In order to isolate germacrenes **1–4**, 300 g of fresh costus roots was powdered in liquid N_2 and extracted with Et_2O. The organic extract was shaken with aq Na_2CO_3 to remove germacrene acid (**4**) and other acidic/polar compounds; the lactones (mainly costunolide and dehydrocostus lactone, 1.5 g) were partially removed by crystallisation from pentane (Somasekar Rao et al., 1960). Germacrenes **1–3** could be selectively extracted from pentane with aq $AgNO_3$ (Southwell, 1970; Minnaard, 1997), because of the complex-formation between the Ag^+-ions and the diene-ring system present in the germacrenes. Subsesquent flash column chromatography of the obtained crude germacrene-mixture in combination with a second $AgNO_3$ extraction yielded: 1.5 mg germacrene A (**1**), 1.5 mg germacrene aldehyde (**3**), and a mixture of germacrene alcohol (**2**) with β-costol (**11**), hedycaryol, costunolide (**5**), and dehydrocostus lactone. The isolated germacrene A contained a small impurity of 4% (determined by GC–MS) humulene that is extracted with aq $AgNO_3$ as well due to the presence of a cylic diene moiety. Purification of the germacrene alcohol (**2**) was more elaborate because β-costol (**10**) with its two adjacent exocyclic bond is also extracted with aq $AgNO_3$, whereas α- and γ-costol are not. Furthermore germacrene alcohol, in our hands, could hardly be separated from costunolide on silica gel. Argentation chromatography yielded 3 mg of germacrene alcohol (**2**)

that was, however, unlike the isolated germacrenes **1**, **3** and **4**, contaminated with elematrien-12-ol (**7**) (approx. 30%).

The germacrene acid (**4**) containing alkaline (Na_2CO_3) extracts were carefully brought to pH 6 and extracted with Et_2O. As expected from the protocol of Bawdekar and Kelkar (1965), the sesquiterpenoid acids did not dissolve in aq $NaHCO_3$ and acidification to a lower pH was not necessary, thus preventing the undesired cyclisation of germacrene acid to costic acid (**13**). Extraction with aq $AgNO_3$ and column chromatography yielded 1.5 mg of germacrene acid (**4**).

GC-analyses of germacrene aldehyde (**3**) at a GC-injection port temperature of 150 °C results in a "broad hump" is (Fig. 3 A) that displays the mass spectrum of elematrien-12-al (**8**) over its entire range. At a GC-injection port temperature of 250 °C a sharp peak of elematrien-12-al is visible instead (Fig. 3B), because the germacrene aldehyde is immediately rearranged in the GC-injection port and not during its migration through the GC-column (de Kraker et al., 2001). In the presence of *p*-toluenesulfonic acid the germacrene aldehyde is completely cyclised to costal (**12**) (Fig. 3C). This indicates that the sample is free of elemene aldehyde, because the elemene aldehyde does not cyclise to costal. ^{1}H NMR of the germacrene aldehyde confirmed that it did not contain any of its Cope rearrangement product, since a double doublet at δ 5.85 of $C_2{=}C_1H{-}C_{10}$ typical for the elemene aldehyde was clearly missing. Unfortunately, in solution many germacrenes show broadened NMR signals or even multiple NMR signals, due to the existence of different conformations of the ten-membered ring (Fig. 4) (Takeda, 1974; Minnaard, 1997). This hinders a complete interpretation of the NMR. Most striking is the presence of two aldehyde proton signals of similar height at δ 9.37 and δ 9.35 that cannot be due to coupling with a proton at C_{13}, accompanied by two very small signals at δ 9.47 and δ 9.45 (ratio 1:1:0.01:0.01).

The existence of different germacrene conformations also explains the formation of a small amount of diastereomeric elematrien-12-al during the Cope rearrangement of germacrene aldehyde (Fig. 3B). Cope rearrangement is a stereospecific reaction that preferably proceeds via a chair-like transition state (March, 1992), via either the UU or DD conformation of the germacrene (Fig. 4). However, the UU conformation with the isopropenal group in the equatorial position predominates and consequently the diastereomer of **8** will be formed only in low yield (Takeda, 1974; Piet et al., 1995; Minnaard, 1997). Small amounts of diastereomeric elemenes were also detected for the GC-injection port induced Cope rearrangement of germacrene A, germacratrien-12-ol

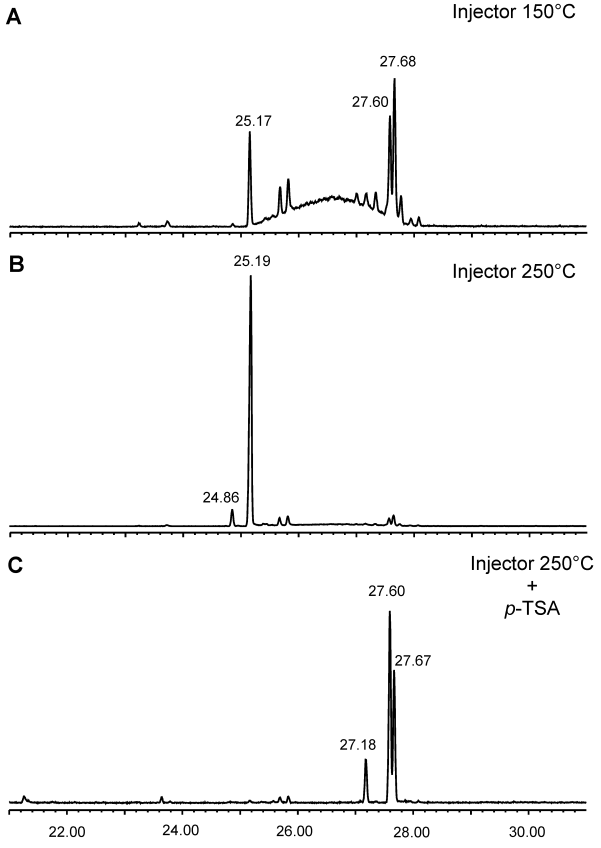

Fig. 3. GC–MS analyses of the germacrene aldehyde (**3**) at an injection port temperature of 150 °C (A) yields a broad hump that starts at the position of elematrien-12-al (**12**) (25.17 min). Injection at an temperature of 250 °C (B) gives almost complete rearrangement of **3** to elematrien-al (**12**) (25.19), whereas a small amount of diastereomeric elemene aldehyde can also be detected (24.86). In the presence of *p*-toluenesulfonic acid (C) the germacrene aldehyde (**3**) is completely converted into costal (**8**): γ-costal (27.18 min), β-costal (27.60 min), and α-costal (27.67 min).

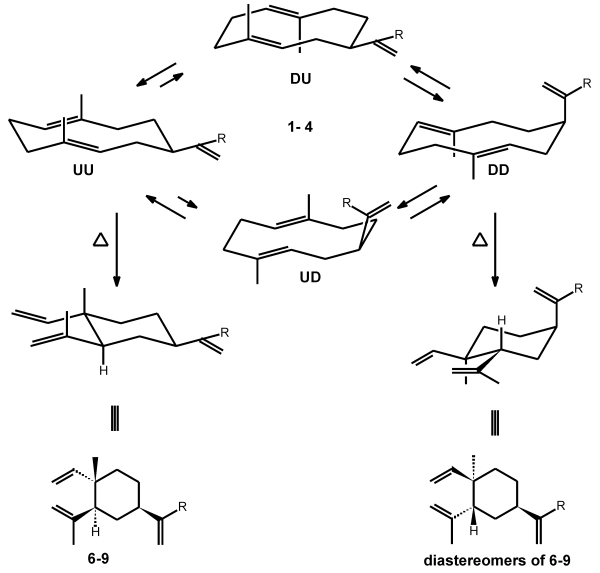

Fig. 4. Conformations of germacrenes **1–4** denoted as UU, UD, DU, and DD. U (up) and D (down) refer to the orientation of the C-14 and C-15 methyl groups. Both conformations UU and DD will easily undergo Cope rearrangement, however, the UU conformation is predominant and will yield elemenes **6–9**, whereas the diastereomeric elemenes that origin from the DD conformation will hardly be formed.

and germacratrien-12-oic acid. These diastereomers have a mass spectrum very similar to their true elemene and typically constitute only 2–7% of the total amount of Cope rearrangement product formed. Although we failed to detect the β-elemene diastereomer before (de Kraker et al., 1998), small amounts of it are not unusual in samples containing β-elemene/germacrene A (Dr. M. A. Posthumus, personal communication). The structure of the elematrien-12-ol diastereomer has tentatively been assigned by Maurer and Grieder (1977).

When the injection port temperature of the GC was varied between 150 and 250 °C, germacrene alcohol (**2**) and germacrene acid (**4**) showed chromatogram patterns similar to that of germacrene aldehyde (**3**). Both germacrene A (**1**) and germacrene acid (**4**) were completely converted into their eudesmane analogues (**10** and **13**, respectively) in the presence of *p*-toluenesulfonic acid. However, the GC-chromatogram of the germacrene alcohol (**2**) still showed a peak of elematrien-12-ol (**7**) after acid treatment, indicating that isolated sample of germacrene alcohol is actually a mixture of germacrene- and elemene alcohol. This was confirmed by ^{1}H NMR that showed a double doublet ($J=18$ and 10 Hz) at δ 5.81 typical for elematrien-12-ol (Maurer and Grieder, 1977). It is not known whether the presence of elematrien-12-ol is caused by an intrinsic higher instability of the germacrene alcohol and/or by the more difficult and time-consuming purification of this compound. Although less likely, we cannot rule out that the elematrien-12-ol was already present in the crude plant material. In this respect it is remarkable that the germacratrien-12-ol produced in an enzyme assay from germacrene A (de Kraker et al., 2001) was free of any elematrien-12-ol and could be fully cyclised into costol (**11**), notwithstanding the fact that the germacratrien-12-ol had been exposed to 30 °C, a temperature unlikely to occur in costus roots that are underground.

The ^{1}H NMR of germacrene acid (**4**) was free of the double doublet at δ 5.85 from elematrien-12-oic acid (**9**) (de Kraker et al., 2001), but once again only few signals could be assigned. Similar observations were made by Zdero et al. (1991) for 3α- and 3β-acetoxygermacra-1(10)-,4,11(13)trien-12-oic acid whose structures could only be resolved after Cope-rearrangement to their corresponding elemene derivatives.

The isolation under mild conditions from fresh costus roots of (+)-germacrene A (**1**), germacra-1(10),4,11(13)-trien-12-al (**3**), and germacra-1(10),4,11(13)-trien-12-oic acid (**4**) clearly demonstrates that their reported elemene derivatives (**6–9**) are indeed heat-induced artefacts formed during drying of the roots or the manufacturing of costus resinoid/oil as literature on germacrenes suggests (e.g. Bohlmann et al., 1983; Wichtman and Stahl-Biskup, 1987; Teisseire, 1994). Very similar, has for example, been reported for the Australian shrub *Phebalium ozothamnoides* F. Muell whose main essential oil component is elemol, whereas the petroleum extract of macerated leaves yields hedycaryol instead (Southwell, 1970). Only in the case of germacra1(10),4,11(13)-trien-12-ol (**2**), it cannot completely be ruled out that a small quantity of its corresponding elemene is already present in fresh costus roots. The presence of elemenes instead of germacrenes was the only significant difference between an Et_2O-extract from fresh costus roots and the commercial costus root oil,[1] such as thoroughly described by Maurer and Grieder (1977). It is less certain whether the eudesmanes **10–13** have to be regarded as artefacts as well. Although they can be formed from germacrenes under acidic conditions, maybe during storage in the plant—an enzyme specifically producing β-selinene from FPP has been isolated from *Citronella mitis* fruits (Belingheri et al., 1992). It cannot be ruled out that costus root also contain such an enzyme and the eudesmanes present are genuine enzymatic products.

The presence of germacrenes **1–4** together with vast amounts of costunolide (**5**) in costus roots supports the pathway for costunolide as depicted in Fig. 1. The isolated germacrene acid (**4**) is currently being used to investigate the formation of costunolide (**5**) during sesquiterpene lactone biosynthesis in chicory.

3. Experimental

3.1. General experimental procedures

^{1}H NMR and ^{13}C NMR: recorded at 400 MHz with C_6D_6 as solvent and TMS as internal standard. GC–MS: HP 5890 series II gas chromatograph and HP 5972A mass selective detector (70 eV), equipped with a capillary HP5-MS column (30 m×0.25 mm, film thickness of 0.25 μm) at a helium flow rate of 0.969 ml min^{-1}, programmed at 55 °C for 4 min followed by a ramp of 5 °C min^{-1} to 280 °C, and a standard injection port temperature of 250 °C. CC: Silica gel flash (Janssen, 0.035–0.07 nm, pore 6 nm; column width 1.8 cm) (Still et al., 1978). 5% $AgNO_3$/Silica gel was prepared according to Maurer and Grieder (1977). TLC: Silica gel (Merck) 60 F254, eluent EtOAc–hexane (1:4); spray of 5 ml *p*-anisaldehyde in 5 ml H_2SO_4 and 95 ml EtOH, 1–2 min heating at 120 °C.

3.2. Plant material

Seeds of *Saussurea lappa* Clarke were introduced from Hortus Botanicus Vilr, Moscow (USSR) to the fields of Hokkaido Experimental Station for Medicinal Plants (Japan) in 1981 (Accession No. 9678-81) (Hatakeyama

[1] Less volatile compounds like fatty acids are not taken into account, because they are for obvious reasons not present in the costus oil that is produced by steam-distillation.

et al., 1989). Five-year old roots were harvested in August 2000 and transported by courier to The Netherlands. Upon arrival they were cut into pieces, powdered in liquid N_2 with a Waring blender and stored at −80 °C. Dried costus roots were obtained via internet from gaines.com (El Cajon CA, USA) and ginseng4less.com (Petaluma CA, USA).

3.3. Chemicals and reference compounds

Costus resinoid and costus oil were obtained from Pierre Chauvet SA (Seillans, France). Costunolide (**5**) and dehydrocostus lactone were isolated from costus resinoid according to Fischer et al. (1990) making use of the described TLC-spot colour (Asakawa et al., 1981), and recrystallised in pentane; NMR date were identical to those reported in literature (Kuroda et al., 1987; Takahashi et al., 1987). Standards of (−)-elema-1,3,11(13)-trien-12-al (**8**) [NMR in C_6D_6 did not markedly differ from those recorded in $CDCl_3$ (Maurer and Grieder, 1977; Bohlmann et al., 1983)], elema-1,3,11(13)-trien-12-oic acid (**9**) and costal (**12**) were isolated/synthesised as previously described (de Kraker et al., 2001). A mixture of α- and γ-costic acid (**13**) was synthesised from a mixture of α- and γ-costal with $NaClO_3$ (de Kraker et al., 2001). (−)-Elema-1,3,11(13)-trien-12-ol (**7**) was a gift of Dr. B. Maurer (Firmenich SA, Geneva, Switzerland), standards of (+)-germacrene A (**1**) and (−)-β-elemene (**6**) were a gift of Professor W. A. König (Hamburg University, Germany).

3.4. Screening of crude materials for the presence of germacrene A (*1*)

Samples of dried costus roots were powdered in liquid N_2, and 0.2 g of powdered root was shaken in 3 ml Et_2O and centrifuged after 5 min. The Et_2O was passed through a Pasteur pipette with 0.4 g silica gel. A spatula tip of costus resinoid and a droplet of costus oil were also dissolved in 3 ml of Et_2O and passed over silica gel. The Et_2O extracts were screened at an injection port temperature of 150 °C for a germacrene A (**1**) peak that should be replaced by a peak of β-elemene (**6**) at an injection port temperature of 250 °C (de Kraker et al., 1998).

3.5. Isolation of germacrenes *1–3*

Powdered fresh costus root (300 g) was extracted twice with 500 ml of Et_2O at 6 °C; the Et_2O was filtered and the volume reduced to 75 ml by rotary evaporation at room temperature. The concentrate was extracted with 5% aq Na_2CO_3 (3×50 ml). The aq Na_2CO_3 layers were combined and stored at 4 °C. The Et_2O layer was washed with brine, dried with Na_2SO_4, and the solvent removed yielding 2.8 g of a yellow-brown solid. Lactones (1.5 g) were partially removed by dissolving the residue in pentane and cooling at −20 °C, after which the crystallised lactones were filtered off and the solvent removed in vacuo. This procedure was repeated twice. The obtained oil was dissolved in 15 ml pentane and extracted with 20% aq. $AgNO_3$ (4×10 ml). The Ag^+ ions were complexed by adding carefully 10 ml of aq. NH_3 (25%) on ice, after which the water layer was extracted with pentane (3×50 ml) (Southwell, 1970). The pentane layers were washed with brine and dried with Na_2SO_4 yielding 100 mg of a yellow oil. This oil was chromatographed with 350 ml pentane–CH_2Cl_2 (3:7) after which the column was eluted with CH_2Cl_2. Fractions of 10 ml were collected and monitored by GC–MS and TLC; costunolide and dehydrocostus lactone could easily be distinguished by their greenish-blue (R_f 0.30) and blue (R_f 0.35) spots respectively. After removal of aplotaxene [a major constituent of costus root oil (Klein and Thömel, 1976; Maurer and Grieder, 1977)] by a second silver-ion extraction (4×1.5 ml 20% aq. $AgNO_3$, etc.), fractions 2+3 yielded 4 mg of germacrene A (**1**) with an impurity of 4% of humulene. Fractions 19–33 yielded, after a second silver-ion extraction, 1.5 mg germacratrien-12-al (**3**). Fractions 40–64 contained a mixture of costunolide (**5**), dehydrocostus lactone, β-costol (**11**), hedycaryol and germacrene alcohol (**2**). Attempts to separate the latter from β-costol and costunolide by column chromatography on silica gel using pentane–CH_2Cl_2 (1:9) or Et_2O–pentane (1:4) failed. Column chromatography on 5% $AgNO_3$-silica gel (10 gram) was more successful: costol and subsesquently costunolide were eluted with Et_2O (400 ml), whereas germacratrien-12-ol (2 mg, of which ≈ 30% elematrien-12-ol) was eluted with 150 ml MeOH–Et_2O (1:9).

3.6. Isolation of germacra-1(10),4,11(13)-trien-12-oic acid (*4*)

The aq. $NaCO_3$ layers (150 ml) were carefully acidified on ice to pH 6 with 5 M HCl and extracted with Et_2O (4×60 ml). The Et_2O layers were washed with brine, dried with Na_2SO_4, concentrated to 15 ml, and extracted with 20% aq $AgNO_3$ (4×10 ml). The Ag^+ ions were precipitated with 35 ml 2 M NaCl, and the remaining solution was extracted with Et_2O (4×50 ml). After washing with brine and drying with Na_2SO_4, 20 mg of a yellow solid was obtained that mainly contained germacratrien-12-oic acid (**4**), costunolide (**5**) and dehydrocostus lactone. Column chromatography with 350 ml of EtOAc–pentane (1:4) removed the lactones after which the germacrene acid was eluted with 100 ml EtOAc. The last minor impurities were removed by column chromatography with Et_2O–pentane (1:4; 400 ml), and 1.5 mg of germacratrien-12-oic acid was obtained.

3.7. Acid induced cyclisation of germacrenes

A small amount (≈ 10 nmol) of germacrene (**1–4**) was dissolved in 2 ml of CH_2Cl_2 and a crystal of *p*-toluenesulphonic acid was added (Minnaard, 1997). After 7 min at room temperature, the solution was washed with 1 ml of $NaHCO_3$ (satd.) and passed through a Pasteur pipette filled with 0.25 g $MgSO_4$. The solvent was reduced to 100 μl under a stream of N_2 and the sample was analysed by GC–MS. In case of germacratrien-12-oic acid (**4**) $NaHCO_3$ was replaced by NaH_2PO_4. The experiments were repeated with elemenes **6–9** that did not cyclise.

3.8. Compound characterisation

3.8.1. Germacrene A (*1*), 4 mg

Colourless oil, purple TLC-spot R_f 0.75, R_I 1511, EIMS *m/z* (rel int) M^+ 204 (8), $[M–Me]^+$ 189 (37), 93 (100), 67 (99), 68 (94), 107 (79), 81 (77), 41 (68), 79 (67), 105 (59), 91 (57), 53 (54), 147 (47), 119 (43), 121 (41), 55 (41), 161 (36), 133 (36). Cope rearrangement to **6**, R_I 1396, EIMS *m/z* (rel int) M^+ 204 (1), $[M–Me]^+$ 189 (28), 93 (100), 81 (96), 67 (83), 68 (76), 41(67), 79 (64), 107 (63), 53 (51), 91 (48), 147 (45), 121 (42), 105 (42), 55 (41), 161 (31), 119 (31), 133 (29); and diastereomer of **6**, R_I 1388, EIMS *m/z* (rel int) M^+ 204 (1), $[M–Me]^+$ 189 (23), 93 (100), 81 (78), 67 (61), 68 (58), 41 (52), 79 (51), 107 (50), 91 (41), 121 (35), 161 (34), 55 (33), 53 (32), 105 (31), 119 (27), 133 (23), 147 (21). Cyclisation yields **10**, R_I 1479 (γ), 1491 (β) and 1500 (α) [MS-data are comparable with those of Maurer and Grieder (1977) and were used in combination with the R_I's reported by Adams (1995) to determine the elution order].

3.8.2. Germacra-1(10),4,11(13)-trien-12-ol (*2*), 2 mg, mixture with 7 (≈ 30%)

Colourless/slightly yellow oil, pink/purple TLC-spot R_f 0.29, R_I 1673 to ± 1806. Cope rearrangement to **7**, R_I 1673 EIMS *m/z* (rel int) M^+ 220 (1), $[M–Me]^+$ 205 (4), 79 (100), 81 (94), 41 (91), 91 (90), 67 (86), 93 (85), 55 (69), 105 (66), 53(60), 119 (58), 77 (55), 68 (53), 189 (42), 121 (37), 133 (35), 145 (33), 163 (25), 161 (25); and diastereomer of **7**, R_I 1657, EIMS *m/z* (rel int) M^+ 220 (1), $[M–Me]^+$ 205 (3), 81 (100), 41 (94), 79 (92), 93 (78), 67 (78), 91 (71), 69 (70), 55 (63), 105 (55), 119 (50), 77 (46), 53 (45), 161 (28), 133 (24), 145 (18), 189 (15). Cyclisation yields **11**, R_I 1755 (γ), 1775 (β) and 1781 (α) [MS-data are comparable with those of Maurer and Grieder (1977) and used to determine elution order].

3.8.3. Germacra-1(10),4,11(13)-trien-12-al (*3*), 1.5 mg

Colourless/slightly yellow oil with strong mossy odour, pink spot R_f 0.58, R_I 1585 to ± 1715. ^1H NMR δ 9.35 (*s*) 9.37 (*s*), 9.45 (*s*) and 9.47 (*s*) (ratio 1:1:0.01:0.01, 1H, H-12); 5.77 (*br s*) and 5.72 (*s*) (ratio 1:1, 1H, H-13); 5.36 (*br s*) and 5.33 (*s*) (ratio 1:1, 1H, H′-13); 5.22 (*br s*,1H, H-1); 4.84 (*br d*, J = 13.3 Hz) and 4.62 (*br d*, J = 10.3 Hz) (ratio 1:1, 1H, H-5) 2.75–2.55 (*br m*, 1H, H-7). Cope rearrangement to **8**, R_I 1585 EIMS *m/z* (rel int) M^+ 218 (1), $[M–Me]^+$ 203 (12), 81 (100), 67 (70), 79 (68), 41 (63), 91 (56), 53 (50), 93 (46), 95 (38), 77 (38), 55 (37), 107 (37), 105 (35), 119 (27), 161 (25), 121 (24); and diastereomer of **8**, R_I 1570 EIMS *m/z* (rel int) M^+ 218 (ND), $[M–Me]^+$ 203 (8), 81 (100), 79 (64), 67 (60), 41 (57), 91 (48), 93 (43), 95 (41), 53 (40), 77 (36), 105 (36), 107 (35), 68 (34), 55 (34), 119 (25), 121 (22), 175 (22). Cyclisation yields **12**, R_I 1673 (γ), 1692 (β) and 1695 (α) [MS-data are comparable with those of Maurer and Grieder (1977) and used to determine elution order].

3.8.4. Germacra-1(10),4,11(13)-trien-12-oic acid (*4*), 1.5 mg

White crystals, blue TLC-spot (note: **9** gives pink spot) R_f 0.18, R_I 1771 to ± 1845. ^1H NMR δ 6.44-6.37 (*m*) and 6.36 (*s*) (ratio 1:1, 1H, H-13); 5.44 (*br m*) and 5.38 (*s*) (ratio 1:1, 1H, H′-13); 5.30–5.15 (*br s*, 1H, H-1); 4.85 (*br m*) and 4.63 (*br d*, J = 10.6 Hz) (ratio 1:1, 1H, H-5); 2.75-2.55 (*br m*, 1H, H-7). Cope rearrangement to **9**, R_I 1771 EIMS *m/z* (rel int) M^+ 234 (1), $[M–Me]^+$ 219 (7), 81 (100), 67 (50), 79 (47), 41 (43), 68 (40), 91 (38), 53 (34), 93 (29), 105 (29), 55 (26), 77 (26), 107 (26), 121 (23), 119 (19), 69 (17), 177 (15); and diastereomer of **9**, R_I 1750 EIMS *m/z* (rel int) M^+ 234 (ND), $[M–Me]^+$ 219 (4), 81 (100), 79 (67), 41 (58), 67 (56), 107 (55), 91 (49), 93 (49), 53 (41), 55 (40), 68 (39), 105 (38), 121 (35), 162 (33), 147 (26), 119 (25), 163 (25). Cyclisation yields **13**; R_I 1854 (γ), EIMS *m/z* (rel int) M^+ 234 (26), $[M–Me]^+$ 219 (100), 91 (57), 41 (35), 79 (35), 81 (34), 105 (34), 147 (34), 107 (32), 93 (31), 55 (30), 77 (30), 173 (25); R_I 1876 (β), EIMS *m/z* (rel int) M^+ 234 (25), $[M–Me]^+$ 219 (67), 91 (100), 79 (95), 93 (85), 41 (78), 121 (78), 77 (63), 81 (63), 55 (61), 67 (59), 105 (55), 107 (55), 53 (45), and R_I 1879 (α), EIMS *m/z* (rel int) M^+ 234 (27), $[M–Me]^+$ 219 (100), 91 (57), 79 (46), 41 (38), 81 (37), 107 (36), 105 (35), 93 (35), 55 (29), 205 (26) (elution order of isomers presumed to be the same as for **10–12**).

Acknowledgements

The authors are most grateful to Dr. B. Maurer for the gift of elematrien-12-ol and to Professor Dr. W. A. König for the gift of the germacrene A and β-elemene standard. We would also like to thank Dr. M. A. Posthumus for the GC–MS analyses of the costus root oil and resinoid, A. van Veldhuizen for recording NMR data, Dr. J. B. P. A. Wijnberg for his help in the interpretation of the NMR data, and ing. F. W. A. Verstappen for technical assistance.

Received 19 March 2001; received in revised form 11 May 2001

Abstract

Hydrodistilled oil from leaves of the Ethiopian plant *Laggera tomentosa* has been shown to contain (−)-chrysanthenone (5%), (−)/(+)-filifolone (92:8; 8%) and (*Z*)-isogeranic acid (8%)—all likely to be artefacts. The main constituent of the oil, (+)-chrysanthenone (53%), is believed to be the precursor undergoing thermal and solvolytic reactions during the hydrodistillation process.

Keywords: *Laggera tomentosa*; Asteraceae; Chrysanthenone; Filifolone; (*Z*)-Isogeranic acid; Hydrodistillation; Artefacts

1. Introduction

The common procedure for isolation of essential oil from plant material involves hydrodistillation. Recently we reported (Asfaw et al., 1999) that hydrodistillation of the Ethiopian plant *Laggera tomentosa* Sch. Bip. ex Oliv. & Hiern yielded chrysanthenone (**1**, 58%), isochrysanthenone (**2**, 5%) and filifolone (**3**, 8%). Further analysis of the hydrodistillate of the oil revealed the presence of an acidic component identified as (*Z*)-isogeranic acid (**4**, 8%).

Enantioselective GC analyses of the ketones in the hydrodistilled oil showed enantiomerically pure (−)-isochrysanthenone ($[\alpha]_D^{21}$ −67 ° ($CHCl_3$; c 0.47)) while chrysanthenone ($[\alpha]_D^{21}$ +97.6 ° ($CHCl_3$; *c* 4.0)) and filifolone ($[\alpha]_D^{22}$ −636 ° ($CHCl_3$; *c* 0.30)) were found to be enantiomeric mixtures with a (+)/(−) ratio of 92:8 and 8:92, respectively.

The presence of filifolone (**3**) in plant material has frequently been reported after Beereboom (1965) first synthesised the cyclobutanone by cyclisation of geranic acids. Its natural occurrence was first published by Bates et al. (1967) who found the (+)-enantiomer (“D-filifolone”; $[\alpha]_D^{24}$ +307 °) in the Australian plant *Zieria smithii* Andrews and the (−)-enantiomer (“L-filifolone”; $[\alpha]_D^{25}$ −270 °) in the Arizonian sage *Artemisia filifolia* (Torrey). In the essential oil obtained by hydrodistillation of *Z. smithii*, D-filifolone co-occurred with (−)-**1** ($[\alpha]_D$ −88 °; Penfold et al., 1939). Bates et al. (1967) reported that (−)-**1** isomerised to racemic **3** during gas chromatography. They did not, however, record any isolation procedure for “L-filifolone”. A more detailed work by Torrance (1973) on *Artemisia filifolia* established the presence of (−)-**3** in the hydrodistillate together with several other monoterpenoids including (−)-verbenone but not chrysanthenone (**1**). The thermal instability of **1** to yield racemic **3** suggests, according to Bates et al., that the filifolone in *Zieria smithii* might conceivably be an artefact. However, due to the presence of optically active **3** in the plant oil, they concluded, nevertheless, the latter to be a natural constituent of the plant since a mechanistic route from (−)-**1** to optically active **3** seemed “difficult to imagine”. In a later work on *Zieria smithii* by Flynn and Southwell (1987), the authors suggest that milder isolation techniques may reveal that (+)-**1** is the heat and photo labile precursor of (−)-**3**.

2. Results and discussion

The reported coexistence of naturally occurring chrysanthenone (**1**) and filifolone (**3**) in the essential oil of *Z.*

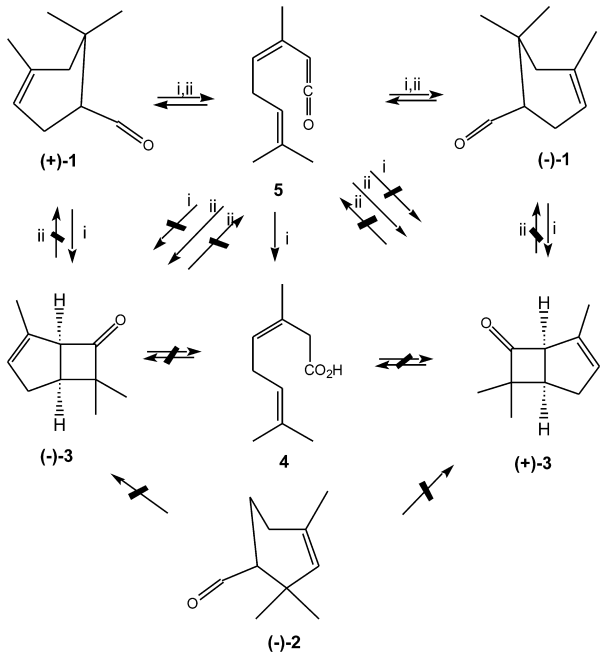
smithii as well as in oils of other plants, where hydrodistillation method of isolation had been employed (Uchio, 1978; Weyerstahl et al., 1999; Kalemba and Kusewicz, 2000), may be challenged as pentane/ether extractions at room temperature of the leaves of *L. tomentosa* provided extracts containing barely detectable amounts of filifolone and (*Z*)-isogeranic acid. Increased amounts of chrysanthenone (72% as compared to 58% in the hydrodistillate) were instead recorded. Interestingly, enantioselective GC analysis of the extract revealed the presence of (+)-**1** of >99% optical purity implying that ca 16% racemisation had taken place during the hydrodistillation (see above). (*Z*)-Isogeranic acid (**4**) was isolated from the hydrodistilled oil by flash chromatography and identified by GC–MS and NMR. The spectroscopic data were in agreement with those reported for the acid by Weyerstahl et al. (1987).

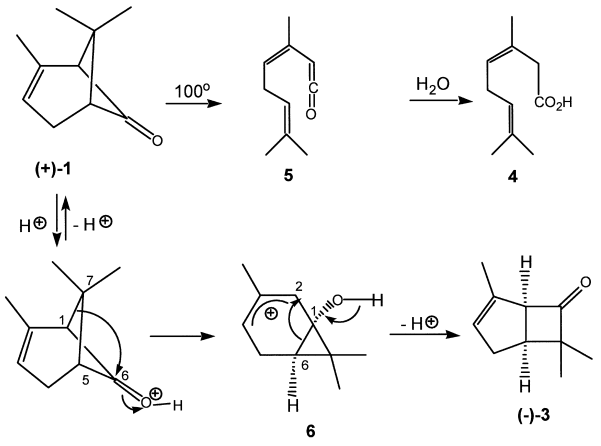
In a study of cyclobutanones Erman et al. (1971) report 29% racemisation as the sole reaction on thermolysis of (−)-**1** in refluxing cyclohexane (81 °C) for 25 h. Similar treatment of (+)-**3** in the same solvent gave high yield of recovered starting material with complete retention of configuration. Furthermore, thermolysis of **1** in refluxing methanol (65 °C) for 16 h was reported by the same authors to yield ca 50% of the methyl ester of **4** in addition to recovered **1** (ca 50%) of unquoted optical purity. Filifolone (**3**) was not, however, detected. On the other hand, treatment of **1** ($[\alpha]_D^{25}$ −12.3 ° ($CHCl_3$)) in glacial acetic acid at 60 ° for 77 h was reported to produce 71% of **3** ($[\alpha]_D^{25}$ +24.2 ° ($CHCl_3$; *c* 0.24)) and partially racemised starting material together with some other minor products. Unlike Bates et al. (1967) we found no evidence for thermolysis of **3** — neither racemisation nor isomerisation to chrysanthenone—under the chromatographic conditions employed. However, nearly complete racemisation of chrysanthenone and partial isomerisation to racemic filifolone were observed during preparative GC conditions (Scheme 1).

To visualise the racemisation process of chrysanthenone (**1**) and its isomerisation to filifolone (**3**) at elevated temperatures (i.e. GC conditions) the achiral ketene **5** (Scheme 1) is a likely intermediate for both reactions as depicted by reaction path ii. The ketene may either revert to racemic **1** or undergo [2+2] cycloaddition to produce racemic **3**. Of the two competing reactions the cycloaddition reaction has the higher energy of activation and is probably important only at temperatures above 200 °C. However, the observed racemisation of **1** in cyclohexane at 81 °C and the formation of the methyl ester of (*Z*)-isogeranic acid (**4**) on treatment of **1** at 65 °C in MeOH, suggest thermal cleavage of **1** to the ketene **5** even at moderate temperatures, and thus explain the presence of (−)-**1** and (*Z*)-isogeranic acid (**4**) in the hydrodistilled oil from *L. tomentosa* (reaction path i). Consequently, both compounds (−)-**1** and **4** are most likely artefacts.



Scheme 1. (i) Hydrodistillation, (ii) 260 °C/preparative GC.

The presence of (−)-**3** with 84% e.e. was more difficult to rationalise. A route involving the achiral ketene **5** can be ruled out for obvious reasons. Chrysanthenone (**1**) with the same enantiomeric excess as that of **3**, though with opposite sign, seems nevertheless to be an attractive alternative, considering the observations of Erman et al., (1971) on acetic acid treatment of **1** (see above). On the other hand, it cannot be excluded that the essential oil might contain constituents, which might produce **3** with the observed stereochemistry under hydrodistillation conditions. Initially, our approach was that **3** might constitute a part of a larger molecule which might liberate optically active **3** in the boiling water. In order to examine such a possibility Soxhlet extractions of dried plant material using pentane, ether and methanol were carried out, followed by column chromatographic separation into fractions that were individually subjected to hydrodistillation. It turned out that only fractions containing chrysanthenone (**1**) and isochrysanthenone (**2**) produced **3** and **4** during the distillation. A sample containing **1** (92%), **2** (4%) and trace amounts of **3** and **4** was prepared by irradiation of (−)-verbenone (Erman, 1967), and for comparison hydrodistilled in the same way. Analysis of the distillate revealed unchanged contents of **2**, significant amounts of **4** (15%) and **3** (4%), and a marked reduction in the amount of **1** (57%) This result strongly suggests a relationship between chrysanthenone and filifolone/(*Z*)-isogeranic acid. This is further substantiated by enantioselective GC analyses of the hydrodistilled fractions from the plant oil and from the synthetic material, containing compounds **1** and **3**; the fractions invariably showed the enantiomeric ratio of (+)-**1**/(−)-**1** to be equal to the ratio of (−)-**3**/(+)-**3**.



Scheme 2.

Thus under hydrodistillation conditions, (−)-**3** seems to originate exclusively from (+)-**1** while the (−)-enantiomer is apparently the sole precursor of (+)-**3** as shown in path i (Scheme 1). Accordingly, none of the enantiomers of filifolone (**3**) are naturally occurring constituents of *L. tomentosa*.

Scheme 2 illustrates how the above reactions may proceed in order to preserve optical activity *en route* from (+)-**1** to (−)-**3** in an assumed acid catalysed rearrangement. Bearing in mind that the treatment of **1** in refluxing methanol gave high yield of the methyl ester of **4** but no filifolone (Erman et al., 1971), we may now attribute its absence to lack of an acid catalyst. Returning to *L. tomentosa*, the first step in the hydrodistillation of **1** is consequently believed to be a thermally induced rearrangement of the ketone to the ketene **5**, which by water addition provides the acid catalyst necessary for the subsequent transformations of **1** to the observed products. The latter pathway is believed to involve two consecutive 1.2 alkyl shifts—migration of the 1.7 bond in (+)-**1** affords the optically active allylic carbocation **6**, which by a shift of the 1.6 bond provides (−)-**3**.

Our results show that the analytical data of the constituents of a plant obtained from hydrodistillation must be treated with great caution if labile compounds are present in the plant material. Accordingly, comparative routine analysis of the essential oil from cold pentane/ether extractions of the plant is strongly recommended in order to minimise confusion caused by formation of artefacts.

3. Experimental

3.1. Plant material

L. tomentosa was collected on 18 October 1998 near Chancho, about 40 km Northwest of Addis Ababa, Ethiopia. A voucher specimen has been authenticated and deposited at the National Herbarium, Biology Department, Addis Ababa University.

3.2. Isolation and analysis

3.2.1. Hydrodistillation

Fresh leaves (1.2 kg) of *L. tomentosa* were hydrodistilled for 3 h using a Clevenger-type apparatus to yield 2.0 ml of oil (0.16% v/w). Chrysanthenone-enriched fractions from *L. tomentosa*—contaminated with trace amounts of filifolone (**3**) and *Z*-isogeranic acid (**4**, <0.1%) and isochrysanthenone (**2**, 5–11%)[1] were hydrodistilled in a similar way. Chrysanthenone (from irradiation of verbenone), containing small amounts of compounds **3**, **4** and **2** (4%), was hydrodistilled as described above.

3.2.2. Cold extraction

L. tomentosa fresh leaves (50 g) were soaked in pentane (100 ml) for 24 h at room temperature. The extract was drained and the remaining material was subsequently soaked in ether (100 ml) for 24 h at room temperature. Both extracts were analysed by GC before and after removal of solvent.

3.2.3. Soxhlet extraction

Samples of powdered leaves (10–50 g) were extracted successively by pentane, ether and methanol using Soxhlet for periods of 3 h. Each extract was separated into fractions by flash chromatography using pentane, ether and methanol as eluents followed by hydrodistillation of the fractions. Hydrodistilled fractions containing filifolone (**3**) and *Z*-isogeranic acid (**4**) were registered.

3.2.4. GC analysis

The samples were analysed by GC and enantioselective GC. A Supelcowax 10 (30 m×0.25 mm, 0.2 μm film thickness) fused silica capillary column with helium as carrier gas at a flow rate of 1 ml min^{-1}, and with a split ratio of 82, was used for GC analysis. The column temperature was programmed from 70 °C (5 min), 70–180 °C (5 min), 180–240 °C (10 min) and 240 °C (10 min). An FID detector was used at a temperature of 260 °C and the injector temperature was 210 °C. Enantioselective GC analyses were performed on a CP Chirasil-DEX CB (25 m×0.25 mm, 0.25 μm film thickness) fused silica capillary column temperature programmed as follows: 100 °C (10 min), 1.5 °C min^{-1} to 180 °C (15 min). Carrier gas flow rate was 1 ml min^{-1}. Injector and detector temperatures were 210 and 260 °C, respectively. Preparative GC was conducted on a Hewlett Packard GC instrument equipped with a glass column (15% OV-17; 2.26 m×4 mm). Injector and detector temperatures were 260 °C. The column temperature for sample analysis of

[1] All compositional % quoted in this work are based upon relative amounts from GC analyses.

chrysanthenone and filifolone was 150 and 200 °C, respectively. Nitrogen was used as a carrier gas at a flow rate of 100 ml min^{-1}.

Received in revised form 23 January 2001

Abstract

Four anthocyanins from *Ajuga reptans* flowers and its cell cultures were isolated, and a fifth was also characterized by HPLC-mass spectrometry. By means of chemical and spectroscopic analyses, their structures were identified as delphinidin 3-(*p*-coumaroyl-feruloyl)sophoroside-5-malonylglucoside, delphinidin 3-(diferuloyl)sophoroside-5-malonylglucoside, and cyanidin 3-(di-*p*-coumaroyl)sophoroside-5-glucoside, respectively. The other two were tentatively identified as delphinidin 3-(diferuloyl)sophoroside-5-glucoside and cyanidin 3-(feruloyl-*p*-coumaroyl)sophoroside-5-malonylglucoside. In neutral aqueous solution, the crude extract from *A. reptans* flower cell cultures and the major anthocyanin cyanidin 3-(di-*p*-coumaroyl)sophoroside-5-malonylglucoside were more stable than cyanidin 3-glucoside, and also prevented more efficiently peroxidation than did the latter. *A. reptans* flower cell culture anthocyanins may have a potential as natural colorants for food utilities or other purposes. © 2001 Elsevier Science Ltd. Keywords: *Ajuga reptans* L.; Lamiaceae; Cell culture; Flavonoid; Anthocyanin; Acylated anthocyanidin 3-Sophoroside-5-glucosides; Stability; Antioxidative activity

1. Introduction

In recent years, many studies of anthocyanin production by plant cell, tissue and organ cultures have been conducted in either the biochemical or the food chemical fields (Yamamoto et al., 1981; Harborne et al., 1983; Tamura et al., 1989; Calsteren et al., 1991; Takahashi et al., 1991; Mori et al., 1993; Sakamoto et al., 1993; Baker et al., 1994; Cormier et al., 1994; Tholakalabavi et al., 1994). *Ajuga reptans* L., (Lamiaceae), is a plant grown in Europe, North America and West Asia, and is called "Bugle" in France, "Günsel" in Germany and "Seiyo-Kiransou" in Japan. It has bluish-purple flower and reddish-purple leaf colored with anthocyanin pigments. The cell cultures of the flower and leaf produce acylated anthocyanins (Callebaut et al., 1990a,b, 1993) under appropriate conditions. In the flower culture system, both the composition and the amounts of anthocyanins produced were shown to be stable (Callebaut et al, 1997). Thus, it is a good anthocyanin producing system and a suitable tool to investigate anthocyanin modification (Callebaut et al., 1996). A preliminary examination showed that the major pigments of the flower cell cultures were cyanidin 3-sophoroside-5-glucoside-based, and resembled more the pigments of the leaf or the leaf cultures rather than those of the flower itself, i.e. delphinidin 3-sophoroside-5-glucoside-based (Callebaut et al., 1990a, 1993).

Recently, the major anthocyanins of *A. reptans* flower and flower cell cultures were determined as delphinidin 3-(di-*p*-coumaroyl)sophoroside-5-malonylglucosides and cyanidin 3-(di-*p*-coumaroyl)sophoroside-5-malonylglucosides, respectively (Terahara et al., 1996). The leaf culture of the related species *A. pyramidalis* Metallica Crispa was shown to produce the same type of anthocyanins. It mainly accumulated cyanidin 3-(diferulyl)sophoroside-5-malonylglucoside (Madhavi et al., 1996).

We have now established the structures of three new anthocyanins from *A. reptans* flower and the

corresponding cell cultures by chemical and spectroscopic methods comprising HPLC-electrospray ionization mass spectrometry (LC–ESIMS), FABMS, Electrospray Ionization Fourier transform Ion Cyclotron Resonance Mass Spectrometry (ESI/FT–ICRMS) and various NMR spectroscopic methods. For application of cell culture anthocyanins as food colorants, the stability and the antioxidative activity of the crude extract were also examined, together with the major anthocyanin cyanidin 3-(di-*p*-coumaroyl)sophoroside-5-malonylglucoside, its deacylated derivative cyanidin 3-sophoroside-5-glucoside and cyanidin 3-glucoside .

2. Results and discussion

By HPLC analysis under improved conditions, *A. reptans* flower crude extract contained more than seven anthocyanins, and the corresponding cell cultures contained more than 16, as shown in Fig. 1.

Preliminary acid hydrolysis of *A. reptans* flower crude extract gave predominantly delphinidin (Dp) and to a lesser extent cyanidin (Cy). In contrast, the flower crude extract c gave mainly Cy and a lower amount Dp (Callebaut et al., 1993; Terahara et al., 1996). These extracts were purified and isolated through several forms of column chromatography as in the previous report (Terahara et al., 1996). Three anthocyanins **1**–**3** were isolated from *A. reptans* flowers, and one (**4**) from the corresponding cell cultures.

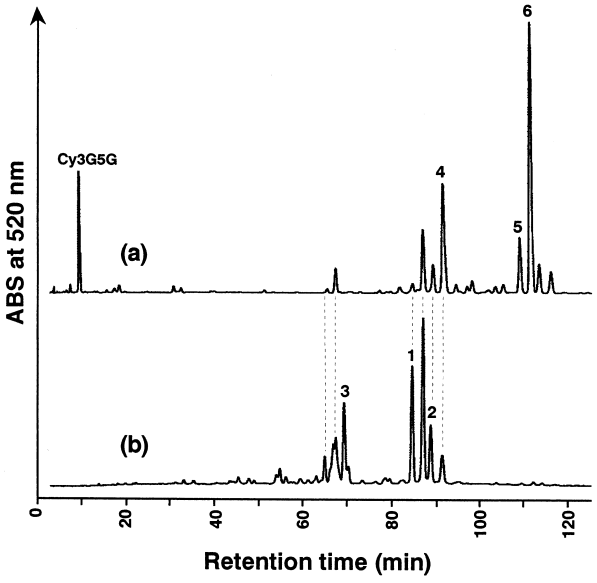

Fig. 1. Anthocyanin compositions of the crude extracts from (a) flower cell culture and (b) flower of A. reptans. HPLC was run on Inertsil ODS-2 column at 35°C with a flow rate of 1 ml min^{-1} monitoring at 530 nm. Cy3G5G indicates cyanidin 3,5-diglucoside. Anthocyanin six indicates cyanidin 3-(di-*p*-coumaroyl)sophoroside-5-malonylglucoside determined on a previous experiment (Terahara et al., 1996).

On acidic hydrolysis, **1**–**3** gave Dp and **4** gave Cy as aglycons, respectively. All the hydrolysates gave only glucose (G) as the released sugar component. In the UV-VIS spectra of **1**–**4**, the presence of the characteristic absorptions around 315 nm (**1** and **4**) and 325 nm (**2** and **3**) suggested that these were acylated with hydroxycinnamic acids such as *p*-coumaric acid (P) and ferulic acid (F), respectively. The numbers of bound hydroxycinnamic acids in all pigments could be estimated as 2 moles, when the values (about 160%) of $E_{acid.max}$ /$E_{VIS.max}$ (a ratio of absorbances at hydroxycinnamic acid absorption maximum and at visible absorption maximum) were compared with Harborne's data (1958). Especially, **2** and **3** have two ferulic acids because of a characteristic bathochromic shift of $\lambda_{acid.max}$ of about 10 nm compared with *p*-coumaric absorption. On alkaline hydrolysis, the acylating acids from **1** were identified as P, F and malonic acid (m), from **2** as F and m, from **3** as F, and from **4** as P by TLC and HPLC. Other than organic acids, the alkaline hydrolysis of **1**–**3** and **4** gave the deacylated anthocyanins delphinidin 3-sophoroside-5-glucoside (Dp3S5G) and cyanidin 3-sophoroside-5-glucoside (Cy3S5G), respectively. The 3,5-disubstitution patterns of **1**–**4** were also confirmed from the values (about 12%) of E_{440}/$E_{VIS.max}$ (a ratio of absorbances at 440 nm and visible absorption maxima), similar to those of common delphinidin 3,5-diglucoside and cyanidin 3,5-diglucoside (Cy3G5G) which are 10 and 13%, respectively (Harborne, 1958).

FABMS spectra of **1**–**4** were measured under a positive mode with a linked-scan of the molecular cations. Moreover, **5**, in addition to **4**, could be characterized by HPLC-electrospray ionization mass spectrometry (LC-ESIMS) in *A. reptans* flower cell culture crude extract. LC-ESIMS is a powerful tool for analysis of bio-molecules like anthocyanins, since it can separate chromatographically and simultaneously ionized unstable compounds softly, and then clearly gives the fragment ions as well as the molecular ions (Whitehouse et al., 1985; Sakairi and Kambara, 1988; Balidi et al., 1995). On FABMS and LC-ESIMS measurements, anthocyanins **1**, **2** and **5** were respectively determined as mono-malonylated. The molecular weight of each anthocyanin, the construction of partial structures, and the molecular formula based on the molecular ion and its fragmentation patterns could be determined as shown in Fig. 2. It shows that each molecular ion is decomposed to the aglycone via two routes. One is the pathway releasing the hexosyl-hexoside (glucosyl-glucoside) fragment (GG) diacylated with ferulic or *p*-coumaric acid (**1** and **5**: PGFG, **2** and **3**: FGFG, and **4**: PGPG), and followed by the elimination of glucose (**3** and **4**: G) or malonylglucose (**1**, **2** and **5**: mG) fragment. The other route is a reversed order case. The result indicates that each anthocyanin has two structural units (PGFG/FGFG/PGPG and mG/G) in

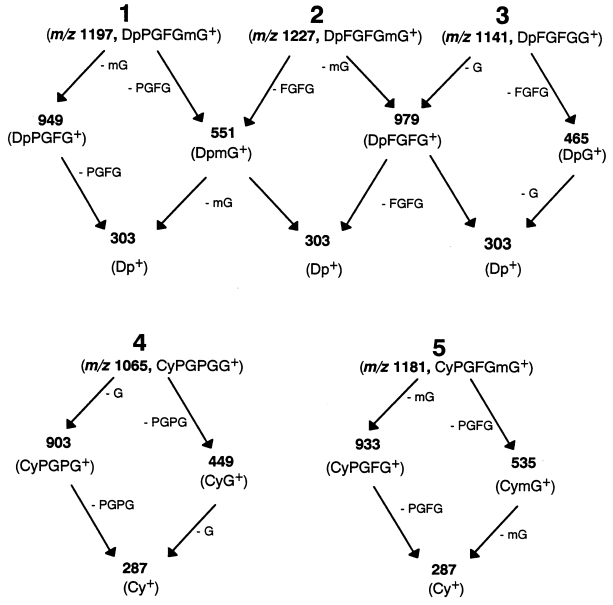

Fig. 2. Mass fragmentation patterns of *Ajuga reptans* flower and the cell culture anthocyanins. The values in the scheme show mass numbers (m/z) of molecular and fragment cations from the anthocyanins **1**–**5**. Abbreviations: Dp = delphinidin, Cy = cyanidin, G = glucose, F = ferulic acid, P = *p*-coumaric acid, and m = malonic acid.

the molecule. Combined with previous data (Terahara et al., 1996), the structural compositions of **1**–**5** can be deduced as DpPGFGmG, DpFGFGmG, DpFGFGG, CyPGPGG and CyPGFGmG, respectively. Thus the molecular formulas of **1**–**5** were respectively determined as $C_{55}H_{57}O_{30}^{+}$, $C_{56}H_{59}O_{31}^{+}$, $C_{53}H_{57}O_{28}^{+}$, $C_{51}H_{53}O_{25}^{+}$ and $C_{55}H_{57}O_{29}^{+}$. The molecular formulas of **1**, **2** and **4** were verified by high-resolution mass measurement using an electrospray ionization Fourier-transform ion cyclotron resonance mass spectrometer (ESI-FTICRMS) within an error of 5×10^{-4} (0.4 ppm) in mass assignment on the samples. ESI–FTICR mass spectrometry allows for high-resolution and accurate mass analyses of many biomolecules (Green et al., 1998).

Since anthocyanin **3** was obtained in insufficient amounts and **5** was not isolated, only **1**, **2** and **4** were used for further examinations.

Determination of detailed chemical structures of **1**, **2** and **4** were performed through ^{13}C and ^{1}H NMR analyses using DQF–COSY, NOESY, ROESY, 2D-HOHAHA, HSQC and HMBC methods as previously reported (Terahara et al., 1996). The assigned data are depicted in Table 1. At low field (δ_H 7–9 ppm) in the ^{1}H NMR spectra, the aglycone and hydroxycinnamoyl protons occurred as well separated signals, and at high field (δ_H 3–6 ppm), glucosyl (and malonyl) protons were observed as overlapping signals. In the low field area, four singlets of **1** and **2** were assigned to the protons of a Dp-unit having a symmetric B-ring, while three singlets, two doublets, and one double-doublet of **4** are to Cy-unit protons. In **1**, **2** and **4**, two pairs of characteristic doublets with large coupling constants ($J = 16$ Hz) were allocated to two pairs of olefinic α- and β-protons of *trans* (*E*)-hydroxycinnamoyl moieties. The superimposed proton signals at high field were assigned with the aid of HOHAHA spectra. As three anomeric protons of a-, b- and c-glucoses (G_a-1-H, G_b-1-H and G_c-1-H) in each pigment were characteristic doublets shifted to lower field with large coupling constants (7–8 Hz) and the glucosyl ring protons had large coupling constants (7–9 Hz), all sugars have a β-D-glucopyranosyl configuration. Proton and carbon signals of a-glucose (G_a-2-H/C) of each anthocyanin shifted to lower magnetic field (chemical shift differences ($\Delta\delta_H$): from +0.5 to +1.0 ppm, $\Delta\delta_C$: from +7.6 to +10.1 ppm) from those of G_b-2-H/C and G_c-2-H/C, indicating G_a-2-OH was glycosylated with G_b. Thus, the connectivity of G_a and G_b was deduced as 2-*O*-(β-D-glucopyranosyl)-β-D-glucopyranoside, a sophoroside. All glucosyl 6-methylene protons/carbons in **1** and **2** were also observed at lower field ($\Delta\delta_H$: from +0.4 to +0.8 ppm, $\Delta\delta_C$: from +6.5 to +10.1 ppm) compared with those of Cy3S5G (Terahara et al., 1996), indicating that the 6-OH positions of G_a, G_b and G_c were acylated. Similarly only G_a and G_b in **4** were observed at lower magnetic field, indicating that the 6-OH of G_a and G_b were acylated, but that G_c-6-OH was not. Malonyl methylene protons and carbons were observed at δ_H 3.38 (δ_C 41.33) and δ_H 3.39 (δ_C 41.29) ppm in **1** and **2**, respectively, but were not observed in **4**. At lower field, δ_C 166–168 ppm, four (**1** and **2**) and two (**4**) ^{13}C-signals could be easily assigned to carbonyl carbons of two hydroxycinnamoyl and one malonyl (not observed in **4**) moieties.

Connectivities of the three sugar moieties in **1**, **2** and **4** were unequivocally determined from NOESY and/or ROESY spectra. Cross-peaks of intense NOEs between Dp/Cy-4-H and G_a-1-H, Dp/Cy-6-H and G_c-1-H, and G_a-2-H and G_b-1-H proved that G_a, G_b and G_c were glycosylated to Dp/Cy-3-OH, Dp/Cy-5-OH and G_a-2-OH, respectively. Hence these basic structures are Dp/Cy 3-{G_b-(1→2)-G_a}-5-G_c that is Dp/Cy3S5G. The connectivity was also supported by the observation of weak NOEs between Dp/Cy-B-ring protons (2′- and 6′-H /2′-, 6′- and 5′-H) and G_b-1-H, showing that G_b was spatially close to the Dp/Cy-B-rings, respectively. Similarly, the connecting positions on the sugars of the acyl residues in **1**, **2** and **4** were mainly determined by HMBC spectra. In **1** and **2**, malonic acid was linked to G_c-6-OH due to the presence of ^{1}H–^{13}C cross-peaks between G_c-6-H and malonyl-carbonyl carbon. In **1**, **2** and **4**, the cross-peaks between G_a-6-H and hydroxycinnamic acid-I-carbonyl carbon and between G_b-6-H and acid-II-carbonyl carbon provided decisive proof that acids-I and-II were respectively linked to G_a-6-OH and G_b-6-OH.

In conclusion, the new anthocyanins **1**, **2** and **4** were unambiguously determined as 3-*O*-{2-*O*-(6-*O*-*E*-feruloyl-β-D-glucopyranosyl)-(6-*O*-*E*-*p*-coumaroyl-β-D-

[a] Abbreviations: G = glucose; Mal = malonic acid; *s* = singlet; *d* = doublet; *t* = triplet; *m* = multiplet; *brd* = broad doublet and brt = broad triplet. Values in parentheses indicate coupling constants (*J* in Hz).

glucopyranosyl)}-5-*O*-(6-*O*-malonyl-β-D-glucopyranosyl) delphinidin, 3-*O*-{2-*O*-(6-*O*-*E*-feruloyl-β-D-glucopyranosyl)-(6-*O*-*E*-feruloyl-β-D-glucopyranosyl)}-5-*O*-(6-*O*-malonyl-β-D-glucopyranosyl) delphinidin, and 3-*O*-{2-*O*-(6-*O*-*E*-*p*-coumaroyl-β-D-glucopyranosyl)-(6-*O*-*E*-*p*-coumaroyl - β-D-glucopyranosyl)}-5-*O*-(β-D-glucopyranosyl) cyanidin, respectively. The anthocyanins **3** and **5** were tentatively determined as 3-(di-feruloyl)sophorosyl-5-glucosyl delphinidin and 3-(feruloyl-*p*-coumaroyl)sophorosyl-5-malonylglucosyl cyanidin, respectively (Fig. 3).

The stability and antioxidative activity of *A. reptans* flower cell culture crude extract, its major anthocyanin cyanidin 3-(di-*p*-coumaroyl)sophoroside-5-malonylglucoside (**6**) whose structure had been already determined (Terahara et al., 1996), and the deacylated derivative Cy3S5G were compared with cyanidin 3-glucoside (Cy3G) in neutral aqueous solution. The stability could be evaluated on the basis of the half-life ($t_{1/2}$) which was defined as the time to reach 50% residual color. As shown in Fig. 4, **6** ($t_{1/2} > 600$ min) and the cell culture crude extract ($t_{1/2} = 270$ min) were more stable than Cy3G ($t_{1/2} = 80$ min) and Cy3S5G ($t_{1/2} = 15$ min). Comparison of the stability of **6** and Cy3S5G suggested that the two *p*-coumaric acids protect the aglycone nucleus by a sandwich type hydrophobic stacking mechanism, and inhibit the attack of a water molecule that leads to a loss of color (Brouillard, 1983; Goto and Kondo, 1991).

The antioxidative activity of the cell culture crude extract and **6** were measured as the inhibitory ratio to β-carotene bleaching induced with linoleic acid peroxidation by lipoxygenase (Igarashi et al., 1989, 1993). As shown in Fig. 5, **6** and the cell culture crude extract showed weaker antioxidative activity than a natural antioxidant α-tocopherol and a synthetic antioxidant BHT. However, **6** demonstrated stronger activity than non-acylated anthocyanins Cy3G5G, Cy3S5G and Cy3G which had strong antioxidative activity as reported by Tsuda et al. (1994), and than other polyphenols like *p*-coumaric acid and (+)-catechin. The difference of antioxidative activity between **6** and Cy3S5G was considered that the

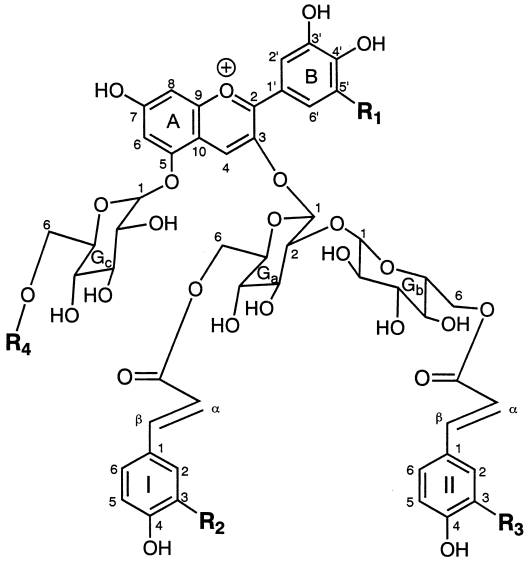

Fig. 3. Structures of *Ajuga reptans* flower and the cell culture anthocyanins. The anthocyanins **3** and **5** are the tentative structures.

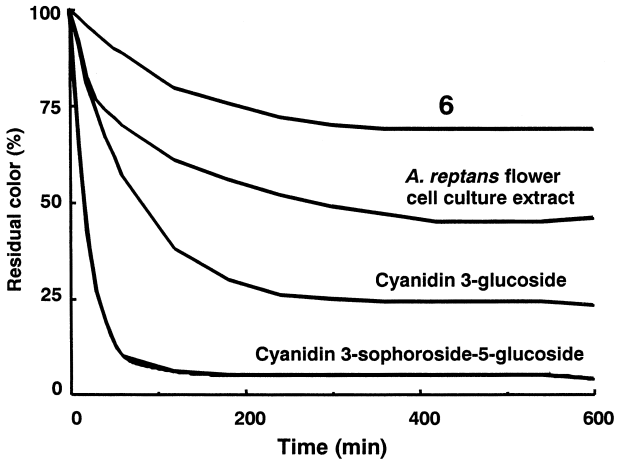

Fig. 4. Stability of *Ajuga reptans* flower culture anthocyanins in neutral aqueous solution at room temperature. Anthocyanin **6** indicates cyanidin 3-(di-*p*-coumaroyl)sophoroside-5-malonylglucoside.

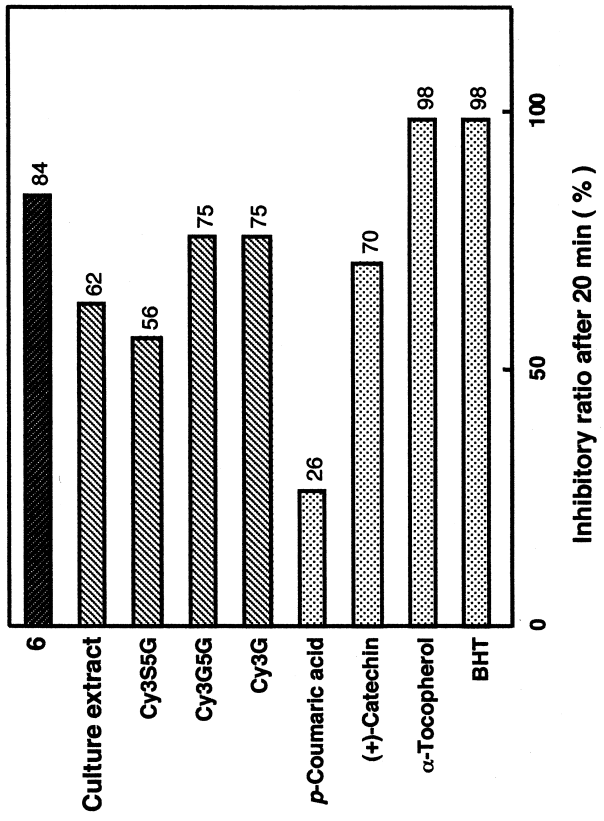

Fig. 5. Antioxidative activity of *Ajuga reptans* flower culture anthocyanins on β-carotene bleaching by linoleic acid — lipoxygenase system. Abbreviations: Crude extract = *A. reptans* flower cell culture extract, **6** = cyanidin 3-(di-*p*-coumaroyl)sophoroside-5-malonylglucoside, Cy3S5G = cyanidin 3-sophoroside-5-glucoside, Cy3G5G = cyanidin 3,5-diglucoside, Cy3G = cyanidin 3-glucoside, and BHT = butylated hydroxytoluene.

two intramolecular *p*-coumaric acids synergistically operated with **6** to prevent lipid peroxidation (Tamura and Yamagami, 1994). Therefore, hydroxycinnamic acid moieties in anthocyanins from *A. reptans* flower cell culture could play important roles for enhancement of stability and antioxidative activity.

Thus, *A. reptans* flower cell cultures are an excellent anthocyanin source for natural colorants of foods or others, because they produce anthocyanins with a constant composition and amount for a long time (Callebaut et al., 1997), and the produced anthocyanins have higher stability and antioxidative activity than Cy3G which is major anthocyanin in a purple corn pigment used currently as a commercially available food colorant.

3. Experimental

3.1. General procedures

All the reagents and solvents employed were of analytical grade and used without further purification. TLC, analytical HPLC and preparative HPLC were run under established conditions (Terahara et al., 1996). However, in order to get better resolution, the analytical HPLC elution mode was improved by using a linear gradient elution for 140 min from 18 to 46% solvent B (1.5% H_3PO_4, 20% AcOH, 25% MeCN in H_2O) in solvent A (1.5% H_3PO_4 in H_2O) on Inertsil ODS-2 column (4.6 i.d.×250 mm, GL Sciences Inc.) at 35°C with a flow rate of 1 ml min^{-1} monitoring at 530 nm. UV-VIS spectra were recorded on MPS-2000 spectrophotometer (Shimadzu Co., Ltd.) in 0.01% HCl–MeOH. FABMS spectra were measured on a JMS SX102 (Jeol Co., Ltd.) in MeOH with *m*-nitrobenzyl alcohol as a matrix in the positive mode and a linked scan method. ^{13}C (150.8 MHz) and ^{1}H (600.1 MHz) NMR spectra were run on alpha-600 (Jeol Co., Ltd.) in DMSO-*d*6: CF_3COOD = 9:1. LC–ESIMS analysis was performed on a PU-980 Intelligent pump system (Jasco Co., Ltd.) and run on a L-column ODS (4.6 i.d.×250 mm, Chemical Inspection and Testing Institute, Japan) at 40°C with a flow rate of 1 ml min^{-1} with detection at 530 nm by a UV–visdetector (UV-970, Jasco Co., Ltd.) coupled with an electrospray ionization (ESI) interfaced mass spectrometer Platform (VG biotech Co., Ltd.). It eluted with a linear gradient for 30 min from 15 to 20% solvent B (MeCN) in solvent A (0.4% HCOOH). Electrospray ionization Fourier-transform ion cyclotron resonance mass spectra (ESI–FTICRMS) were measured on ApexII mass spectrometer (Bruker Daltonics, Inc., USA) in 50%MeOH in 1%AcOH. Spectronic 20A (Shimadzu Co., Ltd.) was used for colorimetric measurements of antioxidative activity assay.

3.2. Plant materials

Anthocyanin producing cell cultures were induced from young flowers according to previous reports (Callebaut et al., 1990a, 1993).

3.3. Isolation and preparation of pigments

Isolation and preparation of anthocyanins of *A. reptans* flower and the cell cultures were carried out as was previously reported (Terahara et al., 1996). Three anthocyanins **1**–**3** were isolated from *A. reptans* flowers and one (**4**) from the cell cultures as red amorphous powders of trifluoroacetic acid (TFA) salts. The crude pigment of *A. reptans* flower cell cultures was prepared as described in the report (Terahara et al., 1996). Cy3S5G were prepared by alkaline deacylation of the major culture anthocyanin, **6**. Cy3G5G and Cy3G were isolated from *A. reptans* flower cell culture crude extract and a purple corn, respectively.

3.4. Pigment composition

As shown in Fig. 1, *A. reptans* flower cell culture crude extract contained anthocyanins at retention times

(contents%); Cy 3G5G: 8.4 (8%), 63.9 (1%), 65.8 (3%), **1**: 82.6 (1%), 85.0 (7%), **2**: 87.2 (4%), **4**: 89.5 (16%), **5**: 106.4 (7%), **6**: 108.8 (34%), unknown: 110.6 (4%) and unknown: 113.3 (3%) min. *A. reptans* flower crude extract contained anthocyanins at retention times (contents%); 63.9 (3%), 65.8 (12%), **3**: 67.9 (10%), **1**: 82.6 (16%), 85.0 (24%), **2**: 87.2 (8%) and **4**: 89.5 (5%) min.

3.5. FABMS analytical data

FABMS spectra of isolated anthocyanins gave m/z as follows; **1**: 1197 ($M = DpPGFGmG = C_{55}H_{57}O_{30})^+$, 949 ($DpPGFG = C_{46}H_{45}O_{22})^+$, 551 ($DpmG = C_{24}H_{23}O_{15})^+$, 303 ($Dp = C_{15}H_{11}O_7)^+$, 177 ($F = C_{10}H_9O_3)^+$, 147 ($P = C_9H_7O_2)^+$; **2**: 1227 ($M = DpFGFGmG = C_{56}H_{59}O_{31})^+$, 979 ($DpFGFG = C_{47}H_{47}O_{23})^+$, 551 ($DpmG_c = C_{24}H_{23}O_{15})^+$, 303 ($Dp = C_{15}H_{11}O_7)^+$, 147 ($P = C_9H_7O_2)^+$; **3**: 1141 ($M = DpFGFGG = C_{53}H_{57}O_{28})^+$, 979 ($DpFGFG = C_{47}H_{47}O_{23})^+$, 465 ($DpG = C_{21}H_{21}O_{12})^+$, 303 ($Dp = C_{15}H_{11}O_7)^+$, 147 ($P = C_9H_7O_2)^+$; **4**: 1065 ($M = CyPGPGG = C_{51}H_{53}O_{25})^+$, 903 ($CyPGPG = C_{45}H_{43}O_{20})^+$, 449 ($CyG_c = C_{21}H_{21}O_{11})^+$, 287 ($Cy = C_{15}H_{11}O_6)^+$, 147 ($P = C_9H_7O_2)^+$.

3.6. High-resolution mass data

ESI–FTICRMS afforded accurate mass assignments for single charged ions of anthocyanins at a mass resolution in excess of 2×10^4, and with an error of about 0.4 ppm as follows; **1**: obsd. m/z 1197.29338 (calc. 1197.29292 as $M^+ = C_{55}H_{57}O_{30}^+$); **2**: 1227.30389 (calc. 1227.30348 as $M^+ = C_{56}H_{59}O_{31}^+$); **4**: 1065.28738 (calc. 1065.28704 as $M^+ = C_{51}H_{53}O_{25}^+$).

3.7. LC–ESIMS analytical data

The crude extract from *A. reptans* flower cell culture crude extract gave the following mass numbers at retention times (m/z of molecular and fragment ions); $DpPGPGG^+$: 14.8 (1081: $M^+ = C_{51}H_{53}O_{26}^+$, 919, 465, 303), $CyPGPGG^+$ (**4**): 22.3 (1065: $M^+ = C_{51}H_{53}O_{25}^+$, 903, 449, 287), $DpPGPGmG^+$: 24.7 (1167: $M^+ = C_{54}H_{55}O_{29}^+$, 551, 303), $CyPGFGmG^+$ (**5**): 32.3 (1181: $M^+ = C_{55}H_{57}O_{29}^+$, 933: $CyPGFG^+ = C_{46}H_{45}O_{21}^+$, 535: $CymG^+ = C_{24}H_{23}O_{14}^+$, 287: $Cy^+ = C_{15}H_{11}O_6^+$), $CyPGPGmG^+$: 33.8 (1151: $M^+ = C_{54}H_{55}O_{28}^+$, 903, 535, 287) min

3.8. UV–vis spectral data

UV–vis spectra gave following data; **1**: λ_{max} (0.01% HCl–MeOH) nm: 542 (shifted bathochromically by 53 nm with $AlCl_3$), 316, $E_{440}/E_{VIS.max} = E_{440}/E_{542} = 11\%$, $E_{acid.max}/E_{VIS.max} = E_{316}/E_{542} = 164\%$; **2**: λ_{max} (0.01% HCl–MeOH) nm: 542 (shifted bathochromically by 53 nm with $AlCl_3$), 325, $E_{440}/E_{VIS.max} = E_{440}/E_{542} = 13\%$, $E_{acid.max}/E_{VIS.max} = E_{325}/E_{542} = 184\%$; **3**: λ_{max} (0.01% HCl–MeOH) nm: 544 (shifted bathochromically by 50 nm with $AlCl_3$), 284, 326, $E_{440}/E_{VIS.max} = E_{440}/E_{544} = 12\%$, $E_{acid.max}/E_{VIS.max} = E_{316}/E_{544} = 141\%$; **4**: λ_{max} (0.01% HCI–MeOH) nm: 527 (shifted bathochromically by 50 nm with $AlCl_3$), 299, 314, $E_{440}/E_{VIS.max} = E_{440}/E_{527} = 19\%$, $E_{acid.max}/E_{VIS.max} = E_{314}/E_{527} = 158\%$.

3.9. Stability test

Citric acid 1-hydrate (Chameleon), and disodium hydrogenphosphate 12-water (Chameleon) were used for McIlvaine (10^{-1} M citrate — 2×10^{-1} M phosphate) buffer components. Each anthocyanin mono-TFA salt (10^{-6} mol) and the cell culture crude extract (5 mg) were dissolved in 20 ml of pH 7.0 McIlvaine buffer solution (pure anthocyanin concentration: 5×10^{-5} M, the cell culture crude extract: 25×10^{-2} mg ml^{-1}), and the VIS spectra (400–700 nm) were measured automatically at appropriate time intervals. Based on the absorbance at $\lambda_{VIS.max}$ of each spectrum, the residual color (%) was calculated as percent of the initial absorbance (=100%). The stability of the anthocyanin could be evaluated on the basis of the half-life ($t_{1/2}$), defined as the time to reach 50% residual color.

3.10. Antioxidative activity assay

β-Carotene (Wako Pure Chemical) was used as indicator for antioxidative activity. Linoleic acid (Nippon Oil & Fats Co., EXTRA LINOLEIC-90) was used as model lipid for peroxidation with lipoxygenase (lipoxydase from soybean, Boehringer Ingelheim Bioproducts). *p*-Coumaric acid (Tokyo Chemical), (+)-catechin (Extrasynthese) and α-tocopherol (Wako Pure Chemical) were used as natural antioxidants, and butylated hydroxytoluene (BHT, Wako Pure Chemical) as synthetic antioxidant. Each sample solution was tested according to the modified method of Igarashi et al. (1989). Four milliliters of 150 μg ml^{-1} linoleic acid in pH 7.0 McIlvaine buffer (containing 0.8 mg ml^{-1} of Tween 80), 300 μl of 50 μg ml^{-1} β-carotene in acetone, and 200 μl of 1 mM-substrate ethanol solution (concentration of the cell culture crude extract: 1 mg ml^{-1}) were mixed in a test tube. To this solution, 500 μl of 100 μg ml^{-1} lipoxygenase aqueous solution was added and shaken immediately. Final sample concentration was 40 μM (or 40 μg ml^{-1}), and pH of the test solution was about 7.2. The mixture was kept standing at 20°C, then measured the residual β-carotene content at 460 nm at appropriate interval times. A reaction mixture without substrate was similarly treated and used as a control in colorimetry. The antioxidative power of substrates was evaluated with inhibitory ratio (IR%) between each substrate and control.

Isolation of solasodine and other steroidal alkaloids and sapogenins by direct hydrolysis-extraction of *Solanum* plants or glycosides therefrom

Martin Weissenberg*

Laboratory of Natural Products Chemistry, Department of Plant Genetics, Institute of Field Crops, Agricultural Research Organization, The Volcani Center, PO Box 6, Bet Dagan 50 250, Israel

Received 16 January 2001; accepted 1 March 2001

Abstract

Concomitant extraction and hydrolysis of *Solanum* steroidal glycoalkaloids in a two-phase system containing an aqueous mineral acid and an organic water immiscible solvent, and having a boiling point under 100°C, is described. It is essentially a "one-pot" process, combining direct acid hydrolysis of the glycosides in the plant material and in situ extraction of the released aglycones after alkali treatment, in a single step, the various ingredients being added simultaneously or sequentially, as required. Application of the process to fruits, leaves, and tissue cultures of *Solanum khasianum* Clarke plants, either fresh or in dried, finely ground form, using a two-phase aqueous hydrochloric acid-toluene system, proved to be very suitable for continuous production of pure solasodine which is a valuable raw steroid for the preparation of steroidal drugs. Pure *Solanum* glycoalkaloids were also prepared and hydrolysed accordingly. The process has analytical applications too, and could be extended in a general way to glycosides in other series for preparation of their related aglycones. © 2001 Elsevier Science Ltd. 1. Introduction

Proliferation of papers dealing with simultaneous isolation and hydrolysis of *Solanum* glycoalkaloids using either single-phase (Löken and Sollins, 1970; Hardman and Williams, 1976; Panina et al., 1976; Weston, 1976; Pandeya et al., 1981; Chandler and Dodds, 1983; Ntahomvukiye et al., 1983; Chungath and Nair, 1989; Kittipongpatana et al., 1999) or two-phase (van Gelder, 1984) solvent systems, prompts us to report our own results which have been patented (Weissenberg, 1982) and only briefly reviewed at the time (Chem. Abstr., 1983 [see Weissenberg, 1982]; Harrison, 1984), and thus apparently underexposed to general attention. Our investigation was part of an extensive study concerned with the development of high-yielding varieties and mutants of solasodine-bearing *Solanum khasianum* Clarke plants (Yaniv et al., 1981) as a convenient source of 16-dehydropregnenolone acetate (DPA), which is a starting material for anti-fertility and anti-inflammatory steroidal drugs (Mann, 1978).

In *S. khasianum* plants, solasodine (**1**) occurs mainly as triosides solasonine (**2**) and solamargine (**3**) (Figs. 1 and 2). The reported procedures for preparation of solasodine were reviewed (Weston, 1976; Mann, 1978; Crabbe and Fryer, 1983), and include either enzymatic hydrolysis of solasodine glycosides by fermentation of plant raw material (Fonin et al., 1996), or their extraction by means of aqueous and/or alcoholic acids; simultaneously with, or subsequent to the extraction, occurred hydrolysis of the glycoalkaloids by which the sugar moiety is split off. In these acid extraction methods, the separation of the plant material from the liquid phase after the extraction is slow and tedious. Alternatively, extraction might be carried out with an alcohol alone, whereby the extracted material is isolated by precipitation with an alkali, and is then subjected to

hydrolysis with an alcoholic acid solution. The free base obtained according to either of these methods is precipitated from alcoholic acid solution by alkalinisation, and the raw material prepared in this way is then purified.

All these methods require at some stage boiling with an aqueous or alcoholic acid solution. It has been found that following this process, the yield of **1** is significantly reduced due to the occurrence of side reactions that leads to degradation products (Weston, 1976; Crabbe and Fryer, 1983). They include 3,5-solasodiene (**4**), which is formed by dehydration of solasodine upon boiling with acids. As a result, the crude material is obtained in only moderate yields as a brown-greenish powder contaminated with by-products, pigments, salts, sapogenins, and a fair amount of **4**. The latter, of course, is useless as a steroidal drug precursor being devoid of a 3-oxygenated function, and the purification of the crude **1** thus obtained proved to be laborious, to involve loss of material, and finally to afford modest yields of a satisfactory raw product. The object of our study was to provide a simplified and improved process for the isolation of alkaloidal steroids from plant material that contains them in glycoside form. The present communication describes the process, as well as its preparative and analytical applications.

