fractions (P1 and P2). SDS–PAGE analysis revealed that while the P1 active fraction contained a single protein with M_r of 33 kDa, the P2 active fraction contained two

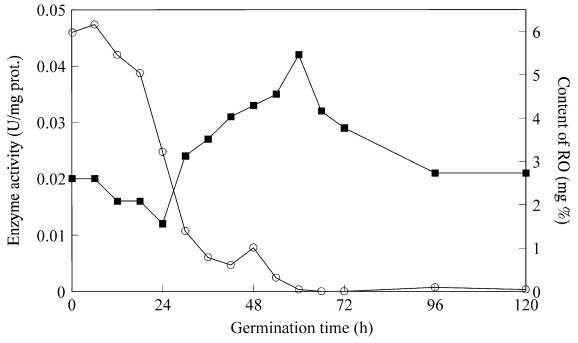

Fig. 1. α-Galactosidase activity (■) and content of raffinose oligosaccharides (raffinose + stachyose) (○) in soybean seeds after germination.

protein forms with M_r of 31 and 33 kDa. Affinity chromatography of the enzyme fractions resulted in further purification of the enzyme forms as indicated by their higher specific activities (Table 1). The electrophoretic profile of the two enzyme preparations in SDS-polyacrylamide gel (Fig. 3) confirmed the presence of a single protein band in the P1 fraction (33 kDa), and a broad band corresponding to the two protein forms of 31 and 33 kDa in P2. It was previously reported that the cotyledonary α-galactosidases from *Vigna unguiculata* have M_r of 33 kDa (Oliveira-Neto et al., 1998). In addition, a recombinant protein from *Glycine max* produced in *Pichia pastoris* purified by affinity chromatography showed a relative molecular mass of 39.8 kDa under reducing conditions, and of 38 kDa under non-reducing conditions as judged by electrophoretic analysis (Davis et al., 1996). Another α-galactosidase purified to near electrophoretic homogeneity from dry soybean seeds was shown to be monomeric at pH 7.0 with a molecular mass of 40 kDa, and to be tetrameric at pH 4.0 with a molecular mass of about 160 kDa (Porter et al., 1990). Both the tetrameric and monomeric forms were enzymically active but displayed different kinetic properties (Campillo and Shannon, 1982). It is not clear whether the 31 kDa protein present in the P2 enzyme preparation reported here is also active. *Phaseolus vulgaris* has two α-galactosidase isoenzymes with molecular masses of 38.3 and 39.6 kDa which co-migrate after several salt precipitation and chromatographic procedures (Dhar et al., 1994). The 31 and 33 kDa proteins, which could not be separated even after affinity chromatography, might well be isoforms, but additional studies are needed to characterize the 31 kDa protein.

Substantial activity against *ρ*NPGal was observed for both enzyme preparations in the temperature range of 20–70°C and in the pH range of 6.5–7.0. Maximal substrate hydrolysis by the P1 and P2 enzymes were achieved at the temperature of 45 and 50°C, respectively. The optima pH for the P1 and P2 enzymes were 5.0 and 5.5, respectively. These pH optima and temperature values are close to those determined for hydrolysis of *ρ*NPGal and melibiose by a crude α-galactosidase from germinating soybean seed (Cruz and Silva, 1986), by the cotyledonary α-galactosidases from *V. unguiculata* (Oliveira-Neto et al., 1998) and by the fungal raffinose-hydrolysing enzymes (De Rezende and Felix, 1999). The K_m and V_{max} values calculated by the Lineweaver–Burk plot for hydrolysis of *ρ*NPGal by the P2 and P1 enzymes were 0.76 mM and 1.76 μmol min^{-1} ml^{-1}, and 1.55 mM and 2.43 μmol min^{-1} ml^{-1}, respectively. These values are comparable to those determined for hydrolysis of the same substrate by a crude α-galactosidase from germinating soybean seed (Cruz and Silva, 1986). Both the P1 and P2 α-galactosidases were moderately thermostable. The enzymes retained about 50% of their original activity following incubation for 2 h at 40°C

Table 1
Summary of the purification steps of the α-galactosidases from germinating soybean seeds

Purification step	Total protein (mg)	Total activity (U)	Specific activity (U/mg protein)	Purification (fold)	Recovery (%)
Crude extract	21488.0	574.9	0.026	–	–
Upper layer of ATPS	1203.4	401.9	0.33	12.7	69.9
Dialyzed sample	728.5	263.5	0.36	13.9	45.8
CM-sepharose					
P1	12.6	42.0	3.33	128	7.3
P2	9.6	88.0	9.2	352	15.3
Con-A (P1)	0.48	6.8	14.2	545	1.2
Con-A (P2)	0.18	11.25	62.50	2404	2.00

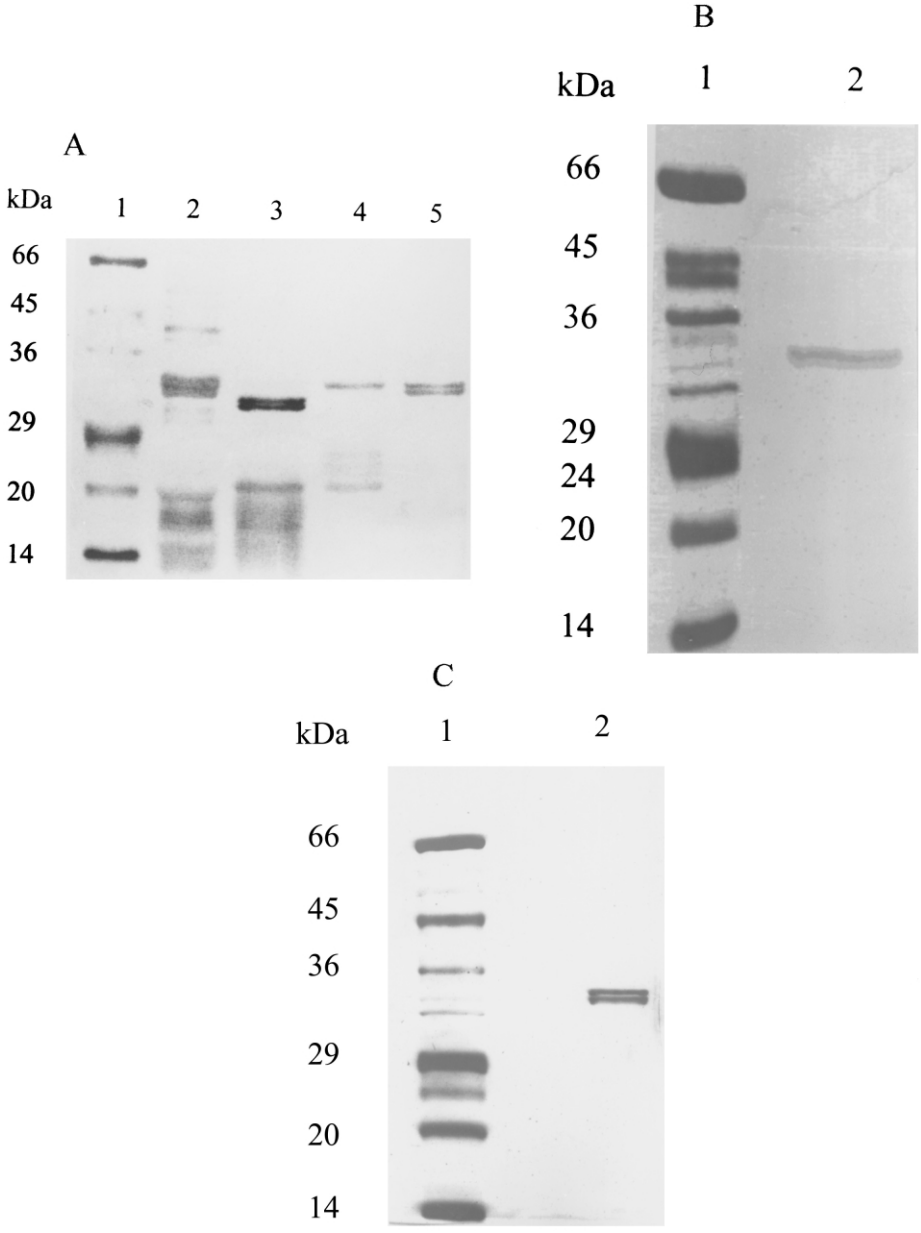

Fig. 3. SDS–PAGE of different purification steps of α-galactosidases from germinating soybean seeds. Lanes are as follows: A: 1, molecular mass standards; 2, crude extract; 3, upper phase of ATPS; 4, enzyme preparation P1 from CM-Sepharose; 5, and P2, enzyme preparation P2 from CM-Sepharose; B: 1, molecular mass standards; 2, P1 eluted through ConA; C, 1, molecular mass standards; 2, P2 eluted through ConA.

(Fig. 4), but 90% of the activity was lost by both enzyme preparations following 45 min of incubation at 50°C (Fig. 5).

The activities of the P1 and P2 α-galactosidases against other substrates are shown in Table 2. Both enzymes were able to hydrolyze melibiose, raffinose and stachyose. However, the affinities for these substrates were much lower in comparison to that against ρNPGal. The K_m and V_{max} values for hydrolysis of melibiose by the P2 enzyme were 5.34 mM and 0.13 μmol min^{-1} ml^{-1}, respectively. Values for raffinose were 5.53 mM and 0.43 μmol min^{-1} ml^{-1}, respectively. The K_m value for hydrolysis of raffinose is close to that determined for the α-galactosidase purified from dry soybean seeds (Porter et al., 1990), but much lower than those reported for hydrolysis of raffinose by enzymes from *Aspergillus fumigatus* (De Rezende and Felix, 1999) and *Trichoderma reesei* (Zeilinger et al., 1993). Lactose and synthetic substrates containing β-linkage were hydrolyzed by the P1 enzyme but not by the P2 enzyme. None of the enzyme preparations showed substantial activity against sucrose and cellobiose and the synthetic substrates containing xylose ρNP-X, arabinose ρNP-A and mannose ρNP-M (Table 2).

The P1 and P2 α-galactosidases showed distinct sensitivities to simple sugars and mono and divalent ions (Table 3). The P1 enzyme showed very low or no inhibition by galactose, glucose, sucrose, melibiose, magnesium, potassium, sodium, calcium and β-mercaptoethanol, but was highly inhibited by copper and SDS. The P2 enzyme was only partially inhibited by galactose, melibiose, copper, and SDS. This is in agreement with the results reported for the cotyledonary α-galactosidases from *V. unguiculata* (Oliveira-Neto et al., 1998). Inhibition by galactose was found to be competitive and the K_i value was 0.65 mM as determined by the Dixon plot. In a previous work Porter et al. (1990) reported that galactose competitively inhibited (K_i of

[a] The final concentration of SDS was 1 mM. The final concentrations of all the other effectors were 2 mM.

0.12 mM) the α-galactosidase purified from dry soybean seeds with raffinose as substrate.

As the enzymes were able to hydrolyze also melibiose, raffinose and stachyose, the ability of P1 and P2 to hydrolyse RO present in the soybean aqueous extract (soymilk) was tested. Sucrose, raffinose and stachyose were present in dried soymilk at the concentrations of 10.25, 1.33 and 8.47 mg% (w/w), respectively. No change was observed for the amount of the RO in the control reactions. The P1 enzyme could not hydrolyze the RO present in soymilk, in contrast the P2 enzyme reduced considerably the amount of raffinose (by 73.3%) and stachyose (by 40.6%) after an incubation period of 8 h at 30°C. Hydrolysis of RO in soymilk by enzymic treatment was tested in 1982 by Cruz and Park (1982), and later by other researchers (Mulinami et al., 1997; Sanni et al., 1997; Scalabrini et al., 1998). However, no reliable, inexpensive and efficient enzymic process with indigenous or recombinant enzymes is available so far. In general, the enzymes suggested for this purpose are of microbial origin and therefore present the disadvantage of having no GRAS (generally regard as safe) status. The results presently reported indicate that the soybean seed α-galactosidases or the corresponding genes may be used for establishment of a process to improve the nutritional value of soymilk. Cloning of the genes encoding the P1 and P2 α-galactosidases is underway.

3. Experimental

3.1. Plant material and enzyme preparation

Soybean seeds (*G. max* L. Merr. cv. Doko) were allowed to germinate for 54 h, on a water-soaked filter paper (Germitest) at 27°C, and then frozen at −20°C. The frozen pre-germinated seeds (400 g fresh weight) were powdered in a blender and then resuspended in 800-ml of 0.1 M citric acid containing 0.05 M sodium phosphate, pH 5.5, and incubated with agitation for 1 h at 4°C. The suspension was then filtered through cheesecloth, the filtrate centrifuged (15,300 *g*) for 40 min at 4°C, and the supernatant used as a crude enzyme preparation.

3.2. α-Galactosidase assay

The enzyme was assayed using a reaction system (1 ml final volume) containing 650–750 μl of 0.1 M sodium acetate buffer, pH 5 (except when stated), 0–100 μl of enzyme preparation and 250μl of 2 mM ρ-nitrophenyl α-D-galactopyranoside (ρNPGal) or, other synthetic substrates. Reaction was conducted for 15 min at 37°C and stopped by the addition of 1 ml of 0.5 M sodium carbonate. The reaction was shown to be a first order reaction over a 60-min period. One unit (U) of enzyme was defined as the amount of protein necessary to produce one μmol of ρ-nitrophenol per min. For determination of thermal stability the enzyme fractions were pre-incubated for several time periods at either 40 or 50°C, and the residual activity was determined using the standard assay. The activities against raffinose, stachyose and sucrose were assayed for 20 min at 37°C using a reaction mixture containing 500 μl of 0.1 mM sodium acetate buffer, pH 5.0, 100μl of enzyme extract, and 400 μl of a 0.1 M substrate solution. The amount of reducing sugar produced was determined by adding 1 ml of 3,5-dinitrosalicylate reagent according to Miller (1956). The activities against melibiose, lactose, maltose and cellobiose were assayed using the same reaction conditions and substrate concentrations used for raffinose, stachyose and sucrose. In this case, the amount of glucose formed was determined by the glucose–oxidase method (Bergmeyer and Bernt, 1974). The data presented for all α-galactosidase activity determinations are mean values of triplicate assays in which the standard deviations were always smaller than 10%.

3.3. α-Galactosidase purification

The soybean enzyme was purified by separation on an ATPS (Hustedt et al., 1985) followed by two chromatography procedures. The ATPS consisted of 224 g of a 50% (w/w) polyethyleneglycol (PEG 1500) solution, 280 g of a 40% (w/w) monobasic and dibasic sodium phosphate solution, pH 5.0, 84 g of sodium chloride, and 112 g of crude enzyme extract. Samples (50 g each) of the aqueous mixture was transferred to centrifuge tubes which were vortex mixed for 1 min and then centrifuged for 5 min at 4100 *g* and 8°C. The volumes of the upper and lower phases were determined in graduated tubes, and collected separately. Protein and enzyme partition coefficients in the ATPS were calculated by measuring the amount of protein and enzyme in each phase. The effect of NaCl on the partition coefficient was investigated using 0, 3, 6, 9 and 12% NaCl in the ATPS. The upper phase resulting from the ATPS containing the enzyme was dialyzed overnight against 50 mM sodium acetate buffer, pH 4.0, and loaded onto a CM-Sepharose Fast Flow column (3×13 cm) equilibrated with 0.1 M sodium acetate buffer, pH 4.0. The proteins were eluted at 4°C at a flow rate of 40 ml/h, with a linear gradient formed with 300 ml of the acetate buffer and 300 ml of the same buffer containing 0.8 M NaCl. Five-ml fractions were collected. Fractions containing α-galactosidase activity were pooled and mixed with equal volume of sodium acetate buffer, pH 5.0, containing 1 mM each of $MnCl_2$, $MgCl_2$ and $CaCl_2$, and 0.9% NaCl. The resulting enzyme preparations where then chromatographed on a concanavalin-A Sepharose column (2×15.5 cm) equilibrated with the acetate ion-contain-

ing buffer. Proteins were recovered with 150 ml of equilibrating buffer containing 0.1 M methyl α-D mannoside.

3.4. Electrophoresis analysis

Enzyme preparations were analyzed by SDS–PAGE (12.5% gels) as described by Laemmli (1970). Proteins were silver-stained according to Blum et al. (1987).

3.5. Enzyme characterization

Kinetic experiments were performed at 37°C and pH 5.0. The Michaelis–Menten constant (K_m) and V_{max} for substrate hydrolysis and the inhibition constant (K_i) for galactose were calculated by the Lineweaver–Burk plot and Dixon plot, respectively. The substrate concentrations were: 0.025, 0.05, 0.1, 0.15, 0.25, 0.50, 0.75, 1.0, 1.5, and 2.0 mM in the case of ρNPGal, 0.25, 0.5, 1.5, 2.5, 5.0, 10.0, 20.0, and 40.0 mM for melibiose and raffinose. For K_i determination for galactose, the following ρNPGal concentrations were used: 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, and 1.0 mM. The galactose concentrations used were 0.25, 0.5, and 1.0 mM. The effect of ions, simple sugars and reducing agent on the enzyme activity was tested by the standard assay with enzyme samples preincubated with each of the compounds tested for 15 min at 37°C.

3.6. Treatment of soybean milk with α-galactosidase

Soymilk was prepared from dry seeds (50 g). The seeds were chopped, homogenized in 400 ml water at 80°C, incubated for 10 min at 85°C, and filtered through cheese-cloth. Soymilk samples (2 ml) were then incubated with either water or 2 U of purified α-galactosidase for zero or 8 h with shaking (100 rpm) at 30°C. Each reaction mixture was dried and the soluble sugars extracted from 20 mg of dried powder with organic solvents according to Saravitz et al. (1987). The solvent was evaporated at 40°C and the sugars resuspended in 1 ml water. The sugars were analyzed by HPLC on a Shimadzu series 10A chromatograph using an analytical column [aminopropil (-NH_2)] eluted with an acetonitrile–water isocratic mixture (80:20 v/v). Individual sugars were automatically identified and quantified by comparison with retention times and known concentrations of standard sugars. Gentiobiose was used as an internal standard as it does not interfere with the other sugars and it is not found in soybean seeds.

3.7. Protein determination

Protein was quantified by the Coomassie Blue binding method (Bradford, 1976) with bovine serum albumin as standard.

Received 13 December 2000; received in revised form 27 March 2001

Abstract

The characteristic pigmentation of ripe tomato fruit is due to the deposition of carotenoid pigments. In tomato, numerous colour mutants exist. The *Cnr* tomato mutant has a colourless, non-ripening phenotype. In this work, carotenoid formation in the *Cnr* mutant has been studied at the biochemical level. The carotenoid composition of Ailsa Craig (AC) and *Cnr* leaves was qualitatively and quantitatively similar. However, *Cnr* fruits had low levels of total carotenoids and lacked detectable levels of phytoene and lycopene. The presence of normal tocopherols and ubiquinone-9 levels in the ripe *Cnr* fruits suggested that other biosynthetically related isoprenoids were unaffected by the alterations to carotenoid biosynthesis. In vitro assays confirmed the virtual absence of phytoene synthesis in the ripe *Cnr* fruit. Extracts from ripe fruit of the *Cnr* mutant also revealed a reduced ability to synthesise the carotenoid precursor geranylgeranyl diphosphate (GGPP). These results suggest that besides affecting the first committed step in carotenoid biosynthesis (phytoene synthase) the *Cnr* mutation also affects the formation of the isoprenoid precursor (GGPP).

1. Introduction

Carotenoid pigments are synthesised by all higher plants, algae, and some bacteria and fungi (Britton et al., 1995). Although essential for human health, carotenoids can not be synthesised de novo in the body and must be acquired from the diet (Parker, 1996). Tomato fruit and its products (e.g. ketchup, juices, soups and sauces) are the principal source of carotenoids in the western diet. Lycopene, the predominant carotenoid found in tomato, is a powerful antioxidant and may prevent the onset of serious disease states such as prostate cancer (Giovannucci et al., 1995). In addition, β-carotene is a provitamin A carotenoid and its deficiency can cause xerophthalmia, blindness, and premature death (Mayne, 1996). It is not surprising therefore, that the regulation of carotenoid biosynthesis in higher plants and especially crop plants, has become an area of considerable interest.

In higher plants, carotenoid biosynthesis and sequestration occurs in the plastid. In photosynthetic tissues, this occurs in the chloroplasts, while in non-photosynthetic plant tissues such as fruits and flowers carotenoid accumulation occurs in chromoplasts. Carotenoid formation utilizes the ubiquitous isoprenoid precursor geranylgeranyl pyrophosphate (GGPP). Two molecules of GGPP are condensed to form phytoene and this reaction is catalysed by phytoene synthase (PSY). Phytoene is then converted to lycopene in a series of dehydrogenation reactions, which introduce four double bonds into the phytoene molecule. This conversion is performed by the sequential action of phytoene and ζ-carotene desaturase enzymes respectively. The biosynthesis of β-carotene and α-carotene and xanthophylls then proceeds following the scheme shown in Fig. 1. Genes encoding the majority of the enzymes in the carotenoid biosynthetic pathway have been cloned. The ripening enhanced cDNA pTOM5 was identified as *Psy-1* in transgenic experiments (Bramley et al., 1992). The same sequence restores lycopene accumulation in transgenic *yellow-flesh* mutants identifying the mutation as a lesion in a *Psy-1* gene (Fray and Grierson, 1993). In both transgenic

plants containing *Psy-1* in an antisense orientation and in the *yellow flesh* mutant there are virtually no carotenoids in the ripe fruits (Fray and Grierson, 1993), although carotenoid levels in leaf and green fruit are essentially unaffected. This is due to the presence of another phytoene synthase, *Psy-2*, which is principally responsible for phytoene formation in chloroplast containing tissues (Fraser et al., 1999).

The regulation of carotenoid biosynthesis in higher plants is poorly understood. Tomato ripening mutants such as high-pigment (*hp*) (Yen et al., 1997) and colourless non-ripening (*Cnr*) (Thompson et al., 1999) are useful tools for exploring the regulation of this process. In *hp,* the level of carotenoids is twice that in normal fruits, but with a quantitatively very similar pattern (Bramley, 1997). This difference almost certainly reflects an increase in plastid number (Yen et al., 1997). The *hp* gene maps to chromosome 2 and is not allelic with any known carotenoid biosynthetic genes. In the *Cnr* mutant, carotenoid biosynthesis is all but abolished resulting in mature fruit with a white pericarp. This mutation also has other pleiotropic effects including altered fruit softening (Thompson et al., 1999). Like *hp,* the *Cnr* mutation maps to chromosome 2 in a location devoid of other known fruit ripening genes.

The purpose of this study was to characterise carotenoid biosynthesis in developing and ripening *Cnr* fruits at the biochemical level, in order to provide a greater insight into the mechanism of action of the C*nr* mutation.

2. Results and discussion

2.1. Carotenoid and isoprenoid analysis of Ailsa Craig (AC) and Cnr tissues

HPLC-PDA (photodiode array) analysis of carotenoids extracted from AC and *Cnr* chloroplast-containing tissues (leaf and developing fruit) show a very similar pigment profile (Table 1). The predominant pigment was the xanthophyll lutein (55–80%) also present in appreciable amounts were violaxanthin and β-carotene. Although not drastically reduced, less total carotenoid was found in the leaf and mature green fruit stage of the *Cnr* mutant (70 and 57% less respectively). As fruit ripening proceeded the characteristic accumulation of lycopene was not observed in the *Cnr* mutant, the intermediate phytoene also appeared to be absent. The total carotenoid content of AC fruit was 100-fold higher than in the mutant (Table 1), confirming previous data (Thompson et al., 1999). The profile of carotenoids in the ripe Cnr fruit resembles that found in green fruit or leaf tissue (Fig. 2, Table 1). However, the mature green and ripe Cnr fruits appear to lack violaxanthin, which would presumably result in an inhibition of ABA biosynthesis. Determination of other related isoprenoids e.g. tocopherols and ubiquinone-9 revealed no differences between *Cnr* and AC fruits (Table 2). The apparent reduction in leaf carotenoid levels in *Cnr* may reflect an affect of the mutation in tissues other than fruits. The data for the leaf samples was, however, quite variable due probably to effects of position of leaf with respect to others in the canopy and leaf carotenoid levels requires further investigation.

Comparison of the carotenoids present in AC and the *Cnr* mutant indicates that *Cnr* lacks the characteristic accumulation of ripening (or chromoplast) related carotenoids (e.g. lycopene and phytoene). Previous studies (Thompson et al., 1999) have shown that *Psy*-1 is not expressed in the *Cnr* mutant fruit. Characterisation of AC and *Cnr* carotenoids supports the absence of *Psy*-1 expression and show that *Psy-2* can not compensate for its absence in the formation of carotenoid in ripe fruit, as postulated previously (Fraser et al., 1999). Both *Psy-1* down-regulated mutants (Bramley et al., 1992; Fray and Grierson, 1993) and the *Cnr* have a characteristic

yellow skin colour. This is due to the presence of the flavonoid naringen chalcone and not the presence of carotenoids (Bolwell, Fraser and Bramley, unpublished data).

Structurally, tocopherols possess a prenyl moiety, which is derived from GGPP. In *Cnr* tocopherols were not affected, suggesting that a pool of GGPP is available and that the *Cnr* mutation does not result in an absolute block in the formation of GGPP during fruit ripening. Unlike both the carotenoids and tocophorols, which are synthesised in the plastid from isopentenyl pyrophosphate (IPP) formed by the 'Rohmer' pathway, ubiquinone is a non-plastidic isoprenoid derived from IPP resulting from the mevalonate pathway. In the *Cnr* mutant ubiquinone content was unaffected.

2.2. In vitro analysis of phytoene synthesis from IPP

In order to confirm phytoene synthase as the biochemical block in *Cnr*, in vitro analysis was performed. Stromal extracts were prepared from both the AC and *Cnr*. The ability of these extracts to incorporate the precursor isopentenyl pyrophosphate (IPP) was determined. Data were expressed on a protein and fresh weight (FW) basis to eliminate possible discrepancies that may result from alterations in textural properties of the *Cnr* mutant. Comparisons clearly show (Table 3) that phytoene formation from [^{14}C]-IPP is significantly reduced (27-fold) in the *Cnr* mutant. Although not reduced as dramatically (5-fold), the levels of GGPP are also affected in *Cnr*. In contrast the total acid hydrolysable prenyl phosphates formed from IPP are not affected in the *Cnr* mutant. These data confirm that phytoene formation in the *Cnr* fruit is virtually abolished. Furthermore, besides

Table 3

	IPP isomerase activity		Formation from IPP			
			GGPP		Phytoene	
	dpm/g FW	dpm/mg Protein	dpm/g FW	dpm/mg Protein	dpm/g FW	dpm/mg Protein
AC	799±129	$6.0\times10^{6}\pm1.0$	68.0±22	$3.3\times10^{5}\pm0.7$	4.1±0.6	$3.0\times10^{4}\pm0.4$
Cnr	1186±190	$3.0\times10^{6}\pm0.5$	18±4.0	$6.7\times10^{4}\pm1.3$	0.47±0.1	$1.1\times10^{3}\pm0.2$

phytoene synthesis, it would appear that the formation of GGPP is also reduced in the mutant. The reduction in GGPP does not, however, affect tocopherols suggesting that another pool of GGPP separate from that utilized for carotenoid biosynthesis is available. To date only one GGPP synthase has been isolated from tomato (Römer et al., 1993) but several GGPP synthases have been identified in *Arabidopsis* (Scolnik and Bartley, 1996). It is, therefore, feasible that alternative GGPP synthase(s) exist in tomato one of which is responsible for the supply of GGPP into the carotenoid pathway.

The *Cnr* mutation is the result of a lesion in a single gene which has pleiotropic effects on ripening including abnormal softening and colour development . The *Cnr* gene is likely to be involved in the regulation of normal ripening in tomato (Thompson et al., 1999). Data presented in this article show that carotenoid formation is an important component of the co-ordinated fruit ripening processes upon which the *Cnr* gene product exerts its effects. Typically PSY-1 is regarded as the most influential step for carotenoid formation in tomato, but the biochemical data obtained from the *Cnr* mutant suggest that an accessible pool of GGPP is a prerequisite for carotenoid accumulation. Future isolation of the *Cnr* gene could provide an important tool in the engineering of quality traits into tomato fruit.

3. Experimental

3.1. Plant material, radiolabelled substrates and reagents

Tomato (*Lycoperiscon esculentum* Mill. cv Ailsa Craig) fruit and a near isogenic line of *Cnr,* produced by back-crossing five times to Ailsa Craig, followed by selfing to generate a homozygous mutant line.mutant line, were grown in a heated greenhouse using standard cultural practices with regular additions of N,P,K fertilizer and supplementary lighting when required. Fruits were harvested at the following days post anthesis (DPA): immature green (IMG, c. 20 days DPA), mature-green (MG, 35 DPA), breaker (B, 49 DPA) and breaker + 7 (B + 7, 56 DPA). The radiolabelled [1-^{14}C]-IPP (2.2 GBq/mmol) was purchased from Amersham International, Amersham, Bucks, UK. Biochemical reagents were supplied by Sigma, Poole, UK, unless otherwise stated.

3.2. Extraction, separation, and identification of carotenoids and isoprenoids

Procedures for the solvent extraction, HPLC separation, identification (PDA) and quantification are provided in Fraser et al. (2000a).

3.3. Preparation of subcellular extracts

Pericarp tissue typically from three to four tomatoes (65–100 g per tomato) were homogenised in a Waring blender at 4°C. The homogenisation buffer contained 0.4 M sucrose, 1 mM EDTA, and 1 mM DTT, buffered with 50 mM Tris–HCl (pH 8.0). Ice-cold buffer was added until it covered the pericarp tissue (about 1:3/1:4 fruit vol: buffer). The mixture was left for 20 min before homogenising for two 3 s bursts. The suspension was filtered through cotton wool sandwiched by two layers of muslin. The filtrate (homogenate) was subjected to further subcellular fractionation as described in Fraser et al. (2000b).

3.4. In vitro assays

[^{14}C]-Isopentenyl diphosphate (19 kBq) was used to ascertain incorporation into prenyl diphosphates as well as phytoene. Incubations were buffered with 0.4M Tris–HCl (pH 8.0), containing 1 mM DTT, 4 mM $MgCl_2$, 6 mM $MnCl_2$, 3 mM ATP, 0.1%(w/v) Tween 60, 1 mM KF and substrate. The total volume of the buffer mixture was 150 μl, to which 150 μl of the enzyme preparation was added. Incubations were shaken for 3–4 h at 28°C unless stated otherwise. Radiolabelled products were separated and identified as described in Fraser et al. (2000b).

3.5. Other determinations

Protein contents were estimated as detailed previously (Lowry et al., 1951). Prior to determination, proteins were precipitated (Wessel and Flugge, 1984). Determination of

radioactivity by liquid scintillation counting was carried out according Bramley et al., 1973).

Effect of culture conditions on the synthesis of vitamin D_3 metabolites in *Solanum glaucophyllum* grown in vitro

Alejandro Curino, Lorena Milanesi, Silvia Benassati, Mario Skliar, Ricardo Boland*

Departamento de Biología, Bioquímica y Farmacia, Universidad Nacional del Sur. San Juan 670, 8000 Bahia Blanca, Argentina

Received 27 July 2000; received in revised form 15 November 2000

Abstract

In cultured *Solanum glaucophyllum* we have recently described the operation of a light-independent pathway of 1α,25-dihydroxy-vitamin D_3 (1α,25$(OH)_2D_3$) biosynthesis which involves similar intermediates as in vertebrates. In this work we investigated factors influencing the formation of 1α,25$(OH)_2D_3$ and related sterols in *S. glaucophyllum* grown in vitro in darkness. Callus tissue and cells cultured in Murashige and Skoog medium in the absence of light were employed. Lipids were extracted with chloroform–methanol. The remaining water soluble fraction was incubated with β-glucosidase to release vitamin D_3 compounds from their glycoconjugated derivatives followed by organic solvent extraction. Vitamin D_3 derivatives were isolated by Sephadex LH-20 and high-performance liquid chromatography (HPLC). HPLC or competitive protein binding assays with intestine 1α,25$(OH)_2D_3$ receptor and serum vitamin D binding protein were used to quantify the metabolites. The levels of 1α,25$(OH)_2D_3$ in calli varied according to the tissue explant origin, e.g. stem > leaf > fruit. For all organs, the metabolite was mainly present as free sterol (> 80% of total). There were larger amounts of 25$(OH)D_3$ than 1α,25$(OH)_2D_3$. It was found that Ca^{2+}, auxin and kinetin are important factors upregulating 1α,25$(OH)_2D_3$ synthesis in *S. glaucophyllum* tissue and cells. Irradiation with UV light increased vitamin D_3 but not 1α,25$(OH)_2D_3$ levels. In agreement with these results, incubation of cells with [^{3}H]25$(OH)D_3$ revealed a low conversion rate to [^{3}H]1α,25$(OH)_2D_3$. The operation of a light-dependent pathway formation of vitamin D_3 coupled to higher expression of 25$(OH)D_3$-1α-hydroxylase may account for the large concentrations of 1α,25$(OH)_2D_3$ normally found in differentiated field-grown plants. © 2001 Elsevier Science Ltd. 1. Introduction

Solanum glaucophyllum Desf. (*Solanum malacoxylon* Send.) is a plant native to South America which causes calcinosis in animals (Worker and Carrillo, 1967; Morris, 1982). Early studies correlated this property to the existence in the plant of the hormonally active form of vitamin D_3, 1α,25-dihydroxy-vitamin D_3 [1α,25$(OH)_2D_3$; calcitriol] (Wasserman et al., 1976). It was subsequently reported that *S. glaucophyllum* also contains vitamin D_3 and 25-hydroxy-vitamin D_3 (Esparza et al., 1982). Vitamin D_3 derivatives have been detected in several members of the Solanaceae as well as species belonging to other families (Boland, 1986; Prema and Raghuramulu, 1994; Aburjai et al., 1998; Skliar et al., 2001). Studies with in vitro systems have shown that vitamin D sterols stimulate root development (Buchala and Schmid, 1979; Talmon et al., 1989) through activation of the Ca^{2+} messenger system (Vega and Boland, 1986; Vega et al., 1988), suggesting a physiological function for these compounds in plants. Congruent with the participation of a photolytic reaction in the generation of vitamin D_3, it has been reported that the vitamin D activity of *Trisetum flavescens*, when tested in rachitic rats, is dependent on UV light exposure (Zucker et al., 1980; Rambeck et al., 1981). Further metabolism of the sterol through a pathway similar to that occurring in animals has been suggested by the detection of vitamin D_3-25-hydroxylase and 25$(OH)D_3$-1α-hydroxylase activities in *S. glaucophyllum* leaf extracts and subcellular fractions (Esparza et al., 1982).

There is controversial evidence regarding the native structure and the tissue distribution of $1\alpha,25(OH)_2D_3$ and related metabolites in *S. glaucophyllum*. On the basis of their solubility properties it has been reported that vitamin D_3 derivatives are mainly found as glycoconjugates (Humphreys, 1973; Wasserman et al., 1976; Esparza et al., 1982). However, other lines of evidence are indicative of the presence of free vitamin D_3 sterols (Masselin et al., 1969; Procsal et al., 1976). Also, in contradiction to the initial belief that $1\alpha,25(OH)_2D_3$ was exclusively localized in the leaves of *S. glaucophyllum,* the application of sensitive assay procedures has allowed detection of this metabolite in all plant organs (Weissenberg et al., 1989). The first aspect is of pharmacological importance as free secosterols act faster and more potently than the corresponding glycosides (De Boland et al., 1978) and the second of economical significance when considering *S. glaucophyllum* tissues as a source of calcitriol for use in medicine and animal husbandry (Boland, 1986).

Recent studies have shown the presence of 7-dehydrocholesterol, vitamin D_3, $25(OH)D_3$ and $1\alpha,25(OH)_2D_3$ in *S. glaucophyllum* callus and cell cultures (Weissenberg et al., 1989; Aburjai et al., 1996; Curino et al., 1998), confirming that the plant itself, and not opportunistic organisms, is able to produce these sterols. More important, calcitriol formation in *S. glaucophyllum* grown in vitro under strict conditions of darkness could be shown, suggesting that a metabolic route independent of light is also operative in the generation of vitamin D_3 compounds (Curino et al., 1998). As UV irradiation of cultures increased only slightly the concentration of $1\alpha,25(OH)_2D_3$ the question arose as to whether either photolytic cleavage of 7-dehydrocholesterol or the following hydroxylations of vitamin D_3 and $25(OH)D_3$ would be limiting the efficiency of the light-dependent synthetic pathway of $1\alpha,25(OH)_2D_3$ in culture systems. The elucidation of this aspect as well as the identification of medium constituents influencing calcitriol synthesis in *S. glaucophyllum* in vitro may help to optimize conditions for its biotechnological production, i.e. as a potentially convenient alternative to the expensive chemical procedures designed to cover the widespread medical application of the secosteroid hormone and analogs (Bouillon et al., 1995).

In view of the above considerations, in the present work we measured in *S. glaucophyllum*, grown in the field or green-house and in vitro, the relative contents of free and glycoconjugated $1\alpha,25(OH)_2D_3$ from different plant organs, and examined the effects of UV light on the levels of $1\alpha,25(OH)_2D_3$ and its precursors. The latter study led us to measure the activity of $25(OH)D_3$-1α-hydroxylase in cultured *S. glaucophyllum*. In addition, we investigated the influence of medium concentration of Ca^{2+} and plant growth factors on calcitriol production.

2. Results and discussion

2.1. Distribution of free and conjugated forms of $1\alpha,25(OH)_2D_3$ in calli and organs from *S. glaucophyllum*

Previous studies have shown that calli derived from leaves *of S. glaucophyllum* synthesize $1\alpha,25(OH)_2D_3$ in vitro (Weissenberg et al., 1989; Aburjai et al., 1996; Curino et al., 1998). The ability of calli derived from other organs of the plant to produce the sterol was studied. The levels of both free and glycoconjugated $1\alpha,25(OH)_2D_3$ generated by the in vitro systems under darkness were quantitatively evaluated using a specific radioreceptor assay. As shown in Fig. 1, the amounts of metabolite in calli derived from stem and leaves were appreciably more elevated than in calli derived from fruits and roughly comparable to those found in the tissues of origin. However, fruits from *S. glaucophyllum* grown in the field contained considerably higher concentrations of $1\alpha,25(OH)_2D_3$. The latter is in agreement with the results of a previous study reporting the presence of calcitriol bioactivity in all vegetative organs of the plant, the berries being the highest accumulating tissue (Weissenberg et al., 1989). The differences in calcitriol levels observed between in vitro and in vivo conditions are in accordance with observations made with other plant secondary products and may be explained by cell transformation occurring upon culture. The distribution of free $1\alpha,25(OH)_2D_3$ and the corresponding glycosidic derivatives in calli from stem, leaf and fruit was 94/6, 80/20 and 78/22%, respectively. In tissues obtained from the plant the free form of the metabolite was also predominant (Fig. 1). Although it has been reported that $1\alpha,25(OH)_2D_3$, $25(OH)D_3$ and vitamin D_3 are mainly present as glycosides in *S. glaucophyllum* leaves (Humphreys, 1973; Wasserman et al., 1976; Esparza et al., 1982), our data are in agreement with various lines of evidence supporting the existence of free secosterols in the plant. Thus, it was early found that the ether soluble fraction of *S. glaucophyllum* exhibited vitamin D_3-like activity when given to animals (Masselin et al., 1969). In addition, other workers observed that plant extracts not hydrolyzed with glycosidases had the ability to compete with $[^3H]1\alpha,25(OH)_2D_3$ for binding to the chick intestine vitamin D receptor, known to interact with the hormonal metabolite with high specificity (Procsal et al., 1976). Weissenberg et al. (1989) have detected both $1\alpha,25(OH)_2D_3$ and $1\alpha,25(OH)_2D_3$-glycoside in *S. glaucophyllum* cultivated in the field, the free form prevailing in some tissues. Greater amounts of $1\alpha,25(OH)_2D_3$ than its glycoside counterpart have been detected also in several different plant species, e.g. *Cestrum diurnum* (Prema and Raghuramulu, 1994), *Lycopersicon esculentum* (Prema and Raghuramulu, 1996), *Nicotiana glauca* (Skliar et al., 2001), *Solanum tuberosum*, *Solanum melongena* and *Cucurbita pepo* (Aburjai et al.,

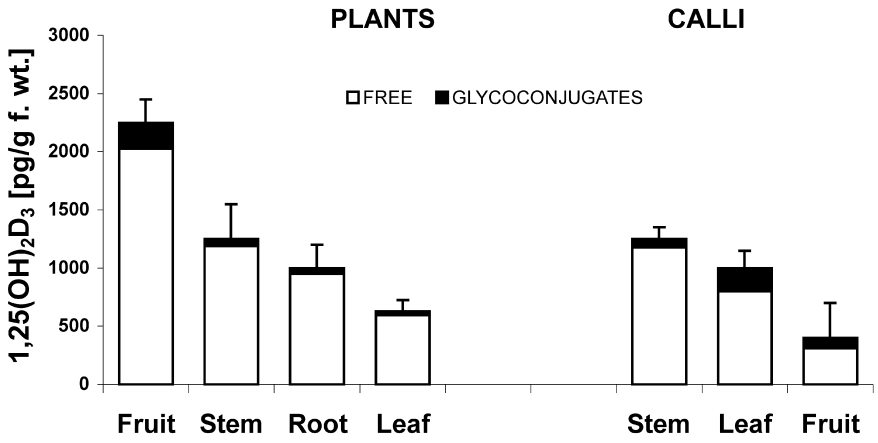

Fig. 1. Concentration of free and glycosidic $1\alpha,25(OH)_2D_3$ in *Solanum glaucophyllum* tissues and calli from different primary explants. Lipids were extracted with chloroform–methanol (1:2) by the Bligh and Dyer (1959) procedure. The remaining water soluble fraction was incubated with β-glucosidase to release sterols from their glyconjugated derivatives followed by organic solvent extraction. The $1\alpha,25(OH)_2D_3$ content of extracts was measured by radioreceptor assays as described in Experimental. Values are average of three determinations.

1998). In callus and cell suspension cultures derived from *S. glaucophyllum* leaves shown to contain 1α, $25(OH)_2D_3$, 7-dehydrocholesterol, vitamin D_3 and $25(OH)D_3$, again the free forms of these metabolically related vitamin D sterols are more abundant than their glycosides (Weissenberg et al., 1989; Aburjai et al., 1996; Curino et al., 1998). Comparison of the experimental conditions among the various studies cited brings about the possibility that formation of glycoconjugates of vitamin D_3 compounds in plants occurs to a great extent during drying and storage of collected tissues at the expense of the content of free sterols. In our work, *S. glaucophyllum* leaves were obtained in the field under dry-ice and stored lyophilized at −80°C until extraction, while calli were immediately extracted after removal from the culture medium. In contrast, investigations reporting the presence of substantial amounts of glycoside derivatives of $1\alpha,25(OH)_2D_3$ have used plant material oven-dried (60°C) for prolonged periods of time (Wasserman et al., 1976; Esparza et al., 1982; Weissenberg et al., 1989).

As recently reported (Curino et al., 1998), using a highly specific in vitro radioreceptor assay we have detected lower levels of $1\alpha,25(OH)_2D_3$ in field- and culture-grown *Solanum glaucophyllum* (Fig. 1) than those reported in other studies (Aburjai et al., 1996, 1997). Our results were validated by measuring the ability of plant and callus/cell extracts to stimulate intestinal ^{45}Ca absorption in vitamin D-deficient chicks (data not shown). Factors which may explain these differences are the distant geographic locations of the plants used for direct analysis or generation of cultures (Puche et al., 1980), the specifity/sensitivity of the assay procedures used to quantitate the metabolite (Boland, 1986) and, as addressed below, the culture medium composition.

2.2. Modulation by plant growth factors and calcium of $1\alpha,25(OH)_2D_3$ production in cultured *S. glaucophyllum*

Culture conditions are known to influence plant secondary product metabolism. In connection to the present work, it has been reported that *S. glaucophyllum* calli grown in Gamborg et al. (1968) medium synthesize greater amounts of cholesterol, 7-dehydrocholesterol and vitamin D_3 sterols than in Murashige and Skoog (1962) medium (Suardi et al., 1994; Aburjai et al., 1996). In agreement with this observation, significantly higher levels of $1\alpha,25(OH)_2D_3$ could be detected in the former than in the latter culture solution (Curino et al., 2001). As both media have a different content of plant growth factors and calcium, we investigated the effects of culturing *S. glaucophyllum* in the presence of varying concentrations of auxin (2,4-D), kinetin and Ca^{2+} on the formation of $1\alpha,25(OH)_2D_3$. The studies with plant hormones comprised four different treatment conditions, as follows: A: 0.5 mg/l 2,4-D + 0.2 mg/l kinetin; B: 1.0 mg/l 2,4-D + 0.4 mg/l kinetin; C: 2.5 mg/l 2,4-D + 1.0 mg/l kinetin, and D: 0.5 mg/l 2,4-D + 2.0 mg/l kinetin. The concentrations of metabolite were determined by radioreceptor assays and the results obtained were expressed relative to the standard condition A used in the other experiments included in the present investigations. As shown in Fig. 2, 1.7-, 4.2- and 17.9-fold increases in $1\alpha,25(OH)_2D_3$ levels could be measured for treatments B, C and D, respectively, as compared to condition A. Less evident changes were detected when cell suspensions were used instead of calli, e.g. 1.3-fold for B, 1.4-fold for C and 3.1-fold for D (Fig. 2). Similar relative increases were detected for calcitriol secreted into the culture medium (data not given). These results show then a clear stimulation by the plant growth factor binary

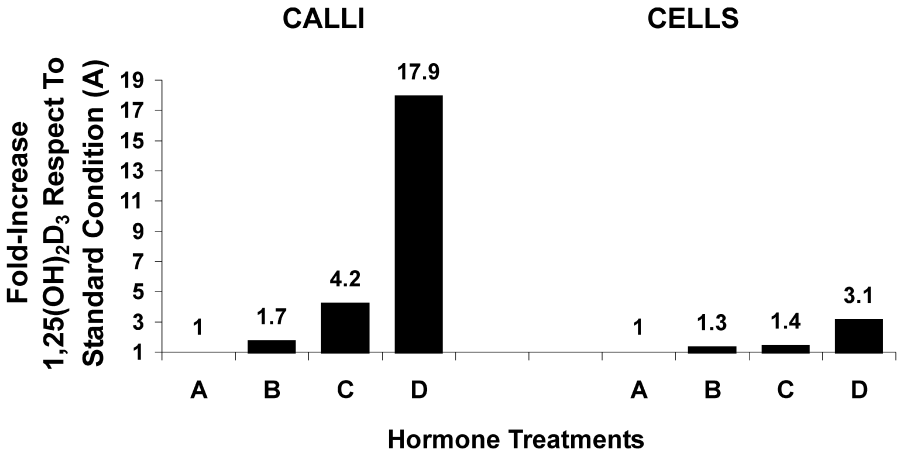

Fig. 2. Effect of plant growth regulators on the $1\alpha,25(OH)_2D_3$ content of cultured *Solanum glaucophyllum* calli and cells. Levels of free $1\alpha,25(OH)_2D_3$ in lipid extracts were measured as in Fig. 1. Values are average of three determinations. A = 0.5 mg/l 2,4D + 0.2 mg/l kinetin; B = 1 mg/l 2,4D + 0.4 mg/l kinetin; C = 2.5 mg/l 2,4D + 1 mg/l kinetin; D = 0.5 mg/l 2,4D + 2 mg/l kinetin.

mixture of $1\alpha,25(OH)_2D_3$ synthesis in *S. glaucophyllum*. As suggested by the data obtained with condition D, kinetin may play a major role in upregulating the production of the metabolite.

Regarding the influence of medium calcium concentration on calcitriol production by *S. glaucophyllum* grown in vitro, the studies performed with calli showed that media deprived of Ca^{2+} contained low levels of calcitriol. When using cation concentrations of 1, 8 and 13 mM the levels of metabolite detected by radioreceptor assays were increased 2.6-, 4.8- and 1.7-fold, respectively (Fig. 3). However, when similar experiments were performed with cell suspensions, only at 13 mM Ca^{2+} a significant increase in $1\alpha,25(OH)_2D_3$ was observed (1.7-fold). Contrary to our observations, an inverse relationship between medium Ca^{2+} concentrations and $1\alpha,25(OH)_2D_3$ formation has been reported before (Aburjai et al., 1997), curiously compared by these authors with Ca^{2+} regulation of calcitriol synthesis in animals which is known to be mediated by parathyroid hormone.

2.3. Effect of UV irradiation on the levels of vitamin D_3 and hydroxylated metabolites of S. glaucophyllum grown in vitro and in vivo

The operation of the light-dependent pathway in the generation of vitamin D_3 sterols was reinvestigated measuring the effects of UV irradiation on the levels of $25(OH)D_3$ and vitamin D_3, in addition to $1\alpha,25(OH)_2D_3$, in view that the concentration of calcitriol could not be altered previously by this treatment (Curino et al., 1998). In this study, calli were irradiated with UV light for 5, 10 and 15 days. The concentrations of vitamin D_3, $25(OH)D_3$ and $1\alpha,25(OH)_2D_3$ were measured by HPLC after prepurification of lipid extracts as described in the Experimental, and compared to those of non-irradiated calli. As shown in Table 1, the irradiation procedure induced marked increases in the levels of vitamin D_3 with respect to the tissue non-exposed to UV light; however, considerable less significant relative changes were observed for its mono- and dihydroxylated derivatives.

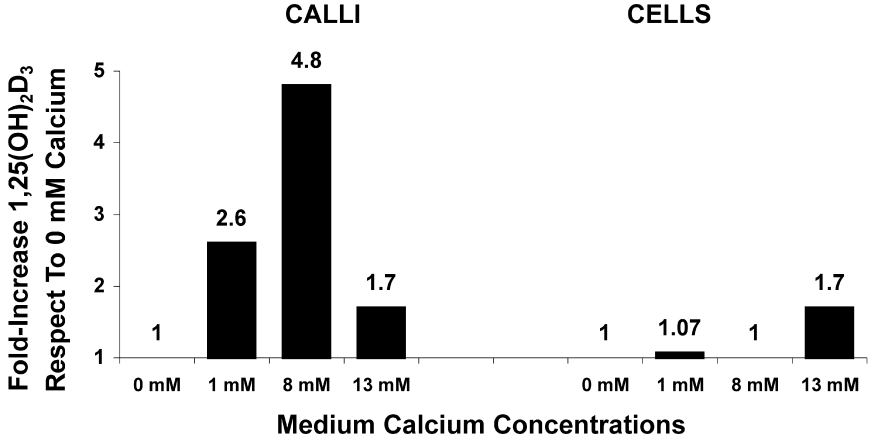

Fig. 3. Influence of medium calcium concentration on $1\alpha,25(OH)_2D_3$ production by cultured *Solanum glaucophyllum* calli and cells. Levels of free $1\alpha,25(OH)_2D_3$ in lipid extracts were measured as in Fig. 1. Values are average of two determinations.

In contrast, UV irradiation of mature *S. glaucophyllum* plants markedly increased the amounts of 1α, $25(OH)_2D_3$ and less significantly the quantities of 25(OH) D_3 and vitamin D_3, in comparison to non-irradiated plants (Fig. 4). These results together with those obtained by UV exposure of calli suggest that in the less differentiated cultured plant cells low activity and/or expression of the vitamin D_3 and $25(OH)D_3$ hydroxylases and not the photolytic breakdown of 7-dehydrocholesterol hinder the production of $1\alpha,25(OH)_2D_3$ in vitro. Specially, the reaction catalyzed by the 25-hydroxy-vitamin D_3-1α-hydroxylase could be the most rate limiting step as the application of a novel DBP-based competitive binding assay for $25(OH)D_3$ applied for the first time in plant tissues (see Experimental) revealed 8-10 fold higher levels of $25(OH)D_3$ than 1α, $25(OH)_2D_3$.

Table 1
Effect of ultraviolet light irradiation on the content of vitamin D_3, $25(OH)D_3$ and $1\alpha,25(OH)_2D_3$ of cultured *Solanum glaucophyllum* calli

	Percent increase above control		
Irradiation times (days)	Vitamin D_3	$25(OH)D_3$	$1,25(OH)_2D_3$
5	350	28	32
10	556	5	37
15	280	0	22

2.4. Detection of $25(OH)D_3$-1α- hydroxylase activity in *S. glaucophyllum* cell suspensions

25-Vitamin D_3-1α-hydroxylase assays were performed by incubating *S. glaucophyllum* cells in culture medium containing $[^3H]25(OH)D_3$ for 2–18 h followed by isolation of $[^3H]1\alpha,25(OH)_2D_3$ according to Bligh and

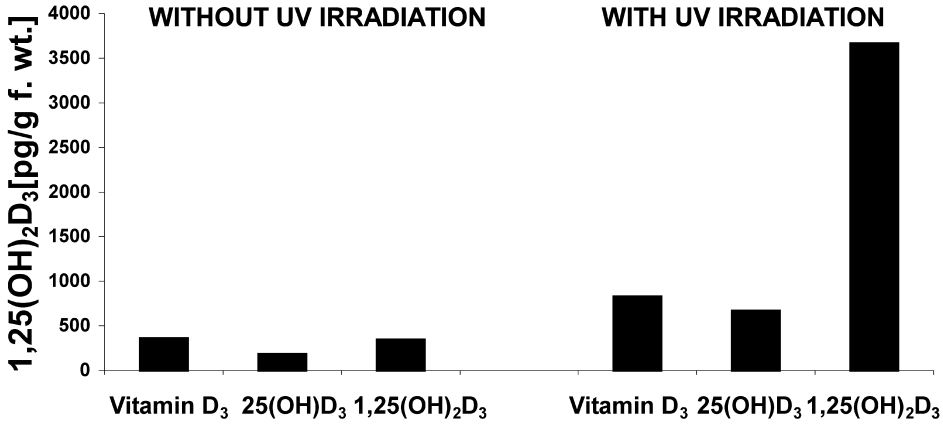

Fig. 4. Ultraviolet light irradiation of *Solanum glaucophyllum* increases its $1\alpha,25(OH)_2D_3$ leaf content. *S. glaucophyllum* plants grown in the greenhouse were either kept under darkness or irradiated with ultraviolet light for 7 days. Free $1\alpha,25(OH)_2D_3$ was quantified as in Fig. 1. Results from a typical experiment are shown.

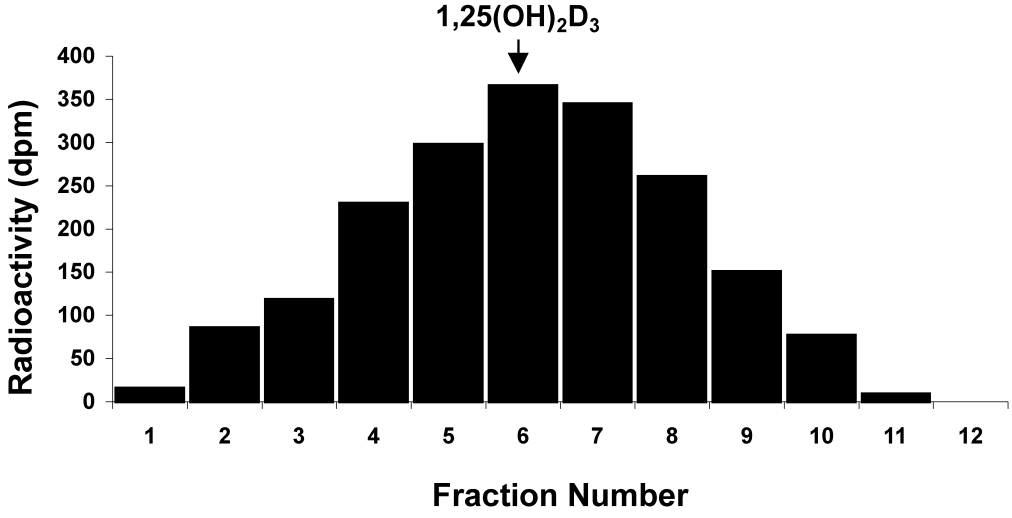

Fig. 5. 25-Hydroxy-vitamin D_3-1α-hydroxylase activity of cultured *Solanum glaucophyllum* cells. Cells were incubated in culture medium containing $[^3H]25(OH)D_3$ for 2 h followed by isolation of $[^3H]1\alpha,25(OH)_2D_3$ produced by Sephadex LH-20 followed by HPLC as indicated in Experimental. HPLC fractions of 0.2 ml were collected. Only the radioactivity of the $1\alpha,25(OH)_2D_3$ fraction of the entire chromatogram is shown.

Dyer (1959), Sephadex LH-20 chromatography and HPLC. The conversion of [^{3}H]25(OH)D_3 to [^{3}H]1α,25(OH)$_2D_3$ was time-dependent but as shown in Fig. 5, low 1α-hydroxylase levels were detected, supporting the interpretation in the section above. Furthermore, when compared with *S. glaucophyllum* leaves (Esparza et al., 1982) the activity of the enzyme was ca. 7 times lower (6 vs 40 pmol/mg prot./h, respectively).

3. Conclusions

In conclusion, the results of this study show that 1α,25(OH)$_2D_3$ and related vitamin D_3 compounds are present mainly as unconjugated forms in *S. glaucophylllum* calli and cells. The precursor 25(OH)D_3 is in greater concentration than the former metabolite. So culture preparations of *S. glaucophyllum* may represent a readily source of both metabolites for pharmacological use. The synthesis of 25(OH)D_3 and 1α,25(OH)$_2D_3$ in cultures strictly kept under darkness, confirms the participation of an non-photolytic reaction capable of opening the B ring in the absence of light (Curino et al., 1998). Of interest, this non-photolytic reaction leading to synthesis of 1α,25(OH)$_2D_3$ can be upregulated by the medium levels of calcium and growth factors. The alternative light-dependent generation pathway of 1α,25(OH)$_2D_3$ appears to operate efficiently in differentiated field-grown plants. The lack of significant effects of UV light irradiation on 1α,25(OH)$_2D_3$ production in cultured material may be explained by low levels of hydroxylase enzymes converting vitamin D_3 into 25(OH)D_3 and 1α,25(OH)$_2D_3$. Clearly of biotechnological importance are the development of experimental maneuvers to upregulate the expression and activity of vitamin D_3-25-hydroxylase and 25(OH)vitamin-D_3-1α hydroxylase in order to increase hormone synthesis for human and animal applications.

4. Experimental

4.1. Materials

Solvents used for isolation and chromatographic procedures were HPLC grade (J.T. Baker Co., Phillipsburg, NJ, USA). Compounds for culture media, purified almond β-glycosidase, salicin (2-[hydroxymethyl] phenyl β-D-glucopyranoside) and Sephadex LH-20 were obtained from Sigma-Aldrich Co. (St. Louis, MO, USA). The LiChroCART cartridge and the Nucleosil C_{18} column for HPLC analysis were from Merck Co. (Darmstadt, Germany) and Sigma-Aldrich, respectively. Other reagents were of analytical grade. [^{3}H]25(OH)-vitamin D_3 (171 Ci/mmol) and [^{3}H]1α,25(OH)$_2D_3$ (171 Ci/mmol) were purchased from New England Nuclear (Chicago, IL, USA). Non-radioactive, chemically synthetized, vitamin D_3, 25(OH)-vitamin D_3, and 1α,25(OH)$_2D_3$ were a gift from Dr. Lise Binderup, Leo Pharmaceutical Products Ltd. (Ballerup, Denmark). Purified human serum vitamin D binding protein was generously provided by Dr. H. van Baelen (Laboratorium voor Experimentele Geneeskunde en Endocrinologie, Katholieke Universiteit Leuven, 3000 Leuven, Belgium).

4.2. Plant material

S. glaucophyllum was collected from fields located in Monte Hermoso and Ensenada (Buenos Aires Province, Argentina). For determination of the vitamin D_3 metabolite content of tissues, the plants were immediately placed in dry ice. Fruits, stems, roots and leaves were separated followed by lyophilization. Lyophilized tissues were kept at −80°C until analyzed. To obtain green-house material, young plants were transplanted intact with soil from the field into pots and watered daily.

4.3. Cultures

To culture *S. glaucophyllum* tissue (callus), aseptic stem, root, fruit and leaf explants from plants grown in the greenhouse were inoculated in solidified (0.8% agar) Murashige–Skoog or Gamborg media supplemented with 2,4-dichlorophenoxyacetic acid (2,4-D) and kinetin, 0.5 mg/l and 0.2 mg/l, respectively, or as otherwise indicated in the experiments testing the influence of the concentrations of these hormones on 1α,25(OH)$_2D_3$ production. The tissue was grown at 25°C under complete darkness. The calli started to develop after approximately 15 days. Subculture was performed when all the surface of culture flasks was covered with tissue (ca. 2 months).

Cell suspensions were initiated by mechanical dispersion of calli and then cultured in 125 ml Erlenmeyer flasks containing 50 ml of liquid Murashige-Skoog medium supplemented with hormone as above, without agar. The cells were grown in culture chambers with constant agitation (100 rpm) at 25°C in strict darkness. The growth of cultures was evaluated by counting cell numbers, protein content, cellular weight and packed cell volume (PCV). Typical growth curves were obtained.

4.4. Irradiation experiments

Calli and cell cultures grown under darkness were placed in a Dubnoff incubator at 25°C, with shaking in the case of cell suspensions, and exposed to a Osram UV lamp (400 W) with a 280–450 nm emission wavelength range for a single period of 1 or 1.5 h daily during 5, 10 and 15 days. Cultures grown in parallel under identical conditions without receiving UV light were used for comparison. Green-house plants were kept in a dark room under glass covered with aluminum foil for

7 days. During this interval irradiated plants were exposed to UV light 1.5 h/day.

4.5. Extraction and chromatography of free vitamin D_3 metabolites

Free vitamin D_3-related compounds present in *S. glaucophyllum* callus and cell cultures and plant leaves were extracted following essentially the method of Bligh and Dyer. Briefly, the samples were homogenized with chloroform-methanol (1:2, v/v; 3.6 ml/g) using an Ultraturrax homogenizer (Janke and Kunkel, Germany) for 2 min at maximum speed. The suspension was further homogenized for 30 s with chloroform and then with water (1.2 ml/g each). The final homogenate was centrifuged in a Sorvall rotor SS-34 (Du Pont Co., Delaware, USA) at 4385 *g* during 10 min and the lower lipid soluble phase was collected. The upper phase containing polar compounds was saved to determine the amounts of glycoside derivatives of $1\alpha,25(OH)_2D_3$.

When the lipid extracts were used for $1,25(OH)_2D_3$ radioaceptor assays, they were evaporated by flushing nitrogen at 35°C and then dissolved in an appropriate volume of isopropanol.

Prior to HPLC, the lipid extracts were passed through a Sephadex LH-20 column (1×15 cm) using hexane–chloroform–methanol (9:1:1, v/v/v) as the solvent system. The fractions which eluted with similar retention times as authentic standards of vitamin D_3, $25(OH)D_3$ and $1,25(OH)_2D_3$ were collected. Each fraction was further resolved by high performance liquid chromatography (HPLC). HPLC was performed with an Isco Model 2360 gradient programmer equipped with an Isco Model V^4 multiwavelength programmable detector set at 265 nm and a pump Isco Model 2350 (Isco Co., Lincoln, NE, USA). A reversed-phase LiChroCART (4 mm×25 cm) cartridge or a Nucleosil C_{18} column (4.6 mm×25 cm) were eluted isocratically with methanol–water (86:14, v/v), (75:25, v/v) and (86:14, v/v) to isolate vitamin D_3, $25(OH)D_3$ and $1,25(OH)_2D_3$, respectively. The elution times of the plant vitamin D_3 sterols were similar to those of synthetic samples of vitamin D_3 (80.1 min), $25(OH)D_3$ (34.7 min) and $1,25(OH)_2D_3$ (8.9 min). Spectroscopic analysis of these HPLC compounds gives molecular ion and fragmentation peak patterns which match exactly those of authentic standards of the corresponding vitamin D_3 metabolite (Curino et al., 1998). Vitamin D_3, $25(OH)D_3$ and $1,25(OH)_2D_3$ were quantified on the basis of their absorption at 265 nm in the HPLC detector. $1,25(OH)_2D_3$ and $25(OH)D_3$ were also measured by radioreceptor and competitive protein binding assays, respectively, as indicated below.

4.6. $1,25(OH)_2D_3$ radioreceptor assays

The $1,25(OH)_2D_3$ content of lipids extracts from *S. glaucophyllum* and chromatographic fractions derived therefrom was measured by a specific radioreceptor assay. The $1,25(OH)_2D_3$ receptor preparation was obtained by homogenization of mucosa from duodena of 4 week-old vitamin D-deficient chicks in TEKDP buffer (10 mM TrisCl, pH 7.4; 1.5 mM EDTA; 0.3 M KCl; 2 mM dithiothreitol; 0.3 mM phenylmethylsulfonylfluoride) followed by centrifugation at 100,000 *g* during 60 min. The supernatant was collected and stored at −80°C until use. Binding assays were performed incubating the samples with 5.87×10^{-10} M $[^3H]1\alpha,25(OH)_2D_3$ for 4 h at 0°C. Free from bound radioactive steroid was separated by the hydroxylapatite procedure (Wecksler and Norman, 1979).

4.7. Quantification of $1\alpha,25(OH)_2D_3$-glycoside

To quantify glycoside derivatives of $1\alpha,25(OH)_2D_3$, the upper polar phase obtained after Bligh and Dyer (1959) fractionation of *Solanum glaucophyllum* tissue and calli (see above) was concentrated to eliminate methanol and the remaining aqueous fraction incubated with β-glycosidase for 4 h under nitrogen in 0.4 M acetate buffer pH 5.0 at 37°C. The activity of the enzyme was checked prior to the experiments by measuring the hydrolysis rate of the synthetic glycosidic substrate salicin under the same conditions for incubation of the aqueous fraction. The sterols released from their glycoconjugates by this procedure were extracted with Bligh and Dyer (1959) as described above.

4.8. In vivo measurement of $1\alpha,25(OH)_2D_3$ levels in whole extracts of S. glaucophyllum using intestinal calcium absorption (ICA) assays

Vitamin D-deficient 4-week-old chicks fed a diet free of vitamin D_3 (Reichel et al., 1987; Massheimeret et al., 1997) were used. *S. glaucophyllum* tissue and callus were extracted for 45 min at 38°C with H_2O (1 ml/g FW) under nitrogen followed by centrifugation and lyophilization of the supernatant to a small volume. Twenty hours before the assay, the chicks, which had been fed a Ca^{2+}-deficient diet for 48 h, were administered intramuscularly with the concentrated extracts. At the time of assay, the chicks were lightly anesthetized with ether, the duodenal loop was exposed, and 5 μCi of ^{45}Ca was injected into the duodenum. After 30 min, blood was collected for analysis. For quantification of the responses, chicks administered with known amounts of $1\alpha,25(OH)_2D_3$ (4–600 pmol) were assayed in parallel.

4.9. $25(OH)_2D_3$ binding assays

The $25(OH)D_3$ content of lipid extracts from *S. glaucophyllum* and chromatographic fractions derived therefrom was measured by a competitive protein binding assay using purified human serum vitamin D binding

protein (DBP). The binding assays were performed incubating the samples in barbital buffer pH 8.6 containing 8.2×10^{-10} M [^{3}H]25(OH)D_3 (380,000 dpm/ml) and 31.3 ng DBP/ml, during 3 h at 0°C. Free from bound radioactive steroid was separated as in 1,25$(OH)_2D_3$ radioreceptor assays.

4.10. Measurement of 25(OH)-vitamin D_3-1α-hydroxylase activity

S. glaucophyllum cells cultured for 5 days were resuspended (230,000 cells/ml) in Murashige and Skoog (1962) medium containing 4×10^{-5} M [^{3}H]25(OH)D_3 (33,000 dpm/ml) and incubated during 2, 7 or 19 h at 25°C with shaking, using a final volume of 3 ml. To stop the reaction the samples were extracted according to Bligh and Dyer (1959). Non-radioactive 1,25$(OH)_2D_3$ was added to the concentrated lipid extract followed by Sephadex LH-20 and HPLC chromatography as described above. The HPLC fraction which comigrated with 1α,25$(OH)_2D_3$ was collected and the radioactivity measured by liquid scintillation spectrometry.

Seasonal variation in leaf glucosinolates and insect resistance in two types of *Barbarea vulgaris* ssp. *arcuata*

Niels Agerbirk*, Carl E. Olsen, Jens K. Nielsen

Chemistry Department, Royal Veterinary and Agricultural University, Thorvaldsensvej 40, DK-1871 Frederiksberg, C, Denmark

Received 13 November 2000; received in revised form 19 March 2001

Abstract

Leaves from natural populations of *Barbarea vulgaris* ssp. *arcuata* (Brassicaceae) in Denmark were examined for glucosinolate content and resistance to the crucifer specialist flea beetle *Phyllotreta nemorum*. Two types of the plant (P- and G-type) could be recognized. Leaves of the G-type contained the glucosinolates (only side chains mentioned): (*S*)-2-hydroxy-2-phenylethyl- (**2S**), indol-3-ylmethyl- (**4**) and in trace amount (*R*)-2-hydroxy-2-phenylethyl- (**2R**), 2-phenylethyl- (**1**) and 4-methoxyindol-3-ylmethyl- (**5**). Leaves of the P-type were dominated by **2R** and **4**, and had only trace amounts of **1**, **2S**, and **5** but contained in addition the previously unknown (*R*)-2-hydroxy-2-(4-hydroxyphenyl)ethyl- (**3R**). The epimer, (*S*)-2-hydroxy-2-(4-hydroxyphenyl)ethyl- (**3S**) was found in populations believed to be hybrids, and in *B. orthoceras*. **2S**, **2R**, desulfo **2S**,-**2R**, -**3S** and -**3R** were isolated and identified by NMR and MS. Acylated glucosinolates or allylglucosinolate were not detected in leaves. The glucosinolate content in August was variable, 3–46 μmol/ g dry wt, but was low in most populations, 3–15 μmol/g dry wt. In general, the glucosinolate content increased during the autumn, to 35–75 μmol/g dry wt in November. The G-type was resistant to neonate larvae of *Phyllotreta nemorum* in August and September (survival in 3-day bioassay typically 0%), and gradually lost the resistance in October and November (survival in 3-day bioassay 40-90%), and there was no correlation between glucosinolate content and resistance. Neither did glucosinolates explain the difference in resistance between the P-type (always susceptible) and the G-type (resistant in the summer season). © 2001 Elsevier Science Ltd. 1. Introduction

Barbarea vulgaris R. Br. ssp. *arcuata* (Opiz.) Simkovics (Brassicaceae) is a biannual or perennial plant. The leaves of first year rosettes stay green in the autumn, and may often stay green during the winter. Early in the following spring, the flowering shoot with bright yellow flowers is rapidly developed. These are the reasons for the common names of *B. vulgaris*; ''Wintercress'' and ''Yellow Rocket'' (MacDonald and Cavers, 1991).

As a glucosinolate containing plant, *B. v.* ssp. *arcuata* is a potential host plant for the characteristic fauna of crucifer adapted, glucosinolate-requiring insects. It is a very variable plant and its interactions with Danish populations of the flea beetle *Phyllotreta nemorum* L. (Coleoptera: Chrysomelidae: Alticinae) are rather complex. Genetic differences have been found in the resistance of the plant towards flea beetles, as well as in counteradaptations of the flea beetles to the plant defences (Nielsen, 1997a). The plant could be divided into two types: The P-type had pubescent leaves and was a suitable host plant for all flea beetle larvae throughout the year. The G-type had glabrous leaves and was resistant to the most common flea beetle genotype during the summer period. But some flea beetle genotypes were able to live on the G-type even in the summer period, and it was shown that the ability of these larvae to live on the plant was controlled by major, dominant genes (R-genes), specific for the defences of the G-type (Nielsen, 1997b, 1999). These genes were rare in most flea beetle populations, but frequent in two populations which utilized the G-type of *B. vulgaris* ssp. *arcuata* as a natural host plant (de Jong and Nielsen, 1999). The finding that a single dominant gene enabled flea beetles to overcome the resistance, suggested that a single biochemical factor was responsible for resistance.

The chemical basis of resistance in the G-type of *B. v.* ssp. *arcuata* to flea beetles is yet unknown. A seasonal variation in resistance has been demonstrated in rosette leaves from plants grown under uniform conditions in a common garden experiment. These plants were resistant during the summer period, but there was a gradual loss of resistance from September to November (Nielsen, 1997a). The uniform conditions in the common garden experiment were quite different from conditions in natural habitats where *B. v.* ssp. *arcuata* plants may vary tremendously in appearance. New plants may germinate throughout the year, and plants that have germinated in the spring and contain more than 20 large rosette leaves co-occur at the end of the season with plants which have germinated recently and contain only 1–6 small leaves. Moreover, new cauline rosettes may be formed from the root neck of plants that have flowered earlier in the year (MacDonald and Cavers, 1974). It was the aim of the present experiments to investigate whether there was a seasonal variation in resistance in all types of leaves occurring in natural habitats, and whether the changes in resistance were correlated with chemical changes in the plants.

Plant resistance to insects is often related to their content of secondary metabolites, which influence insect behaviour and performance on the plants (Fritz and Simms, 1992). *B. v.* ssp. *arcuata* and other crucifers contain a group of sulfur containing secondary metabolites known as the glucosinolates. The predominating glucosinolate in several species of *Barbarea* is (*S*)-2-hydroxy-2-phenylethylglucosinolate (**2S**, glucobarbarin) (Kjær and Gmelin, 1957; Jensen, 1990; Anderson et al., 1999). Leaves and seeds of the G-type of *B. v.* ssp. *arcuata* have been reported to contain mainly this compound while the epimer (*R*)-2-hydroxy-2-phenylethylglucosinolate (**2R**, glucosibarin) is the predominating compound in the P-type (Huang et al., 1994; Nielsen, 1997a). It was not known whether this chemical difference was a reliable character for the two types under natural conditions, or whether the seasonal variation in resistance of the G-type to flea beetles could be explained by changes in glucosinolate levels.

In the present study, leaves of *B. v.* ssp. *arcuata* were collected at seven natural growth sites once a month from August to November. Each leaf sample was subjected to measurements of (1) insect resistance, (2) numbers of hairs on the leaf margin, (3) leaf size and (4) glucosinolate content. The localities were chosen as sites where the G-type (localities 1–4) or the P-type (localities 5–7) was growing. The study tested four questions: (1) Can the existence of two plant types be confirmed in natural populations, and is there a consistent difference in glucosinolate structures between the two types? (2) Can the difference in insect resistance between the two types be explained by glucosinolate content? (3) Is the decline in insect resistance during the autumn in the G-type correlated with environmental or developmental factors? (4) Can the decline in insect resistance in the autumn be explained by changes in glucosinolate content?

[a] Cauline rosettes are formed from the root neck of plants which had flowered earlier in May–June the same year.
[b] No. of hairs were counted on one fourth of the leaf margin as shown in Fig. 2.
[c] These rosettes were small, so almost all leaf positions were sampled except the very upper and lower leaves.

2. Results and discussion

2.1. Seasonal variation in resistance

Plants from four localities (1–4) were resistant to *P. nemorum* larvae in August and September, and belonged to the G-type according to counts of hairs along the leaf margin. Plants from three localities (5–7) were susceptible during this period, and were of the P-type according to counts of hairs along the leaf margin (Table 1). A small population (3a), growing a few hundred meters from locality 3, was intermediate since at least one third of the larvae survived in leaves collected in September. This population was also intermediate with respect to hairiness (Table 1).

Resistance in the G-type (localities 1–4) was not correlated with leaf size or plant age since small as well as large leaves, and young as well as old rosettes were resistant in August–September. Lower leaves from large rosettes that germinated in spring (locality 1) tended to be slightly less resistant than middle and upper leaves (Table 1). There were no differences between rosettes which originated from germinating seeds and cauline rosettes formed from the root neck of plants which had flowered earlier in the season (localities 4 and 7).

Plants from localities 1–4, corresponding to the G-type, gradually lost their resistance during October and November. The loss of resistance was not correlated with plant age or development, as it occurred in young as well as older rosettes, in upper as well as lower leaves, in cauline as well as first year rosettes, and independent of leaf size (Table 1). Plants from localities 5–7 (P-type) remained susceptible to *P. nemorum* larvae in October and November, and there was no seasonal variation in resistance in plants from these localities. Plants collected late in the season at localities 5–7 (P-type) were less hairy than those collected in August and September, but they remained more hairy than those collected in localities 1–4 (G-type) (Table 1).

The loss of resistance in the G-type of *B. vulgaris* ssp. *arcuata* in late autumn was confirmed for wild populations. As the loss of resistance was not correlated with plant age or-development, we suggest that it was regulated by environmental factors associated with the season, such as temperature or day length. Previous studies (Nielsen, 1997a) were unable to distinguish between effects of environmental and developmental factors on plant resistance.

2.2. Identification of glucosinolates

The glucosinolates **1**, **2S**, **2R**, **3S**, **3R**, **4** and **5** were detected in leaves of the P- and G-type of *Barbarea vulgaris* ssp. *arcuata*, collected at different growth sites (Table 2, Fig. 1). The phenolic glucosinolates **3S** and **3R** have not previously been described from the genus *Barbarea*, while the glucosinolates **1**, **2S**, **2R**, **4** and **5** are well established constituents of *Barbarea vulgaris* (Jensen, 1990; Sørensen, 1990; Huang et al., 1994; Andersson et al., 1999).

The absolute configurations of **2S** and **2R** at C-2 (Fig. 1) could be concluded from comparisons with reported NMR spectra of authentic **2R** and **2S** (Jensen, 1990; Sørensen, 1990). The absolute configurations at C-2 of **2R** and **2S** were originally proved by comparison of the enantiomeric phenyloxazolidine-2-thiones, produced by enzymatic hydrolysis of **2R** and **2S**, with the synthetic enatiomers of phenyloxazolidine-2-thione (Kjær and Gmelin, 1957; Gmelin et al., 1970). The chemical shift of H-1′, the anomeric proton, was approximately 0.23 ppm further downfield in **2R**, compared to **2S**. And the chemical shifts of H-1a and H-1b differed

[a] Chemical shifts labeled with an asterisk may be interchanged.

by 0.15 ppm in **2S**, giving rise to two double doublets, while the corresponding protons in **2R** had identical shifts, giving rise to a single doublet (Table 2).

MS proposed that **3R** was a hydroxylated form of the co-occurring **2R**, as the molecular mass of desulfo **3R** was 16 higher than for desulfo **2R**. ^{1}H and ^{13}C NMR confirmed this hypothesis, as the spectra were mostly identical to the spectra of **2R**, but with characteristic differences due to the hydroxy group in the *para* position relative to the alkyl group: An aromatic doublet in the ^{1}H NMR spectrum indicated a *p*-substituted aromatic ring, and the ^{13}C NMR spectrum showed a signal at 156.5 ppm, characteristic of a phenolic carbon (Tables 2 and 3). A HMBC spectrum confirmed the position of the phenolic C-4″ carbon.

In a few samples, **3S** was detected as a minor compound by HPLC of desulfoglucosinolates, tentatively identified by comparison of its diode array UV spectrum with that of authentic desulfo **3S**. Authentic desulfo **3S** could be isolated in sufficient amounts from desulfoglucosinolates prepared from leaves of *Barbarea orthoceras* Ledeb., and was identified by ^{1}H NMR and MS as an epimer of desulfo **3R** (Table 3). **3S** was not previously known to occur in *B. orthoceras*, but a screening of different *Barbarea* species showed that *B. orthoceras* contained **3S** in addition to **2S** (Agerbirk et al., unpublished).

	R_1	R_2	R_3

3R	OH	H	OH

	R_1
4	H
5	OMe

Fig. 1. Glucosinolates identified in *Barbarea* leaves. For glucosinolates, $R_0 = SO_3^-$. For desulfoglucosinolates, $R_0 = H$.

The diode array UV spectra of the two phenolic desulfoglucosinolates desulfo **3R** and **3S** were identical, and showed characteristic bands at 224 nm and 272 nm which can be attributed to the hydroxyphenyl group. This feature was helpful in the routine identification of the compounds, but indicates that the assumption of an identical HPLC response factor at 229 nm of desulfo benzylglucosinolate and desulfo **3R** and **3S** may have led to a moderate overestimation of **3R** and **3S**.

The biological occurrence of **2S** with **3S**, and **2R** with **3R** suggested a common biosynthetic basis of the 2-hydroxylation, and thus a common absolute configuration at C-2. Comparison of ^{1}H NMR spectra of the four desulfo derivatives confirmed this hypothesis. The significant difference in the chemical shift of the anomeric proton (H-1′) of **2S** and **2R**, was also found for desulfo **2S** and desulfo **2R**, and indeed for desulfo **3S** and desulfo **3R**: The H-1′ signal was 0.19–0.27 ppm further downfield in the (*R*)-isomers. The chemical shift of H-1a was also lower in desulfo **2S** and-**3S** than in desulfo **2R** and-**3R**. And while one of the H-6′ signals was unaltered in all four desulfoglucosinolates, the chemical shift of the other (H-6′b) was higher in desulfo **2S** and-**3S** than in desulfo **2R** and **3R** (Table 3). A model suggested that the 2-OH group can be spatially close to the 1′ and 6′ positions in the thioglucoside moiety, thus explaining the particular effects on these positions (data not shown).

Finally, the empirical relationship (Jensen, 1990; Sørensen, 1990) between absolute configuration and relative HPLC retention time on reversed phase columns for epimeric 2-hydroxydesulfoglucosinolates ("*R* is rapid, *S* is slow"), supported the proposed absolute configurations: On the Supelcosil LC-ABZ column, which carries an amide-C16 stationary phase, desulfo **3R** eluted at 12.6 min, desulfo **3S** at 13.5 min, desulfo **2R** at 17.8 min and desulfo **2S** at 19.3 min in a typical run. Based on the empirical NMR- and HPLC relationships, it is concluded that desulfo **3R** is desulfo (*R*)-2-hydroxy-2-(4-hydroxyphenyl)ethylglucosinolate (desulfo *p*-hydroxyglucosibarin), and desulfo **3S** is desulfo (*S*)-2-hydroxy-2-(4-hydroxyphenyl)ethylglucosinolate (desulfo *p*-hydroxyglucobarbarin). The existence of the corresponding intact glucosinolates in the extracted plant material was deduced, based on the binding of the native compounds to an anion exchange column, and the release of the desulfoglucosinolates after sulfatase treatment. This is to our knowledge the first report of chain-elongated phenolic glucosinolates, but a related glucosinolate, (*R*)-2-hydroxy-2-(4-methoxyphenyl)ethylglucosinolate, has been identified in seeds of *Arabis hirsuta* (Kjær and Schuster, 1972), which is phylogenetically close to *Barbarea* (Koch et al., 1999).

The identification of **1** and **5** in leaves was tentative as the levels were low. Several small, presumably non-glucosinolate peaks were observed in the chromatograms.

Allylglucosinolate (“sinigrin”) is sometimes claimed to be a constituent of *B. vulgaris* (MacDonald and Cavers, 1991; Senatore et al., 2000), but was not detected in any of the investigated leaf samples.

Isoferuloyl-**2S** or -**2R** have been reported from seeds of several *Barbarea* species (Andersson et al., 1999), and can be detected by e.g. electrophoresis of intact glucosinolates, but not by the desulfoglucosinolate method (Sørensen, 1990). Upon electrophoresis of extracts of seeds of both the P-type and the G-type, isoferuloyl-**2S** and -**2R** could be detected by a pink colour in UV light, changing to yellow with NH_3 vapour. But isoferuloyl substituted glucosinolates- or any other acylated glucosinolates visible in UV light after paper electrophoresis-were not detected in any of the leaf extracts, with a detection limit estimated to 0.2 μmol/g dry wt (10% of the concentration in seeds, reported as 2 μmol/g dry wt, Andersson et al., 1999). This finding is in agreement with the result that acylated glucosinolates quickly disappear during germination (H. Sørensen, 1999, personal communication).

2.3. Differential content of glucosinolates in the P- and G-types of B. v. ssp. arcuata, and its relation to insect resistance

The distinction of two types of *B. v.* ssp. *arcuata*, based on different leaf pubescence, and insect resistance in the summer period, was supported by structural differences in the accumulated leaf glucosinolates. The P-type (localities 5–7) preferentially accumulated 2-hydroxyglucosinolates with *R* configuration (**2R**, **3R**), while the G-type (localities 1–4) preferentially accumulated the epimer **2S** (Table 4). This difference was reflected in the concentration of **2S** relative to the sum of **2R** and **2S**, which differed significantly between the two types, independent of season and leaf type (Table 5). Furthermore, all populations of the P-type accumulated the *p*-hydroxylated glucosinolate **3R** during the autumn, while *p*-hydroxylated glucosinolates were only rarely detected in the G-type (see later).

However, the apparent hybridisation of the two types, which was detected at localities 3 and 3a, is an exception to the distinction of two types. The relative concentration of **2S** was around 50% in pooled leaves from localities 3a (Tables 4 and 5). When leaves from individual plants were later analysed, some were dominated by only **2R** or **2S** as found for the pure types. But most of the individual plants apparently contained the sum of the biosynthetic capabilities outlined above, as **2R**, **2S**, **3R** and **3S** were all accumulated in significant amounts in individual leaves (data not shown). This result, and observations of hairiness and insect resistance mentioned above, suggests that the plants at locality 3a are hybrids between the P- and the G-type. The hybrids seem to have inherited the ability to produce both epimers of 2-hydroxylated glucosinolates (from both parents), as well as the ability to produce *p*-hydroxylated glucosinolates (from the P-type). The presence of **3S** in these supposed hybrid plants suggest that the enzyme which catalyses *p*-hydroxylation is not specific for the configuration of the 2-hydroxygroup. At the nearby locality 3, the *p*-hydroxylated glucosinolate **3S** was detected in a few samples otherwise dominated by **2S**, as expected if a gene for *p*-hydroxylation [or a gene channelling a *p*-hydroxylated precursor into glucosinolate biosynthesis (Bak et al., 1999)] had been introduced to a genotype with ability for 2-hydroxylation in *S*-configuration. This observation suggests that the responsible gene from the P-type has been transferred to an otherwise morphologically and chemically typical G-type. Apparent hybridisation between the two types is rare in Denmark (Nielsen, unpublished), since most populations consist of either the P-type or the G-type (Nielsen, unpublished).

Table 5
Content (μmol/ g dry wt) of **2S** relative to the sum of **2R** and **2S**, in pooled leaves of each of the examined populations of *Barbarea vulgaris* ssp. *arcuata*. As the ratio of **2R** to **2S** did not vary with month or leaf type, results from the entire experimental period and for all examined leaf types were pooled

Locality	Type	[**2S**]/([**2R**] + [**2S**]) × 100%		
		Mean	S.D.	N
1	G	98.0	0.11	11
2	G	98.9	–	1
3	G	93.5	4.5	7
3a	"Hybrid"	51.3	11	5
4	G	98.5	0.77	10
5	P	0.83	0.24	5
6	P	0.89	0.06	4
7	P	4.1	3.2	7

The differences in resistance between the G- and P-type could not be attributed to differences in glucosinolate content. High levels of **2S** did not deter *P. nemorum* larvae, since high levels were found in susceptiple leaves collected in November. Furthermore, high levels of **2R** were not invariably correlated with susceptibility, since hybrid leaves collected at locality 3a in September were resistant although they contained high levels of **2R**, and since P-type leaves from locality 7 with widely different levels of **2R** were accepted by *P. nemorum* larvae to a similar extent (Tables 1 and 4). Differential effects of **2R** and **2S** had previously been mentioned as factors influencing oviposition behaviour of *Pieris* species on *Barbarea* plants (Huang et al., 1994).

2.4. Seasonal variation in glucosinolate content and its relation to insect resistance

The glucosinolate content in August was very variable, 3–46 μmol/ g dry wt, but was low in most populations, 3–15 μmol/g dry wt. The levels of all major glucosinolates increased from August to November in plants from five localities (2, 3, 4, 5 and 7), and increased from September to November in plants from the remaining two localities (1 and 6). The concentration-increase of the phenolic glucosinolate **3R** in the P-type was especially distinct during the autumn (Table 4).

Two observations demonstrate that glucosinolates are not the defensive compounds that confer resistance in the G-type of *B. v.* ssp. *arcuata* to *P. nemorum* larvae. First, the levels of glucosinolates increased in several populations at the same time as resistance decreased. Second, the resistance levels were consistently high in all populations of the G-type in August, although glucosinolate levels were variable during this period (Tables 1 and 4).

Glucosinolates are considered to be defensive compounds that protect the plants from a range of generalist herbivores and pathogens (Louda and Mole, 1991; Bennet and Wallsgrove, 1994). The role of these compounds in defences against specialized insects is far less clear, and many specialized insects are insensitive to changes in concentrations of these compounds (Nielsen et al., 2001). Although glucosinolates are obligate feeding stimulants for larvae of *P. nemorum* (Nielsen, 1989), low levels of glucosinolates were apparently sufficient for feeding stimulation: Low levels of glucosinolates in the P-type in August did not result in reduced larval acceptance of these susceptiple plants (localities 5 and 7). On the other hand, high levels of glucosinolates in the G-type in August did not result in increased larval acceptance of these resistant plants (locality 1).

2.5. Seasonal regulation of defence chemistry

Two types of chemical defence in *B. vulgaris* foliage were studied: Glucosinolates, and the unidentified compounds conferring resistance to *P. nemorum* and probably other specialist insects as well (Chew, 1981; Idris and Grafius, 1996). Our results suggest a seasonal regulation of defences: One or more seasonally dependent environmental signals seemed to (1) induce general glucosinolate biosynthesis; (2) induce a particular side chain modification (*p*-hydroxylation in the P-type) and (3) reduce the level of the *P. nemorum* resistance factor (in the G-type). The seasonal variation of insect resistance may be an adaptation to the seasonal variation in insect activity (Nielsen, 1997a).

Winter types of oilseed rape accumulate high levels of glucosinolates late in the year (Giamoustaris et al., 1994), while there is a decline in glucosinolate levels late in the season in *Cardamine cordifolia* and in *Dentaria* species (Feeny and Rosenberry, 1982; Louda and Rodman, 1983; Rodman and Louda, 1985). Rosette leaves of oilseed rape and *B. vulgaris* may remain green throughout the winter, while leaves of *Dentaria* and *Cardamine* species wilt late in the season. The physiological or defensive functions of the accumulation of glucosinolates in overwintering leaves of *B. vulgaris* and oilseed rape is to our knowledge unknown.

3. Experimental

3.1. Plants

Leaves of *B. vulgaris* ssp. *arcuata* were collected from seven localities on the Danish island Zealand. 1: Herlev (old grass field; accession No. 3), 2: Gl. Svebølle (waste area, accession No. 6), 3: Ejby (waste area; accession No. 8), 4: Kværkeby (wet meadow), 5: Tissø (wet meadow close to a lake; accession No. 9), 6: Trundholm Mose (meadow) and 7: Skellingsted (dry slope; close to accession No. 10). Accession numbers refer to Nielsen (1997a). Plants from Ejby and Kværkeby (localities 3 and 4) are natural host plants for populations of *P. nemorum* (with R-genes) (de Jong and Nielsen, 1999).

Leaf samples were collected once a month from August to November. Eight leaves from each sample were used in bioassays with *P. nemorum* larvae. The width (*a*) and length (*b*) of the end lobe of these eight leaves were measured, and the number of hairs on one fourth of the leaf margin (*c*) was counted (Fig. 2). The correlation between width × length ($a \times b$) and leaf area was determined using linear regression on data from a larger leaf sample (60 leaves) where *a* and *b*, as well as leaf area was measured (on a LiCor Model 3100 area meter). Leaves for glucosinolate analyses were lyophilized and stored at −20°C until the analyses could be performed.

B. orthoceras, for the isolation of desulfoglucosinolates from leaves, was grown from seeds collected at Wolcott, Vermont, USA, 1994, kindly provided by F.

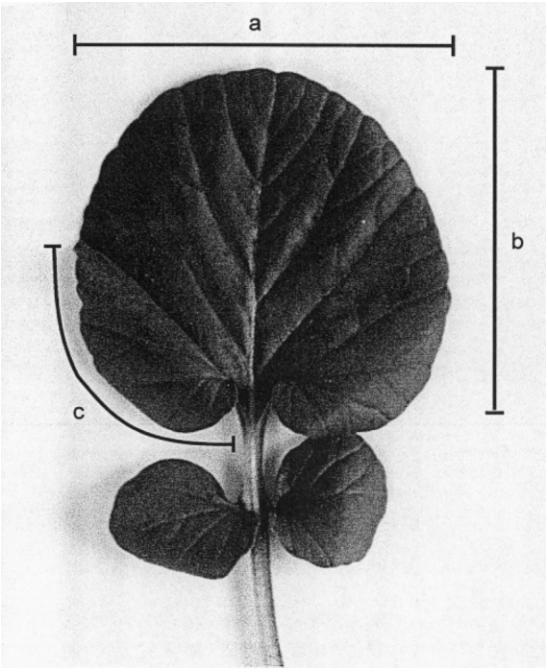

Fig. 2. Leaf of *Barbarea vulgaris* ssp. *arcuata*, showing width (a), length (b) and the basal fourth of the end lobe margin for counts of hairs (c).

Chew (Chew, 1981). *B. vulgaris* ssp. *arcuata* type P, for the isolation of desulfoglucosinolates from roots, was grown from seeds collected by J. K. Nielsen at Trundholm Mose, Denmark, 1997. Voucher specimens from the investigated populations of *B. vulgaris* ssp. *arcuata* type P and *B. vulgaris* ssp. *arcuata* type G have previously been deposited at the Botanical Museum in Copenhagen (Nielsen, 1997a). A voucher specimen of *B. orthoceras* has now additionally been deposited.

3.2. Insects and bioassays

P. nemorum was reared in the laboratory as described previously (Nielsen, 1978). The larvae belonged to a line (ST) which did not contain any R-genes conferring resistance to defences in the G-type of *B. v.* ssp. *arcuata* (Nielsen, 1999). A three-day bioassay was performed as described by de Jong and Nielsen (1999). Single leaves were presented to inexperienced, neonate larvae in small plastic vials (20–160 ml depending on the size of the leaf; 5 larvae per leaf). A piece of moist filter paper provided sufficient humidity to keep the leaves fresh. After three days at 24±2°C and a photoperiod of 18 h light and 6 h darkness, the number of surviving larvae was counted under a preparation microscope.

3.3. Spectroscopy

NMR spectra of intact glucosinolates were recorded on a Bruker AC250P spectrometer, while NMR spectra of desulfoglucosinolates were recorded on a Bruker Avance 400 spectrometer. Chemical shifts are based on dioxane as internal reference (δ_H (dioxane) = 3.75, δ_C(dioxane) = 67.4). Assignments were based on COSY, HSQC and HMBC spectra. UV spectra of desulfoglucosinolates were measured with the HPLC diode array detector.

Electrospray-ionisation MS of desulfoglucosinolates were measured in H_2O-AcCN (1:1) + 1% NH_3, with a "Platform LC" from Micromass Ltd, Manchester, UK, except desulfo **3R**, which was obtained in 50 μM NaOAc-MeOH 1:1 with a Bruker Esquire-LC ion trap mass spectrometer.

3.4. Glucosinolates

Glucosinolates (gls) were determined by conversion to desulfogls and analysis by HPLC with UV detection, following the principles described by Sørensen (1990). Ca. 100 mg dry wt of leaf material, omitting the petioles, was weighed and extracted three times with 3 × 3 ml of boiling 70% aq. MeOH with a T25 Basic homogenizer from Janke & Kunkel, Staufen, Germany. As internal standard, 100 µl of a 5 mM solution of benzylgls (Merck, Darmstadt, Germany) was added to the boiling extract. The crude extract was brought to 10 ml in a volumetric flask, from which 4 ml was applied to a 0.1 g dry wt column of DEAE Sephadex A-25 (Pharmacia, Uppsala, Sweden) on OAc^- form (achieved by incubation overnight with 3 ml of aq. 0.5 M HOAc–NaOAc pH 5.0, followed by a wash with water). The column was washed with 5×2 ml water followed by 2×2 ml of 0.02 M HOAc–NaOAc pH 5.0. Then, 0.5 ml of *Helix pomatia* sulfatase (Sigma) dissolved (2.5 mg/ml) in 0.02 M HOAc–NaOAc buffer was applied to the column, which was left overnight. The resulting desulfogls were eluted with 5×1 ml of water, and subjected to HPLC analysis. The HPLC apparatus was a LC-10AT with a SPD-M10AVP diode array detector, both from Shimadzu, Kyoto, Japan, equipped with a Supelcosil LC-ABZ column, 25 cm × 4.6 mm, 5 µm, from Supelco, Bellefonte, PA. The flow rate was 1 ml/min, and the desulfogls were eluted with water for 2 min followed by a linear gradient of MeOH from 0 to 60% in 48 min, followed by a brief wash with MeOH and equilibration with water.

For quantification, UV detection at 229 nm (bandwidth 8 nm) was employed. The response factors reported by Buchner (1987) were used: desulfobenzylgls: 0.95, desulfo **4**: 0.29, desulfo **5**: 0.25. Desulfobenzylgls and the desulfogls from **1**, **2S**, **2R**, **3S** and **3R** were assumed to have identical response factors at 229 nm. The purity of commercial benzylgls used as internal standard was found to be 90% by UV ($\varepsilon_{227.5}$ = 8870 M^{-1} cm^{-1}, Thies, 1988), this was considered in the calculation of absolute gls concentrations.

The completeness of binding and the sulfatase reaction, the complete elution also of desulfo **4**, and the overall linearity of the gls determination, was confirmed by appropriate controls. The relative standard deviation on the determination was tested for a leaf sample of the G-type analysed six times, and found to be 12, 8 and 14% for **2R**, **2S** and **4**, respectively. Other samples were only analysed once or twice. The detection limit was around 0.05 μmol/g dry wt for aliphatic gls, 0.01 μmol/g dry wt for the indoles.

In addition, the possibility of acylated gls was tested by high voltage paper electrophoresis of crude extracts at pH 1.9 (Olsen and Sørensen, 1981), followed by inspection in UV light with and without NH_3 vapour.

3.5. Purification of glucosinolates and desulfoglucosinolates

Intact **2R** and -**2S** were purified from seeds of the two plant types, as described by Thies (1988). Desulfogls for NMR were purified by preparative HPLC: Desulfo **2S** and -**3S** were obtained from leaves of *B. orthoceras*. Desulfo **2R**, -**4** and -**5** were purified from roots of *B. vulgaris* ssp. *arcuata* type P. Spectroscopic identification of **4** and **5** has been published elsewhere (Agerbirk et al., 2001). **3R** was purified from leaves collected at locality 6 in November.

3.6. Desulfo *2S*

Amorphous solid. UV: 228 nm (*sh*), 260 nm (*sh*). ESMS, pos. mode, cone voltage 110 V, *m/z*: 360 $[M+H]^+$, 382 $[M+Na]^+$, 342 $[M–H_2O+H]^+$, 198 $[M–C_6H_{10}O_5+H]^+$, 180 $[M–C_6H_{10}O_5–H_2O+H]^+$.

3.7. Desulfo *2R*

Amorphous solid. UV: 228 nm (*sh*), 260 nm (*sh*). ESMS, pos. mode, *m/z*: 382 $[M+Na]^+$.

3.8. Desulfo *3S*

Amorphous solid. UV: 224 nm (100%), 272 nm (12%, 281 nm (*sh*, 8%). ESMS, cone volt. 25 V, pos. mode, *m/z*: 376 $[M+H]^+$, 398 $[M+Na]^+$, 414 $[M+K]^+$, 358 $[M–H_2O+H]^+$, and neg. mode, *m/z* (rel. int.): 374 $[M–H]^-$.

3.9. Desulfo *3R*

Amorphous solid. UV: 224 nm (100%), 272 nm (12%, 281 nm (*sh*, 8%). ESMS, cone volt. 25 V, pos. mode, *m/z*: 376 $[M+H]^+$, 398 $[M+Na]^+$, 414 $[M+K]^+$, 358 $[M–H_2O+H]^+$, and neg. mode, *m/z* (rel. int.): 374 $[M–H]^-$.

Acknowledgements

The assistance of K.B.H. Herath, Boyce Thompson Institute for Plant Research at Cornell University, with electrospray mass spectrometry, and of Lena Rasmussen, Celestin A. Gnahore, Lars Borup and Hanne O. Frandsen with glucosinolate isolation and analysis, is gratefully acknowledged. We thank the Department of Agricultural Sciences, RVAU, for access to the Licor Area meter. The Danish Agricultural and Veterinary Research Council supported this research.

Abstract

The fatty acid composition of photosynthetic tissues from 137 species of gymnosperms belonging to 14 families was determined by gas chromatography. Statistical analysis clearly discriminated four groups. Ginkgoaceae, Cycadaceae, Stangeriaceae, Zamiaceae, Sciadopityaceae, Podocarpaceae, Cephalotaxaceae, Taxaceae, Ephedraceae and Welwitschiaceae are in the first group, while Cupressaceae and Araucariaceae are mainly in the second one. The third and the fourth groups composed of Pinaceae species are characterized by the genera *Larix,* and *Abies* and *Cedrus*, respectively. Principal component and discriminant analyses and divisive hierarchical clustering analysis of the 43 Pinaceae species were also performed. A clear-cut separation of the genera *Abies, Larix,* and *Cedrus* from the other Pinaceae was evidenced. In addition, a mass analysis of the two main chloroplastic lipids from 14 gymnosperms was performed. The results point to a great originality in gymnosperms since in several species and contrary to the angiosperms, the amount of digalactosyldiacylglycerol exceeds that of monogalactosyldiacylglycerol. © 2001 Elsevier Science Ltd. Keywords: Gymnospermae; Chemotaxonomy; Plant lipids; Plant fatty acids; Δ5-Olefinic fatty acids; Anteiso 17:0 fatty acid; Multivariate analysis; Divisive hierarchical analysis

1. Introduction

The gymnosperms represent an ecologically, morphologically and taxonomically very diverse botanical group. However, in the northern hemisphere, although one tree out of two is a conifer, the gymnosperms do not represent many different species. Indeed, according to one of the most recent gymnosperm databases (Earle, 1999), 873 species are referenced among 14 families. Nevertheless, many complex subfamilial and tribal classification problems remain to be solved. Elsewhere, information on the chemotaxonomic and phylogenetic relationships between angiosperm families were obtained by studying the leaf fatty acid composition of 468 species (Mongrand et al., 1998). This work clearly evidenced that the fatty acid composition of photosynthetic tissues can be a powerful tool for chemotaxonomic studies, and could be used for the classification of gymnosperms.

It is known that gymnosperm leaves contain branched-17:0 fatty acid, and quite high amounts of short and very long chain fatty acids (Jamieson and Reid, 1972; Vickery et al., 1984; Itabashi and Takagi, 1982). It has also been shown that seeds (e.g. Wolff et al., 1997b) and leaves (Jamieson and Reid, 1972) of gymnosperms contain Δ5-olefinic acid. These fatty acids are characteristic of mosses, ferns and gymnosperms (Karunen, 1990). Angiosperms, with a few exception such as the Ranunculaceae (Aitzetmüller, 1996), have lost the ability to synthesize such fatty acids. Hence, Δ5 fatty acids could be considered as an archaic fatty acid marker.

Even so, the fatty acid composition of gymnosperm leaves has been determined for only approximately 50 species belonging to only 8 of the 14 families in the gymnosperm classes (Jamieson and Reid, 1972; Vickery

et al., 1984; Itabashi and Takagi, 1982; Grahl-Nielsen et al., 1991; Mongrand et al., 1998). In other words, the leaf fatty acid composition of a high number of gymnosperm genera (and even of entire families: e.g. Podocarpaceae, Araucariaceae, Cephalotaxaceae) is still almost completely unknown. Therefore the aim of the present study was to analyze the fatty acid composition of 137 species belonging to each of the 14 gymnosperm families. Principal component and discriminant analyses were performed using the fatty acid composition of photosynthetic tissues of gymnosperms to establish relationships between and within the different families.

2. Results and discussion

2.1. Fatty acid composition of leaves

The word gymnosperm — also synonymous with Pinophyta Cronquist, Takht. et Zimmerm. ex Reveal or Gymnospermae — is used *s.l.* in the present paper. Hence, this group contains the gymnosperms *s. str.* (i.e. conifers and others), the former pre-spermatophytes (i.e. Ginkgoales) and previously termed chlamydosperms (i.e. Gnetales). In the present study, 137 plants distributed among the 14 gymnosperm families have been analyzed. Table 1 shows the overall leaf fatty acid composition of these gymnosperm species determined by gas chromatography. Orders, families, and sub-families are listed according to the classification of Earle (1999). Species names are according to Farjon's nomenclature (1998).

The fatty acid compositions of gymnosperm and angiosperm photosynthetic tissues are similar in that the major fatty acids are linolenic (C18:3), linoleic (C18:2) and palmitic (C16:0) acids. However, in most cases, the gas chromatography patterns of fatty acids from the photosynthetic tissues of gymnosperms (e.g. Fig. 1) showed the presence of a higher number of molecules than that observed with angiosperm species, with as many as 26 different fatty acids detected. In gymnosperm leaves, several unusual fatty acids with a *cis*-5 ethylenic bond (also called Δ5-olefinic acids, or Δ5-unsaturated polymethylene-interrupted fatty acid) were detected as widely described for gymnosperm oils (e.g. Wolff et al., 1996). The role of these fatty acids remains unknown but it has been hypothesized that it might be related to a cold acclimatization (Wolff et al., 1997c). Most of these fatty acids have 18 and 20 carbon atoms: *all cis*-Δ5, 9–18:2 (taxoleic), *all cis*-Δ5, 9, 12–18:3 (pinolenic), *all cis*-Δ5, 9, 12, 15–18:4 (coniferonic), *all cis*-Δ5, 11–20:2, *all cis*-Δ5,11, 14–20:3 (sciadonic or podocarpic), and *all cis*-Δ5, 11, 14, 17–20:4 (juniperonic). A few species do not contain any Δ5 fatty acids such as *Welwitschia mirabilis*. The Δ5, 11, 14, 17–20:4 fatty acid is detected in almost all of the gymnosperm species. By contrast, C18-Δ5 fatty acids are not uniformly distributed in the gymnosperm kingdom, and are almost exclusively present in Pinaceae. Hence, the C18-Δ5 fatty acids could be a powerful chemometric tool to discriminate Pinaceae among the gymnosperm families.

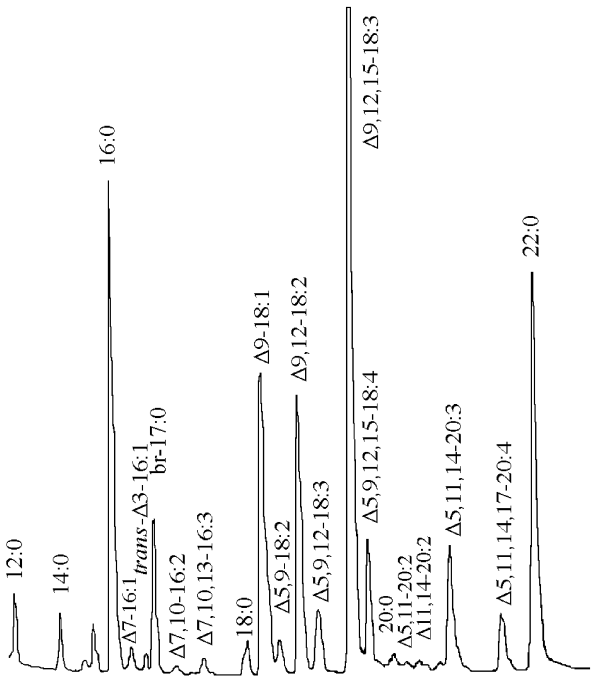

Fig. 1. Gas chromatography pattern of leaf fatty acid methyl esters of *Abies concolor* (Gord.) Lindl. ex Hildebr. (Pinaceae Abietoideae).

Another unusual fatty acid present in gymnosperm leaves is the branched-17:0 acid (also called 14-methyl-palmitic acid, or anteiso 17:0). This peculiar fatty acid has also been identified in the wood of several pines (Zinkel and Foster, 1980), in *Ginkgo biloba* seed oil (Hierro et al., 1996) and in conifer needles (Jamieson and Reid, 1972). Its role as well as the pathway of its biosynthesis remain totally unknown (Wolff et al., 1997a). From our results, br-17:0 fatty acid appeared particularly present in *Abies* (ca. 4%) and *Picea* (ca. 2%), while this fatty acid was not — or only poorly — detected in Ginkgoaceae, Sciadopityaceae, and Gnetales. Interestingly, some Araucariaceae and Podocarpaceae (e.g. *Araucaria montana*, *Podocarpus nivalis*) contain relatively high amounts of br-17:0 acid.

Small amounts of *cis*-Δ11-18:1 fatty acid were detected in some species, but this fatty acid never rose above 0.2% of the total fatty acid content. Higher amounts of short chain fatty acids (C12:0, C14:0) were detected, particularly in *Microbiota decussata* leaves. Like the short chain fatty acids, very long chain fatty acids, *i.e.* C20:0 (arachidic) and C22:0 (behenic) were detected in almost all of the gymnosperm photosynthetic tissues in which they could reach 30–40% of the total fatty acid content (*Cedrus libani, Tetraclinis articulata*), in contrast with what is observed with angiosperms leaves. Relatively high amounts of very long chain fatty acids were

[a] –: Not detected.

[b] tr.: Trace, percentage less than 0.05%.

[c] (a): Origin of gymnosperm leaves: (1): Arboretum of Chèvreloup (Muséum National d'Histoire Naturelle, Paris, France); (2): Botanical garden of Bordeaux (France); (3): Botanical garden of Talence (France); (4): Provided by Mr. Bernard Bouet (Parc Floral Phoenix de Nice, France); (5): Botanical garden Les Cèdres (Saint-Jean-Cap-Ferrat, France); (6): Arboretum of Barres (Nogent-sur-Vernisson, France); (7): Villa Thuret (INRA Antibes, France); (8): Botanical garden of Nancy (France); (9): Botanical garden of Brest (France); (10): Bocca alla Leccie San Nicolao (Corse, France); (11): National Botanic Garden of Belgium (Domain of Bouchout, Meise); (12): Maymou tree nursery (Bayonne, France); (13): Gymnosperm oils are provided by Dr. Robert L. Wolff (University Bordeaux 1, France).

[d] (b): Undetermined short chain fatty acid eluting just before 16:0 acid (probably 15:0 or branched 15:0).

[e] (c): Sum of the *cis*-Δ7 and the *trans*-Δ3 C_{16} fatty acids.

[f] (d): Anteiso C_{17} fatty acid (14-methylhexadecanoic acid).

[g] (e): Undetermined very long chain fatty acid.

detected in different genera of Pinaceae (*Pinus, Picea, Pseudotsuga, Abies, Cedrus, Keteleeria*) and in Cupressaceae (*Thujopsis, Tetraclinis*). The various elongation products of oleic (C18:1), linoleic (C18:2) and linolenic (C18:3) acids — namely *all cis*-Δ11–20:1 (gondoic), *all cis*-Δ11, 14–20:2 (bishomo-linoleic) and *all cis*-Δ11, 14, 17–20:3 (bishomo-a-linolenic) acids, respectively — were also detected. In addition, *Welwitschia mirabilis* leaves contained two undetermined fatty acids (probably with 16 carbon atoms) eluted just before and after C16:3. These fatty acids represented 2.4 and 2.0% of the total fatty acids, respectively.

Our study also focused on the presence or the absence of *all cis*-Δ7, 10, 13-hexadecatrienoic acid (C16:3) in gymnosperm leaves. The presence of this fatty acid in leaves of some angiosperms (called "16:3 plants") indicates the existence of a "prokaryotic" galactolipid biosynthesis pathway which is probably inherited from cyanobacteria (for review see Browse and Somerville, 1991). In "16:3 angiosperms" (e.g. *Arabidopsis thaliana*, spinach, tomato), the content in 16:3 fatty acid can account for 17% of total fatty acids as it was observed for example in Apiaceae leaves (e.g. Rullkötter et al., 1975; Mongrand et al., 1998; Mongrand, 1998). Table 1 shows that the percentage of 16:3 fatty acid in gymnosperm leaves never reached the values obtained with photosynthetic tissues of "16:3" angiosperms. In gymnosperms, the highest levels of C16:3 were detected in *Ginkgo biloba*, *Larix laricina*, *Thuja standishii* and *Taxus brevifolia* (4.5, 4.4, 5.4 and 9.5%, respectively), but in most cases this fatty acid represented only around 0.5-3% of the total fatty acids.

2.2. Fatty acid composition of leaf gymnosperm galactolipids

The fatty acid composition of the two main leaf lipids digalactosyldiacylglycerol (MGD) and monogalactosyldiacylglycerol (DGD) from 14 gymnosperm species was then determined. Results are shown in Table 2. It was found that C16 and C18 poly-unsaturated *omega* 3 fatty acids (C16:3, C18:3) could reach 75% of the total fatty acids associated with galactolipids. However as already noted by Jamieson and Reid (1972), the amount of polyunsaturated fatty acids was slightly lower in gymnosperm than in angiosperm tissues. Furthermore, the analysis of the fatty acid composition of gymnosperm galactolipids showed that: (i) only small amounts of both long- and short-chain fatty acids and of Δ5-olefinic acids were esterified to galactolipids; (ii) C16:3 fatty acid levels were higher in MGD than in DGD; (iii) As in angiosperm leaves, DGD from gymnosperm photosynthetic tissues contained a large amount of palmitic acid (C16:0), probably esterified to the *sn*-1 position of the glycerol backbone (Roughan and Slack, 1982). However, MGD from some gymnosperm leaves also contained a high amount of palmitic acid, in contrast with that was observed in angiosperm tissues

Another difference with angiosperms appeared when the mass of both of the galactolipids was calculated from that of each fatty acid determined by gas chromatography. In gymnosperms, the ratio MGD/DGD varied from 0.28 to 1.52, so in some species, the amount of DGD is higher than that of MGD (Table 2). In *Cupressus dupreziana* and *C. bakerii* (Cupressaceae), DGD was 3-fold more concentrated than MGD. These results underline an originality of gymnosperms since unlike in angiosperm leaves, the amount of DGD does not exceed that of MGD (Roughan and Batt, 1969).

2.3. Multivariate analyses

A statistical analysis was performed to try to separate the orders and the families within the gymnosperm phylum by using only the 137 fatty acid compositions determined in this study (see Experimental). Thereafter, to obtain more details within a given family, the statistical analysis was performed for the 44 taxa of Pinaceae. Although the data on the types and distribution of fatty acids did not provide an unequivocal guide to the classification of plants, many correlations of taxonomic significance became apparent.

Principal component analysis (PCA) applied to the whole series of gymnosperms was carried out after ruling out *Araucaria montana* (see Experimental). The results show that the first two axes explain 25.4 and 11.1% of the total variation. Although these percentages are low, the analysis provides a global statistical distinction between four groups (Fig. 2): the first includes the Ginkgoaceae, Cycadaceae, Stangeriaceae, Zamiaceae, Sciadopityaceae, Podocarpaceae, Cephalotaxaceae, Taxaceae, Ephedraceae and Welwitschiaceae; the second contains most of the Araucariaceae and Cupressaceae. Both of the other groups contain the Pinaceae species with the genus *Larix* in group 3, and the genera *Abies* and *Cedrus* in group 4. *Gnetum gnemon* is in group 3, not far from the Ephedraceae. Groups 1 and 4 are separated by axis 1 and groups 2 and 3 by axis 2. It must be noted that the statistical analysis clearly shows that the variables associated with *all cis*-Δ5, 9–18:2, *all cis*-Δ5, 9, 12–18:3 and *all cis*-Δ; 5, 9, 12, 15–18:4 are strongly correlated, that can reflect a likely common metabolic pathway of these fatty acids. Nevertheless, our results did not allow us to conclude whether a specific C18 or C20 Δ5 desaturase is responsible for the synthesis of the very long chain Δ5 fatty acids, or whether the very long chain fatty acids were first synthesized before to be desaturated.

In Fig. 2, it appeared that (i) all seven of the eight genera of Zamiaceae (*Chigua* was not studied) belong to the statistical group 1, which underlines a very homogeneous leaf fatty acid composition in this family. In

[a] – : Not detected.
[b] tr. : Trace, percentage less than 0.05%.
[c] (a): Undetermined short chain fatty acid eluting just before 16:0 acid (probably 15:0 or branched15:0).
[d] (b): Sum of the *cis*-Δ7 and the *trans*-Δ3 C_{16} fatty acids.
[e] (c): Anteiso C_{17} fatty acid (14-methylhexadecanoic acid).

addition, their content in Δ7, 10, 13–16:3 is low contrary to the neighboring Cycadaceae family; (ii) the separation of the Pinaceae, an exclusively northern family, from other conifers is in good agreement with the multivariate analyses of the fatty acid composition of seed oils (Imbs and Pham, 1996; Wolff et al., 1997b) and with results obtained after comparison of 18S rRNA sequence data (Chaw et al., 1995); (iii) The Podocarpaceae, a morphologically and ecologically very diverse family, appears homogeneous in view of the leaf fatty acid composition. These results are in agreement with the comparison of 18S rDNA sequence data which support the monophyly of Podocarpaceae (Kelch, 1998); (iv) The species of the cosmopolitan Cupressaceae family *s.l* (i.e. including Taxodiaceae *s. str*. and Cupressaceae *s. str*.) are closely related (Wolff et al., 1997b), and form a monophyletic lineage. According to Brunsfeld et al. (1994) and Stefanovic et al. (1998), Cupressaceae *s. str*. are monophyletic and derive from the Taxodiaceae. Our results do not contradict this view since the Cupressaceae *s. str*. analyzed in this paper belong to group 2 (with the exclusion of some *Cupressus* species). The other genera are distributed between groups 1 and 2. The monotypic *Metasequoia* from eastern Asia clearly belongs to group 1, contrary to the monotypic genera *Sequoia* and *Sequoiadendron* from North western America. These results are not in agreement with data for *rbc*L and *mat*K, which strongly support a clade for these three genera (Brunsfeld et al., 1994; Gadek et al., 1997); (v) Ephedraceae, Gnetaceae and Welwitschiaceae (a monospecific family) together form the order of Gnetales, and the analysis of morphological and ribosomal

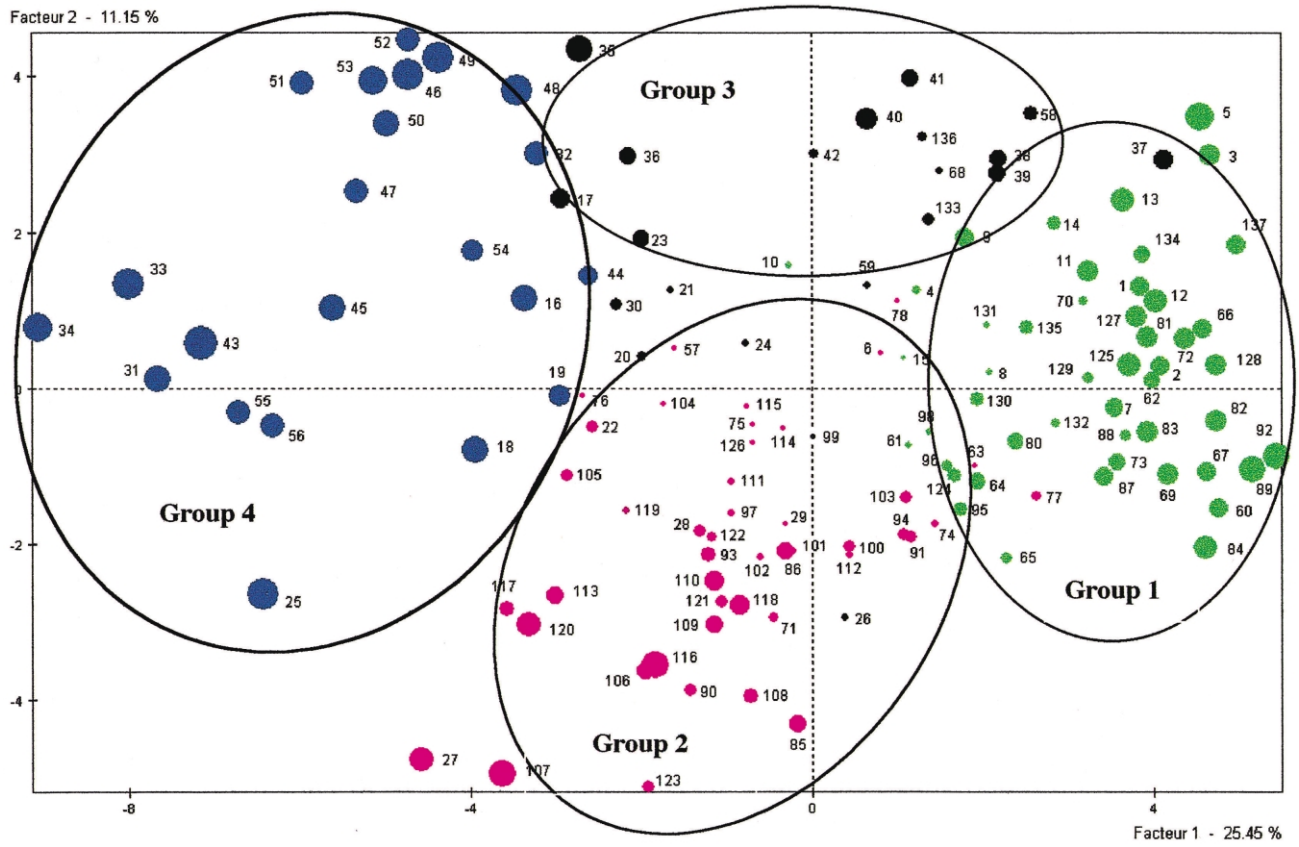

Fig. 2. Principal component and hierarchic analysis of 137 gymnosperm taxa, indexed from 1 to 137 according to Table 1. Four groups were evidenced by the hierarchic analysis. The size of each dot represents the quality of representation.

RNA data shows that these plants can be regarded as the closest living relatives of angiosperms (Doyle et al., 1994). For example, the internal transcribed spacer 1 region of rDNA of *Welwitschia* is the shortest among the Gnetales, so that its length is close to that of the longest one in the angiosperms (Liston et al., 1996). Despite obvious morphological differences, this group is widely regarded as monophyletic (Crane et al., 1995). Nevertheless, the analysis of *rbc*L gene sequences also shows that *Gnetum* and *Welwitschia* are more closely related to each other than either is to *Ephedra* (Hasebe et al., 1992). From our results it appears that the genera *Gnetum* belongs to group 3, whereas *Ephedra* and *Welwitschia* belong to group 1. In addition, both the leaves and seed oil (Aitzetmüller and Vosmann, 1998) of *Welwitschia* do not contain sciadonic and juniperonic acids whereas *Ephedra* species do. Moreover, unlike *Ephedra, Gnetum* and *Welwitschia* seed oils contain cyclopropenoic fatty acid which is known to be present in the angiosperm order Malvales (Aitzetmüller and Vosmann, 1998). Hence it appears that the monophyletic or the polyphyletic origin of Gnetales requires further consideration.

Principal component and discriminant analyses of the 44 Pinaceae taxa were also performed. Results are shown Fig. 3. Because of their very peculiar fatty acid composition, *Pinus pinaster* and *P. palustris* were omitted from these analyses and are shown as illustrative species. Under these conditions, the first and second axes explain 34.7 and 11.9% of the total variation, respectively. The most discriminant variables along axis 1 are 20:0, 22:0, 16:0, 18:0 and *all cis*-Δ7, 10, 13–16:3. Axis 1 clearly discriminates group 1 from the others. Along axis 2, br-17:0, which is at the highest level in the genus *Abies*, makes it possible to discriminate this genus from other Pinaceae. In other words, the analysis allows a clear-cut distinction between three groups: group 1 containing the genera *Larix, Pinus* and some *Picea* species; group 2 strongly clustering the genus *Abies*; and finally group 3 composed of the genera *Picea* and *Cedrus*. These results differ somewhat from those obtained by Wolff et al. (1997b), who carried out a multivariate analysis of the fatty acid composition of 58 Pinaceae seed oils. These authors observed 4 groups: *Cedrus*, *Abies*, *Larix* plus *Picea*, and *Pinus*, this last group including *Tsuga* and *Pseudotsuga*. Except for the genus *Abies,* our results did not make it possible a so-clear distinction; in addition *Larix* and *Picea* in one hand, and *Tsuga* and *Pseudotsuga* in an other hand appeared to be in a closer relationship than that was observed in Wolff et al. (1997b).

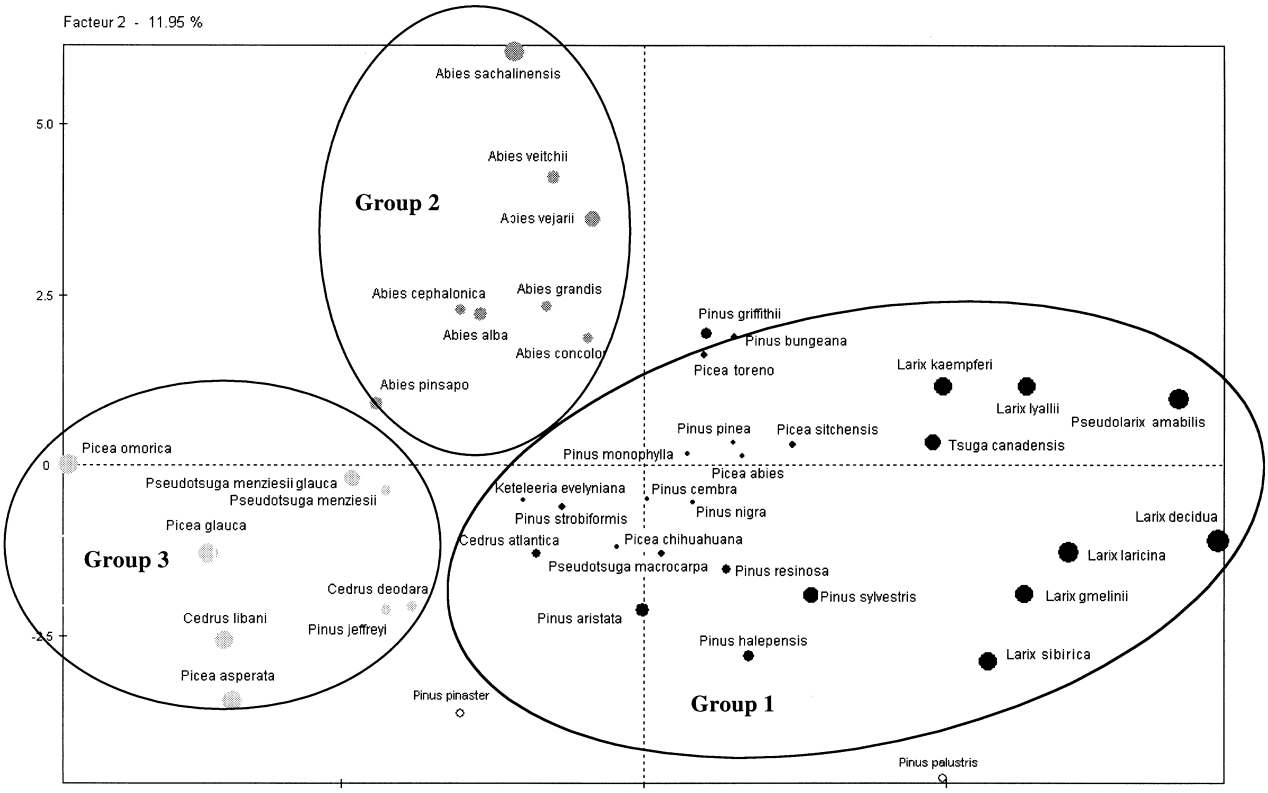

Fig. 3. Principal component and hierarchic analysis of 44 Pinaceae taxa. Three groups were evidenced by the hierarchic analysis. The size of each dot represents the quality of representation.

The Ward hierarchical clustering method — used in the previous two-step statistical analysis (Fig. 3) — is an agglomerative clustering algorithm which starts with n singleton clusters (each consisting of one element of the data set) and merges two clusters on the basis of a similarity measure. Another statistical method — termed "divisive hierarchical clustering method" — was also performed. This method reverses the process of agglomerative clustering by starting with all elements in one cluster (the 44 Pinaceae), and by dividing successively each cluster into two smaller ones, until a suitable stopping rule prevents further divisions (Chavent, 1997, 1998). The divisive clustering method — used to define a 5-cluster partition of the 44 Pinaceae — is closed in a non-supervised context to the segmentation methods (Breiman et al., 1984). During the hierarchy construction, each split is carried out by selecting one single variable (which is selected optimally) and its binary transformation. In the latter case, each cluster is characterized by a conjunction of logical properties both necessary and sufficient for membership in the cluster. An easily interpretable classification is obtained, and the resulting hierarchical tree is the decision tree presented in Fig. 4. This method makes it possible to divide the Pinaceae family into 5 clear-cut classes separating the genera *Larix*/*Pseudolarix* in group 1, *Abies* in group 4, and *Cedrus*/*Pseudotsuga* in group 5. The genera *Pinus* and *Picea* are distributed in groups 2 and 5. *Tsuga* and *Pseudotsuga* are not clustered in the same group and the genus *Keteleeria* is isolated with *Pinus pinea* in group 3.

3. Experimental

3.1. Material

Solvents used were of analytical grade. Thin layer chromatography plates were high-performance TLC (HPTLC) silica-gel 60F254 plates (Merck).

3.2. Plant material

Samples of gymnosperm photosynthetic tissues were collected during spring and summer 1998 from adult plants in the Arboretums of Chèvreloup (Muséum National d'Histoire Naturelle, Paris) and Barres (Nogent-sur-Vernisson, France), in the French botanical gardens of the cities of Bordeaux, Brest, Nancy, San Nicolao and Talence, in the National Botanic Garden of Belgium, in the Botanical garden of Les Cèdres (Saint-Jean-Cap-Ferrat, France), in the Villa Thuret (INRA Antibes, France), in the Maymou tree nursery (Bayonne, France) and in a private collection via Mr. B. Bouet.

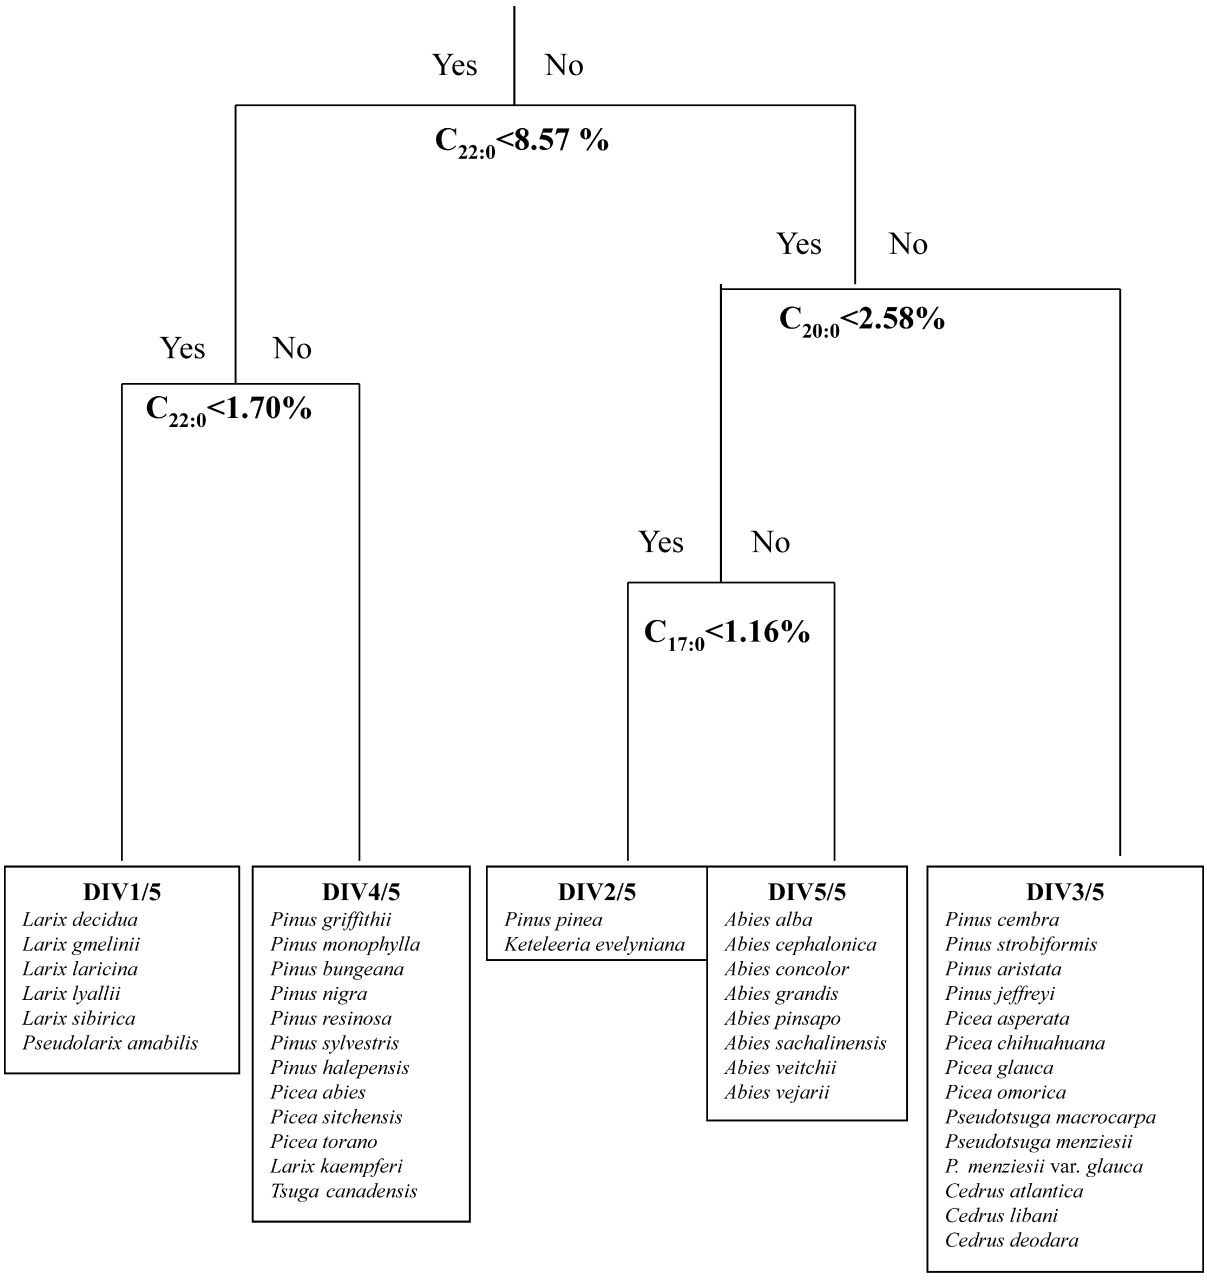

Fig. 4. Divisive hierarchical clustering method performed on the 44 taxa of Pinaceae. This method provides a 5-cluster partition.

3.3. Fatty acid analysis

Fatty acids of gymnosperm leaf lipids were analyzed by GLC after conversion to the corresponding methyl esters. The procedure used was described by Browse et al. (1986) and used hot methanolic H_2SO_4 to digest fresh photosynthetic tissue and simultaneously convert fatty acids of leaf lipids to methyl esters. Samples (approx. 250 mg of fresh tissue) were placed in screw-capped tubes. After addition of 1 ml MeOH, 2.5% H_2SO_4 (v/v), tubes were heated to 80°C for 1 h. After samples were cooled, 500 μl hexane and 1 ml H_2O were added. Fatty acid methyl esters were extracted into hexane by vigorous shaking, then a two-phase system was established by centrifugation (1500 *g*, 10 min). A sample (1 μl) was taken directly from the hexane phase and used for GC analysis on a 15 m×0.53 mm Carbowax column (Altech). The gas chromatograph used (Helwet Packard 5890 series II) was fitted with flame-ionization detector and electronic integrator (Hewlett Packard 3396 series III). The GC was programmed for an initial temp. of 160° for 1 min, followed by a 20° min^{-1} ramp to 190° and a secondary ramp of 5° min^{-1} to 210°. This final temp. was maintained constant for a further 5 min. The retention times of Δ5-olefinic fatty acids were determined by comparison with the well-known fatty acid composition of different gymnosperm

oil seeds: *Pinus sylvestris*, *Fokienia hodginsii*, *Austrocedrus chilensis*, *Prumnopitys andina* and *Taxus chinensis* (Wolff and Bayard, 1995; Wolff et al., 1998; Wolff et al., 1999a,b; Dr. R.L. Wolff, personal communication). Other fatty acid peaks were quantified and identified by comparison of their retention times with standards (Sigma Chemical Co., St. Louis, MO, USA). Because of the very close proximity of the the *cis*-Δ7 and the *trans*-Δ3 C16 peaks which didn't allow us to clearly separate them for all of the analyses carried out, the percentages of C16:1 in Table 1 represents the sum of these two peaks. It can be noted that the differences of C16:1 amount between the various species are mainly due to the *cis*-Δ7 C_{16} fatty acids. Several analyses of the same sample led to similar results. The fatty acid composition of photosynthetic tissue at various stage of development showed no significant differences.

3.4. Analysis of fatty acid galactolipids (MGD, DGD)

Two hundred and fifty milligrams of gymnosperm leaves were harvested and ground at −80°C with 6 ml of $CHCl_3$–MeOH-HCOOH (10:10:1) as described by Miquel and Browse (1992). Tubes were stored overnight at −20°C. The extraction procedure was continued by adding 2.2 ml of $CHCl_3$–MeOH–H_2O (5:5:1). The organic phase was washed with 3 ml of 0.2 M H_3PO_4–1 M KCl (Hajra, 1974). Lipids were recovered in the organic phase, dried and redisolved in 500 μl of $CHCl_3$–MeOH (2:1). Individual lipids were purified from the extracts by monodimensional TLC using the solvent system $CHCl_3$–MeOH–H_2O (65:25:2). To avoid any fatty acid contamination by silica of the TLC plates (mainly oleic and palmitic acids), we used plates previously washed by carrying out a chromatography for 3 h using $CHCl_3$–MeOH (2:1) as solvent. After chromatography, lipids were localized by spraying plates with a solution of 0.01% (w/v) primuline in 80% acetone, followed by visualization under UV light (366 nm). The silica gel zones corresponding to MGD and DGD, determined according to standards, were scraped from the plates and placed in 1 ml of methanolic H_2SO_4 reagent to convert galactolipid fatty acids to methyl esters. The analytical procedure was continued as described above.

3.5. Statistical analyses

Three data sets were studied by a two-step statistical analysis. The first data table is composed of 137 rows corresponding to the 137 plants, and 24 columns corresponding to 24 fatty acids (*Araucaria montana* was omitted during the calculation process because of its very high percentage of br-17:0). Because of the skewness of the distribution of the 24 numeric variables, the Box–Cox transformation $y = (x^a - 1)/a$ was performed on the 24 variables with $a = 1/2$ (Jobson, 1992a). The measurement was stretched and the distribution shapes were more normal-like. A third data table was extracted from this second data table which corresponds to 44 taxa of Pinaceae. The following two-step statistical process was applied to the three data tables: (1) a Principal Component Analysis (PCA) (Hotelling, 1933; Jobson 1992b) was performed, in order to visualize and reduce the dimension of the three data sets; this PCA was non-normalized, so the principal components were computed on the variance-covariance matrix, instead of the usual correlation matrix; (2) the Ward hierarchical clustering methods (Ward, 1963; Jain and Dubes, 1988) were performed on the species described by the 10 first principal components; the 4-cluster partitions were taken into account for each of the three data sets. The results were obtained with the Data Analysis software SPAD (Lebart et al., 1996).

The divisive clustering method (Chavent, 1997, 1998) used to define a 5-cluster partition of the 44 Pinaceae is in a non-supervised context, close to the segmentation methods (Breiman et al., 1984). During the hierarchy construction, each split is carried out by selecting one single variable (which is selected optimally) and its binary transformation. In the latter case, each cluster is characterized by a conjunction of logical properties both necessary and sufficient for membership in the cluster. Results are presented as a hierarchical decision tree.

Acknowledgements

This work was in part supported by the Conseil Régional d'Aquitaine. S.M. was supported by a grant from the Ministère de la Recherche et des Technologies, France. The authors are highly indebted to Dr. Robert L. Wolff (University Bordeaux 1) for helpful discussion and for providing gymnosperm oils. Acknowledgments to Mr. Bernard Bouet (Parc Floral Phoenix, Nice, France), Mr. Elmar Robbrecht (National Botanic Garden of Belgium), Mrs. Suzanne Marnier-Lapostolle (Botanical garden Les Cèdres, Saint-Jean-Cap-Ferrat, France), Mrs. Catherine Ducatillion (Villa Thuret, INRA Antibes, France), to the Arboretums of Chèvreloup (Muséum National d'Histoire Naturelle, Paris) and Barres (Nogent-sur-Vernisson), to the botanical gardens of the cities of Bordeaux, Brest, Nancy, San Nicolao and Talence, to the Maymou tree nursery (Bayonne, France), who kindly provided the samples analyzed in the present study.

Received 11 October 2000; received in revised form 30 March 2001

Abstract

Fourteen species of the genus *Echium* (Fam. Boraginaceae) collected in the Macaronesia were surveyed in a search for high levels of γ-linolenic acid (GLA, 18:3ω6) in the seed oil. High amounts of this fatty acid were found in all of them, ranging from 18.85% (*E. pitardii* var. *pitardii*) to 27.42% (*E. gentianoides*) on total seed fatty acids. The GLA content related to total seed weight was also significant, ranging from 1.26% (*E. handiense*) to 8.22% (*E. gentianoides*). In addition, considerable amounts of stearidonic acid (SA, 18:4ω3) were detected, ranging from 3.78% (*E. bonnetii* var. *bonnetii*) to 8.81% (*E. pininana*) on total fatty acids. Besides all the perennial species, the four herbaceous *Echium* taxa endemic to the Macaronesia also showed high GLA percentages. This is in contrast to the low GLA level found in continental *Echium* species, all of them bearing an herbaceous habit. These results are in good agreement with the available genetic data and show the ability of GLA to discriminate between Macaronesian and continental *Echium* species. The analysis of five other Macaronesian species belonging to plant families rich in GLA are also reported. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Boraginaceae; *Echium*; γ-Linolenic acid; Macaronesia; Stearidonic acid; Fatty acid; Seed oil

1. Introduction

Seeds from Macaronesian *Echium* (ME) species (Fam. Boraginaceae) have been recently identified as among the richest sources of γ-Linolenic acid (GLA, 18:3ω6) found so far in nature, which are also rich in stearidonic acid (SA, 18:4ω3) (Guil-Guerrero et al., 2000a). In that study a partial survey of the genus covering 18 endemic species was made, all of them bearing a perennial woody habit. However, a number of *Echium* species from the Macaronesian area remained untested.

Finding of species producing high amounts of GLA is a great interest due to its pharmaceutical and dietary importance in addition to the use of GLA as a purified product in clinic and dietary investigations (Gunstone, 1992; Horrobin, 1992). Moreover, high GLA percentages in the oil make easier the purification bioprocess (Guil-Guerrero et al., 2000b).

A total of 27 *Echium* taxa at the specific level was reported to be present in the Macaronesia. All except *E. plantagineum*, which seems to be introduced by man, are exclusively from this area (Bramwell, 1972). Genetic studies based on the analysis of the mitochondrial genome indicated that all the island *Echium* plants descend from an herbaceous continental ancestor, through a single and relatively recent colonisation event followed by a rapid speciation process (Böhle et al., 1996). While all except two Macaronesian *Echium* species are woody perennials, continental species are herbaceous plants. Previous data (Guil-Guerrero et al., 2000a, 2001c) showed important ifferences in the fatty acid profile between European and North-African *Echium* plants (Continental Echium, CE) and their ME relatives thus an increase in the GLA content of the ME species — up to 100% as compared to the CE- in expense of a decrease of the α-linolenic acid (ALA, 18:3ω3) amount was obsered.

In this paper we report the fatty acid composition of 14 endemic *Echium* species, including two herbaceous taxa that were remaining, essentially complete the analysis of the whole genus in the area. In addition, the analysis of five Macaronesian and north-african endemic species belonging to other genera from the families rich in GLA is also reported. The results are discussed in relation to the available genetic data besides to a possible evolutionary role of the fatty acid profile.

2. Results and discussion

Seed oil content and fatty acid composition of the 14 endemic *Echium* species here analyzed are given in Table 1. Seed oil content ranged from 6.28% in *E. handiense* to 29.97% in *E. gentianoides*. The percentage of GLA ranged between 17.83% of total fatty acids in *E. virescens* var. *angustissimum* to 27.42% in *E. gentianoides*. The percentage on total seed weight varied from 1.26% GLA in *E. handiense* to 8.22% GLA in *E. gentianoides*.

The amounts determined for other polyunsaturated fatty acids on total oil were in good agreement with previous reports for other plants of the same genus (Wolf et al., 1983; Tsevegsüren and Aitzetmüller, 1996; Guil-Guerrero et al., 2000a). SA ranged from 3.48% in *E. x bond-spranguei* to 8.81% in *E. pininana*. Linoleic acid (LA, 18:2ω6) ranged from 15.97% in *E. handiense* to 30.22% in *E. bonnetii* var. *bonnetii*. α-Linolenic acid (ALA, 18:3ω3) ranged from 16.52% in *E. bonnetii* var. *bonnetii* to 27.07% in *E. webbii*. For monounsaturated fatty acids we obtained similar values to those reported in other species from this group. Oleic acid (OA, 18:1ω9) ranged from 10.31% in *E. webbii* to 22.18% in *E. x bond-spranguei*. Other monounsaturated fatty acids

(20:1ω9, 22:1ω9 and 24:1ω9) were found in low amounts in agreement to the composition reported for other Boraginaceae species (Wolf et al.,1983; Tsevegsüren and Aitzetmüller, 1996; Guil-Guerrero et al., 2000a, 2001). Results for saturated fatty acids also agree with the reports mentioned above. Palmitic acid (16:0), for instance, ranged from 6.19% in *E. gentianoides* to 9.76% in *E. bonnetii* var. *fuerteventurae*.

Among *Echium* species five showed GLA values above 23% in a seed oil, and four showed GLA percentages in total seeds above 4% in a seed dry weight. For these species, the high relative amount of GLA in oil is paralleled by a high oil content within the seed (>20%). *E. gentianoides* seed oil was the richest source of GLA, with 8.22% of GLA on the total seed weight. Except for *E.handiense* and *E. wildprettii* ssp. *trichosiphon* seeds of all the surveyed *Echium* species have more than 2% (w/w) of GLA. Seed oils of all the surveyed *Echium* species, except those of *E. virescens* var. *angustissimum*, *E. pitardii* var. *pitardii*, and *E. pitardii* var. *macrantha*, have more than 20% of GLA.

Four herbaceous varieties (*E. bonnetii* var. *bonnetii*; *E. bonnetii* var. *fuerteventurae*; *E. pitardii* var. *pitardii* and *E. pitardii* var. *macrantha*) showed GLA contents in good agreement to those of other species from the Macaronesian sections behaving as perennial shrubs. Nevertheless, due to their herbaceous habit they have been included within the *Echium* section (Bramwell, 1972), a taxonomical group that gather herbaceous continental plants showing GLA percentages in the oil below a 12% (Guil-Guerrero et al., 2001). This is in good agreement with genetic data from Böhle et al. (1996), that groups *E. bonnetti* in a cluster together with the perennial ME, and apart from the herbaceous CE plants. A good example, that can be considered as a negative control, is *E. plantagineum*, an herbaceous plant which is considered as a continental island invasor. This species exhibits a low GLA level (9% GLA on a seed oil) (Guil-Guerrero et al., 2000a) and genetically lies far away from the ME group (Böhle et al., 1996). These data argue in favour of the usefulness of the fatty acid composition, and in particular of GLA, as a taxonomic marker as it has been claimed by other authors (Velasco and Goffman, 1999). On the other hand, these data indicate that it could be more appropriate to include the herbaceous ME in a new taxonomical group. Variability of the GLA content at the infraspecific level, as in the case of *E. virescens* var. *angustissimum* (17.83%) vs. *E. virescens* var. *virescens* (24.00%) (Guil-Guerrero et al., 2000a), or *E. wildprettii* ssp. *trichosiphon* (24.86%) vs. *E. wildprettii* ssp. *wildprettii* (15.16%) (Guil-Guerrero et al., 2000a) is probably reflecting the rapid diversification of the ME species.

The conspicuous presence of a high GLA level in the seeds of ME plants raises the question of whether this characteristic conferred to them a selective advantage during evolution. Conversely, in a neutral hypothesis, one can think that time since the island colonisation event took place (less than 20 millions years ago according to genetic estimations) was not enough for the loss of this character that was present in the common ancestor of the ME. Nevertheless, it remains intriguing why none of the CE plants that we have analysed do not show a high GLA level. Perhaps, a high GLA content is deleterious for the seeds of CE plants in their particular environmental conditions. In this context it is known that fatty acid composition in lipids determines the fluidity of structures where they are present. To test whether a high GLA content, at the expense of a reduction in the ALA amount, could have an influence on the fluidity of the seed content we have measured a "melting range" (oils are complex mixtures and therefore have no defined melting points) of the oils of several *Echium* species, and the results corroborate this idea. Thus, the seed oil from the mediterranean *E. sabulicola* (10% GLA) (Guil-Guerrero et al., 2001) melted in the range 13–18°C, while those from the Macaronesian *E. fastuosum* (18–22°C) and *E. nervosum* (19–25°C) had higher melting ranges (both 25% GLA, Guil-Guerrero et al., 2000a). An explanation for these data is that substitution of ALA by GLA at the second position of the storage lipids raises the melting point due to the particular spatial configuration of the GLA, in which the double bonds are more distant to the terminal methyl of the molecule than in the ALA. Considering these data, one can speculate that an increase in the proportion of GLA at the second position of tryglicerides in CE plants would reduce the fluidity of the seed oil. As the average continental temperature all year long is supposed to be lower than at the Macaronesian area, the high GLA content might affect negatively the mobilisation of tryglycerides during the seed germination of CE plants.

Although it has been reported that environmental factors such as soil type and temperature, can affect to GLA and other polyunsaturated fatty acids contents in the seed oil of *Boraginaceae* or *Onagraceae* (Gunstone, 1992), in our experience those factors do not seem to affect significatively the profiles found in *Echium* plants. For instance, seeds from *E. gentianoides* collected from different locations and times were analyzed with similar results for the fatty acid profiles (less than 1% variation of the GLA content). The same was true for other plants such as *E. fastuosum* and *E. virescens* var. *angustissimum*, as we could establish from other experiments. Thus, in the absence of a more exhaustive study, we can assume a constancy in the seed fatty acid profile in plants belonging to this genus.

Table 1 also shows the fatty acid profile of other endemic species from the Macaronesian area, belonging to families which are considered as good sources of GLA. Note that the small GLA percentages are in good

agreement with previous reports from European species (Wolf et al., 1983; Tsevesüren and Aitzetmüller, 1996; Guil-Guerrero et al., 2001). This indicates that, in some way, the characteristic fatty acid profile of the ME species could be restricted in the area to these plants.

The results of the present work indicate that ME species shown here had a high percentage of GLA in the seed oil, with *E. gentianoides* as the species showing the higher amount among them. The possibility of finding plant species with a much higher GLA content seems to be unlikely, due to the fact that the GLA in Boraginaceae is mainly found at the second position of triglycerides (Gunstone, 1992) and that, consequently, impose a theoretical limit around 33%. In addition, we found that the endemic herbaceous ME have percentages of GLA in the range found for the woody perennial ME species. This finding possesses agronomic interest as annual species producers of GLA have obvious advantages in the cultivation compared to the perennial shrubs, due to their shorter biological cycle.

3. Experimental

3.1. Materials

Mature seeds were collected at maturity in the natural habitats of these plants. Seeds of *E. brevirame*, *E. gentianoides*, *E. x bond-spraguei*, *E. webbi*, *E. bethercoutianum*, *E. wildpretti* ssp. *trichosiphon*, *E. pininana*, *Scrophularia smithii* and *Myosotis latifolia* were collected in La Palma island in June 1999. Seeds of *E. pitardii* var. *pitardii*, *E. pitardii* var. *macrantha*, *E. decaisnei* ssp. *purpuriense* and *Kickxia heterophylla* were gathered from Lanzarote island in April 2000. Seeds of *E. bonnetii* var. *bonnetii*, *E. bonnetii* var. *fuerteventurae*, *E. handiense*, and *Heliotropium erosum* were collected from Fuerteventura island in April 2000. Seeds of *Isoplexis chalcantha* were gathered from Gran Canaria island in May 2000. Seeds of *E. virescens* var. *angustissimum* were collected from Tenerife island in July 2000. Precautions accomplishing the harvesting were taken as previously reported (Guil-Guerrero et al., 2000a).

Oil extraction and transesterification, gas-liquid chromatography (GLC) and GC–mass spectrometry, were made as is previously reported (Guil-Guerrero et al., 2000a). Melting ranges of oils were determined by freezing the oils at −78°C and slowly rising the temperature until they become liquids.

Abstract

A triterpenoid, 3β-*cis*-*p*-coumaroyloxy-2α,23-dihydroxyolean-12-en-28-oic acid (**1**), and two natural products, 3β-*trans*-*p*-coumaroyloxy-2α,23-dihydroxyolean-12-en-28-oic acid (**2**) and 23-*trans*-*p*-coumaroyloxy-2α,3β-dihydroxyolean-12-en-28-oic acid (**3**), were isolated from a chloroform-soluble extract of the stems of *Eugenia sandwicensis*, along with 10 known compounds. Of these compounds, **2** showed significant inhibitory activity (79.2% at 4 μg/ml) in a 7,12-dimethylbenz[*a*]anthracene-induced mouse mammary organ culture assay system of relevance to cancer chemoprevention. Gallic acid was isolated as an antioxidative constituent of an ethyl acetate-soluble extract of *E. sandwicensis* stems. Isolates **1**–**3** were characterized on the basis of spectral and chemical evidence. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

The genus *Eugenia* of the Myrtaceae comprises over 500 species, and is most common in tropical and subtropical America and tropical Asia, with a few species occurring in Australia and Africa (Hillebrand, 1888). Previously, coumarins (Lowry, 1968; Yazaki, 1977), ellagic acid (Yazaki, 1977), flavonoids and their glycosides (Mitscher et al., 1973; Painuly and Tandon, 1983a), hydrolysable tannins (Nonaka et al., 1987; Lee et al., 1997), steroids (Govindachari et al., 1969; Schapoval et al., 1994), and triterpenoids of the lupane (Yazaki, 1977) and ursane (Painuly and Tandon, 1983b) types have been found as constituents of this genus. *Eugenia sandwicensis* A. Gray, collected in Hawaii, is a perennial woody tree or shrub. Up to the present, no chemical and biological work has been carried out on this plant.

As part of an ongoing collaborative search for novel chemopreventive principles from plants (Kinghorn et al., 1998; Pezzuto et al., 1999), the methanolic extract of the stems of *E. sandwicensis* showed significant biological activities in preliminary screening, in both a 7,12-dimethylbenz[*a*]anthracene (DMBA)-induced mouse mammary organ culture model (Mehta and Moon, 1991) and a 1,2-diphenyl-2-picrylhydrazyl (DPPH) free-radical scavenging antioxidative assay (Fujita et al., 1988). The compounds responsible for the significant activities exhibited in the mouse mammary organ culture assay and the DPPH assay were partitioned selectively into subsequent chloroform- and ethyl acetate-soluble extracts, respectively. This paper describes the isolation, structure elucidation, and evaluation of biological activities in the mouse mammary organ culture assay of one triterpene derivative (**1**) and two triterpenoid natural products (**2** and **3**) from the chloroform-soluble extract of *E. sandwicensis* stems. Also, 10 known compounds were obtained from this extract, and gallic acid was isolated as an antioxidative principle from an ethyl acetate-soluble extract of the stems.

2. Results and discussion

Ten compounds of previously known structure were isolated from the $CHCl_3$ extract of the stems of *E. sandwicensis*, as described in the Experimental section, and were identified, in turn, as alphitolic acid (Yaguchi et al., 1988), arjunolic acid (Jayasinghe et al., 1993), betulinic acid (Ikuta and Itokawa, 1988), 3-*epi*-betulinic acid (Kitajima et al., 1990), 2α,3α-dihydroxylup-20(29)-en-28-oic acid (Kumar et al., 1985), 3β,23-dihydroxylup-20(29)-en-28-oic acid (Ikuta and Itokawa, 1988), hederagenin (Ikuta and Itokawa, 1988), maslinic acid (Tchivounda et al., 1991), β-sitosteryl 3-*O*-β-D-glucopyranoside (Fujita and Nakayama, 1993), and syringaldehyde (Kokpol et al., 1993), by comparison of their physical and spectral data with reported values. Among these isolates, arjunolic acid was the major compound found in this investigation, in a yield of greater than 0.06% w/w of the dried plant material.

Compound **1** was obtained as a white amorphous powder. A molecular formula was deduced as $C_{39}H_{54}O_7$ from the HRFABMS data at *m/z* 657.3763 $[M+Na]^+$ ($C_{39}H_{54}O_7Na$ calcd for 657.3767). This compound exhibited UV maxima at 223 and 312 nm, suggesting the presence of considerable conjugation in the molecule. In the IR spectrum, absorption bands at 3330 (OH), 1695 (ester carbonyls), 1604 and 1514 cm^{-1} (trisubstituted double bond and aromatic ring) were apparent. The EIMS of **1** exhibited characteristic ion peaks at *m/z* 248 and 203, due to *retro*-Diels–Alder type fragmentation of an olean-12-en-28-oic acid or an urs-12-en-28-oic acid unit bearing no other oxygenated substituent in any of the C, D or E rings (Bombardelli et al., 1974).

Interpretation of the ^1H and ^{13}C NMR spectral data of **1** with the use of ^1H–^1H COSY, HOHAHA, HMQC, HMBC, and NOESY experiments, and comparison with arjunolic acid (Jayasinghe et al., 1993), which, as mentioned, was also obtained in the present investigation, allowed full assignment of chemical shifts (Tables 1 and 2). Two methine protons at δ_H 5.80 (1H, *d*, $J=9.9$ Hz) and δ_H 4.39 (1H, *td*, $J=4.5$, 9.9 Hz) assigned to H-3 and H-2 were determined from the ^1H–^1H COSY and HOHAHA spectra, and were in conformity with a *trans*-diequatorial (2α,3β) configuration of two oxygen-bearing groups. The ^1H NMR spectrum also revealed a hydroxymethylene (CH_2OH) group (δ_H 3.60, 3.50, each $J=11$ Hz), which was confirmed by a HMQC experiment from the correlations of these two protons with the carbon signal of C-23 (δ_C 64.7). Moreover, the aromatic protons at δ_H 8.10 and 7.10 (each 2H, *d*, $J=8.5$ Hz) of a *p*-disubstituted benzene ring suggested the presence of a *p*-substituted *cis*-cinnamoyl moiety in **1**. Had the configuration of H-2′ and H-3′ been *trans*, a characteristic *J* value of about 16 Hz would have been expected (Lee, 1998). This ester substituent was placed at C-3 as a result of the downfield shift observed for H-3 in the ^1H NMR spectrum, compared with that of arjunolic acid (Jayasinghe et al., 1993), and the correlations between H-3 (δ_H 5.80) and C-2 (δ_C 66.7), C-4 (δ_C

[a] Carbon chemical shifts (ppm) were recorded at 75.6 MHz using C_5D_5N as solvent and TMS as internal standard. Assignments were based on COSY, HMQC and HMBC experiments.
[b] Carbon multiplicity.

43.7), C-23 (δ_C 64.7), C-24 (δ_C 14.9) and C-1′ (δ_C 167.5) of the *p*-coumaric acid unit in the HMBC spectrum. Moreover, the structure of the *p*-coumaroyl moiety was confirmed by the correlations between H-2′ (δ_H 6.07) and C-1″ (δ_C 126.6), and those of H-3′ (δ_H 6.89) and C-2‴/C-6″ (δ_C 133.9). The relative configuration of H-2, H-3 and H-23 and the other spatial information of compound **1** were further supported by a NOESY experiment, wherein NOEs were observed between H-24 (δ_H 0.90) and H-2 (δ_H 4.39), between H-3 (δ_H 5.80) and H-9 (δ_H 1.92), and between H-23 (δ_H 3.60, 3.50) and H-5 (δ_H 1.83) (Fig. 1). Therefore, based on all the above evidence, the structure of the new compound **1** was assigned as 3β-*cis*-*p*-coumaroyloxy-2α,23-dihydroxyolean-12-en-28-oic acid.

The natural product **2** was obtained as a pale yellowish powder and its molecular formula was deduced as $C_{39}H_{54}O_7$ by the HRFABMS data at *m*/*z* 657.3787 $[M+Na]^+$ ($C_{39}H_{54}O_7Na$ calcd for 657.3767). Compound **2** was characterized as 3β-*trans*-*p*-coumaroyloxy-2α,23-dihydroxyolean-12-en-28-oic acid, by comparison of its NMR spectroscopic data with those of compound **1** (Tables 1 and 2). Compound **2** was previously characterized as its C-28,C-4″-dimethylated derivative (Tapondjou et al., 1995; Lee, 1998), but not in its natural form. When the C-28,C-4″-dimethylated derivative was prepared from **2** as described in Section 3, the spectral data of the methylate were comparable with literature values.

The natural product **3** was obtained as a pale yellowish powder and its molecular formula was deduced as $C_{39}H_{54}O_7$ by the HRFABMS data at *m*/*z* 657.3751 $[M+Na]^+$ ($C_{39}H_{54}O_7Na$ calc. for 657.3767). Compound **3** was also previously characterized as its C-28,C-4″-dimethylated derivative (Lee, 1998). In a similar manner to compound **2**, the new natural product **3** was characterized as 23-*trans*-*p*-coumaroyloxy-2α,3β-dihydroxyolean-12-en-28-oic acid, and its ^{1}H NMR and ^{13}C NMR spectroscopic data are also assigned in Tables 1 and 2, respectively.

Compounds **1–3** were evaluated for potential to inhibit the development of DMBA-induced preneoplastic mammary lesions using a mouse mammary organ culture assay system (Mehta and Moon, 1991). The results summarized in Table 3 illustrate that compound **2** exhibited significant inhibitory activity (79.2% at 4 μg/ml) while compounds **1** and **3** were inactive. This is the first oleanane ester triterpenoid found to inhibit DMBA-induced preneoplastic lesions in this test system. Therefore, compound **2** appears worthy of additional biological evaluation to further define its promise as a cancer chemopreventive agent.

The sole compound from the EtOAc extract of *E. sandwicensis* stems found to be active in the DPPH antioxidant assay (Fujita et al., 1988) was obtained as yellowish needles and identified as gallic acid, by a comparison of the physical and spectral data with reported values (Sakar et al., 1993) and direct comparison with an authentic sample. It exhibited potent antioxidative activity with an IC_{50} value of 3.6 μg/ml in a DPPH assay system. This compound is among the most active substance we have evaluated in this system to date. However, gallic acid was inactive when tested in the above-mentioned mouse mammary organ culture assay system.

Effects of compounds **1**–**3** on DMBA-induced preneoplastic lession with mouse mammary gland organ culture

Compound	Concentration (μg/ml)	Inhibition (%)[a]
1	10	36.6
2	4	79.2
3	10	48.1

[a] Pure compounds are considered active if they exhibit >60% inhibition at 10 μg/ml.

were measured with a Perkin-Elmer 241 polarimeter using MeOH as solvent. UV spectra were recorded on a Beckman DU-7 spectrometer using MeOH as solvent. IR spectra were recorded on a JASCO FT/IR-410 spectrometer. EIMS (70 eV) were obtained using a Finnigan MAT-90 mass spectrometer, and HRFABMS using a VG 7070-HF mass spectrometer. The ^{1}H NMR and ^{13}C NMR spectra were recorded in C_5D_5N with TMS as internal standard, using a Brüker Avance DPX-300 instrument operating at 300 and 75.6 MHz, respectively. HMBC and NOESY experiments were performed on a Brüker Avance DRX-500 instrument operating at 500.2 MHz with a TAXI probe.

Open column chromatography (CC): silica gel (200–400 mesh, Natland International Corporation, Morrisville, NC); Sephadex LH-20 (Sigma). Semi-preparative HPLC: a YMC-pack ODC-AQ column (5 μm, 25×2 cm i.d., YMC Co., Ltd., Wilmington, NC) and a YMC-guardpack ODC-AQ guard column (5 μm, 5×2 cm i.d.); two Waters 515 HPLC pumps; a Waters 2487 dual λ absorbance detector; a Millennium chromatography manager system (Waters, Milford, MA). Preparative TLC: Kieselgel 60 F_{254} (Merck) plates (silica gel, 0.5 mm layer thickness, 20×20 cm). TLC: Kieselgel 60 F_{254} (Merck) plates (silica gel, 0.25 mm layer thickness), with compounds visualized by dipping plates into either 10% (v/v) H_2SO_4 or phosphomolybolic acid reagent (Aldrich, Milwaukee, WI) followed by charring at 110°C for 5–10 min.

3.2. Mouse mammary gland organ culture assay

This assay was carried out according to an established protocol (Mehta and Moon, 1991). In brief, BALB/c female mice were pretreated for 9 days with 1 μg of estradiol and 1 mg of progesterone. On the 10th day, the mice were sacrificed and the second pair of thoracic mammary glands were dissected on silk and transferred to 60-mm culture dishes containing 5 ml of Waymouth's 752/1 MB medium supplemented with streptomycin, penicillin and glutamine. The glands were incubated for 10 days (37°C, 95% O_2 + 5% CO_2) in the presence of growth-promoting hormones (5 μg of insulin, 5 μg of prolactin, 1 μg of aldosterone, and 1 μg of hydrocortisone per ml of medium). Glands were exposed to 2 μg/ml DMBA between 72 and 96 h. After the exposure, glands were rinsed and transferred to new dishes with fresh medium. The fully differentiated glands were then permitted to regress by withdrawing all hormones except insulin for 14 additional days. Test compounds were present in the medium during days 1–10 of culture; mammary glands were scored for incidence of lesions.