2. Results and discussion

The process is based on the different solubility in certain selected solvents of the polar glycoalkaloids and the

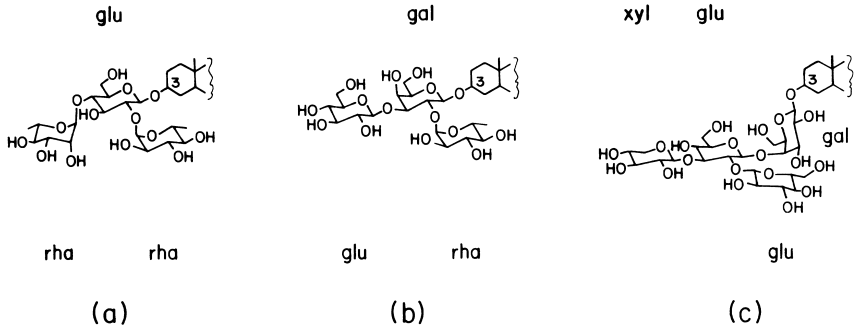

Fig. 2. Carbohydrate moieties attached to the position 3 in the steroidal framework of some spirosolane glycoalkaloids. (a) chacotriose; (b) solatriose; (c) lycotetraose. glu = D-glucose; gal = D-galactose; xyl = D-xylose; rha = L-rhamnose.

apolar aglycones. Thus, it has been found that pure aglycones can be obtained in high yield by conducting the hydrolysis of their corresponding glycosides in a two-phase liquid system comprising an aqueous solution of a mineral acid and a water immiscible organic solvent, and having a boiling point at a temperature below 100°C. Following reflux of the reaction mixture, the glycosides undergo hydrolysis in the aqueous acid phase, and the aglycone set free by alkalinisation is simultaneously extracted into the organic phase of the liquid system, thus being protected from further contact, with the acid phase. Prior to alkalinisation, the presence of the organic solvent suppresses the side reactions of the solasodine salt and of the partially hydrolysed products formed, prevents their precipitation, and thus ensures complete hydrolysis. Moreover, the temperature of the reaction mixture in the two-phase liquid system is, as a rule, lower than in the one-phase process, which is also a contributory factor to the decrease of side reactions. Following alkalinisation, the alkaloidal steroid is selectively removed into the organic solvent phase from which it can be readily recovered, either by direct crystallisation from the concentrated extract, or by extraction with an aqueous acid followed by alkalinisation of the aqueous acid extract. In both cases, the crude product consisting of colourless crystalls or amorphous precipitate, respectively, of solasodine, is obtained in over 90% recovery, and is sufficiently pure to serve as the starting material for conversion into DPA. Other examples of alkaloidal steroids that could be isolated in accordance with this process beside the previously mentioned solasodine (**1**), are the latter 22S,25S isomer tomatidenol (**5**) which occurs as glycosides α- and β-solamarines (**6** and **7,** respectively) in *S. dasyphyllum* Thonn. and *S. dulcamara* L., and its 5,6-saturated derivative tomatidine (**8**) which occurs as a 3β-lycotetraoside (tomatine, **9**) in *Lycopersicon esculentum* Mill (Figs. 1 and 2). All these spirosolane aglycones can be readily degraded to 16-dehydropregnane derivatives. Solaverbascine (**10**), a 16β-hydroxy derivative of **1** occurring in *S. verbascifolium L. (*Adam et al., 1980), was prepared in the same way both from its solatrioside (**11**) and chacotrioside (**12**) synthesised in turn by reduction with sodium borohydride of **2** and **3**, respectively (see Experimental).

Among the various mineral acids that are suitable as the aqueous acid component of the two-phase system in the process, hydrochloric acid and sulphuric acid may be mentioned in particular. The organic water-immiscible solvents that were evaluated comprise aromatic hydrocarbons such as benzene, toluene, and xylene, as well as halogenated aliphatic hydrocarbons like chloroform, carbon tetrachloride, and ethylene dichloride. The preferred solvent was toluene, used in a 1:1 v/v mixture with hydrochloric acid whose concentration is from 3.5 to 7% by weight, and preferably about 5% by weight. Such a two-phase system has a first boiling point at about 85°C.

In a preliminary attempt, purified mixtures of glycoalkaloids **2**, **3**, **6** and **7** (see Experimental) were refluxed for 3 h under stirring in the above mentioned two-phase liquid system; the reaction mixture was then alkalinised by addition of 40% w/v aqueous sodium hydroxide solution, and further refluxed under stirring. Phase separation and concentration in vacuo of toluene afforded the aglycones **1** and **5**, respectively. TLC monitoring of the process indicates that hydrolysis of the glycosides proceeds smoothly to yield the corresponding aglycones, practically free of dehydration products (TLC and NMR evidence).

Application of the process to fruits, leaves, and tissue cultures of various *Solanum* plants, either fresh or in dried, finely ground form (see Experimental), proved to be very suitable for continuous operation. It is essentially a ''one-pot'' process combining direct hydrolysis of steroidal glycoalkaloids in the plant material and in situ extraction of the released aglycones in a single step, the various ingredients being added into one vessel simultaneously or sequentially, as required. In experiments done with *S. khasianum* fruits, pure solasodine readily crystallised out from the concentrated toluene extracts, and the distilled off, or remaining mother liquor solvent may be recovered and recycled. As expected, work with fresh plant material avoids the time and energy-consuming steps of drying and milling.

In practicing the process, certain conditions proved to be imperative in order to obtain optimal yield and purity of the desired aglycone: (a) when processing oven-dried or lyophylised plant material, it should be finely ground before being submitted to hydrolysis; (b) the stirring of the two-phase system should be very efficient during the hydrolysis stage, and just moderate during alkalinisation in order to avoid formation of emulsions; (c) the proportions (by weight and volume) between plant material and reactants, the reaction duration, and the choice of the reagents, should be kept under the limits underlined in the Experimental section; (d) toluene is suggested as the solvent of choice since it leads to a two-phase system having an optimal boiling point, and has low propensity to emulsion formation. Besides, it allows spontaneous separation of crystalline solasodine from concentrated extracts. All the same, slight variations in the selection of appropriate solvents and conditions permit extension of this method to other saponins and glycosides of plant origin, substantially, as described.

Further application of this process for analytical purposes, which will be described elsewhere, enabled extensive screenings of large *Solanum* plant populations, as well as analyses of solasodine derivatives like immunogenic protein conjugates and inclusion complexes with cyclodextrin, prepared in connection with other works (Weissenberg, unpublished results). Among the solasodine-bearing *Solanum* plants examined, *S. khasianum* appears to be the best suited for the commercial production of **1**–**3**, as it was found to contain about 6% of **1** in dry whole fruits, most of it in the mucilage layer of the fruit (Yaniv et al., 1981). Spineless lines with high **1** content and concentrated fruit set were developed (A. Levy, unpublished results), and optimal cultivation practices were established for its eventual large-scale cultivation (Yaniv et al., 1983, 1984).

Besides its potential value as a raw starting material for synthesis of steroidal drugs, solasodine has been shown to possess some biological activity like antifungal (Wolters, 1976; Nes et al., 1982; Rowan et al., 1983; Kusano et al., 1987b), insect growth regulation (Raja et al., 1987; Kaur et al., 1988), and enzyme inhibition (Kusano et al., 1987a). Also it is noteworthy mentioning several reports on solasodine pharmacological effects, including significant cytotoxic activity in vitro against a variety of cancer cell lines (Lin et al., 1990; Nakamura et al., 1996), and DNA repair-deficient yeast mutants (Kim et al., 1996). It was also found to heal various *Herpes* skin lesions (Chataing et al., 1997), to inhibit *Trypanosoma cruzi* growth in vitro (Chataing et al., 1998), to inhibit proliferation of murine spleen cell cultures (Bähr and Hänsel, 1982), to mobilise glucocorticoids from the adrenals of rats (Dároczy and Hernádi, 1971), and to exhibit an antihepatotoxic effect on mice (Lin et al., 1988), It had an antiartherosclerotic effect on cholesterol-fed rabbits (Dixit et al., 1992), a hypotensive effect on cat (Basu and Lahiri, 1977), and an antispermatogenic effect on humans and bovines (Kanwar et al., 1990), Rhesus monkey (Dixit et al., 1989), and dog (Dixit and Gupta, 1982), respectively. On the other hand, a relatively low teratogenicity (Gaffield and Keeler, 1996), embryotoxicity (Friedman et al., 1992), and benign hapatomegaly (Friedman et al., 1996) were also noted. Likewise, intravenously injected solasodine was found to be excreted slowly in humans and in Syrian hamster (Claringbold et al., 1980). The occurrence, biological properties and ecological relevance of *Solanum* glycoalkaloids including **2**, **3**, **7**, **11** and **12**, have recently been assessed (Roddick et al., 2001).

3. Experimental

3.1. General

Mps, uncorr. ^{1}H and ^{13}C NMR at 400 and 100 MHz, respectively, in $CDCl_3$ or C_5D_5N. FAB–MS, glycerol matrix. TLC: precoated Kieselgel 60 F_{254} aluminium sheets (Merck), detection I_2 vapours. CC: silica gel 60, 70-230 mesh (Merck) or Al_2O_3 activity III (Woelm).

3.2. Plant material

Leaves and fruits of *S. khasianum, S. laciniatum* Ait., *S. aviculare Forst., S. marginatum* L., *S. mammosum* L. and *L. esculentum* were obtained from plants grown in an experimental field at the Volcani Center, Agricultural Research Organization, Bet Dagan, Israel, and harvested at about 8 months after sowing (courtesy of Professor A. Levy, Department of Plant Genetics, the Volcani Center, Agricultural Research Organization). A sample of purified *S. dulcamara* glycoalkaloids mixture was obtained through the courtesy of Professor J.F. Verbist, Faculty of Pharmacy, University of Nantes, France.

3.3. Reference compounds

Solasodine (**1**), tomatidine (**8**), tomatine (**9**), and solanidine were of commercial origin (Sigma, St. Louis, MO, USA). Pure reference samples of tomatidenol (**5**) and β-solamarine (**7**) were kindly provided by Dr. I. Merfort, University of Düsseldorf, Germany, and by Dr. M. Suffness, NCI, NIH, Bethesda, MD, USA, respectively. The following compounds were prepared in our laboratory according to published procedures:

3.3.1. (22R,25R)-Spirosola-3,5-diene (Solasodiene, 4)

This compound was prepared from solasodine refluxed with conc. HCl in MeOH by a modification of the method of Uskert (1963), and identified by comparison (mp, ^{1}H NMR) with reported data (Bird et al., 1979).

*3.3.2. (22S,25R)-22,26-Epiminocholest-5-ene-3β,16β-diol (Solaverbascine, Dihydrosolasodine A, **10**)*

This compound was prepared by reaction of **1** with $NaBH_4$ in MeOH for 3 h at room temp. according to Bird et al. (1979), and identified by comparison of physical and spectral data with reported data for solaverbascine isolated from *S. verbascifolium* (Adam et al., 1980), and for the synthetic compound (Bird et al., 1979).

3.4. Preparation of glycoalkaloids

*3.4.1. Solasonine (**2**) and Solamargine (**3**)*

Dried, finely ground berries of *S. khasianum* (150 g) were submitted to a preliminary purification which involved defatting with petroleum ether, and pigments removal with CH_2Cl_2. Subsequent exhaustive extraction with hot EtOH and evaporation of the solvent under reduced pressure afforded a crude glycosides extract (23.5 g) which was subjected to alumina CC. Elution with H_2O-satd *n*-BuOH yielded **3** (7.8 g) followed by mixtures of **3** and **2**, and finally **2** (2.8 g). The separation was monitored by TLC. Compounds **2** and **3** were repeatedly recrystallised from aqueous MeOH, and their identity ascertained by comparing physical and spectral data (mp, ^1H and ^{13}C NMR, and FAB–MS) with reported assignments (Fukuhara and Kubo, 1991). The mixtures of **2** and **3** were collected and rechromatographed on subsequent batches. Berries of *S. marginatum* were similarly processed; however, work with leaves of *S. laciniatum* or other species, which of course, do have a higher pigment content, would require an alkali treatment of the EtOH extract before CC, in order to have them removed.

*3.4.2. β-Solamarine (**7**)*

A purified glycoalkaloids mixture of *S. dulcamara* was subjected to repeated alumina CC (elution with H_2O-satd *n*-BuOH) monitored by TLC, followed by repeated prep. TLC ($CHCl_3$–MeOH–1% aq. NH_3 2:2:1) of the combined fractions enriched in **7**, which finally afforded pure **7** crystallised from MeOH–Me_2CO, and identified by comparison (mp, TLC) with reported data (Boll, 1962), and with an authentic sample. Since spectral data of **7** do not appear to have been reported previously, we note herein the positive FAB–MS, *m/z* (rel.int.) 868 $[M+H]^+$(100), 850 $[M+H-H_2O]^+$ (5), 722 $[M+H-C_6H_{10}O_4]^+$ (8), 704 $[M+H-C_6H_{12}O_5]^+$ (8), 414 $[C_{27}H_{43}NO_2+H]^+$(13); negative FAB–MS, *m/z* 866 $[M-H]^+$ (100), 720 $[M-H-C_6H_{10}O_4]^+$(12). ^{13}C NMR(C_5D_5N, TMS), aglycone signals: δ16.19 (C-21), 16.86 (C-18), 19.42 (C-19), 19.80 (C-27), 21.17 (C-11), 27.07 (C-23), 29.26 (C-24), 30.18 (C-2), 31.42 (C-25), 31.61 (C-8), 32.42 (C-7), 33.15 (C-15), 37.17 (C-10), 37.52 (C-1), 38.98 (C-4), 40.13 (C-12), 40.73 (C-13), 43.01 (C-20), 50.38 (C-9), 50.58 (C-26), 56.05 (C-14), 62.22 (C-17), 78.10 (C-3), 78.63 (C-16), 99.44 (C-22), 121.85 (C-6), 140.82 (C-5); oligosaccharide signals: δ100.28, 78.10, 77.87, 78.72, 76.94, 61.31 (glucose, C-1–C-6), 102.92, 72.57, 72.85, 74.13, 69.56, 18.52 (4-*O*-rhamnose, C-1–C-6), 102.08, 72.54, 72.75, 73.93, 70.45, 18.67 (2-*O*-rhamnose, C-1–C-6). ^1H NMR (C_5D_5N, TMS), aglycone signals: δ0.81(27-H_3), 0.87(18-H_3), 1.05(19-H_3), 1.08(21-H_3), 2.95(26-H_2), 3.80(3α-H), 4.11(16α -H), 5.32(6-H); oligosaccharide signals: δ4.94(glucose, H-1), 5.87 (4-*O*-rhamnose, H-1), 6.41 (2-*O*-rhamnose, H-1).

*3.4.3. (22S,25R)-16β-Hydroxy-3β-{O-α-L-rhamnopyranosyl-(1→2)-[O-β-D-glucopyranosyl-(1→3)]-β-D-galactopyranosyloxy}-22,26-epiminocholest-5-ene (solaverbascine 3β-O-solatrioside, **11**)*

To a solution of **2** (200 mg) in MeOH (40 ml) was added $NaBH_4$ (200 mg) and the reaction mixture was stirred for 1 h at room temp., then concentrated in vacuo, treated with ice-H_2O and extracted with *n*-BuOH (3×50 ml). The organic phase was washed with H_2O, and the solvent evapd in vacuo. The residue (186 mg, homogeneous on TLC) was treated with MeOH to give pure **11**, amorphous (92 mg); positive FAB–MS, *m/z* 886 $[M+H]^+$ (100), 868 $[M+H-H_2O]^+$(5), 416 $[C_{27}H_{45}NO_2+H]^+$(4); negative FAB–MS, *m/z* 884 $[M-H]^+$(7), 367 (100). ^{13}C NMR (C_5D_5N,TMS), aglycone signals: δ13.48 (C-18), 17.19 (C-21), 19.42 (C-19), 19.70 (C-27), 21.12 (C-11), 28.90 (C-23), 30.19 (C-2), 31.95 (C-25), 32.19 (C-8), 32.30 (C-7), 34.32 (C-24), 35.61 (C-15), 37.07 (C-10 and C-20), 37.53 (C-1), 38.84 (C-4), 40.44 (C-12), 42.75 (C-13), 50.52 (C-9), 54.74 (C-26), 55.19 (C-14), 59.22 (C-17), 61.77 (C-22), 71.21 (C-16), 78.38 (C-3), 121.96 (C-6), 140.93 (C-5); oligosaccharide signals: δ100.44, 76.53, 84.89, 70.45, 75.06, 62.57 (galactose, C-1–C-6), 105.87, 74.97, 78.54, 71.66, 77.59, 61.77 (glucose, C-1–C-6), 102.22, 72.61, 72.87, 74.22, 69.46, 18.64 (rhamnose, C-1–C-6). ^1H NMR (C_5D_5N, TMS), aglycone signals: δ0.73 (27-H_3), 0.75 (18-H_3), 1.09 (19-H_3), 1.10 (21-H_3), 2.80 (26-H_2), 3.80 (3α-H), 4.43 (16α-H), 5.34 (6-H); oligosaccharide signals: δ4.93 (glucose, H-1), 5.20 (galactose, H-1), 6.32 (rhamnose, H-1).

*3.4.4. (22S,25R)-16β-Hydroxy-3β-{O-α-L-rhamnopyranosyl-(1→2)-[O-α-L-rhamnopyranosyl-(1→4)]-β-D-glucopyranosyloxy}-22,26-epiminocholest-5-ene (solaverbascine 3β-O-chacotrioside, **12**)*

Compound **3** (200 mg) in MeOH (40 ml) was treated with $NaBH_4$ (200 mg) for 2 h at room temp., and the reaction mixture processed as described for **11**. The crude product (195 mg, homogeneous on TLC) was treated with EtOH with a few drops of H_2O to give pure **12** amorphous (119 mg), positive FAB–MS, *m/z* 870 $[M+H]^+$ (100), 852 $[M+H-H_2O]^+$(7), 724 $[M+H-C_6H_{10}O_4]^+$ (8), 706 $[M+H-C_6H_{12}O_5]^+$ (7), 416 $[C_{27}H_{45}NO_2+H]^+$ (3), 398 $[416-H_2O]^+$(6); negative FAB–MS, *m/z* 868 $[M-H]^+$(100), 722 $[M-H-C_6H_{10}O_4]^+$(16). ^{13}C NMR

(C_5D_5N,TMS), aglycone signals: δ13.48 (C-18), 17.19 (C-21), 19.42 (C-19), 19.70 (C-27), 21.13 (C-11), 28.92 (C-23), 30.21 (C-2), 31.93 (C-25), 32.21 (C-8), 32.28 (C-7), 34.33 (C-24), 35.62 (C-15), 37.06 (C-10 and C-20), 37.53 (C-1), 39.01 (C-4), 40.44 (C-12), 42.75 (C-13), 50.55 (C-9), 54.73 (C-26), 55.20 (C-14), 59.23 (C-17), 62.67 (C-22), 71.21 (C-16), 78.17 (C-3), 122.02 (C-6), 140.84 (C-5); oligosaccharide signals: δ100.31, 77.97, 77.81, 78.73, 76.93, 61.35 (glucose, C-1–C-6), 102.03, 72.75, 72.84, 73.93, 70.45, 18.65 (4-*O*-rhamnose, C-1–C-6), 102.94, 73.75, 72.54, 74.15, 69.53, 18.50 (2-*O*-rhamnose, C-1–C-6). ^{1}H NMR (C_5D_5N, TMS), aglycone signals: δ0.73 (27-H_3), 0.75 (18-H_3), 1.08 (19-H_3), 1.10 (21-H_3), 2.79 (26-H_2), 3.80 (3α-H), 4.42 (16α-H), 5.33 (6-H); oligosaccharide signals: δ 4.95 (glucose,H-1), 5.89 (4-*O*-rhamnose, H-1), 6.43 (2-*O*-rhamnose, H-1).

3.5. Isolation of solasodine and/or other steroidal alkaloids by direct hydrolysis- extraction of Solanum plants

3.5.1. From dried plant material

A suspension of dried, finely ground powder of different *Solanum* fruits and/or leaves (100 g) in toluene (300 ml), H_2O (200 ml) and conc. HCl (32%, 100 ml), was refluxed under stirring for 5 h. The reaction mixture was subsequently alkalinised with 40% aq. NaOH (200 ml) and refluxed again under stirring for 2 h. Following phase separation, the upper, pale-yellow toluene layer was siphoned out, and the remaining dark brown aqueous mixture was extracted three times with 100 ml portions of toluene. The combined toluene extracts were clarified with charcoal, then concentrated in vacuo to small volume. Further treatment involved either direct crystallisation of the cooled concentrate, or alternatively extraction with an equal volume of 25% aq. HOAc by stirring twice for 1 h at room temp. In the case of direct crystallisation, the mother liquor resulted following filtration of the colourless crystalline solasodine was subjected to extraction with dilute HOAc as described above. In both cases, the aqueous acid extract was separated off from the toluene layer and then alkalinised with 25% aq. NH_3. The mixture was briefly heated, then cooled at room temp. The solasodine which precipitated was filtered off, washed with cold H_2O and dried in air. The directly crystallised solasodine had mp 199–200°C, and the purity of both crystalline and precipitate samples was ascertained by TLC and NMR evidence, and by comparison with an authentic sample. The procedure gave consistently colourless and crystalline solasodine in 90–95% recovery, out of 5% content for *S. khasianum* fruits, 2.5–4% for *S. marginatum* fruits, 1.5% for *S. laciniatum* leaves, which solasodine contents were previously assayed by spectrophotometric analysis (Weissenberg, unpublished). The toluene recuperated during the process by concentration or by phases separation, was recirculated. Similarly processed *L. esculentum* (tomato) and *Solanum tuberosum* L. (potato) plants afforded pure tomatidine and solanidine, respectively, characterised by comparison with authentic samples.

3.5.2. From fresh plant material

The procedure is identical to that used in the previous example, Section 3.5.1, except that fresh fruits of different *Solanum* plants were processed instead of the dried, milled plant powder. Thus, fresh green-yellow fruits (containing about 80% moisture) were cut into slices, taking care to discard, as much as possible, seeds and retaining the richest glycoalkaloids-containing sap next to seeds. The slices were homogenised in a blender to a thick slurry which was transferred to the reaction vessel with a minimal volume of H_2O. Alternatively, the fresh fruits could be processed in a press to a past consisting of juice and pulp, which was subsequently homogenised and transferred as above. Proper amounts of conc. HCl and toluene were then added in proportion to the water content of the slurry, such as to obtain a 1:1 v/v mixture of toluene and aqueous phase, with about 5% acid concentration. The process was further carried out as described in Section 3.5.1.

3.5.3. From pure glycoalkaloids

Pure samples of glycoalkaloids solasonine (**2**), solamargine (**3**), β-solamarine (**7**), solaverbascine solatrioside(**11**), solaverbascine chacotrioside (**12**), were submitted to the two-phase hydrolysis as described in Section 3.5.1, to give quantitatively the pure aglycones: solasodine (**1**) from **2** and **3**, identified as described in Section 3.5.1; tomatidenol (**5**) from **7**, identified and characterised by comparing mp, TLC, and ^{1}H NMR with reported data (Kaneko et al., 1981), and with an authentic sample. ^{13}C NMR (C_5D_5N, TMS): δ15.91(C-21),16.74 (C-18),19.35(C-19), 19.43(C-27), 20.91 (C-11), 26.67 (C-23), 28.57 (C-24), 31.05 (C-2), 31.42 (C-25), 31.65 (C-8), 32.12 (C-7), 32.78 (C-15), 36.67 (C-10), 37.25 (C-1), 39.96 (C-4), 40.61 (C-12), 41.76 (C-13), 43.03 (C-20), 50.14 (C-9), 50.25 (C-26), 56.02 (C-14), 61.93 (C-17), 71.68 (C-3), 78.52 (C-16), 99.13 (C-22), 121.38 (C-6), 140.87 (C-5); solaverbascine (**10**) from **11** and **12**, identified by comparison with an authentic sample synthesised from **1** as described in Section 3.3.

Acknowledgements

The author is indebted to Professor J.F. Verbist, Faculty of Pharmacy, University of Nantes, France, to Dr. I. Merfort, University of Düsseldorf, Germany, and to Dr. M. Suffness, the Natural Products Branch, Division of Cancer Treatment, NCI, NIH, Bethesda, MD, USA, for their kind gifts of *S. dulcamara* glycosides mixture, tomatidenol, and β-solamarine samples,

respectively. Also to Ms. Irit Schaeffler, for skillful assistance in the chemical work; to the Mass Spectrometry Center under the direction of Professor A. Mandelbaum, the Technion-Israel Institute of Technology, Haifa, for the FAB-MS determinations; to Mr. Mircea Gruenberg, the Department of Organic Chemistry, the Weizmann Institute of Science, Rehovot, for the NMR spectra. Finally to Professor A. Levy of our Department for his kind cooperation in developing and making available all plant samples, including spineless, high solasodine-yieding *S. khasianum* cultivars.

Glycoside esters from lichens of central Asia

Tomáš Řezanka[a,*], Irene A. Guschina[b]

[a]*Institute of Microbiology, Vídeňská 1083, 14220 Prague, Czech Republic*
[b]*Institute of Ecology of the Volga River Basin of the Russian Academy of Sciences, Togliatti 445003, Russia*

Received 5 December 2000; received in revised form 17 May 2001

Abstract

Ten compounds isolated from the extract of the central Asian lichens comprised new glycosides and glycoside esters having 18*R*-hydroxy-dihydroalloprotolichesterinic, 18*S*-hydroxy-dihydroprotolichesterinic and 18*S*-hydroxy-neodihydroprotolichesterinic acids, as the aglycones and a saccharide moiety linked at C-18 and also at C-21 made by glucose, xylose or rhamnose. The structures were elucidated using extensive spectroscopic analysis (1D and 2D NMR, MS, IR, UV and ORD) and by biochemical methods. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Glycoside esters; Lichens of central Asia; NMR, MS, IR, ORD and UV spectra

1. Introduction

The lichens of the genera *Acarospora gobiensis, Cladonia furcata, Lecanora fructulosa, Leptogium saturninum, Peltigera canina, Rhizoplaca peltata, Xanthoparmelia camtschadalis, X. tinctina* and *Xanthoria elegans* are a central Asia species found in Tian-Shan mountains. The present study is the general phytochemical investigation carried out on these species and we report herein on the isolation and structure elucidation of seven new glycosides and glycoside esters.

Although many tens of thousands of plant glycosides and glycoside esters have been discovered in nature (Ikan, 1999), only a few of these have as yet been identified from lichens. These include, e.g. 1-(*O*-β-D-glucopyranosyl)-3*S*,25*R*-hexacosanediol from *Solorina crocea* (Huneck and Yoshimura, 1996), galapagin, lobodirin, mollin and roccellin (Huneck et al. 1992).

In our continuing search for unusual bioactive compounds from central Asian lichens (Řezanka and Dembitsky, 1998, 1999; Řezanka and Guschina, 1999, 2000a,b), we have examined the nine above-mentioned lichens. The ten compounds isolated from the extract of the thallus comprised new glycosides (**4**–**10**) having 18*R*-hydroxy-dihydroalloprotolichesterinic, 18*S*-hydroxy-dihydroprotolichesterinic and 18*S*-hydroxy-neodihydroprotolichesterinic acids as the aglycones and an oligosaccharide moiety linked at C-18 and C-21 made by glucose, xylose or rhamnose.

2. Results and discussion

In recent papers (Řezanka and Gushina, 2000a,b), we reported the isolation of lichen's acids, i.e. hydroxy-murolic, hydroxy-protoconstipatic, hydroxy-allo-murolic acids and their glycosides from the water–methanolic extract of the central Asian lichens. All nine lichen species were extracted independently and the extracts were also chromatographed separately by means of column chromatography over Sephadex LH-20 eluted with EtOH-i-PrOH (fraction 1), EtOH (fraction 2) and then MeOH (fraction 3). Repeated RP–HPLC of fraction 1 afforded new compounds (**1**), together with (**2**) and (**3**) (Table 1). Fraction 2 accounted for the largest amount of the EtOH extract by weight. Repeated column chromatography of this fraction afforded compounds (**4**–**6**) (Table 1). Fraction 3 was also purified by a further RP–HPLC method to give compounds (**7**–**10**) (Table 1). Comparing their spectral data, i.e. predominantly 1D and 2D NMR, MS, IR, UV and ORD with previously reported data performed the identification of the above-mentioned compounds. All compounds (**1**–**10**) are new natural products.

The unknown compound **1** isolated as white solid crystals was 18*R*-hydroxy-dihydroalloprotolichesterinic acid and was identified by comparison of its ^{1}H, ^{13}C NMR, MS, and ORD data with our and previously published values for dihydroalloprotolichesterinic acid (Huneck and Takeda, 1992). The HREIMS of **1** showed a molecular ion at *m/z* 370.5293. These data are consistent with the molecular formula of $C_{21}H_{38}O_5$. The ^{13}C NMR spectrum of **1** showed 21 signals corresponding to 21 carbons of acid, and DEPT measurements revealed the presence of two methyl groups, 13 methylenes, four methines (two bearing oxygen), and two oxygenated quaternary carbons at δ 170.1 and 177.5 assigned to carboxylic acid and lactone, respectively. The ^{1}H NMR spectrum of **1** showed signals at δ 2.93 (1H, *dq*, $J=7.0$, 7.5 Hz, H-2), 3.30 (1H, *dd*, $J=7.0$, 8.0 Hz, H-3), and 4.64 (1H, *ddd*, $J=8.0$, 8.0, 5.0 Hz, H-4), typical for a trisubstituted γ-butyrolactone acid. Examination of NMR, MS, and physical data for compound **1** showed that they are very similar to the data of (−)-dihydropertusaric and dihydroalloprotolichesterinic acids. The relative stereochemistry of **1** was assigned on the basis of the 2D NOESY spectrum, which exhibited the presence of NOEs, indicating that the Me on C-2 (C-20), H-3 and H-4 are oriented on the same side of the molecule, while H-2 has the same orientation as the lipophilic side chain (Fig. 1), suggesting that **1** have the following relative stereo configuration, i.e. 2*R*,3*S*,4*S*. The presence of signals at δ 1.17 (3H, *d*, $J=6$ Hz, H-19) and 3.74 (1H, *m*, H-18) were of the terminal hydroxyethyl group. The absolute configuration at C-18 of all three acids, i.e. **1**, **2** and **3** was determined by the modified Mosher's method (Ohtani et al., 1991a,b; Rieser et al., 1992).

Treatment of each hydroxy acid with (*R*)-(−)-MTPACl or (*S*)-(+)-MTPACl converted them into the (*S*)- and (*R*)-2-methoxy-2-trifluoromethylphenylacetic acid (MTPA) esters (**1s**, **2s** and **3s** and **1r**, **2r** and **3r**, respectively). The values of $\Delta\delta=[\delta(S\text{-MTPA ester})-\delta(R\text{-MTPA ester})]$ in the ^{1}H NMR spectra suggested that the absolute configuration at C-18 of compound **1** was (*R*) while that of **2** and **3** were (*S*) (Ohtani et al., 1991b). The data are shown in Table 7.

Compound **2**, i.e. 18*S*-hydroxy-dihydroprotolichesterinic acid, had according to the high-resolution mass spectrum the formula $C_{21}H_{38}O_5$. Its UV spectrum showed a maximum at 207 nm (log ε 2.74), indicative of a saturated γ-lactone. The ^{1}H NMR spectrum (Table 2) and ORD data (Fig. 2) of 18*S*-hydroxy-dihydroprotolichesterinic acid gave the structure and absolute configuration shown in formula 2 (Fig. 1). The ORD curve of compounds **2** is very similar to the ORD curve of (−)-dihydroprotolichesterinate (Huneck and Takeda, 1992), thus proving the same relative and absolute configuration of both compounds. Contrary to this the ORD spectra of 18*R*-hydroxy-dihydroalloprotolichesterinic acid (**1**) and 18*S*-hydroxy-neodihydroprotolichesterinic acid (**3**)

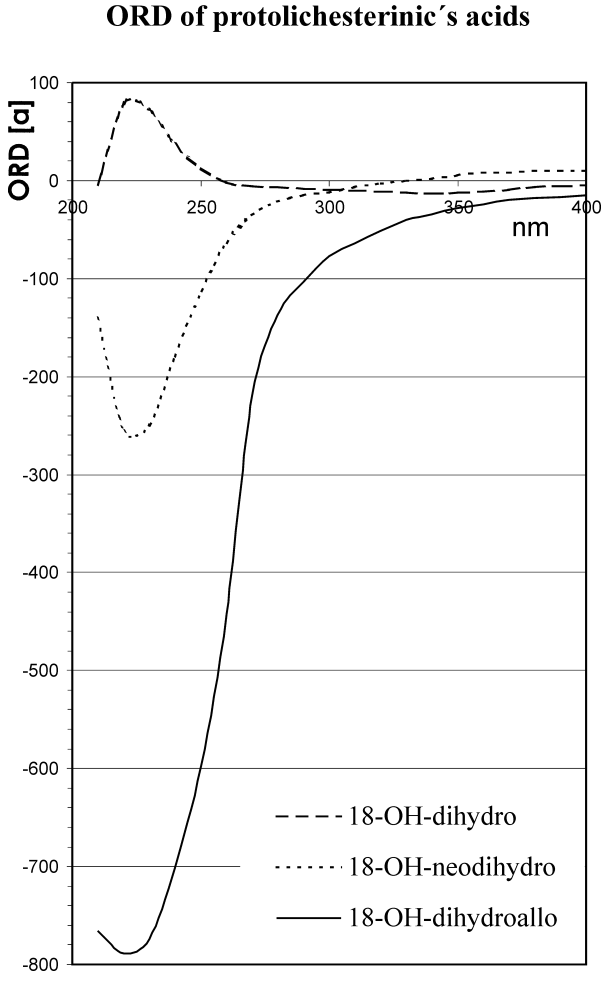

Fig. 2. The ORD spectra of lichen's acids [18*R*-hydroxy-dihydroalloprotolichesterinic (**1**), 18*S*-hydroxy-dihydroprotolichesterinic (**2**) and 18*S*-hydroxy-neodihydroprotolichesterinic (**3**)].

were quite different (Fig. 2). As Table 2 shows, the signal of H-18 in **2** (δ 3.81) is shifted downfield in relation to the chemical shift of H-18 in dihydroprotolichesterinic acid (δ 1.26) (Huneck and Takeda, 1992). The deshielding of the H-18 through the OH group in 2 causes this shift. Hence dihydro acid has relative stereochemistry 2*S*,3*R*,4*S*,18*S*.

HREIMS of compounds **3** showed the molecular ion at 370.5295 corresponding to the formula $C_{21}H_{38}O_5$, which implies three unsaturated sites. Its IR spectrum displayed two, intense carbonyl absorption, the stronger at 1740 cm^{-1} (lactone) and the second at 1705 cm^{-1} (acid). The remaining unsaturation was assigned to the lactone ring.

The spectrum of **3** showed double quartet (1H) at δ 2.99 ppm as well as a double doublet (1H) at δ 3.30 ppm and also signal at δ 4.44 (1H, *ddd*). The high relative values of coupling constants ($J_{2,3}=11.1$ Hz and $J_{3,4}=9.5$ Hz) indicate trans orientations of hydrogen on C-2, the hydrogen on C-3 and also the hydrogen on C-4. The absolute configuration on C-18 determined by Mosher's method is *S*. For data of chemical shifts, see Table 7. Thus, the structure of compound **3** is 18*S*-hydroxy- neodihydroprotolichesterinic acid.

Treatment of esters (**4**–**10**) with esterase (E.C. 3.1.1.1, from porcine liver) gave compounds (**4a**–**10a**) and free sugars. Their analysis by GC–MS according to Gerwig et al. (1978) indicated that the ester bound sugars were rhamnose (**4** and **7**) and glucose (**5**, **6**, **8**–**10**). According to ^{1}H NMR and ORD spectra, free acids **4a**–**6a** were identical with compounds **1**–**3**. Enzymatic hydrolysis of the compounds **7a**–**10a** by β-glucosidase (E.C. 3.2.1.21) liberated free sugars, i.e. glucose from **7** and **10**, xylose from **8** and rhamnose from **9**, and aglycones **7b**–**10b**. The latter were again identical with free acids **1** and **3**, according of their ^{1}H NMR and ORD spectra.

The combined positive ion HRFABMS (see Experimental) and NMR data (Tables 3 and 4) confirmed the molecular formula and identity of the acids and sugars present. The positive HRFABMS of al three esters (**4**–**6**) showed pseudomolecular ions $(M+H)^+$ and the negative ion FABMS spectra $(M-H)^-$ and $(M-H-146)^-$ for a deoxyhexosyl unit (**4**) and $(M-H-162)^-$ for a hexosyl unit (**5** and **6**). Substitution of the sugar at C-21 of the acid was unambiguously established from correlations of this carbon with the appropriate anomeric protons in the 2D HMBC NMR spectra.

Analysis of the ^{13}C NMR chemical shifts of sugar moieties (**7**–**10**), conducted by a combination of homo-

and heteronuclear COSY spectra, indicated their unsubstituted nature (Huneck and Takeda, 1992).

These data indicated that one monosaccharide was linked to the C-18 position of the aglycone, the other monosaccharide being linked to the C-21 of the aglycone through an ester bond.

Comparison of the ^{13}C NMR chemical shifts of glycoside **7** with those of **1** (Tables 3 and 6) revealed that a glycosidation shift at C-19 (3.6 ppm) larger than that at C-17 (3.1 ppm) was observed in pyridine-(d_5) as solvent. Application of the glycosidation shift rule (Seo et al., 1978; Tori et al., 1977; Kasai et al., 1977) to these shifts indicated the configuration at C-18 of glycoside **7** to be *R*; the glycoside **7** was thus confirmed to be 18*R*-glycoside. In the spectrum of **8**, **9** and **10**, the glycosidation shift is the opposite (Δ at C_{19} = 3.5–3.7 ppm and Δ at C_{17} = 3.8–4.1 ppm), and the configuration in **8**, **9** and **10** is thus *S*.

A correlation in the HMQC spectrum of **7** showed that the rhamnose residue was attached to the carboxylic group of the aglycone by an ester linkage. HMBC experiments showed that the second sugar (glucose) was connected by a glycosidic bond to hydroxyl group on C-18.

The chemical shifts of C-18 δ 76.6 and C-21 δ 163.8 indicated that **8** was at the same time a glycoside and glycoside ester, with xylose linked to C-18 and glucose to C-21, as indicated from their ^{13}C NMR data (Table 4).

Compound **9** again contained two sugar residues in a HMQC NMR experiment. The anomeric ^{13}C-NMR signals gave cross-peaks with anomeric protons and long-range ^{1}H–^{13}C correlations were observed between the signals at δ_C 163.4 and δ_H 6.25, δ_C 77.1 and δ_H 5.82. Accordingly, the glucose unit was again linked to C-21 of the aglycone, while the rhamnose units were linked to the C-18 position of the aglycone. These linkages were confirmed from the NOESY spectrum of **9**.

The HMBC spectrum of **10** showed that one glucose unit was at the C-21 position of the aglycone and another glucose exhibited correlation peaks between H-1 δ 5.14 of glucose and C-18 δ 77.2 of the aglycone. The names of compounds **4**–**10** are given in Experimental.

To summarize the present study, the chemical structures and structural relationships among the new 10 component of lichen acids produced by lichens from Central Asia are shown in Fig. 1.

We have isolated three hydroxy substituted γ-lactonic carboxylic acids of which only the optical antipode, i.e. neodihydromurolic acid has previously been described (Huneck et al., 1979). The absolute configuration of the hydroxyl group of all three acids (**1**–**3**) were determined and also the all three were described for the first time in

Table 7
Stereochemical analysis of compounds **1**, **2** and **3** with (*R*)- and (*S*)-MTPA (Mosher) derivatives[a]

MTPA esters of compound No.	$\Delta\delta = \delta_{S\text{-ester}} - \delta_{R\text{-ester}}$ (Hz)		
	H-19	H-17	Carbinol configuration
1	+12.8	−30.1	*R*
2	−16.9	+26.7	*S*
3	−15.8	+34.2	*S*

[a] The aglycones from glycosides **4**–**10** are identical from **1** or **2** or **3**.

nature. Absolute new is the discovery of glycoside esters containing rhamnose, xylose and glucose.

3. Experimental

3.1. General experimental procedures

UV spectra were measured in heptane within the range of 200–350 nm by a Cary 118 (Varian) apparatus. Optical rotatory dispersion (ORD) measurement was carried out under a dry N_2 on a Jasco-500A spectropolarimeter at 24 °C. A Perkin-Elmer Model 1310 (Perkin-Elmer, Norwalk, CT, USA) IR spectrophotometer was used for scanning IR spectroscopy of acids and glycosides as neat films. NMR spectra were recorded on a Bruker AMX 500 spectrometer (Bruker Analytik, Karlsruhe, Germany) at 500.1 MHz (^1H), 125.7 MHz (^{13}C) in mixture of deuterated pyridine and CD_3OD (v/v 1:1). High- and also low-resolution MS were recorded using a VG 7070E- HF spectrometer (70 eV). HRFABMS (positive and/or negative ion mode) were obtained with a PEG-400 matrix. RP–HPLC was carried out using Shimadzu gradient LC system (Shimadzu, Kyoto, Japan). Gas chromatography analysis was made on a Hewlett Packard HP 5980 gas chromatograph (Hewlett Packard sro, Czech Republic).

3.2. Plant material

The specimens of *Acarospora gobiensis* H. Magn., *Cladonia furcata* (Huds.) Schrad, *Lecanora fructulosa* (Dicks.) Ach., *Leptogium saturninum* (Dicks.) Nyl., *Peltigera canina* (Neck.) Hoffm., *Rhizoplaca peltata* Ram., *Xanthoparmelia camtschadalis* Ach., *X. tinctina* Mah. et Gill., and *Xanthoria elegans* (Link.) Th. Fr. were collected in July 1996 along the shore of Lake Issyk Kul, Tian-Shan Mountains.

3.3. Extraction and isolation

All nine lichen species (100 g of air-dried lichens, see Řezanka and Guschina, 2000a) were extracted independently by the Blight and Dyer (1959) method and the extracts were also chromatographed separately be means of the column chromatography over Sephadex LH-20 eluted with EtOH-i-PrOH (fraction 1), EtOH (fraction 2) and then MeOH (fraction 3). Fraction 1 was further fractionated by RP–HPLC on a C18-Bondapak (Waters sro, Czech Republic) column (30 cm×7.8 mm, flow rate 2.0 ml/min) with ACN–H_2O (1:2) to yield compounds **1**–**3**. Fraction 2 was separated by RP-HPLC with ACN–H_2O (2:5) to yield the compounds **4**–**6**. Fraction 3 using ACN–H_2O (1:3), yielded compounds **7**–**10**.

The identification and the D or L configuration of sugars (i.e. D-xylose, L-rhamnose and D-glucose) was determined using GC–MS (according to the method of Gerwig et al., 1978), with some modifications, as previously described (Řezanka and Guschina, 2000a) with SPB-1 (Supelco) column (30 m×0.25 mm I.D.). The column temperature was programmed to rise 5 °C/min from 170 to 260 °C. The flow rate of the helium carrier gas through the column was 1.5 ml/min. The temperature of the injector was 270 °C.

3.4. Acid hydrolysis of *4*

The glycoside (~1 mg) was refluxed in 2 N HCl (0.5 ml) for 2 h. The aglycone was extracted three times with EtOAc (10 ml). After separating the organic layer, the

aqueous phase was neutralized with $NaHCO_3$ and lyophilized.

3.5. Enzymatic hydrolysis

A solution of glycoside (1 mg) in acetate buffer (pH 4.4, 10 ml) was treated with β-glucosidase (20 mg) for 48 h at 37 °C. The reaction solution was evaporated to dryness, and the residue was chromatographed on a column of silica gel (10 g), using CH_2Cl_2–MeOH–H_2O (90:10:1) to provide lichen's acids for ^{1}H NMR and ORD analysis.

Glycosides (~0.5 mg) were suspended in $(NH_4)_2SO_4$ solution of enzyme (E.C. 3.1.1.1, from porcine liver) at pH ~8 and incubated 15 min at 25 °C. Aglycone was extracted three times with EtOAc (10 ml). After separating the organic layer, the aqueous phase was neutralized with 0.5 N HCl and lyophilized.

3.6. (S)-MTPA and (R)-MTPA esters

(*S*)-MTPA esters of free acids (**1**–**3**) and aglycones from glucosides **4**–**10** (Ohtani et al., 1991a,b). To a CH_2Cl_2 solution (100 μl) of aglycone (0.3 mg), DMAP (1.0 mg), and Et_3N (2 μl) was added (*R*)-(−)-MTPACl (2.0 mg) at room temperature, and stirring was continued for 3 h. After evaporation of solvent, the residue was purified by Silica gel TLC (hexane–AcOEt, 2:1) to provide the (*S*)-MTPA ester as a colorless oil.

(*R*)-MTPA Esters of free acids (**1**–**3**) and of aglycones from glucosides **4**–**10**. Each aglycone (0.3 mg) was treated with (*S*)-(+)-MTPACl (2.0 mg) by the same procedure as described above to provide the (*R*)-MTPA ester as colorless oil.

18*R*-Hydroxydihydroalloprotolichesterinic acid **1**, white crystals, m.p. 143 °C, $[\alpha]_D^{24}$ −48° (*c* 0.19, $CHCl_3$), UV λ_{max} (EtOH, nm) 218 (log ε 2.28); ORD: $[\alpha]_{222}^{24}$ nm (−790), see also Fig. 2; IR (KBr) (cm^{-1}): 3450 (OH), 2950, 2920, 1740 (lactone), 1705 (acid); HREIMS *m/z*: 370.5293 (M^+, calc. for $[C_{21}H_{38}O_5]^+$ 370.5297; LREIMS *m/z* (%), 370 $[M]^+$ (2), 355 $[M–Me]^+$ (21), 352 $[M–H_2O]^+$ (56), 334 $[M–2xH_2O]^+$ (67), 326 $[M–CO_2]^+$ (14), 308 $[M–CO_2–H_2O]^+$ (58); ^{1}H and ^{13}C NMR spectra, see Tables 2 and 3.

18*S*-Hydroxydihydroprotolichesterinic acid **2**, white small needles, mp 105–107 °C, $[\alpha]_D^{24}$ +7.9° (*c* 0.10, $CHCl_3$), UV λ_{max} (EtOH, nm) 207 (log ε 2.74); ORD: $[\alpha]_{220}^{24}$ nm (+90), see also Fig. 2); IR (KBr) (cm^{-1}): 3450 (OH), 2950, 2920, 1740 (lactone), 1705 (acid); HREIMS *m/z*: 370.5301 (M^+, calc. for $[C_{21}H_{38}O_5]^+$ 370.5297; LREIMS *m/z* (%), 370 $[M]^+$ (3), 355 $[M–Me]^+$ (19), 352 $[M–H_2O]^+$ (67), 334 $[M–2xH_2O]^+$ (81), 326 $[M–CO_2]^+$ (10), 308 $[M–CO_2–H_2O]^+$ (51); ^{1}H and ^{13}C NMR spectra, see Tables 2 and 3.

18*S*-Hydroxyneodihydroprotolichesterinic acid **3**, white plates, mp 127.5 °C, $[\alpha]_D^{24}$ −28.5° (*c* 0.21, $CHCl_3$), UV λ_{max} (EtOH, nm) 217 (log ε 2.42); ORD: $[\alpha]_{220}^{24}$ nm (−260), see also Fig. 2; IR (KBr) (cm^{-1}): 3450 (OH), 2950, 2920, 1740 (lactone), 1705 (acid); HREIMS *m/z*: 370.5295 (M^+, calc. for $[C_{21}H_{38}O_5]^+$ 370.5297; LREIMS *m/z* (%), 370 $[M]^+$ (4), 355 $[M–Me]^+$ (17), 352 $[M–H_2O]^+$ (63), 334 $[M–2xH_2O]^+$ (73), 326 $[M–CO_2]^+$ (9), 308 $[M–CO_2–H_2O]^+$ (42); ^{1}H and ^{13}C NMR spectra, see Tables 2 and 3.

21-*O*-α-L-Rhamnopyranosyl-18*R*-hydroxydihydroalloprotolichesterinate **4**, colorless powder, mp 146.5 °C, $[\alpha]_D^{24}$ −188° (*c* 0.15, MeOH); UV 219 nm (log ε 3.88); IR (KBr) (cm^{-1}): 3400 (OH), 2950, 2920, 1750 (lactone), 1710 (ester); HRFABMS *m/z* 517.6801 $[M+H]^+$, calc. for $[C_{27}H_{49}O_9]^+$ 517.6807; negative LRFABMS *m/z* 515 $(M–H)^-$, 369 (M–H-146)$^-$ and ^{1}H and ^{13}C NMR spectra see Table 3 and 4.

21-*O*-β-D-Glucopyranosyl-18*S*-hydroxydihydroprotolichesterinate **5**, colorless powder, mp 157 °C, $[\alpha]_D^{24}$ −179° (*c* 0.14, MeOH); UV 218 nm (log ε 3.82); HRFABMS *m/z* 533.6806 $(M+H)^+$ calc. for $[C_{27}H_{49}O_{10}]^+$ 533.6800; negative LRFABMS *m/z* 531 $(M–H)^-$, 369 (M–H–162)$^-$, and ^{1}H and ^{13}C NMR spectra, see Table s3 and 4.

21-*O*-β-D-Glucopyranosyl-18*S*-hydroxyneodihydrolichesterinate (**6**), white amorphous powder, $[\alpha]_D^{23}$ −14°; HRFABMS *m/z* 533.6797 $(M+H)^+$, calculated for $[C_{27}H_{49}O_{10}]^+$ 533.6800; negative LRFABMS *m/z* 531 $(M–H)^-$, 369 (M–H–162)$^-$ and 353 (M–H–178)$^-$; and ^{1}H NMR and ^{13}C NMR spectra see Tables 3 and 4.

18-*O*-β-D-Glucopyranosyl-18*R*-hydroxydihydroalloprotolichesterinate 21-*O*-α-L-rhamnopyranoside (**7**), white amorphous powder, $[\alpha]_D^{23}$ −35°; HRFABMS *m/z* 679.8234 $(M+H)^+$, calc. for $[C_{33}H_{59}O_{14}]^+$ 679.8231; negative LRFABMS *m/z* 677 $(M–H)^-$, 531 (M–H–146)$^-$, 515 (M–H–162)$^-$, 499 (M–H–178)$^-$, 369 (M–H–162–146)$^-$; ^{1}H and ^{13}C NMR spectra, see Tables 5 and 6.

18-*O*-β-D-Xylopyranosyl-18*S*-hydroxydihydroprotolichesterinate 21-*O*-β-D-glucopyranoside (**8**), white powder, $[\alpha]_D^{23}$ −18°; HRFABMS *m/z* 665.7961 $(M+H)^+$, calc. for $[C_{32}H_{57}O_{14}]^+$ 665.7960; negative FABMS *m/z* 663 $(M–H)^-$, 501 (M–H–162)$^-$, 369 (M–H–162–132)$^-$; ^{1}H and ^{13}C NMR spectra, see Tables 5 and 6.

Received 4 December 2000; received in revised form 19 April 2001

Abstract

The chemical compositions of five species of the red algal genus *Laurencia* from coastal waters of Okinawa Prefecture, Japan, have been investigated. A halogenated C_{15} acetogenin, (12*E*)-lembyne-A, was isolated from *L. mariannensis*, and a halogenated sesquiterpene, (6*R*,9*R*,10*S*)-10-bromo-9-hydroxy-chamigra-2,7(14)-diene, was first found from *L. majuscula* as a naturally occurring compound. *Laurencia nidifica* yielded previously known laurinterol and isolaurinterol. Samples of *L. cartilaginea* and *L. concreta* afforded no halogenated metabolites. The structures of these halogenated metabolites as well as their antibacterial activity against some marine bacteria are reported. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Laurencia*; Rhodomelaceae; Red alga; Sesquiterpene; C_{15} acetogenin; Halogenated compound; Chemotaxonomy; Antibacterial activity

1. Introduction

The red algal genus *Laurencia* is unique due to its ability to produce a wide variety of halogenated secondary metabolites with diverse structural features depending on the species and localities. Although the roles of these halogenated compounds are still a matter of speculation, their importance as chemical defense substances against marine herbivores is undeniable (Hay et al., 1987; Kurata et al., 1998).

Some halogenated metabolites have been shown to possess antibacterial activities against terrestrial bacteria (Waraszkiewicz and Erickson, 1974; Wratten and Faulkner, 1977; Carter et al., 1978; Caccamese et al., 1980; König and Wright, 1997a). More recently, we reported on the antibacterial potential of halogenated compounds isolated from the Malaysian *Laurencia* against marine bacteria from the algal habitat (Vairappan et al., 2001), suggesting the possible role played by these halogenated compounds as the seaweed's chemical defense substances.

As part of our continuing study on the chemical compositions of *Laurencia* species from the Okinawan waters, we harvested five species of *Laurencia*; *L. mariannensis* Yamada, *L. majuscula* (Harvey) Lucas, *L. nidifica* J. Agardh, *L. cartilaginea* Yamada, and *L. concreta* Cribb from four different sites. *Laurencia mariannensis* contained a new C_{15} acetogenin, (12*E*)-lembyne-A (**1**), along with 2-bromo-3-chloro-5-acetoxy-chamigra-7(14), 9-dien-8-one (**2**) that was previously isolated from the Okinawan sea hare *Aplysia dactylomela* (Sakai et al., 1986) and from the Okinawan *L. majuscula* collected at Taketomi (Masuda et al., 1997). *Laurencia majuscula* contained a brominated sesquiterpene, (6*R*,9*R*,10*S*)-10-bromo-9-hydroxy-chamigra-2,7(14)-diene (**3**), together with previously known (*Z*)-10,15-dibromo-9-hydroxy-chamigra-1,3(15),7(14)-triene (**4**) and (*E*)-10,15-dibromo-9-hydroxy-chamigra-1,3(15),7(14)-triene (**5**) from this species collected at Kochi Prefecture, Japan (Suzuki and Kurosawa, 1978; Suzuki et al., 1979). Metabolite **3** has not been previously found as a natural source. Furthermore, *L. nidifica* produced laurinterol (**6**) and isolaurinterol (**7**), characteristic metabolites of the Japanese *L. okamurae* Yamada (Suzuki and Kurosawa, 1979), while *L. cartilaginea* and *L. concreta* produced no halogenated secondary metabolites.

We report herein the chemical compositions of these *Laurencia* species, structures of halogenated compounds,

and their antibacterial activity against marine bacteria isolated from the algal habitat.

2. Results and discussion

2.1. Laurencia mariannensis

A sample collected from Teruma, Yonashiro, was extracted with methanol. The methanol extract was fractionated by CC over silica gel with a stepped gradient (hexane and EtOAc). The fraction eluted with hexane–EtOAc (9:1) was further subjected to prep. TLC with hexane–EtOAc (3:1) to give 2-bromo-3-chloro-5-acetoxy-chamigra-7(14),9-dien-8-one (**2**) (Sakai et al., 1986; Masuda et al., 1997) in 14% yield based on the weight of the extracts. The fraction eluted with hexane–EtOAc (4:1) was also separated using prep. TLC with hexane–EtOAc (3:1) to give compound **1** (6%).

Compound **1**, oil, $[\alpha]_D^{24}$ +42° ($CHCl_3$), was assigned the molecular formula $C_{15}H_{16}BrClO_2$ (HRFDMS). Its IR spectrum revealed absorptions due to a terminal acetylenic group (ν_{max} 3310 cm^{-1}), a vinyl ether stretching (ν_{max} 1680 cm^{-1}), and C–O bands (ν_{max} 1110 and 1050 cm^{-1}). In addition, since there were no hydroxyl or carbonyl absorptions, both oxygens were suggested to be involved in ether links. The presence of a terminal conjugated enyne moiety, which is frequently encountered in *Laurencia* C_{15} acetogenins, was evident from the ^1H NMR spectrum (Table 1) [δ_H 3.31 (1H, *br s*), 5.58 (1H, *dd*, J=10.7, 1.5 Hz) and 6.06 (1H, *dd*, J=10.7, 10.7 Hz)]. Interpretation of the ^1H–^1H COSY spectrum showed the presence of a partial structure **1a**

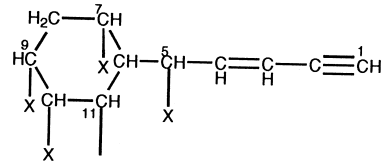
[b] Assignments were made with the aid of the HSQC spectrum.



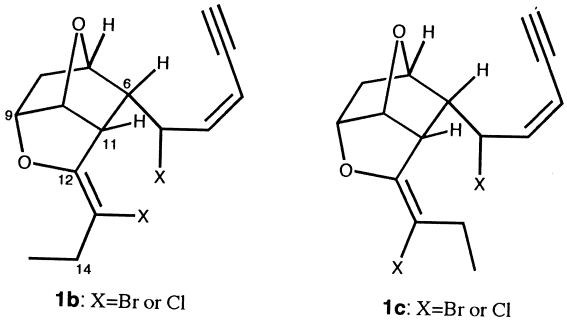


Fig. 1. Partial and planar structures for **1**.

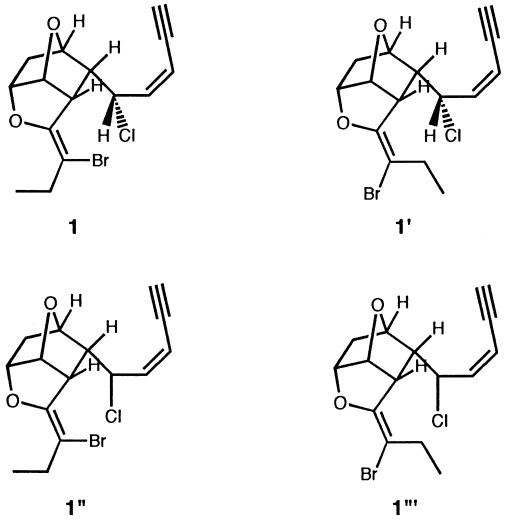
(Fig. 1) together with an isolated ethyl group. The J-value (10.7 Hz) between H-3 and H-4 as well as the chemical shift value (δ_H 3.31) of the acetylenic proton indicated the geometry of the double bond at C-3 to be Z (Suzuki and Kurosawa, 1987).

The ^{13}C NMR spectrum (Table 1) revealed the presence of 14 carbon atoms, 12 of which were hydrogen-bearing carbons. Among 14 carbon atoms, three oxygen-bearing carbons were demonstrated by the signals at δ_C 77.9, 81.5 and 84.2 and further attributed to C-7, C-9 and C-10, respectively, by HSQC spectrum. Furthermore, based on the chemical shift values of H-5 (δ_H 4.72) and C-5 (δ_C 54.9), a halogen atom was deduced to be attached to C-5 position. The planar formula for compound **1** could be assigned by the HMBC spectrum whose results are summarized in Table 1. In the HMBC spectrum, cross peaks of C-7/H-10 and C-10/H-7 established the ether ring closure between C-7 and C-10. In addition, a cross peak between the terminal methyl group and the vinyl carbon at δ_C 105.8 indicated that the ethyl group was attached to the tetrasubstituted double bond. The chemical shift value (δ_C 105.8) of this vinyl carbon atom suggested that another substituent is a halogen atom (Suzuki et al., 1983). Therefore, this double bond had to be inserted between C-9 and C-11 to give a planar formula **1b** or **1c**. Facile loss of a chlorine atom on the FDMS is evident from the fragment ion of m/z 309, 307 $[M\text{-}Cl]^+$ which strongly suggested the presence of a vinyl bromide moiety in **1**. Hence the chlorine atom was linked to C-5 and the bromine atom to C-13.

The ^1H and ^{13}C NMR spectral data of **1** were very similar to those of lembyne-A (**1′**), which has recently been isolated from the Malaysian *Laurencia* sp. (Vairappan et al., 2001). The chemical shifts and coupling constants of the protons from C-1 to C-10 in the ^1H NMR spectrum of **1** are almost identical to those of **1′**. However,

distinct differences are observed in the chemical shift values of H-11 and H_2-14. The low-field chemical shift of the H-11 in **1** is due to the deshielding being caused by the bromine atom at C-13 that is situated close to the H-11. Furthermore, the large magnetic nonequivalence of the H_2-14 in **1** is attributed to the electronic influence of the oxygen atom that is *cis* to the ethyl group. Thus the stereochemistry of the vinyl ether moiety in **1** is established as *E*-configuration. In consequence, the structure of compound **1** must be represented by formula **1**, (12*E*)-lembyne-A, including the same relative stereochemistry, 5*S**, 6*R**, 7*R**, 9*R**, 10*R**, and 11*S**, as lembyne-A (**1′**).

(12*E*)-Lembyne-A (**1**) and lembyne-A (**1′**) have structures very similar to *cis*-maneonene-C (**1″**) and (12*Z*)-*cis*-maneonene-C (**1‴**), respectively, the latter of which was obtained from *cis*-maneonene-C by treatment with *p*-toluenesulfonic acid (Waraszkiewicz et al., 1978). However, there are some obvious differences between our ^{1}H and ^{13}C NMR spectral data (in C_6D_6) and the published data (Waraszkiewicz et al., 1978) along with their optical rotations (**1**: $[\alpha]_D$ +42°; **1′**: $[\alpha]_D$ +198°, **1b″**: $[\alpha]_D$ +336°, **1‴**: $[\alpha]_D$ +137 °C). Thus *cis*-maneonene-C and (12*Z*)-*cis*-maneonene-C may be a stereoisomer at C-5 of (12*E*)-lembyne-A and lembyne-A, respectively.



2.2. *Laurencia majuscula*

The methanol extract of a sample collected from Yagachi, Nago, was subjected to a combination of column and thick-layer chromatography to give 10-bromo-9-hydroxy-chamigra-2,7(14)-diene (**3**) (9%) along with previously known (*Z*)-10,15-dibromo-9-hydroxy-chamigra-1,3(15),7(14)-triene (**4**) (3%) and (*E*)-10,15-dibromo-9-hydroxy-chamigra-1,3(15),7(14)-triene (**5**) (4%), isolated from this species which had been collected at Kochi Prefecture, Japan (Suzuki and Kurosawa, 1978; Suzuki et al., 1979).

Compound **3**, oil, $C_{15}H_{23}OBr$, $[\alpha]_D^{25}$ −110° ($CHCl_3$), was readily assigned the planar structure by its 1D and 2D (^{1}H–^{1}H COSY, HSQC, and HMBC) NMR spectra. The relative configuration was determined by the NOESY spectrum. A NOE between H-10 and Hb-5 showed that the H-10 adopts an axial configuration and hence the bromine atom is equatorial. Since based on the *J*-value ($J_{9,10}$ = 2.9 Hz), the vicinal bromine and hydroxyl groups are in *cis*-configuration as in the case of compounds **4** and **5**, the C-9 hydroxyl group is axial. Furthermore, NOEs between Ha-14/Ha-1 and H_3-13 (one of *gem*-dimethyl)/Ha-4 also confirmed the stereochemistry of the spiro carbon at C-6. Thus the relative stereochemistry of **3** would be represented by formula **3a** as shown in Fig. 2.

A literature survey indicated that the ^{1}H and ^{13}C NMR spectral data of **3** were almost identical with those of deschloroelatol (**3′**), which has previously been isolated from *Laurencia obtusa* (Kennedy et al., 1988) and *L. rigida* (König and Wright, 1997b). However, judging from the signs of the optical rotations, compound **3** must be an enantiomer of deschloroelatol. Compound **3** had previously been obtained from obtusol as the partially dehalogenated compound by treatment with lithium aluminum hydride in ether (González et al., 1976). Co-occurrence of compound **3** with halochamigrenes **4** and **5** in the same alga also suggested that the absolute configurations of chiral centers at C-6, C-9, and C-10 are the same as those of **4** and **5**.

7

Accordingly, the structure of compound **3** should be (6*R*,9*R*,10*S*)-10-bromo-9-hydroxy-chamigra-2,7(14)-diene, which has not previously been found as a naturally occurring compound.

The difference of the chemical compositions in the samples from Yagachi, Nago (present study) and Taketomi island (Masuda et al., 1997) suggests that chemical races (Abe et al., 1999) are also present in *Laurencia majuscula*.

2.3. Laurencia nidifica

The methanol extract of a sample collected from Toyohara, Nago, gave laurinterol (**6**) (22%) and isolaurinterol (**7**) (4%) (Suzuki and Kurosawa, 1979). The chemical composition of *Laurencia nidifica* collected at two sites (Teruma and Toyohara) is different from that of a sample harvested from Goza, Mie Prefecture, Japan (Shizuri et al., 1984); it is, however, rather similar to that of a Hawaiian sample (a clumpy pink variety) from Oahu island (Waraszkiewicz and Erickson, 1974, 1975).

2.4. Laurencia cartilaginea and Laurencia concreta

No halogenated secondary metabolites were found in both extracts of *Laurencia cartilaginea* and *L. concreta*. As reported in a previous paper (Suzuki et al., 1987), a sample of *L. cartilaginea* collected at Sakurajima, Kagoshima Prefecture in Japan, close to the type locality, Moji, Fukuoka Prefecture, also showed the absence of halogenated compounds in its extract. Both *Laurencia* species have no "*corps en cerise*" (our unpublished observations). "*Corps en cerise*" are considered to be the sites of synthesis and/or storage for the halogenated secondary metabolites of *Laurencia* (Young et al., 1980). Although the Hawaiian *L. cartilaginea* was reported to produce halogenated chamigrane-type sesquiterpenes (Juagdan et al., 1997), the identification of their material seems to be questionable.

2.5. Antibacterial activity

The antibacterial activities of the isolated halogenated metabolites of Okinawan *Laurencia* were tested against eight species of marine bacteria. These were *Alcaligenes aquamarinus*, *Alteromonas* sp., *Azomonas agilis*, *Azotobacter beijerinckii*, *Erwinia amylovora*, *Escherichia coli*, *Halobacterium* sp., and *Halococcus* sp. All these bacteria were Gram-negative strains. The results of the paper disc diffusion assays are shown in Table 2. Prominent antibacterial activities were seen in compounds **1**, **3**, **6** and **7**, while **4** and **5** only showed very marginal activity. Compound **2** was inactive towards the bacteria tested. Compound **1** showed activity against *Alcaligenes aquamarinus*, *Azomonas agilis*, *Erwinia amylovora*, and *Escherichia coli*. Their minimum inhibitory concentration (MIC) values are in the range of 20–30 μg/disc as shown in Table 3. Compound **3** showed antibacterial activity against five species of bacteria, *Alcaligenes aquamarinus*, *Azomonas agilis*, *Azotobacter beijerinckii*, *Erwinia amylovora*, and *Escherichia coli*. Its MIC values were in the range of 10–30 mg/disc (Table 3). Compounds **6** and **7** showed better antibacterial activity than compounds **1** and **3**. Their antibacterial activities and respective MIC values are shown in Tables 2 and 3, respectively.

Table 2
Antibacterial activity of the halogenated compounds against marine bacteria isolated from algal habitats in the Japanese coastal waters

Test bacteria	Compounds[a]			
	1	**3**	**6**	**7**
Alcaligenes aquamarinus	+ +	+ +	–	–
Alteromonas sp.	–	–	+ +	+ + +
Azomonas agilis	+ +	+ +	+ + +	+ + +
Azobacter beijerinckii	–	+ +	+ +	–
Erwinia amylovora	+ +	+ +	+ + +	+ + +
Escherichia coli	+ +	+ +	+ +	+ + +
Halobacterium sp.	–	–	–	–
Halococcus sp.	–	–	–	–

[a] Inhibition zone diameter; + + +: 19–24 mm, + +: 12–18 mm, +: 7–12 mm, –: no inhibition. Concentration: 90 μg/disc.

Table 3
Minimal inhibitory concentration (MIC[a]) of the halogenated compounds against marine bacteria isolated from algal habitats in the Japanese coastal waters

Test bacteria	Compounds[a]			
	1	**3**	**6**	**7**
Alcaligenes aquamarinus	20	20	–	–
Alteromonas sp.	–	–	5	10
Azomonas agilis	30	20	5	5
Azobacter beijerinckii	–	15	15	–
Erwinia amylovora	30	15	5	5
Escherichia coli	30	10	5	10
Halobacterium sp.	–	–	–	–
Halococcus sp.	–	–	–	–

[a] Concentration: μg/disc. –: no inhibition.

The possibility that these halogenated compounds are involved in protecting these *Laurencia* species against bacterial intrusion is real when we look at the distribution of these compounds. Basically, halogenated compounds are reported to be contained in "*corps en cercise*" (Young et al., 1980), an unusually swollen refractile inclusion, that are located in the outer cortical layer and trichoblast cells of *Laurencia*. "*Corps en cercise*" are absent in the inner cortical layers, and their specific distribution pattern could be suggestive of their importance as barricades to withhold any bacterial intrusion.

3. Experimental

3.1. General

^{1}H (400 MHz) and ^{13}C NMR (100 MHz); $CDCl_3$ or C_6D_6, TMS as int. standard (coupling constant, *J* in Hz); low and high resolution MS: 70 eV; optical rotations: $CHCl_3$; CC: silica gel (Merck, Kieselgel 60, 70–230 mesh); prep. TLC: silica gel 60 F_{254} (Merck). All known metabolites were identified by comparison of the spectral data with those of the authentic specimens. Yields are based on the weights of the extracts.

3.2. Collection

Five *Laurencia* samples were collected from four sites in Okinawa Prefecture, Japan: *L. mariannensis* Yamada at Teruma, Yonashiro, on 4 June 1997; *L. majuscula* (Harvey) Lucas at Yagachi, Nago, on 6 June 1997; *L. nidifica* J. Agardh at Teruma,Yonashiro, on 4 June 1997, and Toyohara, Nago, on 5 June, 1997; *L. cartilaginea* Yamada at Yagachi, Nago, on 6 June 1997; *L. concreta* Cribb at Hedomisaki, Kunigami, on 6 June 1997. The voucher specimens are deposited in the Herbarium (SAP) of the Graduate School of Science, Hokkaido University.

3.3. Extraction and separation of Laurencia mariannensis

The partially dried alga (4 g) was soaked in methanol for one week. The MeOH soln was concentrated in vacuo and partitioned between Et_2O and H_2O. The Et_2O soln. was washed with water, dried over anhydrous Na_2SO_4, and evaporated to leave a dark green oil (65 mg). The extract was fractionated by Si gel column chromatography with a stepped gradient (hexane and EtOAc). The fraction eluted with hexane–EtOAc (9:1) was further submitted to prep. TLC with hexane–EtOAc (3:1) to give 2-bromo-3-chloro-5-acetoxy-chamigra-7(14),9-dien-8-one (**2**) (14%). Further separation of the fraction eluated with hexane–EtOAc (4:1) under the above-mentioned TLC yielded compound **1** (6%).

3.4. Compound *1*

Oil; $[\alpha]_D^{24}$ +42° ($CHCl_3$; *c* 0.02); IR ν_{max} (neat) cm^{-1}: 3310, 1680, 1110, 1050, 930, 880; ^{1}H and ^{13}C NMR spectra, Table 1; ^{1}H NMR spectrum (400 MHz, C_6D_6), δ 1.21 (3H, *dd*, *J* = 7.3, 7.3 Hz, H_3-15), 1.28 (1H, *m*, Ha-8), 1.78 (1H, *d*, *J* = 13.6 Hz, Hb-8), 2.41 (1H, *ddd*, *J* = 10.7, 9.3, 4.4 Hz, H-6), 2.50 (1H, *dq*, *J* = 14.6, 7.3 Hz, Ha-14), 2.71 (1H, *dd*, *J* = 2.4, 0.9 Hz, H-1), 2.84 (1H, *dq*, *J* = 14.6, 7.3 Hz, Hb-14), 3.39 (1H, *dd*, *J* = 9.3, 4.9 Hz, H-11), 3.85 (1H, *dd*, *J* = 4.9, 4.4 Hz, H-7), 4.18 (1H, *dd*, *J* = 6.8, 4.9 Hz, H-9), 4.52 (1H, *dd*, *J* = 4.9, 4.9 Hz, H-10), 4.86 (1H, *dd*, *J* = 10.7, 10.7 Hz, H-5), 5.02 (1H, *dd*, *J* = 10.7, 2.4 Hz, H-3), 5.43 (1H, *ddd*, *J* = 10.7, 10.7, 0.9 Hz, H-4); LR-FDMS *m*/*z* (rel. int.): 346, 344, 342 (30:90:76) $[M]^+$, 309, 307 (11:10) $[M–Cl]^+$; HR–FDMS *m*/*z*: 342.0013. Calc. for $C_{15}H_{16}{}^{79}Br^{35}ClO_2$, 342.0022 [M].

3.5. Extraction and separation of Laurencia majuscula

Extraction of partially dried alga (8 g) was carried out by conventional methods described above to yield a brownish green extract (95 mg). A combination of column and thick-layer chromatography of the MeOH extract gave three halochamigrenes, 10-bromo-9-hydroxy-chamigra-2,7(14)-diene (**3**) (9%), (*Z*)-10,15-dibromo-9-hydroxy-chamigra-1,3(15),7(14)-triene (**4**) (3%), and (*E*)-10,15-dibromo-9-hydroxy-chamigra-1,3(15),7(14)-triene (**5**) (4%).

3.6. 10-Bromo-9-hydroxy-chamigra-2,7(14)-diene (*3*)

Oil; $[\alpha]_D^{25}$ −110° ($CHCl_3$; *c* 0.20); IR ν_{max} (neat) cm^{-1}: 3550, 3450, 1640, 1395, 1365, 1220, 1200, 1180, 1085, 1070, 1035, 895, 830, 810; ^{1}H NMR (400 MHz, $CDCl_3$), δ 1.10 (6H, *s*, H_3-12 and H_3−13), 1.50 (3H, *br s*, H_3-15), 1.67 (1H, *m*, Hb-4), 1.75 (1H, *m*, Hb-5), 1.80 (1H, *m*, Ha-5), 1.84 (1H, *m*, Ha-4), 2.19 (1H, *m*, Hb-1), 2.20 (1H, *m*, Ha-1), 2.48 (1H, *dd*, *J* = 14.2, 2.9 Hz, Hb-8), 2.71 (1H, *dddd*, *J* = 14.2, 2.9, 2.9, 1.5 Hz, Ha-8), 4.16

(1H, *dd*, $J=2.9$, 2.9 Hz, H-9), 4.68 (1H, *d*, $J=2.9$ Hz, H-10), 4.80 (1H, *br s*, Hb-14), 5.10 (1H, *dd*, $J=1.5$, 1.5 Hz, Ha-14), 5.29 (1H, *br s*, H-2); ^{13}C NMR (100 MHz, $CDCl_3$), CH_3: δ 21.5 (C-13), 23.8 (C-15), 25.0 (C-12), CH_2: δ 26.6 (C-5), 28.5 (C-4), 30.9 (C-1), 38.8 (C-8), 116.5 (C-14), CH: δ 72.6 (C-10), 73.2 (C-9), 120.2 (C-2), C: δ 43.9 (C-11), 47.8 (C-6), 133.4 (C-3), 141.9 (C-7); LR–EIMS *m/z* (rel.int.): 300, 298 (14:15) $[M]^+$, 285, 283 (12:12) $[M-CH_3]^+$, 219 (21) $[M-Br]^+$, 217 (32) $[M-Br-H_2]^+$, 201 (100) $[M-Br-H_2O]^+$, 173 (27), 119 (64), 105 (54), 69 (52), 55 (45), 41 (44); HR–EIMS *m/z*: 298.0927. Calc. for $C_{15}H_{23}{}^{79}BrO$, 298.0933 [M]. The ^{1}H and ^{13}C NMR spectral data were almost identical with those reported in the literature for deschloroelatol (König and Wright, 1997b).

3.7. Extraction and separation of Laurencia nidifica

Extraction of partially dried alga (10 g) was carried out by conventional methods as described above to give a green oily extract (110 mg). A combination of column and thick-layer chromatography of the MeOH extracts gave laurinterol (**6**) (22%) and isolaurinterol (**7**) (4%).

3.8. Extraction and separation of Laurencia cartilaginea and Laurencia concreta

The MeOH extracts of both samples contained no halogenated compounds.

3.9. Antibacterial bioassay

Antibacterial bioassay was carried out using eight species of marine bacteria isolated from algal surfaces collected from the Japanese waters. These bacteria are *Alcaligenes aquamarinus*, *Alteromonas* sp., *Azomonas agilis*, *Azotobacter beijerinckii*, *Erwinia amylovora*, *Escherichia coli*, *Halobacterium* sp., and *Halococcus* sp. One loopful of each organism was precultured in 20 ml of peptone water (3% NaCl) overnight. The turbidity of the culture was adjusted to an optical density (OD) McFarland 0.5 (Sonnerwirth and Jarett, 1980; Hindler et al., 1990). Then 0.1 ml of the precultured bacterial suspension was used to seed Nutrient Agar plates (3% NaCl). Paper discs (Whatman, 6 mm) impregnated with various amounts of the respective pure compounds were placed on the seeded agar plates and the diameters of the inhibitory zones were measured after the plates were incubated at 28 °C for 24 h.

Received 11 September 2000; received in revised form 5 February 2001

Abstract

A fucosylated xyloglucan was isolated from the leaves of *Hymenaea courbaril* by alkaline extraction, followed by ethanol precipitation and ion-exchange chromatography. The isolated polysaccharide showed Glc:Xyl:Gal:Fuc in molar ratio of 8:5:2.5:1 and $[\alpha]_D^{25}$ +40.5°. Composition and linkage analyses, supported by NMR spectroscopic measurements, showed that the polysaccharide has a glucan backbone which is highly substituted at *O*-6 with D-xylopyranose residues, about a half of which are substituted at *O*-2 by D-galactopyranosyl units. Some of the galactose residues are further substituted by L-fucopyranose at *O*-2. The M_r, as determined by HPSEC, was 49,500. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Hymenaea courbaril*; Caesalpiniaceae; Leaf polysaccharides; Cell wall; Hemicellulose; Fucosylated xyloglucan

1. Introduction

The primary cell wall is a dynamic and highly ordered complex network of several macromolecules, mainly polysaccharides, comprising pectic substances, hemicelluloses and fibrillar cellulosic material. Structural proteins and phenolic compounds are also present (Varner and Lin, 1989; McCann et al., 1995; Schindler, 1998). It plays an important role in controlling the growth rate of cells and morphogenetic processes, and acts as a barrier to plant pathogens (Keegstra et al., 1973).

Xyloglucan is a major hemicellulosic polysaccharide in Type I primary cell walls (Dicotyledoneae), which makes up about 20–25% (dry wt) (McNeil et al., 1984; Fry, 1989; Carpita and Gibeaut, 1993). It is also present as 2–5% of the Type II primary walls, the typical wall of Poaceae (Varner and Lin, 1989; Carpita, 1996). Xyloglucan was also found in gymnosperms (Kakegawa et al., 1998). Besides being a structural component of primary cell walls, xyloglucans play diverse important roles, namely the control of cell expansion, growth substance effects and as a reserve carbohydrate in seeds (Fry, 1989; Hayashi, 1989).

Xyloglucan is tightly bound to cellulose microfibrils by hydrogen bonds and forms a cellulose-xyloglucan network (Bauer et al., 1973; Hayashi et al., 1987; Carpita and Gibeaut, 1993). The dynamic nature of this cross-linking is proposed to be a major factor in controlling the rate of cell wall expansion, thereby regulating the plant cell wall (Bauer et al., 1973; Darvill et al., 1992). All xyloglucans, storage or structural, have a cellulosic backbone substituted at *O*-6 by α-D-xylopyranosyl units. Some xylosyl residues are further substituted at *O*-2 by β-D-galactopyranosyl units. In primary cells, some galactopyranosyl residues are substituted by fucopyranose (Fry, 1989; Carpita and Gibeaut, 1993).

Degradation and reconstruction of xyloglucan molecules, catalyzed by enzymes, such as endo-1,4-β-D-glucanases, xyloglucanases, α-L-fucosidase and xyloglucan endotransglycosylase are involved in the auxin- or acid-promoted breakdown of xyloglucans and regulate the ability to loosen the network in the cell wall and allow the cells to expand during growth (Hayashi et al., 1984; Nishitani and Tominaga, 1992; Fry et al., 1992). The nonasaccharide XXFG, an end-product of the digestion of xyloglucan by cellulase, has antiauxin activity in the pea stem segment straight-growth bioassay (York et al., 1984; McDougall and Fry, 1988). Substitution of the heptasaccharide XXXG core with one or two Gal residues to give XXLG and XLLG resulted in growth promotion

and *in vitro* stimulation of cellulase (McDougall and Fry, 1990). These oligosaccharides were also used to demonstrate their role as signal molecules in plant cells by ligand-binding experiments (Dunand et al., 2000).

Hymenaea courbaril, family Caesalpiniaceae, is a species that occurs abundantly throughout Brazilian forests. The seeds contain 40–45% xyloglucan, as reserve carbohydrate, whose structure consists of a cellulosic-type (1→4)-linked β-D-glucan main chain and side chains containing α-D-xylopyranosyl and β-D-galctopyranosyl-(1→2)-α-D-xylopyranosyl residues, each (1→6)-linked to the main chain (Lima et al., 1993, 1995). The ability of endoglucanase I of *Humicola insolens* to cleave the (1→4)-linked β-D-glucosyl residues of xyloglucan from *H. courbaril* seeds was carried out and the released oligomers examined in terms of their biological activity (Vargas-Rechia et al., 1998). The auxin activity of the xyloglucan oligosaccharides in their reduced form was investigated. The octasaccharide (XXLGol), at nanomolar concentrations, promoted growth of wheat coleoptiles, independent of the presence of 2,4-dichlorophenoxyacetic acid (2,4-D). In addition, a system of *Rubus fruticosus* protoplasts or cells was used to study the signalling effect of induction of glycohydrolases and significant responses were found. The octasaccharide has the ability to induce, at nanomolar concentrations, a rapid increase in a α-L-fucosidase and to modulate 2,4-D or gibberellic acid-induced α-L-fucosidase (Vargas-Rechia et al., 1998).

This paper reports the isolation, composition and structural features of *H. courbaril* leaf xyloglucan and its relation with the xyloglucan from seeds of the same species.

2. Results and discussion

2.1. Polysaccharide isolation

Powdered leaves were defatted (~20%) with ethanol, then toluene–ethanol and extracted with 2% EDTA. The residual solid was delignified with sodium chlorite–acetic acid (Wise et al., 1946) and then extracted with water. EDTA, sodium chlorite-acetic acid and water extracts were treated with ethanol, yielding fractions which were denominated EI, EII and EIII, respectively. The hemicelluloses were recovered from the residual holocellulose by sequential extraction with 1 M KOH (×3) and 4 M KOH (×3). The alkaline extracts were treated with HOAc to pH 5. No precipitation was observed due to acidification in 1 M KOH extracts, and further precipitation with ethanol gave rise to hemicellulosic fractions, denominated IHT, IIHT and IIIHT. The extracts obtained with 4 M KOH, when treated with HOAc gave rise to hemicellulose A precipitates (IHA, IIHA and IIIHA). Hemicelluloses B were isolated from the supernatant of the 4 M KOH fractions, by precipitation with EtOH (IHB, IIHB and IIIHB) (Whistler and Feather, 1965). Table 1 indicates the yield and composition of each fraction.

The protein content (Table 1) was determined using two methods and the results were significantly different. The differences are due to the interference of phenolic compounds, which react with the Folin–Ciocalteu reagent of the modified method of Lowry (Hartree, 1972). The Peterson (1977) method is also a modification of the Lowry method, but the protein is previous precipitated with sodium deoxycholate-trichloroacetic acid, so that the interfering substances remained in the supernatant. After solubilization of the protein precipitates using sodium dodecyl sulfate, the colorimetric reaction was also performed with the Folin–Ciocalteu reagent.

The fraction obtained in highest yield was IHT (14.1%, Table 1). However, its total sugar content was low and the protein content, obtained with the Hartree and Peterson methods, was 66.5 and 58.9%, respectively. The similarity of the values obtained by both methods confirms the high protein content. On the other hand, the interference of phenolic compounds was observed in EII, IHB, IIHB and IIIHB fractions.

Table 2 shows the monosaccharide composition of the fractions obtained. Fractions EI, EII and EIII are rich in uronic acid, galactose and arabinose, probably due to the presence of pectins. The sugar composition of fractions IHT, IIHT and IIIHT suggested that they contain a mixture of pectic and hemicellulosic polymers. Pectic polymers are predominant in IHT (41% uronic acid) and xylans in the other fractions (about 50% xylose).

The main monosaccharide component of hemicellulose A fractions (IHA, IIHA and IIHA) is xylose (Table 2), indicating the occurrence of xylans. The chemical structure of the first fraction (IHA) was determined (Busato et al., 2000). It is an acidic xylan, $[\alpha]_D^{25}$ −78° (0.5

[c] Not determined.

M NaOH; *c* 0.1), M_r 183,800, and is composed of a linear main chain of β-xylopyranosyl residues linked (1→4), substituted at *O*-2 with glucuronic acid and/or its 4-*O*-methyl derivative.

The final residue of alkaline extractions (28.6% yield; Table 2) contained 39.0% of glucose, probably from cellulose, and 32.3% of xylose, that indicates the presence of remaining xylans and xyloglucans.

Fraction IHB, extracted with 4 M KOH, was rich in xylose, glucose and contained fucose (Table 2), indicating the presence of xyloglucan, which could be present also as minor component in fractions IIHB and IIIHB. Most of the xyloglucan is strongly bound to cellulose and required 4 M KOH to be extracted. Once xyloglucan has been made soluble with alkali, it usually remains water-soluble even after neutralization, so that xyloglucan is a hemicellulose-B (Fry, 1989). Fraction IHB contained uronic acids (~12.4%) and was subjected to anion-exchange chromatography, in order to eliminate the acidic polymers (Table 3).

The column was eluted with water followed by saline solutions. The water-eluted fraction (52% yield; XG-1), showed Glc:Xyl:Gal:Fuc in a molar ratio of 7:5:3:1, respectively and a low amount of acidic residues (~4.1%). It was re-chromatographed on the same column. The purification steps increased the total sugar content in the purified sample, as observed in Table 3. Most protein and phenolic components were eliminated from original sample (IHB, Table 1). The protein content in the purified xyloglucan (78% yield, XG-2) was 2.3%. This fraction showed Glc:Xyl:Gal:Fuc in a molar ratio of 8:5: 2.5:1. The molar proportions are consistent with the ratio obtained for xyloglucans from other plant sources (Siddiqui and Wood, 1977; O'Neill and Selvendran, 1983; Buchala et al., 1993; Vincken et al., 1994; Cutillas-Iturralde et al., 1998).

Table 3
Fractionation of hemicellulose B (IHB) by DEAE-trisacryl

Fraction	Total sugar (%)	Mol%[a]							
		Rha	Fuc	Ara	Xyl	Man	Gal	Glc	Uronic acids[b]

XG-2[e]	83.3	–	5.6	1.2	29.2	3.1	13.9	46.8	–

[a] Neutral sugar analyzed by GLC.
[b] Blumenkrantz and Asboe-Hansen (1973), based on total sugar.
[c] Original fraction.
[d] Obtained by elution of IHB with water.
[e] Obtained by rechromatography of XG-I under the same conditions.

The purified fraction also contained manosyl residues (3.1%, Table 3). The presence of mannose during xyloglucan purification has been previously described (O'Neill and Selvendran, 1983; Redgwell and Selvendran., 1986; Vincken et al., 1994,1996; Cutillas-Iturralde et al., 1998) and was said to be an impurity (Fry, 1989).

2.2. Fucosylated xyloglucan analysis

The purified xyloglucan was soluble in water. The polysaccharide showed a specific rotation of $[\alpha]_D^{25}$ + 40.5° (H_2O; *c* 0.5) that it is in close agreement with reported values for other fucosylated xyloglucans (Siddiqui and Wood, 1977; Watanabe et al., 1980).

Fraction XG-2 was analyzed by high performance size exclusion chromatography (HPSEC) with multidetection for molecular weight determination. HPSEC, using a light scattering detector, was considered by Rinaudo (1993) as the only valid method to characterize polysaccharides over a wide range of molecular weights. The molecular weight (M_r) of XG-2 fraction is 49,500 by this method. The elution profile of xyloglucan indicates its homogeneity (Fig. 1).

The purified xyloglucan was subjected to methylation analysis (Ciucanu and Kerek, 1984), and the results are shown in Table 4. The overall recoveries of methylated alditol acetates (Glc: Xyl: Gal: Fuc ratio 8: 4: 2: 1) were in good agreement with the ratio found for the original polysaccharide after hydrolysis, reduction and acetylation. The methylation analysis data show that the polysaccharide has a highly branched structure. The results suggest that the xyloglucan contains a (1→4)-glucan backbone, ~60% of the units of which were substituted at *O*-6. Terminal fucose, galactose and xylose both substituted at *O*-2 are present, suggesting the presence of Fuc*p*-(1→2)-Gal*p*(1→2)-Xyl*p*-(1→ as a side chain, and all sugars are in the pyranose form. The peak whose retention time is 737 s (Table 4) could be also, under the

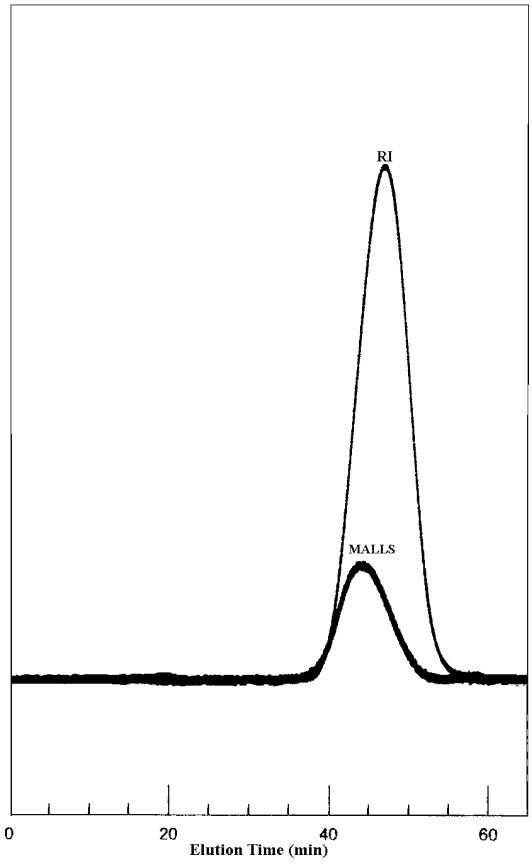

Fig. 1. High performance size exclusion chromatography (HPSEC) of the fraction XG-2, with light scattering (MALLS) and refractive index (RI) detection.

experimental conditions used, 2,3-Me_2Xyl, indicating 4-*O*-substituted xylopyranosyl or 5-*O*-substituted xylofuranosyl residues. However, this is not likely.

These data are consistent with those found for xyloglucans from other plant sources (Siddiqui and Wood, 1977; O'Neil and Selvendran, 1983, 1985; Stevens and Selvendran, 1984; Redgwell and Selvendran, 1986; Mabusela et al., 1990; Renard et al., 1992; Buchala et al., 1993; Vincken et al., 1994; Cutillas-Iturralde et al., 1998). In addition small amounts of 2,3,6-Me_3Gal and traces of 2,3,4-Me_3Glc were detected.

Table 4
Methylation analysis of xyloglucan (XG-2) from the leaves of *Hymenaea courbaril*

O-Methylated alditol acetate[a]	Linkage indicated	Mol%	RT[a]
2,3,4-Me_3Xyl	(Xyl*p*)1→	12.9	545

[a] Retention time in s.

Fig. 2 shows the ^{13}C NMR spectra of XG-2 fraction. In Table 5, the anomeric carbon chemical shifts of XG-2 are compared with those of xyloglucan obtained from the seeds of *H. courbaril* (Buchala et al., 1993; Lima et al., 1993). The well-defined anomeric signals at about 104.4, 102.4, 99.4, 98.9 ppm are attributed to terminal β-galactopyranosyl, β-glucopyranosyl and terminal and internal α-xylopyranosyl residues respectively. The anomeric carbon chemical shifts of XG-2 are compared with those of xyloglucan from the seeds (Lima et al., 1993) and they are closely related (Table 5). The other signals present in the anomeric region of ^{13}C NMR spectrum of the leaf xyloglucan, were not found in that of seeds. These are attributed to internal β-galactose and α-fucose, confirming the presence of Fuc*p*-(1→2)-Gal*p*(1→2)-Xyl*p*-(1→ as a side chain. It was also possible to distinguish signals from the C-4 and C-6 substituted β-glucopyranosyl residues at about 79.9 and 66.3 ppm respectively, and the latter is inverted in ^{13}C DEPT spectrum. The other signals that are inverted in ^{13}C DEPT spectra, between 61.6 and 60.2 ppm can be assigned to C-6 of β-galactopyranosyl, C-5 of α-xylopyranosyl and C-6 of β-glucopyranosyl units. The signal at high field (15.8 ppm) arises from C-6 of fucopyranosyl residues.

The structure of the xyloglucan from the leaves of *H. courbaril* is broadly typical of those xyloglucans detected in primary cell walls of other plants. It has a cellulosic backbone which is highly substituted at *O*-6 with D-xylopyranosyl residues, about a half of which are substituted by D-galactopyranosyl residues at *O*-2. Some of the galactosyl residues are further substituted at *O*-2 by L-fucose. The two most abundant subunits of type I cell wall xyloglucans are the nonasaccharide, XXFG, and the heptasaccharide, XXXG (Bauer et al., 1973; Hayashi et al., 1984; Guillén et al., 1995). However, the presence of a well-defined anomeric signal of terminal β-galactopyranose at ~104.4 ppm (Fig. 2, Table 5) could indicate that the xyloglucan from the

Table 5
Comparison of C-1 chemical shifts (δ) of ^{13}C NMR spectra for XG-2 fraction and xyloglucan from the seeds of *Hymenaea courbaril*[a]

	δ (ppm)	
C-1	Fraction XG-2	Seeds xyloglucan
Terminal β-D-galactose	104.4	104.5
Internal β-D-galactose	103.2	–
β-D-Glucose	102.4	102.5
α-L-Fucose	101.6	–
Terminal α-D-xylose	99.4	99.1
Internal α-D-xylose	98.9	98.7

[a] Lima et al. (1993).

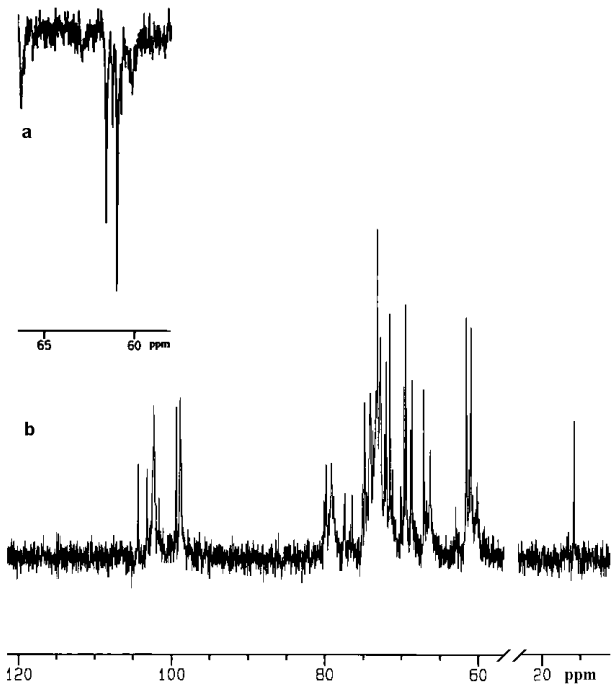

Fig. 2. (a) ^{13}C DEPT and (b) ^{13}C NMR spectrum of fraction XG-2 in D_2O, 50°C.

leaves of *H. courbaril* is also composed of some decasaccharide XLFG and/or nonasaccharide XLLG, in addition to XXFG and XXXG. These will be confirmed by future characterization of the oligosaccharides.

Comparative analysis of xyloglucans from seeds and leaf of *H. courbaril* gives rise results which are compatible with their functions, such as the differences observed in the M_r 300,000 for the polysaccharide from the seeds (Lima et al., 1993) and 49,500 for that obtained from the leaves. Another difference was observed in the $[\alpha]_D^{25}$ value, that was $+79.3°$ for the seeds xyloglucan (Lima et al., 1993) and $+40.5°$ for the leaf xyloglucan. The lower value obtained for the latter is probably due to the presence of α-L-fucosyl residues.

3. Experimental

3.1. General experimental procedures

Specific rotation was obtained, from a 0.5% solution, in water at 25°C, using an Autopol III automatic polarimeter.

Uronic acid was estimated according Blumenkrantz and Asboe-Hansen (1973), using galacturonic or glucuronic acids as standards. Total carbohydrate was determinated by the PhOH–H_2SO_4 method (Dubois et al., 1956), using glucose as standard, and protein content by the Hartree (1972) and Peterson (1977) methods, using BSA as standard.

Polysaccharide fractions were hydrolyzed with M TFA (5 h, at 100°C), except final residue with 72% H_2SO_4 (1 h, at 0°C) and then diluted to 8% (5 h, at 100°C) (Saeman et al., 1954). After removal of acid, monosaccharides were reduced with $NaBH_4$ and acetylated with Ac_2O–pyridine (1:1 v/v, 16 h, at 25°C). The resulting alditol acetates were analyzed by GLC, using a 5890 A II HP gas chromatograph at 220°C (FID and injector temperature, 250°C) with DB-210 capillary column (0.25 mm i.d.×30 m), film thickness 0.25 μm, the carrier gas being N_2 (2.0 ml/min).

The xyloglucan was methylated according to Ciucanu and Kerek (1984). The procedure was repeated until the products did not show OH absorption in the IR at 3400 cm^{-1}. The methylated polysaccharide was refluxed with 3% MeOH–HCl for 2 h and then hydrolyzed with 0.5 M H_2SO_4 (14 h, at 100°C). The resulting mixtures of *O*-methylated aldoses were reduced with $NaBH_4$ and then acetylated. The partially *O*-methylated alditol acetates were analyzed by capillary GC–MS, using a 3300 Varian gas chromatograph linked to an 810 R-12 Finnigan ion-trap mass spectrometer, using He as the carrier gas (2.0 ml/min). A capillary column of DB-210 (0.25 mm i.d.×30 m) was used. The former was held at 50°C during injection and then programmed at 40°C/min to 220°C (constant temperature).

The ^{13}C NMR and ^{13}C DEPT spectra were obtained with a DRX-400 Bruker spectrometer at 100 MHz in the Fourier transform mode, with complete proton decoupling at 50°C, using D_2O as solvent, contained in a tube of 0.5 cm i.d. Chemical shifts are reported as δ (ppm) relative to the resonance of DDS (sodium 4,4-dimethyl-4-silopentano-1-sulphonate), used as a internal standard ($\delta = 0$). The spectral width was 200 ppm.

High pressure size exclusion chromatography (HPSEC) was carried out on 5 mg/ml XG-2 fraction solutions, using a multidetection equipment in with a Waters 2410 differential refractometer (RI) and a Wyatt Technology Dawn F multi-angle laser light scattering (MALLS) detector were adapted on-line. Four Waters Ultrahydrogel 2000/500/250/120 columns were connected in series and coupled to the multidetection equipment. A 0.1 M $NaNO_3$ solution, containing NaN_3 (0.5 g/l), was used as eluent. The refractive index increment was determined by using a refractive index detector. The value of dn/dc (differential refractive index increment of the solvent-solute solution with respect to a change in solute concentration) was 0.172 at 633 nm.

3.2. Plant material

Hymenaea courbaril leaves were collected in August 1997, from the campus of the University of São Paulo, Ribeirão Preto, Brazil, where a voucher specimen is deposited in the Herbarium (SPFR), under the number 05312.

3.3. Polysaccharide extraction

Dry leaves (100 g) were triturated and extracted successively with absolute EtOH (170 h) and C_6H_5–CH_3:EtOH (2:1, 48 h) in a Soxhlet. The remaining solid material (80 g) was extracted with 2% EDTA (3 h, at 25°C), delignified with 2% aq. $NaClO_2$ and HOAc (6 h, at 70°C, pH 4) (Wise et al., 1946) and was submitted to aq. extraction at 60°C (6 h). The extracts were neutralized with 50% (v/v) HOAc, completely dialyzed against H_2O when necessary, conc., and pptd. with EtOH. The extracts were solubilized with H_2O and freeze-dried. The resulting holocellulose was then sucessively treated with 1 M KOH and 10 mM $NaBH_4$ (8 h, at 25°C, under a N_2 atmosphere, ×3). The alkaline extracts were adjusted with 50% (v/v) HOAc to pH 5, and then pptd. with EtOH, yielding IHT, IIHT and IIIHT fractions. The residue of 1M KOH extraction were treated with 4 M KOH and 10 mM $NaBH_4$ (8 h, at 25°C, under a N_2 atmosphere, ×3). The 4 M KOH extracts were acidified to pH 5 with 50% (v/v) HOAc, giving rise to hemicellulose A precipitation (IHA, IIHA and IIIHA fractions). Supernatants were dialysed against running water and treated with ethanol, giving rise to precipitation of hemicellulose B fractions, namely IHB, IIHB and IIHB (Whistler and Feather, 1965).

3.4. Xyloglucan isolation

Ion-exchange chromatography of the IHB fraction was carried out on a DEAE-Trisacryl (chloride form) column (23 × 0.8 cm) and eluted successively with H_2O, 0.5, 1 and 2 M NaCl, and 0.5 M NaOH. The collected fractions were analyzed for total sugar (Dubois, et al., 1956). After dialysis, polysaccharide fractions were recovered by pptn. with EtOH, solubilized with H_2O and then freeze-dried. The fraction eluted with H_2O (XG-1) was further purified by fractionation on the same column.

Book reviews

Basil. The Genus *Ocimum*

R. Hiltunen and Y. Holm (Eds.). Harwood Academic Publishers, Amsterdam, 1999. 182 pp., ISBN 90-5702-432-2, EUR 66, £49 or $80

The last couple of decades have seen a surge of interest in medicinal and aromatic plants by industry, life and health sciences and the general public. However, the information on the ethnobotany, cultivation and processing of these plants is scattered in the scientific literature. For this reason, Harwood Academic Publishers have brought out a series of Industrial Profiles, which aim to provide an in-depth coverage of the major medicinal and aromatic plants that are of industrial importance. I was asked to give my views on Volume 10, *Basil. The genus Ocimum*. Several species of this genus in the plant family Lamiaceae (Labiatae) are economically important because of the production of essential oils, especially *Ocimum basilicum, O. americanum, O. x citriodorum* and *O. gratissimum*, and they also have been used medicinally for a large number of ailments and as insect repellents. Although the cultivation of basil is usually associated with warm climates such as India, Africa and the Mediterranean, the book is edited and most chapters are written by Finnish scientists. However, many species of basil can be successfully cultivated in greenhouse conditions in colder climates, and research teams in Finland have studied the cultivation and essential oils of basil plants for many years.

Estimates of the number of species in the genus vary widely, from 30 to 160. Industrial and economic papers on basil frequently do not follow the International Code of Botanical Nomenclature, and the same species is often referred to by more than one name. For this reason, the first chapter of the book is a useful overview of the classification and relationships of the genus, written by Kew taxonomists A. Paton, R. Harley and M. Harley. According to their treatment the genus now comprises 65 species. They also provide a key to all these species together with their geographic distribution, habitat and synonyms. Unfortunately, some other authors of the book do not seem to have read this chapter before submitting their manuscripts. For instance, they write about *O. sanctum* without referring to its correct name *O. tenuiflorum,* although this has been the botanically accepted name for the species for quite some time.

Many aspects of the production systems of basil are described in Chapter 2 by experts E. Putievski (Israel) and B. Galambosi (Finland), including ecology, propagation and pests and diseases. In the next three chapters, the editors R. Hiltunen and Y. Holm write about the chemical composition of the *Ocimum* species, their essential oils and bioactivity. For most readers of *Phytochemistry* these chapters will probably be the most interesting. All the different oils detected in the various species are described, including monoterpenoids, sesquiterpenoids and phenylpropanoids. The phenomenal number of different chemotypes found in the various species, especially *O. basilicum, O. americanum* and *O. gratissimum*, are also listed here and so is the variation in oil composition due to the environment. Medicinal and insect-deterrent properties of *Ocimum* species may be due to a large extent to the essential oils, although few of the other constituents in *Ocimum* have been investigated for their bioactivity. The chapter about these other types of compounds in *Ocimum* species, e.g. flavonoids, is already slightly out of date, as this area is currently actively explored by a number of research groups including our own. In the sixth and last chapter, S.M. Mäkinen and K.K. Pääkkönen give an interesting overview of the processing and use of basil in food.

I was not disappointed by the current volume, and found a lot of new information. The scientific level is much higher than that of most books on herbs, their constituents and uses. I would therefore like to recommend it to all researchers and graduates in botany, phytochemistry, pharmacognosy, agronomy, pharmacology and medicine interested in the subject, especially because the price of the book is quite reasonable.

Ginseng: The Genus *Panax* Medicinal and Aromatic Plants—Industrial Profiles
Vol. 15, Edited by William E. Court, Harwood Academic Publishers, Amsterdam, The Netherlands, 2000. 266 + x pp. ISBN 90-5823-034-1. $95, £64, €86

This monograph is a superbly written treatise in the very important series on medicinal and aromatic plants from Harwood Academic. The overall series editor is Roland Hardman, and immense credit is due him for the selection of the overall editors of these monographs. In this case, the editor of the volume, William Court, is also the sole author of all but one of the ten chapters, and the result is an extraordinary effort.

Even thinking about writing a comprehensive volume on ginseng makes my head ache. This is a truly vast field of study, and much of the older literature is in the Korean, Chinese, and Japanese primary literature, and thus quite difficult to access. Consequently, an appreciation of these studies on this plant in its various forms, and its profound significance and almost mythical powers over the millennia, is more laborious than some of the other monographs. Anyone going to Korea for the first time can only be awed by the enormous commercial displays in department stores of this, the emperor of medicinal plants. These exhibits of the bottled, magnificently prepared, roots of ginseng, each costing thousands of dollars, and almost imitating the displays of fine, rare wine one might see in Europe, offers a new perspective on both the power of the doctrine of signatures and the deep cultural reverence this plant engenders.

This volume addresses the science behind the myths. Is ginseng a panacea? Does it really have anti-aging and anti-stress properties? Is the older root material more potent that the younger? Are all of the active compounds to be found in an aqueous extract? Can the various ginsengs in use be distinguished chemically?

Following an introductory chapter there is a botanical overview of the genus *Panax*, a chapter on the specialized growth and cultivation of ginseng, one on the tissue culture of ginseng by Čellárová and Kimáková and an overview of the substantial chemistry of the genus, highlighting the differences between the various species that are grown in the countries of eastern Asia. A thorough discussion of the pharmacology and therapeutics of ginseng is followed by an overview of the side effects of ginseng, and then there is a terrific compilation of the patents associated with ginseng. Finally, there are the other "ginsengs", those plants which in various systems of traditional medicine have been borrowing the claim to fame of ginseng, perhaps the most famous of which is *Eleutherococcus senticosus*, Siberian ginseng. The volume concludes with an index of author names and a general index. Each chapter is fully referenced.

Overall, the production values are high and there are a number of very attractive color plates of ginseng and its cultivation and propagation. The printing is clear and attractive, and the paper is of good quality. However, there are some irritating aspects which detract somewhat from the volume. Many of the structures in the chemistry chapter are of surprisingly poor quality and very difficult to read, and there is a substantial absence of commas, making for some long and awkward sentences. Most surprisingly, the volume I received had a number of pages which were completely out of sequence! On the other hand, the critical reviews of this field make for fascinating reading and consequently, this volume is recommended for all chemical libraries, and also for anyone interested in learning about this important genus of medicinal plants.

Tea Tree—The Genus *Melaleuca*
Edited by Ion Southwell and Robert Lowe, Harwood Academic Publishers, The Netherlands, 1999, 285 pp., ISBN 9057024179

Interest in medicinal and aromatic plants is increasing in the pharmaceutical, cosmetic, and perfume industries as well as at universities and in the field of medicine. These plants yield, for example, gums, resins, essential oils, juices, and secondary metabolites (e.g. flavonoids, alkaloids, terpenes) which can be used in medicines and fragrances. All these natural products are available in international trade.

In the last ten years **tea tree oil** (TTO), as a naturally occurring agent, has become increasingly more popular for a wide range of health care products. To all appearances, the name **tea tree** arose when Captain James Cook, on his exploratory voyage to Australia in 1770, encountered a myrtaceous shrub (possibly a *Leptospermum* species) with leaves that were used by his sailors as a substitute for tea (*Camellia sinensis*). Today a variety of myrtaceous shrubs derived from the genera *Leptospermum*, *Melaleuca* and

Kunzea are collectively termed tea tree. All these myrtaceous shrubs produce an essential oil in their leaves known as tea tree oil. Throughout the present book "**Tea Tree—The Genus *Melaleuca***", the term "**tea tree oil**" is reserved for "Oil of Melaleuca — Terpinen-4-ol Type," which is derived from *Melaleuca alternifolia*, *M. linariifolia*, *M. dissitiflora* and other species of *Melaleuca*.

About 230 species of *Melaleuca* are known in the world. The most well-known is *Melaleuca alternifolia,* which, like most other *Melaleuca* species, is indigenous to Australia. Some *Melaleuca* species also come from neighboring regions in Indonesia and Papua New Guinea. Typically, the paper-like bark of the trees can be pulled off in large strips. Australian beekeepers are very fond of the blossoms (flowers) as the honey from these flowers is excellent. The leaves of most of the species contain essential oil.

Because of its antimicrobial activity against a wide range of bacteria and fungi, TTO is increasingly being used in cosmetics and other health care products as well as in nursing and traditional medical treatments. Clinical data have also shown beneficial effects in treating acne vulgaris, onychomycosis, and Tinea pedis. On the other hand, undesirable side effects such as allergic contact dermatitis or local skin irritations associated with the use of TTO have also been reported. It is assumed that oxidized monoterpenes are the sensitizing agents of the oil.

Various aspects of *Melaleuca* research are discussed in the present volume, which contains 16 chapters written by competent experts in the field of tea tree oil research. The primary focus of the individual contributions, which are based on the scientific literature up to 1998, is the commercially most important species *Melaleuca alternifolia*. A discussion of the botanic aspects of the plant and a systematic distinction from other *Melaleuca* species as well as the cultivation and diseases and their treatment have been included. Furthermore, production, distillation, analysis, and chemical structure of the essential oil of *M. alternifolia* and the toxicological and medical aspects of its use are presented. Aspects of marketing conclude the discussion of *M. alternifolia*. Fortunately, the authors (editors) have included a discussion of side effects which can develop as a result of uncritical use of the essential oil. They describe dermatotoxicologic and allergic reactions which can occur with the use of undiluted TTO or its use over longer periods of time.

In two chapters towards the end of the book, cajuput oil (derived from *M. cajuputi)* and naiouli oil (from *M. quinquenervia*) are discussed. Both of these essential oils are commercially available; however, they do not have the same economic value as the essential oil from *M. alternifolia*. In the last chapter the editors also present botanical and chemical data on other *Melaleuca* species (about 16) which could potentially be commercially produced.

The book is suitable for use both by the various industries (for example, the pharmaceutical, cosmetics, and perfume industries) and in academic research at universities. It contains good illustrations, informative tables, and a comprehensive index. The extensive list of references provides both expert and newcomer alike with a complete survey of the subject and also lends itself to a more intensive study of particular topics. The book can be recommended to all interested readers with no reservations.

Received 1 May 2001; received in revised form 25 June 2001

Abstract

From the leaves of *Cryptostegia grandiflora,* four new cardiac glycosides oleandrigenin 3-*O*-β-glucopyranosyl-(1→4)-β-cymaropyranosyl-(1→4)-β-digitoxopyranoside, cryptostigmin I, oleandrigenin 3-*O*-β-glucopyranosyl-(1→4)-α-rhamnopyranoside, cryptostigmin II, 16-propionylgitoxigenin 3-*O*-β-glucopyranosyl-(1→4)-α-rhamnopyranoside, cryptostigmin III and oleandrigenin 3-*O*-β-glucopyranosyl-(1→6)-β-glucopyranosyl-(1→4)-β-cymaropyranosyl-(1→4)-β-digitoxopyranoside, cryptostigmin IV have been isolated together with two known cardenolides subalpinosid and 16-*O*-acetyl-digitalinum verum. The structures of the isolated compounds were verified by means of MS and NMR spectral analyses. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Cryptostegia grandiflora; Asclepiadaceae; Cardenolides; Cryptostigmin I–IV

1. Introduction

Cryptostegia grandiflora R.Br. (Asclepiadaceae) is an ornamental plant commonly cultivated in Egypt and warm countries (Metcalf and Chalk, 1950; Chopra et al., 1965; Hutchinson, 1973). The plant has a wide use in manufacturing of rubber and as a source of hydrocarbon fuels from its latex (Mehta et al., 1982). Three cardiac glycosides were isolated from *Cryptostegia madagascarensis* (14, 16-dianhydrogitoxigenin-3-rhamnoside, 16-propionylgitoxigenin-3-rhamnoside and 16-anhydrogitoxigenin-3-rhamnoside) (Sanduja et al., 1984) while few cardenolides (cryptograndoside A, B and digitalinum verum) have been already isolated and identified from *C. grandiflora* (Watt and Breyer, 1962). Moreover, the macro and micromorphological characters of the leaves and stems of *C. grandiflora* have been also investigated (Assaf, 1998). The present study deals with the isolation and structure elucidation of four new cardiac glycosides together with two known glycosides from the leaves of *C. grandiflora*.

2. Results and discussion

The ethanolic extract of the leaves of *C. grandiflora* was defatted with CH_2C1_2 and the aqueous layer was subjected to a column chromatography of Diaion HP-20. The 80% methanol eluate was repeatedly chromatographed on columns of silica gel and then by MPLC and HPLC to afford 6 glycosides.

Comparison of the NMR spectra of compound **1** with the published data revealed its structure as subalpinosid previously isolated from *Digitalis subalpina* (Lichius et al., 1991).

The molecular formula of compound **2** was deduced as $C_{44}H_{68}0_{17}$ from HR FAB–MS spectrometry (see Experimental section). The ^{13}C NMR spectrum (Tables 1 and 2) of **2** displayed the presence of one unsubstituted β-g1ucopyranosy1 unit from the signals at δ_c 104.3 (C-1), 74.9 (C-2), 78.2 (C-3 and 5), 71.9 (C-4) and 63.0 (C-6), one substituted β-digitoxopyranosyl unit from the signals at δ_c 96.5 (C-1), 38.9 (C-2), 71.8 (C-3), 83.0 (C-4), 67.5 (C-5) and 18.6 (C-6) and one substituted β-cymaropyranosyl unit from the signals at δ_c 101.3 (C-1), 37.2 (C-2), 78.5 (C-3), 83.4 (C-4), 68.5 (C-5), 18.7 (C-6) and 56.7 (OMe) (Bradbury and Jenkins, 1984) together with 25 carbon signals for the aglycone. The chemical shifts of the aglycone carbons were similar to those reported for 3-0 substituted oleandrigenin (Lichius et al., 1991). The downfield shifts of C-4 of the digitoxo- and

cymaropyranosyl units (δ_c 83.0 and 83.4 respectively) proved their substitution at C-4 of each unit (Bradbury and Jenkins, 1984). In the ^1H NMR spectrum of **2**, the doublet signal at δ_H 5.04 (1H) with *J* (constant) 7.8 Hz for the anomeric proton of the glucosyl residue indicated the β configuration. Moreover, the broad doublet signal at δ_H 5.39 (*J* constant 9.1 Hz) and the doublet of doublet signal at δ_H 4.71 (*J* constant 4.7 and *9.5* Hz) indicated the β configuration of the digitoxo- and cymaropyranosyl units respectively. The HMQC spectral data of **2** revealed the correlations between each carbon and its directly attached protons while H–H COSY interpreted the proton–proton couplings. The HMBC spectral analysis of **2** (Fig. 1) displayed significant correlation peaks between H-1 of the digitoxopyranosyl unit with C-3 of the aglycone as well as H-16 with COMe and H-22 with C-23. The negative FAB–MS spectrum of **2** exhibited M^+ at *m/z* 867 $[M–H]^-$ as well as a significant peak at *m/z* 705 $[M–H\text{-glucose}]^-$ and a peak at *m/z* 561 $[M–H\text{-(glucose + cymarose)}]^-$. Therefore, the internal sugar unit was confirmed as the digitoxopyranosyl unit and the structure of compound **2** was assigned as oleandrigenin 3-*O*-β-glucopyranosyl-(1→4)-β-cymaropyranosyl-(1→4)-β-digitoxopyranoside and named cryptostigmin I.

The molecular formula of compound **3** was deduced as $C_{37}H_{56}O_{15}$ from HR FAB–MS spectrometry (see Experimental section). ^{13}C NMR spectral data of **3** (Tables 1 and 2) were very similar to those of **2** in the aglycone moiety indicating the presence of 3-*O* substituted oleandrigenin as aglycone. The signals of the sugar moiety revealed the presence of a terminal β-glucopyranosyl unit in addition to α-substituted a rhamnopyranosyl unit from the signals at δ_c 99.6 (C-1), 71.4 (C-2), 72.2 (C-3), 85.1 (C-4), 68.3 (C-5) and 18.4 (C-6) (Breitmaier and Voelter, 1987). The downfield shift of C-4 of the rhamnopyranosyl unit (δ_c 85.1) indicated its substitution at this position. The β configuration of the glucopyranosyl unit was deduced from the doublet signal of its anomeric proton at δ_H 5.20 with *J* constant 7.7

Hz in the ^{1}H NMR spectrum while the configuration of the rhamnopyranosyl unit was established from the upfield shift of its C-5 (δ_c 68.3) in the ^{13}C NMR spectrum (Kasai et al., 1979). The structural assignment was confirmed by carrying out 2D NMR techniques such as HMQC and H–H COSY. The HMBC spectral analysis of **3** (Fig. 1) displayed correlation peaks between H-3 and C-1 of the rhamnopyranosyl unit, the anomeric proton of the glucosyl residue and C-4 of the rhamnosyl unit, H-16 and both COMe and C-20, H-17 and COMe, H-21, 21′ with C-23 and H-22 with C-23. The negative FAB–MS spectrum of **3** showed significant peaks at m/z 739 [M–H]$^-$ and 577 [M–H-glucose]$^-$ confirming the sequence of the sugar moiety. Consequently, the structure of **3** was determined as oleandrigenin 3-*O*-β-glucopyranosyl-(1→4)-α-rhamnopyranoside and named cryptostigmin II.

The molecular formula of compound **4** was established as $C_{38}H_{58}O_{15}$ from HR FAB–MS spectrometry (see Experimental section). Inspection of ^{13}C NMR spectral data of **4** (Tables 1 and 2) revealed their similarity to those of **3** both in the aglycone and sugar moieties. However, the presence of a methylene signal at δ_c 27.7 and a methyl signal at δ_c 9.1 in addition to the absence of the methyl signal at δ_c 20.6 in compound **4** proved the presence of a propionyl instead of the acetyl moiety at C-16 of the aglycone. At the same time, ^{1}H NMR spectrum of compound **4** showed a quartet at δ_H 2.13 (J constant 7.3 Hz) and a triplet at δ_H 0.93 (J constant 7.6 Hz) for the the methylene and methyl groups of the propionyl moiety, respectively, in addition to the absence of the methyl singlet at δ_H 1.82 of the acetyl group when compared with compound **3**. Moreover, FAB–MS spectrum of **4** exhibited significant peaks at m/z 753 [M–H]$^-$, 591 [M–H-glucose]$^-$ and 445 [M–H-(glucose + rhamnose)]$^-$. Consequently, the structure of compound **4** was assigned as 16-propionylgitoxigenin 3-*O*-β-glucopyranosyl-(1→4)-α-rhamnopyranoside and named cryptostigmin III.

The molecular formula of compound **5** was determined as $C_{50}H_{78}O_{22}$ from HR FAB–MS spectrometry (see Experimental section). Inspection of ^{13}C NMR spectral data of **5** (Tables 1 and 2) revealed their similarity to those of **2** both in the aglycone and sugar moieties. However, the downfield shift of C-6 of the glucosyl unit to δ_c 70.2 (+ 7.2 ppm) revealed its substitution at this position with an additional glucopyranosyl unit from the signals at δ_c 105.1, 74.9, 78.2, 72.1, 78.3 and 62.8 (Bradbury and Jenkins, 1984). In the ^{1}H NMR spectrum of **5**, the doublet signals at δ_H 5.19 and 4.99 (each 1H) with J constant 7.8 Hz for each one of the anomeric protons of the glucosyl residues indicated the β configuration. Moreover, the broad doublet signal at

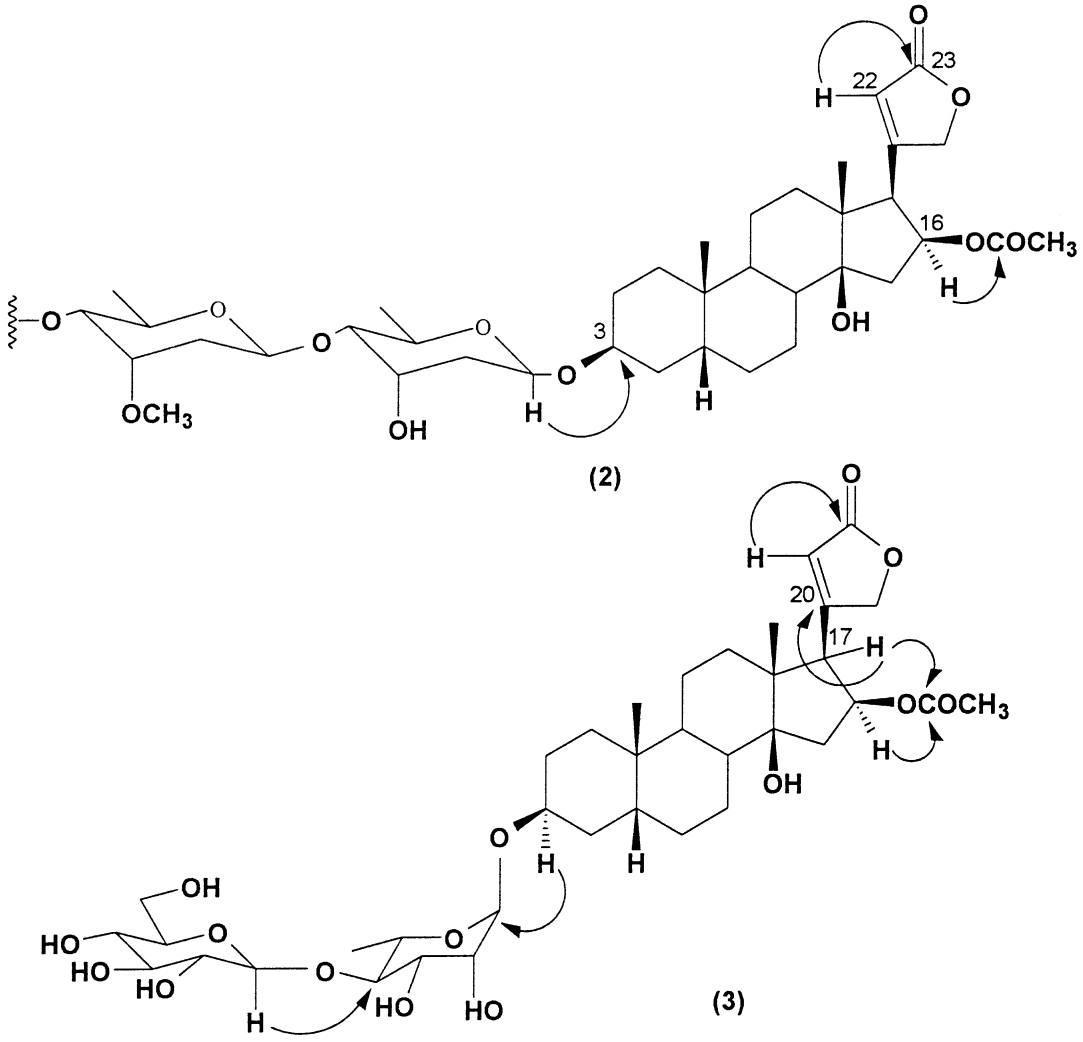

Fig. 1. Significant HMBC correlations of compounds **2** and **3**..

δ_H 4.79 (*J* constant 11.7 Hz) and the doublet of doublet signal at δ_H 4.73 (*J* constant 3.9 and 7.2 Hz) indicated the β configuration of the digitoxo- and cymaropyranosyl units respectively. FAB–MS spectrum of **5** exhibited significant peaks at *m/z* 1029 $[M–H]^-$, 867 $[M–H\text{-glucose}]^-$, 705 $[M–H\text{-(2 glucose)}]^-$ and 561 $[M–H\text{-(2 glucose + cymarose)}]^-$. Consequently, the structure of compound **5** was assigned as oleandrigenin 3-*O*-β-glucopyranosyl-(1→6)-β-glucopyranosyl-(1→4)-β-cymaropyranosyl-(1→4)-β-digitoxopyranoside and named cryptostigmin IV.

Comparison of the ^1H and ^{13}C NMR spectra of compound **6** with the published data deduced its structure as 16-*O*-acetyl-digitalinum verum previously isolated from *Addenium obesum* (Yamauchi and Abe, 1990).

3. Experimental

^1H and ^{13}C NMR (TMS as int. standard): 400 and 100 MHz, respectively were recorded on a JEOL JNM α-400 spectrometer. FAB–MS spectra were taken on a JEOL JMS-SX 102 spectrometer by direct inlet method at an ionizing voltage of 70 eV. Optical rotations were measured with a Union PM-I digital polarimeter. MPLC: RP-18 column (20 mm i.d. ×40 cm); flow rate of mobile phase 3 ml/min. HPLC: D-ODS-5 and polyamine columns (each 20 mm i.d. ×25 cm, YMC) with a Toyo Soda high speed chromatograph HLC-803 D pump and a Tosoh refraction index (R1-8) detector; flow rate of mobile phase 6 ml/min, injection vol. 0.8–1.0 ml. On the ODS column, 30% MeCN (I) and 25% MeCN (II) were used while 90% MeCN (III) and 85% MeCN (IV) were used on the polyamine column. CC: Kieselgel 60 (70-230 mesh, Merck) and Diaion HP 20 (Mitsubishi). TLC: silica gel 60 precoated plates F-254 and HPTLC using RP-18 precoated plates, F-254 s (Merck).

3.1. Plant material

Leaves of *C. grandi flora* R.Br. (Asclepiadaceae) were collected from the trees cultivated in the Experimental

Station of Faculty of Agriculture, Assiut University, Assiut, Egypt, in March 1997. The plant was identified by Professor N. El-Keltawi, Department of Horticulture, Faculty of Agriculture, Assiut University, Assiut, Egypt. A voucher specimen is deposited at the Herbarium of Department of Pharmacognosy, Faculty of Pharmacy, Assiut University, Assiut, Egypt.

3.2. Extraction and isolation of compounds (*1*–*6*)

The air-dried powdered leaves of *C. grandiflora* (2 kg) were extracted with 70% EtOH. The dried ethanolic extract (499 g) was suspended in H_2O and defatted successively with *n*-hexane and CH_2C1_2. The aq. fr. was applied to a column of Diaion HP-20 and eluted with H_20, 40% MeOH, 80% MeOH, MeOH and acetone successively. The 80% MeOH eluate (12 g) was chromatographed by silica gel CC using CH_2C1_2–MeOH–H_20 (85: 15: 1) and finally with (70 : 30 : 3) to give 4 fractions. Fraction 1 (760 mg) was separated by MPLC on RP-18 using 35% MeCN and HPLC using ODS column and solvent I to afford compounds **1** (white powder, 14 mg) and **6** (white powder, 53 mg). Fraction 2 (718 mg) was subjected to HPLC using polyamine column and solvent III to give compound **2** (white powder, 70 mg). Fraction 3 (610 mg) was separated by HPLC using polyamine column and solvent IV to afford compounds **3** (white powder, 149 mg) and **4** (white powder, 43 mg). Fraction 4 (2.5 g) was separated by MPLC on RP-18 using 30% MeCN as a solvent system and HPLC using ODS colunm and solvent II to afford compound **5** (white powder, 29 mg).

3.2.1. Compound (*2*)

Cryptostigmin I, $[\alpha]_D^{25}$ −15.4° (MeOH; *c* 5.70). HR FAB–MS (negative) *m/z*: 867.4371 $[M–H]^-$ $C_{44}H_{68}O_{17}$ (req. 867.4378). ^{13}C NMR (C_5D_5N, Tables 1 and 2). ^1H NMR (C_5D_5N): δ_H 6.30 (1H, *s*, H-22), 5.63 (1H, *m*, H-16), 5.40 (1H, *d*, *J* = 18.1 Hz, H-21), 5.39 (1H, *bd*, *J* = 9.1 Hz, H-1 Dig), 5.20 (1H, *d*, *J* = 18.1 Hz, H-21′), 5.04 (1H, *d*, *J* = 7.8 Hz, H-1 Glc), 4.71 (1H, *dd*, *J* = 4.7 and 9.5 Hz, H-1 Cym), 3.49 (3H, *s*, OMe), 3.35 (1H, *d*, *J* = 8.8 Hz, H-17), 2.77 (1H, *dd*, *J* = 8.6 and 14.6 Hz, H-15), 2.02 (1H, *d*, *J* = 13.2 Hz, H-15′), 1.82 (3H, *s*, COMe), 1.58 (3H, *d*, *J* = 5.4 Hz, Me-6 Cym), 1.42 (3H, d, *J* = 6.1 Hz, Me-6 Dig), 1.04 (3H, *s*, Me-18) and 0.84 (3H, *s*, Me-19).

3.2.2. Compound (*3*)

Cryptostigmin II, $[\alpha]_D^{25}$ −39.4° (MeOH; *c* 3.73). HR FAB–MS (negative) *m/z*: 739.3604 $[M–H]^-$ $C_{37}H_{56}O_{15}$ (req. 739.3541). ^{13}C NMR (C_5D_5N, Tables 1 and 2). ^1H NMR (C_5D_5N): δ_H 6.32 (1H, *bs,* H-22), 5.66 (1H, *m,* H-16), 5.40 (1H, *dd,* *J* = 1.8, 18.3 Hz, H-21), 5.32 (1H, *bs,* H-1 Rha), 5.22 (1H, *dd,* *J* = 1.5, 18.3 Hz, H-21′), 5.20 (1H, *d,* *J* = 7.7 Hz, H-1 Glc), 4.18 (1H, *m*, H-3), 3.37 (1H, *d,* *J* = 8.6 Hz, H-17), 2.78 (1H, *dd,* *J* = 9.5 and 15.7 Hz, H-15), 2.03 (1H, *dd,* *J* = 2.1, 15.3 Hz, H-15′), 1.82 (3H, *s,* COMe), 1.67 (3H, *d,* *J* = 6.4 Hz, Me-6 Rha), 1.05 (3H, *s,* Me-18) and 0.81 (3H, *s,* Me-19).

3.2.3. Compound (*4*)

Cryptostigmin III, $[\alpha]_D^{25}$ −41.3° (MeOH; *c* 2.01). HR FAB–MS (negative) *m/z*: 753.3683 $[M–H]$ $C_{38}H_{58}O_{15}$ (req. 753.3697). ^{13}C NMR (C_5D_5N, Tables 1 and 2). ^1H NMR (C_5D_5N): δ_H 6.32 (1H, *bs,* H-22), 5.70 (1H, *m,* H-16), 5.41 (1H, *d,* *J* = 18.3 Hz, H-21), 5.22 (1H, *d,* *J* = 18.3 Hz, H-21′), 5.20 (1H, *d,* *J* = 7.1 Hz, H-1 Glc), 3.40 (1H, *d,* *J* = 8.8 Hz, H-17), 2.80 (1H, *d,* *J* = 14.8 Hz, H-15), 2.13 (2H, *q*, *J* = 7.3 Hz, $COCH_2$), 2.10 (lH, *d*, *J* = 14.8 Hz, H-l5′), 1.68 (3H, *d,* *J* = 6.1 Hz, Me-6 Rha), 1.07 (3H, *s,* Me-18), 0.93 (3H, *t,* *J* = 7.6 Hz, CO–CH_2-Me) and 0.83 (3H, *s*, Me-19).

3.2.4. Compound (*5*)

Cryptostigmin IV, $[\alpha]_D^{25}$ −37.8° (MeOH; *c* 1.80). HR FAB–MS (negative) *m/z*: 1029.4891 $[M–H]$ $C_{50}H_{78}0_{22}$ (req. 1029.4906). ^{13}C NMR (C_5D_5N, Tables 1 and 2). ^1H NMR (C_5D_5N): δ_H 6.32 (1H, *s,* H-22), 5.40 (1H, *d,* *J* = 18.6 Hz, H-21), 5.22 (1H, *d,* *J* = 18.6 Hz, H-21′), 5.19 and 4.99 (each 1H, *d,* *J* = 7.8 Hz, H-1 Glc and Glc′), 4.79 (1H, *bd,* *J* = 11.7 Hz, H-1 Dig), 4.73 (1H, *dd,* *J* = 3.9 and 7.2 Hz, H-1 Cym), 3.60 (3H, *s,* OMe), 3.36 (lH, *d,* *J* = 9.1 Hz, H-17), 2.78 (1H, *dd,* *J* = 10.0 and 15.2 Hz, H-15), 2.04 (1H, *d,* *J* = 15.2 Hz, H-15′), 1.83 (3H, *s,* COMe), 1.57 (3H, *d,* *J* = 6.1 Hz, Me-6 Cym), 1.43 (3H, *d,* *J* = 6.4 Hz, Me-6 Dig), 1.05 (3H, *s,* Me-18) and 0.85 (3H, *s,* Me-19).

Abstract

Two enmein type diterpenoids, taibaijaponicains A and B, were isolated from the ethanol extract of the leaves and branches of *Isodon japonica*. Their structures are designated as 6β,11α-dihydroxy-16α-methoxymethyl-6,20-epoxy-6,7-*seco*-*ent*-kaur-15-one-1,7-olide and 3β-acetoxy-6β,11α-dihydroxy-16α-methoxymethyl-6,20-epoxy-6,7-*seco*-*ent*-kaur-15-one-1,7-olide, respectively, on the basis of detailed spectroscopic analyses. © 2001 Elsevier Science Ltd. Keywords: *Isodon japonica*; Labiatae; Taibaijaponicains A and B; Enmein type diterpenoids

1. Introduction

Enmein was first isolated from *Isodon japonica* in 1958. Enmein type diterpenoids are bitter constituents of the plants of genus *Isodon* (Labiatae). They have varied biological activities, i.e. anti-bacterial, anti-inflammatory, anti-tumor, etc. (Cheng et al., 1987). Previous studies on *I. japonica* led to the isolation of more than 16 diterpenoids (Fujita et al., 1973; Li et al., 1982; Liu et al., 1982; Zhao et al., 1984; Wang et al., 1987; Zhao and Li., 1987; Meng et al., 1989; Xu et al., 1996). A further study of the minor diterpenoid constituents of this species was aimed at finding substances with even higher biological activities. We have isolated two new enmein type diterpenoids, taibaijaponicains A (**1**) and B (**2**), together with six known diterpenoids, norhendosin A, rabdophyllin G, dihydroenmein, nodosin, enmein, rabdosin A, and two other known compounds, β-sitosterol and oleanolic acid. In this paper, we report the isolation and structure elucidation of the new diterpenoids by means of spectroscopic methods including 1D and 2D NMR spectroscopy.

2. Results and discussion

Taibaijaponicain A (**1**) was obtained as an amorphous powder. Its molecular formula was determined as $C_{21}H_{30}O_7$ by positive HR–FABMS ($[M+1]^+$ m/z 395.4644, calc. 395.4666) and FABMS ($[M+Li]^+$ m/z 401, $[M+Na]^+$ m/z 417). The ^1H, ^{13}C and DEPT NMR spectra of **1** (see Tables 1 and 2) showed signals for two methyl groups, one methoxy group, six methylene groups, seven methine groups, three quaternary carbons, one ketonic carbon and one ester carbonyl carbon. Taibaijaponicain A (**1**) contains a five-membered ketone group [ν_{max} 1765 cm^{-1}, δ_c 212.3(*s*)], δ-lactone [ν_{max} 1720 cm^{-1}, δ_H 4.77(1H, *dd*, $J=11.2$, 3.9 Hz), δ_c 171.2(s)], and a hemiacetal group [δ_H 5.27(1H, s), δ_c 102.6(d)]. In addition, the IR and ^1H NMR spectra also revealed that the compound possessed two hydroxyl groups [ν_{max} 3358 cm^{-1}, δ_H 5.27 (1H, s), 4.30 (1H, *ddd*, $J=10.6$, 8.8, 3.4 Hz)]. Considering the known structures of diterpenoids from the genus *Isodon*, these data suggest that **1** was an enmein type diterpenoid of pentacyclic 6,7-*seco*-*ent*-kaurane type, with one methoxy group and two hydroxyl groups.

Compound **1** did not show an absorption maximum band above 220 nm in the UV spectrum, which indicated the absence of a five-membered ketone conjugated with the *exo*-methylene group. The ^{13}C NMR spectroscopic data of **1** were very similar to those of nodosin (**3**) (Takeda et al., 1994) except for one more methoxyl group and one less C–C double bond. Comparison of their ^{13}C NMR spectral data indicated that the difference between **1** and **3** was only in the ring D. This meant that two hydroxyl groups were attached at C-6 and C-11, and a methoxyl group was in ring D in compound **1**. In the ^1H NMR spectrum of **1**, besides an AB peak at δ 3.92, 3.73 (each 1H, AB, *d*, $J=9.2$ Hz, H-20a, 20b),

[a] Two-bond correlations are indicated in parentheses.
[b] n.o. Indicates no clear correlations with this proton.

there was an AB peak at δ 3.64, 3.56 (each 1H, AB, *dd*, $J = 10.4$, 4.5 Hz, H-17a, 17b). In the HMBC spectrum of **1** (see Table 1), the signals at δ 3.64 and 3.56 correlated with the signals at δ 31.3 (*d*, C-13), 58.8 (*d*, C-16) and 56.4 (*q*, OCH_3); the signal at δ 2.79 (1H, *m*, H-13β) showed a correlation with the signals at δ 69.3 ppm (*t*, C-17), 32.6 ppm (*t*, C-12) and 35.0 ppm (*t*, C-14). These results suggested that the methoxyl group should be located at the C-17 position.

In enmein type diterpenoids, the ring A is in a chair conformation, the rings B_1 and D are in envelope conformations and ring B_2 is in a boat conformation. Ring C can adopt either a chair or boat conformation depending on the substituents present in ring C (Xu, 1985). In compound **1**, the coupling constant between H-5β (δ 2.75, *s*) and H-6 (δ 5.27, *s*) was zero, which indicated that its dihedral angle approximated 90°, consistent with a β-orientation of the hydroxyl group at C-6 of **1**. Ring C of **1** appears to be in a boat conformation judging from that the coupling constant of H-11 (δ 4.30, *ddd*, $J = 10.6$, 8.8, 3.4 Hz) with H-9α (δ 2.14, *bs d*, $J = 10.6$ Hz) and H-12α(δ 2.40, m), H-12β (δ 1.45, overlap). For a chair conformation of the ring C, the dihedral angles between H-9α and H-11, H-11 and H-12α or H-12β should approximate 60°, and all of their coupling constants should be less than 4 Hz. This fact suggests that the hydroxyl group at C-11 of **1** was in the α-orientation. These results were further verified by a NOESY experiment, where correlations are shown in Fig. 1. In addition, in the NOESY spectrum of **1**, the signal at δ 1.45 (1H, m, H-16) exhibited a NOE correlation with both the signals at δ 2.79 (1H, *m*, H-13β) and δ 1.81 (1H,

		20.9, *q*

overlap, H-14α). This indicated that C-17 was in the α-orientation. Therefore, taibaijaponicain A (**1**) was 6β, 11α-dihydroxy-16α-methoxymethyl-6,20-epoxy-6,7-*seco-ent*-kaur-15-one-1,7-olide.

Taibaijaponicain B (**2**) was obtained as an amorphous powder. Its molecular formula was determined as $C_{23}H_{32}O_9$ by FABMS ($[M+Li]^+$ *m/z* 459, $[M+Na]^+$ *m/z* 475). The IR, ^1H, ^{13}C and DEPT NMR data of **2** (see Tables 1 and 2) were very similar to those of taibaijaponicain A (**1**) except for the presence of one acetoxyl group in **2** [ν_{max} 1742 cm^{-1}, δ_H 2.07 (3H, *s*), δ_c 170.6 (*s*), 20.9(q)]. The ^{13}C NMR spectral data of **2** differed from those of **1** only at C-2, C-3 and C-4. The downfield shift of C-3 from δ 37.4 ppm in **1** to δ 71.6 ppm in **2** indicated that the acetoxyl group at C-3 in **2** had replaced the H in **1**. These assignments were further confirmed by the HMBC spectrum of **2** (see Table 1).

The relative configuration of the acetoxyl group at C-3 of **2** was established on the basis of the coupling constants of H-3 (δ 4.79, 1H, *dd*, $J=3.5$, 3.6 Hz) with H-2α (δ 2.12, 1H, *m*) and H-2β (δ 2.34, 1H, *m*). The coupling constants suggested that the dihedral angles between H-3 and H-2α, and H-2β approximated 60°, thus the H-3 was in the α-orientation and the acetoxyl group was in the β-orientation in compound **2**. On the basis of the above evidence, the structure of taibaijaponicain B (**2**) was determined to be 3β-acetoxy-6β,11α-dihydroxy-16α-methoxymethyl-6,20-epoxy-6,7-*seco-ent*-kaur-15-one-1,7-olide.

3. Experimental

3.1. General

FAB mass spectra were recorded on a ZAB-HS Instrument (data system: MASPEC II); HR–FAB mass spectrum was recorded in an Autospec 3000 instrument. IR spectra were recorded in KBr pellets on a Nicolet AVATAR 360 FT–IR spectrometer. The optical rotations were measured with a JASCO-20C polarimeter. NMR spectra were recorded on a Bruker AM-400 Instrument. The chemical shift values are given in ppm using TMS as the internal standard.

3.2. Plant material

The plant material of *I. japonica* was collected in Taibai Mountain, Shaanxi Province, PR China, in August 1997. A voucher specimen (SNU 97-08-03, Li) was deposited in the Herbarium of Department of Biology, Shaanxi Normal University.

3.3. Extraction and isolation

The dried powdered leaves and tender branches of *I. japonica* (7.0 kg) were extracted with 95% EtOH (18 l×2) at room temperature for 7 days. After removal of the solvent in vacuo, the residue was partitioned in H_2O and extracted with petroleum ether (4 l×3) and EtOAc (4 l×3), respectively. The EtOAc extract (130 g) was subjected to CC on silica gel (3 kg, 200–300 mesh), eluting with $CHCl_3$ and increasing proportions of Me_2CO (from $CHCl_3$ 100% to Me_2CO 100%). Fractions were combined by monitoring with TLC. All components were further purified by column chromatography and preparative TLC on silica gel to give β-sitosterol (1.13 g, 0.016%), oleanolic acid (2.6 g, 0.037%), norhendosin A (273 mg, 0.0039%), rabdophyllin G (67 mg, 0.00096%), dihydroenmein (315 mg, 0.0045%), nodosin (**3**, 110 mg, 0.0016%), enmein (384 mg, 0.0055%), taibaijaponicain A (**1**, 236 mg, 0.0034%), taibaijaponicain B (**2**, 89 mg, 0.0013%), rabdosin A (95 mg, 0.0014%), orderly.

3.4. Taibaijaponicain A (*1*)

An amorphous powder; $[\alpha]_D^{17}$ −104.7° (*c* 0.49, acetone); IR ν_{max}^{KBr} cm^{-1}: 3358, 2925, 2800, 1765, 1720, 1504, 1461, 1264, 1126, 1072 and 1050; FABMS *m/z*: 401 $[M+Li]^+$, 417 $[M+Na]^+$; HR–FABMS *m/z* 395.4644 $[M+1]^+$ for $C_{21}H_{30}O_7$ (calc. 395.4666); ^1H NMR spectral data (400 MHz) and principal HMBC correlations are listed in Table 1; DEPT, ^{13}C NMR spectral data are listed in Table 2. Most of the NOESY correlations are shown in Fig. 1.

Received 30 November 2000; received in revised form 22 March 2001

Abstract

The volatile composition of ten Piperaceae species, comprising three genera (*Ottonia, Piper* and *Peperomia*) has been studied. The species were collected in a typical fragment of the Brazilian Atlantic forest, constantly being damaged by human action. The essential oils were obtained by hydrodistillation in a modified Clevenger-type apparatus and their analyses were performed by GC and GC/MS. Identification of the substances was made by comparison of mass spectra and retention indices with literature records. A great number of non-oxygenated monoterpenes and sesquiterpenes were identified. Most of these sesquiterpenes are derived from *E,E*-farnesyl-PP, suggesting a preference of these species to synthesize metabolites from this pathway. Arylpropanoids, although being common compounds produced by Piperaceae species, were not found in these oils. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Piperaceae; *Piper*; *Peperomia*; *Ottonia*; Essential oil composition; Monoterpenes; Sesquiterpenes

1. Introduction

The family Piperaceae belonging to the superorder Nymphaeiflorae, order Piperales (Dahlgren, 1980), comprises about 5 genera and 1400 species (Joly, 1977). The genera *Piper* and *Peperomia* are the most representative of the Piperaceae (700 and 600 species, respectively). Some *Piper* species are used in folk medicine to treat many diseases while species of the genus *Peperomia* are mainly used as ornamentals (Duke, 1985). Analysis of volatile constituents from Piperaceae species has revealed the presence of monoterpenes, sesquiterpenes and arylpropanoids (apiol, dillapiol, myristicin, safrole, sarisan,) that have shown interesting biological properties (Parmar et al., 1997; Martins et al., 1998; Moreira et al., 1998). Recently we reported the presence of a butylbenzene derivative in the volatile fraction of *Ottonia anisum* (Moreira et al., 1997). The essential oil compositions of ten species from the Brazilian Atlantic forest, an ecosystem in constant change due to human devastation, were studied. These species are *Ottonia anisum* Sprengel, *Piper amplum* Kunth., *Piper arboreum* var. *arboreum* Yunck., *Piper dilatatum* L.C. Rich, *Piper goesii* Yunck., *Piper hispidum* var. *hispidum* Kunth., *Piper hoffmanseggianum* Rocker & Sehulter, *Piper mollicomum* Kunth., *Peperomia blanda* Kunth. and *Peperomia rupestris* var. *rupestris* Humb. Bonpl. & Kunth. The structures of the compounds in the volatile fractions of these ten species were elucidated satisfactorily by using GC and GC/MS analyses as well as by comparison of their mass spectra and RI values with literature data (McLafferty and Stanffer, 1989; Adams, 1995).

2. Results and discussion

GC/MS analyses and comparison of their MS and RI values with those in the literature permitted records allowed the identification of monoterpenes (acyclic and monocyclic) and sesquiterpenes (acyclic, monocyclic, bicyclic and tricyclic) in the essential oils. In total, 71 different compounds were identified (Tables 1 and 2, Fig. 1). The ketone, 2-tridecanone, was found in significant concentration (> 3%) in the essential oil of *Peperomia rupestris* var. *rupestris* (4.30%), *Piper dilatatum* (4.39%) and *P. mollicomum* (4.29%). The volatile fraction composition

of *Peperomia rupestris* var. *rupestris, Piper dilatatum*, *P. goesii* and *P. hoffmansegianum* were found to be rich and diversified with more than 80% of the structures oil constituents successfuly elucidated. The *Ottonia anisum* essential oil had *E*-nerolidol in great concentration (11.28%). Surprisingly, 1 - butyl - 3,4 - methylenedioxybenzene, the major compound (90.00%) identified in the *O. anisum* essential oil collected in Teresopolis (Moreira et al., 1997), was not found in this sample (Table 1). The volatile compositions of the studied *Peperomia* species showed sesquiterpenes as the major fraction (*Peperomia blanda*—51.24% and *Peperomia rupestris* var. *rupestris*—65.89%). Monoterpenes were also identified in these oils in minor amounts (*Peperomia blanda*—3.20% and *Peperomia rupestris*—8.51%). These results are in agreement with published data for some other Brazilian *Peperomia* (Tables 1 and 2, Fig. 1) (Moreira et al., 1999). The essential oil composition from the seven studied *Piper* species was mainly found to be sesquiterpenes (Tables 1 and 2, Fig. 1).

Analysis of the major compounds identified in the oils showed a preference of the Piperaceae (8 of 10 species) to

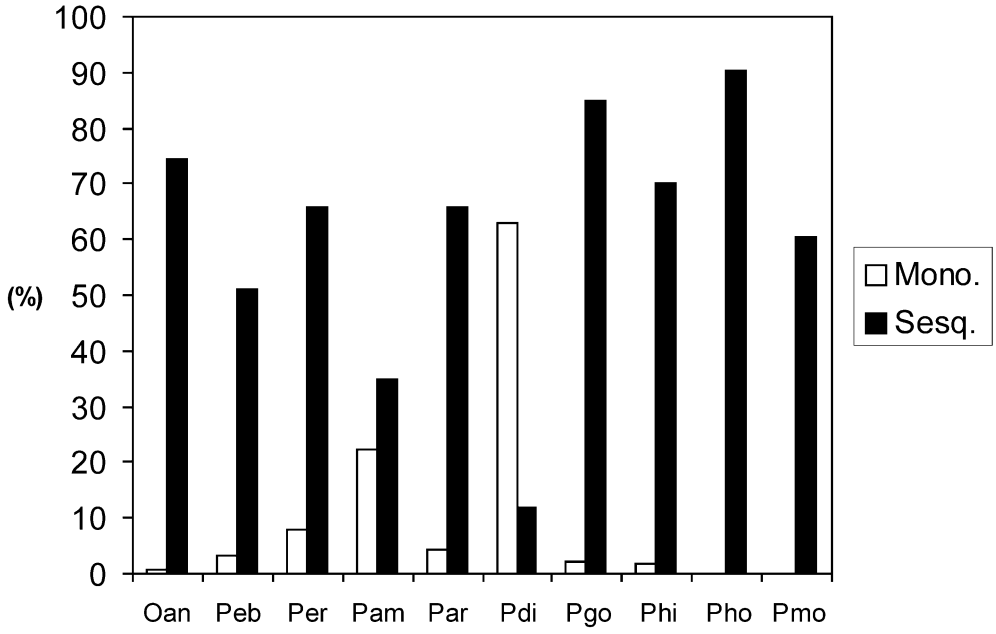

Fig. 1. Monoterpene and sesquiterpene distribution in the selected Piperaceae species for study. Mono. = monoterpenes; Sesq. = sesquiterpenes.

synthesize sesquiterpenes. Non-oxygenated sesquiterpenes were identified as the major compounds of the essential oil of *P. blanda* (guaiene: 6.80%), *P. rupestris* var. *rupestris* (germacrene D: 14.95%), *P. goesii* (gemacrene D: 28.87%), and *P. hispidum* var. *hispidum* (α-caryophyllene: 9.21%). Oxygenated sesquiterpenes were found in great amount in the oils of *O. anisum* (*E*-nerolidol: 11.28%), *P. mollicomum* (*E*-nerolidol: 23.20%), *P. arboreum* var. *arboreum* (γ-eudesmol: 14.61%), and *P. hoffmansegianum* (hinesol: 19.33%). Whereas monoterpenes were found as the major compounds in the essential oils of *P. amplum* (α-pinene: 16.78%) and *P. dilatatum* (myrcene: 41.77%).

The most frequent compounds identified in the oils were also sesquiterpenes. However, the non-oxygenated monoterpenes (*Z*)-β-ocimene (5/10)[1], α-pinene (6/10) and β-pinene (6/10) were well represented. Only 13 different types of sesquiterpenes were identified in at least 5 of the 10 studied species, and among them, 10 were non-oxygenated. A biosynthetic approach showed that the most common sesquiterpenes identified in the oils from these species have the *E*,*E*-farnesyl-PP as fundamental precursor (Dewick, 1997). In fact, a great number of the most representative sesquiterpenes (11 types), including those of higher occurrence (*E*-caryophyllene: 9/10 and gemacrene D: 10/10), are formed primarily from *E*,*E*-farnesyl-PP. This analysis also showed that only 2 different sesquiterpenes types originated from *E*,*Z*-farnesyl-PP reactions (α-copaene: 8/10 and δ-cadinene: 9/10).

Considering the average mono- and sesquiterpene contents for each studied Piperaceae genus (*Ottonia, Peperomia* and *Piper*), it is interesting that significant differences were not observed for the sesquiterpene fractions (oxygenated and non-oxygenated) but for monoterpenes, the non-oxygenated representatives were considerably more abundant (Table 2).

Our observations suggest the trend of these Piperaceae from the Brazilian Atlantic forest to give larger number of non-oxygenated sesquiterpenes derived from the *E*,*E*-farnesyl-PP precursor.

3. Experimental

3.1. Plant material

Leaves from *Ottonia anisum* Sprengel (Oan), *Piper amplum* Kunth. (Pam), *Piper arboreum* var. *arboreum* Yunck. (Par), *Piper dilatatum* L.C. Rich (Pid), *Piper goesii* Yunck. (Pgo), *Piper hispidum* var. *hispidum* Kunth. (Phi), *Piper hoffmanseggianum* Rocker & Sehulter (Pho), *Piper mollicomum* Kunth. (Pmo) and aerial parts of *Peperomia blanda* Kunth. (Peb) and of *Peperomia rupestris* var. *rupestris* Humb. Bonpl. & Kunth. (Per) were collected near Paraty, Rio de Janeiro State, Brazil, in May 1997. The plants were identified by the botanist Prof. Elsie F. Guimarães and botanical samples are found at the Herbarium of the Botanical Garden of Rio de Janeiro, Rio de Janeiro, Brazil.

3.2. Isolation of the essential oil

Each fresh plant material was submitted to hydrodistillation for one hour in a modified Clevenger-type apparatus. A sample of the obtained essential oils was dissolved in dichloromethane for GC and GC/MS analyses (Moreira et al., 1997).

[1] Frequence in the studied species.

3.3. Analysis of essential oil

GC analysis: GC analysis was performed using a Varian Star 3400 CX gas chromatograph, fused silica capillary column (DB-5, 30 m×0.20 mm), flame-ionization detector, hydrogen as carrier gas and temperature programming from 60 to 240 °C (3 °C/min). Retention times (RT) were measured in minutes and the relative amount in percent values of each compound in the mixture was obtained directely from the GC data.

3.3.1. GC/MS analysis

GC/MS analysis was performed using a HP5890 SII gas chromatograph coupled to a VG Autospec mass spectrometer at 70 eV, fused silica capillary column (DB-1, 30 m×0.20 mm), helium as carrier gas and temperature programming from 60 to 240 °C (3 °C/min).

3.3.2. Retention indices

Retention indices (RI) were calculated using GC data of a saturated aliphatic hydrocarbon homologous series within C_8 to C_{22}, performed in the same column and conditions as used in the GC analysis for the essential oils.

3.3.3. Compound identification

Identification of the substances was carried out primarily by comparing the mass spectra with a computer databank (National Institute for Standard Technology–NIST–62,235 compounds). Further visual comparison of the mass spectra with literature records and comparison of the RI permitted identification of the major compounds (McLafferty and Stanffer, 1989; Adams, 1995).

Received 13 October 2000; received in revised form 15 March 2001

Abstract

Two saponins, designated as bacopaside I and II, have been isolated from *Bacopa monniera* Wettst. and their structures have been elucidated as 3-*O*-α-L-arabinofuranosyl-(1→2)-[6-*O*-sulphonyl-β-D-glucopyranosyl-(1→3)]-α-L-arabinopyranosyl pseudojujubogenin **(1)** and 3-*O*-α-L-arabinofuranosyl-(1→2)-[β-D-glucopyranosyl (1→3)]-β-D-glucopyranosyl pseudojujubogenin **(2)** mainly on the basis of 2D NMR and other spectral analyses. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Bacopa monniera*; Scrophulariaceae; Saponins; Bacopaside I; Bacopaside II; Pseudojujubogenin; 2D NMR

1. Introduction

The reputation of *Bacopa monniera* Wettst. as a nervine tonic is well known in Indian traditional medicine (Chopra et al., 1969). Recent pharmacological studies indeed confirmed the activity (Singh and Dhawan, 1978, 1982; Singh et al., 1988). It was also confirmed that the activity was due to the saponins present in the alcoholic extract of the plant. Because of the presence of a large number of glycosidic constituents in the extract as an intimate mixture, two groups of workers could isolate and characterize only a part of the constituents (Jain and Kulshrestha, 1993; Rastogi et al., 1994; Garai et al., 1996a,b; Rastogi and Kulshrestha, 1998; Mahato et al., 2000). In view of the increasing interest on this herb drug, we undertook a thorough chemical re-investigation of the glycosidic fraction of the methanol extract of the plant and have been able to isolate two new pseudojujubogenin glycosides, designated as bacopaside I (**1**) and II (**2**). The present paper reports the isolation and structure elucidation of these two saponins.

2. Results and discussion

Bacopaside I (**1**) and II (**2**) were isolated from the dark green solid which separated out from the methanol extract of the plant on concentrating and cooling. While **1** was obtained by direct crystallization of a chromatographic fraction of the above mentioned green solid, **2** could be isolated by prep. HPLC of a less polar fraction of the chromatography (vide Experimental). Both the compounds gave a positive froth test for the saponins and Liebermann–Burchard test for triterpenes. The sugar constituents present in the saponins were identified to be glucose and arabinose by PC and GC of their acid hydrolysates. The absolute configuration of the sugars as D and L respectively were determined by the specific rotations (vide Experimental) of the sugars isolated by prep. paper chromatography of the hydrolysates.

^{13}C NMR spectrum (Table 1) of **1**, mp 260–261 °C (decomp.), $[\alpha]_D$ −35.6°, displayed signals for 46 carbons, of which 30 were assigned to the triterpene moiety and 16 to the sugar units indicating that there must be one unit of glucose and two units of arabinose in the molecule and this was corroborated by the GC analysis of their alditol acetates. Its 600 MHz ^{1}H NMR spec-

trum (Table 2) exhibited signals for seven methyl groups on tertiary carbons, two –CH_2–O–, one –CH–O– protons and one vinylic proton of a trisubstituted double bond, besides the protons of two arabinose and one glucose units. Moreover, the presence of a ketal group (δ_C 110.3 s) and an oxygenated quaternary carbon (δ_C 71.8 s) in the aglycone moiety was evident from its ^{13}C NMR spectrum (Table 1). Detailed analysis of the 2D HMBC spectrum of the compound clearly revealed that the compound is a saponin containing pseudojujubogenin (Garai et al., 1996a) as the aglycone and that a trisaccharide unit is attached through the oxygen at C-3 of the aglycone.

Of the two arabinose units of the trisaccharide moiety, one exists in pyranose form and the other in furanose form as would be evident from the splitting pattern and chemical shifts (Table 2) of their anomeric protons (Garai et al., 1996a). The chemical shifts of all the individual protons of the three sugar units were ascertained from a combination of 2D ^1H–^1H HOHAHA and ^1H–^1H COSY spectral analyses and accordingly ^{13}C chemical shifts of their attached carbons could be assigned unambiguously from the HMQC spectrum of the compound.

Having thus assigned all the ^{13}C and ^1H chemical shifts of the three sugar units (Tables 1 and 2), it is clear that the arabinofuranose and glucopyranose units are linked to C-2′ and C-3′ of the arabinopyranose unit. However, the exact positions of attachment of the two sugar units to arabinopyranose unit could be established from its HMBC spectrum as follows.

The HMBC correlations between (i) arabinofuranose anomeric proton (H-1″, δ 6.04) and C-2′ (δ 76.3) of arabinopyranose, (ii) glucopyranose anomeric proton (H-1‴, δ 4.99) and C-3′ (δ 84.1) of arabinopyranose, and (iii) anomeric proton (H-1′, δ 4.81) of arabinopyranose and C-3 (δ 88.7) of the aglycone conclusively proved that the arabinofuranose and glucopyranose units are linked respectively to C-2′ and C-3′ of the arabinopyranose

[a] Chemical shifts were assigned on the basis of 2D NMR, viz. ^1H–^1H COSY, HMQC, HMBC and NOESY spectral analyses. Spectra of **1** and **2** were recorded in 600 and 500 MHz instruments respectively.

which, in turn, is linked to C-3 of the aglycone. The above structural assignment was in total agreement with the NOE interactions observed in the NOESY spectrum of the compound.

Based on the above assigned structure, the molecular mass of the compound should be 898 ($C_{46}H_{74}O_{17}$). However, the positive and negative ion FAB mass spectra showed the molecular mass to be 978. This difference of 80 mass units could, however, be accommodated by assuming that the compound is a sulphate. This contention was indeed confirmed by high resolution positive ion FAB mass spectral analysis which showed $[M+H]^+$ ion at m/z 979.4592 and $[M+Na]^+$ ion at m/z 1001.4383 corresponding to the molecular formula $C_{46}H_{74}O_{20}S$.

Now, a careful look at the ^1H and ^{13}C chemical shifts of the compound revealed that the methylene protons (H_2-6‴) and carbon (C-6‴) of the glucopyranose unit experienced deshielding by more than 0.5 (Table 2) and 4.5 ppm (Table 1) respectively compared to those observed in **2** demonstrating that the sulphate group must be linked to C-6‴ of the glucopyranose unit. This was also supported by the observed up-field shift of C-5‴ signal by 2.3 ppm (γ effect) as against that of **2**.

Based on the above observations, bacopaside I may be represented as 3-*O*-α-L-arabinofuranosyl-(1→2)-[6-*O*-sulphonyl-β-D-glucopyranosyl-(1→3)]-α-L-arabinopyranosyl pseudojujubogenin (**1**).

Bacopaside II (**2**), mp 249–251 °C, $[\alpha]_D$ -34.3^0, showed in its positive ion high resolution FAB–MS, the $[M+H]^+$ at m/z 929.5110 corresponding to the molecular formula $C_{47}H_{76}O_{18}$. Of the 47 carbon signals in its ^{13}C NMR spectrum (Table 1), 17 signals were due to sugar units demonstrating the presence of two glucose and one arabinose units and this was indeed confirmed by the GC analysis of their alditol acetates. A comparison of the ^{13}C chemical shifts of the aglycone part of the compound with those of **1** (Table 1) revealed that this compound also contains pseudojujubogenin as the aglycone, and it differs from **1** only with respect to the trisaccharide moiety attached to C-3 of the aglycone.

For determining the linkages among the sugar units of the trisaccharide moiety, the ^{13}C and ^1H chemical shifts of the individual sugar units were assigned from a combination of 2D ^1H–^1H HOHAHA, ^1H–^1H COSY and HMQC spectral analyses (Tables 1 and 2). It was clear from the chemical shifts of the arabinose unit that it exists in the furanose form. That the arabinofuranose and one glucopyranose units are linked to C-2′ and C-3′ respectively of another glucopyranose unit became evident from the HMBC correlations between (i) the anomeric proton (H-1″, δ 6.24) of the arabinofuranose and C-2′ (δ 79.1) of the inner glucose, and (ii) the anomeric proton (H-1‴, δ 5.18) of the terminal glucose and C-3′ (δ 88.7) of the inner glucose. The correlation of the anomeric proton (H-1′, δ 4.83) of the inner glucose with C-3 (δ 89.1) of the aglycone demonstrated that the trisaccharide moeity is attached to C-3 of the aglycone through the inner glucose unit. The assigned linkages were also found to be in excellent agreement with the NOE interactions observed in the NOESY spectrum of the compound.

Based on the above evidence, bacopaside II may be represented as 3-*O*-α-L-arabinofuranosyl-(1→2)-[β-D-glucopyranosyl (1→3)]-β-D-glucopyranosyl pseudojujubogenin (**2**).