3.3. Assay for DPPH free radical scavenging potential

This assay is based on the scavenging activity of stable 1,1-diphenyl-2-picrylhydrazyl (DPPH) free radicals and was carried out according to established protocols (Fujita et al., 1988). In brief, reaction mixtures containing test samples (dissolved in DMSO) and 300 μM DPPH ethanolic solution in 96-well microtiter plates were incubated at 37°C for 30 min. Absorbances were then measured at 515 nm, and percent inhibition by

sample treatment was calculated. IC_{50} values denote the concentration of sample required to scavenge 50% of DPPH free radicals.

3.4. Plant material

The stems of *E. sandwicensis* were collected on the island of Kauai, Hawaii in June 1978 and identified by Dr. Yoneo Sagawa. A voucher specimen (accession no. CH-2507) is deposited at the Harold L. Lyon Arboretum, University of Hawaii, Honolulu, HI.

3.5. Extraction and isolation

The milled air-dried stems of *E. sandwicensis* (1.9 kg) were extracted with MeOH (6 L×3) at room temperature and the solution was evaporated in vacuo. On drying, this initial methanolic extract exhibited significant inhibitory activity (62.5% inhibition at a concentration of 10 μg/ml) in the mouse mammary gland organ culture assay and antioxidative activity (13.6 μg/ml) in the DPPH free-radical scavenging bioassay. The dried MeOH extract (296 g) was resuspended in 10% H_2O in MeOH (700 ml) and partitioned with petroleum ether (1 L×2) to afford a petroleum ether soluble-residue (8 g). To the aqueous MeOH layer was added H_2O (300 ml), and this was then partitioned with $CHCl_3$ (1 L×2) to afford a $CHCl_3$-soluble extract (12 g). The aqueous MeOH layer was further partitioned with EtOAc (1 l×2) to afford an EtOAc-soluble extract (46 g).

The $CHCl_3$ extract (12 g), with 50% inhibitory activity at a concentration of 10 μg/ml in the mouse mammary gland organ culture assay, was subjected to silica gel CC and eluted with increasing concentrations of MeOH in $CHCl_3$ from 1 to 50% to give six fractions (I–VI). Fraction I (500 mg) was subjected to silica gel CC eluted with mixtures of petroleum ether and acetone in a step-gradient mode to afford 3-*epi*-betulinic acid (10 mg, eluted with petroleum ether/acetone 10:1 v/v) and betulinic acid (5 mg, eluted with petroleum ether/acetone 8:1 v/v). Similarly, fraction II (1.0 g) was subjected to silica gel CC eluted with mixtures of *n*-hexane and acetone to yield five subfractions (VII-XI). Syringaldehyde (3 mg) was obtained from subfraction VIII (130 mg, eluted with *n*-hexane/acetone 5:1 v/v), which was further subjected to silica gel CC eluted with mixtures of *n*-hexane and EtOAc (2.5:1 v/v). 2α,3α-Dihydroxylup-20(29)-en-28-oic acid (12 mg) was obtained from subfraction X (100 mg, eluted with *n*-hexane/acetone 2.5:1 v/v), which was subjected to preparative TLC on silica gel developed with $CHCl_3$/acetone (3:2) and then followed by Sephadex LH-20 CC eluted with MeOH. In turn, fraction III (1.5 g) was subjected to silica gel CC eluted with mixtures of *n*-hexane and EtOAc to afford alphitolic acid (90 mg, eluted with *n*-hexane/EtOAc 5:1 v/v) and a subfraction XI (500 mg, eluted with *n*-hexane/EtOAc 3:1→2.5:1 v/v), which was further subjected to silica gel CC eluted with mixtures of *n*-hexane and acetone to afford four further subfractions (XI–XIV). Three compounds, 3β,23-dihydroxylup-20(29)-en-28-oic acid (9.2 mg), hederagenin (25 mg), and maslinic acid (5 mg) were isolated from subfraction XII (80 mg, eluted with *n*-hexane/acetone 3.5:1 v/v), and were purified by semi-preparative HPLC eluted with mixtures of MeOH and H_2O (85:15) (flow rate, 8 ml/min; detection wavelength, 205 and 280 nm) at room temperature. Compounds **1** (5 mg) and **2** (20 mg) were obtained from subfraction XIII (50 mg, eluted with *n*-hexane/acetone 3:1 v/v) by preparative TLC on silica gel developed twice with $CHCl_3$-MeOH (15:1). Fraction IV (560 mg) was subjected to silica gel CC and eluted with mixtures of *n*-hexane and acetone to afford three further subfractions (XV–XVII). Compound **3** (10 mg) was obtained from subfraction XVI (23 mg, eluted with *n*-hexane/acetone 2:1 v/v) by preparative TLC developed with $CHCl_3$–MeOH (10:1, R_f 0.45). Finally, arjunolic acid (1.2 g) and β-sitosteryl 3-*O*-β-D-glucopyranoside (10 mg) were crystallized in $CHCl_3$–MeOH from fractions V and VI.

The EtOAc-soluble extract (46 g) exhibited 12.5% inhibitory activity at a concentration of 10 μg/ml in the mouse mammary organ culture assay, and was deemed to be of no further interest in this regard. However, since it exhibited an IC_{50} 8.6 μg/ml in the DPPH free-radical scavenging assay, it was subjected to silica gel CC eluted with mixtures of $CHCl_3$ and MeOH to obtain 13 fractions (XVIII–XXX). Gallic acid (35 mg) was purified from fraction XXII (200 mg, eluted with $CHCl_3$/MeOH 5:1 v/v) by activity-guided fractionation, and finally purified by Sephadex LH-20 CC eluted with MeOH.

3.5.1. 3β-cis-p-Coumaroyloxy-2α,23-dihydroxyolean-12-en-28-oic acid (*1*)

White amorphous powder ($CHCl_3$–MeOH), mp 252°C (dec), $[\alpha]_D^{20}$ +34.9° (MeOH, *c* 0.032). UV λ_{max} MeOH nm (log ε): 229 (4.09), 312 (4.28). 3.5.4. Methyl 3β-(trans-4-methoxycinnamoyloxy)-2α,23-dihydroxyolean-12-en-28-oate

A stirred mixture of **2** (7.0 mg, 0.011 mol), anhydrous K_2CO_3 (7.6 mg, 0.055 mol), CH_3I (15.6 mg, 0.142 mol) in acetone (4 ml) was heated under reflux for 5 h. After cooling, the mixture was filtered and the filtrate evaporated to give the title compound (6.7 mg, 92%). Its physical and spectral data were comparable with literature values (Lee, 1998).

3.5.5. Methyl 23-(trans-4-methoxycinnamoyloxy)-2α,3β-dihydroxyolean-12-en-28-oate

A stirred mixture of **3** (9.0 mg, 0.014 mol), anhydrous K_2CO_3 (9.8 mg, 0.071 mol), CH_3I (20.2 mg, 0.14 mol) in acetone (4 ml) was heated under reflux for 5 h. After cooling, the mixture was filtered and the filtrate evaporated to give the title compound (9.3 mg, 99%). Its physical and spectral data were comparable with literature values (Lee, 1998).

3.5.6. Identification of known compounds

Alphitolic acid (Yaguchi et al., 1988), arjunolic acid (Jayasinghe et al., 1993), betulinic acid (Ikuta and Itokawa, 1988), 3-*epi*-betulinic acid (Kitajima et al., 1990), 2α,3α-dihydroxylup-20(29)-en-28-oic acid (Kumar et al., 1985), 3β,23-dihydroxylup-20(29)-en-28-oic acid (Ikuta and Itokawa, 1988), hederagenin (Ikuta and Itokawa, 1988), maslinic acid (Tchivounda et al., 1991), β-sitosteryl 3-*O*-β-D-glucopyranoside (Fujita and Nakayama, 1993), and syringaldehyde (Kokpol et al., 1993) were identified by comparison with reported data.

Acknowledgements

We are grateful to Dr. Yoneo Sagawa, University of Hawaii, Honolulu, HI for collecting and identifying the plant material with financial support of the National Cancer Institute, Bethesda, Maryland. We thank Mr. Richard Dvorak of the Department of Medicinal Chemistry and Pharmacognosy, University of Illinois at Chicago (UIC) for recording the EIMS, and Dr. Rob Kleps of the Research Resource Center, UIC for facilitating the running of the 500 MHz NMR spectra. We also thank Mr. Keith Fagerquist of the Mass Spectrometry Service Laboratory, Department of Chemistry, University of Minnesota for recording the HRFABMS. This research was supported by program project P01 CA48112, funded by the National Cancer Institute, NIH, Bethesda, MD.

Received 28 November 2000; received in revised form 4 April 2001

Abstract

Induced formation of a series of carbazole alkaloids was observed in leaves of *Glycosmis parviflora* and *G. pentaphylla* after wounding, UV-irradiation, and particularly after inoculation with the fungus *Botrytis cinerea*. Chemical variation between different provenances and even individuals of *G. parviflora* led to an accumulation of different derivatives from which three proved to be undescribed natural products. Their structures were identified by spectroscopic methods and named carbalexins A, B, and C. Bioautographic tests on TLC plates with *Cladosporium herbarum* exhibited strong antifungal activity for the new carbalexins as well as for the already known 2-hydroxy-3-methylcarbazole, but only weak effects for the pyranocarbazole glycoborinine. Detailed experiments with marked infection areas confirmed the restricted accumulation of carbazole derivatives which could not be detected in non-infected areas of the same leaf. Apart from carbazoles, in some individuals of *G. parviflora* an additional accumulation of the pyranoquinolones flindersine and methylflindersine was induced, which supports the already previously discussed biogenetic connections between carbazoles and prenylated quinolones. © 2001 Elsevier Science Ltd. 1. Introduction

The formation of 3-methylcarbazole alkaloids represents a rare biogenetic trend mainly restricted to the four Rutaceae genera *Clausena*, *Glycosmis*, *Micromelum*, and *Bergera* (formerly section Bergera of the genus *Murraya*) (Kong et al., 1986; Samuel et al., 2001), and is known elsewhere only from *Ekebergia senegalensis* of the related family Meliaceae (Lontsi et al., 1985). Although the biosynthesis of this type of carbazoles is not yet entirely understood, it most likely derives from the anthranilic acid pathway via prenylated quinolones (Kong et al., 1986). Biogenetically 3-methylcarbazoles can be clearly separated from all other carbazole structures known from micro-organisms which are formed either via the polyketide or tryptophan pathway (Chakraborty and Roy, 1991). Based on literature and our current comparative phytochemical analyses within many *Glycosmis* species, carbazoles were shown to be mainly accumulated in the stem bark and to a lesser extent in the roots (Bhattacharrya et al., 1985; Chowdhury et al., 1987; Jash et al., 1992; Vajrodaya, 1998; Lukaseder, 2000) but they were only rarely found in the leaves (Kamaruzzman et al., 1989; Greger et al., 1992). However, we show that wounding, UV-irradiation, and infection with the fungus *Botrytis cinerea* resulted in an accumulation of carbazoles in the leaves of two *Glycosmis* species. Since the isolated compounds displayed pronounced antifungal activity in bioautographic tests on TLC plates and were accumulated only in the area of infection, they were regarded as a new class of phytoalexins. Especially different provenances of the more widespread *G. parviflora* (Sims) Little (syn.: *G. citrifolia* (Willd.) Lindley) responded clearly with the formation of a series of carbazoles (Fig. 1). Various accumulation trends towards different carbazole derivatives were observed between different geographical provenances and even different individuals. Three compounds were shown to be hitherto undescribed natural compounds named carbalexins A (**1**), B (**2**), and C (**3**) from which however, carbalexin B (**2**) was already previously reported as a synthetic product

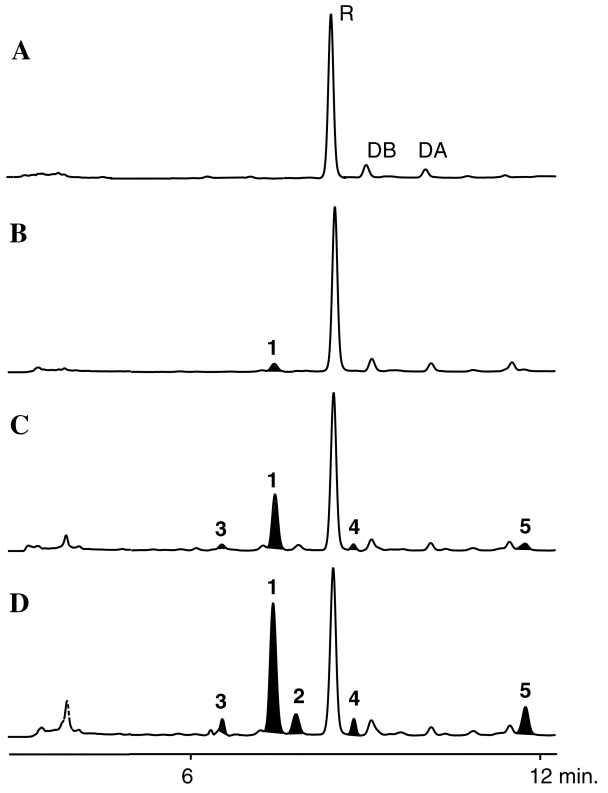

Fig. 1. Chronological composite of HPLC profiles obtained from combined leaves of different individuals of *G. parviflora* (RUT-69) after inoculation with *B. cinerea* : (A) untreated leaves without carbazoles, (B) after 2 days with small amount of carbalexin A (**1**), (C) and (D) different carbazoles were progressively accumulated after 3 and 4 days, respectively. **1**–**3** = carbalexins A-C, **4** = 2-hydroxy-3-methylcarbazole, **5** = glycoborinine, R = ritigalin, DA = dehydrothalebanin A, DB = dehydrothalebanin B. Mobile phase was MeOH (gradient 60–100%) in aqueous buffer (see Experimental).

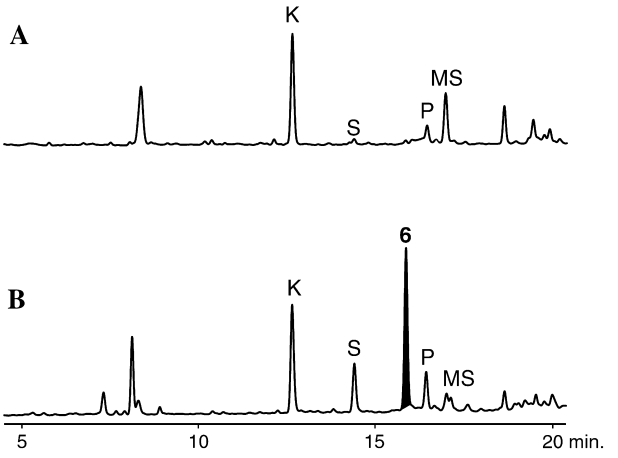

Fig. 2. HPLC comparison of lipophilic crude extracts of dried leaf parts from herbarium material of one individual of *G.* ex aff. *mauritiana* collected in Sri Lanka (WU, HG20-A). (A) Profile of an intact terminal leaf and (B) an infested basal leaf accumulating the carbazole glycozolidol (**6**). K = kokusaginine, S = sinharine, MS = methylsinharine, P = phenaglydon. Mobile phase was acetonitrile (gradient 20–60%) in aqueous buffer (see Experimental).

(Mester et al., 1980). A similar multi component response was also detected in *G. pentaphylla* (Retz.) DC. collected in Sri Lanka. In this case, however, only small quantities of carbazoles were formed. In light of these results the previously published carbazole glycozolidol (**6**) from the leaves of *G.* ex aff. *mauritiana* (Lam.) Tanaka (erroneously reported as *G. cyanocarpa* (Bl.) Spreng.) (Greger et al., 1992) is now also suggested to be formed after induction. In fact, a reinvestigation of small samples of corresponding herbarium material has shown that glycozolidol was only accumulated in infested older leaves, whereas younger intact leaves of the same individual did not contain any carbazole (Fig. 2). However, it should be pointed out that in this case only dried material was used and no induction experiments could be carried out with fresh leaves.

Although some 300 structures of phytoalexins were already isolated after experiments with approximately 900 species belonging to 40 plant families (Harborne, 1999), no carbazoles were described so far as phytoalexins. Moreover, only few reports on phytoalexins in the family Rutaceae were known, focussing only on the root bark of *Citrus limon* where the coumarins scoparone (Afek and Sztejnberg, 1988), xanthyletin (Khan et al., 1985), and seselin (Vernenghi et al., 1987) as well as the acetophenone xanthoxylin (Hartmann and Nienhaus, 1974) were isolated. The present paper reports on different induction experiments on different provenances of *G. parviflora* and one from *G. pentaphylla*. We also describe herein antifungal activity of the isolated carbazoles against the test fungus *C. herbarum* by bioautographic tests on TLC plates as well as structure elucidation of the new phytoalexins by spectroscopic methods.

2. Results and discussion

HPLC profiles of lipophilic crude extracts of freshly harvested leaves of *G. parviflora* and *G. pentaphylla* showed clear chemical differences after wounding, UV-irradiation and especially after inoculation of the leaves with aqueous spore suspensions of *Botrytis cinerea*. Besides the constitutive metabolites, consisting of the previously published amides ritigalin (Hofer et al., 1995) and dehydrothalebanins A and B (Greger et al., 1996) in *G. parviflora* (Fig. 1) and the well-known alkaloids arborine, skimmianine, and arborinine (Mester, 1983; Greger et al., 1993) in *G. pentaphylla*, both species additionally produced a series of carbazoles. Fungal infection mostly resulted in higher levels of accumulation than mere wounding or UV-irradiation. However, in wounded leaves, later infection can never be completely excluded during storing in a humid chamber. Comparisons of three provenances of *G. parviflora* originating from south China (Kwangchou), Indonesia

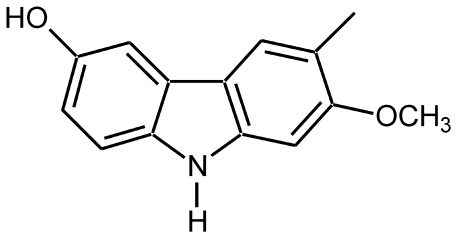
5 glycoborinine



6 glycozolidol

(Java), and USA (California) as well as between different individuals from the same provenance showed chemical variation in accumulating different carbazoles. However, carbalexin A (**1**) was the most common and dominating derivative. In general, the individuals from south China (RUT-69) showed the highest degree of carbazole accumulation, whereas those from USA (RUT-402) and Indonesia (RUT-331, RUT-333) deviated by a rather weak phytoalexin response mostly leading only to small amounts of carbalexin A (**1**). Compared with individuals from south China, these provenances could also be distinguished by greater amounts of the two amides dehydrothalebanin A and B.

To confirm the role of carbazoles as phytoalexins only a limited area of a leaflet (ca. 1 cm^2) of a pinnate leaf of *G. parviflora* was infected with *B. cinerea*. After 4 days of incubation the leaf was separated into different parts around the infection zone which were subsequently extracted for comparative HPLC analyses. Importantly, only the extract from the infected zone showed an accumulation of carbazoles **1**–**5** with a preponderance of **1**, whereas those from the surrounding areas exhibited profiles identical to untreated leaves.

Besides the formation of different carbazoles, some individuals of *G. parviflora* additionally accumulated quinoline alkaloids after elicitation. They were identified as flindersine and methylflindersine by co-chromatography with authentic samples. However, in contrast to the carbazoles they did not show any antifungal activity against *C. herbarum*. With regard to previous findings of that species it should be pointed out that the chemical profile reported for a Taiwanese collection, published as the synonym *G. citrifolia* (Wu et al., 1995), completely deviated from all our samples derived from different geographical provenances. With respect to the many acridones already reported for other Taiwanese collections of *G. citrifolia* (e.g. Furukawa et al., 1984), which could never be detected in our provenances, it was tempting to suggest that all these collections did not belong to *G. parviflora* but to *G. erythrocarpa* (Hay.) Hayata. The latter species is widely distributed and endemic in Taiwan (Stone, 1985). This taxonomic confusion was probably caused by the Flora of Taiwan (Anon, 1993), where the old synonym *G. citrifolia* is erroneously used instead of *G. erythrocarpa*.

In order to obtain sufficient amounts of the new carbazoles for isolation and structure elucidation as well as for subsequent bioassays, fresh leaves from different individuals of the Chinese provenance (RUT-69), cultivated in the Botanical Garden of the University of Vienna, were collected and combined. Subsequently they were cut into small pieces and sprayed with an aqueous suspension of conidiospores of *B. cinerea*. After 4 days in a moist chamber the infected leaves were extracted with MeOH and analyzed by preparative MPLC linked with UV detection. Based on spectral characteristics and on comparison with already published data, compounds **4** and **5** were readily identified as the known carbazoles 2-hydroxy-3-methylcarbazole (**4**) (Mester et al., 1979; Bhattacharyya et al., 1986) and glycoborinine (**5**) (Chakravarty et al., 1999). However, compounds **1**–**3** proved to be new natural products.

They could already be distinguished by characteristic UV spectra showing three distinct maxima at 330, 293, and 239 nm (MeOH) for carbalexin A (**1**) and only two at 310 and 231 nm for carbalexin C (**3**). Carbalexin B (**2**), by contrast, was characterized by an intermediate spectrum with only a weak maximum at 330 nm but two strong ones at 299 and 235 nm. The IR spectra of all three compounds showed typical signals at 3598–3616 cm^{-1} ($CHCl_3$) for phenolic hydroxy groups and at 3468–3474 cm^{-1} for >N–H stretching. In addition, a prominent signal in the range of 1046–1108 cm^{-1} was also characteristic for this type of carbazole. From the ^1H NMR spectra of compounds **1**–**3** it followed immediately that they are, like the already known derivatives **4** and **5**, 2-hydroxy-3-methylcarbazoles. This was indicated by the methyl singlet at δ ca. 2.40 ppm and the two characteristic aromatic singlets at δ ca. 6.85 (H-1) and ca. 7.7–8.0 ppm (H-4). While in compound **4**, the previously reported 2-hydroxy-3-methylcarbazole (Bhattacharyya et al., 1986), one aromatic ring was not further substituted, the ^1H NMR spectra of compounds **1**–**3** were characterized by an additional methoxy group at that ring. The EIMS spectra were very similar and showed molecular ions of $m/z = 227$ (100%), which suggested also a series of three isomeric methoxy-hydroxy-methylcarbazoles. The coupling patterns of the three remaining A ring protons in combination with NOE measurements allowed the determination of the structures of the compounds and the assignments of all proton resonances. Carbalexins A (**1**) and B (**2**), were characterized by three neighbouring protons (*d*, *dd*, and *d*, with *ortho* couplings of 8.0 Hz and *meta* couplings <1 Hz), which left only positions 5 and 8 for the methoxy group. Irradiation at the methoxy resonance of **1** resulted in strong effects at the characteristic low-field singlet at $\delta = 8.02$ ppm (H-4) and the dublet at $\delta = 6.65$ ppm (consequently H-6), proving position 5 for the methoxy group. In the case of compound **2** only the dublet at $\delta = 6.83$ ppm (H-7) showed a strong effect which is only compatible with the 8-methoxy derivative. Irradiation of the methoxy group in carbalexin C (**3**) gave strong NOEs for the characteristic low-field signal at $\delta = 7.44$ ppm (H-5, *d* with a *meta* coupling of 2.5 Hz) and the *dd* at $\delta = 6.96$ ppm (consequently H-7, $J = 8.6$ and 2.5 Hz), which proved position 6 for the methoxy substituent.

Because of the weak phytoalexin response in *G. pentaphylla* (RUT-202), the additionally accumulated carbazoles could not be isolated and were only identified by HPLC comparison with authentic samples. In addition to the constitutive metabolites, consisting of the quinazoline arborine, the furoquinoline skimmianine, and the acridone arborinine, mainly carbalexin C (**3**) and glycoborinine (**5**) were additionally formed in different individuals, sometimes accompanied by traces of carbalexin A (**1**). However, in contrast to *G. parviflora* carbalexin C (**3**) was dominating in most individuals.

To determine the antifungal activity of carbazoles **1**–**5**, bioassays were carried out on TLC plates sprayed with a conidiospore suspension of *C. herbarum*. Definite amounts from 50 to 3 μg showed nearly the same activity for all the new carbalexins A–C (**1**–**3**) as well as for compound **4**. All four compounds exhibited clear inhibition zones even at the lowest concentration. In contrast, glycoborinine (**5**) showed very weak activity only at the higher doses (Fig. 3). In addition to antifungal properties, the most prominent phytoalexin carbalexin A (**1**) was also tested against the bacterium *Staphylococcus aureus* on TLC plates as well as screened for cytotoxicity against brine shrimp nauplii (*Artemia salina*) in a micro-dilution assay. In this case compound **1** also showed a strong antibacterial activity with inhibition zones even at the lowest concentration at 3 μg, but only a weak cytotoxic effect with LC_{50} at 36 and LC_{90} at 108 ppm. The antibacterial activity of hydroxycarbazoles was already observed in the case of glycozolidol (**6**), which was especially effective against Gram-positive bacteria (Battacharyya et al., 1985). In contrast to the carbazoles, the induced pyranoquinolones did not exhibit any antifungal activity and hence could not be interpreted as phytoalexins.

The present data again showed that the type of phytoalexin produced in plants is often related to existing preinfectional agents present in a given relationship (Harborne, 1999). Carbazoles represent a class of secondary metabolites typical for *Glycosmis* and closely related genera grouped together in the tribe Clauseneae of the Rutaceae subfamily Aurantioideae (Kong et al., 1986; Samuel et al., 2001). However, extensive studies within the genus *Glycosmis* showed that they are mainly accumulated in the stem and root bark (Chowdhury et al., 1987; Vajrodaya, 1998; Lukaseder, 2000). Their presence in the leaves (Kamaruzzman et al., 1989; Greger et al., 1992) might have been caused by extracting larger quantities of plant material containing leaves infested with different organisms. This hypothesis could now be supported by a reinvestigation of *G.* ex aff. *mauritiana* where the previously reported glycozolidol (**6**) (Greger et al., 1992) was only found in infested older leaves (Fig. 2). Preliminary inoculation studies with fresh leaves of many *Glycosmis* species showed however, that the formation of carbazole phytoalexins is probably restricted to only a few species. Chromosome counts have shown that all provenances of *G. parviflora* and *G. pentaphylla* from Sri Lanka deviate from the other species by higher numbers, being hexaploid ($2n = 54$) in the former and pentaploid ($2n = 45$) in the latter species (Lambrou, unpubl.). Hence, it is tempting to speculate about a link between the additional formation of carbazoles and polyploidy.

Regarding the bioactivity of hydroxy-3-methylcarbazoles, one would suggest that their antifungal and antibacterial properties were due to the free phenolic hydroxy group at C-2. However, the very weak activity

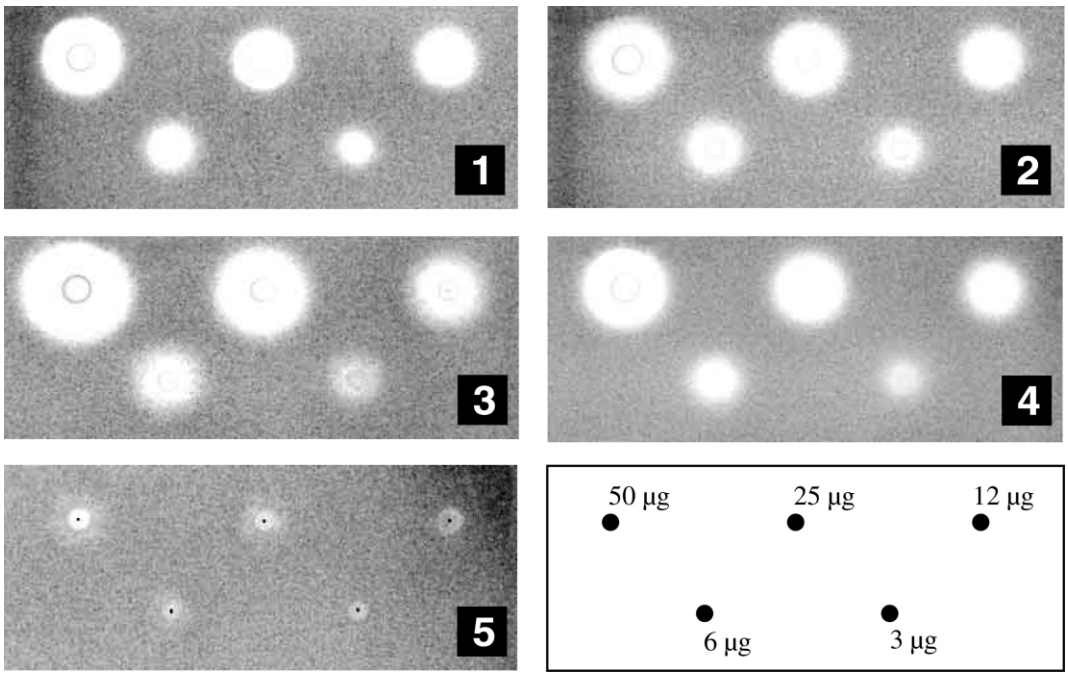


Fig. 3. Bioautographic comparison of different antifungal activities of five carbazole phytoalexins by direct spraying of TLC plates with a conidial suspension of the test fungus *Cladosporium herbarum*. (**1**) Carbalexin A, (**2**) carbalexin B, (**3**) carbalexin C, (**4**) 2-hydroxy- 3-methylcarbazole, (**5**) glycoborinine. The quantities used for each plate for serial dilution are indicated in the box.

of glycoborinine (**5**) (Fig. 3), containing such a hydroxy group but an additionally condensed pyran ring in aromatic ring A, clearly demonstrated that other substitutions in the molecule also play an important role in bioactivity. With regard to the still unknown biosynthesis of carbazoles, their co-occurrence with pyranoquinolones in infected leaves of *G. parviflora* deserves special attention and supports the hypothesis of a common biosynthetic origin. In this context it should also be pointed out, that the very rare phenanthridine alkaloid phenaglydon (Wurz et al., 1993) was also detected in the leaves of *G.* ex aff. *mauritiana* (Greger et al., 1992) (Fig. 2). This compound is also characterized by a methyl group in aromatic ring B, which suggests a similar ring closure with a prenyl group as in 3-methylcarbazoles. A possible close biogenetic relation of phenaglydon towards prenylated quinolones was already mentioned previously (Wurz et al., 1993).

3. Experimental

3.1. General

NMR: Bruker, DRX 250. MS: Finnigan MAT 900 S, IR: Perkin-Elmer 16PC FT-IR. UV: Hewlett-Packard, 8452A diode array spectrophotometer. HPLC: Hewlett-Packard 1090 II, UV diode array detection at 230 nm, column 250 × 4 mm, Hypersil BDS C-18, 5 µm, mobile phase MeOH (gradient 60–100%) or acetonitrile (gradient 20–60%) in aqueous buffer (0.015 M *o*-phosphoric acid, 0.0015 M tetrabutylammonium hydroxide, pH 3), flow rate 1 ml/min.

3.2. Plant material

Fresh leaves of *G. parviflora* and *G. pentaphylla* were collected from plants grown from seeds and cultivated in the Botanical Garden of the University of Vienna (HBV). Seeds from *G. parviflora* were obtained from (i) Botanical Garden Kwangchou, south China (RUT-69), (ii) Citrus Research Institute Riverside, California, USA (RUT-402), (iii) Botanical Garden Bogor, Java, Indonesia (RUT-331, RUT-333). Seeds from *G. pentaphylla* were collected by the late Professor S. Balasubramaniam in the campus of the University of Peradeniya, Sri Lanka (RUT-202). Plants were kept in the greenhouse during winter. Voucher specimens are deposited at the Herbarium of the Institute of Botany, University of Vienna (WU).

3.3. Induction of carbazoles

3.3.1. Fungal infection

Freshly harvested leaves were cut into small strips of 1–2 mm and divided into three portions from which one, serving as control, was immediately homogenized and extracted with MeOH. The second portion was placed on moistened blotters in the bottom of a plastic chamber and sprayed with a spore suspension of *Botrytis cinerea*. After incubation for 4 days at room temperature the leaf strips were homogenized and extracted

as above. The third portion was treated in the same manner but without fungal infection.

3.3.2. UV-irradiation

Freshly harvested intact leaves were irradiated with UV light (254 nm) at each surface for 1/2 h and transferred into a moist chamber. For control, intact leaves were directly placed in a humid chamber without UV light. After 4 days both samples were homogenized and extracted as mentioned above.

3.4. Extraction and isolation

Infected leaves from different provenances and individuals of *G. parviflora* and *G. pentaphylla* were ground and extracted separately with MeOH at room temp. for 3 days, filtered and conc. The aqueous residues were extracted with $CHCl_3$ and the conc. $CHCl_3$ fractions were used for comparative HPLC and preliminary bioassays. For preparative isolation infected leaves of different individuals of the Chinese *G. parviflora* (RUT-69) were combined (92 g) and treated in the same way. The lipophilic crude extract was evapd to dryness under reduced pressure (980 mg), and roughly separated by column chromatography (Merck silica gel 60, 35–70 mesh) with hexane, Et_2O and MeOH. The combined fractions eluted with 50% Et_2O in hexane, 100% Et_2O, and 5% MeOH in Et_2O (210 mg) were further separated by MPLC (400 × 40 mm column, Merck LiChroprep Si 60, 25–40 μm, UV-detection, 254 nm) to yield 14 mg impure carbalexin A (**1**), 2 mg carbalexin B (**2**), 2 mg carbalexin C (**3**), 2.5 mg 2-hydroxy-3-methlycarbazole (**4**), and 4 mg glycoborinine (**5**). Final purification of carbalexin A (**1**) was achieved by prep TLC (Merck, Si gel 60, 0.5 mm; CH_2Cl_2 : Et_2O = 85 : 15) to give 10 mg pure compound. In addition, 60 mg nearly pure ritigalin was isolated from the unpolar CC fractions eluted with 25% Et_2O in hexane. Small amounts of dehydrothalebanin A and B, and flindersine together with methylflindersine were isolated with 50% Et_2O in hexane and 10% MeOH in Et_2O, respectively, and were identified by HPLC comparison with authentic samples.

3.5. Fungal and bacterial bioassays

Definite amounts of pure compounds were applied on TLC plates (Merck, Si gel 60, 2.5 mm) in a twofold dilution series from 50 to 3 μg and sprayed either with an aqueous spore suspension of *C. herbarum* containing malt bouillon (Merck) as nutrient or with a freshly prepared bacterial suspension of *S. aureus* in nutrient broth (Merck). Plates for antifungal bioassays were incubated in moist chambers for 3 days in the dark at room temp. For antibacterial tests the plates were incubated for 18 h at 37°C, sprayed with 3-(4-iodophenyl)-2-(4-nitro-phenyl)-5-phenyl-2H-tetrazoliumchloride (3 mg/ml H_2O), stored for another 3 h and sprayed with 70% EtOH to stop bacterial growth. White inhibition zones of different size indicated the degree of antifungal activity on the dark mycelial layer, and white zones on a pinkish background were indicative for antibacterial activity.

3.6. Brine shrimp toxicity assay

Tests were performed in triplicate in 96-well microplates as described by Solis et al. (1993). Brine shrimp (*Artemia salina*) eggs were purchased and kept in artificial, aerated seawater at room temp. After 48 h, 10–15 freshly hatched nauplii were added to each well containing different concentrations (100–3.12 ppm) of carbalexin A (**1**). 1% DMSO was added to improve solubility. After 24 h the number of killed nauplii in each well was counted and compared to controls. LC_{50} and LC_{90} values were calculated by probit analysis with 95% confidence intervals.

3.7. Carbalexin A, 2-hydroxy-5-methoxy-3-methylcarbazole (*1*)

Colourless crystals from $CHCl_3$, mp 178–180°C. UV λ^{MeOH} nm 330, 317, 293, 239. Received 12 October 2000; received in revised form 26 January 2001

Abstract

The crown gall opines heliopine from tumors induced by octopine type *Agrobacterium tumefaciens* strains A6, A136(pTiB6-806), E9, A652 and 1590-1 and vitopine from tumor induced by grapevine strains S4 and T2 are identical to synthetic N^2-(1′*R*-carboxyethyl)-L-glutamine. Tumors produced by strains S4 and T2 do not contain octopine or lysopine, but they do contain heliopine and the new opine ridéopine identified as *N*-(4′-aminobutyl)-D-glutamic acid. Grapevine strains S4 and T2 grow normally on tumor heliopine or synthetic heliopine and on tumor and synthetic ridéopine as well as on ridéopine lactam as sole carbon source. While octopine strains A6 and A136(pTiB6-806) do not grow on heliopine, mutant colonies do appear after a few weeks. Heliopine catabolism by octopine strains is not induced by octopine. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Crown gall; *Agrobacterium tumefaciens*; Grapevine strains; Opines; Ridéopine; *N*-(4′-Aminobutyl)-D-glutamic acid; Heliopine; Vitopine; N^2-(1′*R*-Carboxyethyl)-L-glutamine

1. Introduction

Crown gall disease is induced at plant wound sites by the soil bacterium *Agrobacterium tumefaciens* possessing a tumor-inducing Ti-plasmid. A portion of the Ti-plasmid DNA (T-DNA) is transferred from the bacterial plasmid into the host plant cell where the T-DNA is integrated into host plant chromosomal DNA by an illegitimate recombination process. Some of the transferred genes encode enzymes responsible for the synthesis of plant hormones out of control of normal regulation by the plant, causing abnormal cell divisions that produce a plant gall. Other transferred genes encode biosynthetic enzymes capable of tying up plant metabolites into a class of compounds called opines that are not catabolizable by the host plant, but are catabolizable by the tumor-inducing bacterial strain. More than two dozen crown gall opines have been structurally characterized (Dessaux et al., 1992). They are typically reductive conjugates of L-amino acids and common carbonyl compounds of primary metabolism (e.g. pyruvate, α-ketoglutarate or glucose). There are also several structurally uncharacterized opines or incompletely characterized opines (Chang and Chen, 1983; Chilton et al., 1984b, 1995). These include heliopine from tumors incited by octopine strains A6NC and B6 (Chang et al., 1989) and vitopine from tumors induced by some grapevine strains (Szegedi et al., 1988).

Heliopine is present in some octopine type tumors in which octopine synthase (lysopine dehydrogenase), a T-DNA encoded enzyme, reductively conjugates pyruvate with four basic L-amino acids. In addition to the better-known octopine, an arginine reductive conjugate, and lysopine, a lysine conjugate, these tumors also contain small amounts of the ornithine and histidine conjugates octopinic acid and histopine, all products of the enzyme octopine synthase. A few octopine strains also have been shown to reductively conjugate pyruvate and methionine to produce methiopine (Otten and Szegedi, 1985). In all of these opines the newly generated alanyl asymmetric center has R-chirality (D-alanyl). Tumors induced on sunflower (*Helianthus annuus* L.) by *A. tumefaciens* A6NC, B6, 15955, W1 and 27 also contain acidic iminodiacids derived from neutral and acidic amino acids (Chang et al., 1989). The major new opine

PII: S0031-9422(01)00166-2

in the acidic iminodiacid fraction of A6NC-induced tumor was identified as N^2-(1-carboxyethyl)-glutamine (heliopine) by oxidative cleavage to alanine and glutamine. Chang et al. (1989) reported that tumors induced by an octopine synthase deletion mutant of A6NC were devoid of heliopine. Octopine synthase purifed from B6 sunflower tumor has substate specificity for L-arginine, L-ornithine, L-lysine, L-histidine, L-methionine and L-glutamine (Kemp, 1982). Different octopine strains induce tumors containing opines derived from various combination of these six L-amino acids, presumably reflecting availability of the precursors in the gall cells. The stereochemistry of heliopine has not been investigated, although evidence that it is synthesized by octopine synthase strongly suggests that heliopine is the D-alanyl reductive conjugate of pyruvate and L-glutamine.

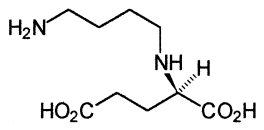
The new opine, vitopine, was first reported to be present in tumors induced on *Kalanchoe daigremontiana* by three biotype 3 grapevine (*Vitis vinifera*, Vitaceae) isolates of *A. tumefaciens* (Szegedi et al., 1988). Like other iminodiacids, vitopine chelates silver ion and has anionic electrophoretic mobility at pH 2.8. However vitopine is resolvable from other opines of this class (*S*,*S*-leucinopine, *S*,*S*-succinamopine and R^{asn}, S^{gln}-succinamopines). Vitopine has not been structurally characterized. We report here the full stereochemistry of heliopine, the identity of heliopine and vitopine, and the structure and stereochemistry of a further new opine, ridéopine, discovered in the course of the present work on vitopine-type tumors.

2. Results

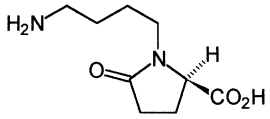
2.1. Structure and synthesis of ridéopine

Ridéopine (**1**) is readily detectable with the ninhydrin reagent without heating, indicating the presence of a primary amine. The NMR of ridéopine in D_2O (pH 1) indicated a glutamic acid substituted with an aminobutyl group on the amine: 4-aminobutyl moiety: α′-CH_2, 3.15, *t*; β′,γ′-CH_2CH_2,1.78, *br*; δ′-CH_2, 3.03, *t*; glutamic acid moiety: α-CH, 3.96; *t*; β-CH_2, 2.1-3.4, *m*; γ-CH_2, 2.61, t. Racemic ridéopine was synthesized by reductive amination of putrescine with α-ketoglutaric acid. Synthetic *N*-(4′-aminobutyl)-D,L-glutamic acid had the same NMR spectrum and electrophoretic mobility between pH 1.8 and 10.8 as tumor ridéopine

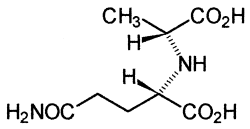
Ridéopine, like other glutamyl and glutaminyl opines, is readily converted to a lactam. Lactamization creates an amide chromophore whose n–π^* circular dichroism has been correlated with chirality at the α-carbon of the glutamyl moiety (Goodman et al., 1969). Previous work has shown that lactams with L-glutamyl chiral center have a positive CD extremum near 215 nm (L-glutamic acid lactam, *S*,*S*-succinopine lactam, agropinic acid), while those with D-glutamyl configuration have a negative CD extremum ca. 215 nm ($S^{asp}R^{glu}$-succinopine lactam, nopaline lactam; Chilton et al., 1984b, 1985b). Ridéopine lactam (**2**) from S4 *Datura* tumor has a negative CD at 215 nm. Therefore, the natural opine induced by *A. tumefaciens* strains S4 and T2 is R-ridéopine (**1**).



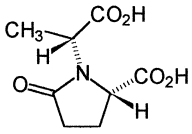
1: Rideopine



2: Rideopine lactam



3: Heliopine



4: Heliopine lactam

2.2. Catabolism of ridéopine

Catabolism of S4-induced, tumor-extracted ridéopine in liquid medium was monitored by high voltage paper electrophoresis (HVPE). Grapevine strains S4 and T2 catabolized all of the opine within 72 h. None of the other assayed strains degraded this compound within 7 days whether they were nonpathogenic (C58C1) or pathogenic *A. tumefaciens* (C58, B6s3, ACH5, R10, Bo542, ANT4) or *A. rhizogenes* (15834, 2659, 8196, 1724) isolates.

A similar result was observed when tumor-extracted ridéopine was substituted with racemic ridéopine which was not degraded by any of the assayed strains (C58C1, C58, ACH5, ANT4) except S4 and T2. Surprisingly, in liquid culture the ridéopine strains S4 and T2 completely consumed both enantiomers of this opine. In addition, strains S4 and T2 were able to grow on agar plates containing racemic ridéopine as the sole carbon source. Strains S4 and T2 can also grow on racemic ridéopine lactam as the sole carbon source in liquid culture, but they utilize only one enantiomer. The residual enantiomer of ridéopine lactam not catabolized by strain S4 and T2 has positive CD extremum at 215 nm, indicating that these strains catabolize only R-ridéopine lactam (**2**), the lactam of R-ridéopine produced in the S4 and T2 tumors.

2.3. Identity and stereochemistry of heliopine and vitopine

The proton NMR spectra of heliopine isolated from tobacco tumors incited by *A. tumefaciens* A6 and A136 (pTi B6-806) and from sunflower tumors incited by *A. tumefaciens* A6 are identical to those of vitopine isolated from *Datura stramonium* tumors incited by grapevine strains S4 and T2. The spectra in D_2O at pH 2 are

consistent with structure **3**, N^2-(1′-carboxyethyl)-glutamine: carboxyethyl moiety: α′ 3.91 ppm, *q*; β′ 1.53, *d*; glutamine moiety: α CH, 3.82 ppm, *t*; β CH_2, 2.20, *m*; γ CH_2, 2.52, *t*. Heliopine isolated from A6 and A136 (pTiB6-806) tobacco tumors and from A6 sunflower tumors was indistinguishable electrophoretically at pH 2.8 from vitopine purified from *Datura stramonium* tumors incited by *A. tumefaciens* S4. Heliopine lactam (**4**) and vitopine lactam, prepared by heating in aqueous acid, also comigrated at pH 2.8, 4.0 and 10.8. Thus, heliopine and vitopine are identical. Since the structure (without stereochemistry) of heliopine has been published (Chang et al., 1989), we use the name heliopine in preference to vitopine (Szegedi et al., 1988).

All four diastereomers of heliopine were prepared pairwise by reductive alkylation of pyruvic acid and L-glutamine or D-glutamine. In addition single-isomer N^2-(1′*R*-carboxyethyl)-L-glutamine was prepared by alkylation of L-glutamine with 2*S*-bromopropionic acid. This single-isomer heliopine comigrated electrophoretically at pH 2.5 with S4, A6 and A277 tumor heliopine and with the slower, barely resolved isomer of the diastereomeric pair prepared by reductive alkylation. For better resolution of diastereomers by HVPE the heliopines were converted to the conformationally less flexible lactams which enhances the difference in pKa_2, providing better resolution of the more mobile erythro heliopine lactam, **4**, from the threo lactam (isoheliopine lactam). The circular dichroism spectrum of natural heliopine lactam from both S4 *Datura* and A6 tobacco tumors had the positive CD extremum at 215 nm expected for L-glutamyl lactams (Goodman, 1969; Chilton et al., 1984a, 1985b). Thus, the tumor heliopine from both octopine type tumors and from heliopine type tumors is the erythro isomer N^2-(1′*R*-carboxyethyl)-L-glutamine, **3**.

2.4. Catabolism of opines by heliopine type strains S4 and T2

Catabolism of synthetic, single isomer heliopine (*N*-[1′*R*-carboxyethyl]-L-glutamine) in liquid medium was monitored by HVPE. Grapevine heliopine strains S4 and T2 catabolized all of the heliopine within 72 h. The same strains grown on a 1:1 mixture of heliopine and isoheliopine [N^2-(1′*S*-carboxyethyl)-L-glutamine] selectively catabolized heliopine within 72 h but did not reduce the concentration of isoheliopine within 1 week. Neither strain was able to catabolize either of the isomeric N^2-(1′-carboxyethyl)-D-glutamines. Strains S4 and T2 also catabolized heliopine lactam [*N*-(1′*R*-carboxyethyl)-L-pyroglutamic acid], within 72 h in liquid culture, but not the 1′*S*-isomer. Growth of heliopine type strains S4 and T2 was tested on agar plates containing other opines as sole carbon source. Neither of these strains grew on plates containing octopine, nopaline, agropine, agropinic acid or mannopine as sole carbon source. They were not tested for ability to grow on cucumopine, mikimopine, R^{asn},S^{gln}-succinamopine or *S*,*S*-leucinopine.

2.5. Catabolism of heliopine by diverse opine type strains of A. tumefaciens

None of the nopaline [A136 (pTi K27), A136 (pTi 223), A136 (pTi T37, T37Braun, C58, IIBV7], mannopine [C58C1 (pRi 8196)], chrysopine (ANT4), or leucinopine [A136(pTi Bo542)] type strains grew on heliopine as sole carbon source. Typical octopine strains did not grow at all within 1 week in liquid culture containing as sole carbon source the heliopine isomeric pair prepared from L-glutamine. These strains were tested for growth on solid medium containing the same isomers. There was no detectable confluent growth after one week, but isolated mutant colonies were detected after several weeks. Several mutant colonies of B6 and R10 were picked, purified and found able to grow rapidly on heliopine in liquid medium as well as on agar. Each of the eight mutants picked utilized the natural heliopine, *N*-(1′*R*-carboxyethyl)-L-glutamine, and not the 1′S-isomer. To test whether heliopine is a non-inducing substrate for uptake and catabolism by the octopine pathway, the original wild type octopine strains were inoculated into liquid medium containing heliopine and isoheliopine plus octopine to induce the octopine-utilization pathway. None of the octopine strains tested was able to utilize heliopine (or isoheliopine) after consuming octopine (Table 1).

3. Discussion

Glutamine derivatives are known to undergo slow lactamization. Thus aging solutions of glutamine-derived opines contain some opine lactam. Nonenzymatic lactamization occurs in the tumor as well. Therefore, it is not surprising that mannopine, nopaline, succinamopine, leucinopine and heliopine strains causing synthesis of glutamine-type opines in tumors can also catabolize the corresponding glutamyl opine lactam. (Chilton et al., 1984a, 1985b, 1995). Strains S4 and T2 that catabolize heliopine [N^2-(1′*R*-carboxyethyl)-L-glutamine] conform to this pattern and catabolize heliopine lactam [N^2-(1′*R*-carboxyethyl)-L-glutamic lactam but none of the other three lactam diastereomers. *A. tumefaciens* S4 and T2 also catabolize R-ridéopine and *R*-ridéopine lactam, but not *S*-rideopine lactam. This makes evolutionary sense because the tumors they incite contain *R*-rideopine and not *S*-ridéopine, consequently no *S*-ridéopine lactam. However these strains catabolize *both* enantiomers of unlactamized ridéopine, even though they induce tumors containing only *R*-ridéopine. Catabolism of the S-enantiomer may be accomplished by the transport

Table 1
Growth of *Agrobacterium tumefaciens* strains on octopine and heliopine

		Utilization in liquid culture				Growth on agar plates

and catabolic machinery responsible for the uptake and degradation of the *R*-enantiomer. Alternatively, degradation of the *S*-enantiomer could occur via some L-amino acid catabolic enzyme of primary metabolism.

The high frequency with which heliopine-utilizing mutants of octopine strains B6 and R10 appeared was reminiscent of the mannityl opine constitutive mutants that appeared when mannopine strains were grown on mannopine analogs which turned out in most cases to be non-inducing substrates for the catabolic pathway involved (Chilton and Chilton, 1984). We reasoned that uptake and catabolism of heliopine, a structural analog of octopine, might be facilitated by induction of the octopine uptake and catabolism pathway. According to this hypothesis, the heliopine catabolizing mutants might be constitutive for octopine utilization. However, because of the failure of strains A6, B6 and 15955 to consume heliopine after induction with octopine, we cannot declare these strains (which produce heliopine along with octopine and lysopine in the tumors they induce) to be heliopine strains in the classical sense that S4 and T2 may be called heliopine strains. Octopine strains A6, B6 and 15955 do produce mutants that consume heliopine. The failure of unmutated strains A6, B6 and 15955 to catabolize heliopine after completing catabolism of octopine indicates that induction of the octopine uptake and catabolism pathway is not sufficient to permit catabolism of heliopine by these octopine strains. If induction is required for catabolism of heliopine by these mutants, heliopine, but not octopine must presumbably act as the inducer. It is unclear what aspect of the utilization process is acquired in our mutant octopine strains that consume heliopine, but we have seen that mutation has left octopine catabolism unimpared.

Methiopine is another example of a non-catabolized octopine analog produced by octopine-lysopine dehydrogenase in some octopine strains. Enzyme kinetic studies showed that partially purified lysopine dehydrogenase isolated from B6S3 tobacco tumor accepts glutamine and methionine in addition to the four basic amino acids and reductively conjugates them with pyruvate to make heliopine and methiopine (Otten et al., 1977). Methiopine was later shown to be present in octopine tumors induced by octopine strains A6 and B6 (Otten and Szegedi, 1985). Similar to our finding with heliopine, methiopine was not catabolized by the tumor inducing strains even after induction with octopine. However cell lysates of octopine-induced strains were able to catabolize [^{35}S]methiopine, leading later authors to refer to methiopine as a "pseudo-opine" (Firmin et al., 1985).

We have now identified the glutamine conjugate of pyruvic acid (heliopine) as a true opine, not of octopine strains but of the grapevine strains S4 and T2. It appears to us that production of the gratuitous opine analogs heliopine and methiopine in tumors induced by various octopine strains is a result of unselected "substrate promiscuity" of octopine-lysopine dehydrogenase. We speculate that such gratuitous analogs may be an intermediate step toward evolution of new opine type *Agrobacterium* strains.

4. Experimental

4.1. Opine catabolism and analysis

Opine catabolism experiments were carried out on agar plates containing AT medium (Guyon et al., 1980)

and 1 mg/ml of each opine diastereomer as sole carbon source, or in some cases with the addition of 0.05 mg/ml octopine as inducer. No growth was detected on control plates containing 0.05 mg/ml octopine as sole carbon source. Plates were observed for growth in the confluent area at 24 and 48 h and for isolated mutant colonies in diluted streaks after one or more weeks. Catabolism in liquid culture was conducted in AT medium containing 1 mg/ml of each opine diastereomer as described in previous work (Chilton and Chilton, 1984, Chilton et al., 1984a). *A. tumefaciens* strains S4 and T2 required the addition of 0.1 mg/ml yeast extract (Difco) for growth on AT medium. Tubes containing 3 ml of medium were inoculated with 100 ul of the appropriate *Agrobacterium* strain grown overnight at 28°C on a rotary drum. Aliquots (0.1 ml) were collected at intervals up to 168 h, centrifuged and analyzed by HVPE.

High voltage electrophoreses were performed on Whatman 3MM paper at 50 V/cm under Stoddard standard solvent or Isopar H (Exxon) as heat transfer liquid for 30–40 min. The pH 1.9 HVPE buffer was prepared by adding HCO_2H to 2 M HOAc. The pH 2.8 and 4.0 buffers were prepared by titration of 0.1 M HCO_2H or 0.1 M HOAc with NaOH, and the pH 10.8 buffer was prepared by titrating 0.1 M NH_4OH with HOAc. Heliopine was detected using Ag chelation with $AgNO_3$-mannitol reagent (Chilton et al., 1984b), and heliopine lactam was visualized using aniline-xylose reagent for acidity (Zweig and Sherma, 1972). Heliopine was generally lactamized before analysis to achieve better resolution of isomers. For this purpose 0.05 ml aliquots from catabolism experiments were added to 0.1 ml 6 M HCl in a microcentrifuge tube and heated at 100°C for 1 h. Aqueous HCl was evaporated, and the microcentrifuge tube was then placed in a vacuum dessicator over NaOH to remove HCl which interferes in the electrophoretic analysis. Ridéopine was detected with ninhydrin.

4.2. Purification of vitopine (heliopine) and ridéopine from strain S4 tumors

Tumors initiated by strain S4 on *Datura stramonium* (15 g, f.w.) were minced and extracted with 300 ml water for 5 min at 100°C. The aqueous extract was filtered and sterilized at 105°C for 20 min. No loss of opines was detectable by electrophoresis at pH 1.9. The sterilized tumor extract was inoculated with strain C58.00, lacking both the tumor-inducing plasmid and the cryptic plasmid and incubated at 28°C for 68 h. after which time HVPE showed that all amino acids had been metabolized and that the concentrations of vitopine and ridéopine were undiminished. Bacteria were removed by centrifugation and the water was evaporated to give 380 mg of brown residue from 15 g tumor (f.w.). The brown residue (140 mg) was dissolved in water and passed through a 12 ml column of Dowex $50H^+$. The column was then washed with 4 bed volumes of distilled water to remove any neutral compounds, followed by 20 bed volumes of water to remove the iminodiacid fraction in which vitopine appeared. The column was then washed with 3% aqueous ammonia to remove ridéopine. HVPE analysis showed that the iminodiacid fraction contained vitopine (pH 2.8, Ag chelation) and the ammonia fraction contained ridéopine (pH 1.9, ninhydrin)

Pure vitopine (9 mg), containing no ninhydrin positive substances was obtained following preparative HVPE at pH 2.8. The ridéopine fraction contained a small amount of a ninhydrin positive substance which was removed by preparative HVPE (pH 1.9) to give 10 mg pure ridéopine. NMR spectroscopic characterization of these opines is reported in Section 2.

4.3. Purification of heliopine from tumors induced by octopine strains

The pKa_1 of α,α′-iminodiacids like heliopine is so low that the first carboxyl ionization is complete at pH 2, and the isoelectric point for iminodiacids lacking a second basic group is below 2. Consequently, opines such as succinamopine, leucinopine, and heliopine can be eluted from a cation exchange column with a large volume of distilled water in the acidic iminodiacid fraction free of amino acids (Chilton et al., 1984a, 1985a. 1985b). Opines with a second basic group such as octopine, lysopine and nopaline are not eluted by distilled water, but are eluted along with amino acids by dilute, aqueous ammonia. Heliopine was isolated from tobacco tumors incited by *A. tumefaciens* strains A652, A6, E9 and 1590-1 and from sunflower tumor incited by strain A6 by absorption onto cation exhange resin and elution in 20 bed volumes of distilled water as described for vitopine isolation (above). These preparations contained heliopine, pyroglutamic acid (derived from glutamic acid still held on the cation exchange resin) and another, unidentified iminodiacid of slightly lower HVPE mobility than heliopine at pH 2.8. Heliopine from tobacco tumors induced by strain A6 and pTiA136 were further purified by preparative HVPE at pH 2.8 to remove the unidentified iminodiacid and pyroglutamic acid. Oxidation of heliopine from A6 and pTiA136 tobacco tumors with potassium permanganate gave alanine and glutamine as described earlier (Chang, 1989).

4.4. Synthesis of racemic ridéopine

A semi-crystalline putrescine-putrescine carbonate mixture (1.47 g, ca. 12 mmole) and 2.62 g (18 mmole) α-ketoglutaric acid dissolved in 40 ml water was reduced by gradual addition of 0.75 g (12 mmole) sodium cyanoborohydride with periodic addition of HOAc as necessary to maintain pH 6.0–6.8. After several hours, the reaction solution was added to a 50-ml slurry of Dowex $50H^+$ to

destroy borohydride. After hydrogen evolution ceased, the resin was placed in a column and washed with water until the effluent was no longer acidic. Ridéopine eluted with 3% ammonia was electrophoretically pure and did not contain any of the putrescine dialkylation product.

4.5. Synthesis of heliopine diastereomer pairs

A mixture of N^2-(1′*R*-carboxyethyl)-L-glutamine (heliopine) and N^2-(1′*S*-carboxyethyl)-L-glutamine (isoheliopne) was prepared by reductive amination of L-glutamine with excess α-ketoglutaric acid as described for synthesis of ridéopine. A mixture of N^2-(1′*R*-carboxyethyl)-D-glutamine and N^2-(1′*S*-carboxyethyl)-D-glutamine was similarly prepared from D-glutamine.

4.6. Synthesis of N^2-(1′*R*-carboxyethyl)-L-glutamine (heliopine)

L-Glutamine (1.50 g, 10 mmole) was dissolved in 10 ml H_2O by addition of 5 ml 2.5 M NaOH. The solution was adjusted to pH 7. Optically active 2*S*-bromo-propionic acid (Aldrich Chemical Co., 2.595 g, 17 mmole) was added, followed by dropwise addition of 3.86 ml (22.5 mmole) NaOH (final pH 9). Subsequently NaOH was added over the next 2 days as necessary to maintain pH 9. A total of 39 mmole NaOH was consumed (theoretical 38 mmole). The reaction solution was acidified to pH 1 and passed through a Dowex $50H^+$ column. After washing the column with distilled water, the synthetic, single-isomer heliopine was eluted with 3% ammonia. HVPE (pH 2.8) showed only heliopine and no glutamine in the dried product, while pH 2.8 HVPE of its lactam, N^2-(1′*R*-carboxyethyl)-L-pyroglutamic acid, showed the presence of only the more mobile isomer of heliopine lactam comigrating with tumor heliopine lactam and tumor vitopine lactam. Synthetic, single-isomer heliopine (842 mg) crystallized from concentrated aqueous solution. A further 95 mg of heliopine was recovered on evaporation of the mother liquor.

Received 28 September 2000; received in revised form 11 March 2001

Abstract

In previous studies we have elucidated the presence of powerful, natural antioxidants (NAO) in water extracts of spinach leaves and demonstrated their biological activity in both in vitro and in vivo systems. In the present study, the chemical identity of several of these antioxidant components is presented. Spinach leaves were extracted with water and the 20,000 g supernatant which contained the antioxidant activity was extracted with a water:acetone (1:9) solution. The 20,000 g supernatant obtained was further purified on reverse phase HPLC using C-8 semi-preparative column. Elution with 0.1% TFA resulted in five hydrophilic peaks. Elution with acetonitrile in TFA resulted in seven additional hydrophobic peaks. All the peaks were detected at 250 nm. All the fractions obtained showed antioxidant activity when tested using three different assays. Based on ^{1}H and ^{13}C NMR spectroscopy four of the hydrophobic fractions were identified as glucuronic acid derivatives of flavonoids and three additional fractions as *trans* and *cis* isomers of *p*-coumaric acid and others as *meso*-tartarate derivatives of *p*-coumaric acid. The present study demonstrates for the first time the presence of both flavonoids and *p*-coumaric acid derivatives as antioxidant components of the aqueous extract of spinach leaves. © 2001 Published by Elsevier Science Ltd.

Keywords: Antioxidants; Flavonoids; Coumaric acid; Spinach

1. Introduction

Over the past several years, there has been an extraordinarily rapid growth in our knowledge of free radical chemistry and its possible involvement in both normal essential biology and age related disease and dysfunction. Oxidative stress, induced by oxygen radicals, is believed to be a primary factor in various degenerative diseases of the central nervous system, as well as in the normal process of aging (Ramarathnam et al., 1996). The reactive oxygen species formed during normal metabolic processes can easily initiate the peroxidation of membrane lipids, leading to the accumulation of lipid peroxides.

Antioxidants are compounds that inhibit or delay the oxidation of other molecules by inhibiting the initiation or propagation of oxidizing chain reactions. Natural antioxidants constitute a broad range of compounds including phenolic compounds, nitrogen compounds, and carotenoids (Velioglu et al., 1998). In addition, ascorbic acid has been shown to have antioxidant properties. The main role of antioxidants is to help the body protect itself against damage caused by reactive oxygen species and degenerative diseases (Shahidi, 1996).

Antioxidant activity is essential for life, to counteract the strongly oxidizing environment in which we live (Velioglu et al., 1998). Many biological functions, such as protection from mutagenesis, carcinogenesis and aging, among others, are due to antioxidative effects (Cook and Samman, 1996; Huang et al., 1992). The antioxidant activity of several plant materials has recently been described (Oomah and Mazza, 1994; Al-Saikhan et al., 1995; Yen and Duh, 1995; Amarowicz et al., 1996; Cao et al., 1996; Wang et al., 1996). Recently we have reported the presence of a series of powerful water soluble natural antioxidants in spinach leaves and

PII: S0031-9422(01)00137-6

described their potential biological activity (Grossman et al., 1994; Lomnitski et al., 2000a,b,c; Zurovsky et al., 1994, 1995; Zurovsky and Gispaan, 1995). In the present study we describe for the first time the isolation and chemical identification of several of these antioxidant components.

2. Results

2.1. Fractionation of spinach extracts, and antioxidant activity

Previous results from our lab showed that the water extract from spinach leaves, which exhibits antioxidant activity, contained two main fractions: a low molecular weight (under 1000 Da) fraction, which is water soluble, and another fraction which consists of components over 1000 M_W and is water insoluble. Moreover, the HPLC profile using a reverse phase C_{18} column indicated that a significant amount of the first fraction was not eluted from the column (Reznik, 1990). These findings indicate that the antioxidants from spinach contain both hydrophilic and hydrophobic constituents. Since the antioxidants we described appeared to comprise both hydrophobic and hydrophilic fractions, we first tested the solubility of the antioxidants present in the aqueous spinach extract in various solvents. A combination of 1:9 (water:acetone) was found to be optimal for extracting the activity (not shown).

To further fractionate the extract, the acetone was evaporated and the residue was applied onto an analytical reverse phase C_8 HPLC column. The profile obtained at the detection wavelength 250 nm showed a high resolution separation. Moreover, all the fractions isolated exhibited antioxidant activity. In order to enable the chemical structure analysis of these fractions, we decided to use a semi-preparative column. The absorption profile obtained at 250 nm is shown in Fig. 1. Elution with 0.1%TFA (solvent A) resulted in five main peaks. Elution with a gradient of acetonitrile resulted in many additional peaks. According to their chromatographic behavior we divided these peaks into 2 main groups: hydrophilic (for those eluted only with solvent A) and hydrophobic (for the remaining part of gradient).

These various eluted fractions were collected, and each whole fraction was assayed for antioxidant activity using three different assays (Fig. 2a, b and c). These results indicate that the hydrophobic elution contained at least 10 active fractions while the hydrophilic elution contained fewer. The different pattern of the active fractions obtained in the pollarographic assay (Fig. 3c) is probably due to the fact that this assay is more specific compared to the other two assays (TBA and FOX), since it is based on the inhibition of linoleic acid oxidation induced by the lipoxygenase enzyme.

Although, in general, the profile obtained from the semi-preparative column resembled that of the analytical separation, several additional active fractions were detected. The UV spectra of all detected peaks were determined and our results indicated that many of the hydrophobic peaks exhibit additional absorbance at 310 nm. Therefore, we used this wavelength for detection while collecting the hydrophobic peaks (Fig. 3).

Based on their spectra, we could divide the main hydrophobic peaks into two groups: group 1, with two

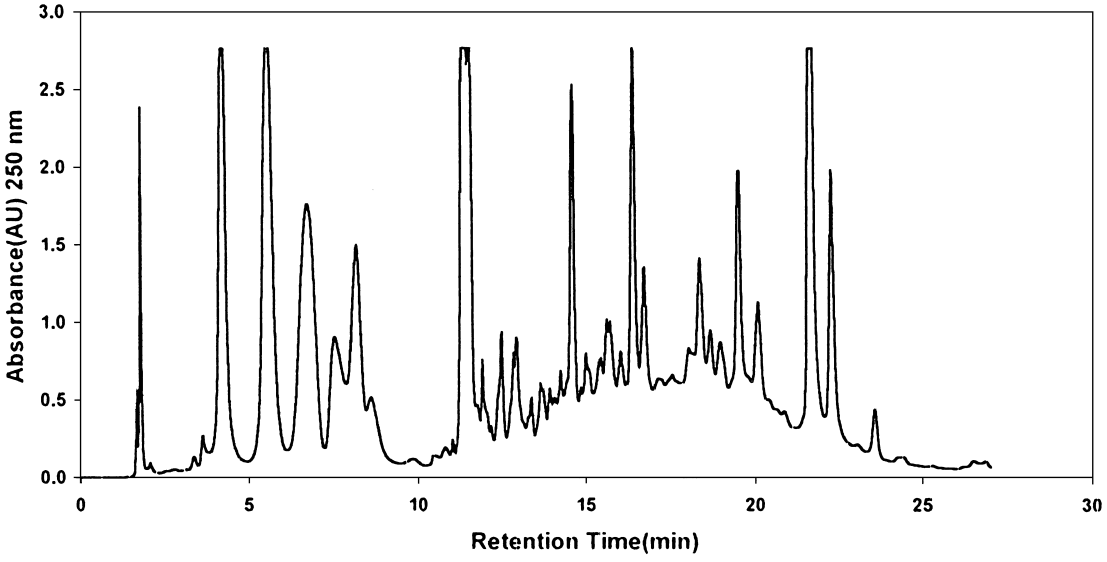

Fig. 1. Reversed phase HPLC profile of natural antioxidants (NAO) isolated from spinach leaves, detected at 250 nm. The residue of an acetone: water extract of a water soluble antioxidant from spinach leaves was applied to a semipreparative LiChrocart 250-10 RP-8 column. Solutions: A, 0.1% TFA in water; B, CH_3CN; run conditions: 0–5 min/100% A (0.1% TFA); 5–27 min/100–56%/A (linear gradient) at a flow rate of 6 ml/min.

(B) Percentage of inhibition of linoleic acid auto-oxidation measured by MDA assay. (C) Percentage of inhibition of linoleic acid oxidation induced by lipoxygenase as measured polarographically.

maxima — at 280 and 350 nm, and group 2, with a single maximum at 314 nm (Fig. 4).

2.2. Spectroscopic identification of antioxidant peaks

Some of the main hydrophobic peaks were then studied in an attempt to determine their chemical nature and structure. Once pure fractions were isolated, their structure was determined mainly by NMR spectroscopy.

The most abundant of the relatively hydrophobic substances were eluted at 21.68 min. The UV spectrum of this peak corresponded to the smooth line trace in Fig. 4, and enough material was obtained to take both ^{1}H and ^{13}C NMR spectra (Table 1). We were also able to establish $^{1}H\times^{1}H$, one-bond $^{13}C\times^{1}H$, and long-range $^{13}C\times^{1}H$ correlations via 2D NMR experiments (COSY, HMQC and HMBC, respectively). These spectra allowed us to unambiguously determine the structure of this material as **1**, a conjugate between a flavone and glucuronic acid (most importantly, a correlation was found between C-4′ and H-1″). A literature search revealed that this compound has been previously described (Aritomi and Kawasaki, 1984; Ferreres et al., 1997). Our more modern techniques permit unambiguous assignment of all the proton and carbon NMR peaks.

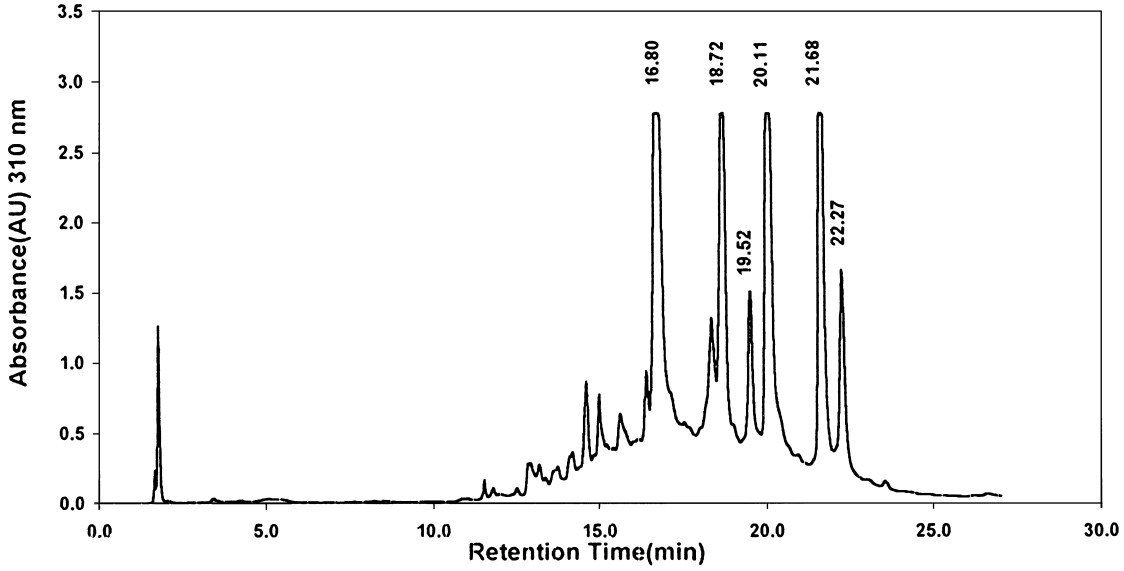

Fig. 3. Reversed phase HPLC pattern of NAO from spinach detected at 310 nm. HPLC conditions were identical to those described for Fig. 1.

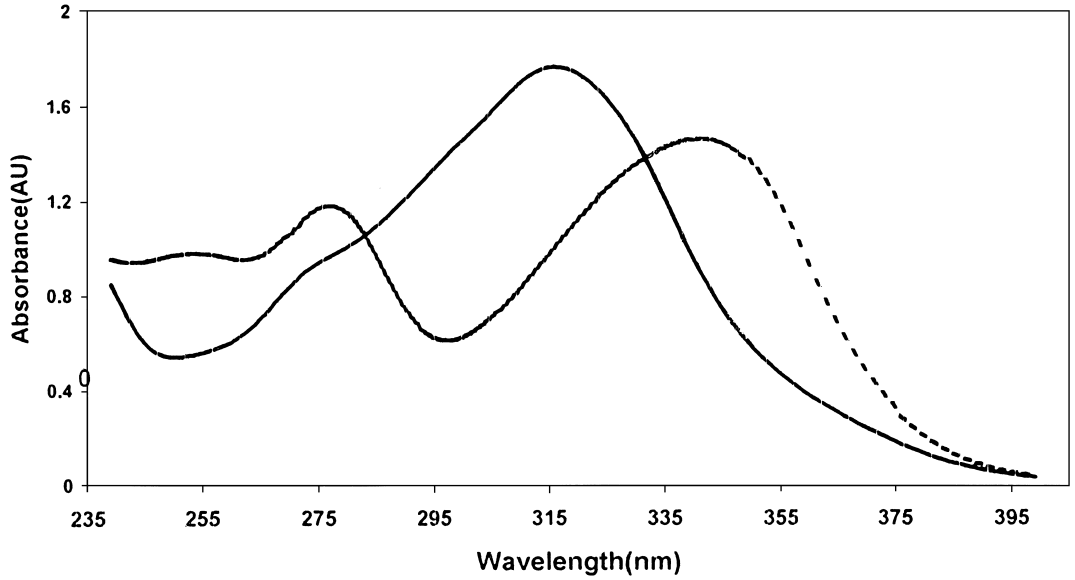

Fig. 4. Spectra of the components eluted from semipreparative HPLC column. — Coumaric acid derivatives; - - - - flavonoids.

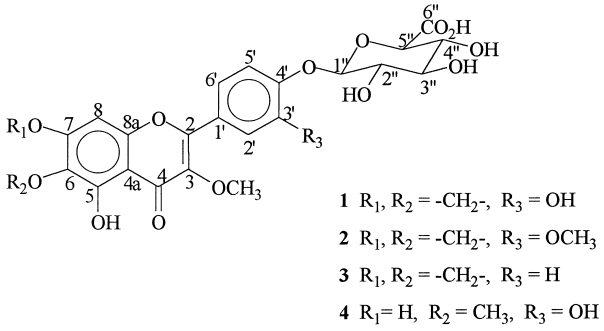

Two other peaks had UV traces virtually identical to that of 1. The ^{1}H NMR spectrum of the fraction eluting at 22.27 min showed this was a mixture of two flavonoids, both glucuronic acid conjugates very similar to **1**. Compound **2** (ca. 85%) only differed from the former in that it was methoxylated at the 3′-OH position; this was confirmed by the detection of through-space interactions (NOESY experiment) between this additional methoxy moiety and H-2′, as well as between the anomeric hydrogen (H-1″) and H-5′. The minor constituent, **3**, lacked this 3′ substituent and the B ring showed a symmetrical AA′XX′ pattern.

The most polar of this family of compounds, eluting at 19.5 min, had structure **4,** similar to **1** but with the 6,7-methylenedioxy unit replaced by 6-methoxy-7-hydroxy substitution; the location of the "new" methoxy moiety at position 7 was ascertained from a long-range coupling interaction (HMBC experiment) between the methoxy protons and C-6, the second of the three adjacent oxygenated ring A carbons, located at δ 132.8 (see Table 2). In view of the small amounts of material isolated, we were not able to determine direct ^{13}C spectra for **2**–**4**. For flavonoid **4**, however, many of the carbon chemical shifts could be inferred from the two-dimensional HMQC and HMBC. While compounds **2** (Aritomi and Kawasaki, 1984; Ferreres et al., 1997) and **4** (Aritomi et al., 1986; Wagner et al., 1977) have been previously reported we find no previous reference to minor constituent **3**.

Another set of peaks in the liquid chromatograph had UV spectra similar to the solid trace in Fig. 4. The ^{1}H NMR spectrum of the fraction eluting at 18.72 min showed it was composed of an ca. 85/15 mixture of two very simple substances; the spectra immediately suggested them to be the *trans* and *cis* isomers of *p*-coumaric acid (**5**), characterized by vicinal olefinic coupling

constants of 16 and 12.5 Hz, respectively (Table 2). A commercial sample of *trans*-*p*-coumaric acid gave a ^{1}H spectrum identical to the natural product; the ^{13}C chemical shifts of the latter are also listed in the table.

We cannot exclude the possibility that coumaric acid is formed by hydrolysis of its esters or that the *cis*/*trans* mixture observed for the acid and its derivatives (vide infra) was generated by light-induced isomerisation. However, we are quite convinced both reactions are unlikely in view of our isolation procedures (see Experimental).

The fraction eluting at 16.8 min had very similar spectra, also showing a mixture of *trans* and *cis* *p*-coumarate fragments. The ^{1}H spectrum had an additional pair of doublets for each isomer; a ^{13}C spectrum indicated this to be a tartaric acid derivative, with two oxymethines and two carboxylate groups. This fraction, therefore, corresponds to *trans*- and *cis*-forms of compound **6** (see Table 2).

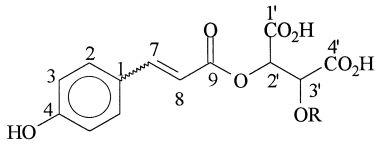
[b] Chemical shifts measured indirectly from HMQC and HMBC spectra.



6 R = H
7 R = $COCH_3$

The least polar of this group of peaks (retention time 20.11 min) had a very similar ^{1}H NMR spectrum, with the addition of only a methyl group at δ 2.12 (δ 2.15 for the minor constituent) and strong deshielding of one of the tartarate methines, suggesting acetylation of **6** at position 3'. The structure was confirmed as an 85/15 mixture of *trans*- and *cis*- forms of **7,** with the aid of 2D ^{13}C×^{1}H correlation experiments (HMQC and HMBC). The carbon chemical shifts measured indirectly via these techniques are also shown in Table 2. A literature search revealed that *trans*-**6** and **7** had been previously identified in spinach leaves (Tadera and Mitsuda, 1970). These authors unambiguously assigned a *meso* configuration to the tartrate moieties, based on the value of $^3J_{2',3'}$. Using the same criterion, we can also establish **6** and **7** as having *meso*-tartarate residues. As far as we can tell, the *cis*-isomers have not been previously reported.

Based on ^{1}H NMR and ^{13}C NMR spectra the most active hydrophilic fraction (RT 5.6, Fig. 1a and b) was identified as uridine. Commercial sample of uridine exhibited similar antioxidant activity compared to the RT 5.6 fraction.

2.3. Synergism of antioxidant effects

In order to test the possibility of a synergistic effect among the antioxidant fractions isolated by HPLC, we took representative samples of the three main categories of the antioxidant fractions after HPLC separation (Fig. 1). The three fractions selected were RT 5.6 (uridine), RT 20.11 (*p*-coumaric) and RT 21.8 (flavonoid). From the hydrophilic group we chose the most active fraction and the two others were chosen as representatives of the two other groups. Each fraction was tested for its antioxidant activity in the TBA and FOX assays, and a mixture of these fractions was also analyzed as shown in Table 3.

Table 3
Synergism of antioxidant effects

Fractions[a]	Retention time (min)	% Inhibition (FOX)	% Inhibition (TBA)
Flavonoid	21.68	5.3±0.13	5.4±0.21
p-Coumaric acid	20.11	6.9±0.15	7.3±0.42
Hydrophilic (uridine)	5.60	5.3±0.20	5.0±0.14
Mixture[b]	–	35±0.21	34.5±0.41

[a] Fractions were taken from HPLC separation based on their retention time (Fig. 1).
[b] The mixture contained all the three fractions together (flavonoid, *p*-coumaric acid and hydrophilic). Inhibition of linoleic acid oxidation was followed by the FOX and TBA assays as described in Experimental.

The antioxidant activity obtained from the combination of these fractions was at least double the sum of activity of the three fractions, when each was assayed individually.

The antioxidant activity of the isolated purified fractions was compared on a molar basis to that of other known antioxidants and the IC_{50} values obtained are presented in Table 4. The data obtained show that the antioxidant potential of the purified aromatic polyphenol

Table 4
The IC_{50} values of purified fractions isolated from spinach (HPLC — Fig. 1) in comparision to other antioxidants. The antioxidant activity was measured by both TBA and FOX assays as described in Experimental

Fractions and antioxidants	Retention time (min)	IC_{50} (μM)
Flavonoid	21.8	15
p-Coumaric acid	20.1	18
Hydrophilic	5.60	120
EGCG (epigallocatechin gallate)	–	20
Vitamin E (trolox)	–	12
BHT (butylated hydroxytoluene)	–	100

fractions of spinach is similar to that of EGCG and vitamin E and even superior to that of BHT.

3. Discussion

We have previously shown that spinach contains a very effective natural antioxidant system (NAO) capable of preventing lipid peroxidation both in plant and animal systems (Grossman et al., 1994). The potential physiological role of NAO as an antioxidant was shown in several in vitro and in vivo systems (Grossman et al., 1994; Lomnitski et al., 2000a,b,c; Reznik, 1990; Zurovsky et al., 1994, 1995; Zurovsky and Gispaan, 1995). We have shown its efficacy in preventing lipid peroxidation in the skin of mice, rats and humans (Grossman et al., 1994; Renzik, 1990). Zurovsky et al. have shown the beneficial effect of NAO in preventing metabolic damage to the kidney, following exposure to hyperoxia,-induced by reperfusion in the rat (Zurovsky et al., 1995; Zurovsky and Gispaan, 1995). Recently, the efficacy of NAO in preventing LPS-induced hepatic injury both in rats and rabbits was demonstrated (Ben-Shaul et al., 1999; Lomnitski et al., 2000a,b,c). Moreover, NAO is very active in reducing the cardiotoxicity induced by antitumoral agents (Breitbart et al., 1999). In all these studies, the isolated fraction A from a water extract of spinach leaves was used (Grossman et al., 1994).

In the present study, a comprehensive investigation was performed to isolate and identify the active antioxidant components present in spinach leaves. Although this goal is not yet complete, we were able to characterize several antioxidant components, among them at least two whose structure was not previously described in spinach (structure **3** of the flavonoid, and the *cis-trans*-isomers **6** and **7** of the *meso*-tartarate residues).

Using a combination of solvents (1:9, water:acetone), a significant part of the antioxidant activity present in spinach leaves was extracted and resolved into several active peaks by HPLC on a C-8 column. High resolution separation of the active antioxidant peaks was obtained with a semi-preparative C-8 column in the HPLC separations (Figs. 1 and 3).

The identification of the chemical structure of the various fractions was based mainly on NMR spectroscopy. The active antioxidant peaks identified can be separated into three categories of chemicals: (a) flavonoid derivatives (b) coumaric acid derivatives (c) and hydrophilic components, one of them was identified as the nucleoside, uridine.

The possible presence of flavonoid-like compounds in spinach was first reported by Weatherby and Cheng (1943). Williams islolated a flavonoid. Zane and Wender (1961) established the structure of isolated flavonol from spinach leaves as patuletin and also described the presence of spinacetin in this extract. Aritomi et al. (Aritomi et al., 1986; Aritomi and Kawasaki, 1984) reported the presence of seven flavonol glycosides in methanolic extract of spinach leaves. Recently, Ferreres et al. (1997) isolated and identified five novel naturally occurring flavonoids from alcoholic extracts of spinach leaves. In all these studies there was no reference to the possible biological or physiological role of these compounds. The main goal of the present study was to identify the active components which comprise the powerful antioxidant activity present in aqueous spinach leaf extracts. Our NMR data indicate that several of the flavonoids, compounds **1**, **2** and **4**, which were described previously, and the new naturally occurring compound **3** described in this study, are present in the water extract of spinach leaves and contribute to its antioxidant activity (Fig. 2).

For some time it has been recognized that several classes of flavonoid show antioxidant activity toward a variety of easily oxidizable compounds (Larson, 1988). Early work of Clemetson and Andersen showed that many flavonoids and other plant phenolic compounds protect against ascorbic acid destruction (Clemetson and Andersen, 1966). The past two decades have witnessed a renewed interest in the study of flavanoids and of their biological interactions with mammalian cells and tissues. Flavonoids are known to display a broad array of pharmacological and biochemical actions (Middleton and Kandaswami, 1992, 1993). The flavonoids are typical phenolic compounds and powerful chain- breaking antioxidants (Lea and Swoboda, 1956; Clemetson and Andersen, 1966; Hughes and Wilson, 1977; Baumann et al., 1980b; Jones and Hughes, 1984; Torel et al., 1986; Pratt, 1992). It was reported that lipid peroxidation can be inhibited by flavonoids, possibly through their activity as strong $O_2^{\cdot -}$ scavengers (Baumann et al., 1980b) and singlet oxygen quenchers (Sorata et al., 1984). Recently, the ability of eight structurally related naturally occurring flavonoids to inhibit lipid peroxidation and mitochondrial membrane permeability transition was described (Santos et al., 1998). It was suggested that flavonoids have multiple biological

activities including potent anti-allergic, anti-inflammatory, and antiviral actions, which may result, at least in part, from their antioxidant and free radical-scavenging abilities (Kahl, 1991; Middleton and Kandaswami, 1993; van Acker et al., 1996; Santos et al., 1998). We have shown here that the flavonoid-containing fractions from the spinach extract inhibited lipid peroxidation in all three assays used in this study. Moreover, the spinach flavonoids significantly inhibited soybean lipoxygenase activity. These data are in agreement with other studies (Baumann et al., 1980a; Robak et al., 1988; Laughton et al., 1991) which demonstrated inhibition of lipoxygenases by flavonoids from other sources.

In addition to the flavonoids, the spinach extract was found to contain derivatives of the isomers of *p*-coumaric acid (**5, 6** and **7**), while **6** and **7** have *meso*-tartarate residues. Moreover, **7** was confirmed to be a mixture of *trans* and *cis* isomers. The *cis* isomer had not been previously reported in spinach. The presence of *p*-coumaroyl-meso-tartaric acid detected in spinach leaves in large amounts was reported by Winter and Herrmann (1986). As can be seen from Fig. 2, these *p*-coumaric derivatives are very strong antioxidants. The ability of some phenolic compounds to act as antioxidants has been previously shown (Clemetson and Andersen, 1966). In a recent publication, Velioglu et al. (1998) studied the antioxidant activity and total phenolics of 28 plant products including seeds, fruits, vegetables and medicinal plants and reported a significant correlation between total phenolics and antioxidative activity. The antitumor activity of a polyphenolic fraction isolated from grape seeds has also been demonstrated (Zhao et al., 1999).

In summary, the present study demonstrates for the first time the presence of both flavonoids and p-coumaric acid derivatives as antioxidant components of the aqueous extract of spinach leaves. About seven individual active fractions were isolated in the aromatic polyphenol group (Figs. 1 and 3). Although each isolated fraction exhibits antioxidant activity (Fig. 2), we may assume that the combination of these fractions contributes to the synergistic efficacy of the NAO extract as a powerful antioxidant in protecting against oxidation damages in biological systems that we tested. As shown in Table 4 several of the isolated antioxidants are as active as other known antioxidants such as EGCG (green tea) and the water soluble derivative of vitamin E. The aromatic polyphenols that we isolated are all glycosylated. This is expected to increase their intestinal absorption and bio-availability in a manner similar to the flavonoid quercetin, which was shown to be absorbed in much greater amounts than the pure aglycone (Hollman and Katan, 1999). We are currently pursuing the chemical identification of the isolated hydrophilic fractions (Fig. 1, RT 3.5–11.5). Preliminary results indicate the presence of amino acids, sugars, organic and nucleic acids in these fractions. The main active fraction was identified as uridine. Determination of the exact chemical structure of the other fractions and their antioxidative nature remains to be completed.

4. Experimental

4.1. Chemicals

All the standard chemicals used and Soybean Lipoxygenase (Type II) were obtained from Sigma Chemical (St. Louis, MO). Organic solvents were purchased from Merck (Darmstadt, Germany) for HPLC analyses and from Bio labs (Jerusalem, Israel) for acetone extraction.

4.2. Antioxidant preparation and purification

Spinach extract was prepared at room temperature (25°C). Fresh leaves of spinach (*spinacia oleracea*) were mixed 1:1 (w/v) with distilled water and homogenized in a blender for about 5 min. The homogenate was filtered through two layers of cheesecloth and centrifuged at 20,000×*g* for 10 min. The supernatant was collected. The concentration of solids in the supernatant was about 3%, as determined by reflectometry. The supernatant was concentrated to 25% by evaporation at 80°C. One ml of this supernatant was mixed with 9 ml of acetone AR for 5 min by stirring. This mixture was centrifuged at 20,000×*g* for 10 min. The supernatant was collected and the acetone was evaporated at 85°C; this residue was used for HPLC analysis and separation.

4.3. HPLC analysis and separation

LaChrom chromatography system was used with LaChrom L-7450 Diode Array Detector (DAD); data for each run was documented by the HSM program included with the LaChrom software. For analytical separations, a LiChrocart 125-4 column was used, packed with Lichrospher 100, RP8, 5 um. For semipreparative separation, a LiChrocart 250-10 column was used packed with the same resin. Solutions: A 0.1% TFA in water; B CH3CN; The running conditions were as follows: 0–5 min/100% A; 5–27 min/100–56%/A (linear gradient); flow rate:1 ml/min (for the analytical column) and 6 ml/min (for the semipreparative column); detection was at 254 or 310 nm. Using the DAD, we were able to analyze the run at any wavelength and to see the spectrum of any peak.

4.4. Antioxidant activity of peaks eluted from HPLC

The peaks were collected to clean tubes and acetonitrile (CH_3CN) was evaporated in a Speed Vac Plus SC110A (Savant), and freeze dried. The dried peaks were diluted in 100 μl of water and equal volumes were taken for antioxidant activity assays.

4.5. Determination of antioxidant activity

Antioxidant activity was determined by measuring the inhibition of auto-oxidation of linoleic acid at 37°C for 24 h. Linoleic acid was prepared in Tween 20 as described by Grossman and Zakut (1979). In brief, a stock solution of 3×10^{-2} M linoleic acid was prepared by addition of 3 nmoles of linoleic acid to 50 ml of distilled water containing 1 ml of Tween 20. Three to 5 ml of 1 N NaOH were added in order to clarify the resulting emulsion and the volume was adjusted to 100 ml with distilled water. This stock solution was diluted with 100 mM of phosphate buffer pH 7.0 to 7.5×10^{-3} M. The solution was stored at 4°C for up to two weeks. One ml of this solution was used for the auto-oxidation assay. It was incubated at 37°C for 24 h in the presence or absence of antioxidants, and from this solution 25–100 μl were taken for TBA assay and 2–5 μl for the FOX determination.

The level of auto-oxidation was measured by two methods: (a) the Thiobarbituric acid (TBA) assay measuring malonedialdehyde (MDA) and, (b) the ferrous oxidation in the presence of xylenol orange (FOX method) for measuring peroxide levels. TBA was reacted colorimetrically with MDA according to the method of Wasowicz et al. (1993). The colored product was monitored at 532 nm.

In the FOX method (Wolff, 1994), peroxides mediate the oxidation of Fe^{+2} to Fe^{+3} under acid conditions. In the presence of xylenol orange, Fe^{+3} forms a blue-purple complex with absorption at 560 nm.

4.6. The polarographic method

In some cases antioxidant activity was determined as inhibition of soybean lipoxygenase oxidation of linoleic acid using the polarographic method in which oxygen consumption during lipoxygenase activity is determined (Grossman and Zakut, 1979).

Lipoxygenase activity was determined using a YSI Biological Oxygen Monitor (Yellow Springs Instrument, Ohio) equipped with Clark electrode in a closed chamber. The substrate for Lipoxygenase activity was Linoleic acid, 7.5×10^{-3} M, in 50 mM phosphate buffer, pH 6.5. To assay lipoxygenase activity, 0.9 ml of linoleic acid (7.5×10^{-3} M) were added to the oxygen monitor chamber containing 50 μl of lipoxygenase (1 mg/10 ml) in phosphate buffer pH 6.5, and 50 μl of antioxidant fractions after HPLC analysis. Oxygen consumption was recorded.

4.7. Identification of molecular structure of HPLC peaks by NMR

NMR spectra were run, in CD_3OD solutions, on a Bruker DMX-600 instrument, operating at 600.1 and 150.9 MHz (^1H and ^{13}C, respectively). In all cases chemical shifts are given in ppm units downfield from internal TMS and coupling constants are reported in Hz.

Received 5 September 2000; received in revised form 9 March 2001

Abstract

The organic soluble extract from the leaves of *Glycyrrhiza lepidota* showed moderate activity in the US National Cancer Institute in vitro anti-HIV-1 bioassay. Chromatographic separation of this extract resulted in the identification of a new diprenylated bibenzyl as the compound responsible for the observed anti-viral activity. Extensive spectroscopic experiments provide the complete ^{1}H NMR and ^{13}C NMR spectral assignments to support the proposed structure. Known compounds glepidotin B and glepidotin A were also isolated from the extract and shown to be inactive in the anti-viral assay. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Glycyrrhiza lepidota*; Fabaceae; Prenylated; Glepidotin; HIV-1

1. Introduction

Over the past several years, this laboratory has been investigating the chemistry of medicinal native plants of the North American prairie. Plant collection was guided by historical accounts of plant medicinal uses by early European settlers traveling across the plains and by indigenous North Americans (Dilwyn, 1980). The ethnobotanical literature cites 203 plant species used for medicinal purposes by the Indian tribes of the Prairie Bioregion of North America (Kindscher, 1992). With the ethnobotanical uses of plants for medicinal purposes clearly documented, a study of native prairie plants as sources of new pharmaceuticals was begun. The initial investigation examined the anti-HIV activity of 22 species of medicinal plants using the US National Cancer Institute's (US NCI) in vitro AIDS anti-viral assay (Weislow et al., 1989). The assay results identified three organic extracts as "active" in the anti-HIV screen (Kindscher et al., 1998). An active extract was defined as a crude extract that showed at least 50% growth inhibition in HIV-infected white blood cells compared to the non-infected control at a maximum test concentration of 250 μg/ml. One of the three active species was *Glycyrrhiza lepidota* (wild licorice). This communication describes the isolation and structure elucidation of the diprenylated bibenzyl **1** responsible for the observed anti-HIV activity.

The genus *Glycyrrhiza* ("sweet root") is a member of the Fabaceae family and contains 18 species world-wide (Mabberly, 1997). *Glycyrrhiza lepidota* (common names: wild licorice, American licorice, and desert root) is the only member of the genus native to North America and is widely distributed throughout the western United States and Canada. It is a perennial herb that grows to 0.3–1.1 m in height. Its use by native North Americans has been well documented (Gilmore, 1977; Camazine and Bye, 1980; Munson, 1981). The antimicrobial agents from *G. lepidota* have been previously studied (Mitscher et al., 1983; Gollapudi et al., 1989). In the work by Mitscher et al. (1983) antimicrobial bioassay-guided fractionization afforded the flavanol glepidotin A (**2**), the flavanol glepidotin B (**3**), and the prenylated bibenzyl glepidotin C (**4**). Additionally, a number of other flavanoids and bibenzyls were isolated and identified that had been previously isolated from *G. glabra* (Saitoh et al., 1976; Mitscher et al., 1980), *Helichrysum umbraculigerum* (Bohlmann and Hoffmann, 1979), and *Radula camplanata* (Asakawa et al., 1978).

2. Results and discussion

The dried leaves of *G. lepidota* were extracted with both water and CH_2Cl_2:MeOH (1:1) . Both the aqueous and organic extracts were submitted for in vitro screening against HIV-1 as previously described by Wieslow et al. (1989). The water extract was inactive in the assay while the organic extract gave an EC_{50} of 30 μg / ml in duplicate testing. Subsequent bioassay-guided fractionation (LH-20) yielded one active fraction which was then subjected to normal phase HPLC purification to yield three pure compounds.

The first eluting compound from HPLC was identified as glepidotin B (**2**) based on its high resolution accurate mass, ^{13}C, and ^{1}H NMR spectral characteristics. The coupling constant of 13.4 Hz and the lack of a NOE between H-2 and H-3 suggested a *trans* stereochemistry. The second eluting compound was identified as glepidotin A (**3**). Subsequent in vitro assay for anti-HIV activity showed that neither of these two compounds were responsible for the observed anti-viral activity of the parent fraction.

The third compound isolated proved to be somewhat difficult to work with. After its initial purification by HPLC and removal of solvent, spectral data (^{1}H and ^{13}C NMR, IR and UV) could be obtained if the experiments were performed immediately after solvent removal. However, if the solvent was removed and the sample stored overnight, only about 50% would re-dissolve in the NMR solvent ($CDCl_3$ or CD_3OD) the next day. The insoluble material appeared as a white film on the flask. Attempts to dissolve this material in any common solvent (e.g. DMSO, THF, H_2O) failed. It was determined that if the sample was stored dry for any extended period of time (i.e. over approximately 6 h), substantial decomposition occurred and reisolation by HPLC was required with a concomitant loss of material. Eventually it was determined that the material could be stored for long periods of time in solution without decomposition. Therefore, once isolated, **1** would be quickly weighed and stored in solution ($CDCl_3$) for subsequent experiments.

The ^{1}H NMR spectrum of **1** showed a four-proton multiplet at δ 2.82. A subsequent ^{1}H–^{1}H COSY analysis showed no coupling outside the multiplet which suggested an isolated pair of non-equivalent methylene protons. This observation initially led us to believe that the compound was the earlier isolated bibenzyl **4**. However, high resolution mass spectrometry indicated a molecular formula of $C_{24}H_{30}O_3$. This molecular formula suggested a diprenylated bibenzyl. Two prenyl groups could be identified from two methyl groups at δ 1.76 and δ 1.78 and an overlapping six-proton methyl singlet at δ 1.73 ppm thus accounting for the expected four methyl groups. The one-proton signals for the prenyl olefin triplets were at δ 5.25 and δ 5.45. There was a substantial difference between the chemical shifts of the prenyl methylene groups, δ 3.39 and δ 4.45 ppm, which suggested that one of the prenyl groups was bonded to an oxygen (Williams and Flemming, 1989). Analysis of the aromatic region of the ^{1}H NMR 1D and ^{1}H–^{1}H COSY spectra identified an isolated *meta* coupled spin system at δ 6.29 and δ 6.34. This suggested that one of the aromatic rings was 1,2,3,5-tetra-substituted. Four other aromatic protons appeared as a triplet at δ 7.15 ($J = 7.65$), a *meta* coupled doublet of triplets at δ 6.78 ($J = 7.65$, 1.02), and a pair of overlapping signals centered at δ 6.66 and δ 6.65. The signal at δ 6.66 was a poorly resolved, finely coupled triplet while the one centered at δ 6.65 appeared as an unresolved mulitplet. Careful examination of the ^{1}H–^{1}H COSY identified the proton signal centered at δ 6.65 as being coupled to the triplet at δ 7.15. This implied that the proton at δ 6.66 showed only *meta* coupling. These observations suggested that this ring was *meta* disubstituted with the resonance centered at δ 6.66 corresponding to the isolated proton.

In order to establish the ring substitution patterns, a HMBC experiment was performed. Shown in Fig. 1 are the key long range correlations. Essential to establishing the structure was the correlation from the non-oxygenated prenyl methylene protons at δ 3.39 to C-1 and C-3. The oxygen-bonded prenyl methylene protons at δ 4.45 ppm also correlated to C-3, thus establishing the ether oxygen carbon at δ 157.0. This indicated that the tetra-substituted ring had the two prenyl groups *ortho* to each other and a hydroxy group *ortho* to the non-oxygenated prenyl group. These HMBC data, in combination with the 1D proton data, established the substitution pattern for the tetra-substituted ring as shown in Fig. 1. This is also consistent with the substitution previously established for glepidotin C (**4**) (Gollapudi et al., 1989).

The *meta* substitution pattern on the other aromatic ring had been established from its ^{1}H–^{1}H COSY spectrum. The results of the HMBC experiment confirmed the assignment of the signal at δ 6.66 to be assigned to H-2″ based on its long range correlation to the hydroxyl bearing carbon at δ 155.3 (C-3″) and the bibenzyl carbon at δ 37.7 (C-1″a). The assignment of the H-6″ signal at δ 6.78 was established based on its long range correlation to the same bibenzyl carbon as H-2″ (C-1″a). Given in Table 1 are the complete ^{1}H and ^{13}C NMR spectra assignments for **1** based on the acquired HMBC, ^{13}C–^{1}H HETCOR, and ^{1}H–^{1}H COSY experiments.

Compound **1** is, therefore, 2-(3-methyl-2-butenyl)-3-*O*-(3-methyl-2-butenyl)-5-[2-(3-hydroxyphenyl)ethyl]-1, 3-benzenediol. However, Mitscher et al. (1980, 1983) have established the common name ''glepidotins'' for bibenzyls and flavanols from *G. lepidota*. Therefore, we refer to this compound as glepidotin D.

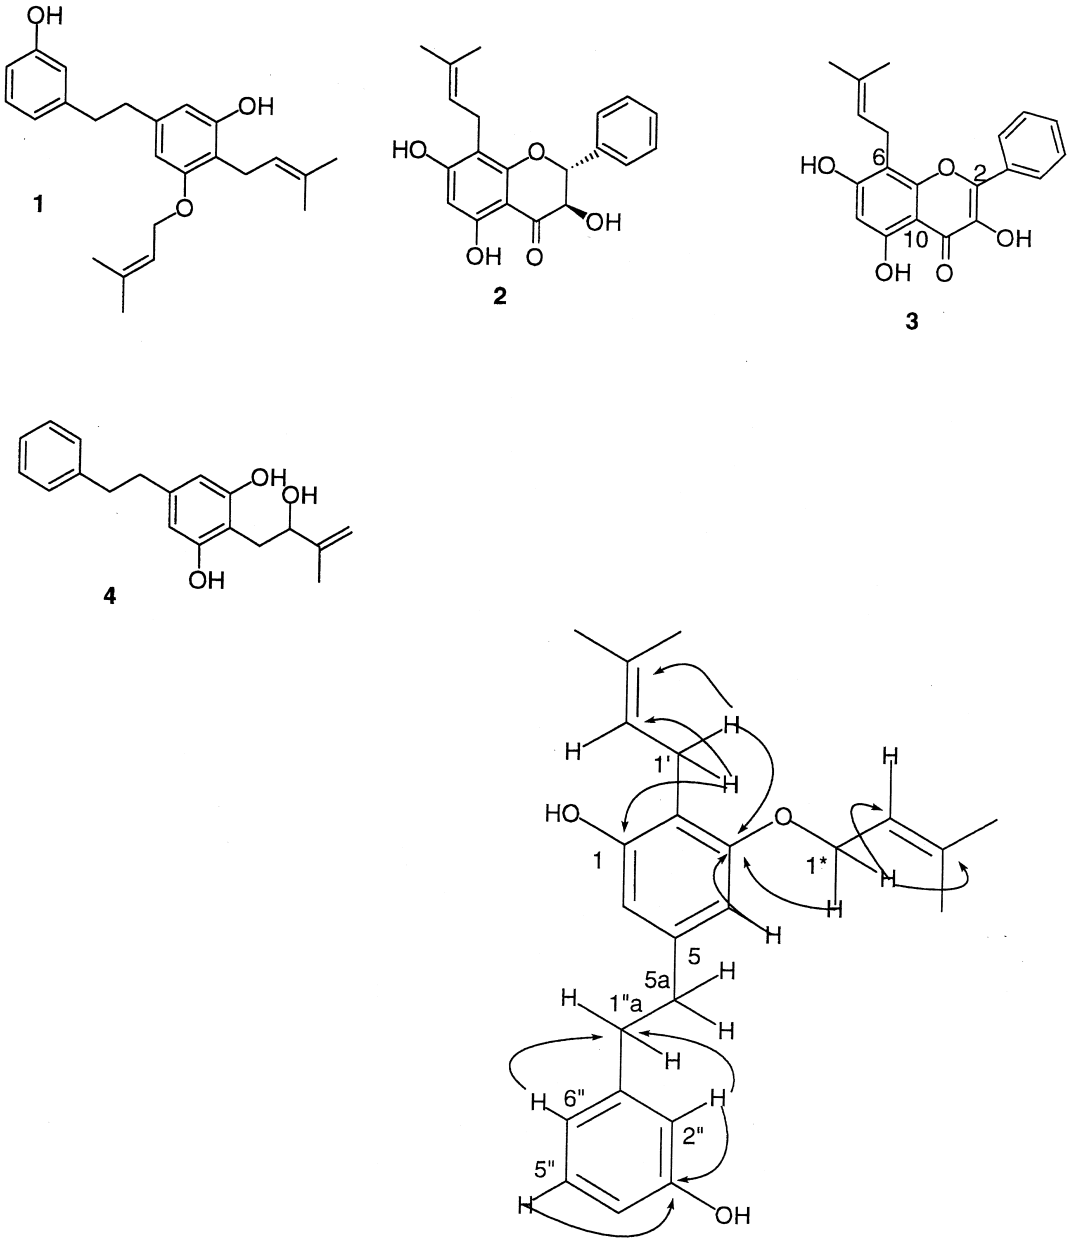

Fig. 1. Key long range HMBC correlations for **1**.

3. Biological activity

In conjuction with the Laboratory of Drug Discovery, Research and Development (LDDRD) at the US NCI, an in vitro assay against HIV-1 was performed. Compound **1** achieved an EC_{50} of 2.0 μg/ml and an IC_{50} of 5.0 μg/ml. The activity of **1** is a full order of magnitude greater than that of the crude extract and supports the hypothesis that the observed anti-HIV activity may solely be due to **1**. We were unable to isolate any glepidotin C (**4**) from the plant to determine if this related compound possessed anti-viral properties. The activity associated with this compound may be suspect because of its instability. However, we have determined that it is stable for prolonged periods of time in organic solvents, but are unsure of its stabilty under the assay conditions. Because of the instability of compound **1** and its small therapuetic index (TI: EC_{50}/IC_{50}) no further testing in the anti-viral assays is planned.

4. Experimental

4.1. General

NMR experiments were acquired on a Tecmag Aquerius (GE QE 300) at 300 or 75 MHz. The inverse-detected HMBC experiment was acquired on a Varian

[a] Because these signals overlapped, the coupling constants could not be determined from the 1D ^1H NMR spectrum at 300 MHz.

[b] These carbons and hydrogens could not be resolved. The long range correlations must be assigned based on the proposed structure.

VXR 500 at LDDRD at the US NCI in Frederick, Maryland. All chemical shifts are reported in ppm relative to TMS. Mass spectral data were obtained on a JOEL SX 102 mass spectrometer operating at 10 kV (NIDDK, US NIH, Bethesda, Maryland). Samples for FABMS were desorbed from a nitrobenzyl alcohol matrix using 6 keV xenon atoms. Accurate mass FAB was performed at a resolution of 10,000. IR data were acquired on a Galaxy series 2020 FT–IR spectrometer. HPLC chromatography was performed on an ISCO gradient HPLC with a ISCO V-4 UV detector. All solvents were purchased from Fisher Scientific and were HPLC grade. HPLC columns were either Altech (Econosil) or Rainin (Varian) Dynamax.

4.2. Biological testing

The anti-HIV assay was carried out at LDDRD at the US NCI in Frederick, Maryland as previously described by Wieslow et al. (1989). The assay involves the killing of T4 (CD4+) lymphoid cells (CEM-SS line) by HIV-1 (RF strain). The EC_{50} is the concentration at which a compound or fraction inhibits the killing of the lymphoid cells by 50% relative to the HIV infected, non-treated lymphoid cells. The IC_{50} is a measure of the compound's or fraction's toxicity to uninfected lymphoid cells. The growing lymphoid cells were pelleted from the growth medium, infected at a multiplicity of infection (MOI) of 0.05 at room temperature for 45 min with constant shaking. The infected cells were then diluted in the growth medium to yield a desired concentration of infected cells of 5000 cells/well after inoculation into individual wells of a 96-well microtiter plate. The extracts, fractions and compounds were dissolved in H_2O–DMSO and incubated for 6 days at 37°C. (Typically, fractions and extracts were tested at an initial concentration of 250 μg /ml and serially diluted. Pure compounds were tested at an initial concentration of 100 μg/ml.) After incubation, cell viability and growth were measured using the XTT-tetrazolium method as described. *G. lepidota* extract and subsequent fractions were tested through the high-flux assay lab by SAIC Frederick, PO Box B, Frederick, MD. Pure compounds were tested by Dr. Robert Gulowkoski at LDDRD. To avoid decomposition associated with **1** when stored neat, all samples were sent to LDDRD in $CDCl_3$ solutions in sealed tubes.

4.3. Plant material

G. lepidota was collected and identified by Hillary Loring at a location 1 km west and 0.5 km north of Brookville, KS. Plant identification follows the *Flora of the Great Plains* (Great Plains Flora Association, 1986). A voucher specimen is archived at the R.L. McGregor Herbarium at the University of Kansas.

4.4. Extraction and isolation

The air-dried leaves and stems of *G. lepidota* (500 g) were chopped into small pieces and covered with CH_2Cl_2:MeOH (1:1) for 24 h. The solvent was then removed and the plant material covered with MeOH. After another 24 h, this MeOH extract was added to the CH_2Cl_2:MeOH extract and the solvent removed at reduced pressure. The plant material was then extracted with H_2O and freeze-dried. Small samples of the organic and aqueous extract were submitted for HIV testing. All activity was associated with the organic phase (EC_{50} = 30 μg/ml). The crude organic extract (5.4 g) was dissolved in MeOH (100 ml) and H_2O (10 ml). This suspension was then extracted with three aliquots (50 ml each) of hexane, which was removed at reduced pressure to give a residue (1.0 g). Water was then added to the aqueous layer to bring the total H_2O content to 20% and then extracted with CCl_4 which was removed at reduced pressure to give extract (1.8 g). (CCl_4 extraction has now been eliminated in our lab due to environmental concerns.) Water was then added to the aqueous layer to bring the total concentration to 30%, and extracted with $CHCl_3$ to give a residue (0.90 g). The methanol was then removed from the aqueous layer under reduced pressure and the subsequent water layer

extracted with EtoAc to give a residue (0.28 g). The aqueous layer was then freeze dried to give a residue (1.3 g). Subsequent anti-HIV assay indicated that all of the activity was associated with the CCl_4 fraction. The CCl_4 fraction was then applied to a Sephadex LH-20 column (Pharmacia-Upjohn; 100×2.5 cm i.d.; 1:1 CH_2Cl_2:MeOH). Collected fractions were analyzed by TLC using a (H_2SO_4–EtOH–H_2O–vanillin) spray reagent and UV for visualization. Like fractions were combined and assayed (8 total).

4.5. Glepidotin B (2)

Compound **2** (32 mg) was isolated using HPLC purification on a silica HPLC column and a solvent gradient of hexane : 2-propanol (6% 2-propanol increasing to 15%). HRMS (FAB) calc. for $C_{20}H_{21}O_5$ (M + H) 341.1389, obs. 341.1379. ^{13}C NMR spectral data (75 Mhz, $CDCl_3$): δ 196.0 (*s*, C-4), 164.6, 161.2, 161.0 (*s*, C-5, C-7, C-9), 136.1 (*d*, C-2″), 136.0 (*s*, C-1′), 129.3 (*d*, C-4′) 128.7, 127.5 (4C, *d*, C-2′, 3′, 5′,6′), 121.0 (*d*, C-2″) 107.5 (*s*, C-6), 100.8 (*s*, C-10) 96.0 (*d*, C-8), 83.3 (*d*, C-3), 72.5 (*d*, C-2), 25.8 (*t*, C-1″), 21.0, 18.0 (*q*, C-4″, C-5″). Its ^1H NMR and IR spectral data were identical to those reported by Mitscher et al. (1983).

4.6. Glepidotin A (3)

Compound **3** (56 mg) was isolated using the same solvent gradient as above, with **3** eluting 0.5 min after **2**. HRMS (FAB) calcd. for $C_{20}H_{19}O_5$ $(M-H)^+$ 339.1227, obs. 339.1234. All spectral data were consistent with that previously reported by Mitscher et al. (1983).

4.7. Glepidotin D (1)

Compound **1** (18 mg) was isolated using the same HPLC solvent system as for **2** and **3**, and eluted approximately 0.1 min after **3**. Attempts to eliminate traces of **3** were initially thwarted by the apparent decomposition of **1** when it was stored neat for any length of time (>6 h). An insoluble white material formed on the walls of the flask which could not be dissolved in any common solvent. To circumvent this problem, repurification of **1** was accomplished by keeping the compound in a small amount of hexane-isopropanol HPLC solvent. Once purified, **1** could be stored in solution without appreciable decomposition as measured by periodic ^1H NMR spectral comparisons. The ^1H and ^{13}C NMR spectral data are given in Table 1. IR spectral data (neat, thin film, NaCl, ν_{max} cm^{-1}): 3382, 1588, 1489, 1453, 737, 697. EIMS (probe) 70 eV, *m*/*z* (rel. int): 366 $[M]^+$ (18), 298 (33), 69 (100). HRMS (FAB) calc. for $C_{24}H_{31}O_3$ $(M-H)^+$ 367.2273, obs. 367.2260.

Acknowledgements

The authors would like to thank Dr. Kirk Gustafson from the US NCI LDDRD, Frederick, Maryland for performing the HMBC experiments. Dr. Michael R. Boyd is acknowledged for use of the anti-HIV assay and Dr. Robert Gulowkoski for running the assay. Dr. John Cardellina is also acknowledged for helpful discussions. Dr. Hillary Lorring is acknowledged for plant collection. Financial support for this work was provided by the Iowa Carver Foundation, College of Natural Sciences at UNI and the Graduate College at UNI. The Office of International Programs is acknowledged for support of M.D. who was a summer undergraduate student from Herzen State University, Saint Petersburg, Russia.

Abstract

The betalains of yellow, orange and red inflorescences of common cockscomb (*Celosia argentea* var. *cristata*) were compared and proved to be qualitatively identical to those of feathered amaranth (*Celosia argentea* var. *plumosa*). In addition to the known compounds amaranthin and betalamic acid, the structures of three yellow pigments were elucidated to be immonium conjugates of betalamic acid with dopamine, 3-methoxytyramine and (*S*)-tryptophan by various spectroscopic techniques and comparison to synthesized reference compounds; the latter two are new to plants. Among the betacyanins occurring in yellow inflorescences in trace amounts, the presence of 2-descarboxy-betanidin, a dopamine-derived betacyanin, has been ascertained. The detection of high dopamine concentration may be of toxicological relevance in use of yellow inflorescences as a vegetable and in traditional Chinese medicine, common uses for the red inflorescences of common cockscomb. © 2001 Elsevier Science Ltd. Keywords: *Celosia argentea* var. *cristata*; *Celosia argentea* var. *plumosa*; Amaranthaceae; Common cockscomb; Feathered amaranth; Betalains; Betaxanthins; Miraxanthin V; Dopamine; 3-Methoxytyramine

1. Introduction

The plant genus *Celosia* consisting of about 60 species in the family Amaranthaceae (Caryophyllales) is native in subtropical and temperate zones of Africa, South America and South East Asia. *Celosia argentea* var. *cristata* (L.) Kuntze, (*Celosia cristata* L.) (common cockscomb), and *Celosia argentea* var. *plumosa* (Burvenich) Voss, (*Celosia plumosa* Burvenich) (feathered amaranth), are widespread ornamental plants. Seedlings, young leaves and inflorescences are used as a vegetable in China and other countries (Palada and Crossman, 1999), and also dried leaves, inflorescences and seeds are used in traditional Chinese medicine (Wong, 1994; Xu, 1996). Among the garden varieties, inflorescence colour variation from yellow to various shades of red and violet occurs. At an early date (Wehmer, 1929) it was claimed that red inflorescences of common cockscomb contain a nitrogen-containing pigment. Later, amaranthin and betanin were found in red inflorescences, whereas violet ones contain additional hydroxycinnamoyl-amaranthins (celosianins) (Piattelli and Minale, 1964; Minale et al., 1966). The structures of the latter were presumed to be identical with compounds from cell suspension cultures of *Chenopodium rubrum* L. identified as 2″-*O*-*E*-(4-coumaroyl)-amaranthin (celosianin I) and 2″-*O*-*E*-feruloyl-amaranthin (celosianin II) (Bokern and Strack, 1988; Strack et al., 1988). Protein extracts from inflorescences of *C. plumosa* catalysed the transfer of ferulic acid from 1-*O*-feruloyl-β-glucose to amaranthin forming celosianin II (Bokern et al., 1992). The knowledge of betaxanthins in the Amaranthaceae family is very limited (Reznik, 1975), although betalamic acid has been electrophoretically detected in *Celosia* species (Reznik, 1978). Yellow betaxanthin-synthesizing seedlings of *C. plumosa* reacted upon illumination with a 3–4-fold increase in betaxanthin content (Giudici de Nicola et al., 1973, 1974). Dopa feeding to inflorescences of *Amaranthus caudatus* and *Celosia argentea* did not induce betaxanthin formation (Rink and Böhm, 1991), whereas the administration of this central intermediate to seedlings of *A. caudatus* led to the occurrence of a betaxanthin

mixture (French et al., 1974; Colomas, 1977; Bianco-Colomas, 1980) from which vulgaxanthin II [(*S*)-Glu-BX] and miraxanthin II [(*S*)-Asp-BX] were identified by comparison to authentic samples, but dopaxanthin [(*S*)-Dopa-BX] was entirely absent (Giudici de Nicola et al., 1975). Cell cultures of *A. caudatus* and *Celosia argentea* showed only pigmentation by betalains in auxin-free, but GA_3-containing nutrient solutions (Constabel and Nassif-Makki, 1971; Böhm and Rink, 1988). As no betaxanthins from *Celosia* have so far been identified, structural elucidation of the betaxanthins of two *Celosia* varieties was performed, which led to two new betaxanthins. In addition, the levels of pharmacologically active precursors were determined.

2. Results and discussion

HPLC analysis of extracts prepared from differently pigmented inflorescences of *C. cristata* and *C. plumosa* (Fig. 1) confirmed the presence of the already known amaranthin (**1**) and its (2*S*,15*R*)-isoform (**1′**) as well as betalamic acid (**2**), but celosianins and also betanin, formerly claimed to be a minor constituent (Piattelli and Minale, 1964), were not found. The main pigment **1** in extracts from inflorescences, red leaves and epidermal layers of the stem of red flowering *C. cristata* was accompanied by minor unknown betaxanthins (Table 1). In contrast, these pigments are the major components (**3**–**5**) in yellow- and orange-coloured inflorescences (Fig. 2). The same held true also in yellow and orange-red inflorescences of *C. plumosa* which showed a qualitatively identical betalain pattern. Compounds **1** and **2** were readily identified by UV-vis spectroscopy and co-chromatography (HPLC) with authentic standards from callus culture of *Chenopodium rubrum* (Bokern et al., 1992) and hypocotyls of fodder beets (Schliemann et al., 1999) as amaranthin (**1**) and betalamic acid (**2**). The identification of **1** was corroborated by LC–MS of the purified

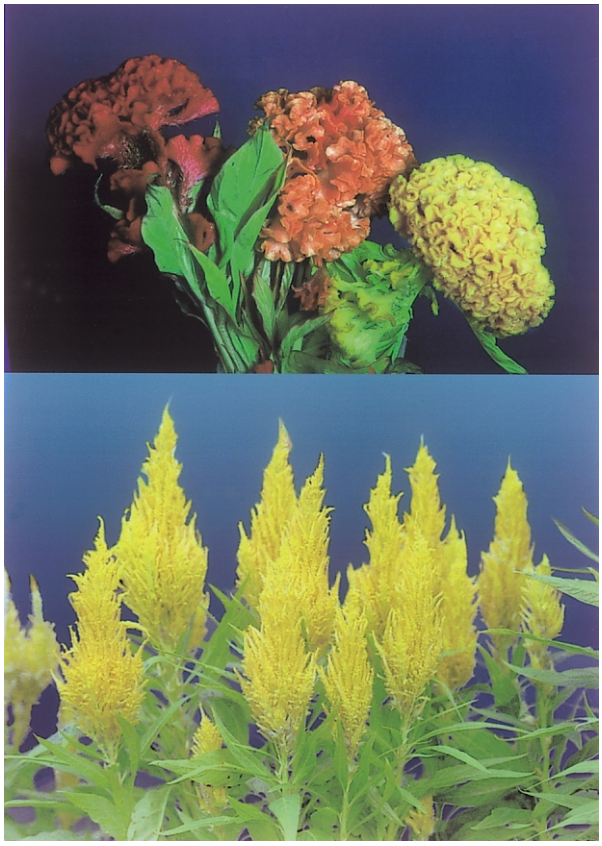

Fig. 1. Flowering *Celosia argentea* var. *cristata* (L.) Kuntze (red, orange, yellow) (above) and *Celosia argentea* var. *plumosa* (Burvenich) Voss (yellow) (below).

compound giving the expected protonated molecular ion $[M+H]^+$ (**1**, *m*/*z* 727) (Table 2). Furthermore, the collision induced dissociation (CID) mass spectrum of *m*/*z* 727 gave the main fragments *m*/*z* 551 $[betanin+H]^+$ and *m*/*z* 389 $[betanidin+H]^+$ indicative for the presence of **1**. Finally, high-resolution LC–ESI–TOF–MS yielded *m*/*z* 727.1913 ($C_{30}H_{35}N_2O_{19}$, calculated mass: 727.1829) completing the structure elucidation of **1** as amaranthin.

A, red inflorescences (maxplot detection 400–650 nm; full scale: 1.55 AU); B, orange inflorescences (470 nm; full scale: 0.255 AU); **C**, yellow inflorescences (470 nm; full scale: 0.185 AU). Peak numbers correspond to the numbers in Tables 1 and 2 and Fig. 3.

From the retention time and the characteristic HPLC-PDA data (R_t 23.0 min; λ_{max} 261/457 nm), compound **3** was suggested to be miraxanthin V (dopamine-derived betaxanthin, dopamine-BX), recently found as the major betaxanthin in hairy root cultures of yellow beets (Schliemann et al., 1999). Co-chromatography (HPLC) with synthetically prepared authentic standard and LC–MS giving the protonated molecular ion $[M+H]^+$ at m/z 347 confirmed the suggestion. The CID mass spectrum of m/z 347 was shown to be identical in its fragmentation pattern with recently published data (Schliemann et al., 1999). Additionally, ESI–TOF–MS yielding m/z 347.1264 ($C_{17}H_{19}N_2O_6$, calculated mass: 347.1238) supported the structural elucidation of **3** as miraxanthin V. For compound **4** a similar structure was suggested because the UV-vis spectral data were identical with **3**, but showed a longer retention time than **3** (Fig. 2). This lower polarity observed could be caused by the lack of a hydroxyl group in the aromatic amine moiety (tyramine instead of dopamine) or by modification of a hydroxyl group with an acyl or alkyl residue. The first proposal could be disproved as synthesized miraxanthin III (tyramine-BX) (R_t 26.6 min; λ_{max} 262/457 nm) did not coelute with compound **4**. Subsequently, the betaxanthins derived from 4-methoxy-3-hydroxy-phenylethylamine and 3-methoxy-4-hydroxy-phenylethylamine (3-methoxytyramine) were prepared and used as reference compounds in co-injection experiments. Both compounds were identical with compound **4** with respect to UV-vis data (λ_{max} 261/457 nm). 4-Methoxy-3-hydroxy-phenylethylamine-BX eluted at R_t 29.2 min, clearly different from **4**, whereas 3-methoxy-4-hydroxy-phenylethylamine-BX (3-methoxytyramine-BX) showed complete co-elution with the endogenous betaxanthin. This chromatographical identity was supported by comparison of the mass spectral data of the standard compound with that of compound **4**. Both compounds showed in LC–MS a protonated molecular ion at m/z 361 ($[M+H]^+$) indicative for a methyl derivative of **3** (m/z 347). In the CID mass spectrum of m/z 361 the fragment ion at m/z 151 represents the deaminated component conjugated with betalamic acid in **4**, whereas the fragment ion at m/z 211 is the complementary aminated betalamic acid. In addition, the fragment at m/z 317 ($[M+H\text{-}CO_2]^+$) can be explained by the loss of a carboxyl group from the molecular ion. In LC–ESI–TOF–MS the protonated molecular ion was found at m/z 361.1417 ($C_{18}H_{21}N_2O_6$, calculated mass: 361.1394) confirming the structure elucidation of **4** as 3-methoxytyramine-BX, a new betaxanthin.

One of the most unpolar betaxanthins synthesized so far as a reference compound (Trezzini and Zryd, 1991; Schliemann et al., 1999) is (*S*)-tryptophan-BX [(*S*)-Trp-BX]. As compound **5** showed in our RP-HPLC system a long retention time (R_t 34.7 min), a comparison to betaxanthins synthesized from (*S*)-Trp and tryptamine was performed. Whereas tryptamine-BX was different from **5** with respect to both retention time and UV-vis data (R_t 37.8 min; λ_{max} 217/262/456 nm), the corresponding data for (*S*)-Trp-BX matched with compound **5** and both betaxanthins co-eluted in HPLC. In LC–MS the protonated molecular ion was found at m/z 398 ($[M+H]^+$), expected for (*S*)-Trp-BX. In the CID mass spectrum of m/z 398 the fragment ion at m/z 188 represents the deaminated (*S*)-Trp conjugated to betalamic acid in **5**, whereas the fragment ion at m/z 211 is the complementary aminated betalamic acid. In addition, the fragment at m/z 354 ($[M+H\text{-}CO_2]^+$) can be

explained by the loss of a carboxyl group from the molecular ion. The fragments at m/z 130 and 180 are typical Trp ions in ESI–CID-spectra of Trp conjugates (Schmidt et al., 1995). By ESI–TOF–MS the protonated molecular ion was found at m/z 398.1327 ($C_{20}H_{20}N_3O_6$, calculated mass: 398.1347) completing the structure elucidation of **5** as (*S*)-Trp-BX, a new betaxanthin from plants.

A hypothetical scheme (Fig. 3) illustrates the proposed steps of betaxanthin biosynthesis in *Celosia*. In addition to the known pathway, a methylation step has to be included which is required for the formation of **4**. The question arises whether **4** is formed by methylation of the main compound **3** or by methylation of a biosynthetic intermediate. An indication for the latter option would be the detection of 3-methoxytyramine in the extract. The analysis of the extract from yellow inflorescences of common cockscomb with respect to the precursors of betaxanthins **3**–**5** gave the results shown in Table 3. All three precursors, dopamine, 3-methoxytyramine and (*S*)-Trp could be detected and quantified in comparison with standard compounds. 3-Methoxytyramine was found to be present at low concentration, but in the same order of magnitude as the derived betaxanthin **4**. Therefore, it is most probable that the methylation takes place at the catecholic level rather than at the betaxanthin level. 3-Methoxytyramine is a known dopamine catabolite in humans and animals (Bidard and Cronenberger, 1977; Faraj et al., 1981; Fitoussi et al., 1998), but it was found for the first time in plants as a constituent of cactus alkaloids from *Trichocereus pachanoi* (Agurell, 1969; Crosby and McLaughlin, 1973). Cacti, like *Celosia*, belong to the Caryophyllales, and therefore, it may be speculated about the occurrence of cactus alkaloid-derived betaxanthins in cactus species. In contrast to the relatively

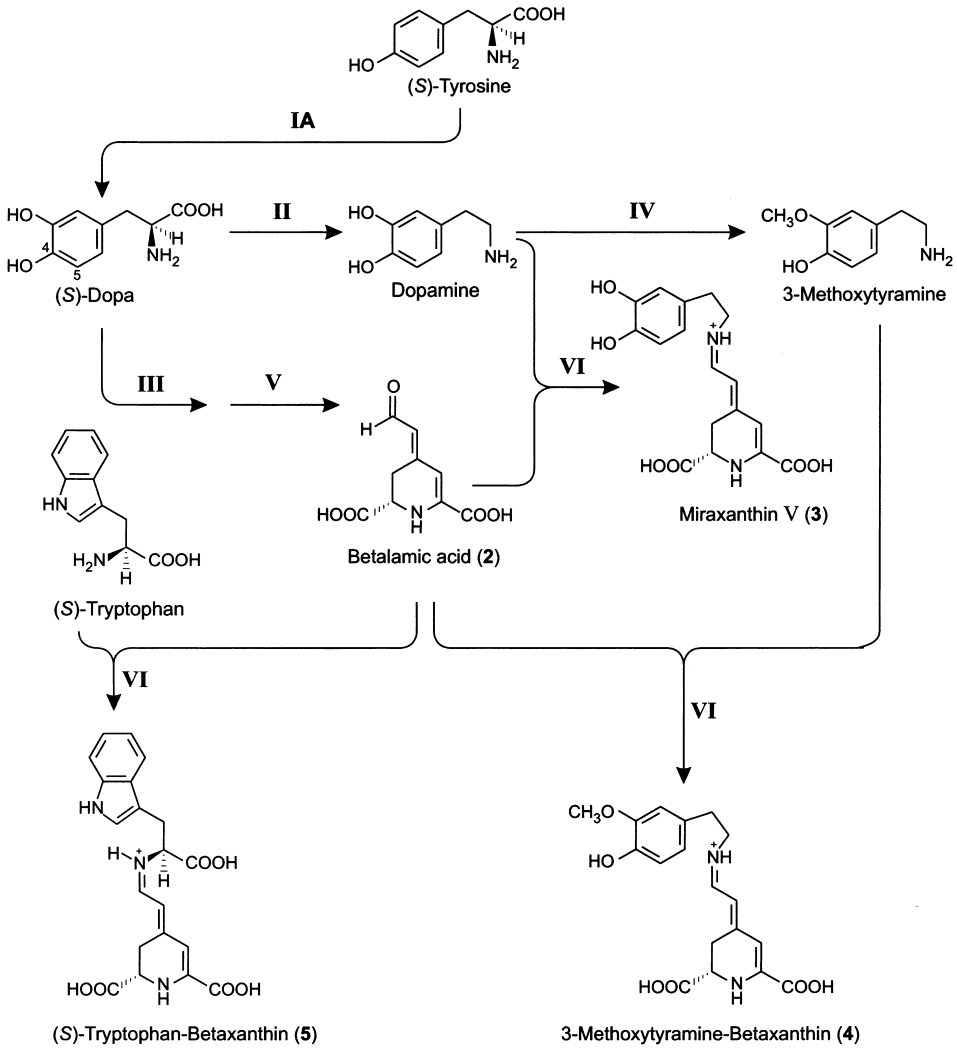

Fig. 3. Proposed scheme of betaxanthin biosynthesis in *Celosia*. Enzymatically catalysed steps: IA — hydroxylating activity of the tyrosinase; II — Dopa decarboxylase; III — dopa dioxygenase; IV — *O*-methyltransferase. Spontaneous steps: V — cyclization reaction; VI — condensation reaction (aldimine formation). Compound numbers of this scheme correspond to peak numbers in Tables 1 and 2 and Fig. 2.

Table 3
Content and HPLC data of dopamine, 3-methoxytyramine and (*S*)-tryptophan in yellow inflorescences of *Celosia argentea* var. *cristata* (L.) Kuntze

Precursor	Content [nmol (g fr. wt)$^{-1}$]	R_t (min)	HPLC–PDA (λ_{max}, nm)
Dopamine	41150	5.7	220sh/278
3-Methoxytyramine	35	10.9	223/277
(*S*)-Tryptophan	283	21.5	216/276

low concentration of 3-methoxytyramine and (*S*)-Trp, the precursor of **3**, dopamine, occurs in thousand-fold higher concentration than 3-methoxytyramine. Due to its various biological actions, these high dopamine concentrations found may be toxicologically relevant when yellow inflorescences are consumed as a vegetable or used as material in traditional Chinese medicine.

Recently, the rare betacyanins derived from 2-descarboxy-*cyclo*-Dopa were isolated from hairy root cultures of yellow beets and their origin from dopamine elucidated (Kobayashi et al., 2001). As extracts from yellow *Celosia* inflorescences also contain high concentration of dopamine, the occurrence of this type of compounds seems probable. By isolation of betacyanins occurring in trace amounts in yellow inflorescences of *C. cristata* and co-injection with a hairy root extract from yellow beets the presence of 2-descarboxy-betanidin was ascertained. The distribution of the occurrence of 2-descarboxy-betanidin, isolated for the first time from flowers of *Carpobrotus acinaciformis* (L.) L. Bol. (Aizoaceae) (Piattelli and Impellizzeri, 1970), identified recently together with its glucoside and corresponding malonyl derivative from beet cultures (Chenopodiaceae) (Schliemann et al., 1999; Kobayashi et al., 2001) has to be expanded now to the Amaranthaceae.

The betalain content of differently coloured inflorescences and tissues of the two *Celosia* varieties presented in Table 1 reveals that all tissues of red *C. cristata* contain minor amounts of the betaxanthins **3**–**5** which are the major compounds in the yellow and orange/orange-red inflorescences. This colour change implies a gradual reversion of the pigments' biosynthesis, from Dopa via *cyclo*-Dopa to amaranthin on the one side to betaxanthins (**3**, **4**) derived from Dopa via dopamine on the other side. The betalain patterns in the two *Celosia* varieties are qualitatively the same, and a direct comparison of the concentrations between them is not reasonable because *C. cristata* was grown in Halle (Germany), and *C. plumosa* in Wuhan (China) under different climatic conditions.

In summary, the presented data describe the betalain patterns of two *Celosia* varieties. In addition to amaranthin and betalamic acid, the structures of three betaxanthins are elucidated by comparison with synthetic standards and using MS techniques as miraxanthin V, 3-methoxytyramine-BX and (*S*)-tryptophan-BX, with the latter two newly described from plant origin. Evidence is obtained for the occurrence of the dopamine-derived 2-descarboxy-betanidin. Furthermore, the detection of 3-methoxytyramine may be indicative for a methylation reaction on a catecholic intermediate rather than at the miraxanthin V level.

3. Experimental

3.1. Plant material

Common cockscombs [*Celosia argentea* var. *cristata* (L.) Kuntze] (yellow, orange and red) were grown from seeds and then further cultivated in the institute's experimental garden (Halle, Germany). Two yellow- and orange-red-coloured inflorescence genotypes of *Celosia argentea* var. *plumosa* (Burvenich) Voss were selected from the genetic resource collections of the Hubei Academy of Agricultural Sciences, Wuhan, China. All genotypes were planted in the field in Wuhan in 1999. Plant materials were harvested at full bloom. Callus cultures of *Chenopodium rubrum* (Bokern et al., 1992), hairy root cultures of yellow beet (*Beta vulgaris* L. subsp. *vulgaris*, Garden Beet Group "Golden Beet") (Schliemann et al., 1999) and fodder beets (*Beta vulgaris* L. subsp. *vulgaris*, Fodder Beet Group "Altamo") were cultivated as recently described (Schliemann et al., 1999).

3.2. Isolation, quantification and purification of betalains

The materials were frozen in liquid N_2, homogenized in a mortar and extracted with 80% aq. MeOH (containing 50 mM ascorbate) for 30 min [3 ml (g fr. wt)$^{-1}$]. After centrifugation at 14,000 *g* for 10 min at 4°C, the supernatant was removed and its betalain content was quantified photometrically at 540 nm (betacyanins) and 475 nm (betaxanthins) using the molar extinction coefficients described (amaranthin, 56.6×10^6 cm^2 mol^{-1}, Piattelli et al., 1969; the mean molar extinction coefficient for betaxanthins, 48×10^6 cm^2 mol^{-1}, Girod and Zryd, 1991). For the calculation of the composition of extracts containing both amaranthin and betaxanthins as well as betalamic acid, amaranthin (from *Chenopodium rubrum* callus culture), miraxanthin V (from hairy root culture of yellow beets) and betalamic acid (from yellow fodder beets) were isolated by semi-prep. HPLC (solvent system 1), their absorbancies measured and aliquots of known content analyzed by HPLC (solvent system 2). The peak areas of analyzed extracts were used to calculate the individual betalain content expressed in nmol (g fr. wt)$^{-1}$. All experiments were performed in duplicate. For LC–MS and LC–ESI–TOF–MS amaranthin and the betaxanthins **3**–**5** were isolated by semi-prep. HPLC (solvent system 1).

3.3. Isolation of betalamic acid and preparation of standard betaxanthins

Yellow hypocotyls (50 g) of fodder beet seedlings (*Beta vulgaris* L. subsp. *vulgaris*, Fodder Beet Group "Altamo") (4-weeks-old) were frozen in liquid N_2, homogenized in a mortar and extracted for 30 min with 150 ml aq. 80% MeOH containing 50 mM Na-ascorbate (pH 8.2). After centrifugation (14,000 *g*; 10 min at 4°C) the supernatant was concentrated to 20 ml in vacuo at 30°C. Betalamic acid was isolated by semi-prep. HPLC (solvent system 3) and the acidic eluate (10 nmol) was added directly to 10 μmol of the amino acid or amine, respectively. After evaporation of the reaction mixtures in vacuo to dryness, the residues containing the betaxanthins formed were dissolved in 100 μl water and used for co-injection experiments either directly or after purification by semi-prep. HPLC (solvent system 1).

3.4. Quantification of catecholamines and (S)-tryptophan

For quantification of dopamine, 3-methoxytyramine and (*S*)-Trp 50 μl extract from yellow inflorescences of *C. cristata* (in the case of dopamine only 5 μl) was separated by HPLC (solvent system 2) with detection of the native fluorescence emission at 314 nm (Steiner et al., 1999) and absorbance at 280 nm. The endogenous compounds were identified and quantified with reference to the corresponding standard compounds. The experiments were performed in duplicate.

3.5. HPLC

Analytical and semi-prep. HPLC was performed with a system from Waters (Milford, MA, USA), including the separation module 2690. The liquid chromatograph was equipped with a 5-μm Nucleosil C_{18} column (250×4 mm i.d.; Macherey-Nagel, Düren, Germany). The following solvent and gradient systems were used. Solvent system 1: A: 1% aq. HOAc; B: acetonitrile; gradient: linear gradient from 100% A to 24% B in (A + B) within 40 min; the flow rate was 1 ml min^{-1}. Solvent system 2: A: 1.5% aq. H_3PO_4 B: acetonitrile; gradient as in solvent system 1. Solvent system 3: A: 1% aq. HOAc; B: acetonitrile; gradient: linear gradient from 5 to 18% B in (A + B) within 10 min. The betalains were detected at 540, 460 and 405 nm or by maxplot detection between 400 and 650 nm (photodiode array detection). The injection volume was 20 μl in analytical (solvent system 2) and 100 μl in semi-prep. work (solvent systems 1 and 3).

3.6. LC–MS

Positive ion electrospray ionization mass spectra were recorded on a Finnigan MAT TSQ 7000 instrument [electrospray voltage 4.5 kV; capillary 220°C; sheath gas N_2] coupled to a Micro-Tech Ultra-Plus Micro LC system equipped with a 4-μm C_{18} column (100×1 mm i.d, ULTRASEP). For LC, a gradient system starting from 10% B (0.2% aq. AcOH in acetonitrile) in 90% A (0.2% aq. AcOH) to 50% B in (A + B) within 10 min was used, followed by 10 min isocratic elution at a flow rate of 70 μl min^{-1} (injection volume: 2 μl). The CID mass spectra during the LC run were obtained under the following conditions: collision energy (collision cell) −25 eV; collision gas: argon; collision pressure: 1.8 mT. All mass spectra are averaged and background subtracted.

Positive LC–ESI–TOF mass spectra were recorded on an API QSTAR Pulsar instrument (Perkin Elmer Sciex, Foster City, USA) [electrospray voltage: 5.5 kV; sheath gas: N_2] coupled to an Ultimate micro-HPLC system (Software Ultichrom 2.5)(LC Packings, Amsterdam, Netherlands) equipped with a 3-μm Fusica C_{18} column (150 ×0.3 mm i.d, PepMap). For LC, a gradient system starting from 100% A [0.05% aq. HCOOH/acetonitrile (95/5)] to 100% B [HCOOH/ acetonitrile (0.05/99.95)] within 20 min was used, at a flow rate of 4 μl min^{-1} (injection volume: 0.5 μl).

Received 19 January 2001; received in revised form 22 March 2001

Abstract

Leaves of *Cucumis sativus* plants treated with silicon and infected with *Sphaerotheca fuliginea* yielded five new acylated flavone *C*-glycosides identified as isovitexin 2″-*O*-(6‴-(*E*)-*p*-coumaroyl)glucoside (**6**), isovitexin 2″-*O*-(6‴-(*E*)-*p*-coumaroyl)glucoside-4′-*O*-glucoside (**7**), isovitexin 2″-*O*-(6‴-(*E*)-feruloyl)glucoside-4′-*O*-glucoside (**11**), isoscoparin 2″-*O*-(6‴-(*E*)-*p*-coumaroyl)glucoside (**9**), and isoscoparin 2″-*O*-(6‴-(*E*)-feruloyl)glucoside-4′-*O*-glucoside (**12**). The known flavone-glycosides isovitexin (**1**), saponarin (**2**), saponarin 4′-*O*-glucoside (**3**), vicenin-2 (**4**), apigenin 7-*O*-(6″-*O*-*p*-coumaroylglucoside) (**5**), isovitexin 2″-*O*-(6‴-(*E*)-feruloyl)glucoside (**8**) and isoscoparin 2″-*O*-(6‴-(*E*)-feruloyl)glucoside (**10**), were also identified in this plant material. © 2001 Elsevier Science Ltd. Keywords: *Cucumis sativus*; Cucurbitaceae; Cucumber; Acylated flavone *C*-glycosides

1. Introduction

The *Cucurbitaceae* is characterised chemically by the presence of cucurbitacins, bitter-tasting triterpenoids that are present in high concentrations in root tissue and toxic to mammals (Hegnauer, 1964, 1989). In contrast, the fruits of many species in this family are edible and used as foods, including pumpkin, marrow and zucchini (*Cucurbita* spp.), watermelon (*Citrullus lanatus* (Thunb.) Matsum. & Nakai), melon (*Cucumis melo* L.) and cucumber (*Cucumis sativus* L.). The phenolic constituents of these valuable crop plants have not been investigated extensively, although there is some evidence for their involvement in mechanisms of resistance to fungal infection in *C. sativus* (Menzies et al., 1991; Daayf et al., 1997). In a recent investigation, a flavonol phytoalexin (7-*O*-methoxy-3,5,3′,4′-tetrahydroxyflavone) was identified in seedlings of *C. sativus* treated with silicon and infected with *Sphaerotheca fuliginea* (Schlechtend.:Fr) Poll., a fungus causing powdery mildew (Fawe et al., 1998). A role for Si in mediating the accumulation of this compound was also demonstrated. The present report describes a more extensive survey of the flavonoids of this plant material. Among these are five new acylated flavone *C*-glycosides that were identified using a combination of LC–MS and NMR techniques.

2. Results and discussion

A MeOH extract of fresh leaves of *C. sativus* from plants treated with silicon (as potassium silicate) and infected with *Sphaerotheca fuliginea* yielded flavone *C*-glycosides **1**–**7** by column chromatography and semi-preparative HPLC. The purified fractions of **6** and **7** also contained **8**–**10** and **11**–**12**, respectively, as minor components. Five of the compounds were identified as isovitexin (**1**), saponarin (**2**), saponarin 4′-*O*-glucoside (**3**), vicenin-2 (**4**) and apigenin 7-*O*-(6″-*O*-*p*-coumaroylglucoside) (**5**), on the basis of chemical and spectroscopic data (see Experimental section). These flavone *C*-glycosides are well-known from other plant sources (Harborne and Baxter, 1999). Gallic acid and *p*-coumaric acid were also identified as constituents of the leaves of *C. sativus* by the same methods.

Acid hydrolysis (2 M HCl) of **6** and **7** afforded isovitexin, vitexin, glucose and *p*-coumaric acid in each case. The UV spectra of both compounds were similar,

and characteristic for flavonoid glycosides acylated by hydroxycinnamic acids (Markham, 1982). The 1D ^{1}H NMR spectrum of **6** acquired in DMSO-d_6 at 37°C contained a significant number of exchange-broadened resonances, a feature observed previously in some flavone *C*-glycosides (Markham and Geiger, 1993; Lewis et al., 2000). One of these resonances, corresponding to 5-OH, appeared as two components which coalesced at 50°C. An acceptable level of spectral resolution overall was achieved at 60°C, the temperature used for all subsequent NMR measurements. The molecular structure of **6** was obtained using 1D ^{1}H, 1D XSROESY, 1D ^{13}C, DEPT, DQF-COSY, HSQC and HMBC experiments. Characteristic ^{1}H and ^{13}C chemical shift values and coupling constant data indicated that the structure was based on that of isovitexin (apigenin 6-*C*-β-glucopyranoside) (Agrawal, 1989; Markham and Geiger, 1993). This was confirmed by the detection of a long-range ^{1}H–^{13}C connectivity (HMBC) from the anomeric proton of the *C*-β-glucopyranosyl moiety at δ 4.71 (*d*, $J=9.9$ Hz, H-1″) to the ^{13}C resonance at δ 107.9 (C-6). The remaining resonances of the primary sugar residue (6-*C*-Glc) were assigned from DQF-COSY, HSQC and HMBC data using the anomeric proton at δ 4.71 as a starting point (Table 1). A second anomeric sugar proton was noted in the 1D ^{1}H NMR spectrum at δ 4.28 (*d*, $J=7.3$ Hz), with a ^{13}C resonance at δ 105.2 by HSQC. Assignment of the corresponding set of sugar resonances identified their origin as a second β-glucopyranosyl moiety *O*-linked to the *C*-β-glucopyranose (Table 1). The precise nature of the linkage between the two sugar residues was determined using ^{1}H–^{1}H dipolar connectivities detected in 1D XSROESY experiments (Gradwell et al., 1997). Strong ROE connectivities were found between the resonances of the two anomeric protons indicating that the interglycosidic linkage was 1‴→2″. This was also evident from the significant downfield shifts experienced by H-2″ and C-2″ in comparison to their values in the

NMR spectra of isovitexin (Agrawal, 1989). The β-configuration of the two glucose moieties was confirmed by observation of ROE connectivities from H-1″ to H-3″ and H-5″, and H-1‴ to H-3‴ and H-5‴.

The remaining resonances in the 1D ^{1}H NMR spectrum of **6** were typical of those of (*E*)-*p*-coumaric acid (Table 1). A weak ROE connectivity was detected between one of the 6‴-CH_2 protons of the *O*-linked β-glucopyranose at δ 3.89 and the α-CH resonance of the *p*-coumaric acid moiety at δ 6.07. In addition, the ^{13}C resonance of C-6‴ was downfield shifted to 62.4 ppm. These observations indicated that the *O*-linked β-glucopyranose was acylated by (*E*)-*p*-coumaric acid at the 6‴ position. APCI–MS (negative mode) of **6** gave a deprotonated molecule ($[M-H]^-$) at *m*/*z* 739 which together with NMR data indicated an empirical formula of $C_{36}H_{36}O_{17}$. MS–MS of the deprotonated molecule gave three major product ions at *m*/*z* 593, 413 and 293, which were in accordance with cleavage of the ester bond of the acyl (coumaroyl) moiety (fragmentation Y_3), cleavage of the glycosidic bond at C-2″ (fragmentation Y_2), and fragmentation Y_2 plus elimination of a 120 Da ring fragment from the *C*-linked glucose (fragmentation Y_1), respectively (Fig. 1a). Minor product ions at *m*/*z* 619 (fragmentation Y_1) and *m*/*z* 473 (fragmentations $Y_1 + Y_3$) were also present. The molecular structure of **6** was, therefore, confirmed as isovitexin 2″-*O*-(6‴-(*E*)-*p*-coumaroyl)-β-glucopyranoside on the basis of both MS and NMR data.

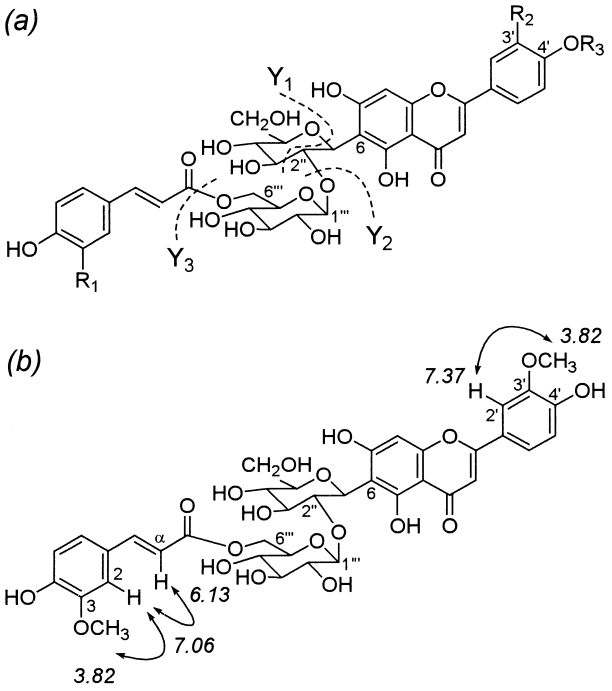

Fig. 1. (a) Fragmentation patterns Y_1–Y_3 observed for **6**–**12** in MS–MS experiments; (b), Summary of ^{1}H–^{1}H ROE connectivities observed for **8**–**10** in 1D XSROESY NMR experiments. The corresponding proton chemical shift values are given for reference. Although compound **10** (the dimethoxy derivative of **6**) is shown here, the NMR data for the 'feruloyl' and 'flavone' parts of the molecule are also valid for compounds **8** and **9**, respectively (the monomethoxy derivatives of **6**).

were assigned from DQF-COSY, HSQC and HMBC data, and were typical of those for an *O*-linked β-glucopyranoside. Site selective excitation of the anomeric proton resonance at δ 5.00 using 1D XSROESY gave a strong ROE connectivity to the H-3′,5′ resonance at δ 7.12. This confirmed the site of attachment of the additional *O*-Glc residue to be at C-4′. The resonance assignments of the NMR spectra of **6** and **7** (Table 1) were similar with the exception of the downfield shifts of H-3′,5′ and H-2′,6′ in **7** due to substitution of 4′-OH by *O*-Glc. APCI–MS (negative mode) of **7** gave a deprotonated molecule ($[M–H]^-$) at *m*/*z* 901, which together with NMR data indicated an empirical formula of $C_{42}H_{46}O_{22}$. MS–MS of the deprotonated molecule gave only one major product ion, at *m*/*z* 739 $[(M–H)–162]^-$, corresponding to loss of the C-4′ glucopyranosyl group. Collision induced dissociation (CID) of this ion in a MS^3 experiment yielded the same array of product ions as in the CID spectrum of deprotonated **6**. Compound **7** was therefore identified as isovitexin 2″-*O*-(6‴-(*E*)-*p*-coumaroyl)-β-glucopyranoside-4′-*O*-β-glucopyranoside, the 4′-*O*-glucoside of **6**.

Further analysis of the samples containing **6** and **7** by reverse phase HPLC/APCI–MS (negative mode) showed that neither gave a chromatographically pure peak. Minor components with slightly shorter retention times and giving deprotonated molecules at *m*/*z* 769 (**8** and **9**) and 799 (**10**) eluted within the peak of **6**, and components giving deprotonated molecules at *m*/*z* 931 (**11** and **12**) eluted within **7**. The similarities observed in the CID spectra of the minor components compared to **6** and **7** indicated that they might be methoxy derivatives of these compounds. This was supported by the observation of minor component resonances in the NMR spectra of the samples of both **6** and **7** at chemical shift values typical of $ArOCH_3$ (δ_H 3.82 and δ_C 55.7).

MS–MS of deprotonated **10** (60 Da greater than **6**) gave three major product ions, all 30 Da greater than those observed in the CID spectrum of **6**, and a minor product ion at $[(M–H)–120]^- = m/z$ 679 (i.e. a Y_1 cleavage). These data were in accordance with **10** being a dimethoxy derivative of **6** with one methoxy group located on the aglycone moiety and one on the acyl moiety (suggesting a feruloyl group). The location of a methoxy group on the aglycone moiety was further supported by a MS^3 experiment in which CID of the 'aglycone' product ion at *m*/*z* 323 (generated by Y_1+Y_2 cleavage) showed the loss of a methyl radical. On the basis of the fragmentation shown by **6** and **10**, the negative ion CID spectrum of the peak at *m*/*z* 769, observed in the LC–MS analysis of **6**, was in accordance with it being a mixed spectrum of two methoxy derivatives of **6**. One (**9**) showed a Y_3 cleavage product at $[(M–H)–146^-] = m/z$ 623, in accordance with the loss of a coumaroyl moiety, and the loss of a methyl radical from the aglycone ion, as shown by a MS^5 (*m*/*z* 796→623→443→323) experiment to ensure the fragmented ion was pure. The other (**8**) showed a Y_3 cleavage product at $[(M–H)–176]^- = m/z$ 593, consistent with the loss of a feruloyl moiety, and no loss of methyl radical from the aglycone ion.

The precise location of the methoxy groups in **8**–**10** was established using 1D XSROESY experiments, as illustrated in Fig. 1b. Site selective excitation of the minor proton resonance at δ 3.82 (corresponding to the coincident methoxy resonances of **8**–**10**) gave ROE connectivities to δ 7.06 and 7.37. Similarly, site selective excitation of δ 7.06 (which was not obscured by the resonances of **6**, the major component of the sample) gave ROE connectivities to resonances at δ 6.13 (*d*, *J* = 15.9 Hz) and 3.82 (*s*). The resonance at δ 6.13 was located in the 1D ^1H NMR spectrum of the sample as a low intensity signal appearing slightly downfield of α-CH of the coumaroyl group of **6** at δ 6.08 (*d*, *J* = 15.9 Hz), and with the same multiplet structure. This allowed the ROE connectivities to be assigned as H-2 (δ 7.06) to α-CH (δ 6.13) and 3-OCH_3 (δ 3.82), and confirmed the presence of a feruloyl group (Fig. 1b). Compound **8**, the monomethoxy derivative of **6** with the OCH_3 group located on the acyl moiety was therefore confirmed to be isovitexin 2″-*O*-(6‴-(*E*)-feruloyl)-β-glucopyranoside. The minor component resonance at δ 7.37, although obscured by H-2,6 of the coumaroyl group of **6**, was assigned to H-2′ of the flavone. This was supported by data obtained from an analogous set of 1D XSROESY experiments for the sample containing **7** (and **11** and **12** as minor components), where the equivalent minor component resonance at δ 7.41 appeared as a low-intensity doublet with *J* = 2.2 Hz (satisfied only by H-2′). Compound **9**, the monomethoxy derivative of **6** with the OCH_3 group located on the flavone moiety was therefore identified as 3′-methoxyisovitexin 2″-*O*-(6‴-(*E*)-*p*-coumaroyl)-β-glucopyranoside (= isoscoparin 2″-*O*-(6‴-(*E*)-*p*-coumaroyl)-β-glucopyranoside). The dimethoxy derivative of **6**, compound **10**, was identified as 3′-methoxyisovitexin 2″-*O*-(6‴-(*E*)-feruloyl)-β-glucopyranoside (isoscoparin 2″-*O*-(6‴-(*E*)-feruloyl)-β-glucopyranoside).

The minor components **11** and **12** observed in the LC–MS analysis of the sample containing **7** (both giving deprotonated molecules at *m*/*z* 931) were resolved chromatographically. Both generated a $[(M–H)–162]^-$ product ion in MS–MS experiments, like **7**, and in MS^3 experiments the CID spectra of these ions, at *m*/*z* 769, were the same as the CID spectra of deprotonated **8** and **9**, respectively. These data suggested that **11** and **12** were the 4′-*O*-glucosides of **8** and **9**. Site selective excitation of the minor component methoxy resonances for **11** and **12** at δ 3.82 was carried out by 1D XSROESY as before. This gave ROE connectivities to minor component resonances at δ 7.09 and 7.41 (*d*, *J* = 2.2 Hz) (analogous to δ 7.06 and 7.37 in the sample containing **6** and

8–**10**), and a much weaker connectivity to δ 5.00, the anomeric proton of the 4′-*O*-glucosyl group. The two methoxy derivatives **11** and **12**, were therefore identified as isovitexin 2″-*O*-(6‴-(*E*)-feruloyl)-β-glucopyranoside-4′-*O*-β-glucopyranoside, and 3′-methoxyisovitexin 2″-*O*-(6‴-(*E*)-*p*-coumaroyl)-β-glucopyranoside-4′-*O*-β-glucopyranoside (isoscoparin 2″-*O*-(6‴-(*E*)-feruloyl)-β-glucopyranoside-4′-*O*-β-glucopyranoside). Deprotonated molecules of an equivalent glucoside of **10** were not observed in the LC–MS analysis.

Compounds **6** and **7** have not been reported previously in the literature, and are new examples of acylated flavone *C*-glycosides. Of the minor components **8**–**12**, only two (**8** and **10**) are known, and were isolated originally from methanolic extracts of the rice plant, *Oryza sativa* (Besson et al., 1985). Earlier work on *Cucumis* flavonoids appears to be relatively limited. Monties et al. (1976) partially characterised four flavone *C*-glucosides from *C. melo* as 6-*C*-diglucosylapigenin, 6-*C*-diglucosylluteolin, and the caffeic acid esters of these compound, and Saunders and McClure (1976) reported orientin in *C. maxima*. It is interesting to note in the context of the present study that the acylated flavone *C*-glucosides **6**–**12** were only detected in extracts of leaves of *C. sativus* that had been treated with silicon and infected with *Sphaerotheca fuliginea*, a causative agent of powdery mildew. This may indicate that they are accumulated as a response to stress conditions experienced by the plant.

3. Experimental

3.1. General

^{1}H NMR (500 and 300 MHz) and ^{13}C NMR (125 and 75 MHz) spectra were recorded in DMSO-d_6, with the residual solvent resonances used as internal standards at δ 2.50 and 39.5, respectively. Negative ion APCI-mass spectra were obtained with a quadrupole ion-trap instrument (Finnigan LCQ) using a vaporiser temperature of 550°C, sheath and auxiliary nitrogen gas pressures of 80 and 20 psi, a needle current of 5 μA, and a heated capillary temperature of 150°C. Samples were introduced by direct infusion, or via an HPLC fitted with a Merck LiChrospher 250×4.6 (i.d.) mm (5 μm particle size) C18 column using a 20 min linear gradient of 25–100% methanol in 1% aqueous acetic acid at 1 ml/min. MS^n experiments were performed in the ion trap using an ion isolation width of 5 Da and a collision energy of 50%.

3.2. Plant material

Seeds of cucumber, *Cucumis sativus* L. cv. Mustang, were sown in rockwool cubes and watered with distilled water until emergence. Seedlings were transferred individually to 500 ml jars containing nutrient solutions to which silicon (1.7 mM) had been added in the form of potassium silicate, and placed in a growth chamber (16 h photophase of ca. 145 μE m^{-2} s^{-1}, 23°C day/19°C night). Plants were grown until the fourth leaf had fully expanded, following which a conidial suspension of the biotrophic powdery mildew fungus *Sphaerotheca fuliginea* was sprayed onto the adaxial leaf surfaces until run-off, as described previously (Fawe et al., 1998). Non-treated control plants grown as above but without the addition of silicon were transferred to a similar growth chamber to minimise cross-infection. After 3 weeks both treated and untreated leaves were harvested and immediately frozen in liquid nitrogen. Leaf samples were stored at −80°C prior to analysis.

3.3. Extraction and isolation procedures

Infected leaf material of *C. sativus* grown in the presence of silicon was ground to a fine powder in liquid nitrogen (amount equivalent to 2.2 kg fr. wt). This was extracted at room temp. in two stages; first by steeping for 24 h in 100% MeOH and decanting the solvent, and second by steeping the residue for an additional 24 h in 50% aqueous MeOH (10 g fr. wt/100 ml solvent). Combined methanolic extracts were evaporated under reduced pressure to near dryness and the residue freeze-dried to yield 257 g crude extract. 200 g of this material was redissolved in a minimum quantity of MeOH and adsorbed onto polyvinylpolypyrrolidone (PVPP) packed in a Buchner funnel (2 l). The initial elution solvent was H_2O, followed by aq. EtOH (20, 50, 70%) and finally 100% EtOH. The 50% aq. EtOH bulk fraction was further chromatographed on a PVPP column using CH_2Cl_2–EtOH–MeCOEt–Me_2CO (1:1:1:1), yielding a mixture of flavone glycosides. Separation by low pressure liquid chromatography (Chemco low-prep. pump) using a MeOH-water gradient afforded **1**–**5**. Final purification of these compounds was achieved by column chromatography using Sephadex LH-20 (50×1 cm i.d.) with MeOH as eluting solvent, and gave **1** (28.0 mg), **2** (3.3 mg), **3** (2.4 mg), **4** (18.4 mg) and **5** (8.1 mg). Identification was achieved by standard procedures (Mabry et al., 1970; Markham, 1982), including acid hydrolysis in 2 M and 0.1 M HCl, alkaline hydrolysis, H_2O_2 oxidation, UV spectroscopy (with the use of shift reagents), MS, and comparison of ^{1}H and ^{13}C NMR spectra with literature data (Agrawal, 1989; Markham and Geiger, 1993). Compounds **6** and **7** were also present in the 50% aq. EtOH bulk fraction, but required further separation by HPLC (see Section 3.4).

3.4. Analytical and semi-prep. HPLC

A Waters Delta Prep 4000 LC system equipped with a 996 photodiode array detector was used for HPLC. For analytical work, dilute solutions of freeze-dried crude

extracts (10 mg ml^{-1}; both with and without spiking by standards) were passed through Acrodisc filters (0.45 μm) and 10 μl aliquots injected onto a Waters reverse-phase analytical column of 150×3.9 mm (i.d.) packed with Nova-Pak C18 material (4 μm, 60 Å). A gradient profile using two solvents was applied at room temp. (Van Sumere et al., 1993), with solvent A = 5% aq. HCO_2H, solvent B = CH_3CN:MeOH (5:95) and a flow rate of 0.9 ml min^{-1}. Compounds of interest were detected on the basis of characteristic UV-vis spectra (spectral range 220–390 nm) and retention time. Semi-prep. HPLC was carried out using two Waters prep. cartridges in series, each of 100×25 mm (i.d.), and packed with Nova-Pak HR C18 material (6 μm, 60 Å). A gradient profile using two solvents was applied at room temp. (Grayer and Veitch, 1998), with solvent A = H_2O, solvent B = MeOH and a flow rate of 3 ml min^{-1}. This procedure was applied to those fractions identified from analytical HPLC as containing the acylated flavone *C*-glycosides **6** and **7** (recognised from their distinctive UV-vis spectra). Repeated cycles of semi-prep. HPLC gave **6** (15.0 mg) and **7** (13.6 mg) in quantities sufficient for spectroscopic analysis and with a purity of ca. 90–95%.

3.5. Isovitexin 2″-O-(6‴-(E)-p-coumaroyl)-β-glucopyranoside (6)

Yellow solid; UV λ_{max} MeOH nm: 273, 294*sh*, 321; + NaOMe 280, 335*sh*, 380 (increased intensity); + $AlCl_3$ 280, 305, 330, 356*sh*, 384*sh*; + $AlCl_3$ and HCl 282, 302, 330, 382*sh*; + NaOAc 279, 298*sh*, 309*sh*, 375; + NaOAc and H_3BO_3 274, 319; ^1H NMR (DMSO-d_6): see Table 1; ^{13}C NMR (DMSO-d_6): see Table 1; APCI–MS (negative mode) *m*/*z*: 739 $[M\text{-}H]^-$.

3.6. Isovitexin 2″-O-(6‴-(E)-p-coumaroyl)-β-glucopyranoside-4′-O-β-glucopyranoside (7)

Yellow solid; UV λ_{max} MeOH nm: 278, 316; + NaOMe 269*sh*, 282*sh*, 293, 308*sh*, 363 (no change in intensity); + $AlCl_3$ 283*sh*, 305, 325, 385*sh*; + $AlCl_3$ and HCl 283*sh*, 305, 325, 382*sh*; + NaOAc 280, 303*sh*, 312*sh*, 380*sh*; + NaOAc and H_3BO_3 280, 303*sh*, 315; ^1H NMR (DMSO-d_6): see Table 1; ^{13}C NMR (DMSO-d_6): see Table 1; APCI–MS (negative mode) *m*/*z*: 901 $[M–H]^-$.

Abstract

Two 3(2H)-benzofuranones and three chromanes were isolated from the mycoparasitic fungus *Coniothyrium minitans*. Their structures and absolute stereochemistry were determined by spectroscopic methods. © 2001 Published by Elsevier Science Ltd.

Keywords: *Coniothyrium minitans*; Benzofuranones; Chromanes; Circular dichroism; Absolute configuration

1. Introduction

The fungus *Coniothyrium minitans* Campbell (Cm) is an aerobic mycoparasite capable of attacking the fungal plant pathogen *Sclerotina sclerotiorum* (Lib) de Bary (Huang and Hoes, 1976) resulting in the degradation of sclerotia (Huang and Kokko, 1987) and hyphae (Huang and Kokko, 1988) of the pathogen. Different strains of *C. minitans* have been identified based on morphological features such as color of cultures grown on artificial media (Huang, 1981). These features are, however, developmentally regulated or influenced by genotypic traits and environmental interaction. Jones et al. (1974) reported that β-1,3-endo- and exo-glucanases from *C. minitans* were responsible for the degradation of cell-wall glucans of *S. sclerotiorum*. *C. minitans* is used as a biological agent against Sclerotinia wilt of sunflower (Huang, 1980) and lettuce drop (Budge et al., 1995) caused by *S. sclerotiorum*. The plant pathogen *S. sclerotiorum*, commonly known as a white mold fungus, causes major losses in oilseed and pulse crops (Purdy, 1979) and no effective plant resistance has been identified so far. Whether metabolites of *C. minitans* might play a role in attacking and colonizing *S. sclerotiorum* is still unknown. In this paper we report the isolation and characterization of secondary metabolites produced when *C. minitans* is grown in artificial medium in which the only source of carbon is a sterilized powder made from sclerotia of *S. sclerotiorum*.

2. Results and discussion

The culture of *Coniothyrium minitans* strain LRS2130 was filtered and the filtrate was concentrated and extracted with EtOAc. The crude EtOAc extract was subjected to flash chromatography on silica gel with petroleum ether–CH_2Cl_2–EtOH gradient to give eight fractions. Further preparative TLC or HPLC purification of these fractions provided the new metabolites **1**–**5**, the common metabolites tyrosol, thriptophol, indole-3-carboxylic acid, and uracil, as well as dibutylphthalate and bis-(2-ethylhexyl)phthalate which are probably artifacts. In this study we report the structure elucidation of compounds **1**–**5**.

Compound **1** was isolated as an amorphous powder. The molecular formula, $C_{10}H_{10}O_3$, was established from the HREIMS spectrum. The ^{1}H NMR spectrum of **1** showed signals for three adjacent aromatic protons [δ 6.82, 6.84 (each 1H, *br d*, $J = 7.9$ Hz, 7.47 (1H, *t*, $J = 7.9$ Hz)] and two methyl group singlets. The ^{13}C NMR spectrum showed, in addition to the signals for a 1,2,3-trisubstituted phenyl ring, signals for two methyl groups, of a quaternary carbon atom (δ 102.7), and of a carbonyl group. Therefore, the structure of **1** was

established as 2-hydroxy-2,4-dimethyl-3(2H)-benzofuranone.

Compound **2** was isolated as an amorphous yellow powder with a molecular formula $C_{10}H_{10}O_4$ as determined by HREIMS. Its ^1H and ^{13}C NMR spectra were similar to those of **1** and of cycloarthropsone isolated from liquid cultures of the fungus *Arthropsis truncata* (Ayer et al., 1992). The ^1H and ^{13}C NMR spectra, however, lacked signals due to an (E)-propenyl moiety at C-4 in cycloarthropsone and instead showed signals of an aromatic methyl group [δ_H 2.42 (3H, *s*), δ_C 17.1]. Furthermore, the HREIMS spectrum displayed the characteristic loss of hydroxyl and acetyl groups (see Experimental), which suggested that compound **2** is 2,7-dihydroxy-2,4-dimethyl-3(2H)-benzofuranone. This structure was confirmed by the HMBC spectrum which placed the aromatic methyl group at C-4 (cross peak between the methyl group signal (δ_H 2.42) and C-3a (δ_C 118.7)).

Compound **3** was isolated as an amorphous powder, $[\alpha]_D$ +39.0°C. Its molecular formula, $C_{13}H_{16}O_4$, was determined by HREIMS. The ^1H NMR spectrum of **3** showed signals for two methyl groups, one acetyl group, two mutually coupled methine protons at δ 3.52 and 4.55 (each 1H, J = 8.5 Hz) and three aromatic protons characteristic of a 1,2,4-trisubstituted phenyl ring. The ^1H NMR spectroscopic data were similar to those of *trans*-2,2-dimethyl-3,4,7-trihydroxy-6-acetylchromane isolated from *Helianthella quinquenervis* (Herz and Kulanthaivel, 1984), except for the aromatic proton signals. The HMBC spectrum positioned the acetyl group at C-6 (cross peak between H-5 (δ 8.15) and C-4 (δ 69.6). From the above data, the structure of compound **3** was established as that of 2,2-dimethyl-3,4-dihydroxy-6-acetylchromane. The relative stereochemistry of the two hydroxyl groups at C-3 and C-4 was determined as *trans* on the basis of the coupling constant $J_{H\text{-}3,H\text{-}4}$ = 8.5 Hz. A W-type long range coupling between H-3 and one of the methyl signals on C-2 (δ 1.21) was observed. Furthermore, the conformation of the pyrane ring was deduced from the ^1H–^1H COSY and the TROESY spectra. The TROESY spectrum showed a cross peak between H-4 and the methyl signal at δ 1.21. The above information indicated that the relationship between H-3 and methyl group at δ 1.21 to be quasi-trans axial and between H-4 and this methyl group to be 1,3-di-quasi axial in a pyrane ring with a half-chair conformation. The absolute configuration of **3** was derived from the CD spectrum of the corresponding p-nitrobenzoate (**3a**) which showed a negative first Cotton effect ($\Delta\varepsilon$ −9.92 at 270 nm) and a positive second Cotton effect ($\Delta\varepsilon$ + 4.10 at 243 nm) (Harada and Nakanishi, 1983; Jennings, 1982). Hence, **3** is (3*S*, 4*R*)-6-acetyl-3,4-dihydroxy-2,2-dimethylchromane.

Compound **4** was isolated as an amorphous powder, $[\alpha]_D$ −25.6°C. Its ^1H NMR spectrum closely resembled that of **3**, except that the proton signals at H-3 (δ 3.73) and H-4 (δ 4.85) were shifted downfield and their coupling constant (J = 4.2 Hz) was significantly smaller than that of **3** which indicates that **4** is a *cis*-diol. The stereochemistry of **4** was further supported by the

TROESY spectrum which showed correlations between H-4 and one of the methyl group signals (δ 1.29), and between H-3 and H-4. This leaves 3-OH and the methyl group at δ 1.29 in quasi-*trans*-axial orientation. Furthermore, the *p*-nitrobenzoate derivative **4a** showed a negative first ($\Delta\varepsilon$ −9.89 at 275 nm) and a positive second ($\Delta\varepsilon$ +5.39 at 250 nm) Cotton effect which is consistent with the absolute configuration (3*S*,4*S*)-6-acetyl-3,4-dihydroxy-2,2-dimethylchromane for compound **4**.

Compound **5** was isolated as an inseparable mixture (2:1) of two isomers. The molecular formula, $C_{13}H_{18}O_4$, was deduced from the HREIMS spectrum. Its ^1H and ^{13}C NMR spectra were similar to those of **3**. The ^1H NMR spectrum of **5**, however, lacked the signals due to the C-6 acetyl group of **3** and instead showed signals of an oxygenated methine proton [δ 4.76 (1H, *q*, $J=6.5$ Hz)] and a methyl group [δ 1.41 (3H, *d*, $J=6.5$ Hz)]. Furthermore, the ^1H NMR spectrum of **5** showed two sets of H-5, H-7 and H-8 signals, and H-5 and H-7 were shifted upfield compared with those of **3**. The relative stereochemistry of **5** at C-3 and C-4 was established as *trans* on the basis of the vicinal coupling $J_{H\text{-}3,H\text{-}4}=8.5$ Hz which is identical to the same coupling of the diol **3**. Compound **5** is, therefore, a mixture of epimers at C-11 of *trans*-6-(1-hydroxyethyl)-3,4-dihydroxy-2,2-dimethylchromane. The absolute configuration at C-3 and at C-4 was not determined since there was insufficient quantity of this compound available.

This is the first report of the isolation of metabolites from fungi of the genus *Coniothyrium*. Evaluation of the biological activity of the new metabolites is currently in progress.

3. Experimental

3.1. General experimental procedures

The HREIMS, LRESMS and HRESMS were recorded on an AEI-50 mass spectrometer. Optical rotations were determined with a Perkin Elmer 241 polarimeter with a cell length of 10 cm and CD spectra were measured on a Jasco ORD-CD spectrometer with a cell path of 1 mm. UV spectra were measured on a Hewlett Packard Diode Array UV–vis spectrometer (ICP) with a cell path of 1 mm. ^1H NMR, ^{13}C NMR, TROESY, ^1H–^1H COSY, HMQC and HMBC spectra were recorded on Brüker AM-200, AM-300, Varian IINOVA 300 and 500 spectrometers. Chemical shifts are given on a δ (ppm) scale and the solvent signal was used as reference. Carbon multiplicities were measured with APT and HMQC sequences. Pre-coated TLC plates, SIL G-25, 20×20 cm, 0.25 mm layer (Macherey-Nagel) were used for preparative TLC. Column chromatography (C.C.) was carried out on silica gel 60 (EM Science; 230–400 mesh) and Sephadex LH-20 (Pharmacia Fine Chemicals). Preparative HPLC was carried out on a Waters HPLC system (pump, 600E; detector, 490E) using Waters μ-Bondapak C_{18} (7.8 mm i.d.× 30 cm) column. SKB refers to Skelly Oil Company light petroleum, bp 60–68°C.

3.1.1. Fungal growth

Coniothyrium minitans strain LRS2130 was originally isolated from sclerotia of *S. sclerotiorum* produced on a diseased sunflower plant in Manitoba, Canada and stock cultures were lyophilized (Huang, 1981). Voucher specimens are deposited at the Lethbridge Research Centre, Agriculture and Agri-Food, Canada, as LRS2130 and at ATCC (Manassas, VA) as ATCC 74417. The fungus was grown in shake cultures (140 rpm) using modified Czapek-Dox medium (per litre: $NH_4H_2PO_4$, 2.0 g, K_2HPO_4, 1.0 g, $MgSO_4.7H_2O$, 0.5 g, KCl, 0.5 g, $FeSO_4$, 0.01 g, 1 ml 1% $ZnSO_4$, 1 ml 0.5% $CuSO_4$ and 1% dry powder of sclerotia of *S. sclerotiorum* as carbon source). Cultures were grown in 4 l brown glass bottles for 12 days at 20°C.

3.1.2. Isolation of metabolites

The mycelium was separated by filtration and the broth (80 l) was concentrated under reduced pressure to approximately 1/10 of its original volume. The broth was extracted by stirring with an equal volume of EtOAc (3 times). Due to poor separation, each extraction had to be filtered through celite to result in definitive layers. The EtOAc extract was dried (anhydr $MgSO_4$) and filtered with the solvent evaporated under reduced pressure to afford 5.84 g of crude EtOAc extract. The latter was subjected to flash column chromatography (C.C.) on silica gel using SKB–CH_2Cl_2–EtOH of increasing polarity, and the eluate was separated into eight fractions [fr. 1 (131 mg), fr.2 (150 mg), fr.3 (2600 mg), fr.4 (1104 mg), fr.5 (538 mg), fr.6 (469 mg), fr.7 (133 mg) and fr. 8 (187 mg)]. Fraction 1 (80 mg) was subjected to preparative TLC with benzene–EtOAc (10:0.5). The UV-active zone at R_f 0.28 gave pure dibutylphthalate (1.5 mg). The UV-active fraction of R_f 0.44 gave a crude product which was further subjected to preparative HPLC (solvent: MeOH, UV detection: 220 nm, flow rate: 1.5 ml/min) to give pure bis-(2-ethylhexyl)phthalate (Rt 11.0 min, 4.0 mg). Fr. 2 (80.0 mg) was subjected to preparative TLC with benzene–EtOAc (10:1, two-fold development). The UV-active zone at R_f 0.45 gave a crude product which was further purified by preparative TLC with hexane–Et_2O (8:5, three-fold development, R_f 0.49) to give pure **1** (1.5 mg). Fraction 3 (2600 mg) was applied to a silica gel column using SKB–EtOAc (5:1, 4:1, 3:1, 3:2, 1:1, 1:2 and 1:4) and EtOAc as eluant, with it separated into seven fractions [fr. 3-1 (99.7 mg), fr. 3-2 (103.0 mg), fr. 3-3 (83.6 mg), fr. 3-4 (83.3 mg), fr. 3-5 (928.6 mg), fr. 3-6 (155.5 mg) and fr.3-7 (1109.4 mg)]. Fraction 3-5 (200 mg) was subjected

to preparative HPLC [solvent: MeOH–H_2O (2:3), UV detection: 215 nm, flow rate: 1.5 ml/min) to give pure tyrosol (Rt 11.0 min, 4.0 mg) and **3** (Rt 27.6 min, 3.0 mg) and a mixture of three compounds (Rt 18.0–20.2 min). This mixture was further purified by preparative HPLC [solvent: CH_3CN–H_2O (2:3) and MeOH–H_2O (2:3); UV detection: 215 nm] to give pure indole-3-carboxylic acid (15.0 mg), tryptophol (5.0 mg) and **2** (3.0 mg). The remainder of fr. 3-5 was combined with fr. 3-4 (fr. 3-4, 5). Fraction 3-4,5 (810 mg) was applied to a Sephadex LH-20 column eluted with 50% MeOH, and the eluate was separated into five fractions [fr. 3-4,5-1 (410 mg), fr. 3-4,5-2 (188 mg), fr. 3-4,5-3 (68 mg), fr. 3-4,5-4 (24 mg) and fr. 3-4,5-5 (10 mg)]. Fraction 3-4,5-2 (100 mg) was subjected to preparative HPLC [solvent: MeOH–H_2O (2:3), UV detection: 280 nm, flow rate: 1.25 ml/min] to give pure **2** (Rt 24.4 min, 6.0 mg), **3** (Rt 35.6 min, 5.0 mg) and **4** (Rt 29.0 min, 2.0 mg). Fractions 3-4,5-3 and 3-4,5-4 were purified by preparative TLC with hexane-acetone (1:1), respectively. The UV active zone at R_f 0.38 gave tryptophol (2.0 mg) while the zone at R_f 0.24 gave indole-3-carboxylic acid (6.0 mg). Fraction 3-6 (148.0 mg) was crystallized from MeOH to afford pure uracil (5.0 mg). The remainder of fr. 3-6 was subjected to Sephadex LH-20 chromatography (50% of MeOH as eluant) to give three fractions (Frs. 3-6-1 ~ 3-6-3). Fraction 3-6-2 (23.8 mg) was purified by preparative HPLC [solvent: MeOH–H_2O (3:2), UV detection: 220 nm, flow rate: 1.5 ml/min] to give **5** (Rt 25.0 min, 2.0 mg).

*3.1.2.1. 2-Hydroxy-2,4-dimethyl-3(2H)-benzofuranone (**1**).* Amorphous powder; $[\alpha]_D$ −15.0°C (*c* 0.02, MeOH); UV λ_{max}(MeOH) nm (log ε): 216 *sh* (4.07), 256 (3.65), 340 (3.16), 342 (3.14); ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.63 (3H, *s*, 8-CH_3), 2.56 (3H, *br s*, 9-CH_3), 6.82, 6.84 (each 1H, *br d*, *J* = 7.9 Hz, H-5,7), 7.47 (1H, *t*, *J* = 7.9 Hz, H-6); ^{13}C NMR (125.7 MHz, $CDCl_3$): δ 17.9 (C-9), 22.7 (C-8), 102.7 (C-2), 110.5 (C-7), 114.5 (C-3a), 123.7 (C-5), 138.5 (C-6), 141.0 (C-4), 170.4 (C-7a), 199.3 (C-3); HREIMS *m*/*z* (rel. int.): $[M]^+$ 178.0630 (15, $C_{10}H_{10}O_3$ required 178.0630), 161.0598 (6, $C_{10}H_9O_2$ required 161.0603), 135.0445 (100, $C_8H_7O_2$ required 135.0446), 118.0419 (16, C_8H_6O required 118.0419), 107.0496 (15, C_7H_7O required 107.0497), 90.0468 (23, C_7H_6 required 90.0469), 77.0395 (17, C_6H_5 required 77.0391).

*3.1.2.2. 2,7-Dihydroxy-2,4-dimethyl-3(2H)-benzofuranone (**2**).* Amorphous yellow powder; $[\alpha]_D$ −7.03°C (*c* 0.37, MeOH); UV λ_{max}(MeOH) nm (log ε): 204 (3.90), 208 (3.91), 232 (3.76), 274 (3.69), 358 (3.18); ^{1}H NMR (300 MHz, CD_3OD): δ 1.52 (3H, *s*, 8-CH_3), 2.42 (3H, *br s*, 9-CH_3), 6.65 (1H, *dq*, *J* = 7.9, 0.8 Hz, H-5), 6.98 (1H, *d*, *J* = 7.9 Hz, H-6); ^{13}C NMR (75.5 MHz, CD_3OD): δ 17.1 (C-9), 22.1 (C-8), 104.9 (C-2), 118.7 (C-3a), 124.0 (C-5), 125.0 (C-6), 130.9 (C-4), 142.6 (C-7), 160.6 (C-7a), 202.6 (C-3); HREIMS *m*/*z* (rel. int.): $[M]^+$ 194.0586 (17, $C_{10}H_{10}O_4$ required 194.0579), 177.0553 (9, $C_{10}H_9O_3$ required 177.0552), 151.0392 (100, $C_8H_7O_3$ required 151.0395), 134.0371 (3, $C_8H_6O_2$ required 134.0368), 123.0445 (12, $C_7H_7O_2$ required 123.0446), 106.0418 (15, C_7H_6O required 106.0419), 77.0390 (15, C_6H_5 required 77.0391).

*3.1.2.3. (3S,4R)-6-Acetyl-3,4-dihydroxy-2,2-dimethylchromane (**3**).* Amorphous powder; $[\alpha]_D$ +39.0°C (*c* 0.42, MeOH); UV λ_{max}(MeOH) nm (log ε): 223 (4.01), 276 (4.07) ; ^{1}H NMR (300 MHz, CD_3OD): δ 1.21 (3H, *s*, 9-CH_3), 1.46 (3H, *s*, 10-CH_3), 2.54 (3H, *s*, 12-CH_3), 3.52 (1H, *d*, *J* = 8.5 Hz, H-3), 4.55 (1H, *d*, *J* = 8.5 Hz, H-4), 6.80 (1H, *d*, *J* = 8.6 Hz, H-8), 7.81 (1H, *dd*, *J* = 8.6, 2.2 Hz, H-7), 8.15 (1H, *d*, *J* = 2.2 Hz, H-5); ^{13}C NMR (50.3 MHz, CD_3OD): 19.7 (C-9), 26.4 (C-12), 27.1 (C-10), 69.6 (C-4), 76.4 (C-3), 81.0 (C-2), 117.9 (C-8), 126.0 (C-4a), 130.7, 131.0 (C-5 and 7), 131.2 (C-6), 158.5 (C-8a), 199.4 (C-11); HREIMS *m*/*z* (rel. int.): $[M]^+$ 236.1044 (64, $C_{13}H_{16}O_4$ required 236.1049), 221.0808 (10, $C_{12}H_{13}O_4$ required 221.0814), 203.0696 (9, $C_{12}H_{11}O_3$ required 203.0708), 178.0621 (16, $C_{10}H_{10}O_3$ required 178.0630), 165.0552 (100, $C_9H_9O_3$ required 165.0552), 149.0241 (62, $C_8H_5O_3$ required 149.0239), 123.0440 (25, C_7H_7O required 123.0446), 105.0339 (7, C_7H_5O required 105.0340), 77.0394 (19, C_6H_5 required 77.0391); CD: $\Delta\varepsilon_{300}$ +0.65 (MeOH, *c* 0.00093 M).

*3.1.2.4. Preparation of diester of **3**.* To a solution of **3** (2.0 mg, 0.0085 mmol) and 4-dimethylaminopyridine (1.0 mg) in pyridine (1.0 ml) and dry CH_2Cl_2 (1.0 ml) was added *p*-nitrobenzoyl chloride (5.9 mg, 0.032 mmol). The reaction mixture was kept at Rt for 2 days, then the mixture was diluted with 15 ml of EtOAc and washed with 8 ml of 5% Na_2CO_3 solution and then with water. The organic layer was separated and the solvent was removed under vacuum. The residue was subjected to preparative TLC with hexane-acetone (1:1). The UV-active zone (R_f 0.55) was extracted with EtOAc to give 3.0 mg (66.2%) of diester **3a** as a colorless solid, $[\alpha]_D$ −56.7° (*c* 0.3, MeOH); UV λ_{max}(MeOH) nm (log ε): 222 sh (4.25), 262 (4.53); ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.51, 1.57 (each 3H, *s*, 9, 10-CH_3), 2.50 (3H, *s*, 12-CH_3), 5.66 (1H, *d*, *J* = 6.1 Hz, H-3), 6.45 (1H, *d*, *J* = 6.1 Hz, H-4), 7.02 (1H, *d*, *J* = 8.3 Hz, H-8), 7.90 (1H, *dd*, *J* = 2.2 Hz, H-5), 7.92 (1H, *dd*, *J* = 8.3, 2.2 Hz, H-7), 8.12–8.28 (8H, *m*); HREIMS *m*/*z* (rel. int.): $[M]^+$ 534.1270 (0.5, $C_{27}H_{22}O_{10}N_2$ required 534.1274); CD: $\Delta\varepsilon_{270}$-9.92, $\Delta\varepsilon_{243}$ +4.10 (MeOH, c 0.00028 M).

*3.1.2.5. (3S,4S)-6-Acetyl-3,4-dihydroxy-2,2-dimethylchromane (**4**).* Amorphous powder; $[\alpha]_D$ −25.6°C (*c* 0.09, MeOH); UV λ_{max} (MeOH) nm (log ε): 202 (4.07), 225 (3.89), 280 (3.95); ^{1}H NMR (300 MHz, CD_3OD): δ 1.29 (3H, *s*, 9-CH_3), 1.47 (3H, *s*, 10-CH_3), 2.54 (3H, *s*,

12-CH_3), 3.73 (1H, *d*, $J=4.0$ Hz, H-3), 4.85 (1H, *d*, $J=4.0$ Hz, H-4), 6.80 (1H, *d*, $J=8.6$ Hz, H-8), 7.81 (1H, *dd*, $J=8.6$, 2.1 Hz, H-7), 8.18 (1H, *d*, $J=2.1$ Hz, H-5); ^{13}C NMR (75.5 MHz, CD_3OD): δ 24.8, 25.0 (C-9 and 10), 26.3 (C-12), 65.7 (C-4), 72.1 (C-3), 80.3 (C-2), 117.7 (C-8), 124.4 (C-4a), 130.5, 131.3 (C-5 and 7), 131.1 (C-6), 160.0 (C-8a), 199.5 (C-11); HREIMS *m*/*z* (rel. int.): $[M]^+$ 236.1045 (56, $C_{13}H_{16}O_4$ required 236.1048), 221.0814 (6, $C_{12}H_{13}O_4$ required 221.0814), 203.0703 (4, $C_{12}H_{11}O_3$ required 203.0708), 178.0627 (11, $C_{10}H_{10}O_3$ required 178.0630), 165.0548 (100, $C_9H_9O_3$ required 165.0552), 149.0233 (63, $C_8H_5O_3$ required 149.0238), 123.0445 (21, C_7H_7O required 123.0446), 105.0340 (4, C_7H_5O required 105.0340), 77.0390 (16, C_6H_5 required 77.0391); CD: $\Delta\varepsilon_{285}$ −0.56 (MeOH, *c* 0.00076 M).

*3.1.2.6. Preparation of diester of **4***. To a solution of **4** (0.5 mg, 0.0021 mmol) and 4-dimethylaminopyridine (0.5 mg) in pyridine (0.5 ml) and dry CH_2Cl_2 (0.5 ml) was added *p*-nitrobenzoyl chloride (1.5 mg, 0.0081 mmol). The reaction mixture was kept at Rt for 2 days. The crude product was purified by preparative TLC with hexane-acetone (1:1) (R_f 0.56) to give 1.0 mg (88%) of diester **4a** as a colorless solid, $[\alpha]_D$ −58.9°C (*c* 0.09, MeOH); UV λ_{max}(MeOH) nm (log ε): 225 *sh* (4.00), 261 (4.27); ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.54, 1.56 (each 3H, *s*, 9,10-CH_3), 2.52 (3H, *s*, 12-CH_3), 5.75 (1H, *d*, $J=4.2$ Hz, H-3), 6.55 (1H, *d*, $J=4.2$ Hz, H-4), 7.04 (1H, *d*, $J=8.2$ Hz, H-8), 7.92–8.22 (10H, *m*); HREIMS *m*/*z* (rel. int.): $[M]^+$ 534.1243 (2, $C_{27}H_{22}O_{10}N_2$ required 534.1274); CD: $\Delta\varepsilon_{275}$-9.89, $\Delta\varepsilon_{250}$ +5.39 (MeOH, *c* 0.00034 M).

*3.1.2.7. Trans-6-(1-hydroxyethyl)-3,4-dihydroxy-2,2-dimethylchromane (**5**)*. Received 12 October 2000; received in revised form 1 February 2001

Abstract

Four 7,20-epoxy *ent*-kaurane diterpenoids, xerophilusins G (**1**) and I–K (**2**–**4**), were isolated from the leaves of *Isodon xerophilus*, along with four known ones, enanderianin C (**5**), rosthorin A (**6**), longikaurin B (**7**), and rabdoternin D (**8**). Their structures were determined primarily using NMR spectroscopic techniques. The structure and stereochemistry of **3** were confirmed by X-ray crystallography. Compounds **4** and **7** exhibited broad cytotoxicity against four kinds of human tumor cells (K562, HL-60, HCT, and MKN-28 cells) in the range of 2.23–15.35 and 0.30–8.61 μg/ml, respectively. © 2001 Elsevier Science Ltd. Keywords: *Isodon xerophilus*; Labiatae; *ent*-Kaurane diterpenoids; Xerophilusins G, I–K

1. Introduction

In the course of searching for biologically active diterpenoids from *Isodon* species, we have discovered a series of *ent*-kaurane diterpenoids with antitumor activity from *Isodon xerophilus* (C.Y. Wu and H.W. Li) H. Hara (Labiatae) (Hou et al., 2000). Continuing phytochemical investigation on this plant led to the isolation of four new 7,20-epoxy *ent*-kauranoids, xerophilusins G (**1**) and I–K (**2**–**4**), along with four known ones, enanderianin C (**5**) (Wang et al., 1998a), rosthorin A (**6**) (Li and Wang, 1984), longikaurin B (**7**) (Takeda et al., 1988) and rabdoternin D (**8**) (Takeda et al., 1994). Compounds **1**, **2**, and **5** are three of a few compounds having 1β substituents (Wang et al., 1997, 1998b). Compounds **1**–**7** were tested for their cytotoxicity toward K562, HL-60, HCT, and MKN-28 cells. This paper describes the structural characterization of **1**–**4** and the biological evaluation of **1**–**7**.

2. Results and discussion

After chromatographic purification on silica gel, the EtOAc soluble portion of the Me_2CO extract of *I. xerophilus* yielded four new diterpenoids, xerophilusins G (**1**) and IK (**2**–**4**), as well as four known ones, enanderianin C (**5**), rosthorin A (**6**), longikaurin B (**7**) and rabdoternin D (**8**).

Xerophilusin G (**1**), colorless needles, had a molecular formula of $C_{22}H_{30}O_8$ established by positive HRFABMS (obsd 423.1955, calc. 423.2019). Its UV (λ_{max} at 237.5 nm), IR (ν_{max} at 1704 and 1642 cm^{-1}), and NMR [^1H NMR δ 6.21 and 5.44 (each 1H, *s*); ^{13}C NMR δ 209.3 (*s*), 152.9 (*s*), and 119.6 (*t*)] spectra showed an *exo*-methylene group conjugated with a carbonyl group on a five-membered ring. In addition, the ^{13}C NMR and DEPT spectra exhibited signals of an acetoxyl group [δ 170.9 (*s*) and 20.8 (*q*)], one methyl, six methylenes (including two oxygenated ones), six methines (including three oxygen-bearing ones), and four quaternary carbons (including a ketalic group at δ 98.9). These facts and the degree of unsaturation indicated the presence of a pentacyclic ring system. Considering the types of diterpenoids in the *Isodon* genus (Takeda et al., 1992; Wang et al., 1998b), the basic skeleton of **1** was considered to be 7β-hydroxy-7α, 20-epoxy-*ent*-kaur-16-en-15-one, which was substituted by three hydroxyl and one acetoxyl groups.

One oxygenated group was possibly at C-19 because only one methyl at δ 27.6 (Me-18) was observed. The methylene at δ 67.2 (C-19) and the correlation between Ha,b-19 and the ester carbonyl at δ 170.9 in HMBC spectrum proved the acetoxyl group at C-19. The signals at δ 3.63 (1H, *br s*) and δ 64.6 (*d*) and the downfield

shift of C-10 in NMR spectra suggested one hydroxyl group at C-1. The broad singlet of H-1 resulted from the β-orientation of 1-OH (Wang et al., 1997). On the basis of ^{1}H–^{1}H COSY and HMQC spectra, the other two hydroxyls were assigned to C-6 and C-14. According to the NOE effects (H-6α with Me-18 and Ha-19; H-14α with H-11α and H-20a), the two hydroxyls at C-6 and C-14 both had β-orientation. In conclusion, xerophilusin G (**1**) was elucidated as 1β, 6β, 7β, 14β-tetrahydroxy-19-acetoxy-7α, 20-epoxy-*ent*-kaur-16-en-15-one.

Xerophilusin I (**2**), isolated as an amorphous powder, had a molecular weight of 349.2039 (positive HRFABMS) corresponding to $C_{20}H_{29}O_5$. The difference between **2** and enanderianin C (**5**) was that Me-19 in **2** was unsubstituted, which was explained by the following findings. In the ^{13}C NMR spectrum of **2**, no signals attributed to an acetoxyl group were observed while a methyl signal at δ 23.1 replaced the signal at δ 67.1 (*t*, C-19) in **5**. Furthermore, the signals of C-3 and Me-18 in **2** shifted downfield without the γ-steric compression effect of OAc. A comparison of the ^{1}H NMR spectroscopic data showed that the absence of two AB-type doublets and a 3H singlet of OAc, and the presence of a methyl signal at δ 1.14 (Me-19) were notable characteristics of **2**. Therefore, xerophilusin I (**2**) was identified as 1β, 6β, 7β-trihydroxy-7α, 20-epoxy-*ent*-kaur-16-en-15-one.

Xerophilusin J (**3**), colorless needles, had a molecular formula of $C_{22}H_{30}O_8$ inferred from positive HRFABMS (obsd 423.2007, calc. 423.2019). Its UV, IR and NMR spectroscopic data, and the degree of unsaturation indicated that **3** was a 7β-hydroxy-7α, 20-epoxy-*ent*-kaur-16-en-15-one. The NMR spectra of **3** also suggested the presence of an acetoxy-bearing methine and two secondary hydroxyl groups. Moreover, the signals at δ 6.09 (1H, *s*) and δ 92.9 (*d*) were assigned to a hemiacetal structure at C-20. ^{1}H–^{1}H COSY, HMQC, and HMBC techniques disclosed that the acetoxyl and two hydroxyl groups were located at C-1, C-6 and C-14, respectively. The α-oriented 1-OAc was determined mainly through the peak form (*dd*) and the coupling constants (J = 4.9, 11.5 Hz) of H-1. The β-orientation of 6-OH and 14-OH was determined by the ROESY correlations: H-6α with Me-19; H-14α with H-11α and H-20. The *R* form of C-20 was also defined by the cross peaks of H-20 with H-11α and H-14α in the ROESY spectrum. Thus, xerophilusin J (**3**) was established as 1α-acetoxy-6β, 7β, 14β, 20(*R*)-tetrahydroxy-7α, 20-epoxy-*ent*-kaur-16-en-15-one, which was further confirmed by X-ray crystallographic analysis (Fig. 1).

Xerophilusin K (**4**), $C_{22}H_{30}O_7$ (positive HRFABMS, obsd 407.2061 calc. 407.2070), was isolated as colorless needles. The ^{1}H and ^{13}C NMR spectra of **4** were very similar to those of rosthorin A (**6**) (Li and Wang, 1984). However, observed in the ^{1}H NMR spectrum of **4** were the appearances of a signal due to an acetyl group (δ 2.07) and the downfield shift of the signal assigned to H-11 ($\Delta\delta$ + 0.99 ppm). Accordingly, xerophilusin K (**4**) was presumed as 11-acetylated rosthorin A as verified by the downfield shift of C-11 ($\Delta\delta$ + 3.0 ppm) and the upfield shift of C-9 ($\Delta\delta$ −6.1 ppm) and C-12 ($\Delta\delta$ −4.7 ppm) in the ^{13}C NMR spectrum of 4. Consequently, xerophilusin K (**4**) was assigned as 6β, 7β, 14β-trihydroxy-11β-acetoxy-7α,20-epoxy-*ent*-kaur-16-en-15-one.

Compounds **1**–**7** were examined for their cytotoxicity against four kinds of human tumor cells. From Table 1, it is noticeable that most of these compounds were more cytotoxic against K562, HL-60, and MKN-28 cells than HCT cells. The IC_{50} values of **4** and **7** against four kinds of tumor cells were all less than 16 μg/ml (2.23–15.35 and 0.30–8.61 μg/ml, respectively), indicating their broad cytotoxic activity. Compounds **2**, **3** and **5** exhibited significant inhibitory effects on K562, HL-60, and MKN-28

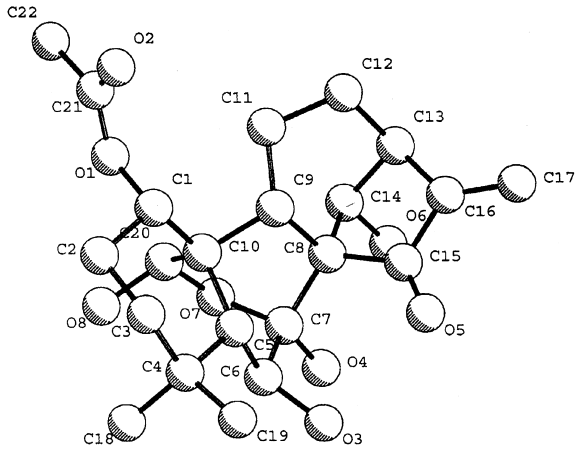

Fig. 1. Stereostructure of **3**.

cells with IC_{50} values lower than 5 μg/ml. However, they were inactive to HCT cells. Compound **1** was non-cytotoxic against K562, HCT, and MKN-28 cells, but it had the selectivity on HL-60 cells (IC_{50} = 3.93 μg/ml).

3. Experimental

3.1. General

All melting points were measured on an XRC-1 micro melting point apparatus and are uncorrected. Optical rotations were taken on a SEPA-300 polarimeter. IR spectra were measured on a Bio-Rad FTS-135 spectrometer with KBr pellets. UV spectra were obtained on a UV 210A spectrometer. MS were recorded on a VG Auto Spec-3000 spectrometer. 1D- and 2D-NMR spectra were run on a Bruker AM-400 and DRX-500 instrument with TMS as internal standard, respectively.

3.2. Plant material

The leaves of *I. xerophilus* were collected in Yuanyang prefecture of Yunnan Province in November 1998, and air-dried. The identity of plant material was verified by Professor Zhong-Wen Lin, and a voucher specimen (KIB 98-11-25 Lin) is deposited in the Herbarium of the Department of Taxonomy, Kunming Institute of Botany, Academia Sinica.

3.3. Extraction and isolation

The dried and powdered leaves (8.3 kg) were extracted with 70% ag. Me_2CO and filtered. The filtrate was concentrated and extracted with EtOAc and *n*-BuOH, successively. A portion (440 g) of the EtOAc extract (660 g) was applied to a Si gel column eluting with a $CHCl_3$–Me_2CO (1:0–0:1) gradient system to yield fractions I–VII. All fractions were collected and combined by monitoring with TLC. From fraction VI, **6** (1.1 g) was obtained as colorless needles by recrystallization in MeOH. The mother liquor was applied to MCI-gel CHP-20P column chromatography developing with MeOH–H_2O (6:4–9:1). The elute from MeOH–H_2O (8:2) was further purified by a Si gel column (petroleum ether–ether 7:3) to produce five fractions (combined by monitoring with TLC). Purification of the second fraction, using petroleum ether–isopropyl alcohol (4:1) on a Si gel column, gave **1** (3.3 g), **2** (35 mg), and **4** (88 mg). The third fraction afforded **3** (76 mg) and **5** (141 mg) after repeated Si gel column chromatography (petroleum ether–EtOAc 3:2; $CHCl_3$–Me_2CO 9:1) and recrystallization in MeOH. Fraction VII was fractionated by a combination of Si gel column chromatography and recrystallization to give **7** (260 mg) and **8** (98 mg).

White amorphous powder: $[\alpha]_D^{23}$ −146.3 (C_5H_5N,*c* 0.41); UV (MeOH)λ_{max} nm (log ε): 240.5 (3.98); IR (KBr) ν_{max} cm^{-1}: 3464, 3359, 3233, 2930, 1707, 1642, 1453, 1333, 1274, 1193, 1061; ^1H NMR (C_5D_5N, 400 MHz) δ 5.94 (1H, *s*, H-17a), 5.24 (1H, *s*, H-17b), 4.31 (1H, *d*, *J* = 5.1 Hz, H-6α), 4.12 (1H, ABd, *J* = 9.8 Hz, H-20a), 4.08 (1H, ABd, *J* = 9.8 Hz, H-20b), 3.66 (1H, *br s*, H-1α), 2.92 (1H, *dd*, *J* = 3.8, 9.2 Hz, H-13α), 2.53 (1H, *dd*, *J* = 3.8, 12.2 Hz, H-14β), 2.51 (1H, *dd*, *J* = 5.3, 12.5 Hz, H-9β), 2.38 (1H, *d*, *J* = 12.2 Hz, H-14α), 2.21 (1H, *m*, H-3α), 2.13 (1H, *d*, *J* = 5.1 Hz, H-5β), 2.12 (1H, overlap, H-12α), 2.11 (1H, overlap, H-11β), 1.86 (1H, *m*, H-11α), 1.74 (2H, *m*, H-2α,β), 1.36 (1H, *m*, H-12β), 1.30 (3H, *s*, Me-18), 1.22 (1H, *d*, *J* = 13.2 Hz, H-3β), 1.14 (3H, *s*, Me-19); ^{13}C NMR data, see Table 2; EIMS *m/z* (rel. int): 348 $[M]^+$ (100), 330 $[M–H_2O]^+$ (36), 320 (5), 312 $[M-2\times H_2O]^+$ (24), 297 (21), 284 (30), 269 (46), 256 (32), 243 (37); positive HRFABMS *m/z*: 349.2039 (calc. for $C_{20}H_{29}O_5$, 349.2015).

3.6. Xerophilusin J (**3**)

Colorless needles (MeOH): mp 165–166°C; $[\alpha]_D^{23}$ −80.7 (C_5H_5N,*c* 0.41); UV (MeOH) λ_{max} nm (log ε): 232.5 (3.47); IR (KBr) ν_{max} cm^{-1}: 3430, 2951, 1733, 1643, 1459, 1374, 1245, 1084, 1037; ^1H NMR (C_5D_5N, 400 MHz) δ 6.28 (1H, *s*, H-17a), 6.09 (1H, *s*, H-20), 5.50 (1H, *s*, H-17b), 5.17 (1H, *s*, H-14α), 4.95 (1H, *dd*, *J* = 4.9, 11.5, H-1β), 4.68 (1H, *m*, H-6α), 3.12 (1H, *d*, *J* = 9.3 Hz, H-13α), 2.39 (1H, *m*, H-2α), 2.27 (1H, *m*, H-12α), 2.01 (1H, overlap, H-9β), 1.99 (3H, *s*, OAc), 1.94 (1H, *m*, H-11α), 1.92 (1H, *m*, H-2β), 1.73 (1H, *d*, *J* = 9.3 Hz, H-5β), 1.53 (3H, *s*, Me-19), 1.43 (1H, overlap, H-12β), 1.43 (3H, *s*, Me-18), 1.42 (2H, overlap, H-3α,β), 1.41 (1H, overlap, H-11β); ^{13}C NMR data, see Table 2; EIMS *m/z* (rel. int): 422 $[M]^+$ (2), 404 $[M–H_2O]^+$ (18), 386 $[M-2\times H_2O]^+$ (4), 371 (1), 362 $[M–AcOH]^+$ (7), 344 $[M–AcOH–H_2O]^+$ (72), 326 (26), 315 (33), 298 (61), 280 (39), 269 (67); positive HRFABMS *m/z*: 423.2007 (calc. for $C_{22}H_{31}O_8$, 423.2019).

3.7. Xerophilusin K (**4**)

Colorless needles (MeOH): mp 189–190°C; $[\alpha]_D^{23}$ −44.3 (C_5H_5N,*c* 0.30); UV (MeOH) λ_{max} nm (log ε): 237.5 (3.79); IR (KBr) ν_{max} cm^{-1}: 3445, 2931, 1734, 1642, 1372, 1247, 1178, 1090, 1019; ^1H NMR (C_5D_5N, 400 MHz) δ 6.31 (1H, *s*, H-17a), 5.56 (1H, *s*, H-17b), 5.41 (1H, *m*, H-11α), 5.14 (1H, *s*, H-14α), 4.19 (1H, *d*, *J* = 5.8 Hz, H-6α), 4.17 (1H, ABd, *J* = 10.3 Hz, H-20a), 4.07 (1H, ABd, *J* = 10.3 Hz, H-20b), 3.18 (1H, *d*, *J* = 9.0 Hz, H-13α), 3.15 (1H, *m*, H-12α), 2.15 (1H, *d*, *J* = 9.3 Hz, H-9β), 2.07 (3H, *s*, OAc), 1.52 (1H, *m*, H-12β), 1.50 (1H, *d*, *J* = 5.8 Hz, H-5β), 1.34 (1H, *m*, H-3α), 1.29 (1H, overlap, H-1α), 1.26 (2H, *m*, H-2α,β), 1.24 (1H, overlap, H-1β), 1.23 (3H, s, Me-18), 1.11 (1H, *m*, H-3β), 1.05 (3H, *s*, Me-19); ^{13}C NMR data, see Table 2; EIMS *m/z* (rel. int): 406 $[M]^+$ (48), 360 (3), 346 $[M\text{-}AcOH]^+$ (9), 328 $[M\text{-}AcOH\text{-}H_2O]^+$ (8), 315 (3), 285 (6), 257 (7), 215 (10); positive HRFABMS *m/z*: 407.2061 (calc. for $C_{22}H_{31}O_7$ 407.2070).

3.8. X-ray crystallographic analysis of **3**

The compound crystallizes in the monoclinic group $P2_1$, *a* = 6.410 (1) Å, *b* = 11.841 (2) Å, *c* = 14.212 (3) Å, β = 97.34 (1)Å, V = 1069.9 (3) $Å^3$, *Z* = 2 and with the calculated density of 1.367 g/cm^3. The structure was solved by direct methods (SHELXS-86). The final R-factor is 0.087 with R_w 0.090 and *S* 3.108. All measurements were made on a MAC DIP 2030K imaging plate area detector with graphite monochromated Mo–Ka radiation.

3.9. Cytotoxicity against four kinds of human tumor cell

The cytotoxicity assay was performed in a method of MTT, the experimental details of which have been reported previously (Hou et al., 2000).

Acknowledgements

The authors appreciate the assistance of the analytical group in the laboratory of Phytochemistry, Kunming Institute of Botany, Academia Sinica, for the spectral measurements. Crystallographic data for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: +44-(0)1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Book reviews

Biochemistry & Molecular Biology of Plants
B.B. Buchanan, W. Gruissem and R.L. Jones (Eds.), American Society of Plant Physiologists. 2000. 1367 pp. ISBN 0-943088-39-9, $100

This is the book we have been waiting for! Whether we are teachers at undergraduate or postgraduate level or researchers trying to attract high calibre graduate students, we have all encountered the same problem no doubt. This is the fact that plant biochemistry has always suffered for being rather a Cinderella subject in the eyes of students doing general biochemistry degrees, with the result that there is often a low enrollment for courses. Perhaps part of the reason for this is the lack of a text book which could sell the subject like many of the sumptuously produced Biochemistry volumes or other volumes such as Alberts et al., *The Molecular Biology of the Cell*. Well here it is at last! Students nowadays have such sophisticated imagery thrown at them all the time through media and the net, so we desperately needed a textbook that was up to these standards of illustration to make the subject attractive. Regrettable but necessary in this day and age, where scholarship alone is insufficient to enthuse. This is not to denigrate the texts that addressed the subject in a general way and that we all know and love; the two Bonner and Varners, Goodwin and Mercer and more recently Harborne and Dey. Indeed, there is a touching connection and reminder that the concept for this volume lay with a third edition of Bonner and Varner before Joe's untimely death and it is nice to see the dedication up front. It is just that we needed a book to get the student hooked in the first place in the 21st century. It is not just at the undergraduate level, of course, at postgraduate it is often difficult to get the best students to take up research in plants — they all want to cure cancer. Then there is a knock-on effect that some of the best students do not subsequently follow careers in plant biochemistry. This Cinderella aspect even persists in certain societies and in journals where plants have a low profile. This was one of the reasons for founding *Phytochemistry* in the first place (J.B. Harborne 2001. Phytochemistry 56, 219–221). Also it is kind of fitting that this book should have been published in the year of the completion and release of the *Arabidopsis* genome. Some sections of the media flagged this up by saying it was the most important genome to be sequenced, even more so than the human genome, since we ultimately depend on plants for our existence. Hopefully this sort of attention may divert more talent towards plants and this is certainly the book to support and encourage that.

My emphasis on appearance should not detract from the fact that this a work of scholarship. Inevitably things cannot be treated in depth and it is acceptable that treatment of controversial subjects has to be compromised. However, the range of subjects and the breadth of treatment is astonishing. This massive undertaking is organised into 24 chapters in 5 parts dealing with compartmentation, cellular dynamics, energy provision, metabolism and the environment and agriculture. All the contributors, including three *Phytochemistry* board members, are first rate experts in their respective fields and have been assisted by a panel of reviewers to produce outstanding chapters. It is a joy to open at any page and pleasing to the eye — I do not think any double page lacks an illustration. The standard of illustrations is simply first class. It would be invidious to select any one chapter, although we will all have our individual favorites. It will also please the phytochemist. There is ample treatment of biochemistry and there is no shortage of biochemical pathways and chemical structures. Biochemistry gets equal treatment with plant physiology and molecular biology. Chapters have a core text with technical, anecdotal and supplementary information being supplied in a familiar "Box" format. It is up-to-date in all specialist areas and excellent as a core reference on any subject in the biochemistry and molecular biology of plants. For the researcher it is also educational and superb for browsing and for catching up on developments outside one's immediate field.

So Bob, Russell and Wilhelm and all the contributors, a huge thank you! You have suddenly made my job one heck of a lot easier! There's one big problem, however, how do we prevent it going "missing"? Perhaps it should be supplied with a chain and a lock!

Evolution of Metabolic Pathways, Recent Advances in Phytochemistry volume 34
J.T. Romeo, R. Ibrahim, L. Varin and V. de Luca (Eds.), Pergamon Press, Amsterdam, 2000. 480 pp. $222.50. ISBN 0-08-043860-1

This volume of essays is derived from a symposium held by the PSNA in Montreal, Canada and contains 14 contributions on the biosynthetic pathways of secondary metabolites in plants. The book is appropriately dedicated to the memory of Arthur Neish (1916–1972), who pioneered the application of radiolabelled precursors to plant biosynthesis. The most important and admirable feature in many of these chapters is the assembly of comparative data for various key enzymes which are involved in the biosynthesis of many different end products, from alkaloids and flavonoids to stilbenoids and terpenoids. Thus, I. Schröder discusses the functional diversity and evolution of chalcone synthases, while R.A. Kohn and F. Durst cover the multifarious plant cytochrome P450 oxidases. Two-oxo acid-dependent dioxygenases are ably reviewed by A.G. Prescott and the range and diversity of acyl transferases are described by B. St. Pierre and V. de Luca. There are also chapters considering the evolution of glycosyltransferases (T. Vogt) and of methyltransferases (R.K. Ibrahim and I. Muzac). These are all pioneering contributions. A stimulating opening chapter by B.B. Jarvis entitled 'The role of natural products in evolution' sets the scene for these subsequent contributions.

There are further chapters in this volume which are devoted in turn to biosynthetic aspects of phenolics (H.A. Stafford), cyanogenic glycosides (B.L. Moller), terpenoids in conifers (J. Gershenzon) and brassinosteroids (G. Adam). Altogether, this symposium proceedings provides an important summary of our present knowledge on the comparative biochemistry of secondary metabolism in plants. Also, it tells us where we still lack information and where the experiments of the future will be done.

Biodiversity: New Leads for the Pharmaceutical and Agrochemical Industries
S.K. Wrigley, M.A. Hayes, R. Thomas, E.J.T. Chrystal and N. Nicholson (Eds.); Proceedings of the International Meeting held 5–8 September 1999 at the University of St. Andrews. Royal Society of Chemistry, Cambridge, 2000, 313 + vi pp. ISBN 0-85404-830-8, £59.50

Biodiversity, its maintenance, management and commercial importance, are currently hot topics, and rightly so. The profile of a publication is thus enhanced if reference to Biodiversity appears in the title. Unfortunately this can lead to a bit of a let down when the reader finds that for the most part the papers included in this publication are really about drug discovery and the role of secondary metabolites, past, present and future.

What I was hoping for, from the title, was encapsulated in the contribution of Reddell and Gordon (CSIRO, Australia) who explored the hypothesis that ecology can provide new leads, hinting at different chemical diversities in different biomes and different ecological strategies. Unfortunately for the most part authors were really discussing chemical diversity which, unfortunately, seems to have come to be considered as synonymous with biodiversity, which it clearly is not.

However, when I recovered from my disappointment and browsed the many chapters on chemical diversity I am pleased to report that the quality was generally good and the various chapters did cover many different types of biota and revealed them to be excellent sources of bioactive leads. As an information source and as part of an argument to convince the doubters of the continued role of natural products in drug discovery this is a useful and worthwhile contribution and I shall be pleased to have it in my own personal library.

There are 21 Chapters that have been divided into six sections: (a) history, diversity and discovery (6 chapters), (b) microbial natural products discovery (3 chapters), (c) marine natural products (3 chapters), plant natural products (4 chapters), biosynthesis (2 chapters) and synthesis (3 chapters). Chapters are well illustrated and typographical errors are rare.

Review

Visible light-dependent degradation of lipidic phytoplanktonic components during senescence: a review

Jean-François Rontani*

Laboratoire d'Océanographie et de Biogéochimie (UMR 6535), Centre d'Océanologie de Marseille (OSU), campus de Luminy case 901, 13288 Marseille, France

Received 27 February 2001; received in revised form 18 April 2001

Abstract

Though most of the organic components of phytoplankton are susceptible to being photodegraded during senescence, until recent years there has been very little research in this area. Recently, however, there have been a renewal of interest, and the heterogeneous visible light-induced degradative reactions of lipidic compounds associated with phytodetritus have been studied. The present paper reviews the results obtained in the course of these studies. In the first part, the production and quenching of excited states of chlorophyll and toxic oxygen species (singlet oxygen, superoxide ion, hydroxyl radical and hydrogen peroxide) in healthy and senescent phytoplanktonic cells are discussed. Then, the photo-oxidation of the main lipidic cell components (chlorophyll, chlorophyll phytyl chain, carotenoids, sterols, unsaturated fatty acids, alkenones and unsaturated alkenes) in senescent phytoplanktonic cells is examined. Emphasis is given to the degradation rates and the mechanisms of visible light-induced degradation of the main lipidic components of phytoplankton and to the structure of the photoproducts formed. In each case, the selectivity of these compounds is discussed in order to select a ''pool'' of photoproducts able to act as tracers of photo-oxidative alterations in the marine medium. This ''pool'' of photoproducts could provide very useful information concerning the physiological state of phytoplanktonic communities and current environmental problems related to ozone depletion. © 2001 Elsevier Science Ltd. 1. Introduction

To date, due to the lack of adequate tracers, the role played by the photochemical processes during the degradation of phytoplankton in the euphotic layer of the oceans has been virtually ignored. Owing to the problem of stratospheric ozone depletion, some studies have recently examined the degradative effects of enhanced UV-B doses on phytoplanktonic lipids (Skerratt et al., 1998). However, photochemical damages in phytoplanktonic cells are not a monopoly of UV radiation (Nelson, 1993). In fact, due to the presence of chlorophylls [which are very efficient photosensitizers (Foote, 1976)], numerous organic components of phytoplankton are susceptible to being photodegraded during senescence by photosynthetically active radiation (PAR) (Rontani et al., 1998).

The present paper reviews this particular aspect of photodegradation processes, i.e. **the heterogeneous visible light-induced degradative reactions associated with phytodetritus**. Emphasis is given to the degradation rates and the mechanisms of visible light-induced degradation of the main lipidic components of phytoplankton and to the structure of the photoproducts formed. In each case, the selectivity of these compounds is discussed in order to select a "pool" of photoproducts able to act as tracers of photo-oxidative alterations in the marine medium.

It is hoped that this short review will stimulate research in this very interesting area and that the questions raised will be answered in the near future.

2. Different photo-oxidation mechanisms

2.1. Direct photo-oxidative reactions

These processes involve light-absorbing entities called chromophores, which undergo oxidative change as a direct consequence of absorbing photons (Zafiriou et al., 1984). In the marine environment, comparatively few natural molecules of known structure can react in this way (carbonyl compounds, thryptophane, thiamine, vitamin B12, pigments, polyunsaturated fatty acids, etc.) (Zafiriou et al., 1984). In contrast, these reactions must play an important role in the photochemistry of coloured complex organic molecules of unknown structure such as humic and fulvic acids (Zafiriou, 1977; Zafiriou et al., 1984).

2.2. Indirect photo-oxidative reactions

Indirect processes are common in natural waters and are particularly important since they can alter molecules that resist direct photo-oxidative reactions, such as transparent species or chromophores whose reactive states are inefficiently populated by absorption (Zafiriou et al., 1984). These reactions involve substances called photosensitizers. These compounds have two systems of electronically excited states, the singlet (^{1}sens) and the triplet (^{3}sens) (Foote, 1976). Most photosensitized oxidations occur by way of a triplet state (Gollnick, 1968). Many dyes, pigments and aromatic hydrocarbons are very effective sensitizers (Foote, 1976). ^{3}Sens can react: either directly with another molecule, to give radicals after hydrogen atom or electron transfer (type I processes) (Gollnick, 1968) (Fig. 1), or with oxygen (type II processes) (Fig. 1). In this case, the excitation is transferred from the sensitizer to the oxygen, to produce an electronically excited singlet state of oxygen ($^1O_2$). Less efficient electron transfer from sensitizer to oxygen can also occur, affording superoxide ion ($O_2^{\bullet -}$) (Foote, 1976).

3. The photoprotective system of healthy cells

The organisation of the pigments in the lipo-protein membranes of the chloroplasts consists of a series of pigment-protein complexes which cooperate together to promote electron flow (Halliwell, 1987).When a chlorophyll molecule absorbs a quantum of light energy, an excited singlet state (^{1}Chl) is formed. In healthy cells the primary route for energy from the ^{1}Chl is the fast reactions of photosynthesis (Foote, 1976). However, a small proportion (less than 0.1%) of ^{1}Chl may undergo intersystem crossing to form the longer live triplet state (^{3}Chl) (Knox and Dodge, 1985) (Fig. 2). ^{3}Chl is not only potentially damaging itself in type I reactions (Knox and Dodge, 1985), but it may also generate toxic oxygen species ($^1O_2$ and $O_2^{\bullet -}$) by reaction with ground state oxygen ($^3O_2$) (Type II processes) (Fig. 1). Formation of an active complex between ^{3}Chl and $^3O_2$ can also oxidize HO^- to the extremely powerful oxidizing agent $HO^{\bullet}$

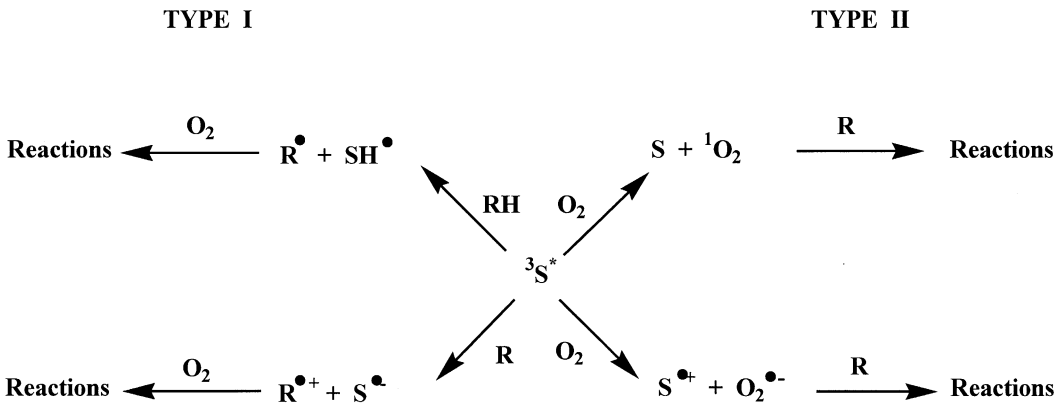

Fig. 1. Reactions of the triplet sensitizer [reprinted from Rontani (1999), with permission from Springer].

(Harbour and Bolton, 1978; Chauvet et al., 1981). Superoxide ion ($O_2^{\bullet -}$) may subsequently disproportionate to $^1O_2$ and hydrogen peroxide (H_2O_2) in the presence of a proton donor [Eqs. (1) and (2)] (Foote, 1976).

$$O_2^{-\bullet} + H^+ \rightleftharpoons HOO^\bullet \quad (1)$$

$$2HOO^\bullet \longrightarrow H_2O_2 + {}^1O_2 \quad (2)$$

In the presence of Fe^{+3}, $O_2^{\bullet -}$ also intereacts with H_2O_2 to give hydroxyl radicals (Haber–Weiss reaction) (Leshem, 1988).

$$O_2^{-\bullet} + H_2O_2 \xrightarrow{Fe^{+3}} HO^\bullet + HO^- + O_2 \quad (3)$$

In view of their susceptibility to oxidative damage, one would expect to find many antioxidant protective mechanisms in chloroplasts. Carotenoids quench ^{3}Chl and $^1O_2$ by energy transfer mechanisms (Fig. 2) at very high rates (Foote, 1976). Tocopherols can remove $^1O_2$, $O_2^{\bullet -}$, $HOO^\bullet$ and $HO^\bullet$ by acting as sacrificial scavengers, these processes resulting in the irreversible oxidation of the tocopherol molecule (Halliwell, 1987). In common with carotenoids, tocopherols and ascorbic acids are also efficient physical deactivators (i.e. "quenchers") of $^1O_2$ (Halliwell, 1987). Superoxide dismutase enzyme (SOD) and ascorbic acid may also scavenge $O_2^{\bullet -}$ (Halliwell, 1987), while catalase activity by virtue of its lowering H_2O_2 levels provides less substrate for $HO^\bullet$ in the Haber–Weiss reaction (Leshem, 1988).

4. The photodynamic effect

As we can see in Section 3, in healthy cells the primary route for energy from the ^{1}Chl is the fast reactions of photosynthesis. In senescent phytoplanktonic cells this pathway would not be functional; thus an accelerated rate of formation of ^{3}Chl would be expected (Nelson, 1993). The rate of formation of ^{3}Chl and toxic oxygen species ($^1O_2$, $O_2^{\bullet -}$, $HO^\bullet$, H_2O_2) might then exceed the quenching capacity of the photoprotective system and photodegradation can occur (Merzlyak and Hendry, 1994) (Fig. 3). In phytodetritus, when the ordered structure of

the thylakoid membranes has been disrupted, pigments tend to remain associated with other hydrophobic cellular components such as membrane lipids (Nelson, 1993). The photo-oxidative effect of chlorophyll sensitization might be strongly amplified within such a hydrophobic micro-environment. Moreover, the lifetime of $^1O_2$ produced from sensitizers in a lipid-rich hydrophobic environment could be longer, and its potential diffusive distance greater, than if produced by sensitizers in aqueous solution (Suwa et al., 1977).

5. Visible light-dependent photodegradation of the main lipidic components of phytoplankton during senescence

5.1. Chlorophylls

Irradiation of killed phytoplanktonic cells by the light used for their growth results in rapid degradation of chlorophylls (Nelson, 1993; Rontani et al., 1995). The light-dependent degradation rates obtained in detrital chlorophytes and diatoms showed a good fit to first-order kinetics (Table 1). The photochemical degradation of chlorophylls has so far been studied almost exclusively with respect to the porphyrin moiety of the molecule, which is the more reactive. In the older literature, light and oxygen were considered as essential for the degradation of the chlorophyll macrocycle in living organisms (Hendry et al., 1987). From the present point of view, this dogma must be called into question since enzymatic degradation of chlorophyll in bleaching cells of algae also takes place in darkness (Engel et al., 1991; Kräutler et al., 1991). It was postulated that these enzymes degrade chlorophyll because the senescent cells must try to eliminate dangerous photodynamic molecules which are liberated upon the mobilisation of the corresponding apoproteins (Gossauer and Engel, 1996). There is a great deal known about the structure of the photoproducts of the chlorophyll tetrapyrrolic structure, probably due to the instability of these substances (Merzlyak and Hendry, 1994). Recently, the 19-formyl-1[21*H*,22*H*]bilinone derivatives **1a** and **1b** (Fig. 4) have been identified in senescent cells of the microalgae *Chlorella protothecoides* (Engel et al., 1991; Iturraspe et al., 1994). These compounds represent the first examples of natural products whose structure corresponds to those of the in vitro photo-oxidation products of chlorophyll macrocycle (Fuhrhop et al., 1974). Unfortunately, enzymatic degradation of chlorophyll yields similar products (Gossauer and Engel, 1996) (Fig. 5). Despite some recent progress regarding intermediary photoproducts, no stable and specific markers of the chlorophyll macrocycle photodegradation could be characterised.

The isoprenoid phytyl side-chain of chlorophyll, which is generally considered to be the major source of acyclic isoprenoids with twenty or fewer carbon atoms in the biosphere (Volkman and Maxwell, 1986), is also sensitive to photochemical processes. In fact, in phytodetritus the visible light-dependent degradation rates were only 3–4 times higher for the chlorophyll tetrapyrrolic structure than for its phytyl side-chain (Table 1). It was previously demonstrated that the photosensitized oxidation (involving $^1O_2$) of the phytol moiety of chlorophyll-*a* or -*b* leads to the production of photoproducts of type **a** and **b** (Fig. 6) quantifiable after alkaline hydrolysis

respectively in the form of 6,10,14-trimethylpentadecan-2-one (phytone) (**2**) and 3-methylidene-7,11,15-trimethylhexadecan-1,2-diol (phytyldiol) (**3**) (Fig. 6) (Rontani et al., 1991). In contrast, oxy-free radical oxidation of the phytyl chain and subsequent alkaline hydrolysis affords mainly *Z* and *E* 3,7,11,15-tetramethyl-2,3-epoxyhexadecan-1-ols (**4** and **5**), 3,7,11,15-tetramethylhexadecan-1,2,3-triol (**6**) and the ketone **2**

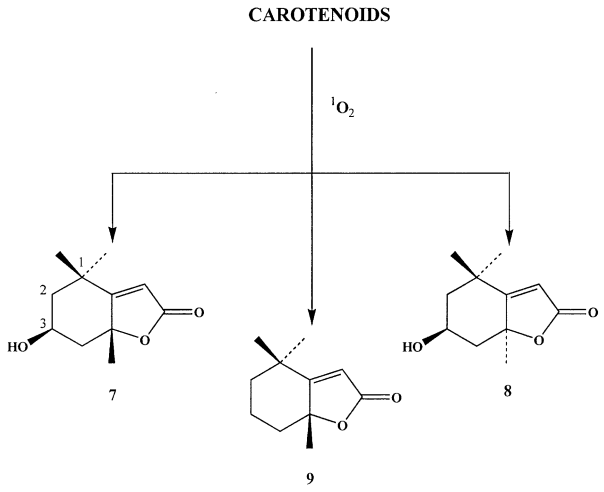

Fig. 8. Structure of the main carotenoid photoproducts.

(Fig. 6) (Rontani and Aubert, 1994). Analysis of isoprenoid photoproducts of chlorophyll after irradiation of killed phytoplanktonic cells by visible light clearly established that the photodegradation of the chlorophyll phytyl side-chain in phytodetritus involved mainly $^1O_2$ and to a small degree free-radicals (Fig. 7) (Rontani et al., 1995). Phytyldiol (**3**), which is a stable, specific (Rontani et al., 1996) and widely distributed (Rontani et al., 1994; Cuny and Rontani, 1999) chlorophyll phytyl side-chain photoproduct, appeared to be a suitable biogeochemical marker of chlorophyll photodegradation. Consequently the molar ratio of phytyldiol (**3**) to phytol named **CPPI** (**C**hlorophyll **P**hytyl side-chain **P**hotodegradation **I**ndex) has been proposed as a useful tool relating to the photodegradation of chlorophylls with a phytyl side-chain in aquatic ecosystems (Cuny et al., 1999).

5.2. Carotenoids

In phytodetritus, chlorophylls and carotenoids remain in a close molecular-scale association at relatively high localized concentrations, even though the structure of the thylakoid membrane has been disrupted (Nelson, 1993). Thus, the sensitized photo-oxidation of carotenoid is enhanced. In a previous paper, Nelson (1993) determined the visible light-dependent degradation rates of carotenoids in killed chlorophyte and diatom cells (Table 1). Using D_2O (which prolongs $^1O_2$ lifetime) and radical scavengers, Takahama (1983) demonstrated that carotenoid photobleaching in isolated chloroplasts involves $^1O_2$ and radical chain reactions. The photosensitized oxidation (involving $^1O_2$) of carotenoids in solvents has been studied (Iseo et al., 1972) and loliolide (**7**), *iso*-loliolide (**8**) and dihydroactinidiolide (**9**) (Fig. 8) were identified as major photo-products, depending on the functionality of carotenoids at C-3. Recently, loliolide (**7**) and *iso*-loliolide (**8**) have been detected in killed cells of *Dunaliella* sp. irradiated by visible light (Rontani et al., 1998). During this study, the production of lesser amounts of these compounds has been also observed after dark axenic incubations of killed cells and attributed to the action of peroxidases (Huff, 1982). Loliolides have been also detected in situ in suspended particles (Repeta, 1989) and in sediments (Klock et al., 1984; Repeta, 1989); however, due to their apparent production by anaerobic bacteria (Repeta, 1989) and during dark incubations of killed phytoplanktonic cells (Rontani et al.,

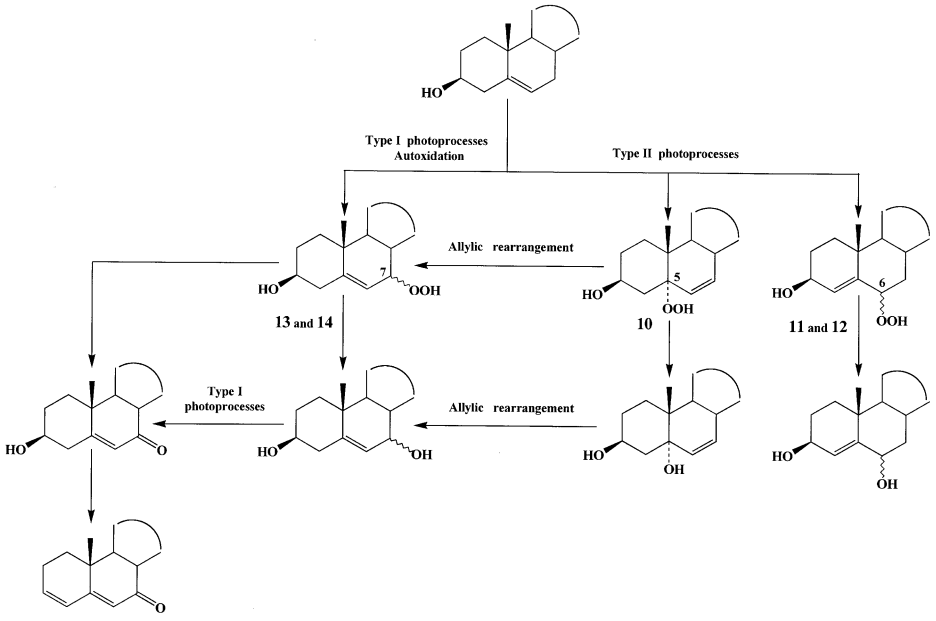

Fig. 9. Photo- and auto-oxidation of sterols (only the major oxidation products are shown) [adapted from Rontani (1999)].

1998), these compounds cannot constitute unequivocal indicators of photo-oxidative processes.

5.3. Sterols

As important unsaturated components of biological membranes, sterols are highly susceptible to photo-oxidative degradation during the senescence of phytoplankton. Type I (free radical) (Rontani et al., 1993) and type II ($^1O_2$) photo-oxidation (Nickon and Bagli, 1961; Kulig and Smith, 1973) of these compounds have been extensively studied in solution. Type II ($^1O_2$) photo-oxidation of sterols gives mainly Δ^6-5α-hydroperoxides (**10**) and to a lesser extent Δ^4-6α/6β-hydroperoxides (**11** and **12**) (Nickon and Bagli, 1961; Kulig and Smith, 1973), whereas type I (free radical) photoreactions (Rontani et al., 1993) and autooxidative processes (Smith, 1981) give Δ^5-7α/7β-hydroperoxides (**13** and **14**) (Fig. 9). Δ^6-5α-hydroperoxysterols (**10**) are relatively unstable and may undergo allylic rearrangement to Δ^5-7α-hydroperoxysterols (**13**), which in turn epimerize to the corresponding 7β-hydroperoxides (**14**) (Fig. 9) (Smith, 1981).

Irradiation by visible light of killed cells of *Skeletonema costatum*, *Dunaliella* sp., *Phaeodactylum tricornutum* and *Emiliania huxleyi* (Rontani et al., 1997a,b; 1998) resulted in a quick photodegradation of the sterol components of these algae. The light-dependent degradation rates thus obtained (Table 1) show a good fit to apparent first-order kinetics. The results obtained clearly established that the photo-oxidation of sterols in senescent cells of phytoplankton involves singlet oxygen-mediated photoprocesses. These processes produce 6-hydroperoxides in considerably higher yields [ratio Δ^4-6-hydroperoxides/Δ^6-5-hydroperoxides = 0.34 in killed cells of *Skeletonema costatum* (Rontani et al., 1997a)] than in homogeneous solutions (Kulig and Smith, 1973). This confirms previous observations made by Korytowski et al. (1992) in cell membranes. Allylic rearrangement does not occur significantly in killed cells of phytoplankton. Korytowski et al. (1992) have observed that Δ^6-5α-hydroperoxides are more stable in membranes containing unsaturated phospholipids than in those containing saturated phospholipids. This stability was attributed either to hydrogen bonding between the unsaturated fatty acyl chain of phospholipids and Δ^6-5α-hydroperoxides which could hinder the allylic rearrangement, or to differences of polarity in the carbon 7–10 zone of the fatty acyl chain [where sterols tend to localize in phospholipid/sterol bilayers (MacIntosch, 1978)]. On the basis of these hypotheses, the lack of allylic rearrangement in phytodetritus can be correlated with the well-known high Δ^9 unsaturated fatty acid content of phytoplankton (Kawamura and Gagosian, 1987; Stephanou, 1992). It is also interesting to note that the reduction of hydroperoxysterols to the corresponding diols (Fig. 9) weakly operates in killed phytoplanktonic cells (Rontani et al., 1997a).

Recently, significant amounts of Δ^6-5α- and Δ^4-6α/6β-hydroperoxysterols have been detected in marine recent sediments (Rontani and Marchand, 2000). These results show that photodegradation of Δ^5-stenols in senescent or dead phytoplanktonic cells plays a role in the degradation of these compounds in the marine environment. The surprising preservation of hydroperoxysterols observed in these sediments was attributed to the weak reducing properties of sulfides towards these compounds. These photoproducts, which are present mainly in esterified and bound forms, could also be protected in intact phytoplanktonic membranes of well-silicified diatoms. Indeed, it is generally considered that most of the bound materials observed in sediments represent the contents of intact biological debris (Cranwell, 1978; Sun et al., 1993). If Δ^6-5α-hydroperoxysterols are particularly stable in phytodetritus, they decay slowly in the sediment to their corresponding Δ^5-7α/7β-derivatives, which are not selective markers. Consequently, Δ^4-6α/6β-hydroperoxysterols (or the corresponding Δ^4-6α/6β-hydroxysterols) may be considered as more reliable *in situ* markers of photodegradation processes than Δ^6-5α-hydroperoxysterols (Korytowski et al., 1992).

5.4. Unsaturated fatty acids

Since damaging effects of $^1O_2$ are primarily concerned with the oxidation of membrane lipids (Percival and Dodge, 1983), chloroplast membrane components are particularly susceptible to type II photo-oxidation (Heath and Packer, 1968). This is the case for unsaturated fatty acids, which generally predominate in algal lipids, particularly in the photosynthetic membranes (Woods, 1974). In killed phytoplanktonic cells, the photodegradation rates of unsaturated fatty acids show a good fit to apparent first-order kinetics and logically increase with their unsaturation degree (Rontani et al., 1998) (Table 1). Singlet oxygen-mediated photo-oxidation of monounsaturated fatty acids involves a direct reaction of $^1O_2$ with the carbon-carbon double bond by a concerted "ene" addition (Frimer, 1979), and leads to the formation of hydroperoxides at each unsaturated carbon. Thus, oleic acid produces a mixture of 9- and 10-hydroperoxides (**15** and **16**) with an allylic *trans* double bond (Frankel et al., 1979) (Fig. 10). These two hydroperoxides may undergo highly stereoselective radical allylic rearrangement respectively to 11-*trans* and 8-*trans* hydroperoxides (**17** and **18**) (Fig. 10) (Porter et al., 1995). Frankel et al. (1977) and Garwood et al. (1977) reported that autoxidation of oleic acid yields mainly a mixture of 8-*trans*, 8-*cis*, 9-*trans*, 10-*trans*, 11-*trans* and 11-*cis* hydroperoxides (**15**–**20**), with minor amounts of 9-*cis* and 10-*cis* hydroperoxides (Fig. 10).

The visible light-induced degradation of mono-unsaturated fatty acids in killed phytoplanktonic cells has recently been studied (Rontani, 1998; Rontani et al., 1998). Comparison of the isomeric distribution of Δ^9 octadecenoic acid (oleic acid) hydroperoxides (quantified after reduction to their corresponding secondary alcohols) obtained in killed cells (Fig. 11) and after oxidation with radicals and $^1O_2$ (Fig. 10) made it possible to show that the photodegradation of mono-unsaturated fatty acids in phytodetritus involves mainly singlet oxygen. The 9- and 10- allylic hydroperoxides (**15** and **16**) thus formed may undergo three main degradative processes: (i) highly stereoselective free radical allylic rearrangement respectively to 11-*trans* and 8-*trans* hydroperoxides (**17** and **18**), (ii) homolysis of the O–O bond leading to carbonyl (dehydration), alcoholic (reduction), fragmentation (β-scission) or oxirane (radical cyclization) products (Frimer, 1979), and (iii) heterolysis of the O–O bond leading to the formation of two carbonyl fragments (Hock cleavage), this proton-catalysed cleavage being initiated by migration of groups to positive oxygen (Frimer, 1979).

The free radical nature of the allylic hydroperoxide rearrangement is supported by the observation that the rearrangement is catalysed by free radical initiators or light and inhibited by phenolic antioxidants (Porter et al., 1995). This allylic rearrangement weakly intervenes in killed phytoplanktonic cells (Fig. 11). This could be attributed to the relatively high localized lipidic concentrations present in phytodetritus (Nelson, 1993), which favoured the dimerisation of hydroperoxides. Hydrogen atom abstraction to form allylperoxyl radicals does indeed occur readily from hydroperoxide monomers but not from hydroperoxide dimers (Porter et al., 1995). Homolysis of the O–O bond of mono-unsaturated acids deriving allylic hydroperoxides in phytodetritus involves mainly reduction to hydroxyacids (**21**) and dehydration to ketoacids (**22**) (Fig. 12). The presence of allylic ketoacids (**22**), which was not easy to prove since these compounds do not survive alkaline hydrolysis of killed cells, has been recently demonstrated thanks to deuterium labelling (Rontani, unpublished results). Proton-catalysed cleavage of allylic hydroperoxides involves mainly the migration of the vinyl group (Frimer, 1979). According to this pathway, allylic hydroperoxides resulting from the light-induced oxidation of phytoplanktonic mono-unsaturated fatty acids affords C_7–C_{12} ω-oxocarboxylic acids (**23**) and C_6–C_{11} aldehydes (**24**) (Rontani, 1998; Rontani et al., 1998) (Fig. 12). In the presence of peroxides or molecular oxygen such compounds are easily oxidized respectively

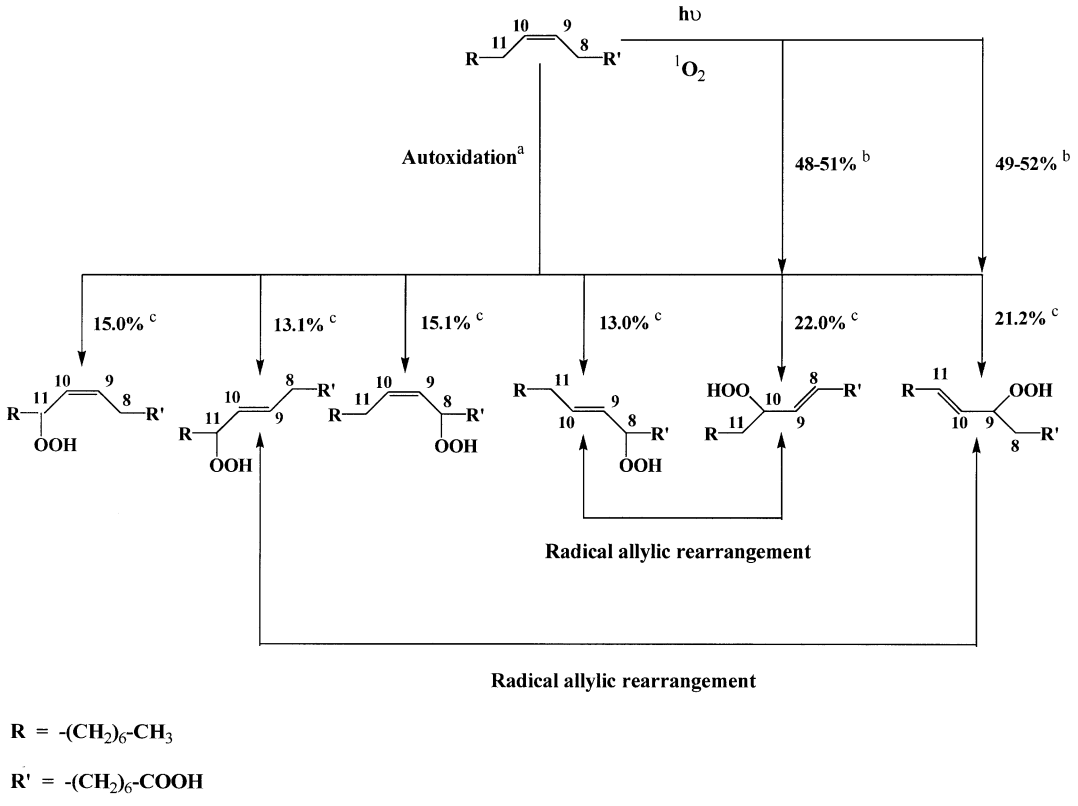

Fig. 10. Hydroperoxides from autoxidation and singlet oxygen-mediated photo-oxidation of octadec-9-enoic acid [reprinted from Marchand and Rontani (2001), with permission from Elsevier Science Ltd]. [a]Cis-9 and 10 hydroperoxides (which represent less than 1% of autoxidation products) have been omitted in order to simplify the scheme. [b]From Frankel, 1998. to ω-dicarboxylic (**25**) and carboxylic acids (**26**) (Fig. 12).

Significant amounts of photo-oxidation products of phytoplanktonic mono-unsaturated acids have been recently detected in particulate matter and sediment samples (Marchand and Rontani, 2001). Deuterium labelling showed that isomeric hydroperoxyacids are relatively stable in the water column. During early diagenesis, hydroperoxides undergo heterolytic cleavage to aldehydes and ω-oxocarboxylic acids or homolytic cleavage and subsequent transformation to the corresponding alcohols or ketones.

The detection of homologous series of ω-oxocarboxylic acids (with C_9 as the most abundant species) and their corresponding α,ω-dicarboxylic acids in marine sediments (Kawamura et al., 1990; Stephanou, 1992) and sediment traps (Kawamura et al., 1990) was interpreted as indicative of atmospheric transport of unsaturated fatty acid photo-oxidation products rather than of an autochthonous formation (Kawamura et al., 1990; Stephanou and Stratigakis, 1993). The production of similar compounds recently observed during the irradiation of senescent phytoplanktonic cells (Rontani, 1998; Rontani et al., 1998) and attributed to heterolytic cleavage of allylic hydroperoxides (Rontani, 1998) calls into question the use of these compounds as tracers of atmospheric input to the sea, since the photosensitized oxidation of unsaturated fatty acids in senescent phyto-

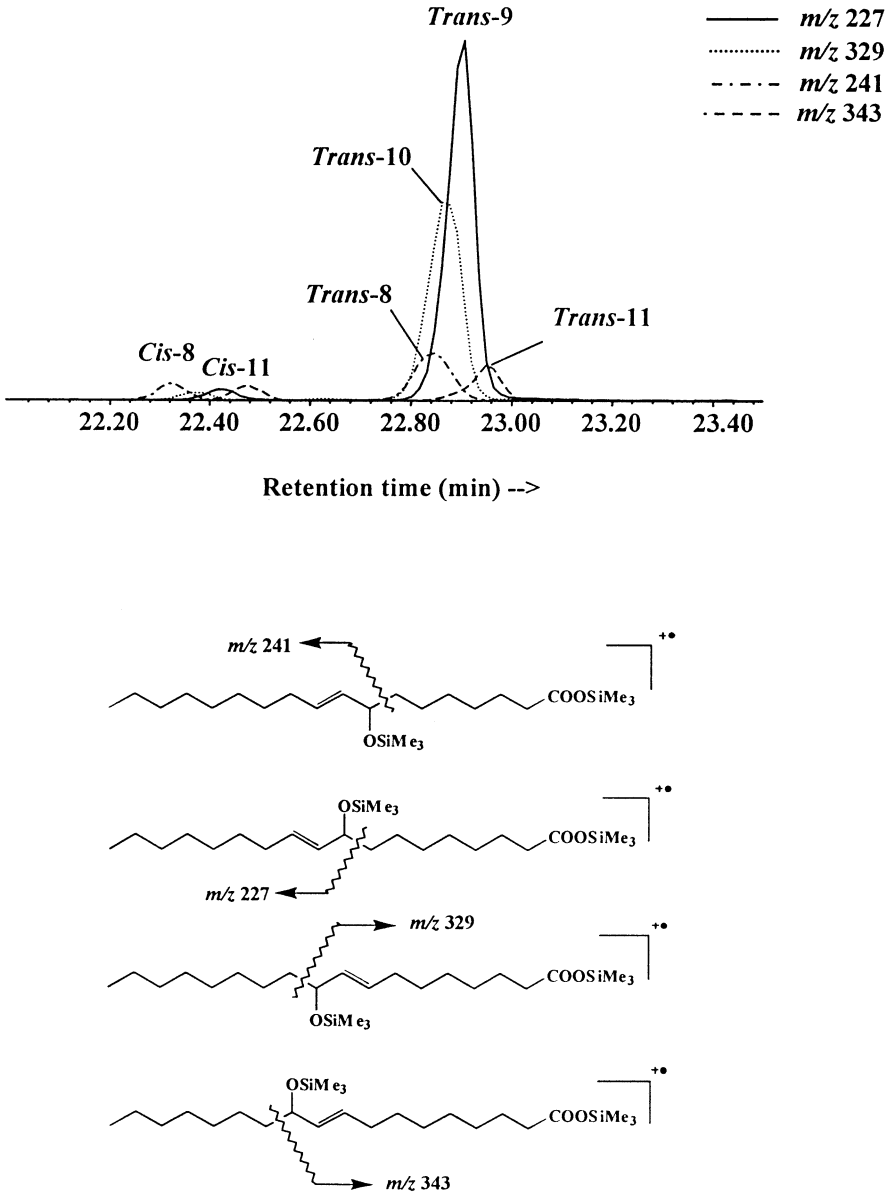

Fig. 11. Mass chromatograms of *m*/*z* 227, 241, 329 and 343 revealing the presence of four octadec-9-enoic acid deriving isomeric hydroxyacids in a reduced ($NaBH_4$) extract of *Dunaliella* sp. killed cells exposed to 66 mol m^{-2} (PAR) [adapted from Rontani (1998)].

planktonic cells, which can act throughout the euphotic layer of the oceans, must constitute a significant source of ω-oxocarboxylic and α,ω-dicarboxylic acids in the marine environment. Moreover, it is important to note that heterolytic cleavage of allylic hydroperoxides produced by autoxidation of Δ^9 unsaturated acids also results in the production of ω-oxocarboxylic and α,ω-dicarboxylic acids (with C_9 as the more abundant species) (Marchand and Rontani, 2001). It is clear that these compounds could not be considered any longer as specific tracers of photo-oxidative degradation of biogenic unsaturated fatty acids but only of their oxidation.

In contrast, the distribution pattern of allylic hydroxyacids (resulting from the reduction of the corresponding hydroperoxides), which is well preserved in recent sediments (Table 2) (Marchand and Rontani, 2001), allows easy differentiation between autoxidative and photo-oxidative processes.

Taking into account the high amounts of photoproducts of mono-unsaturated fatty acids detected in the particulate matter samples, and the well known increasing photo-oxidation rates (Rontani et al., 1998) of fatty acids with their degree of unsaturation, it can be concluded that considerable amounts of poly-unsaturated fatty acids must be photo-oxidized in the marine environment. However, at this time photo-oxidation products of this kind of fatty acids could not be detected in natural samples. This is possibly due to: (i) the instability of the hydroperoxides formed, or (ii) the involvement of cross-linking reactions leading to the formation of macromolecular structures (Neff et al., 1988) nonamenable by gas chromatography. The characterisation and quantification of such structures (which could play a

(2001), with permission from Elsevier Science Ltd].

role in the formation of humic substances (Harvey et al., 1983) in particulate matter or senescent phytoplanktonic samples constitutes an exciting challenge for the future.

5.5. Alkenones

The alkenones comprise an unusual class of long-chain unsaturated methyl and ethyl ketones that are synthesized by a limited number of haptophyte microalgae (Volkman et al., 1980; 1995; Marlowe et al., 1984). The relative abundance of the two main $C_{37:2}$ and $C_{37:3}$ alkenones expressed as the $U^{k'}_{37}$ index $[C_{37:2}]/([C_{37:2}]+[C_{37:3}])$ is now widely used for reconstructing sea surface paleotemperatures (Rosell-Melé et al., 1995).

In recent work, we studied the photodegradation of these compounds in order to determine if photochemical processes could appreciably modify $U^{k'}_{37}$ ratios during algal senescence (Rontani et al., 1997b). In solution, singlet oxygen-mediated photochemical processes degraded alkenones more slowly than fatty acids with the same unsaturation degree. This difference of reactivity was attributed to: (i) the *trans* configuration of the alkenone double bonds (Rechka and Maxwell, 1988), which is known to be less reactive towards singlet oxygen (Hurst et al., 1985), and (ii) the separation of the double bonds by five saturated carbons in the alkenone structure. Though selective, photochemical degradation of alkenones is not fast enough in killed cells of *Emiliania huxleyi* to induce significant modifications of the $U^{k'}_{37}$ ratio before the photodestruction of the photosensitizing substances (Fig. 13) (Rontani et al., 1997b; Mouzdahir et al., 2001). This poor photo-reactivity was attributed not only to the *trans* configuration of the double bonds of alkenones, but also to a localisation of these compounds elsewhere than in cell membranes (Rontani et al., 1997b; Mouzdahir et al., 2001), which could significantly decreases the likelihood of interaction between singlet oxygen and alkenones. This latter hypothesis is well supported by the results of Conte and Eglinton (1993), who failed to detect alkenones in the membranes of *Emiliania huxleyi* after cell fractionation.

5.6. Unsaturated hydrocarbons

The visible light-induced degradation of *n*-alkenes has been studied in killed cells of the Prymnesiophycea *Emiliania huxleyi* and the Eustigmatophycea *Nannochloropsis salina* (Mouzdahir et al., 2001). In *Emiliania huxleyi* killed cells, minor C_{31} and C_{33} *n*-alkenes were strongly photodegraded, while the major C_{37} and C_{38} *n*-alkenes appeared particularly recalcitrant towards photochemical processes (Fig. 13). These differences of photoreactivity imply distinct biological syntheses and/or functions for these two groups of hydrocarbons in *Emiliania huxleyi* cells. As in the case of the corresponding alkenones (see Section 5.5), the particular photochemical recalcitrance of C_{37} and C_{38} *n*-alkenes has been attributed to the chemical structure and localization of these hydrocarbons in the cells. Irradiation of dead cells of *Nannochloropsis salina* resulted in a strong modification of the hydrocarbon fraction (Fig. 14). It did not provide evidence of a significant light-dependent degradation of monounsaturated hydrocarbons; this result was attributed to the terminal position of the double bond in these compounds (Gelin et al., 1997), which is poorly reactive towards singlet oxygen (Hurst et al., 1985). In contrast, di-, tri-, and tetraenes were strongly photodegraded during irradiation (Fig. 14). The visible light-dependent degradation of phytoplanktonic *n*-alkenes showed apparent second-order kinetics with respect to light exposure, and the half-life doses obtained logically decrease with increasing number of double bonds in these compounds (Mouzdahir et al., 2001). During this study, products deriving from *n*-alkene photodegradation could not be detected.

Wakeham et al. (1991) previously observed in the Black Sea decreasing concentrations of C_{31}–C_{33} alkenes with increasing depth, while C_{37}–C_{39} alkenes persisted both in the water column and in the sediment. These authors invoked selective degradation to explain the observed depth profiles. The strong differences of photoreactivity of these two groups of *n*-alkenes observed well support this hypothesis.

6. Conclusions

It is generally considered that approximately 95% of the total particulate organic matter consists of particles < 20 μm having settling velocities of less than 1 m d^{-1} (MacCave, 1975). Consequently, the bulk of the organic particulate matter has a fairly long residence time within the euphotic layer. Assuming a surface daily irradiance of 60 mol m^{-2} (PAR) (a value representative of mid-latitude waters under a clear summer day (Nelson, 1993)), it clearly appears that most of the phytoplanktonic lipids (half-life doses ranging from 1 to 350 mol m^{-2}) (Table 3) may be significantly photodegraded in the upper portion of the euphotic zone during senescence. Some of the more reactive lipids (chlorophylls,

carotenoids, polyunsaturated fatty acids and *n*-alkenes) (Table 3) may be photodegraded even near the limit of the euphotic layer (daily irradiance 0.6 mol m^{-2}). However, under such low light conditions, particle sinking or biologically mediated degradation may have a greater impact on lipid concentration than light-dependent degradation processes (Vernet and Mitchell, 1990).

Probably due to its long lifetime in hydrophobic micro-environments (Suwa et al., 1977), singlet oxygen plays a key role in the photodegradation of most of the lipidic phytoplanktonic components (i.e. chlorophyll phytyl chain, carotenoids, sterols and unsaturated fatty acids). Consequently, we propose a scheme for the photodegradation of lipid compounds in senescent cells of phytoplankton that involves activation by $^1O_2$ (Fig. 15).

After elimination of the insufficiently specific and stable photoproducts, we selected 3-methylidene-3,11,15-trimethylhexadecan-1,3-diol (**3**) (Fig. 6), 6α/6β-hydroxysterols (**11** and **12**) (Fig. 9) and allylic hydroxyacids (**21**) (Fig. 13) to constitute a "pool" of useful markers of photodegradative alterations. This "pool" of photoproducts could provide very useful information concerning the physiological state of phytoplanktonic communities and current environmental problems related to ozone depletion.

In fact, since photoxidative degradation of lipidic components of phytoplankton intervene mainly in senescent cells, the proportion of photo-oxidation products relative to their parent lipidic components could be indicative of the physiological state of phytoplanktonic communities.

Atmospheric scattering is most pronounced in the blue and UV region of the solar light. Consequently, ozone depletion results in the exposure of phytoplankton to enhanced UV-B and blue light doses. If UV-B has been shown to reduce the survival, growth and production of phytoplankton (Skerratt et al., 1998), enhancement of the light doses in the blue region must result in the production of higher amounts of excited chlorophylls and thus to enhanced photodegradation of the lipidic components of phytoplankton. Consequently, photo-oxidation products of lipidic components of phytoplankton could give interesting information about ozone depletion.

Purification and characterization of a Ca^{2+}-dependent protein kinase from sandalwood (*Santalum album* L.): evidence for Ca^{2+}-induced conformational changes

Veena S. Anil, K. Sankara Rao*

Department of Biochemistry, Indian Institute of Science, Bangalore-560 012, India

Received in revised form 16 January 2001; accepted 10 May 2001

Abstract

An early development-specific soluble 55 kDa Ca^{2+}-dependent protein kinase has been purified to homogeneity from sandalwood somatic embryos and biochemically characterized. The purified enzyme, swCDPK, resolved into a single band on 10% polyacrylamide gels, both under denaturing and non-denaturing conditions. swCDPK activity was strictly dependent on Ca^{2+}, $K_{0.5}$ (apparent binding constant) for Ca^{2+}-activation of substrate phosphorylation activity being 0.7 μM and for autophosphorylation activity ~50 nM. Ca^{2+}-dependence for activation, CaM-independence, inhibition by CaM-antagonist (IC_{50} for W7 = 6 μM, for W5 = 46 μM) and cross-reaction with polyclonal antibodies directed against the CaM-like domain of soybean CDPK, confirmed the presence of an endogenous CaM-like domain in the purified enzyme. Kinetic studies revealed a K_m value of 1.3 mg/ml for histone III-S and a V_{max} value of 0.1 nmol min^{-1} mg^{-1}. The enzyme exhibited high specificity for ATP with a K_m value of 10 nM. Titration with calcium resulted in the enhancement of intrinsic emission fluorescence of swCDPK and a shift in the λ_{max} emission from tryptophan residues. A reduction in the efficiency of non-radiative energy transfer from tyrosine to tryptophan residues was also observed. These are taken as evidence for the occurrence of Ca^{2+}-induced conformational change in swCDPK. The emission spectral properties of swCDPK in conjunction with Ca^{2+} levels required for autophosphorylation and substrate phosphorylation help understand mode of Ca^{2+} activation of this enzyme. © 2001 Elsevier Science Ltd. 1. Introduction

In plants, calcium acts as a second messenger in the regulation of a variety of physiological and metabolic processes (Marme and Dieter, 1983; Malho and Trewavas, 1996; Sanders et al., 1999; Trewavas, 1999; Anil and Sankara Rao, 2000). To understand the downstream events in Ca^{2+}-mediated signaling, analogy has been drawn with animal systems wherein the Ca^{2+}-message is perceived by proteins that bind Ca^{2+}, and transduced via protein kinases. Plants predominantly exhibit a calcium-dependent, CaM-independent protein kinase activity. This activity was first purified from soybean (Harmon et al., 1986; Putnam-Evans et al., 1990) and later identified and/or purified from a host of other plant species (Roberts, 1993). The enzyme, calcium-dependent protein kinase (CDPK) is now classified into a novel family of calcium-regulated protein kinases found only in plants (Roberts, 1993) and protists (Zhao et al., 1994). CDPKs have the common feature of a C-terminal CaM-like domain that can directly bind Ca^{2+}, thereby making CaM unnecessary for their activation (Harper et al., 1991). This unique family of protein kinases is now implicated in the regulation of diverse metabolic and physiological processes (Harmon et al., 2000).

We have earlier identified a 55 kDa sandalwood (*Santalum album* L.) CDPK (swCDPK) that exhibits preferential accumulation and activity only in embryos, seedlings and endosperm tissues (Anil et al., 2000). The developmentally regulated expression of swCDPK suggests its involvement in the processes of embryogenesis, seed development and germination. Furthermore, a second messenger role for

Ca^{2+} and a probable intermediary role for swCDPK during sandalwood somatic embryogenesis have been earlier determined (Anil and Sankara Rao, 2000). Knowledge of the biochemical properties of this development-specific kinase would help in understanding modes of regulation of enzyme activity.

Therefore, in this study, we report purification of swCDPK and biochemical characterization of this purified enzyme. swCDPK exhibits both Ca^{2+}-dependent autophosphorylation and substrate phosphorylation activities. However, these activities differ in their Ca^{2+} requirement for activation, autophosphorylation having a 14-fold lower calcium requirement as compared to substrate phosphorylation activity. The study is the first to provide fluorescence spectral evidence for Ca^{2+}- induced conformational changes in CDPK. Interestingly, half-maximal change in conformation was observed at Ca^{2+} concentrations 10 fold lower than that required for substrate phosphorylation activity. Furthermore, the Ca^{2+}-induced changes in tryptophan emission spectra indicate occurrence of at least two distinct changes in conformation/Ca^{2+}-enzyme complexes at low (10–100 nM) and high (>100 nM) calcium levels.

2. Results

2.1. Purification

swCDPK was purified to homogeneity from torpedo/cotyledonary stage somatic embryos following three chromatographic procedures. The ammonium sulfate fraction was subjected to anion-exchange chromatography using DEAE-cellulose. The enzyme activity eluted with 0.4 M NaCl, 20 of the initial fractions showing Ca^{2+}-dependent protein kinase activity were pooled and processed for the next chromatographic step. The DEAE eluant was subjected to hydroxyapatite column chromatography. There was no loss of kinase activity in the wash with 5 mM K_2HPO_4 in buffer B. The kinase activity was eluted from the column, first with a step elution of 25 mM K_2HPO_4 followed by gradient elution with 25–300 mM K_2HPO_4 in buffer B. A minor protein peak that eluted with 25 mM K_2HPO_4 exhibited strong Ca^{2+}-dependent kinase activity. The fractions comprising this peak were pooled and processed for the next chromatographic step. Most of the bound proteins that eluted from the hydroxyapatite column at a higher concentration of phosphate as a second peak showed negligible Ca^{2+}-dependent kinase activity. The final purification was achieved by fractionation on Cibacron Blue–Sepharose. The wash with 0.6 M NaCl eliminated minor contaminants that were present in the hydroxyapatite pool. swCDPK was eluted as a single small peak comprising of three fractions in buffer containing 0.2% CHAPS.

The standard purification of swCDPK was 375-fold, yielding 75 μg (Table 1) from 30 g of starting material. The percentage recovery of protein kinase activity was approximately 10%, the final specific activity in the presence of micromolar Ca^{2+} being 35–43 pmol min^{-1} mg^{-1} (Table 1). Fig. 1A shows the silver staining pattern after SDS–PAGE analysis of pools from different steps of purification. Though only a single major protein band is seen in the hydroxyapatite pool, a minor high molecular weight contaminant was visualized when the gel was developed for longer time, during silver staining. The Blue–Sepharose column eluant resolved into a single protein band at 55 kDa (Fig. 1A). The three Blue–Sepharose fractions that comprised the activity peak resolved into a single protein band under non-denaturing conditions as well (Fig. 1B). This band cross-reacted strongly with polyclonal antibodies raised against the CaM-like domain of soybean CDPK (Fig. 1C), suggesting that the purified protein was an immunological homologue of soybean CDPK. As the purified preparation resolved into a single band both under denaturing and non-denaturing conditions, it is most likely that the band represents a single protein.

2.2. Calcium ion dependency

swCDPK displayed Ca^{2+}-dependent substrate phosphorylation activity (Fig. 2A). Fig. 2B shows the in-gel phosphorylation of histone III-S in a Ca^{2+}-dependent manner. Substrate phosphorylation activity was

[a] One unit of enzyme activity (u) = 0.1 pmol^{32}P/min/mg; EA, enzyme activity; TA, total activity.

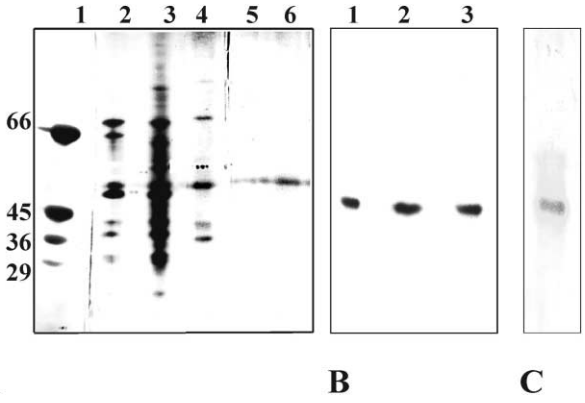

Fig. 1. Analysis of purification pools by gel electrophoresis and western blotting. A. Proteins from different stages of purification were resolved in a 10% polyacrylamide gel containing SDS and visualized by silver staining. Lane 1, molecular weight markers indicated in kilodaltons; lane 2, crude supernatant (10 μg); lane 3, ammonium sulfate fraction (10 μg); lane 4, DEAE pool (1 μg); lane 5, hydroxyapatite pool (0.25 μg); lane 6, Blue–Sepharose fraction (0. 25 μg). B. swCDPK (0.5 μg) was resolved on a non-denaturing 10% polyacrylamide gel and silver stained; lanes 1, 2 and 3 represent fractions 4, 5 and 6 respectively eluted from the Blue–Sepharose column. C. The resolved protein (1 μg) on the non-denaturing gel was analyzed by western blotting using polyclonal antibodies directed against the CaM-like domain of soybean CDPK.

stimulated 80–100 fold in the presence of Ca^{2+} ion, showing a half-maximal activation at 0.7 μM Ca^{2+} (Fig. 2C). The steep increase in histone phosphorylation activity with micromolar Ca^{2+} in a linear plot indicates the cooperative nature of this Ca^{2+}-dependent activation (Fig. 2C, inset). Autophosphorylation activity of swCDPK was observed at nanomolar concentrations of Ca^{2+}, half-maximal activation requiring only 40–50 nM Ca^{2+} (Fig. 3).

2.3. Kinetic properties

From the plot of $1/v$ versus 1/[histone III-S] (figure not shown), the K_m of swCDPK for histone III-S was estimated to be 1.3 mg/ml and the V_{max} value extrapolated from this plot was 0.1 nmol min^{-1} mg^{-1}. The plot of $1/v$ versus 1/[ATP] (figure not shown) indicated that swCDPK has high specificity for ATP, exhibiting a K_m of 10 nM. The turnover number (k_3) of swCDPK was 1×10^2 min^{-1} and the specificity constant (k_3/K_m) for histone III-S and ATP was calculated to be 1.6×10^6 and 1×10^{10} M^{-1} min^{-1} respectively. The observed high specificity for ATP and the low turnover number of swCDPK are different from those of other well characterized CDPKs (Putnam-Evans et al., 1990; DasGupta, 1994; Ganguly and Singh, 1998; Anil, 2000).

2.4. Effect of salt, Mg^{2+}, and pH on swCDPK activity

swCDPK activity was inhibited above 10 mM NaCl, complete inhibition occurring at 100 mM NaCl (figure not shown). swCDPK requires Mg^{2+} for activity, optimal histone III-S phosphorylation occurring only in the

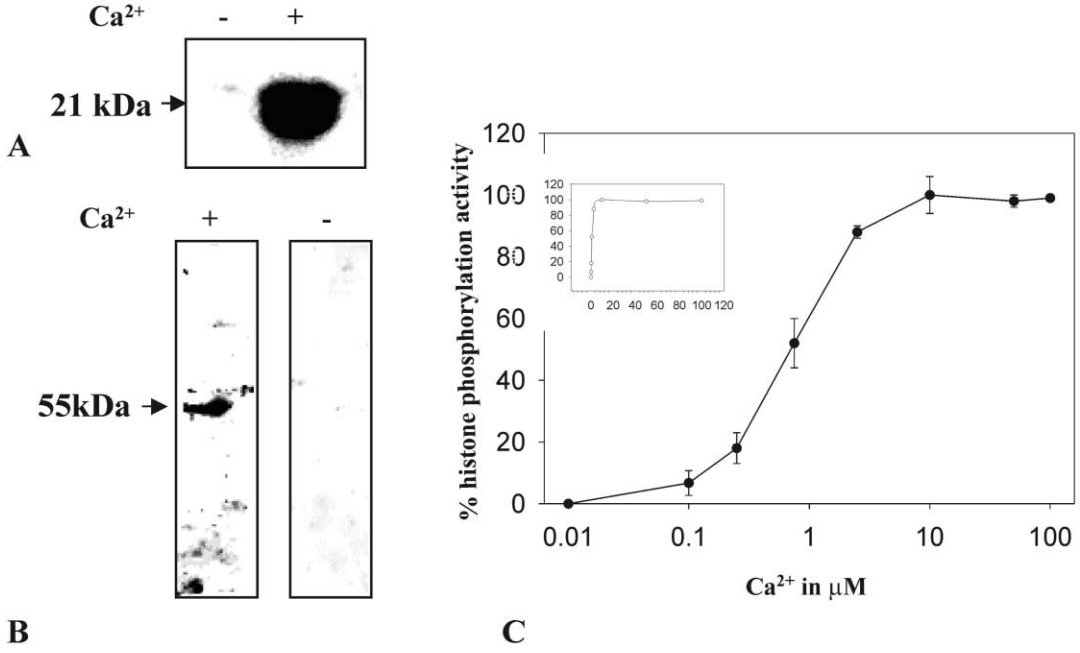

Fig. 2. Ca^{2+}-dependent substrate phosphorylation activity of swCDPK. A. swCDPK (50 ng) was assayed for histone phosphorylation activity as outlined in 'Experimental'. The reaction mix was then resolved by SDS 10% (w/v) polyacrylamide gel electrophoresis. The autoradiogram shows the position of phosphorylated histone III-S in the presence of Ca^{2+}. B. Autoradiogram represents the Ca^{2+}-dependent in-gel phosphorylation of histone III-S. C, Effect of Ca^{2+} on the activity of swCDPK (50 ng). Percentage activity is deduced relative to the activity obtained under standard assay conditions.

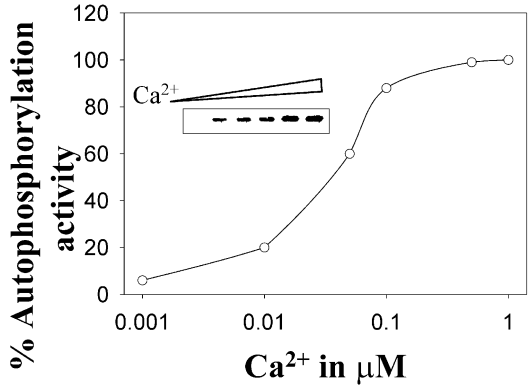

Fig. 3. Effect of Ca^{2+} on swCDPK autophosphorylation activity. Autophosphorylation of swCDPK (50 ng) was monitored at different concentrations of calcium in assay buffer. The phosphorylated swCDPK was resolved in a 10% (w/v) polyacrylamide gel containing SDS and visualized by phosphorimager. The percentage activity as a function of Ca^{2+} concentration was plotted using the photostimulated luminescence minus background (PSL–BG) emitted by phosphorylated swCDPK bands. One hundred per cent activity represents a PSL–BG of 70. Inset is a representative autoradiogram showing increase in swCDPK autophosphorylation within a range of 0.001–1 μM Ca^{2+}.

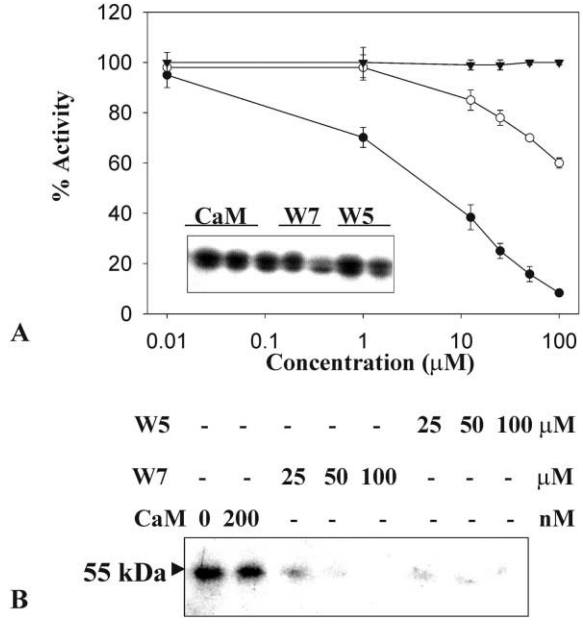

Fig. 4. Effect of CaM, W7 and W5 on swCDPK activity: Protein kinase assays were performed under standard assay conditions using 50 ng purified enzyme and amounts of CaM or inhibitors as indicated. A. Effect of increasing concentrations of CaM (▼), W5 (O), and W7 (●) on histone phosphorylation activity. Inset is a representative autoradiogram showing position of phosphorylated histone III-S in presence of CaM (0, 100 and 200 μM), W7 (0 and 10 μM) and W5 (0 and 10 μM). B. Effect of increasing concentrations of CaM, W7 and W5 on the autophosphorylation activity of swCDPK.

presence of 5–10 mM Mg^{2+} (figure not shown). However, inhibition of activity was observed above 10 mM Mg^{2+}. Purified swCDPK exhibited broad pH optima between pH 6.8 and 8.5, highest activity being observed at pH 7.2 (figure not shown).

2.5. Effect of calmodulin, and CaM-antagonists W7 and W5 on swCDPK activities

Exogenous calmodulin (CaM) did not enhance substrate phosphorylation activity of swCDPK (Fig. 4A). However, CaM- antagonist, *N*-(6-aminohexyl)-5-chloro-1-naphthalene sulfonamide (W7) and its less potent analogue W5 (Fig. 4A) inhibited activity. W7 inhibited with an IC_{50} of 6 μM and W5 inhibited with an IC_{50} of 46 μM. The autophosphorylation of swCDPK also remained unaffected by exogenous CaM, and was inhibited by both W7 and W5 (Fig. 4B). Although W5 has lower affinity towards CaM, it inhibits, albeit to a lesser extent, CaM-dependent enzymes and CDPKs (Harmon et al., 1986). The inhibition by W7 and W5 thus indicates that swCDPK has an endogenous CaM-like domain that regulates both substrate and autophosphorylation activities of the enzyme.

2.6. Phosphoamino acid analysis

Hydrolyzed phosphorylated histone III-S and autophosphorylated swCDPK were subjected to PC so as to identify the phosphorylated amino acid residues. swCDPK phosphorylated the substrate histone III-S exclusively on serine residues and autophosphorylated itself exclusively on threonine residues (Fig. 5).

2.7. Autophosphorylation versus substrate phosphorylation activity of swCDPK

Autophosphorylation reactions carried out in the presence of the exogenous substrate histone III-S resulted in a reduction in the autophosphorylation of swCDPK with increasing concentrations of histone III-S (Fig. 6).

2.8. Spectral properties

The absorption spectra of swCDPK shows that the enzyme exhibits maximum absorption (λ_{max}) at 290 nm, suggesting the presence of a number of tryptophan residues (Spectra not shown). Titration of swCDPK with Ca^{2+} enhanced the emission fluorescence intensity when excited at 280 nm, reaching saturation at approximately 1 μM calcium (Fig. 7A). Plot of the fluorescence intensity values at λ_{max} as a function of Ca^{2+}concentration (Fig. 7B) shows that the Ca^{2+} concentration required for half-maximal-enhancement of fluorescence intensity is 64 nM. The ratio of the fluorescence intensity at 350 nm and 310 nm, that represents emission by tryptophans and tyrosines respectively (Fig. 7A) underwent a reduction from 1.9 to 1.4 with addition of Ca^{2+}. A similar Ca^{2+}-induced fluorescence enhancement was observed when swCDPK was excited at 295 nm (Fig. 7C). The

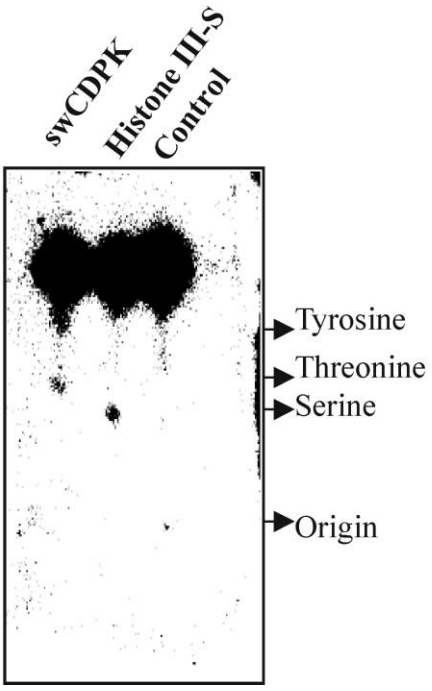

Fig. 5. Identification of phosphorylated amino acids. Phosphorylated histone III-S/phosphorylated swCDPK was hydrolyzed in 6 M HCl. The hydrolysates were resolved by PC. The position of standards is indicated by arrows. swCDPK, position of phosphorylated amino acid by autophosphorylation activity; histone III-S, position of phosphorylated amino acid by substrate phosphorylation activity; control, assay performed in the absence of the enzyme, the intense signal on autoradiogram represents the position of unreacted γ-^{32}P ATP.

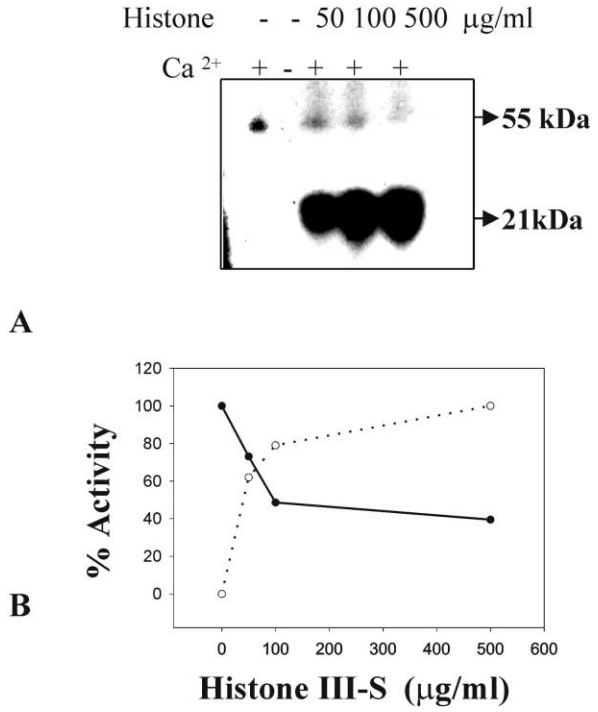

Fig. 6. Effect of histone III-S on autophosphorylation activity of swCDPK. Standard autophosphorylation assays were performed with 50 ng of purified swCDPK with different concentrations of histone III-S. The assay mixture was resolved in a 10% polyacrylamide gel containing SDS. The phosphorylated proteins were visualized by a phosphorimager. A. Autoradiogram shows the effect of increasing concentrations of histone III-S on autophosphorylation of 55 kDa swCDPK; B. Change in percentage autophosphorylation (●) by substrate phosphorylation (O). Percentage activity is derived from the photostimulated luminescence minus background (PSL–BG) of different phosphorylated bands in 'A'. One hundred per cent autophosphorylation represents a PSL–BG of 65 and 100% histone phosphorylation represents a PSL–BG of 790.

fluorescence spectra also showed a shift of λ_{max} from 350 to 367.5 nm with addition of Ca^{2+} (Fig. 7C). In addition, a change in spectral shape was observed above 100 nM Ca^{2+} (Fig. 7C). Fig. 7D clearly shows breaks or discontinuity in the plots representing fluorescence intensity values or λ_{max} as a function of [Ca^{2+}], at low (10–100 μM) and high (>100 μM) Ca^{2+} levels. These observations not only are clear evidence for Ca^{2+}-induced conformational change in swCDPK, but also imply the formation of at least two kinds of Ca^{2+}-enzyme complexes.

3. Discussion

This paper describes the purification and characterization of an early development-specific CDPK from sandalwood. Activation by sub-micromolar Ca^{2+}, independence of exogenous CaM and inhibition by CaM-antagonists of both substrate- and autophosphorylation activities are clear indicators for the presence of an endogenous CaM-like Ca^{2+}-binding domain in the purified enzyme. Furthermore, cross-reaction with antibodies raised against the CaM-like domain of soybean CDPK confirms the existence of an endogenous CaM-like structure. This structural feature acts as a diagnostic character for classifying this developmentally regulated sandalwood enzyme as a member of the CDPK family.

swCDPK exhibited divergent and similar biochemical properties with the prototype, soybean CDPK, and other CDPKs. swCDPK is a Ser/Thr protein kinase that exhibits a Ca^{2+} requirement for substrate phosphorylation activity comparable to that of other CDPKs (Harmon et al., 2000). The inhibition of substrate phosphorylation activity by salt (Section 2.4) implies ionic interactions between the positively charged substrate and the enzyme's active site. In corroboration, the inhibition of activity above 10 mM Mg^{2+} (Section 2.4) also suggests the disruption of ionic interaction between the enzyme and the substrate. Nonetheless, the possibilities of salt-induced conformational changes that result in the inhibition of activity cannot be ruled out from the present study. Highest activity that was obtained at about pH 7 (Section 2.4) indicates the presence of histidine residues at the enzyme's active site. The pH optimum (6.8–8.5) of swCDPK is comparable to that of soybean CDPK (Putnam-Evans et al., 1990), but differs from the alkaline pH

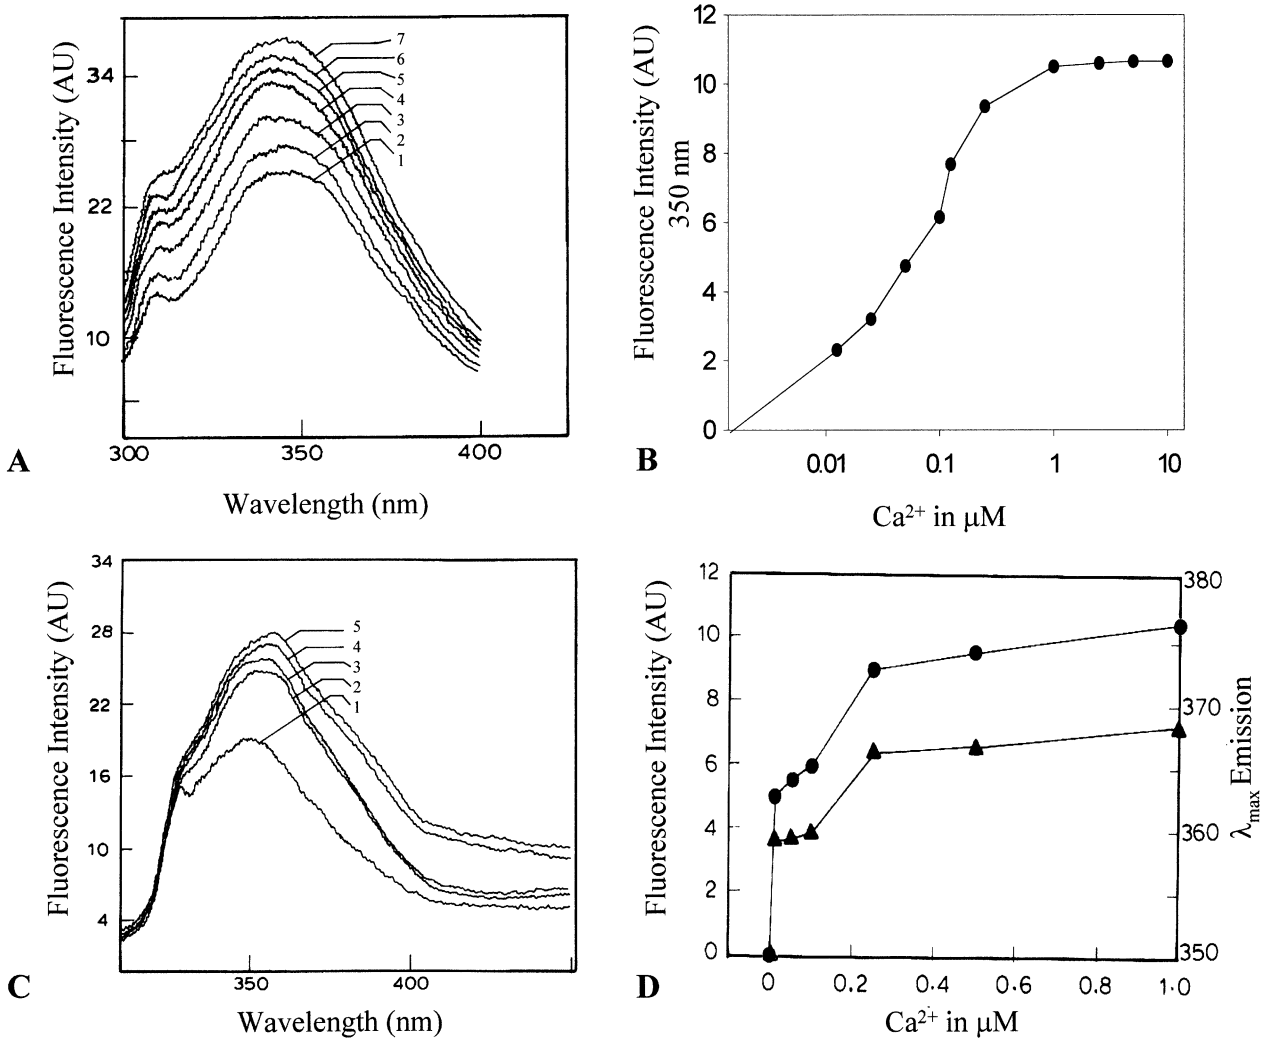

Fig. 7. Spectral properties of swCDPK. A. Change in fluorescence emission spectra of swCDPK (9 nM) with increasing Ca^{2+} at excitation wavelength of 280 nm. Numbers 1–7 represent [Ca^{2+}] of 0, 0.01, 0.05, 0.1, 0.125, 0.25 and 1 μM, respectively (overlapping spectra obtained at Ca^{2+} concentrations between 1 and10 μM are not shown); B. A replot of A showing fluorescence intensity at λ_{max} emission plotted as a function of Ca^{2+} concentration; C. Changes in fluorescence emission spectra of swCDPK (9 nM) with increasing Ca^{2+} at excitation wavelength of 295 nm. Numbers 1–5 represent [Ca^{2+}] of 0, 0.01, 0.1, 0.25 and 1 μM; D. Replot of values obtained from C representing fluorescence intensity (●) or λ_{max} emission (▲) plotted as a function of [Ca^{2+}].

requirement of groundnut CDPK (DasGupta, 1994). These variations in pH optima among CDPKs might indicate variations in the amino acid composition at their active sites.

Histone III-S was found to be the preferred exogenous substrate for swCDPK than histone VII-S, kemptide, BSA, casein or phosvitin (data not shown). Nonetheless swCDPK has a comparatively higher K_m for histone III-S than most other CDPKs (Putnam-Evans et al., 1990; Binder et al., 1994; Saha and Singh, 1995; Ganguly and Singh, 1998). This to some extent explains the low activity and as a result the low V_{max} value exhibited by swCDPK. It is plausible that some members of the CDPK family such as swCDPK and some isoforms of CDPK from potato (MacIntosh et al., 1996) and maize (Ogawa et al., 1998), that exhibit lower specific activity in the order of pmol min^{-1} mg^{-1}, are so designed as to regulate specific signaling pathways, thus having implications at the cellular level. However, it remains to be determined whether swCDPK exhibits higher specificity and different kinetic properties to its hitherto not identified in vivo substrate(s). Kinetic studies further reveal that swCDPK has high specificity for ATP, exhibiting a K_m of only 10 nM. Such a high affinity for ATP has not been reported for other CDPKs and is rather unusual for protein kinases. However, similar K_m values for ATP have been reported earlier in the case of cyclic AMP-dependent protein kinase (Cook et al., 1982; Whitehouse and Walsh, 1983).

There is no consensus on the regulatory role of autophosphorylation in CDPKs as both stimulatory (Chaudhuri et al., 1999) and inhibitory (Saha and

Singh, 1995) effects of autophosphorylation on substrate phosphorylation activity have been reported. The present finding that increasing histone III-S in the reaction inhibits the autophosphorylation of swCDPK (Fig. 6) suggests that the enzyme preferably phosphorylates the substrate rather than itself. This therefore implies that autophosphorylation may not be a prerequisite for substrate phosphorylation activity. However, another plausible explanation for this observation is the occurrence of ATP depletion in the assay that could have led to the ~2-fold increase in substrate phosphorylation over a 10-fold substrate range, catalyzed by a smaller population of autophosphorylated enzyme. In addition preautophosphorylation of swCDPK with 1mM cold ATP was neither inhibitory nor stimulatory for the enzyme's substrate phosphorylation activity (data not shown). With the available data a regulatory role for swCDPK-autophosphorylation therefore cannot be elucidated and requires further study. Nonetheless, the lower calcium requirement for autophosphorylation in comparison to that for substrate phosphorylation activities of swCDPK could be a mechanism of regulation shared by some members of the CDPK family. Similarly, soybean isoforms CDPK α,-β,-γ, also show a 1.3–3.3-fold decrease in the Ca^{2+}-requirement for autophosphorylation ($K_{0.5}=0.03$, 0.3 and 0.3 μM respectively) from that required for substrate phosphorylation ($K_{0.5}=0.06$, 0.4 and 1 μM respectively) (Lee et al., 1998). However, the 14-fold difference in the Ca^{2+} requirement for autophosphorylation ($K_{0.5}=\sim 50$ nM) and substrate phosphorylation ($K_{0.5}=700$ nM) of swCDPK is comparatively higher and physiologically significant as the $K_{0.5}$ values can be correlated with the resting $[Ca^{2+}]_{cyt}$ of ~30–50 nM and stimulus-induced elevation of ~600–800 nM in sandalwood embryogenic cells (Anil and Sankara Rao, 2000). Therefore, in the light of the low calcium requirement for autophosphorylation of swCDPK, it is likely that the enzyme is in an autophosphorylated state at resting levels of $[Ca^{2+}]_{cyt}$. Substrate phosphorylation becomes possible only upon stimulus-induced calcium elevation. In addition, the ~64 nM calcium required for half maximal change in fluorescence enhancement (Fig. 7B) is comparable to that required for autophosphorylation and is approximately 10-fold lower than that required for substrate phosphorylation activity of swCDPK. The fluorescence spectral data (Fig. 7) in conjunction with autophosphorylation properties of the enzyme suggest that low Ca^{2+} levels induce changes in conformation that can stimulate autophosphorylation activity.

According to the 'release of inhibition' model proposed by Huang et al. (1996), Ca^{2+}-binding to CDPK induces the interaction of the CaM-like domain to the autoinhibitory-junction domain (Harper et al., 1994; Harmon et al., 1994), releasing the autoinhibitor from the catalytic domain, thereby activating the enzyme. This model thus implies that Ca^{2+}-induced conformational changes are a necessary prerequisite for enzyme activation. In corroboration, CD analysis of a *Plasmodium falciparum* CDPK (PfCPK) has shown that a change from zero to saturating calcium induces a 16% decrease in the mean molar ellipticity at 222 nm (Zhao et al., 1994). Nevertheless there is lack of information concerning Ca^{2+}-induced conformational changes in plant CDPKs. The present study exploits the intrinsic fluorescence properties of swCDPK to gain insights into this phenomenon. Calcium titration of swCDPK not only results in the enhancement of fluorescence intensity but also in a reduction in the ratio of fluorescence intensity emitted at 350–310 nm (excitation $\lambda=280$ nm). This increased emission from tyrosines at 310 nm could be reflective of minor differences in the abilities of tyrosines to ionize, but it also suggests a decrease in the efficiency of non-radiative energy transfer from tyrosine residues to tryptophan residues. This reduction in energy transfer can be attributed to an increase in the relative distances between tyrosine and tryptophan residues brought about by Ca^{2+} binding. Corroboratively, the shift in λ_{max} emission observed when excited at 295 nm (Fig. 7C) indicates that Ca^{2+}-binding of swCDPK results in tryptophan residues shifting to a much lesser hydrophobic environment. The spectral shift as well as the prominent change in the spectral shape above 100 nM Ca^{2+} (Fig 7C) implies that further changes in conformation occur at higher Ca^{2+} levels. Corroboratively, the discontinuity in the plots of fluorescence intensity at λ_{max} or shift in λ_{max} as a function of $[Ca^{2+}]$(Fig. 7D) clearly indicate distinct changes in conformation of swCDPK at low and high concentrations of calcium. This suggests that at least two distinct Ca^{2+}-enzyme complexes are formed at different calcium concentrations. Considerable variation in the affinity for Ca^{2+} between the four Ca^{2+}-binding sites of vertebrate CaM (Klee and Vanaman, 1982) gives further support to this. Therefore, the monitoring of Ca^{2+}-induced conformational changes in swCDPK with step-wise increases in $[Ca^{2+}]$ within the physiological range provides new insights into this process.

In conclusion, the data presented confirms the identity of swCDPK as a CaM-like domain protein kinase. Nonetheless, considerable variations with respect to enzymatic properties such as a higher sensitivity to W7 inhibition ($IC_{50}=6$ μM), much higher specificity for ATP ($K_m=10$ nM) and a low turnover number ($1\times10^2 min^{-1}$) renders swCDPK a unique member of this family of kinases. Furthermore, biochemical and fluorescence spectral properties of the enzyme suggest the occurrence of considerable changes in conformation and activation of autophosphorylation at low levels of Ca^{2+}. Variation in the affinity to Ca^{2+} among the Ca^{2+}-binding sites of swCDPK could be the probable reason for activation of autophosphorylation- and substrate

phosphorylation activities at two different ranges of Ca^{2+}. However, elucidation of the role of autophosphorylation is necessary for complete understanding of the mechanism of regulation of enzyme activity.

4. Experimental

4.1. Chemicals

Histone III-S, Chelex 100, leupeptin, aprotinin, PMSF, ATP, phosphotyrosine, phosphothreonine, phosphoserine, DEAE-cellulose and other chemicals used were purchased from Sigma chemical company, USA, unless mentioned otherwise. Bovine serum albumin (BSA) fraction V was obtained from Boehringer Mannheim. Hydroxyapatite was purchased from Bio-Rad, USA. HRP conjugated goat anti-rabbit IgG was purchased from Bangalore Genie. Radioactive isotope, γ-^{32}P-ATP (5000 Ci/mmol) was obtained from BRIT, Hyderabad. Cibacron Blue-Sepharose 6B was prepared according to the method of Hughes et al., 1982.

4.2. Plant material

Endosperm explants from mature sandalwood fruits were cultured on MS medium (Murashige and Skoog, 1962) as described by Anil and Sankara Rao (2000), to sequentially induce embryogenic callus, callus proliferation, and embryogenesis. Torpedo- and cotyledonary stage somatic embryos that differentiate from the embryogenic calli, were harvested and used for protein purification.

4.3. Substrate phosphorylation assay

In a total volume of 0.15 ml, the assay mixture contained 1.4 mg ml^{-1} histone III-S in Ca/EGTA buffer (50 mM Hepes pH 7.2, 10 mM $MgCl_2$, 0.25 mM ethyleneglycol-bis (β-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetra acetic acid.[-EGTA]) with or without 0.2 mM $CaCl_2$ and 50 ng of purified swCDPK. The reaction was initiated with addition of 10 nM γ-^{32}P-ATP (5000 nCi/pmol) and incubated at 30 °C for 6 min. Termination of the reaction, spotting of the mixture on glass fiber filters and washing of the filters were carried out according to the method of Putnam-Evans et al. (1990). Counts were recorded on an LKB liquid scintillation counter. Assays were also performed with varying concentration of Ca^{2+}, W7 and CaM in the assay mixture. During purification, 5 μl of each fraction was assayed in Ca/EGTA buffer as described earlier using histone III-S as the exogenous substrate.

4.4. Purification of swCDPK

All steps of purification were performed at 4°C unless mentioned otherwise. Sandalwood torpedo/cotyledonary stage somatic embryos (30 g) were homogenized in liquid nitrogen using pestle and mortar and suspended in 3 volumes of cold buffer A (20 mM Tris, pH 7.2, 2.5 mM EDTA) containing 1 mM PMSF and 20 μg/ml aprotinin. The crude homogenate was centrifuged at 13,650 *g* at 4 °C for 30 min to separate cell debris from the crude supernatant. The crude supernatant was then subjected to 80% ammonium sulfate fractionation. The precipitated proteins were dissolved in buffer A containing 1 mM PMSF and 20 μg/ml aprotinin and dialyzed against 5 l of buffer A twice overnight.

The dialysate was applied on a DEAE-cellulose column (50 ml) equilibrated with buffer A. The column was washed with 100 ml of buffer A containing 0.05 M NaCl and the bound proteins eluted with 100 ml of buffer A containing 0.4 M NaCl. Fractions containing Ca^{2+}-dependent kinase activity were pooled and 1mM PMSF and 20 μg/ml aprotinin added. The pool was then dialyzed overnight against 5 l of buffer B (20 mM Tris, pH 7.2, 0.25 mM EDTA and 0.25 mM $CaCl_2$), twice overnight. The DEAE-pool was applied to a 15 ml hydroxyapatite column, equilibrated with buffer B. The column was washed with 2 column volumes of buffer B containing 5 mM K_2HPO_4. The kinase was eluted first with 20 ml of buffer B containing 25 mM K_2HPO_4 followed by a linear gradient of K_2HPO_4 (25–300 mM) in buffer B. Fractions having kinase activity were pooled. Protease inhibitors (1 mM PMSF, 20 μg/ml aprotinin and 10 μg/ml leupeptin) were added to this pool, followed by dialysis against 5 l of buffer C (20 mM Tris, pH 7.2, 0.2 mM EDTA and 5.5 mM $MgCl_2$), twice overnight.

The hydroxyapatite pool was applied to a 2 ml Cibachron Blue-Sepharose column, equilibrated with buffer C. The column was washed with 5 column volumes of buffer C containing 0.6 M NaCl. swCDPK was eluted with buffer C containing 0.2% CHAPS (buffer D). The purified preparation was stored in buffer D containing 10% glycerol at −80 °C until use. Spectroscopic measurements were carried out with freshly eluted enzyme in buffer D.

4.5. Electrophoresis and protein determination

Electrophoresis on 10% polyacrylamide gels was performed according to the method of Laemmli (Laemmli, 1970) and protein concentrations were measured according to the method of Bradford (Bradford, 1976) using BSA as standard.

4.6. Autophosphorylation assay

Purified swCDPK was assayed to determine Ca^{2+}-dependent autophosphorylation activity. The reaction was carried out as described by Anil et al. (2000), following which, the reaction mixture containing swCDPK

was resolved on a 10% SDS polyacrylamide gel at 45 V overnight. The gels were exposed to Kodak X-ray film for 24 h or visualized by phosphor imager. This assay was also performed in the presence of varying concentrations of Ca^{2+}, W7, CaM and histone III-S.

4.7. In-gel histone phosphorylation assay

In-gel phosphorylation of histone III-S was carried out according to the method described by McCurdy and Harmon (1992). SDS 10% polyacrylamide gel was polymerized in the presence of 0.5 mg/ml histone III-S. The purified preparation was incubated for 2 min in Laemmli's sample buffer at 70 °C. After resolving the protein on the gel, the gel was washed with six changes of 50 mM Hepes buffer (pH 7.2) for a period of 6 h to renature the proteins. The gel was then cut into strips and the CDPK kinase activity of the resolved enzyme was determined following the method of Harmon et al., (1986). The gel strips were washed to remove unreacted γ-^{32}P-ATP as described by Anil et al. (2000).

4.8. Phosphoamino acid analysis

Substrate phosphorylation and autophosphorylation assays were performed as described above. The phosphorylated swCDPK and phosphorylated histone III-S were subjected to acid hydrolysis in 6 M HCl by boiling at 100 °C under vacuum for 2 h. After mixing the hydrolysates with standard phosphoserine, phosphothreonine and phosphotyrosine, they were chromatographed on Whatman 3MM paper using a solvent system comprising of *n*-propanol and 0.5 N HCl (2:1). They were then rechromatographed with *n*-butanol, acetic acid and water (100:22:50) in the same direction. Radiolabeled amino acids were visualized by autoradiography, and standard phosphoamino acids by ninhydrin staining.

4.9. Western blot analysis

Purified swCDPK was resolved on a non-denaturing polyacrylamide gel and transferred to nitrocellulose membrane following standard conditions (Towbin et al., 1979). The immobilized protein was then subjected to western blot analysis as described by Anil et al. (2000), using polyclonal antibodies directed against the CaM-like domain of soybean CDPK (Bachmann et al., 1996).

4.10. Spectral studies

A Shimadzu UV spectrophotometer was used to study the absorption spectral properties of swCDPK between the range of 200–340 nm. Fluorescence spectroscopic studies were carried out in a RF5000 Shimadzu spectrofluorimeter, using excitation wavelengths of 280 and 295 nm, and fluorescence spectra recorded between 300 and 400 nm. Changes in fluorescence spectra of swCDPK with Ca^{2+}-titration were recorded.

Acknowledgements

We thank Professor S.K. Podder for valuable suggestions and critical reading of the manuscript, Professor A. C. Harmon for the gift of polyclonal anti-soybean CDPK and Professor C. Jayabaskaran for helpful discussions. This work was supported by the Department of Science and Technology and the Council of Scientific and Industrial Research, Government of India.

Abstract

α-Galactosidase activity in grape flesh (*Vitis venifera* L. Muscat of Alexandria) was characterized by a marked increase in its activity 4 weeks after fruit bearing. After 12 weeks the specific activity of the enzyme had increased 15-fold. Several other glycosidases were measured at different stages of fruit development but none showed the increased levels of activity displayed by this α-galactosidase. α-Galactosidase activity (unit/g·fresh wt) increased by 52% during postharvest storage, whereas the unripe grape showed a "stagnancy" for 10–15 days prior to the increase. An α-galactosidase was partially purified ca. 103-fold from grape flesh of *Vitis labruscana* Honey black, by a procedure involving ammonium sulfate fractionation, Biogel P-60, melibiose-agarose, and Sephacryl S-200 chromatographic separations. The enzyme was effectively separated by affinity chromatography on melibiose-agarose, and was a monomer of 40–45 kDa as determined by SDS-PAGE and Sephacryl S-200 chromatographic analysis. The hydrolysis rate of *p*-nitrophenyl-α-D-Gal (PNP-α-D-Gal) was 4.2 times higher than that of PNP-β-D-Gal, implying an apparent α-anomer specificity, and natural oligosaccharides such as melibiose, stachyose, and raffinose were also considerably hydrolyzed. The enzyme was active over a narrow pH range with an optimal hydrolysis of stachyose and PNP-α-D-Gal at pH 6.0 and 7.0, respectively. EDTA or 1,10-phenanthroline did not substantially affect enzyme activity. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

α-Galactosidase (E.C. 3.2.1.22, α-D-galactoside galactohydrolase) is one of the exoglycosidases, capable of hydrolysing α-1,6 linked α-galactoside residues. α-Galactosidases are widely distributed in intra- or extracellular forms in microorganisms, plants and animals. The enzyme in plants, especially, has been greatly investigated from seeds in relation to germination (Dey and Pridam, 1969; Barham et al., 1971; McCleary and Matheson, 1974; Dey et al., 1983; Corchette and Guerra, 1987) and is also found in leaves and other tissues (Gatt and Baker, 1970; Thomas and Webb, 1978; Smart and Pharr, 1980; Gaudreault and Webb, 1983; Burns, 1990). Diverse forms of α-galactosidase occur occasionally in many plants, having molecular weights ranging from 25 to 270 kDa and different properties (Dey and Pridam, 1969, 1972; Thomas and Webb, 1977; Hankins et al., 1980; Smart and Pharr, 1980; Dey et al., 1983; Mujer et al., 1984; Haibath et al., 1991; Chrost and Schmitz, 1997; Irving et al., 1997). α-Galactosidases are generally involved in metabolic utilization of oligosaccharides such as raffinose, stachyose, melibiose, and galactomannan, that are even more widely distributed in storage organs such as seeds, roots, and tubers (McCleary and Matheson, 1974; Kandler and Hopf, 1980). α-Galactosidases have been implicated with the metabolism of galactolipids (Sastry and Kates, 1964; Pridam and Dey, 1974). In addition to these hydrolysis reactions, transglycosylation is catalyzed by the enzyme with somewhat broad acceptor specificity (Dey and Pridam, 1972).

Despite this wide distribution and diversity, α-galactosidases seem to be less abundant in fruits compared with other plant organelles. Biochemical/physiological aspects in fruits differ from those of other tissues or organelles in plants, and hence other types of α-galactosidase may be present in grape. Characterization of α-galactosidase in grape flesh would be helpful in understanding the physiological role of the enzyme. In this

paper, we partially purified an α-galactosidase associated with grape flesh and present some of its biochemical characteristics.

2. Results and discussion

2.1. α-Galactosidase activity from grape flesh

The glycosidase activities of flesh (mesocarp plus placental tissue) from *Vitis venifera* L. Muscat of Alexandria are shown in Table 1. Of the various glycosidases assayed, α-galactosidase was the most active, followed by α-mannosidase, as measured by the assays at pH 5.0 or 7.0. Significant activities of α- and β-glucosidase, and β-galactosidase were found at acidic or neutral pH. Glycosidases were also evaluated from the flesh of other grape cultivars, Honey black, Marguerite, Edelweiss, Agawan, Egiodola, Green hungarian, and Takasumi at pH 7.0. For all of the strains tested, α-galactosidase was the most active, although other glycosidases also showed significant activities (data not shown). Fig. 1 shows the variation in the specific activities of galactosidase, glucosidase, and α-mannosidase in flesh from Muscat of Alexandria at different stages of fruit development. These glycosidase activities were scarcely found at the unripe stage (approximately up to 4 weeks from fruit bearing). After this stage, the activities increased rapidly to different extents. Approximately 15 times increase in α-galactosidase activity was observed during the ripening stage from 4 to 12 weeks. The most prominent increase was found at the mid-term of ripening stage (4–8 weeks from fruit bearing). The expression of α-galactosidase in the flesh was characterised by an increase in activity per g·fresh wt as well as in the activity per mg·protein along with the ripening stage. These results suggest that α-galactosidase might play an important role in grape flesh during fruit development. The marked expression of α-galactosidase synchronizing with the ripening stage could be correlated with the report of Gross (1986) that applied galactose stimulated ethylene production and promoted ripening of mature green tomatoes. But the results presented here do not elucidate any role for the α-galactosidase in the grape flesh. Putative variation of α-galacto sidase during postharvest storage at 4°C was assessed from the flesh of Honey black harvested after 9 or 12 weeks from fruit bearing (Fig. 2). In the latter grape, the α-galactosidase activity (unit/g· flesh wt) increased by 52% of control after 15 days of storage and then declined slowly. The unripe grapes harvested after 9 weeks, however, showed a "stagnancy" for 10–15 days of storage before an increase in activity occurred, and then the activity slowly increased albeit to a lesser extent than the more ripe grape.

Table 1
Distribution of glycosidases in grape flesh (*Vitis venifera* L. Muscat of Alexandria). The activity was measured for the grape harvested after 3 months from fruit bearing. The enzyme assay was run by hydrolysis of PNP-glycosides (2 mM) in 50 mM Na-acetate (pH 5.0) or K-phosphate (pH 7.0) containing 0.5% glycerol. Glycosidase activities were represented as units per g·fresh wt. Soluble solids content of the grape berry was 17.1°Bx. Activity values were expressed as means ± S.E. of three independent experiments

Substrate	Glycosidase activity (unit/g·flesh wt)	
	pH 5.0	pH 7.0
PNP-α-D-Gal	545.6±26.5	814.2±31.6
PNP-β-D-Gal	206.4±18.4	190.8± 9.5
PNP-α-D-Glc	195.4±12.0	374.1±11.7
PNP-β-D-Glc	201.9±10.2	309.0±22.1
PNP-α-L-Fuc	49.2± 4.3	101.4± 2.5
PNP-β-D-Fuc	31.3± 2.5	55.4± 3.1
PNP-α-D-Man	398.3±22.3	569.8±18.4
PNP-α-L-Ara	8.9± 0.2	6.1± 0.6
PNP-α-L-Rha	0.6± 0.1	0.8± 0.2
PNP-β-D-GlcUA	0.4± 0.1	0.5± 0.1
PNP-α-D-GlcNAc	2.4± 0.2	0.9± 0.2
PNP-β-D-GlcNAc	1.6± 0.1	0.7± 0.1
PNP-β-D-GalNAc	57.4± 2.4	63.3± 4.5
Polygalacturonic acid[a]	5.9± 0.5	7.7± 0.2

[a] The polygalacturonase activity was measured using 2-cyanoacetamide (Gross, 1982).

2.2. Purification of α-galactosidase

Purification of α-galactosidase was performed using flesh of *Vitis labruscana* Honey black. With regard to

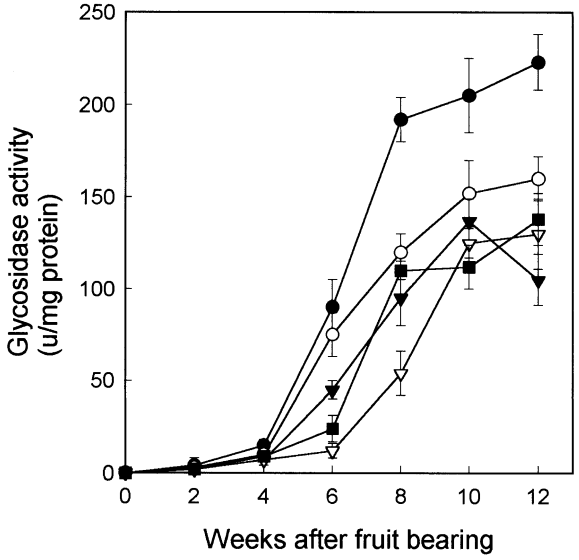

Fig. 1. Occurrence of glycosidases at different stages of fruit development. Glycosidase activities in grape flesh (*Vitis venifera* L. Muscat of Alexandria) was assessed up to 3 months after fruit bearing. α-Galactosidase (-●-), β-galactosidase (-▽-), α-mannosidase (-○-), α-glucosidase (-■-), and β-glucosidase (-▼-) activities were measured using PNP-glycosides and represented as unit per mg·protein. Activities per g·fresh wt increased also gradually along with the ripening stage (These data are not represented in the figure). Each value was the average of three replicate assays.

the α-galactosidase extraction from grape flesh, we note that homogenization of grape flesh with 0.2 M Na_2CO_3 resulted in an increase in α-galactosidase activity (unit/g·fresh wt) by 3.1 times compared with the extraction without Na_2CO_3. Alternatively, addition of 0.05 N NaOH caused the enzyme activity to increase as much as 2.8 times. Thus, the increase of ionic strength and/or the augmentation of pH (pH was elevated to 5.1 from 3.9.) appeared to release more α-galactosidase from the grape flesh. The α-galactosidase from grape flesh was stable during the initial steps of the purification procedures. The stability gradually decreased as the purification steps proceeded and dilution of the enzyme also accelerated a decrease in activity (data not shown). Stabilization or restoration of activity was attempted by adding dithiothreitol (2 and 10 mM) or EDTA (1 and 5 mM), but the stability of α-galactosidase was not affected by these compounds. The activity loss was considerably prevented by addition of glycerol in the equilibration/elution buffers during the purification procedure.

The enzyme was partially purified by salting out with ammonium sulfate and using chromatographic steps involving Biogel P-60, melibiose-agarose, and Sephacryl S-200 columns respectively. A peak of α-galactosidase activity was resolved on melibiose-agarose chromatography.

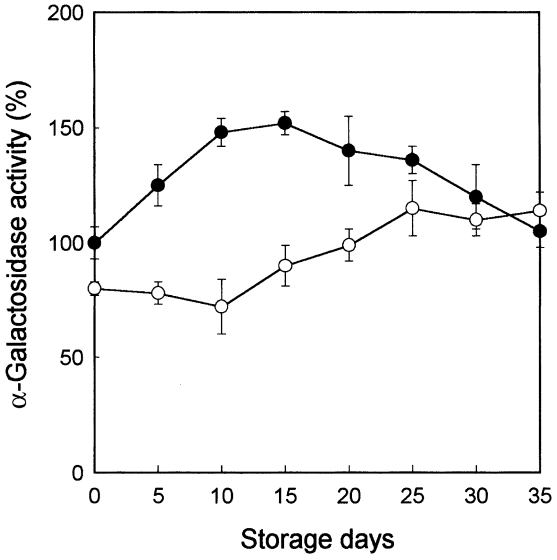

Fig. 2. Activity variation of α-galactosidase during postharvest storage. Grapes (Honey black) were collected after 9 weeks (-○-) and 12 weeks (-●-) and stored at 4°C. The fruits reached each storage day were stored at −70°C. The α-galactosidase activity in flesh was measured at the same time. One hundred per cent activity of α-galactosidase was 109 unit/g·fresh wt. The α-galactosidase activity increased more rapidly at room temperature than at 4°C. Difficulties in storage at room temperature hampered the test for more prolonged intervals (data not shown). Protein concentration was roughly consistent during postharvest storage. Soluble solid contents increased parallel with the storage days as follows: from 12.1 to 14.5 and from 14.7 to 18.1°Bx in grapes harvested after 9 and 12 weeks, respectively. Each value was the average of three replicate assays.

The fractions obtained from the affinity chromatography were further purified using Sephacryl S-200 chromatography (Fig. 3). This gel chromatography was the final step in the purification of α-galactosidase because its instability impeded any further chromatography. Specific activity of the enzyme was increased more than 103-fold by the purification procedure (Table 2). SDS-PAGE analysis of the main fractions with peak activity from the Sephacryl S-200 chromatography showed one major band with a monomeric molecular mass of 45 kDa and some faint bands (Fig. 4). Affinity chromatography on melibiose-agarose was crucial for enzyme purification. Even though melibiose (6-*O*-α-D-galactopyranosyl-D-glucose) might not be perfect as an affinity ligand for chromatography, this carbohydrate seems to be effective for the enzyme purification in

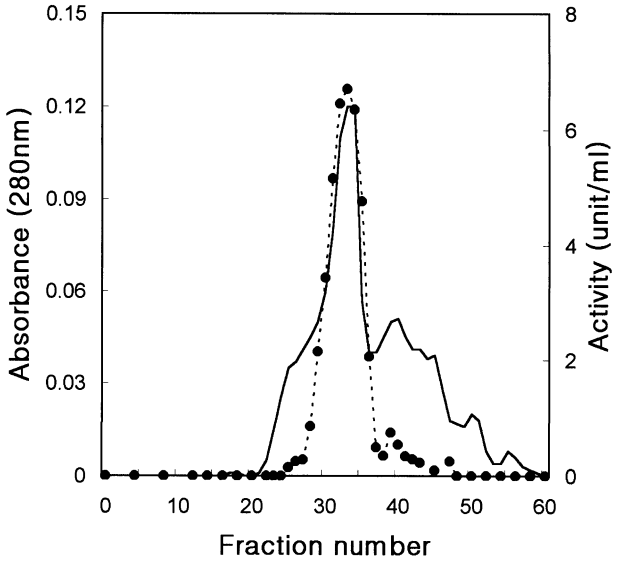

Fig. 3. Elution profile of α-galactosidase from Sephacryl S-200 chromatography. The active fractions from melibiose-agarose chromatography were loaded onto a Sephacryl S-200 column that was equilibrated with K-phosphate buffer (pH 7.0, 50 mM) containing 2% glycerol. Proteins were eluted using the same buffer along with measurement of absorbance at 280 nm (—). The α-galactosidase activity (unit/ml, -●-) was monitored using PNP-α-D-Gal as a substrate. One fraction volume was 5 ml.

Table 2
Purification summary of α-galactosidase from grape flesh of *Vitis labruscana* Honey black[a]

Purification step	Total protein (mg)	Total activity (μ)	Specific activity (μ/mg protein)	Purification fold
Crude extract	980.1	490.1	0.50	1.00
Ammonium sulfate	275.4	294.7	1.07	2.14
Biogel P-60	64.2	201.9	3.14	6.28
Melibiose-agarose	5.8	140.5	24.22	48.44
Sephacryl S-200	1.9	98.0	51.58	103.16

[a] α-Galactosidase assay used 2 mM PNP-α-D-Gal as a substrate.

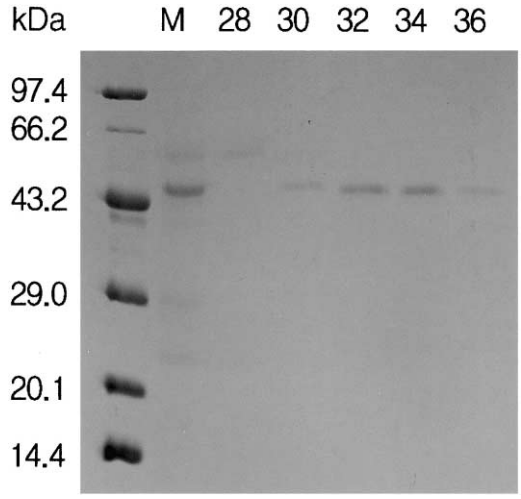

Fig. 4. SDS-polyacrylamide gel electrophoresis of purified α-galactosidase from the grape flesh. Outer left lane: reference proteins consisted of phosphorylase b (M_r; 97,400), BSA (66,200), ovalbumin (43,000), carbonic anhydrase (29,000), trypsin inhibitor (20,100), and lysozyme (14,400). Other lanes: M, the active fraction from melibiose-agarose chromatography; 28–36, the fraction numbers from the Sephacryl S-200 chromatography. The gel was stained with Coomassie Brilliant Blue R-250 and then with silver nitrate. Some faint bands (35 and 38 kDa) were observed in lanes 34 and 36 (not very visible in gel photo).

view of 7.7 times increase in specific activity during the stage from Biogel P-60 to affinity chromatography. The enzyme was stored in 20% glycerol at −70°C, and over 85% of the initial activity was retained after 3 months.

2.3. Substrate specificity of α-galactosidase

The purified α-galactosidase was assayed using different PNP-glycosides (Table 3a). The PNP-α-D-Gal was hydrolyzed more efficiently by the purified galactosidase than any other substrate tested, and *o*-nitrophenyl α-D-Gal (ONP-α-D-Gal) was also easily hydrolyzed. β-D-gal was scarcely hydrolyzed, showing 16% of the α-D-Gal hydrolysis (control), and the extent of 6-*O*-β-D-Gal-β-D-Gal was similarly low. Another galactose-related compounds such as β-D-Lac, Lac-*N*-bioside, and β-D-GalUA were rarely hydrolyzed, resulting in 4.3–12.6% activity of the control, and β-D-GalNAc was not efficiently hydrolyzed. The rapid hydrolysis of α-D-Gal and low hydrolysis of β-D-Gal suggest that the galactosidase is α-anomer specific.

Table 3b shows the hydrolysis of a range of natural or synthetic di-polysaccharides related with galactose. The activity represented as amount of galactose liberated was compared with the hydrolysis of ONP-α-D-Gal (control). ONP-α-D-Gal was used as a control substrate in place of PNP-α-D-Gal since *p*-nitrophenol was an inhibitor of the galactose dehydrogenase used to measure the galactose released (Bhalla and Dalling, 1984). Considerable liberations of galactose were obtained from natural oligosaccharides such as melibiose, stachyose, and raffinose, and the hydrolysis extent from stachyose was the most, showing 32.4% of control. A synthetic disaccharide, 4-*O*-α-D-Gal-D-Gal, was also significantly hydrolyzed. Poly-galacturonic acid was not effectively

Table 3a
Substrate specificity of α-galactosidase assayed using PNP-glycosides. The purified α-galactosidase was assayed for its activity using different PNP-glycosides (2 mM) in K-phosphate (50 mM, pH 7.0) containing 0.5% glycerol. The activities measured by the standard assay method were compared with the hydrolysis of PNP-α-D-Gal (100%), which was 49 units/mg·protein. All values were the mean of two replicate assays

Substrates	Relative activity (%)
PNP-α-D-Gal	100.0
ONP-α-D-Gal[a]	78.2
PNP-β-D-Gal	16.0
PNP-β-D-Lac	4.3
PNP-Lac-*N*-bioside	4.7
PNP-β-D-GalUA	12.6

PNP-α-D-Glc	7.0
PNP-β-D-Glc	6.2
PNP-α-L-Fuc	0
PNP-β-D-Fuc	0
PNP-α-D-Man	3.7
PNP-α-L-Ara	<1.0
PNP-α-L-Rha	0
PNP-β-D-GlcUA	<1.0
PNP-α-D-GlcNAc	<1.0
PNP-β-D-GlcNAc	<1.0
PNP-β-D-GalNAc	<1.0

[a] ONP-α-D-Gal is *o*-nitrophenyl α-D-galactopyranoside.

Table 3b
Substrate specificity of α-galactosidase for natural or synthetic carbohydrates. The purified α-galactosidase was incubated with galactose related carbohydrates (2 mM) in K-phosphate (50 mM, pH 6.0) containing 0.5% glycerol, and estimation of galactose released was performed as described in Experimental. Polygalacturonic acid was used as a substrate for polygalacturonase assay, and the activity determined using 2-cyanoacetamide. The activities were compared with the hydrolysis of ONP-α-D-Gal (100%), which was 42 units/mg · protein. All values were the mean of three replicate assays

Substrates	Free galactose released (%)
ONP-α-D-Gal	100.0
Melibiose	17.1
D-Lactose	7.6
Lactulose	2.0

Stachyose	32.4
Raffinose	19.8
Polygalacturonic acid	<1.0

hydrolyzed, suggesting that the purified enzyme is not a polygalacturonase. Rapid hydrolysis of the synthetic substrate PNP-α-D-Gal and relatively slow hydrolysis of the oligosaccharides were similar to the α-galactosidase from *Cucurbita pepo* leaves (Thomas and Webb, 1977).

2.4. Other characteristics

Apparent molecular mass of the α-galactosidase was also determined by a gel filtration chromatography. The 34th fraction obtained from the final chromatographic step was co-injected with size marker onto a Sephacryl S-200 column. This protein mixture was eluted along with monitoring of the activity (unit/ml) peak, and the molecular mass was calculated to be ca. 40 kDa. On the analogy of the result from this gel chromatography, the 45 kDa band in the SDS-PAGE (Fig. 4) was considered as an α-galactosidase since 40 kDa of molecular mass determined from the chromatography approached to this value and the intensities of the 45 kDa bands were roughly proportional to the activity profile.

The α-galactosidase was further characterized by measuring its activity in buffers of varying pH using 2 mM PNP-α-D-Gal or stachyose as substrates (Fig. 5-A and B). When PNP-α-D-Gal was used as a substrate, the optimum pH for the activity was estimated to be around 7.0. But the pH profile assayed with a natural substrate, stachyose, resulted in a lowered pH optimum of 6.0. The pH for half maximal activity was ca. 4.5–5.2 and the activity rapidly increased from pH 4.0 to 6.0–7.0. This rapid increase in the activity up to pH 6.0–7.0 could have a correlation with the environment of grape since pH in flesh increases into a weaker acidity as ripening proceeds. Thus, increase in pH during ripening might be an important factor of α-galactosidase regulation in the grape flesh. However, it was not confirmed in this experiment whether such pH variation play an exclusive role in the enzyme activation.

The requirement of divalent cations for the α-galactosidase activity was examined using 1 mM Mg^{2+}, Co^{2+}, Zn^{2+}, Fe^{2+}, Cu^{2+}, Mn^{2+}, Cd^{2+}, and Ca^{2+} with chloride ion as a counter part ion. Addition of Fe^{2+} ion to the assay mixture in the absence of EDTA elevated the α-galactosidase activity by 46%. Other cations did not significantly increase or decrease the activity, except 49% inhibitory effect by Cd^{2+} (detailed data not shown). 1, 10-Phenanthroline or EDTA (0.5 and 2.0 mM) resulted in only a slight decrease in activity ranging from 90 to 98% of the initial activity (detailed data not shown).

Heat stability was examined with the 36th fraction from the Sephacryl S-200 chromatography. The enzyme was preincubated at 30, 45, or 60°C for 10 min and assayed using PNP-α-D-Gal. The activity decreased to 62% of the initial activity when preincubated at 60°C (detailed data not shown).

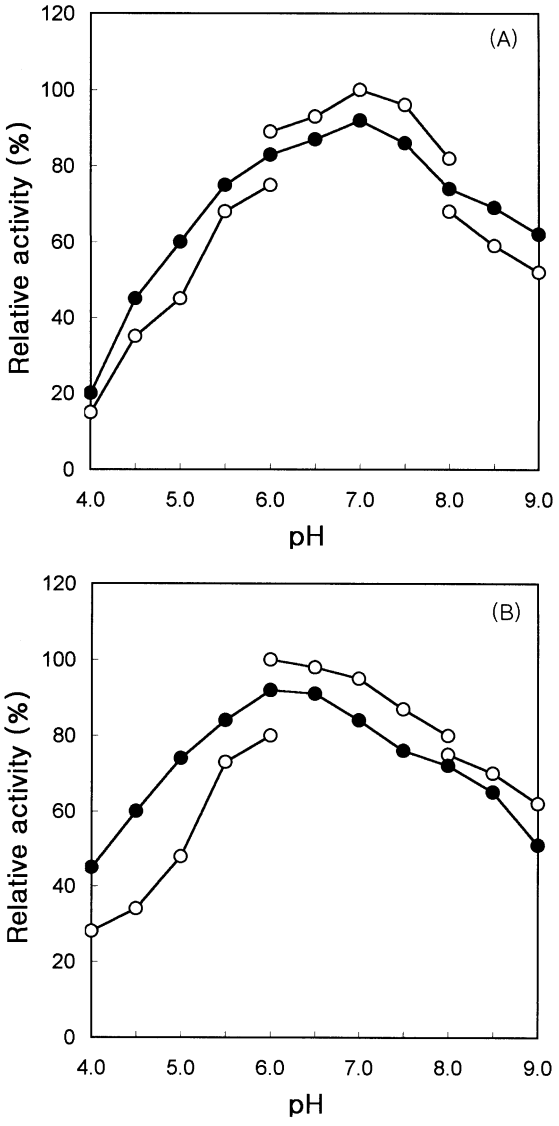

Fig. 5. Effect of pH on the hydrolysis of synthetic and natural substrates by α-galactosidase. The purified α-galactosidase was assayed using the following two series of buffers (1 ml) supplemented with 0.5% glycerol. (1) A three-buffer mixture (25 mM acetic acid, 25 mM Mes, and 50 mM Tris, -●-) titrated to the indicated pH values with KOH or HCl. (2) Acetate buffer 50 mM, pH 4.0–6.0; K-phosphate 50 mM, pH 6.0–8.0; Tris–HCl 50 mM, pH 8.0–9.0 (-○-). The pH effect was examined using PNP-α-D-Gal (A) and stachyose (B) as substrates. The relative activities calculated by two replicate assays were compared with the maximum activities (100%) that were equivalent to 39 and 14 units/mg·protein for (A) and (B), respectively.

3. Experimental

3.1. Plant materials

Grapevines of 4–5 year old *Vitis* cultivars (Muscat of Alexandria, Agawan, Marguerite, Edelweiss, Egiodola, Green hungarian, Honey black, and Takasumi) were cultivated in a greenhouse under ca. 14 h of daylight and 10 h of darkness at temperatures ranging from 18 to 31°C. Healthy, unblemished grapes were harvested up

to 3 months at intervals of 2 weeks after fruit bearing. After surface sterilization with 60% ethanol, fruits were rinsed with sterile water and immediately stored at −70°C until needed.

In order to test variations in α-galactosidase activities during postharvest storage, several bunches of grapes (*Vitis labruscana* Honey black) harvested after 9 or 12 weeks after fruit bearing were stored for 5 weeks at 4°C. Infection was minimized by repetitive rinses using 60% aq. ethanol and sterile water every 5 days during storage. At intervals of 5 days, the grapes were randomly picked from the bunches and immediately stored at −70°C until a simultaneous assay of α-galactosidase activity in flesh could be carried out. The grapes stored at −70°C just after harvest were used as controls for measuring the initial activity of the flesh.

3.2. Measurement of glycosidases

Grape flesh, separated from whole grapes, was mixed with 2% glycerol, and then directly homogenized for 30 s. The resulting paste was filtered through two layers of nylon cloth, and the filtrate was centrifuged at 8000 *g* for 20 min. After eliminating pellets, the supernatant was used for measurement of glycosidase activity in flesh. The standard assay of glycosidase was performed using PNP-glycosides as substrate. Enzyme samples were added to K-phosphate (50 mM, pH 7.0, in 1 ml of final volume) containing 0.5% glycerol. Reactions were initiated by adding 2 mM (final concentration) of substrate. After 30 min of incubation at 37°C, release of *p*-nitrophenol from the hydrolysis of substrate was detected spectrophotometrically by measuring the increase in absorbance at 410 nm (molar extinction coefficient = 1.84×10^4 M^{-1} cm^{-1}). Eventually, hydrolysis of di-, oligo-, and polysaccharides by α-galactosidase was examined by measurement of the galactose content using galactose dehydrogenase according to the method of Kurz and Kurt (1974). Enzyme sample was added to 400 μl of K-phosphate (50 mM, pH 6.0) containing 0.5% glycerol and 2 mM substrates. After incubation for 60 min at 37°C, the reaction was stopped by boiling for 5 min. The hydrolysed sample was cooled and put together with 570 μl Tris/HCl (0.1 M, pH 8.6), 20 μl of 15 mM NAD, and 10 μl galactose dehydrogenase solution (Sigma. from *Pseudomonas fluorescens*, 8.5 units/ml), with the incubation then further continued for 60 min at 37°C. The difference in Abs_{340nm} was measured from zero to the final incubation time. Quantitative analyses were performed from a calibration curve of galactose from 0 to 100 nmol. One unit of enzyme activity, in the method using PNP-glycosides, was expressed as the release of one μmol of free *p*-nitrophenol/min and specific activity as the amount released/min/mg·protein. Activity units from the method using galactose dehydrogenase were defined in the same way, except galactose was released in place of *p*-nitrophenol. Separate blanks were used for each enzyme and substrate preparation.

The pH effect of α-galactosidase was examined with 2 mM PNP-α-D-Gal or stachyose using the following buffers of similar ionic strengths: a three-buffer mixture (25 mM acetic acid, 25 mM Mes, and 50 mM Tris; Ellis and Morrisson, 1982) titrated to different pH values with KOH or HCl. Another buffer series was also used for this pH experiment: acetate buffer 50 mM, pH 4.0–6.0; K-phosphate 50 mM, pH 6.0–8.0; Tris/HCl 50 mM, pH 8.0–9.0. All buffers contained 0.5% glycerol. Hydrolysis of PNP-α-D-Gal in these buffers was determined by the standard assay method as described. The enzyme assay with stachyose was carried out in 500 μl of the two series buffers. After incubation for 1 h, each reaction mixture (200 μl) was taken to minimize the pH effect of these buffers on the subsequent galactose dehydrogenase. These samples were each added to 800 μl of the reaction mixtures for the galactose dehydrogenase assay. Further incubation and determination of galactose were performed as described. Non-enzymatic hydrolysis of PNP-α-D-Gal occurred slightly at alkaline pH, and these values were subtracted.

3.3. Extraction and purification of α-galactosidase

All purification procedures were carried out at 4°C. Grape flesh (2.6 kg) from *Vitis labruscana* Honey black was homogenized for 30 s in the presence of 0.2 M Na_2CO_3, 1% (w/v) insoluble polyvinylpolypyrrolidone, and 5% glycerol. The homogenate was filtered through two layers of nylon cloth. The resulting filtrate was centrifuged at 8000 *g* for 20 min and the pellet discarded. The supernatant was fractionated with ammonium sulfate at 30–55% saturation. The precipitate was recovered by centrifugation at 10,000 *g* for 20 min and resuspended in 100 ml of 40 mM potassium phosphate buffer (pH 7.0) containing 2% glycerol (buffer A). Clarification was done by dialysis with the same buffer and insoluble materials were removed by centrifugation at 10,000 *g* for 20 min.