3. Experimental

The plant material was collected in May from the suburbs of Calcutta and supplied by M/s United Chemical and Allied Products, 10 Clive Row, Calcutta 700 001. A voucher specimen is available in the herbarium of the company. Mps: uncorr; IR: KBr discs; 1D and 2D NMR: 500 and 600 MHz in pyridine-d_5; GC: ECNSS-M, 3% on Gas-Chrom Q at 190 °C for alditol acetates which were identified by co-injection of the authentic samples; HPLC: C_{18} column (7 mm i.d.), H_2O–MeOH (30:70) as the mibile phase, UV absorbance detector (217 nm).

The air-dried and powdered arial parts of *Bacopa monniera* (4.4 kg) were successively extracted with petroleum ether (b.p. 60–80 °C) and MeOH in a percolator at room temp. The MeOH extract was concd. and kept overnight at room temp. The separated deep green solid was filtered, washed with MeOH and air dried to get a pasty solid (20 g). The solid was subjected to column chromatography over Si gel (1 kg) and eluted with $CHCl_3$ and $CHCl_3$–MeOH mixtures having increasing proportions of MeOH. Elution with $CHCl_3$–MeOH (9:1 and 4:1) gave fr. A and with $CHCl_3$–MeOH (7:3) afforded fr.B. The latter fraction on repeated crystallizations from MeOH yielded **1** (49 mg). Fr.A was further purified by repeated CC over Si gel and by precipitation from MeOH solution by addition of acetone to get a mixture of components (single spot in TLC) as white powder (3 g). A part (0.2 g) of this was then subjected to prep. HPLC to afford **2** (36 mg), besides the already known saponins, viz. bacopa saponin C (Garai et al., 1996a), bacoside A_3 (Rastogi et al., 1994) and 3-*O*-α-L-arabinofuranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-α-L-arabinopyranosyl jujubogenin (Higuchi et al., 1984).

3.1. Bacopaside I (*1*)

White powder (MeOH), mp 260–261 °C (dec.), $[\alpha]_D$ −35.6° (MeOH, *c* 0.20). IR ν_{max} (KBr) cm^{-1}: 1221, 696 (sulphate). HR–FABMS (positive) m/z: 979.4592 $[M+H]^+$; calc. for $[C_{46}H_{74}O_{20}S+H]^+$: 979.4572. ^{13}C NMR: Table 1. ^1H NMR: Table 2.

3.2. Bacopaside II (2)

Amorphous powder, mp 249–251 °C, $[\alpha]_D$ −34.3° (MeOH, *c* 0.40). HR–FABMS (positive) *m/z*: 929.5110 $[M+H]^+$; calc. for $[C_{47}H_{76}O_{18}+H]^+$: 929.5109. ^{13}C NMR: Table 1. ^1H NMR: Table 2.

3.3. Hydrolysis of 1 and 2

Compounds **1** and **2** (20 mg each) were hydrolysed separately with 2 N HCl in aq. MeOH (10 ml) on a steam bath for 5 h. The reaction mixtures were cooled, diluted with water (10 ml) and extracted with $CHCl_3$. The aqueous parts were neutralised with Ag_2CO_3 and filtered. The filtrates were concd under reduced pressure and examined for sugars by PC (EtOAc–pyridine–H_2O; 2:1:2). Two spots were detected corresponding to arabinose (R_f 0.23) and glucose (R_f 0.19) in both cases. Small portions of the filtrate concentrates were reduced with $NaBH_4$, worked up as usual and the products were acetylated with Ac_2O–pyridine. The acetates were then subjected to GC analysis. Two peaks corresponding to glucitol acetate and arabinitol acetate in 1:2 ratio in case of **1** and in 2:1 ratio in case of **2** were observed.

The remaining portion of the filtrate concentrate obtained from **1** was subjected to prep. PC to obtain D-glucose, $[\alpha]_D$ +55° (H_2O, *c* 0.15) and L-arabinose, $[\alpha]_D$ +101° (H_2O, *c* 0.21). In an identical way, prep PC of the remaining portion of the filtrate concentrate obtained from the hydrolysate of **2** yielded D-glucose and L-arabinose.

Received 16 August 2000; received in revised form 10 April 2001

Abstract

The bufadienolides, 6β-acetoxy-3β,8β,12β,14β-tetrahydroxybufa-4,20,22-trienolide (12β-hydroxyscillirosidin) (**1**) and 14β-hydroxybufa-4,20,22-trienolide 3β-*O*-{α-L-rhamnopyranosyl-[(1→4)-β-D-glucopyranosyl]-(1→3)-α-L-rhamnopyranoside} (urginin) (**2**) were isolated from *Drimia robusta* and *Urginea altissima*, respectively. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Drimia robusta*; *Urginea altissima*; Hyacinthaceae; Bufadienolides; 6β-Acetoxy-3β,8β,12β,14β-tetrahydroxybufa-4,20,22-trienolide (12β-hydroxyscillirosidin); 14β-Hydroxybufa-4,20,22-trienolide; 3β-*O*-{α-L-Rhamnopyranosyl-[(1→4)-β-D-glucopyranosyl](1→3)-α-L-rhamnopyranoside} (urginin)

1. Introduction

The subfamily Urgineoideae of the Hyacinthaceae, in which both the genera *Drimia* Jacq. ex Willd. and *Urginea* Steinh. have been placed, is phytochemically characterised by the presence of bufadienolides (Speta, 1998). *Urginea* is a heterogeneous, poorly understood genus in need of revision (Speta, 1998), and has at times been included in the genus *Drimia* (Jessop, 1977).

Drimia robusta Bak. from southern Africa is a heavily utilised Zulu medicinal plant (Cunningham, 1990) with preparations employed as diuretics (Van Wyk et al., 1997) emetics, expectorants (Watt and Breyer-Brandwijk, 1962), to treat febrile complaints (Hutchings et al., 1996), diseases of the uterus (Van Wyk et al., 1997) and to promote the healing of broken bones (Ndlovu, pers. commun.). Ethanolic and ethyl acetate extracts of *D. robusta* have, respectively, been found to possess anti-inflammatory and antibacterial activities and although Luyt and co-workers attributed this activity to the presence of proscillaridin A, this compound was not positively identified (Luyt et al., 1999).

Urginea altissima (L.f.) Bak. is extremely widespread, occurring throughout most of sub-Saharan Africa. Across its range, bulbs find both ethnomedical (Watt and Breyer-Brandwijk, 1962) and ethnoveterinary (Burkill, 1955) applications. In South Africa, bulb preparations are variously employed in the treatment of gout (Smith, 1966), rheumatism (Watt and Breyer-Brandwijk, 1962) and a range of respiratory complaints including asthma (Smith, 1966), influenza and bronchitis (Watt and Breyer-Brandwijk, 1962). Although Miyakado et al. (1975) have reported on the isolation and identification of the isoquinoline alkaloids lycorine and acetylcaranine from the bulbs of *U. altissima*, this finding is questionable. Verdcourt and Trump (1969) have pointed out that the cottony appearance of the torn leaf bases of *U. altissima* could lead to its confusion with some amaryllidaceous bulbs, including *Boophane* and *Crinum*, which is likely in this case. Unfortunately, no herbarium voucher was lodged to vouch for the correct identification of their material, which was sourced in Ethiopia. The report of typical Amaryllidaceae type alkaloids from the Hyacinthaceae prompted the reinvestigation of *U. altissima*.

Both *D. robusta* (syn. *D. alta* R.A.Dyer) and *U. altissima* are reportedly toxic (Steyn, 1936; Van der Walt and Steyn, 1943), exhibit digitalis-like action (Sapieka, 1951) and possess caustic saps.

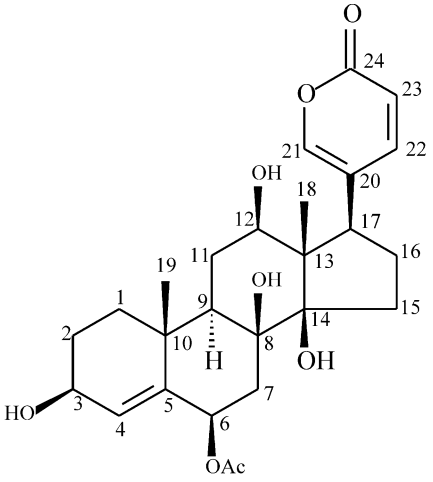
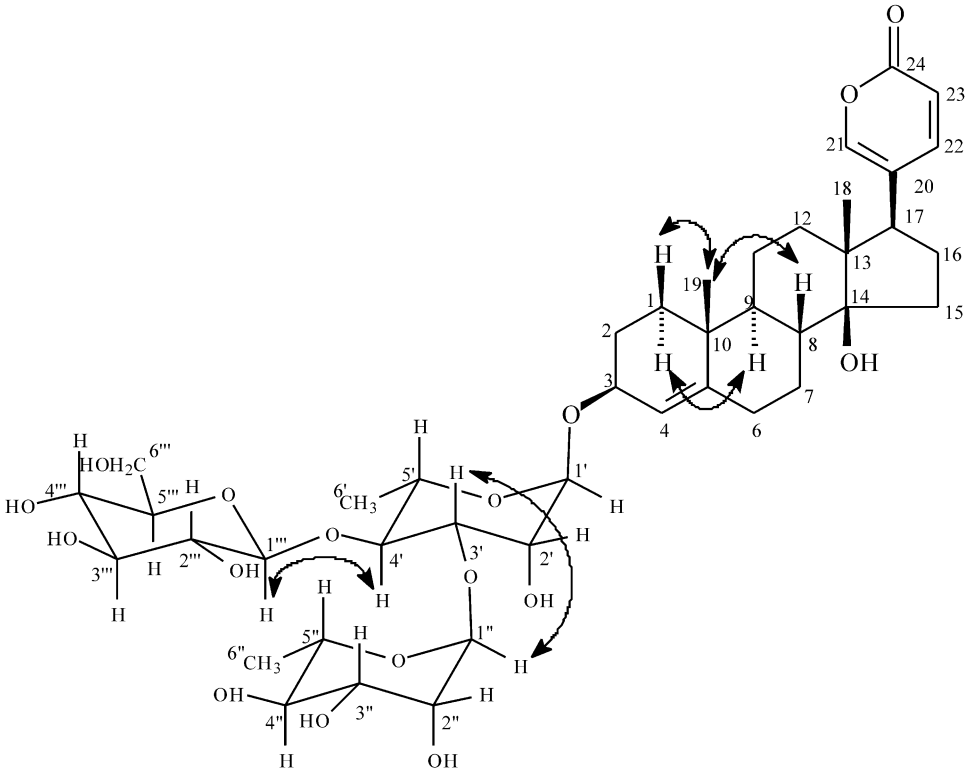
2. Results and discussion

Compound **1** was isolated from the dichloromethane extract of *D. robusta*. High resolution mass spectrometry gave the highest peak at m/z 414.2056 g mol^{-1} which indicated a molecular formula of $C_{24}H_{30}O_6$. However, NMR spectroscopy indicated that this was not the molecular ion, but that a molecule of acetic acid had been lost giving the correct molecular formula $C_{26}H_{34}O_8$. Use was made of ^{1}H, ^{13}C, HSQC, HMBC, COSY, TOCSY and NOESY spectra to determine the structure of the compound and to assign all ^{1}H and ^{13}C NMR resonances (Table 1).

The presence of a bufadienolide side-chain at C-17 was indicated by coupled resonances at δ 7.94, 7.41 and 6.27 in the ^{1}H NMR spectrum ascribable to H-22, H-21 and H-23, respectively, and δ 123.8, 149.6, 148.1, 114.2, and 163.5 ascribable to C-20, 21, 22, 23 and 24, respectively, in the ^{13}C NMR spectrum. Two secondary hydroxy groups and a secondary acetoxy group were indicated by methine resonances at δ 67.1, 76.1 and 76.1 in the ^{13}C NMR spectrum and corresponding resonances at δ 4.10,



1



2 (Showing important NOE correlations)

3.43 and 5.43 and a three proton singlet at δ 1.99 at the ^{1}H NMR spectrum. The presence of two tertiary hydroxyl groups was indicated by carbon resonances at δ 75.7 and 85.6 and a trisubstituted alkene double bond was indicated by resonances at δ 133.3 (CH) and δ 140.7 (C). The alkene proton was present at δ 5.73 in the ^{1}H NMR spectrum and this proton was coupled to the methine resonance at δ 4.10. The TOCSY and HETCOR spectra indicated the presence of two further methylene groups in the same spin system and these were assigned to 2H-1, 2H-2 and the hydroxy group was placed at C-3 and the alkene group at C-4. The acetoxy group was placed at C-6. The H-6 resonance at δ 5.43 was coupled to 2H-7 and the HMBC spectrum showed ^3J correlation with H-4. The tertiary hydroxyl groups were placed at C-8 and C-14 as the TOCSY spectrum showed that H-17 was only coupled to 2H-16 and 2H-15 and that no coupling was present between 2H-7 and H-8. The COSY spectrum showed coupling between H-9 (δ 1.41), 2H-11 (δ 1.34 and 1.36) and H-12 at δ 3.43. Thus, the remaining hydroxyl group was placed at C-12.

The stereochemistry at C-8 and C-14 could not be confirmed but a literature search showed that bufadienolides in which hydroxy groups are present at these position have them in the β-orientation. The stereochemistry at C-3, C-6, and C-12 was determined from the NOESY spectrum. The resonance ascribed to H-9α gave a positive NOE correlation with H-17α and H-12α indicated that the hydroxyl group was present at C-12β. The methyl group protons of the acetate group at C-6 showed a positive NOE with 3H-19 at C-10β, indicating the acetate group was at C-6β. H-6α showed a positive NOESY interaction with H-4 and H-4 showed a positive correlation with H-3α. Thus, the hydroxyl group was placed at C-3β.

This compound (**1**) was reported previously from *Urginea sanguinea* (Krenn et al., 1993) and *Urginea maritima* (Kopp et al., 1996) but no spectroscopic or physical data was provided.

Compound **2** was isolated as the major constituent from the methanol extract of *U. altissima* with no other bufadienolides being isolated from this source. The ^{1}H NMR spectrum indicated the presence of a bufadienolide with resonances at δ 7.41, 7.97 and 6.26 assigned to H-21, H-22 and H-23. Coupled resonances at δ 4.08 and 5.31 and corresponding resonances at δ 74.0 (CH) and δ 120.4 (CH) in the ^{13}C NMR spectrum indicated the presence of an oxygen substituent at C-3 and a 4,5-double bond. A resonance at δ 84.6 was ascribed to C-14 on the basis of a ^3J HMBC correlation with 3H-18 and a hydroxyl group was placed at this position. The stereochemistry at C-8 and C-9 was determined using the NOESY spectrum. A positive NOE correlation between the 3H-19 methyl singlet resonance at C-10β and the H-8 multiplet indicated that H-8 was in the β configuration. Similarly, a positive NOE correlation observed between the 3H-19 singlet and the H-1 resonance at δ 1.78 allowed for the assignment of a β orientation to this proton and hence assignment of the α orientation to the other H-1 resonance at δ 1.32. A correlation between H-1α and the H-9 multiplet confirmed the α orientation of the H-9 proton.

The presence of three anomeric proton resonances at δ 4.55 (J = 7.9 Hz), δ 4.80 (J = 1.5 Hz) and δ 4.97 (J = 1.5 Hz) were indicative of a trisaccharide substituent at C-3β. In addition, the two doublet resonances at δ 1.23 (J = 6.0 Hz) and δ 1.27 (J = 5.5 Hz) confirmed the presence of two rhamnose molecules. The third sugar moiety was identified as a glucose molecule. Use of HSQC, HMBC and NOESY spectra and of literature ^{13}C NMR data enabled assignment of all the glycoside resonances and determination of the manner in which the sugar molecules were attached. A HMBC correlation between C-3 and H-1′ of one of the rhamnose molecules established that a rhamnose molecule was attached at C-3. HMBC correlations (both ^3J) between C-3′ and H-1′ of the first rhamnose molecule and H-1″ of the second rhamnose molecule established the attachment of the second rhamnose to C-3′ of the first. The downfield shift for C-3′ of δ 80.4 supported this. The glucose molecule was attached at C-4′ based on the C-4 downfield shift of δ 77.0. Resonances ascribed to C-3 and C-4 usually occur at about δ 71 and 72 [17]. The NOESY spectrum also confirmed the sugar substitution pattern as positive NOE correlations were observed between H-1″ and H-3′ and between H-1‴ and H-4′.

Confirmation of the glycosidic linkages was obtained from LC MS studies. A molecular ion peak was observed at m/z 838.6 which corresponds to the $C_{42}H_{62}O_{17}$ bufadienolide glycoside structure suggested by NMR studies. Successive MS–MS experiments produced fragment peaks at m/z 691.3 [M^+-147], m/z 675.4 [M^+-163], m/z 529.3 [M^+-147–162] and m/z 383.3 [M^+-147–163–145]. The peaks at m/z 691 and 675 correspond to the loss of a rhamnose and a glucose molecule from the glycoside, respectively. This confirmed that the sugars were not linked in a linear manner. The peak at m/z 529 corresponds to the loss of both a glucose and a rhamnose molecule and indicated that the sugar attached at C-3 was indeed a rhamnose molecule. In addition, the peak at m/z 383 confirmed the monohydroxybufatrienolide aglycone structure proposed by NMR studies.

3. Experimental

Fresh bulbs of both *D. robusta* Bak. and *U. altissima* (L.f.) Bak. were purchased at the Warwick Triangle Herbal Market in Durban, and vouchers retained in the Natal Herbarium (*Crouch 793*, NH and *Crouch 792*, NH, respectively).

The bulbs of *D. robusta* (3.5 kg) were macerated and extracted at room temperature with continuous agitation

for 24 h with dichloromethane. Repeated column chromatography of the extract over silica gel (Merck 9385) yielded compound **1** (12β-hydroxyscillirosidin). The bufadienolide isolated could be identified as a navy blue spot on the t.l.c. plate. The chromatographic techniques involved the use of a step-gradient solvent system using methylene chloride and methanol. Compound **1** eluted with an 18:2 methylene chloride–methanol solvent system.

The bulbs of *U. altissima* (3.2 kg) were macerated and freeze dried. The dried plant material was then extracted with ethanol at room temperature with continuous agitation for three days. The crude aqueous extract was acidified with conc. HCl to pH 2 and extracted with dichloromethane. The pH of the aqueous extract was then increased to pH 9 using 4 M NH_4OH and then followed by extraction, first with dichloromethane, and then with 50:50 dichloromethane:methanol. Thin layer chromatographic analysis of the two basic fractions indicated that they were very similar and they were thus combined. Repeated column chromatography of the basic fraction (4.36 g) over silica gel (Merck 9385) using a gradient solvent system, 100 dichloromethane →20:1 → 10:1 → 20:3 → 10:2 → 10:3 dichloromethane:methanol yielded the novel bufadienolide **2** called urginin.

NMR spectra were recorded on a Varian 400 MHz NMR spectrometer. IR spectra were recorded on a Shimadzu-IR spectrophotometer and mass spectra for **1** were recorded at the Cape Technikon on a Finnigan 1020 spectrometer. LC MS spectra for **2** were recorded on a Finnigan MAT LCQ spectrometer with an electrospray ionization source at the University of Lausanne, Switzerland.

Biflavonoids from the aerial part of *Stephania tetrandra*

Duanyun Si, Dafang Zhong*, Yi Sha, Wen Li

Laboratory of Drug Metabolism and Pharmacokinetics, Shenyang Pharmaceutical University, Shenyang 110016, PR China

Received in revised form 3 May 2001

Abstract

Investigation of the aerial part of *Stephania tetrandra* led to the isolation of two biflavonoids, stephaflavone A and stephaflavone B, with a 3–6″ linkage pattern, together with β-sitosterol. Their structures were established on the basis of their spectroscopic data and their physicochemical properties. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Stephania tetrandra*; Menispermaceae; Aerial part; Biflavonoids; Stephaflavone A; Stephaflavone B

1. Introduction

Different parts of a plant usually contain different types of secondary metabolites. Most of the known alkaloids from "*Fen Fang Ji*", a traditional Chinese medicine from the dried root of *Stephania tetrandra* S. Moore (Menispermaceae), were of the bisbenzylisoquinoline type (Hsing and Chang, 1957; Tomita et al., 1967; Hu and Zhao, 1986; Ogino et al., 1988, 1998; Deng et al., 1990). However, our previous paper showed that the aerial part of *S. tetrandra* mainly contained aporphinoid alkaloids (Si et al., 1992). In the present study on the same plant material, our attention shifted to the non-alkaloid constituents, which resulted in the isolation of two new biflavonoids. This is the first report about biflavonoids from Menispermaceae plants.

2. Results and discussion

The EtOH extract of the aerial part of *S. tetrandra* was subjected to silica gel chromatography to yield two new biflavonoids, stephaflavone A and B (**1** and **2**), and component, β-sitosterol. The identification of β-sitosterol was conducted on the basis of direct comparisons (mp., IR, MS, and co-TLC) with an authentic sample. The color reactions, UV absorption maxima, and IR absorption bands of **1** and **2** were very similar, which suggested that both compounds possessed an identical flavonoid system (Geiger and Quinn, 1975). The molecular ion of **1** at *m*/*z* 594 ($C_{34}H_{26}O_{10}$) showed it to be a methyl derivative of **2** (*m*/*z* 580, $C_{33}H_{24}O_{10}$).

The ^{13}C NMR spectrum of **1** showed signals for all 34 carbons of the molecule including four sp3 carbons for four methoxyl groups at δ 55.3–56.2 and thirty sp^2 carbons, including signals for two carbonyl groups at δ 181.1 and 182.0. The IR spectrum exhibited a broad OH absorption band at 3348 cm^{-1} and a hydrogen-bonded carbonyl band at 1652 cm^{-1}. These observations and selective molecular mass of 594 hinted that **1** could be a flavone-flavone based biflavonoid (Geiger and Quinn, 1982, 1988).

The ^1H NMR spectrum of **1** demonstrated the presence of two hydroxyl protons, twelve alkyl protons for four methoxyl groups, and twelve aromatic protons. The two hydroxyl protons resonated in the downfield region at δ 12.94 and 13.02, indicating the presence of two hydrogen-bonded hydroxyl groups at the 5 and 5″ positions. The presence of two sets of AA'XX' doublets at δ 7.81 (2H, *d*, $J = 8.8$ Hz) and 6.98 (2H, *d*, $J = 8.8$ Hz); δ 7.48 (2H, *d*, $J = 8.8$ Hz) and 6.78 (2H, *d*, $J = 8.8$ Hz) were ascribed to eight aromatic protons of rings B and ring E. Another two protons comprising a set of *meta*-coupled doublets appearing at δ 6.36 (1H, *d*, $J = 2.5$ Hz) and 6.47 (1H, *d*, $J = 2.5$ Hz) represented H-6 and H-8 of ring A, respectively. The remaining two aromatic singlets at δ 6.55 and 6.50 were assigned to H-3″ of ring F and H-6″ or H-8″ of ring D, which implied that either C-8″ or C-6″ of ring D was involved in the interflavonoid C–C linkage with C-3 of ring C. The structure of **1** was, therefore, composed of two 7,4′-dimethoxy-5-

1 R = CH_3 2 R = H

hydroxylflavone units with a C–C linkage either between C-3 and C-6″ or between C-3 and C-8″.

On the basis of systematic ^{13}C NMR spectroscopic analysis of many naturally occurring flavonoids and biflavonoids, Chari et al. (1977) stated that the resonances for unsubstituted C-8 and C-6 of monomeric flavones, flavonols and flavanones with a 5,7-dioxy substitution were found between δ 90.0 and 100.0. The signal for C-6 is usually located at lower fields than that for C-8. This difference is about 4.8 ppm for flavones and flavonols. When the carbon atom at position 6 or 8 was substituted by an alkyl or aryl group, the signal for the quaternary C-substituted carbon atom shifts by 6.0–9.6 ppm downfield whereas the signal for a *meta*-unsubstituted carbon atom is not markedly altered. So, it is apparent that mere inspection of the ^{13}C NMR chemical shift values in the spectral region δ 90.0–100.0 of a biflavonoid can give a good indication of the linkage positions if ring A and/or ring D is involved in a C-C linkage. The DEPT spectra of **1** showed the presence of three methine signals between δ 90.0 to 100.0. The two upfield signals at δ 92.1 and 90.3 corresponded to C-8 of ring A and C-8″ of ring D. The remaining signal at δ 97.9 had to be ascribed to C-6 of ring A. The resonance of C-6″ in ring D appeared as a quaternary carbon atom at δ 105.6, suggested that **1** was a biflavone with a C–C linkage between C-3 and C-6″.

The HMBC spectrum of **1** further confirmed the involvement of C-3 and C-6″ in interflavonoid linkage as C-6″ showed correlations with H-8″ and the hydroxyl proton at position 5″ (Fig. 1). Thus, from the foregoing spectral studies, **1** was characterized as 5,5″-dihydroxy-7,4′,7″,4‴-tetramethoxy-[3→6″]-biflavone and designated stephaflavone A. The complete assignment of the proton and carbon shifts aided by DEPT, HMQC, and HMBC experiments are shown in Table 1.

The ^{13}C NMR spectrum of **2** closely resembled that of **1**, except that compound **2** contained only three methoxyl

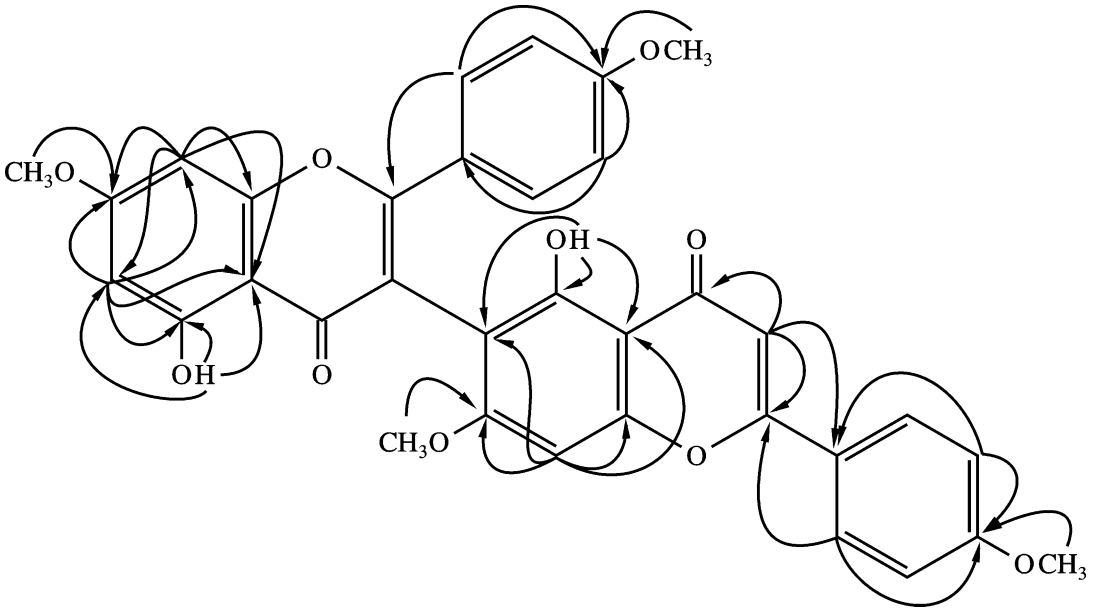

Fig. 1. Major HMBC correlations observed in compound **1**.

[a] 1D NMR data recorded in $CDCl_3$ at 89.61 MHz for ^1H and at 22.53 MHz for ^{13}C; 2D NMR data recorded in $CDCl_3$ at 300.13 MHz for ^1H and at 75.43 MHz for ^{13}C; δ_C and δ_H are in ppm, multiplicities and *J* values (in Hz) are shown in parentheses.
[b] Multiplicities determined by a DEPT experiment.
[c] Protons correlated with carbon atoms on position number.

groups, and there were small but significant differences in four signals for six carbon atoms of ring B. The resonances for C-1′, C-2′ (6′), C-3′ (5′), and C-4′ in **1** appeared at δ 125.5, 129.5, 113.5, 161.2, respectively, whereas in **2** at δ 124.3, 129.7, 115.2, and 159.5, respectively. These alterations suggested a 4′-OH substitution in ring B of **2** instead of a methoxyl group in **1** (Chari et al., 1977; Williams and Fleming, 1995). The ^1H NMR spectrum of **2** also appeared very similar to that of **1**. The slight differences were found at δ 7.41 (2H, *d*, $J=8.8$ Hz) and 6.71 (2H, *d*, $J=8.8$ Hz) for the four aromatic protons in ring B. These also supported the suggestion that the substituent at position 4′ was a hydroxyl group (Geiger and Quinn, 1982; Williams and Fleming, 1995). Thus, the chemical structure of **2** could be established as 5,4′,5″-trihydroxy-7,7″,4‴-trimethoxy-[3→6″]-biflavone and was designated stephaflavone B. The complete assignment of the proton and carbon shifts aided by the comparisons with NMR data of **1** are shown in Table 1.

3. Experimental

3.1. General

Mps were uncorr. UV spectra were obtained on a Shimadzu UV-300 spectrophotometer with 95% EtOH as solvent. IR spectra in KBr disk were recorded on a Nicolet 5S XC spectrometer. ^1H and ^{13}C NMR spectra were determined in $CDCl_3$, with TMS as int. standard,

on a JEOL FX90Q spectrometer for 1D determination and on a Bruker ARX-300 spectrometer for the 2D experiments. EI mass spectra were obtained on Nicolet FTMS-2000 and JMS DX 300 spectrometers. CC was conducted on silica gel H and TLC on silica gel G glass plates, and the latter was detected with conc. H_2SO_4. Silica gels H and G were purchased from the Qingdao Marine Chemical Factory, China.

3.2. Plant material

The aerial part of *S. tetrandra* was collected and identified as description in lit. (Si et al., 1992). A voucher specimen was deposited in the same place.

3.3. Extraction and isolation

Air-dried and ground plant material was extracted exhaustively with boiling EtOH, and the extract was evaporated in vacuo to afford a residue, which was extracted by refluxing with petroleum ether, and then with $CHCl_3$. The $CHCl_3$ fraction was concentrated to give a gum which was treated with 2% HCl. The insoluble mass was subjected to a column of silica gel H with an elution gradient of C_6H_6 and Me_2CO to give β-sitosterol and two combined similar fractions, which were purified by prep. TLC with C_6H_6–Me_2CO–HCOOH (8:1.8:0.2) as the developer to afford **1** (R_f = 0.55) and **2** (R_f = 0.43).

Received 30 March 2001; received in revised form 18 June 2001

Abstract

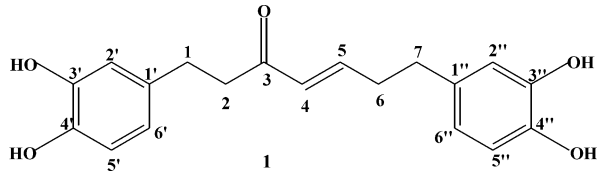
A diarylheptanoid, 1,7-di-(3′,4′-dihydroxyphenyl)-4-hepten-3-one, hirsutanone, has been isolated from the methanolic extract of the aerial parts of *Viscum cruciatum* (Viscaceae) and characterized by spectroscopic methods and chemical transformations. This compound showed cytotoxic activity against melanoma (UACC-62), renal (TK-10) and breast (MCF-7) cancer cell lines. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Viscum cruciatum*; Viscaceae; Diarylheptanoids; 1,7-Di-(3′,4′-dihydroxyphenyl)-4-hepten-3-one; Hirsutanone; ^{1}H and ^{13}C NMR spectra

1. Introduction

Viscum cruciatum is an evergreen hemiparasitic plant, characterized by its whorled leaves and its red berries ("*muérdago colorado*"), usually epiphyting various dicotyledonous trees and shrubs: *Retama sphaerocarpa* Boiss., *Olea europaea* L., *Rhamnus alaternus* L., *Rhamnus lycioides* L., *Prunus amygdalus* Stokes. In the course of our pharmacological and phytochemical studies on the extracts of *Viscum cruciatum,* we have reported the cytotoxic activity (Ayuso et al., 1987a,b; 1988) and we have isolated alkaloids and flavonoids (Martín-Cordero et al., 1989, 1993, 1997). None of them could be clearly shown to possess the established cytotoxic activity.

As part of our continuing study of *Viscum cruciatum* for novel compounds which might posess biological activity, we have undertaken a reexamination of the chemical constituents of the aerial parts of *Viscum cruciatum* and we examined its cytotoxic activity. We report here the isolation and characterization of 1,7-di-(3′,4′-dihydroxyphenyl)-4-hepten-3-one, hirsutanone (**1**) (Terazawa et al., 1984) and cytotoxic activity against three tumor cell lines.



1

2. Results and discussion

From the methanolic extract of the aerial parts of *Viscum cruciatum* a diarylheptanoid (**1**) was isolated on Si gel column. The structural elucidation and the cytotoxic activity of compound (**1**) is described in the present study. This compound was not crystallized. Its IR spectrum showed an absorption at 3350 cm^{-1} corresponding to phenolic groups, a band at 1650 cm^{-1} of an α-β unsatured carbonyl group and another band at 1600 cm^{-1} was ascribed to double bonds. Its ^{1}H NMR spectrum showed multiplets at δ 2.78 and δ 2.43 corresponding to 8H which were attributed to four deshielded methylene groups. The ^{13}C NMR exhibited four signals at 30.0, 34.2, 34.8 and 42.1 that can be ascribed to four methylene groups, tentatively assigned in experimental section. A signal at 200.30 corresponded to a carbonyl of an α-β unsatured ketone. The remainder of the signals were attributable to two aromatic moieties and a double bond. The HRMS showed a molecular ion M^{+} at m/z 328.1307, corresponding to a molecular formula $C_{19}H_{20}O_5$.

By acetylation or methylation, compound **1** gave a tetraacetate ($C_{27}H_{20}O_9$) or a tetramethylether ($C_{23}H_{28}O_5$). The respective spectral data supported the structure thus proposed. Moreover, this same compound **1** was treated with dichloromethane/dimethylformamide and CsF to confirm that the phenolic groups were in *ortho* position (Clark et al., 1976).

The cytotoxic assays of isolated compound **1** were carried out according to the standard protocols established by the NCI (Monks et al., 1991). 1,7-di-(3′,4′-dihydroxyphenyl)-4-hepten-3-one, hirsutanone showed activity against cell lines tested, the GI_{50} values for TK-10 cells, MCF-7 cells and UACC-62 cells were 6.8, 1.9 and 4.8μg/ml, respectively. Etoposide was used as a positive control (GI_{50} values for TK-10 cells, MCF-7 cells and UACC-62 cells were 8.1, 0.33 and 0.97μg/ml, respectively).

Previous reports (Chun et al., 1999; Elattar and Virji, 2000; Hadi et al., 2000; Ramsewak et al., 2000) have pointed to the cytotoxicity of structurally related diarylheptanoids such as curcumin I (1,7-di-(4′-hydroxy-3′methoxyphenyl)-1,4,6-heptatrien-3-one-5-hydroxy), curcumin II (monodemethoxycurcumin) and curcumin III (bisdemethoxycurcumin) from *Curcuma longa* (Zingiberaceae). Curcumin I was found to be more active than other two as a cytotoxic agent (Ramsewak et al., 2000). The structural differences between curcumin I and the isolated compound (1,7-di-(3′,4′-dihydroxyphenyl)-4-hepten-3-one, hirsutanone) are the different substituents at the aromatic ring (C-4′, C-4″) and C-5 and two double bond of the aliphatic chain. In addition, diarylheptanoids such as yakuchinone A and B have the ability to suppress proliferation of human cancer cells via induction of apoptosis (Surh, 1999). These findings suggest that the isolation of an active diarylheptanoid from *Viscum cruciatum* may contribute to its cytotoxic activity.

Open chain diarylheptanoids were isolated previously from Aceraceae, Betulaceae, Zingiberaceae and Leguminosae family (Keserü and Nógrádi, 1995). It is the first report of diarylheptanoids in the Viscaceae and *Viscum* species.

3. Experimental

3.1. General experimental procedure

IR spectra were measured as KBr disc and $CHCl_3$. NMR spectra were taken in $CDCl_3$; ^{13}C NMR at 50 MHz and ^1H NMR at 200 MHz, using TMS as int. standard. MS were recorded at 70 eV. CC: silica gel.

3.2. Plant material

The aerial parts of *Viscum cruciatum* hemiparasitic of *Prunus amygdalus* Stokes were collected in January, during the fruiting period from Zahara de la Sierra (Cádiz, Spain). The identity was kindly verified by Dr. Santiago Silvestre (Department of Botany of the Faculty of Pharmacy, University of Sevilla) and a voucher specimen is deposited, labelled SEV. 82694.

3.3. Extraction and isolation

Air-dried, powdered aerial parts (250 g) of *Viscum cruciatum* were extracted by Soxhlet successively with $CHCl_3$ and MeOH. The MeOH extract (3.3 g) was chromatographed on Si gel column eluting gradient with *n*-hexane–EtOAc and $CHCl_3$–MeOH, the compound (**1**) was isolated from the intermediate fractions eluting with *n*-hexane–Et_2Ac.

3.3.1. 1,7-Di-(3′,4′-dihydroxyphenyl)-4-hepten-3-one (*1*)

Syrupy solid (210 mg) IR ν_{max}^{KBr} cm^{-1}: 3350, 3050, 2920, 1650, 1510. ^1H NMR (200 MHz, $CDCl_3$): δ 2.43–2.78 (8H, *m*, H-6, H-7, H-1, H-2), 6.05 (1H, *d*, $J=16.8$ Hz, H-4), 6.45–6.69 (6H, *m*, H-6′, H-6″, H-2′, H-2″, H-5′, H-5″), 6.86 (1H, *dt*, $J=6.5$, 16.8Hz, H-5). ^{13}C NMR (50 MHz, $CDCl_3$): δ 30.0 (*t*, C-1), 34.9 (*t*, C-6), 34.2 (*t*, C-7), 42.1 (*t*, C-2), 116.0 (*d*, C-5′, C-5″), 116.2 (*d*, C-2′, C-2″), 118.2 (*d*, C-6′, C-6″), 131.1 (*d*, C-4), 133.5 (*s*, C-1′, C-1″) 143.8 (*s*, C-4′, C-4″), 145.5 (*s*, C-3′, C-3″), 147.6 (*d*, C-5), 200.3 (*s*, C-3). EIMS *m*/*e* (rel. int. %) M^+ 328.1307 (calc. for $C_{19}H_{20}O_5$ 328.1310) 328 (20), 206 (19), 191 (18), 149(58), 148(38), 137 (28), 136 (28), 123 (100), 107 (22), 91 (36), 77 (58).

3.3.2. Acetylation of *1*

Fifty milligrams was carried out with Ac_2O–Pyr at room temperature and in the dark for 24 h. IR $\nu_{max}^{CHCl_3}$ cm^{-1}: 3010, 2920, 2823, 1760, 1660, 1620, 1500, 1368, 1256, 1180, 1110, 1010, 900. ^1H NMR (200 MHz, $CDCl_3$): δ 2.27 (12H, *s*), 3.0–2.4 (8H, *m*) 6.1 (1H, *d*, $J=16.8$ Hz), 6.8 (1H, *dt*, $J=6.5$, 16.8 Hz) 7.1–7.0 (6H, *m*). EIMS *m*/*e* (rel. int.%) M^+ 496.1729 (2) (calc. for $C_{27}H_{28}O_9$ 496.1733) 454 (10), 412 (20), 370 (17), 352 (12), 338 (26), 206 (18), 165 (20), 123 (100), 77 (11).

3.3.3. Methylation of *1*

Compound **1** (20 mg) was suspended in Me_2CO (30 ml) and K_2CO_3 (300 mg) and MeI (0.5 ml) was added. The mixture was refluxed for 14 h and extracted in the usual manner. The product was purified by CC to give the tetramethylether derivate. IR $\nu_{max}^{CHCl_3}$ cm^{-1}: 3000, 2960, 2940, 2840, 1660, 1620, 1590, 1510, 1460, 1258, 1155, 1135, 1030, 850. ^1H NMR (200 MHz, $CDCl_3$): δ 2.87–2.48 (8H, *m*), 3.85 (6H, *s*), 3.86 (6H, *s*), 6.11 (1H, *d*, $J=16$ Hz), 6.91–6.68 (7H, *m*). EIMS *m*/*e* (rel. int.%) M^+ 384.1935 (28) (calc. for $C_{23}H_{28}O_5$ 384.1936), 370 (4), 219 (6), 191 (4), 177 (14), 151 (100), 137 (26), 107 (33), 77 (21.).

3.3.4. Methylenedioxy derivate of *1*

The methylenedioxy derivate of **1** (50 mg) was obtained by the Clark method (Clark et al., 1976) and

purified by CC. IR $\nu_{max}^{CHCl_3}$ cm^{-1}: 2990, 2880, 2763, 1720, 1660, 1620, 1498, 1480, 1438, 1090, 1042, 937. ^1H NMR (200 MHz, $CDCl_3$): δ 2.49 (2H, *m*), 2.69 (2H, *m*), 2.81 (4H, *m*), 5.91 (2H, *s*), 5.92 (2H, *s*), 6.08 (1H, *d*, $J=16$ Hz), 6.90-6.60 (7H, *m*). EIMS *m*/*e* (rel. int. %) M^+ 352.1307 (13) (calc. for $C_{21}H_{20}O_5$ 352.1310), 204 (3), 203 (3), 160 (3), 135 (100), 105 (6), 91 (6), 77 (23).

3.4. Human tumor cell lines

The following three human cancer cell lines were used in these experiments: the human renal adenocarcinoma (TK-10), the human breast adenocarcinoma (MCF-7) and the human melanoma (UACC-62) cell lines. They were kindly provided by Dr. G. Cragg, Department of NCI, Maryland, USA. The human tumour cytotoxicities were determined following protocols established by the National Cancer Institute, National Institute of Health (Monks et al., 1991) TK-10, MCF-7 and UACC -62 cell lines were cultured in RPMI 1640 medium (Bio whittaker) containing 20% fetal calf serum, 2 mM L-glutamine, 100 U/ml penicillin and 100 μg/ml streptomycin. All cell lines were maintained at 37 °C in a 5% CO_2 atmosphere with 95% humidity. Maintenance cultures were passaged weekly, and the culture medium was changed twice a week. According to their growth profiles, the optimal plating densities of each cell line was determined (15×10^3, 5×10^3 and 100×10^3 cells/well for TK-10, MCF-7 and UACC-62, respectively) to ensure exponential growth throughout the experimental period and to ensure a linear relationship between absorbance at 492 nm and cell number when analysed by the SRB assay. Data for the isolated compound was analysed according to the standard protocols established by the NCI (Monks et al., 1991).

Received 15 March 2001; received in revised form 21 May 2001

Abstract

Six coumarins have been isolated from the fruits and the stem bark of *Calophyllum dispar* (Clusiaceae). The structures of these minor components were established by means of spectroscopic analysis, including extensive 2D NMR studies. Some of these coumarins exhibited a significant cytotoxic activity against KB cells. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Calophyllum dispar*; Coumarins; Clusiaceae

1. Introduction

The genus *Calophyllum* which comprises 200 species (Stevens, 1980) is widely distributed in the tropical rain forest where several species are used in folk medicine (Perry and Metzer, 1980). This genus is well known as a source of biologically active compounds such as coumarins (Kashman et al., 1992; Kawazu et al., 1972), xanthones (Reyes-Chilpa et al., 1997) and terpenoids (Cao et al., 1997). As part of our phytochemical study of *Calophyllum* species, we have described previously the isolation of twelve new 4-phenylcoumarins from *C. dispar* P. F. Stevens exhibiting cytotoxic activities (Guilet et al., 1999, 2001). In the present work, six new minor coumarins (**1**–**6**) were isolated and characterized from the stem bark and the fruits of the same species.

2. Results and discussion

Compound **1** was isolated as an amorphous residue from an EtOAc-soluble extract of the fruits of *C. dispar*. The UV absorptions of **1** characterized a 5,7-dioxygenated coumarin (Crichton and Waterman, 1978) whereas the ^{1}H and ^{13}C NMR spectra supported the presence of a monosubstituted phenyl group and a 3-methyl-1-oxobutyl moiety in the molecule. Through spectroscopic comparison (^{1}H NMR, MS, UV and IR), compound **1** appeared analogous to a synthetic coumarin previously described by Crombie et al. (1987). Total assignment of the ^{1}H and ^{13}C resonances of **1**, which we have named isodispar A, were finally completed (Tables 1 and 2) through its HMQC and HMBC data analysis. To the best of our knowledge, this compound has not been previously isolated from natural source.

Column chromatography of the EtOAc-soluble extract of the stem bark of *C. dispar* allowed isolation of the new compounds **2**–**6** and the known dihydroxycoumarin disparinol B (**7**). Compound **2** was obtained as an amorphous residue, and the alkaline shifts of its UV spectrum could readily be associated with a 6-acyl-5,7-dihydroxycoumarin chromophore (Crombie et al., 1967; Carpenter et al., 1971). The molecular formula of **2** ($C_{24}H_{24}O_6$) was established by HRFABMS analysis of its negative pseudomolecular ion $[M\text{-}H]^-$ at m/z 407.1530 ($\Delta + 3.5$ mmu). The molecular formula of **2** thus differed from that of disparinol B (**7**), previously isolated from *C. dispar* (Guilet et al., 1999), by the loss of a CH_2 moiety. Comparison of the ^{1}H and ^{13}C NMR spectra of **2** (tables 1 and 2) and **7**, then suggested that they were closely related, differing only in the nature of their acyl substituents. Interlocking DQF-COSY, HMQC and HMBC data of **2**, an isobutanoyl moiety was firmly characterized and therefore, this compound was identified as structure **2** which we have named disparinol D.

Compound **3**, crystallized as yellow needles (mp = 111–112 °C), and exhibited spectroscopic data closely related to those of disparinol D (**2**) and disparinol B (**7**). Its molecular formula $C_{22}H_{28}O_6$ was determined by HREIMS ($\Delta + 0.1$ mmu). An extensive NMR analysis of **3** then showed that this coumarin exhibited identical substituents with those of disparinol B (**7**) except for the 4-position (Tables 1 and 2). Examination of the contours maps of a gradient-selected DQF-COSY and a HMQC experiments then allowed us to distinguish a *n*-propyl system in the molecule. Long-range ^{1}H–^{13}C couplings deduced from the HMBC spectrum of **3** then confirmed the 4-position of this *n*-propyl substituent. Therefore, compound **3**, or disparpropylinol B, could be identified as the first representative of a new disparinol series exhibiting a 4-*n*-propyl substitution.

Compound **4** was obtained as an amorphous residue. In the presence of alkali, the bathochromic shifts of its UV spectrum suggested that **4**, like **2** and **3**, was a 6-acyl-5,7-dihydroxycoumarin chromophore. HRISMS analysis of its pseudomolecular ion $[M + H]^+$ indicated the composition $C_{25}H_{28}O_7$ ($\Delta + 1.4$ mmu). The ^{1}H NMR (Table 1), ^{13}C NMR (Table 2), and 2D-experiments (DQF-COSY, HMQC and HMBC) indicated the

presence of a monosubstituted phenyl group, an isopentanoyl moiety, and showed two chelated hydroxyl groups at δ_H 10.26 and 14.29, respectively. The molecular formula of **4** thus suggested that the remaining substitution of the coumarinic nucleus was a $C_5H_{11}O_2$ side chain. The presence of a 2,3-dihydroxy-3-methylbutyl moiety was then proved by HMQC and HMBC experiments. Long-range ^1H–^{13}C couplings deduced from the HMBC spectrum of **4** also revealed that the methylene group of this chain (δ_H 2.61 and 3.37) correlated with three coumarinic carbons C-7, C-8 and C-8a. The substitution at the 8-position of the coumarinic nucleus with a 2,3-dihydroxy-3-methylbutyl moiety was so established. Finally, from the aforementioned spectroscopic data, this compound was identified as structure **4**, which we have named dispardiol B.

Compound **5** was assigned the molecular formula $C_{25}H_{26}O_6$ by HREIMS ($[M]^+$ m/z 422.1747, Δ +1.7 mmu). As for compounds **3** and **4**, the acyl chain of **5** was established to be an isopentanoyl moiety (Table 1) located at C-6 after inspection of the UV spectrum (Crombie et al., 1967; Carpenter et al., 1971). Furthermore, a monosubsituted phenyl and a phenolic hydroxyl were also located at C-4 and C-5 through NMR evidences. The remaining ring system in **5** was characterized with chemical shifts at δ_H: 1.36 (6H, *s*, H-4‴ and H-5‴), 3.35 (2H, *m*, H-1‴) and 5.25 (1H, *br d*, J=8.5 Hz, H-2‴) and δ_C: 19.9 (C-4‴), 20.5 (C-5‴), 27.1 (C-1‴), 83.0 (C-3‴) and 89.0 (C-2‴), suggesting the presence of a 3-hydroxy-2,2-dimethyldihydropyran in the molecule. The HMBC data (Table 3) confirmed this hypothesis and **5** was concluded to be the mammea A/AB cyclo E, according to the nomenclature already proposed for related compounds (Crombie et al., 1966).

Compound **6** exhibited, in its HREIMS, a molecular ion $[M]^+$ at m/z 436.1528 associated with the molecular formula $C_{25}H_{24}O_7$ (Δ +0.6 mmu). The UV spectrum of **6** showed bathochromic shifts similar to those of 6-acyl-5,7-dioxycoumarin chromophores. The NMR data of **6** suggested the presence of a monosubstituted phenyl, a chelated phenolic hydroxyl (δ_H 14.96), and a 2-methyl-1-oxobutyl chain at the 4, 5 and 6 positions of the coumarin, respectively (Tables 1 and 2). The nature of the remaining susbtituents at the position 7 and 8 were then deduced from NMR evidences. Indeed, the ^1H NMR spectrum of **6** exhibited the presence of two coupled methines [δ_H 5.48 (1H, *d*, J=6 Hz, H-2‴) and 6.22 (1H, *d*, J=6 Hz, H-1‴)] and two methyls [δ_H 1.48 (3H, *s*, H-4‴) and 1.50 (3H, *s*, H-5‴)]. In the HMBC spectrum of **6** (Table 3), these methyls appeared to be long-range coupled with carbons at δ_C 85.7 (C-3‴) and 99.4 (C-2‴), while the methine proton signal at δ_H 6.22 (H-1‴) correlated with four carbons at δ_C 85.7 (C-3‴), 102.9 (C-8), 156.2 (C-8a) and 164.6 (C-7), the three latter resonances being associated with the coumarin nucleus. These elements suggested the presence of a trioxygenated isoprenic skeleton, link to the heterocycle *via* the methine at δ_H 6.22 (H-1‴). According to the molecular formula of **6**, this substituent also had to be a bicyclic structure. Furthermore, a significant correlation was observed between the proton signal at δ_H 5.48 (H-2‴) and the coumarinic carbon at δ_C 164.6 (C-7), implicating the presence, on one hand, of a dihydrofuran cycle and, on the other, of a dioxolane structure. This compound was thus identified as structure **6**, which we have named mammea A/AB dioxalanocyclo F.

It may be noticed that coumarins **2**–**6** did not present any significant optical activities, this point being already stressed for a number of coumarins isolated from the genera *Mammea* (Crombie et al., 1967; Carpenter et al., 1971) and *Mesua* (Morel et al., 1999). We thus may assume that the isoprenic moieties probably derive from non stereoselective functionalizations of the corresponding prenylated precursors, which may justify the racemic nature of **2** (Guilet, 2000). *A contrario*, coumarins substituted by an isopentanoyl moiety, probably issued from a chiral amino acid such as isoleucin (Kunesch and Polonsky, 1969), exhibit weak optical activities for highly concentrated solutions (Finnegan et al., 1972). It thus could be the same for compounds **3**–**6** isolated here in small amounts.

From a chemotaxonomic point of view, it should also be mentioned that the isoprenic moieties identified in

compounds **5** and **6** are recorded here for the first time in the genus *Calophyllum*, whereas they were already identified in coumarins isolated from *Mammea americana* (Crombie et al., 1972).

The cytotoxic effect against KB cells of a number of these coumarins was finally evaluated (Table 4). Most of them tested exhibited a significant activity in this assay since these compounds inhibited 50% of the cellular growth at concentration ranging from 4 to 8 μg/ml.

3. Experimental

3.1. General

Melting points were determined on an Electrothermal 8100 melting point apparatus and are uncorrected. Optical rotations were measured on a Schmidt-Haensch-polartronic-I polarimeter. IR spectra were recorded on a Perkin Elmer 580 spectrophotometer and UV spectra were taken on a Hitachi U-2000 spectrophotometer. HREIMS (70 eV) were recorded on Varian MAT 311 spectrometer and HRFABMS were recorded on a Jeol JMS-700 spectrometer. NMR spectra were recorded in $CDCl_3$ solution on a Bruker Avance DRX 500 instrument, using TMS as the internal standard. Si gel 60 (Macherey-Nagel, 230–400 mesh) was used for column chromatography and precoated Si gel plates (Macherey-Nagel, SIL G/UV254, 0.25 mm) were used for preparative TLC. The compounds were detected under UV light at 254 and 366 nm.

3.2. Plant material

The stem bark and the fruits of *Calophyllum dispar* P. F. Stevens were collected from Terrangganu, Malaysia in October, 1994. An herbarium specimen (KL 4430) is deposited at the University of Kuala-Lumpur, Malaysia.

3.3. Extraction and isolation

The dried and powdered stem bark of *C. dispar* (5 kg) was extracted with EtOAc (7 l) for 72 h in a Soxhlet apparatus. After concentration, the extract gave a residue (238.85 g). A portion of the residue (87.50 g) was chromatographed over Si gel by MPLC, eluting with *n*-hexane and a 5% stepwise gradient of EtOAc (0–80% close up) to afford several fractions labeled, in order of elution A to I. Work-up of fraction F by repeated CC and prep. TLC using pentane-Me_2CO (93:7) led then to the isolation of **3** (32 mg, 0.037%), **6** (3 mg, 0.003%), and **2** (8 mg, 0.009%). Work-up of fraction G also by repeated CC and prep. TLC using $CHCl_3$–EtOAc (9:1) afforded **5** (10 mg, 0.011%) and **4** (4 mg, 0.005%).

The same procedure was applied to the dried and powdered fruits of *C. dispar* (140 g). After extraction with EtOAc, 4.60 g of residue were obtained and then chromatographed on Si gel by MPLC, eluting with *n*-hexane and a 5% stepwise gradient of EtOAc (0–80%) to afford several fractions labeled, in order of elution A to H. Work-up of fraction E by repeated CC and preparative TLC using *n*-hexane–EtOAc (9:1) led to the purification of **1** (13 mg, 0.28%).

3.4. Cytotoxicity testing

The cytotoxicity assays were carried out in triplicate against human nasopharynx carcinoma KB cell lines. After 72 h incubation at 37 °C with or without test compounds, cell growth was estimated by colorimetric measurement of stained living cells by neutral red. The cultured cells were treated at five concentrations of pure test compounds ranging from 50 to 0.01 μg/ml. Optical density was determined at 540 nm on a Titertek Multiscan photometer. The ED_{50} value was defined as the concentration of sample necessary to inhibit the cell growth to 50% of the control. Doxorubicine, as positive control substance, presents an ED_{50} value of 0.058 μg/ml.

Acknowledgements

The authors express their thanks to C. Gaspard (GDR "Substances d'intérêt biologique", I.C.S.N., Gif-Sur-Yvette, France) who performed the cytotoxicity evaluation on KB cells.

Abstract

Two kaempferol glycosides [kaempferol 3-*O*-β-D-glucosyl(1→2)-β-D-galactoside 7-*O*-β-D-glucoside and kaempferol 3-*O*-β-D-glucosyl(1→2)-(6''-*O*-acetyl)-β-D-galactoside 7-*O*-β-D-glucoside] as well as the quercetin glycoside [quercetin 3-*O*-β-D-glucosyl (1→2)-β-D-galactoside 7-*O*-β-D-glucoside] were isolated from the stems of *Trigonella foenum-graecum* L. (Leguminosae) along with a known kaempferol glycoside, lilyn [kaempferol 3-*O*-β-D-glucosyl(1→2)-β-D-galactoside]. Their structures were established by analysis of chemical and spectral evidence. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Trigonella foenum-graecum*; Leguminosae; Stems; Kaempferol glycosides; Quercetin glycoside

1. Introduction

Trigonella foenum-graecum L. (Leguminosae) has been widely cultivated in Asia, Africa and Mediterranean countries for the edible and medicinal values of its seeds (Yoshikawa et al., 1997). In Chinese traditional medicine, the seeds of this plant have been prescribed as a tonic and for stomach disorders, and the whole aerial part of the plant is used as a folk medicine for the treatment of renal diseases in the Northern-East region of China (Liu et al., 1990). Many phytochemical studies on constituents of the seeds have been reported (Varshney and Beg, 1978), but little research has been carried out on other parts of the plant. As part of studies for developing new sources of medicinal materials, we investigated phenolic components of the stems of this plant. Here we report on the isolation and structure elucidation of three new flavonol glycosides from the stems of *Trigonella foenum-graecum*.

2. Results and discussion

The concentrated methanolic extract from the stems of *Trigonella foenum-greacum* was fractionated by successive extraction with petroleum ether, ethyl acetate and *n*-BuOH. The *n*-BuOH extract was subjected to column chromatography (CC) on silica gel, followed by CC on Sephadex LH-20 to yield compound **1**. The aqueous fraction furnished compounds **2**, **3** and **4** by combination of CC on silica gel and Diaion HP-20 and final purification by preparative HPLC.

Complete acid hydrolysis of compounds **1**, **2** and **3** afforded kaempferol, glucose and galactose (TLC for sugars and HPLC, UV for aglycones), respectively.

Compound **1** was identified as kaempferol 3-*O*-β-D-glucosyl (1→2)-β-D-galactoside (lilyn) on the basis of acid hydrolysis, spectral data (UV, ^{1}H NMR,^{13}C NMR and FAB–MS), optical rotation value ($[\alpha]_D$) and comparison with published data (Nagy et al., 1984). This is the second example of isolation of compound **1** from a natural source.

A positive ion FAB-mass spectrum of compound **2** exhibited pseudomolecular ions at *m*/*z* 811 $[M+K]^+$ and *m*/*z* 795 $[M+Na]^+$, thus confirming its $[M]^+$ to be 772 (calc. for $C_{33}H_{40}O_{21}$). The fragment ions at *m*/*z* 449 $[M+H\text{-}324]^+$ and *m*/*z* 287 $[M+H\text{-}486]^+$ indicated successive loss of three hexosyl (glucosyl or galactosyl) moieties. The appearance of three anomeric proton signals in the ^{1}H NMR spectrum further confirmed that compound **2** is a kaempferol triglycoside. Three sugar moieties were identified as two glucoses and one galactose from the ^{13}C NMR spectral data. In the ^{13}C NMR spectrum, a downfield shift (compared with reported

data of unsubstituted galactosyl moiety) (Markham et al., 1978; Nagy et al., 1984) of C-2″ (from 71.4 to 80.5 ppm) and an upfield shift of C-1″ of galactosyl moiety (from 102.5 to 98.3 ppm) suggested the presence of a (1→2) linked glucosyl-galactosyl unit in this structure (Liu et al., 1994). The anomeric carbon (98.3 ppm) and proton shifts (5.66 ppm, 1H, *d*, $J=7.5$ Hz) of the galactosyl moiety indicated the direct connection of the galactosyl moiety at C-3 of the kaempferol moiety, which was confirmed by 2-D NMR spectroscopic and long-range ^{13}C–^{1}H shift correlation (COSY) spectral analyses. Comparison of the carbon shifts of the aglycone with those of published data for kaempferol 3-glycosides (Markham et al., 1978; Budzianowski, 1990) revealed an upfield shift of C-7 ($\Delta\delta$ 1.1 ppm) and downfield shifts at C-6 ($\Delta\delta$ 1.2 ppm), C-8 ($\Delta\delta$ 1.0 ppm) and C-10 ($\Delta\delta$ 1.8 ppm) implying glycosylation of C-7 of the aglycone. The H-6 (6.42 ppm) and H-8 (6.79 ppm) signals in the ^{1}H NMR spectrum supported further evidence for this assignment. An anomeric proton signal (5.05 ppm, 1H, *d*, $J=7.5$ Hz) in the ^{1}H NMR spectrum was assignable to the glucosyl moiety attached to C-7 position of the aglycone. The anomeric carbon shift (99.8 ppm) of a remaining glucosyl moiety agreed well with this assignment, which was confirmed by analysis of the 2-D NMR and long-range ^{13}C–^{1}H shift correlation (COSY) spectra. Therefore, compound **2** was established as kaempferol 3-*O*-β-D-glucosyl(1→2)-β-D-galactoside 7-*O*-β-D-glucoside, a new kaempferol glycoside.

Compound **3** was also confirmed as a kaempferol triglycoside on the basis of its fragmentation behavior in the FAB-mass spectrum and the appearance of three anomeric proton signals in the ^{1}H NMR spectrum. The ^{1}H NMR (δ 1.65 ppm), ^{13}C NMR (δ 20.4 and 169.3 ppm) and IR (1730 cm^{-1}) spectral data indicated the presence of an additional acetyl group in **3**. The ^{13}C NMR spectroscopic shifts of the aglycone corresponded well with those of **2**. In the ^{1}H NMR spectrum, the three anomeric proton signals were very close to those of the glycosyls in the spectrum of **2**. Except for a downfield shift of 3.0 ppm for C-6″ and an upfield shift of 2.8 ppm for C-5″ of the galactosyl moiety in 3, the ^{13}C NMR data of the sugar moieties of **3** showed great similarity to those of **2**. Thus, these data suggested the attachment of the acetyl group to C-6″ hydroxyl group of the galactosyl moiety (Mizuno et al., 1990). Hence, compound **3** was characterized as kaempferol 3-*O*-β-D-glucosyl (1→2)-(6″-*O*-acetyl)-β-D-galactoside 7-*O*-β-D-glucoside, an acetylated derivative of **2**.

Compound **4** released quercetin, glucose and galactose upon complete acid hydrolysis. The ^{1}H and ^{13}C NMR spectral data further confirmed the presence of the quercetin part in the structure. The ^{1}H and ^{13}C NMR spectral data of the sugar moieties of **4** resembled those of compound **2**. Carbon shifts of the aglycone showed typical 3,7-disubstitution of quercetin (Markham et al., 1978; Yasukawa et al., 1988). Thus, the structure of compound **4** was established as quercetin 3-*O*-β-D-glucosyl (1→2)- β-D-galactoside 7-*O*-β-D-glucoside, a new glycoside of quercetin.

3. Experimental

3.1. General

Mp:uncorr., optical rotations were measured on a Jasco DIP-360. UV spectra were recorded on Hitachi U-2000, whereas IR spectra were obtained on a Jasco VALOR-III. ^{1}H and ^{13}C NMR spectra were recorded in DMSO-d_6 or CD_3OD at 300.40 MHz, TMS was used as an internal standard. TLC was carried out on precoated silica gel 60 F254 and RP-8 plates (Merck). Preparative HPLC was performed on a GP RP-18 column (5 μm, 20×250 mm) at a flow rate of 6 ml/min and the purity of compounds was checked by HPLC on Nucleosil 5C18 column (4.6×150 mm).

3.2. Plant material

Trigonella foenum-graecum L. was collected in Heilongjiang province of China in July, 2000. Voucher specimens were deposited at the Department of Pharmacognosy, Faculty of Pharmaceutical Sciences, Health Sciences University of Hokkaido.

3.3. Extraction and isolation

The dried stems of *Trigonella foenum-graecum* (3.7 kg) were extracted with hot MeOH (37 l×3) and concentrated to a small volume under reduced pressure, then H_2O was added and the suspension was filtered. The filtrate was extracted with petroleum ether, EtOAc and *n*-BuOH, successively. The *n*-BuOH extract (20 g) was subjected to CC on silica gel eluted first with

$CHCl_3$, then with a gradient of $CHCl_3$–EtOH with increasing EtOH. A fraction collected from $CHCl_3$-EtOH (4:1) elution yielded compound **1** (177 mg) after repeated CC on Sephadex LH-20 with H_2O and H_2O–MeOH (95:5) as eluent. The aqueous layer (30 g) was applied to a silica gel column eluted with $CHCl_3$, $CHCl_3$–EtOH, EtOH to give 4 fractions. Fraction 3 (collected from EtOH) was applied to CC on Diaion HP-20 eluted with H_2O and a gradient of MeOH in H_2O. The fraction collected from 20% MeOH, was further subjected to preparative HPLC (RP-18 MeOH–H_2O–CH_3CN 20:300:20), to furnish compounds **2** (99 mg) and **4** (12 mg). Fraction 2 ($CHCl_3$–EtOH 45:55) afforded compound **3** (26 mg) after CC on Diaion HP-20 and purification by preparative HPLC (RP-18, MeOH–H_2O–CH_3CN 40:300:20).

3.4. Acid hydrolysis

Acid hydrolysis of compounds **1**–**4** were performed as described in the literature (Bashir et al., 1991); each compound was treated with 2 N HCl (1 h of reaction time, in a sealed vial, at 100 °C) and, after cooling, the reaction mixture was extruded with Et_2O. Sugars in the neutralized acidic phase were analyzed on cellulose TLC (Merck) by comparison with authentic samples [acetone-(2-propanol)-0.2 M lactic acid 4:4:2; detection with anilinephtalate reagent; glucose R_f: 0.3, galactose R_f: 0.24]. The aglycone residues were identified on HPLC (Nucleosil 5C-18, MeOH–H_2O–AcOH, 35:45:3) by comparison with authentic samples and combination of UV spectrum.

3.5. Kaempferol 3-O-β-D-glucosyl(1→2)-β-D-galactoside (*1*)

Light yellow amorphous powder. $[\alpha]_D^{26}$ −40° (MeOH, *c* 0.08); UV λ_{max}^{MeOH}nm (log ε): 267 (4.21), 302 sh (3.97), 350 (4.13); IR ν^{KBr} (cm^{-1}): 1655, 1608, 1508; FAB–MS *m/z* 649 $[M(C_{27}H_{30}O_{16})+K]^+$, *m/z* 633 $[M+Na]^+$, *m/z* 449 $[M+H\text{-}162]^+$, *m/z* 287 $[M+H\text{-}324]^+$; ^1H NMR (CD_3OD): 4.74 (1H, *d*, *J* = 6.0 Hz, H-1‴), 5.33 (1H, *d*, *J* = 7.4 Hz, H-1″), 6.17 (1H, *d*, *J* = 2 Hz, H-6), 6.37 (1H, *d*, *J* = 2 Hz, H-8), 6.88 (2H, *d*, *J* = 9 Hz, H-3′,5′), 8.07 (2H, *d*, *J* = 9 Hz, H-2′,6′); for ^{13}C NMR spectral data: Table 1.

3.6. Kaempferol 3-O-β-D-glucosyl(1→2)-β-D-galactoside 7-O-β-D-glucoside (*2*)

Amorphous powder. mp 220–222 °C; $[\alpha]_D^{26}$ −37° (H_2O, *c* 0.09); UV λ_{max}^{MeOH}nm (log ε): 267 (4.33), 320 sh (4.18), 352 (4.25); IR ν^{KBr} (cm^{-1}): 1655, 1603, 1494; FAB–MS: *m/z* 811 $[M(C_{33}H_{40}O_{21})+K]^+$, *m/z* 795 $[M+Na]^+$, *m/z* 449 $[M+H\text{-}324]^+$, *m/z* 287 $[M+H\text{-}486]^+$; ^1H NMR (DMSO-d_6):4.56 (1H, *d*, *J* = 7.7 Hz, H-1‴), 5.06 (1H, *d*, *J* = 7.5 Hz, H-1⁗), 5.66 (1H, *d*, *J* = 7.5 Hz H-1″), 6.42 (1H, *d*, *J* = 2 Hz, H-6), 6.7 8(1H, *d*, *J* = 2 Hz, H-8), 6.89 (2H, *d*, *J* = 9 Hz, H-3′,5′), 8.10 (2H, *d*, *J* = 9.0 Hz, H-2′,6′); for ^{13}C NMR spectral data: Table 1.

Phenanthrene derivatives from the orchid *Coelogyne cristata*

P.L. Majumder*, S. Sen, S. Majumder

Department of Chemistry, University College of Science, 92, Acharya Prafulla Chandra Road, Calcutta 700 009, India

Received 14 February 2001; received in revised form 15 May 2001

Abstract

Coeloginanthridin, a 9,10-dihydrophenanthrene derivative, and coeloginanthrin, the corresponding phenanthrene analogue, were isolated from the orchid *Coelogyne cristata* which earlier afforded coelogin (**1a**) and coeloginin (**1b**). The structures of coeloginanthridin and coeloginanthrin were established as 3,5,7-trihydroxy-1,2-dimethoxy-9,10-dihydrophenanthrene (**2a**) and 3,5,7-trihydroxy-1,2-dimethoxyphenanthrene (**2c**), respectively, from spectral and chemical evidence including the conversion of coeloginanthridin triacetate (**2b**) to coeloginanthrin triacetate (**2d**) by dehydrogenation with DDQ. In the light of earlier reports on structurally similar compounds, **2a** and **2c** may have biological activities of phytoalexins and endogenous plant growth regulators.

1. Introduction

We reported earlier the isolation of a fairly large number of compounds from a series of Indian orchids. These compounds encompass a wide variety of stilbenoids, viz. stilbene (Majumder et al., 1998b), bibenzyls (Majumder et al., 1999a), phenanthrenes (Majumder and Sen, 1991) and 9,10-dihydrophenanthrenes (Majumder et al., 1996) and their dimers (Majumder and Banerjee, 1988; Majumder et al., 1998a, 1999b), phenanthropyrans and pyrones (Majumder and Sabzabadi, 1988; Majumder and Maiti, 1991) and their 9,10-dihydro derivatives (Majumder et al., 1999c), fluorenonone (Majumder and Chakraborty, 1989) and a few other polyphenolics (Majumder et al., 1994, 1995), several triterpenoids (Majumder and Ghosal, 1991), steroids of biogenetic importance (Majumder and Pal, 1990) and some simple aromatic compounds (Majumder and Lahiri, 1989). As part of this general programme of research we chemically investigated the orchid *Coelogyne cristata* which earlier afforded the first pair of naturally occurring 9,10-dihydrophenanthropyran and pyrone derivatives **1a** and **1b**, respectively (Majumder et al., 1982). Further investigation of this orchid has now resulted in the isolation of two new phenanthrene derivatives, designated coeloginanthridin and coeloginanthrin. The structures of coeloginanthridin and coeloginanthrin were established as **2a** and **2c**, respectively, from ^{1}H and ^{13}C NMR spectral and chemical evidence.

2. Results and discussion

Coeloginanthridin (**2a**), $C_{16}H_{16}O_5$ ([M^+] at m/z 288) showed UV absorptions [λ_{max}^{EtOH} 220.5, 275.5 and 298.5 nm (log ε 4.37, 4.02 and 3.90)] which are strikingly similar to those of 9,10-dihydrophenanthrene derivatives (Majumder et al., 1982). The UV spectrum of coeloginanthrin (**2c**), $C_{16}H_{14}O_5$ ([M^+] at m/z 286) [λ_{max}^{EtOH} 223.5, 260.5, 347 and 364 nm (log ε 4.53, 4.57, 3.63 and 3.64)], on the other hand, exhibited close resemblance to those of fully aromatic phenanthrene derivatives (Majumder and Kar, 1987).

The phenolic nature of both **2a** and **2c** was indicated by their characteristic colour reactions with $FeCl_3$ (violet) and phosphomolybdic acid reagent (deep blue), alkali-induced bathochromic shifts of their UV maxima and by their IR absorption bands [**2a**: ν_{max} 3240–3480 cm^{-1}; **2c**: ν_{max} 3220–3490 cm^{-1}]. The presence of three phenolic hydroxyl groups in both **2a** and **2c** was confirmed by the formation of their respective triacetyl derivatives [coeloginanthridin triacetate (**2b**), $C_{22}H_{22}O_8$

(M^+) at *m*/*z* 414; coeloginanthrin triacetate (**2d**), $C_{22}H_{20}O_8$ ([M^+] at *m*/*z* 412)] with Ac_2O and pyridine. The presence of three phenolic hydroxyl groups in each of **2a** and **2c** was also corroborated by the ^{1}H NMR spectra of the compounds [**2a**: δ 5.76 (3H, *br. s*, disappeared on deuterium exchange); **2c**: δ 4.99, 5.65 and 5.70 (each 1H, *br.s*; also disappeared on dueterium exchange)].

The presence of two aromatic methoxyl groups in each compound was evident from the three-proton singlets at δ 3.83 and 3.95 (**2a**) and 4.00 and 4.10 (**2c**). The ^{1}H NMR spectrum of **2a** showed two two-proton multiplets at δ 2.57 and 2.62, which are typical of the protons of the two benzylic methylene groups of a 9,10-dihydrophenanthrene derivative (Majumder et al., 1982). The signals at δ 2.57 and 2.62 of **2a** were replaced by a pair of one-proton doublets at δ 7.35 and 7.85 (each having J=8.7 Hz), which are characteristic of H-9 and H-10 of a phenanthrene derivative (Majumder and Kar, 1987). This would suggest that **2a** is a 9,10-dihydrophenanthrene derivative and **2c** is the corresponding phenanthrene analogue. Furthermore, the ^{1}H NMR spectrum of **2a** exhibited a one-proton singlet at δ 7.52 corresponding to H-4 or H-5 of 9,10-dihydrohenanthrene derivative (Majumder and Lahiri, 1990), while the spectrum of **2c** was characterized by a one-proton singlet at δ 8.85 similar to that of the corresponding proton of a phenanthrene (Majumder and Lahiri, 1990). The relatively upfield shifts of these proton signals in the ^{1}H NMR spectra of both **2a** and **2c** by about 0.5 ppm (H-4 and H-5 of 9,10-dihydrophenanthrene normally appear at ca δ 8.0 and the corresponding protons

of phenanthrene usually resonate at ca δ 9.5) were attributed to the presence of electron-donating groups (OH or OMe) at *ortho* and *para* to these protons in both **2a** and **2c**. Now, if these downfield aromatic proton signals of **2a** and **2c** are assigned to H-4, then C-5 of both the compounds must be substituted by a hydroxyl or methoxyl group. Again, since the above downfield proton signals of both **2a** and **2c** appeared as sharp singlets, C-3 and C-2 of both the compounds must also be substituted by OH or OMe.

The remaining two aromatic protons of **2a** and **2c** appeared as a pair of doublets corresponding to the *meta*-coupled aromatic protons [**2a**: δ 6.29 and 6.33 (each 1H, *d*, $J=2.0$ Hz); **2c**: δ 6.55 and 6.75 (each ill-resolved *meta*-coupled doublets)]. The signals at δ 6.29 and 6.33 in the spectrum of **2a** resemble those of H-6 and H-8 of calaphenanthrenol (**2e**) (Yoshikawa et al., 1998) having two hydroxyl groups at C-5 and C-7. The corresponding signals at δ 6.55 and 6.75 of **2c** may be similarly assigned to H-6 and H-8 of the compound possessing a phenanthrene skeleton having two hydroxyl functions at C-5 and C-7. This would imply that while two hydroxyl groups in both **2a** and **2c** may be located at C-5 and C-7, the remaining hydroxyl function and the two methoxyl groups in each compound must be distributed between C-3, C-2 and C-1.

The relative positions of the hydroxyl and methoxyl groups in both **2a** and **2c** were ascertained by the observed changes in the chemical shifts of H-4, H-6 and H-8 of the compounds in the ^{1}H NMR spectra of their respective triacetyl derivatives **2b** and **2d**. It has been shown that H-5 of a 4-hydroxyphenanthrene and its 9,10-dihydro derivative is shifted upfield by ca 0.5 and 0.2 ppm, respectively on acetylation (Letcher and Nhamo, 1971; Letcher and Wong, 1978; Majumder and Lahiri, 1990). A similar upfield shift of H-4 was observed in **2b** and **2d** by 0.28 and 0.09 ppm, respectively, affirming the placement of one of the three hydroxyl groups at C-5 in both **2a** and **2c**. The relatively smaller upfield shifts of H-4 of both **2a** and **2c** than those usually observed on acetylation of their hydroxyl function at C-5 may be attributed to the presence of a hydroxyl group at C-3 in both the compounds, which on acetylation produces a deshielding effect on H-4. The remaining hydroxyl group in both **2a** and **2c** was placed at C-7 from the observed downfield shifts of H-6 (*ortho* to two hydroxyl groups at C-5 and C-7) and H-8 (*ortho* to one hydroxyl group at C-7 and *para* to another hydroxyl function at C-5) by 0.52 and 0.61 ppm, and 0.65 and 0.82 ppm, respectively, in the ^{1}H NMR spectra of their triacetyl derivatives **2b** and **2d**. The greater deshielding of H-6 and H-8 of **2c** in the spectrum of its triacetyl derivative **2d** may be partly attributed to the acetylation of its hydroxyl group at C-3, causing a deshielding of its H-9 by 0.23 ppm in the spectrum of **2d**. The two methoxyl groups in both **2a** and **2c** must then be placed at C-1 and C-2. Coeloginanthridin and coeloginanthrin may, therefore, be represented as 3,5,7-trihydroxy-1,2-dimethoxy-9,10-dihydrophenanthrene (**2a**) and 3,5,7-trihydroxy-1,2-dimethoxyphenanthrene (**2c**), respectively.

The structure of coeloginanthridin (**2a**) was also affirmed by the ^{13}C NMR spectral data of the compound and its triacetyl derivative **2b** (Table 1). The degree of protonation of the carbon atoms in **2a** and **2b** was determined by DEPT experiments and the carbon chemical shifts were assigned by comparison with the δ_C values of the structurally similar compound calaphenanthrenol (**2e**) (Yoshikawa et al., 1998). Thus, except that of C-8a, the δ_C values of C-4b, C-5, C-6, C-7 and C-8 of **2a** are essentially similar to those of the corresponding carbon atoms of **2e** supporting the placement of two hydroxyl groups at C-5 and C-7 in **2a**. The ^{13}C NMR chemical shift assignments of **2a** were confirmed by HMQC and HMBC experiments and on the basis of these experiments C-8a of **2a** was assigned the signal at δ_C 142.0. It appears from the following 2D NMR spectral analysis of coeloginanthridin (**2a**) that the signal at δ_C 131.4 earlier assigned to C-8a of calaphenanthrenol (**2e**) (Yoshikawa et al., 1998) should be interchanged with that at δ_C 142.0 assigned to its C-3.

The HMQC spectrum of **2a** (with J_{CH} parameter set to 160 Hz) showed correlations of the hydrogens at δ_H

Table 1
^{13}C NMR spectral data of compounds **2a, 2b** and **2e**

C	Chemical shift (δ, ppm)[a]		
	2a	**2b**	**2e**[b]
1	149.4	149.3	108.0
2	137.8	144.1	145.7
3	147.1	142.5	142.0
4	108.6	117.2	142.1
4a	128.7	128.4	119.2
4b	114.4	126.4	113.0
5	153.7	147.8	154.7
6	102.1	115.2	104.0
7	155.0	151.3	156.0
8	107.7	118.6	108.0
8a	142.0	141.7	131.4
9	30.1	29.6	31.6
10	21.3	21.4	30.5
10a	123.6	130.8	137.2
OMe	60.7 (OMe at C-1)	60.7 (2xOMe)	61.8 (OMe at C-4)
	60.9 (OMe at C-2)		56.4 (OMe at C-2)
OAc	–	168.6	–
	–	168.7	
	–	168.8	–
		20.6	
		20.9	
		21.0	

[a] Spectra were run in $CDCl_3$ and the chemical shifts were measured with $\delta_{(TMS)}=\delta_{(CDCl_3)}+76.9$ ppm.

[b] The carbon resonances of **2e** and their assignments shown here are those reported by (Yoshikawa et al., 1998).

2.57 (H_2-9), 2.62 (H_2-10), 7.52 (H-4), 6.29 (H-6), 6.33 (H-8), 3.83 (OMe) and 3.95 (OMe) with the carbon atoms at δ_C 30.1 (C-9), 21.3 (C-10), 108.6 (C-4), 102.1 (C-6), 107.7 (C-8), 60.7 and 60.9, respectively. In the HMBC spectrum of **2a** (with J_{CH} parameter set to 7 Hz), the signal at δ_H 2.57 (H_2-9) exhibited fairly strong 3-bond correlations with the carbon signals at δ_C 114.4, 107.7 and 123.6, which were thus assigned to C-4b, C-8 and C-10a, respectively. The signal at δ_H 2.57 (H_2-9) also showed a 2-bond correlation with the carbon at δ_C 142.0 assigned to C-8a. In aromatic compounds 3-bond ^1H-^{13}C correlations were found to be a common feature, while 2-bond and other long range (4-bond or more remote) correlations are usually not observed. However, in polyoxygenated phenanthrene derivatives such 2-bond and other long range correlations have sometimes been observed and were assumed to occur due to the presence of oxygenated functions like OH and OMe attached to the aromatic ring, which alter the electron distribution in favour of such couplings (Majumder et al., 1997).