The clarified supernatant was applied to a Biogel P-60 (Bio-Rad) column equilibrated with buffer A. Proteins were eluted with the same buffer at a flow rate of 12 ml/h. An additional aim of this step prior to affinity chromatography was to minimize various small substances such as pigments, which may interfere with chromatographic behavior by nonspecific adsorption. α-Galactosidase activity was monitored using PNP-α-D-Gal as a substrate throughout the purification procedures including this step.

The active fractions obtained were loaded onto a melibiose-agarose (Sigma) column (2 × 10 cm) equilibrated with buffer A. After washing the column, proteins were eluted with 200 ml of buffer A containing a linear gradient of K-phosphate (0–500 mM) at a flow rate of 15

ml/h. Fractions with α-galactosidase activity were collected and clarified by centrifugation for next step.

The pooled fractions from the affinity chromatography were further purified using Sephacryl S-200 (Pharmacia) chromatography. Proteins were eluted with 50 mM K-phosphate buffer (pH 7.0) containing 2% glycerol at a flow rate of 12 ml/h. Purification was followed by monitoring the absorbance at 280 nm and assaying enzyme activity. Except for physiological aspects, all of the experiments on α-galactosidase were performed using this sample obtained from this chromatography.

3.4. Native molecular mass determination

The apparent molecular mass of the purified α-galactosidase was estimated by gel filtration chromatography using a Sephacryl S-200 column (2 × 90 cm), which was equilibrated with 50 mM K-phosphate buffer (pH 7.0) containing 2% glycerol. The following proteins were co-injected with the enzyme to the column for the calibration: aldolase (M_r; 158,000), phosphorylase b (97,400), BSA (66,200), ovalbumin (43,000), and cytochrome c (12,000). The proteins were eluted with the same buffer at a flow rate of 12 ml/h. Along with measuring Abs_{280nm}, the activity peak was monitored by assaying the enzyme activity using PNP-α-D-Gal as substrate.

3.5. Other analytical methods

Soluble solid contents were measured with a refractometer using 50 μl of flesh juice, that was prepared by slightly grinding and subsequent centrifugation at 10,000 *g* for 5 min. Reducing sugars produced from the hydrolysis of polygalacturonic acid were measured using 2-cyanoacetamide (Gross, 1982). SDS-PAGE was performed according to the method of Laemmli (1970). A slab gel that consisted of 12.5% acrylamide resolving gel and 5% acrylamide stacking gel was used, with the gel stained with Coomassie Brilliant Blue R-250 and then with silver nitrate (Wray et al., 1981). Protein concentrations were determined by the dye-binding assay of Bradford (1976) using BSA as a standard protein.

Received 11 May 2000; received in revised form 11 January 2001

Abstract

The effects of two lectins concanavalin A (conA) and soybean agglutinin, on soybean seed acid phosphatase activity were investigated using *p*-nitrophenylphosphate (pNPP), pyrophosphate (PPi) and phosphoenolpyruvate (PEP) as substrates. Of the four acid phosphatase isoforms (AP1, AP2, AP3A and AP3B) purified from soybean seeds, only AP1 was activated 40 and 60% by conA and soybean agglutinin, respectively. Both lectins affected some of the kinetic parameters of AP1. The activation by lectins was not affected by 1 mM Ca^{2+} or Mn^{2+} but glucose and methylmannopyranoside (100 mM) prevented activation by conA. Under the same conditions, galactose had no effect. These results suggest that plant acid phosphatases may be regulated by lectins, the effects vary according to the substrate used. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Acid phosphatases (E.C. 3.1.3.2) are a group of enzymes that catalyze the hydrolysis of phosphate monoesters. These enzymes are widely distributed among mammalian tissues, plants and microorganisms. In particular, plant acid phosphatases have been characterized in roots (Penheiter et al., 1997), tubers (Gellatly et al., 1994), bulbs (Guo and Pesacreta, 1997), seeds (Park and Van Etten, 1986; Ullah and Gibson, 1988; Malhotra and Kayastha, 1990; Ferreira et al., 1998; Granjeiro et al., 1999), aleurone layer (Gabard and Jones, 1986), leaves (Staswick et al., 1994), maize scutellum (Rossi et al., 1981) and suspension cells (Lefebvre et al., 1990; Duff et al., 1989). These phosphatases, usually present in multiple forms, display different biochemical properties and exhibit a broad specificity at pH optima below 6.0. Many roles have been ascribed to acid phosphatases in plants, including participation on signal transduction (Plaxton, 1996), regulation of metabolism by protein dephosphorylation (Duff et al., 1994) and the release of inorganic phosphate from organic phosphate in the environment. Phosphorus not only plays a vital role in energy transfer and in metabolic regulation, but it is also an important constituent of phospholipids and nucleic acids. The growth and development of plants is particularly dependent upon the availability of phosphate (Lefebvre et al., 1990).

Lectins are proteins that bind to carbohydrates with considerable specificity through hydrogen bonds, metal coordination, van der Waals and hydrophobic interactions. These proteins occur in a variety of organisms and are involved in numerous cellular processes. In the seeds of many plants, lectins can account for as much as 10% of the total nitrogen of mature seed extracts, and may be involved in protein storage (Ferens and Morawieka, 1985). Ferens and Morawieka (1985) reported a 20% activation of rye germ acid phosphatase by conA; a similar activation of this enzyme from *Pleurotus ostreatus* was also observed by Corand and Rüdiger (1994).

We have previously purified four acid phosphatase isoforms from soybean seeds, and found that they all contain a carbohydrate moiety in their structures (Ferreira et al., 1998). In this report, we describe the effects of concanavalin A and soybean agglutinin on the activity of

Abbreviations: conA, concanavalin A; PPi, inorganic pyrophosphate; PEP, phosphoenolpyruvate; pNPP, *p*-nitrophenylphosphate.

these phosphatases. Kinetic parameters were determined in the presence of lectins, using potential physiological substrates, such as PPi and PEP.

2. Results and discussion

The lectin conA was used in order to allow us to compare our results with other reports, whereas soybean agglutinin was tested because of its possible participation in the in vivo regulation of soybean acid phosphatase. The isoforms AP1, AP2, AP3A and AP3B contain 30, 28, 18 and 10% carbohydrate, respectively, in their structures (Ferreira et al., 1998). The carbohydrate composition of isoform AP1 consists of mannose (8.3%), galactosamine (50.3%), glucosamine (32.1%), glucose (5.1%) and galactose (4.2%) (not shown).

Although there are several reports of acid phosphatases from plant tissues (Guo and Pesacreta, 1997; Duff et al., 1994), little is known of their regulation by endogenous compounds.

Table 1 shows that conA and soybean agglutinin increased the activity of AP1 by 40 and 60%, respectively, when pNPP was used as substrate, but had no effect on the other isoforms. The extent of activation of AP1 by conA was substrate-dependent. Thus, 50 μg caused 20, 60 and 80% activation of AP1 with PEP, pNPP and PPi, respectively (Fig. 1A). No significant effect was observed when PEP was used as substrate, suggesting that the presumed conformational change in AP1 produced by conA was not sufficient to increase PEP hydrolysis. It is also possible that the high affinity of AP1 for PEP may have prevented activation by the lectin (Ferreira et al., 1999). In contrast to conA, the activation by soybean agglutinin was independent of the substrate used (Fig. 1B). In addition, soybean agglutinin significantly increased the activation by about 60% seen with PEP as substrate. These results agree with an previous demonstration that PEP may be a physiological substrate for the AP1 isoform (Ferreira et al., 1999), and suggest that the specificity for PEP in vivo may be increased by the presence of this lectin.

The activation by both lectins was concentration-dependent up to about 50 μg (Fig. 1). Additional activation was observed after preincubating the enzyme with conA (Fig. 2), although the pattern of the curves was similar to those obtained in the absence of preincubation (Figure 1A). In contrast to our results, Ferens and Morawieka (1985) reported that rye germ acid phosphatase was activated by conA only after preincubation for 15 min.

The activation by conA was prevented when glucose or mannose, but not lactose, was present in the assay medium (Table 2). In contrast to lactose, glucose and mannose can efficiently bind to conA. The divalent cations Ca^{2+} and Mg^{2+} had no effect on the activation by conA (Table 2). A similar result was obtained for the activation by soybean agglutinin (Table 3), although in this case, only galactose prevented the activation by soybean agglutinin, in agreement with this lectins preferential binding to this sugar.

Table 4 shows the effect of the two lectins on the K_m, V_{max} and specificity constant (V_{max}/K_m) of soybean seed AP1 acid phosphatase with different substrates. Both lectins increased enzyme specificity, but this effect was higher with PEP in the presence of soybean agglutinin, thus reinforcing the data in Fig. 1B. The acid phosphatase AP1 showed a particularly high affinity in the presence of soybean agglutinin, as suggested by the very low K_m. PPi, another potential physiological substrate, showed specificity constants with both similar to those obtained with PEP and soybean agglutinin.

These results show that the effects of lectins depend on the substrate used rather than being caused by enzyme stabilization, AP1 was not stabilized by these proteins (data not shown). Soybean agglutinin had a strong effect on the specificity of PEP and PPi, since with these substrates, the specificity constants for AP1 were at least 10 times higher than that for the synthetic substrate pNPP. This observation suggested that soybean seed lectin may play an important role in the regulation of a specific acid phosphatase isoform, in addition to its function as a storage protein. The increase in plant acid phosphatase activity, during germination could thus be associated with the nature of the lectin constituents of the seed.

Some authors have reported the presence of hydrolytic enzymes (acid phosphatases, proteinases and α-D-mannosidase) in the protein bodies and that levels of the enzymes are elevated during germination (Asghar and Demason, 1992; Elpidina et al., 1992, 1993). It is possible that soybean lectin may contribute to the increase in acid phosphatase activity during germination. This activation may be important in the role of these enzymes in phosphorus aquisition, an important nutrient for plant development and growth.

Table 1
Effect of conA and soybean agglutinin on the activity of acid phosphatase isoforms[a]

Isoform	Relative activity (%)	
	conA	Soybean agglutinin
AP1	137 (±4)	160 (±7)
AP2	94 (±5)	90 (±2)
AP3A	103 (±3)	110 (±6)
AP3B	98 (±6)	102 (±3)

[a] The isoforms were incubated for 10 min (period of the enzyme assay) in the absence and in the presence of 50 μg conA or soybean agglutinin and the enzyme activities determined measuring the pNP released. The activities in the absence of lectins were considered as 100%. All data were obtained in triplicate and shown with their standard deviations (in parentheses).

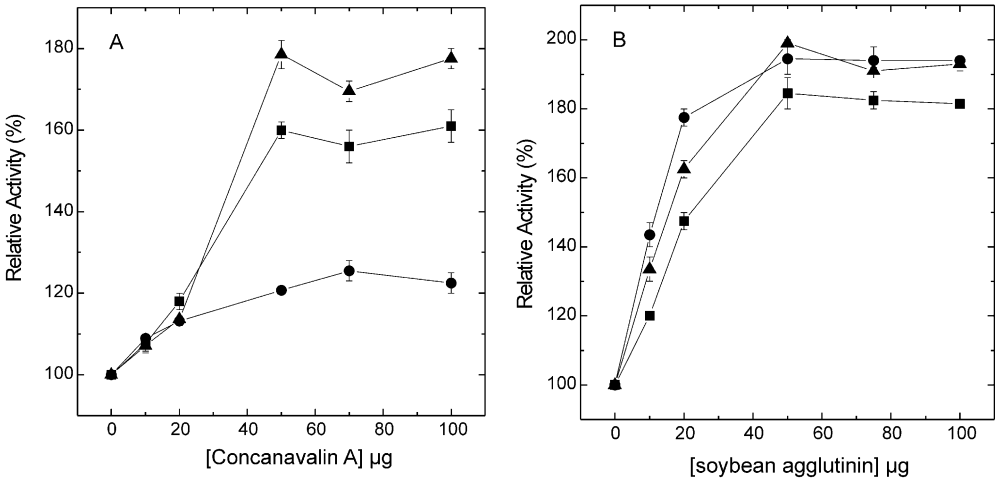

Fig. 1. Effect of conA and soybean agglutinin on the activity of soybean seed acid phosphatase (AP1). The incubation mixture included pNPP (■), PPi (▲) or PEP (●) as substrate, in the presence of increasing concentrations of conA (A) and soybean agglutinin (B). The samples were incubated with the lectins for 10 min (period of the enzyme assay). The activity in the absence of lectin was considered as 100%. The experiments were performed in triplicate and bars represent the standard deviations.

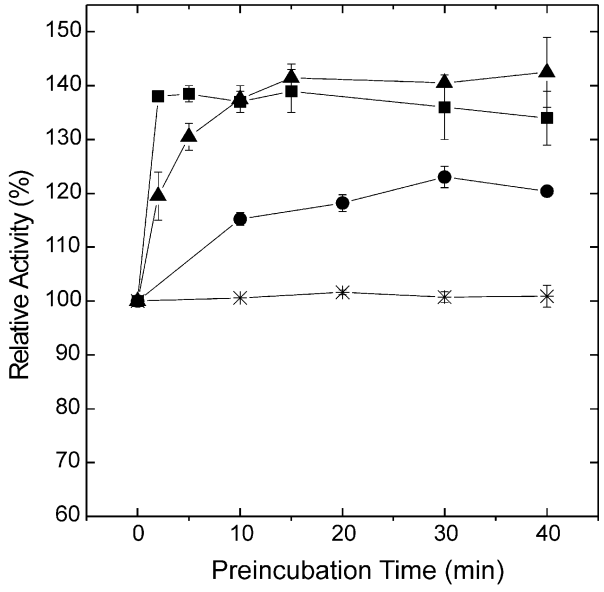

Fig. 2. Effect of preincubation of conA with the acid phosphatase. The AP1 was incubated with or without conA (50 µg), and enzyme activity was determined with pNPP (■), PPi (▲) or PEP (●) as substrates. The activity in the presence of lectin and without preincubation was considered as 100% (*). The experiments were performed in triplicate and bars represent the standard deviations.

3. Experimental

3.1. Plant materials

Soybean seed acid phosphatases (AP1, AP2, AP3A and AP3B) were purified 910-, 180-, 15- and 73-fold, with specific activities of 50, 10, 0.8 and 4 µmol min^{-1} mg^{-1} of protein, using pNPP as substrate, as previously described (Ferreira et al., 1998).

Table 2
Effect of different compounds on AP1 acid phosphatase activity in the presence of ConA[a]

Compound	Relative activity (%)
Control	100
conA	139 (±5)
conA + Ca^{2+} + Mn^{2+} (1 mM)	147 (±5)
Glucose 100 mM	99 (±4)
conA + glucose 100 mM	104 (±2)
Methylmannopyranoside 100 mM	95 (±6)
conA + methylmannopyranoside 100 mM	100 (±3)
Lactose 100 mM	97 (±5)
conA + lactose 100 mM	135 (±6)

[a] The compounds were added to the assay medium containing pNPP, as described in Experimental. The enzyme activity in the absence of the compounds was considered as 100%. All data were obtained in triplicate and shown with their standard deviations (in parentheses).

3.2. Chemicals

pNPP, PEP, PPi, conA and soybean agglutinin were obtained from Sigma Chemical Company. All other chemicals were of the highest purity available.

3.3. Enzyme assay

The amounts of AP1, AP2, AP3A and AP3B used in the assays were 0.06, 0.5, 3.2 and 2.2 µg, respectively, with equal activities in all assays. The reaction mixture (1 ml) containing 100 mM sodium acetate buffer (pH 5.0), 5 mM pNPP, and enzyme was incubated for 10 min at 37°C, and then terminated by the addition of 1 ml of 1 M NaOH. The relative absorbance was read at 405 nm. The molar extinction coefficient of *p*-nitrophenolate ion, at 405 nm, in alkaline medium is 18,000 M^{-1} cm^{-1}.

Table 3
Effect of different compounds on the AP1 acid phosphatase activity in the presence of soybean agglutinin[a]

Compound	Relative activity (%)
Control	100
Soybean agglutinin	169 (±4)
Soybean agglutinin + Ca^{2+} + Mn^{2+} (1 mM)	160 (±5)
Glucose 100 mM	100 (±6)
Soybean agglutinin + glucose 100 mM	150 (±5)
Methylmannopyranoside 100 mM	99 (±7)
Soybean agglutinin + methylmannopyranoside 100 mM	167 (±6)
Lactose 100 mM	98 (±5)
Soybean agglutinin + lactose 100 mM	132 (±6)
Galactose 100 mM	99 (±4)
Soybean agglutinin + galactose 100 mM	95 (±8)

[a] The compounds were added to the assay medium, as described in Experimental, using pNPP as substrate. The activity in the absence of compounds was considered as 100%. All data were obtained in triplicate and shown with their standard deviations (in parentheses).

Table 4
Effect of conA and soybean agglutinin on the kinetic parameters of the soybean seed acid phosphatase[a]

Substrate	Control	conA	Soybean agglutinin
	V_{max}/K_m	V_{max}/K_m	V_{max}/K_m
pNPP	114/0.49 (233)	162/0.10 (1620)	180/0.10 (1800)
PPi	121/0.13 (930)	175/0.05 (17,500)	200/0.02 (20,000)
PEP	89/0.23 (387)	120/0.08 (1500)	190/0.01 (19,000)

[a] The assay conditions were as described in Experimental. K_m (mM) and V_{max} (μmol min^{-1}) values were calculated from Lineweaver–Burk plots, and are given as ratios. The specificity constant values are shown in parentheses. All data were obtained in triplicate.

When PEP and PPi were used as substrates, the activities were assayed by measuring the amount of phosphate released. The incubation mixtures were as described for pNPP, using 10 mM PEP or PPi. After a 10 min incubation at 37C, the reaction was stopped by addition of 1 ml of 3% ammonium molybdate (in 200 mM acetate buffer, pH 4.0), followed by addition of 0.1 ml of ascorbic acid (in 200 mM acetate buffer, pH 4.0). The color was developed for 30 min and the relative absorbance was read at 700 nm. The amount of inorganic phosphate produced was calculated using a molar extinction coefficient of 4000 M^{-1} cm^{-1} (Lowry and Lopez, 1945).

Abstract

Expression of the yeast Δ9 desaturase gene in tomato (*Lycopersicon esculentum* Mill.) resulted in changes in the profiles of fatty acids in tomato leaves. Transgenic leaves displayed a dramatic increase in *cis*-Δ9 16:1, which only existed in a small quantity in control leaves. Also higher, but not as dramatic, were 18:1 and 16:3 fatty acids. Several fatty acids, viz. 16:0, 18:0, and 18:3 declined in transgenic leaves. Changes in fatty acids were accompanied by changes in certain volatile compounds derived from fatty acids. On a percentage basis, most notable increases (>3-fold) were 1-hydroxy-2-butanone, 1-penten-3-ol, heptanal, 3-hexen-1-ol, 2-octanol,*cis*-3-hexenal, hexanal and 2-nonenal. Several flavor compounds not known to be biochemically derived from fatty acids, viz. 2-ethyl-furan, 5-ethyl-2- [5H]-furanone, eugenol, and 2-ethylthiophene also showed sharp increases in transgenic leaves. © 2001 Published by Elsevier Science Ltd.

1. Introduction

Plant leaves are an important constituent of our diet. Their desirability is affected by many factors, one of the most consequential being flavor. Many volatile compounds, including fatty acid derivatives, terpenoids, phenylpropanoids, and benzenoids contribute to leaf flavor. Some of these compounds are used as flavoring agents in manufactured products and thus have additional economical value. However, many valuable leaf volatiles are only present in minute quantities, making utilization of most leaves economically impractical. Although chemical synthesis could be used to produce many of these compounds, consumers in general prefer natural products. Conventional plant breeding has been used to empirically alter plant flavor. With the advancement of genetic engineering, another option is available, i.e. to genetically modify specific pathways that produces the compound of interest.

Leaf volatiles derived from fatty acids constitute a conspicuous component of a leaf flavor profile. Most of these volatiles are formed through the lipoxygenase/hydroperoxide lyase enzyme pathway (Stone et al., 1975; Galliard et al., 1977; Vick and Zimmerman, 1986). It usually begins with release of free fatty acids from lipids by lipases, then peroxidation of specific double bonds of polyunsaturated fatty acids, such as linoleic and linolenic acids, by lipoxygenase to produce the corresponding hydroperoxides. These hydroperoxides are then converted to various C6 and C9 aldehydes by hydroperoxide lyase. The aldehydes can subsequently be reduced by alcohol dehydrogenase to form corresponding alcohols (Vick and Zimmerman, 1986). Only polyunsaturated fatty acids serve as substrates for lipoxygenases in this pathway. Our laboratory has previously demonstrated that supply of linolenic acid fatty acids is a limiting factor in the production of *cis-3*-hexenal by cultured alfalfa cells (Chou and Chin, 1994). Thus, increasing the level of polyunsaturated fatty acids may increase the flavor compounds derived from these acids.

Fatty acids in plants are first produced in saturated forms, which are later desaturated to mono- and

polyunsaturated fatty acids. Desaturation starts with the conversion of 16:0-acyl carrier protein (ACP) and 18:0-ACP into 16:1-ACP and 18:1-ACP respectively by a soluble plastid Δ-9 desaturase (McKeon and Stumpf, 1982; Shanklin and Sommerville, 1991). Further desaturation of 18:1-ACP is accomplished by two desaturases: the Δ12 desaturase adding the second double bond at Δ12 position of 18:1 to form 18:2, and the Δ15 desaturase adding the third double bond at Δ15 position to form 18:3. For most plants, the levels of monounsaturated fatty acids are lower than that of saturated and polyunsaturated fatty acids, inferring that the first desaturation by Δ9 desaturase is a limiting factor in polyunsaturated fatty acid production. We have previously observed that the levels of 18:2 in tomato fruit could be dramatically increased by expressing the yeast Δ9 desaturase gene in tomato (Wang et al., 1996).

Concomitantly, certain flavor compounds derived from fatty acids, most notably *cis*-3-hexenol, 1-hexanol, hexanal, *cis*-3-hexenal, and 2-nonenal were also elevated. Tomato fruit and leaf have different fatty acid and flavor volatile profiles. Here, we report that expression of the yeast Δ9 desaturase gene in tomato also alters the profiles of fatty acids and flavor volatiles in tomato leaves.

2. Results

2.1. Expression of the yeast Δ9 desaturase gene alters fatty acid profile

Fig. 1 shows the levels of various fatty acids in the leaves of control and 2 transgenic (T4 and T5) plants expressing the yeast Δ9 desaturase gene. Predominant fatty acids in the control leaves were 18:3, 18:2, and 16:0. Leaves from both transgenic plants displayed dramatic increases in*cis*-Δ9 16:1, which only existed in small quantity in control leaves. Also higher, but not as dramatic, were 18:1 and16:3 fatty acids. Several fatty acids, viz. 16:0, 18:0, and 18:3 declined in transgenic leaves.

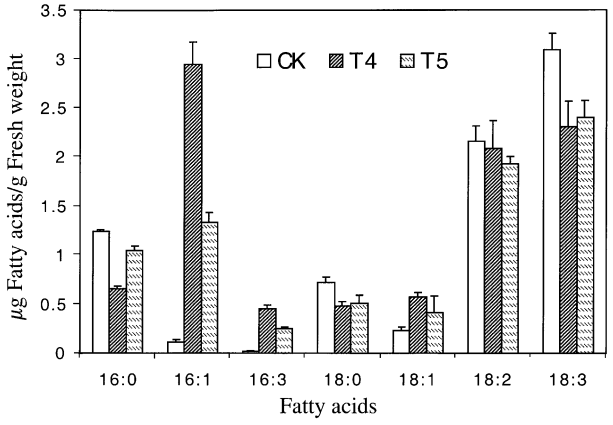

Fig. 1. Fatty acids in control (CK) and transgenic (T4 and T5) tomato leaves.

The much higher increase in 16:1 than 18:1 likely reflects the relative availability of substrates to the yeast Δ9 desaturase and not the substrate specificity of the enzyme. The yeast Δ9 desaturase is a cytochrome b5-dependent endoplasmic reticulum (ER) enzyme that converts 16:0-CoA and 18:0-CoA to 16:1-CoA and 18:1-CoA respectively (Stukey et al., 1990). As the yeast Δ9 desaturase lacks the known characteristics of the chloroplast targeting sequences, it is expected to be located in the cytosol and not in the chloroplasts (Heijne and Nishikawa, 1991). Consequently, it can only utilize the fatty acids in the cytosol as substrates. Fatty acid synthesis in plants has been found to be almost exclusively localized in the plastids (Ohlrogge and Browse, 1995). Some of the synthesized fatty acids, mostly 18:1 and 16:0, are subsequently exported to the cytosol (Ohlrogge and Browse, 1995). The availability of the exported saturated 16:0 could explain the sharp increase in 16:1. The smaller increase in 18:1 indicates that 18:0 was also exported to the cytosol, albeit presumably at a level significantly less than 16:0. Generally, 18-carbon fatty acids, except 18:1, declined in transgenic leaves. This could be a consequence of shunting of 16:0, the precursor of 18-carbon fatty acids, to 16:1. The increase in unsaturated fatty acids exceeded the decline in saturated fatty acids indicating an overall increase of total fatty acids on per fresh weight basis in transgenic leaves.

2.2. Expression of the yeast Δ9 desaturase gene alters the profile of volatile compounds

The identities of the major volatile compounds and their concentrations are shown in Table 1. Oxygenated aliphatic compounds constitute 18% of the total volatile compounds in control leaves. Most of these compounds are likely derived from unsaturated fatty acids. This group of compounds increased 3.2- and 2.7-fold in the T4 and T5 leaves respectively, supporting the contention that changes in the levels of fatty acids can significantly alter the levels of compounds derived from them. By far the most abundant oxygenated aliphatic compound found in tomato leaves was *trans*-2-hexenal. The levels of *trans*-2-hexenal were significantly higher in transgenic than in control leaves. *trans*-2-Hexenal was likely an artifact of GC thermal conversion of *cis*-3-hexenal (Karmas et al., 1993). Thus, the amounts of *trans*-2-hexenal reported here should represent a sum of *cis*-3-hexenal and *trans*-2-hexenal. *Cis*-3-hexenal is derived from linolenic acid in a 2-step process. Linolenic acid is first converted to linolenic acid 13-hydroperoxide (13-Ln OOH) by lipoxygenase, and 13-Ln OOH is in turn converted by hydroperoxide lyase to *cis*-3-hexenal (Hatanaka et al., 1977, 1986). Unlike lipoxygenase in tomato fruits, lipoxygenase in tomato leaves has not been extensively studied. The overwhelming amount of *cis*-3-hexenal produced by tomato leaves suggests that

tomato leaves possess lipoxygenase active in production Δ^6 13-Ln OOH, the substrate of *cis*-3-hexenal. The lipoxygenase/hydroperoxide lyase pathway that produces hexenal from linolenic acid can also produce hexanal from linoleic acid (Hatanaka et al., 1986). However, in spite of the similar levels of linolenic and linoleic acids in tomato leaves, the amount of hexanal found was only a small fraction of that of hexenal. This discrepancy may be explained by the specificity of the tomato leaf hydroperoxide lyase, which has a strong preference towards 13-Ln OOH over linoleic acid 13-hydroperoxide (13-La OOH) (100% against 9.8%). The specificity of tomato leaf hydroperoxide lyase may also explain the low amounts of 9-carbon aldehydes in tomato leaves. Tomato leaf hydroperoxide lyase is only active against 13-La OOH and 13-Ln OOH, but has no activity against 9-La OOH and 9-Ln OOH (Fauconnier et al., 1997).

As hexenal is derived from linolenic acid, we expected a positive correlation of linolenic acid and hexenal. Instead, we observed that the sharp increase in the levels of hexenal in transgenic leaves was associated with a reduction in 18:3. This appears to suggest that hexenal production in tomato leaves is not limited by 18:3. We have previously proposed that hexenal production could also be limited by hydroperoxide lyase activity (Chou and Chin, 1994). Thus, a stimulation of hydroperoxide lyase activity could produce an increase in hexenal. Indeed, expression of the yeast Δ9 desaturase in planta has been found to affect enzyme activity. Specifically, expression of the yeast Δ9 desaturase gene in eggplant leaves has been found to increase the activity of phospholipase A_2, an enzyme that releases free fatty acids from phospholipids (Xing and Chin, 2000). It would be of interest to examine whether the transgenic leaves also have higher lipid hydroperoxide lyase activity.

Compared to C6 aldehydes, the amounts of other aliphatic compounds found in tomato leaves were relatively insignificant. Nonetheless, several of these compounds showed significant increases in transgenic leaves. There were moderate increases in nonanal, and octanal, which could be formed by autooxidation of 18:1 fatty acid (Frankel, 1977; Gardner, 1989). Other oxygenated aliphatic compounds, including heptanal, 2-octanol, and 2-nonenal that showed significant increase, could be formed by autooxidation of palmitoleic acid following the pattern of autooxidation of 18:1 (Frankel, 1977). If so, the sharp increase in palmitoleic acid in transgenic leaves may explain the multi-fold increases of these compounds.

In addition to aliphatic compounds, a number of monoterpenes, sesquiterpenes, and aromatic compounds were found in tomato leaves. Most dramatically, two aromatic compounds, 2-ethylfuran and 5-ethyl-2 [5H] furanone, were present in minute amounts in control leaves but showed dramatic increases of >36-fold and >9-fold, respectively, in transgenic leaves. It is not clear how these 2 compounds are being synthesized in plants. Two monoterpenes, viz. ß-phelladrene and 2-carene (Buttery et al., 1987) existed in relatively high amounts in control leaves but the amounts declined in the transgenic leaves.

This study lends support to the contention that changes in fatty acids can lead to changes in lipid-derived flavor compounds, even though changes of flavor volatiles did not always correlate with the levels of the fatty acid precursors. Since fatty acids of a plant can be changed by the expression of a specific gene in the fatty acid pathway, engineering fatty acid metabolism could be an effective approach in flavor modification.

It should be pointed out that compound identification in this study was based on mass spectra matching with that of the National Institute of Standards and Technology mass spectral library. Thus, the probability of misidentification of certain compounds cannot be ruled out.

3. Experimental

3.1. Production of transgenic plants

Open-pollinated tomato (*Lycopersicon esculentum*) line PSR55809 from the New Jersey Agricultural

Experimental Station was used in this study. The transformation procedure was as previously described (Wang et al., 1996). *Agrobacterium tumefaciens* LBA 4404 containing the yeast Δ9 desaturase and NPTII gene sequence driven by CaMV 35S promoters (Polashock et al., 1992) was used to infect tomato cotyledon segments. Kanamycin resistant plantlets regenerated were subjected to Southern blotting (Southern, 1975). Fifteen kanamycin-resistant and Southern blot positive plants were produced. Eleven of these plants displayed dramatically higher levels of 16:1 fatty acid, (over 10-fold increase, data not shown). Plantlets with high levels of palmitoleic were multiplied in vitro and later transplanted to greenhouse. Two of the high 16:1 plants, T4 and T5, were selected and propagated by cuttings for this study.

3.2. Fatty acid analysis

Fatty acid analysis was carried out with leaf preparations with a protocol according to Browse et al. (1986). A Shimadzu 17A gas chromatograph equipped with a FID detector and HP-2330 capillary column (30m × 1.5 mm, 1 μm thick film) was used. Injector temperature was 230 °C, and detector temperature was 240 °C. A column temperature program was set initially at 170 °C and ramped at 3 °C/min to 210 °C 3 min after injection. The fatty acid methyl ester (FAME) peaks were identified with the authentic standards of FAME from Sigma Chemical.

3.3. Volatiles analysis

Tomato plants were maintained in a greenhouse and leaves were collected from 6 to 7-week-old plants. Leaves (10 g) were frozen (liquid nitrogen) in a mortar and pulverized with a pestle. The resulting slurry in liquid nitrogen was quickly transferred to a 250 ml Wheaton Purge and Trap apparatus and 50 ml of distilled water and 10 μl of 1000 ppm tridecane dissolved in methylene chloride were then added. Volatile compounds were trapped onto Tenax-Carbotrap tube, with a flow of nitrogen gas at 40 ml/min at 52 °C for 1 h. The trapped tube was dried at room temperature with nitrogen at a flow rate of 40 ml/min for 45 min. The trapped volatile compounds were thermally desorbed at 250 °C with a TD-4 short path thermal desorption system from SIS (Ringoes, New Jersey) and injected into a HP 6890 GC with a HP 6973 MS detector. The GC was equipped with a DB-1 capillary column (60m × 0.32 mm, 1 μm film thickness, J&W Scientific Co.). The injector temperature and the interface temperature were both set at 250 °C. The desorbed sample was frozen on the head of the column by a cryotrap with liquid CO_2 at −40 °C. A split ratio of 10:1 was used. Column temperature was programmed linearly 30 to 280 °C at 2 °C/min. The mass spectra were identified with the aid of the National Institute of Standards and Technology mass spectral library and the data of Buttery et al. (1987). Some of the peaks were also identified using authentic standards.

Roots and shoots of tomato produce 6-deoxo-28-norcathasterone, 6-deoxo-28-nortyphasterol and 6-deoxo-28-norcastasterone, possible precursors of 28-norcastasterone

Abstract

Roots and shoots of tomato (*Lycopersicon esculentum*) were investigated for the occurrence of biosynthetic precursors of 28-norcastasterone, a C_{27} brassinosteroid that we have shown to be present in shoots of tomato. A series of putative precursors, including 6-deoxo-28-norcathasterone, 6-deoxo-28-norteasterone, 3-dehydro-6-deoxo-28-norteasterone, 6-deoxo-28-nortyphasterol and 6-deoxo-28-norcastasterone, were synthesized and used as GC-MS standards, resulting in the identification of 6-deoxo-28-norcathasterone, 6-deoxo-28-nortyphasterol and 6-deoxo-28-norcastasterone in both roots and shoots. These findings indicate that the biosynthesis of 28-norcastasterone may parallel that of castasterone. The endogenous levels of brassinosteroids differed between roots and shoots, indicating that the biosynthesis of brassinosteroids is differently regulated between these tissues. Regulation of root growth by brassinosteroids is also discussed. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Tomato; *Lycopersicon esculentum*; Solanaceae; Shoot; Root; Brassinosteroid; 6-Deoxo-28-norcathasterone; 6-Deoxo-28-norteasterone; 3-Dehydro-6-deoxo-28-norteasterone; 6-Deoxo-28-nortyphasterol; 6-Deoxo-28-norcastasterone; 28-Norcastasterone; Castasterone

1. Introduction

Unusual phenotypes such as dwarfism and leaf curling in the tomato mutants *dwarf* (Bishop et al., 1999) and *dumpy* (Koka et al., 2000) have recently been ascribed to brassinosteroid (BR) deficiency, while a similar appearance in the tomato mutant *curl-3* was attributed to insensitiveness to BRs (Koka et al., 2000). These findings revealed that BRs play an essential role in the growth and development of tomato. In tomato shoots, castasterone (**1**), a C_{28} BR, seems to be biologically active since brassinolide was not detected in this tissue (Yokota et al., 1997a,b; Bishop et al., 1999; Nomura et al., 2001). Castasterone is biosynthesized from campestanol through either early C-6 oxidation or late C-6 oxidation (Sakurai, 1999). GC–MS analyses of biosynthetic precursors of castasterone in tomato shoots led to the identification of 6-deoxoBRs rather than 6-oxoBRs, indicating that the late C-6 oxidation pathway is exclusively operative in this tissue (Yokota et al., 1996; Bishop et al., 1999; Nomura et al., 2001).

In addition to castasterone (**1**), tomato shoots contain 28-norcastasterone (**2**) which may be another bioactive BR with the same C_{27}-carbon skeleton as cholesterol, its endogenous level being comparable to that of castasterone (Bishop et al., 1999; Nomura et al., 2001). Since cholesterol, along with cholestanol, was detected in the shoots with the former being the major sterol, it is likely that the synthesis of 28-norcastasterone from cholesterol *via* cholestanol occurs through late C-6 oxidation in analogy to the biosynthesis of castasterone. To ascertain this hypothesis, we synthesized a series of putative C_{27} precursors of 28-norcastasterone that have a 6-deoxo structure and, using these chemicals as standards, analyzed

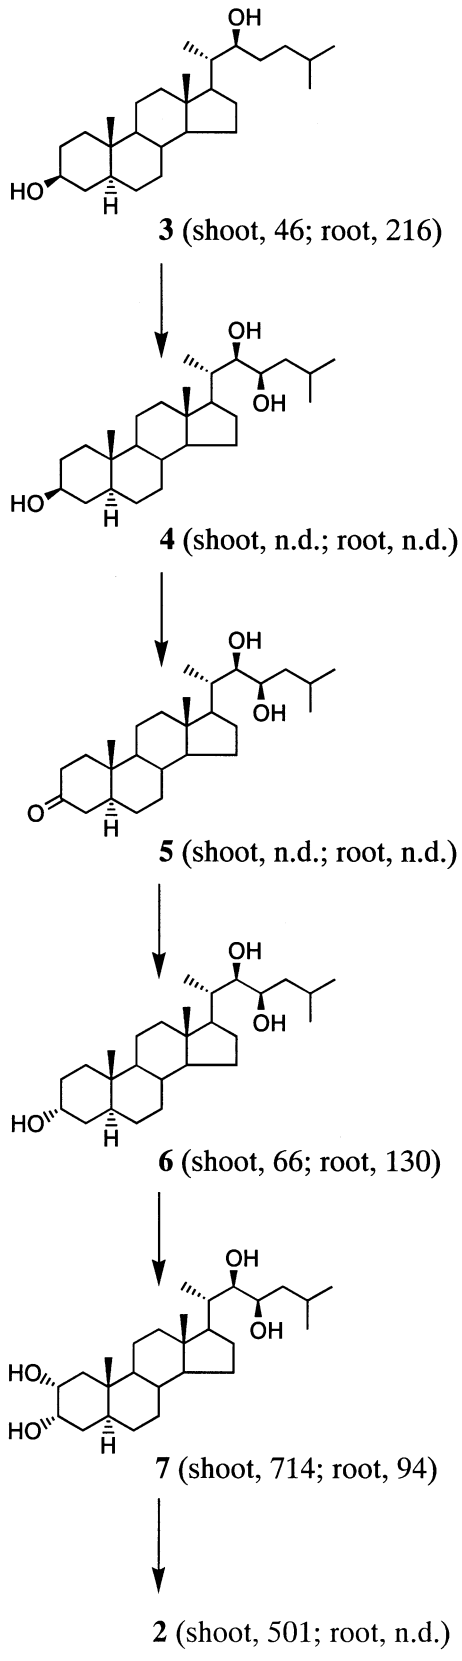

Fig. 1. Putative biosynthetic pathway of 28-norcastasterone (**2**) in tomato. The endogenous levels of BRs (ng/kg fresh weight) in shoots and roots of tomato are shown in parentheses.

the shoots and roots of tomato by GC–MS. In this paper, we report the successful identification of some 6-deoxo intermediates in these tissues and will discuss the biosynthesis of 28-norcastasterone by comparing our results with recent work on the putative biosynthetic pathway of 28-norcastasterone from castasterone in some plants, including tomato (Fujioka et al., 2000). Requirement of BRs in the root growth is also discussed.

2. Results and discussion

28-Norcastasterone (**2**) was assumed to be derived from 6-deoxo-28-norcathasterone (**3**) via 6-deoxo-28-norteasterone (**4**), 3-dehydro-6-deoxo-28-norteasterone (**5**), 6-deoxo-28-nortyphasterol (**6**) and 6-deoxo-28-norcastasterone (**7**) (Fig. 1). These compounds were synthesized as described in Experimental. The Rts and mass spectra of these BRs were determined by GC–MS after being converted into appropriate derivatives (Table 1).

Tomato seedlings, grown hydroponically, were separated into shoots and roots. These tissues were extracted with methanol and subjected to solvent partitioning and then to chromatography on charcoal and/or Sephadex LH-20. The purified extracts were chromatographed on reversed phase HPLC. HPLC fractions corresponding to the Rts of compounds **2**–**7** were analyzed by selected ion monitoring (SIM) on the basis of the GC–MS data obtained for respective authentic specimens (Table 1). Ions characteristic of 6-deoxo-28-norcathasterone (**3**) bisTMSi ether, 6-deoxo-28-nortyphasterol (**6**) methaneboronate-TMSi ether and 6-deoxo-28-norcastasterone (**7**) bismethaneboronate were detected in the extracts obtained from shoots and roots of tomato with the Rts (Table 1) and intensities (Table 2) being comparable to authentic compounds. These results corroborate our hypothesis that 28-norcastasterone may be synthesized from 6-deoxo-28-norcathasterone. But to positively confirm this, feeding experiments will be needed in the

future. Although ions characteristic of 6-deoxo-28-norteasterone (**4**) methaneboronate-TMSi ether and 3-dehydro-6-deoxo-28-norteasterone (**5**) methaneboronate were not detectable, this does not contradict the present conclusion since corresponding C_{28} BRs, 6-deoxoteasterone and 3-dehydro-6-deoxoteasterone are also known to be scarce in tomato, pea and *Arabidopsis thaliana* (Nomura et al., 2001).

Recently, [26, 28-$^2H_6$] castasterone has been found to be converted with removal of C-28 to [26-$^2H_3$] 28-norcastasterone in seedlings of *A. thaliana,* and tomato, and cultured cells of *Catharanthus roseus* (Fujioka et al., 2000). On the basis of this evidence, it was postulated that 28-norcastasterone is synthesized from castasterone. Likewise, *Marchantia polymorpha* cells also remove C-28 of [26, 28-$^2H_6$]brassinolide to give [26-$^2H_3$]28-norbrassinolide (Kim et al., 2000). However, *Marchantia* cells cannot remove C-28 from unlabelled brassinolide and instead detach its C-26. Thus, there is the possibility that the removal of C-28 only occurs in [26, 28-$^2H_6$] BRs but not in unlabelled, natural BRs. The intermediary of castasterone in the biosynthesis of 28-norcastasterone, therefore, may remain ambiguous.

The present work demonstrates that roots can synthesize BRs, agreeing with the recent finding that maize roots produce castasterone (Kim et al., 2000), and suggesting that BRs are necessary for the growth of not only shoots, but also roots. In support of this, the pea mutant *lk* which is deficient in BRs (Yokota et al., 1997a,b) has unusually thick and less lateral roots (T. Yokota, unpublished). The levels of a series of 28-norBRs in shoots and roots of tomato are shown in Fig. 1. Quantification of **2** was made by GC–SIM using deuterated brassinolide as an internal standard. However, the levels of **3**–**7** were obtained only by comparing the areas of their molecular ions with those of authentic compounds, because appropriate deuterated standards were not available. Thus, the loss encountered during purification could not be compensated for and hence the values obtained for **3**–**7** were less than the actual ones. However, the data presented in Fig. 1 at least suggest that relative amounts of these BRs are significantly varied between shoots and roots. Thus, the biosynthesis of BRs seems to be differently regulated between shoots and roots.

Of further interest, the level of 28-norcastasterone (**2**) is high in shoots, but undetectable in roots (Fig. 1) and this relationship was also the case in the levels of castasterone which is abundant in shoots but only in a trace amount in roots (T. Yokota, to be published elsewhere), indicating that roots require 28-norcastasterone and castasterone to a much lesser extent than that required by shoots. Less requirement of endogenous gibberellin by roots has also been demonstrated in *Lactuca sativa* (Tanimoto, 1987, 1991), *Pisum sativum* (Tanimoto, 1991) and *Lemna minor* (Inada et al., 2000; Inada and Shimmen, 2000) by applying gibberellin A_3 to respective

seedlings treated with gibberellin biosynthesis inhibitors. In contrast to gibberellin, even low levels of brassinolide and/or 24-epibrassinolide have been known to be inhibitory to root growth of wheat, mung bean and maize (Roddick and Ikekawa, 1992), *A. thaliana* (Clouse et al., 1993) and tomato (Roddick, 1994) and hence, in roots, there seems to be a homeostasis keeping the levels of biologically active BRs very low. Conversely, one may propose that castasterone and 28-norcastasterone are biologically active in their own right (Yokota, 1997).

3. Experimental

3.1. Plant materials

Seeds of tomato (cv. Sekaiichi) were sown in vermiculite and grown for 31 days in a greenhouse under natural light: day, 23 °C (13 h); night, 20 °C (11 h). Seedlings were fed with Hyponex (×1000) 20 and 27 days after sowing. Seedlings were then grown for a further 15 days hydroponically using Tadano and Tanaka (1980) liquid medium. One hundred and ninety-six seedlings were separated into shoots (349 g) and roots (95 g).

3.2. Bioassay

To monitor the biological activity of BRs, sample aliquots were assayed by the rice lamina inclination test (Yokota et al., 1996).

3.3. Extraction and purification of BRs

Shoots and roots were subjected to the following purification procedures although charcoal chromatography was avoided in the case of roots. Plant tissues were homogenized in MeOH containing [$^2H_6$]-labeled internal standards (100 or 1000 ng) of C_{28}-BRs were added before reduction to an aq. residue. The latters were partitioned between EtOAc and 0.5 M K_2HPO_4. The EtOAc phases were evaporated to dryness and partitioned between hexane and 80% MeOH. The 80% MeOH phase was evaporated to dryness and the residual solid was purified on a column of charcoal (chromatography grade; Wako Pure Chemicals, Japan) which was eluted with MeOH–H_2O (6:4 and 8:2, v/v), MeOH, MeOH–$CHCl_3$ (9:1, 7:3, 5:5, 3:7, and 1:9, v/v) and $CHCl_3$. The MeOH–$CHCl_3$ (9:1–3:7) fractions were applied on a Sephadex LH-20 column (bed volume, 500 ml; Pharmacia) using MeOH–$CHCl_3$ (4:1) as a mobile phase. Successive 10-ml fractions were collected. Fractions 37–41 (shoots) and 37–40 (roots) were combined, dissolved in MeOH and passed through columns of diethylaminopropyl silica (Bondesil, Varian. Palo Alto, CA) and octadecyl silica (ODS-SS-1020-T; Senshu Science, Tokyo, Japan). Reversed-phase HPLC was carried out on a Senshu Pak ODS-3251-D column (250×8 mm i.d.; Senshu Science) eluted with an acetonitrile–H_2O gradient at a flow rate of 2.5 ml min^{-1}: 0–20 min, 45% acetonitrile; 20–40 min, 45–100% acetonitrile; 40–60 min, 100% acetonitrile. Fractions were collected every min. The column oven temp. was maintained at 40 °C. Based on bioassay and the HPLC Rts of authentic BRs, BR fractions were collected for analysis by GC–MS/SIM. The following fractions were analyzed: fr.14/15 (28-norcastasterone), fr. 35/36 (6-deoxo-28-norcastasterone), fr. 40 (6-deoxo-28-norteasterone), fr. 43 (3-dehydro-6-deoxo-28-norteasterone), fr. 45 (6-deoxo-28-nortyphasterol), fr. 48/49 (6-deoxo-28-norcathasterone).

3.4. GC–MS/SIM analysis of BRs

Methaneboronation was conducted by dissolving BRs in pyridine that contains 2 mg ml^{-1} methaneboronic acid prior to heating at 70 °C for 30 min. Further trimethylsilylation of methaneborones was conducted by reacting with *N*-methyl-*N*-trimethylsilyl-trifluoroacetamide (MSTFA) at room temp. for 10 min. 6-Deoxocathasterone was converted to a TMSi derivative with MSTFA–pyridine (1:4) at 70 °C for 30 min. GC–EI MS/SIM (70 eV) was carried out on a JMS AX 505W instrument (Jeol, Tokyo, Japan) fitted with a DB-5 column (0.25 mm i.d. ×15 m; 0.25 μm film thickness; J&W Scientific, Folsom, CA). The carrier gas was He at a flow rate of 1 ml min^{-1}, the injection port temp. was 280 °C, and samples were introduced by splitless injection. The column oven temp. was programmed at 170 °C for 1.5 min, before being elevated to 280 °C at 37 °C min^{-1}, and then to 300 °C at 1.5 °C min^{-1}. The amount of 28-norcastasterone was determined from a calibration curve constructed from the peak area ratios of the $[M]^+$ ions of 28-norcastasterone bismethaneboronates and [$^2H_6$]brassinolide bismethaneboronates. The contents of other 28-norBRs were calculated by comparing the peak areas of $[M]^+$ ions with those of authentic samples.

3.5. Synthesis of C_{27} BRs

Compound **3** was prepared from a known 22α-hydroxycholesterol (Ishiguro et al., 1978) by hydrogenation. **4**–**7** were synthesized from a known (22*R*, 23*R*)-dihydroxycholesterol (Takatsuto and Ikekawa, 1987) by using the same method as described for their corresponding 6-deoxo type C_{28} steroids (Takatsuto et al., 1997).

Abstract

An unusual alkaloid, the 2-aza-anthraquinone derivative, 5-deoxy-7-methyl bostrycoidin, was identified in the cultures of the spore-derived mycobionts of the lichen *Haematomma* sp., but not in the natural lichen thallus. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Haematomma* sp.; Lichen; Mycobiont; Aza-anthraquinone; Bostrycoidin; nitrogen

1. Introduction

Lichens are distinctive organisms resulting from a symbiosis between algae and fungi. They are well known for their production of unique metabolites, generally referred to as lichen substances. Although the cooperative mechanisms for the biosyntheses of lichen substances are not fully understood, they are thought to be produced by the fungal portion (mycobiont) of the symbiotic system. However, it is very likely that the algal component (photobiont) has some role in their production, since there are many lichen substances characteristically produced in the symbiotic systems, and not in the isolated form. In this regard, the metabolic differences between the isolated fungal or algal cultures and the symbiotic form are likely to give us clues how these metabolic systems arise. Recent studies in our laboratories demonstrated that isolated lichen mycobionts are, in some cases, capable of producing new compounds under osmotically stressed conditions (Miyagawa et al., 1993, 1994, 1997; Tanahashi et al., 1997, 1999; Amano et al., 2000),which are not detected in the natural lichen specimens. These compounds are of interest, because they could be regarded as indicators of the "independent state" of the fungal mycobionts which are free from the interactions with the algal partners. In continuing the study of differences in secondary metabolism between lichens and mycobionts, we isolated and identified a bright yellow pigment produced by the spore-derived culture of the mycobiont from *Haematomma* sp., which was not detected in the natural lichen thallus. This paper describes the structural elucidation of this new and unusual pigment.

2. Results and discussion

The isolated mycobiont from *Haematomma* sp. was cultured on a malt-yeast extract medium supplemented with 10% sucrose. After a 7-month culture period, the mycobiont formed elevated round-shaped compact colonies on the agar slants. The brown colored colonies and culture medium were extracted in several groups using diethyl ether, and the production of a bright yellow pigment was detected in all the extracts by TLC analysis. The extract was then purified by chromatographic means to obtain compound **1** as a yellow powder.

The molecular formula of compound **1** was established to be $C_{16}H_{13}O_4N$ based on the HR–EI-mass spectrum ($[M]^+$ observed at m/z 283.0848, calculated

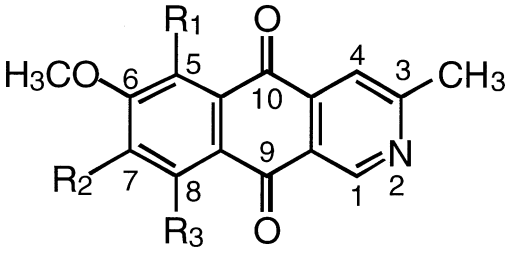
PII: S0031-9422(01)00167-4

283.0845); its degree of unsaturation was calculated to be 11. The presence of a hydrogen-bonded hydroxyl group was deduced from a characteristic signal observed in the ^{1}H NMR spectrum (δ H 12.87, s). In addition, signals assignable to two aryl methyl groups were observed in the ^{1}H (δ H 2.78, *s* and 2.22, *s*) and ^{13}C NMR (δ C 25.3 and 8.3). One methoxyl function was also identified from ^{1}H and ^{13}C NMR spectra (δ H 4.03, *s* and C 56.3).

The two carbon resonances at δ C 186.7 and 182.5, characteristic of anthraquinonoidal carbonyl δ C atoms, were assigned to C-10 and C-9, respectively. Treatment of **1** with acetic anhydride in the presence of catalytic amounts of sulfuric acid gave the monoacetylated derivative **2**, as evidenced by MS and NMR spectroscopic analyses. This suggested that only one hydroxyl group was present in **1**, assigned to that being hydrogen-bonded as mentioned above. On acetylation, the carbon resonance at C-9 shifted to higher field [$\Delta = -6.3$ ppm], revealing that the C-9 cabonyl group was involved in hydrogen bond formation.

The signals corresponding to the remaining eight carbon atoms resonated in the region from δ C 100 to 170 ppm. The proton resonances at δ H 9.42, 7.88 and 7.39, which showed no spin-interaction, were correlated by HMQC experiments with the methine signals at δ C 148.9, 118.5 and 102.7, respectively. These data, together with the presence of a nitrogen atom in the molecular formula, allowed the formulation of a 2-aza-anthraquinone ring. This structure is consistent with the degree of unsaturation calculated for this compound (Fig. 1).

The substitution pattern of the anthraquinone ring was determined from carbon-proton long range couplings observed in HMBC experiments and NOE correlations observed in NOESY spectra. The correlations are shown in Fig. 2. From these data this new pigment was formulated as **1**, or 3,7-dimethyl-8-hydroxy-6-meth oxy-2-aza-anthraquinone.



1 R_1 = H, R_2 = CH_3, R_3 = OH
5-deoxy-7-methylbostrycoidin

2 R_1 = H, R_2 = CH_3, R_3 = $OCOCH_3$

3 R_1 = OH, R_2 = H, R_3 = OH
bostrycoidin

Fig. 1. 2-Aza-anthraquinone derivatives.

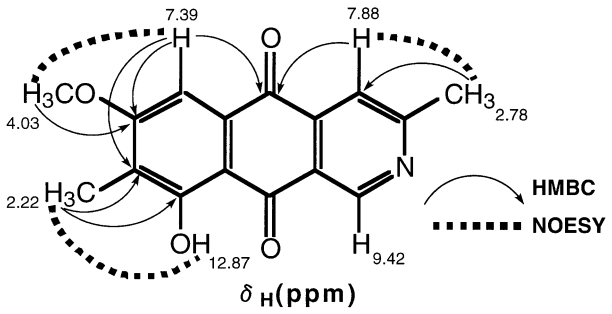

Fig. 2. HMBC and NOESY correlations of **1**.

It is noteworthy that compound **1** has not been described before and cannot be related to any known *N*-containing substances of lichen origin (Huneck and Yoshimura, 1996). Compound **1** rather has quite a similar structure to that of the antibiotic, bostrycoidin (**3**), produced by the fungus *Fusarium bostrycoides* (Arsenault, 1965), and thus, is named 5-deoxy-7-methyl bostrycoidin. No 5-deoxy-7-methylbostrycoidin was found in the lichen thallus, or the symbiotic form of fungi and algae, but atranorin was detected by TLC. It is interesting that without the algal counterpart, the isolated mycobiont produced a 2-aza-anthraquinone derivative, which is structurally related to bostrycoidin with an antibiotic activity (Cajori et al., 1954). It could be hypothesized that the metabolic capacity of fungi to produce this antibiotic compound, which is unfavorable for symbiosis, is suppressed by algae in this lichen symbiotic form.

Some *N*-containing compounds produced by lichens are biosynthetically related to amino acids (Begg et al., 1978; Huneck et al., 1992, 1993). In contrast, compound **1** appears to be formed biosynthetically from a heptaketide (Kurobane et al., 1980; Parisot et al., 1988) and is distinct from the *N*-containing lichen substances reported.

3. Experimental

3.1. General experimental procedures

The mycobiont of the lichen specimen was obtained from spores from apothecia in the thallus and was cultured in test tubes containing MY10 medium (malt extract 10 g, yeast extract 4 g, agar 15 g in 1 l H_2O, pH 7), supplemented with sucrose at a conc. of 100 g l^{-1}. The culture was maintained at 15°C in the dark for ca. 7 months. The culture media along with the entire mycelia were then extracted with diethyl ether and the extract was filtered to remove the debris. After evaporating the filtrate, the residue was subjected to column chromatography (Kieselgel 60) eluting with $CHCl_3$. The eluate (47 mg) containing the substance of interest was evaporated

and then applied to a 10×20 cm silicagel TLC plate of Merck 60 PF 254, 1.5 mm thick. The development was done twice in $CHCl_3$ and the zone containing the target compound was confirmed by its R_f value of 0.31 under UV light. The corresponding band was excised, with the compound of interest being extracted with $CHCl_3$. The yield of the pigment was 1.6 mg g^{-1} culture including both mycelia and the medium.

Received 2 October 2000; received in revised form 14 May 2001

Abstract

A fluorinated analogue of coniferyl alcohol has been reported to be a specific inhibitor of oxidases involved in the biosynthesis of lignin. The *Z* isomer of β-fluoro-coniferyl alcohol was synthesized and used for the preparation of dehydrogenation polymers (DHPs) and was also tested on lignin producing suspension cultures of spruce (*Picea abies* (L.) Karst.). The growth of the cells or the production of lignin by the suspension cultures was not significantly affected by the addition of fluoroconiferyl alcohol. This analogue did not form polymers quite as easily as did coniferyl alcohol in oxidation with hydrogen peroxide and horseradish peroxidase. In both cases the β-fluoroconiferyl alcohol became incorporated in the polymeric product. We were unable to detect any specific inhibition of peroxidase activity, which is at variance with earlier reports of pronounced inhibition of lignin biosynthesis in poplar plantlets by fluoroconiferin, a potential inhibitor of oxidases involved in lignin biosynthesis. © 2001 Elsevier Science Ltd. 1. Introduction

Fluorinated analogues of lignin precursors, so called monolignols, have been studied as possible inhibitors of peroxidase activity (Goldberg et al., 1988). Fluorine, being similar in size to hydrogen but very different in reactivity can, when substituted in a reactive position, give rise to analogues which may act as antimetabolites towards the fluorine-free parents (Welch, 1987). In monolignols, the β position in the side chain is the most reactive. Such fluoro analogues of cinnamic compounds have been reported to function as hydrogen donors for peroxidase reactions, forming "lignin-like" polymers (Goldberg et al., 1988). In a more recent report it was stated that β-fluoroconiferyl alcohol acts as a specific inhibitor of lignin biosynthesis in poplar shoots (Daubresse et al., 1997). In view of the importance for the study of lignin forming enzymes of finding a specific inhibitor of lignin polymerization, we have synthesized β-fluoroconiferyl alcohol and studied its effect on the lignin formation ability of suspension cultures of spruce as well as its reactivity in peroxidatic oxidation experiments. We could not observe any significant effects on lignin production in the suspension cultures after addition of the fluoro analogue of coniferyl alcohol.

2. Results

2.1. The preparation of β-fluoro coniferyl alcohol

The synthesis of the *Z* isomer coniferyl alcohol with a fluorine in the β position, using a Horner–Emmons reaction with phosphonofluoroacetate and vanillin acetate, has been mentioned in an article by Goldberg et al. (1988) but no physical or spectroscopic data for the product have been published. The Horner–Emmons is a general route for obtaining mainly the E isomer, which in this case has to be isomerized to the *Z* isomer by treatment with bromine. We have used a more direct stereoselective route to (*Z*)-2-fluoroalkenoates (Clemenceau and Cousseau, 1993) to prepare the acetate of (*Z*)-β-fluoro ethyl ferulate which we then reduced to the cor-

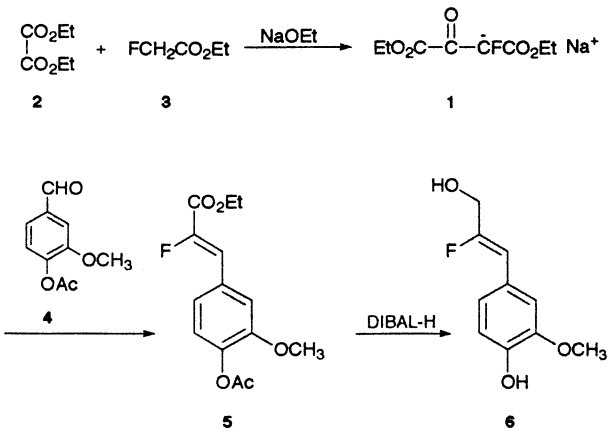

Scheme 1.

responding alcohol with DIBAL-H (Quideau and Ralph, 1992) in 86% yield (Scheme 1).

2.2. The preparation of DHPs

The synthetic lignins (DHPs) were prepared by oxidation with H_2O_2/horseradish peroxidase (HRP) at pH 4 using a suspension with cellulose powder to facilitate the isolation of the polymer. The experiments were carried out with fluoroconiferyl alcohol, coniferyl alcohol, and a mixture of the two. As can be seen in Table 1 the fluoro analogue formed less polymer and more unreacted starting material was left at the end of the reaction, compared to coniferyl alcohol, with the mixture being intermediate in reactivity (Table 1).

Mixtures of dimers isolated from an interrupted oxidation of fluoroconiferyl alcohol were analyzed by chromatography, NMR and mass spectrometry. NMR studies indicate that the main dimer is a β-5 product; the presence of β-O-4 and a β-β dimers were also indicated (the spectra will be published separately).

Table 1
Yields (%) of dehydrogenation polymers formed in H_2O_2/HRP oxidation of fluoroconiferyl alcohol (F-CA) and coniferyl alcohol (CA)

Starting material	Unreacted	EtAc-soluble	Dioxane-soluble
F-CA	31	31	38
CA	3	13	84
F-CA + CA	12	9	79

2.3. The suspension culture experiments

In the suspension cultures, the extracellular precipitate became visible on day 3 after initiation of the suspension culture regardless of the added compound. The chemical analysis of this extracellular lignin precipitate has been described (Brunow et al., 1993). In day 6 some of the suspension cultures showed signs of ageing so a 5-day culture period was used in the following replicate cultures.

Neither coniferyl alcohol nor fluoroconiferyl alcohol had a statistically significant effect on the fresh weight of the cells, on the pH of the nutrient medium at the end of culture, on the amount of secreted proteins in the medium or on the amount of extracellular precipitate formed according to variance analysis (Table 2). Also, the peroxidase isoenzyme pattern was similar as revealed by IEF and peroxidase activity staining, showing that the presence of this fluoro analogue did not induce secretion of any new peroxidase isoenzymes into the suspension culture medium (Fig. 1).

According to kinetic data nutrient medium peroxidases from cultures 1 and 2 showed a higher apparent utilization efficacy towards coniferyl alcohol, as evidenced for a higher value of V_{max}/K_m (Table 3): it was ca. 1.7-fold towards coniferyl alcohol compared to its fluorinated analogue. It should be noted that this apparent difference could be explained by the different stability of the radicals formed from the coniferyl alcohol and its fluoro analogue (Daubresse et al., 1997). However, for the nutrient medium peroxidases from culture 3 and for HRP types I and II the apparent utilization efficacy was similar for both the fluorinated analogue and for the coniferyl alcohol (Table 3). The substrate concentration of 150 μM inhibited coniferyl alcohol and fluoroconiferyl alcohol oxidation by nutrient medium peroxidases as well as by HRP (data not shown). K_m values calculated for coniferyl alcohol and fluoroconiferyl alcohol or their mixture were similar for nutrient medium peroxidases (20–50 μM), however, the affinity of HRP types I and II was over two-times higher for the fluorinated analogue

Table 2
Fresh weight of the cells, pH of the nutrient medium at the end of culture period, amount of secreted proteins in the nutrient medium and the amount of extracellular precipitate per 25 ml of suspension culture of *Picea abies* after 5 days in suspension culture[a]

	Fresh weight of the cells (g)	pH	Secreted proteins in the medium (mg/ml)	Extracellular precipitate (mg/25 ml culture)
Control	0.62±0.04	4.0±0.13	0.067±0.03	5.98±0.74

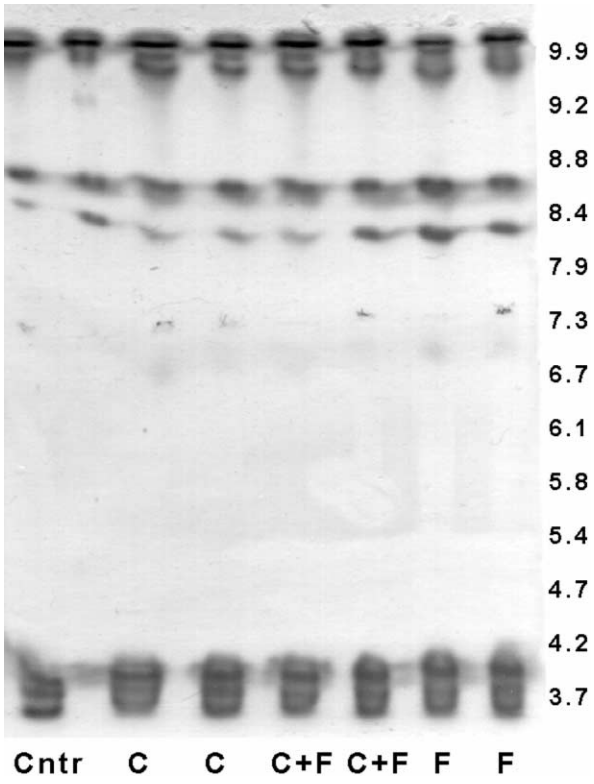

Fig. 1. Peroxidase isoenzymes from the nutrient media of fluoroconiferyl alcohol feeding experiment separated on polyacrylamide gel by isoelectric focusing (pH 3.5–10). Control culture (Cntr), 0.1 mM coniferyl alcohol (C), 0.05 mM coniferyl alcohol + 0.05 mM fluoroconiferyl alcohol (C + F), 0.1 mM fluoroconiferyl alcohol (F). The amounts of proteins loaded onto the gel were counted as 80 pkat of peroxidase activity. Peroxidases were visualised by activity staining with 3,3-diaminobenzidine and H_2O_2 as described in Experimental.

than for the non-fluorinated one (Table 3). The K_m value for HRP type I for the mixture of both substrates was in the middle of those of pure coniferyl alcohol or its analogue as a substrate. On the contrary, K_m values of HRP type II for the mixture of substrates and for the fluoro analogue were almost similar (159 and 197 μM, respectively; Table 3).

3. Discussion

Lignin precursors such as coniferyl alcohol are oxidized by many kinds of oxidizing enzymes, and no specificity has yet been established. The presence of a fluorine atom on the β-carbon of the side chain of coniferyl alcohol does not prevent the oxidation by peroxidases. Oxidation of fluoroconiferyl alcohol with hydrogen peroxide and horseradish peroxidase produced polymers albeit in smaller yields than with coniferyl alcohol itself. Analysis of dimers formed in the reaction indicated the formation of β-5, β-O-4 and β–β coupling products. The use of fluoroconiferyl alcohol in the kinetic assays showed that nutrient medium peroxidases used the native substrate coniferyl alcohol apparently more efficiently as a substrate its fluorinated analogue. In suspension cultures, however, the amount of precipitate formed was not statistically significantly decreased when the fluoroconiferyl alcohol was feeded to the cells. On the other hand, HRP preparations did not make any difference in the oxidizability between these substrates, as evidenced for the same V_{max}/K_m (Table 3). We were thus unable to reproduce in cell cultures the results of Daubresse et al. (1997) who observed a pronounced inhibition of lignin biosynthesis in feeding experiments with poplar plantlets with fluorooconiferin, that was designed as a potential inhibitor of oxidases involved in the biosynthesis of lignin.

4. Experimental

4.1. β-Fluoro coniferyl alcohol

The sodium salt of diethyl fluoro-oxaloacetate **1** was prepared from diethyl oxalate **2**, ethyl fluoroacetate **3** (Aldrich) and alcohol free sodium ethoxide, according to a published procedure (Blank et al., 1995).

The sodium salt of diethyl fluoro-oxaloacetate (8.58 g, 38 mmol) **1** was suspended in dry THF (100 ml) and cooled to 0 °C. Acetyl vanillin **4** (7.4 g, 38 mmol) in THF (40 ml) was added to the suspension with stirring (Clemencau and Cousseau, 1993). Then the reaction mixture was heated for 7 h at 80 °C. After a further 3 days at room temperature most of the THF was evaporated in vacuo and 100 ml diethyl ether was added. Then 50 ml saturated aq. $KHCO_3$ was added with stirring during 30 min. The organic layer was washed with water and with aqueous sodium bisulfite (10%). The organic layer was then dried ($NaSO_4$) and evaporated. The yield was 8.33 g (79%). The acetylated β-fluoro ethyl ferulate **5** was recrystallized from ethanol and water to give 5.3 g (50%) of light yellow crystals of melting point 63–66 °C.

Acetylated β-fluoro ethyl ferulate: δ_H (200 MHz) 1.39 (3H, *t*,–CH_3) 2.33 (3H, *s*,–$OCCH_3$) 3,86 (3H, *s*,–OCH_3) 4.36 (2H, *q*,–CH_2-) 6.89 (1H, *d*, α–CH) 7.05–7.31 (3H, *m*, arom.); δ_C(50 MHz) 14.3 (*s*, $OOCCH_3$) 20.8 (*s*, OCH_2CH_3) 56.0 (*s*, OCH_3) 62.1 (*s*,-OCH_2CH_3) 113.8 (*d*, C-α, J_{CF} = 9.6 Hz) 116.9 (*d*, ArC-2, J_{CF} = 4.55 Hz) 123.1(*s*, ArC-6) 123.4 (*d*, ArC-5, J_{CF} = 7.25) 130,0 (*d*, ArC-1, J_{CF} = 4.55) 140.8 (*d*, ArC-4, J_{CF} = 3.6) 147.0 (*d*, C-β, J_{CF} = 266) 151.2 (*s*, ArC-3) 161.3 (*d*, C-γ, J_{CF} = 40) *m*/*z* (%) 58 (11) 197 (13) 212 (27) 240(100) 282 (M^+,12) (HRMS: $C_{14}H_{15}O_5F$ requires M 282.0904. Found: M^+ 282.0901)

The ester was reduced using DIBAL-H (Aldrich) in toluene to give the β-fluoro coniferyl alcohol **6**, 86% yield. The recrystallized product (66%) had a melting point of 105–107 °C.

β-Fluoro coniferyl alcohol: δ_H (200 MHz) 3.90 (3H, *s*, OCH_3) 4.27 (2H, *d*, γCH_2) 5,70 (1H, *d*, α-CH) 6.85-7.14

(3H, *m*, arom.); δ_C(50 MHz) 55.9 (*s*, OCH_3) 62.1 (*d*, C-γ, $J_{CF}=15.4$ Hz) 107.7 (*d*, C-α, $J_{CF}=6.9$ Hz) 111.0 (*d*, ArC-2, $J_{CF}=9.6$ Hz) 114.4 (*s*, ArC-6) 122.5 (*d*, ArC-3, $J_{CF}=5.9$ Hz) 125.1 (*d*, ArC-1, $J_{CF}=2.74$ Hz) 145.3 (*d*, ArC-4, $J_{CF}=2.75$ Hz) 146.4 (*s*, ArC-3) 156.7 (*d*, C-β, $J_{CF}=264$ Hz). *m/z* (%) 58 (33), 107 (12), 109 (24), 121 (13), 124 (14), 137 (52), 149 (45), 165 (11), 180 (28), 198 (M^+,100) (HRMS: $C_{10}H_{11}O_3F$ requires M 198.0692. Found: M^+ 198.0701).

4.2. Coniferyl alcohol

Ferulic acid was prepared from vanillin and malonic acid (Pearl and Beyer, 1951). The acid was methylated with concentrated sulfuric acid and methanol (Adler and Gustafsson, 1963). The methyl ester of ferulic acid was reduced with DIBAL-H in toluene to give coniferyl alcohol (Quideau and Ralph, 1992).

4.3. DHP

Three different DHPs were prepared; one from 1.53 mmol β-fluoro coniferyl alcohol, another from 1.53 mmol coniferyl alcohol and a third from a mixture of 0.77 mmol coniferyl alcohol and 0.77 mmol β-fluoro coniferyl alcohol. An enzyme (12 mg) (horseradish peroxidase 529 U/mg, RZ 1.29, Serva, E.C. 1.11.1.7) was added to a suspension of cellulose (10 mg) and buffer pH 4 (10 ml). The alcohol (in 1 ml acetone) and 1 ml 5% hydrogen peroxide (2 eq.) were added to the mixture continuously for 5 h. The enzyme (12 mg) was added after 2 h. The mixture was allowed to react overnight. The suspension was filtered and the solid was washed with small amounts of water and then fractionated into an ethyl acetate soluble and a dioxan soluble fraction. The unreacted alcohol was extracted from the aqueous phase with ethyl acetate. All the fractions were acetylated, and identified with NMR.

4.4. The suspension culture experiments

A chlorophyllous callus line of *Picea abies* (L.) Karst. was used for suspension cultures that were cultured in a liquid medium containing T-macroelements (NH_4^+/NO_3^-, 1:2) and SS-microelements (Simola and Santanen 1990; Simola et al., 1992). 2,4-Dichlorophenoxyacetic acid (0.5 μM) and kinetin (2.5 μM) were used as growth regulators. No organic nitrogen was added to the liquid medium. Cells were cultured in 100 ml Erlenmeyer flasks with a culture volume of 25 ml. For feeding experiments, cells were transferred to basic medium supplemented with (A) 0.1 mM coniferyl alcohol, (B) 0.1 mM fluoroconiferyl alcohol, (C) 0.05 mM coniferyl alcohol and 0.05 mM fluoroconiferyl alcohol, (D) control (distilled water). Stock solutions (5 mM) of coniferyl alcohol and fluoroconiferyl alcohol were made by dissolving them first to a small volume of acetone after which H_2O was added. They were filter-sterilized into the autoclaved medium. Cultures were incubated in a shaker (100 rpm) at 25°C in 18 h light/6 h dark photoperiod (20–30 μmol m^{-2} s^{-1} Osram L36/30, Warmton Warm White). Three separate cultures were made with 3–5 replicates in each treatment.

In order to reduce the variation in replicate cultures, a fourth repetition was made with a modified method with 9 replicates. Suspension cultures were initiated normally. On day 1, A_{262} was measured to check the amount of lignin precursors secreted into the nutrient medium. Culture flasks of the same absorbance were divided into four groups and coniferyl alcohol and fluoroconiferyl

alcohol were added to the treatment bottles. The cultures were allowed to grow for 4 days (5-day culture in total) after which the nutrient medium was collected.

4.5. Isolation of proteins from culture medium

The nutrient medium was collected after 5 or 6 days in culture. Because on day 6 some of the suspension cultures showed signs of ageing, a 5-day culture period was used in the following replicate cultures. The nutrient medium was decanted, filtered through glass wool and the extracellular precipitate collected using centrifugation (12,000 *g*, 15 min at 4 °C). The pellet was washed twice with distilled water, freeze-dried, quantified and stored at −20 °C for NMR studies. pH of the nutrient medium was measured, the medium was frozen and stored at −80 °C until used. The cells were washed in a Büchner funnel with distilled water and the fresh weight of the cells was measured. The viability of cells was checked by staining with Evans Blue (Yeoman, 1986).

After quick thawing the nutrient medium was centrifuged for 45 min at 4 °C at 12,000 *g*. The supernatant was concentrated over 10-fold using an Amicon ultra-filtration apparatus (YM 10 membrane) and passed through Sephadex G-25 columns (PD10, Pharmacia) pre-equilibrated with 50 mM Tris–HCl buffer, pH 7.5 containing 0.5 mM $CaCl_2$, 5 mM $Na_2B_4O_7$, 30 mM NaCl and 0.5 mM phenylmethylsulfonyl fluoride (PMSF; modified from Fagerstedt et al., 1998). Peroxidase activity measurements were made using concentrated bulk proteins of the nutrient medium.

4.6. Enzyme assays and quantitation of protein

Kinetic behaviour of nutrient medium peroxidases was studied with coniferyl alcohol and its fluorinated analogue as hydrogen donors at 262 nm. Assays were carried out in a volume of 1.0 ml in a Shimadzu UV-2100 spectrophotometer at 25 °C. The reaction mixture contained coniferyl alcohol and/or fluoroconiferyl alcohol (5–100 μM), and 250 μM H_2O_2 in 45 μM Na-citrate buffer, pH 5.0. The activities were determined using nutrient medium protein fractions of three separate cultures and horseradish peroxidase type I (HRP, Sigma P-8125) and type II (Sigma P-8250). Hanes plots were constructed from initial velocity data and K_m and V_{max} values determined after linear regression analysis by Shimadzu UVPC Optional Kinetics Software. Because bulk proteins of nutrient medium were used, rate values are normalized per gram of fresh tissue (Gonzàles et al., 1999). The extinction coefficient for coniferyl alcohol was estimated and was found to be 14,000 M^{-1} cm^{-1}.

Protein contents of the nutrient medium and enzyme samples were determined with the Bio-Rad microassay procedure (Bradford, 1976) using bovine serum albumin (Sigma) as a standard.

4.7. Isoelectric focusing (IEF)

IEF was accomplished with a Multiphor II apparatus (Pharmacia) in a 4% polyacrylamide gel containing Ampholine with a pH range of 3.5–10.0 according to the manufacturer's instructions. Peroxidase was visualized in the gel by staining with 50 mM Na-citrate buffer, pH 5.0 containing 0.03% 3,3-diaminobenzidine, 10 mM $CaCl_2$ and 10 mM H_2O_2 (Sato et al., 1993). After pre-incubation for 20 min in staining buffer without H_2O_2 the reaction was started by addition of H_2O_2.

Received 15 March 2001; received in revised form 11 May 2001

Abstract

Three naturally occurring ajugarins and seven semisynthetic derivatives of them, possessing different functionalities in the decalin part, together with two natural furoneoclerodane diterpenes, have been assessed as feeding behavior modifying agents of larvae of the generalist *Spodoptera exigua* and a specialist like *Leptinotarsa decemlineata*. Ajugarin I and some of its derivatives exhibited a significant antifeedant activity against larvae of *S. exigua* in both choice and no-choice assays. Conversely, the furoneoclerodane diterpenes only presented antifeedant activity against larvae of *L. decemlineata*. These results indicate that the biological action of the tested substances is strongly modulated by minimal structural variations, which are also responsible for the specificity of action.

Keywords: Diterpenes; Ajugarins; Furoneoclerodanes; Antifeedant activity; *Leptinotarsa decemlineata*; *Spodoptera exigua*

1. Introduction

Clerodanes are a large group of naturally occurring diterpenoids isolated mainly from Compositae and Labiatae plants (Merritt and Ley, 1992; Rodríguez-Hahn et al., 1994). These compounds have attracted interest in the last years on account of their biological activities against some economically important lepidopteran (Simmonds and Blaney, 1992; Rodríguez et al., 1999), coleopteran (Ortego et al., 1995; López-Olguín et al., 1999) and orthopteran (Hanson et al., 1982) pests. Among these substances, ajugarins I (**1**) (Kubo et al., 1976; Savona et al., 1984; Beauchamp et al., 1996) and II (**2**) (Kubo et al., 1976; Beauchamp et al., 1996; Bruno et al., 2000) and deacetylajugarin II (**3**) (Savona et al., 1984; Fontana et al., 1998) are neoclerod-13-en-15,16-olide derivatives that have been shown to have significant insect antifeedant properties against larvae of the lepidopteran *Spodoptera littoralis* (Boisduval) (Kubo et al., 1976; Simmonds et al., 1989; Cole et al., 1990; Simmonds and Blaney, 1992; Bremner et al., 1998), *S. frugiperda* (J. E. Smith) (Simmonds and Blaney, 1992; Bruno et al., 2000), *S. exempta* (Walker) (Kubo et al., 1976) and *Helicoverpa* (*Heliothis*) *armigera* (Hübner) (Simmonds et al., 1989; Bruno et al., 2000).

The interesting insect antifeedant action of ajugarins, together with the uncertain knowledge available on the structure–activity relationships of these substances (Kubo et al., 1983; Simmonds and Blaney, 1992), prompted us to undertake some chemical transformations of **2** and **3** in order to establish how the functionalities of their decalin part modulate feeding behavior of larvae of the specialist *Leptinotarsa decemlineata* (Say) (Coleoptera: Chrysomelidae) and the generalist *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae). In addition to the neoclerod-13-en-15,16-olide derivatives **1**–**10**, we have also tested teumassilenins A and C (**11** and **12**, respectively), recently isolated (Fontana et al., 1998) from *Teucrium massiliense* L. (Labiatae), whose structures possess a β-

substituted furan ring instead of the α,β-unsaturated γ-lactone of **1**–**10**.

2. Results and discussion

Deacetylajugarin II (**3**) (Savona et al., 1984; Fontana et al., 1998), one of the major constituents of the acetone extract of the aerial parts of *Teucrium massiliense* (0.73% on dry plant material), was used as the starting material for obtaining compounds **1**, **2** and **4**–**10**. Ajugarin I (**1**) was prepared by treatment of **3** with acetic anhydride-pyridine at room temperature for 24 h (Savona et al., 1984). Reaction of **3** with the same reagent for 1.5 h yielded a mixture of three compounds, which were easily separated by column chromatography giving unreacted **3** (41%), ajugarin II (**2**, 32%) (Kubo et al., 1976; Beauchamp et al., 1996; Bruno et al., 2000) and compound **4** (24.5%). Selective oxidation of **3** with the Dess–Martin periodinane (Dess and Martin, 1991) gave the aldehyde **5** in almost quantitative yield (96%), whereas oxidation of **2** with chromium trioxide-pyridine (Poos et al., 1953) yielded the expected 6-keto derivative **6** (79%). Treatment of **4** with the Dess–Martin periodinane gave the 19-aldehyde **7** in poor yield (30%), probably due to the steric hindrance caused by the acetoxyl group at the C-6α position. Best results (60% yield of **7**) were achieved by using 4-methylmorpholine-*N*-oxide (NMO) and catalytic amounts of tetrapropylammonium perruthenate (TPAP) as an oxidizing reagent (Ley et al., 1994). The chlorohydrin derivative **8** was obtained in poor yield (22%, see Experimental) by treating ajugarin II (**2**) with pyridinium chlorochromate (PCC), which produces the oxidation of the C-6α hydroxyl group and the oxirane-opening by attack of the nucleophile (Cl^-) on the primary center of the epoxide (C-18) (Rodríguez et al., 1994). Remote oxidation of **3** with iodobenzene diacetate (IBD)-iodine (Majetich and Wheless, 1995) gave the 1α,19-epoxy derivative **9** in 72% yield. Treatment of ajugarin II (**2**) with an excess of Jones' reagent (Bowers et al., 1953) gave the 18-nor-neoclerodane derivative **10** (56%), via oxidation of the C-6α hydroxyl group and opening of the 4α,18-oxirane, followed by oxidation of the resulting glycol to an α-hydroxycarboxylic acid, which undergoes decarboxylation to yield **10** (Chen et al., 1995).

The structures of all the above compounds are strongly supported by their ^1H and ^{13}C NMR, IR and mass spectra, and other analytical data (see Experimental Section). The derivatives **4**–**10** have not been described previously.

Among the compounds tested (**1**–**12**) we have found an outstanding differential antifeedant pattern depending on the insect species. The two naturally occurring furoneoclerodane diterpenes (**11** and **12**), possessing a β-substituted furan ring in which the C-13–C-16 carbon atoms are involved, showed antifeedant activity against last instar larvae of the specialist *L. decemlineata*, but no activity was detected on *S. exigua* (Table 1). On the contrary, compounds possessing a β-substituted α,β-unsaturated γ-lactone instead of the furan ring, like natural ajugarin I (**1**) and the semisynthetic derivatives **4**, **8** and **10**, only showed antifeedant effect on the fifth instar larvae of the generalist *S. exigua* (Table 1). These results indicated that the antifeedant action on *L. decemlineata* larvae is associated with the presence of a furan ring in the molecule of the active compounds (**11** and **12**), whereas the rest of the chemical structure does not play a significant role for such biological effect. The 12*S*-hydroxyl group of **11** and **12**, however, could also be an important structural feature for the mode of action of these compounds at a molecular level, because it modifies drastically the reactivity of the furan.

Ajugarin I (**1**) showed antifeedant activity against larvae of *S. exigua* in both choice and no-choice assays (Table 1). Deacetylation at C-19 (**4**) resulted in a decrease of the activity and no antifeedant effect was observed when there is an α-hydroxyl function (**2**) or a ketone (**6**) at the C-6 position, or when both C-6α and C-19 sub-

Table 1
Effect of compounds **1–12** on the feeding behaviour of *Leptinotarsa decemlineata* and *Spodoptera exigua* larvae

[a] At 1000 ppm.
[b] Average antifeedant index $[(C-T)/C]\times 100\% \pm$ standard error ($n = 10$). C and T represent consumption of control and treatment disks, respectively.
[c] Average antifeedant index $[(C-T)/C+T)]\times 100\% \pm$ standard error ($n = 10$). C and T represent consumption of control and treatment disks, respectively, within each arena.
[d] Average suppression index $[(C-T)/C]\times 100\% \pm$ standard error ($n = 10$). T represents consumption of both treated and untreated disks in test arenas and C in control arenas that contain untreated leaf disks only.
[e] Antifeedant activity considered for indexes over 50%.

stituents are deacetylated (**3**) (Table 1). Moreover, transformation of the C-19 acetoxyl group into an aldehyde (**5** and **7**) or a 1α,19-ether function (**9**), together with deacetylation at the C-6α position in the case of **5** and **9**, also caused the loss of the activity (Table 1). These results suggest that both acetoxyl groups at the C-6α and C-19 positions play a major role in the antifeedant activity of ajugarin I (**1**) against this species. However, when the C-19 acetoxyl group was maintained, but the functionality at C-6 was a ketone and the 4α,18-epoxide was replaced by a chlorohydrin (**8**) or it was eliminated giving the 18-nor-4-oxo derivative **10**, a very high antifeedant activity was found in choice assays for these compounds (Table 1). This suggests that **8** and **10** act predominantly as feeding deterrents of *S. exigua* in a choice situation, but the larvae will feed on it when other resources are not available, as compared with ajugarin I (**1**). The effect of ajugarins **1**–**10** on the feeding behavior of *S. exigua* larvae (Table 1) establishes that the activity is strongly dependent on the functionality of the *trans*-decalin part of the molecule, as has been suggested previously (Kubo et al., 1983). In addition, the furoneoclerodanes **11** and **12** have no activity on *S. exigua* (Table 1), as reported for some related diterpenoids tested against other lepidopteran species (Simmonds and Blaney, 1992).

The data presented in this study on the antifeedant activity of compounds **1**–**12** against *L. decemlineata* and *S. exigua* larvae, reveal that minimal structural changes in the substance can account for large variations in the activity and cause remarkable differences of specificity between both insect species.

3. Experimental

3.1. General

Mps uncorr. ^{1}H NMR chemical shifts are reported with respect to residual $CHCl_3$ (δ 7.25). ^{13}C NMR chemical shifts are reported with respect to solvent signals (δ_{CDCl_3} 77.00). ^{13}C NMR assignments were determined by gHSQC and gHMBC spectra. MS were recorded in the positive EI mode and no fragments below m/z 50 were registered. Merck Si gel no. 7734 (70-230 mesh) deactivated with 15% H_2O, w/v, was used for column chromatography.

Deacetylajugarin II (**3**) and teumassilenins A (**11**) and C (**12**) were available from our previous studies on *T. massiliense* (Savona et al., 1984; Fontana et al., 1998). Ajugarin I (**1**) was obtained from **3** as described previously (Savona et al., 1984).

3.2. Preparation of 19-acetoxy-4α,18-epoxy-6α-hydroxyneoclerod-13-en-15,16-olide [ajugarin II (**2**)] and 6α-acetoxy-4α,18-epoxy-19-hydroxyneoclerod-13-en-15,16-olide (**4**) from deacetylajugarin II (**3**)

Treatment of **3** (1 g, 2.85 mmol) with Ac_2O-pyridine (1:1, 20 ml) at room temperature for 1.5 h yielded, after workup in the usual manner, a mixture of **2**, **4**, and starting material (**3**). Column chromatography of this mixture [gradient of elution from EtOAc–petroleum ether (2:1) to 100% EtOAc] gave, in order of increasing chromatographic polarity, **4** (275 mg, 0.70 mmol, 24.5%), **2** (362 mg, 0.92 mmol, 32.3%), and **3** (411 mg, 1.17 mmol, 41.1%).

[a] At 125.7 MHz, in $CDCl_3$ solution; chemical shifts are reported in, δ values. All these assignments were in agreement with HSQC and HMBC spectra. Multiplicities were determined from HSQC data.

960, 890, 855, 845; ^{1}H NMR: Table 2; ^{13}C NMR: Table 3; EIMS *m/z* (rel. int.): 392 $[M]^+$ (1), 361 (12), 332 (3), 331 (5), 320 (21), 319 (100), 301 (17), 289 (23), 191 (11), 189 (13), 147 (8), 136 (8), 123 (12), 121 (11), 107 (10), 105 (10), 95 (10), 93 (12), 91 (14), 79 (14), 67 (11), 55 (15). (Found: C, 67.21; H, 8.13. $C_{22}H_{32}O_6$ requires: C, 67.32; H, 8.22%.)

3.3. Preparation of 4α,18-epoxy-6α-hydroxy-19-oxoneoclerod-13-en-15,16-olide (5) from deacetylajugarin II (3)

To a stirred solution of **3** (120 mg, 0.342 mmol) in dry CH_2Cl_2 (5 ml) an excess of the Dess–Martin periodinane (157 mg, 0.37 mmol) (Dess and Martin, 1991) was added at room temperature under Ar. After 20 h, the reaction mixture was filtered through a short column of Si gel and the solvent was evaporated under vacuum. The residue was then subjected to column chromatography (EtOAc as eluent) yielding pure **5** (115 mg, 0.330 mmol, 96.4%) as colorless needles (EtOAc–petroleum ether): mp 163–165 °C; $[\alpha]_D^{23}$ +25.1° ($CHCl_3$,*c* 0.422); ν_{max}^{KBr} cm^{-1}: 3460 (OH), 3110, 1775, 1750, 1645 (α,β-unsaturated γ-lactone), 3070 (oxirane), 2770, 1715 (aldehyde), 2970, 2880, 1460, 1395, 1330, 1260, 1135, 1060, 1020, 915, 880; ^{1}H NMR: Table 2; ^{13}C NMR: Table 3; EIMS *m/z* (rel. int.): 349 $[MH]^+$ (1), 302 (2), 287 (4), 275(2), 231 (3), 211 (10), 191 (17), 189 (21), 173 (14), 171 (11), 163 (12), 161 (11), 159 (10), 149 (14), 147 (17), 145 (18), 138 (34), 136 (20), 135 (18), 123 (24), 122 (33), 121 (43), 98 (44), 95 (47), 93 (70), 91 (84), 81 (57), 79 (100), 77 (62), 67 (64), 55 (87). (Found: C, 69.09; H, 8.17. $C_{20}H_{28}O_5$ requires: C, 68.94; H, 8.10%.)

3.4. Preparation of 19-acetoxy-4α,18-epoxy-6-oxoneoclerod-13-en-15,16-olide (6) from ajugarin II (2)

To a solution of **2** (80 mg, 0.20 mmol) in dry pyridine (8 ml) a mixture of CrO_3 (200 mg) and pyridine (2 ml) was added, and the reaction mixture was stirred at room temperature for 20 h under Ar (Sarett oxidation procedure, Poos et al., 1953). Then, the reaction mixture was poured into H_2O (50 ml) and extracted with EtOAc (4×25 ml). The extracts were dried ($MgSO_4$) and evaporated to dryness. The residue was chromatographed (Si gel column, petroleum ether–Me_2CO from 20 to 40% in Me_2CO as eluent), giving unreacted **2** (12 mg, 0.03 mmol, 15%, less polar constituent) and **6** (63 mg, 0.16 mmol, 79.1%) as colorless needles (EtOAc–*n*-hexane): mp 147–148 °C; $[\alpha]_D^{22}$ +11.9° ($CHCl_3$, *c* 0.184); ν_{max}^{KBr} cm^{-1}: 3100, 1780, 1750 br, 1645 (α,β-unsaturated γ-lactone), 1740, 1250 (OAc), 1725 (ketone), 2960, 2950, 1450, 1370, 1215, 1140, 1035, 905, 885, 865; ^{1}H NMR: Table 2; ^{13}C NMR: Table 3; EIMS *m/z* (rel. int.): $[M]^+$ absent, 330 $[M–AcOH]^+$ (1), 317 $[M–CH_2OAc]^+$ (100), 299 (13), 289 (20), 189 (17), 137 (13), 121 (11), 105 (10), 93 (10), 91 (15), 81 (11), 79 (14), 69 (13), 67 (11), 55 (15). (Found: C, 67.76; H, 7.61. $C_{22}H_{30}O_6$ requires: C, 67.67; H, 7.74%.)

3.5. Preparation of 6α-acetoxy-4α,18-epoxy-19-oxoneoclerod-13-en-15,16-olide (7) from compound 4

To a stirred solution of **4** (60 mg, 0.153 mmol) in dry CH_2Cl_2 (10 ml) NMO (20 mg, 0.170 mmol), TPAP (3 mg, 0.0084 mmol), and powdered molecular sieve (4 Å, 77 mg) were added (Ley et al., 1994). The reaction mixture was stirred at room temperature under Ar for 2 h, and then filtered through a pad of Celite. Removal of the solvent under vacuum, followed by column chromatography of the residue [EtOAc–petroleum ether (4:1) as eluent] yielded **7** (36 mg, 0.09 mmol, 60.3%) and unreacted **4** (9 mg, 0.02 mmol, 15%).

Oxidation of **4** with the Dess–Martin periodinane, as described above for **3**, gave **7** in 30% yield after 24 h of reaction.

Compound **7** was crystallized from EtOAc–*n*-hexane: colorless needles, mp 233–235 °C; $[\alpha]_D^{23}$ +38.1° ($CHCl_3$, *c* 0.063); ν_{max}^{KBr} cm^{-1}: 3130, 1790, 1750, 1635 (α,β-unsaturated γ-lactone), 2780, 1725 (aldehyde), 1740, 1240 (OAc), 2990, 2950, 2880, 1445, 1375, 1175, 1120, 1030, 1015, 1000, 890, 860; ^{1}H NMR: Table 2; ^{13}C NMR: Table 3; EIMS *m/z* (rel. int.): $[M]^+$ absent, 330 $[M\text{-}AcOH]^+$ (2), 319 (64), 302 (32), 301 (30), 290 (55), 289 (100), 287 (25), 205 (23), 193 (29), 191 (48), 189 (46), 187 (30), 173 (47), 171 (32), 163 (39), 159 (49), 145 (44), 136 (59), 121 (62), 105 (55), 93 (51), 91 (72), 79 (68), 67 (47), 55 (62). (Found: C, 67.54; H, 7.82. $C_{22}H_{30}O_6$ requires: C, 67.67; H, 7.74%.)

3.6. Preparation of 19-acetoxy-18-chloro-4α-hydroxy-6-oxoneoclerod-13-en-15,16-olide (8) from ajugarin II (2)

To a stirred solution of **2** (76 mg, 0.19 mmol) in dry CH_2Cl_2 (5 ml) an excess of PCC (85 mg, 0.39 mmol) and powdered molecular sieve (4 Å, 30 mg) were added, and the reaction mixture was stirred under Ar at room temperature. After 5 days, the mixture was filtered through a short column of Si gel and the filtrate was evaporated to dryness. Then, the residue was subjected to column chromatography [EtOAc–petroleum ether (1:1) as eluent] yielding starting material (**2**, 36 mg, 0.09 mmol, 47.3%, most polar constituent) and compound **8** (18 mg, 0.04 mmol, 21.7%): colorless needles (EtOAc–*n*-hexane), mp 154–156 °C; $[\alpha]_D^{22}$ −41.7° ($CHCl_3$, *c* 0.285); ν_{max}^{KBr} cm^{-1}: 3490, 3460 (OH), 1790, 1755, 1635 (α,β-unsaturated γ-lactone), 1745, 1245 (OAc), 1700, 1690 (chelated ketone), 2960, 2930, 1450, 1385, 1335, 1180, 1130, 1035, 1010, 890, 790, 730, 630; ^{1}H NMR: Table 2; ^{13}C NMR: Table 3; EIMS *m/z* (rel. int.): $[M]^+$ absent, 391 $[M\text{-}Cl]^+$ (12), 377 (12), 317 (100), 305 (18), 301 (35), 289 (15), 271 (11), 269 (10), 205 (14), 201 (11), 189 (23), 187 (13), 165 (21), 149 (31), 137 (24), 121 (21), 95 (23), 93 (20), 91 (27), 81 (30), 79 (29), 69 (32), 67 (26), 57 (25),

55 (41). (Found: C, 61.68; H, 7.41; Cl, 8.21. $C_{22}H_{31}ClO_6$ requires: C, 61.89; H, 7.32; Cl, 8.30%.)

3.7. Preparation of 1α,19;4α,18-diepoxy-6α-hydroxyneoclerod-13-en-15,16-olide (9) from deacetylajugarin II (3)

Compound **3** (100 mg, 0.286 mmol) was dissolved in dry benzene (40 ml) and treated with IBD (94 mg, 1 eq.) and I_2 (73 mg, 1 eq.) (Majetich and Wheless, 1995). The reaction mixture was heated at 50 °C under Ar while it was irradiated with a 200 W tungsten lamp. After 35 min, the reaction mixture was poured into an aqueous saturated solution of $Na_2S_2O_3$ to eliminate the excess of I_2, and extracted with EtOAc (4×30 ml). The organic extract was dried (Na_2SO_4) and the solvents removed under vacuum. The residue was then chromatographed (Si gel column, gradient of elution petroleum ether–EtOAc from 20 to 70% in EtOAc) to give **9** (72 mg, 0.207 mmol, 72.4%): colorless fine needles (EtOAc– *n*-hexane), mp 148–151 °C; $[\alpha]_D^{22}$ −15.9° ($CHCl_3$, *c* 0.169); $\nu_{max}^{KBr}cm^{-1}$: 3510, 3490 (OH), 3100, 1780, 1750, 1640 (α,β-unsaturated γ-lactone), 2940, 2880, 1455, 1445, 1365, 1320, 1160, 1130, 1050, 1015, 900, 880, 865, 640; ^1H NMR: Table 2; ^{13}C NMR: Table 3; EIMS *m*/*z* (rel. int.): $[M]^+$ absent, 316 $[M\text{-}CH_3OH]^+$ (1), 287 (3), 219 (5), 205 (6), 191 (8), 177 (9), 175 (10), 173 (16), 149 (15), 135 (17), 133 (18), 121 (28), 119 (25), 111 (43), 105 (40), 98 (38), 95 (39), 93 (39), 91 (68), 85 (36), 81 (54), 79 (65), 77 (50), 69 (59), 67 (69), 57 (34), 55 (100). (Found: C, 68.79; H 8.16. $C_{20}H_{28}O_5$ requires: C, 68.94; H, 8.10%.)

3.8. Preparation of 19-acetoxy-4,6-dioxo-18-nor-neoclerod-13-en-15,16-olide (10) from ajugarin II (2)

To a solution of **2** (60 mg, 0.153 mmol) in Me_2CO (10 ml) an excess (0.5 ml) of Jones' reagent (Bowers et al., 1953) was added at 0 °C with stirring. The reaction mixture was then stirred at room temperature for 2.5 h and the excess of Jones' reagent was destroyed by addition of EtOH (5 ml). Then, the reaction was diluted with H_2O (50 ml). Extraction with EtOAc (4×20 ml), and workup as usual gave a residue which was subjected to column chromatography [petroleum ether–EtOAc (7:3) as eluent] yielding **10** (32 mg, 0.085 mmol, 55.6%): colorless prisms (EtOAc– *n*-hexane), mp 176–177 °C; $[\alpha]_D^{22}$ +8.2° ($CHCl_3$, *c* 0.294); ν_{max}^{KBr} cm^{-1}: 3140, 1805, 1775, 1655 (α,β-unsaturated γ-lactone), 1750,1245 (OAc), 1740, 1715 (ketones), 2995, 1460, 1395, 1210, 1160, 1045, 1000, 910, 895; ^1H NMR: Table 2; ^{13}C NMR: Table 3; EIMS *m*/*z* (rel. int.): 376 $[M]^+$ (9), 346 (16), 334 (80), 329 (15), 316 (15), 305 (25), 303 (30), 288 (60), 275 (19), 274 (19), 260 (18), 224 (63), 206 (29), 205 (37), 177 (28), 169 (30), 165 (54), 137 (100), 123 (36), 121 (31), 119 (29), 109 (63), 105 (32), 98 (39), 95 (32), 69 (66), 67 (43), 55 (86). (Found: C, 66.87; H, 7.46. $C_{21}H_{28}O_6$ requires: C, 67.00; H,7.50%.)

3.9. Insects for the bioassays

Newly ecdysed fourth instar larvae of *L. decemlineata* were obtained from a colony reared on potato, *Solanum tuberosum*, cv. Kennebec, at 25±2 °C, 90±10% rh and 16:8 h (L:D) photoperiod in a environmental chamber. This colony is renewed annually with wild adults collected from potato fields. *S. exigua* eggs were obtained from the University of Leiden (The Netherlands). The larvae were reared on a semi-artificial diet (Poitout and Bues, 1970) under environmental conditions identical to those described for *L. decemlineata*.

3.10. Feeding experiments

Assays were performed in plastic Petri dishes (15×90 mm), coated on their bottom half with about 20 ml of a 2.5% agar solution (Escoubas et al., 1993). Potato and sugar beet leaf disks (1.77 cm^2) for *L. decemlineata* and *S. exigua*, respectively, were cut with a cork borer No. 15 and fit into holes punched in the agar layer.

The disks were treated on the upper surface with 20 μl of an acetone solution containing 1000 ppm of the test compound or the solvent carrier alone. After complete evaporation of the solvent, newly emerged fourth instar *L. decemlineata* larvae and fifth instar *S. exigua* were starved for 6 h, and placed in each dish in a growth chamber at 26±0.5 °C and 85±10% rh, where they were allowed to feed. In the choice assay, three treated and three control disks were alternately arranged in each arena. For the no-choice assays, six treated or control disks were used in each arena. Feeding was terminated after the consumption of 50% of the disks (control plus treated) in the choice assay and when larvae had ingested about 75% of the control disks in the no-choice assay. Ten replications per treatment were used in all assays.

Feeding indexes were calculated on a dry weight basis. For each assay, initial dry weight of the leaf disks was estimated with 100 leaf disks to calculate the ratio of fresh to dry weight. At the end of the experiment, the uneaten leaf disks were oven dried at 60 °C for 2 days and weighed. The antifeedant index (AI) was calculated in the no-choice assay by the equation $[(C-T)/C]\times100\%$ (Bentley et al., 1984), and in the choice assay by the equation $[(C-T)/(C+T)]\times100\%$ (Simmonds et al., 1989), where *C* and *T* represent the consumption in control and treated disks, respectively. The suppression index (SI) was determined by the equation $[(C-T)/C]\times100\%$, where *T* represents consumption of both treated and untreated leaf disks in choice arenas, and C represents the consumption in control arenas that contain untreated leaf disks only (Raffa and Frazier, 1988). No antifeedant activity was considered for indexes below 50%.

Acknowledgements

We thank N. J. De Boer for providing the eggs of *S. exigua*. This work was supported by funds from the Spanish Comisión Asesora de Investigación Científica y Técnica (grant AGF98-0805) and from the Italian Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST).

Received 23 January 2001; received in revised form 18 April 2001

Abstract

The primary structure of syringicin (syr), a new acidic α-elicitin, isolated from culture filtrates of *Phytophthora syringae*, causal agent of citrus fruit rot, has been determined using a combined approch based on Edman degradation and MALDI-MS (TTCTT TQQTA AYVAL VSILS DSSFN QCATD SGYSM LTATA LPTTA QYKLM CASTA CKTMI TKIVS LNAPD CELTV PTSGL VLNVY SYANG FSSTC ASL). Syr has 98 amino acids with a M_r of 10194.6±0.2, which was determined by electrospray ionisation-mass spectrometry (ES-MS) and in agreement with three disulphide bridges, located between Cys3-Cys71, Cys27-Cys56 and Cys51-Cys95. Syr induces a hypersensitive response and electrolyte leakage in tobacco. These are characteristic elicitor properties of the group and in agreement with the molecular mechanism recently proposed for this kind of protein. Finally, its possible applications in biological agriculture and biomedicine are briefly discussed. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Phytophthora syringae*; Citrus fruits; Elicitins; Amino acid sequence; Syringicin; Biological activity

1. Introduction

An approach to controlling plant diseases is to induce natural plant defence mechanisms without relying on synthetic pesticides.

In this view, proteins with elicitor activity named elicitins have been isolated from the culture filtrates of several *Phytophthora* species. Elicitins, 98 amino acid proteins with a M_r of about 10 kDa, are divided into α-elicitins and β-elicitins, of acid and basic nature, respectively (Ponchet et al., 1999; Churngchow and Rattarasarn, 2000).

Their characteristic biological activities are the induction of a hypersensitive response (HR) and systemic acquired resistance (SAR) in tobacco, with the formation of phytoalexins, PR proteins and salycilic acid (Ricci, 1997). Both types induce electrolyte leakage from the same plant cell (Zimmermann et al., 1998).

Moreover, they induce protection against phytopathogenic micro-organisms in tobacco and in some species of *Brassicaceae* (Kamoun et al., 1993; Bonnet et al., 1996; Blancard et al., 1998; Keizer et al., 1998; Tepfer et al., 1998; Keller et al., 1999). Churngchow and Rattarasarn (2000) have recently reported that palmivorein, a new α-elicitin purified from *Phytophthora palmivora*, isolated from rubber tree leaf, is also active on *Hevea* and a susceptible rubber clone.

The secondary and tertiary structure of some α-elicitins was also assessed by ^{1}H NMR (Bovaziz et al., 1994; Fefeu et al., 1997; Gooley et al., 1998) and X-ray diffraction studies (Boissy et al., 1996).

The gene (Inf1) encoding the α-elicitin infestin in *Phytophthora infestans* was identified and cloned (Kamoun et al., 1998). In addition, a mutant of a phytopathogenic *P. infestans* lacking Inf1 proved to be virulent to a tobacco species (*Nicotiana benthamiana*) (Kamoun et al., 1997), indicating an in vivo defence

PII: S0031-9422(01)00201-1

mechanism of the protein and, in all likelihood, of all elicitins.

It has recently been found that the bioactivity of the elicitins is correlated to the interaction of an elicitin-sterol complex with its plant plasmalemma receptor, which is proposed to be an allosteric calcium channel (Ponchet et al., 1999). The property of these proteins to load sterols has been exploited for the preparation of anticholesteremic agents, and their medical use has recently been patented (Mikes et al., 1998).

In a previous paper we reported the isolation and biochemical characterisation of elicitin 172, produced by an isolate pathogenic to tomato (Capasso et al., 1999). Elicitin 172 proved to be identical to parasiticein (Ricci et al., 1992) and elicitin 310 (Mouton-Perronet et al., 1995).

Here we describe the primary structure of syr, a new α-elicitin purified from the culture filtrates of *P. syringae,* which is the causal agent of rot of citrus fruit, and compare it to the other known α-elicitins (Huet et al., 1994; Churngchow and Rattarasarn, 2000).

Moreover, we report and discuss its elicitor activity identified by the usual HR and the electrolyte leakage test on tobacco (*Nicotiana tabacum* L., cv. Rustica).

We also briefly describe its potential applications in biological agriculture and biomedicine.

2. Results and discussion

The purification of syr was performed by a procedure slightly more simple than the one used for elicitin 172 (Capasso et al., 1999). The last step was low pressure chromatography through a reverse phase column (Lichroprep RP-18), giving rise to a very sharp and intense peak (Fig. 1). The protein (20 mg per litre of culture filtrate of *Phytophthora syringae*) was obtained in high purity grade as shown by native or SDS–PAGE.

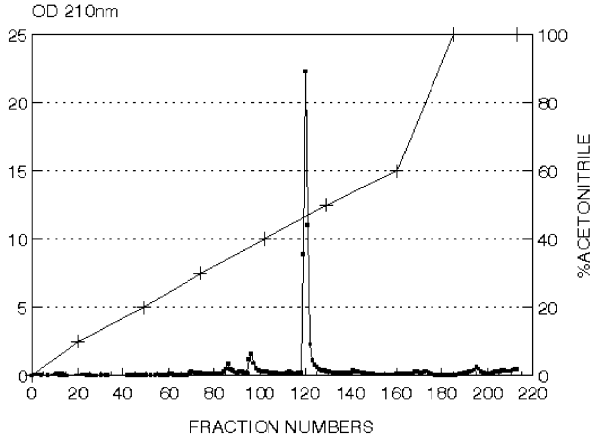

Fig. 1. Chromatogram of α-syringicin obtained by step-wise elution from an RP-HPLC C-18 column (31×2.5 cm), using H_2O/CH_3CN as eluant, under low pressure (3 bar). Flow rate: 15 ml/min; fractions of 5 ml.

After staining the tricine–SDS–PAGE electrophoregram with silver nitrate or with Coomassie blue, a single band appeared. Its apparent M_r was 10 kDa. The protein appeared as a single band in correspondence of 10 kDa on SDS-PAGE, even after heating in presence of 2-mercaptoethanol.

The protein, analysed by ES–MS, exhibited the characteristic bell-shaped distribution of multiple charged ions from which a M_r of 10194.6 ± 0.2 was calculated.

The experimental amino acid composition (Ala12, Asx7, Cys6, Glx5, Gly3, Ile3, Leu10, Lys3, Met3, Phe2, Pro3, Ser13, Thr17, Tyr5, Val6) of the purified syringicin account for a total of 98 amino acid residues and a M_r of 10195, considering the presence of three disulphide bridges.

Therefore, here we consider that threonine, serine and alanine are the most abundant amino acid residues; that the acidic nature, indicated by the theoretical pI value 4.31 and confirmed by the native alkaline PAGE, is consistent with the presence of seven Asx and five Glx and of only three lysyl residues and the absence of hystidinyl and arginyl residues.

The UV absorbance with a maximum at 277 nm (not shown) is in accordance with the presence of phenylalanyl and tyrosinyl residues and the absence of tryptophan.

Automated Edman degradation both on the native and *S*-pyridylethylated protein, allowed the N-terminal sequence of syr to be identificated up to residue 30. The rest of the syr sequence came from the CB-peptides (Fig. 2).

Native syr was treated with CNBr, *S*-pyridylethylated and then subjected to RP–HPLC chromatography, which furnished all CB-peptides.

CB-1 (positions 1-35), CB-2 (36-50) and CB-3 (51-59) were completely sequenced by Edman degradation, while CB-4 (60-98) was sequenced up to residue 94. The last four residues of syr were obtained by combining CPaseA digestion with MALDI–MS analysis as already reported for elicitin 172 (Capasso et al., 1999). In particular,

Fig. 2. Complete amino acid sequence of syringicin. Automated Edman degradation (<====>, <——–>) and CPase A digestion (<<<<), and MALDI–MS were employed for sequence determination. CB-peptides are numbered according to their position in the polypeptide chain. Alignment of CB peptides 2 and 3 was obtained by homology with other elicitins. CB, Cyanogen bromide.

aliquots of CB-4 peptide, incubated with the enzyme, were analysed at five minute intervals and the amino acid residues removed in sequence from the C-terminus were identified by the mass change relatively to the mass (4259.14) of *S*-pyridylethylated CB-4 peptide, as shown in Table 1. Therefore, the C-terminal sequence was determined as Cys-Ala-Ser-Leu, which is characteristic for all α-elicitins, with the exception of cactorein (cact).

The alignment of CB-2 and CB-3 peptides was inferred from the sequence homology with elicitin. The complete sequence of syr is reported in Fig. 2.

Syr contains no Trp, His and Arg residues. Furthermore, as found for all other known α-elicitins, the six cysteine residues are located in positions 3, 27, 51, 56, 71 and 95 and are, very likely, engaged in disulphide bridges. This conclusion is based on the negative reaction of native syr with Nbs_2 [5,5′-(ditiobis(2-nitrobenzoic acid)] (Parente et al., 1985), showing no free sulphydryl groups and confirmed by the value for the M_r of 10194.6±0.2, found for the native syr by mass spectrometry (see above). The three disulphide bridges are located, in all likelihood, between Cys3-Cis71, Cys27-Cys56 and Cys51-Cys95, as demonstrated for capsicein (Bovaziz et al., 1994), from which syr differs only in four amino acid positions (i.e. positions 1, 57, 68 and 93; Fig. 3).

Table 1
Time course digestion of CB-4 peptide with CPase A

t (min)	M_r (u)	ΔM_r	Removed residue
0	4259.14	–	–
5	4146.14	113.0	Leu/Ile
10	4059.04	87.1	Ser
15	3987.64	71.4	Ala
20	3779.54	208.1	Cys (pyridylethyl)

The comparison of the primary structure of syr with all other known α-elicitins allowed us to assess the novelty of this protein, as shown in Fig 3. In particular, cact from *P. cactorum* shows the higher number of amino acid differences (thirteen) and caps, from *P. capsicum,* the lower one (four). The other α-elicitins with known amino acid sequence show intermediate amino acid differences: (i) twelve [α-drechselerin (dre-α) from *P. drechseleri*]; (ii) nine [parasiticein (Ricci et al., 1992); elicitin 310 (Mouton-Perronet et al., 1995) and elicitin 172 (Capasso et al., 1999)]; and seven [α-megaspermin (meg-α) from *P. megasperma* and infestin (inf.) from *P. infestans*].

Palmivorein, isolated from *Phytophthora palmivora* and sequenced up to residue 26, shows, with respect to syr, an amino acid replacement in position 22 (Ser replaced by Thr, see Fig. 3). When we compare the amino acid composition of syr with that of palmivorein we found six amino acid differences: Ala (+2), Val (+1), Pro (−2) and Asx (−1).

The identification of syr as α-elicitin was also confirmed by the hypersensitive response (HR) (Ricci, 1997) and the electrolytes leakage (Zimmermann et al., 1998) induced on tobacco.

In fact, from 1 to 20 μM, syr induced necrosis in tobacco. When applied to the leaves at 1 μM, syr

Fig. 3. Comparison of syr with the all known α-elicitin sequences.

induced necrosis estimated in amount of 1 in the relative evaluation scale (see experimental) and 4 when applied at 20 μM; when tobacco leaves were immersed in a solution of syr at 1 μM, little necrotic spots appeared on tobacco leaves (1); at 10 μM, necrosis was observed on entire leaves (4). These data indicate that syr induced in tobacco a weak HR at 1μM, whereas the highest HR was obtained at 10 μM.

As expected, syr significantly stimulates the electrolytes leakage through the cell membranes of tobacco plant tissues (Fig. 4) at 0.02 mM, which is the lowest concentration used in our experiments.

It is also noteworthy that, even if syr stimulates the electrolyte leakage from tobacco with increasing intensity, corresponding to the concentration values of 0.1 and 0.2 mM, as shown by the two respective curves in Fig. 4, however, these converge to the same value after 9 h, and remain constant for an extended period of time. This result is fully consistent with the molecular mechanism of elicitins, recently proposed by Ponchet et al. (1999). These authors report that four elicitin molecules, loaded with an ergosterol molecule, which is trapped from a plant cell, interact with the calcium channel of the plant cell plasmalemma, triggering the considered biological and physiological responses. At 0.1 mM, all tobacco cells have, in all likelihood, the site saturated in nine hours, while at 0.02 mM only a part, in our experimental conditions.

In conclusion, syr is a new α-elicitin (see Fig. 2) with the closest primary structure to caps and the farthest from cact (Fig. 3).

The structural specificity of the elicitins produced by the different species of *Phytophthora* suggests that syr also could be used as a taxonomic marker for *P. syringae*.

Furthermore, syr could be used to extend the studies on triggering the resistance of tobacco and other plants towards many pathogenic microrganisms, using directly the protein or by means of the preparation of transgenic plants, as already performed in the last decade for other well known elicitins (Kamoun et al., 1993; Bonnet et al., 1996; Blancard et al., 1998; Tepfer et al., 1998; Keller et al., 1999; Churngchow and Rattarasarn, 2000).

Finally, the property of elicitins as sterol carriers has recently been exploited, by patenting the use of some of them, including caps, as anticholesteremic agents (Mikes et al., 1998), suggesting a similar use for syr for their high analogy.

3. Experimental

3.1. General

Protein was estimated by the Bradford method (Bradford, 1976) using bovine serum albumin as a standard. UV (Perkin Elmer): H_2O.

3.2. Production of culture filtrates

A pathogenic strain of *Phytophthora syringae* was isolated from Citrus lemon plants in Meta di Sorrento and deposited in the culture collection at the Dipartimento di Aboricoltura, Botanica and Patologia Vegetale, Università di Napoli "Federico II", 80055 Portici, and numbered Ph 254. The stock culture was maintained on V-8 agar Petri plates. Liquid cultures were obtained by growing the fungus in flasks containing ASYT medium composed of: L-asparagine, 1 g; sucrose, 10 g; yeast extract, 5 g; thiamine, 0.001 g; $KH_2PO_4 \cdot 7H_2O$, 0.5 g; distilled water, 1000 ml. The flasks were incubated and stirred for 12 days at 26°C. Then, the culture fluid was strained through cheese cloth and filter

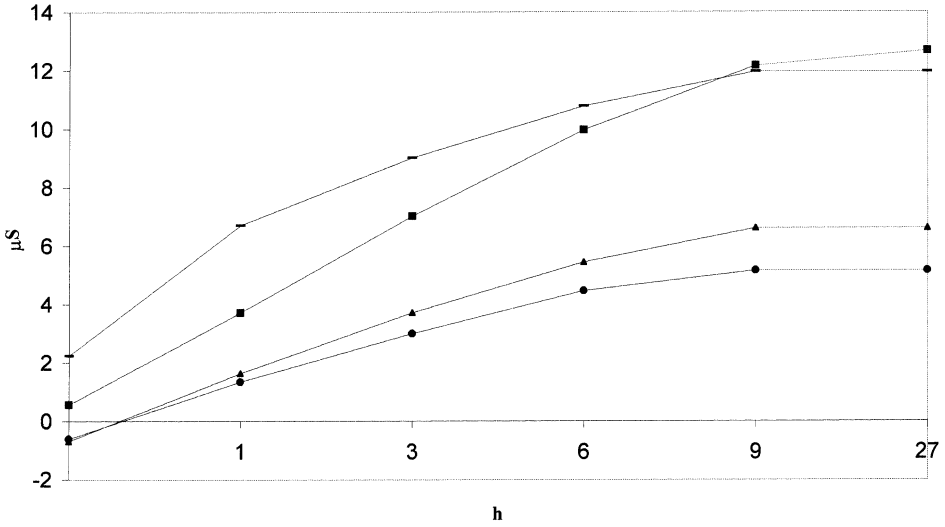

Fig. 4. Electrolytes leakage curves stimulated by syr on tobacco (*Nicotiana tabacum* L., cv. Rustica) leaf discs: the curves are corresponding to concn 0.2 mM (–), 0.1mM (■), 0.02 mM (▲) and control (0.0 mM) (●).

paper, sterilised by filtration through a 0.22 μm membrane and stored at −20°C.

3.3. SDS–PAGE

Polyacrylamide gel electrophoresis in the presence of SDS, using also tricine–SDS or tricine–SDS with urea 6 M and alkaline PAGE performed at pH 8.3 with glycine were performed as reported for elicitin 172 (Capasso et al., 1999).

3.4. Purification of syringicin

Syringicin was purified using a four-step procedure. This is slightly more simple than that used for the purification of elicitin 172 (Capasso et al., 1999), which consisted of five steps. The only difference regarding the purification of syringicin was the elimination of the rechromatography (fourth step) of the raw elicitin through a Sephadex G 50 column, which was directly substituted by the chromatography through a Lichroprep RP-18 column (Merck). In particular, the partially pure syingicin (19 mg each time of a raw sample of 38 mg coming out from the third step) was eluted stepwise with H_2O containing CH_3CN (0, 1, 5, 10, 20, 30, 40, 50 and 100% of acetonitrile in water, 150 ml every step) at low pressure (3 bar). Fractions of 5 ml were collected and monitored by UV absorbance at 210 nm. The purity of syr in every step was controlled by SDS–PAGE, whereas alkaline native PAGE was only used for the monitoring the purity after the final purification step.

3.5. Electrospray–mass spectrometry (ES–MS)

Syr was analysed by ES–MS using a Platform single quadrupole mass spectrometer (micromass). Aliquots (1 μg/10 μl) of protein solution were injected into the ion source at a flow rate of 2 μl/min. The mass spectrometer was scanned from m/z 1000 to 2500 at 10 s/scan, using a capillary voltage of 3.6 kV and a cone voltage of 40 V.

3.6. Cyanogen bromide cleavage

Cleavage of native syr with cyanogen bromide was carried out in 70% formic acid as already reported (Parente et al., 1993).

3.7. S-Pyridylethylation

Samples of native (10 μg) or CNBr-treated (25 μg) syr were *S*-pyridylethylated as previously reported (Scudiero et al., 1995). At the end of the incubation time the modified syr absorbed on ProSorb™ to remove reagents and solvent. The modified protein was then sequenced at the N-terminus. CNBr-treated syr, after *S*-pyridylethylation, was brought to 50% formic acid and chromatographed by RP-HPLC on a Beckman C_{18} column, using acetonitrile containing 0.1% TFA as eluant.

3.8. Amino acid composition

Samples of native syr were hydrolysed at 110°C for 20 h in the presence of 0.02% phenol. Amino acid analyses were obtained with an amino acid analyser (Beckman) equipped with the post-column, ninhydrin detection system. Chemicals and experimental were as suggested by the manufacturer.

3.9. pI Determination

Theorical pI was determined by CHARGPRO in PC-GENE software package.

3.10. Amino acid sequencing

Samples of native, *S*-pyridylethylated syr or CB-peptides were sequenced by automated Edman degradation on a pulsed phase sequencer (Model 473A; Applied Biosystems) as previously reported (Parente et al., 1993).

3.11. CPase A digestion and MALDI–mass spectrometry (MALDI–MS)

Cyanogen bromide peptide CB-4 was dissolved in 0.02 M ammonium bicarbonate and incubated with CPase A (Sigma; final enzyme: substrate ratio of 1:50, w:w), at 37°C. Aliquots of 10 μl were removed from the incubation mixture after 0, 5, 10, 15 and 20 min and analysed by MALDI-MS. The timed aliquots (1 μl, about 0.5 μg) of CPase A-treated CB-4 peptide were prepared in the following way, using α-cyano-4-hydroxycinnamic acid (Fluka) as matrix. The sample was loaded on the target and dried. Then 1 μl of a mixture composed by 0.1% TFA in water–ethanol–10 μg/μl of matrix in H_2O (l:1:1; v/v). The sample was analysed using a Voyager (Persective Biosystem) mass spectrometer in linear mode.

3.12. Hypersensitivity induction assay

Induction of hypersensitivity by pure syr was determined by infiltrating sterile distilled water solutions of protein into tobacco leaves (*Nicotiana tabacum* L., cv. Rustica). A hypersensitive response (HR) was scored when a brown necrosis occurred in the infiltrated area 48 h after inoculation. HR was scored on the basis of necrotic areas: 0 = necrosis of 0–5% infiltrated tissues; 1 = 6–25% infiltrated tissues; 2 = 26–50% infiltrated tissues; 3 = 51–75% infiltrated tissues; 4 = 76–100% infiltrated tissues. To test the induction of distal HR, petiole dip assays (Huet et al., 1992) were carried out on cut tobacco leaves. Leaf petioles were dipped into a 50 ml-solution of protein. The solution was taken up after

about 2 h. Then the leaves were transferred to sterile water. Necrotic lesions were visible after 24–48 h and ranged from minute necrotic spots to large, confluent necrotic areas.

3.13. Electrolytes leakage assay (LEA)

Thirty tobacco leaf discs (5 mm diameter) were incubated overnight in 0.0, 0.2, 1.0 and 2.0 mg/ml (corresponding to 0.0, 0.02, 0.1 and 0.2 mM, respectively) of syr, respectively. Than six leaf disks were transferred in sterile distilled water 20 ml and the corresponding conductance was measured in microsiemens using a conductivity meter CRISON 525 with 20 electrodes (range 20 μS–200 mS cm; $K=1$) connected to a computer with a specific program. Each value was the mean of at least five replicate samples and was calculated as the difference from the reading at the beginning of the assay, after 1, 3, 6, 9 and 27 h. These values where then corrected by subtracting those obtained for the control.

Received 28 December 2000; received in revised form 19 April 2001

Abstract

The effects of a low temperature (13 °C) treatment known to provide protection against sulphur dioxide (SO_2) injury were assessed on leaf lipid composition in two cultivars of *Coleus blumei* Benth, found previously to differ in sensitivity to SO_2 and other environmental stresses. After 5 days growth at 13 °C, there were significant differences in membrane lipid fatty acid composition as well as in free fatty acid (FFA) levels between SO_2-sensitive 'Buckley Supreme' ('BS') and SO_2-insensitive 'Marty' ('M'). Molecular species of chloroplast galactolipids in 'M' contained increased levels of linolenic acid (18:3). In the leaf FFA pools, the saturated components, palmitic (16:0) and stearic (18:0) acids, were predominant at 20 °C. After temperature hardening at 13 °C, the total amount of FFAs decreased in 'M' but increased in 'BS.' These modifications in lipid composition suggest an additional mechanism for cultivar differences in tolerance to SO_2 and other stressors in coleus. Published by Elsevier Science Ltd.

Keywords *Coleus blumei*; Labiatae; Cross protection; Lipid metabolism; SO_2-membrane interactions; SO_2 tolerance; Stress tolerance; Temperature hardening

1. Introduction

The physiological and morphological effects of sulfur dioxide (SO_2) on higher plants have been investigated extensively (Peiser and Yang, 1985; Darrall, 1989). The phenomenon of cross-protection against SO_2 by drought, salinity, low temperature, and other environmental factors is well documented (Kobriger and Tibbitts, 1985; Krizek et al., 1986, 2001; Menser et al., 1963). There are several reports which suggest that abscisic acid (ABA) may be involved in this phenomenon (Kondo and Sugahara, 1978; Krizek et al., 1986, in press; Terry et al., 1988), causing closure of the stomates and a corresponding reduction in uptake of SO_2 and a decrease in visible leaf injury (Krizek et al., 1986, in press).

Genotypic differences in SO_2 sensitivity under natural and experimental conditions have been reported for several ornamental plants, including poinsettia (Krizek et al., 1985b, 1986) and other species (Semeniuk and Heggestad, 1981; Unsworth and Ormrod, 1982). Published studies have demonstrated considerable genetic variability within cultivars of *Coleus blumei* Benth. in their responses to different environmental stresses. These include ozone (Semeniuk and Heggestad, 1981), SO_2 (Krizek et al., 2001; Semeniuk and Heggestad, 1981), UV-B radiation (Semeniuk and Stewart, 1979), water stress (Terry et al., 1988), chilling (Moline and Semeniuk, 1983; Krizek et al., 1985a), and aluminum stress (Krizek et al., 1997).

Krizek et al. (1985b) have suggested that both morphological and physiological properties of stomata may

contribute to the differential sensitivity to SO_2 observed between certain poinsettia cultivars. A subsequent study (Krizek et al., 1986) showed that poinsettia plants subjected to soil moisture stress prior to SO_2 fumigation were equally protected compared with well-watered plants given exogenous applications of ABA, suggesting a protective role for ABA in certain cultivars of poinsettia.

Reducing the growth temperature from 20 to 13 °C for 5 days prior to fumigation (at 27 °C) provided effective protection against subsequent SO_2 exposure in 'Buckley Supreme' ('BS'), a drought- and SO_2-sensitive cultivar of coleus (Krizek et al., 2001). ABA was found to play a major role in this low temperature-induced phytoprotection (Krizek et al., 2001). After 5 days growth at 13 °C, the levels of ABA were significantly increased over those in plants maintained at 20 °C. This was associated with a decrease in stomatal conductance and transpiration rate and a corresponding decrease in SO_2 injury in 13 °C-treated plants.

There are many citations in the literature on changes in plant membrane polyunsaturated fatty acids in response to a shift in growth temperature. It is well known that lipids enriched in polyunsaturated FA are potentially subject to damage by peroxidative reactions (Khan and Malhotra, 1977; Sandmann and Gonzales, 1989). One of the primary modes of action of air pollution injury in plants has been identified as the generation of free radicals and the resultant peroxidation of cellular components (Asada, 1980; Peiser and Yang, 1985; Lee et al., 1992). We have, therefore, included lipid analyses in our investigations of differential SO_2 tolerance in coleus.

The present study was conducted to determine: (a) whether changes in membrane lipid composition occur during a low temperature pretreatment known to provide cross protection against SO_2 and other environmental stresses, and (b) whether alterations in lipids may also be related to the differential SO_2 sensitivity between coleus cultivars. The composition of leaf FFA as well as membrane lipids were included in these analyses since FFA are also potential substrates for SO_2-induced peroxidation, and if elevated levels of polyunsaturated FFA in chloroplasts were accessible to superoxide ions and other reactive oxygen species, then SO_2 sensitivity may be increased.

2. Results and discussion

The molecular species composition of leaf galactolipids, monogalactosyldiacylglycerol (MGDG) and digalactosyldiacylglycerol (DGDG), after 5 days growth of each cultivar at 20 or 13 °C are recorded in Tables 1 and 2, respectively. In the shorthand notation used to define molecular species, pairs of numbers representing fatty acids and separated by a slash, represent the components in the *sn*-1 and *sn*-2 positions, respectively, of the molecular species. The major MGDG molecular species in leaves of each cultivar was 18:3/18:3 at both 20 and 13 °C (Table 1). In plants maintained at 20 °C, this component was about 10% lower in 'BS' compared with 'M', and the relative amount of 18:2/18:3 MGDG was increased. This latter molecular species is a precursor for desaturation of 18:2 at the *sn-2* position to form 18:3/18:3 MGDG in the chloroplast (Norman and St. John, 1986). The relative amount of 16:0/18:3 MGDG was less in 'BS' at 20 °C compared to the level in 'M' and the 16:0/18:2 molecular species was correspondingly increased.

Plants of both cultivars showed an increase in 18:3/18:3 MGDG in response to 5 days of temperature preconditioning at 13 °C. This could be predicted from previous studies reporting temperature-induced changes in the fatty acid composition of membrane lipids of some plant species. The increases in 18:3/18:3 MGDG in coleus were accompanied by decreases in 18:2/18:3, 18:2/18:2, and 16:0/18:2 molecular species (Table 1). The amounts of these three MGDG components, however, differed between the two cultivars, with 'M' maintaining a relative enrichment in 18:3/18:3 MGDG. The corresponding DGDG molecular species showed the same trends between the two cultivars and in response to low temperature pretreatment (Table 2). The total and relative amounts of galactolipids showed little or no difference between cultivars or treatments (Tables 1 and 2).

The composition of PC was also compared at the molecular species level in the two cultivars. In plants grown at either 20 or 13 °C, 18:3/18:3 PC was relatively higher in leaves of SO_2-insensitive 'M' than in SO_2-sensitive 'BS,' and levels of 18:2/18:3 PC and 18:2/18:2 PC were lower (Table 3). In contrast to the composition of the galactolipids, the distribution of the 16:0/18:3 and 16:0/18:2 molecular species of PC was not significantly different between the cultivars grown at 20 °C. Temperature pretreatment at 13 °C for 5 days increased 18:3/18:3 PC in both cultivars and caused declines in the corresponding 18:2-containing molecular species (Table 3). Only in the leaves of 'M,' however, did the amount of 16:0/18:3 PC increase and 16:0/18.2 PC decrease. In contrast to the galactolipids, analyses of the levels of individual phospholipids revealed an increase in PC in 'M' after 5 days at 13 °C (Tables 3 and 4).

In coleus plants grown at 20 °C, there were no differences between cultivars in the leaf FFA pool size or composition (Table 5). The major components were the saturated fatty acids, 16:0 and 18:0. After 5 days at 13 °C, 'BS' showed an increase in total FFA (on a per mg chlorophyll basis); there was a decline in the relative amount of the unsaturated components of the FFA pool due to increases (both relative and absolute) in

16:0 and 18:0. Conversely, in 'M,' the total FFA pool was reduced by approximately 45% at 13 °C and the new pool was depleted in the saturated fatty acid components. The absolute amount of unesterified 18:3 declined in 'M' but showed no significant change in 'BS' (data not shown).

There was no visible leaf curling, senescence, or abscission, in either 'M' or 'BS' after growth at 13 °C for 5 days. We used lipid peroxidation as a parameter to assess any indication of intercellular low temperature damage by estimating total peroxides in leaf extracts. There was no detectable increase in MDA accumulation in plants of either cultivar after 5 days at 13 °C as compared to 20 °C. MDA levels were approximately the same in both cultivars at 20 °C, while at 13 °C, MDA levels in 'M' tended to decline (Table 6).

The precise mode of action of SO_2 in plant cells is still largely uncertain despite considerable research in this area, and in related fields examining plant cross-tolerance to environmental stresses (Menser et al., 1963; Kobriger and Tibbitts, 1985; Krizek et al., 1985a, 1986, 2001; Terry et al., 1988). There is growing evidence, however, that one of the prominent effects of SO_2 in plant cells involves the initiation of a free radical generating mechanism resulting in peroxidative destruction of cellular constituents (Peiser and Yang, 1985). The multiple effects of both SO_2 and sulphite on the plant include pigment destruction (Peiser and Yang, 1985), depletion of cellular lipids (Khan and Malhotra, 1977), and peroxidation of polyunsaturated fatty acids (Sandmann and Gonzales, 1989).

The fact that coleus cultivars such as 'BS' and 'M' are fundamentally different in their response to temperature hardening and a wide range of environmental stresses, including SO_2, chilling, drought, and UV-B radiation (Semeniuk and Stewart, 1979; Semeniuk and Heggestad,

1981; Terry et al., 1988; Krizek et al., 2001) suggest a commonality in stress adaptation.

We proposed that cellular differences in sensitivity to oxidative stress between these two coleus cultivars may serve as one basis for their genotypic differences in SO_2 sensitivity (Krizek et al., 2001). Differences in lipid composition between SO_2-sensitive 'BS' and SO_2-insensitive 'M' would appear to support this hypothesis. Our data on differences in ascorbate and ascorbate peroxidase between the two coleus cultivars (Krizek et al., in press) also implicate some role for antioxidants. Lee et al. (1992) have suggested that free-radical scavenging enzymes or endogenous antioxidant compounds are more important than stomatal restriction of pollutant diffusion to sensitive leaf mesophyll sites in determining genotype differences in response to SO_2 and O_3.

Temperature-induced changes in plant lipid fatty acid composition have been a subject of numerous investigations. An increase in the degree of unsaturation in response to a reduction in growth temperature, as seen in coleus, is a predictable, although certainly not a universally occurring response. The increases seen in molecular species containing linolenic acid in coleus grown at 13 °C (Tables 1, 2 and 4) suggest that both of the coleus cultivars employed have some ability to adapt to low temperature by altering membrane lipid composition. Inherent differences were found in membrane lipids of the two cultivars when grown at 20 °C; cultivar 'M' which is the least sensitive to the air pollutants SO_2 and O_3, contained elevated levels of the 18:3/18:3 molecular species of MGDG. The direct precursor proposed is 18:2/18:3 MGDG (Norman and St. John, 1986), and this was correspondingly at lower levels in 'M,' possibly due to an increase in the activity of a specific chloroplast desaturase.

Reactions leading to the biosynthesis of the 18:3/18:3 molecular species of DGDG and PC are less certain (Heemskerk and Wintermans, 1987). Both lipid components were increased in 'M' relative to 'BS,' again implying a difference in activities of specific enzymes regulating levels of membrane polyunsaturated fatty acids, or possibly enhanced 18:3 peroxidation in 'BS,' although there was no evidence of an increase in peroxidation products as measured by MDA (Table 6).

We propose that there is a protective mechanism in 'M' for membrane lipids. Growth at 13 °C for 5 days, a pretreatment which decreases visible injury during subsequent SO_2 fumigation (Krizek et al., 2001), increased the 18:3/18:3 molecular species of MGDG, DGDG, and PC in both cultivars. Collectively, our data could be interpreted to indicate that coleus plants with membrane lipids enriched in 18:3 will be predictably less sensitive to SO_2. Without further knowledge, this might appear contradictory, since this fatty acid is a preferred substrate for SO_2-induced lipid peroxidation (Sandmann and Gonzales, 1989). Therefore, the increase in 18:3 (as in 'M' relative to 'BS' at 20 °C, and in both cultivars grown at 13 °C as opposed to 20 °C) may require a concomitant enhancement of protective mechanisms to reduce enzymatic and nonenzymatic peroxidation of fatty acids, particularly within the chloroplast, where the galactolipids are modified. Mechanisms possibly required to protect 18:3 synthesized in response to reduced growth temperature may also protect the plant during subsequent SO_2 fumigation. For example, low temperature can increase the levels of cellular antioxidants including glutathione (de Kok and Oosterhuis, 1983; Alscher, 1989; Alscher et al., 1987). SO_2 damage involves membrane lipid peroxidation and several independent studies have implicated cellular glutathione as an antioxidant in SO_2 tolerance (Alscher, 1989; Sandman and Gonzales, 1989; Madamanchi and Alscher, 1991). However, we found little evidence for changes in glutathione metabolism in coleus (Krizek et al., 2001).

Unesterified fatty acids typically constitute an extremely low proportion of the total fatty acid complement of plant cells (1–2%). Elevated levels of polyunsaturated FFA particularly within the chloroplast stroma would be unfavorable considering that they are a substrate for peroxidation. The changes in the total FFA pool seen

here in coleus possibly reflect cultivar differences in the rates of lipid metabolism at 13 °C. The analyses of lipid peroxidation products in coleus cultivars maintained at 20 °C or transferred to 13 °C showed no large difference between cultivars, and no indication of any enhanced peroxidation resulting from lowered growth temperature (Table 6). Conversely, peroxidation products tended to decline at 13 °C in 'M.' In the present paper, changes in fatty acid composition gave no evidence for loss of linolenic acid. Although FFA complements were essentially identical in 'BS' and 'M' at 20 °C, differences in pool size and composition were found in plants grown at 13 °C (Table 5). Currently, we have insufficient data to interpret these changes, although they do imply a differential lipid metabolic response to lowered growth temperature between the two cultivars. One explanation to offer is that the overall changes seen in FFA composition at 13 °C constitute part of an adaptive mechanism modifying lipid metabolism which operates at different levels in the two coleus cultivars.

3. Experimental

3.1. Plant material

Cultivars of coleus compared in this study were identified previously (Terry et al., 1988; Krizek et al., in press) as differing in sensitivity to various environmental stresses, with 'Buckley Supreme' ('BS') (a red pigmented cultivar) being highly sensitive and 'Marty' ('M') (a red and yellow pigmented cultivar), being relatively insensitive. Reducing the growth temperature from 20 to 13 °C for 5 days prior to SO_2 fumigation was shown to increase SO_2 tolerance in both cultivars (Krizek et al., in press).

3.2. Culturing procedures

Cuttings from clonal stocks of coleus cultivars were propagated in a charcoal-filtered greenhouse on a hot pad (25 °C) under mist in a synthetic peat-vermiculite mix (Jiffy Mix, Jiffy Products of America, West Chicago, IL, USA).[4] After 2 weeks, cuttings were selected for uniformity and transplanted to pots containing the same peat-vermiculite mix. Plants were maintained in the greenhouse under a 16 h photoperiod [25 μmol m^{-2} s^{-1} supplemental photosynthetic photon flux (PPF), provided by General Electric 200 W, 130 V incandescent lamps], at 28 ± 3 °C day temperature, 21 ± 2 °C night temperature, ambient CO_2 and ambient relative humidity.

[4] Use of a company or product name by USDA does not imply approval or recommendation of the product to the exclusion of others which may also may be suitable.

3.3. Temperature preconditioning

At 10 days after transplanting, the cuttings were preconditioned for 5 days in Revco (Asheville, NC) Model 511-38 growth chambers maintained at constant temperatures of either 13 or 20 ± 0.5 °C, 70 ± 5% relative humidity and ambient CO_2. Plants were grown under a 16 h photoperiod at 320 ± 35 μmol m^{-2} s^{-1} of PPF provided by General Electric 1500 mA cool white fluorescent lamps.

3.4. Lipid analyses

Pairs of leaves from the lower and middle nodes were removed from three plants of each cultivar from each treatment. The leaves collected from an individual plant were combined and treated as one sample. The tissue was boiled in isopropanol for 5 min, and then lipids were extracted using a modification of the procedure of Folch et al. (1957). Separation into neutral lipid, galactolipid, and phospholipid classes was achieved using silica Sep-Pak cartridges (Waters Assoc., Milford, MA) (Norman and St. John, 1987). Individual galactolipid and phospholipid components were resolved by TLC on silica gel H using $CHCl_3$–HOAc–MeOH–H_2O (75:25:5:1.1) as developing solvent, and then eluted from the silica gel (Norman and St. John, 1986).

Galactolipids were quantified based on sugar content according to Roughan and Batt (1968), and lipid phosphorus was determined using the procedure of Marinetti (1962). Lipid molecular species were resolved by isocratic HPLC procedures (Smith et al., 1985; Norman and St. John, 1987), employing a 25 cm×4.6 mm i.d. Beckman Ultrasphere (5 μm) reversed-phase C-18 column, and quantitated directly using a Tracor 945 Flame Ionization LC Detector (Tracor Instruments, Austin, TX) operated as previously described (Norman and St. John, 1986). Neutral lipid fractions were redissolved in hexane and FFA extracted according to Anderson and McCarty (1972). FA methyl esters were prepared directly with boron trifluoride/methanol (Sigma Chemical Co., St. Louis, MO) (Morrison and Smith, 1964). GLC analysis was performed on a Hewlett Packard (model 5880A) gas chromatograph using previous specifications (Norman and St. John, 1986). Chlorophyll was assayed spectrophotometrically (Arnon, 1949). Data represent the means ± S.E. of four analyses each of three plant samples.

3.5. Measurement of lipid peroxidation

The extent of lipid peroxidation was estimated by measuring the thiobarbituric acid (TBA) reactive substances, primarily malondialdehyde (MDA), in aqueous 5% (w/v) trichloroacetic acid (TCA) extracts of leaf tissue (Heath and Packer, 1968; Buege and Aust, 1978).

The extracts were centrifuged (8000 *g*, 10 min) and then 1 ml aliquots were combined with 4 ml of TBA reagent [0.5% (w/v) TBA in 20% (w/v) TCA], boiled at 100 °C for 20 min, and immediately cooled on ice. After centrifugation for 15 min at 8000 *g*, the absorbance was determined at 532 nm and values corrected by subtracting the absorbance value at 600 nm. The concentration of MDA was calculated using the extinction coefficient of Heath and Packer (1968).

Received 30 November 2000; received in revised form 5 April 2001

Abstract

Myrothecium verrucaria was found to be an effective pathogen against kudzu grown in the greenhouse and the field. *M. verrucaria* produced large amounts of macrocyclic trichothecenes when cultured on solid rice medium, including epiroridin E (16.8 mg/g crude extract), epiisororidin E (1 mg/g), roridin E (8.7 mg/g), roridin H (31.3 mg/g), trichoverrin A (0.6 mg/g), trichoverrin B (0.1 mg/g), verrucarin A (37.4 mg/g), and verrucarin J (2.2 mg/g). Most of these toxins were also isolated from *M. verrucaria* spores and mycelia grown on potato dextrose agar medium, including epiroridin E (32.3 mg/g), epiisororidin E (28.6 mg/g), roridin E (0 mg/g), roridin H (60 mg/g), trichoverrin A (1.3 mg/g), trichoverrin B (1.8 mg/g), verrucarin A (13.8 mg/g), and verrucarin J (131 mg/g). When *M. verrucaria* was cultured on liquid media, the numbers but not the amounts of toxins decreased. Only epiroridin E (28.3 mg/g), epiisororidin E (29.6 mg/g), verrucarin B (195 mg/g) and verrucarin J (52.6 mg/g) were measured when the fungus was cultured on cornsteep medium. On soyflour–cornmeal broth *M. verrucaria* produced several toxins, including epiroridin E (58.1 mg/g), epiisororidin E (5.8 mg/g), verrucarin B (29.9 mg/g) and verrucarin J (32 mg/g). In contrast, no macrocyclic trichothecenes were detected by HPLC analysis of plant tissues of kudzu, sicklepod, and soybean treated with aqueous suspensions of *M. verrucaria* spores formulated with a surfactant. Chloroform–methanol extracts of kudzu leaves and stems treated with *M. verrucaria* spores were less cytotoxic to four cultured mammalian cell lines than the corresponding extracts from control plants. Purified macrocyclic trichothecenes (verrucarin A and T-2 toxin) were very cytotoxic to the same cell lines ($\leqslant 2$ ng/ml). These results show that neither intact macrocyclic trichothecenes nor toxic metabolites could be detected in plant tissues after treatment with *M. verrucaria* spores. These results argue for both safety and efficacy for the use of *M. verrucaria* in biological control of kudzu and other noxious weeds, and support proceeding to animal feeding trials for further evaluation of safety. © 2001 Elsevier Science Ltd. 1. Introduction

Myrothecium verrucaria is a fungal pathogen that has been known to attack important crop and ornamental plants including beet, marigold, sunflower, zinnia, peanut, cotton, red clover, and potato (Cunfer et al., 1969; Walker and Tilley, 1997). *M. verrucaria* also attacks important weed plants such as redroot pigweed, cocklebur, velvetleaf, and johnsongrass (Yang and Jong, 1995a,b; Walker and Tilley, 1997). A few reports have shown the potential of various isolates of *M. verrucaria* for use in biological control of weeds (Sutton and Peng, 1993; Zhang et al., 1994). Recently, it has been reported (Boyette et al., 1999) that *M. verrucaria* is also pathogenic to kudzu (*Pueraria montana*). Kudzu is an exotic invasive vine that is responsible for massive economic and aesthetic losses every year in the southern US. Kudzu, native to eastern Asia, was introduced into the eastern and southern US in the 1800s (Beckwith and Dangerfield, 1996; Piper, 1920). It was originally promoted for

PII: S0031-9422(01)00214-X

erosion control and as an inexpensive forage for livestock (Bailey, 1944; McKee and Stephens, 1943). It is now present from Florida to New York, westward to central Oklahoma and Texas, with heavy infestations in Alabama, Georgia and Mississippi (Everest et al., 1991; US Congress, 1993). Kudzu grows up the sides of buildings, along fences and on telephone poles, and dies in the winter, leaving behind ugly, brown foliage (Miller, 1997). *M. verrucaria* has been shown in preliminary experiments to cause 90% mortality to kudzu plants in the greenhouse and the field (Boyette et al., 1999). Other weed species such as sicklepod, leafy spurge (*Euphorbia esula* L.) (Yang and Jong, 1995a) and plumeless thistle (*Carduus acanthoides* L.) (Yang and Jong, 1995b) are also susceptible to isolates of *M. verrucaria*. Fortunately, the pathogen has shown no toxic or pathogenic effects to oak, sycamore and other forestry trees (unpublished data). The potential of *M. verrucaria* spore suspensions as a bioherbicide has been limited by its broad host range, and because isolates produce macrocyclic trichothecene toxins in culture (Jarvis et al., 1985; Jarvis, 1991; Grove, 1993). The toxins include verrucarin A, B and J, and roridin A, D, E, H and J, which are known to be toxic to cultured mammalian cells as well as phytotoxic (Mortimer et al., 1971; Busam and Habermehl, 1982; Cutler and Jarvis, 1985; Jarvis et al., 1988; Schiefer et al., 1989; Jarvis, 1991). However, macrocyclic trichothecenes have not been isolated from plants infected with high toxin-producing strains of *Myrothecium* sp. (Bean et al., 1984). The present study was designed to evaluate the production of macrocyclic trichothecenes by *M. verrucaria* on a variety of culture media, and to determine the fate of these toxins in kudzu plants treated with spore suspensions of the same isolate.

2. Results and discussion

A culture of the fungus *M. verrucaria,* originally obtained from naturally infected sicklepod (*Senna obtusifolia* L.), exhibited potential application as a biocontrol agent for use against sicklepod and kudzu. Published studies (Jarvis et al., 1982; Bloem et al., 1983; Lee and Mirocha, 1984) and previous experience in this laboratory (Abbas et al., 1988) indicate that isolates of *M. verrucaria* vary widely in terms of toxin production when cultured on various media [solid, liquids, potato dextrose agar (PDA)]. Some isolates produced large numbers and quantities of toxins on solid media such as rice, whereas others produced more in liquid media. The toxin-producing capabilities of the *M. verrucaria* isolate used in this study were initially characterized with respect to its ability to produce macrocyclic trichothecene toxins on both solid and liquid media. *M. verrucaria* produced large quantities of numerous toxins when cultured on solid rice medium (Table 1). These toxins were epiroridin E, epiisororidin E, roridin E, roridin H, trichoverrin A, trichoverrin B, verrucarin A, verrucarin B, and verrucarin J. Several toxins were present at high levels in spores and mycelia of *M. verrucaria* grown on PDA, including epiroridin E, epiisororidin E, roridin H, trichoverrin A, trichoverrin B, verrucarin A, and verrucarin J (Table 1). *M. verrucaria* also produced macrocyclic trichothecenes when cultured in two different liquid media. However, fewer toxins were produced in liquid media than on solid rice substrate, or were present in spores and mycelia. The fungus produced the following four toxins in cornsteep liquor and soyflour liquid media: epiroridin E, epiisororidin E, verrucarin B and verrucarin J (see Table 1). Verrucarin A was not produced in either liquid medium.

In greenhouse experiments, the isolate of *M. verrucaria* was active in controlling kudzu in the absence of dew, using conidia suspensions formulated in 0.2% Silwet L-77 surfactant. Potted kudzu plants at the 3- to 5-true leaf stage developed disease symptomatology of *M. verrucaria* infection, including necrotic flecking, within 6 h after treatment with conidia suspensions at temperatures 28–35 °C. Disease symptoms progressed from infected leaves to necrotic stem lesions within 48 h. Based on the disease symptoms, treated kudzu plants were harvested for toxin analysis. At 24 h, infection percentages were 50% in treated trays with symptoms including wilted leaves and petioles and necrotic lesions. The roots of the same plants showed no disease symptomatology. At 72 h, infection was present in 70% of treated kudzu plants, which exhibited more pronounced disease symptoms than at 24 h, including necrotic lesions on stems, but the roots remained healthy. At 120 h, 95% of treated kudzu plants were diseased. From 168 h to 14 days, 100% of treated kudzu plants were diseased, while the roots remained healthy. All control kudzu plants for each time period remained healthy, and showed minimal or no damage from 0.2% Silwet L-77. Plants treated in the field, including kudzu, sicklepod, and soybean also showed symptoms of disease at either high or low dose treatment levels. At 72 h, low dose level (1.0×10^6 conidia/ml) plots had an infection rate from 20 to 30%, and high dose level (2.0×10^7 conidia/ml) plots were 80 to 100% infected. At 5, 7, 10, and 14 days, diseased and non-diseased tissues were taken for toxin analysis. The roots of the plants species in the field were not evaluated for disease symptoms or toxin content.

None of the plant tissues studied (leaves and stems and greenhouse plant roots) of kudzu, soybean or sicklepod contained any macrocyclic trichothecenes detectable by HPLC analysis at any time after treatment, despite their presence in the *M. verrucaria* spore and mycelia preparations used for treatment. Similarly, all kinds of tissues of each plant species (kudzu, soybean, sicklepod) were negative by HPLC analysis for other toxins examined in this study (Fig. 1). To eliminate the

possibility that toxic derivatives or metabolites were present in the tissues of treated plants, but were not detected by HPLC because their HPLC elution times differed from available standards, we examined tissue extracts for in vitro toxicity to cultured mammalian cells. The results of these studies are presented in Tables 2–4. Extracts from kudzu foliage tissues (leaves and stems) treated with fungal *M. verrucaria* at 2×10^7 conidia/ml in 0.2% Silwet L-77 generally caused less cytotoxicity to the four mammalian cell lines tested (Table 2) than extracts prepared in the same manner from untreated control tissues. Also, sicklepod and soybean foliage treated with fungal *M. verrucaria* at 2×10^7 conidia/ml in 0.2% Silwet L-77 generally caused less cytotoxicity to four cell lines tested (Tables 3 and 4) in comparison to extracts prepared in the same manner from untreated control tissues. We speculate that low levels of cytotoxicity observed in control tissues results from phytoalexins produced from progenitors during sampling and extraction, and the generally lower levels of cytotoxicity in *M. verrucaria*-treated tissues reflects prior depletion of phytoalexin progenitors in response to exposure to *M. verrucaria*. Consistent with this, the most toxic extract from *M. verrucaria*-treated kudzu tissues was obtained after 14 days recovery time following treatment (Table 2). The purified toxins verrucarin A,

[a] SW = Silwet L-77, an organo-silicone surfactant (Union Carbide, Tarrytown, NY). Each sample was extracted with MeOH–chloroform, 1:1, v/v, dried, and redissolved in growth media containing 0.5% DMSO for cytotoxicity testing.

[b] The concentration of toxin which causes a 50% reduction in cell number after 5 days in culture. Cell lines used were H4TG, thioguanine-resistant rat hepatoma cells; MDCK, Madin-Darby canine kidney cells; NIH3T3; NIH Swiss mouse embryo fibroblasts, and KA31T, Kirsten strain of Moloney sarcoma virus-transformed 3T3 cells.

roridin E and T-2 toxin were very cytotoxic to the four cell lines used (Table 2). The IC_{50} of these toxins were $\leqslant 4$ ng/ml while the IC_{50} of kudzu plant tissues extracted with C:M, 1:1 was $\geqslant 5$ mg/ml.

These results demonstrate that *M. verrucaria* is an effective pathogen against kudzu and sicklepod, causing disease on all kudzu plants after 96 h. Therefore, *M. verrucaria* shows good potential for control of these noxious weeds. The isolate of *M. verrucaria* used in this study was found to produce large amounts of macrocyclic trichothecenes in culture. These toxins, specifically verrucarin A and roridin E, have proven to be very toxic to plants and animals (Cutler and Jarvis, 1985; Bean et al., 1988; Jarvis and Acierto, 1989). Toxin production has caused concern about the safety for animals and humans of using *M. verrucaria* in biological control. Although the amounts and numbers of toxins produced varied with substrate, none of these toxins were detected in the tissues of treated kudzu plants. To ensure that kudzu was not unique in this, soybean and sicklepod, which are in the same family (Leguminosae) as kudzu, were also studied. No toxins were isolated from *M. verrucaria*-treated sicklepod or soybean. These results are in agreement with previous reports (Bean et

al., 1984; Kuti et al., 1987) on watermelon, muskmelon and cucumber (all from the family "Cucurbitaceae") infected with *Myrothecium* species. These investigators were also unable to detect macrocyclic trichothecenes in infected tissues. However, there are numerous reports of macrocyclic trichothecenes being produced by fungal endophytes in shrubs known as *Baccharis* spp. (Busam and Habermehl, 1982; Jarvis, 1992; Jarvis et al., 1996; Rizzo et al., 1997). These toxins may have been made by the plants using genes for trichothecene biosynthetic enzymes acquired from fungi, but it is also possible that the toxins may be metabolites of trichothecenes produced by contaminating fungi. The failure to find in treated tissue either intact trichothecenes by HPLC, or toxic metabolites by cytotoxicity tests in the present study supports the case for using *M. verrucaria* as a biological control agent. The results support animal feeding trials as the appropriate next step in evaluating safety. Additional studies are needed to quantitate the extent of colonization of kudzu tissues after treatment with *M. verrucaria* conidia preparations. The results obtained to date provide evidence for both safety and efficacy for the use of *M. verrucaria* in biological control of kudzu and other noxious weeds.

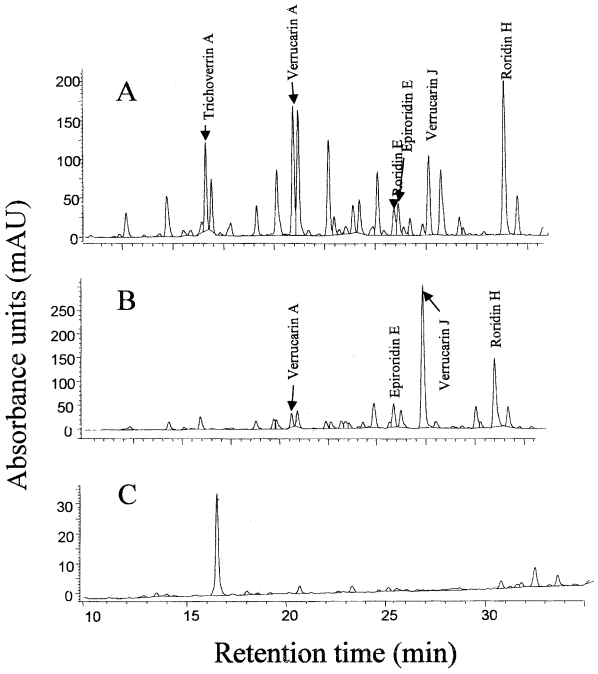

Fig. 1. HPLC chromatographs of extracts from (A) rice culture medium infected with *Myrothecium verrucaria* spores, (B) rice culture medium infected with *M. verrucaria* fungal mycelia, and (C) kudzu plant tissue treated with *M. verrucaria* conidia. Note the presence of various macrocyclic trichothecenes in the extracts of moldy rice culture medium infected with spores or mycelia. No toxins were detected in the extract of kudzu tissues treated with this fungus.

3. Experimental

3.1. Mycotoxin production on rice culture media

Converted long-grain enriched parboiled rice (200 g; Uncle Ben's Inc., Greenville, MS) was mixed with 120 ml of distilled water in one liter flasks, and allowed to stand about 1 h until the water was absorbed. The flasks were shaken to uniformly distribute the moist substrates, closed with light cotton stoppers and autoclaved 60 min at 15 lb pressure. Immediately after autoclaving, the flasks were shaken vigorously to break up clumps. They were allowed to stand 24 h and the autoclaving and shaking process was repeated. The flasks were inoculated when cool with *M. verrucaria* (International Mycological Institute, Bakeham Lane, Egham, Surrey, UK; holding IMI No. 361690) maintained in stock cultures on sterile soil or silica gel in small test tubes. The flasks were incubated for 3 to 4 weeks either in the laboratory at 22–24°C, or in an incubator at 28°C with 12 h light intervals. Daily shaking for the first few days was used to enable the fungus to penetrate the rice uniformly. The fungus-infested rice was removed from the flasks and air dried on a screen-bottomed tray. Five grams of mouldy rice were ground to the consistency of flour using a Stein Mill grinder (Fred Stein Laboratories, Inc., Atchison, KS), and samples taken for chemical analyses (Abbas et al., 1984; 1988). All operations with fungal cultures and spores were carried out in a vented hood to prevent exposure to investigators and facilities.

3.2. Mycotoxin standards

Verrucarin A and J, roridin E and isororidin E were purchased in analytically pure form from Sigma Chemical Co., St Louis, MO. An additional 55 mycotoxin standards were prepared in the laboratory of B.B. Jarvis, Department of Biochemistry and Chemistry, University of Maryland, College Park, MD (Jarvis and Wang, 1999).

3.3. Extraction and determination of mycotoxins

Dried, ground moldy rice cultures (5 g) of *M. verrucaria* were extracted with methanol:chloroform, 1:1 (v/v) at a ratio of 1 g mouldy rice to 5 ml extracting solvent, using ultrasound agitation for 1 h, or homogenization for 3 to 5 min with a Brinkmann Polytron PT 3000 at 27.8×1000 rpm. The flask and contents were allowed to sit overnight (4°C) before filtration and concentration of the organic extract. The concentrated organic extract was dissolved in a minimum amount of methylene chloride and applied to a polyethyleneimine column (Jarvis, 1992). Elution of the column with methylene chloride gave fractions which were analyzed by reversed phase HPLC on a HP-1100 system using an 150×2.0 mm, 3 μ C-18 column and a UV–vis diode array detector at 260

nm (Hinkley and Jarvis, 2000). Samples (5 μl) were eluted with gradients of 25 to 100% acetonitrile in water as the mobile phase. Peak assignments were made by a combination of retention times and UV spectra compared to purified trichothecene standards. Extraction efficiencies of 90–95% were obtained in plant tissues for the various macrocyclic trichothecenes.

3.4. Mycotoxin production in liquid media

This study evaluated *M. verrucaria* fermentation in two liquid media, cornsteep medium according to the method of Jarvis et al. (1986), and cornmeal–soyflour medium according to the method of Walker and Riley (1982). Fermentation in cornsteep medium was carried out in two stages. Five inoculum cultures were prepared in Erlenmeyer flasks (500 ml) each containing 100 ml of cornsteep medium (15.6 g of glucose and 10 ml of cornsteep liquor per l water) autoclaved at 121°C for 20 min. The flasks were inoculated with one or two 1 cm^2 pieces of PDA agar (Difco) medium from plates carrying *M. verrucaria* mycelium and conidia (spores), and shaken at 150 rpm at 28°C for 3 days to produce the inoculum for the production phase. Five Erlenmeyer flasks (4 l) each containing 1 l of production medium (1.0 g $NH_4H_2PO_4$, 3.0 g K_2HPO_4, 5.0 g NaCl, 0.2 g $MgSO_4$–$7H_2O$, 40 g sucrose and 10 g glycerol per l of water) were autoclaved for 30 min at 121°C, and one inoculum culture was poured into each flask. The cultures were incubated with shaking (150 rpm, 28°C) for 7 days, and the mycelium and the fermentation beer harvested separately by centrifuging for 10 min at 10,000 rpm and filtering through glass wool. The mycelium was soaked in acetone three times and homogenized at high speed using Polytron PT 3000, for 3 to 5 min and centrifuged. All the acetone extracts were combined and the acetone removed on a rotary evaporator. The aqueous concentrate was extracted with ethyl acetate three times. Ethyl acetate extracts were combined and dried over Na_2SO_4, filtered and evaporated. The fermentation beer was extracted with ethyl acetate. The ethyl acetate extract was dried over Na_2SO_4, filtered and evaporated. The material obtained from the mycelium and the fermentation beer were combined to give 9 g of total extract. The toxin content of these extracts was determined by HPLC as described above.

The second medium consisted of cornmeal (0.44 g), soyflour (3.75 g), sucrose (7.5 g) and calcium carbonate (0.75 g) in 600 ml of deionized water. Aliquots of 50 ml were placed in 300 ml Erlenmeyer flasks and autoclaved. The flasks were inoculated with one or two 1 cm^2 pieces of PDA agar medium from plates carrying *M. verrucaria* mycelium and conidia (spores), and incubated with shaking at 150 rpm for 7 to 10 days at 28°C. When the fungal biomass formed, the same procedure was followed for extraction and determination of toxin content as described above for cornsteep medium.

3.5. Determination of mycotoxins in fungal spores and mycelia

Spores and mycelia of *M. verrucaria* for this study were produced on Petri dishes (9 cm inside diameter) containing 20 to 25 ml PDA as described in detail previously (Abbas and Riley, 1996). After inoculation Petri dishes were incubated 12 days at 28°C with 12 h light and 12 h dark cycles. Spores and mycelia were harvested from agar surfaces using a plastic scraper and transferred to a sterile beaker. Five hundred grams (wet weight) of mycelium was obtained from 500 Petri dishes. The mycelium sample was mixed well, and an aliquot of 5 g was taken for extraction and mycotoxin analysis by the same procedure as described above for mycelium from liquid cultures.

3.6. Determination of mycotoxin from infected plant tissues

Kudzu (*Pueraria montana*), sicklepod [*Senna obtusifolia* (L.) Irwin and Barneby], and soybean [*Glycine max* (L.) Merr.] were used in this study. Kudzu seedlings (2 to 3 true leaf stage) were grown from seed (Adams-Briscoe Seed Co., Jackson, GA 30233) in 30×60 cm plastic trays containing a 1:1 commercial potting mix (Jiffy mix®): soil combination supplemented with a controlled-release 13:13:13 (N:P:K) fertilizer. Sicklepod and soybean seedlings were grown from seed (collected locally, Stoneville, MS 38776) in the field during the growing season. All plants were kept outdoors. Seedlings at the 1st to 3rd leaf growth stage were inoculated by aerosol sprayers until foliage was fully wetted with 2×10^7 conidia/ml suspended in 0.2% aqueous Silwet L-77 surfactant. Control (non-infected) groups received 0.2% Silwet L-77 surfactant only. Following inoculation, infected and non-infected plants were sampled at the following times: 0, 1, 2, 3, 4, 5, 7, 10, and 14 days. Each sample was divided based on disease symptoms into two groups: (i) severely infected (total necrosis, brown dry tissues, dead) and (ii) moderately or partially infected tissue (minimal necrosis, green, healthy tissue to partially-infected leaves). Also, root samples were kept separate from the above-ground samples for each treatment and species. Root samples were washed with water to remove dirt before storage inside plastic bags. Samples were brought to the laboratory and each sample was cut into small pieces prior to processing for analyses. Half of each sample was frozen in liquid nitrogen and lyophilized. The other halves of the samples were put into paper bags and dried in an oven at 70–75 °C for 72 h. Each dried sample was ground to the consistency of powder using a Stein Mill grinder before analysis. All samples were stored at −20 °C. Aliquots of 5 g were taken for mycotoxin analyses using the same procedure as described above.

3.7. Cytotoxicity assay

The mammalian permanent cell line 3T3 Swiss mouse fibroblasts (strain NIH3T3) was obtained from S. Aaronson, National Cancer Institute, Bethesda, MD, USA, and KA31T was obtained from R. Pollack, Columbia University, New York, NY. Rat hepatoma cell line H4TG and dog kidney cell line MDCK were purchased from the American Type Culture Collection, Rockville, MD, USA. The cells were cultured and the cytotoxicity assays were conducted as described previously (Abbas et al., 1995; Shier et al., 1991).

Acknowledgements

The authors thank Bobbie J. Johnson, Jimmey R. McAlpine, and Mary V. Duke, USDA-ARS, Stoneville, MS, for their valuable technical assistance.

Received 8 September 2000; received in revised form 7 February 2001

Abstract

Three-week-old plants of safflower (*Carthamus tinctorius* L.) were subjected to a water-deficit stress. The lipid composition of the shoot parts of both control (well-watered) and water stressed plants was analyzed. Experimental data revealed that moderate stress induced an increase in total lipid content within all lipidic classes. However, severe water-deficit induced a sharp decrease in the total lipid content and specially in polar lipids, particularly in phosphatidylethanolamine, phosphatidylcholine, monogalactosyl-diacylglycerol and digalactosyl-diacylglycerol. Also, the content of neutral lipids was increased. Concerning the fatty acid composition, water-deficit induced a decrease in their degree of unsaturation expressed by a reduction in the proportions of linolenic (18:3) and linoleic (18:2) acids and most of lipidic classes. © 2001 Elsevier Science Ltd. 1. Introduction

Among the different environmental stresses, drought is the constraint which induces a highly negative effect on crop production. When subjected to this constraint, plants manifest a wide range of behaviors varying from great sensitivity to high tolerance.