In light of the observation that presence of a substituent like methoxyl group at C-1 in 9,10-dihydrophenenthrene derivatives causes an upfield shift of C-10 by ca 7 ppm as in coelogin (**1a**), coeloginin diacetate and coeloginin dimethyl ether (Majumder et al., 1982), the upfield benzylic methylene carbon at δ_C 21.3 of **2a** having a methoxyl group at C-1 must be assigned to C-10 which showed 1-bond correlation to the protons at δ_H 2.62. The signal at δ_H 2.62 of **2a** must then be assigned to its H_2-10 which showed 3-bond correlations with the carbons resonating at δ_C 142.0, 149.4 and 128.7, which may, therefore, be assigned to C-8a, C-1 and C-4a, respectively, of **2a**. The signal at δ_H 2.62 (H_2-10) also exhibited a 2-bond correlation with the carbon at δ_C 123.6 which has already been assigned to C-10a. Since both **2a** and **2e** have identical substituents in their ring C (OH at C-5 and C-7), the confirmation of the assignment of the carbon resonance at δ_C 142.0 of **2a** to its C-8a implies that the signal at δ_C 142.0 of **2e** (earlier attributed to its C-3) may, by analogy, be also assigned to its C-8a. The signal at δ_C 131.4 of **2e** (earlier assigned to its C-8a) would correspond to its C-3. The proton at δ_H 7.52 corresponding to H-4 showed 3-bond correlations with the carbons at δ_C 114.4 (C-4b), 123.6 (C-10a) and 137.8 which must correspond to C-2. H-4 (δ_H 7.52) also exhibited a 2-bond correlation with the carbon at δ_C 147.1 (C-3) and a weak 4-bond correlation with the carbon at δ_C 149.4 (C-1). The proton at δ_H 6.29 assigned to H-6 was found to exhibit 3-bond correlations with the carbons at δ_C 107.7 and 114.4 which were already assigned to C-8 and C-4b, respectively. H-6 (δ_H 6.29) also showed 2-bond correlations with the non-protonated carbons at δ_C 153.7 and 155.0, which corresponded to C-5 and C-7, respectively. Similarly, the proton at δ_H 6.33 assigned to H-8 showed 3-bond correlations with the carbons at δ_C 102.1 (C-6), 114.4 (C-4b) and 30.1 (C-9) and a weak 2-bond correlation with the carbon at δ_C 155.0 (C-7). The methoxyl protons at δ_H 3.83 and 3.95, which were associated with methoxyl carbons at δ_C 60.7 and 60.9, respectively, as evident from HMQC spectrum of **2a**, showed 3-bond correlations with the carbons at δ_C 149.4 (C-1) and 137.8 (C-2), respectively. All the above ^1H–^{13}C correlations observed in the HMBC spectra of **2a** are depicted in its structural diagram. The above spectral data thus unequivocally established the structure of coeloginanthridin (**2a**).

Although similar spectral analysis could not be made with coeloginanthrin (**2c**) due to paucity of material, the structure of the compound was confirmed by the conversion of coeloginanthridin triacetate (**2b**) to coeloginanthrin triacetate (**2d**) by dehydrogenation of the former to the latter with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in dry benzene. Acid-hydrolysis of the dehydrogenation product finally afforded coeloginanthrin (**2c**).

Coeloginanthridin (**2a**) and coeloginanthrin (**2c**) are thus two new additions to the growing lists of the naturally occurring 9,10-dihydrophenanthrenes and phenanthrenes respectively. In the light of the earlier reports that a variety of phenanthrene derivatives were found to be potent phytoalexins (Gaumann and Kern, 1959a,b; Gorham, 1980; Purkayastha, 1985, 1995), while several others were shown to act as endogenous plant growth regulators (Gorham, 1980), it would be interesting to study **2a** and **2c** for similar biological activities.

3. Experimental

Melting points: uncorr. CC: Silica gel (100–200 mesh). MPLC: silica gel (230–400 mesh). TLC: silica gel G. UV: 95% aldehyde-free EtOH. IR: KBr discs. ^1H and ^{13}C NMR: 300 and 75 MHz, respectively (for **2b**, **2c** and **2d**); 500 MHz (for ^1H, HMBC and HMQC of **2a**), 125 MHz (for ^{13}C NMR of **2a**). NMR spectra were recorded in $CDCl_3$ using TMS as internal standard and chemical shifts are expressed in δ (ppm). MS: direct inlet system, 70 eV. All analytical samples were routinely dried over P_2O_5 for 24 h in vacuo and were tested for purity by TLC and MS. The petrol used had bp 60–80 °C.

3.1. Plant materials

Coelogyne cristata was collected from Kalimpong (Darjeeling), India in October, 1998. A voucher specimen (Majumder s.n.) was deposited in the Herbarium of the Department of Botany, University of Calcutta (CUH).

3.2. Isolation of coeloginanthridin (**2a**) and coeloginanthrin (**2c**)

Air-dried finely powdered whole plant of *Coelogyne cristata* (5 kg) was kept soaked in MeOH (10 l) for 3 weeks. The MeOH extract was concentrated to ca. 100 ml, diluted with H_2O (750 ml) and exhaustively extracted with Et_2O. The Et_2O extract was fractionated into acidic and nonacidic fractions with 2 M NaOH. The aqueous alkaline solution was acidified in the cold with conc. HCl and the liberated solids were extracted with Et_2O, washed with H_2O, dried and the solvent removed. The residue was subjected to CC. The petrol–EtOAc (7:1) eluate gave a mixture of **1a** and **1b**. The above mixture of **1a** and **1b** was then subjected to CC and the early fractions of the petrol–EtOAc (7:1) eluate also gave a mixture of **1a** and **1b** containing predominantly **1b**. The later fractions of the same eluate also afforded a mixture of **1a** and **1b** containing mostly **1a**. The fractions containing mostly **1a** and those containing mostly **1b** were separately mixed together and evaporated. The two residues enriched with respect to **1a** and **1b** were then separately subjected to MPLC using petrol–EtOAc (5:1) as the solvent system. The early fractions of the residue containing mostly **1b** gave pure **1b**, while the later fractions of the same eluate gave pure **1a**. Similarly, MPLC of the residue containing mostly **1a** gave in the early fractions pure **1b**, while the later fractions afforded pure **1a**. The fractions containing pure **1b** and **1a** were separately mixed together and the solvent removed to give pure **1b** (0.3 g), crystallized from petrol–EtOAc in yellowish needles, mp 198 °C and pure **1a** (0.25 g), also crystallized from the same solvent mixture in fine colourless needles, mp 151 °C. Washing the main column with petrol–EtOAc (3:1) gave a gummy residue comprising mainly coeloginanthridin (**2a**) and coeloginanthrin (**2c**). The above mixture was subjected to MPLC using petrol–EtOAc (2:1) as the solvent system. The early fractions gave a residue which contained coeloginanthridin (**2a**) as the major constituent, while the later fractions gave a mixture containing mostly coeloginanthrin (**2c**). The above two mixtures were again separately subjected to MPLC using the same solvent system to give finally pure coeloginanthridin (**2a**) (0.10 g) and coeloginanthrin (**2c**) (0.02 g), both as semisolid mass.

Coeloginanthridin (**2a**) (found: C, 66.61; H, 5.48; $C_{16}H_{16}O_5$ requires: C, 66.67; H, 5.60%). UV $\lambda_{max}^{EtOH-0.1\ M\ NaOH}$ nm: 212.5, 286.0 and 311.5 (log ε 4.51, 3.98 and 4.00); IR ν_{max} cm^{-1}: 3240–3480 (OH), 1610, 1550, 1480, 880 and 840 (aromatic nucleus); MS *m*/*z* (rel. int.): 288 [M^+] (100), 273 (25), 258 (15) and 230 (10); ^1H NMR: δ 7.52 (1H, *s*; H-4), 6.33 and 6.29 (each 1H, *d*, $J=2.0$ Hz, H-8 and H-6), 5.76 (3H, *br*. *s*, 3xArOH), 3.95 and 3.83 (each 3H, *s*, 2xArOMe), 2.62 and 2.57 (each 2H, m, H_2-10 and H_2-9). Acetylation of coeloginanthridin (**2a**) with Ac_2O and pyridine in the usual manner gave coeloginanthridin triacetate (**2b**), also as a semisolid mass. (found: C, 63.71; H, 5.25; $C_{22}H_{22}O_8$ requires: C, 63.77; H, 5.35%). IR: ν_{max} cm^{-1}: 1215, 1220, 1225, 1745, 1755 and 1770 (OAc), 1615, 1600, 1580, 1475, 820, 775, 735, 715, 690 and 595 (aromatic nucleus); ^1H NMR: δ 7.43 (1H, *s*, H-4), 6.94 and 6.81 (each 1H, *d*, $J=2.34$ Hz, H-8 and H-6), 3.89 and 3.84 (each 3H, *s*, 2xArOMe), 2.80 and 2.77 (each 2H, *m*, H_2-10 and H_2-9), 2.35, 2.29 and 2.27 (each 3H, *s*, 3xOAc); MS *m*/*z* (rel. int.): 414 [M^+] (25), 372 (30), 330 (35), 288 (100), 273 (20), 258 (10) and 230 (10).

Coeloginanthrin (**2c**): (found: C, 67.02, H, 4.83. $C_{16}H_{14}O_5$ requires: C, 67.13; H, 4.93%). UV $\lambda_{max}^{EtOH-0.1\ M\ NaOH}$ nm: 212, 228.5, 277, 307 and 377 (log ε 4.47, 4.45, 4.44, 4.15 and 3.69); IR ν_{max} cm^{-1}: 3220–3490 (OH), 1625, 1615, 1585, 1480, 885, 840 and 650 (aromatic nucleus); MS *m*/*z* (rel. int.) 286 [M^+] (100), 271 (30), 256 (20) and 228 (10); ^1H NMR: δ 8.85 (1H, *s*, H-4), 7.85 and 7.35 (each 1H, *d*, $J=8.7$ Hz, H-10 and H-9), 6.75 and 6.55 (each 1H, ill-resolved *meta*-coupled *d*, H-8 and H-6), 5.70, 5.65 and 4.99 (each 1H, *br*.*s*, 3xArOH), 4.10 and 4.00 (each 3H, *s*, 2xArOMe). Acetylation of coeloginanthrin (**2c**) with Ac_2O and pyridine in the usual manner gave coeloginanthrin triacetate (**2d**), also as a semisolid mass. (found: *C*, 63.97; H, 4.78. $C_{22}H_{20}O_8$ requires: C, 64.07; H, 4.89%). IR ν_{max} cm^{-1}: 1205, 1220, 1230, 1775, 1780 and 1785 (OAc), 1615, 1585, 1555, 1485, 845, 820, 810, 765 and 740 (aromatic nucleus); ^1H NMR: δ 8.57 (1H, *s*, H-4), 8.08 and 7.67 (each 1H, *d*, $J=9.2$ Hz, H-10 and H-9), 7.57 and 7.20 (each 1H, ill-resolved *meta*-coupled d, H-8 and H-6), 4.07 and 4.03 (each 3H, *s*, 2xArOMe), 2.49, 2.42 and 2.36 (each 3H, s, 3xOAc); MS *m*/*z* (rel. int.) 412 [M^+] (35), 370 (30), 328 (20), 286 (100), 271 (25), 256 (10) and 228 (8).

3.3. Conversion of coeloginanthridin triacetate (**2b**) to coeloginanthrin triacetate (**2d**) by dehydrogenation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) and acid-hydrolysis of coeloginanthrin triacetate (**2d**) to coeloginanthrin (**2c**)

To a soln. of coeloginanthridin triacetate (**2b**) (0.03 g) in dry C_6H_6 (25 ml) was added 0.07 g of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone. The resultant mixture was heated under reflux for 16 h. The solvent was removed under red. pres. to give a solid which was extracted with Et_2O, washed three times with 2 M aq. NaOH and then with H_2O, dried and the solvent removed. The residue was chromatographed. The petrol-EtOAc (10:1) eluate gave coeloginanthrin triacetate (**2d**) (0.018 g) as a semi-solid mass. To a soln. of 0.01 g of coeloginanthrin triacetate (**2d**) was added 5 ml of 2 M aq. methanolic HCl and the mixture was heated under reflux for 5 h. MeOH was removed under red. pres. and

the residue was extracted with Et_2O, washed with H_2O, dried and the solvent removed. The residue was chromatographed. The petrol–EtOAc (3:1) eluate gave coeloginanthrin (**2c**) (0.008 g) as a semi-solid mass.

Received 29 January 2001; received in revised form 6 June 2001

Abstract

A straight-chain oligomeric structure composed of five secoisolariciresinoldiglucoside (SDG) residues interconnected by four 3-hydroxy-3-methyl glutaric acid (HMGA) residues (molecular weight ca. 4000 Da) was assigned to the main lignan of flaxseed on the basis of nuclear magnetic resonance spectroscopy (NMR). © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Flaxseed; *Linum usitatissimum*; Linaceae; Lignan; Oligomer; Secoisolariciresinoldiglucoside; 3-Hydroxy-3-methyl glutaric acid

1. Introduction

Within the paradigm of bioactive phytochemicals in foods, lignans may be appreciated as health-promoting dietary micronutrients (Bentsath et al., 1937; Mazur and Adlercreutz, 1998; Challem, 1999). Flaxseed (*Linum usitatissimum*, Linn., Linaceae) is one of the richest sources of lignans as its defatted flour may contain 1–4% of secoisolariciresinoldiglucoside (SDG) (Bakke and Klosterman, 1956; Johnsson et al., 2000; Westcott and Muir, 1996, 2000). SDG and its mammalian lignan metabolites produced by the intestinal microflora were reported to enhance health by having phytoestrogenic, anticarcinogenic and antiatherosclerotic effects (Axelson et al., 1982). Bakke and Klosterman (1956) noted that SDG is present in flaxseed in a tan polymeric powder that includes, inter alias, 3-hydroxy-3-methyl glutaric acid (HMGA) (Klosterman and Smith, 1954) and 4-*O*-β-D-glucopyranosyl-*p*-coumaric acid which they called linocinnamarin (Klosterman et al., 1955). We isolated and identified 4-*O*-β-D-glucopyranosyl ferulic acid as one of the components in the flaxseed polymer and suggested that SDG and other phenolic compounds of flaxseed exist in acylated forms (Johnsson et al., unpublished). Other phenolic compounds found to be present in flaxseeds include a SDG isomer (Bambagiotti-Alberti et al., 1994a,b), pinoresinoldiglucoside (Qiu et al., 1999), isolariciresinol (Meagher et al., 1999) and *p*-hydroxybenzoic, gentisic, vanillic, and sinapic acids in free and/or bound forms (Kozlowska et al., 1983; Dabrowski and Sosulski, 1984). In this paper, we used nuclear magnetic resonance spectroscopy to assign an average straight-chain oligomeric structure composed of five SDG residues interconnected by four HMGA residues to the main phenolic polymer in flaxseed.

2. Results and discussion

In a previous study, the major fraction of the 1,4-dioxane/ethanol (1:1, v/v)-extractable phenolic polymer in flaxseed was isolated by solid-phase extraction and analyzed by HPLC to show a relatively broad peak suggesting structural heterogeneity or differences in molecular weight (Johnsson et al., unpublished). In this study, ^{1}H NMR (Fig. 1) of this fraction showed, in the aromatic region, peaks due to SDG (δ 6.4–6.7 ppm) as well as to other phenolic compounds, most probably *p*-coumaric acid and ferulic acid moieties (δ 6.1–7.7 ppm).

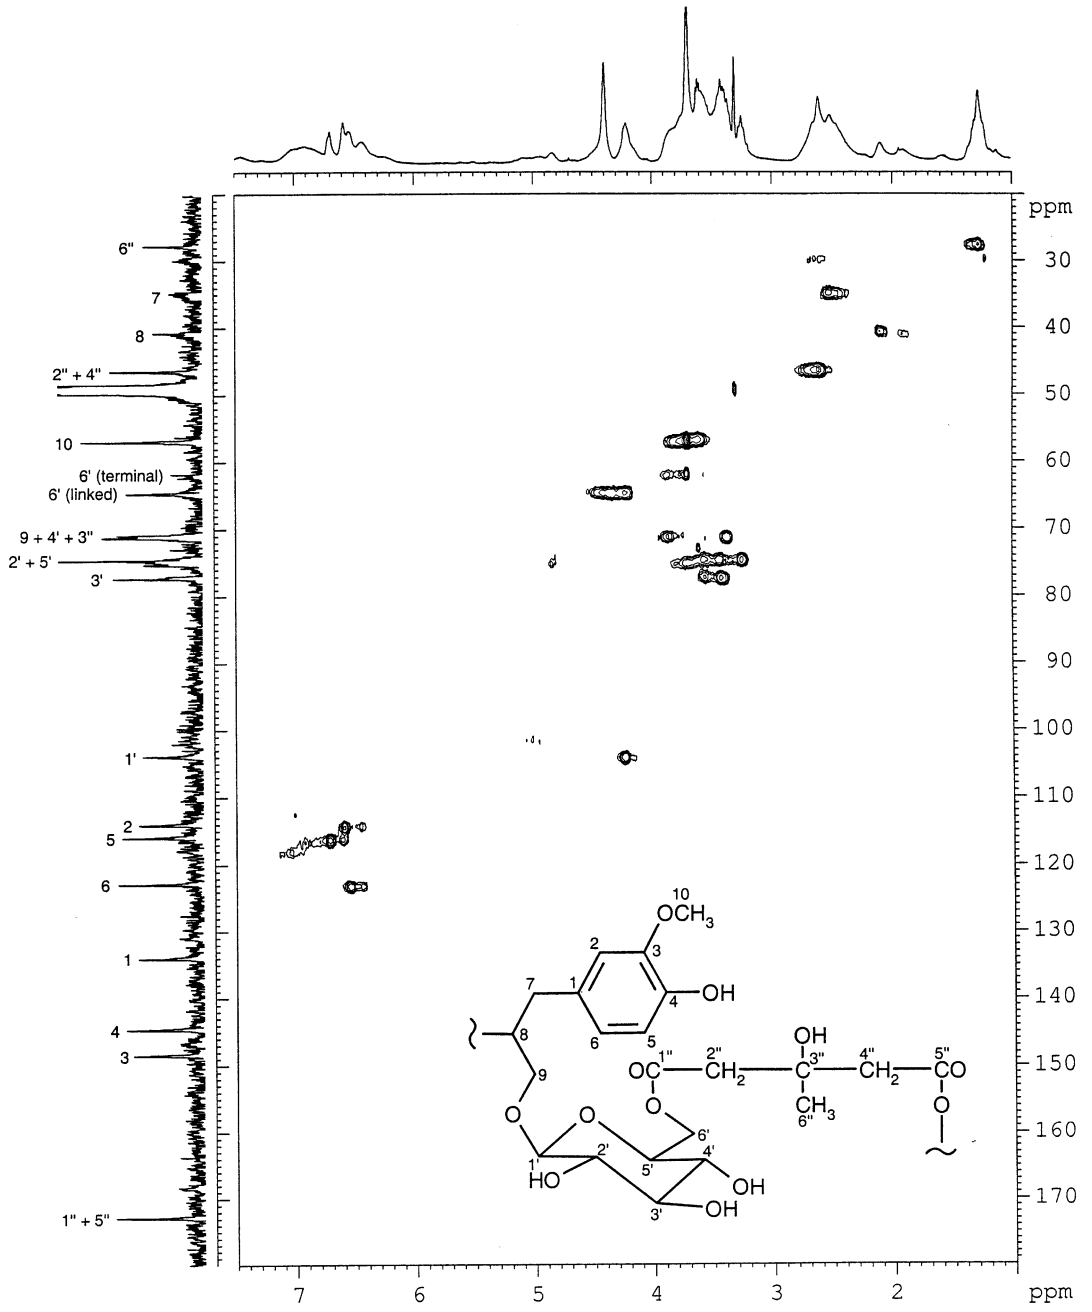

Fig. 1. ^{1}H NMR, ^{13}C NMR and HSQC–DEPT spectra of the oligomer composed of SDG (secoisolariciresinoldiglucoside) and HMGA (3-hydroxy-3-methyl glutaric acid) residues in flaxseed. Insert shows the numbering system used to assign ^{13}C NMR signals. For the complete structure of the oligomer, see Fig. 3.

Also observed were peaks corresponding to the aliphatic CH_3 (δ 1.28 ppm) and CH_2 (δ 2.61 ppm) groups of HMGA which has also been reported to be present in flaxseed (Klosterman and Smith, 1954; Bakke and Klosterman, 1956). ^{13}C NMR (Fig. 1) showed only peaks for SDG (Chimichi et al., 1999; Qiu et al., 1999) and HMGA residues but no visible peaks for the other phenols (mainly *p*-coumaric acid-*O*-glucoside and ferulic acid-*O*-glucoside) which also seem to exist in polymeric forms involving ester bonds. Very weak and broad NMR signals from these "other phenolic polymers" were visible in the phenolic region of ^{1}H NMR (Fig. 1) indicating a more rigid structure and, consequently, shorter relaxation times.

The fact that the carboxylic carbon signal of the isolated fraction was 2 ppm upfield ($\delta = 173$ ppm) as compared with that of the free HMGA ($\delta = 175$ ppm) suggests that HMGA is solely present in symmetrically esterified form. The HSQC–DEPT spectrum (Fig. 1) revealed that C-6 of the glucose in SDG gives two types of strong cross peaks; one peak (^{13}C: $\delta =$ 62.4 ppm, ^{1}H: $\delta = 3.8$ ppm) characteristic of a non-esterified $-CH_2OH$

group, and another (down-field) peak (^{13}C: $\delta =$ 64 ppm, ^{1}H: $\delta = 4.2$ ppm) characteristic of an ester-linked carbon (Farah et al., 1992). Since some of the C-6 of the glucose residues in SDG are ester-linked and some are not, some glucose residues must be in terminal position in the polymer. This finding is confirmed by TOCSY (Fig. 2) which showed two types of spin systems for the protons at positions 7, 8 and 9 where signals from the linked SDG were downfield compared to those from terminal SDG. HMBC (results not shown) revealed that the ester link is between the carboxylic carbon of HMGA (^{13}C: $\delta =$ 173 ppm) and some of the C-6 of glucose (^{1}H: $\delta =$ 4.2 ppm). Taken together, these results suggest a linear and symmetrical structure composed of SDG and HMGA units. On basis of HSQC–DEPT, the structure of the polymer was elucidated from two types of calculations: (i) the ratio of terminal versus linked glucose residues in the polymer, and (ii) the ratio between SDG and HMGA units. The ratio of terminal versus intermediate SDG groups was roughly calculated as 1:4 from the ^{13}C NMR spectrum by integration of the peaks at $\delta = 61.6$–62.3 ppm (terminal glucose) and $\delta =$ 64.6 ppm (linked glucose). Integration of peaks, in the ^{1}H NMR spectrum, at $\delta = 1.8$–2.1 ppm (two protons at positions 8 of SDG) and $\delta = 2.3$–2.9 ppm (four protons at positions 7 of SDG and the $-CH_2-$ groups of HMGA) gave the SDG/HMGA ratio as 0.56/0.44 from which the average number of SDG and HMGA molecules in this polymer can be calculated as 4.67 and 3.67, respectively. Both calculations support an average structure of ca. 4000 Da (Fig. 3), containing two terminal and eight linked glucose residues.

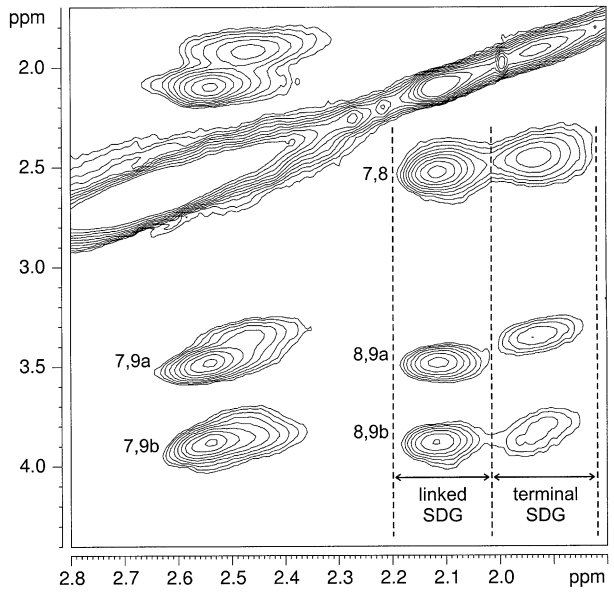

Fig. 2. Part of TOCSY spectrum of the oligomer isolated from flaxseed illustrating two spin systems (linked and terminal SDG) for the cross peaks between the protons at positions 7, 8 and 9. For numbering, see Fig. 1 and for the complete structure of the oligomer, see Fig. 3.

Structures containing glucose residues glycosidically linked to flavonoid residues and esterified at C-6 to malonate residues were found in red clover (Lin et al., 2000). Conjugation to malonate was thought to increase the solubility of phenolic aglycones for storage by the plant till further release, by hydrolysis, as phytoalexins in events of microbial or viral invasion of the cells. The polymeric structure of SDG–HMGA presented here is different from other known biopolyesters of plants, e.g. cutin and suberin (Kolattukudy, 1980) and cinnamate-containing arabinoxylan (Ishii, 1997). Since both SDG (Axelson et al., 1982, Westcott and Muir, 2000) and HMGA (Laurenti et al., 1990) are known for beneficial health effects, this oligomer might be of interest for nutritional and pharmaceutical applications. Knowledge about this structure is important from nutritional (bioavailability, bioconversion and bioactivity) as well as biochemical (biosynthesis and biosynthesis elicitors) points of view.

3. Experimental

A crude polymeric flaxseed extract was obtained by stirring of a sample of defatted flaxseed flour (50 g) twice with 1,4-dioxane/ethanol (1:1 v/v, 200 ml) at 60 °C for 7 hours as described earlier (Johnsson et al., 2000). Part of this polymeric extract, called whole polymer, was fractionated using pre-packed reversed-phase solid phase extraction column (1 g C18, Mega Bond Elut®, Varian, Harbor City, LA, USA) preconditioned with methanol (5 ml) followed by water (5 ml). An aqueous solution of the extracted polymer (0.1 g/ml, 5 ml) was loaded on the column, washed with 5 ml of 50% methanol and then

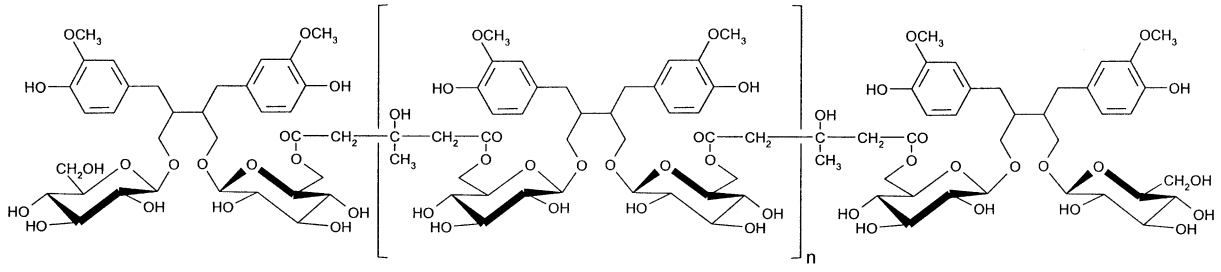

Fig. 3. The structure of a polymer composed of SDG and HMGA residues in flaxseed (average value of $n = 3$).

eluted with 60% methanol to obtain the major fraction of the polymer.

Before NMR analysis, the purified hygroscopic fraction was dried using a rotary evaporator, re-dissolved in either D_2O or a mixture of D_2O and CD_3OD and re-dried three times to exchange water followed by overnight incubation in a *vacuum* oven. All spectra (^1H MR, ^{13}C NMR, TOCSY, HMBC and HSQC-DEPT) were recorded at frequencies of 400 (^1H) and 100 (^{13}C) MHz on a Bruker DRX 400 instrument (Karlsruhe, Germany). Measurements were performed in a D_2O: CD_3OD mixture (1:1, v/v) at 60 °C. ^1H NMR chemical shifts were referenced to TMS while ^{13}C chemical shifts were referenced to the methyl group signals from residual methanol ($\delta = 49.0$ ppm). ^1H and ^{13}C NMR chemical shifts of the polymer, standard SDG (Johnsson et al., 2000) and HMGA (Sigma-Aldrich Chemie, Germany) were assigned by consideration of chemical shift values, coupling patterns and coupling constants, where appropriate. A sequence with pre-saturation of the water peak was used for ^1H NMR. TOCSY was recorded with a mixing time of 80 ms and HMBC was recorded with a delay of 65 ms for evolution of long range couplings and 164 scans over 256 increments. For HSQC–DEPT, the number of scans was 64 over 256 increments.

Stilbenoids from the lianas of *Gnetum pendulum*

Xiao-Mei Li, Ying-Hong Wang, Mao Lin*

Institute of Materia Medica, Chinese Academy of Medical Sciences and Peking Union Medical College, No. 1 Xiannongtan Street, Beijing 100050, People's Republic of China

Received 11 January 2001; received in revised form 3 May 2001

Abstract

Two stilbenoids, gnetupendin A and B, were isolated from the lianas of *Gnetum pendulum* C. Y. Cheng, together with four known compounds, resveratrol, isorhapontigenin, shegansu B and β-daucosterol. Their structures were determined on the basis of analysis of spectral evidence, especially 2D NMR spectroscopic techniques. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Gnetum pendulum*; Gnetaceae; Gnetupendins A and B; Stilbenoid; Cyclo-oxgyenase-2 inhibitory activity

1. Introduction

Oligostilbenes have attracted much attention for their unique structures and various biological activities, including antifungal (Langcake and Pryce, 1977; Ducrot et al., 1998), protein kinase C inhibitory (Kulanthaivel et al., 1995), hepatoprotective and hepatotoxic (Oshima et al., 1995), anti-HIV, cytotoxic (Dai et al., 1998; Cichewicz et al., 2000) and cyclo-oxygenase (COX) and COX II inhibitory (Cichewicz et al., 2000) activities, etc.. Our research group has focused on naturally occurring oligostilbenes in recent years and three *Gnetum* species, *G. parvifolium*, *G. montanum* and *G. hainanense*, have been investigated (Li et al., 1991; Lin et al., 1991, 1992; Xu and Lin, 1997; Chen and Lin, 1998, 1999a,b; Huang et al., 2000a,b; Wang et al., 2001). As part of our systematic research on oligostilbene constituents, we investigated another Gnetum species, *G. pendulum*, and two stilbenoids, gnetupendin A and B were obtained together with resveratrol (Ingham, 1976), isorhapontigenin (3′,4,5′-trihydroxy-3-methoxystilbene) (Li et al., 1991), shegansu B (Zhou,and lin, 2000) and β-daucosterol (Chen and Lin, 1999a,b). The structures of the two stilbenoids, gnetupendin A (**1**) and B (**2**), contain a new stilbenoid skeleton in which the position 2 of 3,5-dihydroxybenzene ring (B) of the isorhapontigenin unit are substituted with a 4-hydroxybenzyl in **1** and a 3,4-dihydroxybenzyl group in **2** respectively. These are the first reports of this skeleton. Cyclo-oxygenase-2 inhibitory activity of **2** was tested.

2. Results and discussion

Gnetupendin A (**1**) was obtained as a pale yellow solid, exhibiting strong blue violet fluorescence under UV light at 254 nm. The high resolution EIMS *m/z* 364.1316 agreed with a molecular formula of $C_{22}H_{20}O_5$ (required 364.1311) with 13 degrees of unsaturation. The UV absorption spectrum of **1** at 228 and 325 nm suggested the presence of a stilbene skeleton (ring A and B) in **1**. The ^{1}H NMR spectrum of **1** (Table 1) showed eleven aromatic and olefinic protons and displayed the presence of ABX, AB and A_2B_2 systems respectively. Its spectrum showed signals as follows: an ABX system for ring A at δ 7.07 (1H, *br s,* H-2), 6.78 (1H, *d,* $J=8.4$ Hz, H-5) and 6.93 (1H, *dd*, $J=1.8$ and 8.4 Hz, H-6); an AB system for ring B at δ 6.41 (1H, *d*, $J=2.1$ Hz, H-12) and 6.68 (1H, *d*, $J=2.1$ Hz, H-14); an A_2B_2 system for ring C at δ 7.08 (2H, *br d*, $J=8.7$ Hz, H-17, 21) and 6.68 (2H, *br d*, $J=8.7$ Hz, H-18, 20); two *trans* olefinic protons at δ 6.85 (1H, *d*, $J=16.2$ Hz, H-7) and 7.24 (1H, *d*, $J=16.2$ Hz, H-8); one methoxyl singlet at δ 3.87 (3H, *s*, OCH_3) and one benzylic methylene singlet at δ 4.02 (2H, *s*, H-15). The ^{13}C NMR and DEPT spectra of **1** exhibited one methoxy group at δ 56.1 and one benzylic methylene group at δ 30.4, besides 20 aromatic and olefinic carbons at 102.5–157.0 (Table 1). The above spectral data indicate that structure of **1** consists of an isorhapontigenin

2

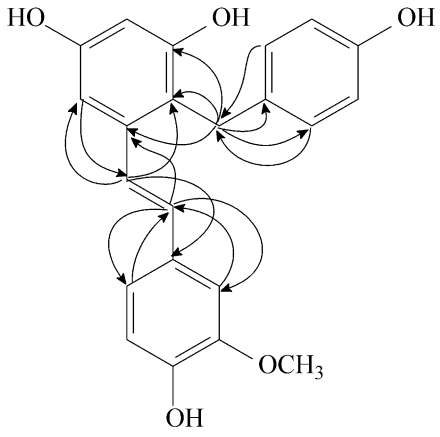

Fig. 1. Important ^{13}C–^{1}H long-range correlations for compound **1**.

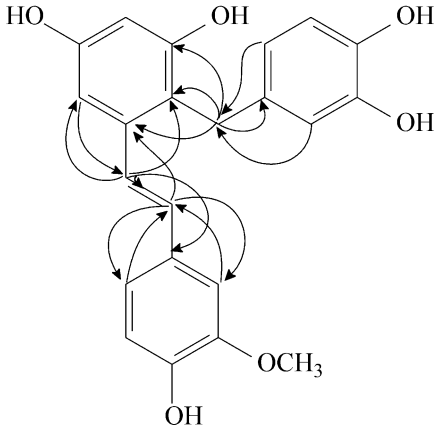

Fig. 2. Important ^{13}C–^{1}H long-range correlations for compound **2**.

(or a rhapontigenin) unit and a 4-hydroxybenzyl group. The location of the benzyl group was determined by HMBC spectral analyses of **1** (Fig. 1) and was confirmed by the following cross peaks: H-15/C-9, 10, 11, 16, 17(21) and H-17(21)/C-15. The correlations between H(C-4-OH) /C-3, 4, 5, H-6/C-4 and H(-OCH_3)/C-3 confirmed that the stilbene unit was isorhapontigenin. Thus, the structure of **1** was characterized as 10-(4-hydroxybenzyl)-isorhapontigenin.

Gnetupendin B (**2**) was obtained as a brown solid, exhibiting strong blue violet fluorescence under UV light at 254 nm. The high resolution EIMS *m/z* 380.1279 agreed with a molecular formula of $C_{22}H_{20}O_6$ (requires 380.1260) with 13 degrees of unsaturation. The ^{1}H NMR spectrum (Table 1) of **2** displayed similar patterns to those of **1**. However, the ^{1}H NMR spectrum of **2** (Fig. 2) showed ten aromatic and olefinic protons, including two ABX systems which appeared at δ 7.07 (1H, *d*, $J=2.1$ Hz, H-2), 6.86 (1H, *d*, $J=8.1$ Hz, H-5), 6.91 (1H, *dd*, $J=2.1$ and 8.1 Hz, H-6) for ring A and δ 6.64 (1H, *d*, $J=1.8$ Hz, H-17), 6.67 (1H, *d*, $J=7.5$ Hz, H-20), 6.69 (1H, *d*, $J=1.8$ and 7.5 Hz, H-21) for ring C; two *meta*-coupled doublets at δ 6.41 (1H, *d*, $J=2.1$ Hz, H-12) and 6.68 (1H, *d*, $J=2.1$ Hz, H-14) in ring B and two *trans* olefinic protons at δ 6.85 (1H, *d*, $J=16.2$ Hz, H-7) and 7.23 (1H, *d*, $J=16.2$ Hz, H-8). The ^{1}H NMR spectrum also showed the presence of one methoxy singlet at δ 3.88 (3H, *s*, OCH_3) and one benzyl methylene singlet at δ 3.98 (2H, *s*, H-15). The ^{13}C NMR and DEPT spectra of **2** revealed the presence of one methoxy group at δ 56.1 and one benzylic methene group at δ 30.5 in addition to 20 aromatic and olefinic carbons at 102.5–157.0 (Table 1). Thus, **2** was similar to **1**, its structure was composed of an isorhapontigenin unit and a 3, 4-dihydroxybenzyl group. The connectivity of the two units were determined by the correlations between H-15/C-9,

[a] Measured in CD_3COCD_3 at 300 MHz for ^1H and 75 MHz for ^{13}C, respectively, with assignments confirmed by ^1H-^1H COSY, HMQC, HMBC and NOESY spectra.
[b] *Each was a broad singlet, and the signals cannot be assigned unambiguously; hence, they are interchangeable.

10, 11, 16; H-17/C-15 and H-21/C-15. Thus, **2** was characterized as 10-(3,4-dihydroxybenzyl)-isorhapontigenin.

The inhibitory effect of compound **2** on prostaglandin E_2 (PGE_2) production in mouse peritoneal macrophages stimulated with lipopolysaccharide (LPS) was tested (Hu and Cheng, 2000). The inhibitory rate of compound **2** was 24.4% ($P < 0.05$) at the concentration of 10^{-7} mol/l, with meloxicam used as a positive control with IC_{50} of 2.86×10^{-8} mol/l. It suggested that compound **2** may has cyclo-oxygenase-2 inhibitory activity.

3. Experimental

3.1. General experimental procedures

UV spectra were recorded on a Shimadzu UV-3000 spectrophotometer. IR spectra were recorded on a Perkin-Elmer 683 infrared spectrometer as KBr pellets. NMR spectra were recorded on a Varian Mercury-300 NMR spectrometer using TMS as internal standard. EIMS and HREIMS were obtained using an Autospec-UltimaTof mass spectrometer. HPLC was performed on a Waters Model 510 instrument equipped with a Waters 2487 Dual λ Absorbance UV Detector.

3.2. Plant material

The lianas of *G. pendulum* C. Y. Cheng (Gnetaceae) were collected at Menghai in Xishuangbanna County of Yunnan Province, People's Republic of China in July 1999, and were identified by Professor W.Z. Song, Institute of Materia Medica, Chinese Academy of Medical Sciences and Peking Union Medial College. A voucher specimen has been deposited in the herbarium of this Institute.

3.3. Extraction and isolation

The dried and powdered lianas of *G. pendulum* (10 kg) were extracted with 60% aq EtOH under conditions of refluxing, and the crude extract (1.5 kg) obtained after removing solvent in vacuo was further extracted with EtOAc to provide a EtOAc soluble residue (90 g) after evaporating to dryness. The residue was next subjected to silica gel column chromatography (140–180 mesh, 10 $\times$150 cm) eluted with $CHCl_3$–MeOH–H_2O (8:2.5:1) to provide five fractions (A-E). Isorhapontigenin (4.5 g, 0.045%) and resveratrol (100 mg, 0.001%) were obtained from fraction A by additional silica gel column chromatography (40 μm, 5×100 cm) with $CHCl_3$–

MeOH (9:1). Fraction B (12 g) was subjected to ODS column chromatography (RP-18, 35–75 μm, 4×35 cm) eluted with a MeOH–H_2O gradient of increasing MeOH to provide fractions B_1–B_3. Fraction B_3 (5.9 g) was subjected to ODS column chromatography (RP-18, 35–75 μm, 4×35 cm) eluted with MeOH–H_2O (4.5:5.5) and then purified by medium-pressure liquid chromatography (Lobar column, RP-18, 43–63 μm, 2.5×31 cm, MeOH–H_2O of 3.5:6.5) to provide shegansu B (570 mg, 0.0057%). Fraction B_2 (60 mg) was subjected to preparative HPLC (10 μm, 300×7.8 mm) with MeOH–H_2O (1:1) to provide **1** (24 mg, 0.00024%). Fraction B_1 (0.7 g) was subjected to medium-pressure liquid chromatography (Lobar column, RP-18, 43–63 μm, 2.5×31 cm, MeOH–H_2O of 3.5:6.5) to provide **2** (144 mg, 0.0014%).

3.4. Gnetupendin A (*1*)

Pale yellow solid; UV ($c = 0.02$, MeOH) λ_{max} (log ε): 228 (4.5), 291 (*sh*), 306 (*sh*), 325 (4.6) nm; IR (KBr) ν_{max} cm^{-1}: 3410, 1604, 1599, 1514, 1466, 1344, 1267, 1159, 1020, 1007, 953, 849, 833, 800, 781; ^1H (300 MHz) and ^{13}C (75 MHz) NMR spectral data: see Table 1; FABMS *m/z*: 364.1; HR–EIMS *m/z*: 364.1316 $[M]^+$ (calc. for $C_{22}H_{20}O_5$, 364.1311).

Abstract

Glycyrrhiza pallidiflora hairy roots were induced from axenic young plants by direct infection with *Agrobacterium rhizogenes*. The chemical constituents were then investigated after mass culture. The isoflavone, licoagroisoflavone and the coumestan, licoagroside C, were isolated along with seven known flavonoids. Their structures were determined on the basis of spectroscopic evidence.

1. Introduction

The roots of *Glycyrrhiza* species are one of the most important crude drugs in China and Europe. In our studies on hairy root cultures to produce useful compounds, we have established several hairy root culture lines of *Glycyrrhiza* species, including *G. glabra*, *G. ularensis*, *G. eurycarpa*, *G. aspera* and *G. pallidiflora*. The chemical constituents of *G. glabra* have been reported previously (Asada et al., 1998, 1999; Li et al., 1998, 2000). In the analysis of the flavonoid constituents of these hairy root cultures, *G. pallidiflora* hairy root cultures showed a very different HPLC pattern than *G. glabra* hairy root cultures. We report here the isolation and structure determination of chemical constituents from *G. pallidiflora* hairy root cultures.

2. Results and discussion

Hairy roots of *G. pallidiflora* were induced from axenic young plants by direct infection with *Agrobacterium rhizogenes* pRi 15834; pGSGlu1 (GUS) as described previously (Yoshikawa and Furuya, 1987). The opines, agropine and mannopine, were detected from the hairy roots by paper electrophoresis.

Mass culture was carried out on Gamborg's B5 plant medium. After 4 weeks of culture, the hairy roots were harvested. The dried roots were extracted with methanol and the extract was partitioned between ethyl acetate and water. The ethyl acetate extract was applied to a silica gel column and further purified by normal-phase and reversed-phase HPLC to give two new flavonoids, named licoagroisoflavone (**1**) and licoagroside C (**2**), together with seven known flavonoids, calycosin (**3**), erythrinin (**4**), isoliquiritigenin (**5**), echinatin (**6**), maackiain (**7**), trifolirhizin (**8**) and ononin (**9**) (Fig. 1).

Licoagroisoflavone (**1**) was obtained as a pale yellow powder. In the EI mass spectrum, **1** exhibited a molecular ion peak at m/z 336, which is smaller by 18 mass units than that of erythrinin (**4**). Its molecular formula, $C_{20}H_{16}O_5$, was established based on its the HR–EI mass spectrum. The ^{1}H NMR spectrum of **1** was similar to that of **4,** except for proton signals due to a prenyl group. The ^{1}H NMR spectrum of **1** showed a singlet at δ 8.17, which is characteristic of the olefinic proton of isoflavones (Markham and Geiger, 1994). The spectrum also showed the presence of AA′XX′-type aromatic proton signals at δ 7.30 (2H, *d*, $J=8.5$ Hz) and 7.75 (2H, *d*, $J=8.5$ Hz) due to B ring protons and a singlet aromatic proton signal at δ 6.55 (1H, *s*) due to an A ring proton. Proton signals due to a prenyl moiety were observed at δ 1.75 (3H, *br s*, H_3-8″), 3.07 (1H, *dd*, $J=15.0$, 7.5 Hz, H_a-4″), 3.39 (1H, *dd*, $J=15.0$, 9.5 Hz, H_b-4″), 4.95 (1H, *br s*, H_a-7″), 5.17 (1H, *br s*, H_b-7″),

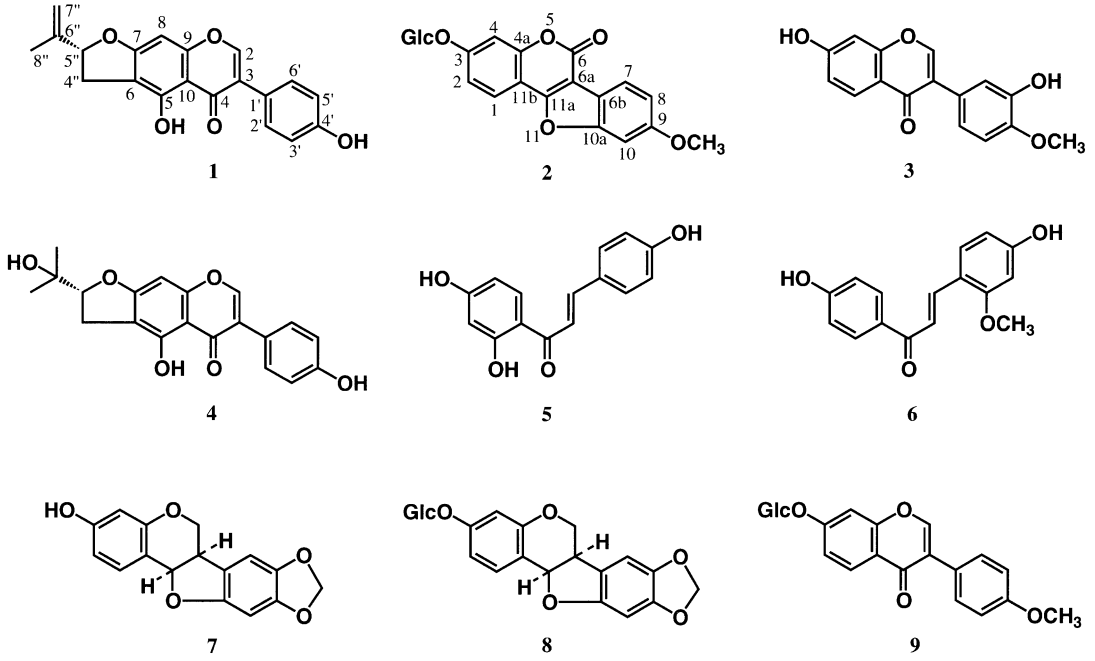

Fig. 1. Flavonoids from *Glycyrrhiza pallidiflora* hairy root cultures.

and 5.40 (1H, *br dd*, $J=9.5$, 7.5 Hz, H-5″), indicating the presence of an isopropenyl-dihydrofuran group (Tahara et al., 1984). The position of the isopropenyl-dihydrofuran side chain was assigned to be located at C-6 based on HMBC experiments (Fig. 2). The absolute configuration of C-5″ was determined by CD spectrum analysis of the osmate ester/pyridine complex. A negative Cotton effect at 470 nm indicated that **1** had an *S*-configuration at C-5″ (Tahara, Ingham, Mizutani, 1987). Thus, the structure of licoagroisoflavone (**1**) was determined as 5″-(*S*)-5, 4′-dihydroxy-5″-isopropenyl-4″, 5″-dihydrofurano [2″, 3″: 6, 7] isoflavone.

Licoagroside C (**2**) was obtained as colorless needles. The FAB mass spectrum of **2** showed a pseudo-molecular ion peak at m/z 445 $[M+H]^+$, which is larger by 14 mass units than that of ononin (**9**). Its molecular formula, $C_{22}H_{20}O_{10}$, was established based on its HR–FAB mass spectrum. The IR spectrum of **2** showed a band at 1731 cm^{-1}, indicating the presence of an unsaturated δ-lactone group (Abe et al., 1987). The ^1H NMR spectrum of **2** showed two ABX-type aromatic proton signals at δ 7.17 (1H, *dd*, $J=8.5$, 2.0 Hz), 7.36 (1H, *d*, $J=2.0$ Hz), 8.11 (1H, *d*, $J=8.5$ Hz) and δ 7.38 (1H, *dd*, $J=8.5$, 2.0 Hz), 7.48 (1H, *d*, $J=2.0$ Hz), 7.88 (1H, *d*, $J=8.5$ Hz), as well as a methoxy proton signal at δ 3.79 and an anomeric proton signal at 5.81(1H, *d*, $J=7.0$ Hz). The coupling constants of the sugar moiety protons suggested the presence of a β-D-glucopyranose. Comparison of the ^1H NMR spectrum of **2** with that of **9** showed that the olefinic proton disappeared in **2** and the AA′XX′-type aromatic proton signals in **9** changed to ABX-type aromatic proton signals in **2**. By reference to published ^1H NMR data of coumestans (Ohshima et al., 1988), the signal at δ 8.11 was assigned to the proton at C-7, which is shifted downfield by the effect of the neighboring carbonyl. Based on analyses of the HMQC and HMBC spectra of **2**, the carbons on the two aromatic rings were assigned as shown in the Experimental section, and the remaining three carbon signals (δ 104.3, 158.2, 160.0) in the aglycone moiety also suggested that **2** is a coumestan-like compound (Fukai et al., 1989). The positions of the methoxy and glucopyranosyloxy groups in **2** were determined from the HMBC spectrum, as shown in Fig. 3. The H-7 and methoxy protons were correlated to C-9 at δ 160.0. On the other hand, correlation peaks between the anomeric and H-1 protons and C-3 at δ 161.4 were observed. Thus, **2** was identified as 3-β-D-glucopyranosyl-9-methoxycoumestan, named as licoagroside C.

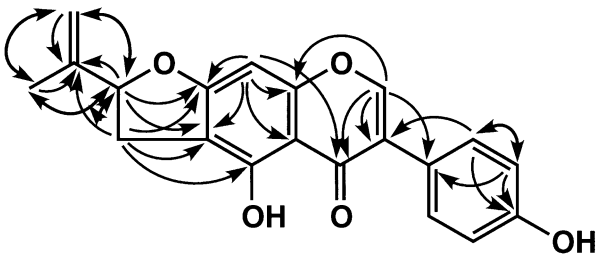

Fig. 2. ^1H–^{13}C long-range correlations (HMBC) of compound **1**.

In conclusion, we isolated two new flavonoids and seven known flavonoids from the hairy roots of *G. pallidiflora*. The known flavonoids calycosin (**3**), isoliquiritigenin (**5**), echinatin (**6**) and ononin (**9**) were previously

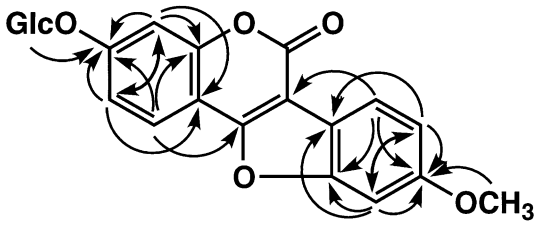

Fig. 3. ^{1}H–^{13}C long-range correlations (HMBC) of compound **2**.

obtained from the roots of *G. pallidiflora* (Nomura and Fukai, 1998). Echinatin (**6**) and ononin (**9**) were obtained from hairy root cultures of *G. glabra* in our previous studies (Li et al., 2000). The flavonoid constituents of *G. pallidiflora* hairy roots were rich in prenylated isoflavones, compared to those of *G. glabra*. *G. pallidiflora* hairy root cultures may have greater prenylation ability than *G. pallidiflora* roots, and thus give new compound **1**.

3. Experimental

3.1. General experimental procedures

Melting points were measured on a Yanaco micro melting point apparatus. The UV spectra were obtained with a Shimadzu UV-160 spectrophotometer, whereas the IR spectra were measured with a JASCO FT/IR-300E (by a KBr disk method) spectrometer. The optical rotations were measured with a JASCO DIP-370 digital polarimeter in a 0.5 dm-long cell, while the CD spectra were recorded on a JASCO J-720 W spectropolarimeter. EI–MS, FAB–MS, HR–EI–MS and HR–FAB–MS were taken on a Jeol JMS-AX505HA. ^{1}H and ^{13}C NMR spectra were measured with a Varian XL-400 spectrometer. For HPLC, a Waters model 510 HPLC system was used. Column chromatography was carried out using Wako-gel C-200. TLC was conducted on Kieselgel 60 F_{254} plates (Merck).

3.2. Mass culture of G. pallidiflora hairy root

The methods used to induce hairy root cultures of *G. pallidiflora* have been described previously (Yoshikawa and Furuya, 1987). The opines of hairy roots were detected by paper electrophoresis. Mass culture was carried out on Gamborg's B5 medium (Gamborg et al., 1968) containing 2% sucrose at 25 °C in the dark, at 50 rpm on a rotary shaker, using 500 ml Erlenmeyer flasks each containing 200 ml of medium.

3.3. Extraction and separation of flavonoids

After 4 weeks of culture, the hairy roots were harvested. The freeze-dried hairy roots (134.97 g) were extracted with MeOH. Evaporation of the solvent under reduced pressure from the combined extract gave the MeOH extract (43.85 g). The extract was then partitioned between EtOAc and H_2O. Removal of the solvent from the EtOAc phase under reduced pressure below 40 °C yielded the EtOAc extract (5.01 g). The EtOAc extract was subjected to silica gel chromatography (Wako gel C-200, ca 250 g) and eluted by $CHCl_3$:MeOH at ratios from 100:0 to 0:100 to give 11 fractions, fr. 1 (432.5 mg), fr. 2 (127.6 mg), fr. 3 (211.9 mg), fr. 4 (107.6 mg), fr. 5 (231.3 mg), fr. 6 (175.7 mg), fr. 7 (176.0 mg), fr. 8 (149.6 mg), fr. 9 (500.4 mg), fr. 10 (513.1 mg) and fr. 11 (95.8 mg). Further purification of fractions 2–10 was achieved by repeated NP–HPLC (μ-Bondasphere, 5 μm Si–100 Å, 19×150 mm) and RP–HPLC (μ-Bondasphere, 5 μm C18–100 Å, 19×150 mm) to give **1** (61.6 mg), **2** (4.4 mg), **3** (1.7 mg), **4** (1.7 mg), **5** (0.4 mg), **6** (1.0 mg), **7** (10.1 mg), **8** (25.0 mg) and **9** (13.0 mg).

3.4. Licoagroisoflavone (*1*)

Pale yellow powder, mp 196–198 °C, $[\alpha]_D$ −68.1° ($c=0.81$, MeOH, 24 °C). UV λ nm (log ε): 214 (4.57), 264 (4.67). IR υ cm^{-1}: 3403, 1673, 1619, 1571. EI–MS *m/z* (%): 336 (M^+, 100), 321 (100), 319 (43), 295 (43), 149 (54). HR–EI–MS: Found: 336.0996; Calcd for $C_{20}H_{16}O_5$ (M^+): 336.0998. ^{1}H NMR (400 MHz, pyridine-d_5): δ 1.75 (3H, *br s*, H_3-8″), 3.07 (1H, *dd*, $J=15.0$, 7.5Hz, H_a-4″), 3.39 (1H, *dd*, $J=15.0$, 9.5 Hz, H_b-4″), 4.95 (1H, *br s*, H_a-7″), 5.17 (1H, *br s*, H_b-7″), 5.40 (1H, *br dd*, $J=9.5$, 7.5 Hz, H-5″), 6.55 (1H, *s*, H-8), 7.30 (2H, *d*, $J=8.5$Hz, H-3′ and 5′), 7.75 (2H, *d*, $J=8.5$ Hz, H-2′ and 6′), 8.17 (1H, *s*, H-2). ^{13}C NMR (100 MHz, pyridine-d_5): δ 17.2 (C-8″), 31.0 (C-4″), 88.5 (C-5″), 89.3 (C-8), 107.1 (C-10), 109.1 (C-6), 112.7 (C-7″), 116.5 (C-3′ and 5′), 122.3 (C-1′), 123.7 (C-3), 131.2 (C-2′ and 6′), 144.0 (C-6″), 153.6 (C-2), 157.9 (C-5), 158.7 (C-9), 159.5 (C-4′), 166.7 (C-7), 181.6 (C-4).

3.5. Licoagroside C (*2*)

Received 28 December 2000; received in revised form 24 April 2001

Abstract

The biflavanone (2*S*,2″*S*)-7,7″-di-*O*-methyltetrahydroamentoflavone and five known flavonoids, 7-*O*-methylnaringenin, 7,3′-*O*-dimethylquercetin, 7-*O*-methylapigenin, 7-*O*-methylluteolin, and eriodictyol were isolated from the leaves of *Rhus retinorrhoea* Steud, Ex Olive. The biflavanone exhibited moderate antimalarial activity with IC_{50} 0.98 μg/ml against *Plasmodium falciparum* (W2 Clone) and weak activity against *P. falciparum* (D6 Clone) with IC_{50} 2.8 μg/ml. Nevertheless, it did not display any cytotoxicity. 7-*O*-Methylnaringenin showed weak antimicrobial activity against *Candida albicans, C. krusei, Staphylococcus aureus, Mycobacterium smegmatis, M. intracellulare, and M. xenopi* with MIC∼ 100 μg/ml. Characterization of each compound was based on spectral analysis and comparison with reported data. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Rhus retinorrhoea*; Anacardiaceae; Biflavonoids; Biflavanone; Tetrahydroamentoflavone; Antimicrobial activity; Antimalarial activity

1. Introduction

Rhus retinorrhoea (Anacardiaceae) is a tree growing in the southern parts of Saudi Arabia. In a previous publication dealing with its first phytochemical investigation, we reported the isolation of four flavonoids from the leaves (Mossa et al., 1996). Some species of the genus *Rhus* are used in traditional medicine either as antimicrobial concoctions (Saxena et al., 1994) or for their cytotoxic properties (Lin et al., 1989), while others display insecticidal activities against aphids (Bestman et al., 1988). Biflavonoids have been isolated from a number of *Rhus* species (Lin and Chen, 1973; Chen et al., 1974; Young, 1979; Bestman et al., 1988). Here we report the structure of a new biflavanone **4** and the known flavonoids **1**–**3**, **5**, **6** that were purified from the dichloromethane extract of the dried leaves of *R. retinorrhoea*.

2. Results and discussion

The positive ion HRESIFTMS of compound **4** displayed a peak at *m/z* 571 $[M+H]^+$ which was consistent with a molecular formula $C_{32}H_{26}O_{10}$. The IR spectrum of **4** indicated broad OH absorption bands at 3550 and 3400 cm^{-1}, while the UV spectrum showed absorption maxima at 287 and 330 nm, characteristic of a flavanone derivative (Mabry et al., 1970). The ^1H and ^{13}C NMR spectra of biflavanoid **4** at 300 K showed the typical adverse effects of restricted rotation about the interflavanyl bond. At this temperature all the proton resonances are duplicated, hence indicating the presence of two distinct rotamers. Intramolecular NOE effects between protons of the constituent flavanyl units in the vicinity of the bond axis, represent a powerful tool to identify the rotamers in such a mixture (Brandt et al., 1987). The close proximity of e.g. the 7″-OMe (D-ring) and 2-H (C-ring) resonances of the rotamers of compound **4**, however, precluded rotamer differentiation. The biflavanone skeleton of **4** was evident from the presence of two benzylic methine carbon signals [δ 78.3 (C-2″) and 79.3, 79.2 (C-2), two methylene carbon signals [δ

4

42.8, 42.5 (C-3) 42.1, 41.8 (C-3″) and two carbonyl carbon signals [δ 197.5, 197.4 (C-4), 198.0, 197.9, (C-4″)]. The ^{1}H NMR spectrum of **4** showed four hydroxyl signals, two are hydrogen bonded and resonate at δ 12.12, 12.10 (1H, *s*, OH-5) and 12.39, 12.37 (1H, *s*, OH-5″) and the other two non hydrogen bonded hydroxyl groups are located at δ 9.32, 9.28 (1H, *s*, OH-4′) and 9.52, 9.50 (1H, *s*, OH-4‴). The ^{1}H NMR spectrum also exhibited two methoxyl signals resonating at δ 3.77, 3.76 (3H, *s*, OMe-7), and 3.73, 3.72 (3H, *s*, OMe-7″). The location of the hydroxyl groups was defined on the basis of HMBC and ROESY correlation studies. The ^{13}C NMR spectrum exhibited two methoxyl signals at δ 56.32 (OMe-7) and 56.62 (OMe-7″), their location being assessed by the ROESY correlations. Such ROESY correlation between OMe-7, H-8 and H-6 and between OMe-7″ and H-6″ as shown in Fig. 1 strongly suggested C-8″(D-ring) as bonding site on the lower DEF flavanone unit. The carbon–carbon bond between the two flavanone moieties linking C-3′ of ring B to C-8″ of ring D was established via the following considerations; ^{1}H NMR showed a signal at δ 6.27 (1H, *s*) attributed to H-6″ which indicated the absence of proton H-8″ which in turn supported the involvement of C-8″ in the suggested linkage. The ROESY correlation between H-2 and OMe-7″ was an additional support of involvement of C-8″ in the linkage. The presence of a signal at δ 6.84 (1H, *d*, J= 8.4 Hz) attributed to H-5′ and indicated the absence of H-3′

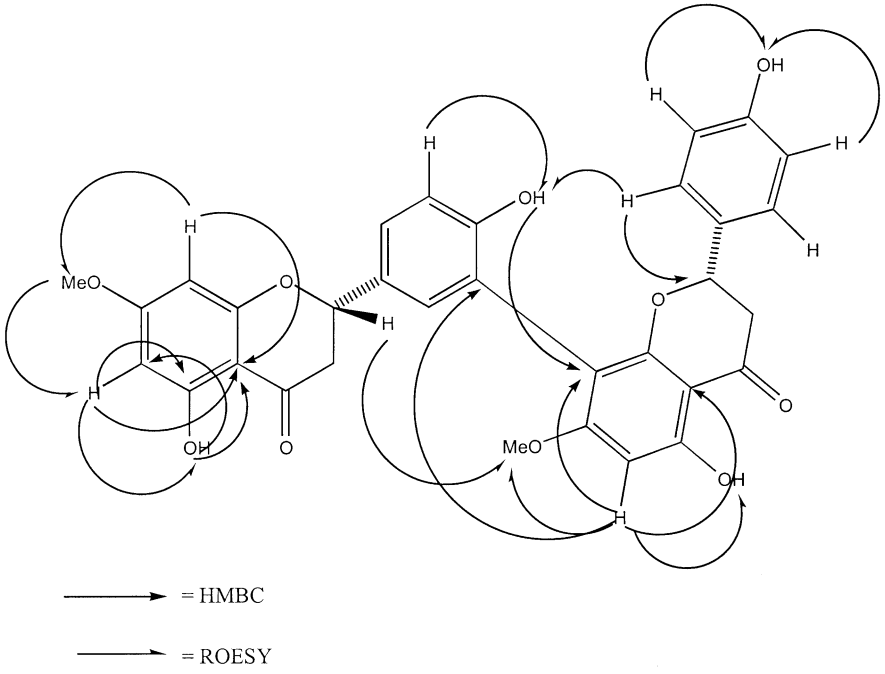

Fig. 1. Important HMBC and ROESY correlations of **4**.

and consequently suggested involvement of C-3′ in the interflavonoid linkage. The location of the linkage was confirmed by the presence of ^{2}J-HMBC correlation between H-6″ and both C-5″ and C-7″, and ^{3}J-HMBC correlation between C-6″ and both C-8″ and C-10″. In addition, there was also important ^{4}J-HMBC correlation between H-6″ and C-3′ and another between C-8″ and OH-4′.

The CD spectrum of **4** showed sequential positive and negative Cotton effects at 332 and 291 nm, respectively, which established a 2*S*, 2″*S* absolute configuration (Gaffield, 1970). Thus, on the basis of spectral analysis and comparison with published NMR spectroscopic data of closely related compounds (Markham et al., 1987), the structure of **4** was established as (2*S*,2″*S*)- 7,7″-di-*O*-methyltetrahydroamentoflavone. The identities of compounds **1**, **2**, **3, 5**, and **6** were based on comparison of their spectral data with reported values (Wagner et al., 1976; Calvert et al., 1979; Noro et al., 1983; Agrawal, 1989).

All isolated new and known compounds were tested for antimicrobial and antimalarial activity. For the antimicrobial testing, a modified microtiter-plate assay was used (National Committee for Clinical Laboratory Standards, 1997). For antimalarial testing, the method conducted is described elsewhere (Khalid A. El Sayed et al., 1996). Compound **1** showed weak antimicrobial activity against *Candida albicans, C. krusei, Staphylococcus aureus, Mycobacterium smegmatis, M. intracellulare,* and *M. xenopi* with MIC ~100 μg/ml (positive controls; nystatin for *Candida* with MIC 2.0 μg/ml, chloramphenicol for *S. aureus* with MIC 4.0 μg/ml and isoniazide for *Mycobacterium* with MIC 10.0 μg/ml). Compound **4** exhibited moderate antimalarial activity against *Plasmodium falciparum* (W2 Clone) with IC_{50} 0.98 μg/ml and weak activity against *P. falciparum* (D6 Clone) with IC_{50} 2.8 μg/ml (positive control; chloroquine with IC_{50} 0.026 and 0.238 μg/ml against D6 Clone and W2 Clone, respectively). Nevertheless, compound **4** did not display any cytotoxicity.

3. Experimental

3.1. General

IR spectra were recorded with an ATI Mattson genesis series Fourier transform (FT–IR) spectrophotometer. UV spectra were obtained on a Hewlett Packard 8452A diode array spectrophotometer. Optical rotations were recorded at ambient temperature using a JASCO DIP-370 digital polarimeter. CD spectra were recorded in MeOH at ambient temperature on a Jasco J715 spectropolarimeter. 1D and 2D NMR spectra were obtained on a Brüker Avance DRX 500 spectrometer. HRESIFTMS was obtained using a Bruker Bioapex FT–MS in ESI mode. For TLC, glass supported silica gel plates (0.25 mm layer, F_{250}, E. Merck) were used and Silica gel 60 (230–400 mesh, E. Merck) was employed for column chromatography.

3.2. Plant material

R. retinorrhoea was collected during 1993 from the southern region of Saudi Arabia. The plant was identi-

fied by Dr. Sultan-ul-Abdeen, College of Pharmacy, King Saud University. A voucher specimen is deposited at the herbarium of the College of Pharmacy, King Saud University, Riyadh, 11451, Saudi Arabia.

3.3. Extraction and isolation

Dried and ground leaves of *R. retinorrhoea* (1.4 kg) were extracted with CH_2Cl_2 in a Soxhlet apparatus. The CH_2Cl_2 extract (133 g) was partitioned between hexane and MeCN (1:1, 6 L). A portion of the MeCN extract (30 g) was applied to a Si gel column (900 g) using gradients of C_6H_6 and EtOAc(0→50%). This column yielded **1** (2.6 g), **2** (59.0 mg), **3** (342 mg), **4** (40 mg), respectively, and a mixture of two compounds (7.0 g) which was subjected to a Si gel column (360 g) chromatography using gradients of EtOAc in hexane (25→75%) then gradients of MeOH in EtOAc (5→10%) to afford compounds **5** (33 mg), and **6** (31 mg).

Compound **4** : yellow powder, amorphous. $[\alpha]_D$ −25.4 (*c* 0.024, DMSO). CD (MeOH, *c* 0.00012) $[\theta]_{332}$ 15517, $[\theta]_{291}$ 44114.4; UV λ_{max} MeOH nm (logϵ): 287 (4.68), 330 (3.20). Received 30 November 2000; received in revised form 19 April 2001

Abstract

Two phenanthropyran derivatives, 3-methoxy-2,7-dihydroxy-5H-phenanthro[4,5-*bcd*]pyran and 2,3,7-trihydroxy-5H-phenanthro[4,5-*bcd*]pyran were isolated from the orchid *Phalaenopsis equestri*. Their chemical structures were elucidated from spectroscopic (NMR, MS etc.) analyses. © 2001 Elsevier Science Ltd. All rights reserved.

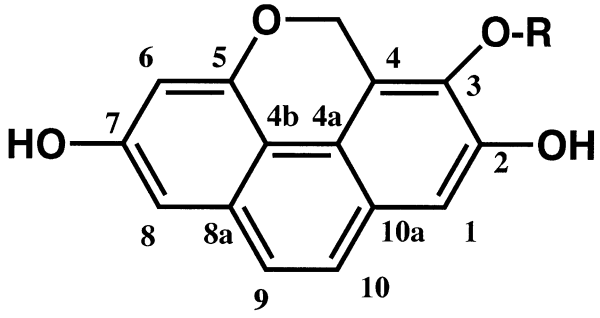
Keywords: *Phalaenopsis equestris*; Orchidaceae; Phenanthropyran

1. Introduction

The secondary metabolites of the Orchidaceae plants have been intensively investigated and various constituents, such as bibenzyl (Majumder and Basak, 1991a; Majumder and Pal, 1993; Majumder et al., 1997; Leong et al., 1997), stilbenoid (Majumder and Basak, 1991b; Majumder and Ghosal, 1993, 1994; Majumder et al., 1996), phenanthrene (Majumder and Sen, 1991; Majumder and Maiti, 1989; Leong et al., 1997), dihydrophenanthrene (Leong et al., 1997) and phenanthropyran (Majumder and Sabzabadi, 1988) derivatives have been reported. The orchid plants are worldwide popular ornamentals indoors and some genera such as *Vanilla, Gastrodia, Bletilla, Dendrobium* etc. are also used as important medicinal resources (e.g. Kimura and Kimura, 1991). In the present study, the secondary metabolites of *Phalaenopsis equestris*, a most popular potting orchid in Japan, were investigated and two new phenanthropyran derivatives were isolated. Their chemical structures were established following spectroscopic analyses.

2. Results and discussion

The methanol extract of the lyophilized leaves of *Phalaenopsis equestris* was subjected to column chromatography with Sephadex LH-20 and preparative C_{18} gel to afford compounds **1** and **2**.



1 : R=Me
2 : R=H

Compound **1** was obtained as an off-yellow amorphous powder. The positive-ion fast atom bombardment mass spectroscopy (FAB–MS) of **1** gave a quasi-molecular ion peak at m/z 269 $[M+H]^+$, which corresponding to the molecular formula of $C_{16}H_{12}O_4$. The ^1H NMR

PII: S0031-9422(01)00249-7

spectrum of **1** showed five aromatic protons; meta-coupled doublets at δ 6.61 ($J=2$ Hz) and δ 6.85 ($J=2$ Hz), ortho-coupled doublets at δ 7.50 ($J=9$ Hz) and δ 7.55 ($J=9$ Hz) and one-proton non-coupled singlet at δ 7.23 (*s*) (Table 1). Together with one low-field methylene proton signal at δ 5.62 (*d*, $J=0.7$ Hz), The ^{1}H NMR spectrum of **1** suggested the existence of 2,3,7-substituted phenanthropyran structure (Majumder and Sabzabadi, 1988). The ^{13}C NMR spectrum of **1** exhibited 14 signals (Table 2, C-1–C-10 and C-4a, C-4b, C-8a and C-10a) whose chemical shifts supported the presence of 2,3,7-substituted phenanthropyran (Majumder and Sabzabadi, 1988). The ^{1}H and ^{13}C NMR spectra of **1** also indicated the existence of one methoxyl moiety (δ 3.93 in ^{1}H NMR spectrum and δ 61.3 in the ^{13}C NMR spectrum). The carbon atoms of the aromatic methoxyl groups having at least one *ortho*-hydrogen atom appear at the expected positions (δ 54–56), while those of such groups flanked by two *ortho*-substituents were shifted downfield by 5–6 ppm (Majumder and Sabzabadi, 1988). Therefore, the methoxyl signal at δ 61.3 in ^{13}C NMR spectrum of **1** corresponded to a methoxyl group at C-3 position. The position (C-3) of the methoxyl moiety was also supported by having no observable NOE correlation cross peak between the methoxyl proton signal (δ 3.93 in ^{1}H NMR spectrum) and three aromatic proton signals (H-1, 6 and 8). From the data mentioned above, **1** was characterized as 3-methoxy-2,7-dihydroxy-5H-phenanthro[4,5-*bcd*]pyran.

Compound **2**, an off-yellow amorphous powder, exhibited $[M+H]^+$ ion peak at *m/z* 255 ($C_{15}H_{10}O_4$) in the positive-ion FAB–MS. The ^{1}H (Table 1) and ^{13}C (Table 2) NMR spectra of **2** were almost identical to those of **1**, except for the disappearance of the methoxyl signal which was observed in **1**. Therefore, **2** was concluded to be as 2,3,7-trihydroxy-5H-phenanthro[4,5-*bcd*]pyran. Both compounds are the first examples of phenanthropyrans isolated from the genus *Phalaenopsis*.

3. Experimental

3.1. General

^{1}H and ^{13}C NNR spectra were measured at 500 and 125 MHz, respectively. Column chromatography was performed on Sephadex LH-20 (Pharmacia Fine Chemical) and preparative C_{18} 125 Å (Waters) column-gels. TLC analyses was employed silica-gel plates (Merck, Kieselgel 60F254), with the mobile solvent of $CHCl_3$–MeOH (5:1). Spots of compounds on TLC plates were visualized by exposure to UV (254 nm).

3.2. Extraction and isolation

Lyophilized leaves (4.1 g) of *Phalaenopsis equestri* were mashed by a pestle and extracted with MeOH (2×200 ml, each for 2 h) at room temperature. The extract was concentrated in vacuo at 40 °C and was subjected to Sephadex LH-20 column chromatography eluted with 60% aqueous MeOH to afford three fractions (Fr. 1–3). Fr. 1 was applied to preparative C_{18} 125 Å using H_2O–MeOH (1:0–2:3) elution solvent to afford compound **1** (3.8 mg). Fr. 3 was also purified by Sephadex LH-20 (EtOH–90% aqueous EtOH) to afford compound **2** (4.6 mg).

3.2.1. Compound *1*

An off-yellow amorphous powder, ^{1}H and ^{13}C NMR spectral data of **1**, see Tables 1 and 2. Positive FABMS *m/z* (rel. int.); 269 $[M+H]^+$ (60), (Found: C, 71.32; H, 4.29. $C_{16}H_{12}O_4$ requires: C, 71.64; H, 4.48%).

3.2.2. Compound *2*

An off-yellow amorphous powder, ^{1}H and ^{13}C NMR spectral data of **2**, see Tables 1 and 2. Positive FABMS *m/z* (rel. int.); 255 $[M+H]^+$ (12), (found: C, 70.55; H, 3.88. $C_{15}H_{10}O_4$ requires: C, 70.87; H, 3.94%).

Flavone C-glycosides from *Scleranthus uncinatus*

Nurettin Yayli*, Hasan Seymen, Cemalettin Baltaci

Karadeniz Technical University, Faculty of Science, Department of Chemistry, 61080 Trabzon, Turkey

Received 15 November 2000; received in revised form 14 March 2001

Abstract

Two flavone C-glycosides, 5,7,4′-trihydroxy-3′-methoxyflavone-8-C-β-D-xylopyranoside-2″-*O*-glucoside, 5,7-dihydroxy-3′-methoxy-4′-acetoxyflavone-8-C-β-D- xylopyranoside-2″-*O*-glucoside and one known maltol β-D-glucopyranoside were isolated for the first time from the *Scleranthus uncinatus* and their structures deduced by high field 1D and 2D 400 MHz NMR and (+) FAB–MS spectra. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Scleranthus uncinatus*; Illecebraceae; Flavone C-glycosides; Chrysoeriol 8-C-D-xyloside-2″-*O*-glucoside; 5,7-Dihydroxy-3′-methoxy-4′-acetoxyflavone-8-C-xyloside-2″-*O*-glucoside

1. Introduction

The genus *Scleranthus* comprises three species of the Illecebraceae family (Davis, 1967). One species, *S. uncinatus* Schur., which is naturalized in northern Turkey (Davis, 1967) where it has been used in traditional medicine against uterine bleeding by women. The active principles of this plant are unknown but as many flavonoids are biologically active (Agrawal, 1989), it is possible that the flavonoid constituents in this plant may contribute to its therapeutic properties. As part of a phytochemical investigation of a methanolic extract of *S. uncinatus,* two new flavone C-glycosides (**1**, **2**), isomer of scoparin 2″-*O*-xyloside (Gluchoff-Fiasson et al., 1989; Chopin and Dellamonica, 1988; Harborne, 1988) and one known maltol β-D-glucopyranoside (**3**) (Tanaka et al., 1986; Numata et al., 1990) were isolated for the first time from this plant. This paper describes the isolation and identification of two new and one known compounds, **1**–**3** through spectral analyses.

2. Results and discussion

Compound **1** showed $[M+H]^+$ at *m/z* 595 (100%) in its (+)-FABMS corresponding to the molecular formula $C_{27}H_{30}O_{15}$. This was corroborated by the ^{13}C NMR spectrum, which showed signals for all the 27 carbons of the molecule. The UV spectrum, exhibited absorption maxima at 272, 305 and 338 nm, was typical of flavones with 5,7,3′,4′-tetraoxygenation (Kuo at al., 1996). A free C_5 hydroxyl was confirmed by a bathochromic shift of 42 nm in the presence of $AlCl_3$ and a free 7-hydroxyl group was indicated by a bathochromic shift (ring A) of 11 nm upon the addition of sodium acetate (Merghem et al., 1995; Kuo et al., 1996).

The ^1H NMR spectrum showed one proton singlet at δ 6.22 indicating that ring A was trisubstituted. The absence of an aromatic methine carbon signal in the range 90.0–96.0 ppm indicated that C_8 was substituted. The clear differentiation between a 5,6,7- and 5,7,8-substition-pattern on the basis of the chemical shift of the A ring methine resonance has been previously described (Markham and Chari, 1982). From HMBC data, this proton (δ 6.22) showed correlations with carbons 5 and 8 rather than with 6 and 9 and, therefore, was assigned to position 6 (Merghem et al., 1995; Pauli and Junior, 1995). Ring B showed a pattern of three one-proton signals at δ 7.50 (1H, *d*, $J=1.2$ Hz), 6.88 (1H, *d*, $J=7.2$ Hz) and 7.42 (1H, *dd*, $J=1.2$, 7.2 Hz), the multiplicity of which showed one proton coupled to the remaining two which were, in turn, not coupled to each other. The size of the coupling constants (1.2 and 7.2 Hz) is characteristic of *meta* and *ortho* couplings as found in a 3′, 4′-oxygenated flavonoids (Venturella et al., 1995; Kuo et al., 1996). In addition, signals in the ^{13}C NMR spectrum at δ 149.30 and 151.73 indicated that the oxygenated carbons are adjacent due to the shielding effect (>10) each oxygen exerts on its neighbouring ortho carbons (Agrawal, 1989,

PII: S0031-9422(01)00289-8

Venturella et al., 1995). The presence of one methoxyl group in the molecule was indicated by a peak in the ^{1}H NMR spectrum at δ 3.96 appearing as a singlet and integrating for 3 protons and in the ^{13}C NMR spectrum as one signal at δ 56.60. This one methoxyl group was placed on carbon 3′ (149.30) based on HMBC correlations of the methoxyl group with carbon 3′ (Fig. 2). In addition, from long-range COSY connectivities (Fig.2) the positions of the methoxyl group on ring B was confirmed since cross-peaks from $H_{2'}$ to OMe and a cross NOE correlation were seen to $H_{2'}$ to the methoxyl group in the NOESY spectrum. In the ^{1}H NMR spectrum of 1, the characteristic H_3 signal of a flavone was exhibited at δ 6.53 (1H, s) and in its the ^{13}C NMR spectrum (Table 1), the presence of signals at δ 184.12 agreed with α,β-unsaturated carbonyl group in ring C (Chopin et al., 1988; Gluchoff-Fiasson et al., 1989; Pauli, and Junior, 1995; Ventutella et al., 1995; Kuo et al., 1996).

In the ^{1}H NMR, spectrum of **1** two anomeric protons appeared at δ 4.27 (1H, *d*, J= 6.0 Hz) and 5.02 (1H, *d*, J= 10.0 Hz) indicating the presence of two sugars with a β-configuration. In the ^{13}C NMR, anomeric carbons of the sugar moieties appeared at δ 105.89 and 76.04 (HMQC, HMBC) (Table 1) (Pauli and Junior, 1995). Using 1D (^{1}H, ^{13}C, DEPT) and 2D NMR (H-COSY, TOCSY, HMQC, HMBC and NOESY) data individual sugar chemical shifts were assigned as in Table 1. Therefore, it is found that one of the sugars was β-D-glucose and the other was β-D-xylose in the pyranose form. The ^{13}C NMR spectrum showed signals for xylose at δ 76.04 (C_1), 81.34 (C_2), 77.04 (C_3), 70.17 (C_4) and 72.10 (C_5) characteristic of a C-glucoside (Chopin et al., 1988; Gluchoff-Fiasson at al., 1989; Nunes at al., 1989; Pauli and Junior, 1995; Wu et al., 1997). The xylose residue was assigned to position 8 based on HMBC correlations. The ^{1}H and ^{13}C NMR data are presented in Table 1. The sugar was also analyzed on TLC after acid hydrolysis of compound **1** and was identified as glucose.

The sequence and the linkage sites of the sugar chain were subsequently confirmed by the observation of

[a] Spectra recorded in CD_3OD.
[b] Assignments based on ^{1}H, ^{13}C, DEPT, 2D-COSY, HMQC, HMBC and NOESY spectra.