Belhassen et al. (1995) reported three adaptive strategies used by plants in response to drought:

- escaping by reducing their life cycle to a short period,
- avoidance of dehydration which allows plants to maintain a high water potential,
- tolerance of dehydration by establishing a wide range of physiological and biochemical changes allowing the plant to resist a low water potential (mechanical resistance, membrane degradation mechanisms etc.).

Previous workers reported that tolerance of plants to environmental stresses induced a variation in their glycerolipidic composition which could result in a decrease or even of an inhibition of the biosynthesis of many lipidic classes and/or an acceleration of their degradation (Stuiver et al., 1981; Hegazy and Lösel, 1992; Selstam et al., 1992; Navari-Izzo et al., 1993; Aid et al., 1995). Regarding drought, many studies showed that this stress could induce serious alterations of phospholipid and galactolipid contents on one hand and an increase of the neutral lipid content on the other hand (Navari-Izzo et al., 1989). Also, it was reported that water deficit could induce a reduction in the level of free sterols in corn plants (Quartacci et al., 1995). Similar results were found in rape roots (Svenningson and Liljenberg, 1986). In addition, it was reported that water deficiency leads to a decrease of the degree of fatty acids unsaturation explained by the fact that drought inhibits the biosynthesis of polyunsaturated fatty acids and desaturase activities (Pham-Thi et al., 1985).

The aim of the present work was to study the effect of water deficit on the glycerolipids of safflower (*Carthamus tinctorius* L.) shoot parts.

2. Results

2.1. Effect of water deficit on fatty acids and on total lipids

Safflower (*Carthamus tinctorius* L.) is a plant which uses the "eukaryotic" desaturation pathway. Therefore, the fatty acid composition of the shoot part lipids was

Table 1
Effect of water-deficit on total fatty acid composition of safflower aerial parts[a]

Treatment[b]	% Of total fatty acids					
	16:0	16:1	18:0	18:1	18:2	18:3
C	14.6±1.6	0.7±0.1	2.0±0.3	4.9±0.6	23.2±2.4	54.3±3.5
MS	14.7±2.0	0.6±0.2	2.6±0.6	9.0±0.4	22.6±3.7	50.4±2.6
SS	28.4±2.4	0.3±0.1	20.4±1.3	7.0±0.6	12.9±1.7	30.8±1.8

[a] Results are given as % of total fatty acids. Values are means of six plants±S.D.
[b] C, control; MS, mild stress; SS, severe stress.

characterized by an appreciable content of linoleic acid (18:2) at 23.2% of the total fatty acids. In addition, the other main fatty acids were scored: 18:3 (the major component), 16:0, 16:1, 18:0, and 18:1 (Table 1).

The total fatty acid composition of safflower was affected by drought. There was an increase in the proportion of both palmitic (16:0) and stearic (18:0) acids as well as a decrease in those of linoleic (18:2) and linolenic (18:3) acids in accordance to the degree of severity of the stress (Table 1).

Based on our experimental data, it was shown that the content of total lipids of safflower aerial parts, as measured by total fatty acid content (mg g^{-1} dry wt.), increases by about 15% in mildly stressed plants, nevertheless, it declines sharply in severely stressed plants (Table 2).

2.2. Effect of water deficit on the main glycerolipids

The analysis of the main glycerolipidic components showed that the moderate water stress led to an increase of both phospholipid (PL) and galactolipid (GL) contents of 37.4% and 5.4%, respectively. However, the severe water stress induced a depressive effect for both groups. For the severe stress, the decrease reached 6.5% for PL and 49.4% for GL (Table 2).

Among the different phospholipids, the significant variation concerned the phosphatidylcholine (PC) class which showed an increase of its content for about 40.4% in mild stressed plants. For the severely stressed plants, the PC content was decreased of 22.1% in comparison to the control level (Table 2).

For the two main galactolipids of aerial parts, we observed that the digalactosyldiacylglycerol (DGDG) was the most affected by water deficit. In the case of mild stress, its content was decreased of about 23%. This decrease was more significant when the degree of water stress was increased (Table 2). For severely stressed plants, the decrease reached 70.7% compared to the control (Table 2). Likewise, for the monogalactosyldiacylglycerol (MGDG), was less affected by water deficit. In fact, at a mild stress, the MGDG content was increased for about 42%, but as soon as the water deficiency became severe, its content was sharply decreased by 21.4% compared to the control (Table 2).

Regarding the neutral lipids, their levels increased under severe water stress and reached 180% compared to the control (Table 2). This was due, mainly, to a similar increase of the triacylglycerol (TAG) content which was also increased by about 487% in the severely stressed plants (Table 2).

These results are similar to those obtained by Svenningson and Liljenberg (1986), who reported a significant decrease in total lipids, galactolipid and phospholipid contents and an increase of neutral lipids of rape roots submitted to drought treatment. In the same way, it has been shown (Hubac et al., 1989) that water deficit resulted in a large decrease in various lipidic classes (MGDG, PC and PE), while the TAG amounts increased considerably at the level of two *Lupinus albus* genotypes leaves.

2.3. Effect of water deficit on the degree of fatty acid unsaturation

The computation of the double binding index (DBI) calculated according to Rie De Vos et al. (1993) showed a decrease in these parameters for all lipidic classes and which was more pronounced in plants under severe stress. This decrease was confirmed by a

significant reduction in the rates of 18:3 and 18:2 in all lipidic classes in parallel with an increase in both of 16:0 and 18:0 with extending stress severity (Table 3). Overall, these results showed that water stress tends to reduce the degree of unsaturation of safflower aerial part lipids. Seqqat Dakhma et al. (1995) have also reported a decrease in the unsaturated lipids of rape leaves subjected to water deficit.

3. Discussion

Severe water deficit induced a large decline in the levels of total lipids in the aerial parts of safflower. The amounts of galactolipids (MGDG and DGDG) and phospholipids (PC, PG and PE) which are the major lipidic classes present, decreased significantly in response to water deficit (Table 2). Such results are in agreement with previous works (Pham, Thi et al., 1985-1992; Quartacci et al., 1995).

The decrease in galactolipids (main chloroplastic lipids) indicated that water stress could affect the photosynthesis, since the structure of chloroplastic membranes could be affected.

The reduction in PC under drought conditions was explained by Thomas et al. (1982) by the fact that water stress stimulates the mobilization of choline for the biosynthesis of glycine-betaine, an osmoregulative substance elaborated by stressed corn plants leaves.

The increase in polar lipids of moderately stressed plants indicates that a mild water deficit activates the biosynthesis of new membranes.

Fatty acid composition of the main lipids of safflower aerial parts was also affected by water deficit. The major variation consisted in a decrease of the unsaturated acids (18:2 and 18:3) in a favor of an increase in saturated ones (16:0 and 18:0). These results are in agreement with those obtained by Pham-Thi, et al. (1985) in cotton leaves submitted to water stress.

The decrease in the level of polar lipids is accompanied by an increase in the neutral lipids, particularly in triacylglycerols of safflower aerial parts subjected to drought conditions. Triacylglycerol accumulation have been previously reported in two *Lupinus albus* genotypes submitted to water deficit (Hubac, et al., 1989).

Overall, tolerance of safflower towards drought is expressed by structural modifications; which allow the plants to adjust their membranous fluidity by not only an appropriate rearrangement of their glycerolipids but also by an adjustment of their unsaturated fatty acid composition.

4. Experimental

4.1. Plant material

Safflower (*Carthamus tinctorius* L.) plants were cultivated in clay pots (20 cm diameter) filled by commercial standard compost and kept in a greenhouse under controlled conditions: 14 h day length at 26–30°, 10 h night at 8–12°, relative humidity 60%. Plants were irrigated 3× per week and used for experiment when they were three weeks old.

4.2. Drought treatments

Water treatment was started when the second leaf emerged. Water deficit was realised by withholding irrigation during different times according to the desired stress. Watering was suspended for six days for mildly stressed plants (MS, leaf water potential $\psi = -7.2$ bar) and 10 days for severely stressed ones (SS, leaf water potential $\psi = -8.8$ bar). Control plants (C, well hydrated) were irrigated twice a week and maintained a leaf water potential ($\psi = -6.7$ bar). Leaf water potentials were measured by a pressure chamber (Scholander et al., 1965). After seven weeks of treatment, a sample of six plants was used.

4.3. Lipid extraction

Plant material was fixed by boiling water to inactivate the tissue phospholipases (Benson, 1964). Total lipids were extracted by pouring the sample into a mixture of $CHCl_3$–MeOH–H_2O (1:1:1) (Bligh and Dyer, 1959). Finally, the water of fixation was added to collect the lipids which have been swept along by the fixation. After a centrifugation step at 2000 rpm during 15 min, two phases have been obtained and the chloroform phase (lower phase) containing the lipids was dried under N_2 then the residue was dissolved in a known volume of toluol–EtOH (4:1).

4.4. Lipid analysis

Polar lipids were separated by TLC on silica gel plates 60 (Merck) in a mixture of $CHCl_3$–Me_2CO–MeOH–HOAc–H_2O (1:4:2:2:1) (Lepage 1967)., Lipid spots were detected by brief exposure to I_2 vapor. The identification was made by comparison to a reference lipids and by specific stains for phospholipids and galactolipids. Fatty acids from total lipids and lipidic classes were transmethylated according to the procedure described by (Carreau and Dubacq, 1978) . Fatty acid Me esters were analyzed by FID–GC on a capillary column (30 m $\times$0.25 μm $\times$250 μm) with a stationary phase made of PEG. Carrier gas N_2, flow rate 1.5 ml min^{-1}. The analysis was performed under this temps program: oven temps isotherm at 150° for 1 min, from 150 to 200° at the rate of 15° min^{-1}, from 200 to 225° at the rate of 2° min^{-1} and isotherm at 225° during 2 min. Injector and detector temps were held, respectively, at 250 and 275°. In order to measure the amounts of fatty acids, 17:0 was added as int. standard before methylation. Calculation of fatty acid quantities was performed using a HP-Chemstation software.

Amino acids in seeds and seedlings of the genus *Lens*

Pascale Rozan, Yu-Haey Kuo, Fernand Lambein*

Laboratory of Physiological Chemistry, Faculty of Medicine and Health Sciences, Ghent University, Jozef Kluyskensstraat 27, B-9000 Ghent, Belgium

Received 19 June 2000; received in revised form 17 April 2001

Abstract

The amino acid content of seeds and 4-day-old seedlings were studied in five species of lentil: *Lens culinaris, L. orientalis, L. ervoides, L. nigricans* and *L. odemensis*. Free amino acid and also total protein amino acid content after HCl hydrolysis were determined by HPLC. The nonprotein UV-absorbing amino acids were determined by capillary zone electrophoresis (CZE). The content of free protein amino acids in seeds varied among species and increased dramatically after germination. Asparagine is quantitatively most important in both seed and seedling. The content of free nonprotein amino acids is variable in seeds and seedlings. γ-Hydroxyarginine, γ-hydroxyornithine, α-aminobutyric acid and taurine were found in both seeds and seedlings. Homoarginine was found in four species but not in *L. orientalis* while γ-aminobutyric acid (GABA), α-aminoadipic acid (α-aaa) and three isoxazolinone derivatives: β-(isoxazolin-5-on-2-yl)-alanine (BIA), γ-glutamyl-BIA (γ-glu-BIA) and 2-carboxymethyl-isoxazolin-5-one (CMI) were found exclusively in the seedlings. CMI was identified for the first time in lentil species. Lathyrine, β-(2-aminopyrimidine-4-yl)-alanine, which was reported to be in the seeds of some *Lathyrus* species was confirmed to be present also in the seedling of *L. culinaris* (trace amount), *L. nigricans* and *L. odemensis*. Trigonelline (*N*-methyl-nicotinic acid), a plant hormone, is present both in seeds and seedlings in different concentrations except in *L. ervoides*. The different combination of nonprotein amino acids among the species gives indication of their genetic relationship and might partly explain the varying compatibility for interspecies crossing. © 2001 Elsevier Science Ltd. Keywords: *Lens culinaris*; *Lens orientalis*; *Lens ervoides*; *Lens odemensis*; *Lens nigricans*; *Leguminosae*; Lentil seedling; Nonprotein amino acids; Isoxazolinone; Chemotaxonomy

1. Introduction

Lentil is a common grain legume known since biblical times. The seedlings are also sold as a fresh food commodity and contribute to the increasing varieties of seedlings now offered to consumers. The chemical composition of seedlings can be dramatically different from the seeds and the nutritional value of these seedlings is not well known.

The different species of the genus *Lens* (*L.*) are mainly studied to check the intra and interspecific variation in the genus. Wild lentil is potentially an important source of genetic variability for the improvement of the cultivated lentil (Ferguson and Robertson, 1999). Sharma et al. (1995) found that *L. orientalis* (Boiss.) Schmalh [present nomenclature: *L. orientalis* (Boiss.) Ponert; Ferguson (1998)] is most similar to the cultivated lentil and that *L. ervoides* (Brign.) Grande is the most divergent wild taxon, followed by *L. nigricans* (M. Bieb) Godron. Abo-Elwafa et al. (1995) found that the intraspecific variations were lower in *L. ervoides* than in cultivated lentils. *L. orientalis* is the most likely candidate as progenitor of the cultivated species (Abo-Elwafa et al., 1995; Ahmad et al., 1996). The origin of the cultivated lentil from the taxon *L. orientalis* has been proven by morphological evidence and breeding experiments. This wild form exhibits variability in many characters and is distributed over a vast area from the Middle East to central Asia (Ladizinsky, 1999). Abbo and Ladizinsky (1994) studied the hybrid embryo abortion that is an effective crossing barrier in the genus *Lens*. It divides the genus into two crossing groups: the *culinaris* and the *nigricans* groups.

L. culinaris Medik. (present nomenclature *L. culinaris* Medikus ssp *culinaris,* Ferguson 1998), the most commonly consumed lentil, has been best studied for its

content of nutrients such as carbohydrates (Vidal-Valverde and Frias, 1992; Frias et al., 1996) and vitamins including thiamin, riboflavin and niacin (Prodanov et al., 1997) but also for the presence of antinutritional factors such as trypsin inhibitor (Frias et al., 1995). Weder and Kahleyss (1998) isolated four trypsin-chymotrypsin inhibitors from *L. culinaris* cultivated in Syria. The content of total amino acids including protein amino acids and nonprotein amino acids in lentils is not well studied. During the development of plants important physiological changes occur involving also changes in amino acid content. As contribution to the better phytochemical and nutritional knowledge of this genus, we studied the free amino acids and total protein amino acids in five species of the genus *Lens*. Both HPLC and CZE methods were used to obtain the most accurate evaluation of the amino acids in seeds and seedlings. The nomenclature of the ILDIS database is followed for the four species accepted in this source, recent adaptations by Ferguson (1998) are given in parenthesis when appropriate. *L. odemensis* Ladizinsky is not listed in the ILDIS database and in the literature it is sometimes given the status of a subspecies of *L. culinaris*. Two recently described taxa *L. tomentosus* Ladizinsky (not listed in the ILDIS database) and *L. lamottei* Czefranova (Ferguson, 1998) were not available at the time of the experiments.

2. Results and discussion

All the following results are given in mg/g dry wt.

2.1. Free amino acid content

In non-germinated dry seeds only small amounts of free amino acids were found (Table 1). The major amino acids found in all five species were asparagine, alanine, aspartic and glutamic acids. As in most legumes the sulphur-amino acids methionine and cysteine were the limiting essential amino acids.

After 4 days of germination the content of free amino acids increased dramatically (Table 2). The seedlings were the sites of high amino acid biosynthetic activity resulting in high content of free protein amino acids (Sutcliffe and Bryant, 1977), supporting the synthesis of proteins and the development of the plant. On the other hand during the germination storage protein can undergo proteolysis and results in the increase of free amino acids (Lea and Joy, 1983).

Asparagine was quantitatively by far the most important protein amino acid found in all lentil seedlings studied (Table 2). This was also the case in other commercially available seedlings such as adzuki, kamut, chickpea, mungbean, garden pea and pintobean (Rozan et al., 1999, 2000). The highest content of asparagine was found in *L. nigricans* and the lowest in *L. culinaris* (62.24 and 18.96 mg/g dry wt, respectively).

2.2. Total amino acid content

In nongerminated seeds the total amino acid content was rather different for each species (Table 3). Asparagine and glutamine were hydrolysed to aspartic and glutamic acids respectively, the results were expressed as

ASX and GLX. In all species the amino acids present in low concentrations were methionine and cysteine, while tryptophan was not detected after hydrolysis. Tyrosine was lowest (5.05±1.26 mg/g) in *L. odemensis* and lysine was lowest in *L. culinaris* (4.54±0.92 mg/g). High levels of alanine, ASX, GLX, glycine, serine, leucine, proline and arginine were found in all the species examined. These results confirmed the earlier report of Lea and Joy (1983) that over half of the protein nitrogen in legume seeds is in the form of ASX, GLX, arginine and leucine.

In 4-day-old seedlings the content of most protein amino acids increased, especially alanine and ASX (Table 4). The essential amino acids such as Ile, Leu, Lys, Phe, Tyr, Thr and Val increased after germination in *L. culinaris* and *L. nigricans* except cysteine but this could be a methodological limitation. Also the results

for methionine and tryptophan might be underestimated due to HCl hydrolysis.

2.3. Nonprotein amino acid content

To study the nonprotein amino acids in seeds and seedlings, two methods were combined: HPLC to determine the content of amino acids and trigonelline (Rozan et al., 2000, 2001), and capillary zone electrophoresis (CZE) to determine the content of isoxazolinones. The CZE-method will be published elsewhere.

The results are given in Table 5. In lentil seeds we found trigonelline as well as some nonprotein amino acids such as γ-hydroxyarginine, γ-hydroxyornithine, homoarginine, α-aminobutyric acid and taurine. In lentil seedling we found more nonprotein amino acids comparing to the seeds. These include α-aminoadipic acid (a higher homologue of glutamate), γ-aminobutyric acid (GABA), lathyrine and isoxazolinone derivatives. Fig. 1 presents the structures of the nonprotein amino acids and trigonelline found in these 5 *Lens* species.

In this study, trigonelline was found in all species except in *L. ervoides*. The concentration of trigonelline was variable (Table 5). For *L. nigricans*, no difference in trigonelline content was observed before and after the germination of seeds, for *L. culinaris* and *L. orientalis* the content of trigonelline in seedlings was lower than that in seeds while for *L. odemensis* trigonelline increased after germination. Trigonelline can be considered as a multifunctional natural plant hormone: it has a function as a cell cycle regulator during the early growth of many legume root meristems and also as osmoregulator in salt-stressed legumes (Tramontano and Jouve, 1997).

The total content of nonprotein amino acids in non-germinated seeds was very low and variable between the species. The species *ervoides* contained less nonprotein amino acids than the four other species. The content of α-aminoadipic acid was not detected in non-germinated seeds and increased after germination to about 4 mg/g of dry wt in each species. Bridges et al. (1991) found a gliotoxic activity of α-aminoadipic acid in cultures of neonatal rat astrocytes.

The nonprotein amino acid *erythro*-γ-hydroxyarginine or 2(*S*),4(*R*)-4-hydroxyarginine (Bell et al., 1999) is a specific metabolite in the genus *Lens* and its content in the seeds and in the seedlings is very different among the species (Table 5). Sulser and Sager (1976) found γ-hydroxyarginine (γ-OH-Arg), γ-hydroxyornithine (γ-OH-Orn) and homoarginine (Har) in 5 different varieties of *L. culinaris* seeds. In our study γ-OH-Arg was present in the nongerminated seeds of all five species studied and it increased after 4 days of germination. γ-OH-Orn which eluted out about 1 min after isoleucine in our HPLC system was detected in all our samples of seeds and seedlings in low concentration. γ-OH-Orn is a metabolite of γ-OH-Arg. We also confirmed the presence of Har in four of the lentil species studied except in *L. orientalis*. The seed of *L. ervoides* contained highest concentration of Har.

One of the major peaks in seed extracts was identified as a sulphur-containing amino acid taurine (2-aminoethanesulphonic acid). Taurine is the most abundant nonprotein amino acid in human organisms and is the metabolic product of cysteine after oxidation and decarboxylation (Bezkorovainy and Rafelson, 1996). Taurine has been identified in the seeds of bean (*Phaseolus*

vulgaris L.) and pea (*Pisum sativum* L.) and also in several other plant genera (Kataoka and Ohnishi, 1986; Lähdesmäki, 1986; Stintzing et al., 1999). We confirmed the presence of taurine in all five *Lens* species studied and the concentration in *L. nigricans* and in *L. odemensis* was at least 10–20 times higher than in pea and bean reported by Lähdesmäki (1986). The metabolism and physiological role of taurine in plants is not established and is worth further study because legume seeds in general are low in sulphur-containing amino acids methionine and cysteine. In animals taurine was reported to have multiple functions as neuromodulator, cell membrane stabilizer, antioxidant, detoxifier, bile acid conjugator and osmoregulator (Zelikovic et al., 1990). Another major compound in the seeds with elution time at 29.7 min and absorption max of 265 nm in HPLC analysis is still unknown. The UV absorption spectrum is similar to trigonelline and is not an amino acid.

Arginine is one of the most versatile amino acids in animal cells, serving as a precursor for the synthesis not only of proteins but also of nitric oxide, urea, polyamines, proline, glutamate, creatine and agmatine (Wu and Morris, 1998). There is no information whether γ-hydroxyarginine might affect any of these various physiological functions. While a variety of toxic synthetic analogues of arginine such as *N*-methyl-L-arginine and *N*-nitro-L-arginine are often used in pharmacological studies (Hobbs et al., 1999), the natural occurring homoarginine (high concentration in *Lathyrus sativus* seeds consumed in some countries) and γ-hydroxyarginine are rarely used (Jyothi and Rao, 1999). Buga et al. (1998) found that γ-hydroxyarginine inhibits Caco-2 tumor cell proliferation.

For each species, the total nonprotein amino acids increased dramatically during germination. α-Aminoadipic acid (α-aaa) and γ-aminobutyric acid (GABA) were found in all five lentil species studied only after germination. Homoarginine was found in trace amounts. Two unknowns with elution times of 29.2 and 32.6 min respectively in HPLC analysis were also found in the seedlings. The peak with elution time of 29.2 min is confirmed to be lathyrine, β-(2-amino-pyrimidine-4-yl)alanine, a heterocyclic nonprotein amino acid previously found in some *Lathyrus* species (Brown and Turan, 1996). The standard lathyrine after PITC derivatization was co-eluted out in HPLC at the same position and both peaks have the same absorption spectra and max at 230 nm. Additional analysis by high voltage paper electrophoresis and two-dimensional TLC indicated the presence of the typical bright tomato-red colour of lathyrine at the RF value of authentic lathyrine after ninhydrin spray. Lathyrine was mainly found in the seedling of *L. nigricans* and *L. odemensis*. In *L. culinaris* only trace amount of lathyrine was present. α-Aminobutyric acid was present in all five species of lentil seeds and seedlings studied.

The isoxazolinones were mainly found in the tribe *Vicieae* (Lambein et al., 1990a). These compounds were mostly absent from the dry seeds but their concentration in seedlings can be very high: up to 10% of the dry wt of the seedling axes of some *Lathyrus* species (Lambein et al., 1976, 1992b, 1993). Ten different isoxazolinones

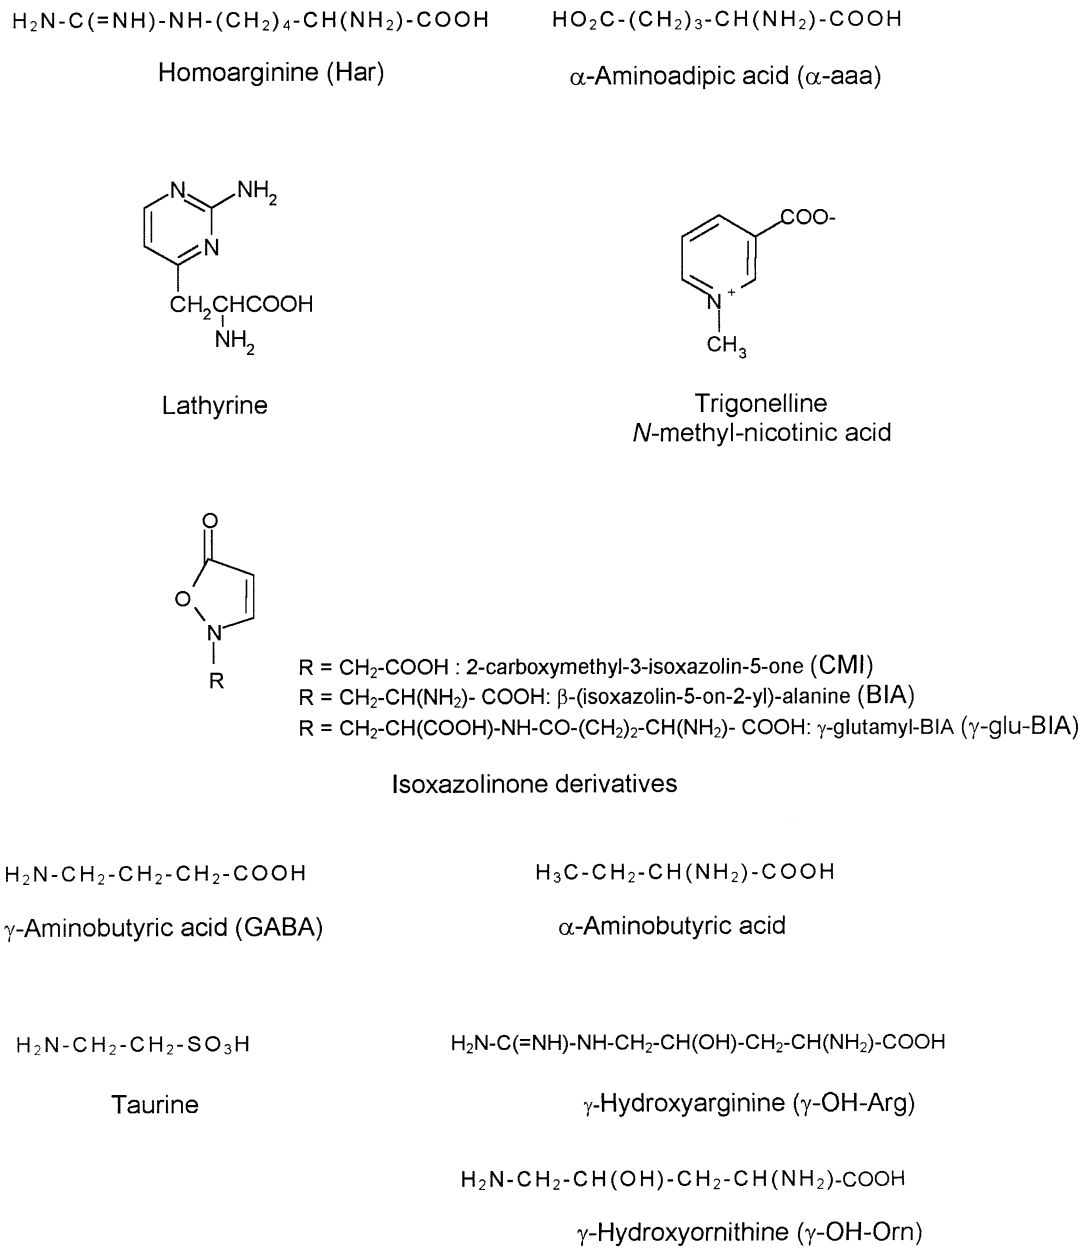

Fig. 1. Structures of nonprotein amino acids and trigonelline found in lentil seeds or seedlings.

were identified from *Lathyrus* species. In the genus *Lens*, three major isoxazolinones were detected in the seedlings by the CZE method. HPLC also permitted to detect these compounds but the number of peaks obtained by HPLC was too numerous to allow a correct quantification of the isoxazolinone compounds that were present in much lower concentrations.

The isoxazolinones detected were BIA (β-(isoxazolin-5-on-2-yl)-alanine), γ-glu-BIA (γ-glutamyl-BIA) and CMI (2-carboxymethyl-3-isoxazolin-5-one). BIA and γ-glu-BIA were previously reported in *L. culinaris* (Kuo et al., 1998; Rozan et al., 2000, 2001). The concentration of BIA ranged between 0.15 mg/g dry wt (*L. orientalis*) and 0.43 mg/g (*L. nigricans*) (Table 5). BIA is the metabolic precursor of γ-glu-BIA and of 3-*N*-oxalyl-L-2, 3-diaminopropanoic acid (β-ODAP) in grass pea (*Lathyrus sativus* L.) seedlings (Lambein et al., 1990b; Kuo et al., 1998). β-ODAP, a neurotoxic nonprotein amino acid, is present in *Lathyrus sativus* seeds and overconsumption of these seeds is responsible for lathyrism (a human irreversible neurodegenerative disease) in India, Bangladesh and Ethiopia. The most recent epidemic of lathyrism occurred in Ethiopia since 1997 after a drought and famine (Getahun et al., 1999). In *L. culinaris* BIA was metabolized to γ-glu-BIA and to four unknown amino acids while ODAP was not found (Kuo et al., 1998).

Riepe et al. (1995) reported that BIA itself is slightly neurotoxic, at concentrations of 0.5–2.0 mM it produced

a concentration-dependent neurodegeneration in mouse cortical explants.

A metabolite of BIA, γ-glu-BIA was first isolated from *L. culinaris* and from *Lathyrus sativus* (Lambein et al., 1992a) and in this study it was found in four of the five species examined. In *L. nigricans* and *L. culinaris* 0.24 and 0.41 mg/g dry wt were found respectively and lower concentrations were present in *L. odemensis* and *L. ervoides*. The physiological role of γ-glu-BIA in the plant is not known. Kusama et al. (2000) found in cultured cortical neurons of the rat that γ-glu-BIA showed weak antagonistic effects against NMDA receptors, and weak agonistic effects at AMPA receptors and cloned glutamate transporter.

CMI which is not an amino acid was the major isoxazolinone compound in all five species of *Lens* studied. CMI was first isolated from *Lathyrus odoratus* seedlings (Van Rompuy et al., 1974) and this is the first report of its detection in lentil seedlings. The biological activity of CMI has not been studied.

In this study we found less than 2% of the dry weight as total isoxazolinones in 4-day-old lentil seedling which is lower than in *Lathyrus* seedlings, but similar to pea seedlings.

3. Conclusion

This study showed some qualitative differences in composition of nonprotein amino acids among the five species of lentil studied: the absence of homoarginine and γ-glu-BIA in *L. orientalis;* the absence of trigonelline in *L. ervoides*. Phylogenetic classification on the basis of this phytochemical information from nonprotein amino acids composition is not an easy task. This was done before on the basis of distribution of nonprotein amino acids in seeds of the two major genera of the tribe *Vicieae (Lathyrus* and *Vicia)* (Bell, 1971). However, when seedlings of the genus *Lathyrus* were screened for a larger number of nonprotein amino acids including isoxazolinones, mostly unique combinations were found (Lambein et al., 1986). In the present study *L. orientalis* showed most different from the other four species studied by the absence of homoarginine, lathyrine and isoxazolinone derivative γ-glu-BIA. *L. nigricans* and *L. odemensis* seem to be more closely related by the presence of higher level of taurine and lathyrine. It was suggested by Simola (1986) that the different qualitative composition of nonprotein amino acids contributes to the barrier against interspecies crossing in some legume genera. In this case lathyrine or taurine might contribute to the crossing incompatibility between certain species of *Lens*.

Most studies on lentils are related to genetic aspects and their nutritional value is less mentioned whereas *L. culinaris* is consumed all over the world. The nongerminated lentil seeds contain some nonprotein amino acids with known or proposed physiological effects such as γ-hydroxyarginine and homoarginine affecting the biosynthesis of NO. The isoxazolinones, α-aminoadipic acid, GABA and lathyrine were only found after germination. The presence of taurine is mostly overlooked in common food legumes including pea, bean and lentil which are known to be low in sulphur-containing amino acids methionine and cysteine. Over-consumption of these seedlings, sold on the European market as new healthy food, might involve health problems. Especially for vegetarians and for those who can not afford animal protein, legumes are the main source of dietary protein. Seedlings of the garden pea, lentil and mungbean (*Vigna radiata* L.) are commonly available as fresh product for human consumption among a large diversity of seedlings. These contain secondary metabolites that are absent from the seeds and on which there is insufficient nutritional, toxicological or pharmacological information.

4. Experimental

4.1. Plant material

Five species of lentil seeds: *Lens culinaris*, *L. ervoides*, *L. nigricans, L. odemensis* and *L. orientalis* were obtained from ICARDA (Aleppo, Syria). The seeds were kept in moist condition in the cold room for 8 days to activate the process of germination and then germinated in the dark at 20°C with constant humidity. The seedlings were harvested after 4 days of germination. In this study the cotyledons and seedling axes were not separated.

Nongerminated seeds and seedlings were lyophilised before analysis. For each species, 4 extractions were done: one extraction for free amino acids analysis and another extraction after hydrolysis for total amino acids analysis in both seeds and seedlings. Each analysis was done in triplicate.

4.2. Protein hydrolysis

The dry weights of the samples varied from 10 to 87 mg. Fifty microlitres of DL-allylglycine (300 μmol/ml, Sigma) were added to samples as internal standard. Protein hydrolysis was done following a classical method with 6 N HCl for 24 h at 100°C in a vacuum-closed vial. Hydrolysates were dried under vacuum and rinsed twice with water.

4.3. Extraction of amino acids

This step was done for the free amino acids and total amino acid content. The dry weight of the free amino acid samples varied from 19 to 185 mg.

Fifty microlitres of DL-allylglycine (100 μmol/ml) was added to samples used for free amino acid extraction as internal standard. Four millilitres of 70% EtOH were added to the samples (protein hydrolysates and free amino acid samples). After keeping overnight at +4°C the samples were centrifuged (34,800 *g*, 20 min) and the pellets were washed twice with 70% EtOH. The supernatants were pooled and concentrated under vacuum and finally stored at −20°C.

4.4. High-performance liquid chromatography (HPLC) analysis

The free amino acid and trigonelline content of the extracts were analyzed by a HPLC gradient system with precolumn phenylisothiocyanate (PITC) derivatization (Khan et al., 1994). Buffer A (0.1 M NH_4OAc, pH 6.5) and Buffer B (0.1 M NH_4OAc, containing ACN and MeOH; 44:46:10; v:v; pH 6.5) were used.

Sample preparation was done as described in one of our previous studies (Rozan et al., 2000). A standard protein amino acid mixture (Food hydrolysate A 9656, Sigma) was prepared as above. Trigonelline and lathyrine were purified from plant extracts; α-aminoadipic acid, homoarginine (Sigma) and taurine (NBC) were used as standards. Standard γ-hydroxyarginine was kindly provided by Prof. E. A. Bell (King's College, London) and γ-hydroxyornithine was obtained by enzymatic reaction of arginase (ICN Biomedicals) with γ-hydroxyarginine as substrate. DL-allylglycine (Sigma) was used as the internal standard with a recovery of 90.5%. The results were analysed by Millennium software (Waters, version 1.10).

4.5. Capillary zone electrophoresis (CZE) analysis

The capillary electrophoresis instrument used was a Quanta 4000E (Waters) equipped with a Mercury lamp and a filter at 254 nm (Chowdhury et al., in preparation). Sodium-barbiturate 4 mM was used as the internal standard. Standards of BIA, γ-glu-BIA were previously isolated from *Lathyrus sativus*, CMI from *Lathyrus odoratus*. The results were analysed by Millennium software (version 3.1).

Acknowledgements

This work was supported by the Agro-industrial research development of EC (FAIR No. CT98-5001) and by a grant from the Flemish Science Foundation. ICARDA in Aleppo, Syria, is acknowledged for freely supplying seed materials. Professor Dr. E.A. Bell of King's College, London is thanked for a sample of standard γ-hydroxyarginine. Dr. W. Erskine of ICARDA is acknowledged for taxonomic clarifications. M.Sc. Delphin Diasolua Ngudi is thanked for performing the arginase test to localize the peak of γ-hydroxyornithine.

Received in revised form 18 April 2001

Abstract

Two halogenated C_{15} acetogenins, named lembyne-A and lembyne-B, have been isolated from an unrecorded *Laurencia* species collected off the Malaysian waters. Their structures were deduced on the basis of spectroscopic evidence. Previously known elatol and iso-obtusol showed potent antibacterial activity against some marine bacteria. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Laurencia*; Rhodomelaceae; Red alga; Sesquiterpene; C_{15} acetogenin; Halogenated compound; Chemotaxonomy; Antibacterial activity

1. Introduction

In the marine ecosystem, seaweeds are directly exposed and are susceptible to ambient microorganisms such as bacteria, fungi and viruses. In Japan, disease caused by pathogenic species of marine bacteria such as *Vibrio* (Ando and Inoue, 1961), *Alteromonas* (Yumoto et al., 1989; Sawabe et al., 1992), and *Pseudoalteromonas* (Sawabe et al., 1998; Sawabe et al., 2000) have appeared in the kelp *Laminaria* species. The selective occurrence and the dynamics of these infections and the ability of the seaweed to survive these diseases have urged us to delve into the possible existence of an inherently available antibacterial defense mechanism in seaweed (Vairappan et al., in press). To date, it is well known that many species of the red algal genus *Laurencia* (Rhodomelaceae, Ceramiales) produce numerous halogenated secondary metabolites with diverse structural features (Erickson, 1983). Although the function of these secondary metabolites has not been clearly studied, it is suggested that these metabolites serve as feeding deterrents against marine herbivores (Hay et al., 1987; Kurata et al., 1998). Furthermore, some halogenated metabolites from *Laurencia* have been shown to have antibacterial activity against terrestrial bacteria (Waraszkiewicz and Erickson, 1974; Wratten and Faulkner, 1977; Carter et al., 1978; Caccamese et al., 1980; König and Wright, 1997), thus suggesting that halogenated compounds have the potential to function as chemical defense substances against pathogenic marine bacteria. In the course of our continuing chemotaxonomic studies of *Laurencia* species, we previously reported chemical components of *Laurencia* specimens collected from the Malaysian coasts; *Laurencia snackeyi* (Weber-van Bosse) Masuda (Masuda et al., 1997), which produced brominated sesquiterpenes, and *Laurencia similis* Nam *et* Saito (Masuda et al, 1999), which produced polybrominated indoles. As part of our chemical analyses of *Laurencia* species from the Malaysian waters, we examined samples of *Laurencia majuscula* (Harvey) Lucas harvested from five locations and a sample of an unrecorded *Laurencia* species. *L. majuscula* contained known chamigrane-type sesquiterpenes, elatol (**1**) (Sims et al., 1974) and iso-obtusol (**2**) (González et al., 1979), as its common metabolites. The unrecorded *Laurencia*

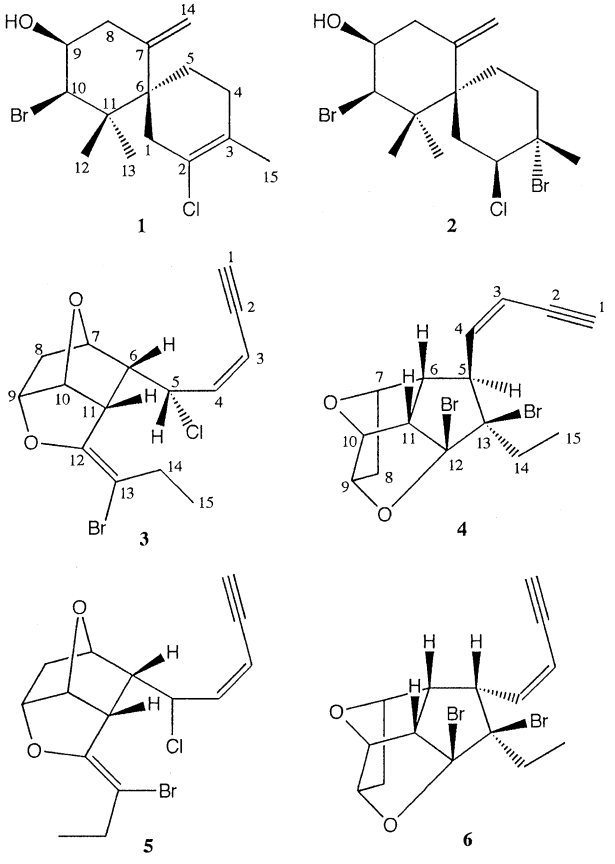
PII: S0031-9422(01)00243-6

contained two new halogenated metabolites, named lembyne-A (**3**) and lembyne-B (**4**), along with elatol (**1**). In this paper we describe the isolation and structure elucidation of these halogenated compounds and their antibacterial activity against marine bacteria isolated from algal habitats in the Malaysian coastal waters.

2. Results and discussion

2.1. Laurencia majuscula

Pulau Tikus and Pulau Nunuyan Laut specimens contained elatol (**1**) as the major metabolite. Specimens that were collected from Pulau Satang Besar, Pulau Bankawan and Pulau Redang contained iso-obtusol (**2**) as their major metabolite. These results indicated that the chemical compositions of the Malaysian *L. majuscula* specimens closely resemble that of the Gran Canarian *L. majuscula* (Masuda et al., 1998).



2.2. Laurencia species

The unrecorded *Laurencia* sp. collected at Pulau Lembu, Kedah, Malaysia, on 29 December 1997, was extracted with methanol. The methanol extract was fractionated by CC over silica gel with a step gradient (hexane and EtOAc). The fraction eluted with hexane–EtOAc (9:1) was further subjected to prep. TLC with hexane–EtOAc (3:1) to give elatol (**1**) in 38% yield based on the weight of the extract. In addition, the fraction eluted with hexane–EtOAc (75:25) was further subjected to prep. TLC with chloroform to give lembyne-A (**3**) (1.7%) and lembyne-B (**4**) (0.9%).

Lembyne-A (**3**), $[\alpha]_D^{24}$ +197.6° ($CHCl_3$), was assigned the molecular formula $C_{15}H_{16}BrClO_2$ (HR–EIMS). The IR spectrum showed signals due to a terminal acetylenic group at ν_{max} 3200 and 2100 cm^{-1} and a vinyl ether stretching at 1685 and 1210 cm^{-1}. Strong C–O bands (1175–1117 cm^{-1}) with no hydroxyl or carbonyl absorptions suggested that both oxygens were involved in ether links. The presence of a 1-buten-3-ynyl moiety was evident from the ^1H NMR spectrum (Table 1) [δ_H 2.71 (1H, *dd*, $J=2.4$ and 0.9 Hz), 5.00 (1H, *br dd*, $J=10.5$ and 2.4 Hz) and 5.40 (1H, *ddd*, $J=10.5$, 10.5 and 0.9 Hz)]. The *J*-value (10.5 Hz) for H-3 and H-4 indicated the geometry of the double bond at C-3 to be *Z* (Suzuki and Kurosawa, 1987). Interpretation of the ^1H–^1H COSY spectrum enabled the partial structural units **a** and **b** to be considered (Fig. 1).

The ^{13}C NMR spectrum (Table 1) showed the presence of three oxygen-bearing methine carbons at δ_C 78.66 (C-7), 80.51 (C-9), and 85.08 (C-10). In addition, the presence of a trisubstituted vinyl ether moiety (partial structural unit **c**) was also shown by two quaternary carbons at δ_C 149.37 and 102.47 (Suzuki et al., 1983). These chemical shift values indicated that the ethereal oxygen atom is attached to C-12 and a halogen atom to C-13. Another substituent at C-13 can be shown to be the ethyl group (**b**) by analyses of the HMBC spectrum, which is summarized in Table 1, indicating a cross peak between the quaternary carbon at C-13 (δ_C 102.47) and the terminal methyl group (H_3–15). Furthermore, the substituent at C-5 was shown to be a chlorine atom by the halogen-induced ^{13}C isotope shifts (Sergeyev et al., 1995; Raynes et al., 1997; Suzuki et al., 1999). The methine carbon at C-5 (δ_C 55.88) showed an isotope shift of 8 ppb with relative intensities of about 3:1 induced by ^{35}Cl and ^{37}Cl, according to natural isotopic abundance of its halogen atom; ^{35}Cl (75.711%)/^{37}Cl (24.229). Hence, the chlorine atom is linked to C-5 and the bromine atom to C-13.

Lembyne-A (**3**), which has seven degrees of unsaturation, should have two ether linkages. Judging from the ^1H NMR spectroscopic data, **3** has no 1,2-disubstituted oxirane (Tori et al., 1964) or 1,3-disubstituted oxetane (Pretsch et al., 2000; Irie et al., 1970) ring, leading to a planar formula **d** derived by bonding between C-9 and C-12 and between C-7 and C-10. The formula **d** was confirmed by the HMBC spectrum (Table 1).

A literature survey indicated that lembyne-A (**3**) has the same carbon skeleton as maneonenes, maneonene-

[a] Measured in benzene-d_6.
[b] Assingments were made with the aid of the HSQC spectrum.

A, -B and -C, isolated from the Hawaiian *Laurencia nidifica* (Waraszkiewicz et al., 1978). Detailed comparisons of the spectral data of **3** with those of maneonenes showed that **3** corresponds to none of the maneonenes.

A study of the molecular models indicated that three oxolane rings in **3** should be proposed as shown in formula **d**. The relative stereochemistries were determined by detailed analysis of the coupling constants in the ^{1}H NMR spectrum as well as from analysis of the NOESY spectrum. The coupling constants, $J_{6,7}=4.4$ Hz and $J_{6,11}=9.5$ Hz, reflecting a ca. 30° dihedral angle between H-6 and H-7 and a ca. 0° angle between H-6 and H-11, were identical to those of *cis*-meneonene-C (**5**). Thus H-6 has an *exo*-configuration, which was also confirmed by NOEs between H-6/H-7 and H-6/H-11. Furthermore, the coupling constant, $J_{5,6}=10.5$ Hz, indicated that the rotation of the C-5–C-6 bond is restricted due to steric hindrance by both the chlorine atom and the conjugated enyne moiety. The conformation between H-5 and H-6 should adopt a *cis*-eclipsed form, which was supported by a NOE between H-5 and H-6. In addition, a NOE between H-4 and H-7 showed that the configuration between C-5 and C-6 is *threo* as shown in formula **e** (Fig. 1). The assignment of the *Z*-configuration to the vinyl ether moiety was made by a NOE between H-11 and H_2-14. Thus lembyne-A has the relative stereochemistry, 5*S**, 6*R**, 7*R**, 9*R**, 10*R** and 11*S**, as shown in formula **3**.

Lembyne-B (**4**), oil, $[\alpha]_D^{24}$ + 157.1° ($CHCl_3$), was assigned the molecular formula $C_{15}H_{16}Br_2O_2$ (HREIMS). The presence of a (*Z*)-1-buten-3-ynyl moiety was also evident from the ^{1}H NMR spectrum (Table 2). The ^{1}H–^{1}H COSY spectrum showed the presence of the same spin systems (**a** and **b**) as in the case of lembyne A (**3**). Since

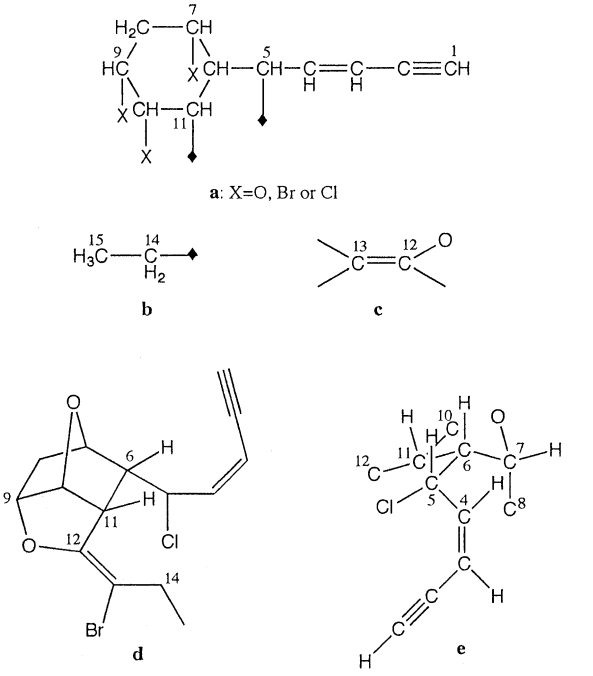

Fig. 1. Partial and planar structures and conformation for lembyne-A (**3**).

the IR spectrum showed no hydroxyl and carbonyl absorptions, both oxygen atoms were suggested to be involved in ether linkages. The ^{13}C NMR spectrum (Table 2) showed fourteen carbon atoms including three oxygen-bearing methine carbons (C-7, C-9 and C-10) which could be correlated with three oxymethine signals in the ^{1}H NMR spectrum by the HSQC measurement. Therefore, the remaining oxygen-bearing carbon must be a quaternary carbon.

[a] Measured in benzene-d_6.
[b] Assingments were made with the aid of the HSQC spectrum.

Since there were no halogen-bearing methine signals in the ^{1}H NMR spectrum, the two bromine atoms were assumed to be attached to quaternary carbons. The chemical shift value of δ_C 108.66 suggested the presence of a quaternary carbon with both bromine and oxygen atoms. Furthermore, a missing quaternary carbon should have a remaining bromine atom adjacent to the isolated ethyl group. Since lembyne-B (**4**) has seven degrees of unsaturation, **4** should be a tetracyclic compound. Detailed analysis of the HMBC spectrum (Table 2) of **4** indicated the existence of a ether linkage between C-7 and C-10 by cross-peaks between H-7/C-10 and H-10/C-7. Moreover, in the HMBC spectrum, the above-mentioned quaternary carbon at δ_C 108.66 displayed cross peaks to H-6 and H-9. This result indicated that this quaternary carbon should be adjacent to C-11, leading to the extended partial structure **f** (Fig. 2). In addition, the cross peaks between H-5/C-14, H_2-14 /C-5 and H_2-14/C-12 showed that the missing quaternary carbon with Br and Et group should be inserted between C-5 and C-12, hence giving rise to the planar formula **g**, which has the same carbon framework as isomaneonenes (-A and -B) isolated from the Hawaiian *Laurencia nidifica* (Waraszkiewicz et al., 1978).

The relative stereochemistry of lembyne-B (**4**) came from analysis of the NOESY spectrum. NOEs between H-5/H_{endo}-8, H-5/H_2-14 and H-4/H-6 were indicative that the conjugated enyne side chain and the ethyl group are in the *exo*- and *endo*-configurations, respectively. Thus lembyne-B has (5*R**, 6*R**, 7*R**, 9*R**, 10*R**, 11*S**, 12*S** and 13*R**)-configuration as shown in formula **4**, i.e., it is a stereoisomer of isomaneonene-A (**6**) at C-5.

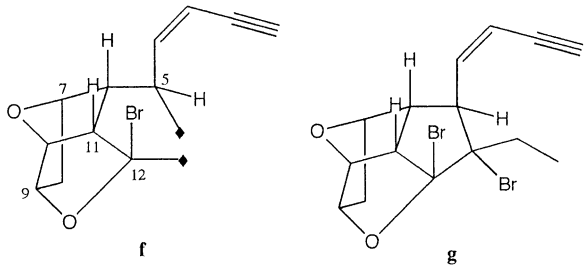

Fig. 2. Partial and planar structures for lembyne-B (**4**).

2.3. Antibacterial activity

The antibacterial activity of the isolated halogenated metabolites was tested against 13 species of marine bacteria isolated from algal habitats in the Malaysian coastal waters. The results of the paper disc diffusion assay are shown in Table 3. Elatol (**1**) showed antibacterial activity against all the 13 species of bacteria tested. It showed minimum inhibitory concentration (MIC) values of 5, 5 and 10 μg/disc against *Clostridium cellobioparum*, *Proteus mirabilis*, and *Flavobacterium helmiphilum* and 15–30 μg/disc against the remaining bacteria. On the other hand, iso-obtusol (**2**) showed MIC values of 10 and 15 μg/disc against *Clostridium cellobioparum* and *Proteus mirabilis*, while those against other bacteria were 40–60 μg/disc. Comparatively, lembyne-A (**3**) showed weaker antibacterial activity with MIC values in the range of 20–60 μg/disc.

"*Corps en cerise*" in superficial cortical cells has been thought to be the site of synthesis and/or storage of halogenated secondary metabolites of *Laurencia* (Young

et al., 1980). These intracellular inclusions are present in all investigated *Laurencia* species that produce halogenated secondary metabolites, whereas the *Laurencia* species without these intracellular inclusions does not produce any halometabolites. Hence, halogenated metabolites of "*corps en cerise*" in superficial cortical cells would appear to inhibit the growth of any penetrating marine bacteria.

These findings are the first report on the possible role of halogenated metabolites as antibacterial defense agents in *Laurencia* spp. against the marine bacteria in these algal habitats.

3. Experimental

3.1. General

^{1}H (400 MHz) and ^{13}C NMR (100 MHz); $CDCl_3$ unless otherwise stated, TMS as int. standard (coupling constant, *J* in Hz). The ^{13}C NMR isotope shifts measurements were deduced from ^{13}C NMR spectra taken in the bilevel complete decoupled mode using JEOL JNM-EX-400 spectrometer. The operating frequency was 100.4 MHz. The spectra were obtained using a 2500 Hz spectral window and acquisition time of 52 s and the number of points acquired was 131 K. The FID was zero-filled to 262 K data points (digital resolution was 0.0095 Hz/Pt). The standard Lorentzian-Gaussian resolution enhancement procedure was used before Fourier transformation to achieve a better separation of ^{37}Cl/^{35}Cl splittings. In the spectrum of lembyne-A, the signal of δ_C 55.90 ppm (C-5) showed an isotopic shift of 8 ppb (0.786 Hz) and a peak intensity ratio of 3.04:1. The isotope shift of the signal for C-13 could not be obtained because the respective carbon was not visible in the ^{13}C NMR spectrum. Low and high resolution MS: 70 eV; Optical rotations: $CHCl_3$; CC: silica gel (Merck, Kieselgel 60, 70-230 mesh); prep. TLC: silica gel 60 F_{254} (Merck). All known metabolites were identified by comparison of the spectral data with those of the authentic specimens. Yields are based on the weights of the extracts.

3.2. Collection

Samples of *Laurencia majuscula* were collected from five different sites in Malaysia: Pulau Tikus (Sandakan, Sabah (6°04′06″N, 117°57′48″E); 14 May 1998), Pulau Satang Besar (Kuching, Sarawak (1°47′20″N, 110°09′53″E); 23 May 1998), Pulau Bankawan (Sandakan, Sabah (6°04′56″N, 117°59′50″E); 17 May 1998), Pulau Nunuyan Laut (Sandakan, Sabah (5°56′00″N, 118°06′36″E); 18 May 1998) and Pulau Redang (Terengganu (5°45′17″N, 103°01′16″E), 24 May 1999). While the unrecorded *Laurencia* species was harvested from Pulau Lembu (Kedah (6°04′20″N, 100°03′21″E); 29 December 1997). The voucher specimens are deposited in the Herbarium (SAP) of the Graduate School of Science, Hokkaido University.

3.3. Extraction and separation of L. majuscula

The partially dried sample (40 g) from Pulau Satang Besar was soaked in methanol for 1 week. The MeOH soln was concentrated in vacuo and partitioned between Et_2O and H_2O. The Et_2O soln was washed with water, dried over anhydrous Na_2SO_4 and evaporated to leave a dark green oil (842 mg). The extract was fractioned by Si gel column chromatography with a step gradient (hexane and EtOAc). The fraction eluted with hexane–EtOAc (3:1) was repeatedly submitted to prep. TLC with hexane–EtOAc (3:1) or chloroform to give elatol (**1**) (35 mg) and iso-obtusol (**2**) (193 mg).

Extraction and separation of other samples were carried out in the same manner as described above. Pulau Tikus and Pulau Nunuyan Laut specimens contained elatol (**1**) as the major metabolite. Pulau Tikus specimen (dried alga, 5g); elatol (**1**) (27 mg) and iso-obtusol (**2**) (1.0 mg); Pulau Nunuyan Laut specimen (dried alga, 10 g): **1** (64 mg) and **2** (1.0 mg). Specimens from Pulau Bankawan and Pulau Redang contained iso-obtusol (**2**) as the major metabolite. Pulau Bankawan specimen (dried alga, 20 g): **2** (32 mg) and **1** (13 mg): Pulau Redang specimen (dried alga, 40 g): **2** (230 mg) and **1** (182 mg).

3.4. Elatol (*1*)

Oil; $[\alpha]_D^{24}$ +75.3° (MeOH; *c* 0.318); ^{13}C NMR ($CDCl_3$), CH_3: δ 20.13 (C-15), 21.46 (C-12 or C-13),

24.94 (C-13 or C-12), CH_2: δ 26.33 (C-5), 30.06 (C-4), 38.71 (C-8), 39.33 (C-1), 116.60 (C-14), CH: δ 71.57 (C-10), 72.89 (C-9), C: δ 43.85 (C-6), 49.88 (C-11), 124.86 (C-2), 128.76 (C-3), 141.49 (C-7). The ^{1}H NMR spectrum was identical to that of authentic sample.

3.5. Iso-obtusol (*2*)

Mp 109–113 °C; $[\alpha]_D^{26}$ +24.8° ($CHCl_3$; *c* 0.48); ^{13}C NMR ($CDCl_3$), CH_3: δ 25.58 (C-12 or C-13), 25.98 (C-13 or C-12), 33.74 (C-15), CH_2: δ 26.27 (C-1 or C-5), 33.96 (C-4), 34.58 (C-5 or C-1), 40.01 (C-8), 114.53 (C-14), CH: δ 65.79 (C-2), 70.40 (C-9), 77.08 (C-10), C: δ 44.32 (C-11), 44.56 (C-6), 71.85 (C-3), 148.07 (C-7). The ^{1}H NMR spectrum was identical to that of an authentic sample.

3.6. Extraction and separation of Laurencia species

The partially dried unrecorded *Laurencia* sp. (40 g) was soaked in methanol for one week. The MeOH soln was concentrated in vacuo and partitioned between Et_2O and H_2O. The Et_2O soln was washed with water, dried over anhydrous Na_2SO_4 and evaporated to leave a dark green oil (500 mg). The extract was fractionated by Si gel column chromatography with a step gradient (hexane and EtOAc). The fraction eluted with hexane–EtOAc (9:1) was further submitted to prep. TLC with hexane–EtOAc (3:1) to give elatol (**1**) (190 mg). Further separation of the fraction eluated with hexane–EtOAc (8:2) under the above-mentioned TLC yielded lembyne-A (**3**) (8.5 mg) and lembyne-B (**4**) (4.5 mg).

3.7. Lembyne-A (*3*)

Mp 95–96 °C; $[\alpha]_D^{24}$ +197.6° ($CHCl_3$; *c* 0.70); IR ν_{max} ($CHCl_3$) cm^{-1} : 3200, 2100, 1685, 1210, 1175, 1158, 1117, 1080, 1032, 1020, 1010, 982, 967, 950, 821, 805, 790; ^{1}H and ^{13}C NMR spectra, Table 1; LR–EIMS *m*/*z* (rel. int.): 346, 344, 342 (9:35:27) $[M]^+$, 309, 307 (99:100) $[M\text{-}Cl]^+$, 265, 263 (24:28), 201, 199 (18:16) $[M–C_5H_4Cl–C_2H_5–O]^+$, 159 (34), 122 (29), 115 (20), 91 (25), 81 (20), 79 (22), 77 (31), 69 (27), 65 (18), 41 (24), 39 (21); HR-EIMS *m*/*z*: 342.0013. Calc. for $C_{15}H_{16}{}^{79}Br\ {}^{35}Cl\ O_2$, 342.0022 [M].

3.8. Lembyne-B (*4*)

Oil; $[\alpha]_D^{24}$ +157.1° ($CHCl_3$; *c* 0.10); IR ν_{max} (neat) cm^{-1} : 3300, 2150, 1280, 1262, 1250, 1100, 1050, 1020, 1003, 959, 935, 890, 879, 820, 807, 785, 752; ^{1}H and ^{13}C NMR spectra, Table 2; LR–EIMS *m*/*z* (rel. int.): 390, 388, 386 (7:14:7) $[M]^+$, 309, 307 (98:100) $[M\text{-}Br]^+$, 227 (57) $[M\text{-}Br\text{-}HBr]^+$, 202, 200 (42:42), 141 (20), 107 (28), 79 (23), 77 (24), 65 (13), 41 (11), 39 (11); HR–EIMS *m*/*z*: 387.9482. Calc. for $C_{15}H_{16}{}^{79}Br^{81}BrO_2$, 387.9497 [M].

3.9. Antibacterial bioassays

Antibacterial bioassays were carried out using 13 species of marine bacteria isolated from an algal bed at Penang Island, Malaysia (Vairappan and Suzuki, 2000 and unpublished data). These bacteria are *Chromobacterium violaceum*, *Clostridium fallax*, *Clostridium novyi*, *Clostridium sordellii*, *Clostridium cellobioparum*, *Escherichia coli*, *Enterobacter aerogenes*, *Flavobacterium helmiphilum*, *Shigella flexneri*, *Proteus mirabilis*, *Vibrio cholerae*, *Vibrio parahaemolyticus* and *Vibrio vulnificus*. One loopful of each organism was precultured in 20 ml of peptone water (3% NaCl) overnight. The turbidity of the culture was adjusted to an optical density (OD) McFarland 0.5 (Sonnenwirth and Jarett, 1980; Hindler et al., 1990). Then 0.1 ml of the precultured bacterial suspension was used to seed Nutrient Agar plates (3% NaCl). Paper discs (Whatman, 6 mm) impregnated with various amounts of the respective pure compounds were placed on the seeded agar plates and the diameters of the inhibitory zones were measured after the plates were incubated at 28 °C for 24 h.

Received 26 February 2001; received in revised form 18 April 2001

Abstract

Six furano-*ent*-labdanes, 19-acetoxy-15,16-epoxy-8(17),13(16),14-*ent*-labdatrien-20-al, 15,16-epoxy-12-oxo-8(17),13(16),14-*ent*-labdatrien-20,19-olide, 12(*S*)-hydroxy-15,16-epoxy-8(17),13(16),14-*ent*-labdatrien-20,19-olide, 10α,19-dihydroxy-15,16-epoxy-8(17),13(16),14-nor-*ent*-labdatriene, 19,20-dihydroxy-15,16-epoxy-8(17),13(16),14-*ent*-labdatriene, 15,16-epoxy-12-oxo-8(17),13(16),14-*ent*-labdatrien-19,20-olide, were isolated, together with the known potamogetonin, from the aquatic plant *Potamogeton natans*. Their structures were determined on the basis of their chemical and spectral data. The compounds showed in vitro phytotoxicity against *Raphidocelis subcapitata*, a microalga used in aquatic tests. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Potamogeton natans*; Potamogetonaceae; *Raphidocelis subcapitata*; *ent*-Labdanes; Furano-diterpenes; Antialgal activity; Spectroscopic analysis

1. Introduction

Chemical interactions between aquatic plants and microalgae play an important role in aquatic ecosystems since the production of metabolites by the macrophytes might control the algal growth (Fitzgerald, 1969). Hasler and Jones (1949) observed that the algal population decreased when plants belonging to the Potamogetonaceae were present in the aquatic systems. The ability of some natural products to inhibit the in vitro development of the microalgae has been reported copiously (DellaGreca et al., 1996 and ref. cit.) and in a previous paper we showed that bioactive products isolated from *Pistia stratiotes* are released into the environment (DellaGreca et al., 1999).

Recently we investigated *Potamogeton natans*, a freshwater Potamogetonacea, distributed throughout the Mediterranean basin (Cangiano et al., 2001). The phytochemical study has already led to the isolation of several diterpene lactones, some of them showing a high antialgal activity.

2. Results and discussion

In pursuing the chemical investigation of *P. natans*, we isolated the potamogetonin (**1**) (Smith et al., 1976) and six new furanoid *ent*-labdanes **2**–**7**, identified by their spectroscopic features.

Spectral data of compound **1** were in good agreement with those of the revised structure of potamogetonin (Hasegawa and Hirose, 1983), but there were some differences in the chemical shift assignments. Our assignments, based on 2D NMR experiments (H–H COSY, DEPT, HMBC, HMQC, and NOESY), are reported in Table 1. The methylene signals at δ 36.0 and 41.8, ascribed to C-3 and C-1, as well as those at δ 23.7 and 25.7, ascribed to C-11 and C-12, were exchanged on the basis of the HMBC experiment. In fact the signal at δ 36.1, showing interaction with the H-2 at δ 1.70, was attributed to the C-1, while the signal at δ 41.2, correlated with the H-1, H-18 and H-19, was attributed to the C-3. The same spectrum showed the interaction of the carbon at δ 23.8 with the H-11, H-14 and H-16 signals and of the carbon at δ 25.8 with the H-9 and H-12. These observations are in agreement with the exchange of the carbon assignments at C-11 and C-12.

The EI mass spectrum of compound **2** showed a molecular ion at m/z 358, which, together with the

elemental analysis, defined the molecular formula as $C_{22}H_{30}O_4$. The spectroscopic data indicate that the compound contains a $\Delta^{8,17}$ exocyclic methylene group. In fact, the ^1H NMR (Table 2) showed two broad singlets at δ 4.96 and 4.64, the ^{13}C NMR (Table 3) exhibited a quaternary and a methylene carbon at δ 145.6 and 108.0, and the IR spectrum showed ν_{max} bands at 2962, 1619 and 896 cm^{-1}. The presence of a furano group was indicated by the chemical shifts of H-14, H-15 and H-16 protons at δ 6.23, 7.34 and 7.17 in the ^1H NMR, and by the signals of the corresponding carbons in the ^{13}C NMR spectrum at δ 110.8, 142.9 and 138.9. The IR absorptions at 1733 and 1713 cm^{-1} indicated the presence of two carbonyl groups in the molecule. The ^1H NMR also showed a singlet proton at δ 9.82, a methylene group as two double doublets at δ 3.85 and 3.75, and two methyl singlets at δ 2.01 and 0.98.

Treatment of compound **2** with $NaBH_4$ and subsequent hydrolysis gave a diol **6**. The same product was obtained from the reduction of potamogetonin **1**. The identical values of the optical rotation of the reduction products indicated that they belong to the same *ent*-labdane series.

On the basis of a HMBC experiment, the formyl group was located at the C-10 carbon, while the acetylated function was located at C-4. In fact, the H-18 methyl protons at δ 0.98 were heterocorrelated to the C-19 acetoxymethyl carbon at δ 20.9, while the H-19 protons at δ 3.75 and 3.85 were correlated to the C-18 carbon at δ 26.7. All five protons gave cross peaks with the C-4 carbon at δ 37.4. The formyl proton at δ 9.82 gave interactions with the C-5, C-9 and C-10 carbons at δ 54.5, 52.7 and 53.7, respectively.

In accordance with the assigned structure, the formyl H-20 proton gave NOE with the H-19 at δ 3.85 and the acetyl protons at δ 2.01.

Compound **3** was identified as the 12-oxo derivative of potamogetonin. In the IR spectrum, bands of a γ-lactone and a α,β-unsaturated ketone group at 1720 and 1677 cm^{-1}, respectively, were evident.

In the ^{13}C NMR two carbonyl groups at δ 173.6 and 194.8 were present. This latter was attributed to the C-12 because of the presence, in the ^1H NMR (Table 2), of two double doublets at δ 3.80 and 3.34, attributed to the diasterotopic H-11 protons, and because of the downfield shifts of the H-14 and H-16 proton, at δ 6.80 and 8.20. The ^{13}C NMR data (Table 3) were in agreement with those reported by Hasegawa and Hirose (1983), for its enantiomer.

Compound **4** showed 20 carbon signals in the ^{13}C NMR spectrum (Table 3), which, along with the mole-

cular ion at *m*/*z* 330 in the EI–MS spectrum, justified a molecular formula $C_{20}H_{26}O_4$. The IR spectrum, besides the signals of the exocyclic methylene, of the furano and of the γ-lactone groups, showed a band at 3290 cm^{-1} attributable to a hydroxyl group. In the ^{1}H NMR (Table 2) the furano protons H-14, H-15 and H-16 were present at δ 6.43, 7.40 and 7.39, the broad singlets H-17 methylene at δ 4.96 and 4.76, the H-19 protons at δ 4.19 and 4.03 and a doublet at δ 4.67 attributable to a proton geminal with a hydroxyl function. This latter proton linked to the carbon at δ 65.1, was heterocorrelated, in the HMBC spectrum, to the furano carbon 13 at δ 130.0 and to the H-11 at δ 2.66 and 2.28, in the H–H COSY. These data located the hydroxyl group at the C-12 carbon univocally. Accordingly, the $NaBH_4$ reduction of ketone **3** gave compound **4**. The configuration of the natural product at C-12 was established by Mosher's method (Dale and Mosher 1973; Othani et al., 1991). The R-MTPA and S-MTPA esters showed a difference in the chemical shift of +0.094 and +0.153 ppm for the H-11 methylene and of −0.07 ppm for the H-14 proton in agreement with the *S* configuration.

Compound **5** had a molecular formula $C_{19}H_{28}O_3$ in accordance with the molecular ion at *m*/*z* 304 in the EI–MS spectrum and 19 carbon signals in the ^{13}C NMR (Table 3). The IR spectrum showed signals for the furano, exocyclic methylene and hydroxyl groups. The ^{1}H NMR spectrum (Table 2) showed a methyl singlet at δ 0.80 and two diasterotopic hydroxymethyl protons at δ 3.54 and 3.20 besides the H-14, H-15 and H-16 furano protons at δ 6.26, 7.36 and 7.20, respectively, and the H-17 methylene signals at δ 5.13 and 4.81. Both the methyl and hydroxymethyl groups were located at C-4 on the basis of the heterocorrelation of their protons, in the HMBC spectrum, with the same carbon at δ 38.1. The compound, after acetylation by Ac_2O in dry pyridine, still showed a hydroxyl absorption in the IR spectrum at 3392 cm^{-1}, attributable to a hindered alcoholic function. In the ^{13}C NMR spectrum, a quaternary carbon at δ 74.1 suggested that this function might be at the C-10 carbon. *Nor*-diterpenes with a hydroxyl group at C-4, have often been isolated from natural sources and data indicate that they are formed by autoxidation of the corresponding aldehydes (Caputo et al., 1974). Accordingly compound **5** was obtained from aldehyde **2** by autoxidation at the light and successive alkaline hydrolysis.

Compound **6** was identified as 19,20-dihydroxy-15,16-epoxy-8(17),13(16),14-*ent*-labdatriene. It had spectral data identical to those reported by Hasegawa and Hirose (1983) for 19,20-dihydroxy-15,16-epoxy-8(17),13(16),14-labdatriene, obtained from chemical reduction of methyl 15,16-epoxy-20-oxo-8(17),13(16),14-labdatrien-19-oate. The opposite rotation indicates that **6** belongs to the *ent*-labdane series.

Compound **7** was easily identified as the isomer of **3**. The spectroscopic data were in accordance with the labdane sciadinone, already isolated from *Sciadopitys verticillata* (Hasegawa and Hirose, 1985 and ref. cit.) unless in the opposite rotation, which confirmed the *ent*-labdane skeleton.

The phytotoxicity profile of these new naturally occurring diterpenes from *P. natans* was determined by the toxicity tests, described in the experimental section, with the unicellular green alga *Raphidocelis subcapitata* (CCAP 278/4, formerly *Selenastrum capricornutum*). Comparison of the toxicity of chemicals after the calculation of their respective median inhibition concentrations (IC_{50}) in μmol/l with the 95% confidence limits, revealed that the toxicity was highly dependent not only on the skeleton but even on the kind of substituent (Table 4).

The most active compounds were **4**, with IC_{50} of 4.40, and **5** with IC_{50} of 2.84. The less active compounds were **2** with IC_{50} of 58.27, and **7** so that it was not possible to estimate the IC_{50} value at the tested concentrations, because of a lack of further available samples. Even compound **3** is not reported in Table 4, because it showed a biostimulation up to the concentration of 25.85 μmol/l and only a slight inhibition of algal growth (8%) at the highest tested concentration (60.89 μmol/l).

3. Experimental

3.1. General experiment procedures

NMR spectra were recorded at 400 MHz for ^1H and 100 MHz for ^{13}C on a Bruker AC400 spectrometer with 0.05 M solns. in $CDCl_3$ at 37 °C. Proton-detected heteronuclear correlations were measured using HMQC (optimised for $^1J_{HC} = 145$ Hz) and HMBC (optimised for $^1J_{HC} = 7$ Hz). Optical rotations were measured on a Perkin-Elmer 343 polarimeter. IR spectra were determined in $CHCl_3$ solns. on a FT–IR Perkin-Elmer 1740 spectrometer. UV spectra were obtained on a Perkin-Elmer Lambda 7 spectrophotometer in EtOH solns. EI–MS spectra were obtained with a Kratos MS 80 apparatus. The HPLC apparatus consisted of a pump (Shimadzu LC-10AD), a refractive index detector (Shimadzu RID-10A) and a recorder Shimadzu Chromatopac C-R6A. Preparative HPLC was performed using RP-8 (Luna 10 μm, 250×10 mm i.d., Phenomenex) columns. Analytical TLC was performed on Merk Kieselgel 60 F_{254} or RP-18 F_{254} plates with 0.2 mm layer thickness. Spots were visualised by UV light or by spraying with H_2SO_4–AcOH–H_2O (1:20:4). The plates were then heated for 5 min at 110°C. Prep. TLC was performed on Merck Kieselgel 60 F_{254} plates, with 0.5 or 1 mm film thickness. Flash column chromatography (FCC) was performed on Merck Kieselgel 60 (230–400 mesh) at medium pressure. Column chromatography (CC) was performed on Merck Kieselgel 60 (70–240 mesh) or on Sephadex LH-20® (Pharmacia).

Table 4
IC_{50} values of diterpenes from *Potamogeton natans* (μmol/l)

Compounds	IC_{50}	95% Confidence limits
1	28.58	23.85–36.63
2	58.27	37.94–89.49
4	4.40	3.11–6.21
5	2.84	2.04–3.95
6	18.45	13.73–24.81

3.2. Plant material

Plants of *Potamogeton natans* were collected from the Volturno River, near Naples (Italy), and identified by Professor Antonino Pollio. A voucher specimen is deposited at the Dipartimento di Biologia Vegetale of University Federico II of Naples.

3.3. Extraction and isolation

The air dried and powdered plant material (13 kg) was sequentially and exhaustively extracted with light petrol, EtOAc and MeOH. The extracts were frozen and stored at −80°C until used.

3.3.1. Light petrol extract fractionation

The light petrol extract (66 g) was chromatographed on silica gel to give fractions A and B. Fraction A eluted with hexane–EtOAc (19:1) was chromatographed using hexane–EtOAc (17:3) as eluent to give pure compounds **1** (125 mg) and **2** (57 mg). Fraction B eluted with hexane–EtOAc (17:3) was filtered on Sephadex LH-20 using hexane–$CHCl_3$–MeOH (3:1:1) as eluent. The elute purified by prep. TLC, using a mixture of C_6H_6–EtOAc (19:1) as eluent, gave pure **3** (85 mg) and **7** (4 mg).

3.3.2. EtOAc extract fractionation

The EtOAc extract (79 g) was chromatographed on silica gel with hexane and EtOAc solns. to give fractions C and D. Fraction C, eluted with hexane–EtOAc (4 : 1), was chromatographed on Sephadex LH-20 with hexane-$CHCl_3$–MeOH (3:1:1). The elute, purified by HPLC using a preparative RP-8 column and a mixture of

MeOH–H_2O (4:1) as eluent, gave pure **4** (35 mg) and **5** (11 mg). Fraction D was chromatographed on prep. TLC [$CHCl_3$–EtOAc (3:1)] to give compound **6** (31 mg).

3.4. Compound characterisation

3.4.1. 15,16-Epoxy-8(17),13(16),14-ent-labdatrien-20,19-olide (1)

White amorphous powder; $[\alpha]_D^{25}$ −29.7° ($CHCl_3$, c 0.34); spectral data: see Table 1.

3.4.2. 19-Acetoxy-15,16-epoxy-8(17),13(16),14-ent-labdatrien-20-al (2)

White amorphous powder; $[\alpha]_D^{25}$ −17.1° ($CHCl_3$, *c* 0.52); UV (EtOH) λ_{max} (log ε): 207 (3.95); IR ν_{max} ($CHCl_3$) cm^{-1}: 2962, 1733, 1713, 1619, 1509, 896, 875; ^1H NMR: see Table 2; ^{13}C NMR: see Table 3; EI–MS: *m/z* 358 $[M]^+$, 343 $[M–CH_3]^+$, 329 $[M–CHO]^+$, 298 $[M–AcOH]^+$, 81 $[C_5H_5O$, pyrylium ion$]^+$; elemental analysis: found: C, 73.86; H, 8.37. $C_{22}H_{30}O_4$ requires: C, 73.71; H, 8.44%.

3.4.3. 15,16-Epoxy-12-oxo-8(17),13(16),14-ent-labdatrien-20,19-olide (3)

Colourless oil; $[\alpha]_D^{25}$ +22.5° ($CHCl_3$, *c* 0.43); UV (EtOH) λ_{max} (log ε): 204 (3.89), 252 (1.95); IR ν_{max} ($CHCl_3$) cm^{-1}: 2969, 1720, 1677, 1615, 1500, 895, 873; ^1H NMR: see Table 2; ^{13}C NMR: see Table 3; EI-MS: *m/z* 328 $[M]^+$, 313 $[M–CH_3]^+$, 247 $[M–C_5H_5O]^+$, 81 $[C_5H_5O$, pyrylium ion$]^+$; elemental analysis: found: C, 73.02; H, 7.36. $C_{20}H_{24}O_4$ requires: C, 73.15; H, 7.37%.

3.4.4. 12(S)-Hydroxy-15,16-epoxy-8(17),13(16),14-ent-labdatrien-20,19-olide (4)

Colourless oil; $[\alpha]_D^{25}$ −25.7° ($CHCl_3$, *c* 0.31); UV (EtOH) λ_{max} (log ε): 204 (4.01); IR ν_{max} ($CHCl_3$) cm^{-1}: 3290, 2944, 1728, 1620, 1500, 891, 875; ^1H NMR: see Table 2; ^{13}C NMR: see Table 3; EI–MS *m/z*: 330 $[M]^+$, 315 $[M–CH_3]^+$, 312 $[M–H_2O]^+$, 249 $[M–C_5H_5O]^+$, 81 $[C_5H_5O$, pyrylium ion$]^+$; elemental analysis: found: C, 72.65; H, 7.96. $C_{20}H_{26}O_4$ requires: C, 72.70; H, 7.93%.

3.4.5. 10α,19-Dihydroxy-15,16-epoxy-8(17),13(16),14-nor-ent-labdatriene (5)

Colourless oil; $[\alpha]_D^{25}$ −4.1° ($CHCl_3$, c 0.21); UV (EtOH) λ_{max} (log ε): 205 (3.89); IR ν_{max} ($CHCl_3$) cm^{-1}: 3392, 2934, 1642, 1463, 890, 878; ^1H NMR: see Table 2; ^{13}C NMR: see Table 3; EI–MS *m/z*: 304 $[M]^+$, 289 $[M–CH_3]^+$, 286 $[M–H_2O]^+$, 223 $[M–C_5H_5O]^+$, 81 $[C_5H_5O$, pyrylium ion$]^+$; elemental analysis: found: C, 74.90; H, 9.29. $C_{19}H_{28}O_3$ requires: C, 74.96; H, 9.27%.

3.4.6. 19,20-Dihydroxy-15,16-epoxy-8(17),13(16),14-ent-labdatriene (6)

Colourless oil; $[\alpha]_D^{25}$ −20.4° ($CHCl_3$, c 0.38); UV (EtOH) λ_{max} (log ε): 204 (3.68); IR ν_{max} ($CHCl_3$) cm^{-1}: 3525, 2931, 1637, 1513, 889, 876; ^1H NMR: see Table 2; ^{13}C NMR: see Table 3; EI-MS *m/z*: 318 $[M]^+$, 303 $[M–CH_3]^+$, 300 $[M–H_2O]^+$, 237 $[M–C_5H_5O]^+$, 81 $[C_5H_5O$, pyrylium ion$]^+$; elemental analysis: found: C, 75.33; H, 9.54. $C_{20}H_{30}O_3$ requires: C, 75.43; H, 9.50%.

3.4.7. 15,16-Epoxy-12-oxo-8(17),13(16),14-ent-labdatrien-19,20-olide (7)

Colourless oil; $[\alpha]_D^{25}$ +65.3° ($CHCl_3$, *c* 0.04); UV (EtOH) λ_{max} (log ε): 205 (3.99), 249 (2.09); IR ν_{max} ($CHCl_3$) cm^{-1}: 2970, 1719, 1680, 1610, 1498, 893, 871; ^1H NMR: see Table 2; ^{13}C NMR: see Table 3; EI–MS *m/z*: 328 $[M]^+$, 313 $[M–CH_3]^+$, 247 $[M–C_5H_5O]^+$, 81 $[C_5H_5O$, pyrylium ion$]^+$; elemental analysis: found: C, 73.06; H, 7.34. $C_{20}H_{24}O_4$ requires: C, 73.15; H, 7.37%.

3.5. Preparation of compound 4

$NaBH_4$ (8 mg) was added to a soln. of **3** (30 mg) in MeOH (2.5 ml) and the reaction mixture was stirred for 5 h at room temperature. The hydride in excess was quenched with AcOH (2 drops). The mixture was then directly purified by prep. TLC with C_6H_6–EtOAc (17:3) to give, beside the unreacted **3** (11 mg), compound **4** (5 mg) and its epimer **8** (10 mg). Compound **8** had $[\alpha]_D^{25}$ −13.3° (*c* 0.01, $CHCl_3$); ^1H NMR: see Table 2; ^{13}C NMR: see Table 3.

3.6. Preparation of compound 6

$LiAlH_4$ (15 mg) was added to a soln. of **1** (30 mg) in dry Et_2O (5 ml) and the reaction mixture was stirred for 6 h at room temperature. After the hydride in excess had been destroyed, the mixture was purified by prep. TLC [$CHCl_3$–EtOAc (3:1)] to give compound **6** (23 mg).

The analogue reduction of aldehyde **2** with $NaBH_4$, after alkaline hydrolysis, gave the same compound **6**.

3.7. Preparation of (R) and (S)-MTPA esters of 4

To a soln. of pure **4** (1.5 mg) in dry pyridine (50 μl) (*S*)-(+)-MTPA-Cl (5 μl) was added. After 4 h under magnetic stirring at room temperature, Et_2O (5 ml) and water (5 ml) were added to the reaction mixture. The organic layer gave a crude ester which was purified by prep. TLC eluting with hexane–EtOAc (5:1). The (*S*)-MTPA ester had the ^1H NMR spectral data (400 MHz, $CDCl_3$): δ 6.45 (1H, *s*, H-14), 5.95 (1H, *d*, *J* = 10.5 Hz, H-12), 5.01 (1H, *s*, H-17), 4.69 (1H, *s*, H-17), 4.18 (1H, *dd*, *J* = 1.5, 11.6 Hz, H-19), 4.01 (1H, *d*, *J* = 11.6 Hz, H-19), 2.65 (1H, *m*, H-11), 2.11 (1H, *m*, H-11), 0.90 (3H, *s*, H-18). The (*R*)- MTPA ester of **4** was prepared using the same procedure. ^1H NMR (400 MHz, $CDCl_3$): δ 6.38 (1H, *s*, H-14), 5.91 (1H, *dd*, *J* = 4.7, 10.5 Hz, H-12), 5.02 (1H, *s*, H-17), 4.76 (1H, *s*, H-17), 4.14 (1H, *dd*, *J* = 1.5, 11.5 Hz, H-19), 3.98 (1H, *d*, *J* = 11.5 Hz, H-19), 2.75 (1H, *m*, H-11), 2.26 (1H, *m*, H-11), 0.89 (3H, *s*, H-18).

3.8. Preparation of compound 5

Pure aldehyde **2** (30 mg) was dissolved in C_6H_6 and the soln. evaporated in a large flask to obtain a thin layer. After 2 days at room temperature, the autoxidation mixture was dissolved in peroxides-free Et_2O and the ether soln. extracted with 10% Na_2CO_3 aq. The residue was purified by prep. TLC with hexane–Me_2CO (4:1) to give compound **5** (4 mg).

3.9. Bioassay

The freshwater toxicity test Algaltoxkit F™ (Creasel, Belgium) with the alga *Raphidocelis subcapitata* currently used for aquatic toxicity assays was applied for the antialgal activity. This test is a 0–72 h algal growth inhibition assay and is independent on the live culture stocks of the alga that is immobilized on beads of alginate. Pure chemicals (99%) were dissolved in DMSO and then diluted in bidistilled water to make the final stock solns. The highest DMSO concentration in the test solns. did not exceed 0.01% (v/v). Blanks were carried out to detect whether the DMSO concentrations might cause toxicity. The dilution water used for the test solns. was the OECD medium (OECD, 1994). The alga was inoculated (1×10^4 cells/ml) in 25 ml of test soln. prepared in five concentrations for each chemical and three replicates included the control. Details on the toxicity test procedures are given in DellaGreca et al., (2000). The cell density was measured at 0 time and every 24 h for 3 days by an electronic particle dual threshold counter (Coulter Counter Z2, 100 μm capillary) and from these data the algal growth inhibition was calculated by integrating the mean values from t_0 to t_{72} h (area under the curve), calculating the median inhibition (IC_{50}) in μmol/l and then operating the log-transformation (OECD, 1994).

Received 29 December 2000; received in revised form 21 March 2001

Abstract

Three chlamydocin analogues that show activity for reducing the height of rice seedlings without blotch and wilting were isolated from the culture filtrate of the soil fungus *Peniophora* sp. and were characterized by spectral data and chemical conversion. For two of these, it is their first isolation as natural products. The proposed role of the functional groups of the 2-amino-8-oxodecanoic acid moiety of these analogues is discussed in terms of growth retardant activity. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Rice plant; *Oryza sativa*; Gramineae; *Peniophora* sp.; Chlamydocin; Plant growth regulators; Structural elucidation

1. Introduction

Use of plant growth regulators to control plant height during rice production could reduce lodging, permit higher nitrogen application rates, and increase yields. Most nitrogen recommendations are based on an application rate that will produce the maximum yield without lodging. Because lodging generally results in lower yield and grain quality, a plant shortener or stalk stiffener would be valuable for the rice industry (Eastin, 1983). We, therefore, conducted a screening-based search among the metabolites produced by soil fungi for natural plant growth regulators which would control rice plant height. We found that cladospolide B and zygosporine D act as rice plant growth retardants (Fujii et al., 1995, 2000). Recently we found a fungus, identified as *Peniophora* sp., whose culture filtrate had activity to reduce the height of rice seedlings without causing either blotch or wilting. From their spectroscopic data three active metabolites (**1**, **2** and **3**) (Fig. 1) isolated from the filtrate were shown to be analogues of chlamydocin (Closse and Huguenin, 1974). Compound **1** is the same as the chlamydocin analogue reported by Gupta et al. (1994). Ours is the first isolation of compounds **2** and **3** as natural products, whereas **2** was reported earlier as a chemical conversion product of chlamydocin (Closse and Huguenin, 1974).

2. Results and discussion

The fungus, whose metabolites reduced the height of rice seedlings in the screening, did not form spores in many trials, making identification of the fungus difficult. Eventually, it was determined to be *Peniophora* sp. on the basis of electron microscopy observations and its 18S rRNA gene sequence. Electron microscopy showed that this fungus has a dolipore-parethesome septum in its hyphae, indicative that it belongs to the holobasidiomycetes (Khan and Kimbrough, 1982). The sequence of its 18S rRNA gene (1737 bases) was determined (data not shown) and a BLAST similarity search of the sequence showed that *Peniophora nuda* is the most closely related fungus (97% similarity).

The fungus was grown on malt extract medium without shaking at 24°C for 14 days in the dark. Metabolites extracted from the culture filtrate and purified by chromatography gave compounds **1**, **2** and **3** in respective yields of 3.3, 0.42 and 0.07 mg/l of medium. Compound **1** had the molecular formula $C_{28}H_{40}N_4O_6$ from its HREIMS, with a molecular ion peak at m/z 528.2955, and NMR spectroscopic data. The IR spectrum of **1**

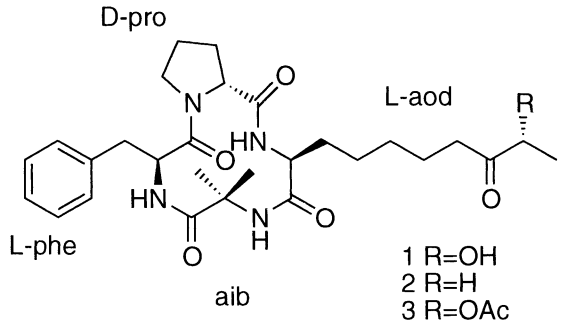

Fig. 1. Chemical structures of compounds **1**–**3**.

showed absorption bands at 3454 cm^{-1} for hydroxyl and/or amide groups, at 1697 cm^{-1} for a ketone carbonyl group, and at 1667 cm^{-1} for amide carbonyl groups. A ketone carbonyl carbon resonance appeared at δ 212.4 in its ^{13}C NMR spectrum, and four amide carbonyl carbon resonances at δ 171.9, 172.8, 174.3, and 175.6. Acetylation of **1** gave a monoacetate, suggesting it has one hydroxyl group. Structural clarifications were based on ^{1}H–^{1}H COSY, HMQC and HMBC data. Analysis of the NMR spectral data (Table 1) for compound **1** suggested that it was the same as the chlamydocin analogue isolated from *Verticillium coccosporum* by Gupta et al. (1994). The reported spectral data, however, were insufficient for unambiguous identification because the NMR data were recorded in C_6D_6 and the optical rotation was not described. We therefore collected NMR spectral data in C_6D_6 and found them identical to the reported data, indicative that compound **1** has the same structure and same relative stereochemistry as the reported analogue. To confirm the absolute stereochemistry of **1**, acid hydrolysis of the compound was carried out. HPLC analysis after derivatizing the hydrolyzate with (+)-1-(9-fluorenyl)ethyl chloroformate (Hayashi and Sasagawa, 1993) showed that the phenylalanine derivative in the hydrolyzate had the same retention time as the L-phenylalanine derivative, evidence that the stereochemistry of the phenylalanine in **1** is L, the same as the reported configuration. Thus **1** was definitively identified as the same as the chlamydocin analogue reported by Gupta et al. (1994).

Compound **2** was characterized as follows: it had the molecular formula $C_{28}H_{40}N_4O_5$ on the basis of its HREIMS data, which showed a molecular ion peak at m/z 512.3001. Its NMR spectral data were similar to those of **1**, indicating that **2** is also a chlamydocin analogue. Its structure was clarified by comparing its NMR spectral data (Table 1) with those for **1**. The carbon resonance (δ 72.6) produced by an oxygenated methine carbon (C-9 of 2-amino-8-oxodecanoic acid (aod)), present in the ^{13}C NMR spectrum of **1**, was absent. Instead, there was a carbon resonance (δ 35.9) due to a methylene carbon in the ^{13}C NMR spectrum of **2**. Furthermore, its ^{1}H NMR spectrum showed a two-proton quartet signal at δ 2.41 and a three-proton triplet signal at δ 1.05, whose signals were coupled. These findings indicate that compound **2** has a structure in which the hydroxyl at the C-9 of aod in compound **1** has been lost. Loss of chirality at the C-9 of aod changed the shape of the proton signal (H-7 of aod) from the AB type triplet in compound **1** to a simple triplet in compound **2**. The amino acid sequence of compound **2** was confirmed from the HMBC correlations between the NH of aod and C-1 of pro, between the NH of 2-aminoisobutyric acid (aib) and C-1 of aod, and between the NH of phe and C-1 of aib. NOE data support this sequence (Fig. 2). The fact that the NOE data for compound **2** are almost the same as those reported for compound **1** suggests that the compounds have the same relative stereochemistry. Compound **2** has been obtained from chlamydocin by chemical conversion (Closse and Huguenin, 1974), but there were insufficient spectroscopic data for unequivocal characterization. Ours is the first report of compound **2** as a natural product and of its full spectroscopic data.

The structure of compound **3** was determined as follows: on the basis of its HREIMS, which showed a molecular ion peak at m/z 570.3035, and its NMR spectral data, this compound has the molecular formula $C_{30}H_{42}N_4O_7$. The NMR spectrum is similar to that of **1**, evidence that **3** also is a chlamydocin analogue. Its structure was established by comparing its NMR spectral data (Table 1) with those for **1** and by chemical conversion. Two new additional carbon resonances (δ 170.4 and 20.7), not observed in the ^{13}C NMR spectrum of **1**, were present in the ^{13}C NMR spectrum of **3**, and an additional new three proton singlet signals appeared at δ 2.15 in its ^{1}H NMR spectrum. These findings indicate there is an additional acetyl group in **3**. Furthermore, the hydroxyl methine proton signal produced by the H-9 of aod was shifted down field (δ 4.23 in the ^{1}H NMR spectrum of **1** to δ 5.08 in that of **3**), indicative that the acetoxyl group is attached to the C-9 of aod. To verify this, compound **1** was acetylated by the usual method. The resulting product was identical in all respects to **3**. Compound **3**, therefore, is a new compound, never before reported.

Plant growth retardant activities for compounds **1**–**3** in a microdrop bioassay (Murakami, 1968) of rice seedlings (*Oryza sativa* L. cv. Koshihikari) are shown in Table 2. Administration of 10 nmol/plant of **1** or **2**

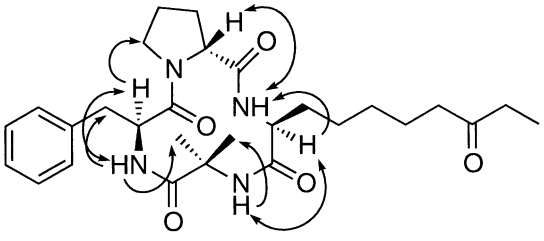

Fig. 2. Key NOE correlations in compound **2**.

[a] Intensities, multiplicities and *J* values (Hz) shown in parentheses.

reduced the second leaf sheath length of the treated plants, respectively to 73 and 71% of the value for the water control. The same amount of **3** produced 83% growth of the second leaf sheath length in the treated as compared to control plants. Interestingly, compound **2** was more active than **3** and as active as **1**. This suggests that the hydroxyl group at the C-9 of aod in **1** is not important for plant growth retardation and that the acetoxyl group at the C-9 of aod in **3** reduced activity. It is noteworthy that the metabolites had this effect with causing neither blotch nor wilting.

Cyclic tetrapeptides, which have both proline and an adjacent novel amino acid, 2-amino-9, 10-epoxy-8-oxodecanoic acid, include Cyl-2 from *Cylindrocladium scoparium*

Table 2
Effects of compounds **1**–**3** on second leaf sheath length of rice (*Oryza sativa* L. cv. Koshihikari) seedlings

Amount (nmol/plant)	Second leaf sheath length[a]		
	1	**2**	**3**
0	100 (49.2 mm)	100 (49.2 mm)	100 (46.8 mm)
0.3	94.5±2.1	95.3±2.9	100.0±4.9
1	81.6±1.3	84.8±3.2	100.4±6.3
3	78.3±1.4	79.1±3.5	94.0±1.8
10	73.0±1.4	71.0±3.2	82.9±3.1

[a] Values are presented as percentage of the control. Data are mean ± standard error ($n=5$).

(Takayama et al., 1984), chlamydocin from *Diheterospora chlamydosporia* (Closse and Huguenin, 1974), and HC toxin from *Helminthosporium carbonum* (Walton et al., 1982), all of which are reported to have phytotoxic activity. A chlamydocin analogue that has 2-amino-9-hydroxy-8-oxodecanoic acid instead of 2-amino-8, 9-epoxy-8-oxodecanoic acid has phytotoxic activity (Gupta et al., 1994). This means that the phytotoxicity is not produced by the epoxide function of aod. Our present findings show that the 9-hydroxyl of aod is not essential for the retardant activity, and thus the 9-hydroxyl of aod may also not be essential for phytotoxicity. It is necessary to determine the role of the ketone function at the C-8 of aod in the retardant activity. An investigation to clarify this role is in progress.

3. Experimental

3.1. General experimental procedures

Optical rotation was measured with a Horiba SEPA-200 polarimeter. UV spectra were recorded with a Hitachi U-2001 spectrophotometer, and IR spectra with a JASCO FT/IR 7000 spectrometer. NMR spectra were measured with a Jeol Lambda 400 NMR spectrometer. Chemical shifts were referenced to $CDCl_3$ (δ_H 7.26, δ_C 77.0). Mass spectra were obtained with a Jeol AX505HA spectrometer (direct probe, 70 eV). Unless otherwise noted, HPLC was carried out with a Cosmosil 5C_{18}–AR column (Nacalai Tesque, 10×250 mm), 70 wt.% MeOH as the solvent, a flow rate of 1.0 ml/min, and monitoring at 220 nm.

3.2. Fungal material

The fungal isolate, obtained from a soil sample collected in Tottori Prefecture, Japan was found to be very close to *Peniophora nuda* based on electron microscopic observations and the sequence of its 18S rRNA gene: for the electron microscopy study the fungus was grown on PDA medium at 25°C for 7 days. Sections prepared according to the procedure reported (Suh et al., 1993) were observed with a Jeol JEM-1010 transmission electron microscope at 100 kV. For analysis of the l8S rRNA sequence, the isolate was grown in YM medium (0.3% yeast extract, 0.3% malt extract, 0.5% peptone, 1% glucose; pH 5.6) at 25°C for 3 days with shaking. Mycelia were collected by centrifugation, freeze-dried, and disrupted in liq. N_2. Genomic DNA was obtained with a Dneasy Plant Mini Kit (QIAGEN GmbH, Hilden, Germany). The PCR used genomic DNA as the template and NS1 and NS8 (White et al., 1990) as the PCR primers. Amplification conditions were 94°C for 1 min, followed by 30 cycles of 94°C for 1 min, 52°C for 30 s, 72°C for 2 min, and lastly 72°C for 2 min. PCR products were purified with a QIAquick PCR purification kit (QIAGEN GmbH, Hilden, Germany) and directly sequenced. NS1-8 were the sequencing primers (White et al., 1990). All the sequencing reactions were done with a Perkin-Elmer BigDye Terminator Kit, and the sequence determination with a Perkin-Elmer ABI PRISM 377 sequencer.

3.3. Fermentation and extraction

The fungus was grown without shaking at 24°C for 14 days in the dark in 500 ml conical flasks (100) containing liquid medium (200 ml/flask) composed of glucose (30 g/1), peptone (3 g/l), the extract from 50 g/l of malt, and H_2O. Metabolites were extracted from the culture filtrate with EtOAc (3×10 l) after adjusting the pH to 2.0 with HCl. The EtOAc solution was washed with 1 M $NaHCO_3$ (2×0.5 volume), dehydrated over Na_2SO_4 and concentrated to dryness for a residue (1.6 g).

3.4. Purification

The residue (1.6 g) was subjected to silica gel column chromatography (Daisogel IR-60, 16×230 mm), with 200 ml (40 ml×5) each of 30, 40 and 60% acetone in *n*-hexane as eluant. The first fraction (143 mg), eluted with 40% acetone in *n*-hexane, was further purified by Sephadex LH-20 column chromatography (20×370 mm, MeOH). Five milliliter portions of the eluate were collected. Fraction 18 was dried by evaporation, giving **1** as a colorless oil (66 mg). The third fraction (48 mg), eluted with 30% acetone in *n*-hexane and purified by HPLC, gave **2** as a colorless oil (8.4 mg, R_t 30.7 min). The fourth fraction (39 mg), eluted with 30% acetone in *n*-hexane and purified by HPLC, gave **3** as a colorless oil (1.5 mg, R_t 26.9 min).

3.5. Compound *1*

3.8. Acetylation of compound 1

Compound **1** (9.5 mg) was treated overnight with 1 ml of acetic anhydride and 0.5 ml of pyridine. The product was purified by HPLC, giving compound **3** (8.8 mg).

3.9. Amino acid analysis

Compound **1** (0.6 mg) was hydrolysed in 0.12 ml of 6 N HCl at 110°C for 20 h. The reaction mixture was dried by evaporation and dissolved in 50 μl of 0.1 M borate buffer (pH 9.0). Ten microliters of CH_3CN and 2 μl of (+)-1-(9-fluorenyl)ethyl chloroformate (Aldrich, 18 mM in acetone) were added to 10 μl of the hydrolysate solution, after which the mixture was kept at 50°C for 15 min. The reaction was terminated by adding 25 μl of 100 mM cysteic acid in 0.1 M borate buffer (pH 9.0). Before HPLC analysis, the reaction mixture was diluted with 153 μl of 0.1 M NaOAc buffer (pH 4.0) (Hayashi and Sasagawa, 1993). Analytical HPLC employed a Shim Pack CLC-C8 (Shimadzu, 6.0×150 mm) column. Derivatives were detected with a Shimadzu RF 550 fluorescence detector (excitation: 260 nm; emission: 315 nm). Two solvents were used; solvent A consisting of THF–NaOAc buffer (pH 4.0) (25:75, v/v) and solvent B consisting of THF–NaOAc buffer (pH 5.1) (50:50, v/v). Gradient elution conditions were 0–25 min, 0–60% B; 25–80 min, 60% B; 80–90 min, 60–100% B; 90–95 min, 100% B; 95–100 min, 100–0% B. The flow rate was 0.8 ml/min. Under these conditions the R_t of D-phenylalanine derivative was 81.4 min and that of the L-form 85.6 min.

3.10. Biological assays

Compounds **1**–**3** were evaluated for their ability to retard the growth of rice plants. Rice seeds (*Oryza sativa* L. cv Koshihikari) were soaked in H_2O for 48 h at 28°C under fluorescent light. Sets of six germinated seeds were planted on 1% agar medium in 30 ml beakers then incubated for 48 h under continuous light. A 1 μl drop of 50% aq. MeOH containing a certain amount of the test compound was placed between the shoot and first leaf of each seedling. After incubation for 72 h under continuous light, the length of the second leaf sheath of the seedling was measured.

Acknowledgements

We thank Dr. Yukihiro Sugimoto of the Arid Land Research Center of this university for his assistance in measuring the NMR and Miss Izumi Sugimoto of this laboratory for her technical assistance. This investigation was supported in part by a Grant-in-Aid for Scientific Research (No. 11660111) to H.N. from the Ministry of Education, Science and Culture of Japan.

Insecticidal compounds from *Kalanchoe daigremontiana* × *tubiflora*

Unang Supratman, Tomoyuki Fujita, Kohki Akiyama, Hideo Hayashi*

Division of Applied Biological Chemistry, Graduate School of Agriculture and Life Sciences, Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, Osaka 599-8531, Japan

Received 20 November 2000; received in revised form 23 February 2001

Abstract

Methyl daigremonate, an insecticidal bufadienolide, was isolated from the leaves of *Kalanchoe daigremontiana*×*tubiflora* (Crassulaceae) along with four known bufadienolides. Its structure was established by spectroscopic analysis, and insecticidal activities were assessed against the third instar larvae of silkworm (*Bombyx mori*). The results suggest that the orthoester and α-pyrone moieties played an important role in the activity. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Kalanchoe daigremontiana* × *tubiflora*; Crassulaceae; Bufadienolide; Methyl daigremonate; Insecticidal activity

1. Introduction

In the course of our continuing search for novel insecticidal compounds from Indonesian medicinal plants, we isolated and described two insecticidal bufadienolides, bryophyllins A (**1**) and C (**2**), along with an inactive bufadienolide, bersaldegenin-3-acetate (**3**), from the leaves of *Kalanchoe pinnata* (Supratman et al., 2000). In the further screening for insecticidal compounds from Indonesian *Kalanchoe* (syn. *Bryophyllum*) species, we found that the methanolic extract of the leaves of *Kalanchoe daigremontiana* × *tubiflora* exhibited an insecticidal activity against silkworm.

K. daigremontiana × *tubiflora* (Crassulaceae) is a hybrid plant between *K. daigremontiana* and *K. tubiflora*. Both *Kalanchoe* species are widely distributed in tropical and subtropical countries (Beckett, 1990). The plant is used in Indonesian folk medicine for the treatment of infections, rheumatism, cough, fever and inflammation (Hutapea, 1994). Previous phytochemical studies on both *K. daigremontiana* and *K. tubiflora* reported the presence of sterols (Kalinowska et al., 1990) and bufadienolides (Wagner et al., 1985, 1986; Capon et al., 1986), but the phytochemistry of *K. daigremontiana* × *tubiflora* is still unknown. We now report on the isolation and structural elucidation of a new insecticidal bufadienolide derivative.

2. Results and discussion

Repeated column chromatography of the methanolic extract of fresh leaves of *K. daigremontiana* × *tubiflora* by bioassay-guided fractionation resulted in the isolation of four bufadienolide derivatives (Fig. 1) together with bryophyllin A (**1**). Based on their spectral evidence and a detailed comparison with published data, compounds **4**–**6** were identified as bersaldegenin-1,3,5-orthoacetate (Kupchan and Ognyanov, 1969; Wagner et al., 1986), daigremontianin (Wagner et al., 1985), and bersaldegenin-1-acetate (Kupchan et al., 1971; Wagner et al., 1986), respectively.

Compound **7** was isolated as colorless prisms from chloroform-methanol; mp 258–261°C, $[\alpha]_D^{20}$ −41.7° ($CHCl_3$; *c* 0.024). The molecular formula of **7** was established to be $C_{27}H_{34}O_9$ by HREIMS data (*m*/*z* 502.2185) together with ^1H and ^{13}C NMR spectral data (Table 1), thus requiring 11 degrees of unsaturation. The UV spectrum showed an absorption maximum at 296 nm (log ε 4.02), indicating the presence of a conjugated carbonyl group. The IR spectrum showed bands which were ascribed to hydroxyls (ν_{max} 3544 and 3478 cm^{-1}), an aldehyde (ν_{max} 1714 cm^{-1}), a conjugated ester (ν_{max} 1692 and 1168 cm^{-1}), and an ether group (ν_{max} 1134 and 1109 cm^{-1}). The ^{13}C NMR together with the DEPT spectra revealed 27 carbon signals including characteristic signals due to an orthoester [δ_C 25.6 (*q*), 66.3 (*d*), 71.1 (*d*), 73.2 (*s*), and 111.0 (*s*)], an aldehyde [δ_C 206.2 (*d*)], an ester carbonyl [δ_C 167.9 (*s*)], three sp^2 methines [δ_C 146.3 (*d*), 141.7 (*d*), and 112.0 (*d*)], one sp^2

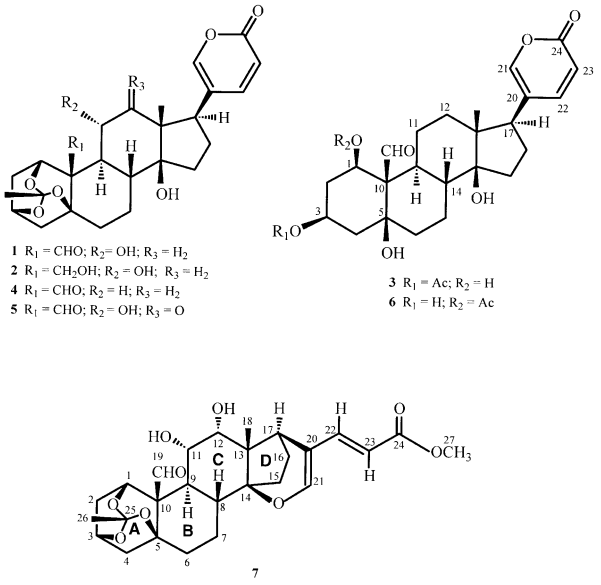

Fig. 1. Structures of bufadienolides derivatives.

quaternary carbon [δ_C 121.3 (*s*)], one carbomethoxyl [δ_C 51.4 (*q*)], one methyl [δ_C 8.8 (*q*)], six methylenes, five methines, and three quaternary carbons, indicating **7** to be a pentacyclic structure with an orthoester moiety.

The ^{1}H NMR spectrum of **7** was quite similar to that of bryophyllin A (**1**), particularly the signals in the A, B, and C rings of **1** (Supratman et al., 2000). The essential differences between the ^{1}H NMR spectra of **1** and **7** consisted of the absence of an α-pyrone ring and appearance of a *trans* olefine [δ_H 5.75 (1H, *d*, J=15.3 Hz) and 7.18 (1H, *d*, J=15.3 Hz)], an olefinic [δ_H 6.54 (1H, *s*)], a carbomethoxyl [δ_H 3.73 (3H, *s*)], and one oxygenated proton [δ_H 3.52 (1H, *dt*, J=5.2, 11.6 Hz)] in the ring C, suggesting that **7** was an α-pyrone opening compound of bufadienolide.

The ^{1}H–^{1}H COSY spectrum of **7** showed correlations in C_1–C_2–C_3–C_4, C_6–C_7–C_8–C_9–C_{11}–C_{12}, and C_{15}–C_{16}–C_{17}, supporting the presence of steroidal structure like that in **1** and remained the cholane skeleton. To determine the connectivity of the partial structure due to an α-pyrone ring cleavage, HMBC experiments were carried out, and the results are shown in Table 1. The carbomethoxyl signal was correlated to an ester carbonyl (δ_C 167.9), and the signals of H-23 (δ_H 5.75) and H-22 (δ_H 7.18) were correlated to the carbonyl and another olefinic carbons at C-20 and C-21, indicating that a conjugated ester was built up at C-21, C-20, C-22, C-23, and C-24. The signal of H-21 (δ_H 6.54) was correlated with C-14 (δ_C 92.8), suggesting that an ether bridge was formed between C-21 and C-14. Other correlations from H-21 to C-20 (δ_C 121.3), and from H-17 to C-13 (δ_C 47.1) and C-14 (δ_C 92.8), also supported the presence of a dihydropyran ring made up of C-21, C-20, C-17, C-13, and C-14. Two oxygenated protons at δ_H 3.89 (δ_C 68.3) and δ_H 3.52 (δ_C 69.0) are mutually coupled, and the signal at δ_H 0.98 (Me-18) was correlated to the oxygenated carbon at δ_C 69.0, while the signal at δ_H 1.95 (H-9) was correlated to the oxygenated carbon at δ_C 68.3, indicating that the signals at δ_C 68.3 and 69.0 were assigned to secondary hydroxyls at C-11 and C-12, respectively. The relative configuration of A and B rings was determined to be the same as those of **1** on the basis of NOESY experiments (Fig. 2). In the differential NOE spectrum, irradiation of the H_3-18 at δ_H 0.98 enhanced the signal intensity of two methine protons (H-8 and H-11), indicating that H_3-18, H-8, and H-11 have a 1,3-diaxial relationship to each other. The relative configuration of a hydroxyl at C-12 was assigned to be α configuration on the basis of ^{1}H–^{1}H coupling constant and NOESY correlation. Consequently, the structure of new insecticidal bufadienolide derivative **7** was determined to be methyl [1β,3β,5β,11α,12α]-(22*E*)-1,3,5-ethylidynetris(oxy)-14,21-epoxy-11,12-dihydroxy-19-oxo-

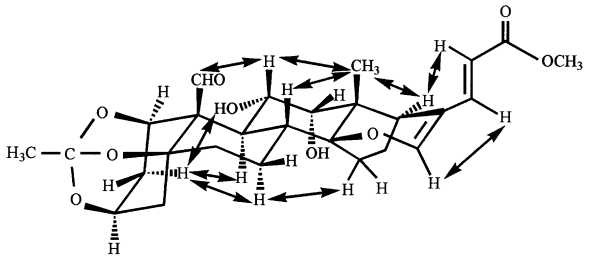

Fig. 2. NOE correlations observed in the NOESY and differential NOE spectra of **7**.

5β,14β-chola-20,22-dien-24-oate, and was named methyl daigremonate.

To determine whether **7** is a natural metabolite or an artifact during the extraction or separation process, identification of **7** was attempted from the acetone extract of the plant. The acetone extract afforded a compound whose HPLC retention time and mass spectrum were identical to those of **7**. Thus, it was confirmed that **7** should be a natural metabolite. The presence of bufadienolides in the parental generation of the hybrid known was not examined in this study.

Compounds **4**–**7** were evaluated for insecticidal activity against the third instar larvae of silkworm. The insecticidal activities of compounds **4**–**7**, and three previously isolated bufadienolides (**1**, **2** and **3**) (Supratman et al., 2000) are shown in Table 2. All bufadienolides having an orthoacetate and α-pyrone moiety showed strong activity, while non-orthoacetate bufadienolides **3** and **6** showed no activity. Methyl daigremonate **7**, an α-pyrone opening type of bufadienolide, showed weak activity. These results suggested that the orthoacetate and α-pyrone moieties were important structural components for insecticidal activity. In addition, daigremontianin (**5**) having oxygenated substituents at C-11 and C-12 showed the strongest activity among these compounds, indicating that oxygenated substituents at C-11 and C-12 on C-ring enhanced the insecticidal activity.

3. Experimental

3.1. General

Melting points were uncorr.; optical rotation was measured with a Horiba model SEPA-300 polarimeter; UV spectra were recorded on a Hitachi model U-3210 spectrophotometer; IR spectra on a Perkin-Elmer 1760X in KBr; mass spectra were recorded with a JEOL JMS-DX300 and Kratos PC-Kompact MALDI instruments; ^{1}H and ^{13}C NMR spectra were obtained with a JEOL JNM A-500 spectrometer using TMS as internal standard. Chromatographic separations were carried out on Wakogel C-200 (Wako Pure Chemical Industries), silica gel 60 (Merck), and Chromatorex ODS (Fuji Silysia, Japan) adsorbents.

3.2. Plant material

Leaves of *K. daigremontiana* × *tubiflora* were collected from plantation trees growing in Bandung District, West Java, Indonesia in September 1999 and identified by staff of the Laboratory of Plant Taxonomy at Bandung Institute of Technology, Bandung, Indonesia. A voucher specimen (No. 10184) was deposited at the herbarium of the Bandung Institute of Technology.

3.3. Extraction and isolation

Fresh leaves of *K. daigremontiana* × *tubiflora* were exhaustively extracted with MeOH at room temp. The MeOH extract was evap. in vacuo to yield a dark brown residue (182.3 g) that was partitioned between CH_2Cl_2 and H_2O to afford an active CH_2Cl_2 extract (21.5 g). This CH_2Cl_2 extract was subjected to CC on Wakogel C-200 (*n*-hexane–EtOAc–MeOH) to obtain two active fractions, I (100% EtOAc and 10% MeOH eluates, 3.1 g) and II (20% MeOH eluate, 2.5 g). These fractions were separately subjected to CC on silica gel 60 eluted with $CHCl_3$ and an increasing ratio of MeOH. The active fraction (259 mg) from fraction I was successively subjected to silica gel flash-chromatography with $CHCl_3$–MeOH (49:1) and *n*-hexane–Me_2CO (7:3) as eluant. This was followed by crystallization in MeOH to yield bersaldegenin-1,3,5-orthoacetate (**4**, 11.4 mg), daigremontianin (**5**, 14.6 mg), and bryophyllin A (**1**, 6.2 mg). The active fraction (138 mg) from fraction II was then successively subjected to silica gel flash-chromatography with $CHCl_3$–MeOH (19:1) and *n*-hexane–Me_2CO (6:4) as eluant, and then subjected to CC on ODS with MeOH–H_2O (6:4). Finally, bersaldegenin-1-acetate (**6**, 5.5 mg) and methyl daigremonate (**7**, 9.1 mg) were obtained by crystallization from $CHCl_3$–MeOH.

3.4. Methyl daigremonate (7)

Colorless prisms ($CHCl_3$–MeOH), mp 258–261°C. $[\alpha]_D^{20}$ −41.7° ($CHCl_3$; *c* 0.024). HPLC (R_t 10.9 min, Inertsil ODS, 10.0×250 mm; CH_3CN–H_2O = 4:6, 0.8 ml/min, A_{296} nm). UV λ_{max}^{MeOH} nm (log ε): 297 (4.02); IR ν_{max}^{KBr} (cm^{-1}): 3544, 3478, 2924, 1714, 1692, 1618, 1339,

1168, 1134, 1109. ^{1}H NMR ($CDCl_3$) and ^{13}C NMR ($CDCl_3$) (Table 1). HREIMS [found m/z 502.2185 (M^+); calc. for $C_{27}H_{34}O_9$, 502.2202]. EIMS m/z (rel. int): 502 (100), 484 (32), 406 (30), 378 (28), 278 (92), 207 (45).

3.5. Identification of 7 from acetone extract

The fresh leaves of *K. daigremontiana* × *tubiflora* (35 g) collected at the same place in June 2000 were exhaustively extracted with Me_2CO at room temp. The Me_2CO extract was separated as mentioned above except for using Me_2CO instead of MeOH. The CH_2Cl_2 extract (2.4 g) was subjected to CC on Wakogel C-200 (*n*-hexane–EtOAc–Me_2CO by stepwise elution) to obtain 11 fractions. The 20% Me_2CO eluate was separated by preparative HPLC using Inertsil ODS (10.0×250 mm, CH_3CN–H_2O = 4:6, 0.8 ml/min, A_{296} nm) to give a compound (R_t 10.9 min). The retention time and mass spectrum of the isolated compound were identical with those of compound **7**.

3.6. Insecticidal activity (Hayashi et al., 1989)

Larvae of *Bombyx mori* were used for the bioassay, and were cultured on an artificial diet purchased from Nippon Nosan Kogyo Co., Ltd. One hundred microlitres of MeOH extract or a certain amount of the sample to be tested were added to one gram of the diet in a petri dish. After removing the solvent, ten larvae of the third instar stage were introduced into the petri dish. Thirty larvae (three petri dishes) were treated at each dosage, and the mortality rate of the silkworm was observed after 24 h. MeOH was used as a control treatment. The insecticidal activities of tested compounds at each dose were examined by triplicate experiments. The average mortality rate of each dose were determined and used for determining of LD_{50} values by using logarithmic increment.

Received 2 February 2001; received in revised form 3 May 2001

Abstract

Dopamine, norepinephrine, and normetanephrine were identified by GC–MS in potato (*Solanum tuberosum* L.) plants, the latter was new for plants. The highest amount of catecholamines was found in leaves. A developmental stage dependent variation in potato leaf catecholamines accumulation was also observed with highest level in third leaves. Catecholamine contents decrease during cold storage of tubers to undetectable levels. Mechanical wounding of leaves led to a small increase in the level of catecholamines investigated. © 2001 Published by Elsevier Science Ltd.

Keywords: Potato; *Solanum tuberosum*; Solanaceae catecholamines; Dopamine; Norepinephrine; Normetanephrine; GC–MS

1. Introduction

Catecholamines are a group of biogenic amines possessing a 3,4-dihydroxysubstituted phenyl ring. Dopamine (**1**), norepinephrine (**2**), epinephrine and their derivatives are widespread in animals and have also been detected in 44 plant families (Smith, 1977). They are formed in plants from tyrosine, either via tyramine or via dihydroxyphenylalanine (dopa) (Smith, 1980). In banana fruits, dopamine is formed by the hydroxylation of tyramine and further hydroxylated to norepinephrine (Fig. 1). In marine alga (*Monostroma fuscum*) and in Scotch broom (*Cytisus scoparius*) dopamine is formed by decarboxylation of dopa (Smith, 1980). Thus, the biosynthetic pathway of catecholamines in plants is similar to that in animals.

The physiological role of catecholamines in animal cells is well studied. Both epinephrine and norepinephrine are synthesized and released from the medulla of the mammalian adrenal gland. Catecholamine catabolism starts via methylation of the hydroxyl group of the catechol ring followed by oxidation to homovanillic acid and vanillylmandelic acid and subsequent secretion via urine (Smith, 1980). In contrast to the vast amount of knowledge concerning the role and action of catecholamines in mammals, very little is known of the role catecholamines play in plants. Several reports suggest that catecholamines are precursors for alkaloids, the hallucinogen mescaline, identified in several species of cacti (Lundstrom, 1983) and tetrahydroisoquinoline alkaloids (Guinaudeau and Bruneton, 1993), both derived from dopamine. Norepinephrine is believed to be a precursor for berberastine, an alkaloid of *Hydrastis canadensis* (Smith, 1980). Other reports suggest that catecholamines may interact with plant hormones (Dai et al., 1993; Protacio et al., 1992). Most of the data describing the presence of catecholamines in plants have arisen using co-chromatography (either HPLC or TLC) as the criterion for identification (Kuklin and Conger, 1995; Smith, 1977; Wilczyński et al., 1998). To the best of our knowledge, no data have been published that unequivocally demonstrate the chemical nature of the compounds by either NMR or mass spectrometry. The lack of such an analytical system has also made difficult the analysis of large numbers of samples with respect to the variations in levels and types of catecholamines present.

In this study, a fast and highly reliable method allowing the unequivocal detection of catecholamines

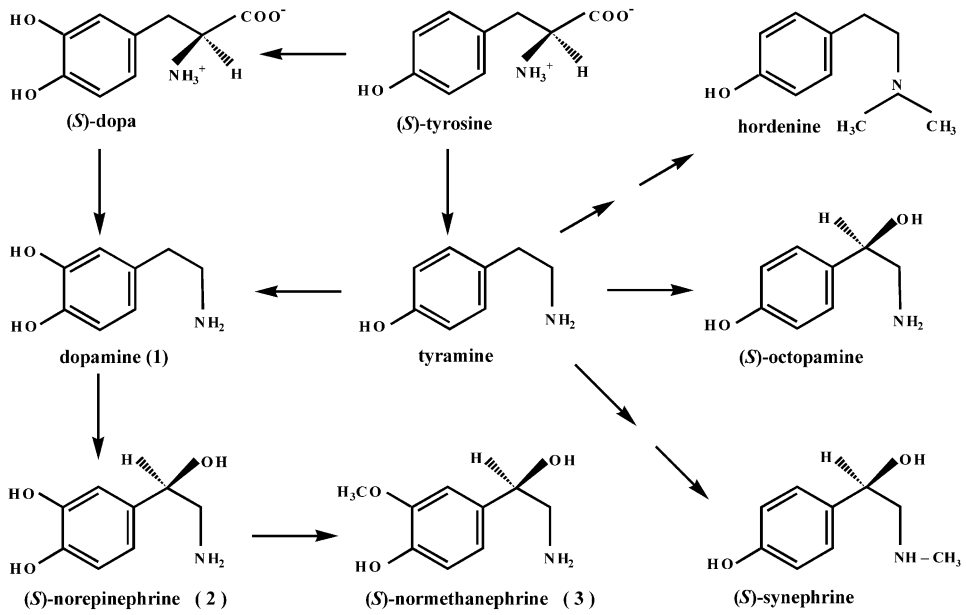

Fig. 1. The biosynthetic pathway of catecholamines in higher plants.

such as **1**, **2**, epinephrine, and their catabolites was developed based on gas chromatography coupled to mass spectrometry (GC–MS). In a second step, this method was applied using potato plants in a variety of physiological states to test whether or not the level of catecholamines correlates in some way with certain developmental, and/or environmental changes. Analysis of a variety of tissues from potato plants definitively revealed the presence of the catecholamines **1**, **2**, and normethanephrine (**3**). Furthermore, some of the data obtained suggest a physiological role of these catecholamines in plants.

2. Results and discussion

Gas chromatography coupled to mass spectrometry allows the quantitative and unequivocal identification of the catecholamines dopamine, norepinephrine, and normetanephrine in plant extracts.

In order to develop an easy and reliable assay for the qualitative and quantitative determination of catecholamines in plants, a sensitive GC–MS method based on the analysis of the trimethylsilylated catecholamine derivatives was developed to monitor the presence and concentration of these compounds and related metabolites. Based on the retention times and the mass spectra of standards, the presence of **1**–**3** of potato leaves was clearly detected (Figs. 2 and 3). The stereochemistry of the identified compounds has not been determined. However, epinephrine, the most prominent hormone of the catecholamine class in mammals, was not detectable. Although the possibility of its presence in the plant extracts analyzed cannot be excluded, epinephrine levels

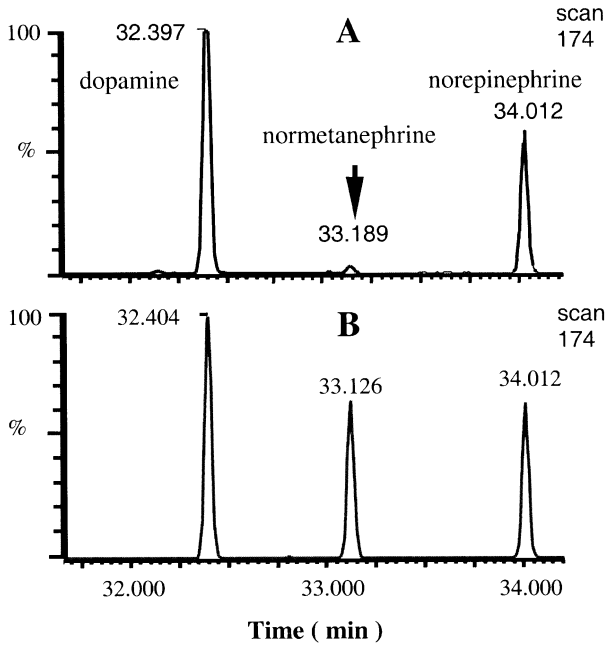

Fig. 2. Chromatographic resolution and single ion monitoring (*m*/*z* 174) of catecholamines in potato leaves. Only a part of chromatogram is shown. (A) potato leaves extract; (B) dopamine, normetanephrine and norepinephrine standards.

would be lower than 20 ng g^{-1} fresh weight as based on recovery and spiking experiments.

In addition, neither homovanillic acid nor vanillylmandelic acid catabolites of **1** and **2**/epinephrine, respectively, were detectable in the extracts analyzed, whereas both octopamine and tyramine, two further derivatives of tyrosine (Fig. 1) with signalling functions in animal systems (Osborne, 1996), were present at levels high enough to be easily identified (not shown). The

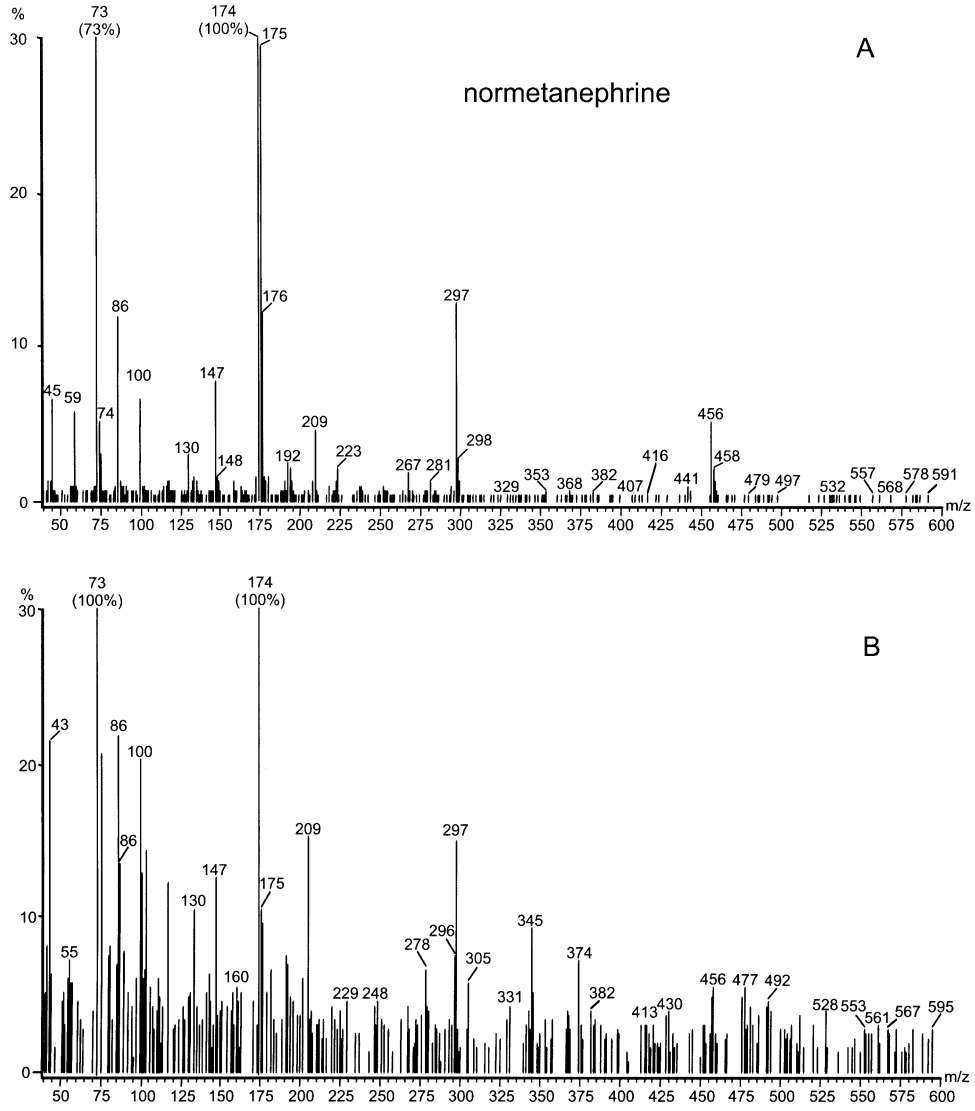

Fig. 3. Comparison of the mass spectra: (A) normetanephrine standard (Sigma); (B) compound from leaf.

catecholamine catabolites homovanillic acid and vanillylmandelic acid are either not present in potatoes or their amounts are below the detection limits.

The content of catecholamines differs significantly between different organs of potato and varies between leaves in different developmental stages.

In order to approach the question concerning possible physiological function of endogenous catecholamines, potato leaves in different developmental stages, tubers, and flowers were analyzed for their content of the various catecholamines.

As shown in Fig. 4, fully developed green leaves (third leaves) contain the highest amounts of catecholamines, whereas significantly lower amounts were found in younger, developing leaves and in older leaves. The contents determined ranged from 1.9–6.9 μg g^{-1} fresh weight for **1**, 2.5–8.4 μg g^{-1} fresh weight for **2**, and 0.2–0.7 μg g^{-1} fresh weight for **3**.

A 10-fold lower amount of **1** and **2** was found for both developing tubers and flowers (Fig. 5). Neither epinephrine nor the catabolites homovanillic acid or vanillylmandelic acid were detected in flower or tuber extracts.

Wounding of leaves consistently leads to a rapid but small increase in norepinephrine.

In mammalian systems, catecholamines serve as stress hormones, displaying a rapid transient increase as a result of stress. In order to see whether or not a similar response occurs in plants, leaves of several plants were wounded and the catecholamine levels prior to and 5, 10 and 30 min after wounding were determined.

Data obtained from three independent experiments are summarized in Fig. 6. Although the data vary, there is a consistent trend towards increasing levels of the three catecholamines analyzed, this is best seen in case of **2**. Potato leaf wounding leads to increase in catecholamine

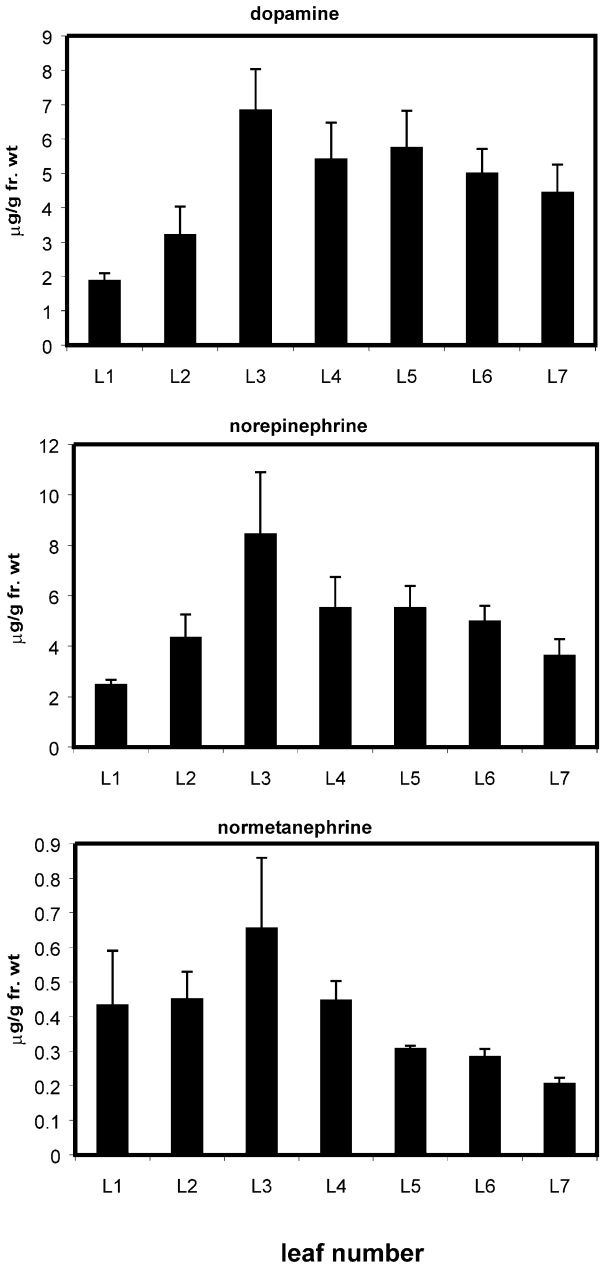

Fig. 4. Catecholamine levels in different leaves of potato plants. L1, 1st leaf from the top of the plant.

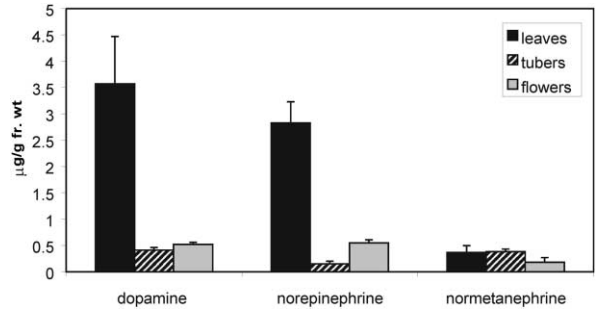

Fig. 5. Catecholamine contents in leaves (average value), tubers, and flowers of potato plant.

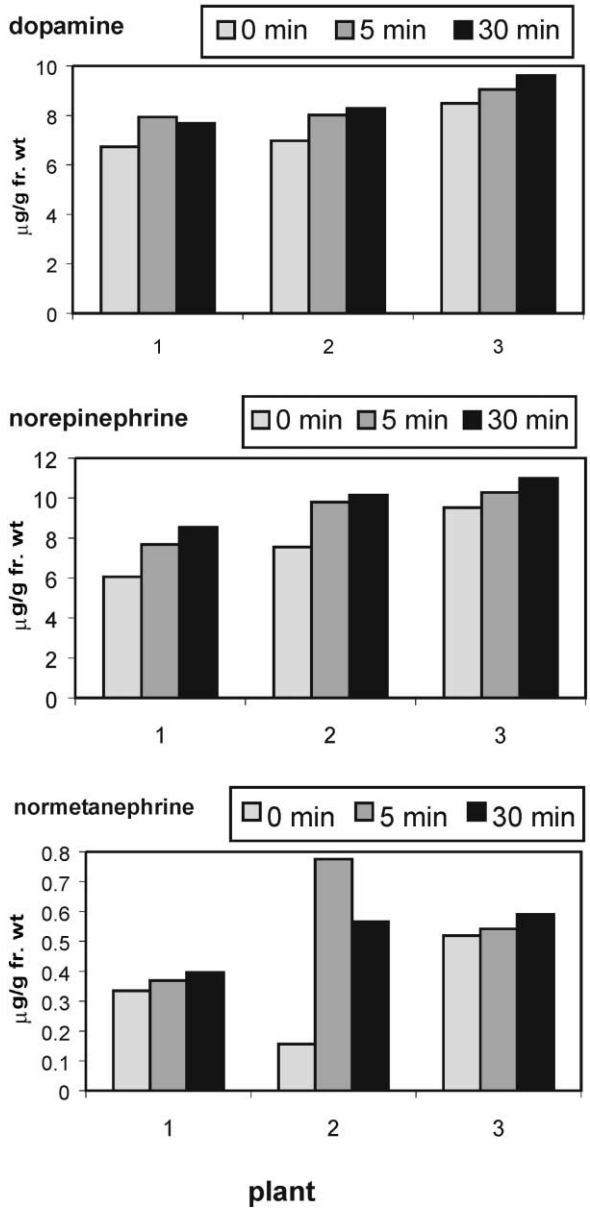

Fig. 6. The effect of leaf wounding on catecholamine levels.

levels. Tyr-dopa decarboxylase is the first key enzyme on the plant catecholamines biosynthesis pathway. Recently the involvement of this enzyme was implicated in plant wounding responses (Park et al., 1999). This observation together with our results may lead to the conclusion that catecholamines or their metabolites may be involved in stress responses.

Storage of tubers at 4 °C leads to decreases in dopamine, norepinephrine, and normetanephrine.

Potato tubers stored at 4 °C react to the low temperature by increasing their solute contents and respiration through starch degradation (Hill et al., 1996). Since one of the best understood examples of the hormonal action of epinephrine and norepinephrine in mammals is the degradation of glycogen, we decided to analyze tubers

undergoing starch degradation for the content of catecholamines.

The data summarized in Fig. 7 show the decrease in **1**–**3** with the time of cold storage, after two months to undetectable levels. Surprisingly, potato tubers when stored at room temperature for the same period of time show almost no decrease in the content of all three catecholamines. The potential correlations between carbohydrate synthesis and metabolism with catecholamine levels remain to be investigated.

3. Experimental

3.1. Plant material

Potato plants (*Solanum tuberosum* L. cv. Desiree) were obtained from Saatzucht Fritz Lange KG (Bad Schwartau, Germany). Plants were cultivated in a greenhouse in soil under a 16 h light (22 °C)/8 h dark (15°C) regime. Plants were grown in individual pots and were watered daily. Leaves were harvested from plants 50 days old. Potato leaves were wounded mechanically. The samples were taken at three time points after 0, 5 and 30 min after wounding. Tubers were harvested three months after transfer of the plants grown in tissue culture to the greenhouse. Tubers were stored than at 4 °C or at room temperature (25 °C) prior to experiments.

3.2. Tissue extraction, derivatization and GC–MS quantification

For GC–MS analysis, frozen plant tissue was powdered in liquid N_2, extracted with MeOH (4 ml g^{-1} fr. wt.), heated for 15 min at 70 °C and centrifuged (5 min, 12,000 *g*). Samples were diluted with H_2O to 50% methanol concentration and extracted with $CHCl_3$ (1:1 v/v). Portion of water phase was dried under vacuum and used for derivatisation. Ribitol was used as an internal standard added directly to the sample homogenate (30 μg g^{-1} fr. wt.).

To the dried extracts, 100 μl methoxyamine hydrochloride (20 mg ml^{-1}) was added and incubated for 90 min at 37 °C. Afterwards, the samples were derivatised with 100 μl *N*-methyl-*N*-trimethylsilyltrifluoroacetamide at 37 °C for 90 min (2 μl of sample was used for analysis). A gas chromatograph GC8000 and AS2000 autosampler (all ThermoQuest, Manchester, UK) combined with a Fisson quadrupole mass spectrophotometer (Voyager), equipped with SPB 50 (Supelco, Bellefonte, CA) fused silica capillary column (30 m×0.25 mm, film thickness 0.25 μm), was used. Dopamine, norepinephrine, and normetanephrine (Sigma) were used as standards. The recovery samples were spiked with dopamine, norepinephrine, and normetanephrine and estimated recoveries were 80, 93 and 85%, respectively. For the quantification (MassLab software-ThermoQuest, Manchester, UK) of catecholamines the corresponding calibration curves ranging from 10 to 1500 ng were used. The following ions were used for quantification: ribitol *m*/*z* 307; 319, dopamine *m*/*z* 174; 426, norepinephrine *m*/*z* 174; 355, normetanephrine *m*/*z* 174; 297. The amounts of catecholamines were determined from the ratio of peak areas of catecholamines to peak area of internal standard (ribitol) and plotted against the amounts ratios using the calibration curves. The curves were fitted by linear regression. The instrument settings were done as recently described (Roessner et al., 2000). The results are the average of three determinations, with S.D. represented by the bars above the graph except for Fig. 6 where the three independent experiments are shown.

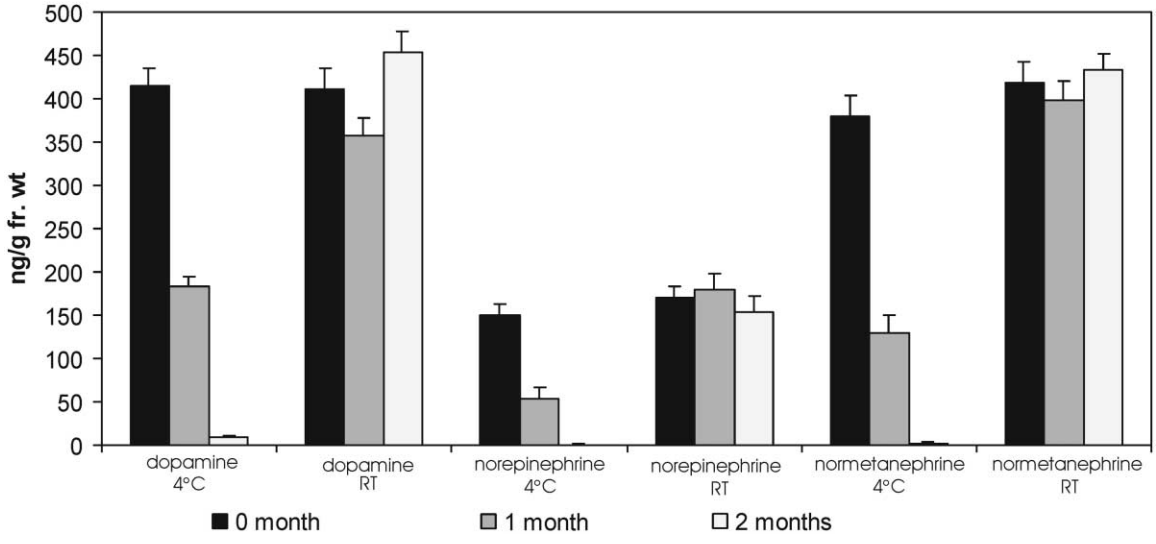

Fig. 7. Catecholamine levels in tubers stored at 4 °C and room temperature for different periods of time.

Acknowledgements

The authors wish to thank C. Wagner and K. Bieberich for help with the GC–MS analysis and M. McKenzie and A. Fernie for linguistic advice. This study was financed by grant 6P04A 02018 from KBN and partially Max Planck Gesellschaft, G.W. was supported by a Max Planck Fellowship.

A flavonol glycoside-lignan ester and accompanying acylated glucosides from *Monochaetum multiflorum*

Jose H. Isaza, Hideyuki Ito, Takashi Yoshida*

Faculty of Pharmaceutical Sciences, Okayama University, Tsushima, Okayama 700-8530, Japan

Received 23 January 2001; received in revised form 12 April 2001

Abstract

Four acylated glycosides along with six known glycosides were isolated from the leaves of *Monochaetum multiflorum*. The new compounds were characterized as 4-*O*-(6′-*O*-galloyl-β-glucopyranosyl)-*cis*-*p*-coumaric acid, 6′-*O*-galloylprunasin, benzyl 6′-*O*-galloyl-β-glucopyranoside, and a novel diester of tetrahydroxy-μ-truxinic acid with 2 mol of hyperin (monochaetin), based on NMR and MS spectral data and chemical evidence. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Monochaetum multiflorum*; Melastomataceae; Galloylglucoside; Galloylprunasin; Di-hyperin ester of tetrahydroxy-μ-truxinic acid

1. Introduction

As part of a phytochemical study on Colombian melastomataceous plants, we previously reported the isolation and structural elucidation of new oligomeric hydrolyzable tannins, nobotanins O and P, along with known ellagitannins characteristic of this family, from *Tibouchina multiflorum* (Yoshida et al., 1999). Chromatographic analysis by HPLC suggested that *Monochaetum multiflorum* (Bompl.) Naudin, a shrub endemic to Colombia, is also rich in polyphenols. The aerial part of the plant has been traditionally used as a topical treatment for infections and skin injuries in parts of Colombia. However, its chemical constituents have been little investigated. Here, we report the isolation and characterization of ten compounds (**1**–**10**), including four new acylated glycosides (**7**–**10**) from the leaves of *M. multiflorum*; one of these is a novel flavonol glycoside diester of a lignan possessing a cyclobutane ring.

2. Results and discussion

Dried leaves of *M. multiflorum* were extracted with aqueous acetone. The concentrated solution was subjected to extraction successively with Et_2O, EtOAc and *n*-BuOH. The EtOAc extract was submitted to column chromatography over Toyopearl HW-40, followed by gel chromatography on MCI gel CHP-20P and preparative HPLC to yield 10 glycosidic compounds (**1**–**10**). Six among them were identified as trifolin (**1**) (Barbera et al., 1986), hyperin (**2**) (Bennini et al., 1992), quercetin 3-(6′-*O*-caffeoyl)-β-D-galactoside (**3**) (Shigematsu et al., 1982), isoquercitrin (**4**), quercetin 3-(6′-*O*-caffeoyl)-β-D-glucopyranoside (**5**) (Lin and Wang, 1987) and 4-*O*-β-D-glucopyranosyl-2-*O*-methylphloroacetophenone (**6**) (Konda et al., 1991) by spectroscopic means and comparison with reference samples or reported data.

Compound **7**, $[\alpha]_D$ −14.3°, was obtained as an amorphous powder. The molecular formula, $C_{22}H_{22}O_{12}$, was established by HRESIMS. The ^1H NMR spectrum indicated the presence of a galloyl group (δ 7.13, 2H, *s*), a 1,4-disubstituted benzene ring (δ 7.04, 7.71, each 2H, *d*, $J=8.5$ Hz), vinyl protons (δ 5.83, 6.84, each 1H, *d*, $J=12.5$ Hz), and signals characteristic of a $^4C_1$-glucopyranosyl residue. The coupling constant of the signal at δ 5.03 (*d*, $J=7.5$ Hz) assignable to an anomeric proton of the glucose indicated a β-configuration for the glucosidic linkage. These spectral features as well as two carboxyl carbon signals at δ 166.9 and 167.9 in the ^{13}C NMR spectrum indicated that **7** is a galloyl ester of 4-*O*-β-glucopyranosyl-*cis*-*p*-coumaric acid. The NOESY spectrum of **7** verified this structure, with NOE correlations in a sequence of the signals of δ 5.83↔δ 6.84↔δ

7.71↔δ 7.04↔δ 5.03 as shown in formula (**7**). The location of the galloyl unit at O-6 of the glucopyranose core was evident from low-field shifts of the H-6′ signals (δ 4.63, 4.28). Furthermore, the galloylglucose carbon signals observed in the ^{13}C NMR spectrum of **7** were almost superimposable on those reported for 6-*O*-galloylglucose (Nonaka and Nishioka, 1983) except for a large downfield shift for the anomeric carbon. Based on these data, compound **7** was identified as 4-*O*-(6′-*O*-galloyl-β-glucopyranosyl)-*cis*-*p*-coumaric acid, which is a new compound though 4-*O*-β-glucopyranosyl-*cis*-*p*-coumaric acid has been described in the literature (Lemmich, 1995).

Compound **8**, $[\alpha]_D$ −17.0°, was obtained as an amorphous powder. Its ESIMS showed an $[M+NH_4]^+$ peak at *m*/*z* 465 and the molecular formula was determined as $C_{21}H_{21}NO_{10}$ by HRESIMS. The ^{1}H NMR spectrum of **8** showed signals ascribable to a galloyl (δ 7.17, 2H, *s*), a monosubstituted benzene ring (δ 7.53, 2H, *dd*, *J*=2, 7.5 Hz; 7.41–7.44, 3H, *m*) and a sugar residue. A methine proton was also observed as a singlet at δ 5.82. The presence of a 6-*O*-galloylated $^4C_1$-glucopyranose residue was suggested by the ^{13}C NMR spectrum which showed sugar signals similar to those of **7**, although the chemical shift of an anomeric proton signal (δ 4.40) in **8** markedly differed from that in **7** (δ 5.03). Based on these spectral characteristics along with the signal at δ 118.8 assignable to a nitrile carbon, compound **8** was assumed to be 6′-*O*-gallate of prunasin (Seigler, 1975) or its (2*S*) isomer, sambunigrin (Jensen and Nielsen, 1973), which was substantiated by correlations in HMBC and NOESY as shown in the formula. The configuration at C-2 was confirmed to be *R* by production of prunasin, $[\alpha]_D$ −26.0°, along with gallic acid upon enzymatic hydrolysis of **8** with tannase. The difference in the chemical shifts of the anomeric protons in **7** and **8** can be explained by an anisotropic effect of the benzene ring directly attached to the glucose in **7**.

Compound **9**, $[\alpha]_D$ −29.4°, had the molecular formula $C_{20}H_{22}O_{10}$ as revealed by HRESIMS. The ^{1}H and ^{13}C NMR spectra of **9** closely resembled those of **8** except for the presence of a methylene group [δ_H 4.61, 4.82 (each *d*, *J*=12 Hz); δ_C 70.9] instead of the cyano group at the benzyl position in **8**. Both methylene protons disclosed clear NOEs with an anomeric proton. There-

fore, compound **9** was characterized as benzyl 6′-*O*-galloyl-β-glucopyranoside.

Compound **10**, $[\alpha]_D$ −25.0°, obtained as a yellow amorphous powder, had the UV absorption characteristic of a flavonol skeleton (λ_{max} 358, 286 *sh*, 267 *sh*, 258 nm). A characteristic feature on normal phase HPLC was the longer retention time than for the flavonoid glycosides **1**–**5**, suggesting a larger molecular size than the ordinary flavonoid. Its ESIMS exhibited an $[M+H]^+$ peak at *m*/*z* 1253 and the molecular formula was established as $C_{60}H_{52}O_{30}$ by HRESIMS. Although the ^1H and ^{13}C NMR spectra of **10** were complicated because most signals appeared in pairs having close chemical shifts and some were overlapped, full assignment of the signals was achieved by means of ^1H-^1H COSY, TOCSY, ^1H *J*-resolved and HMQC spectroscopy at an elevated temperature (50 °C) in DMSO-d_6. These ^1H and ^{13}C NMR (Table 1) spectra included pairs of signals similar to those of quercetin 3-*O*-galactoside (hyperin **2**), suggesting that **10** contains two hyperin moieties. This was also substantiated by MS fragmentation showing a successive loss of quercetin (Q) (*m*/*z* 951 $[M+H–Q]^+$, 645 $[M+H–2Q]^+$) as well as a base peak at *m*/*z* 303 $[Q+H]^+$. Large downfield shifts of the galactose C-6 methylene protons relative to the corresponding signals of **2** (δ 3.28 for **2**→δ 3.52, 3.62 for **10**; δ 3.45 for **2**→δ 3.71, 3.84 for **10**) indicated that both galactose cores are acylated at *O*-6. The presence of a di-(3,4-dihydroxyphenyl)cyclobutane dicarboxyl moiety (lignan) as an acyl unit in the molecule was indicated by the following observations. (1) The ^1H NMR spectrum showed two ABX-type aromatic proton signals and an AA′BB′ system of methine proton signals [each ddd, $J=10.5$ Hz (*cis*), $J=7.0$ Hz (*trans*), $J=2.0$ Hz (long range)], which is characteristic of tetrasubstituted cyclo butane protons (Montaudo and Caccamese, 1973). (2) In the ^{13}C NMR spectrum, signals due to an acyl moiety, $C_{18}H_{14}O_6$, were observed as nine paired-varieties with close proximity, among which seven partly overlapping pairs are of sp^2 carbons including ester carbonyl carbons (δ 171.0, 171.2) and two pairs are of sp^3 carbons (δ 40.1, 40.4; 46.1, 46.3). These carbon signals were assignable to those of a cyclobutane ring possessing two 3,4-dihydroxyphenyl and two ester substituents by HMQC and DEPT. Based on these data, the acyl unit in **10** was deduced to be either μ-truxinyl-type ([7.7′, 8.8′]-lignan) or α-truxillyl-type ([7.8′, 8.7′]-lignan) (Ben-Efraim and Green, 1974), the former being preferred because of the close similarity of chemical shifts and coupling patterns of the cyclobutyl protons to those reported for μ-truxinic acid (**12**) (or its enantiomer) rather than α-truxillic acid (**13**) (Ben-Efraim and Green, 1974). The proposed lignan structure in **10** was substantiated by the HMBC spectrum (Table 2), which revealed three-bond correlations among most of the protons and carbons including those between the proton [H-7 (H-7′)] on the phenyl bearing-carbon and the carboxyl-bearing carbons [C-8′ (8)] (Table 2). The HMBC spectrum also showed correlations of the carboxyl carbons with the C-6 methylene protons of both galactoses. The configuration of the substituents on the cyclobutane ring was established by the NOESY spectrum which showed clear NOE correlations among H-2(6)/H-6′ (2′) and H-2 (2′)/H-7′ (H-7), which are only possible in a μ-truxinate arrangement. These correlations revealed the preferred eclipsed conformation between H-7 and H-6, and between H-7′ and H-6′, which was consistent with the minimal steric energy model calculated by MM2. A similar feature was reported for the μ-truxinic acid moiety of sargerinic acid (Lu and Foo, 1999).

[b] Interchangeable.

Acid hydrolysis of a methylated derivative of **10** followed by remethylation yielded an optically inactive methyl ester (**11**) and penta-*O*-methylquercetin. The ^1H NMR spectral data for **11** were as expected for a symmetrical structure, and included a single carbomethoxyl signal at δ 3.37, shifted upfield by the shielding effect of the *cis*-β-phenyl group (Ben-Efraim and Green, 1974). Based on these data, the structure (**10**) for monochaetin was established as shown in the formula.

Monochaetin is most plausibly formed from **3** via a [2+2] photochemical addition process. Dimeric products having a cyclobutane ring produced from various phenylpropanoid acids have been reported (Atta-ur-Rahman et al., 1998; Lu and Foo, 1999; Seidel et al.,

2000; Sudo et al., 2000; Wang et al., 2000). However, only a few diflavonoid esters of dicarboxylic acid are known (Itokawa et al., 1981; Horie et al., 1986). More notably, only stachysetin isolated from *Stachys aegyptiaca* (Labiatae) was reported as a flavone glycoside truxinate ester (El-Ansari et al., 1995). Monochaetin is thus the second analogue of such a flavonoid cyclodimer in the μ-truxinate form.

3. Experimental

3.1. General

^1H (500 MHz) and ^{13}C (126 MHz) NMR spectra were recorded on a Varian VXR-500 spectrometer. ESI–MS was performed with a Micromass Auto Spec OA–Tof mass spectrometer using 0.1% NH_4OAc in 50% MeOH as solvent, at a flow rate of 0.02 ml min^{-1}. Optical rotations were conducted on a JASCO DIP-1000 polarimeter. Normal phase (NP) HPLC was performed on a YMC Pack Sil A-003 column (5 μm, 4.6 mm i.d. × 250 mm), flow rate 1.5 ml min^{-1}, detected with UV 280 nm. Mobile phases: (NP-1) *n*-hexane–MeOH–THF–HCOOH (55:33:11:1) containing oxalic acid (450 mg l^{-1}), (NP-2) *n*-hexane–MeOH–THF–HCOOH (60:45:15:1) containing oxalic acid (500 mg 1.2 l^{-1}) and (NP-3) *n*-hexane–MeOH–THF–HCOOH (47:39:13:1) containing oxalic acid (450 mg l^{-1}). Analytical reversed-phase HPLC was performed on a J'sphere ODS M-80 column (4.6 mm i.d. × 250 mm), flow rate 1.0 ml min^{-1}, 40 °C, detector UV 280 nm; Mobile phases: (RP-1) 0.01 M H_3PO_4–0.01 M KH_2PO_4–EtOH–EtOAc (42.5:42.5:10:5) and (RP-2) 0.01 M H_3PO_4–0.01 M KH_2PO_4–MeCN (42.5:42.5:15). Preparative HPLC was carried out on a J'sphere ODS M-80 column (10 mm i.d. × 250 mm, 4 μm, 80 Å,), detector MCPD 240–400 nm, flow rate 3.0 ml min^{-1}, 40 °C, mobile phase RP-2.

3.2. Plant material

The leaves of *Monochaetum multiflorum* were collected near Manizales City, Caldas, Colombia and identified by Dr. Gustavo Lozano C. A voucher specimen was deposited at Herbario Nacional de Colombia (COL) (voucher No. 361696).

3.3. Extraction and isolation

Dried leaves (400 g) of *M. multiflorum* were homogenized in 70% aqueous acetone, filtered and concentrated in vacuo. The concentrated solution was subjected to liquid-liquid partition to give Et_2O (4.6 g), EtOAc (13.4 g), *n*-BuOH (33.8 g) extracts and aqueous residue (54.3 g). The EtOAc extract (10.2 g) was fractionated on a Toyopearl HW-40 (coarse grade) column (2.2 cm i.d. × 45 cm) with aq. MeOH and a mixture of acetone–MeOH–H_2O in a step-wise gradient mode to produce four fractions, (A) 40% MeOH (3.9 g), (B) 70% MeOH (2.2 g), (C) acetone–MeOH–H_2O (2:5:3) (3.4 g) and (D) acetone–H_2O (7:3) (0.7 g).

Fraction A (3.5 g) was applied to a Toyopearl HW-40 (coarse grade) column (2.2 cm i.d. × 45 cm), this being eluted with a step-wise water–MeOH gradient from 20 to 70% MeOH (CC-1-1). Fractions showing similar HPLC patterns were pooled and further purified on a YMC ODS AQ120 S-50 column (1.1 cm i.d. × 45 cm), eluting with a binary step-wise gradient from water to MeOH. In this way, fractions (281 mg) eluted with 20% MeOH yielded **6** (36 mg) and the 25% MeOH eluate (105 mg) gave **7** (9.0 mg), **8** (21 mg), and **9** (10 mg). The 30% eluate afforded 1 g of a mixture of **1**, **2** and **4**, from which 50 mg was subjected to preparative HPLC (RP-2) to give **1** (2.5 mg), **2** (23 mg) and **4** (15 mg). The 40–50% MeOH eluate yielded 428 mg of a mixture, which after purification with a combination of MCI gel CHP-20P,

YMC ODS and preparative HPLC (RP-2) gave **1** (0.5 mg), **2** (7 mg), **4** (5.0 mg) and **10** (9.0 mg).

Fraction B (2.0 g) from CC-1, (70% MeOH fraction) was separated on a Toyopearl HW-40C (CC-1-2) eluted with a binary step-wise gradient of MeOH (20–70%) collecting each 5 ml fraction. Fractions 351–460 (380 mg) (Fr. B-1) and 501–530 (91.6 mg) (Fr. B-2) eluted with 40% MeOH were further independently purified on an MCI-gel CHP-20P (1.1 cm i.d. × 45 cm) chromatographic column eluted with a step-wise gradient of EtOH (5 → 60%). Fraction B-1 yielded **1** (0.2 mg), **2** (14 mg), **5** (12 mg) and **10** (59 mg) when eluted with 30% EtOH. Fraction B-2 afforded a mixture (29 mg) of **3** and **5**, when eluted with 30% EtOH. Final purification was performed by preparative RP-HPLC as described above to obtain **3** (7 mg) and **5** (10 mg).

3.4. Quercetin 3-(6″-O-trans-caffeoyl)-β-D-galactopyranoside (3)

A yellow powder, UV λ_{max} MeOH nm (log ε): 366 *sh* (4.15), 335 (4.32), 301 (4.20), 267.0 *sh* (4.24), 253.5 (4.32); MeOH + $AlCl_3$: 440 (426), 354.5 (4.21), 303 *sh* (4.09), 2.74.5 (4.37); MeOH + $AlCl_3$ + HCl: 405 (4.11), 333.0 (4.25), 302 *sh* (4.20), 271.5 (4.35). ESIMS *m/z*: 627 $[M+H]^+$. ^{1}H NMR (DMSO-d_6): δ 12.61 (1H, *s*, 5-OH), 7.65 (1H, *dd*, *J* = 1.5, 8.5 Hz, H-6′), 7.50 (1H, *d*, *J* = 1.5 Hz, H-2′), 6.80 (1H, *d*, *J* = 8.5 Hz, H-5′), 6.36 (1H, *d*, *J* = 1.5 Hz, H-8), 6.15 (1H, *d*, *J* = 1.5 Hz, H-6) (quercetin moiety), 5.39 (1H, *d*, *J* = 8 Hz, H-1″), 4.10 (1H, *dd*, *J* = 4.5, 11.5 Hz, H-6″), 4.04 (1H, *dd*, *J* = 7.5, 11.5 Hz, H-6″), 3.67 (1H, *m*, H-5″), 3.66 (1H, *d*, *J* = 3 Hz, H-4″), 3.56 (1H, *br t*, *J* = 8.5 Hz, H-2″), 3.42 (1H, *dd*, *J* = 3, 10 Hz, H-3″) (galactose moiety), 7.30 (1H, *d*, *J* = 16 Hz, H-7‴), 6.96 (1H, *br s*, H-2‴), 6.81 (1H, *d*, *J* = 8 Hz, H-5‴), 6.74 (1H, *br d*, *J* = 8 Hz, H-6‴), 6.04 (1H, *d*, *J* = 16 Hz, H-8‴) (caffeoyl moiety).

3.5. 4-O-(6′-O-Galloyl-β-D-glucopyranosyl)-cis-p-coumaric acid (7)

A white amorphous powder, $[\alpha]_D$ −14.3° (*c* 1.1, MeOH). UV λ_{max} MeOH nm (log ε): 269 (3.49). ESIMS *m/z*: 501 $[M+Na]^+$. HRESIMS *m/z*: 501.0992 $[M+Na]^+$, calc. for $C_{22}H_{22}O_{12}$ + Na, *m/z* 501.1009. ^{1}H NMR (Me_2CO-d_6 + D_2O): δ 7.71 (2H, *d*, *J* = 8.5 Hz, H-2, 6), 7.13 (2H, *s*, H-2″, 6″), 7.04 (2H, *d*, *J* = 8.5 Hz, H-3, 5), 6.84 (1H, *d*, *J* = 12.5 Hz, H-7), 5.83 (1H, *d*, *J* = 12.5 Hz, H-8), 5.03 (1H, *d*, *J* = 7.5 Hz, glucose (glc) H-1′), 3.49–3.57 (3H, overlapped with HDO, glc H-2′–4′), 4.63 (1H, *dd*, *J* = 2, 12 Hz, glc H-6′), 4.28 (1H, *dd*, *J* = 8, 12 Hz, glc H-6′). ^{13}C NMR (Me_2CO-d_6 + D_2O): δ 167.9 (C-9), 166.9 (C-7″), 159.2 (C-4), 146.0 (2C, C-3″, 5″), 142.9 (C-7), 138.8 (C-4″), 132.9 (2C, C-2, 6), 129.9 (C-1), 121.5 (C-1″), 118.7 (C-8), 116.6 (2C, C-3, 5), 109.9 (2C, C-2″, 6″), 101.5 (glc C-1′), 77.7 (glc C-3′), 75.1 (glc C-5′), 74.5 (glc C-2′), 71.1 (glc C-4′), 64.5 (glc C-6′).

3.6. 6′-O-Galloylprunasin (8)

A white amorphous powder, $[\alpha]_D$ −17.0° (*c* 1.9, MeOH). UV λ_{max} MeOH nm (log ε): 269 (2.8), 351 (2.4). ESIMS *m/z*: 465 $[M+NH_4]^+$. HRESIMS *m/z*: 465.1487 $[M+NH_4]^+$, calc. for $C_{21}H_{21}NO_{10}$ + NH_4, *m/z* 465.1509. ^{1}H NMR (Me_2CO-d_6 + D_2O): δ 7.53 (2H, *dd* *J* = 2, 7.5 Hz, H-4, 8), 7.41–7.44 (3H, *m*, H-5–7), 7.17 (2H, *s*, H-2″, 6″), 5.82 (1H, *s*, H-2), 4.59 (1H, *dd*, *J* = 2, 12 Hz glc H-6′), 4.40 (1H, *d*, *J* = 7.5 Hz, glc H-1′), 4.36 (1H, *dd*, *J* = 6, 12 Hz, glc H-6′), 3.57 (1H, *ddd*, *J* = 2, 6, 10 Hz, glc H-5′), 3.48 (1H, *t*, *J* = 10 Hz, glc H-4′), 3.39 (1H, *t*, *J* = 9 Hz, glc H-3′), 3.36 (1H, *dd*, *J* = 7.5, 9 Hz, glc H-2′). ^{13}C NMR (Me_2CO-d_6 + D_2O): δ 167.1 (C-7″), 146.0 (2C, C-3″, 5″), 138.9 (C-4″), 134.4 (C-3), 130.5 (C-6), 129.8 (2C, C-5, 7), 128.5 (2C, C-4, 8), 121.4 (C-1″), 118.8 (C-1), 109.8 (2C, C-2″, 6″), 101.9 (glc C-1′), 77.4 (glc C-3′), 75.3 (glc C-5′), 74. 2 (glc C-2′), 70.8 (glc C-4′), 68.2 (C-2), 64.3 (glc C-6′).

3.7. Enzymatic hydrolysis of 8

An aqueous solution of **8** (4.1 mg ml^{-1}) was incubated at 37 °C with tannase prepared from *Aspergillus niger* (Yoshida et al., 1989), and the progress of the reaction was followed by HPLC (RP-2) until the starting material disappeared. After 18 h, prunasin and gallic acid were detected. Prunasin was isolated by preparative HPLC (RP-2) and identified by co-chromatography with an authentic sample, and by comparing its optical rotation and ^{1}H NMR spectrum with those reported in the literature.

Prunasin: $[\alpha]_D$ −26.0° (*c* 0.5, MeOH) Lit. $[\alpha]_D$ −30.1° (Seigler, 1975). ^{1}H NMR (Me_2CO-d_6 + D_2O): δ 7.60 (2H, *dd*, *J* = 1, 8 Hz, H-4, 8), 7.45–7.49 (3H, *m*, H-5-7), 5.95 (1H, *s*, H-2), 4.38 (1H, *d*, *J* = 7.5 Hz, glc H-1′), 3.86 (1H, *dd*, *J* = 2.5, 12 Hz, glc H-6′), 3.66 (1H, *dd*, *J* = 6, 12 Hz, glc H-6′), 3.27–3.33 (4H, *m*, glc H-2′-5′).