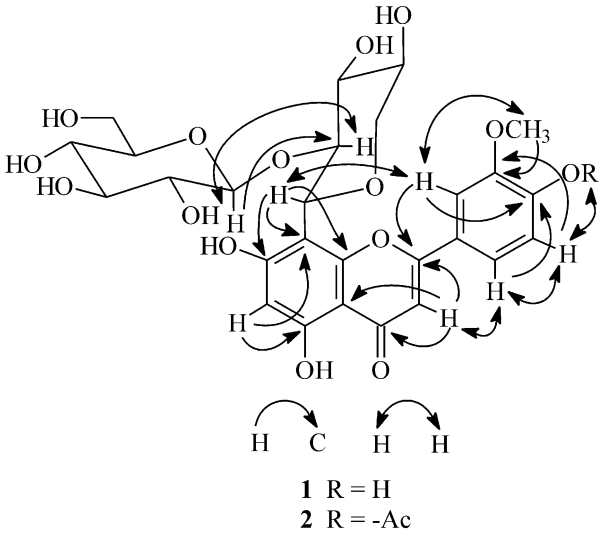

Fig. 1. Important HMBC and NOESY correlations of compounds **1** and **2**.

interresidue NOE's in NOESY between Glc H_1 with Xyl H_2 and by HMBC correlations (Fig. 1) between Glc H_1 with Xyl C_2 and Xyl H_1 with C_8 suggesting that the sacccharide chain had the structure: Glc (1→2) Xyl and this chain was attached to the C_8 of aglycone through a C-glycosidic linkage (HMBC, HMQC) (Fig. 1). Also, in the positive FAB mass spectra, the fragment at *m*/*z* 433 $[M\text{-Glucose}+H]^+$ correspond to the subsequent loss of hexose moiety at the terminal position of 1.

Based upon the above observations, the structure of the major compound **1** was established as 5,7,4′-trihydroxy-3′-methoxyflavone-8-C-β-D-xylopyranoside-2″-*O*-glucoside, which is a novel natural product and an isomer of scoparin 2″-*O*-xyloside (Chopin et al., 1988; Gluchoff-Fiasson et al., 1989).

Compound **2** showed $[M+H]^+$ at *m*/*z* 637 (100%) in its (+)-FAB–MS corresponding to the molecular formula $C_{29}H_{32}O_{16}$. Compound **2** exhibited similar NMR spectra (^1H, ^{13}C, DEPT, H-COSY, HMQC, HMBC and NOESY) (Table 1) to **1** indicating the presence of an identical flavone skeleton with a similar sugar side chain to that of **1** except for the presence of the signal for an acetyl group at the $C_{4'}$ position in ring B. In the ^1H NMR spectrum, the chemical shift for $-CH_3$ of the acetyl (δ 1.97, *s*, 3H) was indicative of acylation at $C_{4'}$. The ^{13}C NMR spectrum (Table 1) showed signals for an acetyl carbonyl carbon at δ 172.92 and methyl carbon resonance at δ 20.73, which were assigned to the $C_{4'}$ position. The site of acylation was further supported by a strong NOE observed for $H_{5'}$ with acetyl methyl protons (δ 1.97) in its NOESY spectrum (Fig. 1). Therefore, the structure of **2** was established as 5,7-dihydroxy-3′-methoxy-4′-acetoxyflavone-8-C-β-D-xylopyranoside-2″-*O*-glucoside, which is a new natural product.

The occurrence of **1**, **2** and **3** constitutes the first report of flavone C-glycosides and a maltol glycoside in the genus *Scleranthus uncinatus*.

3. Experimental

3.1. General

NMR spectra were recorded on a Varian NMR at 400 MHz instrument in CD_3OD. (+) FAB was recorded on a Zabspec MS instrument using NOBA and Glycerol matrix. UV spectra were recorded on a Shimadzu 1201. Mps were uncorr. Flash CC was performed on silica gel (230–400 mesh), PTLC was performed with precoated normal and reversed-phase silica gel RP-18 $F_{254}S$.

3.2. Plant material

Whole plants of *S. uncinatus* Schur. were collected in July 1996 at Artvin Hills (~1800 m), Turkey. A voucher specimen has been deposited in the Department of Chemistry at Karadeniz Technical University. The identification of this specious was according to Flora of Turkey (Davis, 1967).

3.3. Extraction and isolation

Dried and powdered whole plants (980 g) were successively extracted with MeOH (1 l, ×3, 24 h each). The MeOH extract was concentrated in vacuo at 30–35 °C to give a brown viscous residue (8.2 g, wet). Crude mixture (2.2 g) was subjected to flash CC on silica gel (100 g, 230–400 mesh). The column was eluted with *n*-hexane (100 ml) followed by l.c. a discontinuous gradient with *n*-hexane-$CHCl_3$ (9:1, 100 ml; 8:2, 100 ml; 7:3, 100 ml; 6:4, 100 ml), $CHCl_3$ (300 ml), $CHCl_3$–MeOH (7:1, 200 ml; 7:3, 200 ml), MeOH (200 ml) and finally with MeOH–H_2O (5:1, 200 ml) to give 13 fractions (~ 125 ml each). After TLC analysis, fractions 1–4 (fatty acid mixture called SU1), 5–8 (sugars mixture called SU2) and 9–13 (flavonoids called SU3, 220 mg) were combined. Fraction SU3 was purified by Silica gel prep. TLC using $CHCl_3$–MeOH (3:2) to give three bands (SU3A, 27 mg, $R_f=0.72$; SU3B, 147 mg, $R_f=0.48$ and SU3C, 35 mg, $R_f=0.15$, mixture). SU3A and SU3B were rechecked by reverse-phase-18 TLC in MeOH–H_2O (1:1) solvent system and found to be mixture. SU3B was rechromatographed by RP-18 PTLC using MeOH–H_2O (1:1) to give four bands; SU3BA: **3**, 7.2 mg, $R_f=0.75$; SU3BB and SU3BC contained minor unidentified compounds, $R_f=0.52$, $R_f=0.40$; SU3BD: **1**, 74 mg, $R_f=0.22$. SU3A was rechromatographed by RP-18 PTLC using MeOH–H_2O (1:1) to give two bands, SU3AA (7.8 mg, $R_f=0.35$ unidentified) and SU3AB: **2**, 17.2 mg, $R_f=0.23$.

*3.3.1. 5,7,4′-Trihydroxy-3′-methoxyflavone-8-C-β-D-xylopyranoside-2″-O-glucoside (**1**)*

Yellow amorphous crystals, mp 152–155° (dec); $[\alpha]_D$ + 71.60 °C (CH_3OH; *c* 5.14); UV λ_{max}^{MeOH} nm: 272, 305, 338; + NaOAc: 283, 299, 380; + $AlCl_3$: 280, 306, 352, 380; ^1H NMR (CD_3OD, 400 MHz) and ^{13}C NMR (CD_3OD, 100 MHz) δ (ppm) see Table 1; positive FAB–MS (NOBA) *m/z* (%); *m/z* = 595 (100) $[M+H]^+$, 565 (8), 433 (12) [M-Gluc(163) + H]$^+$, 343 (13), 313 (13), 193 (9), 179 (10).

*3.3.2. 5,7-Dihydroxy-3′-methoxy-4′-acetoxyflavone-8-C-β-D- xylopyranoside-2″-O-glucoside (**2**)*

Yellow amorphous crystals, mp 142–144° (dec); $[\alpha]_D$ + 63.04 °C (CH_3OH; *c* 0.94); UV λ_{max}^{MeOH} nm: 250, 372, 315; + NaOAc: 264, 315, 365; + $AlCl_3$: 263, 272, 280, 361; ^1H NMR (CD_3OD, 400 MHz) and ^{13}C NMR (CD_3OD, 100 MHz) δ (ppm) see Table 1; positive FAB–MS (NOBA) *m/z* (%); *m/z* = 637(100) $[M+H]^+$, 459 (8) [M-O-Gluc (179) + H]$^+$, 431 (6), 343 (7), 329 (9), 193 (6), 176 (8), 155 (14), 136 (38).

*3.3.3. Maltol β-D-glucopyranoside (**3**)*

Colorless powder, mp 106–108° (dec); identified by comparison (^1H, ^{13}C, DEPT, COSY, HMQC, HMBC and NOESY) with lit. data (Tanaka et al., 1986; Numata et al., 1990); $[\alpha]_D$ −50.0° (CH_3OH–H_2O (5 drops), 5 ml; *c* 0.36); ^1H NMR (CD_3OD, 400 MHz) δ (ppm); 6.47(H_5, *d, J* = 5.6 Hz), 7.81(H_6, *d, J* = 5.6 Hz), 2.38 (–CH_3, *s*), 5.41 ($H_{1'}$, *d, J* = 7.6 Hz), 4.18 ($H_{2'}$), 4.24 ($H_{3'}$), 4.16 ($H_{4'}$), 3.94 ($H_{5'}$), 4.32 ($H_{6'}$), 4.48 ($H_{6'}$) and ^{13}C NMR (CD_3OD, 100 MHz) δ (ppm); 161.71 (C_2), 143.04 (C_3), 175.24 (C_4), 116.65 (C_5), 155.15 (C_6), 15.26 (CH_3), 105.68 ($C_{1'}$), 75.33 ($C_{2'}$), 70.23 ($C_{3'}$), 77.95 ($C_{4'}$), 78.82 ($C_{5'}$), 62.19 ($C_{6'}$); positive FAB–MS (glycerol) *m/z* (%); *m/z* = 289 (12) $[M+H]^+$.

*3.3.4. Acid hydrolysis of **1***

Compound **1** (9 mg) was refluxed with 2 N HCl in aq. MeOH (4 ml) for 6 h. The reaction mixture was then concentrated under reduced pressure to remove MeOH. It was then diluted with H_2O (3 ml) and the aqueous layer was adjusted to pH 7 with Ag_2CO_3 and filtered. The supernatant was concentrated and compared with reference sugars on TLC (Silica gel, H_2O:MeOH:AcOH:EtOAc, 15:15:20:65). The sugars were detected by spraying the plate with a solution of aniline phthalate in BuOH which showed that the sugar in **1** was glucose.

Received 6 November 2000; received in revised form 28 March 2001

Abstract

The aerial parts of the Egyptian herb *Cornulaca monacantha* have yielded two new galloyltannin analogs (named monacanthin A and monacanthin B) characterized by protoctechuoyl moiety at C-6, and also a new flavonol glycoside, quercetin-4′-*O*-β-D-galactoside. The structures of the new compounds were established by conventional analytical methods and confirmed by spectral analyses. Two known flavonoids, luteolin-7-*O*-rhamnoside, luteolin-7-*O*-glucoside, and two known gallotannins, penta-*O*-galloyl-β-D-glucose and 1,2,3,6-tetra-*O*-galloyl-β-D-glucose were also isolated. © 2001 Elsevier Science Ltd. Keywords: *Cornulaca monacantha*; Chenopodiaceae; Quercetin-4′-*O*-β-D-galactoside; Gallotannins; Monacanthin A and B; Tannins

1. Introduction

Cornulaca monacantha Del. (Chenopodiaceae) is an annual herb growing wild in Egypt (Tackholm, 1974). Decoction of the leaves is used in folk medicine for treatment of jaundice (Boulos, 1983). Previous investigation of the plant revealed the presence of triterpenoid saponins (Amer et al., 1974; Dawidar et al., 1979; Kamel, et al., 2000) and the flavonoids luteolin-8-*O*-glucoside-3′-*O*-rutinoside, quercetin-3-*O*-rutinoside and quercetin-3-*O*-galactoside (Kandil and Husseiny, 1998). In the present study one new flavonol glycoside **1** and two new gallotannin compounds **4** and **5** were isolated, in addition to two known flavonoid compounds and two known gallotannins. The structures of the new compounds are elucidated in this paper.

2. Results and discussion

Three flavonoid compounds **1**–**3** and four gallotannins **4**–**7** were isolated from the ethyl acetate fraction of a 80% alcoholic extract of the aerial parts of *C. monacantha* by column chromatography on silica gel. Compound **1** was obtained as an amorphous yellow powder, which produced quercetin and galactose on acid hydrolysis. Its UV spectra with different shift reagents, before and after acid hydrolysis, suggested a flavonol glycoside with free hydroxyl groups at the 3, 5 and 7 positions and a substituted 4′ position (Mabry et al., 1970). ^{1}H NMR spectrum showed C-2′ proton signals at higher field (δ 7.50 ppm, *d*, $J = 2.5$ Hz) than C-6′ proton (δ 7.65 ppm, *dd*, $J = 8$, 2,5 Hz), indicating substitution at 4′ position. The spectrum showed also a doublet ($J = 8.5$ Hz) at δ 6.81 for H-5′. The anomeric proton of the sugar galactose appeared at δ 5.35ppm (*d*, $J = 7.5$ Hz). ^{13}C NMR confirmed the sugar as galactose and the aglycone as quercetin, except for position 4′, which showed a slight upfield shift (~0.5 ppm) compared to quercetin aglycone (Agrawal and Bansal, 1989). These results suggested that compound **1** is quercetin-4′-*O*-β-D-galactoside, a previously unreported compound. Quercetin-4′-*O*-glucoside and quercetin-4′-*O*-glucouronide have, however, been previously reported (Harborne, 1994; Kandil et al., 1997).

Compounds **2** and **3** were identified as luteolin-7-*O*-rhamnoside and luteolin-7-*O*-glucoside respectively, by acid hydrolysis, UV spectral analysis in presence of customary shift reagents and chromatography with authentic samples and spectral analysis.

Compounds **4** and **5** were both obtained as off-white amorphous powders, which gave dark blue colour with ferric chloride reagent. Both compounds produced protocatechuic acid, gallic acid and glucose on acid hydrolysis.

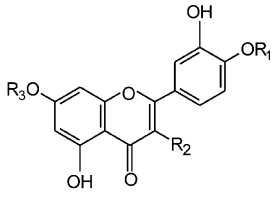
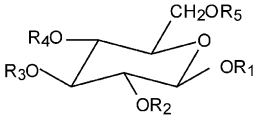
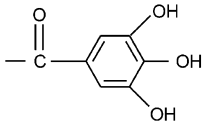
Negative FAB mass spectrometry of compound **4** showed a molecular ion peak at *m/z* 923 [M-1] which indicated a pentagalloylglucose lacking an oxygen atom compared to penta-*O*-galloyl-D-glucose (compound **6**), which gave *m/z* 939 [M-1]. ^{1}H NMR spectrum of **4** showed spectra resembling those of penta-*O*-galloyl-D-glucose **6** (Yoshida, et al., 1984; Haslam, 1989) except for the presence of signals due to the protocatechuoyl moiety which appeared at δ 6.8 ppm (*d*, *J* = 8.5 Hz, H-5) and 7.3 ppm (*m*, H-2, 6). Based on the better resolved ^{13}C NMR spectrum of **4** (Table 1), all carbon signals of the glucose core appeared at the same position as in 1,2,3,4,6- penta-*O*-galloyl-D-glucose **6**, except for C-6, which showed a slight but significant downfield shift (0.5 ppm) indicating that the protocatechuoyl moiety is located at this position. In addition, signals due to C-5 and C-6 of the protocatechuoyl moiety appeared at 114.8 and 117.8 ppm respectively. Accordingly compound **4** has the structure of 1,2,3,4-tetra-*O*-galloyl-6-*O*-protocatechuoyl-β-D-glucose and was named monacanthin A as an unreported natural product.

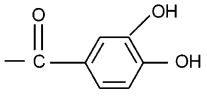


Compound **1**: R_1 = Galactose, R_2 = OH, R_3= H
Compound **2**: R_1 = H, R_2 = H, R_3 = Rhamnose
Compound **3**: R_1 = H, R_2 = H, R_3 = Glucose





Galloyl moiety (G)



Protocatechuoyl moiety(P)

Compound **4** : R1= R2= R3= R4= G, R5= P
Compound **5** : R1= R2= R3= G, R4= H, R5 = P
Compound **6**: R_1= R_2= R_3= R_4= R_5= G
Compound **7**: R_1= R_2= R_3= R_5= G, R_4= H

Negative FAB mass spectrometry of compound **5** showed a molecular ion peak at *m/z* 771 [M-1] corresponding to a tetragalloylglucose lacking one oxygen atom (tetra-*O*-galloyl-D-glucose **7** isolated from this plant showed *m/z* 787 [M-1]). The well resolved ^{13}C NMR spectrum (Table 1) was very close to those of 1,2,3,6-tetra-*O*-galloyl-D-glucose **7** except for the presence of signals due to protocatechuoyl moiety. Signals for C-3 and C-5 of the glucose appeared at δ 76.1, together with the signal at δ 69.5 are typical for a free hydroxyl group at C-4 (Kandil et al., 1996). ^{13}C NMR showed a downfield shift (0.4 ppm) of the C-6 signal of the sugar moiety, which indicated the occupation of the protocatechuoyl moiety at this position. Accordingly compound **5** was characterized as 1,2,3-tri-*O*-galloyl-6-*O*-protocatechuoyl-β-D-glucose and is named monacanthin B as a new natural compound.

Compounds **6** and **7** were identified as penta-*O*-galloyl-β-D-glucose and 1,2,3,6-tetra-*O*-galloyl-β-D-glucose respectively, through acid hydrolysis, chromatography with authentic samples, ^{1}H and ^{13}C NMR analysis.

3. Experimental

3.1. Plant material

Aerial parts of *Cornulaca monacantha* Del. were collected from desert areas around Cairo during December 1997. A voucher specimen of the plant was kindly identified by Dr. Loutfy Boulos, Professor of Botany, National Research Center, Cairo.

3.2. Extraction and isolation

Fresh aerial parts (1 kg) were extracted with 80% ethanol. After evaporation, the remaining aq. sol. was extracted with ether, then with ethyl acetate. The ethyl acetate soluble fraction was fractionated applying vacuum liquid

chromatography technique using column 8 cm height×12 cm i.d. packed with silica gel (40–63 μm Merck). Elution was performed using ethyl acetate and increasing amounts of a mixture of MeOH–H_2O (1:1). Twenty fractions were collected dried and subjected to repeated purification on columns of Sephadex LH-20 to give compounds: **1** (15 mg), **2** (30 mg), **3** (25 mg), **4** (25 mg), **5** (15 mg), **6** (30 mg) and **7** (15 mg).

3.3. Quercetin-4′-O-D-galactoside *1*

Yellow powder, R_f PC: 0.55 (*n*-BuOH–HOAc–H_2O 4:1:5), 0.35 (15% HOAc). Phenylpropanoid glucosides from *Chrozophora obliqua*

Khaled M. Mohamed

Department of Pharmacognosy, Faculty of Pharmacy, Assiut University, Assiut 71526, Egypt

Received 10 October 2000; received in revised form 15 May 2001

Abstract

From the aerial parts of *Chrozophora obliqua*, two phenylpropanoid glucosides: 4-*O*-methyl guaiacylglycerol 9-*O*-β-glucopyranoside (**1**) and 4-*O*-methyl guaiacylglycerol 8-*O*-β-glucopyranoside (**2**) together with syringin, benzyl alcohol glucoside, isorhamnetin-3-*O*-β-glucopyranoside-7-*O*-α-rhamnopyranoside and quercetin-3-*O*-β-glucopyranoside-7-*O*-α-rhamnopyranoside have been isolated. The structures of the isolated compounds were verified by means of MS and NMR spectral analyses. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Chrozophora obliqua Vahl.; Euphorbiaceae; Phenylpropanoid glucosides

1. Introduction

It was reported that *Chrozophora obliqua* is a potent hypoglycemic agent (Kamel, 1991). From the genus *Chrozophora*, the coumarin scopoletin, the alkaloid ricinine (Abdel-Sattar, 1985), flavonoids (Abdel-Sattar, 1985; Hashim et al., 1990), xanthones and chromones (Agrawal and Singh, 1988) were reported. From *C. obliqua*, dolabellane diterpenes have been isolated (Mohamed et al., 1994, 1995). The present study deals with the isolation and structure elucidation of two new phenylpropanoid glucosides (**1**) and (**2**) in addition to the known compounds syringin (**3**), benzyl alcohol glucoside (**4**), isorhamnetin-3-*O*-β-glucopyranoside-7-*O*-α-rhamnopyranoside (**5**) and quercetin-3-*O*-β-glucopyranoside-7-*O*-α-rhamnopyranoside (**6**).

2. Results and discussion

The dried methanolic extract of the aerial parts of *C. obliqua* was suspended in water and partitioned with ethyl acetate. The aqueous layer was subjected to column chromatography on Diaion HP-20 and the 50% methanolic eluate was repeatedly chromatographed on columns of silica gel, reversed phase RP-18 and finally on HPLC to afford six glycosides.

The molecular formula $C_{17}H_{26}O_{10}$ of compound **1** was deduced from HR FAB–MS spectrometry (see Experimental section). The ^{13}C NMR including DEPT mode measurements and ^{1}H NMR spectra of **1** (Tables 1 and 2) displayed signals at δ_C 104.1 with δ_H 4.08 (1H, *d*, $J=7.9$ Hz) corresponding to the anomeric carbon and proton of a β-glucopyranosyl unit (Bradbury and Jenkins, 1984). Enzymatic hydrolysis of **1** with β-glucosidase enzyme afforded glucose and an aglycone **1a**. The ^{1}H NMR spectrum of **1a** (Table 2) showed the presence of signals corresponding to two oxygenated methines at δ_H 4.40 (1H, *d*, $J=5.3$ Hz, H-7) and 3.44 (1H, *m*, H-8), two protons of a hydroxymethyl at δ_H 3.13 and 3.29 (each 1H, *m*, H-9), three ABX aromatic protons at δ_H 6.87 (1H, *d*, $J=1.7$ Hz, H-2), 6.84 (1H, *d*, $J=8.1$ Hz, H-5) and 6.79 (1H, *dd*, $J=1.7$, 8.1 Hz, H-6) and two methoxyl groups at δ_H 3.67 and 3.68 (each 3H, *s*). The ^{13}C NMR spectral data of **1a** (Table 1) including DEPT mode measurements exhibited eleven carbon signals comprising three signals at δ_C 73.5 (*d*), 76.3 (*d*) and 63.1 (*t*) attributable to α-substituted glycerol moiety (Otsuka et al., 1989; Sugiyama et al., 1993), two signals at δ_C 56.1 (*q*) and 56.2 (*q*) for two methoxyl groups, three signals assigned for aromatic quaternary carbons; two of them are *ortho*-oxygenated at δ_C 148.4 (*s*) and 148.9 (*s*) and the third one at δ_C 136.0 (*s*) was assigned for C-1 and three aromatic C-H signals at δ_C 111.1 (*d*), 112.0 (*d*) and 119.7 (*d*). The above mentioned NMR data indicated clearly that **1a** is a phenylpropanoid having two methoxyl groups at C-3 and C-4. Comparison of the aforementioned data with those reported earlier (Ishimaru et al., 1987; Sugiyama et al., 1993) revealed that **1a** is 4-*O*-methyl guaiacylglycerol which is a new compound.

6′	61.5, *t*		61.5, *t*

[a] *s*: singlet, *d*: doublet, *t*: triplet, *q*: quartet.

1a was suggested to be an *erythro*-isomer on the basis of the coupling constant value 5.3 Hz of the benzylic proton H-7 signal at δ_H 4.40 (Braga et al., 1984; Hattori et al., 1987; Ishimaru et al., 1987; Miyase et al., 1987b; Hada et al., 1988). The downfield shift of the hydroxymethyl C-9 (+ 8.2 ppm) in **1** compared with its aglycone **1a** indicated clearly the attachment of the glucose moiety at C-9. The HMQC spectral analysis of **1** assigned significantly the correlations between each carbon and its directly attached protons while the interpretation of the proton–proton couplings were established by measurements of H–H COSY. The results of HMBC spectral analysis (Fig. 1) displayed correlation peaks between H-5 and C-1, H-6 and C-7, H-7 with both C-2 and C-9, H-8 and C-1 and the anomeric proton of the glucose moiety (H-1′) and C-9. From the above mentioned data, compound **1** was identified as 4-*O*-methyl guaiacylglycerol 9-*O*-β-glucopyranoside.

[a] Chemical shifts in ppm, *J* values in parentheses are recorded in Hz.

The HR FAB–MS of compound **2** (see Experimental section) exhibited a molecular formula $C_{17}H_{26}O_{10}$ which is the same as that of **1**. The ^{13}C NMR spectral data of **2** (Table 1) were almost similar to those of **1** except the downfield shift of C-8 of **2** to δ_C 86.9 (+12.8 ppm) with upfield shifts of C-7 to δ_C 72.5 (−0.4 ppm) and C-9 to δ_C 61.7 (−9.6 ppm) when compared with the corresponding shifts of **1**. These data indicated that the glucose moiety of **2** should be linked to the hydroxyl group of C-8. From the ^{1}H NMR spectral data of **2** (Table 2), the coupling constant value 5.6 Hz of the H-7 signal at δ_H 4.47 suggested **2** to be an *erythro*-isomer as **1** and **1a** (Braga et al., 1984; Hattori et al., 1987; Ishimaru et al., 1987; Miyase et al., 1987b; Hada et al., 1988). Enzymatic hydrolysis of **2** with β-glucosidase enzyme provided glucose and the aglycone **1a**. Consequently, compound **2** was characterized as 4-*O*-methyl guaiacylglycerol 8-*O*-β-glucopyranoside.

Compounds **3** and **4** were identified as syringin (Sugiyama et al., 1993) and benzyl alcohol glucoside (Miyase et al., 1987a) respectively by comparison of their physical properties, ^{13}C and ^{1}H NMR spectral data with those reported earlier. The structures of compounds **5** and **6** were determined as isorhamnetin-3-*O*-β-glucopyranoside-7-*O*-α-rhamno-pyranoside and quercetin-3-*O*-β-glucopyranoside-7-*O*-α-rhamno-pyranoside respectively from the results of their FAB–MS, ^{13}C and ^{1}H NMR spectral analyses and by comparison with previously reported data (Mabry et al., 1970; Markham et al., 1978; Harborne and Mabry, 1982; Agrawal, 1989; Nakano et al., 1989).

Compounds **1** and **2** are new natural products while compounds **3**–**6** are isolated for the first time from the genus *Chrozophora*.

3. Experimental

^{1}H and ^{13}C NMR (TMS as int. standard) : 400 and 100 MHz, respectively were recorded on a Jeol JNM α-400 spectrometer. FAB MS were taken on a Jeol JMS-SX 102 spectrometer by direct inlet method at an ionizing voltage of 70 eV. Optical rotations were measured with a Union PM-1 digital polarimeter. HPLC: D-ODS-5 column (20 mm i.d.×25 cm, YMC) with UV detector; flow rate of mobile phase 6 ml/min, injection vol. 0.8–1.0 ml. CC: Kieselgel 60 (70–230 mesh, Merck) and Diaion HP-20 (Mitsubishi). TLC: silica gel 60 precoated plates, F-254 and HPTLC using RP-18 precoated plates, F-254 s (Merck).

3.1. Plant material

Aerial parts of *Chrozophora obliqua* Vahl. (Tackholm, 1974) were collected from North Sinai, Egypt, in April 1998. The plant was identified by Prof. A. Fayed, Dept. of Botany, Fac. of Science, Assiut Univ., Assiut, Egypt. A voucher specimen was deposited at the Herbarium of Dept. of Pharmacognosy, Fac. of Pharmacy, Assiut Univ., Assiut, Egypt.

3.2. Extraction and isolation of compounds (*1*–*6*)

Air-dried and powdered aerial parts (800 g) were extracted three times by maceration with MeOH at room temp. The solvent free residue (120 g) was suspended in H_2O and partitioned with EtOAc. The aq. fr. (48 g) was applied to a column of Diaion HP 20 and eluted with H_2O, 50% MeOH and MeOH successively. The 50% MeOH eluate (6.2 g) was chromatographed on silica gel column using $CHCl_3$–MeOH (7:3) and $CHCl_3$–MeOH–H_2O (7:3:1, lower layer), (13:7:1) and (6:4:1) successively to give 7 fractions. Fraction 2 (620 mg) eluted with $CHCl_3$–MeOH (7:3) was subjected to RP-18 CC using 40% MeOH to give compounds **5** (453 mg) and **6** (16 mg). Fraction 3 (82 mg) eluted with $CHCl_3$–MeOH–H_2O (7:3:1, lower layer) was applied on RP-18 CC using 35% MeOH to afford compounds **3** (30 mg) and **4** (38 mg). Fraction 4 (39 mg) eluted with $CHCl_3$–MeOH–H_2O (13:7:1) was separated by HPLC using ODS column and 30% MeOH as a solvent system to afford compounds **1** (21 mg) and **2** (6 mg).

3.2.1. Compound (*1*)

4-*O*-Methyl guaiacylglycerol 9-*O*-β-glucopyranoside, white amorphous powder, $[\alpha]_D^{21}$ −48.8°C (MeOH; *c* 0.8), R_t 33 min (ODS, 30% MeOH). HR FAB–MS (negative) *m/z*:389.1481 [M–H]$^-$ $C_{17}H_{25}O_{10}$ (req. 389.1448). ^{13}C and ^{1}H NMR (DMSO-d_6): Tables 1 and 2.

3.2.2. Compound (*2*)

4-*O*-Methyl guaiacylglycerol 8-*O*-β-glucopyranoside, white amorphous powder, $[\alpha]_D^{21}$ −42.5 °C (MeOH; *c* 0.4), R_t 35 min (ODS, 30% MeOH). HR FAB–MS (negative) *m/z*:389.1432 [M–H]$^-$ $C_{17}H_{25}O_{10}$ (req. 389.1448). ^{13}C and ^{1}H NMR (DMSO-d_6): Tables 1 and 2.

3.3. Enzymatic hydrolysis of *1* and *2*

Compound **1** (10 mg) was mixed with a soln of β-glucosidase (50 mg) in 5 ml acetate buffer (pH 5.0) and the mixture was incubated with stirring at 37 °C for 48 h. The reaction mixt. was then extracted with Et_2O (4×20 ml). The combined Et_2O layers were evapd and the residue was repeatedly crystallized from MeOH to yield aglycone **1a** (4.3 mg) as colourless crystals, mp 171–172°, $[\alpha]_D^{21}$ −32.1°C (MeOH; *c* 0.28). ^{13}C and ^{1}H NMR (DMSO-d_6 Tables 1 and 2). In the aq. phase, glucose was identified by TLC comparison with authentic substance. A sample of compound **2** (4 mg) was hydrolysed by β-glucosidase in the same way as **1** to give **1a** (1.4 mg).

Received 2 January 2001; received in revised form 14 May 2001

Abstract

Two new quaternary indole alkaloids 5′,6′-dehydroguiachrysine (**1**) and 5′,6′-dehydroguiaflavine (**2**) were isolated from *Strychnos guianensis* stem bark. Their structures were determined by analysis of spectral data. Their inhibitory effects on neuromuscular transmission are also reported and compared to that of other quaternary alkaloids. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Strychnos guianensis* (Aubl.) Mart.; Loganiaceae; Quaternary indole alkaloids; Loganiaceae; 5′,6′-Dehydroguiachrysine; 5′,6′-Dehydroguiaflavine; 2D NMR; Curare

1. Introduction

In the course of our study on phytochemical investigations of the stembark of *Strychnos guianensis* (Penelle et al., 1999, 2000) the first botanically identified plant of South American curare (Bisset, 1992), we describe the isolation and structural determination of two new quaternary indole alkaloids: 5′,6′-dehydroguiachrysine (**1**) and 5′,6′-dehydroguiaflavine (**2**). Furthermore, we present the inhibitory effect of these new compounds and known compounds such as guiachrysine (**3**), guiaflavine (**4**), 9-methoxy-N_b-methylgeissoschizol (**5**) and C-alkaloid O (**6**) on neuromuscular transmission.

2. Results and discussion

After elimination of the tertiary alkaloidal fractions, the crude quaternary extract, precipitated with Mayer's reagent and converted to the chloride form, was separated by MPLC on a Lichrospher RP select B column using a gradient of MeCN (B) in an aq. soln. of heptanesulfonic acid (sodium salt) (A) adjusted to pH 2 with phosphoric acid. The initial fractions when the gradient was 25% B in A contained 5′,6′-dehydroguiachrysine (**1**) while the next fractions when the gradient was 30–35% B in A yielded 5′,6′-dehydroguiaflavine (**2**). These fractions, also containing guiachrysine (**3**) and guiaflavine (**4**), respectively, were submitted to column chromatography on cellulose and eluted with the system C of Karrer and Schmid (methyl ethyl ketone saturated with water and 1–3% MeOH) (Schmid et al., 1952) to afford pure products.

5′,6′-Dehydroguiachrysine (**1**) is an asymmetrical bisindole quaternary alkaloid that gave a blue-green color with ceric sulfate-sulfuric acid reagent, as for guiachrysine (**3**), guiaflavine (**4**), guianensine (Quetin-Leclercq et al., 1995). The orange color of **1** is consistent with its UV-visible spectrum showing maxima at 205, 258, 279, 328 and 421 nm. This highly conjugated chromophore is similar to that of **3**, but differs from it by bathochromic shifts observed in alkali. These bathochromic shifts

(6)

suggested an anhydronium (β-carbolinium) moiety (Gribble, 1988) as for guianensine (Quetin-Leclercq et al., 1995).

The presence of a flavopereirine-type moiety in the molecule as suggested by the UV spectra, was confirmed by ^{1}H NMR spectra. Indeed, four deshielded protons at $\delta > 8$ (two singlets and two doublets) could correspond to the pyridinium protons of rings C and D of a flavopereirine moiety (Giri et al., 1984). So, in the aromatic region of the ^{1}H NMR spectrum of **1**, two deshielded pyridine protons at δ 8.7 and 8.99, due to H-14′ and H-21′, were observed, and therefore, the shifts of C-14′ and C-21′ could be established from the HSQC spectrum at δ 121.6 and 134.8, respectively. Two other deshielded protons at δ 8.49 and 8.75 due to H-6′ and H-5′ were observed. The shifts of C-5′ and C-6′ could be established from the HSQC at δ 127.5 and 118.6, respectively. In the ^{1}H–^{1}H COSY spectrum of the aromatic region, one set of four aromatic protons was observed from an unsubstituted indole and another set of three protons from a

C-9 substituted indole nucleus was also apparent. The protons at δ 7.61 (*t*), 7.34 (*d*) and 6.91 (*d*) could be attributed to a corynanium portion of **1**. Indeed, comparison with the spectra of **3** and **4** indicated that the methoxyl group, corresponding to the three-proton singlet appearing at δ 4.14 ppm, could be at C-9 of this corynanium unit (Verpoorte et al., 1984). Consequently, the four remaining aromatic protons at δ 7.51 (*d*), 7.38 (*t*), 7.18 (*d*) and 7.04 (*t*) were assigned to a strychnan ring as for **3**. The protonated aromatic carbons were deduced by their direct correlations observed in the HSQC spectra (Table 1). In addition, the HMBC spectrum allowed the assignments made for the quaternary carbons. The H-11′ signal correlated to C-9′ and C-13′ (δ 158.0 and 144.3), while H-10′ correlated to C-8′, C-9′ and C-12′ (δ 112.8, 158.0 and 106.1). H-12′ was coupled to C-8′ and C-10′ (δ 112.8 and 102.9). Similar correlations were observed for the indoline ring: H-2, H-9 and H-11 correlated to C-13

[a] Chemical shift (δ) in ppm from TMS, multiplicities and coupling constants in Hz are in parentheses, overlapped signal *J* unresolved.
[b] Chemical shift (δ) in ppm from TMS.
[c] Correlations from H to the indicated carbon.

(δ 146.4), while H-10 and H-12 correlated to C-8 (δ 132.3), as shown in Table 1.

Examination of its NMR spectra revealed for the corynanium portion of **1**, one methylene group at δ 25.6 corresponding to C-19′. In the ^{1}H NMR spectrum, one three-proton singlet observed at δ 3.37 corresponded to N_b-CH_3. The methylene unit H_2-19′ was clearly coupled to the methyl protons H_3-18′ (δ 1.49). In the HMBC spectrum, H_3-18′ correlated to C-19′ and C-20′ (δ 25.6 and 139.1). The other half of the structure was also deduced from NMR data. The chemical shifts of the protons and the carbons (Table 1) support the structure of a strychnan skeleton with four methylene groups (C-5, C-6, C-14 and C-21) and five methine groups (C-2, C-3, C-15 and C-17). The chemical shifts of C-18, C-19 and C-20 (δ 58, 136.0, and 129.7) were in agreement with an 18-hydroxy group and N_b-methyl as for **3**. The assignments of H-17 at δ 4.74 and C-17 at δ 70.3 were consistent with a 17-hydroxy group (Macomber, 1998). The linkage between the two moieties of 1 was deduced from the presence of a low field singlet at δ 7.38 corresponding to H-17′ (Massiot et al., 1983a). H-17′ correlated not only to C-15′ (δ 149.5) but also to C-2 (δ 70.2), C-13 (δ 146.4) and C-17 (δ 70.3). The deshielding of the isolated H-17′ enamine signal could be explained by the presence of a highly conjugated chromophore (Caprasse et al., 1984). As compared with the spectrum of strychnochrysine (Gadi-Biala et al., 1998) and **3** (Penelle et al., 2000), the C-17 signal (δ 70.3) is similar but quite different from the signal of C-17 observed for **4** (δ 79.3). This fact confirms the opening of the seven-membered ring which is observed in longicaudatine (Massiot et al., 1983b) and in **4** (Penelle et al., 1999). The signal for C-16 is shifted downfield (δ 49.8). The stereostructure still must be considered. The positive Cotton effect in the 240–250 nm region of the CD spectrum suggests the configurations of C-2β (2*S*) and C-7β (7*R*) (Klyne et al., 1966). The 15α-H (15*R*) and 3α-H (3*S*) configurations are strictly dependent on that of C-7 (Klyne et al., 1968; Klyne and Buckingham, 1974). Moreover, examination of molecular stereomodels Dreiding confirms that hypothesis. Furthermore, N_b-methyl is deduced to be α by interpretation of NOESY spectra. Indeed, a connection between the N_b-methyl and H-3 is observed. The establishment of the C-16 configuration of **1** is critical, because the influence of the tetrahydropyridinic linkage ring is difficult to determine. The large coupling constant observed between H-16 and H-2 (11 Hz) as well as the absence of connection between these protons in NOESY spectra are consistent with the configuration 16α as in isoretuline (Tavernier et al., 1978). The configuration of H-17 relative to H-16 was deduced as *trans* from the presence of a large coupling constant (10 Hz) between H-16 and H-17 in the 2D-homonuclear correlation NMR spectrum and the lack of connection in NOESY spectrum. This fact indicated an antiperiplanar position of both protons. This H-17β (17*R*) configuration is similar to that of longicaudatine Y (Massiot et al., 1983a), guianensine (Quetin-Leclercq et al., 1995), strychnochrysine (Gadi-Biala et al., 1998), 3′,4′,5′,6′-tetradehydrolongicaudatine Y (Frédérich et al., 1998) and **3** (Penelle et al., 2000) but opposite to strychnine (Blechta et al., 1994) and **4** (Penelle et al., 1999). The orientation of the side-chain is proposed to be *E*, because of the absence of connection in the NOESY spectrum between H-18 and H-21A and H-21B.

5′,6′-Dehydroguiaflavine (**2**) is also an asymmetrical bisindole quaternary alkaloid that gave a blue green color with the ceric sulfate-sulfuric acid reagent. The orange-brown color of **2** is consistent with its UV-visible spectrum showing maxima at 207, 257 and 432 nm. This highly conjugated chromophore is similar to that of **4**, but differs from it by bathochromic shifts observed in alkali. These bathochromic shifts suggested an anhydronium (β-carbolinium moiety) as for compound **1**. The presence of a 9-methoxy-flavopereirine-type moiety in the molecule, as suggested by the UV spectra was confirmed by ^{1}H and ^{13}C NMR spectra, as for compound **1** (see Table 2). The ^{1}H–^{1}H COSY spectrum of the aromatic region led us to detect one set of four benzenic protons from an unsubstituted indole and another set of three protons from 9 substituted indole nucleus. The protons at δ 7.55 (*t*), 7.3 (*m*) and 6.85 (*d*) can be attributed to the corynanium part. The four remaining aromatic protons at δ 7.53 (*d*), 7.29 (*t*), 7.08 (*d*) and 7.02 (*t*) belong to the strychnan ring. The protonated aromatic carbons were assigned by their direct correlations observed in the HSQC spectra. The HMBC spectrum confirms these attributions and allows the assignments of the quaternary carbons. Examination of NMR spectra reveals for the corynanium part, one methylene group at δ 25.3 assigned to C-19′. The methylene unit H_2-19′ was clearly coupled to the methyl protons H_3-18′ (δ 1.44). The HMBC spectrum showed H_3-18′ correlated to C-19′ and C-20′ (δ 25.3 and 138.8). The other half of the structure was also deduced from NMR data. The chemical shifts of the protons and the carbons (Table 2) support the structure of a strychnan skeleton with a N_b-methyl group (δ 55.4), four methylene groups (C-5, C-6, C-14, C-18 and C-21) and five methine groups (C-2, C-3, C-15, C-16 and C-17). The chemical shifts of the C-19–C-20 double bond (δ 137.1 and 135.1) were similar to those of strychnine methiodide (Wenkert et al., 1978) and **4** (Penelle et al., 1999). The chemical shift of H-17 at δ 5.1 is consistent with a linkage to an oxygen atom (Macomber, 1998). Moreover, H_2-18 showed long-range correlations in the HMBC spectrum to C-19, C-20 and C-17 and confirmed the presence of a seven-membered ring in **2**. The linkage between the two moieties of **2** was deduced from the presence of a lowfield singlet at δ 7.4 (Massiot et al., 1983a) which correlated to C-15′ and C-16′ (δ 149.8 and 116.4), and also to C-2 and C-17

(δ 60.6 and 80.0). The stereostructure still must be considered. The configuration of H-2β- (2*S*) and C-7β- (7*R*) are deduced from positive CD in the spectral region of 240–250 nm (Klyne et al., 1966). As shown by the examination of molecular stereomodels Dreiding, the H-3α (3*S*) and H-15α (15*R*) configuration are strictly dependent on the configuration of C-7 (Klyne and Buckingham, 1974). Furthermore, N_b-methyl is deduced to be α by interpretation of NOESY spectra. Indeed, a connection between the N_b-methyl and H-3 is observed. H-16α (16*R*) configuration has been deduced from the same experiments as those depicted for **1**. On the other hand, the configuration of H-17 was deduced from the presence of a very weak coupling between H-17 and H-16 in the 2D homonuclear correlation. The dihedral angle ca. 90°, observed in the dreiding stereomodel between H-16 and H-17, was in good agreement with a H-17α (17*R*) configuration as in longicaudatine (Massiot et al.,

1983b; Mukherjee et al., 1997) and **4** (Penelle et al., 1999). Moreover, a connection between these two protons is observed in NOESY spectra.

The close structural relationship of **1** and **2** to **3** and **4**, respectively, makes it necessary to suggest the possibility that **1** and **2** could be artifacts formed by dehydrogenation during work up and isolation. Little is known about the impact of storage and laboratory processing on the stability of *Strychnos guianensis* alkaloids. However, there are indications that samples of stem bark of at least some other American *Strychnos* species dried immediately after the collection retain the alkaloids well in long storage (Krukoff, 1965). In the framework of our studies, an HPLC chromatography carried out on these quaternary alkaloids indicated the same chromatographic behavior as the crude quaternary alkaloids isolated 13 years earlier (see HPLC analysis). Nevertheless, newer trials are required to fully determine the place of auto-oxidation and/or degradation of alkaloids initially present in freshly collected material, and to rule eventually out the possibility of artifact formation.

We have compared the effects of a crude quaternary extract of *Strychnos guianensis* with isolated compounds **1**–**6** as well as with a Venezuelan calabash curare (based on *Strychnos toxifera*) on neuromuscular transmission from isolated mouse hemidiaphragm preparations. Briefly, twitch height evoked by phrenic nerve stimulation (see Experimental) was evaluated before and after the addition to the medium of different concentrations of the compounds.

Although all the compounds tested induced a dose-dependent decrease in twitch height, marked differences were evident in their respective potency. The inhibitory concentration that reduced in 50% indirectly-elicited muscle contraction (IC_{50}) was calculated from the dose–response curves. Thus, Compound **3** with an IC_{50} of about 12.5 μM was found to be the most potent of the pure quaternary alkaloids isolated from *Strychnos guianensis*. The Venezuelan calabash curare was the most potent; its IC_{50} was about 6.5 μM. Compound **4** (~25.5 μM), compound **1** (~21.5 μM) and compound **2** (~24 μM) had an IC_{50} close to the IC_{50} of a crude quaternary extract of *Strychnos guianensis* (~22.5 μM). On the other hand, the monomeric alkaloids as 9-methoxy-N_b-methylgeissoschizol (**5**) and C-alkaloid O (**6**) clearly display a weaker activity than the dimeric alkaloids. Indeed, the IC_{50} of compounds **5** and **6** were near 120 and 290 μM, respectively. So the ethnobotanical use of *S. guianensis* in the preparation of arrow poisons could be partially explained by the presence of dimeric alkaloids as compounds **1**–**4**. Interestingly, 3,4-diaminopyridine (40–50 μM), after a latency of about 10–30 min, greatly augmented indirectly elicited twitches and completely reversed the neuromuscular blockade caused by the various compounds. Because 3,4-diaminopyridine is known to increase quantal acetylcholine release from motor nerve terminals (Molgo, 1982) it is deduced that the various compounds tested are competitive inhibitors of post-synaptic nicotinic acetylcholine receptors.

3. Experimental

3.1. Instruments

UV and visible spectra were recorded on a Kontron Uvikon 922 spectrophotometer. The CD spectra were measured with a Jobin Yvon CD6 dichrograph. The IR spectra were recorded as a KBr pellet on a Perkin-Elmer 1750 FTIR spectrometer. 1D and 2D NMR, ^{13}C, ^{1}H–^{13}C short- and long-range correlation HSQC, and HMBC spectra were obtained at 400/100 and 500/125 MHz on a Bruker AMX-400 and Bruker AMX-500 spectrometers. The chemical shifts are recorded in δ (ppm) based on δ TMS = 0, and the coupling constants (J) are in Hertz. The ESIMS were recorded on LC MS/MS VG Quattro 2 micromass tandem quadrupole (VG analytical, Manchester). The HRESIMS were recorded on a Q-TOF II micromass spectrometer (Manchester).

Analytical TLC was performed in precoated Si gel F_{254} (Art. 1.05735, E. Merck) plates. After development, the dried plates were examined under short-wave (254 nm) or long-wave (366 nm) UV light and sprayed with 1% ceric sulfate in 10% H_2SO_4. LiChrospher 60 RP-select B, 12 μm (Art. 1.19655.0100, E. Merck) was selected as stationnary support for the first purification, while Whatman CC31 Cellulose was used for the last purification. All solvents used were analytical grade (E. Merck).

3.2. Plant material

Stem bark of *Strychnos guianensis* (Aubl.) Mart. was collected in April, 1988 by one of us (L. A.) at Manaus, near Rio Taruma in Brazilian Amazonia. The stem bark was immediately air-dried in Brazil before being stored in Belgium at a temperature of 15 °C. Dr. A.J.M. Leeuwenberg (Wageningen) confirmed identification of the plant; voucher specimens (INPA herb. No. 150,295) are deposited at the INPA (Instituto Nacional de Pesquisas da Amazônia) at Manaus, at the Pharmaceutical Institute at Liège (Belgium), and at the Agricultural University at Wageningen (The Netherlands). Moreover, some preliminary chromatographic experiments have shown that the quaternary alkaloids gave similar and striking color reactions with respect to crude alkaloids described in the early work of Marini-Bettolo (Marini-Bettolo and Iorio, 1956).

3.3. Extraction and isolation

The powdered stem bark (600 g) was macerated for 24 h with MeOH–HOAc (99:1) and percolated with the

same mixture. After concentration of the extract under reduced pressure, precipitation by addition of H_2O and filtration, the aq. soln. was then extracted with $CHCl_3$. After separation of $CHCl_3$, the aq. soln. was basified to pH 10–11 and again extracted with $CHCl_3$. During this last operation, a ppt. was obtained. The $CHCl_3$ extracts contained tertiary alkaloids and the terminal aq. soln. quaternary alkaloids. This last soln was acidified with 5 N HCl to pH 5 and precipitated by Mayer's reagent (Evans, 1996). The ppt. was then dissolved in $Me_2CO-EtOH-H_2O$ (6:2:1) and the alkaloids converted to the chlorides by passage through an Amberlite® IRA-420 column and concentration under reduced pressure to give 6.7 g residue. A part of this residue (2 g) was chromatographed over a Lichrospher® RP-select B Merck column. The mobile phase was a mixture of two solvents; solvent A was an aq. soln. of heptanesulfonic acid (sodium salt) (1 g in 420 ml) adjusted to pH 2 with phosphoric acid, and solvent B was MeCN (Gadi-Biala et al., 1996). Because of the complexity of this extract, a linear gradient system of elution was selected: from 15 to 35% B in A. After TLC controls, using the solvent system: MeOH–25% aq. MeCOONa soln.–Me_2CO (65:35:20) (Paesen et al., 1994), the eluates of similar profiles were combined and precipitated by Mayer's reagent. Each ppt. was dissolved in $Me_2CO-EtOH-H_2O$ (6:2:1) and the alkaloids converted to the chlorides by passage through an Amberlite® IRA-420 column. Fractions containing 5′,6′-dehydroguiachrysine (12 mg) (detected when the gradient was 25% B in A) were pooled and submitted to column chromatography on cellulose, eluted with system C of Karrer and Schmid (methyl ethyl ketone saturated with water and 1–3% MeOH) (Schmid et al., 1952). This purification led to the isolation of 12 mg of pure compound **1**. Fractions containing 5′,6′-dehydroguiaflavine (**2**) (detected when the gradient was 30–35% B in A) were pooled and submitted to column chromatography on cellulose. This last purification afforded the pure compound **2** (20 mg).

3.4. Identification of compound *1*

Compound **1**: orange-brown colored amorphous powder, on TLC immediately gives a blue-green color with $Ce(SO_4)_2/H_2SO_4$; UV (MeOH) λ_{max} (nm) (log ε) 205 (4.38), 258 (4.29), 279 (4.07), 328 (3.87), 421 (3.98); (MeONa) 208 (4.33), 281 (4.21), 384 (3.92), 455 (3.72); CD_{MeOH} ($\Delta\varepsilon_{nm}$) $\Delta\varepsilon_{200}$ −7.115; $\Delta\varepsilon_{210}$ −9.59; $\Delta\varepsilon_{228}$ 0.10; $\Delta\varepsilon_{239}$ −0.85; $\Delta\varepsilon_{272}$ 4.01; $\Delta\varepsilon_{286}$ 0.40; $\Delta\varepsilon_{318}$ 8.44; $\Delta\varepsilon_{436}$ −3.06; $\Delta\varepsilon_{500}$ −0.41;IR (KBr) ν_{max} 3416, 2924, 2853, 1633, 1587, 1481, 1462, 1405, 1385, 1363, 1321, 1283, 1249, 1203, 1163, 1100, 1060, 897, 874 and 736 cm^{-1}; ^1H and ^{13}C NMR in Table 1; ESIMS m/z 626 (45) $[M]^+$ corresponding to $C_{40}H_{42}N_4O_3$, 625 (100) $[M-H]^+$, 607 (50) $[M-H-H_2O]^+$, 313 (80) $[M]^{2+}$. HRESIMS m/z 625.3179 (calc. for $C_{40}H_{41}N_4O_3$, 625.3178).

3.5. Identification of compound *2*

Compound **2**: orange-brown colored amorphous powder which gives an intense green fluorescence in MeOH at 366 nm, on TLC gives a blue–green color with $Ce(SO_4)_2/H_2SO_4$; UV (MeOH) λ_{max} (nm) (log ε) 207 (4.49), 257 (4.35), 432 (4.11); (MeONa) 207 (4.58), 259 (4.21), 284 (4.22), 392 (4.01), 454 (3.86); CD_{MeOH} ($\Delta\varepsilon_{nm}$) $\Delta\varepsilon_{200}$ −1.22; $\Delta\varepsilon_{211}$ −0.16; $\Delta\varepsilon_{216}$ −0.43; $\Delta\varepsilon_{221}$ −0.17; $\Delta\varepsilon_{225}$ −0.26; $\Delta\varepsilon_{234}$ −0.036; $\Delta\varepsilon_{248}$ −0.40; $\Delta\varepsilon_{265}$ 0.30; $\Delta\varepsilon_{289}$ −0.02; $\Delta\varepsilon_{318}$ 0.47; $\Delta\varepsilon_{351}$ 0.10; $\Delta\varepsilon_{420}$ 0.36; $\Delta\varepsilon_{500}$ 0.043; IR (KBr) ν_{max} 3409, 2965, 2927, 1641, 1583, 1481, 1461, 1402, 1351, 1258, 1201, 1100, 1030, 964, 898, 754 cm^{-1}; ^1H and ^{13}C NMR in Table 2; ESIMS m/z 608 (45) $[M]^+$ corresponding to $C_{40}H_{40}N_4O_2$, 607 (100) $[M-H]^+$, 304 $[M]^{2+}$ (18). HRESIMS m/z 607.2849 (calc. for $C_{40}H_{39}N_4O_2$, 607.3073).

3.6. Biological material

Left and right hemidiaphragm muscles with their associated phrenic nerves were isolated from Swiss–Webster mice (20–25 g) killed by dislocation of the cervical vertebrae followed by immediate exsanguination. The two hemidiaphragms were separated and each was mounted horizontally in a Rhodorsil®-lined Perspex chamber (5 ml volume). For twitch tension recordings, one of the tendons was tied with a silk thread via an adjustable stainless steel hook to an isometric transducer (FT03 Grass Instrument Division, West Warnick, RI, USA), and the other end of the hemidiaphragm muscle was pinned to the Rhodorsil-lined chamber. The phrenic nerve was stimulated at 0.1 Hz via a suction microelectrode, adapted to the diameter of the nerve, with supramaximal current pulses of 0.1 ms duration delivered through an isolation unit of a S48K Grass stimulator. The resting tension was adjusted to about 2 g for each preparation tested to obtain a maximal contractile response upon supramaximal nerve stimulation.

Nerve-evoked muscle twitch signals recorded with the isometric transducer were amplified, collected and digitized with the aid of a computer equipped with an analogue and digital I/O interface board (DT2821, Data Translation MA, USA) at a sampling rate of 2.5 kHz. Computerized data acquisition and analysis was performed with a program kindly provided by Dr. John Dempster (University of Strathclyde, Scotland).

The phrenic-nerve hemidiaphragm muscle preparation was superfused with a physiological solution of the following composition (mM) : NaCl, 154; KCl, 5; $CaCl_2$, 2; $MgCl_2$, 1; Hepes buffer, 5; glucose, 11. The solution gassed with pure O_2 had a pH = 7.4. Drugs to be tested were applied directly to the organ bath at concentrations indicated in the Results section. Usually, 10 min were allowed for drug equilibration between the different concentrations of a given compound tested.

3.7. HPLC analysis

The stationary phase was an ALTIMA C8 column (5 μm, 250×4.6) and sodium laurylsulfonate (2.18 g) in a mixture of methanol/acetonitrile/aq. soln. of potassium dihydrogen phosphate (6.82 g/l) (2:4:4) at a flow rate of 1 ml/min was used as eluent. Alkaloids were detected at 250 and 420 nm by a diode-array detector. Retentions times (in min) of alkaloids **1**–**4** appeared, respectively, at 45, 54, 39 and 46 min. The HPLC of a crude quaternary extract of *Strychnos guianensis*, obtained in 1988 and stored in a cool place, protected from light and oxygen, indicated that it contained these alkaloids because, as they were identified at each retention time, respectively.

Acknowledgements

We are indebted to Professor Burger, Dr. D. Jeannerat and Mr. A. Pinto (Department of Organic Chemistry, University of Geneva, Switzerland) for recording the NMR spectra. The allocation of time in the regional high-field NMR facilities in Lausanne-Dorigny is also gratefully acknowledged. The authors thank Professor E. De Pauw, Professor J. De Graeve, Mr. J.-C. Van Heugen (University of Liège) for providing the mass spectra and Professor P. Colson (Macromolecular Chemistry, University of Liège) for measuring the CD. This work was supported by the "Fondation Léon Frédéricq" and by the Belgian Fund for Scientific Research.

Received 26 September 2000; received in revised form 23 March 2001

Abstract

The indolopyridoquinazoline alkaloid, 3-hydoxyrutaecarpine, was isolated from *Leptothyrsa sprucei*, along with 8-methoxypsoralen, 5-methoxypsoralen, imperatorin, isoimperatorin, kaempferol 3-*O*-α-L-rhamnopyranoside, clematine and cnidioside B. The usefulness of the gradient ^{1}H–^{15}N HMBC NMR spectroscopy in the structure elucidation of 3-hydroxyrutaecarpine is noted.

Keywords: *Leptothyrsa sprucei*; Rutaceae; Alkaloids; 3-Hydoxyrutaecarpine; ^{15}N NMR

1. Introduction

Leptothyrsa sprucei Hooker f. is a monotypic genus plant belonging to the family Rutaceae. A phytochemical investigation of its twigs and leaves has resulted in the isolation of a new indolopyridoquinazoline alkaloid, 3-hydoxyrutaecarpine (**1**), along with known compounds that were identified by their spectral data as 8-methoxypsoralen (Duddeck and Kasier, 1982), 5-methoxypsoralen (Duddeck and Kasier, 1982), imperatorin (Lee and Soine, 1969), isoimperatorin (Lee and Soine, 1969), kaempferol 3-*O*-α-L-rhamnopyranoside (afzelin) (Matthes et al., 1980; Fossen et al., 1999), clematine (Chen et al., 1993) and cnidioside B (Yahara et al., 1993). The structure elucidation of **1** was facilitated by the powerful gradient ^{1}H–^{15}N HMBC NMR spectroscopy (Farley et al., 1997).

2. Results and discussion

Compound **1** was obtained as colorless needles, mp 280–282°. Its molecular formula was established as $C_{18}H_{13}N_3O_2$ by a combination of high resolution ESIMS and ^{13}C NMR spectra. The presence of three nitrogens in **1** was confirmed by the ^{1}H–^{15}N HMBC experiment (Farley et al., 1997), which indirectly detected three nitrogen signals at δ 124.8, 155.0 and 224.9. The IR spectrum of **1** showed absorption of a conjugated carbonyl group at 1652 cm^{-1}. The ^{1}H NMR spectrum, supported by a DQF-COSY experiment, indicated the presence of one 1,2-substituted aromatic ring, two coupled methylenes, one 1,2,4-substituted aromatic ring and two phenolic hydroxy or amino groups (Table 1). The nine carbon signals bearing protons were determined by the HMQC experiment, which establishes one bond correlations (Table 1). The remaining nine quaternary carbon signals were assigned based on long range H/C correlations from a ^{1}H–^{13}C HMBC experiment ($J_{CH}=10$ Hz) (Table 1). With the aid of a ^{1}H–^{15}N HMBC experiment ($J_{NH}=5$ Hz), which provided one, two and three bond H/N correlations, partial structures A–C of **1** were readily constructed, as shown in Fig. 1. Further analysis of the HMBC correlations between the methylene proton at δ 3.14 (*t*, $J=6.8$ Hz, H-8) and the two quaternary carbons at δ 116.6 (C-8a) and 125.0 (C-9a) indicated that the junction of partial structures A/B was C-8→C-8a and C-14a→C-13a. The HMBC correlation between the methylene proton at δ 4.41 (*t*, $J=6.8$ Hz, H-7) and the carbonyl carbon at δ 160.3 (C-5) confirmed that the junction of partial structures B/C should be C-5→N-6 and N-14→C-14a.

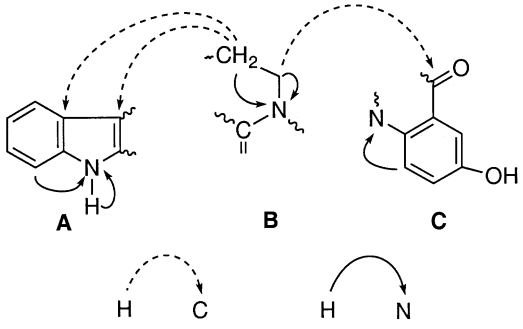

Fig. 1. Partial structures **A**–**C** of **1** based on HMBC experiments.

Based on the above evidence, the structure of **1** was established as 3-hydroxy-8,13-dihydro-indolo[2′,3′:3,4] pyrido[2,1-b]quinazolin-5(7*H*)-one, which has been given the trivial name of 3-hydroxyrutaecarpine. Compound **1** and the seven known compounds that were isolated were tested for antifungal and antibacterial activity by methods previously described (Li et al., 1999) and were found to be inactive.

The ^1H–^{15}N HMBC experiment employed in this study has been demonstrated to be powerful in the structure elucidation of **1**. It not only clearly indicates the number of nitrogens in **1**, but also gives C/N connectivity information as well. For compounds containing several nitrogen atoms, the ^1H–^{15}N HMBC experiment can significantly complement the conventional ^1H–^{13}C HMBC experiment to construct molecular skeletons.

It is interesting to note that rutaecarpine and similar indolopyridoquinazoline alkaloids only occur in rutaceous plants (Mester, 1983). The isolation of 3-hydroxyrutaecarpine, coumarins, flavonoids, and benzofuran derivatives from this key monotypic genus plant might be of significance regarding the chemotaxonomy of the family Rutaceae.

3. Experimental

3.1. General

Melting points: uncorr. Spectra were recorded on the following apparatus: UV, Hewlett Packard 8453 spectrometer; IR, ATI Mattson Genesis Series FTIR; ESI–FTMS, Brüker-Magnex BioAPEX 30es ion cyclotron high resolution HPLC-FT spectrometer; NMR, Brüker Avance DRX-400 (400 MHz) or DRX-500 (500 MHz). Proton and carbon chemical shifts are relative to the internal standard TMS. Nitrogen (^{15}N) chemical shifts are reported relative to liquid ammonia using a nitromethane chemical shift of δ 380.2. DQF-COSY, HMQC, gradient ^1H–^{13}C HMBC ($J=10$ Hz) and gradient ^1H–^{15}N HMBC ($J_{NH}=5$ Hz) were performed with standard pulse programs on DRX-500. Column chromatography was carried out using normal phase silica gel (40 μm, J. T. Baker) or reversed-phase silica gel (RP-18, 40 μm, J. T. Baker). TLC was performed on silica gel sheets (Alugram® Sil G/UV_{254}, Macherey-Nagel, Germany) and reversed-phase plates (RP-18 F_{254S}, Merck, Germany).

3.2. Plant material

The twigs and leaves of *Leptothyrsa sprucei* Hooker f. were collected in Peru in June, 1995. A voucher specimen of this plant is deposited at the National Center for Natural Products Research (Voucher No. IBE 11340).

3.3. Extraction and isolation

Dried twigs and leaves (180 g) were ground and the powdered material was percolated with 95% EtOH (3 l × 3). Removal of the solvent by evaporation under vacuum at 45 °C yielded an EtOH extract (8.5 g), which was dissolved in MeOH–H_2O (9:1, 500 ml) and defatted with hexane (500 ml × 4). To the MeOH–H_2O layer was added 100 ml of H_2O and the resulting solution was

further partitioned with $CHCl_3$ (500 ml). The $CHCl_3$ layer was evaporated to dryness under vacuum at 45 °C to give a residue (2.1 g) that was applied to a silica gel (40 g) using a stepwise gradient solvent system consisting of $CHCl_3$–MeOH (0–100%, a total of 3 l) to yield pooled fractions A–K. Fraction A (430 mg) was loaded onto to a Supelco Discovery RP-18 tube (2 g) and washed with aqueous MeOH. The 80% MeOH eluate (50 ml) was evaporated to give a residue (272 mg), which was further subjected to RP-18 (30 g) chromatography using 70–80% MeOH (2 l) to yield 8-methoxypsoralen (43.8 mg), 5-methoxypsoralen (20.1 mg), imperatorin (8.3 mg) and isoimperatorin (16.0 mg). Fraction B (21.1 mg) was crystallized with MeOH to afford **1** (7.8 mg). Fraction G (80 mg) was applied to a RP-18 column (20 g), using 50% MeOH (500 ml) to yield kaempferol 3-*O*-α-L-rhamnopyranoside (8.8 mg). Fraction I (170 mg) was subjected to RP-18 chromatography (20 g) using an aqueous MeOH gradient (0–100%, a total of 2.7 l) to give clematine (7.5 mg) and cnidioside B (3.8 mg).

3.4. 3-Hydroxyrutaecarpine (*1*)

Colorless needles (MeOH), mp 280–282°; UV λ_{max}^{MeOH} nm (log ε): 220 (4.62), 230 (4.61), 340 (4.66); IR ν_{max}^{KBr} cm^{-1}: 3319, 1652, 1601, 1487, 1314, 989, 828; NMR data: see Table 1; ESI–MS *m*/*z*: 304.1069 {calcd for [M($C_{18}H_{13}N_3O_2$)•H], 304.1086}.

Received 7 May 2001; received in revised form 19 June 2001

Abstract

Two new benzoquinones, heliotropinones A and B, have been isolated from the aerial parts of *Heliotropium ovalifolium*. Their structures were elucidated by spectrometric methods including high resolution electrospray ionization (ESI-HR), EI mass spectrometry, ^{1}H, ^{13}C and 2D NMR experiments. The two quinones demonstrated antifungal activities against *Cladosporium cucumerinum* and *Candida albicans* as well as antibacterial activity against *Bacillus subtilis*. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Heliotropium ovalifolium*; Boraginaceae; Quinones; Heliotropinone A-B; *Cladosporium cucumerinum*; *Candida albicans*; *Bacillus subtilis*

1. Introduction

Since the hypothesis of a plant intoxication was suggested to explain the flaccid trunk paralysis occurring in free-ranging elephants on the southern shore of Lake Kariba in Zimbabwe (Kock et al., 1994), we have focused our investigations on the flora of Fothergill Island.

After observation of the elephant feeding habit,*Heliotropium ovalifolium* Forsk. (Boraginaceae) was suspected to be possibly responsible for the floppy trunk syndrome. This herbaceous plant is known to contain pyrrolizidine alkaloids (Tiwari and Masood, 1977; Mohanraj et al., 1981; Rizk et al., 1991), and has already been reported to be responsible for intoxications of horses, goats and sheep (Abu et al., 1982; Creeper et al., 1999). As there was no evidence of liver injuries in culled elephants (Kock et al., 1994), investigations were not focused primarily on pyrrolizidine alkaloids.

Methanol and dichloromethane extracts from the aerial parts of *H. ovalifolium* have thus been tested for their neurotoxic properties on rat neuronal cell lines, (P. Jenner, Neurodegenerative Diseases Research Center, King's College London, personal communication) and multidimensional neuropharmacological tests concerning behavioral, neurological, and autonomic patterns (P. Gómez-Serranillos, Departamento de Farmacologia, Universidad Complutense, Madrid personal communication), but no evidence of toxicity could be attributed to these extracts.

Besides these assays, the same extracts were also tested in routine screening against different microorganisms. The dichloromethane extract of *H. ovalifolium* showed activities against the phytopathogenic fungus *Cladosporium cucumerinum* (Homans and Fuchs, 1970). As no further chemical nor biological studies have previously been reported on this plant, the investigation of the active extract of *H. ovalifolium* was undertaken.

2. Results and discussion

The active dichloromethane extract was separated by column chroatography on silica gel into fractions A–L. The antifungal activity against *C. cucumerinum* was found to be concentrated in fraction J. A HPLC/DAD analysis of this fraction showed the presence of compounds whose UV spectra appeared to be characteristic of quinone derivatives (Thomson, 1971). Successive purification of fraction J by reversed phase medium pressure chromatography and semi-preparative chromatography using a C-18 radial compression column led to the isolation of the active compounds **1** and **2** (Fig. 1).

On the basis of the high resolution electrospray ionization mass (HR–ESI–MS) analyses, a molecular formula

of C_{18} H_{22} O_4 was established for compounds **1** and **2**. In both cases, the existence of a quinonic moiety suggested by the UV spectra was confirmed by the presence of two ketonic functions located around δ 184.0 (C-1 and C-4) and of two quaternary carbons around δ 144.5 (C-2 and C-3) in the ^{13}C NMR Spectrum (Table 2). Long-range correlations observed in the HMBC spectra of **1** and **2** between these two latter signals and the ^{1}H NMR resonance seen at δ 4.00 (6H), indicated a substitution of C-2 and C-3 by methoxyl groups. This symmetric pattern was confirmed by observation of a typical overlapped signal at δ 61.2 (2 carbons) in the ^{13}C NMR spectra of both products (Table 2).

For compound **1**, aliphatic and olefinic methyl groups were identified by the presence of ^{1}H NMR signals at δ 0.98 and 1.74, both integrating for three protons. The latter resonance was determined as a part of a vinylidene group through HMBC correlation with the ^{13}C NMR signal at δ 112.6 geminally linked to protons at δ 4.71 (*brs*) and 4.91 (*brs*) (H-10). An ABX system observed in the ^{1}H NMR spectrum at δ 4.96 (*d*, J = 17 Hz, H-14), 4.98 (*dd*, J = 1 Hz, J = 11 Hz, H-14) and 5.78 (*dd*, J = 11 Hz, J = 17 Hz, H-13) indicated the presence of a vinyl group. The location of the vinyl, vinylidene and methyl groups on the benzoquinone skeleton was carried out by HMBC experiments. The methyl group at δ 0.98 (CH_3-12) was found to be attached to C-6 after observation of long-range heteronuclear correlations with δ 34.4 (C-5), δ 38.1 (C-6), δ 47.5 (C-7), δ 146.3 (C-13). The vinyl group was also positioned on C-6 through HMBC correlations between the ^{13}C NMR signal at 38.1 (C-6) and the methylene group protons located at δ 4.96 and 4.98 (H-14). Observation of a HMBC cross-peak between the ^{13}C NMR resonance at δ 47.5 (C-7) and the ^{1}H NMR signal at δ 1.74 enabled assignment of the position of the vinylidene moiety at C-7. The structure of the non-quinonic part of the molecule was confirmed by comparison of its spectroscopic data

[a] Values with the same letter may be interchanged.

with those from lobane derivatives isolated from a soft coral of *Lobophytum* sp. (Alcyonidae) (Raju and Subbaraju, 1993). Correct assignment of C-8a is supported by the HMBC connectivity between δ 2.21 (H-7) and δ 139.5 (C-8a). Complete DEPT data and HMBC connectivities for compound **1** are shown in Table 2. Compound **1** was finally identified as 7-isopropenyl-2,3-dimethoxy-6-methyl-6-vinyl-5,6,7,8-tetrahydronaphthalene-1,4-dione named heliotropinone A (Fig. 1).

The UV spectrum of compound **2** was very similar to that of **1**, suggesting also the presence of a benzoquinone structure. The ^{1}H NMR spectrum exhibited two protons at δ 4.71 and 4.87. These signals were attached to the sp^2 hybridized carbon at δ 107.6, as shown by a HSQC experiment, suggesting the presence of a terminal methylene moiety. The ^{1}H NMR spectrum showed also a singlet integrating for three protons at δ 0.66 (CH_3-14) that was attributed to a methyl group. The terminal methylene was attached at C-12 after analysis of the long-range correlations with the carbons δ 43.7 (C-7), 36.8 (C-11) and 148.1 (C-12). The position of the tertiary methyl group (δ 0.66) on C-6 was deduced from the correlations observed in the HMBC spectrum with the carbons δ 34.2 (C-6), 38.6 (C-5), 41.0 (C-9) and 43.7 (C-7). Correct assignment of C-8a is supported by the HMBC connectivity between δ 2.00 (H-7) and δ 139.3 (C-8a). Complete DEPT data and HMBC connectivities for compound **2** are shown in Table 2. Compound **2** was thus identified as 2,3-dimethoxy-8a-methyl-5-methylene-5,6,7,8,8a,9,10,10a-octahydroanthracene-1,4-dione and named heliotropinone B (Fig. 1).

From a biogenetic point of view, it appears important to mention that several terpenoid benzoquinone derivatives (cordiachromes) presenting a closely related structure to those of heliotropinones A and B have already been described from *Cordia* ssp., a genus also belonging to the Boraginaceae family (Moir and Thomson, 1973).

A closely related compound with a structure similar to heliotropinone A was also found in *Arnebia euchroma* (Boraginaceae), with inhibitory effects against prostaglandin biosynthesis (Xin-Sheng et al., 1983).

To our knowledge heliotropinones A and B are the first benzoquinone derivatives to be reported in a plant belonging to the genus *Heliotropium*. This gives further proof of the chemotaxonomic unity of the Boraginaceae family.

Heliotropinones A and B were found to be equally active against *C. cucumerinum* and *Candida albicans* in bioautographic assays on TLC plates (Rahalison et al., 1994) but were less potent than nystatin, a commercially available antifungal agent. Dilution tests on TLC were also performed with *Bacillus subtilis* (Rahalison et al., 1991), showing similar antibacterial effects for both compounds, with lower activities than those of chloramphenicol, used as reference compound. The results of the bioassays are reported in Table 3.

At the moment, a lack of suitable bioassays does not allow any conclusion on the involvement of *H. ovalifolium* in elephant flaccid trunk paralysis. Further investigations will be focused on finding assays convenient to target neurotoxicity in crude plant extracts.

standard. UV: Varian DMS 100S UV–vis spectrophotometer. UV spectra were recorded in MeOH. $[\alpha]_D$: Perkin-Elmer-241 polarimeter. TLC: silica gel 60 F_{254} Al sheets (Merck) using petrol ether–EtOAc 1 :1. CC: silica gel (63–200 μm; 750×65 mm i.d. and 63×200 μm; 400×20 mm i.d., Merck), MPLC: RP-18 Lichroprep (40-63 μm; 270×25 mm i.d.; Merck). EI–MS and D/CI–MS: Finnigan MAT TSQ-700 triple stage quadrupole instrument. HPLC/UV/DAD with a Nova-Pak RP-18 column (4 μm; 250×3.9 mm i.d.; Waters) using a CH_3CN-water gradient (20:80→100:0) in 25 min. The detection was performed at 210 and 254 nm. Semi-preparative HPLC was performed with a Shimadzu LC-8 pump equipped with a Knauer UV detector using a μBondapak® C_{18} prepacked radial-compression column (10 μm, 25×100 mm; Waters).

3.2. Plant material

The aerial parts of *H. ovalifolium* were collected in March 1999 at Fothergill Island, Zimbabwe. A voucher is deposited at the Institut de Pharmacognosie et Phytochimie, Lausannne, Switzerland (No. 99034).

3.3. Extraction and isolation

The air-dried powdered aerial parts (1.3 kg) of *H. ovalifolium* were extracted at room temperature with dichloromethane to afford 49 g of extract. This extract was first fractionated by column chromatography on silica gel with a petrol ether–EtOAc gradient (9:1→1:4) giving fractions A–L. Fr. J (2.3 g) was separated by medium pressure liquid chromatography (MPLC) with CH_3CN–H_2O (70:30). Further purification by semi-preparative chromatography using a μBondapak® C_{18} (10 μm, 25×100 mm) radial compression column with CH_3CN–H_2O (70-30) as the mobile phase led to the isolation of compounds **1** (8 mg) and **2** (11 mg).

3.4. Biological assays

3.4.1. Sample preparation for bioautographic assays

Geometric dilutions were obtained from freshly prepared stock solutions of the isolated and reference compounds at a concentration of 1 mg/ml in an appropriate solvent. Ten microliters of these solutions were applied on the TLC plates using graduated capillaries.

3.4.2. Bioautographic assays

Direct bioautography with *C. cucumerinum*: after application of the samples on a silica gel 60 F_{254} Al sheet (Merck), the TLC plate was developed in petrol ether–EtOAc (1:1) solvent system and thoroughly dried for complete removal of solvent. The plate was then sprayed with a suspension of *C. cucumerinum* in a nutritive medium and incubated for 2–3 days in polystyrene boxes with a moist atmosphere. Clear inhibition zones appeared against a dark gray background. Nystatin (Sigma) was used as reference compound.

3.4.2.1. Agar overlay bioautography with C. albicans. After application of the samples on a silica gel 60 F_{254} glass plate (Merck), this was developed using a petrol ether–EtOAc (1:1) solvent system and thoroughly dried for complete removal of solvents. An inoculum of yeast (approx. 10^7 cells/ml) in molten malt agar (Biokar Diagnostics) was distributed over the plates. The medium solidified as a thin layer (approx. 1 mm) and the plates were then incubated overnight at 30 °C in polystyrene boxes with a moist atmosphere. Inhibition zones were visible after spraying with an aqueous solution of methylthiazolyltetrazolium bromide (MTT) (2.5 mg/ml). Active compounds appeared as clear spots against a purple background. Nystatin (Sigma) was used as reference compound.

3.4.2.2. Agar overlay bioautography with B. subtilis. The same method was used as for *C. albicans*. Concentration of the inoculum, approx. 10^8 cells/ml. Chloramphenicol (Sigma) was used as reference compound.

3.5. Heliotropinone A (*1*)

7-Isopropenyl-2,3-dimethoxy-6-methyl-6-vinyl-5,6,7,8-tetrahydronaphthalene-1,4-dione; dark yellow oil $[\alpha]_D$ 0° (MeOH, *c* 0.05); UV λ_{max}^{MeOH}nm (log ε): 222 (*sh,* 5.64), 279 (5.54), 406 (3.94); ^{1}H NMR (500 MHz, $CDCl_3$): see Table 1. ^{13}C NMR (125 MHz, $CDCl_3$): see Table 2. HR-ESI–MS: (positive mode) *m/z* 303.159 ($C_{18}H_{23}O_4$ $[M+H]^+$, requires 303.152). EI–MS *m/z* (rel. int.): 302 $[M]^+$ (52), 287 (100), 255 (22), 247 (18), 219 (18), 93 (22), 91 (24).

3.6. Heliotropinone B (*2*)

2,3-Dimethoxy-8a-methyl-5-methylene-5,6,7,8,8a,9,10,10a-octahydroanthracene-1,4-dione; dark yellow oil; $[\alpha]_D$ +4, (MeOH, *c* 0.05); UV λ_{max}^{MeOH}nm (log ε): 213 (5.14), 279 (5.39), 412 (3.98); ^{1}H NMR (500 MHz, $CDCl_3$): see Table 1. ^{13}C NMR (125 MHz, $CDCl_3$): see Table 2; HR-ESI–MS: (positive mode) *m/z* 303.158 ($C_{18}H_{23}O_4$ $[M+H]^+$, requires 303.152) EI–MS *m/z* (rel. int.): 302 $[M]^+$ (100), 287 (16), 255 (18), 93 (10), 91 (14).

Received 2 February 2001; received in revised form 8 May 2001

Abstract

From the aerial parts of *Acanthus ilicifolius*, two benzoxazinoid glucosides, 7-chloro-(*2R*)-2-*O*-β-D-glucopyranosyl-2*H*-1,4-benzoxazin-3(4*H*)-one and (*2R*)-2-*O*-β-D-glucopyranosyl-5-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one have been isolated, together with six known compounds. The structural elucidations were based on the analyses of spectroscopic data. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Acanthus ilicifolius; Acanthaceae; Aerial parts; Benzoxazinoid glucoside

1. Introduction

Acanthus ilicifolius L. (Acanthaceae, Thai name: Ngueak-Plaa-Moo) is a spiny herb distributed in the mangroves of southern Thailand. In Thai traditional medicine, the plant is used as a purgative and an anti-inflammatory, as well as the leaves dispensed with pepper (*Piper nigrum* L.) as tonic pills for longevity. In a previous paper (Kanchanapoom et al., 2001), we reported the isolation and structural elucidation of lignan glucosides. Further investigation of the aerial part of the same plant affords two new benzoxazinoid glucosides (**4, 5**) together with six known compounds (**1–3, 6–8**). Benzoxazinoids have been found to occur as allo chemicals from monocotelydonous plants in the family Gramineae (Hofman and Hofmanova, 1969; Nagao et al., 1985), as well as reported from dicotyledonous plants in the family Acanthaceae (Wolf et al., 1985; Pratt et al., 1995), Ranunculaceae (Ozden et al., 1992) and Scrophulariaceae (Pratt et al., 1995). The present paper deals with the structural determination of these compounds. Also the usage of this plant in Thai traditional medicines are discussed.

pyranosyl-2*H*-1,4-benzoxazin-3(4*H*)-one (HBOA-Glc, blepharin) (**1**) (Tietze et al., 1991), (*2R*)-2-*O*-β-D-glucopyranosyl-4-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one (DIBOA-Glc) (**2**) (Hartenstein and Sicker, 1994), (*2R*)-2-*O*-β-D-glucopyranosyl-7-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one (DHBOA-Glc) (**3**) (Nagao et al., 1985), adenosine (**6**) (Otsuka et al., 1989), syringic acid β-glucopyranosyl ester (**7**) (Inoshiri et al., 1987) and 2,6-dimethoxy-*p*-hydroquinone 1-*O*-β-glucopyranoside (**8**) (Otsuka et al., 1989) by comparison of physical data with literature values and from spectroscopic evidence.

Compound **4** (Fig. 1) exhibited the characteristic pattern of a substance having a chlorine atom from negative FAB–MS. The molecular formula was determined by HR–FAB mass spectrometry as $C_{14}H_{16}O_8NCl$. The ^1H and ^{13}C NMR spectral data were similar to those of **1**. However, the ^1H NMR spectrum showed the presence of an ABX system at δ 6.91 (1H, *d*, $J=8.4$ Hz,), δ 7.05 (1H, *dd*, $J=8.4$, 2.5 Hz) and δ 7.23 (1H, *d*, $J=2.5$ Hz), indicating that the chlorine atom was attached to the aromatic ring. The position of the chlorine atom was assigned to C-7 by irridiation of N–H at δ 11.10 which induced a 7% NOE at δ 6.91 ($J=8.4$ Hz, H-5). Moreover, all carbon signals were established by using COSY, HSQC and HMBC. The (*2R*)-stereochemistry of the linkage at the anomeric carbon of the aglycone part could be deduced from the positive values, $[\alpha]_D^{26}$ +198.0°, of the opitical rotation. Such positive values are a typical feature for (*2R*)-configuration. On the basis of these spectral data, the structure of compound **4** was elucidated to be 7-chloro-(*2R*)-2-*O*-β-D-glucopyranosyl-2*H*-1,4-benzoxazin-3(4*H*)-one. This chlorinated compound is a natural product, and was not found as an artifact since the process of extraction and isolation did not involve acidic media. Furthermore, since this plant was collected from the mangrove forest, the source of chlorine atom might come from a mineral source (NaCl).