3.8. Benzyl 6′-O-galloyl-β-D-glucopyranoside (9)

A white amorphous powder, $[\alpha]_D$ −29.4° (*c* 1.7, MeOH). UV λ_{max} MeOH nm (log ε): 272 (3.68). ESIMS *m/z*: 440 $[M+NH_4]^+$. HRESIMS *m/z*: 440.1555 $[M+NH_4]^+$, calc. for $C_{20}H_{22}O_{10}$ + NH_4, *m/z* 440.1557. ^{1}H NMR (Me_2CO-d_6 + D_2O): δ 7.36 (2H, *dd*, *J* = 1.5, 8.5 Hz, H-2, 6), 7.28 (2H, *ddd*, *J* = 1.5, 7.0, 8.5 Hz, H-3, 5), 7.24 (1H, *dt*, *J* = 1.5, 7 Hz, H-4), 7.16 (2H, *s*, galloyl), 4.82, 4.61 (each 1H, *d*, *J* = 12 Hz, H-7), 4.57 [1H, *dd*, *J* = 2, 12 Hz, glc H-6′], 4.40 (1H, *d*, *J* = 8 Hz, glc H-1′), 4.37 (1H, *dd*, *J* = 6, 12 Hz, glc H-6′), 3.29 (1H, *dd*, *J* = 8, 9 Hz, glc H-2′), 3.42 (1H, *t*, *J* = 9 Hz, glc H-3′), 3.44 (1H, *t*, *J* = 9 Hz, glc H-4′), 3.58 (1H, *ddd*, *J* = 2, 6, 9 Hz, glc H-5′). ^{13}C NMR (Me_2CO-d_6 + D_2O) : δ 167.0 (C-7″), 146.0 (2C, C-3″, 5″), 138.9 (C-1), 138.8 (C-4″), 128.9 (2C, C-3, 5), 128.7 (2C, C-2, 6), 128.2 (C-4), 121.6 (C-

1″), 109.8 (2C, C-2″, 6″), 102.9 (glc C-1′), 77.0 (glc C-3′), 75.0 (glc C-5′), 74.7 (glc C-2′), 71.2 (glc C-4′), 70.9 (C-7), 64.5 (glc C-6′).

3.9. Monochaetin (**10**)

A yellow amorphous powder, $[\alpha]_D$ +25.0° (*c* 1.0, MeOH). UV λ_{max} MeOH nm (log ε): 358 (4.61), 286 *sh* (4.46), 267 *sh* (4.67), 258 (4.71); MeOH + $AlCl_3$: 430 (471), 339 *sh* (4.21), 298 *sh* (4.50), 275 (4.84); MeOH + $AlCl_3$ + HCl: 402 (4.59), 367 *sh* (4.50), 198 *sh* (4.38), 271 (4.78); MeOH + AcONa: 273.0 (4.79), 321.0 (4.46), 394.8 (4.57); MeOH + AcONa + H_3BO_3: 260.5 (4.79), 291.5 (4.51), 377.7 (4.62). ESIMS *m/z*: 1253 $[M+H]^+$, 951 $[M+H\text{-quercetin (Q)}]^+$, 645 $[M+H\text{-2Q}]^+$, 303 $[Q+H]^+$. HRESIMS *m/z*: 1253.2689 $[M+H]^+$, calc. for $C_{60}H_{52}O_{30}+H$, *m/z* 1253.2622. ^{1}H NMR (DMSO-d_6, 50 °C): δ 12.56 (2H, *s*, 5-OH), 6.19, 6.20 (1H each, *d*, *J* = 2.0 Hz, H-6), 6.35, 6.37 (1H each, *d*, *J* = 2.0 Hz, H-8), 7.51, 7.52 (1H each, *d*, *J* = 2 Hz, H-2′), 6.79, 6.81 (1H each, *d*, *J* = 8.5 Hz, H-5′), 7.58, 7.59 (1H each, *dd*, *J* = 2, 8.5 Hz, H-6′) (quercetin moieties), 5.24, 5.26 (1H each, *d*, *J* = 7.5 Hz, H-1″), 3.52, 3.54 (1H each, *dd*, *J* = 7.5, 9.5 Hz, H-2″), 3.29, 3.32 (1H each, *dd*, *J* = 3, 9.5 Hz, H-3″), 3.40 (2H, *br d*, *J* = 3 Hz, H-4″), 3.11, 3.12 (1H each, *m*, H-5″), 3.52 (1H, dd, *J* = 5, 10.5 Hz, H-6″), 3.62 (1H, dd, *J* = 7, 11.5 Hz, H-6″), 3.84 (1H, dd, *J* = 6.5, 10.5 Hz, H-6″), 3.71 (1H, dd, *J* = 5, 11.5 Hz, H-6″) (galactose moieties), 6.52, 6.54 (1H each, *d*, *J* = 2.0 Hz, H-2, 2′), 6.56, 6.59 (1H each, *d*, *J* = 8.0 Hz, H-5, 5′), 6.25, 6.30 (1H each, *dd*, *J* = 2, 8 Hz, H-6, 6′), 3.87, 3.89 (1H each, *ddd*, *J* = 2, 7, 10.5 Hz, H-7, 7′), 3.46, 3.54 (1H each, *ddd*, *J* = 2, 7, 10.5 Hz, H-8, 8′) (μ-truxinoyl moiety). ^{13}C NMR (DMSO-d_6, 50 °C): see Tables 1 and 2.

3.10. Methylation and hydrolysis of monochaetin (**10**)

A solution of **10** (17.9 mg) in MeOH (0.5 ml) and trimethylsilyldiazomethane (2.0 M solution in hexane) (0.5 ml) was left standing for 1 h. The solvent was removed under an N_2 stream, and this process of methylation was repeated three times. The reaction mixture was directly hydrolyzed in 2.0 M HCl–MeOH for 2 h. After evaporation and remethylation, the residue was separated by preparative TLC [Si gel, benzene–acetone (2:1)] to yield compounds **11** (0.6 mg) and penta-*O*-methylquercetin (2.2 mg).

3.10.1. Dimethyl 3,3′,4,4′-tetramethoxy-μ-truxinate (**11**)

A white amorphous powder, $[\alpha]_D$ 0.0° (*c* 0.1, MeOH). UV λ_{max} EtOH nm (log ε): 230 (3.66), 280 (3.16). ESI–MS *m/z*: 445 $(M+H)^+$. ^{1}H NMR ($CDCl_3$): δ 6.81 (2H, *d*, *J* = 2.0 Hz, H-2, 2′), 6.83 (2H, *d*, *J* = 8.0 Hz, H-5, 5′), 6.86 (2H, *dd*, *J* = 2, 8 Hz, H-6, 6′), 4.38 (2H, *dd*, *J* = 7.5, 10.5 Hz, H-7, 7′), 3.90 (2H, *dd*, *J* = 7.5, 10.5 Hz, H-8, 8′), 3.37 (6H, *s*, 2 × CH_3OCO–), 3.87, 3.90 (6H each *s*, 4 × CH_3O–).

3.10.2. Penta-O-methylquercetin

^{1}H NMR ($CDCl_3$): δ 7.72 (1H, *d*, *J* = 2.0 Hz, H-2′), 7.70 (1H, *dd*, *J* = 2, 9, Hz, H-6′), 6.98 (1H, *d*, *J* = 9.0 Hz, H-5′), 6.51 (1H, *d*, *J* = 2.5 Hz, H-8), 6.35 (1H, *d*, *J* = 2.5 Hz, H-6), 3.97, 3.96, 3.96, 3.91, 3.88 (3H each, *s*, 5 × CH_3O–).

Received 11 January 2001; received in revised form 11 April 2001

Abstract

The aerial parts of *Halfordia kendack* (Rutaceae) have yielded the known alkaloid *trans*-erioaustralasine ({*rel*}-1-acetoxymethyl-4.8′-epoxy-3-(1′β,2′β-epoxy-3′β,4′α-*para*-menthyl-3′-yl)quinolin-2-one) together with four new alkaloids. The latter were characterised by spectroscopic methods as *trans*-deacetoxyerioaustralasine ({*rel*}-1-methyl-4.8′-epoxy-3-(1′β,2′β-epoxy-3′β,4′α-*para*-menthyl-3′-yl)quinolin-2-one), *trans*-deacetoxyerioaustralasine hydrate ({*rel*}-1-methyl-4.8′-epoxy-3-(1′α,2′α-dihydroxy-3′β,4′α-*para*-;menthyl-3′-yl)quinolin-2-one), *trans*-erioaustralasine hydrate ({*rel*}-1-acetoxymethyl-4.8′-epoxy-3-(1′α,2′α-dihydroxy-3′β,4′α-*para*-menthyl-3′-yl) quinolin-2-one) and *trans*-1-epi-deacetoxyerioaustralasine hydrate ({*rel*}-1-acetoxymethyl-4.8′-epoxy-3-(1′β,2′α-dihydroxy-3′β,4′α-*para*-menthyl-3′-yl)quinolin-2-one). © 2001 Elsevier Science Ltd. Keywords: *Halfordia kendack*; Rutaceae; 3-Monoterpenyl 2,4-dioxygenated quinoline alkaloids; *trans*-Erioaustralasine derivatives

1. Introduction

The small genus *Halfordia* F. Muell. (Rutaceae) is restricted in distribution to the rain forests of Australia, New Guinea and New Caledonia (Richards, 1991). Previous studies on two species, *H. kendack* (Mountr.) Guillaumin. and *H. scleroxyla* F. Muell., have led to the isolation of furoquinoline alkaloids typical of the Rutaceae together with more unusual 5-phenyloxazole alkaloids and a series of 3,4-dioxygenated furanocoumarins (Gray, 1983; Mester, 1983). While the Rutaceae are a rich source of coumarins, the latter are currently unique in the family because of the presence of C-3 and C-4 oxygenation.

We have now been able to re-examine *H. kendack* from material collected in Queensland, Australia. As well as re-isolating the previously reported halfordin we were able to obtain, as a major constituent, a new furanocoumarin possessing the very unusual 2,4-diketo A-ring (Sultana et al., 2000). In this paper we report on the investigation of the alkaloids of the same collection and the surprising isolation of a series of 3-monoterpenyl quinoline alkaloids.

2. Results and discussion

The ground aerial parts were extracted with hexane and then with chloroform. Vacuum chromatography followed by gel filtration and then column chromatography gave the previously reported coumarins from the hexane extract together with very small amounts of the two alkaloids **3** and **4**. Similar treatment of the chloroform extract yielded **1** and **2** as the major alkaloids together with a small amount of **5**. The major alkaloid (**1**) proved to be identical to *trans*-erioaustralasine which had previously been reported from *Eriostemon australasius* var. *banksii* (Da Cunha et al., 1993). The ^{1}H and ^{13}C NMR data obtained are recorded in Tables 1 and 2 and are reproduced here to allow comparison with data obtained for the other, novel, alkaloids. The second major alkaloid gave spectral data very similar to that of **1** but lacked the *N*-acetoxymethyl substituent which was replaced by resonances for an *N*-methyl

group (Tables 1 and 2). Consequently this new alkaloid must be *trans*-deacetoxyerioaustralasine (**2**).

The minor alkaloid **3** revealed a M^+ 18 daltons more than **1** and **2** suggesting the addition of the elements of water (supported by a band at 3370 cm^{-1} in the IR spectrum). The loss of the resonance for the H-2′ epoxy proton and its replacement by a resonance at δ 5.78 (Table 1) further indicated that the 1′,2′-epoxy group had been hydrated to form the 1′,2′-diol. The relative stereochemistry across the ring junction remained *trans* ($J_{3',4'} = 11.4$ Hz) and that between H-2′ and H-3′ has to be cis as $J_{2',3'}$ was small. This left the stereochemistry at C-1′ to be resolved. This was achieved by means of a NOESY experiment (Fig. 1) which showed correlations between the 7′-Me and H-2′ and H-3′. This requires the 7′-Me to be axial on C-1′ and establishes the structure as **3**.

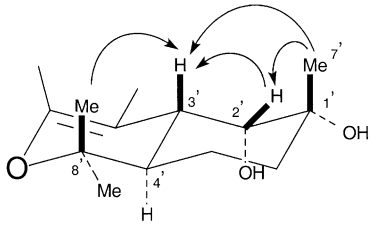

Fig. 1. NOESY correlations of **3**.

A second minor alkaloid (**4**) was identical to **3** accept for the replacement of the *N*-methyl resonances with those for an *N*-acetoxymethyl group. The final alkaloid (**5**) had the same M_r as **3** and the NMR spectra (Tables 1 and 2) confirmed it to be identical to **3** except for the stereochemistry at C-1′.

The isolation of these 3-monoterpenyl-quinoline alkaloids from *Halfordia kendack* was somewhat surprising as they had been found only in *Eriostemon banksii* (formerly *E. australasius* subsp. *banksii*), another Australian Rutaceae but a genus not thought to be at all closely allied to *Halfordia*.

3. Experimental

3.1. General

Melting points are uncorrected. UV spectra were run in methanol and IR spectra as liquid films. HR–EIMS spectra were obtained at 70 eV. NMR spectra were recorded at 400 MHz (^{1}H), 500 MHz (^{1}H–nOe) and 100.56 MHz (^{13}C) using the solvent as internal standard. Vacum liquid chromatography (VLC) and column chromatography were performed on Merck (7736) silica gel 60 H (0.04–0.005 mm) and Merck (7734) silica gel (0.063–0.2 mm), respectively. Analytical TLC and PTLC were performed on precoated Merck F_{254} silica gel plates and spraying with anisaldehyde-H_2SO_4 and Dragendroff's reagents. Gel filtration chromatography (GFC) was performed on Sephadex LH-20 (0.25–1 mm).

3.2. Plant material

Aerial parts of *H. kendack* were collected in southern Queensland in March 1992. A voucher specimen (W.J. MacDonald — 4775) has been deposited at the Queensland Herbarium, Brisbane (BRI).

3.3. Extraction and isolation

The dried, ground plant material (244 g) was sequentially extracted in a Soxhlet with *n*-hexane, $CHCl_3$ and MeOH. The extracts were filtered and evaporated to a gummy mass in a rotary evaporator under vacuum at a maximum temperature of 40°C.

The *n*-hexane extract (6.82 g) was fractionated by VLC over silica gel using solvents of increasing polarity. After removal of coumarins elution with 30–35% EtOAc in *n*-hexane followed by gel filtration of the eluate on Sephadex LH-20 column eluting with $CHCl_3$ and finally rechromatography of the alkaloid fraction over silica gel column with *n*-hexane containing ethylacetate gave **3** (6.1 mg) and then **4** (1 mg).

The $CHCl_3$ extract (6.60 g) was similarly fractionated by VLC and the eluate from 25–30% EtOAc in *n*-hexane was first chromatographed over silica gel with *n*-hexane containing increasing amount of EtOAc to give two alkaloidal-rich fractions. The less polar of these was first treated by gel filtration (Sephadex LH-20) eluting with $CHCl_3$ and then by CC over silica gel to give **1** (12.2 mg). The second subfraction was further fractionated by CC to give **2** (28.6 mg). The VLC fraction from 1 to 4% MeOH in EtOAc was further treated by gel filtration and CC using an EtOAc:MeOH gradient yielded **5** (6 mg).

3.3.1. Trans-erioaustrasine (*1*)

Amorphous solid, UV, $[\alpha]_D = +103°$ (*c*. 0.06 in $CHCl_3$ at 29.6°C) {lit. $[\alpha]_D = +130°$ (*c*. 0.96 in $CHCl_3$)} IR, ^{1}H NMR, ^{13}C NMR, EIMS in agreement with literature data (Da Cunha et al., 1993).

3.3.2. Trans-deacetoxyarioaustrasine (*2*)

Needles from EtOAc, mp 190–192°C. $[\alpha]_D$ + 244° (*c*. 0.242 in $CHCl_3$ at 29.6°C). $[\alpha]_D$ +125° (*c*. 0.08 in $CHCl_3$ at 29.6°C). UV λ_{max} (log ε) (MeOH) nm: 235 (3.84), 276 (3.68), 286 (3.68), 318 (3.65), 331 (3.55). IR (liquid film) ν_{max} cm^{-1}: 1629, 1593, 1502, 1462, 1417, 1386, 1328, 1312, 1271, 1253, 1213, 1196, 1164, 1123, 1099, 1043, 1017, 882, 806, 754. ^{1}H NMR — see Table 1, ^{13}C NMR — see Table 2. EIMS *m*/*z* (rel. int.); 325 [M^+] (100), 310 [M-CH_3]$^+$ (20), 282 [M-CH_3CO]$^+$ (49), 255 (42), 242 (45), 226 (20), 200 (21) 143 (30); found for M^+ 325.16832, $C_{20}H_{23}NO_3$, 325.16779.

3.3.3. Trans-deacetoxyaustralasine hydrate (*3*)

Amorphous, $[\alpha]_D$ +125° (*c*. 0.032 in $CHCl_3$ at 29.6°C) UV λ_{max} (log ε) (MeOH) nm: 234 (3.55), 275 (3.31), 286 (3.32), 317 (3.29), 332 (3.18). IR (liquid film) ν_{max} cm^{-1}: 3370, 1611, 1587, 1502, 1462, 1416, 1390, 1333, 1317, 1283, 1260, 1240, 1213, 1165, 1139, 1107, 1025, 999, 905, 871, 754. ^{1}H NMR — see Table 1. ^{13}C NMR — see Table 2. EIMS *m*/*z* (rel. int.); 343 [M^+] (29), 325 [M–H_2O]$^+$ (50), 310 [M–H_2O–CH_3]$^+$ (71), 308 [M–H_2O–OH]$^+$ (100), 282 [M–H_2O–CH_3CO]$^+$ (50), 240 (31), 226 (42), 200 (34); found for M^+ 343.18722, $C_{20}H_{25}NO_4$, 343.17836.

3.3.4. Trans-australasine hydrate (*4*)

Amorphous, UV λ_{max} (log ε) (MeOH) nm: 234 (4.17), 275 (3.98), 285 (3.99), 317 (3.90), 324 (3.77). IR (liquid film) ν_{max} cm^{-1}: 3406, 1745, 1623, 1595, 1575, 1502, 1462, 1389, 1371, 1333, 1287, 1232, 1200, 1167, 1139, 1107, 1023, 965, 904, 873 and 757. ^{1}H NMR ($CDCl_3$) — Table 1.

3.3.5. Trans-1′-epideacetoxyaustralasine hydrate (*5*)

Amorphous. UV λ_{max} (log ε) (MeOH) nm: 233 (3.93), 276 (3.45), 287 (3.46), 317 (3.44), 329 (3.34). IR (liquid

film) ν_{max} cm^{-1}: 3396, 1717, 1700, 1668, 1616, 1586, 1502, 1560, 1418, 1389, 1333, 1209, 1163, 1108, 1039, 1019, 905, 863, 752. ^1H NMR — see Table 1, ^{13}CNMR — see Table 2. EIMS *m*/*z* (rel. int.); 343 [M^+] (3), 325 [M–H_2O]$^+$ (100), 310 [M–H_2O–CH_3]$^+$ (14), 282 [M–H_2O–CH_3CO]$^+$ (18), 242 (26); found for M^+ 343.18722, $C_{20}H_{25}NO_4$, 343.17836.

Abstract

From the aerial parts of *Clerodendrum inerme*, two megastigmane glucosides (sammangaosides A and B) and a iridoid glucoside (sammangaoside C) were isolated together with 15 known compounds. The structural elucidations were based on analyses of physical and spectroscopic data. © 2001 Published by Elsevier Science Ltd.

Keywords: *Clerodendrum inerme*; Verbenaceae; Megastigmane glucoside; Iridoid glucoside; Sammangaosides A–C

1. Introduction

As part of our ongoing study on Thai medicinal plants, we investigated the constituents of *Clerodendrum inerme* Gaertn. (Verbenaceae, Thai name: Sam-ma-nga) collected in the Botanical gardens, Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand. *C. inerme* is a shrub distributed in South and South-east Asia, Australia and Pacific islands. In Thai traditional medicine, the fresh leaves are externally used for treating skin diseases. In preliminary studies of this plant, flavones (Vendantham et al., 1977) a clerodane diterpene (Achari et al., 1990), a neolignan (Spencer and Flippen-Anderson, 1981), a phenylpropanoid (Fauvel et al., 1989) and iridoid glycosides (Calis et al., 1994a,b) have been isolated. The present study deals with the isolation and structural elucidations of two new megastigmane glucosides (**6**, **7**) and one new iridoid glucoside (**10**), together with 15 known compounds; phenylpropanoid glycosides (**1–3**), phenylethanoid glycosides (**4**, **5**, **15**), iridoid glucosides (**8**, **9**), neolignan glucosides (**11**, **12**), benzyl alcohol glycosides (**13**, **14**), aliphatic glucoside (**16**) and hydroquinone glycosides (**17**, **18**).

2. Results and discussion

The methanolic extract of the aerial part of *C. inerme* was suspended in H_2O and defatted with Et_2O. The aqueous layer was subjected to a column of highly porous copolymer of styrene and divinylbenzene, and eluted with H_2O, MeOH and Me_2O, successively. The fraction eluted with MeOH was repeatedly chromatrographed on columns of silica gel and RP-18, then by HPLC-ODS to afford 18 compounds (**1–18**). Fifteen were identified as known compounds; verbascoside (**1**), isoverbascoside (**2**), leucosceptoside A (**3**) (Miyase et al., 1982), decaffeoylverbascoside (**4**), darendoside B (**5**) (Calis et al., 1993), monomelittoside (**8**) (Chaudhuri and Sticher, 1980), melittoside (**9**) (Swiatek et al., 1981), (7*S*, 8*R*)-dehydrodiconiferyl alcohol 9-*O*-β-glucopyranoside (**11**) (Binns et al., 1987), (7*S*, 8*R*)-dehydrodiconiferyl alcohol 4-*O*-β-glucopyranoside (**12**) (Yoshizawa et al., 1990), benzyl alcohol β-glucopyranoside (**13**) (Miyase et al., 1987), benzyl alcohol β-(2′-*O*-β-xylopyranosyl) glucopyranoside (**14**) (Sudo et al., 2000), salidroside (**15**) (Nonaka et al., 1982), (*Z*)-3-hexenyl-β-glucopyranoside (**16**) (Mizutani et al., 1988) and 2,6-dimethoxy-*p*-hydroquinone 1-*O*-β-glucopyranoside (**17**) (Otsuka et al., 1989), seguinoside K (**18**) (Zhong et al., 1999) by physical data and spectroscopic evidences.

The molecular formula of compound **6** was determined as $C_{19}H_{32}O_8$ by HR–FAB mass spectrometry.

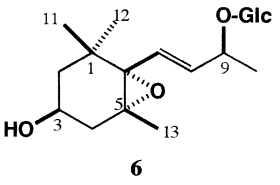
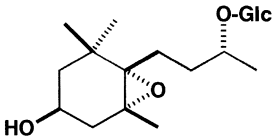
PII: S0031-9422(01)00208-4

Inspection of the ^{13}C NMR spectrum indicated the presence of one β-glucopyranosyl unit together with 13 carbon signals for the aglycone moiety which suggested it to possess the megastigmane skeleton. Compound **6** showed the same planar structure as 3-hydroxy-5,6-epoxy-β-ionyl-9-*O*-β-glucopyranoside, previously isolated from flue-cured tobacco (Kodama et al., 1981) and the absolute configuration at C-9 was confirmed to be *R* (Sudo et al., 2000). Comparison of the ^{1}H and ^{13}C NMR spectral data of **6** with those of 3-hydroxy-5,6-epoxy-β-ionyl-9-*O*-β-glucopyranoside (Sudo et al., 2000) revealed the same relative arrangement of the ring carbons and protons. The difference of the chemical shifts at C-9 (δ 74.7) and 10 (δ 22.4,) with C-9 (δ 76.9) and C-10 (δ 21.0) of the reported data from the ^{13}C NMR spectrum led to conclude the absolute configuration at C-9 to be *S* (Pabst et al., 1992; Takeda et al., 1997). Therefore, the structure of **6** was assigned as (3*S*, 5*R*, 6*S*, 7*E*, 9*S*)-3-hydroxy-5,6-epoxy-β-ionyl-9-*O*-β-glucopyranoside, named sammangaoside A.



6



7

	R
8	**H**
9	**Glc**
10	**Glc (3'–1")-Glc**

The molecular formula of compound **7** was determined as $C_{19}H_{34}O_8$ by HR–FAB mass spectrometry. The ^{1}H and ^{13}C NMR spectral data indicated it to be a megastigmane glucoside. Inspection of the FAB mass spectrometry revealed the two mass units larger than **6** and the signals for the double bond were not observed in the ^{1}H and ^{13}C NMR spectra, indicating the presence of the saturated side chain. The chemical shifts for the signals attributed to the ring were coincident with those of **6**, deduced from the ^{1}H and ^{13}C NMR spectral data. The absolute configuration at C-9 was assigned to be *R* from the chemical shifts at C-9 and 10 (δ 77.8 and 21.8, respectively) (Pabst et al., 1992; Takeda et al., 1997). Consequently, (3*S*, 5*R*, 6*S*, 9*R*)-3-hydroxy-5,6-epoxy-β-dihydroionyl-9-*O*-β-glucopyranoside, was proposed for sammangaoside B.

The molecular formula of compound **10** was determined as $C_{27}H_{42}O_{20}$ by HR–FAB mass spectrometry. The ^{13}C NMR spectrum was very similar to that of **9** (Table 2) except that the ^{13}C NMR signals for one more glucopyranosyl unit were observed. The additional unit was assigned to be attached at C-3″ of the second glucopyranose on C-5 by HMQC and HMBC experiments, in which long-range correlations were observed between (i) H-1‴ (δ 4.54) and C-3″ (δ 88.3), and (ii) H-1″ (δ 4.74) and C-3″ (δ 88.3), C-5 (δ 79.8) as shown in Fig. 1. Moreover, the chemical shifts of C-3″, C-2″ and C-4″ were changed by +10.0,− 0.7 and−1.5 ppm, respectively. Therefore, the structure of compound **10** was elucidated as melittoside 3″-*O*-β-glucopyranoside, named sammangaoside C.

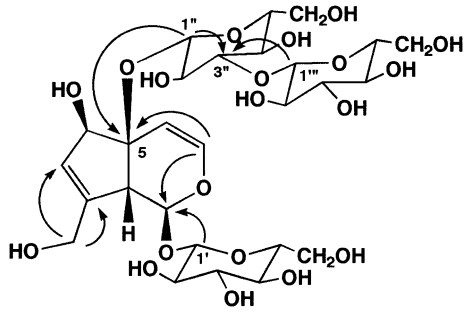
3. Experimental

3.1. General

NMR spectra were recorded in CD_3OD using a JEOL JNM A-400 spectrometer (400 MHz for ^{1}H NMR and 100 MHz for ^{13}C NMR) and JNM-ECP 500 (500 MHz for ^{1}H NMR and 125 MHz for ^{13}C NMR) with tetramethylsilane (TMS) as internal standard. MS were recorded on a JEOL JMS-SX 102 spectrometer. Preparative HPLC was carried out on columns of ODS (150 ×20 mm i.d., YMC) with a Tosoh refraction index (RI-8) detector. The flow rate was 6 ml/min. For CC, silica gel G 60 (Merck), RP-18 (50 μm, YMC) and highly porous copolymer of styrene and divinylbenzene (Mitsubishi Chem. Ind. Co. Ltd) were used. The solvent systems were: (I) EtOAc–MeOH–H_2O (4:1:0.1), (II) EtOAc–MeOH–H_2O (7:3:0.3), (III) EtOAc–MeOH–H_2O (6:4:1), (IV) 15–70% MeOH, (V) 10–50% MeOH, (VI) 10% MeCN, (VII) 20% MeCN, and (VIII) 6% MeCN. The spray reagent used was 10% H_2SO_4 in ethanol.

3.2. Plant material

The aerial part of *Clerodendrum inerme* was collected in August, 1999 from the Botanical gardens, Faculty of



10

Fig. 1. The HMBC correlations of compound **10**.

Pharmaceutical Sciences, Khon Kaen University, Thailand. The identification of the plant was confirmed by Professor Vichiara Jirawongse, Department of Pharmaceutical Botany and Pharmacognosy, Faculty of Pharmaceutical Sciences, Khon Kaen University. A voucher sample is kept in the Herbarium of the Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand.

3.3. Extraction and isolation

The dried aerial part (880 g) of *C. inerme* was extracted with hot MeOH. After removal of the solvent by evaporation, the residue (90.0 g) was defatted with Et_2O. The aqueous layer was subjected to column chromotography, using highly porous copolymer of styrene and divinylbenzene, eluted with H_2O, MeOH and Me_2CO, successively. The fraction eluted with MeOH (17.5 g) was subjected to silica gel column chromotography (systems I, II and III, respectively) affording seven fractions. Fraction 2 (3.12 g) was applied to a RP-18 column using system IV, then followed by prep. HPLC–ODS (system VI and VII) to provide compounds **1** (456 mg), **2** (183 mg), **3** (10 mg), **4** (9 mg), **5** (5 mg), **6** (11 mg), **7** (6 mg), **11** (5 mg), **13** (13 mg), **14** (5 mg), **15** (8 mg), **16** (24 mg), **17** (13 mg) and **18** (4 mg). Fraction 4 (1.74 g) was further separated on a RP-18 column (system IV) and purified by prep. HPLC–ODS (system VII) to give compound **12** (7 mg). Fraction 5 (2.73 g) was similarly subjected to RP-18 column (system IV), then followed by prep. HPLC–ODS (system VII) to afford compounds **8** (50 mg). Fraction 6 (4.8 g) was purified by using columns of RP-18 (system V) and prep. HPLC–ODS (system VIII) to give compounds **9** (1.0 g) and **10** (10 mg).

3.4. Sammangaoside A (6)

Amorphous, $[\alpha]_D^{20}$ −99.1° (MeOH, *c* 0.8); ^{1}H NMR (CD_3OD): δ 6.04 (1H, *d*, *J* = 15.6 Hz, H-7), δ 5.56 (1H, *dd*, *J* = 15.6, 7.6 Hz, H-8), δ 4.52 (1H, *m*, H-9), δ 4.27 (1H, *d*, *J* = 7.5 Hz, H-1′ Glc), δ 3.73 (1H, *m*, H-3), δ 2.28 (1H, *dd*, *J* = 14.2, 1.7 Hz, H-4e), δ 1.61 (1H, *dd*, *J* = 14.2, 9.3 Hz, H-4a), δ 1.56 (1H, *bd*, *J* = 10.7 Hz, H-2e), δ 1.27 (3H, *d*, *J* = 6.3 Hz, H-10), δ 1.24 (3H, *s*, H-13), δ 1.20 (1H, *bt*, *J* = 11.0 Hz, H-2a), δ 1.08 (3H, *s*, H-11), δ 0.93 (3H, *s*, H-12); ^{13}C NMR (CD_3OD): Table 1; Negative HR–FAB–MS, *m*/*z*: 387.2039 $[M–H]^-$ ($C_{19}H_{31}O_8$ requires 387.2019)

Received 29 December 2000; received in revised form 12 April 2001

Dedicated to Professor Vichiara Jirawongse on the occasion of his 83rd birthday

Abstract

From the aerial part of *Barleria lupulina*, 8-*O*-acetyl-6-*O*-*trans*-*p*-coumaroylshanzhiside, saletpangponosides A–C and 8-*O*-acetylmussaenoside were isolated together with 13 known compounds. The structural elucidations were based on analyses of physical and spectroscopic data. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Barleria lupulina*; Acanthaceae; Iridoid glucosides; Saletpangponosides A–C; Shanzhiside derivatives; 8-*O*-Acetylmussaenoside

1. Introduction

As part of our ongoing study on Thai medicinal plants, we investigated the constituents of *Barleria lupulina* Lindl. (Acanthaceae, Thai name: Sa-let-pang-pon, Chong-ra-ar) collected in the Botanical gardens, Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand. *B. lupulina* is a small shrub, distributed in the South-east Asia region. In Thai traditional medicine, the plant is externally used as an antiinflammatory for insect bite, herpes simplex and herpes zoster. In preliminary investigations nine iridoid glucosides (Suksamrarn 1986; Byrne et al., 1987; Tuntiwachwuttikul et al., 1998) have been isolated. In addition, some anti-HSV-2 (herpes simplex virus type 2) activity of organic extracts of the plant have been reported (Yoosook et al., 1999). The present study deals with the isolation and structure elucidation of iridoid glucosides (**1**–**12**), of which five are new (**5**–**8**, **12**), together with six other known compounds; phenylpropanoid glycosides (**13**–**15**), lignan glucoside (**16**), aliphatic glycoside (**17**) and benzyl alcohol glycoside (**18**) from the aerial part of this plant.

2. Results and discussion

The methanolic extract of the aerial part of *B. lupulina* was suspended in H_2O and defatted with Et_2O. The aqueous layer was subjected to column chromatography using a highly porous copolymer of styrene and divinylbenzene, and eluted with H_2O, MeOH and Me_2CO, successively. The fraction eluted with MeOH was repeatedly subjected to column chromatography using silica gel and octadecylsilyl silica gel, then by preparative HPLC-ODS to afford 18 compounds (**1**–**18**). Thirteen were known compounds; shanzhiside methyl ester (**1**), 8-*O*-acetylshanzhiside methyl ester (barlerin) (**2**), 6-*O*-acetylshanzhiside methyl ester (**3**), 6,8-*O*,*O*-diacetylshanzhiside methyl ester (acetylbarlerin) (**4**) (Damtoft et al., 1982; Byrne et al., 1987), ipolamiide (**9**) (Damtoft et al., 1984b), ipolamiidoside (**10**) (Byrne et al., 1987), phlorigidoside B (**11**) (Takeda et al., 2000), forsythoside B (**13**) (Endo et al., 1982), verbascoside (**14**) (Andary et al., 1982), poliumoside (**15**) (Andary et al., 1985), (+)-lyoniresinol 3a-*O*-β-glucopyranoside (**16**) (Achenbach et al., 1992), (3*R*)-1-octen-3-yl-β-primeveroside (**17**) (Yamamura et al., 1998) and benzyl alcohol β-(2′-*O*-β-xylopyranosyl) glucopyranoside (**18**) (Sudo et al., 2000) by physical data and spectroscopic evidences.

The molecular formula of compound **5** was determined as $C_{27}H_{32}O_{14}$ by HR–FAB mass spectrometry. Inspection of the ^{13}C NMR spectral data revealed the

PII: S0031-9422(01)00236-9

presence of one β-glucopyranosyl unit, one coumaroyl moiety and one acetyl group in addition to eleven carbon signals for the aglycone moiety. The coumaroyl moiety was assigned as *trans* by the coupling constant of the α and β protons in the ^{1}H NMR spectrum (δ 6.28 and 7.56, $J = 15.9$ Hz). The ^{1}H and ^{13}C NMR spectral data were very similar to those of 8-*O*-acetyl-6-*O*-*trans*-*p*-coumaroylshanzhiside methyl ester (Tuntiwachwuttikul et al., 1998), except for lacking the methoxy signal due to the carbomethoxy group, which established the presence of a carboxyl group. On the basis of these spectral data, the structure of compound **5** was determined as 8-*O*-acetyl-6-*O*-*trans*-*p*-coumaroylshanzhiside.

The molecular formula of compound **6** was determined as $C_{34}H_{44}O_{19}$ by HR–FAB mass spectrometry. The ^{1}H and ^{13}C NMR spectral data showed the presence of two β-glucopyranosyl units, one *trans*-coumaroyl moiety, as well as the signals for an acetyl group and a carbomethoxy group. The ^{1}H and ^{13}C NMR spectra were very similar to those of 8-*O*-acetyl-6-*O*-*trans*-*p*-coumaroylshanzhiside methyl ester (Tuntiwachwuttikul et al., 1998), except for a set of additional signals arising from a β-glucopyranosyl moiety in **6**. The additional glucopyranosyl unit was assigned to be attached at C-4″ (δ 160.9) of the coumaroyl moiety because the chemical shifts of C-4″, C-3″,5″ (δ 118.0) changed by +0.2 and-2.6 ppm, respectively. Moreover, the HMBC spectrum provided further confirmation with a significant correlation between H-1‴ (δ 4.93, *d*, $J = 7.6$ Hz) of this glucopyranosyl unit and C-4″ of the coumaroyl moiety. Consequently, the structure of compound **6** was assigned as 6-*O*- (4″-*O*-β-glucopyranosyl)-*trans*-*p*-coumaroyl-8-*O*-acetylshanzhiside methyl ester, named saletpangponoside A.

	R_1	R_2
9	H	H

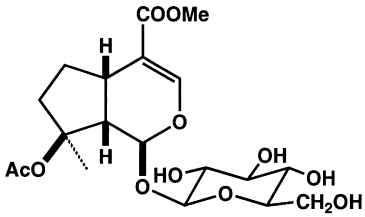
11	OH	Ac



12

The molecular formula of compound **7** had the same elemental composition as **6**, $C_{34}H_{44}O_{19}$, by HR–FAB mass spectrometry. The ^{1}H and ^{13}C NMR spectral data were very similar to those of **6**. The only significant difference was the coupling constants of the olefinic protons (δ 5.86 and 6.94, $J = 12.9$ Hz). Therefore, the structure of compound **7** was determined as the *cis* isomer of **6**, named saletpangponoside B.

The molecular formula of compound **8** was determined as $C_{26}H_{34}O_{13}$ by HR–FAB mass spectrometry. The ^{1}H and ^{13}C NMR spectral data indicated that **8** is a derivative of shanzhiside methyl ester (**1**), with an ester moiety on the 8-hydroxy group because of the downfield shift of C-8 (+10.5 ppm). The ester moiety showed the presence of an AA′BB′ system (δ 6.64 and 6.98, $J = 8.6$ Hz from ^{1}H NMR), two methylenes (δ 2.49 and δ 2.76 from ^{1}H NMR, and δ 38.2 and 31.2 from ^{13}C NMR) and a carbonyl carbon (δ 175.0), identified as a *p*-dihydrocoumaroyl moiety. The complete assignments were confirmed by the HMBC spectrum, in which H-α (δ 2.49) showed a three bond correlation to C-1″ (δ 132.6), and H-β (δ 2.76) showed the significant correlation to C-2″,6″ (δ 130.3). Thus, the structure of compound **8**

was elucidated as 8-*O*-*p*-dihydrocoumaroylshanzhiside methyl ester, named saletpangponoside C.

The molecular formula of compound **12** was determined as $C_{19}H_{28}O_{11}$ by HR–FAB mass spectrometry. The ^1H and ^{13}C NMR spectra indicated an iridoid structure. The chemical shifts were very similar to those of mussaenoside (Damtoft et al., 1984a) except that the acetyl group was observed in the spectra. The attachment of the acetyl group was assigned to C-8 (δ 91.0), the carbon signal of which was shift to downfield by 10.6 ppm. Therefore, the structure of compound **12** was identified as 8-*O*-acetylmussaenoside.

3. Experimental

3.1. General

NMR spectra were recorded in CD_3OD using a JEOL JNM A-400 spectrometer (400 MHz for ^1H NMR and 100 MHz for ^{13}C NMR) with tetramethylsilane (TMS) as internal standard. MS were recorded on a JEOL JMS-SX 102 spectrometer. Optical rotations were measured with a Union PM-1 digital polarimeter. Preparative HPLC was carried out on columns of ODS (20×150 mm i.d., YMC) with a Tosoh refraction index (RI-8) detector. For CC, silica gel G 60 (Merck), YMC-gel ODS (50 mm, YMC), and highly porous copolymer of styrene and divinylbenzene (Mitsubishi Chem. Ind. Co. Ltd) were used. The solvent systems were: (I) EtOAc–MeOH (9:1), (II) EtOAc–MeOH–H_2O (4:1:0.1), (III) EtOAc–MeOH–H_2O (7:3:0.3), (IV) 20–35% MeCN, (V) 15% MeCN, (VI) 25% MeCN, (VII) 10–35% MeCN, (VIII) 10% MeCN and (IX) 40% MeOH. The spray reagent used for TLC was 10% H_2SO_4 in 50% EtOH.

3.2. Plant material

Barleria lupulina Lindl. was collected in September 1999 from the Botanical gardens, Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand. The identification of the plant was confirmed by Prof. Vichiara Jirawongse, Department of Pharmaceutical Botany and Pharmacognosy, Faculty of Pharmaceutical Sciences, Khon Kaen University. A voucher sample (KKU-0018) is kept in the Herbarium of the Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand.

3.3. Extraction and isolation

The dried aerial part (900 g) of *B. lupulina* was extracted with hot MeOH. After removal of the solvent by evaporation, the residue (100 g) was defatted with Et_2O. The aqueous layer was subjected to a column of highly porous copolymer of styrene and divinylbenzene and eluted with H_2O, MeOH and Me_2CO, successively. The fraction eluted with MeOH (29.0 g) was subjected to a column of silica gel (systems I, II and III, respectively) affording five fractions. Fraction 2 (7.4 g) was applied to a RP-18 column using system IV to provide six fractions, together with compound **4** (5.1 g). Fractions 2–5 were purified by prep. HPLC–ODS (system VI) to afford compounds **8** (43 mg) and **12** (27 mg). Fraction 3 (8.4 g) was subjected to a column of RP-18 (system IV) to give eight fractions, along with compounds **2** (2.6 g) and **10** (596 mg). Fractions 3-1 and 3-2 were further purified by prep. HPLC-ODS (system V) to provide compound **3** (398 mg). Fraction 3-8 was purified by prep. HPLC-ODS (system VI) to afford compound **16** (92 mg). Fraction 4 (8.2 g) was applied to a RP-18 column (system VII) to afford fifteen fractions, and compound **1** (1.9 g). Fraction 4-5 was purified by prep. HPLC–ODS (system VIII) to give compounds **9** (50 mg) and **18** (59 mg). Fraction 4-8 was purified by prep. HPLC–ODS (system V) to provide compounds **11** (32 mg) and **17** (27 mg). Fraction 4-9 was further purified by prep. HPLC-ODS (system IX) to give compounds **13** (162 mg), **14** (73 mg) and **15** (138 mg). Finally, fractions 4-13 and 4-14 were purified by prep. HPLC-ODS (system VI) to provide compound **5** (23 mg), **6** (90 mg) and **7** (73 mg).

Abstract

26-Norbrassinolide, identified as a metabolite of brassinolide in cultured cells of the liverwort, *Marchantia polymorpha,* as well as 26-norcastasterone and 26-nor-6-deoxocastasterone were synthesized. Synthesis of these new brassinosteroids was conducted by employing the orthoester Claisen rearrangement and asymmetric dihydroxylation as key reactions. The modified rice lamina inclination test indicated that these three 26-norbrassinosteroids were less active than their corresponding C_{28} brassinosteroids. Growth-promoting activities were also examined by using the brassinosteroid-deficient, dwarf mutant *lkb* of garden pea (*Pisum sativum* L.). In this assay, 26-norbrassinolide was as effective as brassinolide and 26-norcastasterone was more effective than castasterone although 26-nor-6-deoxocastasterone was much less effective than 6-deoxocastasterone. Therefore, removal of C-26 of brassinosteroids does not necessarily reduce the biological activity. The role of C-26 removal in *Marchantia* cells remains unclear. © 2001 Elsevier Science Ltd. 1. Introduction

Brassinosteroids (BRs) are steroidal plant hormones with plant growth promoting activity. More than 40 natural BRs have been characterized (Fujioka, 1999). The biosynthetic pathway of C_{28} BRs including brassinolide (BL) and related BRs has been elucidated by using cultured cells of *Catharanthus roseus* (Fujioka and Sakurai, 1997a) and seedlings of *Arabidopsis thaliana* (Noguchi et al., 2000). At present, it is known that BL is converted from castasterone (CS), which, in turn, is synthesized from campestanol through either early C-6 oxidation and/or late C-6 oxidation pathways (Fujioka and Sakurai, 1997a). These pathways seem to occur widely in the plant kingdom because of the ubiquitous presence of the intermediates involved (Fujioka and Sakurai, 1997b). Moreover, various genes involved in BR biosynthesis have been characterized by investigating a number of BR-deficient dwarf mutants of Arabidopsis, pea, and tomato (Yokota, 1997; Altmann, 1998; Clouse and Feldmann, 1999). In addition to de novo synthesis of BRs, the metabolism and catabolism are important factors controlling the levels of endogenous BRs (Crozier et al., 1999; Yokota, 1999). Recently, we found that BL was metabolized to 26-norbrassinolide (26-norBL) with removal of C-26 in cultured cells of the liverwort, *Marchantia polymorpha* (Kim et al., 2000a). In tomato cells, C-26 hydroxylation occurs presumably as a deactivation process (Winter et al., 1997). Recently the *bas1-D phyB-4* Arabidopsis mutant was found to have enhanced C-26 hydroxylation in response to BL (Neff et al., 1999). These findings suggest that loss or modification of C-26 has an important role in the metabolism of BRs.

In the present work, we give the full account of the synthesis of 26-norBL, that was used as an authentic compound to identify the *Marchantia* metabolite by

GC–MS (Kim et al., 2000a). Furthermore, we have synthesized 26-norcastasterone (26-norCS) and 26-nor-6-deoxocastasterone (26-nor-6-deoxoCS), the presence of which in plants should be also suspected. In order to investigate whether or not the removal of C-26 is a deactivation step, we examined the biological activity of these compounds using the modified rice lamina inclination test and the pea growth test using the BR-deficient dwarf mutant *lkb*.

2. Results and discussion

2.1. Synthesis of 26-norbrassinosteroids

First, we synthesized 26-norCS **2** from the known allylic 22-alcohol **7** (Watanabe et al., 1997) by applying the method used to construct the side chain of BL in which orthoester Claisen rearrangement and asymmetric dihydroxylation were key reactions (Scheme 1). The orthoester Claisen rearrangement of **7** using triethyl orthoacetate gave the ester **8** in 98% yield. The ethoxycarbonyl group of **8** was reduced with $LiAlH_4$ to give the alcohol **9**. The hydroxyl group of **9** was removed by reducing its sulfonate to give the 26-nor compound **10**. Transformation of **10** to the 2,22*E*-dien-6-one **12** was attained in 82% yield using a conventional procedure (Watanabe et al., 1997). Introduction of two vicinal diols into **12** was elaborated through asymmetric dihydroxylation using 1,4-bis(9-*O*-dihydroquinidinyl)phthalazine as a chiral ligand to give **2** in 67% yield. To determine the stereochemistry of the C-22 and -23 positions of **2**, **2** was derivatized to the bisacetonide **4** whose NMR spectra gave well-defined signals and its NMR spectra were compared with those of the known compound **5** (Takatsuto et al., 1984) and its stereoisomer **6** (Watanabe and Takatsuto, unpublished data, Fig. 1). Direct and long-range heteronuclear ^{1}H–^{13}C correlations obtained by HMQC and HMBC techniques resulted in complete assignment of the ^{1}H and ^{13}C NMR signals. ^{1}H and ^{13}C signals in the vicinity of the side chain diol moiety of **4** were almost superimposable with those of **5** but not with those of **6** (Table 1). Consequently, the stereochemistry of the side chain in **4** was determined to be (22*R*, 23*R*) configuration.

C-22	80.22	80.57	83.20

[a] ^{1}H NMR (600 MHz; δ: multiplicity, J in Hz) and ^{13}C NMR (150 MHz; δ) were measured in $CDCl_3$.

Furthermore, acetylation of **2** followed by Baeyer–Villiger oxidation gave 26-norBL tetraacetate **13**, which was then deprotected to afford 26-norBL **1** in 50% yield from **2** (Takatsuto et al., 1984). 26-Nor-6-deoxoCS **3** was subjected to the Huang Minlon reaction (Mori et al., 1984) to give **2** in 38% yield.

2.2. Biological activity of 26-norbrassinosteroids

The rice lamina inclination test is very sensitive to BRs (Wada et al., 1981), and has been used to evaluate biological potency of natural and synthetic BRs. Kim et al. (2000a) already demonstrated using this bioassay that the activity of 26-norBL was 10-fold lower than BL. Recently this bioassay was greatly sensitized by utilizing auxin-BR synergism in intact rice seedlings (Fujioka et al., 1998). Thus this rice bioassay was applied to the new 26-norBRs synthesized. When comparing dosages which caused 50% degree of the maximum inclination angle, 26-norBL was 13 times less active than BL, being in accord with the previously published data (Kim et al., 2000a). Similarly, 26-norCS was 7 times less active than CS, and 26-nor-6-deoxoCS was 80 times less active than 6-deoxoCS (Fig. 2). The strength of biological activities of 26-norBRs were in the following order; 26-norBL > 26-norCS > 26-nor-6-deoxoCS. The same relationship has been observed between corresponding C_{28} BRs (Fujioka et al., 1998). Thus, removal of C-26 of the C_{28} BRs is suggested to be a deactivation step. A similar deactivation due to another demethylation of C-28 of CS is also suggested by the fact that 28-norCS is converted from CS in some higher plants and 28-norCS is ca. 10 times less active than CS in this rice bioassay (Fujioka et al., 2000).

Dwarfism of BR-deficient mutants such as the Arabidopsis *det2* (Li et al., 1996) and pea *lkb* mutant (Nomura et al., 1999) can be rescued by application of brassinolide and its precursors. Based on the above-mentioned result by the rice bioassay, it is expected that respective biological activities of the 26-norBRs are lower than those of the corresponding C_{28} BRs in this growth test. So, we examined the growth-promoting activities of 26-norBRs using the *lkb* mutant. Results are shown in Fig. 3. Although 26-nor-6-deoxoCS had very weak activity, and its activity was much lower than that of 6-deoxoCS, 26-norBL showed strong activity that was comparable to that of BL, and 26-norCS was more active than CS and its activity was nearly equivalent to that of BL. Therefore, it was found that removal of C-26 does not necessarily reduce biological activity of BRs as far as the pea *lkb* bioassay data indicate.

Contradictory data obtained between two bioassay systems suggest that biological activities of BRs cannot be discussed only by a single bioassay system. In support of this, structure–activity relationships of BRs have been known to vary in different bioassay systems. For example, the biological activity of 28-norBL is about one-order of magnitude lower than that of BL in the rice lamina inclination test (Takatsuto et al., 1983a; Wada et al., 1983) and tomato growth test (Takatsuto et al., 1983b), but it is comparable to BL in the radish growth test (Takatsuto et al., 1983b).

In conclusion, we were unable to make clear the roles of C-26 elimination of BRs in *Marchantia* cells. Roles of BR in the growth and development of *M. polymorpha* also remain to be studied although BRs are endogenous in *M. polymorpha* (Kim et al., 2000b).

3. Experimental

3.1. General

Mps were determined under a hot-stage microscope (Yanaco micro melting point apparatus) and were uncorrected. ^{1}H and ^{13}C NMR spectra were recorded

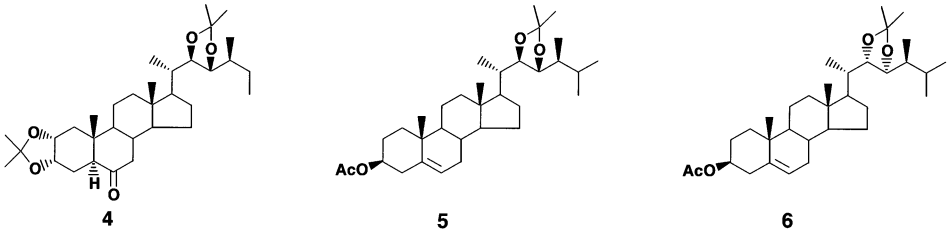

Fig. 1. Structure of 26-norcastasterone bisacetonide **4**, compounds **5** and **6**.

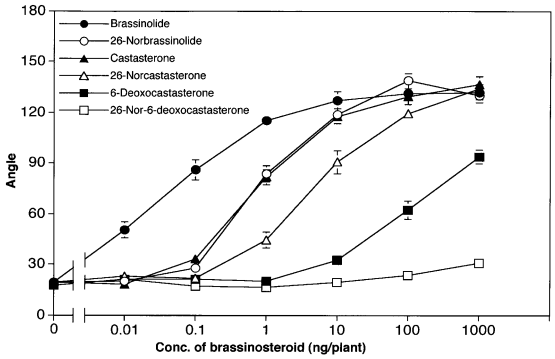

Fig. 2. Rice lamina inclination test of 26-norbrassinosteroids by co-application of the test sample with indole-3-acetic acid (5 μg/plant). Each data point represents the mean of 20–24 replicates ±S.E.

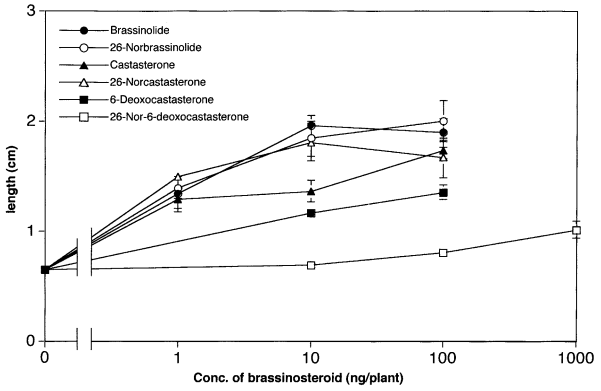

Fig. 3. Effect of 26-norbrassinosteroids on the fifth internode length of *lkb* of pea. Each data point represents the mean of 8 replicates ±S.E.

on a JEOL A400, ECP500 and A600 spectrometers in $CDCl_3$ with tetramethylsilane as an internal standard. HR–MS was recorded on JEOL JMS-AX505H and JMS-AX505HA mass spectrometers.

Silica gel (Kieselgel 60, 70-230 mesh, Merck) was used for column chromatography. Reactions were monitored by TLC on silica gel plates (Kieselgel 60 F_{254}, 0.25 mm thickness, Merck). Spots were visualized with 1% Ceric sulphate–10% aq. H_2SO_4 solution, followed by heating. All purified compounds showed a single spot by TLC analysis.

3.2. Synthesis of 26-norbrassinosteroids

3.2.1. Ethyl (22E,24R)-3α,5-cyclo-6,6-ethylenedioxy-26-nor-5α-ergost-22-en-27-oate **8**

A mixture of the known allylic alcohol **7** (632.6 mg, 1.526 mmol), triethyl orthoacetate (7.0 ml), acetic acid (3 drops) and xylene (5.0 ml) was refluxed under Ar atmosphere for 5 h. MeOH was added and the solvent was removed in vacuo to give a residue, which was applied to a column of silica gel (2.0 cm i.d. ×20 cm). Elution with hexane–EtOAc (50:1) afforded **8** (726.5 mg, 98.2%) as an oil; TLC: hexane–EtOAc (10:1) $R_F = 0.65$; ^{1}H NMR spectral data (500 MHz, $CDCl_3$): δ 0.33 (1H, *t*, *J* = 4.3 Hz, 4-H), 0.61 (1H, *dd*, *J* = 8.3 and 4.7 Hz, 4-H), 0.71 (3H, *s*, 18-H_3), 0.98 (3H, *d*, *J* = 6.6 Hz, 28-H_3), 1.00 (3H, *s*, 19-H_3), 1.01 (3H, *d*, *J* = 6.6 Hz, 21-H_3), 1.26 (3H, *t*, *J* = 7.0 Hz, $OCH_2C\underline{H}_3$), 2.25 (2H, *m*, not assigned), 2.59 (1H, *m*, not assigned), 3.74 (1H, *q*, *J* = 7.0 Hz, ketal ethylene), 3.84 (1H, *q*, *J* = 5.7 Hz, ketal ethylene), 3.90 (1H, *q*, *J* = 8.0 Hz, ketal ethylene), 4.03 (1H, *m*, ketal ethylene), 4.11 (2H, *m*, $OC\underline{H}_2CH_3$) and 5.23 (2H, *m*, 22 and 23-H). HR–EIMS $[M]^+$ *m/z:* 484.3562 (calc. 484.3553) for $C_{31}H_{48}O_4$.

3.2.2. (22E,24S)-3α,5-Cyclo-6,6-ethylenedioxy-26-nor-5α-ergost-22-en-27-ol **9**

The ester **8** (691.5 mg, 1.427 mmol) in THF (70 ml) was treated with $LiAlH_4$ (200 mg, 5.270 mmol) at 0 °C to room temperature under Ar atmosphere for 5 h. Work-up (hexane and EtOAc extraction) was followed by chromatography on silica gel (2.0 cm i.d. ×20 cm). Elution with hexane–EtOAc (10:1) afforded **9** (621.3 mg, 98.4%) as an oil; TLC: toluene–EtOAc (3:1) $R_F = 0.38$; ^{1}H NMR spectral data (500 MHz, $CDCl_3$): δ 0.33 (1H, *t*, *J* 3.9 Hz, 4-H), 0.61 (1H, *dd*, *J* = 8.0 and 4.7 Hz, 4-H), 0.72 (3H, *s*, 18-H_3), 0.98 (3H, *d*, *J* = 7.0 Hz, 28-H_3), 1.00 (3H, *d*, *J* = 7.3 Hz, 21-H_3), 1.01 (3H, *s*, 19-H_3), 3.65 (2H, *m*, 27-H_2), 3.75 (1H, *q*, *J* = 7.5 Hz, ethylene ketal), 3.84 (1H, *q*, *J* = 6.5 Hz, ethylene ketal), 3.91 (1H, *qd*, *J* = 6.7 and 1.3 Hz, ethylene ketal), 4.02 (1H, *qd*, *J* = 6.0 and 1.7 Hz, ethylene ketal) and 5.17 (1H, *dd*, *J* = 15.3 and 8.0 Hz, 22-H) and 5.23 (1H, *dd*, *J* = 5.3 and 8.3 Hz, 23-H). HR–EIMS $[M]^+$ *m/z:* 442.3454 (calc. 442.3447) for $C_{29}H_{46}O_3$.

3.2.3. (22E,24S)-3α,5-Cyclo-6,6-ethylenedioxy-26-nor-5α-ergost-22-ene **10**

The alcohol **9** (601.7 mg, 1.359 mmol) was dissolved in CH_2Cl_2 (50 ml) and triethylamine (3.0 ml) and then treated with methanesulfonyl chloride (0.5 ml) at 0 °C for 2 h. Work-up (CH_2Cl_2) gave a corresponding sulfonate, which was treated with $LiAlH_4$ (200 mg, 5.270 mmol) in THF (50 ml) at 0 °C to room temperature overnight. Work-up (hexane and EtOAc extraction) was followed by chromatography on silica gel (2.0 cm i.d. ×20 cm). Elution with hexane–EtOAc (100:1) afforded **10** (543.5 mg, 93.7% in two steps) as an oil; TLC: toluene $R_F = 0.70$; δ_H (500 MHz): 0.33 (1H, *t*, *J* = 4.1 Hz, 4-H), 0.61 (1H, *dd*, *J* = 7.8 and 4.6 Hz, 4-H), 0.73 (3H, *s*, 18-H_3), 0.83 (3H, *t*, *J* = 7.4 Hz, 27-H_3), 0.92 (3H, *d*, *J* = 6.9 Hz, 28-H_3), 0.99 (3H, *d*, *J* = 6.4 Hz, 21-H_3), 1.01 (3H, *s*, 19-H_3), 3.74 (1H, *q*, *J* = 6.4 Hz, ketal ethylene), 3.85 (1H, *q*, *J* = 6.5 Hz ketal ethylene), 3.91 (1H, *qd*, *J* = 6.4 and 1.4 Hz, ketal ethylene), 4.02 (1H, *qd*, *J* = 6.3 and 1.8 Hz, ketal ethylene) and 5.14 (2H, *m*, 22 and 23-H). HR–EIMS $[M]^+$ *m/z:* 426.3496 (calc. 426.3498) for $C_{29}H_{46}O_2$.

3.2.4. (22E,24S)-3α,5-Cyclo-26-nor-5α-ergost-22-en-6-one **11**

A solution of the compound **10** (513.5 mg, 1.110 mmol) in acetone (30 ml) was treated with 1 M H_2SO_4 (1.0 ml) at room temperature for 1 h. Work-up (EtOAc

extraction) was followed by chromatography on silica gel (2.0 cm i.d. ×20 cm). Elution with hexane–EtOAc (50:1) afforded **11** (435.4 mg, 94.5%), mp 120–121°C (from MeOH); TLC: hexane–EtOAc (20:1) $R_F = 0.14$; δ_H (500 MHz): 0.73 (3H, *s*, 18-H_3), 0.83 (3H, *t*, $J = 7.5$ Hz, 27-H_3), 0.93 (3H, *d*, $J = 6.7$ Hz, 28-H_3), 1.01 (3H, *s*, 19-H_3), 1.01 (3H, *d*, $J = 6.7$ Hz, 21-H_3), 2.43 (1H, *dd*, $J = 14.7$ and 2.4 Hz, 7β-H) and 5.15 (2H, *m*, 22 and 23-H). HR–EIMS $[M]^+$ *m/z:* 382.3244 (calc. 382.3236) for $C_{27}H_{42}O$.

3.2.5. (22E,24S)-26-Nor-5α-ergosta-2,22-dien-6-one 12

A mixture of **11** (424.7 mg, 1.292 mmol), pyridinium *p*-toluenesulfonate (55 mg, 0.219 mmol), LiBr (450 mg, 5.18 mmol) and *N,N*-dimethylacetamide (20 ml) was heated at 160°C under Ar atmosphere for 5 h. Work-up (hexane extraction) was followed by chromatography on silica gel (2.0 cm i.d. ×25 cm). Elution with toluene afforded **12** (368.9 mg, 86.9%), mp 109–111 °C (from MeOH); TLC: hexane–EtOAc (20:1) $R_F = 0.29$; δ_H (500 MHz): 0.68 (3H, *s*, 18-H_3), 0.71 (3H, *s*, 19-H_3), 0.83 (3H, *t*, $J = 7.3$ Hz, 27-H_3), 0.93 (3H, *d*, $J = 6.7$ Hz, 28-H_3), 1.01 (3H, *d*, $J = 6.7$ Hz, 21-H_3), 2.35 (2H, *m*, 5-H), 5.15 (2H, *m*, 22 and 23-H), 5.57 (1H, *m*, 2-H) and 5.69 (1H, *ddd*, $J = 9.5$, 4.9 and 1.9 Hz, 3-H). HR–EIMS $[M]^+$ *m/z*: 382.3228 (calc. 382.3236) for $C_{27}H_{42}O$.

3.2.6. (22R,23R,24S)-2α,3α,22,23-Tetrahydroxy-26-nor-5α-ergostan-6-one, 26-norcastasterone 2

A mixture of **12** (207.9 mg, 0.5434 mmol), $K_3[Fe(CN)_6]$ (3.5 g, 10.63 mmol), K_2CO_3 (1.5 g, 10.85 mmol), methanesulfonamide (365.0 mg, 3.84 mmol), 1,4-bis(9-*O*-dihydroquinidinyl)phthalazine (270.0 mg, 0.347 mmol) and $K_2OsO_4 \cdot 2H_2O$ (71.0 mg, 0.193 mmol) in *t*-BuOH–H_2O (65 ml, 1:1) was stirred at room temperature in the dark for 3 days. Sodium hydrogen sulphite (1.0 g, powder) was added and the mixture was stirred further for 1 h. Work-up (EtOAc extraction) was followed by chromatography on silica gel (2.0 cm i.d. ×25 cm). Elution with CH_2Cl_2–EtOH (50:1) afforded **2** (164.1 mg, 67.0%), mp 275–276 °C (from EtOAc–EtOH); TLC: CH_2Cl_2–EtOH (15:1) $R_F = 0.17$; δ_H (400 MHz): 0.69 (3H, *s*, 18-H_3), 0.76 (3H, *s*, 19-H_3), 0.84 (3H, *d*, $J = 6.4$ Hz, 28-H_3), 0.92 (3H, *d*, $J = 6.4$ Hz, 21-H_3), 0.94 (3H, *t*, $J = 7.2$ Hz, 27-H_3), 2.30 (1H, *dd*, $J = 13.0$ and 4.6 Hz, 7β-H), 2.69 (1H, *dd*, $J = 12.2$ and 2.6 Hz, 5-H), 3.57 (2H, *br s*, 22 and 23-H), 3.77 (1H, *m*, 2-H) and 4.05 (1H, *br s*, 3-H). HR–FABMS $[M + Na]^+$ *m/z*: 473.3263 (calc. 473.3243) for $C_{27}H_{46}O_5Na$.

3.2.7. (22R,23R,24S)-2α,3α,22,23-Tetra-acetoxy-26-nor-B-homo-7-oxa-5α-ergostan-6-one 13

26-Norcastasterone **2** (50.7 mg, 0.1125 mmol) was dissolved in a mixture of CH_2Cl_2 (10 ml) and triethylamine (5.0 ml) and then treated with acetic anhydride (0.5 ml) at 0 °C at room temperature overnight. Work-up (CH_2Cl_2 extraction) was followed by chromatography on silica gel (1.0 cm i.d. ×20 cm). Elution with toluene–EtOAc (5:1) afforded tetracetate (62.7 mg, 90.1%), mp 187–189 °C (from MeOH); TLC: toluene–EtOAc (2:1) $R_F = 0.60$; δ_H (400 MHz): 0.70 (3H, *s*, 18-H_3), 0.83 (3H, *s*, 19-H_3), 0.94 (3H, *t*, $J = 7.2$ Hz, 27-H_3), 0.95 (3H, *d*, $J = 6.4$ Hz, 28-H_3), 1.02 (3H, *d*, $J = 6.8$ Hz, 21-H_3), 2.00 (3H, *s*, acetyl), 2.01 (3H, *s*, acetyl), 2.02 (3H, *s*, acetyl), 2.09 (3H, *s*, acetyl), 2.32 (1H, *dd*, $J = 13.2$ and 4.8 Hz, 7β-H), 2.56 (1H, *dd*, $J = 11.4$ and 4.2 Hz, 5-H), 4.95 (1H, *ddd*, $J = 12.4$, 4.8 and 3.2 Hz, 2-H), 5.19 (2H, *m*, 22 and 23-H) and 5.38 (1H, *d*, $J = 3.2$ Hz, 3-H). HR–FABMS $[M + Na]^+$ *m/z:* 641.3632 (calc. 641.3666) for $C_{35}H_{54}O_9Na$.

Trifluoroacetic anhydride (5.0 ml) was added at 0 °C to a mixture of 30% H_2O_2 (0.8 ml) and CH_2Cl_2 (3.0 ml) and then stirred at 0 °C for 15 min. The prepared trifluoroperacetic acid solution was added to a mixture of the tetracetate (56.7 mg, 0.09163 mmol) and disodium hydrogen phosphate (0.8 g) in CH_2Cl_2 (10.0 ml) at 0 °C for 3 h. After adding saturated aqueous sodium hydrogen sulphite (5.0 ml) the mixture was stirred at 0 °C for 1 h. Work-up (CH_2Cl_2 extraction) was followed by chromatography on silica gel (1.0 cm i.d. ×20 cm). Elution with toluene–EtOAc (7:1) afforded **13** (46.1 mg, 79.3%), mp 248–249 °C (from MeOH); TLC: toluene–EtOAc (2:1) $R_F = 0.38$; δ_H (400 MHz): 0.74 (3H, *s*, 18-H_3), 0.93 (3H, *l*, $J = 7.4$ Hz, 27-H_3), 0.95 (3H, *d*, $J = 6.8$ Hz, 28-H_3), 0.99 (3H, *s*, 19-H_3), 1.01 (3H, I, $J = 6.8$ Hz, 21-H_3), 2.00 (3H, *s*, acetyl), 2.01 (3H, *s*, acetyl), 2.02 (3H, *s*, acetyl), 2.11 (3H, *s*, acetyl), 2.99 (1H, *dd*, $J = 12.0$ and 4.4 Hz, 5-H), 4.04 (1H, *dd*, $J = 12.8$ and 9.0 Hz, 7α-H), 4.12 (1H, *d*, $J = 11.2$ Hz, 7β-H), 4.87 (1H, *ddd*, $J = 13.2$, 4.8 and 2.8 Hz, 2-H), 5.19 (2H, *m*, 22 and 23-H) and 5.36 (1H, *d*, $J = 0.8$ Hz, 3-H). HR–FABMS $[M + Na]^+$ *m/z:* 657.3611 (calc. 657.3615) for $C_{35}H_{54}O_{10}Na$.

3.2.8. (22R,23R,24S)-2α,3α,22,23-Tetrahydroxy-26-nor-B-homo-7-oxa-5α-ergostan-6-one, 26-norbrassinolide 1

A solution of the compound **13** (39.2 mg, 0.06175 mmol) was treated with K_2CO_3 (150 mg, 1.09 mmol) in 70% aq. MeOH (20 ml) with refluxing for 6 h. Work-up (EtOAc extraction) was followed by chromatography on silica gel (1.0 cm i.d. ×25 cm). Elution with CH_2Cl_2–EtOH (20:1) afforded **1** (20.2 mg, 70.1%), mp 286–287 °C (from EtOAc); TLC: CH_2Cl_2–EtOH (5:1) $R_F = 0.40$; δ_H (400 MHz): 0.72 (3H, *s*, 18-H_3), 0.84 (3H, *d*, $J = 6.4$ Hz, 28-H_3), 0.91 (3H, *d*, $J = 7.2$ Hz, 21-H_3), 0.93 (3H, *s*, 19-H_3), 0.95 (3H, *t*, $J = 6.8$ Hz, 27-H_3), 3.12 (1H, *dd*, $J = 12.2$ and 5.2 Hz, 5-H), 3.56 (2H, *m*, *brs*, 22 and 23-H), 3.72 (1H, *m*, 2-H), 4.03 (1H, *br s*, 3-H) and 4.11 (2H, *m*, 7-H_2). HR–FABMS $[M + Na]^+$ *m/z:* 489.3210 (calc. 489.3192) for $C_{27}H_{46}O_6Na$.

3.2.9. (22R,23R,24S)-2α,3α,22,23-Tetrahydroxy-26-nor-5α-ergostane, 6-deoxo-26-norcastasterone 3

A mixture of the 26-norcastasterone **2** (11.0 mg, 0.02441 mmol), $N_2H_2 \cdot H_2O$ (300 μl), NaOH (350 mg,

8.75 mmol) and diethylene glycol (2.0 ml) was stirred at reflux temperature for 2 h. The excess $N_2H_2{\cdot}H_2O$ and H_2O were removed by concentrating in vacuo and the residue was stirred at 200 °C for 30 min. Work-up (EtOAc ectraction) was followed by chromatography on silica gel (1.2 cm i.d. ×15 cm). Elution with CH_2Cl_2–EtOH (20:1) afforded **3** (4.0 mg, 37.5%), mp 254–256 °C (from EtOAc); TLC: CH_2Cl_2–EtOH (15:1) $R_F = 0.21$; δ_H (400 MHz): 0.67 (3H, *s*, 18-H_3), 0.80 (3H, *s*, 19-H_3), 0.84 (3H, *d*, $J = 6.8$ Hz, 28-H_3), 0.90 (3H, *d*, $J = 6.4$ Hz, 21-H_3), 0.94 (3H, *t*, $J = 6.8$ Hz, 27-H_3), 3.57 (2H, *m*, *br s*, 22 and 23-H), 3.76 (1H, *m*, 2-H) and 3.96 (1H, *br s*, 3-H). HR–EIMS $[M]^+$ *m/z:* 436.3548 (calc. 436.3553) for $C_{27}H_{48}O_4$.

3.2.10. (22R,23R,24S)-2α,3α,22,23-Bisisopropylidene-dioxy-26-nor-5α-ergostan-6-one **4**

A mixture of the 26-norcastasterone **2** (10.8 mg, 0.02397 mmol), *p*-toluenesulfonic acid (1.0 mg, 6.4 μmol) and acetone (5.0 ml) was stirred at room temperature for 2 h. Work-up (EtOAc extraction) was followed by chromatography on silica gel (1.2 cm i.d. ×15 cm). Elution with hexane–EtOAc (10:1) afforded **4** (12.0 mg, 94.3%), mp 147–149 °C (from acetone); TLC: toluene–EtOAc (2:1) $R_F = 0.60$; δ_H (600 MHz): 0.66 (3H, *s*, 18-H_3), 0.67 (3H, *s*, 19-H_3), 0.92 (3H, *t*, $J = 7.1$ Hz, 27-H_3), 0.95 (3H, *d*, $J = 6.4$ Hz, 28-H_3), 0.98 (3H, *d*, $J = 6.8$ Hz, 21-H_3), 1.34 (3H, *s*, acetonide), 1.35 (3H, *s*, acetonide), 1.38 (3H, *s*, acetonide), 1.51 (3H, *s*, acetonide), 2.32 (1H, *dd*, $J = 12.7$ and 4.4 Hz, 7β-H), 2.55 (1H, *dd*, $J = 12.7$ and 3.9 Hz, 5-H), 3.60 (1H, *dd*, $J = 7.8$ and 4.8 Hz, 23-H), 3.89 (1H, *br d*, $J = 7.8$ Hz, 22-H), 4.10 (1H, *ddd*, $J =$ 10.3, 6.4 and 4.9 Hz, 2-H) and 4.28 (1H, *ddd*, $J = 4.9$, 4.4 and 1.5 Hz, 3-H). δ_C (150 MHz): 11.67 (C-27), 11.71 (C-18), 12.68 (×2) (C-19 and C-21), 14.21 (C-28), 21.13 (C-11), 22.57 (C-4), 23.88 (C-15), 26.53 (acetonide methyl), 26.58 (C-25), 27.25 (×2) (acetonide methyl), 27.76 (C-16), 28.65 (acetonide methyl), 36.72 (C-20), 37.25 (C-24), 37.62 (C-8), 39.14 (C-12), 41.11 (C-1), 42.51 (C-10), 42.80 (C-13), 46.90 (C-7), 51.48 (C-5), 53.31 (C-9), 53.37 (C-17), 56.40 (C-14), 72.15 (C-3), 72.35 (C-2), 80.22 (C-22), 81.11 (C-23), 107.65 (acetonide), 107.89 (acetonide), 211.45 (C-6). HR–FABMS $[M + Na]^+$ *m/z*: 537.3919 (calc. 537.3920) for $C_{33}H_{54}O_4Na$.

3.3. Bioassay method

The rice lamina inclination test was carried out as described by Fujioka et al. (1998). Normal rice (*Oryza sativa* cv. Akinishiki) was used in our experiment. Totally 20–24 seedlings were used for each treatment.

The pea growth test using the dwarf mutant *lkb* was done as previously reported (Nomura et al., 1999). A total of 8 plants were used for each treatment. The fourth stems were treated with BRs when the third leaves were just expanded and the lengths of the fourth and fifth internodes were measured. Because the fifth internodes were more sensitive, their lengths were employed to evaluate biological activities. This bioassay was repeated three times.

Received 7 December 2000; received in revised form 5 April 2001

Abstract

Calli of *Eucalyptus camaldulensis* Dehn were induced, for the first time, from immature flowers and stamens and established in the presence of 2,4-D and BA, under dark and light conditions. Immature flowers, of the same type used for callus induction, were submitted to hydrodistillation while the induced calli were extracted with *n*-pentane. The constituents of the *n*-pentane extracts and of the hydrodistillate were identified by GC–MS. The main constituents of the hydrodistillate from immature flowers were 1,8-cineole (34.7%), β-pinene (7.7%), and spathulenol (9.5%). The *n*-pentane extract from calli developed from stamens consisted only of alkanes, alkenes and alcohols, while that of calli developed from immature flowers consisted mainly of monoterpenes (92.08–96.56%). The main monoterpenes produced in these calli, cultured in darkness and under light conditions, were 1,8-cineole, 62.70 and 69.26% as well as β-pinene, 27.09 and the 25.31%, respectively. © 2001 Elsevier Science Ltd. Keywords: *Eucalyptus camaldulensis*; Myrtaceae; Callus cultures; Immature flowers; Monoterpenes; Sesquiterpenes; Stamens; Volatiles; 1,8-Cineole; β-Pinene

1. Introduction

Eucalyptus is one of the world's most important and most widely planted genera. Among its main uses is the production of essential oils, which are used for medicinal and pharmaceutical purposes (Ghisalberti, 1996; Leung and Foster, 1996). One of the most important compounds extracted from *Eucalyptus* is 1,8-cineole, mainly due to its antibacterial and expectorant properties (Leung and Foster, 1996). It is reported to be particularly abundant in leaves and its content in the essential oil of different *Eucalyptus* species varies between 25 and 90%. Apart from 1,8-cineole, the essential oil of leaves from *Eucalyptus* species contains, in relatively high amounts, several monoterpene hydrocarbons, (α-pinene, limonene, *p*-cymene, β-pinene, α-phellandrene, camphene, γ-terpinene, etc., with the first three in major amounts) and in lower percentage several sesquiterpene hydrocarbons (aromadendrene, allo-aromadendrene, globulol, etc.), oxygenated monoterpenes (e.g. myrtenal, carvone and pinocarvone) and others (Nicole et al., 1998; Pagula et al., 2000). Although there are many reports on the essential oil composition of *Eucalyptus* aerial parts (Nicole et al., 1998; Pagula et al., 2000), to our knowledge, there is no report on the composition of volatiles from immature flowers. Furthermore, although there are many reports on the uses of *Eucalyptus* species cell culture for the biotransformation of several terpenoid metabolites (Orihara and Furuya, 1994; Orihara et al., 1994), there is no report on the production of monoterpenes and sesquiterpenes by tissue cultures of this species. In this paper, we report the essential oil composition of immature flowers from *E. camaldulensis*, a species that is widely cultivated in Greece, and the production of monoterpenes and sesquiterpenes by tissue cultures.

2. Results and discussion

2.1. Composition of the essential oil from immature flowers

In the essential oil isolated from immature *E. camaldulensis* flowers 42 compounds were identified, corresponding

PII: S0031-9422(01)00193-5

to 82.5% of the total oil (total oil 0.81 mg g^{-1} fr. wt). Among these 18.6% were monoterpene hydrocarbons, 50.0% were oxygenated monoterpenes, while the rest were sesquiterpene hydrocarbons (1.2%) and oxygenated sesquiterpenes (12.7%). 1,8-Cineole (34.7%, 0.28 mg g^{-1}), β-pinene (7.7%, 0.06 mg g^{-1}) and spathulenol (9.46%, 0.08 mg g^{-1}) were determined as the most abundant constituents (Table 1). 1,8-Cineole was also the major component of the leaf oil (Leung and Foster, 1996). In lower, but significant, amounts were the monoterpenes terpinen-4-ol (3.6%), α-pinene (3.3%), cryptone (3.2%), *trans*-pinocarveol (1.9%), α-terpineol (1.8%), and myrtenal (1.5%). Most of the constituents of the essential oil from immature flowers were the same as those from leaves collected from the same tree at the same period (Kretsi et al., 2000). However, the terpenes, caryophyllene oxide (2.4%), γ-terpinene (0.5%), *trans*-sabinene hydrate (0.3%), *cis*-sabinene hydrate (0.2%) *trans*-linalool oxide (0.1%), bornyl acetate (0.1%), α-gurjunene (0.1%), β-caryophyllene (0.2%) and viridiflorol (0.2%) were detected exclusively in immature flowers.

2.2. Tissue culture

Immature flowers and stamens were cultured in seven media, which differed in their concentrations of BA and 2,4-D. Callus formation was observed under the binocular microscope 5 or 6 days after the start of immature stamen or flower culture, irrespectively of the culture medium. Calli from immature flowers, depending on the culture medium seemed to originate either from the ovule (media 5 and 7) or from the stamen filament. They had a yellow-brownish color, and those cultured under dim light conditions were yellow-green.

Calli from immature stamens had a similar appearance with those from immature flowers and seemed to originate from the stamen filament. Although callus initiation was not affected by the concentration of the growth factors in the culture medium, callus growth rate was higher in those media that contained both growth factors (media 5, 6, and 7). Calli were subcultured every 2 months, and after 2 subcultures calli from media 5, 6, and 7 were combined and extracted with *n*-pentane.

2.3. Analysis of the n-pentane extract from calli developed from immature stamens and flowers

Table 2 shows the results of the analysis of the *n*-pentane extracts from calli, which were developed from immature stamens and flowers of *E. camaldulensis* and cultured under dark or light conditions. The percent concentration of the identified volatile constituents from calli that derived from immature stamens and cultured in darkness were not the same as those cultured under light conditions. In calli derived from stamens, 15 compounds were identified corresponding to the 65.7% of

the total extract for those cultured in darkness, while the identified volatiles of calli cultured under light conditions corresponded to the 82.4% of the total extract. These compounds, irrespective of the culture conditions, were alkanes, alkenes, and aliphatic alcohol hydrocarbons. The major compounds were the alkenes 1-octadecene (5.1% under either dark or light conditions) and 5-octadecene (7.9 and 17.1%, under dark and light conditions, respectively). No mono- or sesquiterpenes were detected. Generally, with the exception of few examples (Zito et al., 1991; Figuiredo et al., 1995; Hosokawa and Fukunaga, 1995), there is lack of success in de novo production of monoterpene and sesquiterpene compounds by undifferentiated tissue cultures. One explanation could be the fact that their site of production is not physically separated from their storage site and, as a result, they are exposed to enzymatic degradation (Alves-Pereira and Fernandes-Ferreira, 1998).

In contrast to calli, which were developed from stamens, the volatiles from calli derived from immature flowers (0.17 mg g^{-1} fr. wt in darkness and 0.15 mg g^{-1} fr. wt under light conditions) were mainly monoterpenes. In the extract of calli cultured under dark and light conditions, 21 compounds were identified, corresponding to the 99.7 and 98.6% of the total extract, respectively. The two major compounds identified in the *n*-pentane extract of calli grown either in darkness or under light conditions, corresponding to 89.8 and 94.8% of the total, respectively, were the oxygenated monoterpene 1,8-cineole (62.7%, 0.11 mg g^{-1} fr. wt and 69.3%, 0.1 mg g^{-1} fr. wt, respectively) and the monoterpene β-pinene (27.1 and 25.5%, respectively). In lower amounts were determined α-pinene (1.2 and 1.1%, respectively) and the terpenoids, camphene, myrcene, isocineole, myrtenol, bicyclogermacrene, spathulenol, and *trans*-pinocarveol (in less than 1%). Apart from *iso*-cineole, these constituents were also determined in the essential oil from immature flowers.

In order to check whether extraction with *n*-pentane underestimated the number and the amounts of terpenoids in calli, we determined also the constituents of the *n*-pentane extract of immature flowers. As shown in Table 1, the constituents of the *n*-pentane extract were almost identical with those of hydrodistillate and in comperable amounts.

Our results showed that a very important role on the production of monoterpenes and sesquiterpenes by *E. camaldulensis* calli played the kind of explant used for callus development. On the other hand, light conditions did not considerably affect the production of these compounds by calli developed from immature flowers. It is remarkable that undifferentiated calli are capable of producing high amounts of monoterpenoid compounds (approx. one third of that produced by the explant). This makes immature flowers from *E. camaldulensis* an interesting candidate plant material for the development of calli able to produce high percentages of two important monoterpenes.

3. Experimental

3.1. Plant material

Fresh immature flowers were collected from *E. camaldulensis* in the University Campus of the University of Athens, Zografou, Athens, at the beginning of September 2000. Dr. L. Koumpli-Sovantzi identified a voucher specimen which it has been deposited in her herbarium (KS6187) kept in ATHU.

3.2. Initiation of cultures from immature flowers and stamens

Immature flowers were collected from a tree in the University Campus, at the beginning of April 2000. They were surface sterilized with 70% ethanol for 1.5 min and 10% common bleach for 4 min, and then rinsed three times with distilled sterile water. A batch of flowers was cut in half while from another batch stamens were dissected. Half flowers and stamens were placed separately, under sterile conditions, in petri dishes containing MS (Murashige and Skoog, 1961) supplemented with 8% agar, 2% sucrose, in the presence of either BA, 2,4-D, or both: media 1, 2 and 3 contained only 0.01, 0.1 and 0.5 mg l^{-1} BAP, respectively, medium 4 contained only 0.01 mg l^{-1} 2,4-D, while media 5, 6, and 7 contained both growth factors at concentrations of 0.01, 0.05 and 0.05 mg l^{-1} 2,4-D and 0.1, 0.01 and 0.1 mg l^{-1}, respectively. The pH of the culture media was adjusted to 5.8. The explants were incubated at 25°C in continuous darkness or in 16 h light (3200 lux). Calli were initiated 6 days after the start of flower or stamen culture.

3.3. Identification of volatiles from calli of immature stamens and flowers and of the essential oil from immature flowers

Two weeks after callus initiation (observation under the binocular microscope) calli with (stamens) or without the explant (immature flowers) were transferred to petri dishes with the same culture medium and cultured under the same conditions. After two subcultures, calli that were cultured in media 5, 6, and 7 were collected and extracted with *n*-pentane.

Fresh immature flowers (200 g fr. wt) were submitted to steam distillation for 3 h in 1 l water, in a Clevenger modified apparatus with a water-cooled oil receiver to reduce hydrodistillation-overheating artifacts. The essential oils were taken in pesticide analysis grade diethyl ether and were subsequently dried over anhydrous sodium sulfate and stored at 4–6°C until they were analyzed. The oil was light yellow with distinct sharp odor.

In all cases, the *n*-pentane extracts from calli, which were developed from flowers and stamen and the obtained essential oil of the fresh immature flowers of *E. camaldulenis* were then subjected to GC–MS analysis.

3.4. GC–MS analysis

Analysis was performed with a Hewlett Packard 6890 chromatograph linked to a Hewlett Packard 5973 mass spectrometer system operating on EI mode (equipped with a split/ splitless injector (200°C) 1/10 split ratio), and a 30 m long, 0.25 mm i.d., 0.25 μm film thickness HP 5MS capillary column. The ionization energy was 70 eV. The temperature of the injection block was 200°C. The GC oven temperature was programmed as follows: initial temperature 60°C (for 5 min) followed by a temperature increase of 3°C min^{-1} up to 280°C. The carrier gas was He. Identification of the volatile components was established using a Wiley MS data library as well as\by comparison of Kovats indices (Adams, 1995) and GC–MS data with those of authentic samples.

3.5. Kovats indices

Values were determined relative to the retention times of a series of *n*-paraffin hydrocarbons (Van den Dool, 1963) on a Hewlett Packard 6890 GC. Analytical conditions were identical to those used for the GC–MS analysis.

Anti-inflammatory tetramers of resveratrol from the roots of *Vitis amurensis* and the conformations of the seven-membered ring in some oligostilbenes

Kai-Sheng Huang, Mao Lin*, Gui-Fang Cheng

Institute of Materia Medica, Chinese Academy of Medical Sciences and Peking Union Medical College, 1 Xian Nong Tan Street, Beijing 100050, People's Republic of China

Received 21 November 2000; received in revised form 11 April 2001

Abstract

Five resveratrol tetramers, amurensins I–M, were isolated from the roots of *Vitis amurensis* (Rupr.), together with five known resveratrol tetramers, (+)-hopeaphenol, isohopeaphenol, vitisin A, (+)-vitisifuran A, and heyneanol A. Their structures and stereochemistry were determined by chemical and spectroscopic methods, especially by use of 2D NMR analysis. Some of them had an ampelopsin A or a balanocarpol unit, in which the conformations of the seven-membered carbon ring were described for the first time. The anti-inflammatory activities of the tetramers were also tested. Among them, (+)-hopeaphenol, isohopeaphenol, vitisin A, (+)-vitisifuran A and heyneanol A showed potent inhibition on the biosynthesis of leukotriene B_4 (LTB_4), and amurensins I and L showed strong antagonism of the histamine acceptor. © 2001 Elsevier Science Ltd. 1. Introduction

Hopeaphenol was the first resveratrol tetramer isolated from *Hopea odorata* (thingan) and *Balanocarpus heimii* (chengal) (Coggon et al., 1965), whose structure was determined by X-ray crystallographic analysis (Coggon et al., 1966). Kawabata and his colleagues reported its NMR spectroscopic data (Kawabata et al., 1992). In this study, besides the resveratrol dimers and trimers reported previously (Huang and Lin, 1999; Huang et al., 1999, 2000), ten resveratrol tetramers including five new compounds amurensins I–M (**1**–**5**), were isolated from the roots of *Vitis amurensis*. The known tetramers were determined to be (+)-hopeaphenol, isohopeaphenol (Ito et al., 1997), vitisin A (Oshima et al., 1993), (+)-vitisifuran A (Ito et al., 1999) and heyneanol A (Li et al., 1996) by comparison of their chemical and spectral data with those in the literature.

2. Results and discussion

Amurensin I (**1**) was obtained as a brown amorphous powder, exhibiting strong blue violet fluorescence under UV-254 light, $[\alpha]_D^{20}$ −128.2° (*c* 0.12, MeOH). Its molecular formula of $C_{56}H_{38}O_{12}$ was determined by the high resolution FAB–MS *m*/*z* 903.2385 $[MH]^+$ (calc. for $C_{56}H_{39}O_{12}$, 903.2442), corresponding to a resveratrol tetramer. The ^1H NMR spectrum of **1** contained the signals for an 8b-dehydroxybalanocarpol unit [δ 7.63 (2H, *d*, $J=8.5$ Hz), 7.03 (2H, *d*, $J=8.5$ Hz), 6.33 (2H, *d*, $J=8.8$ Hz), 6.22 (2H, *d*, $J=8.8$ Hz), 6.39 (1H, *d*, $J=2.2$ Hz), 6.35 (1H, *d*, $J=2.2$ Hz), 5.72 (1H, *d*, $J=2.1$ Hz), 4.42 (1H, *d*, $J=2.1$ Hz), 5.63 (1H, *d*, $J=10.1$ Hz), 5.59 (1H, *d*, $J=10.1$ Hz), 5.52 (1H, *d*, $J=4.5$ Hz), 2.98 (1H, *dd*, $J=4.5$, 11.3 Hz)]. The other signals were similar to those of malibatol B (Dai et al., 1998), but there were three hydroxy groups less than in malibatol, suggesting that an extra ring (ring D_4) was formed by the connectivity of C-2d and C-14d to satisfy the ^1H NMR patterns. The two units were bonded at C-8b and C-8c to form **1**, which was confirmed by ^1H–^1H COSY (H-7b→H-8b→H-8c→H-7c) and long range CH correlations (H-8b/C-8c and H-8c/C-8b) in the HMBC spectrum. The up-field

shift of H-14b (δ 4.42) was due to the shielding effect of ring C_2 which can be observed clearly from the molecular model, and the down-field shift of H-3d, 5d, 6d (δ 9.49, 7.25, 8.20) was due to the strong deshielding effect of the highly unsaturated ring system in the structure. The NOE interaction between H-8a and H-2(6)a suggested a *trans* orientation of ring A_3. The NOE enhancements between H-8a/H-8c, H-7b/H-8c, H-8b/H-14b, H-8c/H-14c verified the relative configuration of *rel*-(7a*S*, 8a*S*, 7b*R*, 8b*S*, 7c*R*, 8c*S*) for **1**. In a previous paper (Sotheeswaran and Pasupathy, 1993), it was proposed that all naturally occurring oligomers of resveratrol with dihydrobenzofuran moieties were formed from reveratrol via the dimer ε-viniferin, the absolute configuration of **1** was tentatively assigned as (7a*S*, 8a*S*, 7b*R*, 8b*S*, 7c*R*, 8c*S*) because only (+)-ε-viniferin was isolated from this plant.

Amurensin J (**2**) was obtained as a yellowish amorphous powder, exhibiting strong blue fluorescence under UV-254 light, $[\alpha]_D^{20}$ +174.9° (*c* 0.12, MeOH). The high resolution FAB–MS *m*/*z* 907.2699 $[MH]^+$ (calc. for $C_{56}H_{43}O_{12}$, 907.2755) was in agreement with the molecular formula $C_{56}H_{42}O_{12}$, which corresponds to a resveratrol tetramer. In the ^1H NMR spectrum of **2** at room temperature in acetone-d_6, several protons appeared as very broad signals. This resulted in many difficulties for the structural elucidation because they did not give cross-peaks in the 2D NMR spectra. Considering that the reason for the broad signals was probably spatial congestion, the ^1H and ^1H–^1H COSY spectra of **2** were carried out at a temperature of 100 °C, resulting in improved resolution. The ^1H NMR spectrum of **2** at 100 °C in DMSO-d_6 showed signals for four 1-substituted 4-hydroxybenzene moieties (ring A_1, B_1, C_1, D_1) at δ 7.13 (2H, *d*, *J* = 8.4 Hz) and 6.76 (2H, *d*, *J* = 8.4 Hz) δ 6.96 (2H, *d*, *J* = 8.4 Hz) and 6.72 (2H, *d*, *J* = 8.4 Hz) δ 6.81 (2H, *d*, *J* = 8.2 Hz) and 6.52 (2H, *d*, *J* = 8.2 Hz), δ 6.62 (2H, *d*, *J* = 8.6 Hz) and 6.57 (2H, *d*, *J* = 8.6 Hz); signals for two 1-substituted 3,5-dihydroxybenzene moieties (rings A_2, D_2) at δ 5.78 (2H, *br s*) and 6.04 (1H, overlap), δ 6.04 (2H, *br s*) and 6.04 (1H, overlap); two *meta*-coupled signals at δ 6.22 (1H, *br s*) and 5.98 (1H, *br s*) for ring C_2; one singlet for ring B_2 at δ 6.25; and three sets of signals for the dihydrobenzofuran moieties (rings A_3, C_3, D_3) at δ 5.33 (1H, *d*, *J* = 4.5 Hz) and 4.34 (1H, *d*, *J* = 4.5 Hz), δ 5.13 (1H, *br s*) and 3.61 (1H, *br s*), δ 4.92 (1H, *d*, *J* = 7.7 Hz) and 4.55 (1H, *d*, *J* = 7.7 Hz). The ^{13}C NMR spectrum in DMSO-d_6 revealed the presence of six aliphatic carbons besides 50 aromatic and olefinic carbons. The ^1H and ^{13}C NMR patterns menttioned above were similar to those of flexuosol A (Li et al., 1998), and the CH long range correlations between H-7a/C-2(6), 9a, 10b, H-12b/C-10b, 14b, H-8b/C-10b, 14b, H-8c/C-14b, 13b, 10c, 14c, H-10(14)d/C-8d observed in the HMBC spectrum (measured at 70 °C in DMSO-d_6) supported the same planar structure of **2** as flexuosol A, thus **2** was a stereomer of flexuosol A. Since amurensin B (Huang and Lin, 1999; Huang et al., 1999), a resveratrol trimer with a *cis*-dihydrobenzofuran moiety was iso-

lated from this plant, it was proposed that **2** was derived from amurensin B through addition of a resveratrol unit. The strong NOE interaction between H-7c and H-8c supported a *cis* relationship between H-7c and H-8c. The *trans* orientations between H-7a/H-8a, H-7d/H-8d were confirmed by the NOE interactions between H-7a/H-2(6)a, H-8a/H-2(6)a, H-7d/H-2(6)d, H-8d/H-2(6)d in the NOESY spectrum. Based on consideration of the biosynthesis of naturally occurring oligostilbenes (Sotheeswaran and Pasupathy, 1993) the absolute configuration of **2** was tentatively assigned as (7a*S*, 8a*S*, 7c*S*, 8c*R*, 7d*S*, 8d*S*).

Amurensin K (**3**) was obtained as a brown amorphous powder, exhibiting blue fluorescence under UV-254 light, $[\alpha]_D^{20}$ +195.3° (*c* 0.34, MeOH). A molecular formula of $C_{56}H_{40}O_{13}$ was determined from its high resolution FAB–MS *m*/*z* 921.2566 $[MH]^+$ (calc. for $C_{56}H_{41}O_{13}$, 921.2523), corresponding to a resveratrol tetramer with an extra oxygen atom. The ^1H NMR spectrum of **3** showed similar spectral patterns to those of vitisin A (Oshima et al., 1993) containing the signals of an ampelopsin A unit, except that resonances for two *trans* olefinic protons were not observed. The 37 degrees of unsaturation of **3** were one more degree than the 36 of vitisin A. Therefore, it was proposed that a five-membered ring could be formed between C-7c and C-10c, to account for the additional oxygen atom present in **3**. This supposition regarding the planar structure of **3** was confirmed by the CH long range couplings between H-8a/C-1a, 10a, 10b, H-7b/C-10a, 11a, 9b, H-8b/C-10b, 2c, H-8c/C-7c, 10c, H-12c/C-10c, 14c, H-8d/C-14c, 1d, 10(14)d observed in the HMBC spectrum. The NOEs observed between H-7d/H-10(14)d, and H-8d/H-2(6)d indicated a *trans* orientation for the H-7d and H-8d protons. The *trans* relationship between H-7a/H-8a was revealed by strong NOE between H-8a/H-2(6)a, and the NOEs between H-8a/H-2(6)b and H-8b/H-2(6)b confirmed the *trans* orientation between H-8a/H-7b as well as H-7b/H-8b. Thus, the absolute configuration of **3** could tentatively be assigned as (7a*S*, 8a*S*, 7b*S*, 8b*R*, 7d*S*, 8d*S*), considering the biosynthesis of the oligostilbenes.

Amurensin L (**4**) was obtained as a pale yellow amorphous powder, exhibiting strong white fluorescence under UV-254 light, $[\alpha]_D^{30}$ −116.5° (c 0.058, MeOH). The high resolution FAB–MS *m*/*z* 905.2587 $[MH]^+$ (calc. for $C_{56}H_{41}O_{12}$, 905.2598) gave a molecular formula of $C_{56}H_{40}O_{12}$, which together with the ^1H and ^{13}C NMR spectra suggested that **4** was a resveratrol tetramer. The UV spectrum (λ_{max} 340 nm) revealed the presence of a strong conjugated system in the structure. The ^1H and ^{13}C NMR spectral data (Table 2) of **4** were similar to those of heyneanol A (Li et al., 1996) except that **4** showed only four aliphatic proton signals for two dihydrobenzofuran moieties in the ^1H NMR spectrum and two quaternary carbon signals more than in heyneanol A in the ^{13}C NMR spectrum. This suggested that one dihydrobenzofuran moiety was transformed into an unsaturated benzofuran moiety in **4**, consequently the signals of H-2(6)d were shifted to lower field at δ 7.47. In the HMBC spectrum of **4**, long-range couplings between H-8a/C-9b, H-8a/C-10b, H-8b/C-9b, H-8b/C-10b indicated that rings A_3 and B_3 were dihydrobenzofuran rings, the ring D_3 was a benzofuran ring, and thus the planar structure of amurensin L was as shown in **4**. The relative stereochemistry of **4** was determined on the basis of NOESY experiments. The NOEs between H-7a and 10(14)a; H-7b and 14b; suggested a *trans* orientation of rings A_1 and A_2, and B_1 and B_2, respectively. The NOE between H-8a and H-8b suggested a *cis* orientation between these two protons. Since only (+)-ε-viniferin was isolated from this plant, the absolute configurations of **4** could tentatively be assigned as (7a*S*, 8a*S*, 7b*S*, 8b*S*).

Amurensin M (**5**), obtained as a greenish amorphous powder, exhibited strong white fluorescence under UV-254 light. The high resolution FAB–MS *m*/*z* 903.2484 $[MH]^+$ (calc. for $C_{56}H_{39}O_{12}$, 903.2442) was in agreement with a molecular formula of $C_{56}H_{38}O_{12}$, corresponding to a resveratrol tetramer. Its ^1H and ^{13}C NMR patterns were relatively simple in contrast to the molecular formula, and the presence of a strong ion peak at *m*/*z* 452 in FAB–MS indicated that **5** was composed of two equivalent units. The ^1H and ^{13}C NMR data were similar to those of amurensin H (Huang et al., 1999) except that two *meta*-coupled doublets in amurensin H were transformed into a singlet in **5**. Thus, it was proposed that **5** should be a dimer of amurensin H through formation of a bond between C-12b and C-12b′. This was substantiated by the appearance of a quaternary carbon signal at δ 104.0 in the ^{13}C NMR spectrum of **5**. Amurensin M is the first resveratrol tetramer with a completely unsaturated ring system.

Ampelopsin A (**6**) (Oshima et al., 1990) and balanocarpol (**7**) (Diyasena et al., 1985; Dai et al., 1998) shared the same planar structure. However, the chemical shifts of H-8a (δ 4.10), H-2(6)a (δ 7.07), C-7a (δ 88.4), C-8a (δ 49.5) and the coupling constant between H-7a/H-8a (11.4 Hz) in **6** (Huang and Lin, 1999) were markedly different from those (δ 5.14 for H-8a, δ 7.46 for H-2(6)a, δ 93.0 for C-7a, δ 52.2 for C-8a, *J* 7a, 8a = 9.2 Hz) in **7** (Diyasena et al., 1985). It was considered that a mere change in the *cis* or *trans* configuration between H-7b and H-8b of **6** and **7** would not result in all of these differences after reasonable analysis of the NMR spectral data for both **6** and **7**. Therefore, it was proposed that the conformations of ring B_3 in compounds **6** and **7** were different, one in a pseudo-boat conformation and the other in a pseudo-chair conformation. The NOE interactions (Fig. 1) between H-7a/H-14a, H-8a/H-2(6)a, H-8a/H-2(6)b, H-8b/H-2(6)b, H-8b/H-14b of **6** required ring B_3 to be in a preferred pseudo-boat conformation, while a preferred pseudo-chair conformation of ring B_3 in **7** would satisfy the NOEs between H-7a/H-2(6)a, H-7a/H-2(6)b, H-8a/H-8b, H-8a/H-14a, H-7b/H-8b of 7

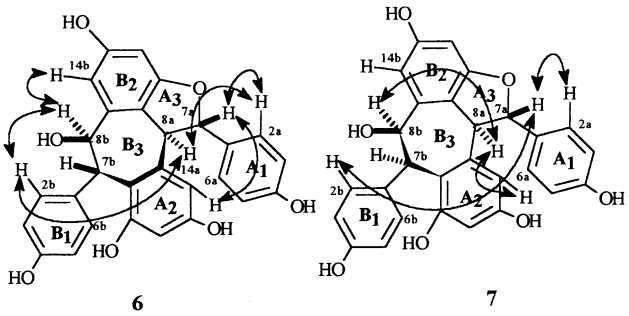

Fig. 1. Significant NOE interactions of compounds **6** and **7**.

(Fig. 1). The obvious downfield shifts of H-8a and H-2(6)a in **7** were due to the deshielding effect of ring A_2, and different conformation of ring B_3 were responsible for the variety of coupling constants between H-7a and H-8a in **6** and **7**. Thus, the stereostructures of **6** and **7** are suggested as shown. The energy-minimized conformations of compounds **6** and **7** were calculated with an Alchemy 3.0 molecular modeling program (Fig. 2), and the results confirmed the above deduction.

(+)-Hopeaphenol and isohopeaphenol were obtained as pale white amorphous powders, whose spectral data were identical with those reported previously (Ito et al., 1997). In both (+)-hopeaphenol and isohopeaphenol, the vicinal coupling constants between H-7b and H-8b were almost zero, H-7b and H-8b appearing as singlets. Consequently, it was impossible that the vicinal dihedral angles between H-7b and H-8b are nearly 90°in both (+)-hopeaphenol and isohopeaphenol if the conformations of ring B_3 were the same. The NMR spectral data of (+)-hopeaphenol and isohopeaphenol were similar to those of **6** and **7**, respectively. It was found that the pseudo-boat conformation of ring B_3 satisfied the 90° angle of *trans* H-7b and H-8b, and that the pseudo-chair conformation satisfied the 90° angle of *cis* H-7b and H-8b from molecular models. It was determined that ring B_3 had a pseudo-boat conformation in (+)-hopeaphenol and a pseudo-chair conformation in isohopeaphenol; (+)-hopeaphenol was the dimer of **6** and isohopeaphenol was the dimer of **7**.

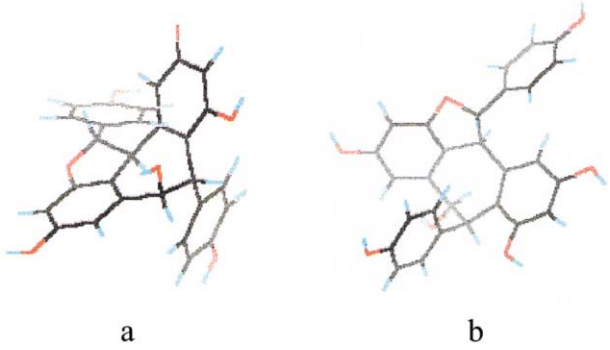

Fig. 2. Energy-minimized stereostructure of **6** with a pseudo-boat conformation (a) and **7** with a pseudo-chair conformation (b) (MM^+ calculation using the Alchemy 3.0 molecular modeling program).

The ^1H and ^{13}C NMR spectral data of vitisin A (Oshima et al., 1993) were the same as those of γ-2-viniferin (Korhammer et al., 1995). Consequently, it was suggeated that vitisin A and γ-2-viniferin had the same structure with a pseudo-boat conformation of the seven-membered ring. Considering that a part of its NMR spectral data were similar to those of **6**, the correct structure was determined to be vitisin A, and we concluded that the structure of γ-2-viniferin was erroneously elucidated. In the reported oligostilbenes containing a seven-membered ring, only isohopeaphenol was the analogue of **7**; and amurensin I reported in this paper was the second one, the others were analogues of **6**.

Since the alcoholic extract of the roots of *Vitis amurensis* showed anti-inflammatory activity, the activities of these tetramers on the inhibition of leukotriene B_4 (LTB_4) biosynthesis and histamine receptor antagonism were tested (Yang et al., 1995). (+)-Hopeaphenol, isohopeaphenol, vitisin A, (+)-vitisifuran A and heyneanol A exhibited a strong inhibitory effect on the biosynthesis of LTB_4 at concentrations of 10^{-5} mol L^{-1} with inhibitory rates of 56, 60, 63, 72 and 76%, respectively. The inhibitory rates of histamine receptor antagonism for compounds **1**, **2**, **4** and **5** at concentrations of 10^5 mol L^1 were 65, −45, −39, and 74%, respectively, compounds **1** and **5** showed potent activity.

3. Experimental

3.1. General experimental procedures

Optical rotations were determined on a Perkin-Elmer digital polarimeter. UV spectra were taken on a Shimadzu UV-300 spectrophotometer. IR spectra were run on a Perkin-Elmer 683 infrared spectrometer recorded in KBr pellet. The NMR spectra were carried out on a Bruker AM-500 using TMS as internal standard. The FAB–MS spectra were taken on an Autospec-Ulma-Tof mass spectrometer.

3.2. Plant material

The roots of *Vitis amurensis* Rupr. were collected from Huairou, Beijing in May 1997, and identified as *Vitis amurensis* by Professor W.Z. Song of our institute. A voucher specimen (97021) was deposited in the herbarium of the Institute of Materia Medica, Chinese Academy of Medical Sciences and Peking Union Medical College.

3.3. Extraction and isolation

Dried and powdered roots of *Vitis amurensis* (20 kg) were extracted with 95% EtOH. The extract was concentrated in vacuo to yield a gum (2.2 kg), which was

mixed with silica gel (60–100 mesh), and the column was eluted successfully with $CHCl_3$, EtOAc, Me_2CO, MeOH, respectively, to give four fractions. The EtOAc fraction (640 g) was subjected to silica gel column chromatography eluted with $CHCl_3$–MeOH (100:1–100:30) to give: A (27.5 g), B (30 g), C (25 g), D (230 g) and E (210 g). Fraction E was further divided into three fractions E_1–E_3 by column chromatography (ODS, RP-18, MeOH–H_2O = 6:4–4:6); (+)-hopeaphenol (840 mg, 0.0042%) and isohopeaphenol (680 mg, 0.0032%) were obtained from fraction E_1, and **1** (10 mg, 0.00005%) and **5** (18 mg, 0.00009%) from section E_2 by MPLC (ODS, RP-18, 40–63 μm, MeOH:H_2O of 4:6). Fraction D was further divided into fractions D_1–D_4 by column chromatography (silica gel, 100–200 mesh, cyclohexane—Me_2CO). Fraction D_1 was subjected to ODS RP-18 column eluted with MeOH–H_2O (6:4) to afford

[a] All assignments were confirmed by ^1H–^1H COSY, ^1H–^{13}C COSY, HMBC and NOESY spectra.
[b,c] May be interchanged within the same column.

vitisin A (25 mg, 0.00013%) and **4** (25 mg, 0.00013%), and was further purified by MPLC (ODS, RP-18, 40–63 μm, MeOH–H_2O = 5.5:4.5). Fraction D_2 was subjected to MPLC (ODS, RP-18, 40-63 μm, MeOH:H_2O of 1:1) to afford **2** (39 mg, 0.0002%) and **3** (14 mg, 0.00007%). (+)-Vitisifuran A (35 mg, 0.00018%) was obtained from fraction D_3 using the same method as above, and heyneanol A (10 g, 0.05%) from fraction C by column chromatography (silica gel, 100–200 mesh, cyclohexane:acetone, 1:1)

3.4. Amurensin I (*1*)

Brown amorphous powder; $[\alpha]_D^{20}$ −128.2° (*c* 0.12, MeOH); HRFAB–MS *m/z* 903.2385 $[MH]^+$ (calc. for $C_{56}H_{39}O_{12}$, 903.2442); UV λ_{max}^{MeOH} (log ε): 280 (4.5), 334 (4.0), 348 (4.1), 377 (3.5) nm; IR ν_{max}^{KBr}: 3359, 1693, 1612, 1512, 1450, 1365, 1221, 1173, 1134, 1082, 1007, 833 cm^{-1}; ^1H NMR and ^{13}C NMR spectral data, see Table 1.

3.5. Amurensin J (*2*)

Yellowish amorphous powder; $[\alpha]_D^{20}$ +174.9° (*c* 0.12, MeOH); HRFAB–MS *m/z* 907.2699 $[MH]^+$ (907.2755 calc. for $C_{56}H_{43}O_{12}$); UV λ_{max}^{MeOH} (log ε): 285 (4.4) 310 *sh* (4.2) nm; IR ν_{max}^{KBr}: 3410, 1614, 1514, 1446, 1338, 1238, 1157, 1122, 1080, 997, 833 cm^{-1}; ^1H NMR and ^{13}C NMR spectral data, see Table 1.

3.6. Amurensin K (*3*)

Brown amorphous powder; $[\alpha]_D^{20}$ +195.3° (c 0.34, MeOH); HRFAB–MS *m/z* 921.2566 $[MH]^+$ (921.2523 calc. for $C_{56}H_{41}O_{13}$); UV λ_{max}^{MeOH} (log ε): 285 (4.7), 310 (4.6), 320 (4.6) nm; IR ν_{max}^{KBr}: 3378, 1613, 1512, 1447, 1338, 1234, 1157, 998, 833 cm; ^1H NMR and ^{13}C NMR spectral data, see Table 2.

3.7. Amurensin L (*4*)

Pale yellow amorphous powder, $[\alpha]_D^{30}$ −116.5° (*c* 0.058, MeOH). HRFAB–MS *m/z* 905.2587 $[MH]^+$ (905.2598 calc. for $C_{56}H_{41}O_{12}$); UV λ_{max}^{MeOH} (log ε): 285 (4.6), 340 (4.4) nm; IR ν_{max}^{KBr} cm^{-1}: 3386, 1697, 1612, 1516, 1442, 1336, 1236, 1153, 999, 835^{-1}; ^1H NMR and ^{13}C NMR spectral data, see Table 2.

3.8. Amurensin M (*5*)

Greenish amorphous powder; HRFAB–MS *m/z* 903.2484 $[MH]^+$ (903.2442 calc. for $C_{56}H_{39}O_{12}$); UV λ_{max}^{MeOH} (log ε): 316 (4.6), 338 (4.6), 380 (4.6) nm; IR ν_{max}^{KBr}: 3379, 1603, 1512, 1439, 1367, 1236, 1171, 1078, 997, 837 cm^{-1}; ^1H NMR and ^{13}C NMR spectral data, see Table 2.

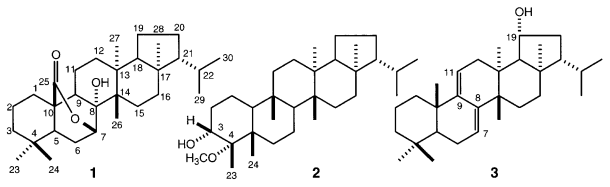
Abstract

Three triterpenoids, 8α-hydroxyfernan-25,7β-olide, 3α-hydroxy-4α-methoxyfilicane and 19α-hydroxyferna-7,9(11)-diene were isolated from the fresh fronds of *Adiantum caudatum*. Their structures were elucidated by spectroscopic techniques. Thirteen known triterpenoids were also identified from this fern. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Adiantum caudatum*; Adiantaceae; Triterpenoid; 9α-Hydroxyfernan-25,7β-olide; 3α-Hydroxy-4β-methoxyfilicane; 19α-Hydroxyferna-7,9(11)-diene

1. Introduction

In the course of chemotaxonomic studies of Adiantaceous ferns, we reported the presence of a large number of triterpenoids belonging to hopane and migrated hopane skeleta (Ageta et al., 1964, 1966, 1968; Ageta and Iwata, 1966). Recently we reported a triterpenoid ether having a fernane skeleton from *A. cuneatum* Langsd. et Fisch (Shiojima et al., 1997a,b,c; Nakane et al., 1999). In a continuation of our study, we have now investigated *Adiantum caudatum* L. (cultivated), resulting in the isolation of three new triterpenoids, characterized as 8α-hydroxyfernan-25,7β-olide (**1**), 3α-hydroxy-4β-methoxyfilicane (**2**) and 19α-hydroxyferna-7,9(11)-diene (**3**), along with 13 known triterpenoids. We report herein the isolation of the constituents and structure elucidation of **1**, **2** and **3**.



2. Results and discussion

The dried fronds of *A. caudatum* were extracted with *n*-hexane and the extract was subjected to silica gel chromatography generating seven fractions. The individual fractions were subjected to rechromatography and preparative HPLC to obtain a total of 16 compounds: new compounds **1**–**3**, and known triterpenoids; neohop-13(18)-ene (**4**), fern-7-ene (**5**), fern-8-ene (**6**), fern-9(11)-ene (**7**), ferna-7,9(11)-diene (**8**), filic-3-ene (**9**), 17β,21β-epoxyhopane (**10**), adiantone (**11**), isoadiantone (**12**), 19α-hydroxyfern-7-ene (**13**), 19α-hydroxyfern-9(11)-ene (**14**), 19α-hydroxyfern-9(11)-ene (**15**) and 19α-hydroxyadiantone (**16**). Known triterpenoids (**4**–**16**) were identified with authentic samples.

Compound **1**, mp 268–271°C, $[\alpha]_D^{23}$ −21.6°, (EtOH; *c* 0.4) was obtained as colorless needles, and its molecular formula was found to be $C_{30}H_{48}O_3$ by high resolution MS (HR–MS M^+ at *m*/*z* 456.3604, calc. 456.3603). Its IR spectrum showed absorption at γ_{max}^{KBr} cm^{-1}; 3470 and 1730 due to a hydroxyl and a six membered ring lactone groups. The ^1H NMR spectra of **1** indicated the presence of five tertiary and two secondary methyl groups, and a methine proton attached to oxygen (Table 1). As the ^1H (Table 1) and ^{13}C (Table 2) NMR spectroscopic data of **1** were not conclusive in the determination of the structure of the compound, its 2D NMR spectra were recorded. Detailed analysis of the heteronuclear multiple bond correlation (HMBC) spectrum of the compound

[a] Multiplicity and coupling constant (*J*, Hz) are shown in parentheses.

[b] Assignments were made on the basis of distortionless enhancement by polarization transfer (DEPT), ^{1}H–^{1}H COSY, ^{1}H–^{13}C COSY, HMBC and NOESY spectra.

revealed that it possesses a fernane skeleton (partial structure as obtained from HMBCs shown in Fig. 1) with an unusual lactone linkage between C-25 and C-7, and a hydroxyl group at C-8 of the molecule as would be evident from the two- and three-bond correlation of protons with the carbons viz.: δ 1.66 (H-5α) with 33.39 (C-4), 29.71 (C-6), 66.60 (C-7), 46.77 (C-9), 50.00 (C-10), 20.47 (C-23), 32.03 (C-24) and 179.70 (C-25); δ 4.315 (H-7α) with 45.49 (C-5), 29.71 (C-6), 88.38 (C-8) and 46.77 (C-9); δ 2.71 (H-9α) with 45.49 (C-5), 60.60 (C-7), 88.38 (C-8), 50.00 (C-10), 16.47 (C-11) and 179.70 (C-25), and δ 1.153 (H_3-26) with 88.38 (C-8), 36.97 (C-13), 44.06 (C-14) and 33.06 (C-15). The mass fragment ions at *m*/*z* (rel. int.) 441 $[M–CH_3]^+$ (14), 438 $[M–H_2O]^+$ (27), 423$[M–H_2O\text{-}CH_3]^+$ (45), 411 [**a**, $M–CO_2H]^+$ (31), 394 [**a**-OH]$^+$ (47), 379 [**a**-OH–$CH_3]^+$ (52), 285 [**b**]$^+$ (14), 241 [**b**-$CO_2]^+$ (43), 239 [**b**-HCOOH]$^+$ (39), 227 [**c**]$^+$ (56), 225 [**c**-H_2]+(37), 215[**d**]$^+$ (22), 213 [**d**-$H_2]^+$ (24), and 191 [**e**]$^+$ (100) (Fig. 2.) also supported the assigned structure. The relative stereochemistry at most of the chiral center of **1** was established by the NOE interactions observed in its NOESY spectrum as depicted in Fig. 1. Configuration of the tertiary hydroxyl group at C-8 was determined by the down field shifts of methyl proton signals at δ 1.153 (H_3-26, C-14) and δ.1.088 (H_3-27, C-13) compare with those of fernenes (Ageta et al., 1994). Thus, the structure of **1** was proved as 8α-hydroxyfernan-25,7β-olide.

OMe	–	49.80	–	–	

[a] Assignments were made on the bases of DEPT, ^{1}H–^{1}H COSY, ^{1}H–^{13}C COSY and HMBC spectra.

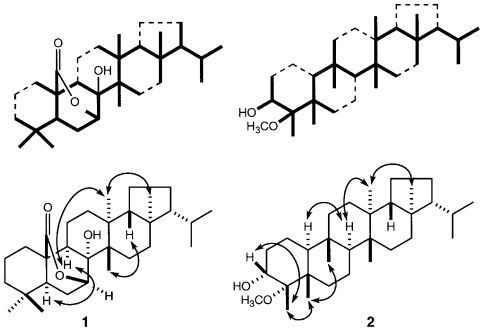

Fig. 1. Partial structures of **1** and **2** derived from HMBC spectrum and NOEs obtained from NOESY spectrum.

Compound **2**, $C_{31}H_{54}O_2$ (HR–MS; M^+ at *m*/*z* 458.4103, calc. 458.4124), mp 198–204°C, $[\alpha]_D^{23}$ +18.7° (EtOH; *c* 0.3), showed strong absorption bands at γ_{max}^{KBr} cm^{-1}; 3300 and 1080 for a hydroxyl group in its IR spectrum. Its ^{1}H NMR spectroscopic data (Table 1) displayed, besides the signals for six tertiary and two secondary methyl groups, a hydroxymethine proton at δ 3.803 (*dd* J = 2.8, 2.8 HZ) and OMe protons at δ 3.176.

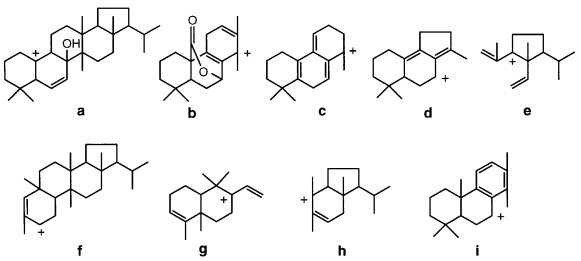

Fig. 2. MS fragment ions of **1**, **2** and **3**.

Its ^{13}C NMR chemical shifts were found to be close to those of filicane (**9**) (Table 2) except those of ring A carbons including that **2** might be a filicane derivative with an oxygen function located in ring A. Detailed analysis of the correlations observed in its HMBC spectrum revealed the presence of the partial structure shown in Fig. 1. Moreover the correlation of the OMe protons with C-3 (δ 71.2), C-4 (δ 79.3), C-5 (δ 42.7) and C-23 (δ 13.9) established that the OMe group is attached to C-4 and the OH group must be located at C-3. The above structural assignment was also supported from the mass spectrum which exhibited besides, the base peak at *m/z* 458 $[M]^+$, the other prominent peaks at *m/z* (rel. int.) 443 $[M–CH_3]^+$ (48), 341 $[\mathbf{f}]^+$ (78), 217 $[\mathbf{g}]^+$ (10), 205 $[\mathbf{h}]^+$ (34), and 191 $[\mathbf{e}]^+$ (28) (Fig. 2). Finally, the relative stereochemistry of **2** was deduced from its NOESY spectrum which showed NOEs connecting δ 3.80 (H-3β) — 1.15 (H_3-23) — 1.08 (H_3-24) — 0.88 (H_3-25), and δ 1.77 (H-10α) — 1.28 (H-8α) — 0.97 (H_3-27) — 0.780 (H_3-28) (Fig 1). Based on the above evidence, the structure of **2** can be represented as 3α-hydroxy-4-methoxyfilicane.

Compound **3**, mp 213–214°C, $[\alpha]_D^{23}$ −180.0°, $C_{30}H_{48}O$ (HR MS; M^+ at *m/z* 424.3704, calc. 424.3705) showed besides the signals for six tertiary and two secondary methyl groups, signals for a carbinyl proton at δ 4.35 (*ddd* J = 8.2, 5.8, 2.6 HZ) and two olefin protons at δ 5.2 (*dd* J = 2.4, 2.4 HZ) and 5.4 (*dd* J = 2.6, 2.6 HZ) in its ^1H NMR spectrum (Table 1). The diagnostic UV absorption bands λ_{max} nm (ε); 232 (30,900), 238 (28,400) and 247 (18,200) suggested that the two double bonds were conjugated and they constituted a heteroannular diene system (Ageta et al., 1964). A comparison its ^{13}C NMR spectrum (Table 2) with those of ferna-7,9(11)-diene (**8**) and 19α-hydroxyfern-9(11)-ene (**14**) (Tanaka et al., 1998) revealed that compound **3** possesses a 19-hydroxyferna-7,9(11)-diene structure. The configuration of the hydroxyl group at C-19 was established to be α by comparison of the chemical shift and coupling constant of H-19 of **3** at δ 4.35 (*ddd* J = 8.2, 5.8, 2.6 Hz) with those of **14** at δ 4.33 (*ddd* J = 8.2, 5.8, 2.6 Hz). The assigned structure of **3** was corroborated by its mass spectrum which showed formation of the diagnostic ion at *m/z* 255 $[\mathbf{I}]^+$ (52) (Fig. 2) (Shiojima et al., 1992). Based on the above observations, **3** could be represented by 19α-hydroxyferna-7,9(11)-diene.

Of these three new compounds, **1** seems to be the most interesting, since a triterpenoid with a lactone ring, as in **1**, has so far not been reported from fern species. The fact that the isolation of 19α-hydroxyadiantone (**16**) in the highest yield from this fern is next to from *Adiantum edgeworthii* HOOK (Shiojima and Ageta, 1994) might support the morphological close relation of both ferns. Also, adiantone (**11**) is the most common triterpenoid among *Adiantum* ferns.

3. Experimental

3.1. General

Uncorr. mps; EI–MS: 30 eV; TLC: on precoated Kiesel gel 60. ^1H NMR (270 MHz for identification and 500 MHz for structure determination) and ^{13}C NMR (125 MHz) spectra: in $CDCl_3$ (TMS as internal standard); HPLC: reversed phase C_{18} column, RI detector, CH_3CN: $CHCl_3$ (9:1); CC: Si gel 60 (230–400 mesh, Merck) and 20% $AgNO_3$-impregnated silica gel (Mallincrodt); GC: 1.4% SE-30 on Chromosorb G Oven: 260°C (cholestane as internal standard).

3.2. Plant material

The material was grown in the green-house of our university in September 1994. The fern is widely distributed in the Old World tropics and cultivated as a foliage plant. The voucher specimen has been deposited in the herbarium of Showa Pharmaceutical University, Tokyo.

3.3. Extraction and separation

The fresh fronds (2.96 kg) were cut into small pieces, then extracted (3×) with *n*-C_6H_{14} using the modified Soxhlet extraction method to give extract (27.3 g) together with separated aqueous filter (2 l). The extract was heated in C_6H_6 until reflux began this being maintained for 1 h. The resulting suspension was then allowed to stand at room temp. for 1 day. The insoluble materials were removed by filtration (fraction A, abbreviated as fr.A) and the filtrate was evaporated to dryness to afford a gummy residue which was subjected to silica gel chromatography to give seven fractions: fr. B (eluted with *n*-C_6H_{14}), fr. C [*n*-C_6H_{14}–C_6H_6 (8:2)], fr. D [*n*-C_6H_{14}–C_6H_6 (1:1)], fr. E (C_6H_6), fr. F [C_6H_6–Et_2O (9:1)] and fr. G and fr. H (Et_2O).

3.4. Isolation of 8α-hydroxyfernan-25,7β-olide (1)

Fr. F was applied to silica gel eluted with C_6H_6, with fractions of interest being subjected to preparative HPLC followed by crystallization from Et_2O–MeOH to give 8α-hydroxyfernan-25,7β-olide (**1**, 16 mg).

*3.4.1. 8α-Hydroxyfernan-25,7β-olide (**1**)*

Mp 268–271°C. $[\alpha]_D$ −21.6°, (EtOH; *c* 0.4). γ_{max} cm^{-1}; 3470 and 1730. EI–MS *m/z* (rel. int.): 456 $[M]^+$ (**15**), 441 $[M- CH_3]^+$ (14), 438 $[M- H_2O]^+$ (27), 423 $[M–H_2O–COCH_3]^+$ (45), 411 (31), 191 (100). EI–HRMS; M^+ *m/z* : 456.3604 (calc. for $C_{30}H_{48}O_3$: 456.3603). ^1H NMR and ^{13}C NMR spectral analysis: Tables 1 and 2.

*3.5. Isolation of 3α-hydroxy-4-methoxyfilicane (**2**), 19α-hydroxyferna-7,9(11)-diene (**3**) and, isolation and identification of other known oxidized triterpenoids*

Repeated recrystallization of fr. D from MeOH–$CHCl_3$ gave adiantone (**11**, 840 mg). The filtrate was evaporated and the residue was applied to silica gel, 20% $AgNO_3$-impregnated silica gel eluted with? Fractions of interest were then subjected to preparative HPLC followed by recrystallization from MeOH-$CHCl_3$ to give 17β,21β-epoxyhopane (**10**, 3 mg), isoadiantone (**12**, 5 mg), 19α-hydroxyfern-7-ene (**13**, 9 mg), 19α-hydroxyfern-9(11)-ene (**14**, 3 mg), 3α-hydroxy-4-methoxyfilicane (**2**, 3 mg), 19α - hydroxyfern - 9(11) - ene (**15**, 30mg) and 19α - hydroxyferna-7,9(11)-diene (**3**, 8 mg).

Chromatography of fr. A on silica gel eluted with C_6H_6–Ex_2O (9:1), followed by recrystallization of the fractions of interest from $CHCl_3$–MeOH gave 19α-hydroxyadiantone (**16**, 1.50 g) in pure form.

*3.5.1. 19α-Hydroxyferna-7,9(11)-diene (**2**)*

Mp 159–161°C. Compound **15** was identified by comparison with literature data (Nakane et al., 1999).

*3.5.9. 19α-Hydroxyadiantone (**16**)*

Mp 281–283°C. Compound **16** was identified by comparison with literature data (Shiojima and Ageta, 1994).

3.6. Isolation and identification of triterpenoid hydrocarbons

Chromatography of Fr. B on 20% $AgNO_3$-impregnated silica gel using n-C_6H_{14} as eluant, followed by recrystallization from Me_2CO gave six triterpenoid hydrocarbons in pure form viz. neohop-13(18)-ene (**4**, 4 mg), fern-7-ene (**5**, 141 mg), fern-8-ene (**6**, 3 mg), fern-9(11)-ene (**7**, 23 mg), ferna-7,9(11)-diene (**8**, 8 mg) and filic-3-ene (**9**, 322 mg). Compounds **4**–**9** were identified by direct comparison with literature data (Ageta et al., 1994).

*3.6.1. Neohop-13(18)-ene (**4**)*

Mp 194–195°C.

*3.6.2. Fern-7-ene (**5**)*

Mp 213–214°C.

*3.6.3. Fern-8-ene (**6**)*

Mp 190–191°C.

*3.6.4. Fern-9(11)-ene (**7**)*

Mp 170–171°C.

*3.6.5. Ferna-7,9(11)-diene (**8**)*

Mp 200–202°C.

*3.6.6. Filic-3-ene (**9**)*

Mp 232–234°C.

Received 30 August 2000; received in revised form 4 April 2001

Abstract

Further investigation on the alcohol extract of the barks of *Taxus yunnanensis* led to the isolation of four taxoids, namely, 7β-xylosyl-taxol D, taxuyunnanines P, Q and R, along with the known taxuyuntin G (**2**). Four are rearranged taxoids with an 11(15→1)-*abeo*taxoid skeleton and an opened oxetane ring moiety. Structures were determined by spectroscopic and chemical means. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Taxus yunnanensis*; Taxaceae; Bark; *abeo*Taxoids; 7β-Xylosyl-taxol D; Taxuyunnanines P–R; Taxuyuntin G

1. Introduction

Since the discovery of the anticancer agent paclitaxel in 1971 (Wani et al., 1971), nearly 400 taxoids have been reported. Our previous studies on *Taxus yunnanensis* Cheng et L.K. Fu have resulted in the isolation of paclitaxel, and 41 other taxoids from the root (Zhang et al., 1993, 1994a,b, 1995a,b, 1997; Xiang et al., 1999); two new bacctin III type (Li et al., 1998) and five new rearranged taxoids (Li et al., 2000) from the bark. Investigation on the more polar part of the alcohol extract of the bark of *T. yunnanensis* afforded a new paclitaxel related compound, 7β-xylosyl-taxol D (**1**), and three new 11(15→1)-*abeo*-taxoids, taxuyunnanines P–R (**3**–**5**), together with a known *abeo*taxoid, taxuyuntin G (**2**) (Fig. 1). This paper deals with the isolation and structure elucidation of these compounds.

2. Results and discussion

7β-Xylosyl-taxol D (**1**) was assigned a molecular formula of $C_{49}H_{61}NO_{18}$ based on its HRFABMS (*m*/*z* 952.4054 ($[M+H]^+$, calc. 952.3967). The ^1H NMR (Table 1) spectrum showed the presence of four characteristic taxane methyl (δ 1.17, 1.16, 1.95 and 1.72) and two acetyl methyl (δ 2.34 and 2.18) groups; a xylosyl group, and a complex side chain of *N*-butanoylphenylisoserine as found in taxol D and its derivatives (Appendino et al., 1994; Guo et al., 1995). A detailed comparison of the ^1H NMR spectral data of **1** and those of 7β-xylosyl-10-deacetyl-taxol D (Guo et al., 1995) indicated that, except for the existence of an additional acetyl group in **1**, the two compounds were very much alike. In the lowfield region, the sharp proton signal at δ 5.37 (1H, *s*) of 7β-xylosyl-10-deacetyl-taxol D was found to have shifted to δ 6.50, which suggested that the additional acetyl group in **1** is positioned at C-10. Since the ^{13}C NMR data of 7β-xylosyl-10-deacetyl-taxol D are not available in the literature for comparative purposes, ^{13}C and 2D NMR (including ^1H–^1H COSY, HMQC, HMBC) experiments were carried out to confirm the proposed structure for **1** and for its unambiguous assignments. The presence of an acetoxy group at C-10 was confirmed by the ^1H–^{13}C long-range correlation of H-10 with an acetyl carbonyl carbon in the HMBC spectrum.

Compound **2** was identified as the known taxayuntin G by comparison of its spectroscopic data (^1H and ^{13}C NMR and FABMS) with those previously reported in the literature (Yue et al., 1995).

Taxuyunnanine P (**3**), $C_{24}H_{38}O_{10}$ (HRFABMS: *m*/*z* 485.2401 ($[M-H]^+$, calc. 485.2487), showed both ester (1718 and 1271 cm^{-1}) and free hydroxyl (3399 cm^{-1}) absorptions in its IR spectrum. Its ^1H NMR spectrum

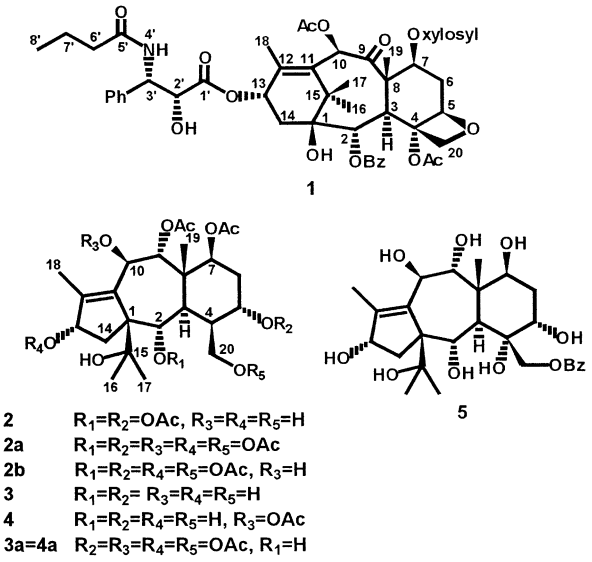

Fig. 1. Compounds **1**–**5** isolated from *Taxus yunnanensis*.

(Table 1) indicated the presence of four taxoid methyl groups at δ 1.40, 1.03, 1.85 and 1.02 (singlets) ascribable to Me-16, -17, -18 and -19, respectively, together with two acetyl methyl groups at δ 2.07 (3H, *s*) and 2.06 (3H, *s*). The ^{13}C NMR (Table 2) spectrum disclosed the existence of two olefinic quaternary carbons at δ 140.0 (C-11) and 145.8 (C-12), one oxygen-bearing quaternary carbon at δ 77.3 (C-15), and a quaternary carbon at δ 69.5 (C-1). These data suggested a 5/7/6 membered 11 (15→1)-*abeo*taxoid skeleton, which was confirmed by the long-range ^{1}H–^{13}C correlation of H-10 [δ 4.58 (1H, *d*, J = 10.1 Hz)] to C-1 in the HMBC spectrum. The COSY, HMQC and HMBC experiments showed that, unlike normal taxoids or *abeo*taxoids, the C-4 of **3** was a methine carbon instead of an oxygen-bearing quaternary carbon; and H-3 of **3** was a doublet of doublets rather than a simple doublet. The relationships of H-2/H-3/H-4/H_2-20 were well displayed in the ^{1}H–^{1}H COSY spectrum. Thus, **3**, like **2**, belongs to the rare group of *abeo*taxoids devoid of an oxygenated substituent at C-4. The opened oxetane ring system was inferred from the relatively highfield chemical shift of C-20 [δ 63.5 (*t*)] in the ^{13}C NMR spectrum and six double bond equivalents in its molecular formula. The downfield chemical shifts of H-7 [δ 5.38 (1H, *dd*, J = 4.8, 11.5 Hz)] and H-9 [δ 5.55 (1H, *brd*, J = 10.00 Hz)] in the ^{1}H NMR, combined with the HMBC correlations of H-7 and H-9 signals with the two carbonyl carbon resonances at δ 172.1 and 173.0, affixed the two acetyl groups to C-7 and C-9, respectively. The relative stereochemistry of **3** was established by comparison of its coupling constants with those of **2** (Yue et al., 1995). Thus, the structure of taxuyunnanine P was established as 7β, 9α-diacetoxy-2α, 5α, 10β, 13α, 15, 20-hexahydroxy-11(15→1)*abeo*taxa-11-*ene* (**3**).

Taxuyunnanine Q (**4**) has the molecular formula of $C_{26}H_{40}O_{11}$ as shown by its HRFABMS (*m*/*z* 527.2464 ([M–H]$^{+}$, calc. 527.2492). Analysis of the IR and NMR spectra (including ^{1}H, ^{13}C, COSY, HMQC and HMBC) (Tables 1 and 2) implied that **4** is an *abeo*taxoid related to **3**, differing in the presence of an additional acetyl

group at C-10. In the ^1H NMR spectrum, the H-10 signal moved downfield from δ 4.58 (1H, *d*, $J=10.1$ Hz) in **3** to δ 6.17 (1H, *d*, $J=10.7$ Hz) in **4**. This assignment was confirmed by the HMBC cross-peak signal of H-10 to an acetyl carbonyl carbon at δ 170.2. Compound **4** was deduced to have the same relative stereochemistry as **3** by virtue of their similar coupling patterns, and was identified as 7β, 9α, 10β-triacetoxy-2α, 5α, 13α, 15, 20-pentahydroxy-11(15→1)*abeo*taxa-11-*ene* (**4**).

Theoretically, compounds **2**, **3** and **4** can be converted to the same heptacetate, which would confirm their proposed structures. Accordingly, they were subjected to acetylation experiments. Under normal conditions, only **2** yielded the expected heptacetate product (**2a**) plus a hexacetate (**2b**). Compounds **3** and **4** afforded the same hexacetate product (**3a**=**4a**) with the hydroxy group at C-2 remained unacetylated even under more vigorous conditions. The failure of **3** and **4** to form heptacetates may be caused by the steric hindrance around the 2-OH group or due to the formation of a hydrogen-bond between the 2-OH and one of the other oxy-groups.

Taxuyunnanine R (**5**), $C_{27}H_{37}O_{10}$ established by HR–FABMS: *m*/*z* 521.2371 $[M-H]^+$, calc. 521.2387. The IR spectrum showed carbonyl, hydroxyl and ester groups at 1711, 3385 and 1279 cm^{-1}, respectively. As in the case of isolates **2**–**4**, spectral features of 11(15→1)-*abeo*taxoids were clearly evident in the NMR (Tables 1 and 2) spectra of **5**. However, contrary to the protonated C-4 in **2**–**4**, the C-4 of **5** was an oxygenated quaternary carbon: the H-3 (δ 2.62) of **5** was a doublet instead of the doublet of doublet found in **2**–**4**; and the H_2-20 were a pair of AB doublets instead of two doublet of doublets. The downfield chemical signals of H_2-20 [δ 4.96 (1H, *ABd*, $J=12.1$ Hz) and 4.65 (1H, *ABd*, $J=12.0$ Hz)] suggested that the benzoxy group could be assigned to C-20. Confirmation for this linkage was achieved by a HMBC experiment, in which the H_2-20 and aromatic protons at δ 8.03 (2H, *d*, $J=7.4$ Hz) correlated with the carbonyl carbon signal at δ 168.2 simultaneously. It is interesting to note that although compound **5** possessed nine oxygenated carbons (one oxymethylene, six oxymethines and two oxyquaternary carbons), there was only one ester substitute group (benzoate) present. Normally, such a highly oxygenated taxane would contain two or more esterified substituents.

In order to determine the relative stereochemistry of compound **5**, a ROESY experiment was performed (Fig. 2). The orientation of the benzoxymethyl at C-4 was established as β due to the NOE correlation between H_2-20 and Me-19. NOE correlations of H-2 with Me-16, 17 and 19, H-7 with H-3, H-9 with H-2 and Me-19, H-10 with H-3 and Me-18, and H-13 with Me-16 and 17, fixed the orientation of the hydroxy groups at C-2, C-7, C-9, C-10 and C-13 as α-, β-, α-, β- and α-, respectively. The configuration of the 5-OH was assigned an α-orientation due to its small coupling constant (H-5, *brs*). Hence the structure of taxuyunnanine R was deduced as 20-benxoxyl-2α, 4α, 5α, 7β, 9α, 10β, 13α, 15-octahydroxy-11(15→1)*abeo*taxa-11-*ene* (**5**).

With the exception of **1**, the isolates obtained in this study belong to the rare 11(15→1)-*abeo*taxoids possessing an opened oxetane ring moiety. To-date, only a few such taxoids have been reported. Further, *abeo*taxoids with a C-4 methine are rarer still (Baloglu and Kingston, 1999; Parmar et al., 1999). To our knowledge, taxuyunnanine R is the most highly oxygenated *abeo*taxoid isolated to-date that contains only a single ester substituent.

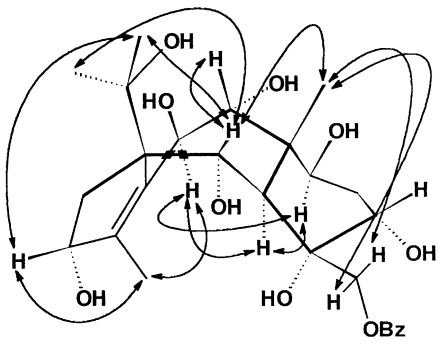

Fig. 2. Significant ROESY correlations of compound **5**.

3. Experimental

3.1. General

1D and 2D NMR experiments were performed either on a Bruker AM-400 or DRX-500 spectrometer. Unless otherwise specified, chemical shifts (δ) were expressed in ppm with reference to the solvent signals. FABMS and HRFABMS were taken on a VG Auto Spec-3000 or on a Finnigan MAT 90 instrument. IR spectra were recorded on a Bio-Rad FTS-135 spectrometer with KBr pellets. UV spectral data were obtained on a UV 210A spectrometer. Optical rotations were carried out on a HORIBA SEPA-300 High Sensitive Polarimeter or Perkin-Elmer model 241 Polarimeter. Column chromatography was performed either on Si gel (200–300 mesh, Qingdao Marine Chemical Inc., China), Si gel H (10–40 μm, Qingdao Marine Chemical Inc., China), Lichroprep RP_{18} gel (40–63 μm, Merck, Darmstadt, Germany), or on. MCI gel (70–150 μm, Mitsubishi Chemical Corporation, Tokyo, Japan). Fractions were monitored by TLC and spots were visualized by heating Si gel plates sprayed with 10% H_2SO_4 in EtOH.

3.2. Plant material

The barks of *T. yunnanensis* Cheng et L. K. Fu (Taxaceae) were collected in Lijiang Prefecture of Yunnan Province of Peoples Republic of China. A voucher specimen has been deposited at the Yunnan Academy of Forestry, Kunming, Yunnan, People's Republic of China.

3.3. Extraction and isolation

Dried bark (50 kg) was milled, extracted and fractionated by silica gel column chromatography as described previously. Briefly, the $CHCl_3$ fraction was successively chromatographed over three columns of silica gel. Fractions 14–29 from the third silica gel column were combined (4.9 g) and chromatographed on silica gel, eluted with $CHCl_3$–*iso*-PrOH (9:1) (Li et al., 2000). The more polar fractions obtained were combined and sequentially re-chromatographed on RP_{18} Si gel eluted with MeOH–H_2O (1:1) and acetonitrile–H_2O (2:8), and on silica gel eluted with petroleum ether–*iso*-PrOH (8:2) to yield compounds **1** (14 mg) and **2** (2 mg). A post Frs. 14–29 combined fraction (14.0 g) obtained from the third silica gel column referred to above was further fractionated successively on MCI gel with Me_2CO–H_2O (2:8), on silica gel with petroleum ether–*iso*-PrOH (8:2) and on silica gel with $CHCl_3$–*iso*-PrOH (7:1) as eluting solvents to provide compound **4** (5 mg). A second post Frs. 14–29 fraction (10.0 g) was also subjected to extensive chromatography on MCI gel using Me_2CO–H_2O (2:8), on silica gel using $CHCl_3$–MeOH (9:1), on silica gel using $CHCl_3$–*iso*-PrOH (5:1) and on RP_{18} gel using acetonitrile–H_2O (1:5) as eluents, stepwise, to afford Compounds **3** (13 mg) and **5** (3 mg).

7β-Xylosyl-taxol D (**1**): white powder, $[\alpha]_D^{28}$: −25.0° (*c* 0.25 MeOH). UV (MeOH) λ_{max} (log ε): 202 (4.3), 229 (4.2). Book reviews

Two Thousand Years of Natural Products Research — Past, Present and Future
T.J.C. Luijendijk (Ed.), Phytoconsult Publishers, Leiden, The Netherlands, 2000, 295 pp., ISBN 90-805866-1-2, 130 NGL

The idea of holding a Millennium meeting to celebrate 2000 years of natural product research seems to have been a good one. In the event, this congress organised by four relevant scientific societies, held in Amsterdam in July 1999, was very successful and it attracted over a thousand participants drawn from 62 countries. Whether the proceedings of this meeting is likely to attract a similar-sized audience is more problematical. The contents consist of 14 unrelated essays, which cannot hope to draw attention to more than a fraction of our current phytochemical knowledge.

A major theme in several papers is the search for new compounds of useful biological activities in tropical plants. Separate chapters deal with biologically active constituents from African plants, from Latin American plants and from Asian tropical forest plants. The chapter from Latin America includes an extensive list of research workers and local firms involved in the exploitation of the local floras. A further chapter reports on recent advances in the synthesis of taxol, the well known anti-cancer agent from *Taxus brevifolia*. The history of medicinal plant research is reviewed in chapters on plant alkaloids and on botanical illustrations of herbals.

The remaining chapters in this symposium volume concentrate on plant-microbial signalling, on allelopathic effects and on flavonoid researches. I particularly appreciated a review by D. Joulain on the use of natural products in modern perfumery. Professor Arnold Vlietinck, the current chairman of the Phytochemical Society of Europe, had the formidable task of bringing all the themes of this book together in a final chapter. In his contribution, he forecasts an exciting future for the phytochemical research of the twenty-first century.

Saffron. *Crocus sativus* L.
M. Negbi (Ed.), Harwood Academic Publishers. Amsterdam, The Netherlands, 1999, 154 pp., £49.00 or US$80.00, ISBN 90-5702-394-6

This book constitutes volume 8 in the series edited by Roland Hardman, *Medicinal and Aromatic Plants — Industrial Profiles* in which other plants of industrial interest have been the topic of the 7 previous volumes (Valerian, Perilla, Poppy, Cannabis, Neem, Ergot and Caraway). This pretends to be a comprehensive book on saffron. After an introductory chapter by the editor, this is divided into three main sections. The first details the botany, including taxonomy, reproduction biology and chemistry. The second deals with the present state of saffron cultivation in different countries (Azerbaijan, Greece, Italy and Morocco) and with saffron technology. The third section describes futuristic aspects of saffron cultivation, usage and industry. Every chapter is produced by a different author and contains an abstract and an individual list of references. It is a pity that there are no chapters with information about the main saffron producing countries (Iran, Spain and India). The editor recognises that the appeals to saffronologists in these countries did not produce any results, and therefore, the book is not as complete as it should be. The chapter on reproduction biology is especially interesting with nice colour pictures from different *Crocus* species and pollen grains as well as micrographs of the fertilisation process. The chapter on Chemistry is probably too short, although it includes a large number of references in which the information will be available. The chapters on the production of saffron in different countries provides a beautiful description of the methods and practices used in different countries for saffron cultivation, harvesting and processing (drying, storage, etc.). There is a short, but

useful, chapter on saffron technology, including short references to picking, separation, drying, milling, packaging and marketing. Chapter 10 reviews the biological effects of saffron and its components in studies in vivo and in vitro, mainly related to its anticarcinogenic properties. In chapter 11 an interesting approach to mechanized cultivation and harvesting is presented. This is a key topic in saffron production, as a reduction in man hours would be essential for the future of this crop. In chapters 12 and 13 plant breeding to improve saffron production and quality and the in vitro propagation and secondary metabolite production are reviewed.

This book can be recommended as a valuable source of information for those researchers interested in spice cultivation and processing, especially to those dealing with saffron. It can be also useful to those dealing with spice quality control. As a volume within the series *Medicinal and Aromatic Plants — Industrial Profiles* the whole collection will be very useful for postgraduate students in agronomy and industrial research, and to phytochemists, pharmacologists and food technologists that are interested in the specific species included in this collection.

Flavonoids of the Sunflower Family (Asteraceae)
B.A. Bohm, T.F. Stuessy, Springer-Verlag, Wien, 2001, 831 pp., 398 DM. ISBN 3-211-83479-6

This book is unique in providing the first comprehensive compilation of available flavonoid data for a large plant family, in this case the Asteraceae. It is not an easy read but it will provide an invaluable source of references to the enormous number of flavonoid constituents discovered in the family during the chemosystematic investigations carried out over the last ca 40 years. This is a very specialized book aimed at two limited audiences: flavonoid chemists working on the chemotaxonomy of the Asteraceae and taxonomists wishing to access flavonoid data for comparison with molecular and morphological data. It is divided into six sections. Section I (two chapters) provides an introduction to the morphology, distribution, classification, phylogeny and biogeography of the family for the benefit of the non-taxonomists. Section II introduces the uses, structural variation, biosynthesis and biological functions of flavonoids, in four chapters, to the non-chemist. The largest Section III (10 chapters), includes comprehensive flavonoid data with text and tables for each tribe. On the whole the data in this section appear to be accurate but I did notice that a 1999 reference to *Tanacetum parthenium* in the text had been omitted from the corresponding table. Section IV (6 chapters) considers the efficacy of flavonoids at subfamilial, tribal, subtribal, generic, specific and infraspecific levels. This section contains much useful information and includes some discussion of the flavonoid data in the light of the new macromolecular perspectives on the higher level classification of the Asteraceae. However, it proves rather tedious reading with many annoying back references to previous sections/chapters. The last two short sections, V and VI (2 chapters each), deal with flavonoids as indicators of the evolutionary process and flavonoids and phylogeny, respectively. These two sections are rather light weight and disappointing. There are 136 pages of references, a very useful key to the common names of those flavonoids included in the book and three indexes: subject, chemical and taxon.

I recommend this book as a novel and useful addition to the literature of plant chemosystematics.

Book reviews

Two Thousand Years of Natural Products Research — Past, Present and Future
T.J.C. Luijendijk (Ed.), Phytoconsult Publishers, Leiden, The Netherlands, 2000, 295 pp., ISBN 90-805866-1-2, 130 NGL

The idea of holding a Millennium meeting to celebrate 2000 years of natural product research seems to have been a good one. In the event, this congress organised by four relevant scientific societies, held in Amsterdam in July 1999, was very successful and it attracted over a thousand participants drawn from 62 countries. Whether the proceedings of this meeting is likely to attract a similar-sized audience is more problematical. The contents consist of 14 unrelated essays, which cannot hope to draw attention to more than a fraction of our current phytochemical knowledge.

A major theme in several papers is the search for new compounds of useful biological activities in tropical plants. Separate chapters deal with biologically active constituents from African plants, from Latin American plants and from Asian tropical forest plants. The chapter from Latin America includes an extensive list of research workers and local firms involved in the exploitation of the local floras. A further chapter reports on recent advances in the synthesis of taxol, the well known anti-cancer agent from *Taxus brevifolia*. The history of medicinal plant research is reviewed in chapters on plant alkaloids and on botanical illustrations of herbals.

The remaining chapters in this symposium volume concentrate on plant-microbial signalling, on allelopathic effects and on flavonoid researches. I particularly appreciated a review by D. Joulain on the use of natural products in modern perfumery. Professor Arnold Vlietinck, the current chairman of the Phytochemical Society of Europe, had the formidable task of bringing all the themes of this book together in a final chapter. In his contribution, he forecasts an exciting future for the phytochemical research of the twenty-first century.

Saffron. *Crocus sativus* L.
M. Negbi (Ed.), Harwood Academic Publishers. Amsterdam, The Netherlands, 1999, 154 pp., £49.00 or US$80.00, ISBN 90-5702-394-6

This book constitutes volume 8 in the series edited by Roland Hardman, *Medicinal and Aromatic Plants — Industrial Profiles* in which other plants of industrial interest have been the topic of the 7 previous volumes (Valerian, Perilla, Poppy, Cannabis, Neem, Ergot and Caraway). This pretends to be a comprehensive book on saffron. After an introductory chapter by the editor, this is divided into three main sections. The first details the botany, including taxonomy, reproduction biology and chemistry. The second deals with the present state of saffron cultivation in different countries (Azerbaijan, Greece, Italy and Morocco) and with saffron technology. The third section describes futuristic aspects of saffron cultivation, usage and industry. Every chapter is produced by a different author and contains an abstract and an individual list of references. It is a pity that there are no chapters with information about the main saffron producing countries (Iran, Spain and India). The editor recognises that the appeals to saffronologists in these countries did not produce any results, and therefore, the book is not as complete as it should be. The chapter on reproduction biology is especially interesting with nice colour pictures from different *Crocus* species and pollen grains as well as micrographs of the fertilisation process. The chapter on Chemistry is probably too short, although it includes a large number of references in which the information will be available. The chapters on the production of saffron in different countries provides a beautiful description of the methods and practices used in different countries for saffron cultivation, harvesting and processing (drying, storage, etc.). There is a short, but

useful, chapter on saffron technology, including short references to picking, separation, drying, milling, packaging and marketing. Chapter 10 reviews the biological effects of saffron and its components in studies in vivo and in vitro, mainly related to its anticarcinogenic properties. In chapter 11 an interesting approach to mechanized cultivation and harvesting is presented. This is a key topic in saffron production, as a reduction in man hours would be essential for the future of this crop. In chapters 12 and 13 plant breeding to improve saffron production and quality and the in vitro propagation and secondary metabolite production are reviewed.

This book can be recommended as a valuable source of information for those researchers interested in spice cultivation and processing, especially to those dealing with saffron. It can be also useful to those dealing with spice quality control. As a volume within the series *Medicinal and Aromatic Plants — Industrial Profiles* the whole collection will be very useful for postgraduate students in agronomy and industrial research, and to phytochemists, pharmacologists and food technologists that are interested in the specific species included in this collection.

Abstract

Peroxidase (POX) from strawberry fruits was analyzed for its capacity to bleach chlorophyll. The partially purified enzyme preperation catalyzed the bleaching of chlorophylls and their derivatives in the presence of H_2O_2 and phenolic compounds. The optimal reaction conditions were 35 °C, pH 5.2 and ionic strength equal to 0.2. The maximum activity was observed at 1 mM of H_2O_2, while higher concentrations inhibited enzyme activity. Compounds with a high affinity to the heme group, radical scavengers and reducing agents, showed an inhibitory effect. Phenolic compounds such as umbelliferone, naringenin and *p*-substituted monophenols acted as cofactors. Instead, other phenolic compounds tested such as caffeic acid, catechin, ellagic acid, esculin and quercetin inhibited the activity of POX on chlorophylls. Phenolic compounds extracted from strawberry fruits showed an inhibitory effect on POX-chlorophyll bleaching activity, although this effect decreased markedly during ripening. POX showed higher affinity for compounds derived from chlorophyll ***a*** than from chlorophyll ***b***, and the enzyme preferentially degraded chlorophyll derivatives with the Mg^{2+} ion present and the phytol group removed. The POX-chlorophyll bleaching activity was found in all ripening stages from small green to ripe, the highest activity corresponding to large green fruits. © 2001 Elsevier Science Ltd. 1. Introduction

Chlorophyll (Chl) degradation is a characteristic symptom of leaf senescence and fruit ripening. During senescence, chlorophyll-protein complexes are disassembled and the pigments liberated. Free chlorophylls (Chls) are highly photoactive compounds that can generate free radicals, causing damage to cell membranes (Matile et al., 1996). It has been suggested that two types of reactions are involved in Chl catabolism (Shioi et al., 1995). Type I reactions include the loss of phytol, Mg^{2+}, and other modifications of the side chains that do not involve the breaking of the tetrapyrrolic ring present in chlorophylls. Chlorophyllase, which removes the phytol and produces chlorophyllides (Chlds), has been involved in the first step of Chl breakdown (Trebitsh et al., 1993; Matile et al., 1996). Another enzyme involved in chlorophyll catabolism is Mg-dechelatase, which eliminates Mg^{2+} from Chl or Chld to produce pheophytin (Phe) or pheophorbide (Pheo), respectively (Langmeier et al., 1993; Vicentini et al., 1995). Further catabolism of Pheo involves the elimination of $-COOCH_3$ to form pyropheophorbide, and oxidation to form hydroxypheophorbide (Shioi et al., 1991) or the formation of C-13^2-carboxylpyropheophorbide by the action of pheophorbidase (Watanabe et al., 1999). Type II reactions involve the oxidative cleavage (bleaching) of the tetrapyrrole ring. It has been reported that the cleavage of Phe ***a*** by a pheophorbide ***a*** oxygenase is the key regulatory step in the Chl catabolism pathway (Matile and Schellemberg, 1996; Hörtensteiner et al., 1998; Matile et al., 1999). However, other oxidative enzymes such as lipoxygenase (Orthoefer and Dugan, 1973), Chl oxidase, and peroxidase also appear to be involved in Chl bleaching.

Peroxidase (POX) is a ubiquitous enzyme located in several subcellular compartments, including chloroplasts (Johnson-Flanagan and McLachlan, 1990; Kuroda et al., 1990). Although the role of POX in Chl degradation 'in vivo' is controversial (Matile et al., 1999), many studies have supported its possible participation in Chl catabolism (Matile, 1980; Huff, 1982; Johnson-Flanagan and McLachlan, 1990; Johnson-Flanagan and Spencer; 1996; Maeda et al., 1998). Probably, the controversy has been caused by the existence of different chlorophyll degradation pathways (Amir-Shapira et al., 1987; Trebitsh et al., 1993) and the presence of multiple POX isoenzymes with uneven capacities to degrade chlorophylls (Kuroda et al., 1990; Adachi et al., 1996).

Strawberry is classified as a non-climacteric fruit, and neither the respiration rate nor ethylene production increase as the fruit changes its color, texture and flavor (Abeles and Takeda, 1990). The chlorophyll content diminishes very quickly as the fruit ripens (Given et al., 1988; Martínez et al., 1994; Perkins-Veazie, 1995), and the chloroplasts disintegrate during the process (Gross, 1982; Perkins-Veazie, 1995) without conversion into chromoplasts or gerontoplasts, as occurs in tomato fruits and leaves respectively (Matile et al., 1996). These characteristics make strawberry fruit an interesting model system in which to study chlorophyll degradation during fruit ripening.

In the present work, we have partially characterized the activity of strawberry peroxidase for bleaching chlorophyll, determined the influence of phenolic compounds on this activity and analyzed the change of POX bleaching activity during ripening.

2. Results and discussion

We have previously reported the presence of two cationic peroxidase isoenzymes in strawberry fruit, both of which are associated with membranes and show maximum activity at the green ripening stage (Civello et al., 1995). It has been suggested that cationic peroxidases, located in the chloroplast, are involved in Chl bleaching (Kuroda et al., 1990). In order to analyze strawberry POX activity on chlorophylls, extracts from green fruits were prepared and partially purified by means of $(NH_4)_2SO_4$ fractionation. The absorption spectrum of complete reaction mixtures (enzyme extract, chlorophyll, H_2O_2, and *p*-coumaric acid) showed a progressive reduction of the absorbance at 669 nm (Fig. 1). According to previous reports, this effect is due to the cleavage of the tetrapyrrolic ring present in chlorophylls (Huff, 1982). Different reaction mixtures were prepared to verify the activity of POX. Complete mixtures degraded Chl at a constant rate during the first 100 s, but then the reaction rate decreased (Fig. 2a). This is probably due to the diminution of H_2O_2 concentration, since the replenishment of H_2O_2 restored the initial bleaching rate. No chlorophyll degradation was observed in the absence of H_2O_2 or the inclusion of boiled extracts, while a low Chl bleaching activity was found in the absence of phenolic cofactors. The effect of H_2O_2 concentration on chlorophyll-bleaching activity was assayed (Fig. 2b). The chlorophyll-bleaching rate was extremely low in the absence of H_2O_2, increased to reach a maximum at 1.0 mM and then decreased slightly at 2.5 mM H_2O_2. Higher concentrations of H_2O_2 were inhibitory and the activity decreased to zero at 50 mM (data not shown). The inhibitory effect of high concentrations of H_2O_2 on peroxidase activity has been attributed to damage caused to the heme group present in the enzyme (Sánchez-Romero et al., 1995).

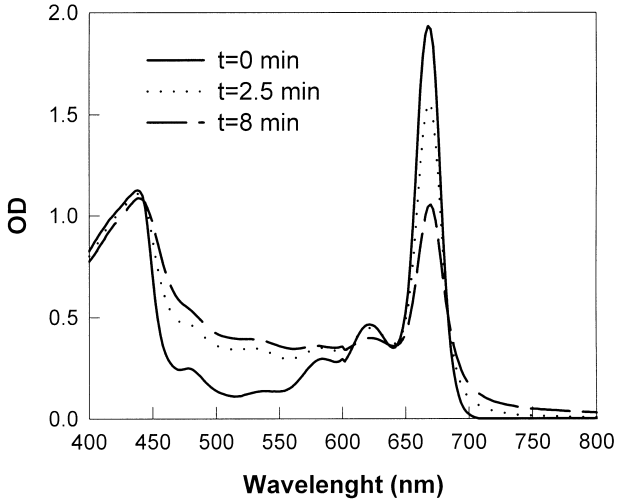

Fig. 1. Changes in the absortion spectra of the complete reaction mixture (enzymatic extract + chlorophyll ***a*** + H_2O_2 + *p*-coumaric acid) after incubation for different times.

2.1. Enzyme characterization

Peroxidase-chlorophyll bleaching activities were measured at different temperatures and pHs (Fig. 3a and b). A steep increase in enzyme activity was found when the temperature rose from 20 to 35 °C, whereas higher temperatures caused diminution of the activity. The activity at 35 °C was nearly twofold higher than at 25 °C, the temperature mostly used to measure POX–Chl-bleaching activity (Kuroda et al., 1990; Adachi and Shimokawa, 1995). The optimum pH was determined to be pH 5.2, being 50% of activity at 3.2 and 6.2. The optimum pH range for POX–Chl bleaching activity is lower than 6.0, the optimum pH for POX–guaiacol activity (Civello et al., 1995), suggesting that the value depended on the hydrogen donor. The highest activity was found at an ionic strength of $\mu = 0.2$ (Fig. 3c), similar to that reported for POX obtained from orange flavedo (Huff, 1982).

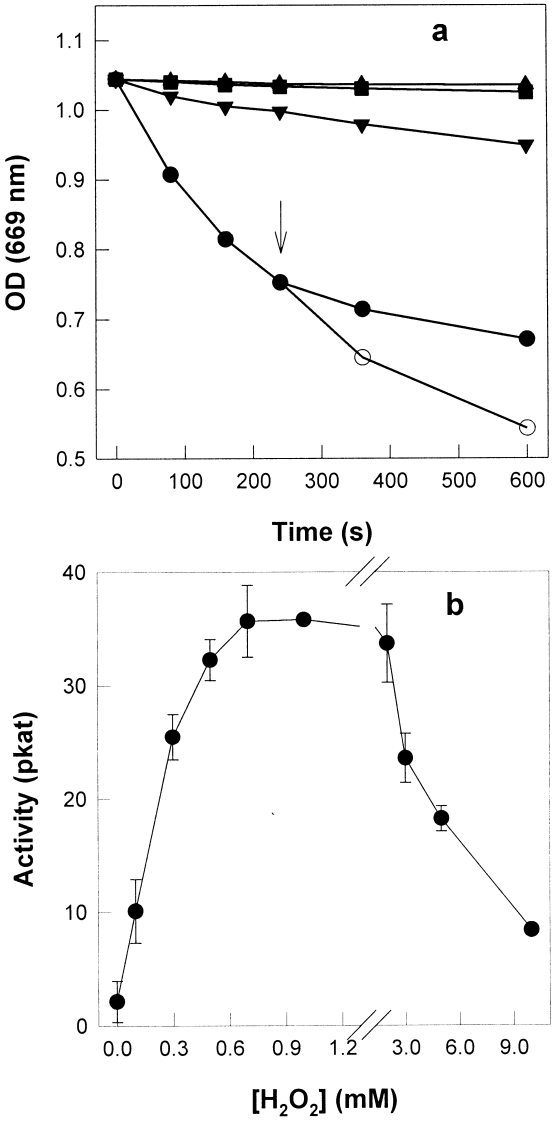

Fig. 2. (a) Time courses of chlorophyll *a* degradation. (▲) Reaction mixtures without H_2O_2. (■) Reaction mixtures with boiled enzymatic extract. (▼) Reaction mixtures without *p*-coumaric acid. (●) Complete reaction mixtures (enzymatic extract + chlorophyll *a* + H_2O_2 + *p*-coumaric acid). (○) Complete reaction mixtures after replenishing H_2O_2. (b) Effect of (H_2O_2) on POX-Chl bleaching activity. Vertical bars denote ± standard deviation when it exceeds the symbol size.

2.2. Substrate specificity

The determination of apparent kinetic parameters (K_m and V_{max}) was performed by using Chls and their derivatives as substrates (Table 1). The K_m value corresponding to Chl *a* was lower than that of Chl *b*, while the V_{max} was higher, indicating that POX from strawberry fruit has higher affinity for Chl *a*. Peroxidase extracted from orange flavedo has been assayed with both chlorophylls, and a preferential degradation of Chl *a* was also reported (Huff, 1982). The fact that Chl *b* can be transformed in Chl *a* (Ohtosuka et al., 1997) suggests that Chl *b* could be degraded after its transformation into Chl *a*. The absence of Mg^{2+} ion in Phe a diminished the affinity for the substrate (higher K_m), although the V_{max} increased. The removal of the phytol group from chlorophylls a and b increased both the affinity and the V_{max}. When catalytic power (V_{max}/K_m) was calculated, the highest value corresponded to Chld *a*, which was 5-fold higher than that of Chl *a*. These results suggest that strawberry fruit POX can preferentially degrade chlorophyll derivatives with the Mg^{2+} ion present and the phytol group removed. It is worth pointing out that chlorophyllase, the enzyme necessary to remove phytol group from chlorophylls, has been found in strawberry fruit and that the enzyme shows highest affinity for Chl *a* (Martínez et al., 1995). Together, the data suggest that the catabolism of both Chls could start from Chl *a* in strawberry fruit.