The molecular formula of compound **5** was determined as $C_{14}H_{17}O_9N$ by HR–FAB mass spectrometry. The ^1H and ^{13}C NMR spectra suggested it to be a benzoxazinoid glucoside. Inspection of the FAB mass spectrometry revealed a molecular ion 16 mass units larger than **1**, and the ABB′ system at δ 6.53 (2H, *brd*, $J=8.3$ Hz) and δ 6.75 (1H, *dd*, $J=8.3$, 8.1 Hz) was observed from the ^1H NMR spectrum, indicating the presence of a hydroxyl group on the aromatic ring. The hydroxyl group was assigned to attach at C-5 due to the downfield shift of C-5 (+29.5 ppm) together with the upfield shift of C-6 (−14.7 ppm), C-8 (−8.2 ppm) and C-10 (−11.5 ppm), compared to **1**. Besides, irradation of the N–H signal at δ 12.20, the NOE enhancement was not observed from the spectrum. The (*2R*)-stereochemistry could be determined from the positive values, $[\alpha]_D^{26}$ +95.0°, of the opitical rotation. Consequently, the structure of compound **5** was concluded as (*2R*)-2-*O*-β-D-glucopyranosyl-5-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one.

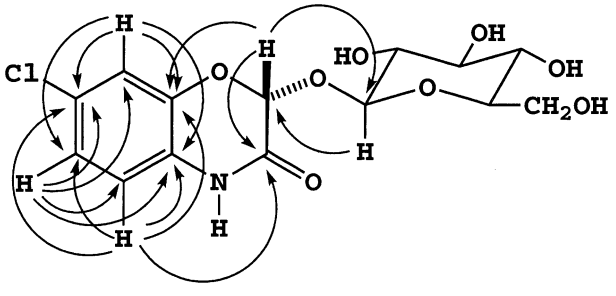

Fig. 1. HMBC correlations of compound **4**.

The biological activities of the isolated benzoxazinoids have not been investigated. The presence of benzoxazinoids (**1, 2**) as the major constituents are in agreement with Thai traditional usage as an anti-inflammatory (Otsuka et al., 1988). However, the toxicological and pharmacological properties of benzoxazinoids have been reported as the chemical resistance factors against insects, fungi, bacteria and virus in many crop plants of the family Gramineae (Niemeyer, 1988; Sicker et al., 2000), as well as mutagenic activities (Hashimoto and Shudo, 1996). In addition, the aglycone of **2** (DIBOA) was shown to be mutagenic in a test with *Salmonella typhimurium* TA 100 and TA 98 (Hashimoto and Shudo, 1996). On the basis of these results, the internal use of this species for treatments in Thai traditional medicine should be considered.

3. Experimental

3.1. General

NMR spectra were recorded in DMSO-d_6 or methanol-d_4 using a JEOL JNM A-400 spectrometer (400 MHz for ^1H NMR and 100 MHz for ^{13}C NMR) and JNM-ECP 500 (500 MHz for ^1H NMR and 125 MHz for ^{13}C NMR) with tetramethylsilane (TMS) as internal standard. MS were recorded on a JEOL JMS-SX 102 spectrometer. Optical rotations were measured with a Union PM-1 digital polarimeter. Preparative HPLC was carried out on columns of ODS (150×20 mm i.d., YMC) with a Tosoh refraction index (RI-8) detector. For CC, silica gel G 60 (Merck), NH-silica gel (Fuji Silysia Chemical, Ltd.), YMC-gel ODS (50 μm, YMC), polyamide C-200 (Wako) and highly porous copolymer of styrene and divinylbenzene (Mitsubishi Chem. Ind. Co., Ltd.) were used. The solvent systems were: (I) EtOAc–EtOH–H_2O (4:1:0.1), (II) EtOAc–EtOH–H_2O (7:3:0.3), (III) EtOAc–EtOH–H_2O (6:4:1), (IV) 14% MeCN, (V) 90–50% MeCN, (VI) 10% MeCN, (VII) 90% MeCN, (VIII) EtOAc–MeOH–H_2O (4:1:0.1), (IX) EtOAc–MeOH–H_2O (7:3:0.3), (X) EtOAc–EtOH–H_2O (6:4:1) and 15% MeCN. The spray reagent used for TLC was 10% H_2SO_4 in 50% EtOH.

3.2. Plant material

Acanthus ilicifolius L. was collected in April 1997 from Satun Province, Southern of Thailand. The identification of the plant was confirmed by Professor Vichiara Jirawongse, Department of Pharmaceutical Botany and Pharmacognosy, Faculty of Pharmaceutical Sciences, Khon Kaen University. A voucher sample (KKU-0001) is kept in the Herbarium of the Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand.

3.3. Extraction and isolation

The dried aerial part (2.5 kg) of *A. ilicifolius* was extracted with hot MeOH. After removal of the solvent by evaporation, the residue (380.0 g) was defatted with Et_2O. The aqueous layer was subjected to a column of highly porous copolymer of styrene and divinylbenzene (Mitsubishi Chem. Ind.) and eluted with H_2O, 30% MeOH, 60% MeOH, MeOH and Me_2CO, successively. The fraction eluted with 30% MeOH (9.2 g) was applied to a column of silica gel (system I, II and III, respectively) affording four fractions. Fraction 2 (3.3 g) was further separated on columns of RP-18 (system IV) and NH-silica gel (system V) to provide compounds **1** (1.0 g), **3** (15 mg), **5** (7 mg), **7** (15 mg) and **8** (10 mg). Fraction 2 (2.2 g) was purified by using RP-18 (system VI) and polyamide (system VII) columns to give compounds **2** (840 mg) and **6** (49 mg). The fraction eluted with 60% MeOH was subjected to a column of silica gel (system VIII, IX and X, respectively) to give five fractions. A portion of fraction 2 was purified by ODS–HPLC (system XI) to provide compound **4** (15 mg).

3.4. 7-Chloro-(2R)-2-O-β-D-glucopyranosyl-2H-1,4-benzoxazin-3(4H)-one

White amorphous powder, $[\alpha]_D^{26}$ +198.0° (DMSO, *c* 0.33); ^{1}H NMR (DMSO-d_6): δ 2.91 (1H, *dd*, *J* = 8.5, 8.3 Hz, H-2 Glc), δ 3.00 (1H, *dd*, *J* = 9.3, 9.0 Hz, H-4 Glc), δ 3.13 (1H, *dd*, *J* = 8.9, 8.8 Hz, H-3 Glc), δ 3.17 (1H, *m*, H-5 Glc), δ 3.41 (1H, *dd*, *J* = 11.7, 5.7 Hz, H-6 Glc), δ 3.69 (1H, *brd*, *J* = 11.7 Hz, H-6 Glc), δ 4.54 (1H, *d*, *J* = 8.1 Hz, H-1 Glc), δ 5.70 (1H, *s*, H-2), δ 6.91 (1H, *d*, *J* = 8.4 Hz, H-5), δ 7.05 (1H, *dd*, *J* = 8.4, 2.5 Hz, H-6), δ 7.23 (1H, *d*, *J* = 2.5 Hz, H-8), δ 11.10 (1H, *brs*, N–H); ^{13}C NMR (DMSO-d_6): Table 1; negative HR–FAB–MS, *m*/*z*: 360.0486 ($C_{14}H_{15}O_8NCl$ requires 360.0486).

3.5. (2R)-2-O-β-D-Glucopyranosyl-5-hydroxy-2H-1,4-benzoxazin-3(4H)-one

Amorphous powder, $[\alpha]_D^{26}$ +95.0° (DMSO, *c* 0.40); ^{1}H NMR (DMSO-d_6): δ 2.89 (1H, *dd*, *J* = 8.3, 8.1 Hz, H-2 Glc), δ 3.02 (1H, *dd*, *J* = 9.3, 9.0 Hz, H-4 Glc), δ 3.13 (1H, *dd*, *J* = 9.3, 8.8 Hz, H-3 Glc), δ 3.14 (1H, *m*, H-5 Glc), δ 3.43 (1H, *dd*, *J* = 11.0, 4.6 Hz, H-6 Glc), δ 3.66 (1H, *brd*, *J* = 11.5 Hz, H-6 Glc), δ 4.53 (1H, *d*, *J* = 7.8 Hz, H-1 Glc), δ 5.62 (1H, *s*, H-2), δ 6.53 (2H, *brd*, *J* = 8.3 Hz, H-6,8), δ 6.75 (1H, *dd*, *J* = 8.3, 8.1 Hz, H-7), δ 12.20 (1H, *brs*, N–H); ^{13}C NMR ((DMSO-d_6): Table 1; negative HR–FAB–MS, *m*/*z*: 342.0820 ($C_{14}H_{16}O_9N$ requires 342.0825).

Glucides of *Cnidium monnieri* fruit

Junichi Kitajima*, Toru Ishikawa, Yoshie Aoki

Showa Pharmaceutical University, Higashi-Tamagawagakuen 3, Machida, Tokyo 194-8543, Japan

Received 31 January 2001; received in revised form 19 April 2001

Abstract

From the fruit of *Cnidium monnieri* Cusson (Umbelliferae), two glucides were isolated together with other known glucides. Their structures were clarified as glycerol 2-*O*-α-L-fucopyranoside and D-quinovitol (6-deoxy-D-glucitol), respectively. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Cnidium monnieri*; Umbelliferae; Glycerol 2-*O*-α-L-fucopyranoside; D-Quinovitol; Glucide

1. Introduction

In previous papers, we reported the separation and characterization of a hemiterpenoid (2*S*,3*R*)-2-methylbutane-1,2,3,4-tetrol (**1**), seven monoterpenoid polyols (3,7-dimethyloct-3(10)-ene-1,2,6,7-tetrols, 3,7-dimethyloctane-1,2,6,7-tetrols, 3,7-dimethyloct-3(10)-ene-1,2,6,7,8-pentols and *trans*-*p*-menthane-1β,2α,8,9-tetrol), five monoterpenoid glucosides and five aromatic compound glucosides as the constituents of the water-soluble portion of a Chinese herbal medicine She chuang zi, the fruit of *Cnidium monnieri* Cusson (Umbelliferae) (Kitajima et al., 1998a, 1999a). The present study was carried out to isolate and characterise glucide fraction.

2. Results and discussion

The methanolic extract of the fruit of *C. monnieri* was partitioned between ethyl acetate and water, and the aqueous layer was subjected to Amberlite XAD-II chromotography to give water and methanol fractions. These fractions were subjected to Sephadex LH-20, silica gel, Lobar RP-8, octadecyl silica (ODS), carbohydrate analysis and polymer type column chromatographies to give eight glucides (**2**–**9**) and a sugar mixture. Glucides **2–5** were identified as erythritol, D-threitol, D-mannitol and 2-deoxy-D-ribono-1,4-lactone (Kitajima et al., 1999b), respectively. The sugar mixture was analyzed by HPLC using a carbohydrate analysis column, and the mixture was found to contain lactose (**10a**), maltose (**10b**), sucrose (**10c**), glucose (**10d**) and fructose (**10e**) in the ratio of 3:5:4:11:1. Glucide **5** is the second example of its isolation from natural sources.

Glucide **6** ($C_9H_{18}O_7$, a colorless syrup, $[\alpha]_D^{23}$ −127°) showed the $[M+H]^+$ ion peak at *m*/*z* 239 in the positive FAB–MS and its formula was determined from the accurate mass number of $[M+H]^+$. Acid hydrolysis of **6** gave fucose, and the ^1H, ^{13}C and ^{13}C-^1H correlation spectroscopy (COSY) NMR spectral data revealed the presence of 1 mol of α-fucopyranose and 1 mol of glycerol. The fucose should be in the L-form as $[M]_D$ of **6** showed a minus value (−302°) same as the methyl α-fucopyranoside (−350°) (Hough and Richardson, 1967). Furthermore, the heteronuclear multiple-bond correlation (HMBC) spectrum showed a H–C long-range correlation between the anomeric proton of fucose and C-2 carbon of glycerol indicating that **6** was glycerol 2-*O*-α-L-fucopyranoside.

Glucide **7** ($C_6H_{12}O_5$, a colorless syrup, $[\alpha]_D^{24}$ −11°) was a diastereoisomeric compound of **8** which was identified as 1-deoxy-D-glucitol (Kitajima et al., 1999b); these diastereomers could be separated by HPLC using polymer type column (Wakobeads T-100S). By comparison of NMR spectral data and optical rotation value with those of deoxyhexitols (L-rhamnitol (**7a**), L-fucitol (**7b**) and D-quinovitol ($[\alpha]_D^{24}$ −8°; Table 1) which were obtained by $NaBH_4$ reduction of the corresponding methylpentoses, **7** was identified as quinovitol (6-deoxy-D-glucitol).

Though **6** and **7** are very simple compounds, they are both new.

Glucide **9** ($C_6H_{12}O_6$, an amorphous powder, $[\alpha]_D^{22}$ -15°), which is one of the main components of the water-soluble portion, was identified as D-hamamelose by comparison of its NMR spectral data and optical rotation value with those published (Szarek et al., 1983; Nonaka et al., 1984).

Recently, a biosynthetic route leading to an isoprene which did not involve the mevalonate route was defined (Rohmer et al., 1996). In this route, hemiterpenoid **1**, which leaded from the rearrangement of deoxyxylulose phosphate (DXP) followed by a concomitant reduction, was considered as the first putative precursor of isopentenyl diphosphate (IPP). Besides, DXP results from the condensation of glyceraldehyde 3-phosphate (GAP) and pyruvic acid. (Duvold et al., 1997a,b; Kuzuzama et al., 2000). We also reported the possibility of the biosynthetic relationship between **1** and branched sugar D-apiose (Kitajima et al., 1998b). As co-existence of **1** and branched sugar D-hamamelose occurs in this fruit, and hamamelose is biosynthesized from two moles of GAP (Vickery and Vickery, 1981), a biosynthetic relationship between these two branched sugars might be suggested.

3. Experimental

Melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. Optical rotations were measured on a JASCO DIP-370 digital polarimeter. FAB–MS were recorded with a Jeol HX-110 spectrometer using glycerol as matrix. ^1H and ^{13}C NMR spectra were taken on Jeol JNM GX-270 and A-500 spectrometers with tetramethylsilane as an internal standard, and chemical shifts were recorded in δ value. ^1H–^{13}C COSY, HMBC and NOESY spectra were obtained with the usual pulse sequence and data processing was performed with standard Jeol software. Column chromatography was carried out under TLC monitoring using Kieselgel 60 (70–230 mesh, Merck), Sephadex LH-20 (25–100 mm, Pharmacia), Lobar RP-8 column (Merck) and Amberlite XAD-II (Organo). TLC was performed on silica gel (Merck 5721) and spots were detected with *p*-anisaldehyde-H_2SO_4 reagent. HPLC separations were carried out on a JASCO chromatograph (980-system) with a JASCO RI-930 detector, and Symmetry Prep$^{TM}C_{18}$ 7 μm [waters; column size, 7.8×300 mm], Carbohydrate Analysis [Waters; column size, 3.9×300 mm] and Wakobeads T-100s [Wako; column size, 6.0×150 mm] were used as columns.

4. Extraction and separation of glucides

As reported in the previous paper (Kitajima et al., 1998a, 1999a), commercial fruit of *C. monnieri* Cusson (1 kg, purchased from Kinokuniya Chinese Medicine Pharmacy, Ltd., Japan, Lot. No. MU961715Y) was extracted with MeOH (5l). The aqueous portion of the MeOH extract was extracted with hot MeOH and the hot MeOH soluble portion was subjected to column chromatography on Amberlite XAD-II ($H_2O \rightarrow$MeOH) to afford water and MeOH eluent (21.2 g and 10.6 g), respectively. The MeOH eluate fraction was applied to a Sephadex LH-20 (MeOH) column which furnished six fractions (frs. 1 to 6). Fr. 2 (8.4 g) was purified by silica gel [$CHCl_3$–MeOH–H_2O (9:1:0.1→17:3:0.3→4:1:0.1→7:3:0.5)→MeOH] column chromatography to afford 14 fractions (frs. 2-1 to 2-14). From fr. 2-4 (465 mg), **5** (24 mg) was isolated by Lobar RP-8 [CH_3CN–H_2O (3:17)] and Sephadex LH-20 (MeOH) column chromatographic steps. The water eluent (21.2 g) was subjected to Sephadex LH-20 (MeOH) column chromatography to afford five fractions (frs. 1′ to 5′). Fr. 2′ (15.3 g) was purified by silica gel [$CHCl_3$–MeOH–H_2O (17:3:0.3→4:1:0.1→7:3:0.5)→MeOH] column chromatography to afford nine fractions. Fr. 2′-6 (369 mg) was subjected to a Lobar RP-8 column [CH_3CN–H_2O (1:99)] and HPLC [Carbohydrate Analysis, CH_3CN–H_2O (19:1)] to give **6** (10 mg), a mixture of **7** and **8** (40 mg) and a mixture of **2** and **3**. A mixture of **2** and **3** was acetylated with Ac_2O and pyridine, and the acetylated fraction was subjected to HPLC [Symmetryprep C_{18}, MeOH–H_2O (1:1)] to give **2**-acetate and **3**-acetate. They were deacetylated by heating with 5% NH_4OH–MeOH for 2 h in a water bath to give **2** (28 mg) and **3** (10 mg), respectively. A mixture of **7** and **8** was subjected to HPLC [Wakobeads T-100S ×2; CH_3CN–H_2O (17:3)] to give **7** (4 mg) and **8** (25 mg). The fr. 2′-7 (2.17 g) was subjected to Lobar RP-8 column [CH_3CN–H_2O (1:99)] and silica gel [$CHCl_3$–MeOH–H_2O (17:3:0.3→4:1:0.1→7:3:0.5)→MeOH] column chromatograpies, and purified by HPLC [Symmetryprep C_{18}, MeOH–H_2O (1:1)] to give **9** (403 mg). Fr. 2′-8 (565 mg) was treated with hot MeOH to give a residue (following solvent removal) and precipitate **4** (520 mg). The residue was applied to a silica gel column, eluted with $CHCl_3$–MeOH–H_2O (3:2:0.5) to afford a sugar fraction which was analyzed by HPLC [Carbohydrate analysis, CH_3CN–H_2O (17:3); flow rate 1.5 ml/min] to show the presence of lactose (**10a**, 11.8 min), maltose (**10b**, 11.4 min), sucrose (**10c**, 8.4 min), glucose (**10d**, 5.7 min) and fructose (**10e**, 5.1 min) in the ratio of 3:5:4:1:11.

The following compounds were identified by comparison with either authentic compounds or by analyses of NMR spectral and $[\alpha]_D$ data.

Erythritol (**2**), D-threitol (**3**), D-mannitol (**4**), 2-deoxy-D-ribono-1,4-lactone (**5**), 1-deoxy-D-glucitol (**8**) and D-hamamelose (**9**).

4.1. Glycerol 2-O-α-L-fucopyranoside (6)

A colorless syrup, $[\alpha]_D^{23}$ −127° ($c = 0.9$, MeOH). Positive FAB–MS m/z: 277 $[M+K]^+$, 261 $[M+Na]^+$, 239.1152 $[M+H]^+$ (base, calc. for $C_9H_{19}O_7$: 239.1131). ^{1}H NMR (pyridine-d_5) δ: 5.63 (1H, *d*, $J = 4.0$ Hz, H-1), 4.64 (1H, *dd*, $J = 4.0$, 10.0 Hz, H-2), 4.53 (1H, *dd*, $J = 3.0$, 10.0 Hz, H-3), 4.14 (1H, *br d*, $J = 3.0$ Hz, H-4), 4.61 (1H, *br d*, $J = 6.5$ Hz, H-5), 1.53 (3H, *d*, $J = 6.5$ Hz, H_3-6), 4.21 (1H, *dd*, $J = 4.0$, 11.5 Hz, H-1′a), 4.23 (1H, *dd*, $J = 6.0$, 11.5 Hz, H-1′b), 4.32 (1H, m, H-2′), 4.20 (1H, *dd*, $J = 6.0$, 11.5 Hz, H-3′a), 4.27 (1H, *dd*, $J = 4.0$, 11.5 Hz, H-3′b).

4.2. Acid hydrolysis of 6

Glucide **6** (5 mg) was dissolved in aq. 2 N H_2SO_4 and heated in a water bath for 3 h. The hydrolysate was neutralized with $NaHCO_3$ and the salt filtered off, and the filtrate was performed on TLC [silica gel, solv.; $CHCl_3$–MeOH–H_2O (7:3:0.5)] to show the presence of fucose [R_f 0.33, rhamnose: 0.41, quinovose: 0.37).

4.3. D-Quinovitol (7)

A colorless syrup, $[\alpha]_D^{24}$ −11° ($c = 0.2$, MeOH). Positive FAB–MS m/z: 189.0733 $[M+Na]^+$ (base, calc. for $C_6H_{14}O_5Na$: 189.0739). ^{1}H NMR (pyridine-d_5) δ: 1.68 (3H, *d*, $J = 6.0$ Hz, H_3-6), 4.50 (1H, *m*, H-5), 4.22 (1H, *br d*, $J = 6.5$ Hz, H-4), 4.56 (1H, *br d*, $J = 6.5$ Hz, H-3), 4.83 (1H, *m*, H-2), 4.35 (1H, *dd*, $J = 6.5$, 11.5 Hz, H-1a), 4.44 (1H, *dd*, $J = 6.5$, 11.5 Hz, H-1b).

4.4. $NaBH_4$ reduction of D-quinovose, L-rhamnose and L-fucose

Commercial L-rhamnose, L-fucose and D-quinovose (each 50 mg) were dissolved in MeOH (10 ml) and stirred with $NaBH_4$ (10 mg) for 5 h at room temperature, respectively. After work-up, the residues were purified by Sephadex LH-20 (MeOH) to give L-rhamnitol (**7a**), L-fucitol (**7b**) and D-quinovitol ($[\alpha]_D^{24}$ −8° ($c = 4.0$, MeOH), each 40 mg), respectively. The ^{1}H and ^{13}C NMR spectral data, and optical rotation value of **7** were identical with those of D-quinovitol.

Received in revised form 12 December 2000

Abstract

Fractionation of the xanthine oxidase inhibitory methanol extract of *Conyza bonariensis* afforded three glycosides, in addition to nine known compounds including amyrin, β-sitostero1 daucosterol, syringic acid 3-hydroxy-5-methoxybenzoic acid, eugenol 4-*O*-glucopyranoside, and luteolin, apigenin and takakin 8-*O*-glucuronide. The structures of the glycosides were established by a combination of spectroscopic methods (IR, MS, ^{1}H and ^{13}C NMR, DEPT, COSY, HMQC and HMBC) as 4-hydroxypyridin-3-carboxylic acid 4-*O*-glucopyranoside, 8-hydroxy-6,7-dihydrolinalool 8-*O*-glucopyranoside and bonaroside [viz. 1,3,4,12-tetrahydroxy-2-(9-hexadecenoylamino)octadecane 1-*O*-glucopyranoside]. The in vitro enzyme assay showed that syringic acid and takakin 8-*O*-glucuronide displayed weak inhibitory activity against xanthine oxidase with IC_{50} values of 500 ± 41 μM and 170 ± 12 μM, respectively. © 2001 Elsevier Science Ltd. Keywords: *Conyza bonariensis*; Asteraceae; 4-Hydroxypyridin-3-carboxylic acid 4-*O*-glucopyranoside; 8-Hydroxy-6,7-dihydrolinalool 8-*O*-glucopyranoside; Bonaroside; Syringic acid; Takakin 8-*O*-glucuronide

1. Introduction

Conyza bonariensis (L.) Crong (Asteraceae) has been phytochemically investigated (El-Karemy et al., 1986; Rizk et al., 1986; Ferraro et al., 1988; Sanz and Marco, 1991). However, the species growing in China has not been examined to date. In continuation of our investigations of plant-derived xanthine oxidase inhibitors (Li et al., 1999; Zhou et al., 1999), the methanol extract was found to be active against the enzyme which is closely related to the hyperuricemia and gout (Tsutomu et al., 1991; Cos et al., 1998). We therefore analyzed the extract in detail in order to characterize the xanthine oxidase inhibitor(s).

2. Results and discussion

Repeated chromatography of the methanol extract of *C. bonariensis* on silica gel and Sephadex LH-20 afforded three new glycosides (**1**–**3**), in addition to the known constituents amyrin, β-sitosterol, daucosterol, apigenin, luteolin, takakin 8-*O*-glucuronide, syringic acid and 3-hydroxy-5-methoxybenzoic acid. The in vitro evaluation of these isolates demonstrated that the enzyme inhibitors present in the title species were syringic acid and the three flavonoids.

The identification of amyrin, β-sitosterol and daucosterol was accomplished by direct comparisons (co-TLC, IR and EIMS) with authentic samples available in our laboratory. The spectral data (IR, EIMS, ^{1}H and ^{13}C NMR) of the two acids revealed that they were syringic acid (Cuenca et al., 1992) and 3-hydroxy-5-methoxybenzoic acid (Majumder et al., 1996), respectively. Syringic acid was previously found to have antioxidant (Yoshiki et al., 1995), antibacterial (Fernandez et al., 1996), antifungal (Lattanzio et al., 1994), properties, as well as being protective against cell damage induced by superoxide anion radicals in murine dermal fibroblasts (Masaki et al., 1995). The structures of apigenin and luteolin were ascertained by their IR, EIMS, ^{1}H and ^{13}C NMR spectra (Markham et al., 1978; Noro et al., 1983; Tosun and Akyuz, 1997). Both flavones were previously

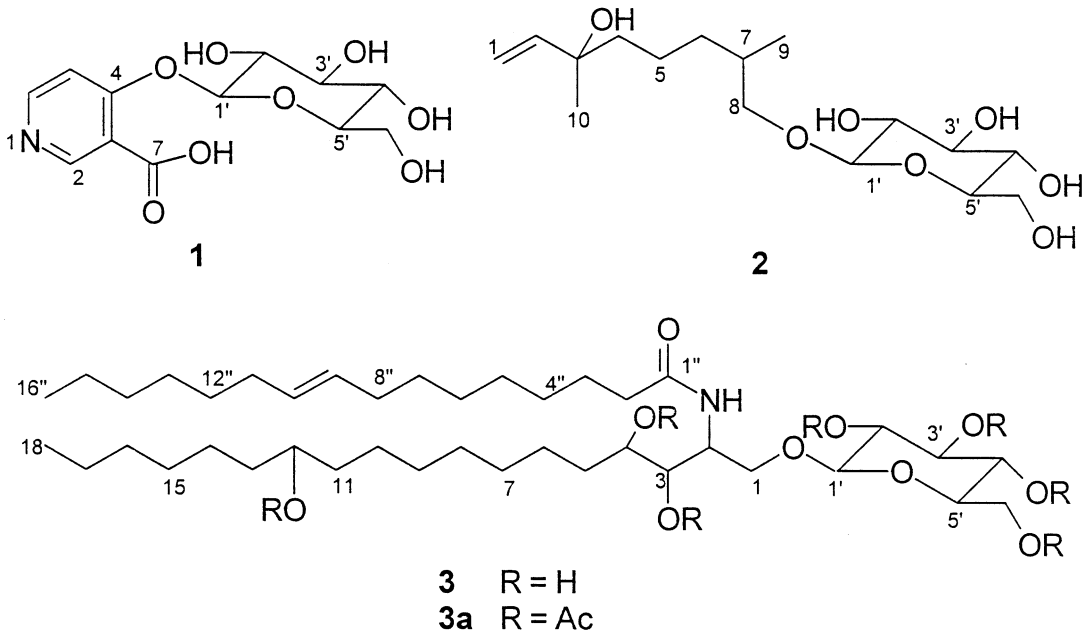
PII: S0031-9422(01)00176-5



investigated biologically and reported to be antioxidant and anti-inflammatory (Maokn et al., 1996; Silvan et al., 1996; Yokozawa et al., 1997). Furthermore, apigenin was found to inhibit tumor necrosis factor-induced intercellular adhesion molecule-1 upregulation in vivo (Panes et al., 1996), and to have anti-TPA-induced transformation, anti-protein kinase C activation and anti-TPA-induced c-jun expression activities (Lee and Lin, 1997), whereas luteolin had cancer chemopreventive and antiplatelet effects (Cai et al., 1997; Lin et al., 1997). Furthermore, luteolin and apigenin have been reported to be xanthine oxidase inhibitors (Cos et al. 1998, Kasai et al., 1999). The flavone glycoside was identified as takakin 8-O-glucuronide by the IR, EIMS, ^{1}H and ^{13}C NMR spectral data (Chen et al., 1994). The second glycoside was demonstrated to be eugenol 4-*O*-glucopyranoside by its spectral data (FABMS, IR, ^{1}H and ^{13}C NMR), characterized previously as the corresponding peracetate from *Artemisia dracunculus* (Jakupovic et al., 1991).

In the ^{1}H NMR spectrum of compound **1**, a broadened singlet at δ 8.34 and a pair of mutually coupled doublets ($J=5.6$ Hz) at δ 8.15 and 6.61 indicated that it was most likely a pyridine derivative carrying presumably 3-carbonyl and 4-hydroxyl (or amino) groups (Rasala, 1993). This hypothesis was subsequently confirmed by the ^{13}C NMR spectrum of **1**, which exhibited a total of twelve carbon resonance lines consisting of one methylene, eight methine and three quaternary carbons. Subtracting a set of carbon signals due to a glucopyranosyl group, the rest was ascribable to the 4-hydroxypyridin-3-carboxylic acid nucleus (Yu et al., 1989). As to the attachment of the glucopyranosyl group, the chemical shift of the anomeric proton doublet ($J=7.8$ Hz) at δ 4.91 supported the formulated glycosidation pattern if compared with that of carboxylic (δ ~6.20) and phenolic (δ~4.90) glucosides described previously (Jakupovic et al., 1991; Tan et al., 1993). Finally, the structure of glycoside **1** was reinforced by its FABMS spectrum which gave an intense protonated molecular ion at m/z 302, accompanied by a strong fragment at m/z 140 produced through the elimination of the glucosyl moiety from the quasimolecular ion.

The structure of glycoside **2** followed from its spectral data. The El mass spectrum of **2** was not informative. However, an intense quasimolecular ion was observed at m/z 335 ($[M+H]^{+}$) in its FABMS spectrum. Besides a set of proton resonances attributable to a glucopyranosyl moiety, the ^{1}H NMR spectrum of glycoside **2** exhibited a methyl singlet at δ 1.20, a three-proton doublet ($J=6.7$ Hz) at δ 0.91, a pair of double doublets at δ 3.82 and 3.66 due to an oxygenated methylene group, and a set of signals at δ 5.88 (1 H, *dd*, $J=17.4$, 10.8 Hz), 5.15 (IH, *dd*, $J=17.4$, 1.5 Hz) and 4.98 (1H, *dd*, $J=10.8$, 1.5 Hz) arising from a vinyl function. These ^{1}H NMR spectroscopic data showed that compound **2** was most probably a 8-hydroxy-6,7-dihydrolinalool glucoside (Tan et al., 1991; Schulz et al., 1997). This proposal was substantiated by its ^{13}C NMR and DEPT spectra. All carbon signals could be assigned by comparing them with those of 6,7-dihydrolinalool analogs (Yu et al., 1989). The glucopyranosyloxy group was shown to be at C-8 by the glycosidation induced downfield shift (δ 76.2) of the 8-oxygenated methylene carbon

signal. In conclusion, glycoside **2** was 8-hydroxy-6,7-dihydrolinalool 8-*O*-glucopyranoside.

The molecular formula of compound **3** was found to be $C_{40}H_{77}NO_{10}$ by its FABMS, ^1H and ^{13}C NMR, and DEPT data and the HREIMS spectrum of the corresponding peracetate (**3a**). The ^1H and ^{13}C NMR spectra of **3** indicated that it was also a glucopyranoside (Table 1). Furthermore, a carbonyl IR absorption at 1720 cm^{-1}, and the six-proton triplet ($J = 7.0$ Hz) at δ 0.86 and a pair of olefinic proton signals at δ 5.34 and 5.42 in its ^1H NMR spectrum demonstrated that it possessed presumably two aliphatic chains, one of which carried a double bond. Thus, the three unsaturations of the molecular formula could be readily assigned to a double bond, a carbonyl and a glucopyranosyl group. This hypothesis was subsequently confirmed by the ^{13}C NMR spectrum and FABMS of **3**. In addition to the quasimolecular ion at m/z 754 $[M+Na]^+$, the FABMS spectrum of **3** exhibited an intense fragment peak at m/z 570 which was produced by elimination of the glucosyl residue from the protonated molecular ion. The loss of hexadecenamide from the molecular ion gave rise to the fragment at m/z 316. The 9,10-double bond was assigned to the hexa decenoyl group on the basis of the typical fragment ion at m/z 500 which was formed by elimination of pentene from that at m/z 570 through McLafferty rearrangement (Fig. 1). Obviously, the other aliphatic chain should consist of eighteen carbons. Moreover, the presence of a total of seven hydroxyl groups in the molecule was deduced by comparison between the molecular ions appearing in the FABMS spectra of **3** and **3a**. Accordingly, after subtraction of the four hydroxyls involved in the glucopyranosyl group, the other three had to be positioned in the C_{18} chain. The ^1H–^1H COSY spectrum of **3** showed that a pair of double doublets of an oxygenated methylene at δ 4.01 (*dd*, $J = 10.5$, 6.2 Hz) and 3.76 (*dd*, $J = 10.5$, 3.5 Hz) coupled to the oxygen-bearing methine signal at δ 4.24 (*ddd*, $J = 6.5$, 6.2, 3.5 Hz). This resonance showed a correlation with the double doublet ($J = 6.5$, 6.0 Hz) at δ 3.56 which coupled further to the signal at δ 3.48 (*ddd*, $J = 6.2$, 6.5, 3.5 Hz). In the HMQC spectrum of **3**, the signal at δ 4.24 correlated to the methine carbon at δ 51.6. These observations required the given 1,3,4-trioxygenated and 2-nitrigenated pattern. The glycosidation at C-1 was indicated by the downfield shifted signal of C-1 at δ 70.0 (Kasai et al., 1999). The 9-hexadecenoylamino group was found to be at C-2 by the resonance of H-2 at δ 4.24 which was shifted remarkably downfield owing to acylation. In addition to the 3,4-diol system, the final hydroxyl group was found to be at C-12 by diagnostic fragment ions in FABMS spectrum of **3a**. The characteristic fragment at m/z 157, which yielded the peak at m/z 115 due to the loss of ketene, was produced through the cleavage of the C_{11}–C_{12} bond (Fig. 2). In conclusion, glycoside **3** was 1, 3,4,1 2-tetrahydroxy-2-(9-hexadecenoylamino)octadecane 1-*O*-glucopyranoside. The configuration at the chiral centers could not be established without chemical transformations that would require much more material. We have named this glycoside bonaroside.

16″	14.5 (CH_3)	0.86 *t* (7.0)

[a] Assigned by spin decoupling, ^1H–^1H COSY and HMQC experiments.

[b] The chemical shifts of C-7–C-9, C–15, C-4″–C-7″, C-12″ and C-13″: 30.9–30.6 (10 CH_2), and those of protons thereon: 1.25–1.32 m (20 H).

All isolates were tested for the xanthine oxidase inhibitory activity as described elsewhere (Li et al., 1999; Zhou et al., 1999). The xanthine oxidase inhibitors present in the methanol extract of *C. bonariensis* were revealed to be syringic acid, luteolin, apigenin and takakin 8-*O*-β-D-glucuronide. In addition to the known xanthine oxidase inhibitory flavone luteolin and apigenin (Kasai et al., 1999; Cos et al., 1998), syringic acid and takakin 8-O-glucuronide were displayed for the first time to be active against the enzyme with IC_{50} values of 500 ± 41 and 170 ± 12 μM, respectively. The IC_{50} value of allopurinol co-assayed in the study as positive control was shown to be 10.

The present phytochemical investigation of *C. bonariensis* growing widely in China has led to the characterization of three new glycosides and four xanthine oxidase inhibitory natural products. However, except widespread compounds such as amyrin, β-sitosterol,

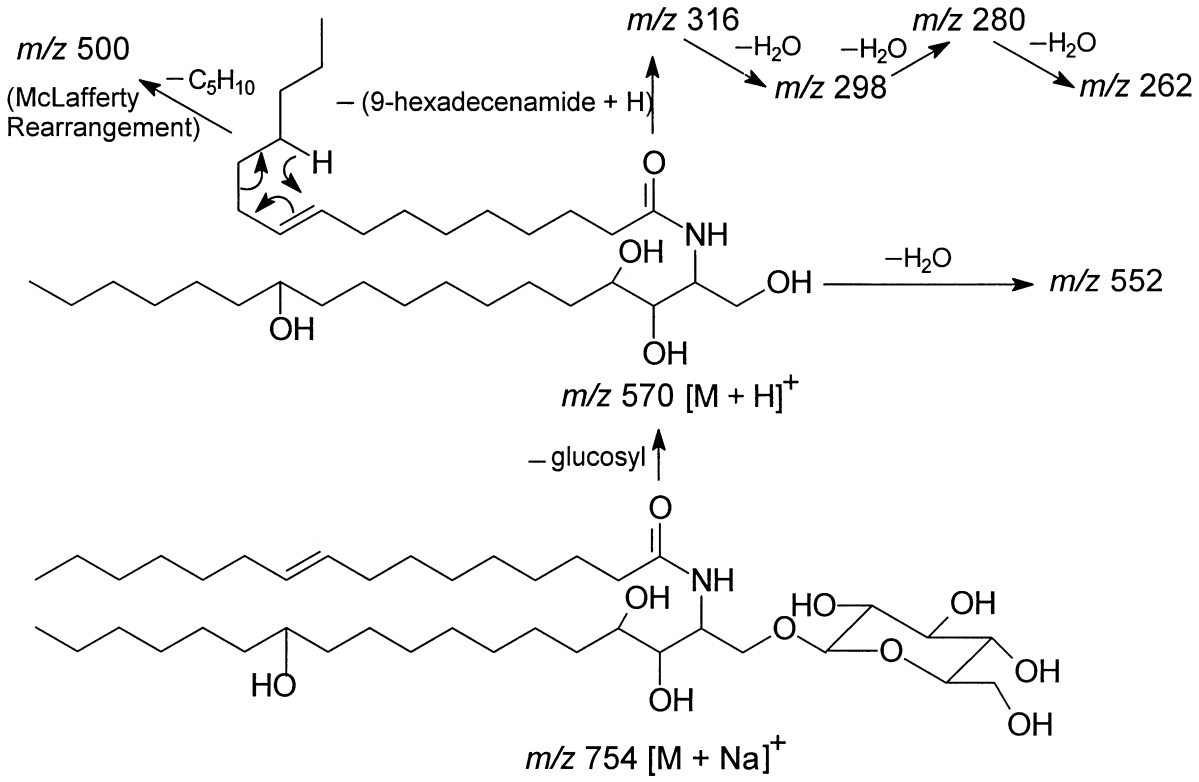

Fig. 1. Diagnostic fragments of glycoside **3**.

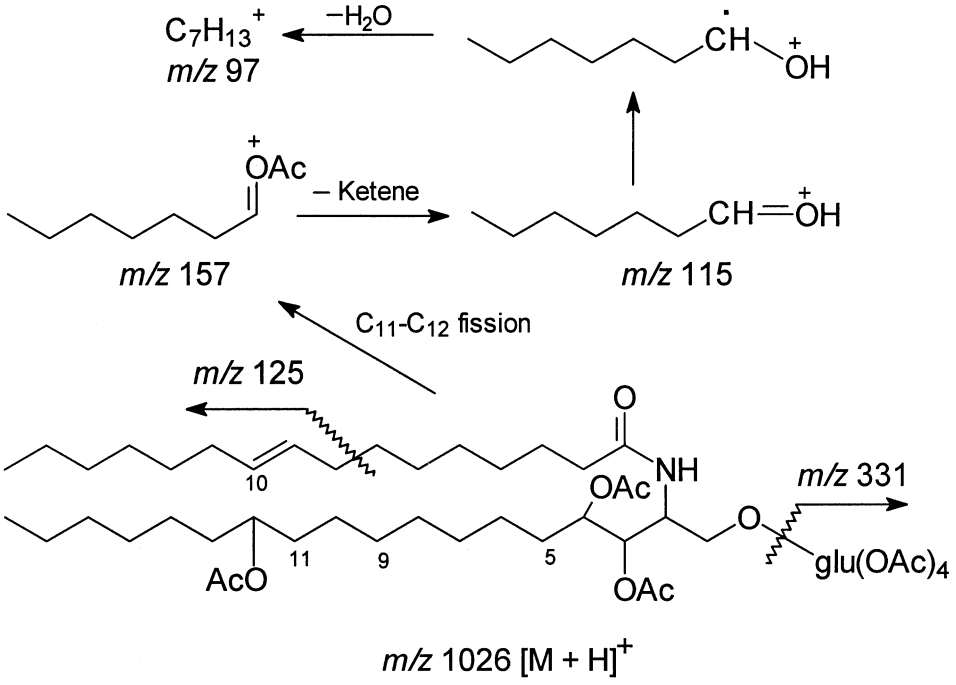

Fig. 2. Diagnostic FABMS fragmentions of **3a**.

daucosterol, luteolin and apigenin, the constituents of *C. bonariensis* growing in China are quite different from those of the same species collected abroad (El-Karemy et at., 1986; Rizk et al., 1986; Ferraro et al., 1988; Sanz and Marco, 1991). This is presumably due to different phytochemical strategies and/or geographical deviation, the latter affecting putatively the biosynthesis and accumulation of plant secondary metabolites.

3. Experimental

3.1. General

Optical rotations were measured on a DXP-118 instrument. IR spectra were recorded in KBr disks on a Perkin-Elmer 577 instrument. All NMR experiments were performed on a Jeol JNM-A 500 FT–NMR spectrometer using TMS as the internal standard. El and FABMS experiments were run on either VG-ZAB-HS or Jeol JMX-HX110 mass spectrometers, respectively. Silica gel (200–300 mesh) for column chromatography and GF_{254} (30–40 μ) for TLC were produced by Qingdao Marine Chemical Factory, Qingdao, China. Sephadex LH-20 was from Pharmacia Biotech, Sweden. Other chemicals used in this study were of analytical grade.

3.2. Plant material

The aerial parts of *C. bonariensis* was collected on 19 June 1996 from the Xuanwu Lake Park, and identified by Professor Z.P. Wang, School of Life Science, Nanjing University, Nanjing 210093, China. A voucher specimen, registered under the number Y 96619B, was preserved in the Herbarium of Nanjing University, Nanjing, China.

3.3. Extraction and isolation

The powdered air-dried plant material (900 g) was extracted twice (24 h each) with MeOH at room temperature. Evaporation of solvent from the combined extracts in vacuo at 55°C gave a dark residue (57 g) which was dissolved in MeOH followed by filtration. The filtrate was concentrated to a black gum (32 g) under reduced pressure and subsequently separated by CC (silica gel, 900 g, 200–300 mesh). Elution with petrol–acetone gradient (9:1→10:1) was followed by acetone and acetone-MeOH mixtures (100:5→1:10). According to TLC monitoring and xanthine oxidase assay, seven fractions were collected (F-1: 3.2 g, F-2: 2.1 g, F-3: 3.4 g, F-4: 2.6 g, F-5: 4.6 g, F-6: 3.5 g and F-7: 2.5 g). F-1 and F-3 contained nothing of interest. F-4 and F-5 showed significant inhibitory activity against xanthine oxidase. CC of F-2 over silica gel (200 g, 200–300 mesh) with a gradient of petrol-acetone mixtures (25:1→1:9) gave β-sitosterol (96 mg) and amyrin (39 mg). CC of F-4 on silica gel with a $CHCl_3$–MeOH gradient (100:1→+2:1) yielded 2 fractions (F-4-1 and F-4-2). Gel filtration of F-4-1 on Sephadex LH-20 with $CHCl_3$–MeOH (1:1) yielded syringic acid (28 mg) and pigments. Luteolin (35 mg) and apigenin (26 mg) were obtained from F-4-2 by column chromatography on silica gel (50 g) using $CHCl_3$–MeOH mixtures of a growing polarity. F-5 was applied to a silica gel column (800 g) eluted with $CHCl_3$–MeOH gradient to afford 3 fractions (F-5-l, F-5-2 and F-5-3). Repeated gel filtration of F-5-1 on Sephadex LH-20 with $CHCl_3$–MeOH (1:1) afforded **2** (18 mg) and **3** (15 mg). Gel filtration of F-5-2 over Sephadex LH-20 with $CHCl_3$–MeOH (1:9) yielded again **3** (7 mg) and takakin 8-*O*-glucuronide (34 mg). CC of F-5-3 over silica gel with $CHCl_3$–MeOH gradient (50:1→2:1) gave daucosterol (120 mg) and eugenol 4-*O*-glucopyranoside (26 mg). Separation of F-6 and F-7 following the same procedure gave again eugenol 4-*O*-glucopyranoside (16 mg), glycoside **1** (220 mg) and 3-hydroxy-5-methoxybenzoic acid (38 mg).

3.4. Xanthine oxidase assay

The xanthine oxidase inhibitory activity was measured according to a slight modification of the previously reported method (Li et al., 1999; Zhou et al., 1999). Xanthine oxidase from cow milk, xanthine and the standard inhibitor allopurinol were purchased from Sigma Chemical Co. (St. Louis, MO, USA). The reaction mixture contains 80 mM sodium pyrophosphate buffer (pH = 8.5), 120 μM xanthine and 0.1 unit of xanthine oxidase. The absorption at 295 nm indicating the formation of uric acid at 25°C was monitored and the initial rate was calculated. The test materials, initially dissolved in DMSO and then diluted with the same buffer, were incorporated in the enzyme assay to assess the inhibitory activity. Extracts, fractions and isolates were tested at 100 μg/ml, and those inhibiting the enzyme >50% were further tested to determine IC_{50} values.

3.5. 4-Hydroxypyridyl-3-oic acid 4-O-glucopyranoside (*1*)

Received 4 December 2000; received in revised form 26 February 2001

Abstract

A new sesquiterpene, scodopin, and a mixture of three tryptamine-type alkaloids, scorodocarpines A–C, were isolated from the fruits of *Scorodocarpus borneensis*, together with a known hemisynthetic sesquiterpene, cadalene-β-carboxylic acid, which was isolated from the bark. The structures of the new compounds were elucidated by interpretation of spectral data, especially tandem mass spectrometry for the alkaloid mixture. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Scorodocarpus borneensis*; Olacaceae; Sesquiterpenes; Tryptamine-type alkaloids; Tandem mass spectrometry

1. Introduction

From the fruits of *Scorodocarpus borneensis* (Baill.) Becc. (Olacaceae) collected in Malaysia, we have isolated a new sesquiterpene scodopin **1** and a mixture of three tryptamine-type alkaloids named scorodocarpines A–C (**2**–**4**). In addition, a sesquiterpene **5** of the cadalene group was isolated from the bark. Compound **5** has been synthesized previously, but was not known as a natural product (Parasmeswara Reddy and Khrisna Rao, 1982). The structures of the new compounds were established especially by 2D NMR along with tandem mass spectrosmetry (LSIMS/MS) for compounds **2**–**4**.

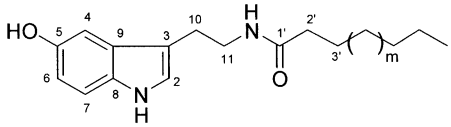
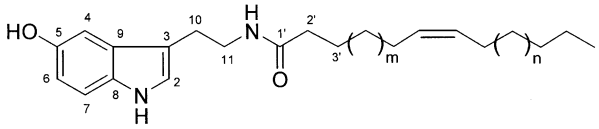
5



2 m = 16



3 m = 8, n = 4
4 m = 6, n = 4

2. Results and discussion

Scodopin (**1**) gave a MH^+ peak in the HRCIMS at *m*/*z* 233.1545 which matched the molecular formula $C_{15}H_{20}O_2$ (Δ 0.0004 u). The UV spectrum (λ_{max} 251 and 333 nm) together with the IR spectrum (ν 1619 and 1603 cm^{-1}) suggested a highly conjugated keto derivative. In the ^{13}C NMR spectrum, the carbonyl resonated at δ 174.7 and a peak at δ 163.5 could be assigned to a phenolic

carbon. Only three signals appeared in the aromatic region of the ^{1}H NMR spectrum, a singlet (1H) at δ 7.23 and two doublets (1H each, $J=11$ Hz) of two vicinal protons at δ 7.12 and 7.25. The aliphatic region showed the resonances of a methyl group at δ 1.22 (3H, *d*, $J=6.5$ Hz). The signals of an isopropyl moiety appeared at δ 0.78 (3H, *d*, $J=6.5$ Hz), 0.87 (3H, *d*, $J=6.5$ Hz) and 1.87 (1H, *m*). The spectrum also showed five other signals, which with the aid of the HMQC spectrum were identified as two methine and four methylene protons (Table 1). The connections between the aliphatic carbons were deduced from the spin system H_{15}–H_1–H_2–H_3–H_4–H_{12}–Me_{13}–Me_{14} revealed in the COSY experiment and were confirmed by the HMBC spectrum (Table 1). The latter was used to establish the linkage with the aromatic seven membered A ring (diagnostic cross peaks Me-15/C-10 and H-4/C-10,C-11), as well as the final structure of this ring, which was deduced together with the ^{1}H and the ^{13}C resonance data from the correlations H-6/C-7,C-8,C-11 and H-9/C-1,C-7,C-8,C-10,C-11. The relative stereochemistry at C-1 and C-4 was determined using the NOESY experiment measured at −40°C (Table 1). In these conditions, scodopin (**1**) adopts the usual half chair conformation for ring B. The correlations H-2βax/Me-13 and H-3αax/Me-15 indicated H-1β and H-4α configurations, respectively.

Scorodocarpines A–C (**2**–**4**),were isolated as a mixture. The EIMS showed three $[M]^{+\cdot}$ peaks at *m/z* 498, 496 and 468 corresponding to the molecular formulas of $C_{32}H_{54}O_2N_2$, $C_{32}H_{52}O_2N_2$ and $C_{30}H_{48}O_2N_2$, respectively. The UV spectrum exhibited maxima at 223, 278 and 304 nm suggesting an indole residue and the IR showed a band at 1636 cm^{-1} assignable to an amide carbonyl group. These data, along with peaks at *m/z* 160 and 146 observed in the mass spectrum (Maeda et al., 1993), were in accordance with the structure of *N*-acyl-5-hydroxytryptamines. The acyl residues were saturated (22 carbons) for compound **2**, and monounsaturated with 22 and 20 carbons for compounds **3** and **4,** respectively. The *N*-acyl-5-hydroxytryptamine type structure was confirmed by the NMR spectra ($CDCl_3$–CD_3OD 9:1, Table 2). The presence of the 5-hydroxyindole moiety

[a] Assignments based on 2D experiments.

was deduced from the coupling pattern of H-7 (δ 7.17, *d*, *J* = 8.5 Hz), H-6 (δ 6.75, *dd*, *J* = 8.5 and 2) and H-4 (δ 6.99, *d*, *J* = 2), while H-2 gave a singulet at δ 6.93, and was further supported by the typical ^{13}C NMR signals of the indole nucleus (Kamano et al., 1999) and the correlations observed in the HMBC experiment (Table 2). The latter also displayed a correlation between C-9 and H-10 of the tryptamine chain (CH_2-10, δ_H 2.85 and δ_C 25.7; CH_2-11, δ_H 3.48, δ_C 40.0). The signals of the amide NH appeared at δ 6.05 (*t*, *J* = 7) and the indole NH at δ 8.40 with small intensities due to partial deuterium exchange. The characteristic resonances of the acyl chains are given in Table 2. The geometry of the double bonds (δ_H 5.32, δ_C 130.1) is *Z*, which is deduced from the chemical shift of the α-CH_2 group (δ_C 27.4). The chains are linear owing to the presence of an unique signal for a terminal methyl at δ 14.3.

The structures of the tryptamine side chains were confirmed by an LSIMS/MS experiment which in addition allowed to determine the position of the double bond inside the chains. The LSIMS spectrum recorded in the presence of lithium iodide showed three peaks at *m/z* 505, 503 and 475 corresponding to ions $[\mathbf{2}+Li]^+$, $[\mathbf{3}+Li]^+$ and $[\mathbf{4}+Li]^+$, respectively.

The CID spectra of the precursor ion $[\mathbf{2}+Li]^+$ at *m/z* 505 displayed a series of peaks separated by 14 mass units in the *m/z* range 475–209. These fragments are generated by charge-remote fragmentation processes leading to losses of C_nH_{2n+2} neutral species from the precursor ion. They can be attributed to $'C_m$-type ions ($m = 1', 2', \ldots, 20'$) in agreement with the nomenclature proposed by Griffiths et al. (1996) and completed by Claeys et al. (1996). The fatty acyl moiety of compound **2** was thus easily identified as a docosanoate chain (Scheme 1).

The CID spectra of the precursor ion $[\mathbf{3}+Li]^+$ at *m/z* 503 showed fragment ion peaks identical to some of those observed on the corresponding spectrum of $[\mathbf{2}+Li]^+$, in particular the signals at *m/z* 209/210, 224, 237/238, 251 and 265. Two other ion peaks at *m/z* 349 and 403 were characteristic of allylic cleavages on both sides of a double bond located at position $C_{13'}$-$C_{14'}$ (Scheme 1). The fragments at *m/z* 335 ($'H_{10'}$) and 417/418 ($'H/_{16'}/H_{16'}$) corresponded to homoallylic cleavages and the ions $'V_{12'}$ and $'V_{14'}$ (*m/z* 363 and 389, respectively) were attributed to the vinylic fragmentations. The 13-docosenoate fatty acyl chain was thus unambiguously recognized by these mass spectrometric data.

The $[\mathbf{4}+Li]^+$ ion at *m/z* 475 showed a very similar behavior under high-energy collisional activation. The abundant fragment ion at *m/z* 321 assigned to the $'A_{9'}$ ion and the ions at *m/z* 375/376 (ions $'A_{13'}/A_{13'}$) indicated the presence of a double bond at position $C_{11'}$–$C_{12'}$. The other signals at *m/z* 293 ($'C_{7'}$), 307 ($'H_{8'}$), 335 ($'V_{10'}$), 361/362 ($'V_{12'}/V_{12'}$) and 389 ($'H_{14'}$) were in agreement with the structure. Thus, compound **4** corresponded to the product of *N*-acylation of serotonine by 11-eicosenoic acid.

Acyl tryptamines were known to exist in other plants, having various side chains (Maeda et al., 1993; Kamano et al., 1999), but unsaturated side chains were found for the first time in this study. They correspond to known acids isolated from several plants species. However,

these acids have not been found in the Olacaceae family whose chemical study is still scarce.

3. Experimental

3.1. General

Optical rotation at 20° were taken on a Perkin-Elmer 241 polarimeter. Spectra were recorded as follow: UV: MeOH, Varian CARY 100; IR: $CHCl_3$ or KBr, Perkin-Elmer SPECTRUM BX; NMR: Bruker AM 300 (^{13}C NMR spectra) and Bruker AMX 400 (^1H NMR and 2D NMR spectra); EIMS: Thermoquest Automass Multi; HRCIMS: Kratos MS-80 RF, MS/MS: see Section 3.4.

3.2. Plant material

Fruits and bark of *Scorodocarpus borneensis* (Baill.) Becc. (Olacaceae) were collected from Kuala Kangsar, Perak (Malaysia). The plant was identified by one of us (C.W). Voucher specimens (K1) are deposited at the Chemistry Department, Universiti Pertanian Malaysia.

3.3. Extraction and isolation

Dried fruits (200 g) of *S. borneensis* were extracted exhaustively with EtOH at room temperature. The extract (5.2 g) was repeatedly chromatographied on silica gel yielding scodopin **1** (12 mg, 1. $CHCl_3$–MeOH 99:1, 2. $CHCl_3$–MeOH 99.5:0.5) and the mixture of scorodocarpines A–C (**2**–**4**) (15 mg, 1. $CHCl_3$–MeOH 99.1, 2. $CHCl_3$–MeOH 98:2, 3. $CHCl_3$–MeOH 98:2).

Dried ground bark (300 g) of *S. borneensis* was extracted in the same way with EtOH. The extract (10.3 g) was again repeatedly chromatographied on silica gel affording compound **5** (20 mg, 1. petroleum ether, 2. petroleum ether–$CHCl_3$ 99:1).

3.4. Tandem mass spectrometry

The MS/MS spectra were obtained using a ZabSpec-T five sector tandem mass spectrometer (Micromass, Manchester, UK) with $E_1B_1E_2$-B_2E_3 geometry (E: electrostatic analyzers, B: magnets). The sample was dissolved in a liquid matrix (*m*-nitrobenzyl alcohol–glycerol–trifluoroacetic acid 50:50:1, saturated with lithium iodide). $[M+Li]^+$ precursor ions were generated by cesium ion bombardment at 30 keV. The precursor ions submitted to MS/MS experiments were selected by MS1 set at appropriate E and B values and then focused in a collision cell located in the fourth field-free region (between E_2 and B_2). Argon was introduced at a pressure leading to an almost 70% attenuation of the precursor ion beam. The collision cell was floated at 4 kilovolts so as to attain a collision energy of 4 keV. Further experimental details are given elsewhere (Gleye et al., 1999).

Gallotannin biosynthesis: β-glucogallin: hexagalloyl 3-*O*-galloyltransferase from *Rhus typhina* leaves

Ruth Niemetz, Georg G. Gross*

Molekulare Botanik, Universität Ulm, D-89069 Ulm, Germany

Received 11 May 2001; received in revised form 22 June 2001

Abstract

Leaves of staghorn sumac (*Rhus typhina*) contain several galloyltransferases that catalyze the β-glucogallin dependent transformation of 1,2,3,4,6-pentagalloylglucose to gallotannins. Among these, an enzyme has been isolated that preferentially acylates the 3-position of the hexagalloylglucose, 3-*O*-digalloyl-1,2,3,4,6-tetra-*O*-galloylglucose, to afford the corresponding heptagalloylglucose being characterized by a 3-*O*-*meta*-trigalloyl side-chain. The enzyme, for which a M_r of ca. 260,000 was determined, was purified to apparent homogeneity. SDS-PAGE suggested an $\alpha_4\beta_4$-conformation of the native enzyme. It had a pH-optimum and an isolelectric point at pH 5.6, was most stable at pH 4.0–4.3, and displayed excellent heat-stability and in particular an extreme cold-tolerance. We propose the systematic name "β-glucogallin: hexagalloylglucose 3-*O*-galloyltransferase" for this new enzyme. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Rhus typhina*; Anacardiaceae; Staghorn sumac; Biosynthesis; Gallotannins; Galloyltransferase

1. Introduction

Gallotannins, a subclass of hydrolyzable plant tannins, are receiving increasing attention as interesting chemotherapeuticals, a function that emerged from ethnopharmacological traditions, in particular of the Far East. For example, their antioxidant and radical scavenging activities have been investigated in relation to tumor prevention (Okuda, 1993); other potential applications regard vasodilatory effects (Goto et al., 1996) or use as diuretica and ailments of bladder and urinary tract (Haslam, 1996). The chemical structure of gallotannins is derived from a central polyphenolic unit, 1,2,3,4,6-penta-*O*-galloyl-β-D-glucose (Fig. 1; **2**). The phenolic hydroxyls of this key compound undergo substitution with additional galloyl residues to yield characteristic *meta*-depsidically linked diaryl or oligoaryl side-chains, like the *m*-digalloyl group (**3**) depicted in Fig. 1. Complex structures containing up to 12 galloyl residues can result from such processes. In the genus *Rhus*, these transitions are confined to positions 2, 3 and 4 of the glucose core (Nishizawa et al., 1982), while gallotannins from *Quercus* or *Paeonia* can bear *meta*-depside bonds also at C-6 (Nishizawa et al., 1980, 1983a, b). Biosynthesis studies with cell-free extracts from leaves of *Rhus typhina* (staghorn sumac) have shown that β-glucogallin (1-*O*-galloyl-β-D-glucose, **1**) is utilized not only as principal galloyl donor in the formation of pentagalloylglucose, but also in the subsequent acylation of this precursor to gallotannins (Hofmann and Gross, 1990). Two enzymes have been recently described that preferentially catalyzed the galloylation of 1,2,3,4,6-pentagalloylglucose (**2**) to hexa- and heptagalloylglucoses (Niemetz and Gross, 1998, 1999). A third enzyme activity encountered in these investigations, in contrast, displayed significant affinity against hexagalloylgucose substrates, in particular towards 3-*O*-digalloyl-1,2,4,6-tetra-*O*-galloyl-β-D-glucose (Fig. 3; **6**). The properties of this latter enzyme are described here .

2. Results and discussion

2.1. Enzyme purification

The transferase was isolated from homogenates of sumac leaves in the presence of PVP and borate, i.e.

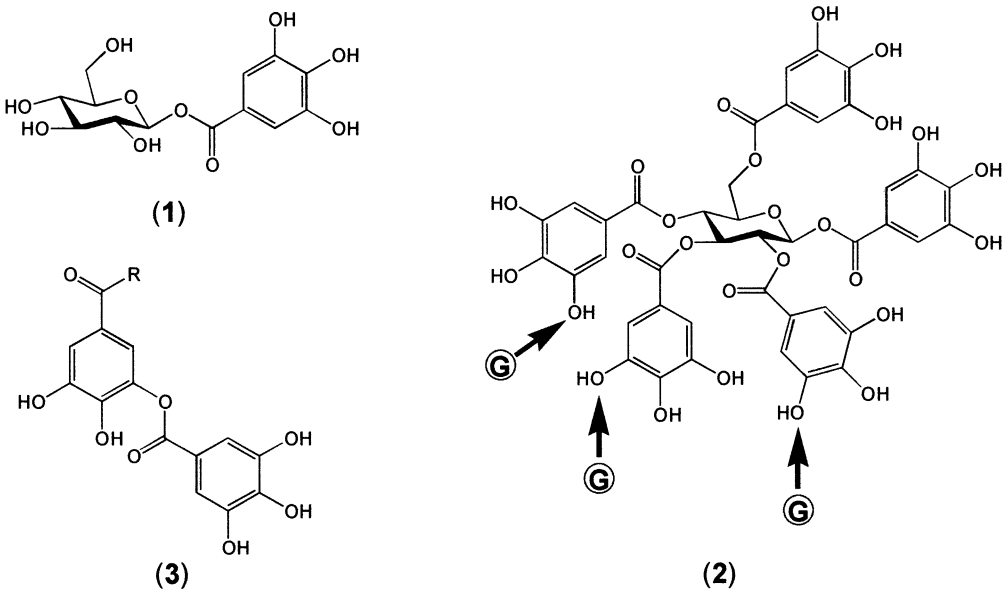

Fig. 1. Important compounds related to the structure and biosynthesis of gallotannins in *Rhus typhina*: (**1**) β-Glucogallin (1-*O*-galloyl-β-D-glucose), the principal galloyl donor; (**2**) 1,2,3,4,6-penta-*O*-galloyl-β-D-glucose, the basic galloyl acceptor in the biosynthesis of gallotannins. Arrows indicate positions for the attachment of additional galloyl groups (Ⓖ) in these transformations to yield *m*-digalloyl residues (**3**) and higher analogs.

agents that effectively form complexes with inhibitory endogenous plant phenolics. Residual contaminants were removed by stirring with Dowex anion-exchange resin, followed by ammonium sulfate fractionation of the crude extract. The enzyme solution was further purified by two gel-filtration steps. A first conventional step on Sephacryl S-300 efficiently removed a gallotannin degrading esterase ("plant tannase"; Niehaus and Gross, 1997), and also revealed the existence of several galloyltransferase activities (Fig. 2). Two of these (peaks A and C in Fig. 2) were ascribed to previously published pentagalloylglucose acylating galloyltransferases with M_r values of 360,000 and 170,000, respectively (Niemetz and Gross, 1998, 1999), while the third enzyme fraction (B in Fig. 2) obviously represented a novel galloyltransferase that preferentially acylated hexagalloylglucose substrates. This fraction was subjected to a second gel-filtration step by HPLC gel-permeation on a Merck GPC-diol column. Final purification was achieved by hydrophobic-interaction chromatography on butyl-sepharose. The transferase had thus been purified 625-fold with 3.2% yield to apparent homogeneity, as shown by PAGE under non-denaturing conditions. The results of a representative purification protocol with the hexagalloylglucose, 3-*O*-digalloyl-1,2,4,6-tetra-*O*-galloyl-β-D-glucose (**6**), as standard substrate are summarized in Table 1. The pure enzyme could be stored at 0–4 °C for several weeks without significant loss of activity.

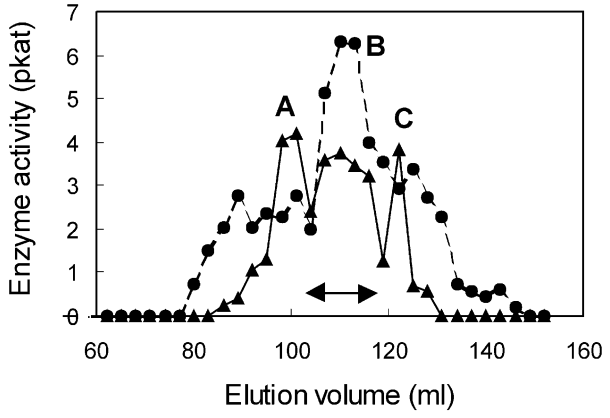

Fig. 2. Separation of gallotannin-synthesizing galloyltransferases from sumac leaves by gel-filtration on Sephacryl S-300. Enzyme activities were assayed with (▲) 1,2,3,4,6-penta-*O*-galloyl-β-D-glucose (**2**) and with (●) the hexagalloylglucose, 3-*O*-digalloyl-1,2,4,6-tetra-*O*-galloyl-β-D-glucose (**6**), respectively. Fractions representing peak B were pooled as indicated by the inserted double-arrow and further purified. Characteristics of the transferases constituting peaks A and C have been reported earlier (Niemetz and Gross, 1998, 1999).

2.2. General properties of the enzyme

The galloyltransferase reaction proceeded linearly between 2 and 18 μg protein under standard assay conditions (up to ca. 4 pkat, depending on the progress of the purification sequence), except for a slight lag-phase at 0–2 μg protein. No reaction occurred with protein denatured by heat or acid. Linearity of the reaction was maintained for ca. 60 min under standard conditions. The enzyme was inactive below pH 3.2 and above pH 7.5, with a maximum at pH 5.6 (citrate buffer); half-maximal activities were at pH 4.2 and 6.2. After pre-incubation at 30 °C for 3 or 24 h, respectively, the transferase was found most stable at pH 4.0–4.3 (half-

maxima at pH 3.2 and 4.7); rapid inactivation occurred below pH 2.5 and above pH 7 (pH 6 after 24 h duration of pH exposure). An isoelectric point of 5.6 was determined for the protein by chromatofocussing on a Pharmacia Mono P-column. The enzyme reaction proceeded optimally at 45 °C, with half-maximal activities at 32 and 55 °C. No reaction occurred above 70 °C, while a relative activity of 50% was observed even at 0 °C. After preincubation at pH 4 for 2 h at different temperatures, the transferase was stable at 0–20 °C (half-maximal at 35 °C) and was inactivated above 50 °C. The enzyme was thus characterized by an extreme cold-tolerance exceeding that of related galloylglucose synthesizing transferases. Its excellent heat-stability is similar to that of the earlier described transferase A (Fig. 2; Niemetz and Gross, 1998), but in clear contrast to the

Table 1

pronounced heat-sensitivity of transferase C (Fig. 2; Niemetz and Gross, 1999). From the above temperature dependence data, an average activation energy of 47 kJ mol^{-1} was calculated that corresponds to a Q_{10} value of 1.9. Gel-filtration experiments with a calibrated Sephacryl S-300 column revealed an apparent M_r of 260,000 ± 20,000 for the enzyme. After denaturing SDS-PAGE of the pure enzyme, the existence of two protein bands of ca. M_r 36,000 and 24,000 was observed which would suggest that the native transferase exist in an $\alpha_4\beta_4$-configuration.

2.3. Substrate specificity and reaction products

The enzyme exhibited normal Michaelis–Menten kinetics with the donor, β-glucogallin (**1**), between 1 and 4 μM concentration (with a lag-phase, i.e. subproportional reactivity, at 0–1 μM) and with the standard acceptor substrate, 3-*O*-digalloyl-1,2,4,6-tetra-*O*-galloyl-β-D-glucose (**6**), at ca. 100–300 μM concentration (lag-phase 0–100 μM). Increasing substrate inhibition ocurred above these values. As summarized in Table 2, numerous galloylglucoses were acylated by the transferase, but it is evident that hexagalloylglucoses were the preferred substrates. Among these, compound (**6**) must be considered as the most prominent substrate according to the criteria of both relative enzyme activities and v_{max} K_m^{-1} values and was therefore chosen as standard enzyme assay substrate. Heptagalloylglucoses (**7–9**) and mixtures of octa- and nonagalloylglucose isomers (compounds with defined structure were not available) were utilized as substrates with reaction rates that were at least equal to that of pentagalloylglucose (**2**).

Analysis of reaction products by reversed-phase HPLC showed that pentagalloylglucose (**2**) was transformed to hexagalloylglucoses (**4**), (**5**) and (**6**) in a ratio of 2:1:1. Upon utilization of hexagalloylglucoses as enzyme substrates, compound (**4**) was predominantly acylated to heptagalloylglucose (**7**), while (**5**) afforded (**7**) and (**8**) in a ratio of 2:1. The standard enzyme assay substrate, hexagalloylglucose (**6**), was exclusively galloylated to yield the heptagalloylglucose, 3-*O*-trigalloyl-1,2,4,6-tetra-*O*-galloyl-β-D-glucose (**9**). In accordance with earlier analyses of the components of Chinese gallotannin from *R. semialata* (Nishizawa et al., 1982) and also with our previous enzyme studies with *R. typhina* (Niemetz and Gross, 1998, 1999), no evidence for the formation of *m*-digalloyl residues in positions 1 or 6 of pentagalloylglucose has been obtained.

In summary, the reported kinetic data and metabolic transformations suggest that this enzyme is primarily involved in acylating the 3-*O*-*meta*-digalloyl group of hexagalloylglucose (**6**) to form the 3-*O*-*meta*-trigalloyl residue of heptagalloylglucose (**9**) (Fig. 3). This reaction was also catalyzed by an earlier reported acyltransferase (Niemetz and Gross, 1998) which, however, was most active in the conversion of pentagalloylglucose to hexagalloylglucose (**6**). Its other properties were also significantly different, like those of an acyltransferase with particular affinity towards the 2- and 4-positions of pentagalloylglucose (Niemetz and Gross, 1999). It is thus evident that the transferase described here is a new enzyme, for which the systematic name "β-glucogallin: hexagalloylglucose 3-*O*-galloyltransferase" is proposed.

3. Experimental

3.1. General experimental procedures

The origin of chemicals used in this investigation has been reported recently, as well as the techniques employed for native and SDS-PAGE, protein determinations and analysis of enzyme reaction products (Niemetz and Gross, 1998). Standard enzyme activitiy assays (70 μl vol.) were composed of 25 mM citrate buffer (pH 5.0), 3.6 mM β-glucogallin (**1**), 265 μM hexagalloylglucose (**6**) and 50 μl enzyme (ca. 7 μg–0.5 mg protein, depending on the purification degree). Acid-denatured enzyme was used for blanks. After incubation at 30 °C for 1 h, reactions were terminated by adding 10 μl 1 N HCl; extraction and HPLC-analysis of reaction products

Table 2
Substrate specificity of sumac leaf galloyltransferase[a]

Substrate	Relative activity (%)	v_{max} (nkat)	K_m (μM)	v_{max} K_m^{-1} ($\times 10^{-3}$)
1-*O*-Galloyl-β-D-glucose (β-glucogallin) (**1**)	–	–	2000	–
1,2,3,6-Tetra-*O*-galloyl-β-D-glucose	3.4	3.7	220	17

[a] Determinations were performed under standard assay conditions. Relative activities are compared to the reaction rate observed with 3-*O*-digalloyl-1,2,4,6-tetra-*O*-galloyl-β-D-glucose (**6**) equal to 100%.

have been described in detail by Niemetz and Gross (1998). The IEP of the enzyme was determined by chromatofocussing on a 200×5 mm i.d. Mono P column (Pharmacia). As buffers were employed: A = 0.025 M bis-Tris (2[bis(2-hydroxyethyl)imino]-2-(hydroxymethyl)-1,3-propanediol; Serva, Heidelberg), adjusted to pH 7.1 with iminodiacetic acid (Sigma); B = Polybuffer 74 (Pharmacia), diluted 1:10 with redistilled H_2O and adjusted to pH 4.0 with iminodiacetic acid. After equilibration with buffer A, elution of applied protein samples (100 μl vol.) was achieved by a linear gradient (0–45 min) of 0–100% B in A (flow rate 0.5 ml min^{-1}). Proteins and pH values of column eluates were monitored by spectrophotometry (UV 280 nm) and with a flow-through pH-electrode.

3.2. Plant material

Young leaves (2–4 months old) of staghorn sumac (*R. typhina*) were collected from trees in the surroundings of the university or plucked from greenhouse-grown plants. After washing with dist. H_2O, they were either immediately used as enzyme source, or frozen in liquid N_2 and stored at −20 °C in evacuated plastic bags where they could be stored for more than 6 months without apparent loss of enzyme activity.

3.3. Enzyme purification

All steps were carried out at 0–4 °C, and 2-mercaptoethanol (5 mM final conc) was added to all buffers. *R. typhina* leaves (80 g) were homogenized, extracted with Tris-borate buffer in the presence of PVP, and treated with Dowex 1X4 (50–100 mesh, borate form) as described previously (Niemetz and Gross, 1998). The filtrate was fractionated with solid $(NH_4)_2SO_4$. The 30–70% ppt. was redissolved in a minimal vol. of 50 mM phosphate buffer (pH 7.5, containing 0.1 M NaCl) and subjected to gel-filtration on Sephacryl S-300 (Pharmacia; column 400×2.4 mm i.d.) equilibrated in the same buffer. The active fractions were concentrated by ultrafiltration (Filtron Macrosep; exclusion limit 10,000 dalton) and subjected to HPLC by gel-permeation chromatography (GPC) on a diol-substituted column (Bio GPC-diol 'Superformance' glass column system; Merck, Darmstadt; 300×10 mm i.d.; 5 μm particle size; eluent 10 mM NaH_3PO_4 plus 300 mM NaCl, pH 7.2; flow rate 0.5 ml min^{-1}). The active frs were combined, adjusted to pH 5.0, supplemented with 1.25 M ammonium sulfate and subjected to HIC on butyl-sepharose (Merck; column 10×18 mm i.d.) equilibrated with 50 mM phosphate buffer (pH 5.0) plus 1.25 M ammonium sulfate. The column was successively washed with decreasing concns of ammonium sulfate (1.25, 0.625 and 0 M) in phosphate buffer (pH 5.0), followed by elution of the enzyme with redistilled H_2O.

Phospholipids modulate the substrate specificity of soluble UDP-glucose:steroid glucosyltransferase from eggplant leaves

Cezary Pązkowski, Małgorzata Kalinowska, Zdzisław A. Wojciechowski*

Department of Biochemistry, Warsaw University, ul. Miecznikowa 1, 02-096, Warsaw, Poland

Received 5 April 2001; received in revised form 14 June 2001

Abstract

UDP-glucose-dependent glucosylation of solasodine and diosgenin by a soluble, partially purified enzyme fraction from eggplant leaves is affected in a markedly different way by some phospholipids. While glucosylation of diosgenin and some closely related spirostanols, e.g. tigogenin or yamogenin, is strongly inhibited by relatively low concentrations of several phospholipids, the glucosylation of solasodine is unaffected or even slightly stimulated. These effects depend both on the structure of the polar head group and the nature of the acyl chains present in the phospholipid. The most potent inhibitors of diosgenin glucosylation are choline-containing lipids: phosphatidylcholine (PC) and sphingomyelin (SM) but the removal of phosphocholine moiety from these phospholipids by treatment with phospholipase C results in an almost complete recovery of the diosgenin glucoside formation by the enzyme. Significant inhibition of diosgenin glucoside synthesis and stimulation of solasodine glucosylation was found only with PC molecular species containing fatty acids with chain length of 12–18 carbon atoms. PC with shorter or longer acyl chains had little effect on glucosylation of either diosgenin or solasodine. Our results indicate that interaction between the investigated glucosyltransferase and lipids are quite specific and suggest that modulation of the enzyme activity by the nature of the lipid environment may be of importance for regulation of in vivo synthesis of steroidal saponins and glycoalkaloids in eggplant. © 2001 Elsevier Science Ltd. 1. Introduction

Solanum melongena L. (garden eggplant) is an interesting model plant for studies on the biosynthesis of steroidal glycoalkaloids and saponins and its regulation since this plant is known for the ability to synthesize both these types of steroid oligosides. Eggplant glycoalkaloids, solamargine and solasonine, which are derivatives of solasodine (a steroidal alkaloid of the spirosolane type) occur mainly in leaves and unripe fruits (Bajak et al., 1979; Vohora et al., 1984; Aubert et al., 1989; Blankemeyer et al., 1998) while saponins, so-called melongosides, which are derivatives of diosgenin and tigogenin (steroidal sapogenins of the spirostane type) accumulate mainly in seeds (Kintia and Shvets, 1985; Kintia, 1996).

Several years ago we reported (Pączkowski and Wojciechowski, 1993, 1994) that crude fraction of soluble proteins (105 000 *g* supernatant) obtained from eggplant leaves efficiently catalyzed glucosylation of diosgenin and tigogenin as well as solasodine in the presence of UDP-glucose (UDPGlc) as the sugar source. The reaction products which were identified as 3β-D-monoglucosides of diosgenin, tigogenin or solasodine, respectively, may be regarded as intermediates in the biosynthesis of melongosides and solamargine. More recently the enzyme (enzymes ?) responsible for UDPGlc-dependent glucosylation of the above mentioned steroids has been partially purified (ca. 50-fold) and characterized (Pączkowski et al., 1997, 1998). Co-purification of UDPGlc:diosgenin GlcTase and UDPGlc:-solasodine GlcTase activities during the purification procedure, identical native M_r values (55 kDa) and very similar sensitivities of these two GlcTase activities to a number of different chemicals indicated that glucosylation of solasodine and diosgenin was catalyzed by a

single enzyme protein exhibiting a relatively broad specificity with respect to the sugar acceptor. On the other hand, some data suggested a possibility that these enzyme activities might reside in two related but separate enzyme proteins. First, the activity ratio of UDPGlc:diosgenin to UDPGlc:solasodine GlcTase activity was significantly different in individual organs of eggplant. Second, these two enzyme activities were affected by several non-ionic detergents in a completely different manner strongly inhibiting glucosylation of diosgenin or tigogenin but having no effect or even slightly stimulating glucosylation of solasodine.

In the present paper we would like to report that several natural phospholipids can act on UDPGlc:diosgenin and UDPGlc:solasodine GlcTase activities in a similar way as demonstrated earlier for non-ionic detergents. It cannot be ruled out that these effects may be of importance for in vivo regulation of steroidal saponin and glycoalkaloid biosynthesis in eggplant.

2. Results

2.1. Effect of membrane lipids on diosgenin, tigogenin and solasodine glucosylation

The influence of several natural or synthetic lipids on activities of soluble, partially purified GlcTase from eggplant leaves is shown in Table 1. GlcTase activities were measured simultaneously with the use of all natural for eggplant steroidal substrates, i.e. diosgenin, tigogenin and solasodine, as acceptors of sugar moiety from UDPGlc. The data summarized in Table 1 demonstrate that glucosylation of steroidal sapogenins characteristic for eggplant, i.e. diosgenin and tigogenin is more or less strongly inhibited by several phospholipids. In contrast, glucosylation of eggplant steroidal alkaloid-solasodine was affected much less or, in some instances, it was even significantly stimulated. Among tested lipids the most pronounced inhibitory effect on sapogenin glucosylation was exerted by phospholipids containing phosphocholine moiety, i.e. by PC and SM. With these two lipids, strong inhibition (70–90%) of diosgenin or tigogenin glucosylation was observed at relatively low concentration 37.5 μM. At the same concentration PC and SM significantly increased glucosylation of solasodine–by 55 or 24% using egg yolk PC or bovine brain SM, respectively. It is worth of mentioning that some acidic glycerophospholipid tested, i.e. PI or PS, exerted much less pronounced inhibitory effect on glucosylation of eggplant steroidal sapogenins as compared to PC but they stimulated glucosylation of solasodine to a similar extent.

Results shown in Table 1 clearly indicate that phosphocholine moiety is essential for inhibition of diosgenin or tigogenin and stimulation of solasodine glucosylation by PC and SM. Neither DAG nor ceramide which are derivatives of PC and SM deprived of phosphocholine moiety had a significant effect on glucosylation of all tested steroid substrates.

Data shown in Fig. 1 demonstrate that inhibitory effects of PC and SM on glucosylation of steroidal sapogenins and stimulatory effects of these lipids on glucosylation of solasodine are concentration-dependent. Significant inhibition of diosgenin and tigogenin glucosylation was found at PC or SM concentrations as low as 4 μM, i.e. at concentrations only *ca.* 10-times higher than those of steroids used as the enzyme substrates.