Table 1
Apparent kinetic constants of different substrates of the POX bleaching system

Compound	K_m (μM)	V_{max} (μM/min)	V_{max}/K_m
Chlorophyll *a*	16.1±2.0	2.6±0.2	0.161
Chlorophyll *b*	66.6±2.1	1.0±0.1	0.015
Pheophytin *a*	59.9±2.4	4.6± 0.3	0.077
Chlorophyllide *a*	10.3±2.0	6.1±0.6	0.588
Chlorophyllide *b*	36.9±3.8	1.3±0.2	0.035

2.3. Effect of inhibitory compounds

Several compounds were analyzed as possible inhibitors of chlorophyll bleaching (Table 2). Although Mn^{2+} ion has been reported to strongly inhibit POX–Chl bleaching activity in other systems (Adachi and Shimokawa, 1995), the ion at 1 mM concentration caused only a slight inhibition in this study. Compounds with high affinity for the heme group (N_3^- and CN^-) induced a high inhibition, confirming the involvement of peroxidase in Chl bleaching. Free radical scavengers such as hydroquinone, *n*-propyl gallate, tiron and α-tocopherol inhibited Chl bleaching, suggesting the participation of free radicals as intermediate products. In addition, strong inhibition of Chl bleaching activity was found when reducing agents such as cysteine, dithiothreitol (DTT), glutathione and ascorbic acid were present at 1 mM concentration. In the cases of cysteine, DTT and ascorbic acid, a lag period ranging from 30 to 240 s was observed, after which the Chl bleaching started (data not shown). Higher concentrations of reducing agents induced longer lag periods and a lower POX activity once the reaction started. This low POX activity could be due to the diminution of H_2O_2 concentration, caused by its consumption during the oxidation of cysteine or DTT. Considering that some plant peroxidases also possess a thiol oxidase activity (Pichorner et al., 1992), another possibility is that the enzyme preferably oxidizes

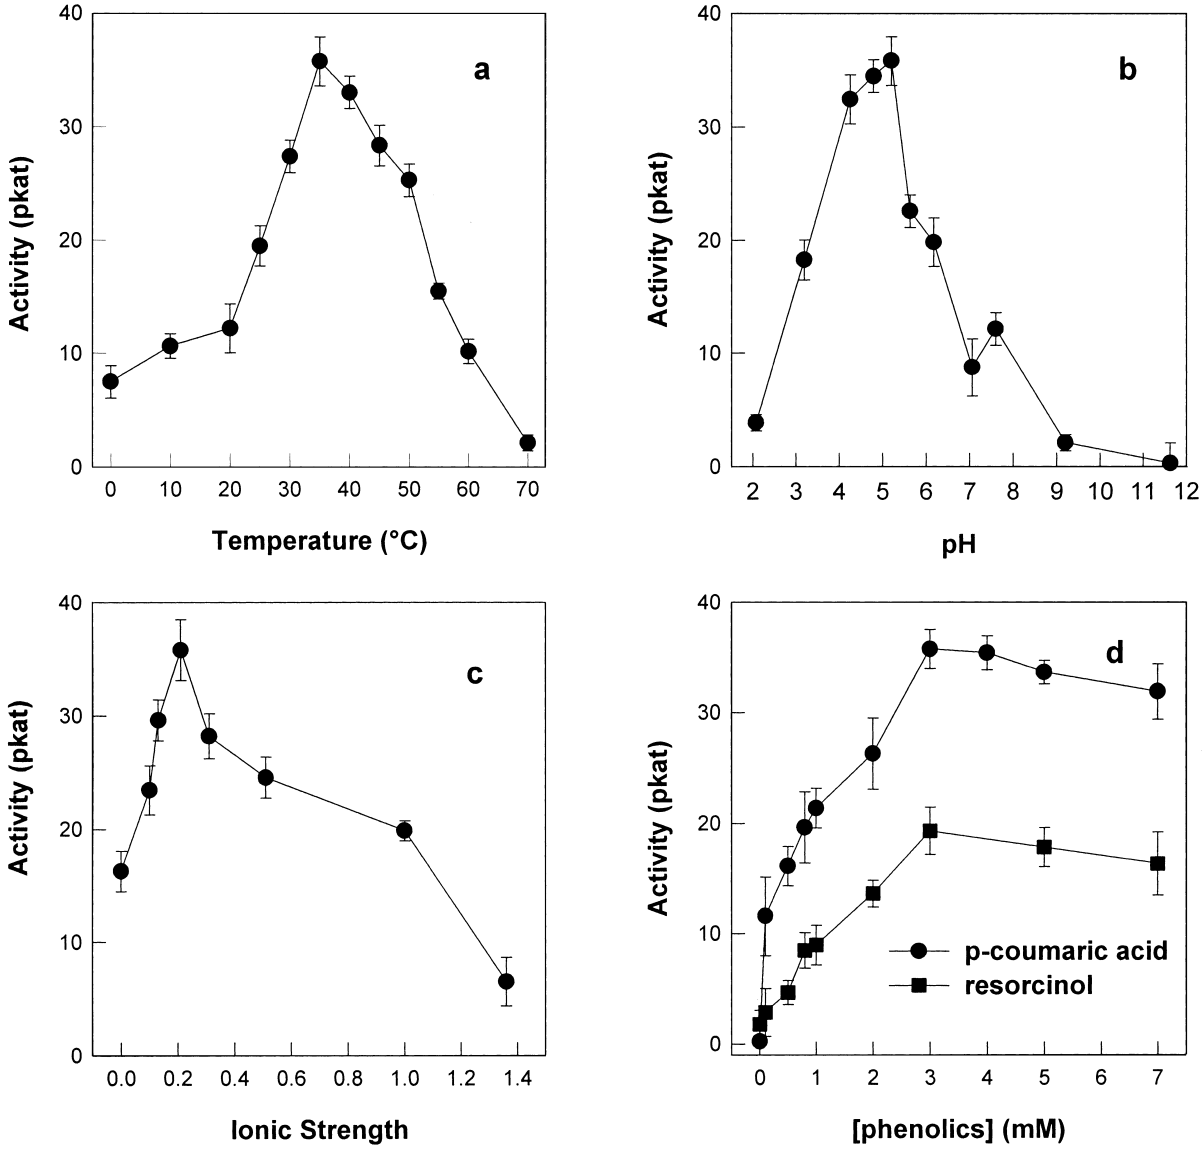

Fig. 3. (a) Effect of temperature on POX–Chl bleaching activity. (b) Effect of pH on POX–Chl bleaching activity. (c) Effect of ionic strength of reaction mixture on POX–Chl bleaching activity. (d) Effect of concentration of phenolic compounds on POX–Chl bleaching activity. Vertical bars denote ± standard deviation when it exceeds the symbol size.

cysteine or DTT instead of chlorophyll. Among the reducing agents tested, the highest inhibition of Chl bleaching was caused by ascorbic acid. It has been reported that ascorbic acid delays the senescence of oat leaves and decreases the chlorophyll loss (Borracino et al., 1994). The content of several antioxidant compounds, including ascorbic acid, decrease during fruit ripening (Baldwin, 1993; Markus et al., 1999). Probably, this compound could inhibit POX 'in vivo', therefore delaying the chlorophyll degradation process. During the course of leaf senescence, the antioxidant defense system, including catalase, is impaired while the activity of H_2O_2-producer enzymes is enhanced, which generates an appropriate environment to increase the chlorophyll bleaching (Hideg, 1997). β-Carotene, which has been mentioned previously as an inhibitor of Chl bleaching (Kato and Shimizu, 1985), did not show any effect in our system.

2.4. Effect of phenolic compounds

As shown in Fig. 2a, POX–Chl bleaching activity is enhanced by the inclusion of *p*-coumaric acid in the mixture reaction. This compound along with resorcinol has been reported among the most effective phenolic cofactors of peroxidase in the Chl bleaching reaction (Kato and Shimizu, 1985). Therefore, we assayed their effect on POX–Chl bleaching activity present in strawberry fruit (Fig. 3d). Either *p*-coumaric acid or resorcinol was more effective at a concentration of 3 mM, while

Table 2
Effect of inhibitors on POX–Chl bleaching activity. Different compounds were added to a control mixture reaction (POX extracted from SG fruits + chlorophyll *a* + H_2O_2 + *p*-coumaric acid) and the remaining enzyme activity was measured

higher concentrations slightly decreased the activity. In addition, the effect of several phenolic compounds on POX–Chl bleaching activity was analyzed (Table 3). The highest enzyme activities were found with phenol or *p*-substituted monophenol (*p*-coumaric acid, *p*-hydroxybenzoic acid and *p*-cresol), in agreement with reports from other systems (Kato and Shimizu, 1985). Low activities were observed with *o*- or *m*-substituted monophenol (*m*-hydroxibenzoic acid and *o*-cresol), while compounds with *o*- and *p*- substitutions in the same compound (e.g. 2,4-dichlorophenol) induced a POX bleaching activity similar to that found with *p*-monophenol. Among diphenols, only resorcinol (a *m*-diphenol) was effective to induce Chl bleaching. When *o*- or *p*-diphenols or their derivatives were used (catechol, guaiacol, caffeic acid, ellagic acid, hydroquinone and chlorogenic acid), no activity was detected. In the case of catechol, guaiacol, caffeic acid and chlorogenic acid, an enhanced absorption in the blue region of the spectrum was observed, probably due to the phenolic oxidation. Regarding triphenols and derivatives, a mild oxidation of pyrogallol and gallic acid and a short lag initial phase were observed, after which the Chl bleaching reaction started. Among natural coumarines, flavonoids and their derivatives, only umbelliferone and naringenin were effective as cofactors, coincidently with reports in other plant systems (Kato and Shimizu, 1985; Yamauchi and Watada, 1994). Finally, catechin and epicatechin showed oxidation as occurred with other diphenols. When mixtures containing some of the non-effective phenolic compounds (caffeic acid, catechin, ellagic acid, esculin, and quercetin) were added with *p*-coumaric acid, a measurably enzyme activity was recovered, indicating that their inhibitory effect is reversible (data not shown). In summary, phenolic compounds could act differently probably depending on their chemical structures. Some of the phenolics can activate POX–Chl bleaching while others inhibit the reaction through competition with Chl as substrate or by scavenging free radicals.

Strawberry fruit have high concentration of phenolics, which could regulate the activity of POX–Chl bleaching. It has been shown that phenolic compounds inhibit the POX (Zieslin and Ben-Zaken, 1993) and lipoxygenase activity (Richard-Forget et al., 1990), and that they can act as radical scavengers (Rice-Evans et al., 1997). In order to analyze the effect of strawberry endogenous phenolic compounds, we prepared crude extracts with and without PVPP, a phenolic adsorbent, and measured guaiacol–POX and POX–Chl bleaching activities (Table 4). The removal of phenolics by PVPP increased markedly the POX activity with both substrates, suggesting that endogenous phenolic compounds could act as inhibitors. Partial recovery of activity was achieved when extracts were prepared without PVPP and then dialyzed, probably due to the removal of some of the inhibitory compounds. The fact that the enzyme activity was only partially recovered could be due to oxidized phenolic-mediated protein modification or to the presence of high

Table 4
Effect of addition of PVPP in the buffer extraction on guaiacol–POX activity and POX–Chl bleaching activity

	Guaiacol (pkat)	Chlorophyll (pkat)
With PVPP	98.4±14.4	39.03±3.94
Without PVPP	16.9±3.1	1.07±0.36
Without PVPP, dialyzed	61.4±9.4	22.56±3.22

molecular mass inhibitors in the extract. According to Huff (1982), these non-dialyzable inhibitory compounds could be polyphenols of high molecular mass.

As the amount and composition of phenolic compounds changes during strawberry fruit ripening, we extracted phenolic compounds at several ripening stages and then assayed their effect on POX–Chl bleaching activity (Tables 5 and 6). The concentration of phenolic compounds decreased six-fold during the course of ripening, from 11.4 mg phenol per gram of fruit in 'small green' fruit to 1.8 mg phenol per gram of fruit in the ripe stage. Phenolic compounds extracted from fruit at several ripening stages were used to prepare reaction mixtures at the same total phenolics concentration (19 μg/ml). These mixtures were used to test the effect of the endogenous phenolic compounds on POX–Chl bleaching activity. A lag phase was found in all cases, after which the Chl bleaching started and a residual activity could be measured. A shortening of lag phase and an increase of residual activity were found as phenolic extracts from more advanced ripening stages were used.

Table 5
Change in phenolic compound content during strawberry fruit ripening

Ripening stage	Concentration of phenolics (mg phenol/g fresh weight)
Small green	11.4±0.5
Large green	6.1±0.4
White	2.3±0.1
Turning	2.1±0.1
Ripe	1.8±0.1

Table 6
Effect of phenolic extracts on POX–Chl bleaching activity. Phenolic compounds extracted from strawberry fruit at different ripening stages were added to a control mixture reaction (POX extracted from SG fruits + chlorophyll ***a*** + H_2O_2 + *p*-coumaric acid) and the effect on lag phase length and residual activity was measured. The concentration of phenolics added was 19 μg per ml of mixture reaction in all cases

Ripening stage	Lag phase (s)	Residual activity (pkat)
Control reaction (no addition)	0	39.03±3.94
Small green	150±10	18.97±1.07
Large green	140±10	21.12±0.72
White	100±10	22.20±1.07
Turning	75±8	23.27±1.07
Ripe	65±7	24.34±1.07

Therefore, the inhibitory effect of endogenous phenolic compounds on POX–Chl bleaching activity decreases during strawberry fruit ripening, probably due to changes in both the amount and the type of phenolic compounds. These results suggest a role for phenolics as regulators of the POX–Chl bleaching activity during strawberry fruit ripening. Schuster and Herrmann (1985) detected esters of *p*-coumaric acid and *p*-hydroxybenzoic acid in strawberry fruit, two of the phenolic compounds that induced POX activity on chlorophyll in this study. As well, ellagic acid, an inhibitor of POX-Chl bleaching, was found in strawberries and its concentration decreased during fruit ripening (Maas et al., 1991).

2.5. Change of chlorophyll content and POX–Chl bleaching activity during ripening

Strawberry fruit changes dramatically over a short period during ripening and, once the SG stage is reached, a rapid loss of chlorophylls is observed. The total chlorophyll content per gram of fruit decreased gradually during ripening, with the level of Chl ***a*** being higher than that of Chl ***b*** at all the stages analyzed (Fig. 4a). Peroxidase chlorophyll bleaching activity was

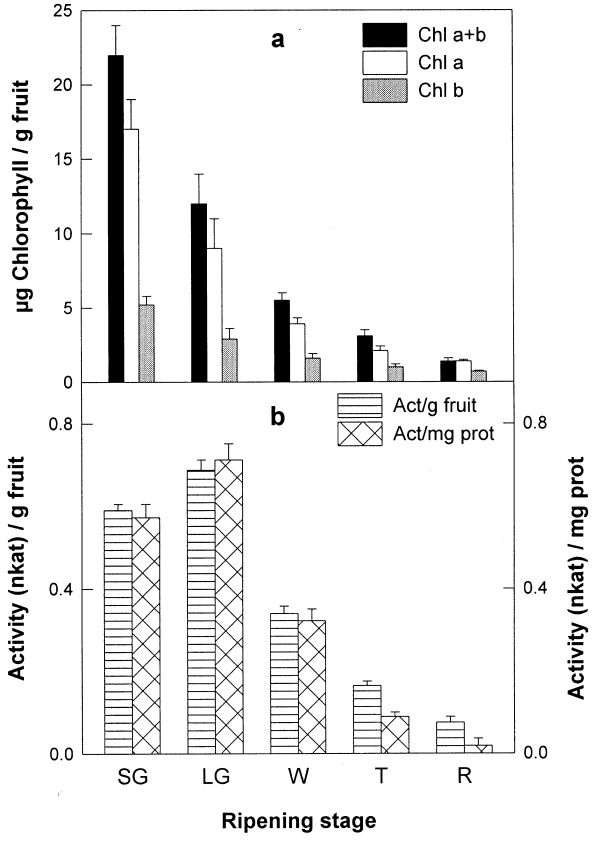

Fig. 4. (a) Changes in chlorophyll content during ripening of strawberry fruit. Chlorophyll ***a*** + ***b***, ■. Chlorophyll ***a*** □ Chlorophyll ***b*** ▒. (b) Changes in POX–Chl bleaching activity during ripening of strawberry fruit. Activity per gram of fruit ▤; activity per mg of protein ▩. SG: small green; LG: large green; W: white; T: turning; R: red.

detected in all ripening stages analyzed (Fig. 4b). It was present in SG strawberries before the onset of ripening, increased in LG fruits and then decreased until the end of fruit ripening.

'In vitro' POX–Chl bleaching activity is high from SG to W stages, coincidently with the period when most of the fruit chlorophyll is degraded. In addition, we have found a diminution along ripening of inhibitory phenolic compounds on POX–Chl bleaching activity, in agreement with findings reported in citrus (Baldwin, 1993). Together, the results encourage further analysis of POX participation in Chl bleaching during strawberry fruit ripening, although more research is needed to prove the 'in vivo' role of peroxidase in chlorophyll degradation.

3. Experimental

3.1. Plant material

Strawberry fruits (*Fragaria×ananassa*, Duch., cv. Selva), grown in a greenhouse, were obtained from local producers. Fruits were harvested and classified according to the external coloration degree and size into different ripening stages: small green (SG), large green (LG), white (W), turning (T) and red (R). Fruits were washed and drained and, after removing calyxes and peduncles, were used immediately or frozen at −60 °C.

3.2. Enzyme extraction

Extractions were performed according to Civello et al. (1995) with slight modifications. Fresh or frozen green strawberries (25 g) were homogenized in an Omnimixer homogenizer with 100 ml of the following extraction buffer: 0.02 M Na_2HPO_4, 0.08 M NaH_2PO_4, 0.2% (v/v) Triton X-100, 1 M NaCl, 30 g/l polyvinylpolypyrrolidone (PVPP), pH 6.0. The mixture was stirred for 1 h at 4 °C and then centrifuged at 9000 *g* for 20 min at the same temperature. Solid $(NH_4)_2SO_4$ was added up to 45% saturation to the extract. The mixture was stirred for 5 h at 4 °C and then centrifuged at 9000 *g* for 1 h at the same temperature. The supernatant was treated with $(NH_4)_2SO_4$ to reach 90% saturation and the resulting mixture was stirred at 4 °C overnight. The suspension was centrifuged at 9200 *g* at 4 °C during 1 h. The retained pellet was dissolved in 20 ml of 0.02 M Na_2HPO_4–0.08 M NaH_2PO_4 buffer (pH 6.0) and dialyzed against the same buffer at 4 °C overnight.

3.3. Determination of peroxidase chlorophyll-bleaching activity

Determination of activities was done according to Huff (1982) with slight modifications. The following reaction mixture was used: 0.2 M sodium phosphate buffer (pH 5.2), 0.3% (v/v) Triton X-100, 1 mM H_2O_2, 3 mM *p*-coumaric acid, 20 μM chlorophyll ***a*** (dissolved in acetone) and enzymatic extract, containing 30 μg of total protein, in a final volume of 1 ml. The mixture was incubated at 35 °C and the reaction was started by adding H_2O_2. The degradation of chlorophylls and their derivatives was evaluated by measuring the decrease of OD at: 669 nm for chlorophyll ***a*** and chlorophyllide ***a***, 649 nm for chlorophyll ***b*** and chlorophyllide ***b*** and 672 nm for pheophytin ***a***. Assays at pH different from 6.0 were carried out by adjusting the pH of the mixture with suitable amounts of 1.0 M NaOH, 1.0 M HCl and 0.5 M NaCl to keep the ionic strength constant. Assays at different ionic strengths were carried out by adding suitable amounts of 4 M NaCl to the reaction mixture.

3.4. Determination of peroxidase–guaiacol activity

The activity of peroxidase using guaiacol as substrate was done according to Civello et al. (1995).

3.5. Protein dosage

Protein concentrations of the extracts were measured by the modified Lowry method described by Potty (1969), measuring OD at 750 nm and using bovine albumin as standard.

3.6. Extraction and measurement of phenolic compounds

Extractions were performed according to Gil et al. (1997) with slight modifications. Samples of 10 g of frozen strawberries were mixed with 30 ml of acetone and homogenized in an Omnimixer. The mixture was centrifuged at 9000 *g* for 10 min at 4 °C. The pellet was re-extracted with 30 ml of acetone and supernatants were pooled (crude extract). This crude extract was extracted three times with 20 ml of hexane to eliminate chlorophylls. The aqueous-acetone phase was evaporated under nitrogen stream at 40 °C until 1 ml. Four milliliters of 3% (v/v) formic acid were added to the concentrate and then passed through a C_{18} Sep-Pak cartridge (Waters), previously activated with 5 ml methanol followed by 5 ml water and then 5 ml of 3% (v/v) formic acid. Phenolics were adsorbed on the column while sugars and other water-soluble compounds were eluted with 10 ml of 3% (v/v) aqueous formic acid. Then, phenolics were recovered with 1.8 ml of 3% (v/v) formic acid in methanol (purified extract). Total phenolic compounds of crude and purified extracts were determined with Folin–Ciocalteau reagent according to Zieslin and Ben-Zaken (1993). Ten microliters of crude extract or a dilution (1:6) of purified extract were mixed with 1.11 ml of water and 200 μl of 1 N Folin–Ciocalteau reagent. After 3 min at 25 °C, 1.5 ml of saturated solution of Na_2CO_3 was added and the reaction mixture was incubated for 1 h at the same

temperature. The content of phenolic compounds was expressed as milligrams of phenol per g of fresh weight, using phenol as standard.

3.7. Extraction and measurement of chlorophylls

Frozen strawberries were homogenized with four volumes of acetone in an Omnimixer. The suspensions were centrifuged at 5000 *g* for 5 min at 4 °C and the chlorophylls (Chls) in the supernatant determined according to Lichtenthaler (1987).

3.8. Preparation of chlorophylls ***a*** and ***b*** and derivatives

Three spinach leaves were homogenized in an Omnimixer with 60 ml of acetone and the resulting suspension was vacuum-filtered through filter paper. The acetone solution obtained was mixed with 50 ml of petroleum ether and 50 ml of saturated NaCl solution to extract the chlorophylls. The ether phase was separated, washed twice with 50 ml of saturated NaCl solution and then evaporated under nitrogen stream. Chlorophylls were redissolved in a solution of 5% (v/v) acetone in hexane and purified by passage through a powdered sucrose column using 5% (v/v) acetone in hexane as mobile phase. Solvents were evaporated under a nitrogen stream and chlorophylls were stored at −20 °C until used. Purified chlorophylls were redissolved in acetone for their use. Chl ***a*** and Chl ***b*** obtained by this procedure were about 98% and 93% pure, respectively. Chlorophyllides (Chld) ***a*** and ***b*** were prepared from purified Chl ***a*** and Chl ***b*** by using chlorophyllase obtained from orange flavedo according to Huff (1982). Pheophytin (Phe) ***a*** was prepared by treating Chl ***a*** with HCl solution, according to Lichtenthaler (1987).

Received 19 March 2001; received in revised form 11 June 2001

Abstract

The linear hexitol altritol has only been identified in six genera, all of them in the order Fucales of the brown algae. Five of these genera are closely related according to molecular phylogenetic and other data, while the sixth (*Notheia*) is an obligate epiphyte on two other altritol-containing genera with which it is symphanic. The possibility that *Notheia* obtains altritol from the algae on which it is epiphytic rather than by synthesizing altritol independently was investigated by supplying ^{13}C-inorganic carbon in the light followed by mass spectrometric and nuclear magnetic resonance analysis. *Notheia* separated from the phorophyte *Hormosira* during exposure to ^{13}C showed ^{13}C enrichment in both altritol and mannitol, while the *Hormosira* only showed significant labelling of mannitol. These data show that altritol can be synthesized by *Notheia*, with implications for the number of gains and losses of the capacity to synthesize altritol in the evolution of the Fucales. © 2001 Published by Elsevier Science Ltd.

1. Introduction

Six-carbon sugar alcohols with the empirical formula $C_6H_{14}O_6$ occur widely in living organisms. Mannitol, sorbitol and dulcitol (Fig. 1) occur in many algae, fungi and embryophytes, with (for example) mannitol as a ubiquitous component of the Phaeophyceae (Heterokontophyta) as well as occurring in some members of the Chlorophyta, Rhodophyta and Embryophyta (Kremer, 1980; Raven et al., 1990; Reed et al., 1985, 1995, Wright et al., 1987). They have functions such as compatible solutes and organic C and energy reserves, although these two functions cannot occur simultaneously for sugar alcohols in the compartments of high enzyme content and diversity such as the cytosol, stroma and mitochondrial matrix. These sugar alcohols can also function in organic C and energy transfer in lichens with green algal photobionts and in parasitism of vascular plants by other vascular plants, and as free radical scavengers. There is considerable knowledge of the pathways by which these sugar alcohols are synthesized and degraded, with aldose and ketose six-carbon sugars of appropriate stereochemistry as substrates for reductive synthesis of the sugar alcohols and as products of their oxidation.

The hexitol altritol (Fig. 1) (isomeric with mannitol, sorbitol and dulcitol) was first discovered as a natural product in the North-East Atlantic brown seaweed *Himanthalia elongata* by Chudek et al. (1984) but not in any of the 12 species of sympatric brown algae that were examined (Reed et al., 1985). It was subsequently found to be present in four other species of brown algae, all from the southern hemisphere, i.e. *Bifurcariopsis capensis* (South Africa) and *Hormosira banksii*, *Notheia anomala* and *Xiphophora chondrophylla* (South-Eastern Australia, and New Zealand) but not in the eight other species of southern hemisphere brown algae which were examined (Wright et al., 1987). The other species of *Xiphophora* (*X. gladiata*) has not yet been examined for the

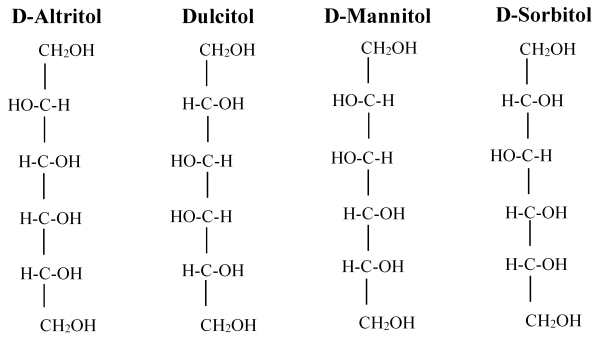

Fig. 1. Structure of altritol, dulcitol, mannitol and sorbitol. In all three cases of optically active hexitols the naturally occurring isomer is the D-form shown here, although D-altritol is equivalent to L-talitol.

occurrence of altritol. All of these algae are members of the Fucales, although the inclusion of *Notheia* involves modification of the definition of the order to include organisms with an anisogamous as well as those with an oogamous diplontic life cycle. Altritol was not detected in the brown algae from orders other than the Fucales which were examined by Reed et al. (1985) and Wright et al. (1987), so that the ability to synthesize altritol is relatively rare.

An estimate of the number of times that the capacity to synthesize altritol has evolved can be made from the molecular phylogeny of the Fucales sensu lato. A large number of genera are included in an analysis based on large and small subunit rDNA genes (de Reviers and Rousseau, 1999; Rousseau and de Reviers, 1999). A smaller data set, but with more overtly rigorous analysis, is that of Serrâo et al. (1999) based on ITS (internal transcribed spacer) 1 and 2 sequences. These analyses show that *Bifurcariopsis*, *Himanthalia*, *Hormosira* and *Xiphophora* are the four earliest-branching genera in the fucacean clade, and that *Notheia* is distantly related to the other altritol-containing genera, although it is a member of the Fucales sensu lato (Fig. 2). The rather distant relationship of *Notheia* to the other altritol-containing genera lends credence to the possibility that altritol synthesis only evolved once, since *Notheia* always grows in nature as an epiphyte on the two genera of altritol-containing brown algae which are geographically accessible, i.e. *Hormosira* and *Xiphophora*

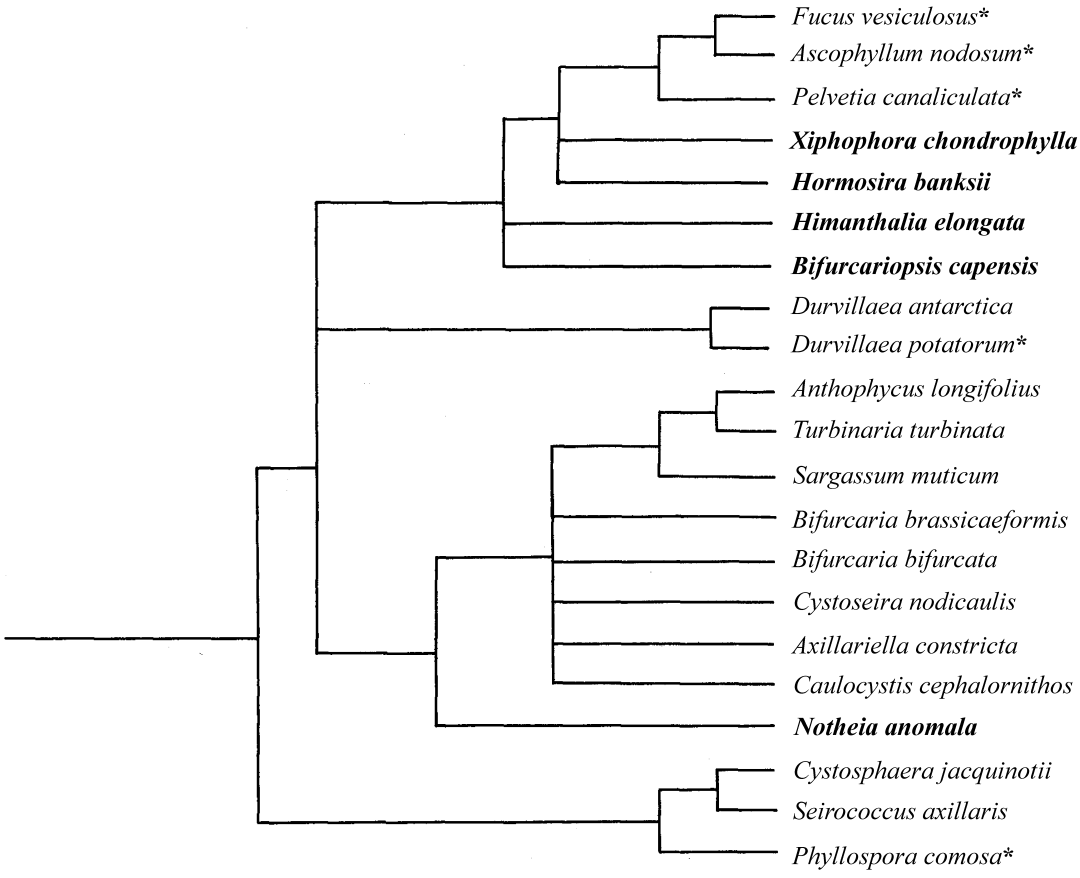

Fig. 2. Phylogeny of the Fucales based on molecular genetic and other evidence, modified, with permission, from de Reviers and Rousseau (1999). The Fucaceae sensu stricto shown here are the genera *Ascophyllum*, *Fucus* and *Pelvetia*, while the Fucaceae *sensu lato* also include *Bifurcariopsis*, *Himanthalia*, *Hormosira* and *Xiphophora* (see de Reviers and Rousseau, 1999). Organisms reported to contain altritol are indicated by bold type, and genera reported to lack detectable quantities of altritol are indicated by an asterisk; other genera in this Figure have not been tested (Chudek et al., 1984; Reed et al., 1985; Wright et al., 1987). Reed et al. (1985) did not find altritol in *Halidrys siliquosa*, a member of the Cystoseiraceae-Sargassaceae clade, which is represented here by the clade containing the genera from *Anthophycus* to *Caulocystis*.

(Raven et al., 1995; de Reviers and Rousseau, 1999). Accordingly, it is possible that *Notheia* obtains the altritol it contains from its phorophyte (Raven et al., 1995; de Reviers and Rousseau, 1999). In this case, altritol synthesis could have had one origin (at the divergence of the Fucaceae *sensu lato* clade from the rest of the Fucales) and one loss (at the origin of the clade of Fucaceae containing *Pelvetia*, *Fucus* and *Ascophyllum*) (Fig. 2; Fig. 7 of de Reviers and Rousseau, 1999; see also Serrâo et al., 1999).

The alternative is that *Notheia* can make its own altritol, which is consistent with the photosynthetic capacity of *Notheia*, which is higher than that of the *Hormosira* on which it is growing on a dry or fresh matter basis and similar to that of *Hormosira* on a surface area or chlorophyll basis (Raven et al., 1995). This alternative is also consistent with the structure of the holdfast attaching *Notheia* to *Hormosira* which resembles that of an attaching rather than that of an absorbing organ. If *Notheia* can make its own altritol, then the most economical hypothesis as to gains and losses of the capacity to synthesize altritol is that there was a single origin of the capacity to make altritol in the clade containing all of the Fucales other than the early-branching Seirococcaceae (Fig. 7 of de Reviers and Rousseau, 1999). This hypothesises losses of the capacity to synthesise altritol after *Notheia* branches from Cystoseiraceae-Sargassaceae clade, in the clade leading to *Durvillaea*, and, as in the hypothesis that *Notheia* obtains all of its altritol from the phorophyte, at the origin of the clade of the Fucaceae containing *Pelvetia*, *Fucus* and *Ascophyllum* (Fig. 2; Fig. 7 of de Reviers and Rousseau, 1999). An alternative phylogeny also based on large and small subunit rDNA (Figs. 1 and 2 of Rousseau and de Reviers, 1999) has an earlier branching of *Durvillaea*, such that altritol synthesis was gained after the rest of the Fucales branched from the Seirococcaceae and *Durvillaea* clades, with the need for only two losses, one after *Notheia* branches from the Cystoseiraceae-Sargassaceae clade, and at the origin of the Fucaceae *sensu stricto*.

A second evolutionary possibility predicated, as in the last paragraph, on the ability of *Notheia* to synthesise altritol, involves two evolutionary gains of the ability to synthesize altritol, i.e. at the branching of *Notheia* from the Cystoseiraceae-Sargassaceae clade and at the branching of the Fucaceae *sensu lato* at the unresolved trichotomy giving rise to the Fucaceae *sensu lato*, *Durvillaea* and the *Notheia* plus Cystoseiraceae-Sargassaceae clade (Fig. 7 of de Reviers and Rousseau, 1999). This possibility involves only one loss of the capacity to synthesize altritol, i.e. that at the origin of the Fucaceae *sensu lato* which is also required in the original suggestion that *Notheia* obtained its altritol from the phorophyte and could not synthesize altritol.

In summary, the hypothesis that *Notheia* obtains its altritol entirely from the phorophyte requires as a minimum one gain and one loss of the capacity to make altritol. The alternative view that *Notheia*, as well as *Bifurcariopsis*, *Himanthalia*, *Hormosira* and *Xiphophora*, can synthesize altritol, requires as a minimum either one gain and two or three losses, or two gains and one loss, of the capacity to synthesize altritol.

In the absence of any knowledge of the pathway of altritol synthesis there are no enzymological or molecular genetic means to distinguish the capacity of *Notheia* to synthesize altritol from its obtaining altritol from the phorophyte. Similarly, it has not so far proved possible to culture *Notheia* for more than a few days independently of altritol-containing phorophytes, and thus to determine whether or not free-living *Notheia* synthesises altritol from measurements (e.g. using NMR: Chudek et al., 1984) of the altritol content of *Notheia* cultured from zygotes growing independently of a phorophyte. Accordingly, this paper reports a study of the ability of *Notheia* detached from *Hormosira*, as well as the *Hormosira* on which it had been growing, to incorporate ^{13}C-labelled inorganic C, *via* photosynthesis, into altritol. The use of ^{13}C label permits the use of ^{13}C NMR to measure the synthesis of altritol, just as ^{13}C at the natural abundance level was used in the original detection and quantification of altritol (Chudek et al., 1984; Reed et al., 1985; Wright et al., 1987). Incorporation of ^{13}C-enriched inorganic C by photosynthesis has been used to study turnover of altritol and mannitol in *Himanthalia elongata* (Reed et al., 1995); the experiments showed that altritol turned over less rapidly than mannitol.

2. Results

Table 1 shows the C and N contents of the dried algal material, and three representations of the ^{13}C content of the algal material. The C and N contents of the algae on a dry matter basis are similar to those reported earlier for *Hormosira* and *Notheia* from Victoria (Raven et al., 1995). The measured $\delta^{13}C$, and the $^{13}C/^{12}C$ ratios and the ^{13}C mol% in excess of the natural abundance level computed from the $\delta^{13}C$, show the ^{13}C enrichment of the algal carbon which occurred in the 52 h labelling period. The ^{13}C mol% in excess of the natural abundance level is higher in the *Notheia* than in the *Hormosira*. This is in accord with the observed greater photosynthetic rate of *Notheia* than of *Hormosira* on a dry matter and on an organic C basis at inorganic carbon and light saturation (Raven et al., 1995). The maximum mole per cent ^{13}C enrichment does not exceed 1.8 in *Hormosira* and 3.8 in *Notheia*, i.e. much lower than the 99.5 mol% ^{13}C enrichment in the inorganic C. However, these rather low enrichments of organic C are not unexpected in view of measured inorganic C fixation rates on an algal organic C basis (Raven et al., 1995),

Table 1
C and N contents, $\delta^{13}C$, $^{13}C/^{12}C$ ratio, and mole per cent excess ^{13}C above natural abundance level for *Hormosira* and *Notheia* incubated in ^{13}C-labelled inorganic C. The ^{13}C mole excess values were calculated using the natural abundance $^{13}C/^{12}C$ values for *Hormosira* and *Notheia* of 0.011115 and 0.01189 respectively (computed from $\delta^{13}C$ values in Raven et al., 1995)

Alga	Conditions during incubation	mg C/g dry matter	mg N/g dry matter	δ ^{13}C	$^{13}C/^{12}C$ ratio	^{13}C mole per cent in excess of the natural abundance value
Hormosira (1)	Detached (from *Notheia* (1))	321; 331	7.4; 7.8	1500; 1500	0.0284; 0.0284	1.64; 1.80

and the turnover of sugar alcohols in *Fucus spiralis* and *Himanthalia elongata* (Wright et al., 1989; Reed et al., 1995) would be expected to yield a much higher enrichment in sugar alcohols than the average in algal organic C. It is not clear why the ^{13}C labelling of both *Hormosira* and *Notheia* is higher in the specimens in which epiphyte and phorophyte were separated before labelling than when the algae were separated after the ^{13}C labelling.

^{13}C spectra of both *Hormosira* and *Notheia* showed resonances which could be attributed to mannitol and altritol. In the enriched *Hormosira* samples the altritol was present only in trace quantities (in spectra of extracts of natural *Hormosira* the mannitol to altritol ratio was ~2:1, see Table 2) while in the equivalent enriched *Notheia* samples altritol made up approximately 47% of the total polyol content (ratio in natural material ~1:1, Table 2). The marked change in the ratios from natural to enriched indicate that in *Hormosira* only mannitol carbons are enriched while in *Notheia* enrichment is in both of the polyols. In *Hormosira* mannitol in the ^{13}C-labelled sample is enriched to 20–30 times natural abundance level. In *Notheia* mannitol is enriched to 20–25 times the natural abundance levels, while altritol enrichment is to 10 times the natural abundance value.

Table 2
Intensities of the C_3 in mannitol and the C_6 in altritol measured with respect to the intensity of the acetate resonance normalised to 1.0, for samples of natural abundance and enriched *Hormosira* and *Notheia*. Intensities are in arbitrary units with a machine precision of ±0.2. Sample numbers are as in Table 1, i.e. the data shown here are for the epiphyte and phorophyte separated prior to incubation in ^{13}C-inorganic C

	Hormosira				*Notheia*			
	Natural abundance	Enriched			Natural abundance	Enriched		
		(1)	(2)	(3)		(1)	(2)	(3)
Mannitol	0.5	15.3	13.3	11.5	0.5	11.3	10.2	12.8
Altritol	0.3	0.2	0.3	0.4	0.6	6.5	6.0	6.0

Around each of the resonances which would be expected for natural abundance spectra of mannitol (C1,6, 64.6 ppm; C2,5, 72.2 ppm; C3,4, 70.7) and altritol (C1, 64.4 ppm; C2, 71.8 ppm; C3, 72.2 ppm; C4, 73.0 ppm; C5, 74.0 ppm; C6, 63.4 ppm) were a number of smaller peaks (Fig. 3). These were attributable to the effect of carbon–carbon splitting, not normally observed in natural abundance ^{13}C spectra, where the probability of adjacent labelled (^{13}C) carbons is 1:10,000, but clearly seen here. Measurement of the intensities of individual carbons was difficult due to line overlap but it would appear that their intensities relative to the standard acetate are equal in both mannitol and altritol, indicating that labelling was equal in all carbons when averaged over all of the sugar alcohol molecules. However, the line splitting shows that labelling is not uniform throughout each polyol molecule. Analysis of the splitting exhibited by carbons 2 and 5 in mannitol in *Hormosira* sample (1) indicates the presence of a singlet, no labelled carbons adjacent; a doublet ($J_{CC} = 40.9$ Hz), one labelled carbon adjacent and a triplet ($J_{CC} = 42.4$ Hz), 2 labelled carbons adjacent. Thus, the line splitting implies that there are polyol molecules with a mixture of ^{13}C and ^{12}C molecules, with more ^{13}C than the natural abundance level (i.e. synthesized from ^{13}C-labelled photosynthate) but with more ^{12}C than would be expected from the 99% ^{13}C-enriched inorganic C substrate supplied for photosynthesis. This implies dilution of the supplied ^{13}C with ^{12}C before the polyols are synthesized, the ^{12}C coming from the (minimal) residual inorganic C

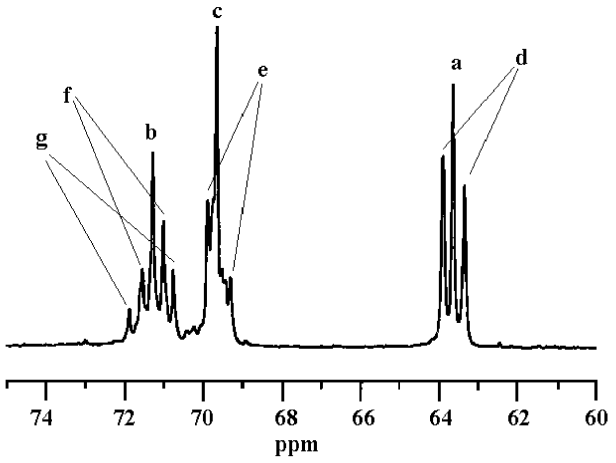

Fig. 3. ^{13}C {H} spectrum of *Hormosira* after photosynthesis in ^{13}C-HCO_3^--enriched medium; only resonances associated with mannitol are observed. Peak (a) resonances for C atoms 1 and 6, (b) for C atoms 2 and 5, and (c) for C atoms 3 and 4. In unenriched samples only these three resonances are observed. The resonances marked (d) and (e) indicate enrichment of at least one C adjacent to C atoms 1 and/or 6 and C atoms 3 and/or 4 respectively. Resonances marked (f) and (g) show the doublet and triplet [central band under (b)], described in the text; these, together with resonance (b) indicates that C atoms 2 and 5 are present in molecules where no neighbouring C atoms are enriched [singlet (b)], where one is enriched [doublet (f)] and where two are enriched [triplet (g)].

in the 'CO_2-free' seawater (see Experimental), and from CO_2 generated within the thallus by respiration of substrates with no significant ^{13}C enrichment (see Table 1 for enrichment of whole-alga organic C) rather than dilution of the supplied ^{13}C by atmospheric air (see Experimental).

3. Discussion

The data reported in this paper clearly show that *Notheia anomala* can synthesise altritol from products of its own photosynthesis when it is detached from its phorophyte *Hormosira banksii*. The data showing labelling of altritol in *Notheia* when the *Hormosira*/*Notheia* combination is incubated in the ^{13}C-enriched inorganic C and only separated after labelling is consistent with the ability of *Notheia* to synthesise altritol, but on its own would be inconclusive since translocation of altritol from phorophyte to epiphyte has not been ruled out. An absence of ^{13}C labelling of altritol when detached *Notheia* were incubated with ^{13}C-labelled inorganic C would not be regarded as conclusive evidence that *Notheia* was unable to synthesise altritol, since some hypothetical labile 'host factor' could be invoked as necessary to permit altritol synthesis in *Notheia*. However, there is no need to hypothesise such a host (phorophyte) factor since detached *Notheia* can synthesis altritol.

The finding that *Notheia* can synthesise altritol means that the first hypothesis as to the phylogeny of altritol synthesis in the Fucales which was proposed in the Introduction can be eliminated. As for the alternative hypotheses, the data presented in this paper do not distinguish between the suggestions of a single gain of the ability to synthesise altritol and three losses of this synthetic ability from the alternative of two gains of the ability to synthesise altritol and a single loss of this synthetic ability.

4. Experimental

4.1. General experimental procedures

Seawater containing ^{13}C inorganic C was prepared by removing inorganic C from 4 dm^3 seawater by adjusting pH to 3.8, purging overnight with CO_2-free air then readjusted to the starting pH (8.17) with freshly made up NaOH solution (1 kmol m^{-3}) and 1.25 g of $NaHCO_3$ which was 99 at.% ^{13}C (Sigma). This gave an added inorganic C concentration of 3.67 mol m^{-3}, with a residual inorganic C concentration prior to ^{13}C addition of less than 40 mmol m^{-3}. Triplicate samples of Hormosira phorophytes (5.91–6.37 g fresh weight) from which the *Notheia* epiphytes had been detached were incubated in 500 cm^3 aliquots of the labelling solution. Triplicate samples of the *Notheia* epiphytes (6.01–6.25 g fresh weight) which had been detached from *Hormosira* were also incubated in aliquots of the ^{13}C solution. Duplicate samples of *Hormosira* bearing *Notheia* (11.60 and 11.81 g fresh weight) were incubated in further aliquots. Samples were incubated in 0.5 dm^3 conical flasks containing 0.5 dm^3 of the ^{13}C-enriched seawater; there was minimal air space above the aqueous phase and the flasks were sealed with a double layer of Parafilm. Incubation conditions were 100 μmol photon m^{-2} s^{-1} continuous photosynthetically active radiation at 16 °C for 52 h. At the end of the incubation the specimens were removed from the labelling solution, washed briefly with unlabelled seawater and dried at 60 °C. Drawdown of inorganic carbon by photosynthesis during incubation was indicated by increase in pH of the incubation medium to 8.64–9.04 (*Hormosira* alone), 9.32–9.66 (*Notheia* alone) and 9.47–9.63 (*Hormosira* plus *Notheia*), despite the initial inorganic C concentration of almost twice that of normal seawater. Some loss of photosynthetic performance during the 52 h incubation was indicated by the decrease in F_v/F_m (a function of the quantum yield of net electron transport through reaction centres of photosystem two: Falkowski and Raven, 1997) from 0.67 to 0.54 for *Hormosira* and from 0.60 to 0.53 for *Notheia*.

The enrichment of ^{13}C algal bulk organic carbon was determined on 1 mg dry matter samples of algae on a

Europa 20–20 isotope ratio mass spectrometer coupled to an ANCA-SL sample converter. This procedure provided values for the C and N contents of the specimens as well as $\delta^{13}C$ of the organic carbon. Computation of the $^{13}C/^{12}C$ ratio of the algal material from the $\delta^{13}C$ involved the use of the known $^{13}C/^{12}C$ of the Pee–Dee Belemnite standard for the $\delta^{13}C$ measurements, i.e. 0.011365. Estimation of the mol percent ^{13}C in the algal material in excess of the natural abundance ^{13}C levels in the algae were performed using $\delta^{13}C$ values for the algae from Raven et al. (1995).

The remainder of the ^{13}C-labelled specimens were individually extracted in boiling 80% v/v aqueous ethanol, followed by overnight extraction in the same solvent at room temperature (Wright et al., 1989; Reed et al., 1995). An internal standard containing 50.0 mg of 20.7 mol percent ^{13}C-enriched sodium acetate was added to each sample vial at the beginning of the extraction procedure. The extract was filtered through a Whatman GF/C filter and then dried by rotary evaporation. The material was then redissolved in 1 cm^3 of D_2O, the deuterium signal of which was used as a field lock.

Samples were placed into 5mm OD NMR tubes and $^{13}C\{^1H\}$ NMR spectra were acquired on a Bruker AVANCE DPX 300 FT NMR spectrometer, resonating at ^{13}C: 75.42 MHz; ^1H: 299.90 MHz. Data were accumulated into 64 k data points using a 30° (5.3 μs) pulse width; a 3.4 s repetition time and a 24 kHz sweep width, these parameters were designed to allow the relative intensities of the polyol resonances to be measured. Data were transformed into 32 k words using 3 Hz line broadening. Resonance frequencies were measured with regard to external TMS; line intensities with regard to the acetate resonance, integral 1.0.

4.2. Biological materials

Hormosira banksii (Turner) Decaisne with epiphytic *Notheia anomala* Harvey and Bailey was collected from rock pools at Sorrento Ocean Beach (Sorrento, Victoria, Australia; 38° 28′S; 144° 43′E) on 16 March 2000 at low tide (13.45). Seawater temperature at the time of sampling was 16–17 °C; air temperatures during the day were 22–23 °C for the prior 3–4 days, after three weeks of much higher temperatures. The samples were taken to the laboratory in a cool box and incubated overnight in aerated seawater before being used in labelling experiments.

A voucher specimen of *Notheia anomala* on *Hormosira banksii* collected from Sorrento is deposited in the Algal Herbarium, School of Biological Sciences, Monash University. The specimen number is 2770 and the collector/identifier is M. Forbes.

Acknowledgements

The assistance of Christine Ashburner, Dr. Antionetta Quigg and Dr. Erica Young is greatly appreciated. We are greatly indebted to Mrs. R. L. MacKay who ran the NMR spectra, and to the authors and publishers of de Reviers and Rousseau (1999) for permission to reproduce the material shown in Fig. 2.

Received 27 February 2001; received in revised form 18 May 2001

Abstract

Lolines (saturated 1-aminopyrrolizidines with an oxygen bridge) are insecticidal alkaloids produced in symbioses of certain *Epichloë* (anamorph-*Neotyphodium*) species (fungal endophytes) with grasses, particularly of the genera *Lolium* and *Festuca*. Prior to the present study, it was unknown whether lolines were of plant or fungal origin. *Neotyphodium uncinatum*, the common endophyte of meadow fescue (*Lolium pratense* = *Festuca pratensis*) produced loline, *N*-acetylnorloline, and *N*-formylloline when grown in the defined minimal media at pH 5.0–7.5, with both organic and inorganic nitrogen sources and sugars as carbon sources. In contrast, lolines were not detected in complex medium cultures. GC–MS and ^{13}C NMR spectroscopic analyses confirmed the identity of the alkaloids isolated from the defined medium cultures. Lolines accumulated to ca. 700 mg/l (4 mM) in cultures with 16.7 mM sucrose and 15–30 mM asparagine, ornithine or urea. Kinetics of loline production and fungal growth were assessed in defined medium with 16.7 mM sucrose and 30 mM ornithine. The alkaloid production rate peaked after the onset of stationary phase, as is common for secondary metabolism in other microbes. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Loline alkaloids (saturated 1-aminopyrrolizidines with an oxygen bridge) (Fig. 1) have been identified in some grass-endophyte associations (Siegel et al., 1990), but are absent in most other organisms. These grasses are naturally infected with symbiotic endophytic fungi, especially *Epichloë* spp. and their asexual derivatives (*Neotyphodium* spp.), which grow in the intercellular spaces (apoplast) of host plants. In these symbioses, an array of other anti-herbivore alkaloids is produced. Three of the alkaloid classes commonly found in endophyte–grass associations—peramine (a pyrrolopyrazine), ergot alkaloids, and lolitrems (indolediterpenes)—are of known fungal origin because these are reported to accumulate in fermentation cultures (Bacon, 1988; Rowan, 1993, Gurney et al., 1994; Porter, 1994). The lolines are produced in a number of grass-endophyte symbioses: *Lolium arundinaceum* (= *Festuca arundinacea*) with *Neotyphodium coenophialum* (Siegel et al., 1990), *Lolium giganteum* (= *Festuca gigantea*) with *Epichloë festucae* (Leuchtmann et al., 2000), *Lolium pratense* (= *Festuca pratensis*) with *Neotyphodium uncinatum* (Bush et al., 1993; Justus et al., 1997), *L. pratense* with *Neotyphodium siegelii* (Craven et al., 2001), and endophyte-infected *Festuca argentina* (Casabuono and Pomilio, 1997), *Lolium temulentum* (Dannhardt and Steidt, 1985), *Poa autumnalis* (Siegel et al., 1990), and *Stipa robusta* (TePaske et al., 1993). The plants, *Argyreia mollis* (Convolvulaceae) and *Adenocarpus* spp. (Fabaceae) have also been reported to contain loline alkaloids, although endophytes have not been implicated (Hartmann and Witte, 1995; Tofern et al., 1999).

The lolines are secondary metabolites and have an unusual structure consisting of a saturated necine ring with an –NRR′ substituent at C1 and an oxygen bridge

between C2 and C7 (Yates et al., 1990; Powell and Petroski, 1992). Lolines thus differ from most plant pyrrolizidines, which are synthesized from homospermidine (Böttcher et al., 1993) and have a $-CH_2OR$ group at C1. Nothing is known about the biosynthesis of the endophyte-associated lolines, but based on this difference, the loline alkaloids have been suggested to be derived from spermidine or spermine (Bush et al., 1993). The alkaloids are found throughout the plant in these associations and have protective effects for the plant due to their anti-invertebrate and feeding deterrent activities (Patterson et al., 1991; Justus et al., 1997; Dougherty et al., 1998; Wilkinson et al., 2000). Lolines are broad-spectrum insecticides (Siegel and Bush, 1997); and in grasses symbiotic with strains of *E. festucae* segregating for loline alkaloid expression, accumulation of these alkaloids was clearly associated with activity against certain aphid species (Wilkinson et al., 2000). Thus, the loline alkaloids are of great interest as natural plant protectants. Although studies do indicate immunosuppressive effects in mice (Dew et al., 1990) and depressed feed intake has been observed in rats fed loline alkaloids (Jackson et al., 1996), it has not been conclusively shown that the loline alkaloids at in planta levels are toxic to mammalian herbivores (Siegel and Bush, 1997). Lolines do not share the same potent anti-mammalian hepatotoxicity and carcinogenicity as plant pyrrolizidines, 1-hydroxymethylpyrrolizidines, which contain C-1,2 unsaturation in the necine ring (Hincks et al., 1991); cytochrome P450 converts the 1-hydroxymethylpyrrolizidines to more bioactive forms, which to varying degrees are capable of crosslinking of DNA (Kim et al., 1999).

Loline alkaloid expression correlates with fungal genotype, and in some grass-endophyte symbiota levels can exceed 2% plant dry mass (Craven et al., 2001). Until the present study lolines have been the only grass-endophyte associated alkaloid class reported in the literature that was not observed in fungal cultures (Porter, 1994). Knowledge of the origin of lolines would be beneficial for elucidating the biosynthetic pathway and its regulation, identifying biosynthesis genes, and expanding biotechnological possibilities for these alkaloids.

Since lolines were only detected in endophyte-infected plants, we hypothesized the endophyte was responsible for their production, and that cultures that adequately mimic the internal environment of the plant may stimulate loline production. In this paper, it is demonstrated that three of the loline alkaloids found in plant tissue—loline (**1**), *N*-acetylnorloline (**2**), and both rotamers of *N*-formylloline (**3** and **3′**)—are produced by *N. uncinatum* under certain minimal medium conditions.

2. Results

The common endophyte of *L. pratense, N. uncinatum,* was examined for potential production of loline alkaloids in culture because grasses symbiotic with this species accumulate lolines at high levels. In a minimal medium modified from Chung and Schardl (1997), with mannitol as the carbon source and asparagine as the nitrogen source, *N. uncinatum* produced **1**, **2**, **3**, and **3′**. The identities of these alkaloids were confirmed by GC–MS and ^{13}C NMR spectroscopic analyses. Another loline alkaloid, *N*-acetylloline, is (together with **3** and **3′**) one of the most abundant alkaloids in *L. pratense–N. uncinatum* symbiota (Siegel et al., 1990), but was not detected in the culture. No loline alkaloids were detected from the cultures grown in potato dextrose broth (PDB).

Various carbon sources typically present in plant apoplasts were examined. Initially, mannitol was chosen because it is a good carbon source for growth of the related endophyte, *N. coenophialum* (Kulkarni and Nielsen, 1986). Fructose, glucose, and sucrose were then tested as alternative carbon sources because sucrose is a major transport sugar in the apoplast, while glucose and fructose are produced from sucrose by the action of invertase secreted by endophytes (Lam et al., 1994). As shown in Fig. 2, sucrose was the best of these carbon sources for loline production, giving a range of 500–750 $\mu g\ ml^{-1}$ (up to 4 mM) total of **2**, **3**, and **3′**. This was a 12-fold increase of production over cultures with mannitol. Glucose or fructose also tended to increase production only slightly compared to mannitol cultures, but not to the level obtained using sucrose.

Nitrogen sources tested were asparagine, arginine, ornithine, glutamine, ammonium sulfate, and urea, in cultures at pH 5.5 with sucrose as carbon source.

Nitrogen concentration was maintained at 30 mM total nitrogen atoms. In this experiment, cultures with urea as the sole nitrogen source yielded the greatest overall level of loline alkaloid production, ca. 425 μg ml^{-1} of culture filtrate (Fig. 3). Ornithine as the sole nitrogen source also gave much greater levels than expressed in cultures with asparagine or arginine. The level of loline alkaloid production at day 20 was 5-fold greater when ornithine rather than asparagine was the nitrogen source (Fig. 3).

Altering concentrations of phosphate between 6.8 and 68 mM, $MgSO_4$ between 0.2 and 4.0 mM, mannitol between 8.3 and 16.7 mM, or asparagine between 15 and 30 mM had only slight effects on loline alkaloid production levels (data not shown).

To determine how loline alkaloid production and growth may be related, a time course experiment was conducted with medium containing 16.7 mM sucrose and 30 mM ornithine (Figs. 4 and 5) (these carbon and nitrogen sources were chosen for the time course because they promote loline alkaloid production and are known substituents of plant apoplasts; Pate, 1973). The proportion of **2** to **3** with **3′** in this experiment (Fig. 4a and b) was consistent with levels obtained in similar experiments. (Levels of **1** were characteristically very low, so they are not included in Fig. 4.) The maximum rate of loline alkaloid accumulation (Fig. 4a and b) consistently occurred after cessation of the fungal growth with onset of stationary phase (Fig. 5a). A slight increase in pH occurred whether the initial pH was 5.5

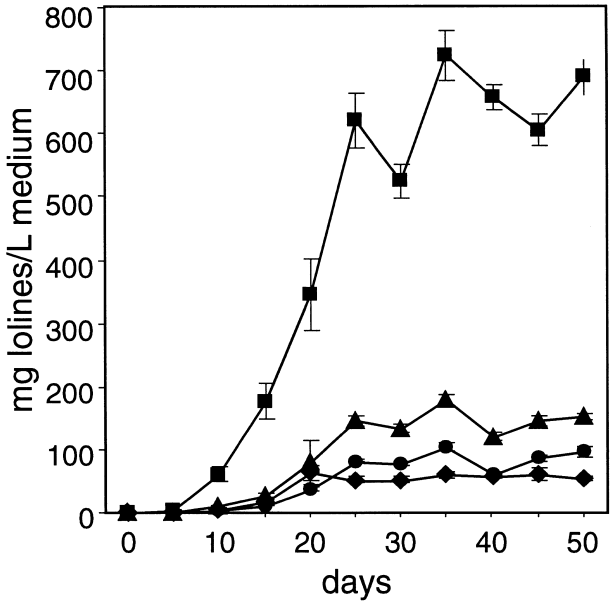

Fig. 2. Effect of carbon source on loline production. Carbon sources were ◆ 16.7 mM mannitol, ▲ 16.7 mM glucose, ● 16.7 mM fructose, or ■ 16.7 mM sucrose. Asparagine concentration was at 15 mM; pH 5.5. Means ($n=5$) are indicated with error bars equal to ± 1 S.D. S.D. smaller than the symbol are not shown.

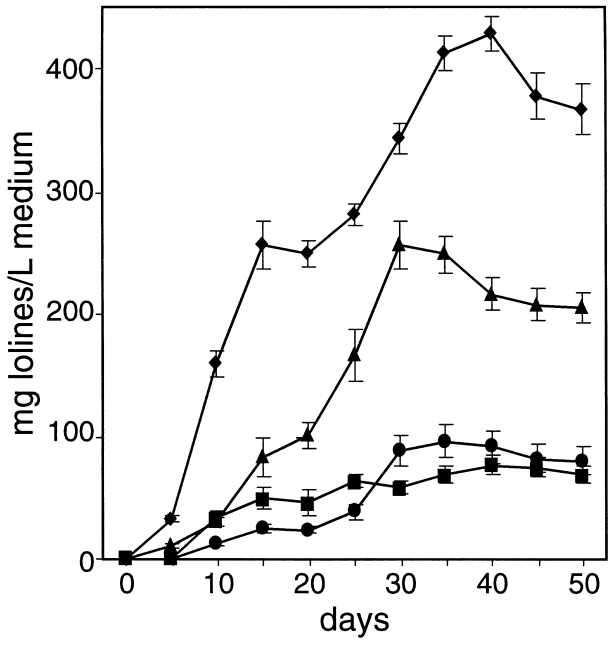

Fig. 3. Effect of nitrogen source on loline production. Nitrogen sources were ▲ 15 mM ornithine, ● 15 mM asparagine, ■ 7.5 mM arginine, or ◆ 15 mM urea. Sucrose concentration was 16.7 mM, and pH was 5.5. Means ($n=4$, except urea $n=3$) are indicated with error bars equal to ± 1 S.D.

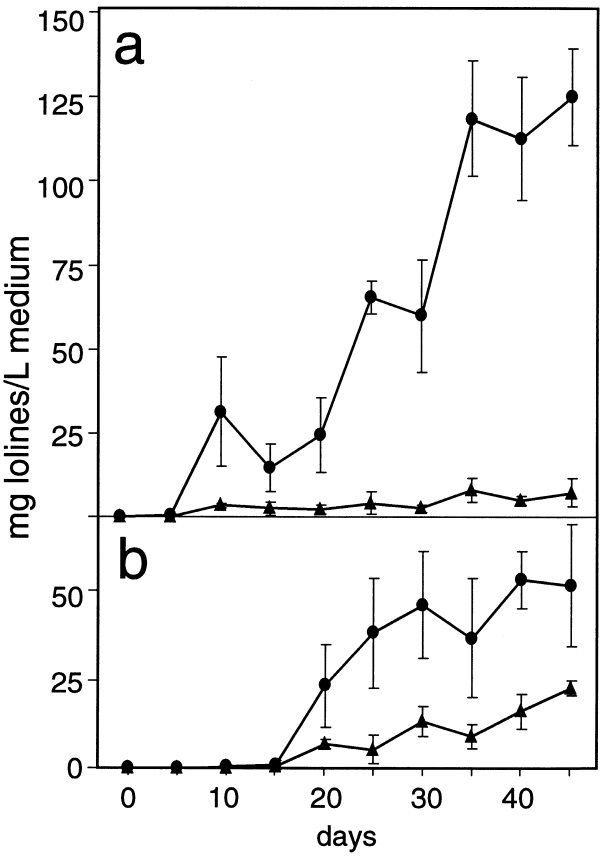

Fig. 4. Levels of ▲ *N*-acetylnorloline and ● *N*-formylloline in cultures. (a) Production at pH 5.5. (b) Production at pH 7.0. Means ($n=4$) are indicated with error bars equal to ± 1 S.D.

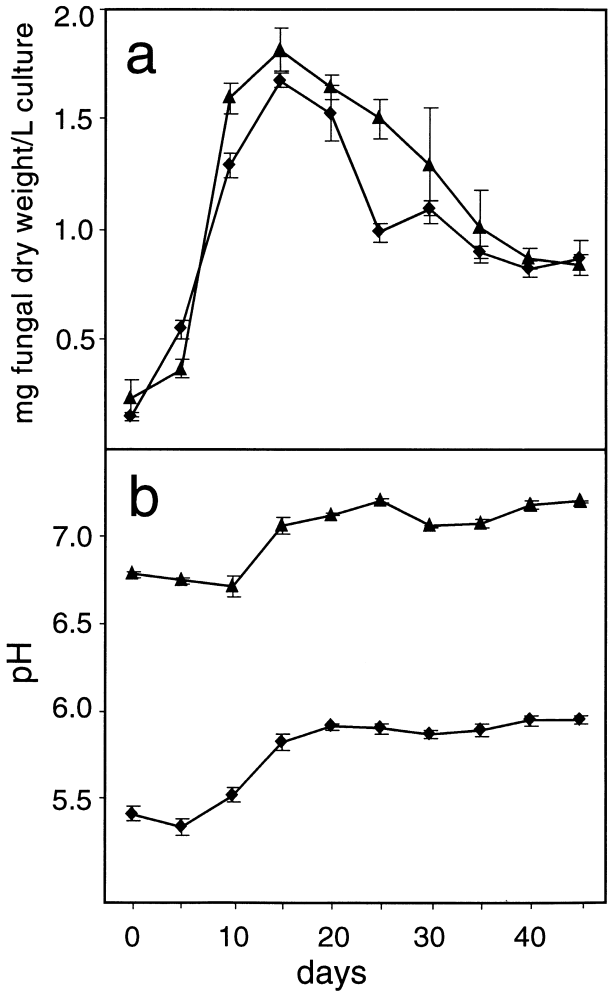

Fig. 5. Comparison of loline production at pH ◆ 5.5 and ▲ 7.0. (a) Growth of *Neotyphodium uncinatum*. (b) Change in pH of culture medium. Carbon and nitrogen sources were 16.7 mM sucrose and 30 mM ornithine, respectively. Means ($n=4$) are indicated with error bars equal to ± 1 S.D.

or 7.0 (Fig. 5b), and the change coincided with the onset of loline production (Fig. 4a and b) and slowing of fungal growth (Fig. 5a).

Other grass endophytes known to produce lolines in planta—*E. festucae* from *L. giganteum* (Leuchtmann et al., 2000), *N. coenophialum* from *L. arundinaceum* (Siegel et al., 1990), and *N. siegelii* from *L. pratense* (Craven et al., 2001)—were also tested for production. These fungi were cultured under the preferred conditions established for *N. uncinatum* (including 20 mM sucrose and 30 mM ornithine), but lolines were not detected in these cultures.

3. Discussion

The *Epichloë* and *Neotyphodium* species, closely related fungi that live as endophytes of grasses, have been implicated in the production of the ergot, lolitrem, and peramine alkaloids (Porter, 1994). Previously, lolines were never observed outside the grass-endophyte symbiota (Schardl and Phillips, 1997). Thus, prior to this study it was not established whether the plant or fungus, or the combination of both, produced the loline alkaloids. By establishing culture conditions for production of the loline alkaloids (specifically *N*-formylloline, *N*-acetylnorloline, and loline) by *N. uncinatum,* it was demonstrated that this fungus has the full biosynthetic capacity for some of the most common loline alkaloids found *in planta.* The observed correspondence of maximal loline production with the stationary phase was in keeping with secondary metabolism in other microorganisms (Campbell, 1984).

Nitrogen sources for these experiments were chosen to test organic and inorganic nitrogen and also based on the known precursors of polyamines and plant pyrrolizidines (Böttcher et al., 1993). Ammonium sulfate was used as an inorganic nitrogen source with levels of production comparable to those with asparagine, glutamine, and arginine. Cultures with urea as nitrogen source yielded the highest levels of lolines, but urea was not examined further because its levels in plant apoplast and xylem are unknown. Arginine and ornithine are apoplast substituents in grasses (Pate, 1973), and ornithine is a direct precursor in the polyamine biosynthetic pathway. It has been proposed, based on structures of the lolines, that spermidine, spermine, or both could be precursors to the lolines (Siegel and Bush, 1997). Arginine and ornithine are closely related, and removal of the urea group from arginine yields ornithine in the urea cycle. A determinant step in polyamine synthesis is decarboxylation of ornithine to form putrescine, which is converted to spermidine with the addition of a propylamine group from decarboxylated *S*-adenosylmethionine. Adding an additional propylamine group to spermidine yields spermine. These propylamine groups ultimately derive from aspartate, which is readily derived from asparagine. Preliminary feeding studies with ^{13}C-labelled ornithine and aspartate confirmed that these are likely loline alkaloid precursors (J.D.B. and C.L.S., unpubl. data).

The absence of *N*-acetylloline in culture, the other major loline alkaloid produced in planta, remains to be explained. Alternative possibilities are that the fungus does not express the necessary enzyme to convert loline (or other lolines) to *N*-acetylloline, or that the plant is responsible for the conversion. Another surprising observation is that no other fungal endophyte that produces the loline alkaloids in planta produced measurable quantities in culture, even under conditions favorable for production by *N. uncinatum*. A possibility is that only *N. uncinatum* has the full competence to produce lolines outside its host, whereas in other grass-endophyte symbiota loline alkaloid production may be accomplished by both symbiotic partners. A more likely possibility, however, is simply that the culture conditions promoting production by *N. uncinatum* were unsuitable for production by the other endophytes.

Now that it has been shown that some common loline alkaloids can be produced by cultured *N. uncinatum*, work is underway on the biosynthetic pathway for loline alkaloids. The high level of their production in culture will significantly facilitate studies of the pathway and will aid in identifying and characterizing the genes that may be responsible.

4. Experimental

4.1. General experimental procedure

For gas chromatography, all samples were run on a Hewlett Packard (Avondale, PA) 5890 Series II Plus GC equipped with a flame ionization detector and a J&W Scientific Inc. (Rancho Cordova, CA) fused silica capillary column (SE 30, 60 m×0.30 mm inner diameter with 0.25 μm film thickness of dimethylpolysiloxane). Nitrogen was used as the carrier gas at a flow rate of 20.4 ml min^{-1}. The run parameters were an initial column temperature of 110 °C, an injection temperature of 250 °C, a detector temperature of 325 °C, a 2.2-min purge time, and a 4 °C min^{-1} increase in column temperature to 188 °C. Between each sample run, the column was purged at 280 °C for 5 min. ^{13}C NMR spectroscopic analysis employed a Varian Gemini 200 equipped with VNMR 6. 1B software (Varian Inc., Palo Alto, CA). Samples of purified alkaloids in 750 μl D_2O (Cambridge Isotopes Laboratories, Inc., Andover, MA) were prepared in 5 mm×17.8 cm NMR tubes (Wilmad, Beuna, NJ) and 10 μl methanol added as an internal standard. ^{13}C NMR spectroscopic conditions were at 200 mHz, ambient temperature, and proton decoupling. Chemicals for these experiments were obtained from Sigma-Aldrich (Milwaukee, WT).

4.2. Fungal isolate isolation

Cultures were obtained by growing *Neotyphodium uncinatum* (W. Gams Petrini et Schmidt) Glenn Bacon et Hanlin (voucher specimen CBS 102646 at Centraalbureau Voor Schimmelcultures) out of an infected plant (number 167 in our plant collection) of *Lolium pratense* (Huds.) Darbysh. [*Festuca pratensis* Huds., realigned with genus *Lolium* by Darbyshire (1993).] Leaf blades were sterilized in 50-ml Costar tubes with 95% ethanol for 1 min, followed by a rinse of sterile water, then soaked for 2 min in 5.25% sodium hypochlorite. The leaf blades were then rinsed with sterile water, cut into 2-mm sections, and plated on potato dextrose agar (PDA, Difco Laboratories, Detroit, MI) with penicillin (167 units ml^{-1}) and streptomycin (76.3 units ml^{-1}). After 14 days, 5 pieces of fungal mycelium grown out (approximately 0.5 cm) of the plant material was removed from the agar and homogenized in 10 ml of the minimal medium in an Omni Homogenizer Model 17105 (Omni International, Waterbury, CT) with six 10-s bursts. The ground mycelium was drop-inoculated onto PDA and grown for 7 days, then 1.5–2 cm plugs were cut out of the agar, homogenized in minimal medium, and 1 ml used to inoculate each 30 ml minimal medium culture for study. Large differences in alkaloid expression between experiments most likely were due to unavoidable differences in inoculum density and physiological condition of the source mycelium, so employing a single source of inoculum for each experiment minimized variation between replicates. Cultures of *Epichloë festucae* Leuchtm. Schardl et Siegel (CBS 102474) from *Lolium giganteum* (L.) Darbysh. (= *Festuca gigantea* L.), *Neotyphodium coenophialum* (Morgan-Jones et W. Gams) Glenn Bacon et Hanlin (American Type Culture Collection accession ATCC 90664) from *Lolium arundinaceum* (Schreb.) Darbysh. (= *Festuca arundinacea* Schreb.), and *Neotyphodium siegelii* K. D. Craven Leuchtm. et Schardl (ATCC 74483) from *L. pratense* were obtained similarly (Craven et al., 2001).

4.3. Culture medium

The defined media used in these experiments were adapted from Chung and Schardl (1997) with modifications. The 10× stock solutions of basal salts—300 mM K_2HPO_4 and 300 mM KH_2PO_4 in water purified by Milli-Q (Nanopure, Model D4751, Barnstead/Thermolyne, Dubuque, IA)—were mixed to the desired pH (4.5–8.0 as specified). Then, 2(*N*-morpholino)ethanesulfonic acid (MES) was added to the basal salt solution to 300 mM, and pH readjusted with NaOH. MES was used to prevent the drastic pH increase that sometimes occurred in cultures with only phosphate as buffer. Final concentrations in the minimal medium were 30 mM potassium phosphate and 30 mM MES. The carbon sources were added to a conc. of 8.3 mM, and nitrogen sources were added to give 30 mM nitrogen atoms, except where otherwise specified. To the medium were added $MgSO_4$ to 2 mM, thiamine to 0.6 μM, and a solution of trace elements (from 1000×stock) to give 3.6 μM H_3BO_3, 1 μM $CuSO_4$, 0.7 μM KI, 0.8 μM FeNa-ethylenediaminetetraacetic acid, 1 μM $MnSO_4$, 0.5 μM $NaMoO_4$, and 0.4 μM $ZnSO_4$ (Kulkarni and Nielsen, 1986). Basal salts and MES in purified water were autoclaved together, and the $MgSO_4$ was autoclaved separately to prevent precipitation of salts. Carbon source, nitrogen source, thiamine, and trace elements were filter-sterilized together then combined with the basal salts and $MgSO_4$ solution. After preliminary trials with cultures in Erlenmeyer flasks proved inconsistent, 100×25 mm polystyrene petri plates (Fisherbrand, Fisher Scientific, Pittsburgh, PA) were used for the 30 ml cultures in all experiments reported here. The cultures were incubated at 21 °C with 100 rpm rotary shaking.

4.4. Sampling from cultures

Aliquots of medium from each culture were transferred into 1.7-ml Eppendorf (Brickmann Instruments, Inc., Westbury, NY) microcentrifuge tubes that had been pretreated at 100 °C for 2 days to remove extractable contaminants that otherwise interfered with the analysis. Prior to day 20 of culture, 1 ml aliquots were sampled; thereafter, aliquots were 0.5 ml. For fungal biomass and loline level determinations, 30-ml cultures were harvested for each time point and filtered through tared Whatmann no. 1 filter paper (Whatmann Limited, England). Then the mycelium on each filter was oven dried (37 °C, 2 days) and weighed, and the culture filtrate was frozen and freeze-dried for later analysis of lolines.

4.5. Alkaloid analysis

For GC analysis, freeze-dried samples were extracted using a modified procedure from Yates et al. (1990) and Robbins et al. (1972). One-tenth volume of a saturated sodium bicarbonate solution (0.25 g ml^{-1} in H_2O) was added to each dried filtrate and the tubes were vortexed. Chloroform (1 ml), with 14.2 mg l^{-1} of quinoline (RR $t=7.60$) as the internal standard was added to each tube. The suspension was vortexed, then shaken 30 min on a platform shaker. The $CHCl_3$ layer was transferred to a capped glass vial. Levels for lolines from GC analysis in these experiments are reported as the total of **2** (RR $t=16.75$) and **3** with **3′** (RR $t=17.44$), because the levels of **1** (RR $t=9.21$) were always very low.

For analysis by GC–MS and ^{13}C NMR spectroscopy, loline alkaloids were isolated using modifications of the procedure of Petroski et al. (1989). Fungal culture filtrates were freeze-dried, then extracted with 1 ml satd. sodium bicarbonate (aq.) and 30 ml $CHCl_3$. The aqueous layer was discarded and the organic solvent evaporated in a stream of nitrogen gas to yield a brown oil. One ml $CHCl_3$ was added to the oil and 500 μl of this mixture was spotted onto a K6F Silica gel 60A TLC plate (Whatmann Inc, Clifton, NJ). After drying, the plate was developed in a chromatography chamber with 140 ml of a 50:50:1 (by volume) mixture of CH_3OH, $CHCl_3$ and satd. NH_3OH. Loline alkaloids were visualized as dark brown spots after exposing the plate to iodine vapor. R*f* values for **1**, **2**, and **3** with **3′** were determined as 0.26, 0.37, and 0.49, respectively. The visible spots corresponding to the loline alkaloids (**1**, **2**, and **3** with **3′**) on the plate were scraped off individually and alkaloids eluted with purified H_2O, extracted with $CHCl_3$ and solvent removed by a stream of N_2 gas. These purified samples were then used in GC–MS and ^{13}C NMR analysis.

4.6. Alkaloid purification and identification:

Loline (**1**) was isolated by separation of the alkaloids by TLC and extracted from the silica with H_2O, and because of its volatility, conc. HCl was added to yield the salt form, which was recrystallized with EtOH: ^{13}C NMR (D_2O, 200 MHz), 29.2 (C6), 34.0 (NMe), 55.5 (C5), 61.8 (C3), 63.8 (C1), 70.1 (C8), 71.9 (C2), 80.9 (C7); EIMS *m*/*z* 154 $[M]^+$ (0), 123(58), 110 (7), 95 (75), 82 (100).

N-Acetylnorloline (**2**) was purified as a clear oil after being separated from the other alkaloids by TLC, extracted from the plate with H_2O followed by extraction with $CHCl_3$ which was removed with a stream of nitrogen gas: ^{13}C NMR (D_2O, 200 MHz), 24.2 (MeC=O), 35.1 (C6), 54.8 (C5), 58.4 (C1), 61.4 (C3), 70.1 (C8), 74.1 (C2), 81.6 (C7), 171.9 (HC=O); EIMS *m*/*z* 182 $[M]^+$ (0), 153 $[M\text{-}29]^+$ (8), 139 (0), 123 (9), 110 (0), 95 (30), 82 (100), 69 (22).

N-Formylloline (**3**) was purified as a viscous brown oil similar to purification of **2**: ^{13}C NMR (D_2O, 200 MHz), 32.0 (C6), 34.8 (NMeth), 54.1 (C5), 59.7 (C3), 65.5 (C1), 67.8 (C8), 74.3 (C2), 83.2 (C7), 165.1 (HC=O); EIMS *m*/*z* 182 $[M]^+$ (0), 154 $[M\text{-}28]^+$ (25), 123 (13), 110 (13), 95 (28), 82 (100).

N-Formylloline (**3′**) extracted with **3** as a brown oil: ^{13}C NMR (D_2O, 200 MHz), 30.4 (NMeth), 31.7 (C6), 54.3 (C5), 60.6 (C3), 63.0 (C1), 68.6 (C8), 73.5 (C2), 81.4 (C7), 167.0 (HC=O); EIMS *m*/*z* 182 $[M]^+$ (0), 154 $[M\text{-}28]^+$ (25), 123 (13), 110 (13), 95 (28), 82 (100).

Acknowledgements

We thank Dr. Mark S. Meier and Mr. John Layton for their expert advice on ^{13}C NMR analysis, and we thank Dr. Harold H. Burton, Dr. Peter A. Crooks and Dr. Xiaochen Wei for their expert advice on GC–MS. Capable assistance was kindly provided by Mr. A.D. Byrd, Ms. J.L. Dueñas, Ms. D.W. Franks, Mr. W. Hollin, Ms. A.C. Mallory, Ms. S.A. Mathews, and Ms. S. Van Orden. This research was supported by National Science Foundation grant IBN-9808554 to C.L.S. and L.P.B., and the United States Department of Agriculture NRI grant 96-35303-3578 to H.H.W.

Abstract

It is widely accepted that the mix of flavonoids in the cell vacuole is the source of flavonoid based petal colour, and that analysis of the petal extract reveals the nature and relative levels of vacuolar flavonoid pigments. However, it has recently been established with lisianthus flowers that some petal flavonoids can be excluded from the vacuolar mix through deposition in the cell wall or through complexation with proteins inside the vacuole, and that these flavonoids are not readily extractable. The present work demonstrates that flavonoids can also be compartmented within the cell cytoplasm. Using adaxial epidermal peels from the petals of lisianthus (*Eustoma grandiflorum*), *Lathyrus chrysanthus* and *Dianthus caryophyllus*, light and laser scanning confocal microscopy studies revealed a significant concentration of petal flavonoids in the cell cytoplasm of some tissues. With lisianthus, flavonoid analyses of isolated protoplasts and vacuoles were used to establish that ca 14% of petal flavonoids are located in the cytoplasm (cf. 30% in the cell wall and 56% in the vacuole). The cytoplasmic flavonoids are predominantly *acylated* glycosides (cf. non-acylated in the cell wall). Flavonoid aggregation on a cytoplasmic protein substrate provides a rational mechanism to account for how colourless flavonoid glycosides can produce yellow colouration in petals, and perhaps also in other plant parts. High vacuolar concentrations of such flavonoids are shown to be insufficient. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

In discussions of flower colour chemistry and its manipulation, it is commonly presumed that flavonoid pigments mix freely with one another in the aqueous environment of the cell vacuole (Brouillard, 1988; Brouillard and Dangles, 1994; Mol, 1991; Norback et al., 1998). However in the course of recent studies of flower colour at the cellular level it has been established that flavonoid pigment types can be selectively compartmentalised within a petal cell, such that not all come in contact with one another in situ (Markham et al., 2000a,b). This can have a significant influence on flower colour since intermolecular interactions such as copigmentation and aggregation within the vacuole have a marked influence on colour hue, intensity and stability (Brouillard and Dangles, 1994). The observation (Markham et al., 2000a) that anthocyanins with specific structural features may be excluded from vacuolar solution through binding to protein to form insoluble anthocyanic vacuolar inclusions (AVIs), is a good example of this. Another example is the selective compartmentalisation of non-acylated flavonol glycosides in the cell walls of petal cells (Markham et al., 2000b). In both cases certain flavonoids are not available to interact freely with other pigments in the vacuole and thus to influence vacuolar colour.

Flavonoids are currently thought to be synthesized within the cell cytoplasm (Ibrahim, 1990, 1992; Stafford, 1990; Hrazdina, 1992; Marrs et al., 1995), perhaps on or in association with the endoplasmic reticulum (Hrazdina and Wagner, 1985; Hrazdina et al., 1987; Ibrahim et al., 1987; Hrazdina, 1992), and then transported to the vacuole via this membrane or via vesicles budded from it (Pecket and Small, 1980; Small and Pecket, 1982). Passage into the vacuole in maize (Marrs et al., 1995) and other plants (Alfenito et al., 1998) is thought to be effected by glutathionation which allows recognition

PII: S0031-9422(01)00276-X

and vacuolar entry of the conjugate via the glutathione pump, although aspects of this mechanism have recently been questioned (Mueller et al., 2000). The presence of flavonoids within the cytoplasm is thus normally considered to be transitory, the cytoplasm not being a repository unless this transport system is disabled, as in the maize "*Bronze-2*" mutant. In this mutant, the "*Bronze-2*" gene, which encodes for a glutathione S-transferase, is not functional and the non-glutathionated cyanidin-3-glucoside consequently accumulates in the cytoplasm (Marrs et al., 1995).

The transitory nature of flavonoids in the cytosol has been noted by Grandmaison and Ibrahim (1996) who used immunogold-labeled monospecific polyclonal antibodies to detect the subcellular localization of quercetin sulphates in leaves of *Flaveria chloraefolia*. A consistent association of the label with the nuclei was observed together with some diffuse labeling in the cytoplasm. Subsequently, quercetin-3-sulphate was shown to exhibit strong affinity for a specific (ca. 30 kD) protein isolated from a total nuclear protein extract from this plant. In a more recent study (Hutzler et al., 1998) involving confocal laser scanning microscopy to detect the subcellular location of flavonoids rendered visible with ammonia or diphenylboric acid 2-aminoethyl ester (commonly referred to as "NA"), flavonoids were detected in both the cell walls and vacuoles, and were found associated with the nucleus in a variety of plants. In the same study, fluorescence attributable to the presence of flavonoids was also observed in the cytoplasm of spruce needle epidermal cells.

Published evidence for the accumulation of significant quantities of flavonoids in the cytoplasm is thus sparse, indicating perhaps that this phenomenon is uncommon in green leaves. In flowers, a knowledge of any sub-cellular compartmentation of specific flavonoid types is of particular significance in view of the potential influence on colour at the cellular level. Recent pigment work on lisianthus (*Eustoma grandiflorum*) petals (Markham et al., 2000b) has established for the first time, the existence of cell-wall sited flavonoids in petal cells. Evidence cited in support of this finding included images from confocal laser scanning microscopy (CLSM) of NA-treated epidermal peels. The yellow-orange fluorescence observed in cell-walls, indicative of the presence of flavonoids (in this case flavonol-*O*-glycosides), was also observed in a thin "brighter region lining the inner surface" of the cell wall. An explanation given for this was that it might indicate the presence of flavonoids in the thin band of cytoplasm surrounding the vacuole. Here, we provide further evidence in support of this concept based on light microscopy and chemical studies.

Yellow flowers most commonly derive their colour from carotenoid pigmentation. However there are examples in which yellow colouration results from the presence of "yellow" flavonoids such as aurones, chalcones and highly oxygenated flavonols (Brouillard, 1988). Of more interest, and as yet without adequate explanation, are the few reported flowers which derive yellow colouration from "colourless" flavonoids such as the flavonols, kaempferol and quercetin, e.g. *Lathyrus chrysanthus* (Markham et al., 1992), *Camellia chrysantha* (Hwang et al., 1992) and *Eustoma grandiflorum* (lisianthus) (Davies et al., 1993; Markham and Ofman, 1993). Although simple flavonols are converted into yellow ionised forms at very high or low pHs, such pHs are not found in petal tissue which is commonly in the 3–7 pH range (Brouillard and Dangles, 1994). This pH range, however, does not exclude another possible yellowing mechanism, that of molecular aggregation, which can occur on surfaces or at high concentrations. This mechanism was proposed by Smith and Markham (1998) who demonstrated through fluorescence and reflectance studies, that kaempferol and quercetin glycosides exist to a significant extent in their yellow (λ_{max} ca. 450 nm for 7-*O*-glycosides) enolic tautomer form when aggregated on a suitable matrix or, to a lesser extent, in a concentrated solution. Evidence presented in the current paper relating to studies on several yellow flowers, demonstrates a correlation between cytoplasmic compartmentation of "colourless" flavonoids and yellow petal colour. It is proposed that the adoption by these flavonoids of their yellow tautomeric or pyrylium forms, is brought about by interaction with protein in the cytoplasm.

2. Results and discussion

2.1. Microscopy studies

Oblique and transverse sections through petals of white and purple lisianthus (*Eustoma grandiflorum*), yellow *Lathyrus chrysanthus* and yellow carnation (*Dianthus caryophyllus*), were stained with NA and examined by epifluorescence microscopy for yellow-green to orange fluorescence. This stain is widely used for the detection of flavones and flavonols, the presence of which is evidenced by yellow-green to orange fluorescence under UV light (Markham, 1982; Sheahan and Rechnitz, 1993; Hutzler et al., 1998). In petals from all flower types, epidermal cells were identified in which such fluorescence was concentrated in regions peripheral to the vacuole, and commonly in irregular patches (e.g. Fig. 1A–C). Varying levels of fluorescence were also visible in the vacuoles. That these irregular patches of fluorescent tissue are indeed cytoplasmic and not associated with the cell wall, was evident from a confocal laser scanning micrograph of the transverse section of purple lisianthus petal in which plasmolysis had occurred (Fig. 1D). A clear dark space is visible, which separates the cell wall from the fluorescing cytoplasm. Furthermore, in a mix of protoplasts prepared from purple lisianthus petals

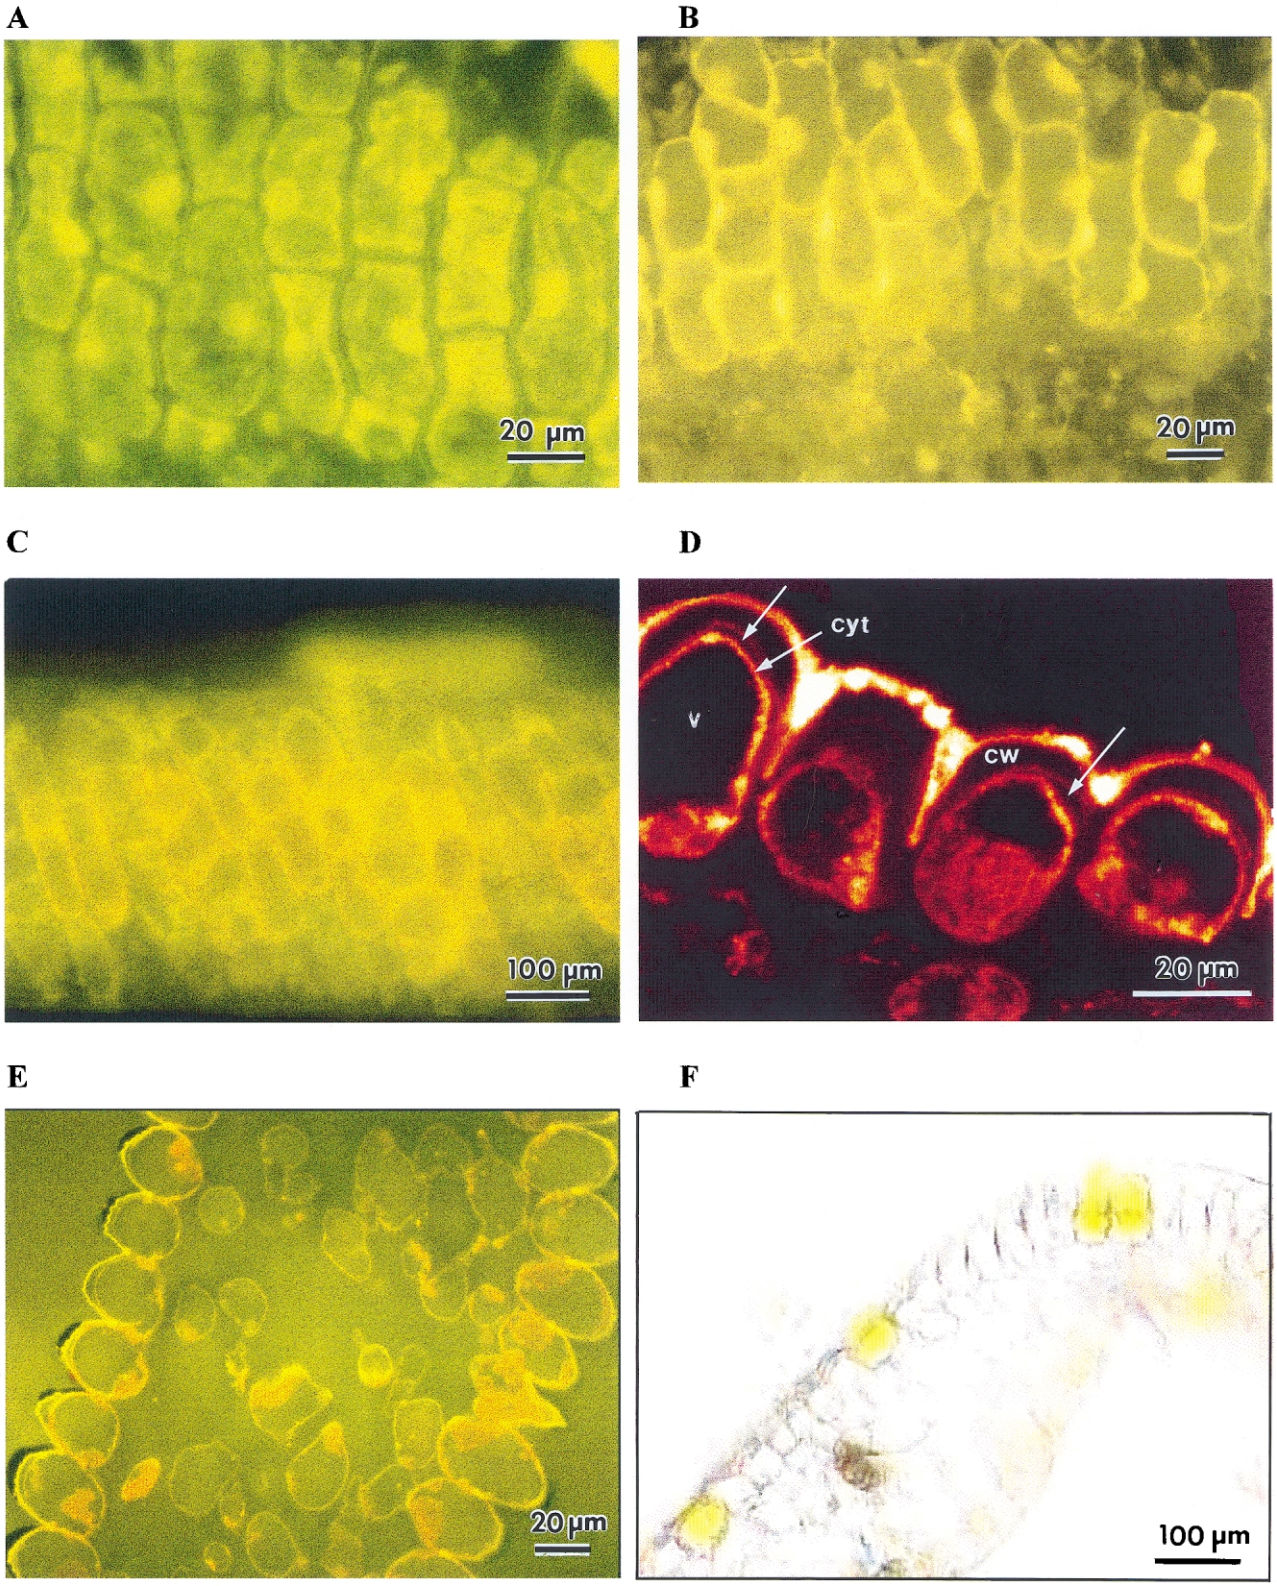

Fig. 1. (A), (B) NA-treated oblique hand-sections through the epidermis of the inner petal region of white lisianthus (*Eustoma grandiflorum*). (C) NA-treated oblique hand-section through the epidermis of a standard petal of *Lathyrus chrysanthus*. (D) Adaxial epidermal cells in the inner petal region of white lisianthus (*Eustoma grandiflorum*) viewed by CLSM after staining with NA (Abbreviations: v = vacuole, cyt = cytoplasm, cw = cell wall. Unlabelled arrows indicate examples of plasmolysis). (E) NA-treated transverse section through the inner petal region of white lisianthus (*Eustoma grandiflorum*). (F) Transverse section through a standard petal of *Lathyrus chrysanthus*.

and stained with NA, some protoplasts displayed blobs and/or streaks of fluorescent tissue on or near the surface, rather than a uniform fluorescence throughout the vacuole (data not shown). This relative lack of fluorescence in the vacuole is also a feature of the examples selected for Figs. 1A–C.

The data from these microscopy studies are thus in accord with previous observations using CLSM, which indicate the presence of flavonoids in the thin layer of cytoplasm surrounding the vacuole (Markham et al., 2000b).

2.2. Intracellular flavonoid distribution in lisianthus petal epidermal tissue

Previous work on the flavonoids of lisianthus flowers has established that the acyanic flavonoids in white and purple flowers are present at about the same levels and possess the same structures (Markham and Ofman, 1993). All are flavonol-tri-*O*-glycosides, the major of which are a 1:2 mix of the non-acylated kaempferol- and isorhamnetin-3-*O*-rhamnogalactoside-7-*O*-rhamnosides and their acylated (4^{Gal}-linked *p*-coumaroyl and ferulyl) derivatives. In order to study the nature of any flavonol glycosides located in the cytoplasm, the approach chosen was to compare the flavonoid composition of protoplasts with that of the vacuoles isolated from them. The flavonoids lost from the protoplast in the production of intact vacuoles would be those sited in the cytoplasm. Protoplasts (Fraction A) were prepared enzymatically from purple lisianthus adaxial epidermal peels, and vacuoles were isolated from these in varying yield. The best yields were in fractions containing, 50% intact vacuoles plus anthocyanic vacuolar inclusions (AVIs) from ruptured vacuoles (Fraction B), and 70% intact vacuoles plus 30% protoplasts (Fraction C). The flavonoid content of each fraction was analysed by HPLC on a reversed phase column. Under the conditions used, acylated flavonol glycosides as a group were well separated from their non-acylated analogues with retention times in excess of 33 min (non-acylated <26 min—see Fig. 2). They were also readily distinguishable from their on-line measured absorption spectra which exhibit hydroxycinnamoyl absorption in the 290–330 nm region.

The HPLC patterns of flavonol glycosides in fractions A (protoplasts), B (vacuoles plus AVIs) and C (7:3, vacuoles:protoplasts) were qualitatively the same and the major peaks in all three were peaks 1–6 (see Fig. 2). Fraction B (Fig. 2) in effect reflects the flavonol pattern of pure vacuoles, since the contaminating AVIs have been shown to contain anthocyanins but no flavonols (Markham et al., 2000a), and fraction C is intermediate between A and B in that it represents a mix of the flavonols from protoplasts and vacuoles. Thus, the *range* of flavonol glycosides present in the vacuoles is the same as that for the intact protoplasts. The main difference

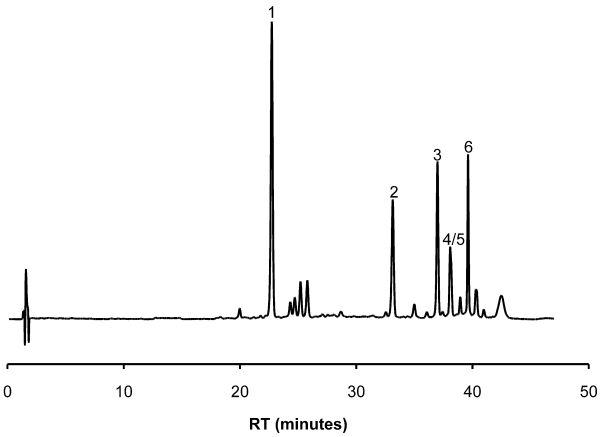

Fig. 2. HPLC profile (352 nm) of the flavonol glycosides from vacuoles (Fraction B) of white lisianthus, *Eustoma grandiflorum*. Peaks with retention times (RT) between 20 and 30 min represent unacylated glycosides and those with RTs between 30 and 45 min represent acylated (hydroxycinnamoyl) glycosides. Structures (see Markham et al., 2000b): 1-kaempferol-3-*O*-[6-*O*-rhamnosylgalactoside]-7-*O*-rhamnoside, 2-kaempferol-3-*O*-[6-*O*-rhamnosyl-4-*O*-*E*-caffeoylgalactoside]-7-*O*-rhamnoside, 3-kaempferol-3-*O*-[6-*O*-rhamnosyl-4-*O*-*E*-*p*-coumaroylgalacto-side]-7-*O*-rhamnoside, 4-isorhamnetin-3-*O*-[6-*O*-rhamnosyl-4-*O*-*E*-*p*-coumaroylgalactoside-7-*O*-rhamnoside, 5-kaempferol-3-*O*-[6-*O*-rhamnosyl-4-*O*-*E*-ferulylgalactoside]-7-*O*-rhamnoside, 6-kaempferol-3-*O*-[6-*O*-rhamnosyl-4-*O*-*Z*-*p*-coumaroylgalactoside]-7-*O*-rhamnoside.

between the flavonol profiles of the vacuoles (B) and the protoplasts (A) is in the *ratio* of total acylated to total non-acylated flavonol glycosides. Quantification by integration of the HPLC peaks demonstrates that vacuoles have a ratio of 1.4:1, and protoplasts a ratio of 2:1. This indicates that the cytoplasm contains a predominance of acylated glycosides. The mix of vacuoles and protoplasts in Fraction C gave a ratio of 1.7:1 which, as expected, falls between the Fraction A and Fraction B ratios. This ratio compares well with the theoretical ratio of 1.6:1 calculated from the ratios determined for pure vacuoles (Fraction B) and pure protoplasts (Fraction A).

The approximate ratio of acylated to non-acylated flavonol glycosides that must be present in the cytoplasm to effect a change in ratio from 2:1 (protoplasts) to 1.4:1 (vacuoles), can be estimated if the relative volumes of vacuole and cytoplasm in a typical epidermal cell are known. The transverse section (Fig. 1E) and the CLSM images [Fig. 1D, and also Fig. 2 (Markham et al., 2000b), which represent optical 'cross-sections' through these cells] suggest that the cytoplasmic volume is about 10% of the vacuolar volume. Assuming this to be typical, the protoplast is thus comprised of about nine parts vacuole and one part cytoplasm. Nine times the vacuolar ratio of 1.4:1 totals 12.6:9, and to convert this to the required protoplast ratio of 2:1 would require that the cytoplasm ratio be 7.4:1, i.e. the total vacuole plus cytoplasm content would equal 20:10. On this basis the cytoplasm located flavonoids would appear to be predominantly (ca. 90%) acylated flavonol glycosides.

Previous work with lisianthus has established that about 30% of the flavonol glycosides biosynthesized in the petal are sequestered into the plant cell wall and that these are exclusively non-acylated (Markham et al., 2000b). The remaining 70% comprise a 2:1 mix of acylated:non-acylated flavonol glycosides (≡ protoplasts). From the observed reduction of this ratio to 1.4:1 in the vacuole, it follows that 30% ((2–1.4)/2×100) of the acylated glycosides, that is 14% of the total petal flavonoids (30% of 67% ×70/100), are retained in the cytoplasm and the remaining 56% transported into the vacuole. The distribution of flavonol glycosides in the epidermal tissue of the lisianthus petals studied is, therefore, *approximately*:

Cell wall	30%	(comprising flavonol-*O*-glycosides)
Cytoplasm	14%	(comprising acylated flavonol-*O*-glycosides)
Vacuole	56%	(comprising 1.4:1, acylated: non-acylated flavonol-O-glycosides)

The glutathione transport system in this tissue is thus apparently capable of transporting both acylated and non-acylated glycosides from the cytoplasm to the vacuole. Retention of a portion of the acylated glycosides in the cytoplasm therefore, may result from competitive binding to cytoplasmic materials. Differences between the protein binding characteristics of acylated and non-acylated flavonoid glycosides have been reported previously. Alluis and Dangles (1999), using a model system involving bovine serum albumin (BSA), chrysin-7-glucoside and its *p*-methoxycinnamate, concluded that flavonoid glycosides bearing aromatic acyl groups can bind with very high affinity and may act as potent bidentate ligands. The acylated flavonoid glycosides found in the cytoplasm of lisianthus are of this general type.

2.3. Intercellular flavonoid distribution and yellowing in *L. chrysanthus* petal epidermal tissue

Examination of epidermal peels and transverse sections of "standard" petals under the light microscope established that yellow colouration occurs essentially only in the adaxial epidermis (Fig. 1F), and therein, in groups of cells. Other cells are colourless (= "white"). Groups of white and yellow cells were separated by manual excision from epidermal peels and their contents analysed by high performance liquid chromatography (HPLC). The white cells were found to be devoid of flavonoids, while the yellow cells contained the major flavonol glycosides (the 3-glucoside-7-rhamnosides of quercetin and isorhamnetin) previously identified in these petals (Markham et al., 1992). This was confirmed by measuring the in situ absorption spectra of groups of cells predominantly of each colour type, which showed for the yellow cells (Fig. 3), strong blue absorption with a peak at 370–375 nm and a shoulder at ca. 440 nm, the intensity of this shoulder varying with the proportion of yellow cells. White cells in contrast, exhibited no absorption at or above 350 nm (data not shown). The absorption of the yellow cells is at surprisingly long wavelengths, since the spectra of the isolated flavonol glycosides in water exhibit peaks at ca. 352 nm, with little or no absorption at or beyond 400 nm (Markham et al., 1992). Additionally, the absorption level for the yellow cells is very high, considering that the flavonoids producing this are contained within the pathlength of a single cell. The actual flavonoid concentration in a typical yellow cell was established after determining that the depth/pathlength of an average yellow cell was ca. 0.005 cm. This figure was used as the pathlength (l) to calculate the flavonoid concentration (c) from a single cell UV-visible transmission spectrum, using the Beer-Lambert law:

$$\text{Optical density} = \log_{10} I_{\text{incident}}/I_{\text{transmitted}} = \varepsilon \times c \times l$$

An area of petal predominant in yellow cells was found to transmit about 5% of incident light at 400 nm. Thus, using an $I_{\text{incident}}\backslash I_{\text{transmitted}}$ of 95/5, and an extinction coefficient (ε) of 14,300 (measured for the major flavonoid glycoside in *L. chrysanthus*), a concentration of 1.8×10^{-2} m l^{-1} is indicated. With the major components possessing molecular weights of ca. 600, this equates to a concentration of about 11 g l^{-1} of flavonoids in an average yellow cell.

In order to establish whether the spectral shift (i.e. yellowing) of the flavonol glycosides in situ could be a concentration effect, the absorption of a clarified, concentrated aqueous extract from *L. chrysanthus* petals was measured. The concentration used (44 g l^{-1} of flavonols—see Markham et al., 1992, for components) was equivalent to 4× that measured in vivo and the spectra were measured on a solution sandwiched between glass slides to reduce the pathlength. Under these conditions, the extract exhibited a $\lambda_{\max}$ at 364 nm, with no sign of a longer wavelength shoulder, compared with 352 nm when diluted 4000× with water. Thus, although a 12 nm bathochromic shift is produced on concentration, the in vivo spectrum could not be reproduced by these means. Deposition of this same concentrated extract on a substrate such as a cellulose sheet however, produced intense yellowing, and the visible absorptance spectrum (Fig. 4) approximated to that of the yellow petal itself ($\lambda_{\max}$ ca. 400 nm. Data not shown), with visible absorptance out to beyond 400 nm. These findings indicate that although the degree of yellow colouration seen in *L. chrysanthus* petals cannot be produced by increasing the flavonoid concentration in solution, it can be produced through flavonoid aggregation on a substrate.

2.4. The proposed significance of cytoplasm sited flavonoids to yellow flower colouration

Evidence from the microscopy and chemical studies described above, establishes that about 14% of the total

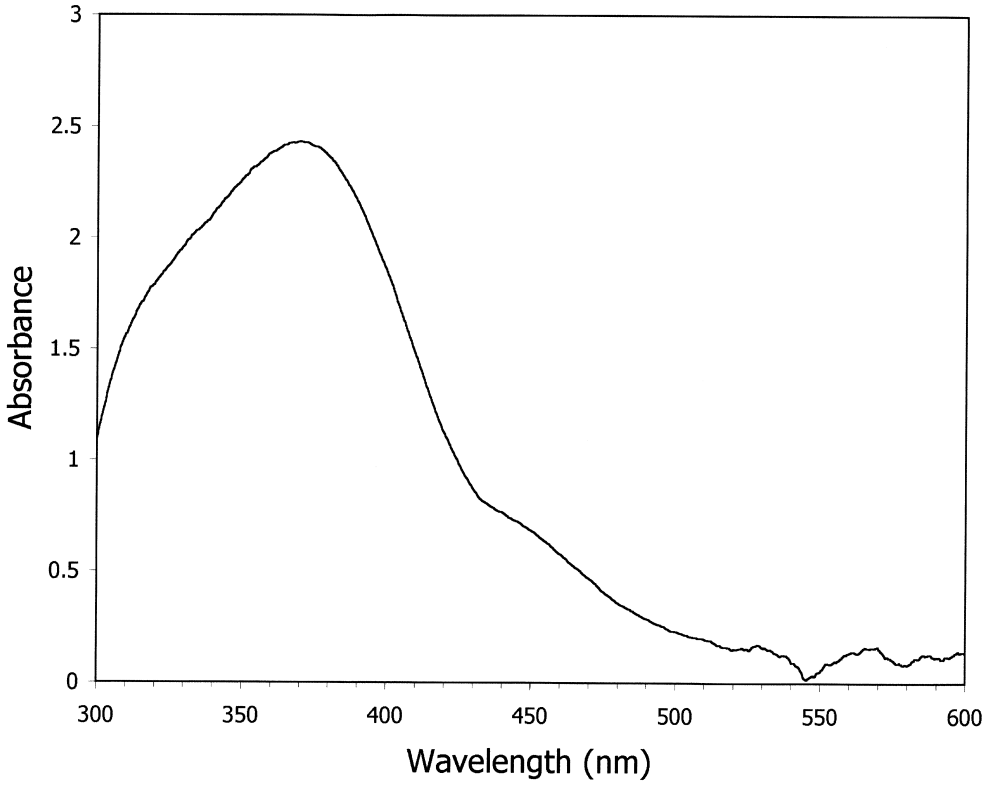

Fig. 3. UV-visible absorption spectrum of a group of yellow cells in an epidermal peel from a *Lathyrus chrysanthus* standard petal.

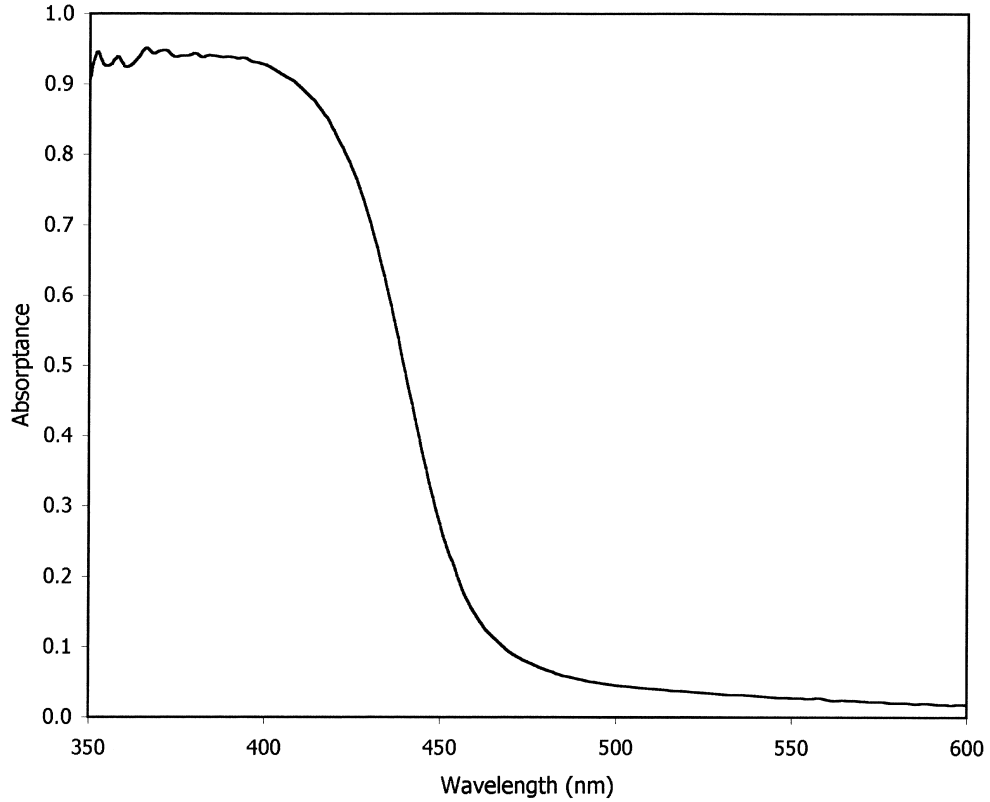

Fig. 4. Absorptance spectrum of an extract of *Lathyrus chrysanthus* standard petals deposited on a sheet of cellulose filter paper.

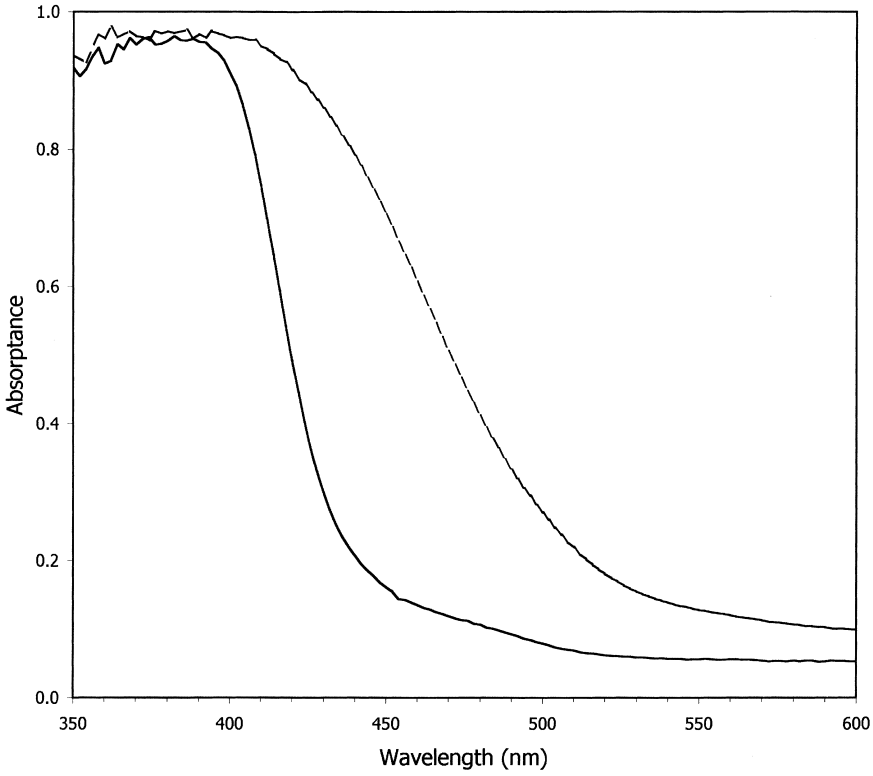

Fig. 5. Absorptance spectra of fresh (lower intensity curve) and dry (higher intensity curve) white lisianthus, *Eustoma grandiflorum*, petals.

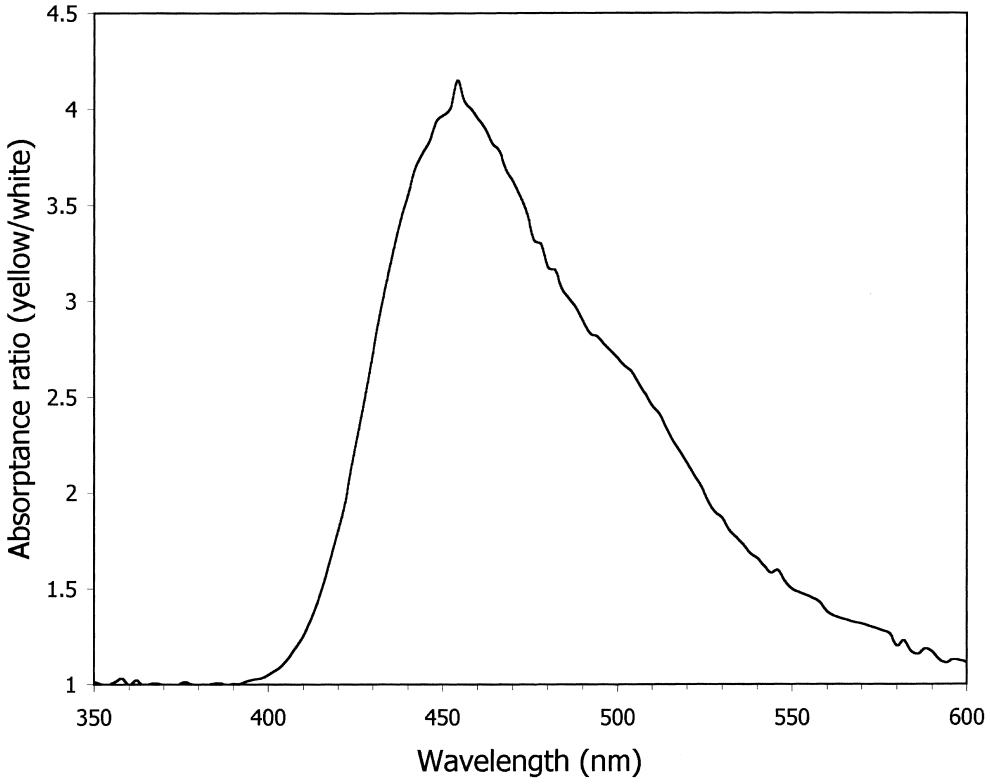

Fig. 6. A plot of the ratios of absorptances of dry white lisianthus petals : fresh white lisianthus petals at wavelengths between 350 and 600 nm. Absorptance data used, was that depicted in Fig. 5.

petal flavonols are concentrated in the cytoplasm of the adaxial epidermal cells of lisianthus petals. In white petals however (where vacuolar staining with NA can be seen as it is not obscured by the presence of anthocyanins), this cytoplasmic concentration is evident mainly in cells from the base (or "inner" region) of the petal. Significantly, this is the yellow region (see Davies et al., 1993). Epidermal cells from the rest of the petal tend to exhibit NA-induced fluorescence evenly throughout the vacuole. The whole petal however, turns a more uniform yellow when it is left to dry (i.e. when the flavonol glycosides throughout the petal are concentrated). No change in the HPLC measured flavonoid profile was evident after this drying. The extent of the observed yellowing was quantified using an integrating sphere and spectroradiometer to compare its absorptance spectrum with that of the "outer" zone of an undried white petal. A marked bathochromic shift was evident in the spectrum of the yellowed petal relative to that of the fresh petal (Fig. 5), such that the difference between the spectra (= Absorptance ratios) produced a single visible maximum at ca. 450 nm (Fig. 6). This difference spectrum is consistent with the visible spectrum measured by Smith and Markham (1998) for the enolic tautomer forms of kaempferol and quercetin glycosides, and thus supports the contention that such yellow forms may be produced in petals by aggregation.

The data resulting from the study of yellow *L. chrysanthus* petals also support a flavonol aggregation explanation for petal yellowing, rather than alternative mechanisms such as cell shape or vacuolar pH. Epidermal cell shape for example is unlikely to be influential as no differences were observed between yellow and white petal zones, and the measured petal vacuolar pH of 6.7 failed to induce yellowing in petal extracts. However, as with lisianthus, microscopic inspection indicated considerable concentration of flavonol glycosides in the cytoplasm of standard petals (Fig. 1C). That a high concentration of these flavonol glycosides in the vacuole at the measured in vivo pH of 6.7 cannot alone account for this yellowing, was demonstrated by reconstituting the petal extract at a flavonol concentration 4× higher than that in vivo (see above). In contrast, the greater degree of aggregation achievable on a substrate did produce yellowing akin to that seen in the petal itself. Thus flavonol glycoside aggregation on a cytoplasmic matrix, through which single cell absorption spectra would be measured, may well account for the bathochromic spectral shift observed in situ in this petal (Fig. 3).

On the basis of the data presented here, it is proposed that yellow colouration in flowers can result from aggregation of (colourless) flavonol glycosides on a protein matrix in epidermal cell cytoplasm. The well established affinity between polyphenolics and appropriately structured proteins (Dangles et al., 1999; Haslam et al., 1999; Siebert, 1999; Wang and Goodman, 1999) provides a plausible mechanism for such aggregation. Binding of flavonoids to cytoplasmic protein however is unlikely to be indiscriminate, in view of the toxic effect this would have within the cell. The binding is more likely to be via a specific site or sites on a protein subgroup, much as has been observed for the binding of flavonols to protein of nuclear origin (Grandmaison and Ibrahim, 1996). Perhaps exemplifying this is our finding that kaempferol-3-*O*-rutinoside-7-*O*-rhamnoside, a lisianthus-type flavonol, produced yellowing (= interaction) with only one of three proteins investigated. When this flavonol was applied to glass slides upon which each of the three proteins, collagen, lysozyme and neutral polyarginine were deposited, conversion to its yellow form (λ_{max}365, 400 nm) was observed on polyarginine, but not on the other two proteins or on glass itself. Whilst this study is only preliminary, yellowing of flavonols with various substrates has previously been ascribed to the adoption of some pyrylium or enolic tautomer character by the bound flavonoid. Pyrylium involvement was inferred from fluorescence studies on the quercetin/BSA complex model system (Dangles et al., 1999), and the enolic tautomer concept from a study of quercetin and kaempferol glycosides deposited on cellulose (Smith and Markham, 1998). In both studies enhancement of flavonol fluorescence at ca. 530 nm (with excitation at 450 nm) was observed. This general mechanism for producing yellow colouration from (colourless) flavonol glycosides in petals, may also account for other examples of unexplained yellowing credited to the presence of (colourless) flavonol glycosides, for example in anthers (Napoli et al., 1999) and in seed coats (Beninger et al., 1998).

3. Experimental

3.1. Plant material

The lisianthus (*Eustoma grandiflorum*) lines used in this study were the purple No. 54 and the white Wakasaki (see Deroles et al., 1998 for further details) and were supplied by Crop & Food Research, Palmerston North, New Zealand. The yellow *Lathyrus chrysanthus* petals were the same as used in earlier studies (Markham et al., 1992) and were supplied by Hammett Plant breeders (NZ) Ltd., Auckland, New Zealand. Yellow *Dianthus caryophyllus* flowers were purchased from a local outlet. Epidermal peels were prepared using adhesive tape as described previously (Markham et al., 2000b).

3.2. Microscopy

Absorbance spectra of transverse and paradermal sections of petals were obtained using a Zeiss compound

microscope, modified such that all glass components were removed and a front-surfaced mirror incorporated to optimise the transmission of UV. Zeiss quartz objectives (40×) were used as condenser and objective. The light source was provided by a 100 W xenon arc lamp fitted with a UG5 filter. Specimens were mounted in water on quartz microscope slides and covered with quartz coverslips. The spectral absorbance of groups of cells was measured using an ocean optics spectrophotometer, connected to the microscope phototube via a fibre optic cable. A reference solution of rutin (λ_{max} 360 nm) was used to check the accuracy of the equipment.

The depth/pathlength of an average yellow cell in the epidermis of *L. chrysanthus* was determined by comparing the microscopically enlarged image of a transverse section of petal (Fig. 1F) with that of a similarly enlarged (134×) 1 mm graduated scale.

Fresh sections of the plant material were examined for the presence of flavonols using epifluorescence microscopy with a Zeiss filterset 09 (excitation: 450 nm; beamsplitter: 510 nm; emission 520 nm) in a Zeiss Axioplan 2 microscope. Sections were then treated for approx. 15 min with a saturated solution of NA (diphenylboric acid 2-amino ethyl ester) (Sigma) in 10% aqueous sucrose, and examined for yellow-green fluorescence.

CLSM of NA stained samples was carried out on a Leica TCS 4D using a 40×/1.Ona oil immersion objective. The filter block used a 488 nm excitation filter, a 488 nm dichroic mirror and a fluorescein isothiocyanate band pass suppression filter.

3.3. Protoplast and vacuole preparation from Lisianthus No. 54 petals

(Methodology based on that described by Martinoia et al. (1981) and Atsumi (1980). Whole petal adaxial epidermal peels prepared by the adhesive tape method (Markham et al., 2000a) were floated, ruptured side down, on an enzyme solution containing 1% cellulase, 0.05% pectolyase, and 0.4 M sucrose in a buffer solution made up from 0.04 M Na_2HPO_4 and 0.02 M citric acid in the ratio of about 5.8:4.2 (pH 5.6). After incubation at 25 °C for ca. 5 h, the mix was filtered through a 50μm stainless steel mesh into a centrifuge tube and stored overnight in the refrigerator to allow the protoplasts to settle. The separated protoplasts were washed twice with buffer solution. A portion was set aside for analysis (Fraction A) and the remainder were ruptured to isolate cell vacuoles using a solution comprising 12 mM Tris–HCl (pH 8.0), 1 mM EDTA and 0.15 M sucrose and monitored under a dissecting microscope. The process of vacuole liberation was usually maximised after about 10 min. Cellular debris was removed by centrifugation (800 rpm) on a Percoll gradient (comprising 2 mls each of 10, 20 and 30% Percoll solutions in the pH 5.6 buffer), for 8–10 min. Vacuoles together with intact protoplasts were recovered as a red band on the Percoll gradient near the 20–30% boundary. AVIs formed an overlapping band just below this boundary. This procedure was carried out several times with fresh protoplasts to maximise yield (which was assessed microscopically). The two best fractions obtained were comprised of 50% intact vacuoles plus 50% AVIs (from broken vacuoles) (Fraction B), and 70% intact vacuoles plus 30% protoplasts (Fraction C). Freezing of these fractions led to protoplast and vacuole rupture. Each fraction was diluted with water and the non-phenolic constituents removed by passing the sample through a cartridge of reversed phase silica and washing with water. A methanol wash eluted the flavonoids which were then analysed by HPLC on a reversed phase column.

3.4. HPLC analyses

HPLC analyses were carried out using a Waters 600E solvent delivery system, Waters 996 diode array detector, and a Jasco 851-AS intelligent sampler, results being analysed using Waters Millennium 2010 software. An injection volume of 20 μl was used with a Merck LiChrospher 100RP-18 endcapped column (5 μl, 4×119 mm). Elution (0.8 ml/min, 30°) was performed using a solvent system comprising solvent A (1.5% H_3PO_4) and solvent B (HOAc–CH_3CN–H_3PO_4–H_2O (20:24:1.5:54.5)) mixed using a linear gradient starting with 80% A, decreasing to 33% at 30 min, 10% A at 33 min, and 0% A at 39.3 min. Flavonols were detected at 352 nm. Retention times and on-line absorption spectra were recorded for all major peaks. Acylated flavonol glycosides were distinguished by the presence of an absorption peak at 320–330 nm (with a shoulder at ca. 350 nm) compared with 350–360 nm for flavonol glycosides. Ratios of acylated: non-acylated flavonols were determined by summation of the integrals of HPLC peaks eluting before 26 min (non-acylated) and after 33 min (acylated). For fractions A, B and C (Section 3.3) the sums of integrals for acylated:non-acylated flavonoid peaks were: for fraction A; 274:136, fraction B; 303:208 and fraction C; 361:212.

3.5. Flavonol-protein studies

Aqueous solutions of collagen (Sigma, Type III), lysozyme (ex saliva) and polyarginine (Sigma) adjusted to pH7 with 1 N HCl, were spread onto separate microscope slides and left to dry. Kaempferol-3-*O*-rutinoside-7-*O*-rhamnoside in MeOH was applied to each of the dried protein layers and to the surface of a clean microscope slide. Visible change was evident only with neutral polyarginine, and the visible absorption of λ_{max} 365, 400 nm compared with λ_{max} 355 nm for the flavonol on glass alone.

3.6. Reflectance measurements

Reflectance (and absorptance) spectra of petals, and flavonoids deposited on substrates, were determined using an external integrating sphere connected via a fibre optic cable to a Li-Cor 1800 spectroradiometer (Lincoln, Nebr.) and compared with those of a barium sulphate standard. Reflectance and transmittance are defined as the proportions of incident, diffuse light that is reflected from, and transmitted through the petal, respectively. Absorptance was calculated as:

$$\text{Absorptance} = 1 - \text{reflectance} - \text{transmittance}$$

Preparation of samples was as follows. (a) Pure flavonoid glycosides or mixtures from extracts were applied in solution to Whatman No. 1 filter paper, repeatedly with drying, until a visible yellow spot was evident. Reflectance spectra were measured on the dried yellow spot. (b) A white lisianthus flower (Wakasaki) was held at room temperature for several weeks in a vase without water. Reflectance spectra were obtained for petals from both the original white flower and the dry (yellowed) flower.

Acknowledgements

The authors would like to thank Kevin Mitchell of Industrial Research for carrying out the HPLC analyses, Dr. Geoff Rickards of the School of Biological Sciences, Victoria University of Wellington, New Zealand for the CLSM measurements, Deborah Huff for the isolation of quantities of lisianthus protoplasts and vacuoles, Crop & Food Research, Palmerston North, New Zealand for the supply of lisianthus petals, Dr Keith Hammett of Hammett Plant Breeders (NZ) Ltd, Auckland, New Zealand for the supply of *L. chrysanthus* petals, and the NZ Royal Society administered Marsden Fund for financial support (Programme IRL701).

Received 19 January 2001; received in revised form 11 April 2001

Abstract

The role of calmodulin on Al toxicity was studied in two maize (*Zea mays* L.) inbred lines, Cat 100-6 (Al-tolerant) and S 1587-17 (Al-sensitive). Increasing levels of Al induced the release of malate at similar rate by roots of both genotypes, while the exudation of citrate, a stronger Al-binding compound, was 3.5 times higher in Cat 100-6 seedlings exposed to 16.2×10^{-6} Al^{3+} activity. The calmodulin inhibitor trifluoperazine significantly reduced the root growth in both genotypes, mimicking the main effect of Al. However, when Cat 100-6 and S 1587-17 seedlings were challenged with Al in conjunction with trifluoperazine, no further reduction in root growth or any other effect of Al toxicity was observed. The rate of Al-induced citrate exudation by both genotypes was not affected by treatment with trifluoperazine or calmidazolium, another calmodulin inhibitor. The Al^{3+} interaction with cytoplasmic CaM was estimated using models for the binding of Al^{3+} and Mg^{2+} with CaM and physiological concentrations of citrate, CaM, $InsP_3$, ATP, ADP, Al^{3+} and Mg^{2+}. In this simulation, Al^{3+} associated with citrate and $InsP_3$, but not with CaM. We conclude that calmodulin is not relevant to the physiological processes leading to the Al tolerance in maize, nor is it a primary target for Al toxicity. © 2001 Elsevier Science Ltd. 1. Introduction

Calcium is an important cellular messenger involved in many biological events. CaM plays a key role in signal transduction pathways because the Ca^{2+} signals generated by $InsP_3$ are translated into intracellular responses by Ca^{2+}-CaM complexes (Garret and Grisham, 1995; Lu et al., 1996). Studies using CaM inhibitors in plants indicate that several responses to environmental stress are dependent on CaM. For instance, Facchini et al., (1996) and Mahady and Beecher (1994) used the CaM inhibitors TFP and W7 to show that CaM was involved in the release of alkaloids in response to fungal attack, and Gong et al., (1997) observed that heat tolerance in maize seedlings decreased in the presence of W7.

Aluminum toxicity in acid soils is the main factor affecting plant productivity (Taylor, 1991; Kochian, 1995). At toxic levels, Al^{3+} inhibits root growth as a consequence of root tip destruction (Delhaize et al., 1993a). Although Al^{3+} tolerance has been observed in several species, the pathways leading to this tolerance are not well understood (Jones and Kochian, 1997). It has been proposed that tolerant plants can detoxify Al^{3+} within the plant cell, or exclude Al^{3+} from the root (Kochian, 1995). The internal mechanism of tolerance requires that Al^{3+} be immobilized in the cytoplasm by chelating compounds, polypeptides or by compartmentalization in the vacuole. The exclusion mechanism proposes that Al^{3+} be immobilized in the cell wall by the formation of a rhizosphere pH barrier or by root exudation of Al-chelating compounds such as organic acids or polypeptides (Kochian, 1995). The latter mechanism has been demonstrated in tolerant plants where the release of citrate and/or malate (Jorge and Arruda, 1997; Pellet et al., 1995, Delhaize et al., 1993b) suggests a signaling process mediated by the Al^{3+}. Recently, Ryan et al. (1997) devised an ion channel that is induced by Al^{3+} and may be responsible for the

organic acids released by wheat roots following Al stress.

Although Al can enter the root symplasm (Lazof et al., 1994), no relationship between the accumulation of Al in the symplasm and toxicity has been established. Al^{3+} may interact with intracellular target sites such as calmodulin (Haug and Vitorello, 1996), plasma membrane lipids (Jones and Kochian, 1997), Ca^{2+}-ATPases and various components of the phosphoinosite signaling pathway (Haug et al., 1994; Jones and Kochian, 1995), to influence the function of intracellular sites. However, the assumption that calmodulin act as a primary site for Al toxicity is still controversial (Jones and Kochian, 1997).

The goal of this work was to analyze the physiological basis of the Al tolerance seen in two tropical maize lines and to evaluate whether calmodulin plays a role in this response. We observed that Al^{3+}-tolerant plants released higher levels of citrate than their Al-sensitive counterparts and that this response was not mediated by CaM. The data obtained were compatible with results from simulations using models from the literature for the interaction of Al^{3+} and Mg^{2+} with CaM, and estimated cytoplasmatic concentrations of citrate, CaM, $InsP_3$, ATP, ADP, Al^{3+} and Mg^{2+}.

2. Results and discussion

2.1. Al tolerance in maize

The inhibition of root growth is a primary effect of Al toxicity (Delhaize et al., 1993a). The relative root growth (RRG) of Cat 100-6 (Al-tolerant) and S 1587-17 (Al-sensitive) grown in complete nutrient solution containing Al^{3+} is shown in Fig. 1.

The two genotypes showed a clear difference in root growth in the presence of 36 μM $AlCl_3$, which corresponds to 16.2×10^{-6} Al^{3+} activity (see Experimental). Although Al^{3+} reduced the RRG of the sensitive and tolerant lines after 12 h, the effect on S1587-17 was greater. In contrast, Cat 100-6 sustained a RRG of around 0.8, indicating that this maize line was able to overcome the toxic effects of Al^{3+}. As the incubation progressed, several symptoms caused by Al toxicity were observed in the roots of S 1587-17, including the swelling of root cells, the destruction of apical meristems and the induction of secondary meristems that were also destroyed (results not shown). Moon et al. (1997) observed the same effects with these maize lines when using another nutrient solution and different growth conditions.

The two genotypes also differed when treated with hematoxylin, which binds to Al and allows the visualization of Al in the apoplast (Delhaize et al., 1993a). After 6 h in the presence of Al, both lines showed an intense color, indicating the binding of Al to the apoplasm.

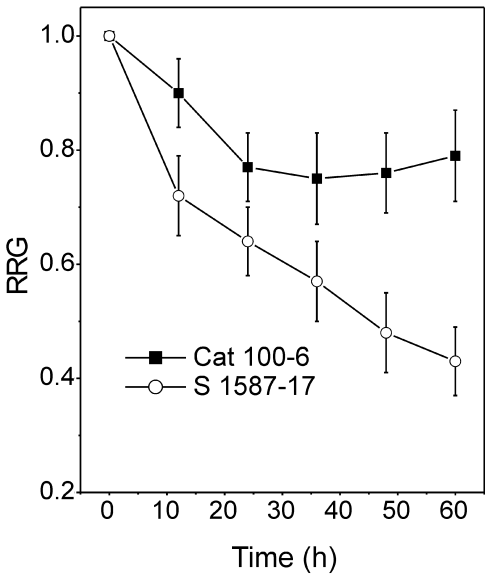

Fig. 1. Time course of Al^{3+} inhibition of relative root growth (RRG) in maize seedlings. Cat 100-6 and S 1587-17 seedlings were exposed to 36 μM $AlCl_3$ in growth solutions and the root growth at various times was used to calculate the RRG. The data are the mean ± S.D. ($n=10$).

After 24 h in the presence of Al, the apical region of tolerant plants was no longer stained with hematoxylin, in contrast to the sensitive roots that remained colored (data not shown). Similar results were also observed for other maize genotypes (Pellet et al., 1995; Jorge and Arruda, 1997). Together, these results indicate that Al tolerance in Cat 100-6 is mediated by an Al exclusion mechanism.

The differences in observed Al^{3+}-tolerance between the two maize inbred lines may be related to the release of organic acids by roots, as observed in several species (Myasaka et al., 1991; Pellet et al., 1995, Jorge and Arruda, 1997). These compounds can bind Al^{3+} to prevent the internalization of the ion, thereby alleviating Al toxicity. To evaluate this hypothesis, the amounts of malate, citrate, isocitrate, succinate, fumarate and oxaloacetate present in the growth solution containing different Al^{3+} activities were determined enzymatically (Jorge and Arruda, 1997). Of the anions analyzed, only a small amount of malate was detected in the exudates of Cat 100-6 and S 1587-17 grown in the absence of Al^{3+} (Fig. 2). Both tolerant and sensitive plants showed a dose-dependent exudation of malate up to 48 μM (21.5×10^{-6} Al^{3+} activity). In contrast, citrate exudation was strikingly different between the two lines. In S 1587-17, the velocity of citrate exudation was constant at the Al concentrations tested, whereas the exudation in Cat 100-6 responded to increasing concentrations of Al^{3+}. At 16.2×10^{-6} Al^{3+} activity, the tolerant line released 3.5 times more citrate than the sensitive line.

Considering that the binding of citrate to Al is stronger than that of malate (Martell et al., 1996), it can be inferred that the exclusion of Al^{3+} in Cat 100-6 is

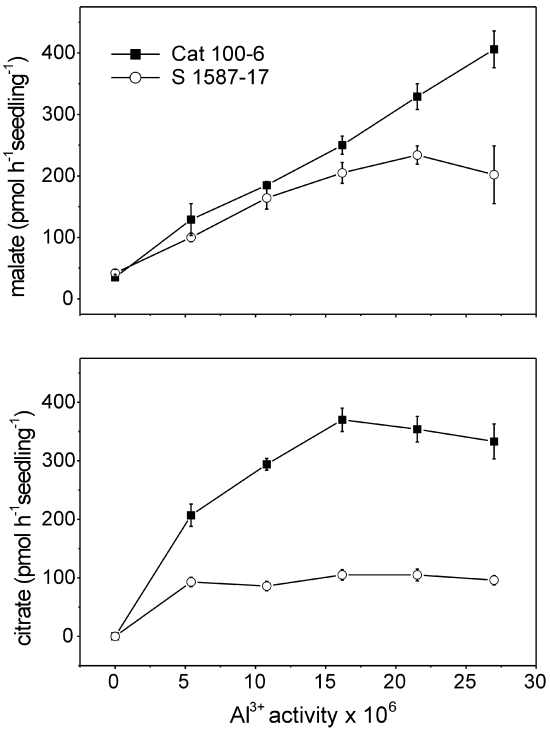

Fig. 2. Dose–response curves for citrate and malate release by intact Cat 100-6 and S 1587-17 roots in response to Al^{3+}. Seedlings were grown in nutrient solution containing increasing Al^{3+} activities. After 24 h incubation, the organic acids released into the nutrient solution were determined. The data are the mean ± S.D. ($n=2$).

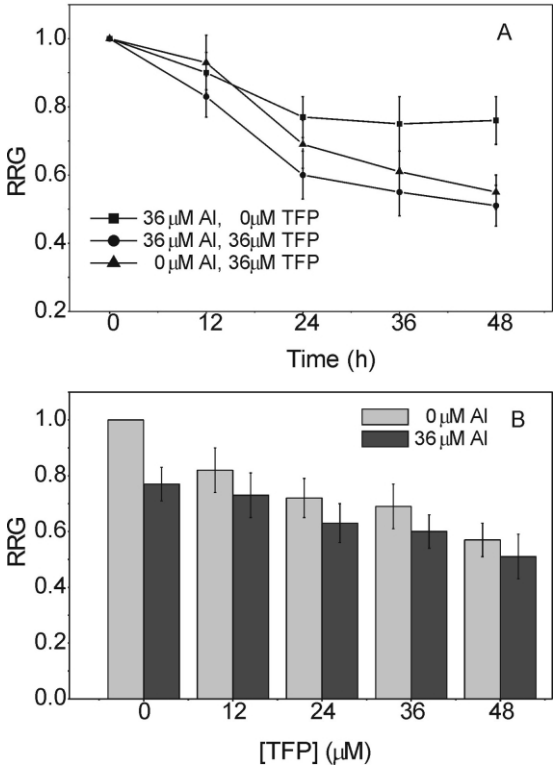

Fig. 3. Effect of TFP and Al^{3+} on RRG in the Al-tolerant maize line Cat 100-6. Seedling RRG was measured as before, in 50 ml recipients under slight agitation at pH 4.1. The data are the mean ± S.D. ($n=10$). (A) Root growth was measured over time at a fixed concentrations of Al^{3+} and TFP as indicated in the figure. (B) After 24 h incubation, root growth was measured with and without 36 μM Al^{3+} and at variable concentrations of TFP.

mediated by the release of citrate by roots. This strategy for overcoming Al toxicity has also been observed in other maize germplasms (Pellet et al., 1995, Jorge and Arruda, 1997). Moreover, the roots transgenic tobacco plants expressing a bacterial citrate synthase gene release up to fourfold more citrate than control plants and show increased tolerance to Al^{3+} (Fuente et al., 1997).

2.2. Effects of calmodulin inhibitors on Al tolerance

To assess the relevance of CaM on the mechanism(s) of Al tolerance Cat100-6 roots, seedlings were exposed to Al in combination with TFP. This compound binds to CaM, causing changes in the protein structure that block interactions with target enzymes (Vandonselaar et al., 1994).

While the RRG of tolerant plants remained practically unchanged by Al^{3+} treatment, 36 μM TFP reduced the RRG to 0.55 after 48 h (Fig. 3A). This inhibition was concentration-dependent up to at least 48 μM (Fig. 3B). A similar effect of TFP on root growth was also observed in *Arabidopsis thaliana* (Sinclair et al., 1996) and in another maize germplasm (Stinemetz et al., 1992). This inhibition probably involves the stabilization-destabilization of cortical microtubules which participate in such diverse processes as the orientation of cellulose microfibrils and chromosome segregation (Goddard et al., 1994), and is at least partly mediated by Ca^{2+}/CaM (Fisher et al., 1996). At the TFP concentrations used, the addition of 36 μM Al^{3+} caused no significant decrease in RRG (Fig. 3B) nor did it trigger the typical effects of Al toxicity (the swelling of the root tip and induction of secondary meristems; data not shown).

CaM antagonists can affect the activation of plant defenses in response to external harmful agents. For example, the release of alkaloids from *Sanguinaria canadensis* and *Papaver somniferum* cells in response to fungi elicitors is blocked by TFP and W7, another CaM inhibitor (Mahady and Beecher, 1994; Facchini et al., 1996). To further evaluate the involvement of CaM in Al^{3+} tolerance, the effects of TFP and CMZ on citrate release was examined. CMZ is 26 times more powerful than TFP in inhibition of CaM-dependent functions (Gietzen et al., 1981) and also more specific (Tuana and Maclennan, 1984). Seedlings were treated with TFP and CMZ in the presence of Al. The rate of citrate release by Al^{3+}-tolerant seedlings does not depend on the concentration of the CaM inhibitors (Fig. 4). The lower levels of citrate in the CMZ-treated seedlings reflected the lower Al concentration used (24 μM); at 36 μM Al^{3+}, the citrate exudation was similar to that of the TFP-treated seedlings as shown in Fig. 4 (results not shown).

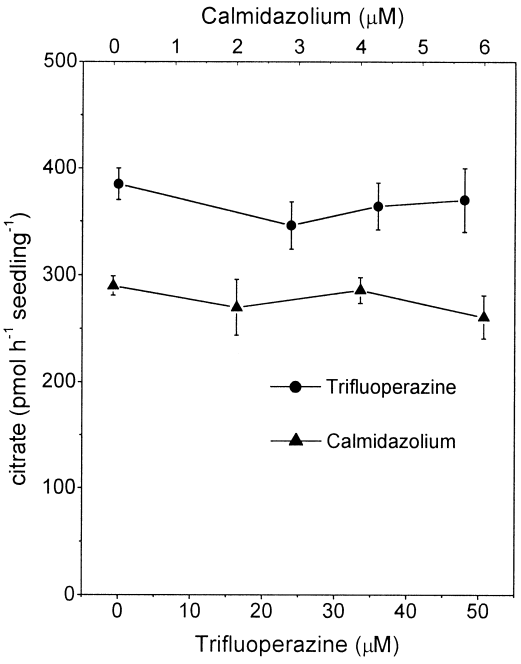

Fig. 4. Citrate exudation by maize roots incubated with calmidazolium (CMZ) and trifluoroperazine (TFP). Intact Cat 100-6 roots were exposed to 36 μM $AlCl_3$, and variable concentrations of TFP and CMZ, for 24 h. The data are the mean ± S.D. ($n=2$).

The rate of citrate release in the presence and absence of calmodulin inhibitors, together with the effect of TFP and Al on root growth, showed that CaM was not involved in the mechanism of Al tolerance.

2.3. The binding of Al to CaM in the symplasm

The most critical aspect of the hypothesized role of CaM as a primary site for Al toxicity is the binding of Al to CaM. This binding has been questioned and the involvement of calmodulin in Al tolerance in vivo is controversial. A study of wheat has indicated that CaM levels are similar in Al-tolerant and Al-sensitive lines and that Al does not induce CaM accumulation, although the results are not incompatible with the hypothesis that CaM is the primary target of Al^{3+} toxicity (Larkin, 1987). The replacement of calmodulin-dependent by calmodulin-independent NAD kinases could be responsible for the differences in tolerance between the two wheat lines (Slaski, 1989). Equilibrium dialysis studies demonstrated that Al^{3+} binds tightly to CaM (Siegel et al., 1983). Moreover, Al/CaM molar ratio of 2:1 induced a major structural change and a molar ratio of 4:1 totally inhibited the activity of the Ca/CaM-dependent phosphodiesterase (Siegel and Haug, 1983). However, Al^{3+} concentrations below 10^{-5} mol l^{-1} neither displaced Ca^{2+} bound to CaM nor depressed the Ca/CaM-dependent and basal phosphodiesterase activities, and failed to mimic the effects of chlorpromazine, another CaM inhibitor (Richardt et al., 1985). Indeed, Al^{3+} binding may not displace Ca^{2+} from the specific Ca^{2+}-binding domain on CaM (Weis and Haug, 1987). Studies with electron paramagnetic resonance spectroscopy, have failed to show a strong Al^{3+} interaction with CaM at pH 6.5 in methionine or tyrosine spin-labeled CaM (You and Nelson, 1991).

So far, no evidence was found that there is enough free Al^{3+} in the cell to interact with CaM. Under physiological conditions, the interaction of Al^{3+} with CaM must take into account the presence of other cytoplasmic components which could also bind to Al^{3+}, such as citrate and phosphate groups (such as $InsP_3$, ATP and ADP). Moreover, Mg^{2+} may compete with Al^{3+} for binding to these compounds, as seen in the association constants in aqueous medium (Table 1). In addition, Mg^{2+} is present at a high concentration in the cytoplasm and has similar ionic radii to Al^{3+}.

The interaction of Al^{3+} with CaM in the cytoplasm can be simulated using estimated cytoplasmic concentrations of citrate, CaM, $InsP_3$, ATP, ADP, Al^{3+} and Mg^{2+} and using the Geochem 2.0 software (Parker et al., 1995). For this simulation models for the binding of Al^{3+} and Mg^{2+} to CaM are necessary. CaM contains two globular domains linked by a flexible tether. These domains, which can be separated by tryptic digestion, are denoted TR1C (N-terminal domain) and TR2C (C-terminal domain). The calcium bindings in these domains is similar to those in the intact protein (Linse et al., 1991). Each domain contains two binding sites with a high affinity for Ca^{2+} (log Ka = 6.0–7.0). Sites III and IV in the C domain have greater affinity than sites I and II in the N domain (Linse et al., 1991). Haug and Vitorello (1996) proposed that the sites of Al^{3+} binding are not the four sites that bind Ca^{2+} and that Al^{3+} will bind to CaM using the same sites for Mg^{2+}. The model of the binding of Al^{3+} to CaM must take into account the models for the binding of Mg^{2+} with CaM. Three conflicting models for the interaction between Mg^{2+} and Ca^{2+} with CaM have been described in the literature: (1) competition between Ca^{2+} and Mg^{2+} for the two sites located in the terminal N domain (Malmendal et al., 1998), (2) direct competition between Ca^{2+} and Mg^{2+} for all four CaM sites (Tsai et al., 1987), and (3) no competition between the two ions for the Ca-specific sites (Gilli et al., 1998). The first model is based on NMR spectroscopy observations showing that Mg^{2+} only binds to the two sites in the TR1C (Malmendal et al., 1998). The absence of binding to the TR2C domain would explain why Mg^{2+} does not induce the same global structural changes provoked by Ca^{2+} in the protein (Malmendal et al., 1998). A later study on the interdependence of the Ca^{2+}/Mg^{2+} bound at the two sites located in the TR1C domain suggested that each site could bind to either Ca^{2+} or Mg^{2+}, but not both simultaneously (Malmendal et al., 1999). The second model is also based on NMR spectroscopy and involves

Table 1
Log β_{pqr} used in the simulation of the composition of the Al-complex. The general formula of the complex was $M_pL_qH_r$, where *p,q,r* refers to the numbers of metal ions (*M*), ligand molecules (*L*) and protons (H^+), respectively. A positive value of *r* indicates that the ligand is protonated and a negative value of *r* indicates the ionization of the ligand. The numbers in parentheses in the seventh column represented (*p,q,r*). β_{pqr} is the overall association constant

the suggestion that the occupation of all four sites by Mg^{2+} could cause small structural changes in the protein, as well as a minimal activation of the protein targets of CaM (Tsai et al., 1987). In the third model, in which the Ca^{2+}/CaM and Mg^{2+}/CaM complexes were characterized by flow dialysis and isothermal microcalorimetry, Mg^{2+} would bind to the auxiliary sites present on CaM (Gilli et al., 1998). The third model is compatible with the supposition of Haug and Vitorello (1996) in which Al^{3+} apparently does not displace Ca^{2+} from its specific sites.

We have simulated the interaction of Al^{3+} with CaM under physiological conditions for the three models. In this simulation, it was supposed that Al^{3+} would compete with Mg^{2+} for the same sites as described by the three models for the competition between Mg^{2+} and Ca^{2+}. Table 1 shows the association constants of the various compounds with Al^{3+}, Mg^{2+} and H^+, which were used with the Geochem 2.0 software. The association constants for Mg^{2+}/CaM refer to the first model.

Kiss et al (1994) estimated the concentrations of the cytoplasmic components in plasma as: total Al (Al^{3+}, $Al(OH)^{2+}$ $Al(OH)_2^+$ and aluminum complexes) = 1 μM, total phosphate (organic and inorganic, and 100 μM of ATP) = 10 mM, small molecular weight ligands containing oxygen-donating atoms (citrate, lactate, etc.) = 100 μM, while Jones and Kochian (1997), based on the work of Lazof et al. (1994) and Martin (1992), have presented the following estimates for plants (root epidermis cells) and animals (blood serum): total Al = 50 μM and citrate = 50–1000 μM. Fisher et al. (1996) estimated cellular CaM at 1 μM. In the present paper, the following initial concentrations were used: CaM = 1 and 50 μM, total Al = 1 and 50 μM, citrate = 0–100 μM; $InsP_3$ = ATP = ADP = 100 and 1000 μM, Mg^{2+} = 1000 μM.

The percentage distribution of Al-citrate and Al-$InsP_3$ complexes at equilibrium based on the above concentrations according to the first model is shown in Fig. 5. In this simulation, Al is associated with citrate and $InsP_3$, but not with CaM. The same results were observed for 1 μM CaM and 100 μM $InsP_3$, ATP and ADP. The binding of Al to ATP and ADP was maximum (0.4%) at 0 μM citrate (not shown in the Fig. 5 for clarity). The concentration of Al-CaM 1 and Al-CaM 2 complexes was minimal (log [Al-$CaM_{1\ or\ 2}$] = −12 to −14), indicating that it would be difficult for Al to bind to CaM under the conditions prevailing in the cytoplasm. This simulation was compatible with the previous results at pH 6.5, which suggested that at a high molar concentration (9:1 for citrate: aluminum and 10:1 for citrate:calmodulin), citrate blocked the binding of Al^{3+} to CaM (Suhayda and Haug, 1985, 1986) and also protected the calmodulin phosphodiesterase from damage caused by Al^{3+} (Suhayda and Haug, 1985). The simulation using the second and third models and the association constants for Mg^{2+} with CaM reported by Tsai et al. (1987) or by Gilli et al. (1998), respectively, produced the same results as obtained with the first model (data not shown).

Jones et al. (1998a,b) found that Al can disrupt cellular Ca^{2+} homeostasis in *Arabidopsis thaliana* root

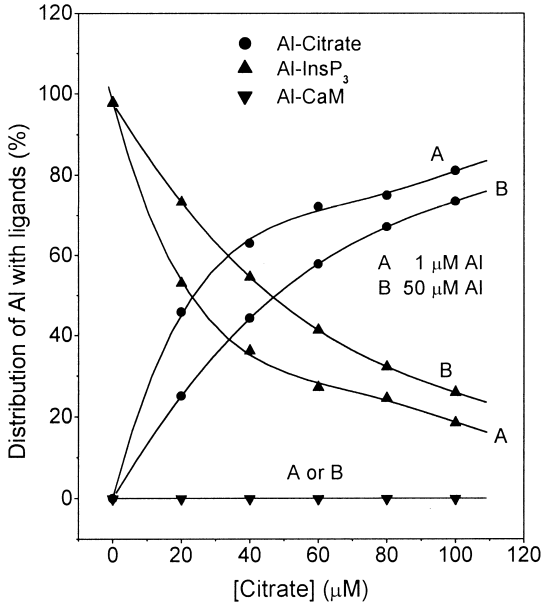

Fig. 5. Al–citrate and Al–$InsP_3$ complex composition at equilibrium based on initial physiological concentrations at pH 7.0 as determined using Geochem 2.0 software. The two CaM sites (CaM 1 and CaM 2) in the N terminal domain, which bind to Mg^{2+}, were considered to be independent, although the figure represents the sum of both sites. In all cases, [CaM 1]= [CaM 2]=50 μM, $[Al]_{total}$=1.0 and 50 μM, [$InsP_3$], [ATP] and [ADP]=1000 μM, and [Mg^{2+}]=1000 μM.

hairs and tobacco culture cells, and suggested that several intracellular sites could be targets for Al toxicity. Recently, Ma et al. (2000) reported evidence that Al inactivates extracellular CaM, leading to the inhibition of germination and pollen tube elongation in *Sorbaria kirilowi* Maxium. However, the role of extracellular CaM on Al^{3+} toxicity in the root apex remains to be proven.

Our results and the simulations using three models indicate that under normal intracellular conditions, CaM is not a primary target for Al toxicity. Our results also indicate that the processes leading to Al^{3+} tolerance in maize are not controlled by CaM.

3. Experimental

3.1. Plant material

The maize (*Zea mays* L.) inbred lines Cat 100-6, (Al-tolerant) and its somaclonal variant S1587-17, (Al-sensitive) (Moon et al., 1997) were obtained from the Germplasm Bank of the Universidade Estadual de Campinas, Campinas, Brazil. The plants were grown in the field and self-pollinated.

3.2. Seedling growth in nutrient solution

Seeds were surface-sterilized with 0.5% (v/v) sodium hypochlorite for 20 min, rinsed eight times with sterile water and germinated between layers of moist filter paper at 30 °C for 60 h.

Following germination, the seedlings were grown in opaque plastic receptacles containing 250 ml of aerated complete nutrient solution (Delhaize et al., 1993a) with small modifications (Jorge and Arruda, 1997). The pH was adjusted to 4.1 with HCl. The Al^{3+} solution was prepared freshly from $AlCl_3$ and standardized according to Kinnunem and Merikanto (1955). In all experiments, the seedlings were exposed to 16 h of light daily at room temperature (~26 °C).

The length of the main roots (n=10) was measured with a ruler and the roots then returned to the nutrient solution. Relative root growth is the mean of the quotients between the root growth of each seedling under a given a treatment and the mean root growth of all seedlings grown in control solution.

To study organic acid exudation, maize seedlings were grown in opaque plastic recipients with 25 ml of complete nutrient solution. To prevent microbial degradation of organic acids exuded by the roots, all the procedures were done under sterile conditions and the $AlCl_3$ solution was filter sterilized to avoid the formation of polynuclear compounds during autoclaving (Delhaize et al., 1993b). TFP and CMZ solutions were also filter sterilized and added to the nutrient solution. UV spectroscopy showed that TFP and CMZ did not interact with Al^{3+} or any other ions of the nutrient solution (data not shown). After 24 h incubation under constant agitation, the solution from each recipient was filtered (0.45 μm), frozen at −20 °C and completely freeze-dried. The organic acid levels were analyzed by enzymatic methods (see below).

3.3. Determination of organic acids in the growth solution

Malate, succinate, oxalate, citrate and isocitrate levels were determined according to Delhaize et al. (1993b), with minor modifications (Jorge and Arruda, 1997) using an HP array diode (HP, USA) spectrophotometer.

3.4. Bacterial control

In the experiments involving the quantification of organic acid exudation, contamination by microorganism was evaluated by plating one aliquot of the growth solution of each treatment in a Petri dish containing LB. In general, 20,000–30,000 bacteria/ml were observed. This concentration did not cause degradation of short chain organic acids, since preliminary experiments with 2000–70,000 bacteria/ml did not affect the amount of malate or citrate detected in the solution containing 36 μM $AlCl_3$ (data not shown).

3.5. Al^{3+} chemical activity

Al^{3+} in liquid media or in soil can be complexed by several ligands. As a result, Al^{3+} toxicity is better

Table 2
Total concentration and free activities of Al^{3+} in the nutrient solutions used to measure organic acid exudation and root growth in the presence and absence of $AlCl_3$ at pH 4.1. For the calculation of the Al^{3+} activity (a non-dimensional quantity), a 1 mol l^{-1} solution was used as standard

Al (μmol l^{-1})	Free Al^{3+} activity ($\times 10^6$)
0	0.0
12	5.4
24	10.8
36	16.2
48	21.5
60	27.0

reflected by the chemical activity of the Al^{3+} ion rather than its total molar concentration. The activities of the ionic species in the growth solutions at pH 4.1 were calculated using the Geochem 2.0 software (Parker et al., 1995).

Table 2 shows the concentrations of $AlCl_3$ used and the respective free Al^{3+} activities in the nutrient solutions.

3.6. Hematoxylin staining of maize roots

Intact roots from Al-tolerant and Al-sensitive root tips grown in nutrient solution with or without $AlCl_3$ were stained with hematoxylin according to Delhaize et al. (1993a).

Soybean sterol composition and utilization by *Phytophthora sojae*

Julie A. Marshall, Allen L. Dennis, Toshihiro Kumazawa, Ann M. Haynes, W. David Nes*

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061, USA

Received 11 January 2001; received in revised form 19 April 2001

Abstract

The sterol fraction of *Glycine max* (soybean) was found to contain a mixture of 13 major sterols which differed dramatically in composition between seeds and shoots. Typical C4-desmethyl Δ^5-sterols, including sitosterol, predominate the sterol mixture of shoots, whereas C4-methyl sterol intermediates, cycloartenol and 24(28)-methylene cycloartanol, accumulate in seeds. The significance of modified sterol profile of shoot compared to seed was relevant to the physiology of *Phytophthora sojae*, a phytopathogen of soybean shown to be auxotrophic for sterol. Sterols native to the host plant containing a C4-methyl group, such as cycloartenol, were not utilized by the fungus. Alternatively, all Δ^5-sterols added to the culture media of *P. sojae* supported normal growth and promoted viable oospore production. The results demonstrate the importance of sterols in plant–fungal interactions and offer the possibility of bioengineering the phytosterol pathway for resistance to phytopathogens which scavenge specific sterols of the host plant to complete the life cycle. © 2001 Elsevier Science Ltd. Keywords: Soybean; *Glycine max*; Leguminosae; Host-pathogen interactions; Oomycetes; *Phytophthora sojae*; Sitosterol; Sterol

1. Introduction

The pythiaceous fungi (*Phytophthora* and *Pythium*) are a less-advanced group of phytopathogens which cannot synthesize sterols (Nes, 1987). This unusual defect in phytosterol synthesis by pythiaceous fungi has evolved into a nutritional dependency for Δ^5-sterols which can be acquired from the host during infection (Hendrix, 1970; Nes et al., 1982; Nes and Stafford, 1983). In the case of *Phytophthora sojae* which attacks soybean (*Glycine max*) (Erwin and Ribiero, 1996), Erwin et al. (1968) observed that the Δ^5-phytosterol, sitosterol can promote vegetative growth and sexual reproduction in an analogous manner to its effect on *P. cactorum* physiology (Nes et al., 1982). Based on these findings, we considered a hypothesis that Phytophthora-soybean interactions can be impaired by limiting sitosterol availability to the fungus. To test our proposal, we determined the phytosterol composition of soybean at two stages of development, one stage where no disease occurs — the seed, and a second stage where disease can cause serious crop losses — the shoot, and evaluated these materials as supplements in the growth media of *P. sojae*. Our results indicate that phytosterol intermediates which accumulate in seeds, C4-methyl sterols, can offer protection to disease and that limiting sitosterol availability can retard growth and interrupt oospore production.

2. Results and discussion

2.1. Sterol composition of soybean

The sterol composition of soybean seeds and shoots was determined by a combination of TLC, GLC, HPLC and MS as described in our earlier publications (Guo et al., 1995; Xu et al., 1988). In addition, the stereochemistry of the 24-alkyl group in the sterol side chain of material which had been purified by reversed-phase HPLC was established unambiguously by ^{1}H NMR (Guo et al., 1995). As shown in Table 1, the sterols of seeds and shoots are the same, but the proportion of the various sterols in the mixture and the total amount of sterol in each plant part differ significantly from seed to shoot (6-day seedling). To our knowledge, the elevated C4-methyl

Total sterol (μg/seedling)			23	60

sterol content of soybean seeds (at ca. 46% of total sterol) is the highest amount of sterol intermediates so far detected from crop plants. From our experience in analyzing phytosterol compositions of vascular plants, the amount of sterol intermediates in seeds is generally 10–20% of the total sterol mixture (Nes, 1990). The major sterols of soybean seeds were determined to be cycloartenol (**1**, Fig. 1) and 24(28)-methylene cycloartanol (**2**) whereas the major sterol of shoots was sitosterol (**9**). Fenner et al. (1986) determined that the shoot sterols of soybean remained in the same proportion to each other during the course of plant development.

2.2. Sterol biosynthetic capabilities of *P. sojae*

P. sojae was cultured initially in liquid culture on a maintenance medium to establish the native sterol composition of the mycelia. A non-saponifable lipid extract of the mycelia was analyzed by GC–MS and found to contain an identical sterol composition to that of the growth media viz., sitosterol, stigmasterol, campesterol and cholesterol (cf. Nes, 1987). Within the limits of detection of our chromatographic system no ergosterol was detected. These observations suggest the fungus lacks an active biosynthetic pathway to sterols. To confirm that *P. sojae* cannot synthesize sterol, the fungus was cultured in liquid medium with 10 ppm [2-^{3}H]lanosterol (9 Ci/Mol) derived from synthesis (Le and Nes, 1986) or [11–^{14}C] squalene (55 Ci/Mol, obtained from Research Products International Corp.). Both compounds were absorbed by the mycelia to ca. 5% of the fresh weight. The labeled material was recovered from the mycelia in unchanged form as indicated by a single band of radioactivity migrating on TLC plates corresponding to standards of lanosterol ($R_f = 0.5$) and squalene ($R_f = 0.9$), respectively (Xu et al., 1988). The radiotracer studies involving *P. sojae* are in agreement with our earlier observations with *P. cactorum* that Phytophthora cannot synthesize sterols de novo (Nes et al., 1986; Nes, 1987). In related studies, we (Nes et al. 1982; Stafford and Nes, 1983) and Gottleib et al. (1978) found that *P. cactorum* and *P. infestans* can synthesize squalene but are unable to epoxidize the olefin to squalene oxide. Thus, the defect in the conversion of squalene to squalene oxide is likely the impaired step in the isoprenoid-sterol pathway responsible for sterol auxotrophy in this class of fungi.

To determine whether the fungus can metabolize sterols at all, the fungus was cultured on minimal broth with several soybean sterols, including cycloartenol, 24(28)-methylene cycloartanol, 24(28)-methylene lophenol, obtusifoliol, 24(28)-methylene cholesterol, sitosterol, and cholesterol (Fig. 1), and two sterols typically synthesized by fungi, lanosterol and ergosterol (Fig. 2). Each of the sterols was recovered from the fungus in unchanged form, except for ergosterol (M^+ 396 amu) which was metabolized to brassicasterol (M^+ 398 amu), the $\Delta^{5,22}$-analog of ergosterol, in 30% yield. The structure of brassicasterol was confirmed by its relative chromatographic mobility on TLC and HPLC and mass spectrum fragmentation pattern compared to that of an authentic specimen (Nes and Le, 1990). From these analyses, it would appear that *P. sojae*, like *P. cactorum* (Nes et al., 1982), has a limited number of enzymes than can act on the sterol substrate. In contrast to insects which are similarly auxotrophic for phytosterols (Nes et al., 1997) and convert sitosterol to cholesterol for hormonal purposes (Ikekawa et al., 1993), species of Phytophthora apparently utilize sitosterol in unchanged form to promote growth and sexual reproduction. These data and the fact sterols accumulate in mycelial membranes (Nes et al., 1982) indicate the primary role of sterols absorbed by Phytophthora is to affect membrane structure and function.

2.3. Sterol structure requirement of *P. sojae*

P. sojae was found to grow and reproduce sexually on a semisynthetic diet containing sitosterol as first reported by Erwin et al. (1968). We have now determined the amount of sitosterol required to promote maximal growth (as measured by hyphal extension) and oospore production is 10 mg/l or 0.001% of the diet (Figs. 3 and 4). In place of sitosterol a series of sterols were added to the fungal diet and their nutritional effects were evaluated. The sterols were chosen based on their relative position in the soybean sterol pathway as either a C4-methyl sterol intermediate or C4-desmethyl sterol end product. None of the C4-methyl sterol intermediates, cycloartenol **1**, 24(28)-methylene cycloartanol **2**, obtusifoliol **3** or 24(28)-methylene lophenol **5** promoted significant growth or induced functional oospore production. Sitosterol **8**, 24(28)-methylene cholesterol **14** and cholesterol **13** were absorbed by the mycelia to simi-

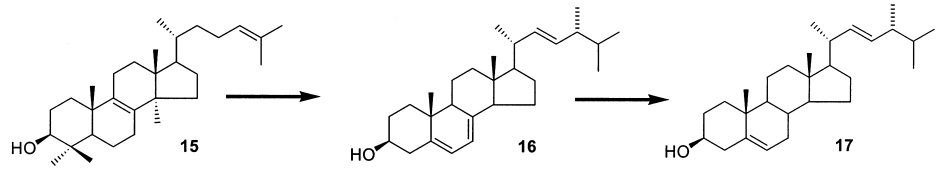

Fig. 2. Hypothetical pathway of fungal sterol biosynthesis. Compounds illustrated are: **15** lanosterol, **16** ergosterol and **17** brassicasterol.

lar levels, ca. 70 μg/g fr. wt, and cycloartenol and 24(28)-methylene lophenol were absorbed to a level of ca. 3 μg/g fr. wt. The amount of sterol absorbed by the mycelium was not necessarily limiting to phytosterol action, since cholesterol and 24(28)-methylene cholesterol were found to induce about half the number of oospores as were generated by treatment with sitosterol. These observations are similar to sterol-structure activity relationships observed with *P. cactorum* (Nes et al., 1982)

To establish the importance of sitosterol availability on *P. sojae* physiology the diet of *P. sojae* was supplemented first with different proportions of cycloartenol and sitosterol then with an equivalent amount of similar sterol types synthesized in the shoot and seed (Table 2).

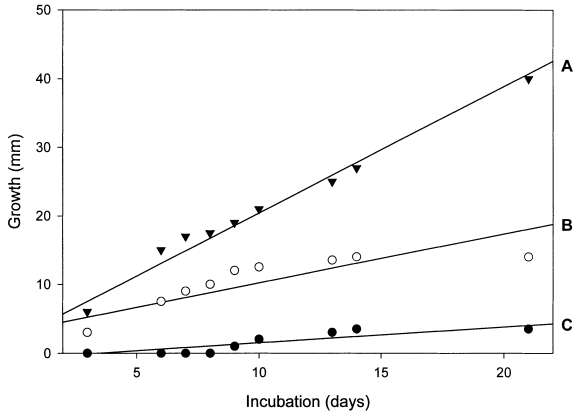

Fig. 3. Growth analysis (measured as hyphal extension) of *Phytophthora sojae* treated with 10 ppm sitosterol **A**, cycloartenol **B** or no sterol **C**. Petri plates were inoculated in the center of the plate with mycelia obtained from a maintenance culture using a 8 mm cork borer.

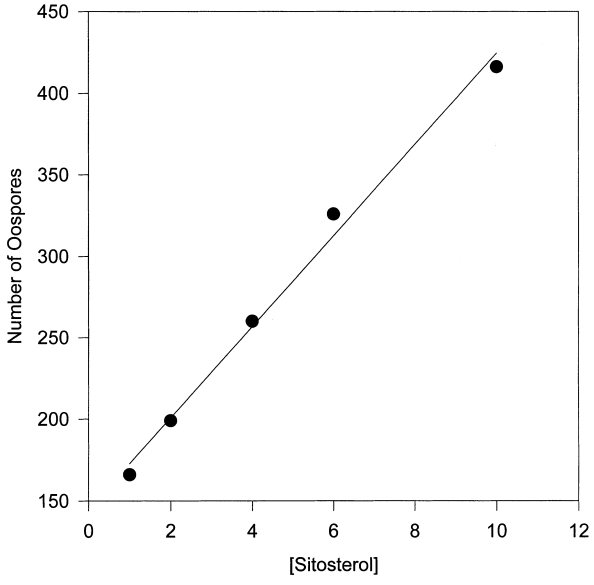

Fig. 4. Plot of increasing numbers of oospores per transect as a function of increasing amounts of sitosterol supplemented to the medium of *Phytophthora sojae*. The number of oopsores per transect remained constant at ca. 450 at higher levels of sitosterol treatment, ca. 15 or 25 ppm. Oospores were counted at 21 days of culture incubation. Microscope (Olympus Model CHT) settings for counting oospores were 40×.

Fungal growth was found to be significantly impaired at a 30/70 mixture of sitosterol to cycloartenol, which corresponds to ca. 50% the growth of sitosterol-treated mycelia. At a 10/90 mixture of the same set of sterols, growth of the mycelia was about the same as the 30/70 mixture of sitosterol to cycloartenol (data not shown). Growth of the fungus on a diet supplemented with 100% cycloartenol was very poor and not much better than the growth of a sterol-less diet, as reported in Fig. 3. *P. sojae* fed shoot or seed soybean sterol grew in a manner similar to mycelia fed a 50/50 mixture of sitosterol to cycloartenol. The number of oospores

dropped from a maximum number of 437 to 0 as the proportion of sitosterol to cycloartenol was modified (Table 2). In the case of shoot sterol-treated mycelia where "sitosterol" levels are high in the sterol mixture, the number of oospores is high. However, in seed sterol-treated mycelia where "sitosterol" levels are low the number of oospores is also low. There is a clear correspondence between the amount of sitosterol in the sterol mixture, that amount of sitosterol absorbed by the mycelium and the number of oospores produced (Table 2). Whereas cycloartenol can be harmful to oospore production (Fig. 5), the amount of cycloartenol accumulated by the cells can be controlled as indicated by the limited absorption of C4-methyl sterols by the fungus.

One explanation for the low accumulation of cycloartenol by *P. sojae* is that species of Phytophthora synthesize a sterol carrier protein which can discriminate structural features of the sterol molecule. Indeed, Boissy et al. (1999) recently identified a pathogenic elicitin protein secreted by Phytophthora species which acts as a sterol carrier protein, favoring the binding over sitosterol to cholesterol and ergosterol. This sterol carrier protein is considered to facilitate movement of the host's sterol to the fungus. We hypothesize that a sterol carrier protein from *P. sojae* will be found to bind sitosterol with much greater efficacy than cycloartenol.

For these reasons, we assume that the unusual mixture of sterol in the seed fails to provide the necessary type or amount of phytosterol for *P. sojae* to grow and reproduce whereas the sterol mixture of the shoot can provide the nutritional sterol. Since the sterol methyl transferase (SMT) enzyme activity can regulate the cycloartenol-sitosterol pathway in soybean (Nes, 2000), it seems reasonable to hypothesize that bioengineering soybean to generate altered SMT levels could impair carbon flux thereby causing a change in phytosterol homeostasis to protect the plant from fungal attack.

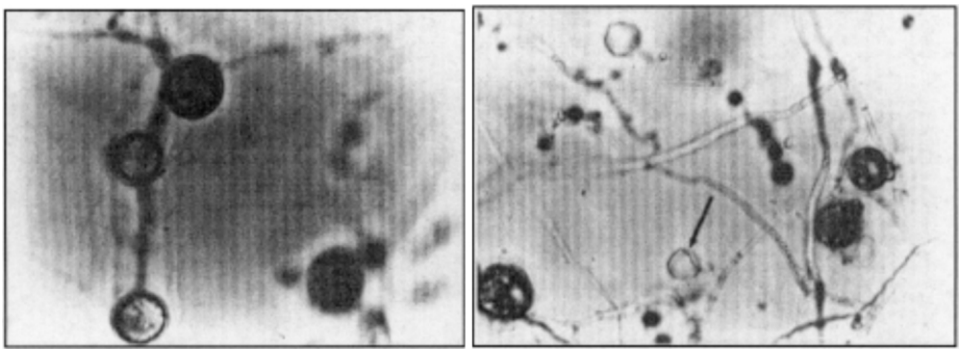

Fig. 5. Micrographs of normal oospores from (left picture) sitosterol-treated cultures and (right picture) aborted oospores from cycloartenol-treated cultures.

3. Experimental

3.1. General

The first set of experiments was designed to establish that *P. sojae* cannot synthesize sterols *de novo* and therefore, as in the case of other pythiaceous fungi, will require sterol to grow and reproduce sexually. To pursue these studies, *P. sojae* was cultured in two ways: Firstly, a maintenance system was developed which consisted of V8 juice/yeast potato dextrose medium added to agar distributed in 30 ml aliquots to 85 mm Petri plates. Secondly, a minimal broth was established which consisted of a synthetically compounded media to which was added sterol at 10 ppm (Nes et al., 1982).

P. sojae strain P7225 was obtained from Dr. Donald Erwin (Department of Plant Pathology at U.C. Riverside). The experimental methods for culturing *P. sojae* on solid and liquid substrates, determining growth rates, counting oospores and for isolating, identifying and quantifying sterols were as described in our earlier publications (Nes et al., 1982). Mycelia were grown in the dark at ambient temperature for 21 days. The sterols used in this study were from soybean or the Nes collection (Xu et al., 1988; Guo et al., 1995). Methods and instrumentation for mass spectroscopic and proton nuclear magnetic resonance spectroscopic analysis of sterols were as described (Guo et al., 1995). Samples for radiotracer analysis were dissolved in 5 ml of Scinti-Verse BD cocktail (Fisher). Radioactivity measurements were obtained on a Beckman LS 6500 liquid counter.

Soybean seeds strain DP3478 were purchased from Delta Pine and Land Co (Lubbock, Texas). Seeds were soaked in a 10% bleach solution for 10 min and washed. These seeds were imbibed with water and grown for 6 days in the dark. The resulting shoots were removed from the seeds and saponified in 10% methanolic KOH. The total sterol fraction was obtained from the non-saponifiable lipid fraction in the usual manner and purified into individual compounds by a combination of TLC and HPLC (Xu et al., 1988; Guo et al., 1995).

Received 5 December 2000; received in revised form 11 May 2001

Abstract

We present results of dynamic head-space collections and GC–MS analyses of floral and vegetative fragrances for 20 species in three genera of Nyctaginaceae: *Acleisanthes*, *Mirabilis* and *Selinocarpus*. Most of the species included in this study are either hawkmoth or noctuid moth-pollinated. A wide variety of compounds were observed, including mono- and sesquiterpenoids, aromatics (both benzenoids and phenylpropanoids), aliphatic compounds, lactones, and nitrogen-bearing compounds. Intraspecific variation in fragrance profiles was significantly lower than interspecific variation. Each species had a unique blend of volatiles, and the fragrance of many species contained species-specific compounds. The fragrance profiles presented here are generally consistent with previous studies of fragrance in a variety of moth-pollinated angiosperms. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Acleisanthes*; *Mirabilis*; *Selinocarpus*; Nyctaginaceae; Four o'clock; Floral fragrance; Pollination; Hawkmoths

1. Introduction

In many pollination interactions, floral fragrance appears to act in concert with visual cues to attract floral visitors (see review by Dobson, 1994). Consequently, a number of studies have examined the relationship of fragrance composition to type of floral visitor (Knudsen and Tollsten, 1993, 1995; Borg-Karlson et al., 1994; Kaiser and Tollsten, 1995; Bestmann et al., 1997; Dobson et al., 1997; Miyake et al., 1998; Grison et al., 1999). The fragrances of hawkmoth-pollinated flowers in a number of plant families have been of particular interest (Knudsen and Tollsten, 1993; Kaiser and Tollsten, 1995; Raguso and Pichersky, 1995; Barthlott et al., 1997; Miyake et al., 1998). Such flowers often have similar morphologies, with long, tubular perianths that are usually white, occasionally yellow or pink (Grant, 1983; Haber and Frankie, 1989). Because these flowers generally emit fragrance at night, when most hawkmoths are active, it has been suggested that convergent evolution for hawkmoth attraction in various angiosperm families may involve scent chemistry as well as floral morphology (Nilsson et al., 1985; Knudsen and Tollsten, 1993; Miyake et al., 1998). To date there has been some support for this idea (Kaiser, 1993; Knudsen and Tollsten, 1993; Miyake et al., 1998); oxygenated terpenoids and nitrogen-bearing compounds are frequently present in the fragrance of hawkmoth-pollinated flowers. However, the high degree of among species variation in fragrance chemistry identified in these studies suggests that convergence is but one of several factors affecting scent chemistry.

Nyctaginaceae are a small family of trees, shrubs, and herbs, distributed mainly in tropical and subtropical regions of the New World. This family is commonly called the Four o'clock family, as most species have flowers that open in the late afternoon to early evening. Further, the flowers of many species are pollinated by hawkmoths (Grant, 1983; Grant and Grant, 1983; Martínez del Río and Búrquez, 1986; Hodges, 1995). Thus, it is an ideal group in which to examine volatiles produced from hawkmoth-pollinated flowers.

Here we present results of head-space volatile collections from flowers and vegetation of species in three genera of Nyctaginaceae: *Acleisanthes*, *Mirabilis*, and

PII: S0031-9422(01)00257-6

Selinocarpus (Table 1). This is the first report of fragrance compounds for any Nyctaginaceae except *Mirabilis jalapa* (Heath and Manukian, 1994). In particular, we investigated within versus among species variation in fragrance compounds for 20 species of Nyctaginaceae. The prediction was that intraspecific variation would be less than interspecific variation, supporting the premise that species have distinct fragrance profiles. Further, we asked how fragrances differed within and among the three genera, and how these differences are related to pollinator affinities.

2. Results and discussion

Our analyses identified a wide variety of volatile compounds across all 20 species examined (Table 2), including representatives of at least seven different biosynthetic classes: monoterpenoids, sesquiterpenoids, fatty acid and amino acid-derived aliphatic compounds and lactones, benzenoids, phenylpropanoids, and nitrogen-bearing compounds [the nitrogen-bearing compounds are known to result from three different biosynthetic pathways (Radwanski and Last, 1995; Wink, 1997)]. The most commonly occurring fragrance compounds were 4,8-dimethyl-nona-1,3,7-triene (present in all species), and *trans*-β-ocimene, *cis*-3-hexenyl acetate, and methyl salicylate (found in 18 of 20 species). There was also a preponderance of *cis*-3-hexenyl esters across all three genera, including both aliphatic and aromatic compounds; these may be the products of a single enzyme or a group of similar enzymes reacting with multiple substrates (see Wang and Pichersky, 1999; Dudareva and Pichersky, 2000).

2.1. Intraspecific vs. interspecific variation

Intraspecific variation in floral and vegetative fragrance quality (types of compounds) and quantity (amounts of compounds) was significantly lower than interspecific variation [$P < 0.0001$, Wilcoxon Signed Ranks Test (SPSS Inc., 1999); mean% dissimilarity of relative amounts of volatiles within species = 12.0 (S.D. = 6.8) vs. among species = 19.1 (S.D. = 7.3)]. These results are consistent with those of Barkman et al. (1997), who found that whereas intraspecific variation was substantial in *Cypripedium* (Orchidaceae), it was not as great as interspecific variation. Thus, it is reasonable to conclude that each species has its own characteristic fragrance profile, which can then be compared to the fragrance profiles of other taxa (Table 2). It should be noted that the interspecific comparisons spanned a wide range of phylogenetic relationships (i.e., some species were more closely related than others; Levin, 2000), and it would be ideal to control for degree of phylogenetic relatedness (Levin, 2001). Levin (2000) has shown that *Acleisanthes* and *Selinocarpus* species together form a monophyletic group, although

Table 1
Species included in this study, and their known pollinator affiliations[a]

Species	Likely pollinators	Evidence
Genus *Acleisanthes* A. Gray		
A. acutifolia Standl.	Hawkmoths	Floral morphology
A. crassifolia A. Gray	Hawkmoths	Pers. observations[a]
A. longiflora A. Gray	Hawkmoths	Pers. observations; Spellenberg and Delson, 1977
A. obtusa (Choisy) Standl.	Hawkmoths	Pers. observations
A. wrightii (A. Gray) Benth. & Hook.	Hawkmoths	Pers. observations
Genus *Mirabilis* L.		
M. alipes (S. Watson) Pilz	Noctuid moths, hawkmoths	Pers. observations
M. bigelovii A. Gray	Noctuid moths	Floral morphology
M. greenei S. Watson	Hawkmoths	Floral morphology
M. jalapa L.	Hawkmoths	Martínez del Río and Búrquez, 1986
M. longiflora L.	Hawkmoths	Grant and Grant, 1983
M. macfarlanei Constance & Rollins	Bees	Barnes, 1996
M. multiflora (Torrey) A. Gray	Hawkmoths	Pers. observations; Cruden, 1970; Hodges, 1995
M. pudica Barneby	Noctuid moths	Pers. observations
M. triflora Benth.	Hummingbirds	Pilz, 1978
Genus *Selinocarpus* A. Gray		
S. angustifolius Torrey	Noctuid moths	Floral morphology
S. chenopodioides A. Gray	Noctuid moths, hawkmoths, long-tongued flies	Pers. observations
S. lanceolatus Wooton	Hawkmoths	Floral morphology
S. parvifolius (Torrey) Standl.	Hawkmoths	Pers. observations
S. purpusianus Heimerl	Hawkmoths	Pers. observations; Fowler and Turner, 1977
S. undulatus Fowler & Turner	Noctuid moths	Floral morphology

[a] Personal observations by R. Levin include floral visitation, examination of visitors for pollen carriage, and microscopic study of stigmas for the presence of moth scales. In addition to nocturnal floral anthesis, floral morphological traits used as evidence of hawkmoth pollination included a tubular perianth >2 cm long; a perianth < 2 cm long suggested noctuid moth pollination.

Table 2

[a] Abbreviations: *Acleisanthes acutifolia* (Aac), *A. crassifolia* (Acr), *A. longiflora* (Alo), *A. obtusa* (Aob), *A. wrightii* (Awr), *Mirabilis alipes* (Mal), *M. bigelovii* (Mbi), *M. greenei* (Mgr), *M. jalapa* (Mja), *M. longiflora* (Mlo), *M. macfarlanei* (Mmf), *M. multiflora* (Mmu), *M. pudica* (Mpu), *M. triflora* (Mtr), *Selinocarpus angustifolius* (San), *S. chenopodioides* (Sch), *S. lanceolatus* (Sla), *S. parvifolius* (Spa), *S. purpusianus* (Spu), *S. undulatus* (Sun).

[b] Compounds within classes are listed according to retention time (RT); for each class its percentage of the total is given.

[c] Sample size (n) is the number of individuals from which fragrance was collected; unless otherwise noted, only one fragrance collection per individual was included.

[d] Only one plant was available, but multiple collections were made of this plant.

[e] Multiple collections from two plants were made during both the day and night for this diurnal species.

[f] Total amount is the mean total unit area (as integrated peak area; see Experimental) of all volatiles produced per 12 h, divided by 10^6 for ease of presentation.

[g] % Floral is the percentage of the total volatiles emitted by flowers.

[h] The total number of both floral and vegetative compounds.

[i] The total number of compounds produced solely or mainly from flowers.

[j] The amount of floral volatiles (an average of the total unit area) was adjusted to give the amount released per mg of floral tissue.

[k] Asterisks indicate compounds for which we have retention times from standards and agreement with mass spectral libraries.

[l] Trace = $<0.01\%$ of volatiles emitted.

[m] Entries in bold identify solely or mainly floral compounds.

[n] Mass fragments for unknowns are listed with the molecular ion first (if known or inferred), followed by the base peak and other fragments in order of decreasing abundance.

[o] 1,5-Cyclo-undecadiene, 8,8-dimethyl-9-methylene.

[p] 12-Oxabicyclo 9.1.0 dodeca-3,7-diene,1,5,5,8-tetramethyl-,1R-(1R@,3E,7E,11R@).

each genus separately is not monophyletic; all *Mirabilis* species also form a monophyletic group. Further, the amount of intraspecific variation varied among taxa. In particular, species that produce many different volatiles have necessarily more sources of variation and, thus, higher levels of intraspecific variation relative to other species. For example, the fragrance profile of *A. wrightii* contains the most compounds (Table 2), and this species also has one of the highest levels of intraspecific variation (mean% intraspecific dissimilarity = 23.5, S.D. = 3.5). By contrast, *Mirabilis* species released fewer volatiles than *Acleisanthes* and *Selinocarpus* species and had fairly low levels of intraspecific variation (mean% intraspecific dissimilarity = 8.8, S.D. = 4.2) compared to *Acleisanthes* and *Selinocarpus* species (mean% intraspecific dissimilarity = 14.1, S.D. = 7.3).

Further exploration of intraspecific variation can be accomplished by comparing our fragrance results for *Mirabilis jalapa* to those previously published (Heath and Manukian, 1994). Despite methodological differences (we sampled the fragrance from one individual whereas they sampled from 12) and selective reporting of fragrance compounds by Heath and Manukian (1994), the results of our two studies are generally consistent. Our study confirms the presence of *trans*-β-ocimene as the major component of the fragrance of *M. jalapa* (38% of total volatiles emitted; Table 2). In further agreement with the previous study, we found *cis*-3-hexenyl acetate and myrcene. Our study did not detect benzaldehyde and indole; this may not be surprising, as Heath and Manukian (1994) report that neither of these compounds was found in all of their *M. jalapa* fragrance samples. We did find other compounds not reported by Heath and Manukian (1994), including α-farnesene (37%) and benzyl acetate (5%) (Table 2).

2.2. Volatiles in taxa with diurnal pollination

The two species in this study known to be pollinated by animals other than moths (Table 1), *Mirabilis triflora* and *M. macfarlanei*, had low total volatile production (Table 2). One of these species, *M. triflora*, is hummingbird-pollinated. Hummingbirds have been shown to ignore fragrance while nectar-foraging (Bené, 1945; van Riper, 1960), and hummingbird-pollinated flowers are generally described as scentless (Faegri and van der Pijl, 1979). Nevertheless, flowers of *M. triflora* released some fragrance (Table 2). It is possible that volatile compounds that are no longer necessary for pollinator attraction may be retained for herbivore deterrence (Mullin et al., 1991; Berenbaum and Seigler, 1992; Dobson, 1994). However, as its closest relatives also produce fragrance (Levin, 2000), the emission of floral volatiles in *M. triflora* may suggest more about its phylogenetic heritage than an absence of strong selection against fragrance production due to its mode of pollination (Levin, 2001).

Mirabilis macfarlanei has been shown to be mainly bee-pollinated (Barnes, 1996). In addition to low overall volatile production, its flowers also released few compounds, with the monoterpene limonene as the main compound (43%; Table 2). This compound is known to be perceived by bees (reviewed by Dobson, 1994), and in combination with visual cues it may be sufficient for attraction.

2.3. Volatiles in moth-pollinated taxa

The majority of species in this study are moth-pollinated (Table 1) and have a clearly discernible and detectable fragrance, but there are many quantitative and qualitative differences among them. One notable finding is that *Acleisanthes* and *Selinocarpus* species generally emit higher total amounts of volatiles than do *Mirabilis* species (Table 2). Also, there are substantial differences in the number of fragrance compounds emitted (Table 2), with *Acleisanthes* and *Selinocarpus* species averaging twice as many compounds (mean = 62) as *Mirabilis* species (mean = 24; conservatively, the average number of compounds = 30 when include only moth-pollinated *Mirabilis* and also exclude *M. greenei*, which has a very weak fragrance, see below).

In terms of biosynthetic classes, fragrances of *Mirabilis* species also are less diverse, with no species producing either phenylpropanoids or lactones (Table 2). The presence of compounds from these two biosynthetic classes appears to be phylogenetically informative, being characteristic of closely related species (Levin, 2000) within both *Acleisanthes* (phenylpropanoids) and *Selinocarpus* (lactones). Interestingly, most of the lactones observed do not appear to have been reported previously from floral fragrances (Knudsen et al., 1993).

In addition to the identity of individual fragrance compounds, the source of the volatiles should also be considered when comparing fragrance profiles among species, as both vegetative and floral volatiles are known to attract floral visitors (Raguso, 2001). For example, crepuscular hawkmoths respond to fragrance from close range (0–10 m) by approaching its source and then probing at bright objects (Brantjes, 1978; Raguso and Willis, in press); they do not functionally distinguish between floral and vegetatively-derived odors. *Acleisanthes acutifolia* and *A. wrightii* have very fragrant vegetation, with most of the total volatile production emanating from vegetation rather than from flowers (ca. 82%; Table 2). Specifically, sesquiterpenoids are released in large amounts from the vegetation of both species. A similar situation is found in *Selinocarpus angustifolius* and *S. undulatus*, where the vegetation is characterized by the emission of high amounts of mono- and sesquiterpenoids. In addition to terpenoids, lipoxygenase-derived "green leaf volatiles" (mainly compounds with a *cis*-3-hexenyl moiety) are often released from vegetation (Hatanaka et al., 1986;

Croft et al., 1993), and these compounds are also emitted vegetatively in *A. acutifolia*, *A. wrightii, S. angustifolius* and *S. undulatus*. Phylogenetic history may explain some of these patterns in fragrance chemistry (Levin, 2001). Interestingly, *S. angustifolius* and *S. undulatus* are strongly supported as sister species, and *A. wrightii* and *A. acutifolia* are also very closely related (Levin, 2000).

Whether floral or vegetative volatiles dominate the fragrance profile depends on the species; among all twenty species the volatiles emitted from flowers varied from 5-100% of the total amount of fragrance emitted (Table 2). Across all taxa some compounds are mainly emitted by flowers (Table 2). These floral compounds include the lactones and phenylpropanoids, the isoleucine-derived tiglates (Hill et al., 1980), *cis*-jasmone, the majority of the benzenoid compounds, and most of the nitrogen-bearing compounds.

The amount of each floral compound produced per μg of floral mass varies substantially among species (Table 2). Although compounds such as *trans*-β-ocimene, nerolidol, *cis*-jasmone, and methyl benzoate are emitted by flowers of many species, the amount produced can differ greatly. This finding suggests that simply the presence of these compounds, rather than their amounts, may be sufficient for moth attraction.

In general, our results are consistent with other studies that have detected floral fragrance in moth-pollinated taxa; however, the one exception is the absence of fragrance in *Mirabilis greenei*. In addition to its low volatile production, of the five volatile compounds collected from this species, only the homoterpene 4,8-dimethylnona-1,3,7-triene was likely to be floral, with the others emitted from the vegetation (Table 2). This lack of fragrance is surprising if this species is indeed moth-pollinated. However, any interpretation of the fragrance of *M. greenei* should be considered preliminary, as the fragrance samples from this species were collected in the field when temperatures were unusually low (these conditions were unique to this species' fragrance collection); low temperatures have been reported to inhibit volatile production (Jakobsen and Olsen, 1994).

2.4. Fragrance and pollination

Several authors have suggested a link between the presence of particular fragrance compounds and moth pollination (Nilsson et al., 1985; Kaiser, 1993; Knudsen and Tollsten, 1993; Miyake et al., 1998). Kaiser (1993) described moth-pollinated flowers as having a "'white-floral'" odor, containing acyclic terpene alcohols such as linalool and nerolidol and simple aromatic alcohols like benzyl alcohol, 2-phenylethanol, and their esters. Jasmonates, tiglates, lactones, and nitrogen-bearing compounds are also prevalent in a variety of moth-pollinated flowers (Kaiser, 1993). Knudsen and Tollsten (1993) obtained results consistent with Kaiser (1993) in their survey of hawkmoth and noctuid moth-pollinated flowers among 15 species in 12 genera and 9 plant families, but they additionally suggested that hawkmoth-pollinated flowers can be distinguished from noctuid moth-pollinated flowers by the presence of geraniolic compounds and oxygenated sesquiterpenes.

The fragrances of all of the moth-pollinated (i.e., both hawkmoth and noctuid moth-pollinated) species included in this study (except *M. greenei*) are similar in containing mono- and sesquiterpenoids, aliphatic compounds, benzenoids, and nitrogen-bearing compounds. These fragrance profiles are consistent with the descriptions of moth-pollinated fragrances reported by Kaiser (1993), and to some extent support the suggestion of Knudsen and Tollsten (1993) that the specific presence of oxygenated sesquiterpenes is more characteristic of hawkmoth-pollinated than noctuid moth-pollinated species. Of the 12 taxa in our study that are likely to be hawkmoth-pollinated, eight had fragrances that contained at least one oxygenated sesquiterpene. However, the fragrances of two likely noctuid moth-pollinated species, *Selinocarpus angustifolius* and *S. undulatus*, also contained oxygenated sesquiterpenes (Tables 1 and 2). Further, we observed that these two *Selinocarpus* species emitted the lowest total amount of volatiles and had the least diversity of compounds compared to other *Selinocarpus*. Based on floral morphology, *Selinocarpus chenopodioides* would appear to be noctuid moth-pollinated, but the white-lined sphinx moth (*Hyles lineata*) has also been observed visiting its flowers, and may move pollen (Table 1; Levin, 2001). Interestingly, flowers of this species emit a fragrance similar to that of hawkmoth-pollinated *Selinocarpus* species in that they produce large amounts of a variety of volatiles, including oxygenated sesquiterpenes (Table 2). Thus, while pollination by smaller insects may be occurring, the flowers are also attractive to hawkmoths. By contrast, the flowers of *Mirabilis alipes*, which are likely noctuid moth-pollinated, emit a low diversity of volatiles and lack oxygenated sesquiterpenoids. However, flowers of *M. alipes* also attract *Hyles lineata*, although the hawkmoths collected while visiting this species did not carry any pollen (Table 1; Levin, 2001). In general, results of this study suggest that a diversity of compounds may attract moths, and oxygenated sesquiterpenes, while commonly found in fragrances of hawkmoth-pollinated taxa, are not restricted to the fragrances of these species.

2.5. Conclusions

The fragrance profiles we observed in Nyctaginaceae are generally consistent with the "'white-floral'" odor described by Kaiser (1993) and the fragrances of moth-pollinated plants reported by Knudsen and Tollsten (1993) and Miyake et al. (1998). However, the floral volatiles reported here and in previous studies are not unique to fragrances of hawkmoth-pollinated flowers;

for example, many of these volatiles have also been reported from beetle-pollinated flowers (Azuma et al., 1997). In addition to the chemical similarities of fragrance across moth-pollinated taxa, there are many differences that give flowers of each species their distinctive odor. These include species-specific compounds (e.g., vanillin in *A. wrightii* and methyl nicotinate in *S. chenopodioides*), compounds shared by closely related species (e.g., δ-octalactone and δ-nonalactone in *S. lanceolatus* and *S. parvifolius*), and species-specific blends of more ubiquitous compounds.

Fragrance plays diverse roles in hawkmoth pollination, attracting moths from a distance (Tinbergen, 1958; Haber, 1984), combining with visual cues to elicit floral approaches and feeding (Brantjes, 1978; Raguso and Willis, 2001), and facilitating associative learning and discrimination (Daly and Smith, 2000). Among diverse hawkmoth-pollinated flowers, the presence of common classes of compounds, such as oxygenated terpenoids and aromatic esters, combined with the species-specific nature of each blend documented in our study and its antecedents, provides a complex ecological signal with the potential to support all of these functions.

3. Experimental

3.1. Study taxa

Fragrance was collected from multiple individuals (sample sizes are given in Table 2) of each of the 20 Nyctaginaceae species (Table 1), the majority of which are found in the Chihuahuan Desert in southwestern North America. These taxa were chosen because of the prevalence of hawkmoth pollination and multiple evolutionary losses of this pollination system (Levin, 2001). Vouchers of all species included in this study are housed in the herbarium at the University of Arizona (ARIZ; see Table 2 in Levin, 2000).

3.2. Volatile collection

Fragrance was collected in the field using dynamic head-space collection methods (see Raguso and Pellmyr, 1998, and references therein). Flowers on a living plant were enclosed within a polyacetate bag (Reynolds® oven bags) where volatile compounds emitted from the plant accumulated and were trapped in adsorbent cartridges through the use of a battery operated diaphragm pump (KNF Neuberger, Inc.). Glass cartridges were packed with 100 mg of the adsorbent Porapak®Q (80–100 mesh), and the pump pulled air over the flowers and into the adsorbent trap at a flow rate of ca. 250 ml/min. Fragrance collections typically commenced at floral anthesis and continued for 12 h. Most of the species included in this study have nocturnal floral anthesis, such that fragrance collection usually began at dusk and ended early the following morning. As all these species have flowers that last only one day, this collection period generally encompassed the entire period during which a flower was open. For a few species, we were unable to collect floral fragrance in the field, and instead did so in the greenhouse using the same protocol as outlined above. In general one fragrance collection was made per individual plant, and the number of flowers included for each fragrance collection was noted. After fragrance collection, flowers were removed from the plants and weighed to obtain an average fresh wt per flower for each species.

Simultaneous collections of ambient and vegetative volatiles were used to distinguish between truly floral compounds, compounds emitted from the vegetation, and ambient contaminants. The architecture of these plants made it impossible to avoid trapping vegetative volatiles while also collecting volatiles from a number of flowers. Ideally the mass of vegetation from which fragrance was collected would have been quantified; however, this would have required destructive sampling of plants (in many cases fragrance was collected from an entire plant), which was not feasible.

3.3. Chemical and data analysis

After the 12 h collection period, cartridges were wrapped in aluminum foil and kept chilled. They were then eluted with 3 ml of hexane, and the eluate was stored frozen in glass vials. Before GC–MS analysis, samples were concentrated to 75 μl with N_2. One microliter (occasionally 3 μl) aliquots of each sample were injected into a Shimadzu GC-17A equipped with a Shimadzu QP5000 quadrupole electron impact MS as a detector. All analyses were done using splitless injections on a polar GC column [diameter 0.25 mm, length 30 m, film thickness 0.25 μm (EC WAX); Alltech Associates, Inc.]. The carrier gas was helium with a flow rate of 1 ml/min and a split ratio of 12. The injector temp. was 240 °C and detector temp. was 260 °C. The oven program began with injection at 60 °C and a constant temp. for 3 min. The temp. then increased by 10 °C per min until 260 °C, where it was held for 7 min. The column pressure at injection was 60.6 kilo Pascals (kPa); the pressure then increased to 400 kPa for 48 s followed by a decrease to 60.6 kPa for 2 min (this pressure pulse was included for peak sharpening at the suggestion of L. Evanicke, Shimadzu Scientific Instruments, Inc.) and then an increase of 3.9 kPa per min until 132.9 kPa, where it was held for 7 min.

Compounds were tentatively identified using computerized mass spectral libraries [Wiley and NIST libraries (> 120,000 mass spectra)]. The identity of many compounds was also verified using retention times of known standards (Table 2). To ensure that even small quantities

of compounds were detected, we searched for the presence of specific mass fragments using single ion chromatograms (SIC). For example, the nitrogen-bearing compounds indole and phenylacetonitrile often were present in very small amounts; by searching for the molecular ion (117 Da) at the appropriate retention times, we were able to detect trace amounts of these compounds. Quantification of compound amounts was achieved by integrating individual GC peak areas of the total ion chromatograms (TIC) using Shimadzu's Class-5000 software (Shimadzu Co., 1993–1996). For each species these compound areas were averaged across individuals and divided by the total average amount of volatiles produced to yield the relative amount (mean percentage) of each compound present in the floral and vegetative fragrance per 12 h collection period (Table 2). For volatiles released mainly or solely from flowers, compound areas were standardized by adjusting for the number and mass of flowers sampled to yield the amount present per μg of floral mass (Table 2).

3.4. Intraspecific vs. interspecific variation

To compare intraspecific variation in fragrance profiles to interspecific variation, we used the relative amounts of both floral and vegetative volatiles for each individual (rarely were multiple samples from the same individual included, see Table 2) to calculate a dissimilarity matrix based on Euclidean distance (SPSS Inc., 1999). Variables were standardized to have a mean of zero and a standard deviation of one. We then used a Wilcoxon Signed Rank Test (SPSS Inc., 1999) to compare the pair-wise% dissimilarities between individuals within a species to those between individuals among species. A lower dissimilarity between conspecific individuals than between individuals among species would suggest that interspecific variation is greater than intraspecific variation in fragrance profiles.

Acknowledgements

We are grateful to T. Tully, A. Boyd, M. Manktelow, D. Hearn, and A. Chetochine, without whose assistance these fragrance collections could not have been made. We thank Big Bend National Park, the Jornada LTER, and J. Duft for access to plants, and A. Le Duc and M. Fishbein for providing seeds. For use of a GC–MS and injection of many of the samples we thankfully acknowledge E. Pichersky and J. D'Auria, University of Michigan. This manuscript was greatly improved by J.S. Miller, who read an early version of the manuscript, and by three anonymous reviewers. The main source of funding for this research was provided by the National Science Foundation DEB9806840 to L.A.M. and R.A.R. Further support was provided by small grants to R.A.L. from the American Society of Plant Taxonomists, Sigma Xi, the Department of Ecology and Evolutionary Biology at the University of Arizona, and the University of Arizona Research Training Group in the Analysis of Biological Diversification (NSF DIR-9113362, BIR-9602246). This paper is part of a dissertation by R.A.L. submitted in partial fulfillment of the requirements for the degree of doctor of philosophy, University of Arizona.

Isolation, characterization, and systematic significance of 2-pyrone-4,6-dicarboxylic acid in Rosaceae

Sonja Wilkes, Heinrich Glasl*

Institut für Pharmazeutische Biologie und Phytochemie der Westfälischen Wilhelms-Universität Münster, Hittorfstraße 56, D-48149 Münster, Germany

Received 12 February 2001; received in revised form 14 May 2001

Abstract

2-Pyrone-4,6-dicarboxylic acid was isolated from *Potentilla anserina*. Until now this substance was only found in bacteria and not in higher plants. By sterile cultivation it was verified that this compound is genuine also in plants. In addition the systematic relevance of 2-pyrone-4,6-dicarboxylic acid within the Rosaceae was tested. The compound seems to be a chemotaxonomic marker for the *Rosoideae sensu stricto* proposed by Morgan et al. (Morgan, D.R., Soltis, D.E., Robertson, K.R., 1994. Systematic and evolutionary implications of *rbc*L sequence variation in Rosaceae. American Journal of Botany 81, 890–903). © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: 2-Pyrone-4,6-dicarboxylic acid; *Potentilla anserina* L.; *Potentilla recta* L.; Rosaceae; Chemotaxonomy

1. Introduction

Some bacterial strains degrade aromatic, especially phenolic substances to 2-pyrone-4-6-dicarboxylic acid (Fig. 1), e.g. *Pseudomonas* (Kersten et al., 1982; Samejima et al., 1987) or *Micrococcus* (Eaton and Ribbons, 1982a,b). The central metabolites of this reactions are protocatechuic or gallic acid followed by 2-pyrone-4,6-dicarboxylic acid. Until now these ring fission reactions resulting in 2-pyrone-4,6-dicarboxylic acid have been known only from bacteria. We recently found 2-pyrone-4-6-dicarboxylic acid in *Potentilla anserina* L. in the family Rosaceae, a member of higher plants (Wilkes and Glasl, 2000).

The family Rosaceae has been often and well studied systematically. Several different compounds are used as taxonomic markers like cyanogenic glycosides (Fikenscher et al., 1981), flavonoids (Harborne, 1967; Challice, 1972), tannins (Okuda et al., 1992) and sorbitol (Wallaart, 1980). We tried to find out if 2-pyrone-4,6-dicarboxylic acid has any taxonomic significance for the family Rosaceae.

2. Results and discussion

2.1. Isolation and characterization of 2-pyrone-4-6-dicarboxylic acid from Potentilla anserina L.

HPLC analysis of crude methanol–water extract of *Potentilla anserina* L. showed a major signal at 315 nm. For isolation and structural elucidation lyophilised plant material was extracted with acetone–water and ethanol–water mixtures. After removing the organic solvents the aqueous extract was prefractionated by partition between ether and ethylacetate. The compound was obtained in a pure form from the ethylacetate fraction after column chromatography on Sephadex LH-20 and preparative HPLC on RP-18 material.

For structure elucidation the compound was subjected to UV and NMR spectroscopy and mass spectrometry. The data are mostly in good agreement with published literature data only the assignment of the ^{13}C NMR signals of C-7 and C-8 had to be exchanged after viewing the HMBC data (Maruyama, 1979; Samejima et al., 1987).

2.2. Detection of 2-pyrone-4,6-dicarboxylic acid in sterile cultivated Potentilla recta seedlings

To establish that the isolated compound originated from the plant and not from bacteria or parasitic fungi

living on the plants, experiments under sterile conditions were necessary. HPLC analysis of sterile seedlings (3–5 cm) of *Potentilla recta* L. detected 2-pyrone-4,6-dicarboxylic acid. *Potentilla recta* was used because seeds of *Potentilla anserina* were not available.

2.3. Occurence of 2-pyrone-4,6-dicarboxylic acid in several members of the family Rosaceae

2-Pyrone-4,6-dicarboxylic acid is a central catabolite of several aromatic or phenolic substances in bacteria (Eaton and Ribbons, 1982a,b; Samejima et al., 1987; Rosazza et al., 1995). Many members of the family *Rosaceae* contain phenolic substances like flavonoids, hydroxycinnamic acids or tannins (Hegnauer, 1973, 1990). Further investigations are necessary to determine whether 2-pyrone-4-6-dicarboxylic acid is a catabolic substance of these phenolic compounds in *Potentilla anserina*.

The systematic significance of 2-pyrone-4,6-dicarboxylic acid in the Rosaceae was studied in more detail. Eighty-three species of the Rosaceae were collected during two seasons (1999 and 2000) with an emphasis on the genus *Potentilla* (Table 1).

In this paper we follow the systematic classification of Schulze-Menz (1964), who divided the family into the subfamilies *Spiraeoideae, Rosoideae, Maloideae* and *Prunoideae*, basing the classification on fruit types and the habit of the plants (woody or herbaceous). We tried to get many tribes and genera described by Schulze-Menz (1964) to get a nearly complete sampling of the family Rosaceae (Table 2).

Aerial parts of the plants were harvested as far as possible during the flowering period. The fresh plants

[a] Abbreviations: IG: Garden of the Institut für Pharmazeutische Biologie und Phytochemie; BG: Botanical Garden, Westfälische Wilhelms-Universität Münster; H: herb, all overhead parts; L: leaves; Fl: flower; S: shoot; St: this year's shoot or twig; Sp: spur shoot; B: branch or twig in general, mostly older than one year; R: roots; F: fruit; HN: herbarium number (Institut für Pharmazeutische Biologie und Phytochemie).

were frozen at −30 °C, lyophilised and finally pulverised followed by extraction with acetone–water mixtures. The solvent was removed and the rest was filled up to a definite volume with water and filtered. A solid phase extraction (RP-18 material) of this crude extract was necessary for the following HPLC analysis.

2-Pyrone-4,6-dicarboxylic acid was found in all 14 investigated *Potentilla* species and in many members of the *Rosoideae*. This compound was found exclusively in the *Rosoideae* and not in any other subfamily. The distribution of 2-pyrone-4,6-dicarboxylic acid among the *Rosoideae* does not correspond to this classification (Schulze-Menz, 1964) (see Fig. 2). The tribe *Dryadeae* includes subtribes with or without 2-pyrone-4,6-dicarboxylic acid. The subtribes *Cercocarpinae* and *Dryadinae* contain no 2-pyrone-4,6-dicarboxylic acid while the subtribe *Geinae* includes two genera with a relative high amount of this substance (2% dry wt, see Table 3). The genera *Sanguisorba* and *Acaena* are combined in the *Sanguisorbinae*. However, *Acaena* contains no 2-pyrone-4,6-dicarboxylic acid whereas *Sanguisorba* does. 2-Pyrone-4,6-dicarboxylic acid is obviously limited to the *Rosoideae* but it does not occur in every member of the subfamily.

The classification of Schulze-Menz (1964) is only one of many suggested classifications of the Rosaceae. Morgan et al. (1994) investigated the family *Rosaceae* without viewing the traditional circumscriptions. The characteristic he used for determining phylogenetic relationships in this family was *rbc*L sequence variation. As a result the *Rosoideae* proposed by Schulze-Menz (1964) do not form a monophyletic group. *Rbc*L evidence splits *Rosoideae* according to chromosome numbers. *Rosoideae* with $x=7$ or 8 form a monophyletic group (*Rosoideae sensu stricto*) while traditional *Rosoideae* with $x=9$ are dispersed throughout the rest of the family.

Of the taxa of Rosaceae investigated for the presence of 2-pyrone-4,6-dicarboxylic acid, the only ones that the compound was found in are members of the *Rosoideae s. str.* proposed by Morgan et al. (1994). No genus outside the *Rosoideae s. str.* was found containing 2-pyrone-4,6-dicarboxylic acid. Therefore 2-pyrone-4,6-dicarboxylic acid seems to be a specific content of the *Rosoideae s. str.* and is perhaps a systematic marker for the *Rosoideae s. str.* proposed by Morgan et al. (1994) (see Fig. 3). In addition, two genera not investigated by Morgan et al. (1994), *Sanguisorba* and *Duchesnea*, contain 2-pyrone-

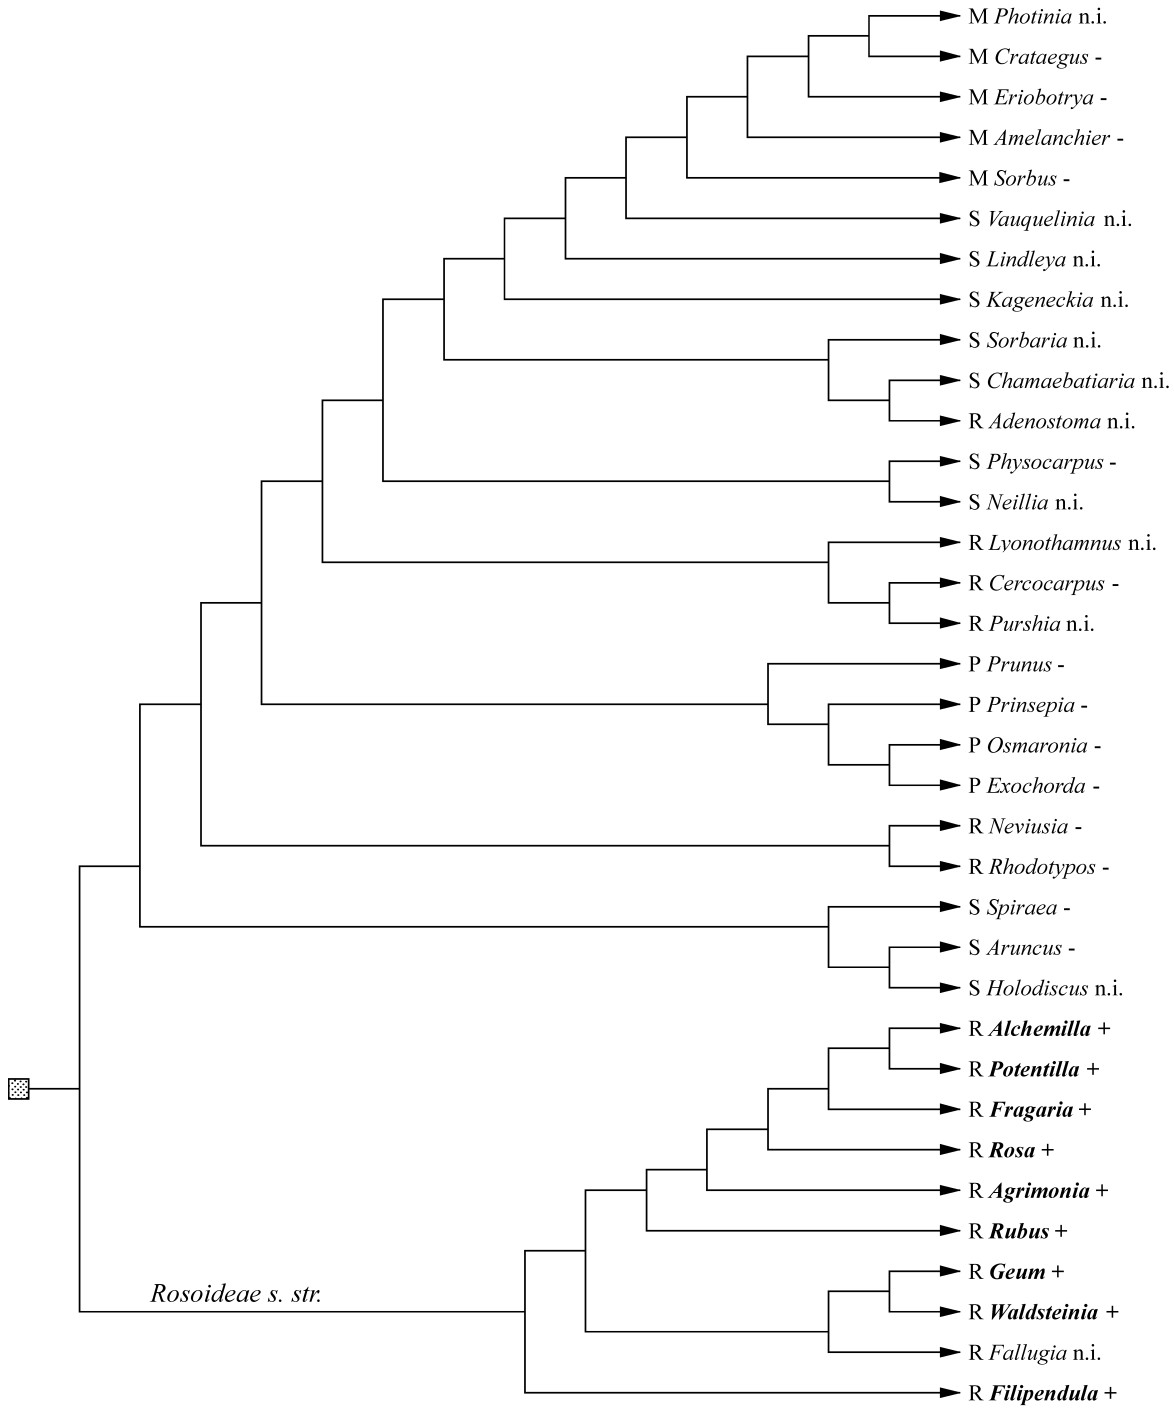

Fig. 3. Phylogenetic relationships in Rosaceae suggested by *rbc*L sequence variation (Morgan et al., 1994). +/−: 2-Pyrone-4,6-dicarboxylic acid existing/ not existing; n.i.: not investigated. S: *Spiraeoideae*; R: *Rosoideae*; M: *Maloideae*; P: *Prunoideae* from Schulze-Menz (1964).

4,6-dicarboxylic acid as well suggesting that they might also belong in *Rosoideae s. str*.

The amount of 2-pyrone-4,6-dicarboxylic acid within the investigated species varies (see Table 3). Most species contain 0.1–0.5% of the compound but species of the genera *Geum* and *Waldsteinia* show a much higher amount of 2 and 1,3% respectively. *Geum* and *Waldsteinia* are close relatives in both systematic systems so the occurrence of high amounts of 2-pyrone-4,6-dicarboxylic acid supports their relationship.

The distribution of 2-pyrone-4,6-dicarboxylic acid within a single plant differs (see Table 4). In *Potentilla*

[a] Today is *Chaenomeles Choenomeles* and *Osmaronia Oemleria* (Encke et al., 1994).
[b] *Aronia* belongs to the genus *Photinia* (Royal Botanic Gardens, Kew, http://www.rbg.kew.org.uk/).
[c] *Osteomeles* is not described by Schulze-Menz, but this genus also belongs to the Rosaceae (Royal Botanic Gardens, Kew, http://www.rbg.kew.org.uk/).

anserina the leaves have the highest concentration of 2-pyrone-4,6-dicarboxylic acid while the shoots and seeds contain lower concentrations.

3. Conclusion

2-Pyrone-4,6-dicarboxylic acid was isolated from *Potentilla anserina* L. It is a genuine compound of several members of the *Rosoideae* and it seems to be a taxonomic marker for the *Rosoideae s. str.* proposed by Morgan et al. (1994).

4. Experimental

4.1. General experimental procedures

^{1}H, ^{13}C and APT NMR spectra were recorded at ambient temperature at 200 respectively 50 MHz on a Varian Gemini 200 spectrometer relative to MeOH ($\delta = 3.35$ ppm). HSQC and HMBC spectra were recorded at 600 MHz on Varian Unity 600. MS was recorded on a GCQ Finnigan - MAT at 70 eV. UV spectroscopy was made on a Shimadzu UV-visible recording spectrophotometer in MeOH, 0.1 N HCl and 0.1 N NaOH. HPLC was made on Waters System (analytic: In-Line Degasser, 717 plus Autosampler, 600 Controller, 996 Photodiode Array Detector, Waters software, column: ProSep C-18 150×4 mm, 5 μm, endcapped, Latek Eppelheim; preparative: In-Line Degasser, Automated Gradient Controller, 515 HPLC Pump, Lambda Max Model 481 LC Spectrophotometer, column: Knauer Refill C-18 250×20 mm, 7 μm).

4.2. Plant material

Aerial plant material of *Potentilla anserina* L. for isolation of 2-pyrone-4,6-dicarboxylic acid was harvested in the garden of the institute in summer 1997. Seeds of *Potentilla recta* L. were purchased from Bornträger GmbH, D-67591 Offstein. Plants for screening were collected in the Botanical Garden of the university, the garden of the institute and in the environs of Münster (see Fig. 2 for the place of collection, collection time and herbarium number). The species were determined using Rothmaler (1995) or the determination was taken from the gardens.

4.3. HPLC analysis of crude Potentilla anserina L. extract

Three grams of lyophilised and pulverised *Potentilla anserina* L. were extracted with 40 ml 80% aq. MeOH

Seed (*Potentilla recta*)	107±1

with Ultra Turrax. After filtration the extract was evaporated nearly to dryness and was filled up with water to 10.0 ml. The extract was held overnight at 8 °C and filtrated. Five microliters were used for HPLC. Analytical HPLC was made with a gradient of CH_3CN/0.1% aq. TFA (flow: 2 ml/min; 0 min: 0/100; 20 min: 7/93; 35 min: 25/75; 40 min: 50/50); 45 min: 100/0. Retention time of 2-pyrone-4,6-dicarboxylic acid: 5.6 min.

4.4. Preparative extraction and separation

Fresh plant material of *Potentilla anserina* (16 kg) was frozen with liquid nitrogen, crushed, lyophilised (3.7 kg) and extracted with aq. Me_2CO (70%, 54 l) followed with aq. EtOH (50%, 45 l) with an Ultra-Turrax homogenizer. After removing the organic solvent at 40 °C under vacuum the aqueous solution was allowed to stand overnight at 8 °C, filtered to remove chlorophyll and defatted with petrol. The crude extract (28 l) was concentrated (6.5 l) by lyophilisation and extracted successively with Et_2O (9 l) and EtOAc (12 l) setting the crude extract before to pH = 2 with HCl. Twenty grams of the dry EtOAc-fraction (82 g) were fractionated on a Sephadex LH-20 column (5×62 cm) using 80% aq. EtOH (6 l). The fraction from elution volume 200–1400 ml contains 2-pyrone-4,6-dicarboxylic acid (2061 mg). A small portion of

this fraction (150 mg) was purified by HPLC using CH_3CN/0.1% aq. TFA (gradient 20/80 to 50/50, 20 min., 7 ml/min.) to yield 2-pyrone-4,6-dicarboxylic acid (10.5 min).

4.5. Analytical extraction and quantification

The fresh plants were frozen at −30 °C and lyophilised without crushing. The plant material was pulverised. Three grams of the powder were extracted four times with 40 ml 70% aq. Me_2CO in ultrasound (3 min.). The extract was evaporated nearly to dryness and was filled up with water to 10 ml. The extract was held overnight at 8 °C and filtered. Two hundered and fifty microliters of the crude extract were taken for solid-phase extraction at LiChrolut® RP-18 (500 mg, Merck). Before use, the columns were cleaned and prepared by eluting 1 ml water, 1 ml Me_2CO and 2 ml water. Then the extract was given up to the column followed by elution three times with 250 µl water. This extract was collected and used for HPLC. Analytical HPLC was made with a gradient of CH_3CN / 0,1% aq. TFA (flow: 2 ml/min; 0 min: 0/100; 5 min: 0/100; 15 min: 7/93; 25 min: 100/0). Calibration was made with freshly isolated 2-pyrone 4,6-dicarboxylic acid (0.1–0.0005 mg/run, four concentrations, $R^2 = 0.9994$).

4.6. Sterile cultivation of Potentilla recta

Seeds of *Potentilla recta* were sterilised 30 min with 5% aq. NaOCl and washed with sterile water before transferring them to the culture medium (Vermiculite; 0.51 g KNO_3, 1.18 g $Ca(NO_3)_2{*}4H_2O$, 0.49 g $MgSO_4{*}7H_2O$, 0.136 g KH_2PO_4 2.5 ml Fe-EDTA (Gamborg, 1966), 0.1 ml microsalts (Gamborg, 1966), all per l). The seedlings were harvested after the second primary leaf emerged (10–12 weeks). Detection of 2-pyrone-4,6-dicarboxylic acid was done as in *Analytical extraction and quantification* above. The seed and the seedlings were tested for sterility by transferring them to a solid culture medium containing 0.9% agar, 3% saccharose, 2% 2,4-D, microsalts (Murashige and Skoog, 1962) and organic compounds (Gamborg et al., 1968). Bacteria and fungi contamination was not detectable.

4.7. NMR, MS and UV

The spectral properties (MS, UV, ^{1}H NMR) of 2-pyrone-4,6-dicarboxylic acid were essentially those reported by Maruyama (1979): EI–MS:184 (5.3%) $[M]^+$139 (100%): 184–45 $[M - COOH]^+$, 111 (6.6%): 184–45–28 $[M–COOH–CO]^+$, 95 (1.5%): 184–45–44 $[M–COOH–CO_2]^+$. UV $\lambda^{MeOH\text{-}max.}$ nm: 316 ($\varepsilon = 4927$), 212 ($\varepsilon = 8218$); $\lambda^{0,1n\ HCl\text{-}max}$ nm: 315 ($\varepsilon = 5506$), 214; $\lambda^{0,1n\ NaOH\text{-}max}$ nm: 353, 220. ^{1}H NMR (CD_3OD): δ 7.44 (*d*, H-3, *J* (3-5) 1.16 Hz), *δ* 7.07 (*d*, H-5, *J* (5-3) 1.17 Hz). ^{13}C NMR data are shown in Samejima et al. (1987) but not in complete. The complete assignment of the carbons C-7 and C-8 was determined by ^{13}C NMR, APT, HSQC and HMBC: ^{13}C NMR (CD_3OD): *δ* 161.7 (*s*, C-2), *δ* 109.8 (*s*, C-3), *δ* 145.8 (*s*, C-4), *δ* 122.7 (*s*, C-5), *δ* 151.3 (*s*, C-6), *δ* 165.1 (*s*, C-7); *δ* 162.1 (*s*, C-8). The data are in good agreement with those published by Samejima et al. (1987).

Received 11 February 2001; received in revised form 22 May 2001

Abstract

Aerial parts of 26 taxa, distributed in 18 genera and all 5 tribes of the Malvaceae have been examined for the presence of betaines. Glycinebetaine was obtained in high yield (0.5–4.6%, dry weight) from all the plants studied, except *Abelmoschus moschatus*, in extracts of which glycinebetaine was not detected. Trigonelline was recorded for 16 of the plants tested, but the yields were low (0.005–0.07%, dry weight). Roots and flowers of a few of the species were also examined for betaines. The same compounds as those found in the aerial parts were usually detected, but the glycinebetaine contents of the roots and flowers were considerably lower. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Malvaceae; Betaines; Glycinebetaine; Trigonelline; Chemotaxonomy

1. Introduction

The taxonomic value of betaines, particularly at the generic level, has been reported, for example, for the Graminae (Wyn Jones and Storey, 1981), marine algae (Blunden et al., 1982, 1992; Blunden and Gordon, 1986), the Labiatae (Blunden et al., 1996), the Capparaceae (McLean et al., 1996), the Amaranthaceae (Blunden et al., 1999) and the Bromeliaceae (Adrian-Romero and Blunden, 2001).

For the Malvaceae, Wyn Jones and Storey (1981) reported glycinebetaine in two species of *Abutilon* and a Dragendorff-positive compound in *Lavatera plebeja*. Later, Popp et al. (1984) recorded high concentrations of methylated onium compounds for *Hibiscus tilaceus*, and Poljakoff-Mayer et al. (1994) isolated glycinebetaine in a yield of about 1%, dry weight, from the seeds of *Kosteletzkya virginica*, prior to germination. Gorham (1995) found glycinebetaine in most of the Malvaceae he investigated and another unidentified betaine was detected in several of the plants examined; no yields were given for any of the species. In a later paper, Gorham (1996) reported glycinebetaine in all but 3 of over 100 species of Malvaceae investigated. He concentrated on *Gossypium* species, which were found to contain large amounts of glycinebetaine (>20 mmol kg^{-1}, fresh weight). In this current investigation we have isolated, characterized and quantified the betaines present in 18 genera of Malvaceae, representing all 5 tribes listed by Jury (1993).

2. Results and discussion

Malvaceae is a family comprised of 75 genera distributed in tropical and temperate areas (Willis, 1973). Classification of the family poses many problems and opinions differ as to deliniation of genera and tribes, but most treatments recognize 5 tribes (Jury, 1993). Aerial parts of 26 taxa, included in 18 genera of the Malvaceae and distributed in all 5 tribes, were extracted and the extracts examined for the presence of betaines; these were detected by TLC in all the extracts (Table 1). The betaines were isolated by preparative TLC and characterized from TLC, ^{1}H NMR spectroscopic and, when possible, FAB mass spectrometric data. Glycinebetaine was found in all the species tested, except *Abelmoschus moschatus*. In an earlier study of the family, Gorham (1995) also reported the absence of glycinebetaine from this species. High yields of glycinebetaine were obtained, ranging from 0.5% of the dry weight of *Malvastrum*

[a] nd, not detected (limits of detection for glycinebetaine and trigonelline are approximately 0.0008 and 0.001%, dry weight, respectively). Unless otherwise stated, aerial parts of the plant were used.

lateritium, *Malva moschata* and *Modiola caroliniana* to 4.6% of the dry weight of *Hibiscus rosa-sinensis*. Trigonelline was detected in 16 of the plants tested, including *Abelmoschus moschatus*, 1 sample of *Abutilon x hybridum*, *Alcea rosea* and *Lavatera cretica*, for all of which an unidentified betaine was recorded by Gorham (1995). It is thus highly probable that this unidentified compound was trigonelline. The highest yield of trigonelline was from *Abelmoschus moschatus* (0.07%), but usually the values were very low and with such small amounts, the ^{1}H NMR spectroscopic assay procedure is subject to considerable error. Because of the low trigonelline contents and the small amount of plant material available of several of the species, confirmation of the identity of trigonelline by FAB mass spectometry was obtained only for *A. moschatus*, *Alcea rosea* and *Malva sylvestris*. Trigonelline was recorded for *Kitaibelia vitifolia*, *Malva moschata* and *M. sylvestris*, whereas Gorham (1995) did not detect the unidentified betaine in these species. In addition to the genera reported in this current study, 10 species of *Kosteletzkya* have recently been examined by Gorham (unpublished data) and all yielded more than 1%, dry weight, glycinebetaine. Trigonelline was detected in only two of the species examined (*K. racemosa* and *K. grantii*).

For a few of the species investigated (*Alcea rosea*, *Callirhoë involucrata*, *Malva sylvestris* and *Sidalcea reptans*), both aerial parts and roots were examined for betaines. In all cases, the yield of glycinebetaine was noticeably lower in the roots than in the aerial parts (Table 1). Moreover, although trigonelline was isolated from the aerial parts of *A. rosea* and *C. involucrata*, this betaine was not detected in the roots. The roots and aerial parts of *Salicornia europaea* L. (Chenopodiaceae) were also examined and, again, the glycinebetaine content of the aerial parts (1.5%) was higher than that of the roots (1.1%).

The flowers of *Hibiscus rosa-sinensis* and *Malva sylvestris* and the fruits of *H. esculentus* were tested for the presence of betaines. Glycinebetaine and trigonelline were detected, but in lower concentrations than those reported for the 'aerial parts', which excluded flowers and fruits (Table 1).

Rhodes and Hanson (1993) divided the betaine-yielding families and genera into those which accumulate betaines and those which do not. With the exception of *Abelmoschatus moschatus*, the results for all the species recorded here show that the Malvaceae should be classified as a betaine-accumulating family. *A. moschatus* was also the exception among the species tested in not containing glycinebetaine. Unlike some families examined, for example the Labiatae (Blunden et al., 1996) and Capparaceae (McLean et al., 1996), in which species in different genera often contain significantly different betaines, in the Malvaceae, all species tested, including examples in all 5 tribes (Jury, 1993), showed very similar betaine compositions.

3. Experimental

3.1. Plant material

The species examined and their places of collection are given in Table 1. Voucher samples of the plants studied are maintained in the herbarium of the Hampshire County Council Museums Service, Winchester, Hampshire, UK (Index Herbariorum code HCMS; accession number Bi 2000. 16).

3.2. Extraction, isolation, characterization and quantitative estimation of betaines

The plant materials were oven dried at 40 °C, powdered and extracted for 6 h with 80% MeOH. The methods of extraction, purification of the extracts by passage through a column of cation exchange resin, two-way TLC examination and isolation of the Dragendorff-positive compounds by prep.TLC have been described previously (Blunden et al., 1981, 1985).

The isolated compounds were identified by TLC, using appropriate reference compounds, ^{1}H NMR spectroscopy (D_2O; 270 or 400 MHz) and, when possible, FAB mass spectrometry.

Estimation of the content of each betaine present in the extracts was achieved using the ^{1}H NMR spectroscopic assay procedure of Blunden et al. (1986). With the quantities of dry plant material extracted (0.5–3 g), the limits of detection for glycinebetaine and trigonelline are approximately 0.0008 and 0.001%, respectively.

Acknowledgements

We thank the following for the supply of plant materials: the Director, University of Cambridge Botanic Garden; Mr. R. Clark, Greenway Gardens Nursery, Churston Ferrers, Devon; Mill Hill Plants, East Stoke, Newark, Nottinghamshire; A. & A. Thorp, Theddingworth, Leicestershire; and Chipchase Castle Nursery, Wark, Hexham, Northumberland. We are grateful to Mr. S. Sumner for technical assistance.

Calystegine distribution in some solanaceous species

Khalid Bekkouche[a], Youssef Daali[b], Samir Cherkaoui[b], Jean-Luc Veuthey[b], Philippe Christen[b,*]

[a]*Laboratory of Medicinal Plants and Phytochemistry, Department of Biology, Faculty of Sciences-Semlalia, PO Box 2390, Marrakech, Morocco*
[b]*Laboratory of Pharmaceutical Analytical Chemistry, University of Geneva, Bd d'Yvoy 20, 1211 Geneva 4, Switzerland*

Received 29 January 2001; received in revised form 7 June 2001

Abstract

The distribution of eight calystegines (A_3, A_5, B_1, B_2, B_3, B_4, C_1 and N_1) and their content was investigated by gas chromatography coupled to mass spectrometry (GC–MS) in *Datura metel*, *Atropa belladonna*, *Hyoscyamus albus*, *Mandragora autumnalis*, *Solanum sodomaeum*, *Withania somnifera*, *Withania frutescens* and *Brunfelsia nitida*. The most frequently encountered calystegines were A_3, B_1, B_2 and B_3, while distribution of N_1 and C_1 was more limited. In all the investigated samples, calystegines A_5 and B_4 were never detected. This report focuses for the first time on calystegines in *Withania* and *Brunfelsia* genera and in *Mandragora autumnalis and Solanum sodomaeum* species. © 2001 Published by Elsevier Science Ltd.

Keywords: *Atropa*; *Brunfelsia*; *Datura*; *Hyoscyamus*; *Mandragora*; *Solanum*; *Withania*; Solanaceae; GC–MS; Calystegines

1. Introduction

In the last 10 years, a large number of nitrogen-containing polyhydroxylated heterocyclic compounds have been isolated from plants (Nash et al., 1996). These natural products are competitive inhibitors of various glycosidases. The most efficient compounds are used to treat various diseases including diabetes, cancer, and viral infections (Jacob, 1995). Furthermore, these compounds exhibit additional activities, such as immunomodulatory properties and inhibition of glycolipid synthesis (Jacob, 1995). Among these metabolites, a new class of nortropane polyhydroxylated alkaloids, called calystegines, has recently been isolated from different species belonging to the Solanaceae, Convolvulaceae and Moraceae (Tepfer et al., 1988; Goldmann et al., 1990; Nash et al., 1993; Asano et al., 1994a,b; Schimming et al., 1998). Calystegines have been suggested to be nutritional mediators in the plant rhizosphere (plant-bacteria relationship) (Tepfer et al., 1988). Moreover, they possess glycosidase inhibiting properties (Asano et al., 1995, 1997a,b) and an allelopathic activity (Goldmann et al., 1996). To date, 14 calystegines have been isolated (Asano et al., 1997a,b). From a biosynthetic point of view, it is assumed that calystegines originate from the tropane alkaloid pathway (Dräger et al., 1994) although the exact details have not yet been confirmed.

Most calystegines have been isolated in several solanaceous species and found to occur in the following genera: *Atropa* (Tepfer et al., 1988; Molyneux et al., 1993; Dräger et al. 1994, 1995; Dräger, 1995; Nash et al., 1997), *Datura* (Nash et al., 1993), *Lycium* (Asano et al., 1997b), *Physalis* (Asano et al., 1995), *Hyoscyamus* (Dräger et al., 1994; Asano et al., 1996b), *Mandragora* (Dräger et al., 1995), *Scopolia* (Asano et al., 1996a), *Duboisia* (Kato et al., 1997), *Solanum* (Nash et al, 1993; Dräger et al., 1995; Keiner and Dräger, 2000) and *Nicandra* (Griffiths et al., 1996). In contrast, and to our knowledge, the occurrence of calystegines in *Brunfelsia* and *Withania* genera has not been reported. This paper discusses calystegine distribution in 8 solanaceous species belonging to 7 different genera. Particular attention is given to the occurrence of calystegines A_3, A_5, B_1, B_2, B_3, B_4, C_1 and N_1 (Fig. 1), which were identified by GC–MS, with authentic samples as reference material.

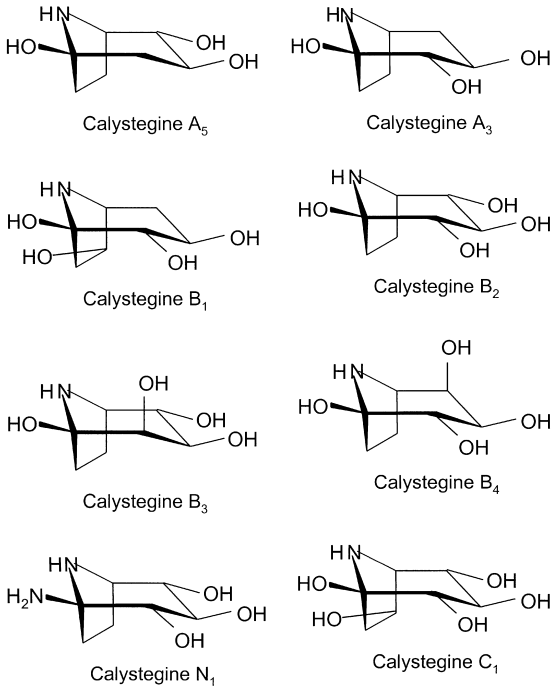

Fig. 1. Structures of investigated calystegines.

2. Results and discussion

Fig. 2 illustrates a typical gas chromatogram of a silylated calystegine standard mixture composed of calystegines A_3, A_5, B_1, B_2, B_3, B_4, C_1 and N_1 with octadecane as internal standard. The method allowed a good separation of the investigated compounds in less than 19 min . As expected, calystegines A (3 OH groups) eluted faster than calystegines B (4 OH groups) and calystegines C (5 OH groups). Indeed, since TMS derivatization occurs on the hydroxy groups, interaction of derivatized calystegines with the hydrophobic stationary phase increases with the number of hydroxy groups. The calystegine profile and the amount of individual alkaloid in each species are reported in Table 1 and Fig. 3. Calystegines were identified by comparing their retention times and mass spectra with those of silylated reference compounds, although no statement can be made on the absolute configuration of the alkaloids, nor even on their enantiomeric purity. Important qualitative and quantitative variations were observed among the species. The absence of reference material precluded the identification of other calystegines. None of the investigated calystegines were detected in *Datura metel* L. Tetrahydroxylated calystegine B_2 was present in all other species and its content varied significantly (from 19.1 to 110.9 μg/g dry wt.). The most frequently encountered calystegines were B_2, B_3, A_3 and B_1, while calystegines B_4 and A_5 were never observed.

Table 1
Distribution of calystegines in the investigated Solanaceae species

Plant species	Organ	Calystegines							
		A_3	A_5	B_1	B_2	B_3	B_4	C_1	N_1

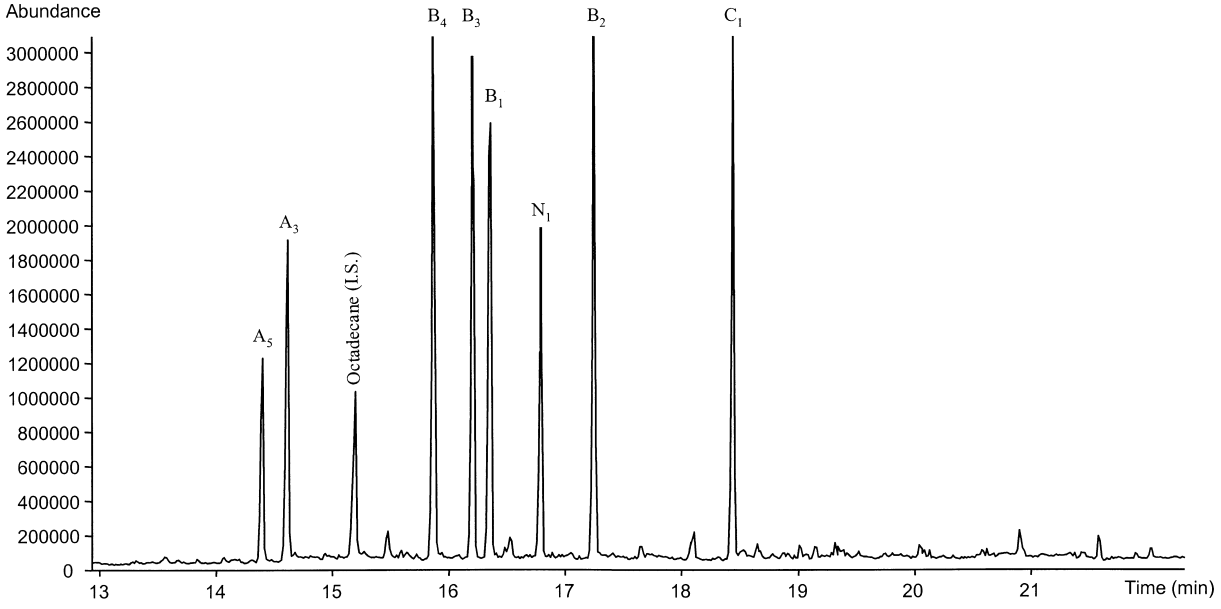

Fig. 2. Typical GC–MS chromatogram of a mixture of silylated standard calystegines with octadecane as internal standard.

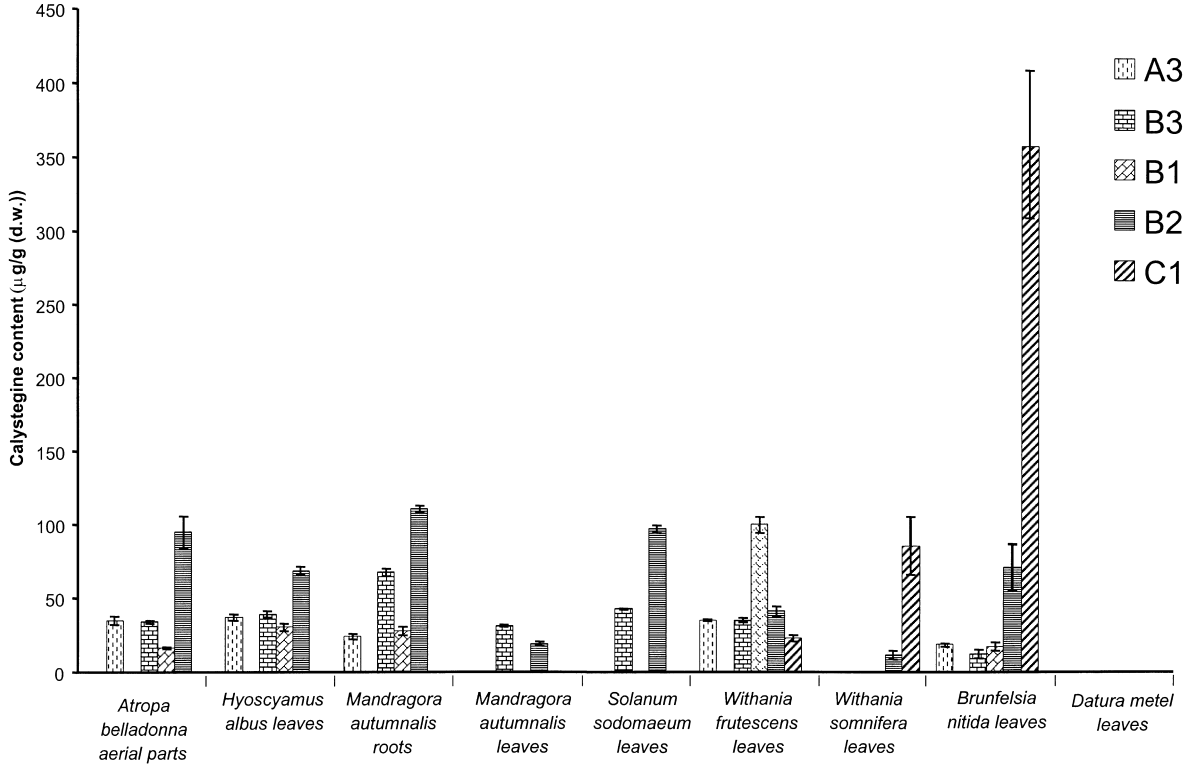

Fig. 3. Calystegine content in eight Solanaceae species.

In the aerial parts of *Atropa belladonna* L., the major compounds were A_3, B_2, B_3 and B_1. Calystegine B_4, previously reported by Nash et al. (1997), was not identified in our extract and calystegine N_1 was detected at a very low level. Calystegines N_1 and B_3 are reported in this species for the first time.

The presence of A_3 and other calystegines of the B-group in cultured roots of *Hyoscyamus albus* L. has already been reported elsewhere (Dräger et al., 1994). However, to the best of our knowledge, N_1 is reported in this species for the first time. Calystegines B_3 and B_2 were detected in leaves and roots of *Mandragora autumnalis* Bertol. B_1 and A_3 were also observed in the latter organ. Analogous studies (Dräger et al., 1995) reported the presence of calystegines B_1, B_2 and A_3 in leaves and roots of *M. officinarum*.

Calystegines B_2 and B_3 were detected in the leaves of *Solanum sodomaeum* L. which is consistent with similar articles reporting the presence of these metabolites in other *Solanum* species (Nash et al., 1993; Dräger et al., 1995; Keiner and Dräger, 2000).

The calystegine profiles of the two *Withania* species were found to be very different. Whilst calystegines B_2 and C_1 were identified in *W. somnifera* L. only, the calystegine spectrum of *W. frutescens* L. was more complex. All the investigated alkaloids, except A_5 and B_4, were found in the leaves *of W. frutescens*. This is the first time that calystegines are reported in the subtribe Solaninae of the Solanaceae family. Calystegines A_3, B_1, B_2, B_3 and C_1 were unambiguously identified in the leaves of *Brunfelsia nitida* Benth. The latter compound was in a high amount (357 μg/g dry wt.), and the most abundant calystegine found in all the investigated species. To the best of our knowledge, this class of compounds has not been reported in this genus before.

To date, calystegine N_1 has been isolated from *Hyoscyamus niger* (Asano et al., 1996b) and *Lycium chinense* (Asano et al., 1997b) only. In our study, this calystegine was found in three other species, *A. belladonna, H. albus* and *W. frutescens*. The distribution of pentahydroxlated calystegine C_1 was more limited as this compound was only found in *B. nitida*, *W. somnifera* and *W. frutescens*. Previous studies have also reported the presence of C_1 in *H. niger* (Asano et al., 1996b), *Duboisia leichhardtii* (Kato et al., 1997) and *Capsicum sp.* (Asano et al., 1997a).

It is noteworthy that most chromatograms of the different investigated species showed additional unidentified compounds with a similar fragmentation pattern to that of calystegines. Fig. 4 shows the chromatogram of *H. albus* leaf extract. Beside calystegines A_3, B_1, B_2, B_3 and N_1, some other peaks (X_1 and X_2) with specific calystegine MS profiles are also present. As shown in Fig. 5, calystegine N_1 (Fig. 5a) and unidentified compound X_1 (Fig. 5b) exhibit similar MS patterns. Beside fragment ions at m/z 390, 375 and 300,

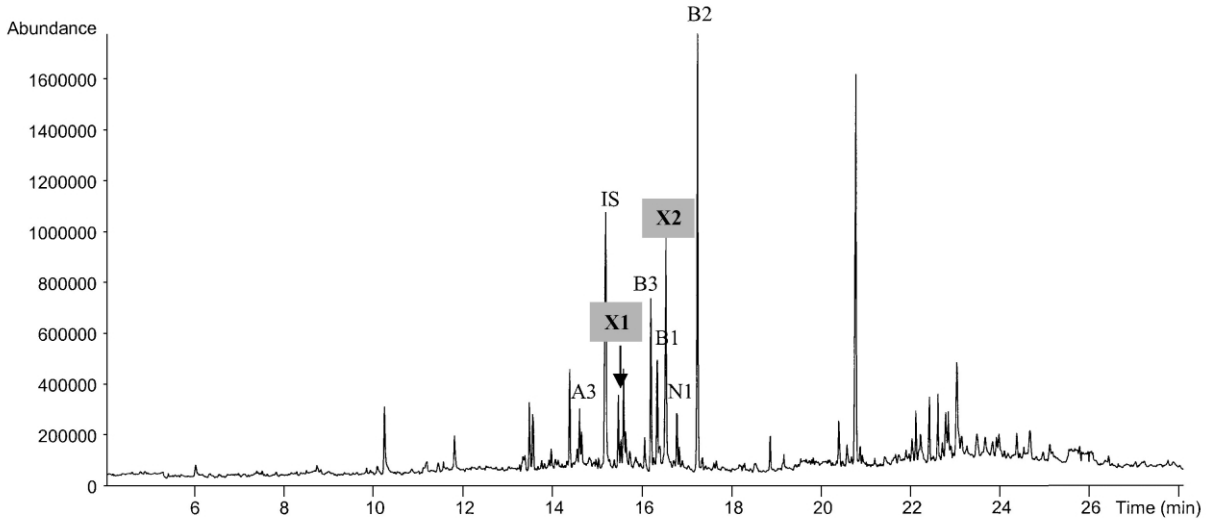

Fig. 4. Calystegine chromatogram from *Hyoscyamus albus* leaf extract.

corresponding to the molecular ion and to the loss of a methyl and dimethylsilyl groups, respectively, other fragments at *m*/*z* 186 and 83, specific of the exocyclic N-group, are found. Indeed, only calystegines belonging to the N-group exhibit such fragments which can be mainly attributed to the underivatized exocyclic amino group, as shown in the suggested fragmentation pattern of calystegines N_1 and X_1 (Fig. 6). As a result, unidentified peak X_1 may correspond to a new calystegine of the N-group, where the NH_2 function is located on the Δ^1-pyrrolinium skeleton at a different position to that of calystegine N_1. Moreover, fragment *m*/*z* 217 is typical of polyhydroxy compounds, as already described elsewhere (DeJongh et al., 1969).

Compound X_2 (Fig. 4) may correspond to a calystegine with a particular hydroxylation pattern. Its mass spectrum (Fig. 5C) clearly demonstrates that this compound does not belong to the N-group. To assess our assumption, further studies are to be performed. In particular isolation and structure characterization of these compounds should be carried out.

Before an overall chemotaxonomic conclusion regarding the occurrence of calystegines throughout this family can be drawn, further detailed phytochemical studies are required.

3. Experimental

3.1. Chemicals

Standard calystegines (A_3, A_5, B_1, B_2, B_3, B_4, $C_1$and N_1) were kindly donated by Dr. N. Asano (Hokuriku University, Kanazawa, Japan). All other chemicals and solvents were of analytical grade.

3.2. Plant material

Roots or aerial parts from wild plants were collected in different localities of Morocco for *Mandragora autumnalis*, *Datura metel*, *Hyoscyamus albus*, *Withania somnifera, Withania frutescens* and *Solanum sodomaeum*. Voucher specimens have been deposited in the Herbarium, Faculty of Sciences-Semlalia, Marrakech, Morocco. Seeds of *Brunfelsia nitida* and *Atropa belladonna* were provided by the Fairchild Tropical Garden, Miami, Florida. Plants were grown at the Station Fédérale de Recherches Agronomiques, Centre des Fougères, in Conthey, Switzerland.

3.3. Extraction

Air-dried and powdered plant material (20 g) was exhaustively extracted using Ultra-Turrax® homogenisation with water/methanol (80/20, v/v) for 30 min. After centrifugation, the supernatant was evaporated to dryness and applied to a cation exchange column (Dowex 50W X8-400 H^+ form). The column was washed with water to remove non-binding contaminants. Calystegines and bound compounds were eluted with 2 N NH_4OH. The concentrated residue was applied to an anion exchange column (Amberlite IRA-400 Cl^- form) and eluted with water to obtain a purified plant extract.

3.4. GC–MS procedure

GC–MS experiments were carried out essentially as described by Dräger (1995) without further validation from our side. An HP 5890 series II gas chromatograph and a HP 5972 mass selective detector (Hewlett-

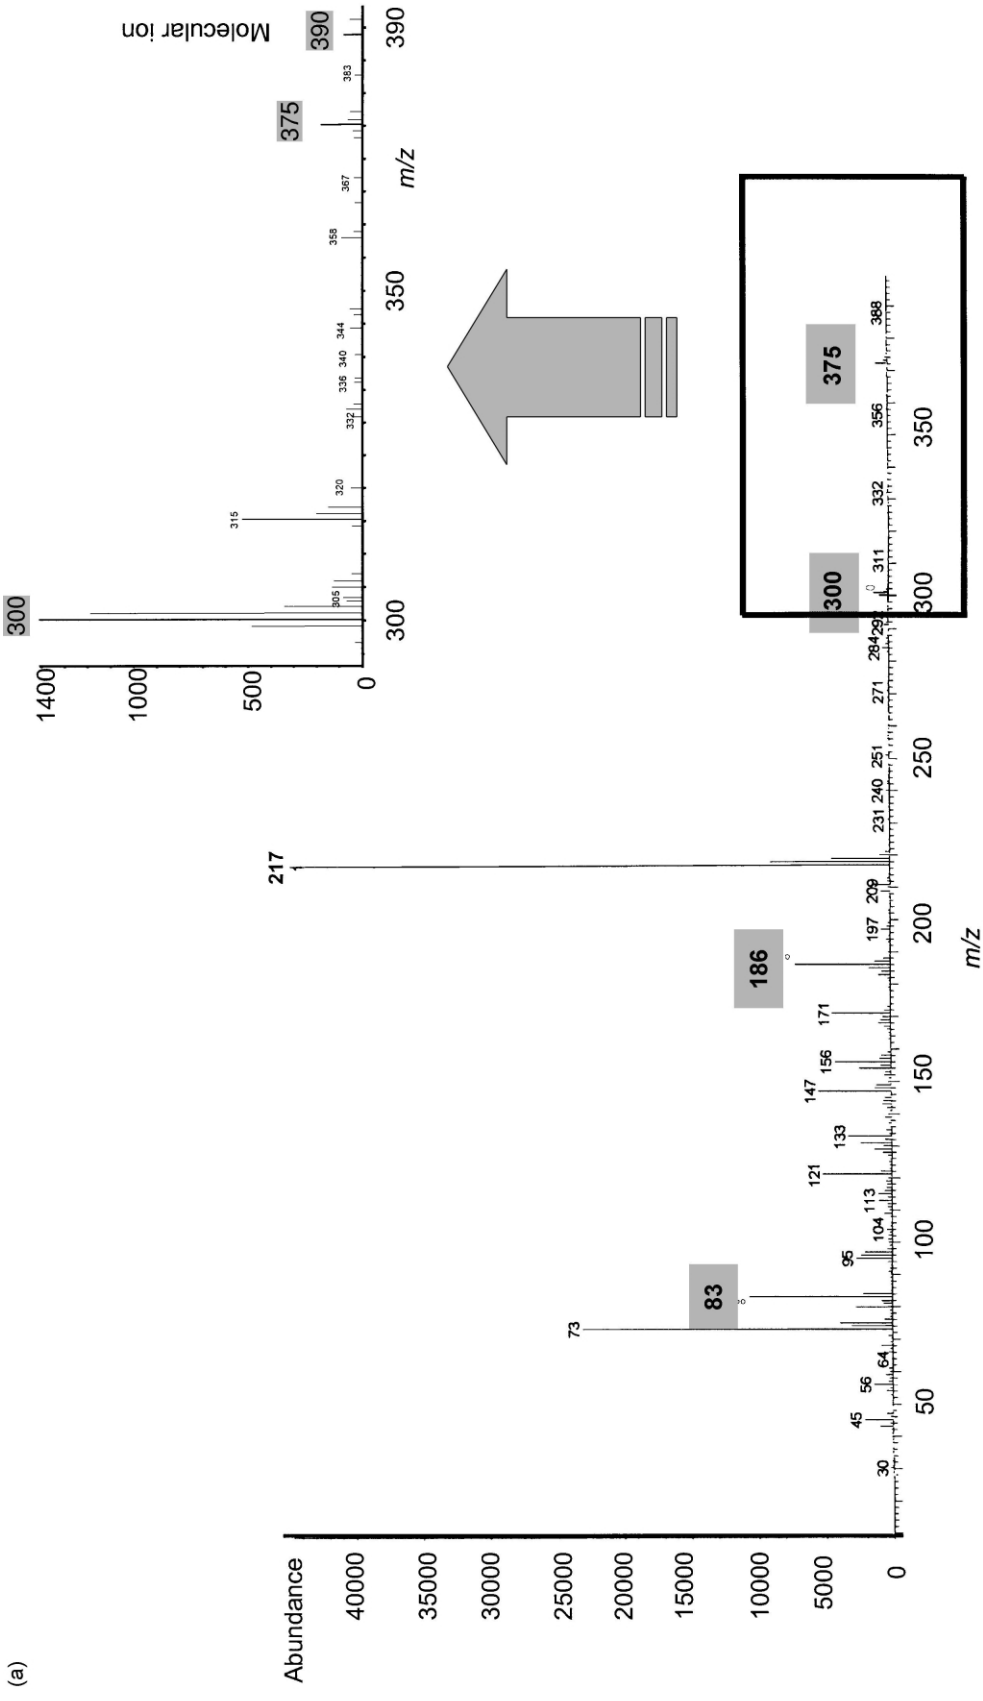

Fig. 5. Mass spectra of calystegines N_1 (a), X_1 (b) and X_2 (c).

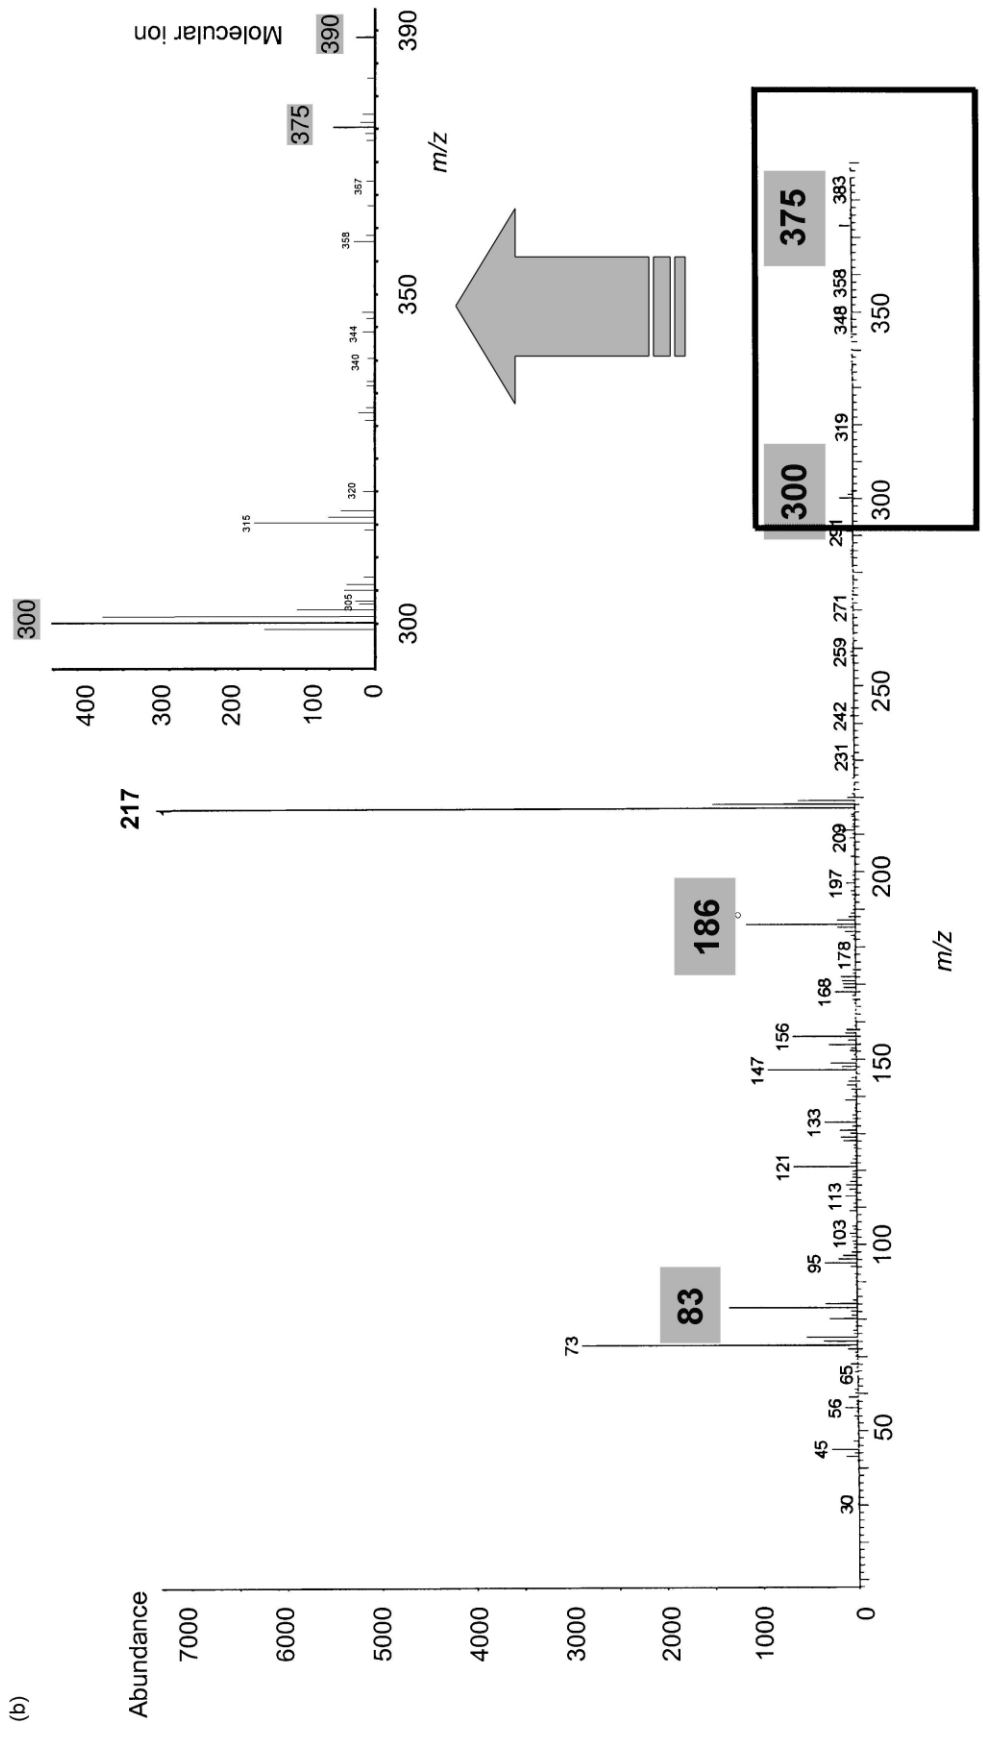

Fig. 5 (*continued*).

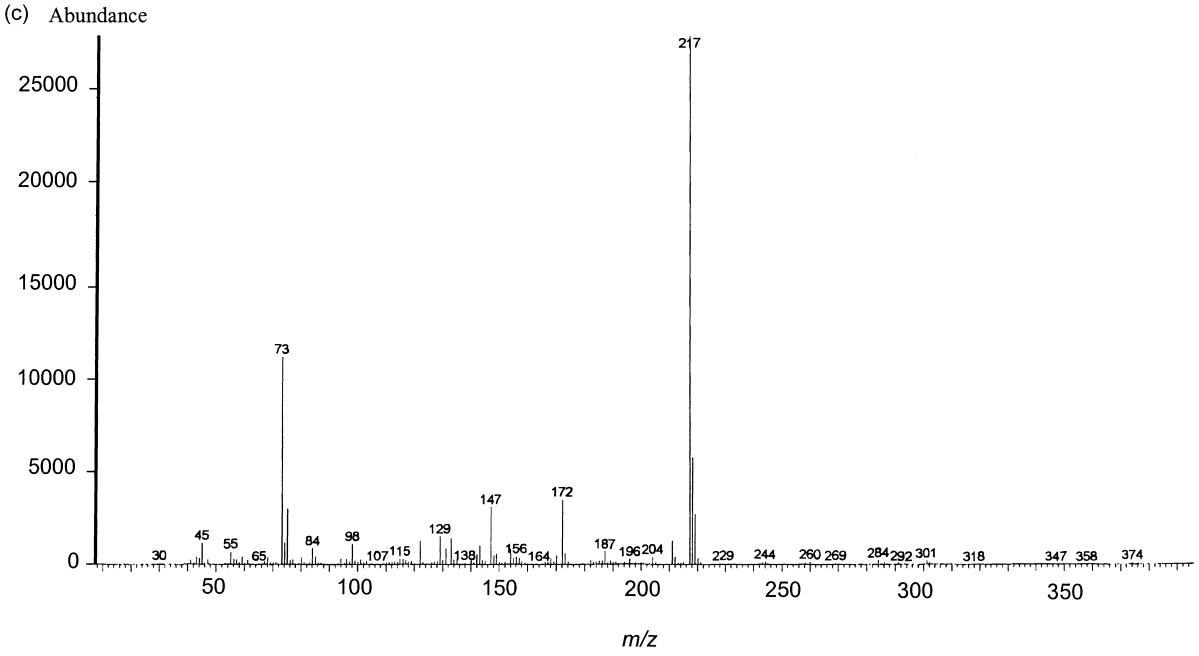

Fig. 5 (*continued*).

Packard) in the EI mode at 70 eV were used. Helium was used as carrier gas at a flow rate of 1 ml/min. The injection was performed in splitless mode at 250 °C and the injected volume was 1 μl. The column was a HP5-MS fused silica capillary (30 m × 0.25 mm i.d.) coated with a phenyl-methyl silicone phase (film thickness 0.25 μm).

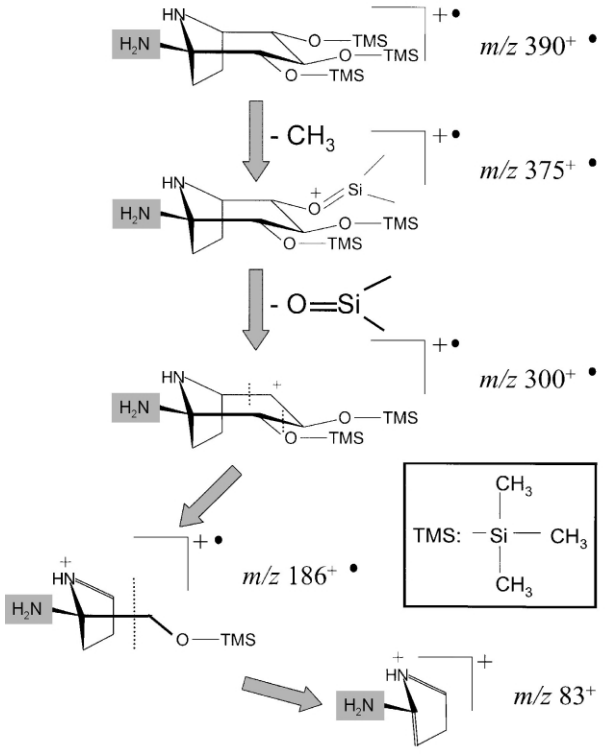

Fig. 6. Suggested fragmentation patterns of calystegines N_1 and X_1.

The temperature program was isothermal 100 °C for 5 min, 100–270 °C at 10 °C min^{-1} and isothermal 270 °C for 5 min. GC–MS interface was heated at 280 °C. Full-scan mode was used and the run time was 25 min.

3.4.1. Derivatization

In order to analyse calystegines by GC, a derivatization procedure was applied to form trimethylsilyl (TMS) ether derivatives, according to the procedure described elsewhere (Dräger, 1995). The reference compounds or the purified plant extract were dissolved in pyridine (1 ml) and mixed with hexamethyldisilazane (HMDS) and trimethylchlorosilane (10:1) to 2 ml and kept at 60 °C for 30 min. After evaporation to dryness under nitrogen at 50 °C, the residue was dissolved in heptane. An octadecane stock solution in heptane was added to the samples as internal standard to a final concentration of 100 μg/ml. The solutions were filtered through a 0.45 μm microfilter and 1 μl of each solution was subjected to GC–MS.

3.4.2. Calibration curves and quantitation

Calibration curves, reporting peak area ratio as a function of silylated calystegine concentration, were established between 10 and 200 μg/ml, in the presence of 100 μg/ml of octadecane as internal standard. No calibration curve was performed for calystegine N_1 which was only available in a small amount. In the studied concentration range, linearity was demonstrated with correlation coefficients higher than 0.992 for all the selected compounds (Table 2). The limit of detection (LOD), defined as the lowest concentration of analyte that can be clearly detected, is estimated as three times

Table 2
Regression data for the calibration curves

	Calystegines						
	A_3	A_5	B_1	B_2	B_3	B_4	C_1
Range (μg/ml)	10–200	10–200	10–200	10–200	10–200	10–200	10–200
Line	$y = 0.4944 + 0.0343\ x$	$y = -0.2159 + 0.0195\ x$	$y = -0.2071 + 0.0344\ x$	$y = -0.1795 + 0.0372\ x$	$y = -0.2867 + 0.0364\ x$	$y = -0.3910 + 0.0405\ x$	$y = 0.0574 + 0.0318\ x$

Abstract

Chemical modification of functional groups on linearol yielded several *ent*-kaurane derivatives. These compounds were tested for their antifeedant activity against larvae of *Spodoptera littoralis*. Although linearol did not influence the feeding behaviour of larvae, some of its derivatives showed significant antifeedant activity. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Lamiaceae; *ent*-Kaurane; Diterpenoids; Linearol; Chemical modifications; *Spodoptera littoralis*; Antifeedant

1. Introduction

ent-Kauranes are naturally occurring diterpenoids isolated from several families, such as Asteraceae and Lamiaceae. These compounds have attracted interest because of their structures and their biological activities as anti-tumorals, anti-HIV and anti-bacterials (Hanson, 1999).

The genus *Sideritis* (family Lamiaceae) is a rich source (Gonzales et al., 1990) of *ent*-kauranes. In a previous paper we described the isolation and identification (Bondì et al., 2000) of many *ent*-kauranes from several Turkish species of *Sideritis*. In the same paper, the antifeedant activity against larvae of *Spodoptera frugiperda* and *S. littoralis* was described. One of the diterpenes, sideroxol (**1**), isolated from *Sideritis akmanii* and *S. rubriflora* had potent antifeedant activity against *S. frugiperda*.

We were able to isolate large amounts of another *ent*-kaurane, linearol (**2**), from species of *Sideritis* (Bondì et al., 2000). This provided us with enough starting material to plan a structure–activity study in which we would modify the different functional groups on the *ent*-kaurane skeleton to evaluate their importance in the antifeedant activity of these compounds.

2. Results and discussion

Linearol (**2**), possessing an exocyclic double bond between carbons 16 and 17, was subjected to catalytic hydrogenation on 10% Pd/C. The reduction that diastereoselectively happened from the sterically less congested side (Piozzi et al., 1971), yielded a mixture of two compounds. After separation, the less polar compound was identified as 16-α-H dihydrolinearol (**3**); the second one (**4**), surprisingly was the transacetylated product of the former, in which the acetyl group migrated from position 18 to position 3.

Since the antifeedant sideroxol (**1**) had an epoxy group we performed an epoxidation on the double bond of linearol. Treatment with 3-chloroperbenzoic acid (MCPBA) in CH_2Cl_2 allowed us to generate, diastereoselectively, the epoxy ring (Piozzi et al., 1973; Gonzales et al., 1990). Also in this case, as described before, we obtained two compounds: epoxylinearol (**5**) and the 18→3 transacetylated product (**6**). Both **5** and **6** were subjected to acetylation to give the same triacetylderivative (**7**).

Next, in order to remove the exocyclic double bond we performed an ozonolysis. Treatment of **2** with ozone

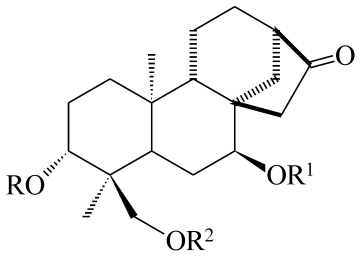
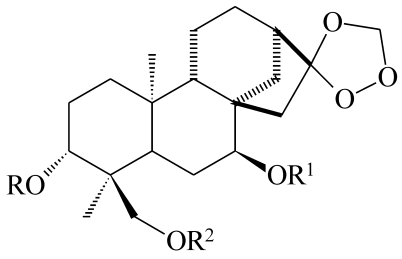
	R	R^1	R^2
3	H	H	Ac
4	Ac	H	H

	R	R^1	R^2
5	H	H	Ac
6	Ac	H	H
7	Ac	Ac	Ac



8 R = R^1 = H R^2 = Ac



9 R = R^1 = H R^2 = Ac

in CH_2Cl_2 resulted in a mixture of two products. One of them was the expected ketone (**8**), the other one showed in ^{1}H NMR spectrum a signal at δ 5.01 (*br s*, 2H) for acetalic protons and in ^{13}C NMR spectrum two signals at ppm 116.0 (*s*) and 93.2 (*t*) for two carbons bearing two oxygens. Therefore this compound was assigned the structure of ozonide (**9**). Furthermore, **9** was transformed to ketone (**8**) by reduction with Zn/AcOH. Isolation of ozonides is not common, due to their instability; in fact, we could not store **9** as after a few hours it started to decompose.

The composition of ester moieties on neoclerodane diterpenoids influences their antifeedant activity (Rodríguez et al., 1999). Therefore, to evaluate the effect of different esters on the activity of *ent*-kauranes, esterification reactions were undertaken on the two free hydroxyl groups of linearol.

Treatment of linearol with propanoyl chloride, triethylamine (TEA), 4-dimethylaminopyridine (DMAP) in CH_2Cl_2 gave 3,7-dipropanoate ester (**10**) and a mono esterified derivative. The ^{1}H and ^{13}C NMR spectra of the latter compound showed signals at δ 3.60 (*t*, J = 3.8 Hz, H-7) and at δ 4.86 (*dd*, J = 11.2 and 5.2 Hz, H-3) and ppm 76.7 (*d*, C-7) and 74.2 (*d*, C-3), clearly indicating that only 3-OH was esterified; therefore, we assigned to it structure (**11**). Similarly, we prepared

3-mono- and 3,7-diester derivatives (**12**), (**13**), (**14**), (**15**), (**16**) and (**17**) using different acyl chlorides such as butanoyl, benzoyl and 4-methoxybenzoyl chlorides. The same reactions performed with 2-furoyl chloride, 3-nitrobenzoyl chloride, 4-cyanobenzoyl chloride and 4-nitrobenzoyl chloride allowed us to isolate compounds (**18**), (**19**), (**20**) and (**21**) in which both hydroxyl groups were esterified. Monoacyl derivatives were not obtained.

Acylation of linearol with tigloyl chloride was not an easy transformation. In fact, treatment of **2** with tiglic acid chloride, TEA, DMAP in CH_2Cl_2 gave an inseparable mixture of two compounds. The ^1H and ^{13}C NMR spectra showed that esterification was achieved only in position 3 (δ_H 4.86 *dd*, H-3; δ_C 74.3 *d*/74.4 *d* C-3) and that the ester moiety was the $\Delta_{3'\text{-}4'}$ isomer of tiglate (δ_C 137.2 *d*/137.1 *d*, C-3′; 115.9 *t*/115.7 *t*, C-4′). There-

fore, compound (**22**) was an epimeric mixture at C-2′ due to the formation of a stereogenic center, a consequence of isomerization. Isomerization of a tigloyl moiety has been already observed by other authors (Hatakeyama et al., 1985).

A different behaviour was observed when linearol and tigloyl chloride were refluxed in toluene for 30 min. In this case an inseparable mixture of di-tiglates (**23**) and (**24**) was obtained, in which the double bond between carbons 16 and 17 was hydrated to give a tertiary hydroxyl group in C-16 (δ_H 1.35, CH_3-17; δ_C 78.6 *s*/78.7 *s*, C-16, 24.3 *q*, C-17). Compound (**23**) was an isomer of **24** in which the acetyl group migrated to position 3 and the tiglic ester was at position 18. Finally, by refluxing linearol, TEA and tigloyl chloride in toluene for 24 h two compounds were isolated. The more polar one was identified as 3,7-ditigloyl-linearol (**25**); the other one (**26**) was the transesterification isomer of the former with the tigloyl moiety in position 18 and the acetyl in position 3.

3. Biological activity

The effects of compounds (**2**–**8**, **10**, **11**, **13**–**22**, **25**–**26**) on the feeding behaviour of larvae of *S. littoralis* are reported in Table 2. Linearol did not influence the feeding behaviour of *S. littoralis*. However, modification to the substitutions on the molecule resulted in a range of analogue esters that differ in their activity when tested at 100 ppm. We selected this dose to allow us to better discriminate among the effects of different substances although, in our experience, many diterpenes show activity at 1000 ppm.

Compounds with a ketone or epoxide group had significant antifeedant activity except for **7**. Modification to the substitutions at R (C-3), R^1 (C-7) or R^2 (C-18) altered the activity of the compounds but there were no clear trends in structure–activity relationship. For example, increasing the length of the substitution at R (**11** vs. **22**), when the substitutes at R^1 and R^2 did not change, resulted in an increase in antifeedant activity. However, the activity of compounds varied when similar substitutes were added to both R and R^1, while R^2 was an acetyl group. Of the compounds tested, **26** was the most active; this was the only compound in which the substitution at R^2 was neither an hydroxy nor an acetyl group. This suggests that the composition and position of the functional groups at C-3, C-7 and C-18 modulate the activity of the compound. This is supported by previous research into the antifeedant activity of *neo*-clerodanes from *Teucrium* (Simmonds et al., 1989; Simmonds and Blaney, 1992), *Scutellaria* (Cole et al., 1990) or *Salvia* (Simmonds et al., 1996). Whilst there appears to be no clear structure–activity relationship the

[b] *, These assignments may be reversed.

data from *neo*-clerodanes suggests that the composition of the substitution at C-4 (C-18) is important. Many of the *neo*-clerodanes with potent antifeedant activity have an epoxide substitution at C-4 but, to date, no *ent*-kauranes with an epoxide at this position have been tested for antifeedant activity against *S. littoralis*. However, sideroxol, one of the most potent *ent*-kaurane diterpenoids tested for antifeedant activity in the binary choice assay used in this study, has an epoxide at C-15–C-16. Although this compound showed potent antifeedant activity, this was against larvae of *Spodoptera frugiperda* (Feeding Index = 54 (4.3), $P < 0.05$) not *S. littoralis* (Feeding Index = 9 (15.9), (Bondì et al., 2000). In the present study no compounds had the C-15–C16 epoxide present in sideroxol, but the two compounds with an epoxide at C-16 (**5** and **6**) had antifeedant feeding activity against *S. littoralis* (Table 2). However, the antifeedant activity of the *ent*-kauranes cannot be totally determined by the presence of an epoxide, as other active antifeedant compounds (**8**, **14**, **18**, **20**, **21** and **26**) lacked this group. Whether the presence of a C-15–C-16 epoxide or addition of an epoxide at C-4 would enhance the activity of the *ent*-kaurenes justifies investigation.

A comparison of the activity of compounds **25** with **26**, the most potent antifeedant in the present study, illustrates how altering the position of substitutions on the molecule can alter its potency. For example, exchange of the acetyl group at C-18 (**25**) with the tigloyl group at C-3 (**26**) resulted in a significant increase in antifeedant activity. This would suggest that the position of these groups influence the ability of the molecule to stimulate receptors on the taste neurones of *S. littoralis*. The position of these groups alters the polarity of the molecule, as compound **26** is less polar

than **25**. Thus, whether changes in the polarity of the compound rather than the position or composition of specific functional groups on the molecule influence activity is not known.

To test the effect of compounds on insect feeding we usually test compounds dry on an inert substrate (glass–fibre discs). This avoids interactions between the test compound and compounds in leaf material but it also avoids problems associated with having to apply solvents to the insect mouth parts that we know could themselves modulate feeding by damaging insect taste neurones, such as high concentrations of ethanol. In our bioassay we apply a set aliquot (100 μl) of test compounds to the discs and always start with a dose of 100 ppm. The test compound is dissolved in an appropriate solvent, which will differ among compounds. An aliquot (100 μl) of the solvent is also applied to the control discs. The discs are dried before being presented to the insect. Although this type of bioassay is only suitable for a range of lepidopteran larvae and locusts it does enable us to provide quantitative comparative data about the potency of compounds for use in structure–activity relationship studies. However, the influence that compounds have on the acceptance or rejection of the discs by insects could depend on their solubility in the saliva produced during feeding or in the fluid that bathes their taste receptors. The composition of these fluids could be modified by the diet the insects are reared on, which is why we try and standardise the diet fed to our insects (Simmonds et al., 1992). As yet we known very little about the role these fluids have in modulating the ability of insects to detect compounds in their food and thus feeding behaviour of leaf chewing insects (Chapman and de Boer, 1995).

21	34.0	(17.82)*
22	36.6	(25.91)
25	−15.5	(8.21)
26	74.1	(12.93)**

[a] Feeding Index ((C−T)/(C+T))%; significant antifeedant activity *$P < 0.05$, **$P < 0.01$; significant phagostimulant activity $^{\#}P < 0.05$, Wilcoxon matched-pairs test.

Despite these limitations in our knowledge the present study has shown that *ent*-kauranes can have potent antifeedant activity in a binary choice bioassay. For example, compound **26** at 100 ppm has elicited a higher Feeding Index than ajugarin I (Feeding Index = 43 (7.3), Simmonds et al., 1989) but not a high as Jodrellin B (Feeding Index = 100 (0.0), Cole et al., 1990) against *S. littoralis*. Further research is required to understand the molecular mechanism associated with the observed behavioural responses to these and other diterpenoids and whether different species of insects will show similar behavioural responses to these compounds.

4. Experimental

4.1. General experimental procedures

IR spectra (film) were registred on a Shimadzu FT–IR 8300 spectrophotometer. ^{1}H NMR spectra were recorded in $CDCl_3$ solution using a Bruker AC 250 E apparatus at 250 MHz and chemical shifts were reported with respect to residual $CHCl_3$ (δ 7.27). ^{13}C NMR spectra were recorded in $CDCl_3$ on the same apparatus at 62.7 MHz and chemical shifts were reported with respect to solvent signals (δ_{CDCl_3} 77.0). ^{13}C NMR assignments were determined by DEPT spectra. MS were recorded on a Finnigan TSQ70 instrument (70 eV, direct inlet). Melting points were determined on a Kofler block and are uncorrected. Merck Si gel no. 7734 (70–230 mesh) deactivated with 15% H_2O wt./v was used for column chromatography. An ozone generator Fischer 500 M has been used to perform ozonolysis. Linearol was isolated from the following species: *Sideritis akmanii, S. niveotomentosa, S. brevidens, S. rubriflora* and *S. gulendamii* (Bondì et al., 2000).

CH_2Cl_2 was dried by distillation over calcium hydride. Toluene was dried by distillation over molecular sieves (3 Å).

4.2. Reduction of linearol (2) to compounds 3 and 4

To a solution of **2** (50 mg) in MeOH (20 ml) was added Pd/C 10% (30 mg). This solution was subjected to a H_2 pressure (3 atm) in a Parr apparatus for 24 h. After filtration, the solvent was evaporated to give a mixture which was resolved by CC (silica gel, petrol–EtOAc 3:2 as eluent) yielding compound **3** (34 mg) and **4** (14 mg) in order of increasing polarity.

Compound **3**: amorphous solid. IR ν_{max} (film) cm^{-1}: 3423, 2970, 2930, 2840, 1712, 1438, 1373, 1255, 1172, 1039, 1018, 979. EI–MS *m/z* (rel. int.): 364 $[M]^+$ (1), 346 $[M–H_2O]^+$ (5), 328 $[M–2(H_2O)]^+$ (14), 304 $[M–AcOH]^+$ (20), 286 $[M–AcOH–H_2O]^+$ (56), 268 $[M–AcOH–2(H_2O)]^+$ (100), 255 (42), 235 (83), 217 (36). ^{1}H NMR ($CDCl_3$): δ 3.52 (*dd*, 1H, $J = 9.0$ and 5.4 Hz, H-3β), 3.59 (*t*, 1H, $J = 3.0$ Hz, H-7α), 1.01 (*d*, 3H, $J = 6.4$ Hz, Me-17), 4.07 (*d*, 1H, $J = 11.6$ Hz, H_A-18), 3.96 (*d*, 1H, $J = 11.6$ Hz, H_B-18), 0.75 (*s*, 3H, Me-19), 1.05 (*s*, 3H, Me-20), 2.09 (*s*, 3H, OAc). ^{13}C NMR: Table 1a.

Compound **4**: amorphous solid. IR ν_{max} (film) cm^{-1}: 3430, 2970, 2930, 2840, 1715, 1438, 1373, 1258, 1170, 1036, 1020, 985. EI–MS *m/z* (rel. int.): $[M]^+$ absent, 346 $[M–H_2O]^+$ (2), 328 $[M–2(H_2O)]^+$ (2), 304 $[M–AcOH]^+$

(4), 286 $[M–AcOH–H_2O]^+$ (10), 268 $[M–AcOH–2(H_2O)]^+$ (10), 255 (100), 241 (30), 213 (21). ^1H NMR ($CDCl_3$): δ 4.91 (*dd*, 1H, $J=11.2$ and 5.4 Hz, H-3β), 3.60 (*t*, 1H, $J=3.0$ Hz, H-7α), 1.01 (*d*, 3H, $J=6.4$ Hz, Me-17), 3.33 (*d*, 1H, $J=12.4$ Hz, H_A-18), 2.99 (*d*, 1H, $J=12.4$ Hz, H_B-18), 0.67 (*s*, 3H, Me-19), 1.08 (*s*, 3H, Me-20), 2.07 (*s*, 3H, OAc). ^{13}C NMR: Table 1a.

4.3. Epoxidation of linearol (2) to compounds (5) and (6)

To a solution of **2** (250 mg) in CH_2Cl_2 (15 ml) was added MCPBA 70% (170 mg). After stirring overnight, the solution was extracted with a saturated aqueous solution of $NaHCO_3$ (3×10 ml) and washed with H_2O (3×10 ml). The organic layer was dried with dry Na_2SO_4 and evaporated under reduced pressure giving a residue which was purified by CC (silica gel, diethyl ether as eluent) yielding compounds **5** (140 mg) and **6** (92 mg).

Compound **5**: amorphous solid. IR ν_{max} (film) cm^{-1}: 3480, 3267, 3040, 2931, 2866, 1714, 1384, 1371, 1255, 1049, 1018. EI–MS *m/z* (rel. int.): 378 $[M]^+$ (1), 360 $[M–H_2O]^+$ (5), 318 $[M–AcOH]^+$ (36), 300 $[M–H_2O–AcOH]^+$ (55), 282 $[M–AcOH–2(H_2O)]^+$ (97), 270 (100), 249 (96), 231 (41), 121 (85). ^1H NMR ($CDCl_3$): δ 3.54 (*dd*, 1H, $J=9.0$ and 5.2 Hz, H-3β), 3.73 (*t*, 1H, $J=3.8$ Hz, H-7α), 2.91 (*d*, 1H, $J=4.5$ Hz, H_A-17), 2.82 (*d*, 1H, $J=4.5$ Hz, H_B-17), 4.06 (*d*, 1H, $J=11.8$ Hz, H_A-18), 3.99 (*d*, 1H, $J=11.8$ Hz, H_B-18), 0.77 (*s*, 3H, Me-19), 1.08 (*s*, 3H, Me-20), 2.08 (*s*, 3H, OAc). ^{13}C NMR: Table 1a.

Compound **6**: amorphous solid. IR ν_{max} (film) cm^{-1}: 3388, 3040, 2933, 2868, 1724, 1369, 1250, 1053, 1024, 1004, 953, 736. EI–MS *m/z* (rel. int.): 378 $[M]^+$ (1), 360 $[M–H_2O]^+$ (2), 318 $[M–AcOH]^+$ (4), 300 $[M–AcOH–H_2O]^+$ (12), 282 $[M–AcOH–2(H_2O)]^+$ (22), 270 (100), 255 (40), 213 (11), 182 (12), 159 (12), 145 (19), 119 (22). ^1H NMR ($CDCl_3$): δ 4.90 (*dd*, 1H, $J=11.2$ and 5.2 Hz, H-3β), 3.72 (*t*, 1H, $J=3.8$ Hz, H-7α), 2.91 (*d*, 1H, $J=4.6$ Hz, H_A-17), 2.79 (*d*, 1H, $J=4.6$ Hz, H_B-17), 3.29 (*d*, 1H, $J=12.6$ Hz, H_A-18), 2.96 (*d*, 1H, $J=12.6$ Hz, H_B-18), 0.67 (*s*, 3H, Me-19), 1.07 (*s*, 3H, Me-20), 2.05 (*s*, 3H, OAc). ^{13}C NMR: Table 1a.

4.4. Acetylation of compounds 5 and 6

Fifty milligrams of compounds **5** and **6** were treated separately with 5 ml of a mixture of pyridine–acetic anhydride (3:2) yielding, after evaporation under reduced pressure, the same compound **7** (98% yield).

Compound **7**: amorphous solid. IR ν_{max} (film) cm^{-1}: 3040, 2939, 2868, 1734, 1732, 1371, 1246, 1030, 962, 902, 734. EI–MS *m/z* (rel. int.): 462 $[M]^+$ (1), 402 $[M–AcOH]^+$ (2), 342 $[M–2(AcOH)]^+$ (5), 329 (2), 300 (2), 282 $[M–3(AcOH)]^+$ (23), 269 (10), 119 (8), 95 (12), 43 (100). ^1H NMR ($CDCl_3$): δ 4.65 (*dd*, 1H, $J=11.2$ and 5.2 Hz, H-3β), 4.79 (*t*, 1H, $J=3.8$ Hz, H-7α), 2.80 (*d*, 1H, $J=4.5$ Hz, H_A-17), 2.72 (*d*, 1H, $J=4.5$ Hz, H_B-17), 3.84 (*d*, 1H, $J=11.9$ Hz, H_A-18), 3.44 (*d*, 1H, $J=11.9$ Hz, H_B-18), 0.75 (*s*, 3H, Me-19), 1.04 (*s*, 3H, Me-20), 1.95 (*s*, 3H, OAc), 1.94 (*s*, 3H, OAc), 1.92 (*s*, 3H, OAc). ^{13}C NMR: Table 1a.

4.5. Ozonolysis of 2 to compounds 8 and 9

A current of O_2/O_3 (30 l/h) was bubbled into a solution of **2** (300 mg) in dry CH_2Cl_2 at −78 °C for 30 min. After evaporation of the solvent under reduced pressure, the residue was purified by CC (silica gel, gradient elution from petrol ether–AcOEt 2:3 to pure AcOEt) giving, in order of increasing polarity, 87 mg of compound **8** and 186 mg of compound **9**.

Compound **8**: white crystals, mp 155–158 °C. IR ν_{max} (film) cm^{-1}: 3433, 2935, 2870, 1732, 1720, 1371, 1251, 1047, 837, 734. EI–MS *m/z* (rel. int.): 364 $[M]^+$ (1), 346 $[M–H_2O]^+$ (4), 328 $[M–2(H_2O)]^+$ (5), 304 $[M–AcOH]^+$ (6), 286 $[M–AcOH–H_2O]^+$ (18), 268 $[M–AcOH–2(H_2O)]^+$ (10), 235 (15), 217 (11), 119 (13), 107 (20), 95 (26), 43 (100). ^1H NMR ($CDCl_3$): δ 3.51 (*dd*, 1H, $J=9.0$ and 5.2 Hz, H-3β), 3.66 (*t*, 1H, $J=3.8$ Hz, H-7α), 2.37 (*m*, 1H, H-13), 2.10 (*br s*, 2H, H-15), 3.99 (*d*, 1H, $J=11.6$ Hz, H_A-18), 3.92 (*d*, 1H, $J=11.6$ Hz, H_B-18), 0.72 (*s*, 3H, Me-19), 1.06 (*s*, 3H, Me-20), 2.02 (*s*, 3H, OAc). ^{13}C NMR: Table 1a.

Compound **9**: white solid, mp 88–92. IR ν_{max} (film) cm^{-1}: 3445, 2937, 2870, 1735, 1372, 1248, 1040, 1005, 956, 734. EI–MS *m/z* (rel. int.): $[M]^+$ absent, 364 $[M–CH_2O_2]^+$ (1), 346 $[M–CH_2O_2–H_2O]^+$ (1), 304 $[M–CH_2O_2–AcOH]^+$ (3), 286 $[M–CH_2O_2–AcOH–H_2O]^+$ (5), 268 $[M–CH_2O_2–AcOH–2(H_2O)]^+$ (3), 245 (7), 227 (10), 145 (12), 119 (10), 107 (15), 91 (20), 43 (100). ^1H NMR ($CDCl_3$): δ 3.48 (*dd*, 1H, $J=9.0$ and 5.2 Hz, H-3β), 3.55 (*t*, 1H, $J=3.8$ Hz, H-7α), 5.01 (*br s*, 2H, H-17), 3.91 (*d*, 1H, $J=11.6$ Hz, H_A-18), 3.89 (*d*, 1H, $J=11.6$ Hz, H_B-18), 0.67 (*s*, 3H, Me-19), 0.98 (*s*, 3H, Me-20), 2.00 (*s*, 3H, OAc). ^{13}C NMR: Table 1a.

4.6. Transformation of compound 9 into compound 8

Twenty milligrams of ozonide **9** were dissolved in 10 ml of glacial acetic acid and added to zinc powder. After 30 min the conversion of **9** to **8** was complete. This was confirmed by TLC comparison with an authentic sample of **8**.

4.7. General esterification procedure

Linearol (150 mg) was solubilized in 10 ml of dry CH_2Cl_2 and added with 1 eq. of DMAP (56 mg), 25 eq. of TEA (1.5 ml) and the appropriate acyl chloride (4 eq.) at room temperature under argon atmosphere. After stirring overnight, the reaction was subjected to usual work-up adding H_2O and extracting with AcOEt; finally, the organic layer was dried over Na_2SO_4 and

evaporated under reduced pressure. Generally, the residue was purified by CC (silica gel, mixtures of petrol–AcOEt as eluent). This procedure gave the following ester derivatives:

Compounds **10** and **11**. Treatment of **2** with propanoyl chloride gave a mixture of two compounds which were separated by CC (silica gel, petrol ether–AcOEt 4:1 as eluent) giving 125 mg of **10** and 47 mg of **11**.

Compound **10**: amorphous solid. IR ν_{max} (film) cm^{-1}: 2937, 2858, 1732, 1660, 1462, 1371, 1230, 1195, 1178, 1150, 1070, 1041, 1024, 875. EI–MS *m/z* (rel. int.): 474 $[M]^+$ (1), 400 $[M–CH_3CH_2COOH]^+$ (9), 340 $[M–CH_3CH_2COOH–AcOH)]^+$ (2), 326 $[M–2(CH_3CH_2COOH)]^+$ (93), 283 (2), 266 $[M–2(CH_3CH_2COOH)–AcOH]^+$ (82), 253 (28), 185 (22), 119 (31), 105 (28), 43 (100). ^1H NMR ($CDCl_3$): δ 4.77 (*dd*, 1H, $J=11.2$ and 5.2 Hz, H-3β), 4.77 (*t*, 1H, $J=3.8$ Hz, H-7α), 2.70 (*m*, 1H, H-13), 2.17 (*dt*, 1H, $J=17$ and 2.2 Hz, H_A-15), 2.13 (*dt*, 1H, $J=17$ and 2.2 Hz, H_B-15), 4.82 (*br s*, 1H, H_A-17), 4.81 (*br s*, 1H, H_B-17), 3.92 (*d*, 1H, $J=11.8$ Hz, H_A-18), 3.53 (*d*, 1H, $J=11.8$ Hz, H_B-18), 0.83 (*s*, 3H, Me-19), 1.09 (*s*, 3H, Me-20), 2.02 (*s*, 3H, OAc), 2.31 (*q*, 2H, $J=7.5$ Hz, H-2′), 1.16 (*t*, 3H, $J=7.5$ Hz, H-3′), 2.30 (*q*, 2H, $J=7.5$ Hz, H-2″), 1.11 (*t*, 3H, $J=7.5$ Hz, H-3″). ^{13}C NMR: Table 1b.

Compound **11**: amorphous solid. IR ν_{max} (film) cm^{-1}: 3435, 2937, 2858, 1730, 1660, 1462, 1423, 1371, 1230, 1180, 1041, 1024. Compound **21**. Treatment of **2** with 4-nitrobenzoyl chloride gave 260 mg of **21**. Amorphous solid. IR ν_{max} (film) cm^{-1}: 3057, 2935, 2862, 1743, 1722, 1656, 1606, 1529, 1344, 1276, 1234, 1118, 1103, 1041, 1014, 873, 842, 785, 736, 719. EI–MS *m/z* (rel. int.): $[M]^+$ absent, 493 $[M–NO_2C_6H_4COOH]^+$ (1), 433 $[M–NO_2C_6H_4COOH–AcOH]^+$ (2), 326 $[M–2(NO_2C_6H_4COOH)]^+$ (40), 266 $[M–2(NO_2C_6H_4COOH)–AcOH]^+$ (100), 251 (57), 185 (35), 150 (82). ^1H NMR ($CDCl_3$): δ 5.02 (*dd*, 1H, *J* = 11.2 and 5.2 Hz, H-3β), 5.04 (*t*, 1H, *J* = 3.8 Hz, H-7α), 2.77 (*m*, 1H, H-13), 2.33 (*dt*, 1H, *J* = 17 and 2.2 Hz, H_A-15), 2.20 (*dt*, 1H, *J* = 17 and 2.2 Hz, H_B-15), 4.85 (*br s*, 1H, H_A-17), 4.77 (*br s*, 1H, H_B-17), 3.86 (*d*, 1H, *J* = 11.7 Hz, H_A-18), 3.59 (*d*, 1H, *J* = 11.7 Hz, H_B-18), 1.00 (*s*, 3H, Me-19), 1.22 (*s*, 3H, Me-20), 1.21 (*s*, 3H, OAc), 8.23 (*br d*, 2H, *J* = 6.8 Hz, H-2′ and H-6′), 8.33 (*br d*, 2H, *J* = 6.8 Hz, H-3′ and H-5′), 8.11 (*br d*, 2H, *J* = 6.8 Hz, H-2″ and H-6″), 8.24 (*br d*, 2H, *J* = 6.8 Hz, H-3″ and H-5″). ^{13}C NMR: Table 1c.

Compound **22**. Treatment of **2** with tigloyl chloride gave 92 mg of **22** an unsemixture of two compounds in a 3:2 ratio. Amorphous solid. IR ν_{max} (film) cm^{-1}: 3531, 2981, 2935, 2877, 1732, 1656, 1639, 1458, 1371, 1250, 1193, 1049, 995, 977, 873, 756. EI–MS *m/z* (rel. int.): 444 $[M]^+$ (1), 426 $[M–H_2O]^+$ (3), 344 $[M–C_4H_7COOH]^+$ (8), 326 $[M–C_4H_7COOH\text{-}H_2O]^+$ (92), 284 $[M–C_4H_7COOH–AcOH]^+$ (23), 266 $[M–C_4H_7COOH–H_2O–AcOH]^+$ (100), 253 (32), 223 (14), 83 (40). ^1H NMR ($CDCl_3$): δ 4.86 (*dd*, 1H, $J=11.2$ and 5.2 Hz, H-3β), 3.57 (*t*, 1H, $J=3.8$ Hz, H-7α), 2.66 (*m*, 1H, H-13), 2.25 (*br s*, 2H, H-15), 4.80 (*br s*, 1H, H_A-17), 4.77 (*br s*, 1H, H_B-17), 4.07 (*d*, 1H, $J=11.6$ Hz, H_A-18), 3.45 (*d*, 0.6H, $J=11.6$ Hz, H_B-18, 22A epimer), 3.49 (*d*, 0.4H, $J=11.6$ Hz, H_B-18, 22B epimer), 0.81 (*s*, 3H, Me-19), 1.07 (*s*, 3H, Me-20), 2.04 (*s*, 3H, OAc), 3.11 (*br quint*, 1H, $J=7.0$ Hz, H-2′), 5.87 (*m*, 1H, H-3′), 5.08 (*br d*, 1H, $J=10.0$ Hz, H_A-4′), 5.12 (*br d*, 1H, $J=17.2$ Hz, H_B-4′), 1.24 (*d*, 1.8H, $J=7.0$ Hz, Me-5, 22A epimer), 1.25 (*d*, 1.2H, $J=7.0$ Hz, Me-5′, 22B epimer). ^{13}C NMR: Table 1c.

Compounds **23** and **24**. Treatment of **2** (150 mg) with 287 mg of tigloyl chloride in refluxing toluene for 30 min gave 140 mg of an unresolvable mixture of **23** and **24** in a 55:45 ratio. Amorphous solid. IR ν_{max} (film) cm^{-1}: 3435, 2935, 2868, 1733, 1708, 1652, 1380, 1270, 1139, 1072, 1028, 732. EI–MS *m/z* (rel. int.): 544 $[M]^+$ (1), 526 $[M–H_2O]^+$ (3), 426 $[M–H_2O–C_4H_7COOH]^+$ (4), 366 $[M–H_2O–C_4H_7COOH–AcOH]^+$ (15), 344 $[M–2(C_4H_7COOH)]^+$ (7), 326 $[M–H_2O–2(C_4H_7COOH)]^+$ (33), 284 $[M–2(C_4H_7COOH)–AcOH]^+$ (97), 266 $[M–2(C_4H_7COOH)–H_2O–AcOH]^+$ (100), 225 (20). ^1H NMR ($CDCl_3$): δ 4.88 (*dd*, 0.55H, $J=11.2$ and 5.2 Hz, H-3β of **23**), 4.82 (*dd*, 0.45H, $J=11.2$ and 5.2 Hz, H-3β of **24**), 4.78 (*t*, 1H, $J=3.8$ Hz, H-7α), 1.35 (*s*, 3H, Me-17), 3.83 (*d*, 0.55H, $J=12.0$ Hz, H_A-18 of **23**), 3.78 (*d*, 0.45H, $J=12.0$ Hz, H_A-18 of **24**), 3.58 (*d*, 0.55H, $J=12.0$ Hz, H_B-18 of **23**), 3.54 (*d*, 0.45H, $J=12.0$ Hz, H_B-18 of **24**), 0.84 (*s*, 1.35H, Me-19 of **24**), 0.86 (*s*, 1.65H, Me-19 of **23**), 1.13 (*s*, 3H, Me-20), 1.99 (*s*, 1.65H, OAc of **23**), 1.82 (*s*, 1.35H, OAc of **24**), 6.69 (*qq*, 1.55H, $J=7.0$ and 1.0 Hz, H-3′ and H-3″ of **23** and H-3″ of **24**), 6.82 (*qq*, 0.45H, $J=7.0$ and 1.0 Hz, H-3′ of **24**), 1.77 (*br d*, 6H, $J=7.0$ Hz, Me-4′ and Me-4″), 1.71 (*br s*, 6H, Me-5′ and Me-5″). ^{13}C NMR: Table 1c.

Compounds **25** and **26**. Treatment of **2** (150 mg) with 287 mg of tigloyl chloride and 1.5 ml of TEA in refluxing toluene for 24 h gave a mixture of two compounds which were separated by CC (silica gel, gradient elution from petrol ether to petrol ether–AcOEt 3:2) giving 50 mg of **25** and 70 mg of **26**.

Compound **25**. Amorphous solid. IR ν_{max} (film) cm^{-1}: 2931, 2858, 1745, 1707, 1653, 1630, 1265, 1236, 1137, 1074, 1021, 732. EI–MS *m/z* (rel. int.): 526 $[M]^+$ (1), 426 $[M–C_4H_7COOH]^+$ (8), 366 $[M–C_4H_7COOH–AcOH]^+$ (10), 326 $[M–2(C_4H_7COOH)]^+$ (90), 266 $[M–2(C_4H_7COOH)–AcOH]^+$ (100), 251 (26), 226 (15). ^1H NMR ($CDCl_3$): δ 4.80 (*dd*, 1H, $J=11.2$ and 5.2 Hz, H-3β), 4.77 (*t*, 1H, $J=3.8$ Hz, H-7α), 2.71 (*m*, 1H, H-13), 2.22 (*dt*, 1H, $J=17$ and 2.2 Hz, H_A-15), 2.10 (*dt*, 1H, $J=17$ and 2.2 Hz, H_B-15), 4.81 (*br s*, 1H, H_A-17), 4.76 (*br s*, 1H, H_B-17), 3.78 (*d*, 1H, $J=11.8$ Hz, H_A-18), 3.56 (*d*, 1H, $J=11.8$ Hz, H_B-18), 0.87 (*s*, 3H, Me-19), 1.13 (*s*, 3H, Me-20), 1.84 (*s*, 3H, OAc), 6.86 (*qq*, 1H, $J=7.0$ and 1.0 Hz, H-3′), 6.79 (*qq*, 1H, $J=7.0$ and 1.0 Hz, H-3″), 1.76 (*br d*, 6H, $J=7.1$ Hz, Me-4′ and Me-4″), 1.78 (*br s*, 6H, Me-5′ and Me-5″). ^{13}C NMR: Table 1c.

Compound **26**. Amorphous solid. IR ν_{max} (film) cm^{-1}: 2925, 2856, 1745, 1709, 1653, 1630, 1269, 1238, 1140, 1074, 1026, 756, 732. 4.8. Antifeedant bioassay

Compounds were exposed to final stadium larvae of *Spodoptera littoralis* in a binary choice test using glass-fibre discs (Simmonds et al., 1990). All compounds were tested at 100 ppm as this is the dose used to compare activity among compounds (Rodríguez et al., 1999; Bondì et al., 2000). The majority of compounds were tested against insects from 2–3 generations, therefore, each compound was tested against either 10 or 15 insects. All discs were treated with 100 μl sucrose (0.05 M), and then the treatment discs were treated with 100 μl of one of the test compounds. The control discs were treated with an aliquot (100 μl) of the solvent used to dissolve the test compound. Larvae were taken from a colony fed on a wheat-germ based diet (Simmonds et al., 1992). Larvae 24–36 h into the final stadium were removed from food 2–3 h prior to the bioassay. These larvae were placed individually in Petri dishes (9.1 cm diam.) with a pair of discs: one treatment (T) and one control (C) disc. The discs were dried and weighed before and after being exposed to the insects. The amount eaten of each disc was used to calculate a Feeding Index $[(C-T)/(C+T)]\%$. A positive Index indicates an antifeedant and a negative Index a phagostimulant. The data did not differ significantly among generations and were pooled for analysis using the Wilcoxon matched-pairs test.

Acknowledgements

This paper was supported by MURST research funds. We thank Mrs. M. Yule and Dr. P. Green for support in rearing the insects. The insects bioassays were carried out at RBG Kew under a MAFF, Plant Health Great Britain licence.

Received 13 September 2000; received in revised form 1 March 2001

Abstract

The antimicrobially active EtOH extracts of *Maytenus heterophylla* yielded a new dihydroagarofuran alkaloid,1β-acetoxy-9α-benzoyloxy-2β,6α-dinicotinoyloxy-β-dihydroagarofuran, together with the known compounds β-amyrin, maytenfolic acid, 3α-hydroxy-2-oxofriedelane-20α-carboxylic acid, lup-20(29)-ene-1β,3β-diol, (−)-4′-methyl*epi*gallocatechin, and (−)-*epi*catechin. In addition, β-amyrin, (−)-*epi*catechin and (−)-4′-methyl*epi*gallocatechin were isolated from *Maytenus arbutifolia*. The structure elucidation of the isolated compounds was based primarily on 1D and 2D NMR analyses, including HMQC, HMBC, and NOESY correlations. Maytenfolic acid showed moderate antimicrobial activity by inhibiting the growth of *Candida albicans, Cryptococcus neoformans, Staphylococcus aureus* and *Pseudomonas aeruginosa*. © 2001 Published by Elsevier Science Ltd.

Keywords: *Maytenus heterophylla*; *Maytenus arbutifolia*; Celastraceae; Alkaloid; Dihydroagarofuran; Heterophylline; Triterpenes; Antimicrobial

1. Introduction

Plants of the genus *Maytenus* are extensively investigated for bioactive compounds as they are widely used in folk medicine as an antiseptic, antiasthmatic, fertility-regulating agent, antitumor, as well as for stomach problems (Flores, 1984; Ghazanfar, 1994). They exhibited diverse types of secondary metabolites, including triterpenes (Shirota et al., 1996), oligo-nicotinated sesquiterpenes and sesquiterpene pyridine alkaloids (Corsino et al.,1998), phenolic glucosides (Sannomiya et al., 1998) and agarofurans (Gonzalez et al., 1993), with an interesting spectrum of biological activities (Lee et al., 1982; Kuo et al., 1990; Gonzalez et al., 1996; Nakamura et al., 1997). Earlier investigation on the Saudi species *M. undata* yielded antiinflamatory and antibacterial 12-oleanene and secooleanene triterpene acids (Muhammad et al., 2000), while *M. heterophylla* and *M. arbutifolia* of South African origin afforded friedelane triterpenes and spermidine alkaloids (Kupchan et al., 1974; Wagner and Burghart, 1977).

A bioautography (antimicrobial)-guided examination of *M. heterophylla* (Eckl. & Zeyh.) and *M. arbutifolia* (A. Rich.) Wilezek., led to the isolation of a new dihydroagarofuran alkaloid **1**, as well as the triterpenes maytenfolic acid, 3α-hydroxy-2-oxofriedelane-20α-carboxylic acid (**2**), and lup-20(29)-ene-1β,3β-diol. The present study represents the isolation, characterization and antimicrobial activity of the isolated compounds.

2. Results and discussions

The antimicrobially active EtOH extract of *M. heterophylla* was subjected to flash-chromatography, followed by Centrifugal Preparative TLC (see Experimental) to give the dihydroagarofuran alkaloid **1**, maytenfolic acid, 3α-hydroxy-2-oxofriedelane-20α-carboxylic acid (**2**), lup-20(29)-ene-1β,3β-diol, β-amyrin (Doddrell et al., 1974), (−)-*epi*catechin (Mossa et al., 1992) and (−)-4′-methyl*epi*gallocatechin (Monache et al., 1967). Maytenfolic acid, 3α-hydroxy-2-oxofriedelane-20α-carboxylic

acid (**2**), and lup-20(29)-ene-1β,3β-diol were analyzed for the molecular formulas $C_{30}H_{48}O_4$, $C_{30}H_{48}O_4$ and $C_{30}H_{50}O_2$, respectively, by EIMS. The carbon skeleta of 12-oleanen-30-oic acid (for maytenfolic acid), 2-oxo-friedelan-30-oic acid (for **2**) and 3-hydroxylupane (for lup-20(29)-ene-1β,3β-diol) were suggested from their ^{1}H and ^{13}C NMR data (Nozaki et al., 1982; Chen et al., 1983; Nick et al., 1994, 1995). They were identified by comparison of their physical (mp and $[\alpha]_D$) and ^{1}H NMR data with those reported previously for maytenfolic acid (Nozaki et al., 1982), 3α-hydroxy-2-oxo-friedelane-20α-carboxylic acid (De Sousa et al., 1990) and lup-20(29)-ene-1β,3β-diol (Savona et al., 1987), respectively. Their structures were further substantiated by complete ^{13}C NMR assignments, which have not been previously reported for 2, using 2D NMR COSY, HETCOR, HMQC, HMBC and NOESY experiments.

Compound **1** was isolated as a crystalline solid, mp 132–135 °C, $[\alpha]_D$ +63.2^0 (*c* 1.00, $CHCl_3$), analyzed for *m/z* 642 $[C_{36}H_{38}N_2O_9]$ by EIMS. It exhibited UV (λ_{max} at 264, 258 and 234 (*sh*) nm) and IR (ν_{max} at 1734, 1710, 1705, 1593 and 1423 cm^{-1}) absorption bands for multi-carbonyl esters and aromatic ring(s). Fragment peaks at *m/z* 106 $[C_5H_4NCO]^+$, 78 $[C_5H_4N]^+$, 105 $[C_6H_5CO]^+$ and 43 $[C_2H_3O]^+$ in the MS indicated the presence of nicotinoyl, benzoyl and acetyl ester groups. The carbon skeleton of the dihydroagarofuran sesquiterpene was suggested from its ^{1}H- and ^{13}C NMR data (Gonzalez et al., 1987; He and Wu, 1994) (Table 1). The ^{13}C NMR spectra showed 36 carbon resonances; five quartets, two

[a] All spectra were recorded at 500 MHz (^{1}H) and 125 MHz (^{13}C); assignments were aided by 2D NMR COSY, HMQC and HMBC experiments.
[b] ^{13}C NMR multiplicities were determined by DEPT 135^O.
[c] Protons correlating with carbon resonance.

triplets, nineteen doublets, and ten singlets. Its ^{1}H NMR spectrum showed signals for one acetyl group, one benzoyl group, two nicotinyl groups, four methyl groups, two sets of methylene protons, and six methine protons. Spectral data proved collectively that compound **1** is a tetrasubstituted dihydroagarofuran sesquiterpene alkaloid. The substitution pattern of ring A was established from the COSY and HMBC spectra. The signal at δ_H 5.74 was assigned to H-1 as it showed ^3J-correlations with δ_C 170.0 (1-OC=O) and 21.1 (C-15) and ^2J-correlations with δ_C 71.8 (C-2). From the COSY spectrum, H-2 was also assigned at δ_H 5.92, since it couples with two methylene protons (δ_H 2.03 and 2.56, H-3), which in turn couple with a methine proton (δ_H 2.59, H-4) that couples with a methyl group (δ_H 1.31, CH_3-14). These assignments were further supported, from the HMBC spectra, by the presence of a ^2J-correlation between H-2 and an oxygenated doublet carbon resonating at δ_C 71.5 (C-1). This carbon showed another ^3J-correlation with H-3, which showed several long range correlations with an oxygenated singlet carbon resonating at δ_C 90.0 (C-5), a quartet carbon resonating at δ_C 19.5 (CH_3-14) and a doublet carbon resonating at δ_C 34.4 (C-4). Other ^{1}H and ^{13}C-resonances were similar to those of ring A in cangorin J (Itokawa et al., 1994). Therefore, the ring A substituents were determined to be 1β-acetoxy, 2β-nicotinoyloxy and 4β-methyl groups. The stereochemical disposition of these substituents was determined from both the similarity in coupling constants and patterns of ring A protons of **1** and those of cangorin J, and from the NOESY spectra. These showed strong cross peaks between H-1 (δ_H 5.74) and H-2 (δ_H 5.92), H-2 and H-3 (δ_H 2.03, 2.56) and H-4 (δ_H 2.59), and H-14 (δ_H 1.31) and H-15 (δ_H 1.62).

The proton signal at δ_H 5.04 (*d*, $J=6.8$ Hz) showed ^3J-correlations with δ_C 165.8 (9-OC=O), δ_C 21.1 (C-15), δ_C 90.0 (C-5) and δ_C 49.4 (C-7). Consequently, this proton was assigned to be H-9. From the COSY spectrum, this proton couples with two methylene protons (H-8) resonating at δ_H 2.25 (*dd*, $J=16.5$, 3.1 Hz) and δ_H 2.56 (*m*); moreover, from the HETCOR spectrum, H-7 was assigned to resonate at δ_H 2.43 as a broad singlet. These assignments were further confirmed by the presence of long range correlations between C-8 (δ_C 32.1, *t*) and H-9, and between C-11 (δ_C 83.5, *s*) and H-8. The proton signal resonating at δ_H 5.72 was determined to be H-6. This proton showed long range correlations with C-8 (δ_C 32.1), C-10 (δ_C 50.4), C-11 (δ_C 83.5), C-5 (δ_C 90.0) and 6-OC=O (δ_C 165.2). Other ^{1}H- and ^{13}C-resonances were almost identical to those of ring B in wilforcidine, isolated from *T. wilfordii* (He and Wu, 1994). Similarity in coupling constants and patterns of ring B protons of **1** and those of wilforcidine determined the substituents of ring B to be 6α-nicotinoyloxy and 9α-benzoyloxy groups. The NOESY spectra showed correlations between H-6 (δ_H 5.72) and H-14 (δ_H 1.31), H-15 (δ_H 1.62) and H-8 (δ_H 2.56), H-7 (δ_H 2.43) and H-8 (δ_H 2.25, 2.56), H-9 (δ_H 5.04) and H-8 (δ_H 2.56) and H-15 (δ_H 1.62), and H-15 and the acetate methyl protons (δ_H 1.58).

Unambiguous assignments of other protons and carbons were made possible from the COSY, HETCOR and HMBC spectra. Compound **1** can thus be identified as 1β-acetoxy-9α-benzoyloxy-2β,6α-dinicotinoyloxy-β-dihydroagarofuran. The key ^3J HMBC correlations of **1** are shown in Table 1. A related positional isomer of compound **1**, namely, 1β-acetoxy-8α-benzoyloxy-9α,13-dinicotinoyloxy-β-dihydroagarofuran, was recently isolated from the Chinese species of *Celastrus angulatus* seed (Tu et al., 1993).

Maytenfolic acid, 3α-hydroxy-2-oxofriedelane-20α-carboxylic acid (**2**), lup-20(29)-ene-1β,3β-diol were tested for antimicrobial activity against bacteria and fungi

and maytenfolic acid showed the most prominent antimicrobial activity by inhibiting the growth of *Staphylococcus aureus, Pseudomonus aeruginosa*, *Candida albicans* and*Cryptococcus neoformans* with MIC values of 12.5 μg/ml (Table 2). The friedelane acid **2** was less active against these organisms with a MIC values in the range of 12.5–50 μg/ml, while lup-20(29)-ene-1β,3β-diol and agarofuran alkaloid **1** were inactive. The antibacterial 12-oleanenes and 3,4-secooleanenes were also isolated from another Saudi species of *M. undata* (Muhammad et al., 2000) and from *D. papuana* (Nick et al., 1994, 1995).

Maytenfolic acid, previously isolated from *M. diversifolia*, showed significant inhibitory activity against P-388 lymphocytic leukemia in BDF_1 mice (Nozaki et al., 1982). 3α-Hydroxy-2-oxofriedelane-20α-carboxylic acid (**2**), was previously isolated from another Celastraceae, *A. populena* (De Sousa et al., 1990), while lup-20(29)-ene-1β,3β-diol was not previously reported from Celastraceae. β-Amyrin, (-)-*epi*catechin and (-)-4′-methyl*epi*-gallocatechin were also isolated from *M. arbutifolia*.

3. Experimental

3.1. General

Mp: uncorr.; IR: KBr; NMR: were taken on a Bruker Avance DRX-500 instrument at 500 MHz (^1H) and 125 MHz (^{13}C) in $CDCl_3$, using TMS as int. standard. Multiplicity determinations (DEPT) and 2D NMR spectra (COSY, HETCOR, HMBC and NOESY) were run using standard Bruker software; MS: were obtained by direct injection using a Shimadzu GC/MS QP 500 and Quattro LC triple quadrupole tandem MS/MS with electrospray (Z-spray) ion source; UV spectra were obtained on an UV-160 IPC UV-visible spectrophotometer using either $CHCl_3$ or MeOH solutions; Optical rotation measurements were taken on a Perkin-Elmer 241 MC polarimeter in $CHCl_3$ at ambient temp.; TLC: silica gel 60 F_{254} plates. solvent: $CHCl_3$–MeOH (4:1); CC: flash-silica gel G (J.T. Baker, 40 μm); Centrifugal preparative TLC (CPTLC, using Chromatotron®, Harrison Research Inc. Model 7924): 2 mm silica gel PF 254 Chromatotron rotor, using a N_2 flow rate of 4 ml min^{-1}. The isolated compounds were visualized by observing under UV-254 nm, followed by spraying with either Dragendorff's or 1% vanillin-H_2SO_4 spray reagents.

3.2. Plant material

The aerial parts and stem bark of *M.heterophylla* and *M. arbutifolia* were collected in February 1997 from the Abha and Albaha regions of Saudi Arabia, respectively. Both are shrubs or small trees widespread in southwestern Arabian Peninsula (Collenette, 1985). The plants were identified by Dr. Sultanul Abidin of Medicinal, Aromatic and Poisonous Plants Research Center, College of Pharmacy, King Saud University. Voucher specimens (*M. heterophylla* 13987, *M. arbutifolia* 13418) were deposited at the herbarium of the College of Pharmacy, King Saud University, Riyadh, Saudi Arabia.

3.3. Extraction method and bioautography

M. heterophylla dried ground leaves (1.5 kg) were percolated at room temperature with 95% EtOH to yield a green residue (115 g). On the other hand, dried powdered stem bark (250 g) of *M. heterophylla* were extracted by percolation with ethyl acetate to afford a brownish residue (10 g). *M. arbutifolia* dried powdered leaves (225 g) were extracted by percolation with 95% EtOH to yield a green residue (50 g). All of the crude extracts showed animicrobial activities against*Bacillus subtilis*,*S. aureus*, *C. albicans*, and *C. neoformans* using the agar dilution assay (Mitscher et al., 1985). Furthermore, these three extracts were separately subjected to bioautography (Hamburger and Cordell, 1987) on Si-gel plates (5×10 cm; solvent: $CHCl_3$–MeOH (9:1) for *M. heterophylla* stem bark; $CHCl_3$–MeOH (4:1) for *M. heterophylla* leaves; $CHCl_3$–MeOH–HCOOH (8:2:0.01) for *M. arbutifolia* leaves), using *B. subtilis* as the test organism. Two major clear elongated zones with R_f values between 0.15–0.30 and 0.55–0.60 were observed for *M. heterophylla* leaves after 24 h of incubation, two zones with R_f values between 0.10–0.25 and 0.45–0.60 were also observed for *M. heterophylla* stem bark, while a single elongated zone with R_f value corresponded to 0.25–0.35 was observed for *M. arbutifolia* leaves.

3.4. Isolation of compounds

A part of the active EtOH extract of *M. heterophylla* leaves (30 g) was flash-chromatographed over Si gel (40 μm, 750 g), using $CHCl_3$–Me_2CO as eluant, to give several mixtures that were pooled by TLC characteristics. Mixtures that eluted with 5–7% Me_2CO–$CHCl_3$ were further subjected to repeated CC over Si-gel, followed by CPTLC (using a Chromatotron®) on 2 mm Si-gel PF_{254} disc, using $CHCl_3$–Me_2CO as eluant, to afford β-amyrin (50 mg), lup-20(29)-ene-1β,3β-diol (30 mg, R_f 0.32) and **1**

(50 mg, R_f 0.28). Further elution of the flash-CC, using 12–15% Me_2CO–$CHCl_3$, afforded (−)-4′-methyl*epi*-gallocatechin (15 mg), followed by (−)-*epi*catechin (18 mg). Likewise, the active ethyl acetate extract of *M. heterophylla* stem bark afforded maytenfolic acid (25 mg, R_f 0.57) and **2** (30 mg, R_f 0.38). A similar isolation procedure adopted for the EtOH extract of *M. arbutifolia* leaves afforded β-amyrin (200 mg), (−)-*epi*catechin (20 mg) and (−)-4′-methyl*epi*gallocatechin (60 mg). The identity of (−)-*epi*catechin (Mossa et al., 1992) were confirmed by direct comparison with an authentic sample.

3.5. 1β-Acetoxy-9α-benzoyloxy-2β,6α-dinicotinoyloxy-β-dihydroagarofuran (heterophylline) (1)

Mp 132–135 °C; $[\alpha]_D$ +63.2° (*c* 1.00, $CHCl_3$); UVλ_{max} (logε) ($CHCl_3$) 264 (3.74), 258 (3.72), 234 (4.10) nm; IR ν_{max} (KBr) 2950, 1734, 1710, 1705 (C=O), 1593 cm^{-1}; ^1H and ^{13}C NMR: Table 1; MS: (*m*/*z*) 642 ($C_{36}H_{38}N_2O_9$; $[M]^+$).

3.6. Maytenfolic acid

Needles, mp: 285–287 °C, $[\alpha]_D$ +45.7° (*c* 0.13, MeOH) [Lit. (Nozaki et al., 1982) mp: 281–282 °C, $[\alpha]_D$ +34.2°]; MS: (*m*/*z*) 472 ($C_{30}H_{48}O_4$; $[M]^+$).

3.7. 3α-Hydroxy-2-oxofriedelane-20α-carboxylic acid (2)

Needles, mp 305–307 °C [Lit. (De Sousa et al., 1990) mp: 313–315 °C]; $[\alpha]_D$ +90° (*c* 0.10, $CHCl_3$); ^{13}C-NMR: 36.5 (C-1), 212.3 (C-2), 77.3 (C-3), 54.8 (C-4), 39.6 (C-5), 40.9 (C-6), 17.9 (C-7), 51.0 (C-8), 38.3 (C-9), 60.9 (C-10), 35.0 (C-11), 29.7 (C-12), 38.0 (C-13), 39.5 (C-14), 30.1 (C-15), 36.5 (C-16), 30.5 (C-17), 44.7 (C-18), 30.6 (C-19), 40.6 (C-20), 29.7 (C-21), 37.1 (C-22), 11.2 (C-23), 14.6 (C-24), 18.1 (C-25), 18.2 (C-26), 16.6 (C-27), 32.2 (C-28), 32.1 (C-29), 182.4 (C-30); MS: (*m*/*z*) 472 ($C_{30}H_{48}O_4$; $[M]^+$).

3.8. Lup-20(29)-ene-1β,3β-diol

Needles, mp 245–247 °C, $[\alpha]_D$ +13.0° (*c* 1.00, $CHCl_3$)] [Lit. (Savona et al., 1978) mp: 249–250 °C; $[\alpha]_D$ +11.0 °C (*c* 0.10, $CHCl_3$)]; EIMS: (*m*/*z*) 442 ($C_{30}H_{50}O_2$; $[M]^+$).

3.9. Antimicrobial activity

The preliminary antimicrobial activity of the extracts/fractions were determined by using agar dilution technique (Mitscher et al., 1985) and the MIC values of maytenfolic acid and **2** were determined by two-fold serial broth microdilution assay (Hufford et al., 1975). The test organisms used were ATCC strains of *C. albicans* (# 10231), *C. neoformans* (# 90113), *S. aureus* (#29213) and *P. aeruginosa* (# 15442). Amphotericin B and chloramphenicol were used as positive controls, while DMSO as a negative control.

Received 20 March 2001; received in revised form 21 May 2001

Abstract

Four germacrenes, previously shown to be intermediates in sesquiterpene lactone biosynthesis, were isolated from fresh costus roots (*Saussurea lappa*). The structures of (+)-germacrene A, germacra-1(10),4,11(13)-trien-12-ol, germacra-1(10),4,11(13)-trien-12-al, and germacra-1(10),4,11(13)-trien-12-oic acid were deduced by a combination of spectral data and chemical transformations. Heating of these compounds yields (−)-β-elemene, (−)-elema-1,3,11(13)-trien-12-ol, (−)-elema-1,3,11(13)-trien-12-al, and elema-1,3,11(13)-trien-12-oic acid respectively, in addition to small amounts of their diastereomers. Acid induced cyclisation of the germacrenes yields selinene, costol, costal, and costic acid respectively. It is highly probable that the elemenes reported in literature for costus root oil are artefacts. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Saussurea lappa Clarke, is a member of the Asteraceae indigenous to parts of India and Pakistan where it grows in the Himalayas at 2500–3500 m elevation. The dried 4–5 year old roots of this plant are known as costus roots and have a reputation for their medicinal properties as well as their fragrance. Attempts are being made to cultivate this plant, since it has become an endangered species due to ruthless collection from forest areas (Paul et al., 1960; Hatakeyama et al., 1989; Ayaz, 1996).

Various studies have shown that costus roots are extremely rich in sesquiterpene lactones (3% of fresh weight), of which the most important are dehydrocostus lactone and (+)-costunolide (**5**) (Paul et al., 1960; Somasekar Rao et al., 1960). The latter is the structurally simplest sesquiterpene lactone and is generally accepted as the common intermediate in the biosynthesis of most sesquiterpene lactones (Herz, 1977; Fischer, 1990). Costunolide (**5**) is presumably formed from farnesyl diphosphate (FPP) via (+)-germacrene A (**1**) (Fig. 1). Enzyme activities that introduce a carboxylic function in the isopropenyl side chain of (+)-germacrene A yielding germacra-1(10),4,11(13)-trien-12-oic acid (**4**) have recently been identified in chicory (*Cichorium intybus* L.), a vegetable rich in sesquiterpene lactones (de Kraker et al., 1998, 2001). Currently, investigations concerning the pathway for sesquiterpene lactones in chicory are hampered by the lack of a source of germacrene intermediates **1–4**, in particular germacrene acid (**4**). These germacrene compounds are themselves not present in chicory (Sannai et al., 1982), and to our knowledge only the isolation of (+)-germacrene A (**1**) from various plant species (e.g. Wichtman and Stahl-Biskup, 1987) and the partial purification of germacra-1(10),4,11(13)-trien-12-al (**3**) from *Vernonia glabra* (Steetz) (Bohlmann et al., 1983) have been described. A reason for the scarcity of reports on these germacrenes might be their instability. They are susceptible to proton-induced cyclisations and to heat induced (e.g. steam distillation, GC-analysis) Cope rearrangement yielding the eudesmane or elemene framework, respectively (Fig. 2) (Southwell, 1970; Takeda, 1974; Wichtman and Stahl-Biskup, 1987; Teisseire, 1994; de Kraker et al., 1998, 2001).

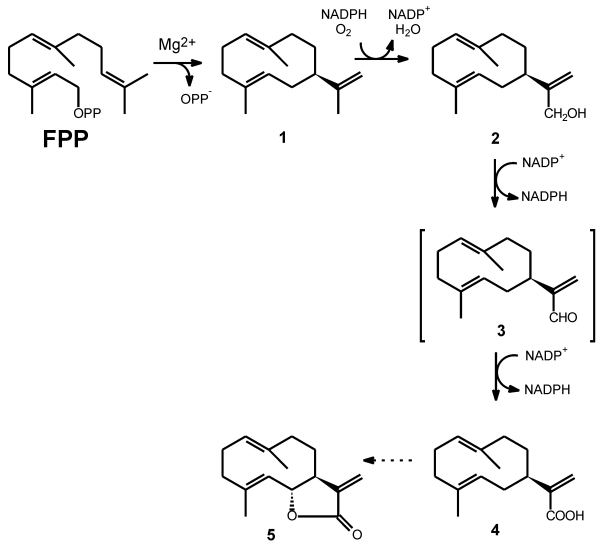

Fig. 1. Biosynthetic route from FPP to (+)-costunolide (**5**) via (+)-germacrene A (**1**), germacra-1(10),4,11(13)-trien-12-ol (**2**), germacra-1(10),4,11(13)-trien-12-al (**3**), and germacra-1(10),4,11(13)-trien-12-oic acid (**4**). Only the last step (dotted arrow) has not yet been demonstrated.

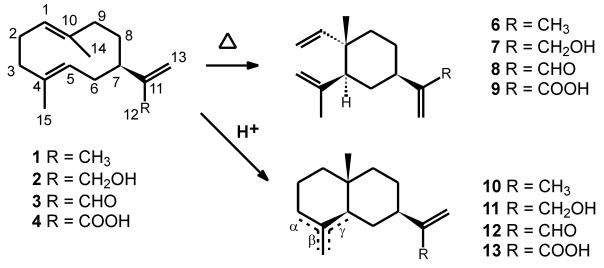

Fig. 2. Heat induced Cope-rearrangement of **1–4** yields (−)-β-elemene (**6**), (−)-elema-1,3,11(13)-trien-12-ol (**7**), (−)-elema-1,3,11(13)-trien-12-al (**8**), and elema-1,3,11(13)-trien-12-oic acid (**9**); acidic conditions are expected to give selinene (**10**), costol (**11**), costal (**12**), and costic acid (**13**).

The presence of β-elemene (**6**), (−)-elema-1,3,11(13)-trien-12-ol (**7**), and (−)-elema-1,3,11(13)-trien-12-al (**8**) in commercially available costus root oil has drawn our attention to these roots (Klein and Thömel, 1976; Maurer and Grieder, 1977). Since this oil is obtained by steam distillation and elemenes are generally considered to be artefacts, we assumed that costus roots originally contain the corresponding germacrenes **1–3**. The reported isolation of costic acid (**13**) from costus roots also suggests the presence of germacrene acid (**4**) (Bawdekar and Kelkar, 1965), since HCl was used in the isolation procedure which might have initiated the cyclisation of germacrene acid.

The aim of the present research was to investigate the presence of the germacrenes **1–4** in fresh costus roots, and to develop a mild isolation procedure for these compounds so that they can be used for further studies on sesquiterpene lactone biosynthesis.

2. Results and discussion

Et_2O extracts of commercially available dried costus roots, costus resinoid and costus root oil were screened on GC–MS for the presence of germacrene A (**1**). This germacrene can be measured as a well resolved peak at a GC-injection port temperature of 150 °C. The more polar germacrenes **2–4** cannot be measured as a real peak, because they will rearrange during migration through the GC-column to their faster migrating elemenes and will be observed as a broad "hump" in the baseline such as described for hedycaryol and 7-hydroxygermacrene (Stahl, 1984; de Kraker et al., 1998, 2001). Yet, in all of these extracts we would detect only the Cope-rearrangement product β-elemene (**6**). It was concluded that the germacrene A originally present in these materials had been exposed to heat and that the commercially available materials are not suitable for the isolation of germacrenes. Interestingly, in the resinoid and dried roots the previously unreported elema-1,3,11(13)-trien-12-oic acid (**9**) was detected in addition to (−)-elema-1,3,11(13)-trien-12-ol (**7**) and (−)-elema-1,3,11(13)-trien-12-al (**8**).

In contrast, the Et_2O extract of fresh costus roots did contain germacrene A (**1**), whereas no (−)-β-elemene (**6**) was observed. At the applied GC-injection port temperature of 150 °C, also the foreseen "broad humps" of the oxygenated germacrenes **2–4** were visible in the GC-chromatogram instead of sharp peaks of the oxygenated elemenes **7–9**.