The kinetic analysis indicated (data not shown) that addition of 10 μM di-$C_{16:0}$ PC had a negligible effect on apparent K_m values for diosgenin (0.33 μM) or UDPGlc (2.1 μM) but decreased the V_{max} of the enzyme ca. 2-fold,

Table 1
Effect of various lipids on glucosylation of diosgenin, tigogenin and solasodine by delipidated and partly purified UDPGlc-glucosyltransferase from eggplant leaves

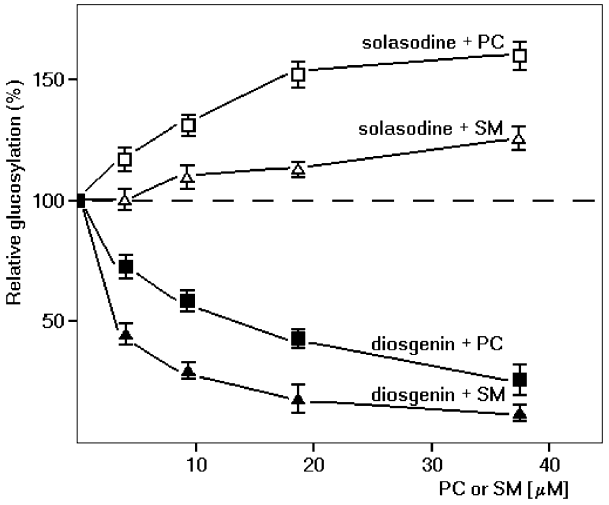

Fig. 1. Inhibition of UDPGlc:diosgenin (closed symbols) and stimulation of UDPGlc:solasodine GlcTase (open symbols) by increasing concentrations of PC (from egg yolk) or SM (from bovine brain).

i.e. from 18.0 to 9.8 nmol×mg protein^{-1} x h^{-1}. We were unable to determine how PC or SM affects kinetic constants for solasodine because in the presence of di-$C_{16:0}$ PC a non-hiperbolic enzyme kinetics was observed – in contrast to a typical Michaelis-Menten kinetics observed in the absence of lipid activator (Pączkowski et al., 1997).

Our earlier work (Pączkowski and Wojciechowski, 1994) has shown that crude fractions of soluble proteins (105 000 *g* supernatant from eggplant seedlings homogenate) can efficiently glycosylate, besides of steroids native to eggplant, several other steroidal sapogenins, e.g. yamogenin, hecogenin or nuatigenin, and steroidal alkaloids, e.g. tomatidine. We have also found (Pączkowski et al., 1998) that several non-ionic detergents, including Tween 80, are potent inhibitors of diosgenin and tigogenin glucosylation but they have little effect on glucosylation of solasodine, i.e. these detergents act in a similar manner to that described in the present paper for PC or SM.

Effects exerted by Tween 80, PC and SM on glucosylation of the above listed structural analogues of eggplant steroids are compared in Table 2. With yamogenin (25 *S*-epimer of diosgenin) the inhibitory effects of PC and SM were quite similar to those found for diosgenin and tigogenin (compare with data presented in Table 1). Tween 80, at 0.1% concentration, reduced glucosylation of yamogenin by more than 95%, similarly as in the case of diosgenin or tigogenin. It is of interest, however, that using other steroidal sapogenins inhibition by Tween 80 was much lower and there was no clear inhibition in the presence of PC or SM. It should be noted that hecogenin differs from tigogenin only by the occurrence of an additional oxo group in the ring C and nuatigenin is a pseudo-spirostane sapogenin containing an additional hydroxyl group in the ring F. Glucosylation of tomatidine, in contrast to that of solasodine, was significantly inhibited by Tween 80 but SM and PC stimulated its glucosylation to a similar extent as in the case of solasodine.

2.2. Influence of acyl moieties present in PC on glucosylation of diosgenin and solasodine

In order to establish whether the above described effects depend on acyl composition of phospholipid molecules we tested several PC species containing saturated fatty acids of different chain length. Results of this experiment demonstrated (see Fig. 2) that marked inhibition of diosgenin glucoside formation as well as significant stimulation of solasodine glucosylation could be found only using PC species containing fatty acids with chain length of 12–18 carbon atoms. PC species containing shorter or longer acyl components were much less effective or even inactive. It should be noted, however, that comparing effects of distearoyl- (di-$C_{18:0}$), dioleoyl- (di-$C_{18:1}$) and dilinoleoyl- (di-$C_{18:3}$) PC's no clear differences could be found in their effects on GlcTase activities studied (data not shown). Using dimyristoyl- (di-$C_{14:0}$) PC, which is, according to data presented in Fig. 2, the most efficient effector, we found that its effects on inhibition of diosgenin glucosylation and stimulation of solasodine glucosylation were temperature-independent. Relative degree of inhibition/stimulation was almost the same regardless incubations

Table 2
Comparison of effects of non-ionic detergent Tween 80, dipalmitoyl-PC or SM (from bovine brain) on glucosylation rates of some steroids structurally related to eggplant sapogenins or alkaloid

Steroidal acceptor added (0.75 μM)	Relative glucosylation rate (%)[a]		
	+ Tween 80[b]	+ PC[c]	+ SM[c]
Yamogenin (25*S*-spirost-5-en-3β-ol)	< 5	23	7
Hecogenin (25*R*-5α-spirostan-3β-ol-12-one)	35	103	74
Nuatigenin (22*S*,25*S*-epoxy-furost-5-ene-3β,26-diol)	48	107	108
Tomatidine (*22S*,25*S*-5α-tomatanin-3β-ol)	60	136	129

[a] Glucosylation rate in the absence of detergent or lipid is taken as 100%.
[b] A final concentration of Tween 80 in the assay mixture was 0.1%.
[c] Final concentrations of PC and SM were 37.5 μM.

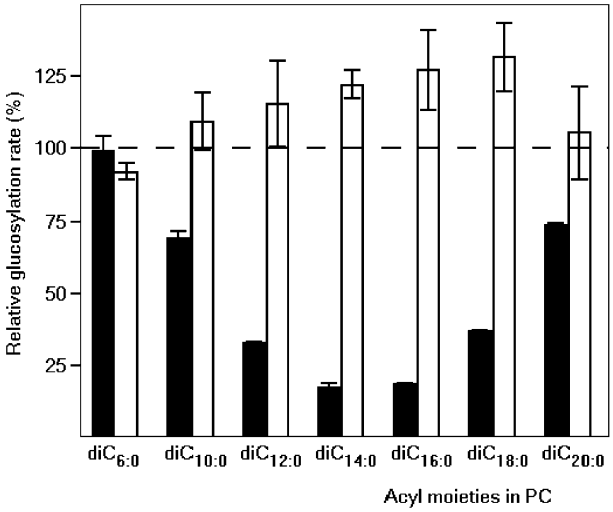

Fig. 2. Effect of phosphatidylcholines with different acyl chains on glucosylation of diosgenin (black bars) or solasodine (empty bars). Broken line shows the relative glucosylation rate in the absence of any PC.

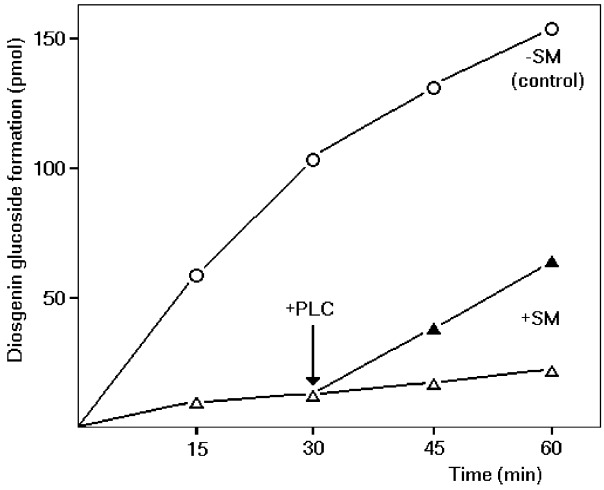

Fig. 3. Reversal of the inhibitory effect of bovine brain sphingomyelin (SM) on diosgenin glucosylation by treatment with phospholipase C from *Clostridium perfringens* (PLC). After 30 min incubation in the presence of 37.5 μM SM (open triangles), PLC (0.1 unit per incubated sample) was added. Black triangles show glucosylation of diosgenin in samples treated with PLC. In a control experiment incubations were carried out in absence of SM (open circles).

were carried out above (30 °C) or below (16 °C) the point of transition from gel to liquid-crystalline phase (22–24 °C) characteristic for dimyristoyl-PC (data not shown). These results clearly suggest that the above described effects of phospholipids on the activity of GlcTase studied are independent on their physical state.

2.3. Reversibility of phospholipid effects on GlcTase activity

It was an interesting question whether strong inhibition of steroidal sapogenin glucosylation by phosphocholine-containing lipids is an irreversible phenomenon. In order to elucidate this question, after 30-min-long incubation of eggplant GlcTase with diosgenin, labelled UDPGlc and bovine brain SM, incubated samples were treated with phospholipase C from *Clostridium perfringens* (type I, Sigma) which is known to remove phosphocholine moiety from both SM and PC.

Data summarized in Fig. 3 clearly demonstrate that hydrolysis of SM into phosphocholine and ceramide resulted in an almost complete recovery of diosgenin glucosylation rate which can be observed in the absence of SM. A similar experiment with the use of di-$C_{16:0}$ PC instead of SM gave in principle the same results (data not shown). Therefore, inhibition of diosgenin glucosylation by PC and SM is entirely reversible after hydrolytic removal of phosphocholine moiety from these lipids.

2.4. Effects of unlabelled diosgenin, tigogenin and solasodine on glucosylation of [3-^{3}H]tigogenin

Fig. 4 shows results of an experiment in which the influence of excess amounts (up to 5-fold) of unlabelled steroidal sapogenins native to eggplant as well as of solasodine was studied on glucosylation rate of tritium labelled tigogenin. As it could be predicted both unlabelled tigogenin and diosgenin decreased amounts of labelled tigogenin glucoside formed. Even a higher decrease of glucosylation of radioactive tigogenin, however, was found in the presence of unlabelled solasodine. This means that solasodine evidently can compete for steroid-substrate binding site in the enzyme responsible for glucosylation of tigogenin. It should be mentioned that in the experiment shown in Fig. 4 a very high concentration of cold UDPGlc were used. Therefore, decrease of [3-^{3}H]tigogenin glucosylation in the presence of unlabelled solasodine cannot be explained simply by competition for donor nucleotide sugar. In this experiment consumption of UDPGlc during the incubation never exceeded 1.5% of the amount added to the assay medium.

3. Discussion

The in vitro influence of lipids on activities of enzymes solubilized from membranous structures is a well-known phenomenon (Sandermann, 1978; Carruthers and Melchior, 1986). Stimulation or inhibition by some specific lipids has been also reported for a number of membrane-bound glycosyltransferases of plant origin (see e.g. Kaushal and Elbein, 1987; Coves et al., 1988; Saugy et al. 1988; Ullmann et al., 1993). The above-mentioned effects are not surprising since lipids constitute a natural environment for all membrane-bound enzymes. Reports on modulation by lipids of typical

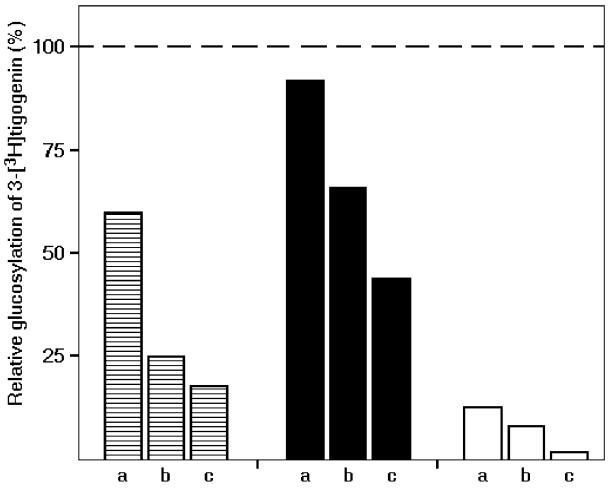

Fig. 4. Effect of excess amounts of unlabelled tigogenin (hatched bars), diosgenin (black bars) or solasodine (empty bars) on glucosylation of 3-[^{3}H]tigogenin. Labelled tigogenin (0.95 μM, sp. act. 11.67 GBq/mmol) and unlabelled UDPGlc (56.6 μM) were incubated in the presence of unlabelled tigogenin, diosgenin or solasodine (0.95, 1.90 or 4.75 μM for a, b and c, respectively). Broken line shows the glucosylation rate of labelled tigogenin in the absence of any unlabelled steroid.

cytosolic enzymes are scarce. In latter cases it has been postulated a subtle regulation of the activity of "cytosolic" enzymes by their binding to the cellular membranes, at least in a temporary way (Żydowo, 1993; Sims et al., 1999). Although steroid-specific GlcTase from eggplant leaves was found in 105 000 *g* supernatant obtained from the crude homogenate and, therefore, it has been initially described as a cytosolic enzyme (Pączkowski and Wojciechowski, 1994; Pączkowski et al., 1997, 1998), it seems quite possible that in vivo this enzyme is weakly membrane-bound or, at least, it can transiently interact with cellular membranes. The well-marked hydrophobic nature of its steroidal substrates as well as its evident sensitivity to some natural lipids, reported in the present study, are serious arguments for such a hypothesis. It is noteworthy that "cytosolic", flavonol-specific GlcTase from *Chrysosplenium americanum* leaves has been found to be associated with vesicle-like structures by immunolocalization (Latchinian-Sadek and Ibrahim, 1991).

In our previous paper (Pączkowski et al., 1998) we have suggested the presence in eggplant leaves of two separate UDPGlc-dependent GlcTases specific for spirostane sapogenins, i.e. diosgenin and tigogenin, and for solasodine, respectively. This suggestion based mainly on two findings: First, the ratios of UDPGlc:diosgenin GlcTase activity to UDPGlc:solasodine GlcTase activity were significantly different in crude cytosolic fractions obtained from various organs of eggplants of different age, ranging from 0.7 (ripening seeds) to 1.9 (stems). Second, several non-ionic detergents including Tween 20, Tween 80, Triton X-100 and Tyloxapol used at very low concentrations (0.05–0.1%) strongly reduced the rate of diosgenin glucosylation but had little effect on the formation of solasodine glucoside or were in the latter case even slightly stimulatory. At first sight the results of our present work support the above suggestion furnishing evidence that some natural lipids, particularly these containing phosphocholine moiety such as PC or SM, exert completely different effects on glucosylation rates of spirostane sapogenins occurring in eggplant, i.e. diosgenin and tigogenin, and glucosylation rate of eggplant steroidal alkaloid–solasodine. However, with some other steroids tested, which have been shown earlier (Pączkowski and Wojciechowski, 1994) to be good substrates for cytosolic GlcTase from eggplant leaves, both non-ionic detergent Tween 80 and choline containing phospholipids had intermediary effects as compared to the effects on glucosylation of diosgenin/tigogenin and solasodine. This is particularly evident for hecogenin which is steroidal sapogenin differing from tigogenin only by the presence of an additional oxo group at C-12. These results suggest rather a possibility that glucosylation of both steroidal sapogenins and alkaloids is catalyzed by a single enzyme but the specificity of this enzyme can be modulated in the presence of some amphipathic molecules such as detergents or phospholipids. Modulatory effects of lipid-enzyme interactions on substrate specificities of some enzymes have been well-documented in several cases (see e.g. Inagaki et al., 1986; Woscholski et al., 1995; Pappan et al., 1998; Frank et al., 1999). Such effects have been also reported by Magdalou et al., (1982) for UDP-glucuronosyltransferase isolated in a pure form from pig liver. The latter enzyme showed variable activity with several phenolic compounds used as substrates depending on the chemical nature of lipid effectors present in assay mixtures and these authors concluded that the ratio of glycosylation rate of various phenolics is not a static property of the enzyme, but can be modulated by the structure of the phospholipid present in the enzyme environment.

An additional evidence for glucosylation of solasodine as well as diosgenin and tigogenin by a single GlcTase furnished experiments in which effects of cold tigogenin, diosgenin and solasodine on glucosylation rate of [3-^{3}H]tigogenin were studied. The results of these experiments clearly indicate that cold solasodine can efficiently compete with labelled tigogenin for a binding site in the enzyme. In fact, cold solasodine decreased the rate of [3-^{3}H]tigogenin glucosylation even more strongly that cold tigogenin or diosgenin– this is, however, in accordance with the results presented in our previous paper (Pączkowski et al., 1998) indicating that K_m value of partially purified eggplant GlcTase for solasodine (0.04 μM) was several-fold lower than that for diosgenin (0.33 μM). In the present study K_m of 0.26 μM was measured for the third natural substrate of eggplant GlcTase, i.e. tigogenin.

Different ratios of glucosylation rates of solasodine and diosgenin reported by us earlier (Pączkowski et al., 1998) for crude cytosolic preparations obtained from various organs of eggplants may be explained by variable quantity and quality of lipids present in these preparations.

4. Experimental

4.1. Enzyme preparations

Crude lipid-depleted enzyme preparations (''acetone powders'') were obtained from crude cytosol fraction (105 000 *g* supernatant) of 8-week-old eggplant, cv. Black Beauty, leaves exactly as previously described (Pączkowski and Wojciechowski, 1994). These ''acetone powders'', when kept dry at −20 °C, retained almost all of the GlcTase activity for several months and were used as a source of partially purified enzyme according to Pączkowski et al. (1998). In contrast to crude ''acetone powders'', partially purified GlcTase preparations were quite unstable and lost ca. 60% activity during 24-h-long storage at 4 °C.

4.2. Glucosyltransferase assays with labelled UDPGlc

GlcTase activities were assayed essentially as previously described (Pączkowski et al., 1998) by measuring the transfer of labelled glucose from UDP-[^{3}H]glucose or UDP-[^{14}C]glucose to a steroid acceptor at saturating concentrations of both substrates. Unless otherwise stated, the standard assay mixture contained in a final volume of 0.53 ml: 30 or 0.6 μg protein, for crude or partially purified enzyme, respectively, in 0.50 ml 0.05 M HEPES buffer, pH 7.3 containing 10 mM 2-mercaptoethanol; diosgenin or solasodine (0.4 nmol) in 0.01 ml EtOH; UDP-[^{3}H]Glc or UDP-[^{14}C]Glc (1.5 nmol, 2×10^5 dpm) in 0.01 ml 50% EtOH, and varying amount of a lipid effector solution in 0.01 ml EtOH. In some experiments a steroid substrate and a lipid effector were added to the assay mixture as a clear dispersion in 0.02 ml water prepared by sonication according to Jensen and Schutzbach (1985). The effects of lipids on the GlcTase activities studied were, however, virtually the same, regardless of the method of their introduction into the incubation medium. Incubations were carried out at least in triplicate, usually at 30 °C, for 45 min. The reaction was terminated and the labelled glucoside product was separated from the labelled substrate and/or its degradation products by extraction with *n*-butanol as described earlier (Pączkowski and Wojciechowski, 1994). Aliquots of the organic phases were transferred to scintillation vials, evaporated to dryness and counted for radioactivity in a toluene-based scintillation fluid.

4.3. Glucosyltransferase assays with labelled tigogenin

The incubation conditions were similar to the above described for enzyme assays with labelled UDPGlc but [3-^{3}H]tigogenin (0.5 nmol, 3.5×10^5 dpm) and unlabelled UDPGlc (30 nmol) were used as the substrates. After extraction with *n*-butanol labelled tigogenin glucoside was separated from labelled tigogenin by TLC as described below, eluted from silica gel with MeOH and counted for radioactivity. Labelled [^{3}H]tigogenin was prepared as previously stated (Pączkowski et al., 1998).

4.4. Identification of the reaction products

For identification of products of the enzymic reaction, the *n*-butanol extracts were evaporated to dryness. Dry residues were dissolved in a small volume of $CHCl_3$–MeOH (2:1) and then subjected to TLC on silica-gel plates (DC Plastikfolien, Kieselgel 60, Merck) developed with $CHCl_3$–MeOH (17:3). Labelled glycosides were localized on the plates by autoradiography. For partially purified enzyme, incubations with all tested steroids afforded a single radioactive product with $R_f = 0.51$ (diosgenin, tigogenin, yamogenin and hecogenin); $R_f = 0.46$ (nuatigenin); $R_f = 0.36$ (tomatidine) and $R_f = 0.20$ (solasodine).

Received 9 March 2001; received in revised form 18 May 2001

Abstract

8-Dimethylallylnaringenin (8-DMAN) 2′-hydroxylase, which is indispensable for the formation of a lavandulylated flavanone, sophoraflavanone G, was detected in cell suspension cultures of *Sophora flavescens*. The enzyme catalyzes the 2′-hydroxylation of 8-DMAN to leachianone G, and is tightly bound to the membrane. It required NADPH and molecular oxygen as cofactors, and was inhibited by several cytochrome P450 inhibitors such as carbon monoxide and cytochrome c, indicating that the reaction is mediated by a cytochrome P450 monooxygenase. The optimum pH of 8-DMAN 2′-hydroxylase was 8.5, and the enzyme hydroxylated only 8-DMAN. Apparent K*m* values for 8-DMAN and NADPH of the enzyme were 55 and 34 μM, respectively. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Sophora flavescens*; Leguminosae; Cell suspension cultures; Biosynthesis; Cytochrome P450 mono-oxygenase; Prenylated flavanones; 8-Dimethylallylnaringenin; Leachianone G; Sophoraflavanone G

1. Introduction

Prenylated flavonoids are widely distributed in leguminous, moraceous, berberidaceous and iridaceous plants (Barron and Ibrahim, 1996). In most cases, one or two dimethylallyl moieties are bound to the A or B rings of flavonoids, and sometimes cyclization of a double bond of this side chain with a neighboring phenolic OH function forms a chromene ring as seen in euchrestaflavanone c and osajin in *Euchresta japonica* (Shirataki et al., 1982). Furthermore, it is characteristic of prenylated flavonoids in *Sophora flavescens*, a leguminous plant, to possess a lavandulyl group, an irregular monoterpenoid unit, at the C-6 or C-8 position of 2′-hydroxyflavanone (Hatayama and Komatsu, 1971; Wu et al., 1985a,b,c, 1986). For elucidation of the formation mechanism of this unique prenyl group, we have established cell suspension cultures of *S. flavescens* which produced sophoraflavanone G (SFG), one of the main lavandulylated flavanones in the intact plant (Yamamoto et al., 1991). We have also found that the production of SFG in the cultured cells was stimulated by the addition of some elicitors (Yamamoto et al., 1995) as well as cork tissues (Yamamoto et al., 1996, 1999). Recently, we reported naringenin 8-dimethylallyltransferase in the microsomal fraction from *S. flavescens* cultured cells that prenylated C-8 of (−)-(2*S*)-naringenin to afford (−)-(2*S*)-8-dimethylallylnaringenin (8-DMAN; sophoraflavanone B) as the sole prenylated product (Yamamoto et al., 2000a). The enzyme prenylated naringenin more effectively compared to other flavanone derivatives. Interestingly, when 2′-hydroxynaringenin was used as a prenyl acceptor, the formation of SFG, a lavandulylated flavanone, together with that of 2′-hydroxy-8-dimethylallylnaringenin (leachianone G, LG) was observed. At that time, any naringenin 2′-hydroxylation activity could not be detected in *S. flavescens* cells. These data suggest that the 2′-hydroxy group of flavanone plays an important role for the formation of a lavandulyl group in *S. flavescens* cells, and that a lavandulyl group is formed by two-step dimethylallylations, between which 2′-hydroxylation is inserted (Fig. 1).

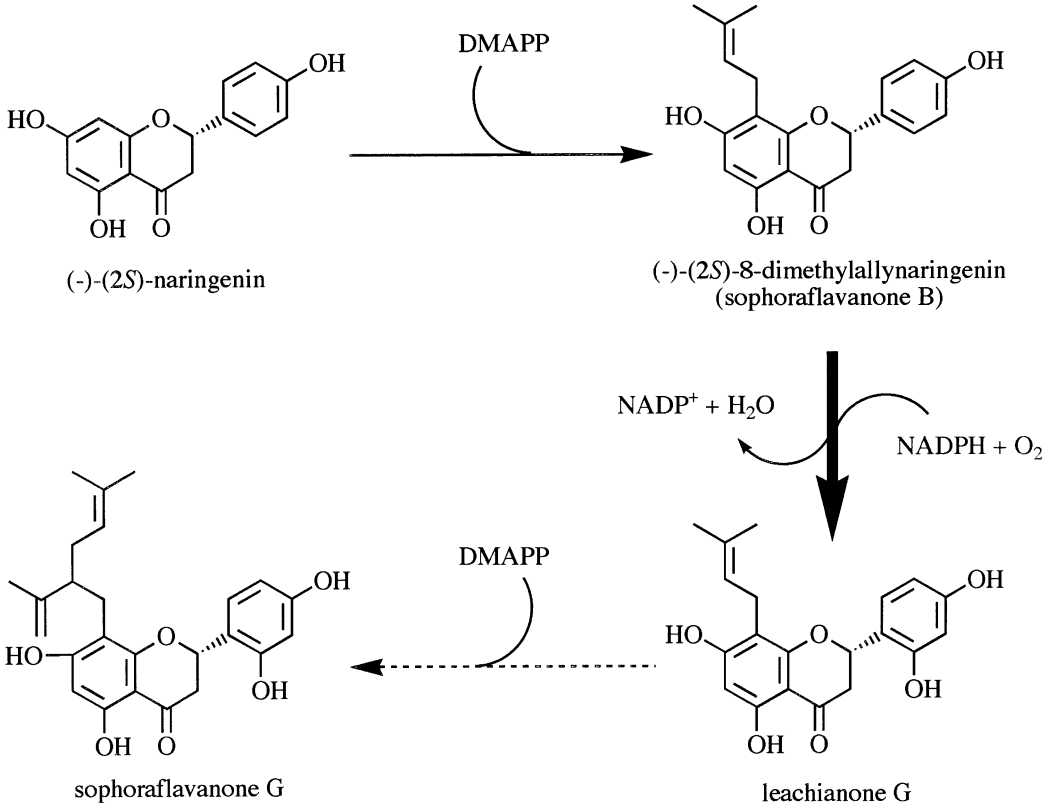

Fig. 1. Proposed biosynthetic route to sophoraflavanone G from naringenin in *Sophora flavescens* cultured cells. DMAPP: dimethylallyl diphosphate.

In the present paper, we report the detection and characterization of 8-DMAN 2′-hydroxylase, essential for the formation of lavandulylated flavanones, in *S. flavescens* cultured cells.

2. Results and discussion

2.1. Detection of 8-DMAN 2′-hydroxylase activity

When crude cell-free extracts or the microsomal fraction from *S. flavescens* cell suspension cultures were incubated with (−)-(2*S*)-8-DMAN and NADPH, the formation of a new compound whose retention time and UV absorption pattern were completely identical to those of leachianone G (LG) was observed in HPLC-photodiode array analysis. The reaction product was isolated on a preparative scale, and was identified as LG by the direct comparison of its EI-MS spectrum with that of authentic LG. More than 90% of the hydroxylation activity still remained in the twice-washed 100,000×*g* pellets, indicating that the hydroxylase was tightly bound to the membrane fraction of the cells (data not shown). The activity depended on the presence of the active enzyme, 8-DMAN and NADPH, and the latter could not be replaced by NADH, FAD or FMN (Table 1).

Table 1
Activity and cofactor requirement of 8-DMAN 2′-hydroxylase from cultured cells of *Sophora flavescens*[a]

Conditions	Relative activity (%)
Complete assay	100.0
Heat-denatured enzyme	0.0
- 8-DMAN	0.0
- Protein	0.0
- NADPH	0.0
- 1 mM NADPH + 1 mM NADH	16.2
- 1 mM NADPH + 1 mM FAD	7.3
- 1 mM NADPH + 1 mM FMN	9.5

[a] The complete assay contained microsomal protein (430 μg), 1 mM (S)-8-DMAN, and 1 mM NADPH. Incubations were carried out as described in Experimental (incubation time: 120 min). 8-DMAN 2′-hydroxylase activity in the complete assay was 13.3 pkat/mg protein.

2.2. Biochemical properties of 8-DMAN 2′-hydroxylase

The pH optimum of 2′-hydroxylase activity was 8.5 in Tris–HCl buffer. The activity in glycine-NaOH buffer at pH 8.5 was only 60% of that observed in Tris–HCl-buffer (data not shown). The hydroxylation of 8-DMAN was linear with time up to 60 min and with protein concentration from 0.06 mg to 0.6 mg in the standard assay. The substrate specificity of 8-DMAN 2′-hydroxylase for

several flavonoids including chemically synthesized dimethylallylated naringenins (Tahara et al., 1994) was investigated. Among these, only 8-DMAN was hydroxylated, but other flavonoids examined, kaempferol, quercetin, apigenin, genistein, naringenin, 6-dimethylallylnaringenin, 3′-dimethylallylnaringenin, 3′,6-di-(dimethylallyl)naringenin, 6″,6″-dimethyl-4″,5″-dihydropyrano-[2″,3″:6,7]naringenin and 6″,6″-dimethyl-4″,5″-dihydropyrano-[2″,3″:7,8]naringenin were not hydroxylated (data not shown). The optimal concentrations of (−)-(2*S*)-8-DMAN and NADPH for enzymatic hydroxylation were between 0.5 and 1 mM, and the apparent K_m values for 8-DMAN and NADPH were calculated as 55 and 34 μM, respectively (Figs. 2 and 3).

2.3. Involvement of cytochrome P450 in 8-DMAN 2′-hydroxylation

In addition to NADPH, 8-DMAN 2′-hydroxylase required molecular oxygen (Table 2). Replacement of O_2 in the reaction mixture by N_2 prior to the incubation led to a significant decrease in the activity. When O_2 in the reaction mixture was completely removed by the addition of an excess of glucose, glucose oxidase and catalase (Kochs and Grisebach, 1987), the formation of LG was hardly detectable (Table 2). These findings suggested the participation of cytochrome P450 haemoprotein in the hydroxylation of 8-DMAN. To confirm this hypothesis, the effects of several cytochrome P450 inhibitors were examined (Table 3). Carbon monoxide, a well-known inhibitor of cytochrome P450 (Ortiz de Montellano and Correia, 1995), strongly inhibited the

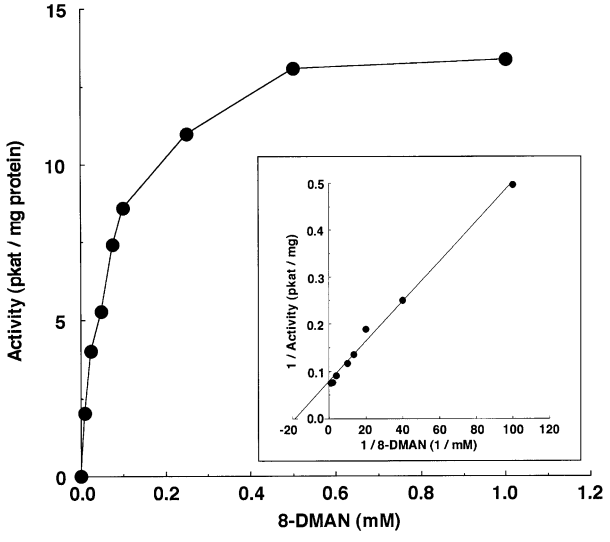

Fig. 2. Dependence of 8-DMAN 2′-hydroxylase on the concentration of (−)-(2*S*)-8-dimethylallylnaringenin (DMAN) measured with the microsomal fraction of *Sophora flavescens*. Insert: Lineweaver-Burk plot with varying concentrations (0.01–1 mM) to calculate the apparent K_m value for (−)-(2*S*)-8-DMAN.

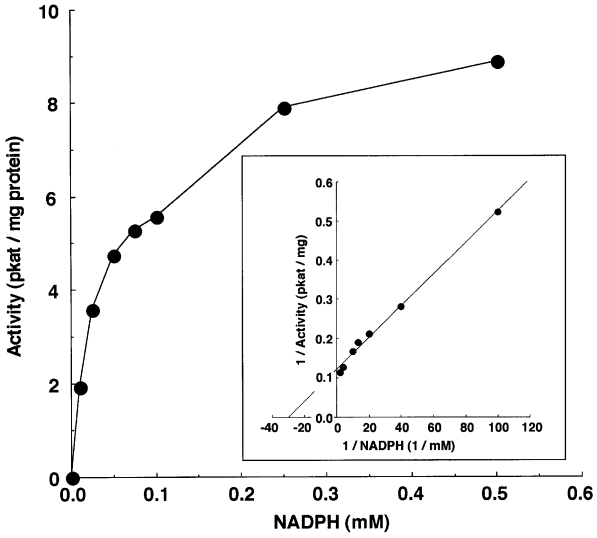

Fig. 3. Dependence of 8-DMAN 2′-hydroxylase on the concentration of NADPH measured with the microsomal fraction of *Sophora flavescens*. Insert: Lineweaver–Burk plot with varying concentrations (0.01–0.5 mM) to calculate the apparent K_m value for NADPH.

Table 2
Oxygen dependence of 8-DMAN 2′-hydroxylase activity[a]

Conditions	Relative activity (%)
Air bubbled	100.0
N_2 bubbled	13.7
+ Glucose + glucose oxidase + catalase	8.8
+ Glucose + heat-denatured glucose oxidase + catalase	89.4

[a] Incubations were carried out as described in Experimental. 8-DMAN 2′-hydroxylase activity in air bubbled control was 12.6 pkat/mg protein

Table 3
Effects of cytochrome P450 inhibitors on 8-DMAN 2′-hydroxylase activity[a]

Inhibitor	Relative activity (%)
Air (dark)	100.0
CO/O_2 (9:1, dark)	14.5
CO/O_2 (9:1, light)	77.0
None	100.0
Ancymidol 1 mM	94.7
Metyrapone 1 mM	76.0
Miconazole 1 mM	63.7
Tropolon 1 mM	69.9
Cytochrome 10 mM	29.1
KCN 1 mM	109.0

[a] Incubations were carried out as described in Experimental. White light (20,000 lx) was used for the reversion experiment. 8-DMAN 2′-hydroxylase activity in the control assay (Air, Dark) was 15.5 pkat/mg protein.

hydroxylation in the dark, and this inhibition was partially reversible by the illumination. Cytochrome c, which competitively removes electrons from the NADPH-cytochrome c reductase complex (Ortiz de Montellano and Correia 1995), was the strongest inhibitor tested. Even at 10 μM cytochrome c, the activity was inhibited by about 70%. Other inhibitors, ancymidol (Graebe 1987), metyrapone and miconazole (Ortiz de Montellano and Correia 1995) and tropolone (Rueffer and Zenk, 1994) showed less pronounced inhibition of 8-DMAN 2′-hydroxylation similar to their effects on other plant cytochrome P450 mono-oxygenases (Tang and Suga 1994; Petersen, 1997; Yamamoto et al., 2000b). Potassium cyanide, an inhibitor of peroxidase, hardly affected the activity (Saunders et al., 1964). These results indicate that 8-DMAN 2′-hydroxylase belongs to the group of cytochrome P450 monooxygenases.

Several studies have been done on the flavonoid hydroxlases, most of which are cytochome P450-dependent. 2′- and 3′-Hydroxylases from *Cicer arietinum* were specific solely for 4′-methoxyisoflavones but the substrate specificity for flavanones was not described (Clemens et al., 1993; Overkamp et al., 2000). Heterologous expression in yeast demonstrated that CYP81E1, a cytochrome P450 cDNA cloned from *Glycyrrhiza echinata,* is isoflavone 2′-hydroxylase, which catalyzed the hydroxylation of isoflavones such as daidzein and formononetin but did not that of flavanones (Akashi et al., 1998). Furthermore, up to the present time, nothing has been reported about flavanone 2′-hydroxylase. The cytochrome P450-dependent hydroxylase investigated in this paper, which catalyzes the hydroxylation of 8-dimethylallynaringenin alone, accordingly, is the first example of the 2′-hydroxylase of prenylated flavanones.

Recently we demonstrated that the presence of 2′-OH function of naringenin is indispensable for the formation of SFG in *S. flavescens* cultured cells (Yamamoto et al., 2000a). We also speculated that a lavandulyl group at C-8 of naringenin is formed by phased dimethylallylations, between which the hydroxylation at C-2′ intervenes, since naringenin 2′-hydroxylase activity was hardly detectable in *Sophora* cells. In this paper, we demonstrated that 8-DMAN was converted to LG by membrane-bound 8-DMAN 2′-hydroxylase from *S. flavescens* cultured cells and that 8-DMAN 2′-hydroxylase is a member of the cytochrome P450 mono-oxygenase family. It follows from these results that SFG is biosynthesized from naringenin via 8-DMAN and LG, successively, by naringenin 8-dimethylallyltransferase, 8-DMAN 2′-hydroxylase and an uncharacterized membrane-bound lavandulyl moiety synthase (Yamamoto et al., 2000a) in *S. flavescens* cells (Fig. 1).

In leguminous plants, prenylation of flavonoids is known to take place in the plastids (Biggs et al., 1990). Furthermore, their dimethylallyl groups are found to be derived from the non-mevalonate pathway (Hano et al., 1994; Asada et al., 2000) which is operative in the formation of isoprenoids biosynthesized in the plastids such as monoterpenoids (Eisenreich et al., 1997; Adam et al., 1998; Turner et al., 1999), as well as β-carotene and prenyl chains of chlorophylls (Lichtenthaler et al., 1997; Disch et al., 1998). In contrast, in *Lithospermum erythrorhizon* cultured cells, geranyl pyrophosphate supplied from the mevalonate pathway in the endoplasmic reticulum/cytosol (Sommer et al., 1995; Li et al., 1998) was utilized for the prenylation of *p*-hydroxybenzoic acid which took place in the endoplasmic reticulum (Yamaga et al., 1993). In SFG biosynthesis, 2′-hydroxylation catalyzed by a cytochrome P450 monooxygenase occurred between two prenylations, and most of cytochrome P450 enzymes were associated with the endoplasmic reticulum (von Wachenfeldt and Johnson, 1995). Thus, in *Sophora* cells, the reaction site of the two prenylations in relation to the source of two dimethylallyl moieties might be different. For the complete elucidation of the lavandulyl moiety formation in *Sophora* cells, it will be necessary to clarify the subcellular localization of the three membrane-bound enzymes including 8-DMAN 2′-hydroxylase and two prenyltransferases as well as the origin of dimethylallyl diphosphate.

3. Experimental

3.1. Chemicals

(−)-(*2S*)-8-Dimethylallylnaringenin was enzymatically synthesized using naringenin 8-dimethylallyltransferase from *Sophora flavescens* cultured cells (Yamamoto et al., 2000a). 6-Dimethylallylnaringenin, 3′-dimethylallylnaringenin, 3′,6-di-(dimethylallyl)naringenin, 6″,6″-dimethyl-4″,5″-dihydropyrano-[2″,3″:6,7]naringenin and 6″,6″-dimethyl-4″,5″-dihydropyrano-[2″,3″:7,8]naringenin were chemically synthesized from naringenin and 2-methyl-3-buten-2-ol in the presence of boron trifluoride/etherate according to the method of Tahara et al. (1994). Apigenin, genistein, kaempferol, naringenin and quercetin were purchased from Funakoshi, Japan.

3.2. Plant material and culture method

The origin and subculturing of callus cultures (Yamamoto et al., 1991) and the establishment of cell suspension cultures (Yamamoto et al., 1996) of *Sophora flavescens* were described in the previous papers.

3.3. Enzyme preparation

For enzyme preparation, all procedures were carried out at 4 °C. Thirty grams of *S. flavescens* cells cultured for 8–10 days were homogenized by a Teflon homogenizer in 100 mM K-Pi buffer (pH 6.5, 60 ml) containing 10 mM

DTT and 3 g PVPP. The homogenate was centrifuged at 12,000×*g* for 20 min, and the supernatant was further ultracentrifuged at 100,000×*g* for 20 min. The pellet was washed twice with 100 mM Tris–HCl buffer (pH 8.5) containing 10 mM DTT and then resuspended in 5 ml of the same buffer.

3.4. Protein content

Protein content was determined according to the method of Bradford (1976).

3.5. Enzyme reaction

The incubation mixture contained 150 nmol 8-dimethylallylnaringenin dissolved in 15 μl EtOH, 150 nmol NADPH and 60 μl of the microsomal fraction (ca. 0.5 mg of microsomal protein) in a total vol. of 150 μl. The reaction was initiated by the addition of NADPH to the mixture and, after incubation for 60 min at 30 °C, was terminated by the addition of 30 μl of 6 M HCl. The reaction mixture was extracted with 150 μl of EtOAc containing 50 nmol 1-naphthaleneacetic acid as an internal standard. The EtOAc extract was evaporated, dissolved in 70 μl MeOH and analyzed by HPLC.

For the investigation of the effects of different gaseous environments, test tubes (10 ml) containing all the reaction components except NADPH were sealed with septum caps in ice-water bath, and 200 ml of N_2, CO/O_2 (9:1) mixture or air was slowly bubbled into the mixture, respectively. The reaction was initiated by the addition of 150 nmol NADPH in the 15 μl of the same buffer. In the System Biotron, incubation was carried out for 60 min at 30 °C in the dark (tubes covered with aluminum foil) and under 20,000 lx of fluorescent lights for examining the effect of the light on the inhibition by CO. The reaction was stopped, treated and analyzed as described above.

For the oxygen consuming experiments, 40 mM glucose, 50 units glucose oxidase (Nacalai Tesque, Japan) and 105 units catalase (Sigma, USA) were added to the enzyme solution containing 150 nmol 8-DMAN and, after preincubation for 30 min at 30 °C, the reactions were initiated by addition of 150 nmol NADPH.

3.6. HPLC analysis

The amount of leachianone G formed was determined by HPLC using Capcellpak C18 AG-120 column (4.6×250 mm, Shiseido, Japan) in an oven at 40 °C, with CH_3CN/H_2O linear gradient solvent system containing 1% AcOH, from 20% to 60% CH_3CN in 40 min, at a flow rate of 0.9 ml/min, monitoring the absorption at 294 nm or using a photodiode-array SPDM-6A system (Shimadzu, Japan). The quantities were calculated from the peak area at 294 nm recorded by Chromatopac C-R4A (Shimadzu, Japan).

3.7. Isolation and identification of the reaction product

The microsomal fraction obtained from 30 g of the fresh cells was incubated with 750 nmol 8-DMAN and 750 nmol NADPH in 100 mM Tris–HCl buffer (pH 8.5, total vol. 7.5 ml) at 30 °C for 2 h. The reaction was terminated by the addition of 1.5 ml of 6 M HCl, and the products were extracted with EtOAc (3×7.5 ml). The organic layers were combined and concd in vacuo. The residue was dissolved in MeOH and purified by HPLC using the following conditions: column, Hikarisil C18 (4.6×250 mm, Asahi Chemical Ind. Co., Ltd., Japan); solvent, CH_3CN/H_2O linear gradient solvent system, from 20% CH_3CN to 50% CH_3CN in 60 min; flow rate, 1 ml/min; oven temp., 40 °C; detection, 294 nm. The fraction around Rt 50 min was collected and evaporated in vacuo.

Received 15 February 2001; received in revised form 5 June 2001

Abstract

An endopeptidase was purified and characterized from green leaves of cucumber (*Cucumis sativus* L. suyo). The purified enzyme, a basic amino acid-specific endopeptidase with a pI of 5.0, was a monomeric protein of 80 kDa whose pH optimum was 9.5. Inhibitor analysis suggested that it was a serine endopeptidase and contained sulfhydryl groups essential for catalytic activity. Analysis of internal amino acid sequences of the endopeptidase showed no significant similarity to other proteins. Its activity was inhibited by L-Arg and guanidino compounds having high hydrophobicity, as well as divalent cations such as Mg^{2+} and Ca^{2+}. The K_i values of L-Arg and Mg^{2+}, which are also likely in vivo inhibitors, were 3.5 and 10 mM, respectively. Inhibition by L-Arg and Mg^{2+} was additive, and more than 70% of the activity was reversibly inhibited under their physiologically significant concentrations. These results suggest that the enzyme is possibly regulated by L-Arg and/or guanidino compounds, and by divalent cations in vivo. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

In all organisms, protein turnover is a highly regulated, selective process. It is well known that the mammalian cell contains highly regulated protein degradation systems such as ubiquitin-proteasome in the cytosol (Hershko and Ciechanover, 1992) and the Ca^{2+}, calpain, and calpastatin systems (Sorimachi and Suzuki, 1998). Many reports also imply the existence of highly regulated proteolytic systems in plants, but only a few have described the role played by plant endopeptidases in regulation of protein turnover (Vierstra, 1993; von Kampen et al., 1996).

It is difficult to investigate endopeptidases since they are both present at low levels and occur in multiple isoforms. To overcome this problem, we have developed both polyacrylamide gel electrophoretic and activity staining methods to separate and detect low proteolytic activities, as well as a method for detection of measurable endopeptidase activities using artificial substrates (Yamauchi et al., 1995). These techniques were used to detect two major endopeptidases that degraded benzoyl (Bz)-Arg-naphthylamide (NA) and carbobenzoxy (CBZ)-Leu-Leu-Glu-NA, respectively (Yamauchi et al., 1996). This report describes the purification and characterization of the Bz-Arg-NA degrading endopeptidase (CEP 5.0). The enzyme was a basic amino acid-specific endopeptidase that is plausibly regulated by L-Arg and/or guanidino compounds and divalent cations whose cellular concentrations may change with environmental conditions.

2. Results and discussion

The Bz-Arg-NA degrading endopeptidase was purified to apparent homogenets by successive chromatography on DEAE-Toyopearl, hydroxyapatite, phenyl-

sepharose, Arg-sepharose, and mono Q columns (Table 1). The endopeptidase was named CEP 5.0 because the purified enzyme migrated as a single band (pI = 5.0) when submitted to nondenaturing isoelectric focusing (Fig. 1A). The molecular mass of CEP 5.0 was 80 kDa as estimated by both SDS-PAGE and gel filtration (Fig. 1B and C), suggesting that CEP 5.0 was an 80 kDa monomeric protein. The enzyme, with an optimum pH of around 9.5, showed half-maximal activities at pH7.4 and 10.5. CEP 5.0 was most active at 50 °C and was completely denatured when incubated at 70 °C (data not shown).

As shown in Table 2, diisopropyl fluorophosphate and phenylmethylsulfonyl fluoride reduced the activity of CEP 5.0 as did leupeptin, suggesting that CEP 5.0 is a serine endopeptidase. Enzyme inhibitors such as *p*-chloromercuribenzoic acid and *N*-ethylmaleimide also inhibited CEP 5.0. This suggests that CEP 5.0 contained sulfhydryl groups essential to its catalytic activity.

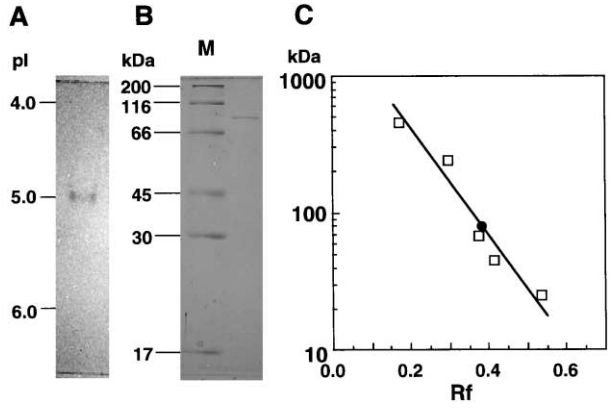

Fig. 1. Estimation of pI and molecular mass of CEP 5.0: (A) 1 μg of purified CEP 5.0 was subjected to isoelectric focusing on a 7.5% (w/v) acrylamide, 2% SERVALYT (pH 4.0–6.0) gel; (B) 1 μg of purified CEP 5.0 was subjected to SDS-PAGE on a 13% (w/v) acrylamide gel under reducing conditions. The molecular mass of protein markers are given in the lane M. (C) Plot of the R_f values against log molecular mass for CEP 5.0 (●) and marker proteins (□) on Superose 12 column. Marker proteins were ferritin (450 kDa), catalase (240 kDa), bovine serum albumin (67 kDa), egg albumin (45 kDa), and chymotrypsinogen A (25 kDa).

The substrate specificity of CEP 5.0 was determined to be trypsin-like by using various artificial substrates. The enzyme cleaved artificial substrates such as Bz-Arg-NA and Bz-Lys-*p*-nitroanilide, but did not cleave those diagnostic for aminopeptidase, caspase, cathepsin D, chymotrypsin, elastase, glutamyl endopeptidase and subtilisin (data not shown). Plant serine endopeptidases of 80–82 kDa whose pH optimum are at alkaline pH, have been isolated from ragweed, *Euphorbia supina* and bamboo (Bagarozzi et al., 1996; Arima et al., 2000a,b); however, their substrate specificities are quite different from CEP 5.0, i.e. they have chymotyrpsin-like or subtilisin-like activities. CEP 5.0 degraded gelatin, but did not degrade azocasein, carboxymethyl-BSA, acid-denatured haemoglobin and Rubisco (data not shown).

Since amino acid sequencing of the N-terminus of CEP 5.0 showed that it was blocked, internal amino acid sequences were analyzed after CNBr cleavage treatment of purified CEP 5.0 and separation of the cleaved peptides by SDS-PAGE. The N-terminal amino acids sequences of a 25 and a 20 kDa polypeptide were "FSLDLEAQE" and "PTGPQAQQE", respectively. Homology search of the Swissplot and translated EMBL databases revealed

Table 2
Effects of inhibitors on CEP 5.0 activity

Inhibitor	Concentration	Relative activity (%)
Control	–	100[a]
Diisopropyl fluorophosphate	1 mM	6.8
	10 mM	0
Phenylmethylsulfonyl fluoride	1 mM	79.3
	10 mM	22.4
p-Chloromercuri benzoic acid	0.5 mM	42.9
	2.5 mM	25.3
N-Ethylmaleimide	1 mM	21.3
	10 mM	11.6
Leupeptin	10 μM	0.9
Pepstatin A	10 μM	78.4
Soybean trypsin inhibitor	0.1%	127
SDS	0.1%	0

[a] Activity in the absence of inhibitor is defined as 100% (0.28 units of Bz-Arg-NA cleaving activity).

Table 1
Summary of purification of CEP 5.0

Step	Total protein (mg)	Total activity (Units)[a]	Specific activity (Units/mg)	Purification-fold	Yield (%)
Crude extract	4430	89 090	22.15	1.0	100
45–55% Ammonium sulfate	653.6	82 600	130	5.87	84.2

[a] Bz-Arg-NA was used as a substrate, and one unit was defined as the formation of 1 nmol of naphthylamine per minute.

no significant similarity of these sequences to other proteins.

Although substrate inhibition at low substrate levels (Fig. 2A) prevented the determination of the Km for Bz-Arg-NA, the Km for Bz-Lys-*p*-nitroanilide was 50 μM. Thus, Bz-Lys-*p*-nitroanilide was used as the substrate in subsequent kinetic experiments. To determine what portion of Bz-Arg-NA inhibited CEP 5.0, we first examined the effects of amino acids on CEP 5.0 activity. Only L-Arg significantly inhibited CEP 5.0 (Fig. 2B), whereas other amino acids, Ala, Asn, Glu, Gln, His, Ile, Lys, Met, L-ornithine, Phe, Pro, Ser, Val, Tyr showed little or no inhibitory effects. The Ki value of L-Arg was 3.5 mM and about 90% of activity was inhibited in the presence of 20 mM L-Arg (Fig. 2B).

The increased inhibition with Bz-Arg-NA compared to L-Arg (Fig. 2A and B) suggests that modification of L-Arg caused the increased inhibition. The effect of modification of L-Arg on inhibitory activity using various L-Arg-derivatives was further examined (Fig. 3A and Table 3). N^{α}-amino group modified L-Arg-derivatives such as acetyl-L-Arg slightly changed its inhibitory activity, compared with the large inhibition observed with Bz-L-Arg (Fig. 2B). Modification of the carboxyl group of L-Arg increased inhibitory activity drastically (Fig. 2C). Methylester and ethylester derivatives became stronger inhibitors, and L-Arg modified by naphthylamine and nitroaniline almost completely inhibited CEP 5.0 at much lower range. N^{γ}-methyl-L-Arg which is a guanidino group-methylated L-Arg-derivative, showed an increase of inhibition. These results indicate that strong inhibition is due to hydrophobicity of L-Arg-derivatives, and that Bz-Arg-NA showed substrate-inhibition because it had hydrophobic bases on both the amino- and carboxyl-groups of L-Arg. Inhibition by L-Arg-derivatives

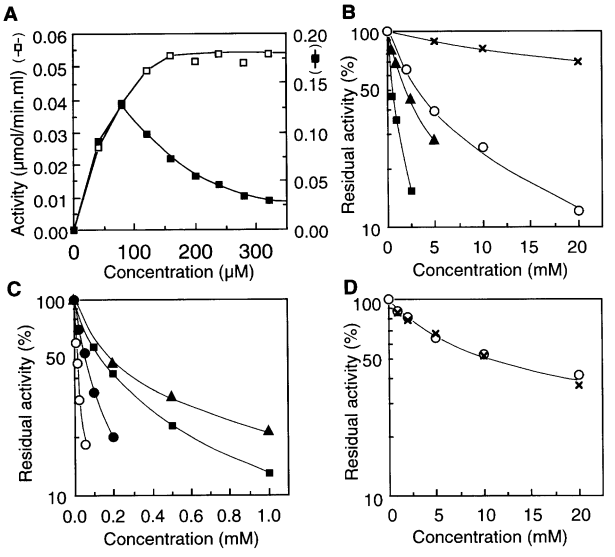

Fig. 2. Inhibition of CEP 5.0 by various Arg-derivatives and divalent cations: (A) CEP 5.0 was incubated with various concentrations of Bz-Lys-*p*-nitroanilide (□) or Bz-Arg-NA (■) as the substrates; (B) CEP 5.0 activity was measured with various concentrations of L-Arg (○), L-Lys (x) or N^{α}-modified L-Arg-derivatives; acetyl-L-Arg (▲) or Bz-L-Arg (■). (C) CEP 5.0 activity was measured with various concentrations of C-modified L-Arg-derivatives; L-arginine methylester (▲), L-arginine ethylester (■), L-Arg-*p*-nitroanilide (●) or L-Arg-NA (○). (D) CEP 5.0 activity was measured with various concentrations of Mg^{2+} (x) or Ca^{2+} (○). Activity in the absence of effector was defined as 100%. The values represent the average of at least three independent measurements using 0.27 units of Bz-Lys-*p*-nitroanilide cleaving activity of CEP 5.0 and the range of the experimental error was within ±3%.

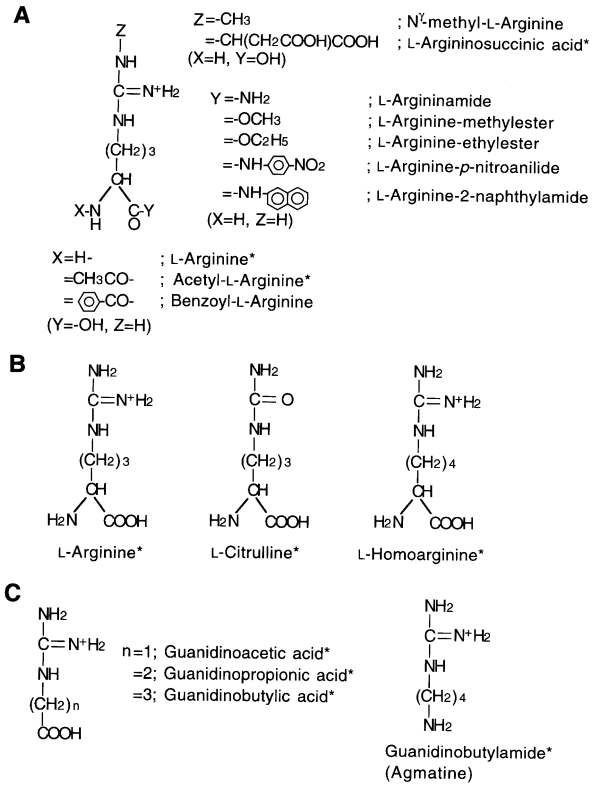

Fig. 3. Structures of L-Arg-derivatives and guanidino compounds using in this study: (A) L-Arg-derivatives modified by various chemical groups; (B) L-Arg and amino acids whose structures are similar to L-Arg; (C) guanidino compounds observed in plants. Asterisk shows substance observed in plants.

Table 3
Summary of kinetic analysis of L-Arg-derivatives against CEP 5.0 activity

Site modified	L-Arg-derivatives	K_i (mM)	Inhibitory fashion
Intact	L-Arg	3.5	Competitive
N^{α}-modified	Acetyl-L-Arg	2.5	Competitive

	L-Arg-*p*-nitroanilide	58×10^{-3}	Non-competitive
	L-Arg-NA	14×10^{-3}	Non-competitive
N^{γ}-modified	N^{γ}-Methyl-L-Arg	1.5	Competitive

0.27 units of Bz-Lys-*p*-nitroanilide cleaving activity was used.

was competitive except for non-competitive inhibition by L-Arg-*p*-nitroanilide and L-Arg-NA (Fig. 4).

Neither L-citrulline, which lacks a positively charged guanidino group (structure is referred to in Fig. 3B), nor L-Lys and L-ornithine that have a positive charge at physiological pH, inhibited the reaction (data not shown). L-Argininosuccinic acid, in spite of having positively charged guanidino group, also did not inhibit activity, indicating steric hindrance by the large succinic group. These results suggest that an intact positively charged guanidino group at physiological pH is essential for inhibition.

We examined whether other guanidino compounds observed in plant tissues also inhibit CEP 5.0 (structures are referred to Fig. 3B and C, Table 4). Guanidino butylic acid showed almost equal inhibition to L-Arg; however, guanidino propionic acid showed less inhibition and guanidino acetic acid showed no inhibitory activity, suggesting that shortening of the hydrocarbon chains of guanidino compounds decreased inhibitory activity. Homoarginine, which has a longer hydrocarbon chain than L-Arg, and guanidinobutylamine (agmatine) showed strong inhibition at much lower range than L-Arg. Although these highly hydrophobic guanidino compounds only occur at low levels (Kato et al., 1986), it is possible that they and other unidentified guanidino compounds might regulate CEP 5.0 activity in vivo.

Arg is thought to be an endogenous inhibitor of CEP 5.0 because plants can contain Arg up to 5 mM (Winter et al., 1993). As Arg is the most economic utilizer of nitrogen because of its high N/C ratio (4N:6C), plants usually use Arg for storage and transport of N. Generally Arg contents in plants are affected by nutrient conditions and aging. For example, Arg content in leaves of young tulips cultivated in a medium containing nitrogen was over 70 times higher than those in leaves

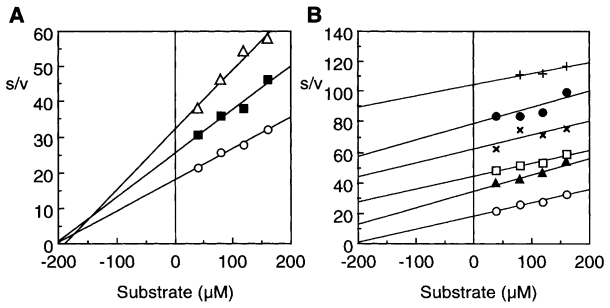

Fig. 4. Kinetic analysis of the inhibition of CEP 5.0 on Hanes–Woolf plots: (A) CEP 5.0 was incubated without (○) or with 5 μM (■) or 10 μM (△) L-Arg-NA; (B) CEP 5.0 was incubated without (○) or with L-Arg-derivatives. Symbols are 10 mM Bz-L-Arg (+), 0.2 mM N^{γ}-methyl-L-Arg (●), 4 mM L-Arg (**x**), 0.1 mM L-arginine methylester (□), or 5 mM Mg^{2+} (▲), respectively. The values represent the average of at least three independent measurements using 0.27 units of Bz-Lys-*p*-nitroanilide cleaving activity of CEP 5.0 and the range of the experimental error was within ±3%.

Table 4
Summary of kinetic analysis of guanidino compounds detected in plants against CEP 5.0 activity

0.27 units of Bz-Lys-*p*-nitroanilide cleaving activity was used.
[a] Not inhibited.

after flowering and in nitrogen starved conditions (Ohyama et al., 1985). Therefore, CEP 5.0 may be regulated in response to nutrient and developmental changes in Arg content. A few endopeptidases inhibited by L-Arg have been reported in animals; however, the inhibition was less effective than the case for CEP 5.0 (Hatton, 1973; Polakoski and McRorie, 1973), and no plant endopeptidase regulated by Arg has been reported.

CEP 5.0 was also competitively inhibited by divalent cations such as Mg^{2+} and Ca^{2+} (Figs. 2D and 4B). This indicates that Mg^{2+} and Ca^{2+} interferes with binding of the substrate, either due to binding of themselves to the catalytic site or to a closely related site. The K_i value of inhibition by divalent cations was about 10 mM.

Divalent cations such as Ca^{2+} and Mg^{2+} are well known regulators of plant endopeptidases (Liu and Jagendorf, 1986; Bushnell et al., 1993; Anastassiou and Argyroudi-Akoyunoglou, 1995), and may play important roles in protein degradation of plants. The most likely divalent cation for regulation of CEP 5.0 in vivo is Mg^{2+} because it is the most abundant soluble divalent cation while intracellular free Ca^{2+} is usually kept to low levels (Kreimer et al., 1988). The concentration of Mg^{2+} is assumed to be 13–17 mM in the vacuole and 2–10 mM in cytosol and chloroplasts (Leigh and Wyn Jones, 1986; Stelzer et al., 1990; Marschner, 1995). These concentrations are high enough to inhibit CEP 5.0.

Moreover, we examined the inhibition of CEP 5.0 in the presence of various physiological concentration of L-Arg and Mg^{2+}, which are the most likely inhibitors in vivo (Fig. 5). Inhibition by L-Arg and Mg^{2+} was additive and reversible (data not shown), and 5 mM of L-Arg and Mg^{2+} inhibited the enzyme activity more than 70% compared to the control activity. This suggests the plausible regulation of CEP 5.0 by physiological concentration of L-Arg and Mg^{2+} in vivo.

In conclusion, CEP 5.0 is possibly regulated by L-Arg and/or guanidino compounds and Mg^{2+} whose cellular concentrations may change with environmental conditions. To clarify the physiological role of CEP 5.0, we will investigate in future the native substrate and localization of CEP 5.0.

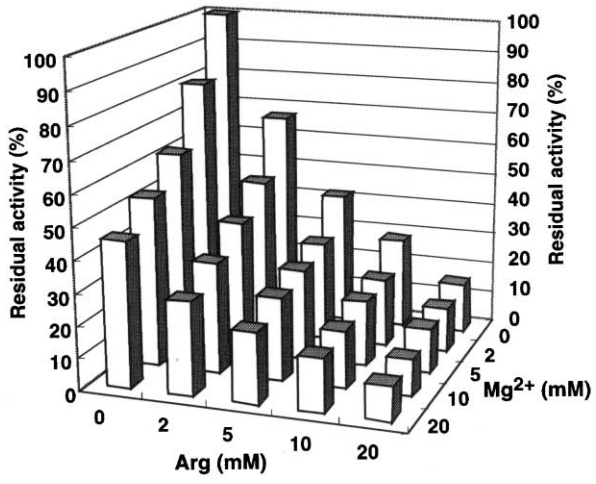

Fig. 5. Inhibition of CEP 5.0 by L-Arg and Mg^{2+} is additive. CEP 5.0 (0.27 units of Bz-Lys-*p*-nitroanilide cleaving activity) was incubated with various combination of L-Arg and Mg^{2+} concentration. Activity in the absence both of L-Arg and Mg^{2+} was defined as 100%.

3. Experimental

3.1. Materials

All of the Arg-derivatives and Fast Garnet GBC were purchased from Sigma Co. Ltd. (St. Louis, MO, USA). Leupeptin and pepstatin A were purchased from Peptide Institute, Inc. (Osaka, Japan). All other reagents were purchased from Wako Pure Chemical Co. Ltd. (Osaka, Japan). Cucumber seeds (*Cucumis sativus* L. suyo) purchased from Takii Seed Co. Ltd. (Kyoto, Japan), were germinated in the dark at 25 °C for 6 days then transferred to a greenhouse. Harvested leaves were frozen in liquid N_2 and stored below −20 °C until use.

3.2. Enzyme activities

To monitor benzoyl (Bz)-Arg-naphthylamide (NA) degrading activity, assays using 60 μM of Bz-Arg-NA as a substrate by the method described previously were employed (Yamauchi et al., 1996). For kinetic analysis of the endopeptidase, 160 μM of Bz-Lys-*p*-nitroanilide was used as a substrate in 50 mM Hepes-KOH, pH 8.0, to a final volume of 1 ml. After incubation at 37 °C, the reaction was stopped by addition of 0.5 ml of 30% (v/v) acetic acid and absorbance at 410 nm measured. One unit was defined as the formation of 1 nmol of nitroaniline or naphthylamine per minute.

3.3. Purification of cucumber endopeptidase with a pI of 5.0 (CEP 5.0)

Leaves (300 g) were extracted with 5 volumes of 50 mM potassium phosphate buffer (K-PB), pH 7.0, containing 2 mM 2-mercaptoethanol (2-ME) and 0.1 mM EDTA. Debris was removed by filtration using two layers of cheesecloth. After centrifugation at 20,000 *g* for 20 min, the supernatant was fractionated by the addition of solid ammonium sulfate. The fraction precipitating between 45 and 55% ammonium sulfate saturation was dissolved in a minimum volume of 25 mM K-PB, pH 7.0, containing 1 mM 2-ME (buffer A) and dialyzed against buffer A. The dialysate was applied to a DEAE-Toyopearl column (4×20 cm, Tosoh Corp., Japan) equilibrated with buffer A, and a linear gradient of 0–0.2 M NaCl (total 1.2 l) was applied to elute the enzymes. Active fractions of CEP 5.0 after DEAE-Toyopearl chromatography were combined and dialyzed against 10 mM Na-PB, pH 6.8, containing 1 mM 2-ME. The dialysate was applied to a hydroxyapatite column (2×15 cm, Bio-Rad, CA, USA) and eluted by a linear gradient of 0–0.2 M Na-PB (total 200 ml). After active fractions were combined, an equal volume of 60% saturated ammonium sulfate in 50 mM K-PB, pH 7.0, containing 1 mM 2-ME was added. This solution was applied to a Phenyl-Sepharose column (1.5×8 cm, Amersham Pharmacia Biotech, Sweden) equilibrated with 30% ammonium sulfate saturated in 50 mM K-PB, pH 7.0, containing 1 mM 2-ME and the proteins were eluted by a linear gradient of 30–0% ammonium sulfate (total 100 ml). Active fractions were concentrated by a DEAE-mini column (1 ml), then applied to an Arg-Sepharose (1.5×8 cm, Amersham Pharmacia Biotech, Sweden) column equilibrated with buffer A containing 0.1 mM EDTA. A linear gradient of 0–0.1 M NaCl was applied to elute the enzyme (total 100 ml). The active fractions were dialyzed against buffer A, then applied to a Mono Q column (0.32×3 cm, SMART system, Amersham Pharmacia Biotech, Sweden). The column was eluted with a linear gradient of 0–0.3 M NaCl in buffer A (total 8 ml). All (purification) steps were performed at temperatures from 0 to 4 °C.

3.4. Characterization of CEP 5.0

To investigate the effect of inhibitors, CEP 5.0 was preincubated with each inhibitor in the reaction mixture without substrate for 30 min at 4 °C. The substrate was then added to the mixture and residual activity was measured. Native molecular weights were estimated on the basis of comparison of the retention time of marker proteins on a Superose 12 column (0.32×30 cm, SMART system, Amersham Pharmacia Biotech, Sweden) equilibrated with 25 mM K-PB, pH 7.0, containing 0.1 M NaCl and 1 mM 2-ME. In the experiment on the effect of L-Arg-derivatives on CEP 5.0, L-Arg-derivatives were used as inhibitors because CEP 5.0 could not cleave them even though their structure resemble the Bz-Arg-NA substrate.

3.5. Protein analysis

Isoelectric focusing was performed with a 7.5% (w/v) polyacrylamide gel containing SERVALYT of pH

range 4.0–6.0 (Serva Electrophoresis GmbH, Germany) under non-denaturing conditions. Cathode and anode buffers were 40 mM Glu and 0.2 M His, respectively. SDS-PAGE and Tricine/SDS-PAGE were performed by the method of Laemmli (1970) and Schägger and von Jagow (1987), respectively. Gels were stained for proteins with Coomassie Brilliant Blue R-250. Protein concentration was determined by the method of Bradford with bovine serum albumin as the standard (Bradford, 1976).

3.6. Sequencing of internal peptides of CEP 5.0

CEP 5.0 (2 μg) was dissolved in 1 ml of 70% formic acid containing 1 mg of CNBr, and allowed to stand overnight in the dark. After evaporation using a SpeedVac concentrator (model A160, SAVANT Instruments Inc., NY, USA), the cleaved peptides were dissolved in 50 μl of SDS sample buffer and separated by Tricine/SDS-PAGE using a 15% polyacrylamide gel. After electroblotting to a poly (vinylidene difluoride) membrane, peptides were stained by CBB R-250 and portions of major bands were excised and sequenced by an automated pulsed liquid protein sequencer (model 491, Applied Biosystems, Foster City, CA, USA).

Received 30 August 2000; received in revised form 19 April 2001

Abstract

The physiological function of vanadium-bromoperoxidase (BPO) in the marine red alga, *Corallina pilulifera*, has been characterized from the viewpoint of allelochemical formation. The algae emit bromoform ($CHBr_3$) depending on the enzyme activity level in vivo (Itoh, N., Shinya, M., 1994. Seasonal evolution of bromomethanes from coralline algae and its effect on atmospheric ozone. Marine Chemistry 45, 95–103). We demonstrated that bromoform produced by *C. pilulifera* played an important role in eliminating epiphytic organisms, especially microalgae on the surface. Such data suggest a strong relationship between the coralline algae and the coralline flat (deforested area in the marine environment: called isoyake in Japanese). *Lithophyllum yessoense*, the main inhabitant of coralline flats in Japan, produced a lower level of $CHBr_3$ than *C. pilulifera*, and showed BPO activity. On the other hand, the seasonal change of BPO activity in *C. pilulifera* in vivo was in proportion to superoxide dismutase (SOD) activity and in inverse proportion to catalase activity. The phenomenon implies that BPO could be a potential substitute for catalase, because the enzyme catalyzes an efficient Br^--dependent catalase reaction. © 2001 Elsevier Science Ltd. Keywords: *Corallina pilulifera*; *Lithophyllum yessoense*; Bromoperoxidase; Allelochemical; Bromoform; Active oxygen

1. Introduction

Volatile halogenated compounds in ocean water and the atmosphere are divided into two groups: anthropogenic compounds such as chlorofluorocarbons (CFC), $CHCl_3$, CCl_4, CH_3Br and trichloroethylene ($ClCH=CCl_2$), and natural volatile halomethanes including CH_3Cl, CH_3Br, CH_3I, $CHBr_3$, CH_2Br_2 and $CHClBr_2$ (Lovelock, 1975; Moore, 1977; Geshwend et al., 1985; Harper, 1994; Itoh, 1997; Butler, 2000). The evaluation of natural halogenated compounds in the atmosphere and ocean water is important to assess the effect of these compounds on the atmosphere (Rasmussen et al., 1982; Class and Ballschmiter, 1988; Harper, 1994; Itoh, 1997; Butler, 2000) and the marine environment. Although natural halogenated compounds in ocean water have been reported (Lovelock, 1975; Geshwend et al., 1985; Harper, 1994; Itoh, 1997), the specific origin, formation and physiological function of these natural compounds is not well understood.

Natural tri- and dihalomethanes are formed by haloperoxidase-catalyzed reactions with organic compounds, especially β-ketoacids including 3-oxo-octanoic acid (Beissner et al., 1981), oxalacetate, phospho-enol-pyruvate, pyruvate etc. (Itoh and Shinya, 1994), which are very common in biological metabolic pathways. In contrast, biogenic monohalomethanes are synthesized by *S*-adenosylmethionine (SAM):halide ion methyltransferase reactions, which have been reported in marine microalga (Itoh et al., 1997), macroalgae (Wuosmaa and Hager, 1990) and terrestrial plants (Attieh et al., 1995; Ni and Hager, 1998) and fungus (Harper, 1985, Saxena et al., 1998).

Haloperoxidases generally oxidize a halide anion (X^-) into a halonium cation (X^+) with H_2O_2, and the produced X^+ acts on many organic substrates as an electrophile

(Itoh et al., 1988). They are divided into three groups: heme types, eukaryotic heme types, and bacterial types containing protoporphyrin IX as a prosthetic group (Morris and Hager, 1966); bacterial non-metal enzymes (Wiesner et al., 1988); and eukaryotic vanadium-containing enzymes (Vilter, 1984, Butler, 1998). Vanadium-haloperoxidases have been found in marine algae (Krenn et al., 1989), fungi (Messerschmidt, et al., 1997), and lichen (Plat et al., 1987). Marine algae containing vanadium-haloperoxidases are widespread and the source of diverse halogenated compounds observed in the marine environment (Neidleman and Geigert, 1986). However, the physiological functions of the enzyme and the halogenated compounds produced by the enzyme are unclear.

We and others have reported on the vanadium-containing bromoperoxidases (BPO) from red algae, *C. pilulifera* (Itoh et al., 1986, 1987c; 1996; Shimonishi et al., 1998) and *C. officinalis* (Yu and Whittaker, 1989; Sheffield et al., 1993), which are immunologically the same enzymes (Itoh, et al., 1987a). BPO of *C. pilulifera* was first characterized as a non-heme iron enzyme because of its high iron content. However, it was found to contain another essential metal, vanadium, for halogenation activity (Krenn et al., 1989a, Itoh et al., 1996). The present study reveals the physiological function of the enzyme as a bromoform producer and hydrogen oxide eliminator. From the data, we also discuss the relationship between bromoform emission from coralline algae and the continuation of coralline flat (isoyake area) in the marine environment.

2. Results and discussion

2.1. Effect of bromoform on supressing surface epiphytes

Fig. 1 shows a scanning electron micrograph (SEM) of the surfaces of living and dead *C. pilulifera* samples which had been incubated for 2 weeks in clean sea water. The surface of the dead algae was completely covered with various types of diatoms. By contrast, the surfaces of living algae, which were releasing bromoform (0.9 ng/min/g wet algae:0.026 ng/min/cm^2 surface area), dibromomethane and chlorodibromomethane (approximately 85:10:5 by weight) (Itoh and Shinya, 1994), were quite clean, with few epiphytic diatoms. As described below, the surface of intact *Lithophyllum yessoense*, which emitted bromoform, was also clean. Although the dead algae had completely lost the ability

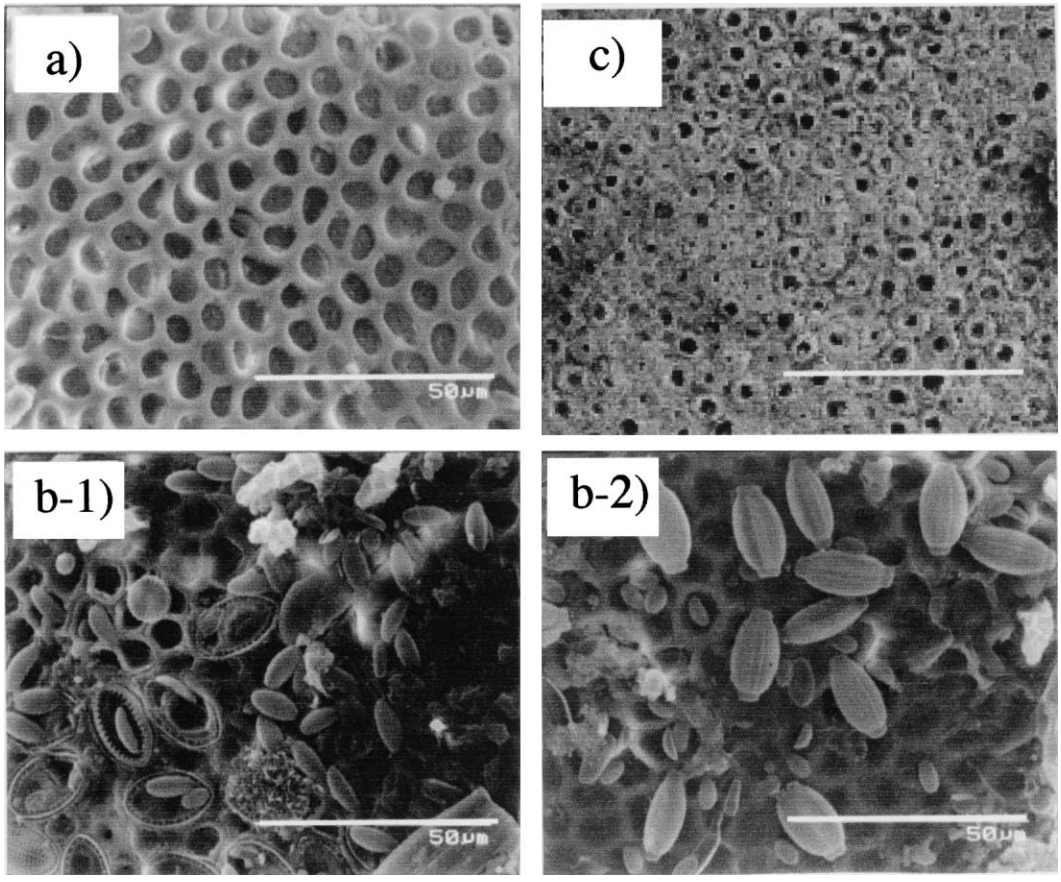

Fig. 1. Photographs of scanning electron microscopy (SEM) of coralline algae. Living (a) and dead (b1 and b2) incubated in natural sea water for 2 weeks in a mesh container with a glass cap. Living *Litophyllum yessoense* (c). The bar indicates 50 μm.

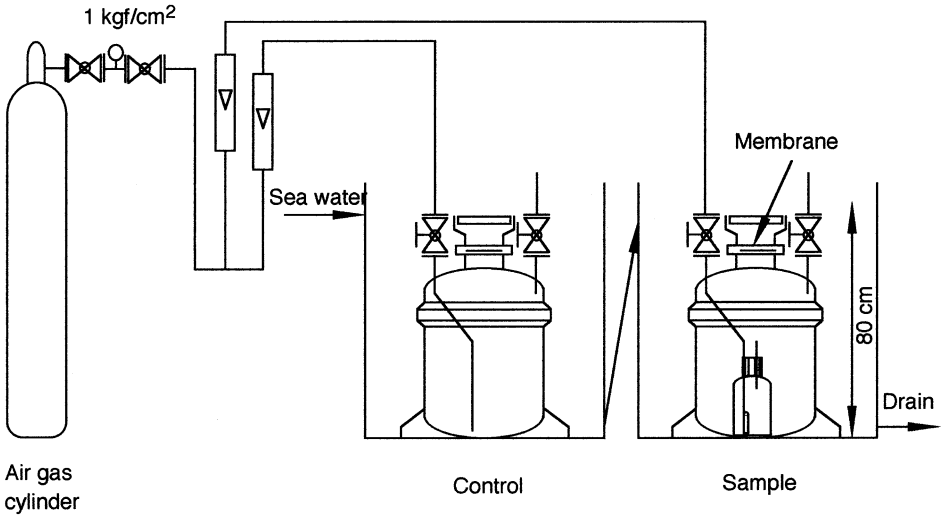

Fig. 2. Schematic of air-pressurized bromoform vaporizer.

to resist epiphyte invasion, bromoform production was speculated to be one of these systems. Therefore, we focused on the physiological function of bromoform, which was the main volatile halogenated product from *C. pilulifera* and *L. yessoense*, to confirm its effect on eliminating epiphytic microalgae. The bromoform vaporizer apparatus (Fig. 2) emitted bromoform with air across a hydrophobic membrane interface (10 cm^2) into natural seawater, and the emission rate was controlled from 0.02 to 0.4 ng/min/cm^2 according to the rate of living *C. pilulifera*. The effect of bromoform on eliminating epiphytic microalgae was observed above the emission rate of 0.09 ng/min/cm^2 of bromoform (Fig. 3). Various microalgae were observed on the control membrane surfaces. At the emission rate of 0.02 ng/min/cm^2 of bromoform, much microalgae was detected on the membrane. Therefore, the lower limit range of bromoform emission for inhibiting the adhesion of microalgae was concluded to be above 0.02 ng/min/cm^2. Although the value was a little high, it almost coincided with the emission rates of *C. pilulifera*, which range from 0.19 to 2.1 ng/min/g wet algae of bromoform (0.005 and 0.06 ng/min/cm^2 of algal surface). Some researchers have speculated that volatile halogenated compounds are involved in the algal control of the surface epiphytes or that Br^+OH^- released by algae is part of a host defense system (Wever et al., 1991), however, there had been no confirmation concerning the physiological aspect of these substances. This is the first report to elucidate the function of bromoform to inhibit the growth of surface epiphytes.

2.2. Emission of bromoform from a major inhabitant, Lithophyllum yessoense, of the coralline flat

Coralline flats (deforested areas in the marine environment:the phenomenon known as isoyake in Japanese) are a serious problem for fisheries. In this region, many algal species disappear and crustose coralline algae such as *L. yessoens* remain to become the prominent species in the subtidal zone. Once isoyake occurs, it continues for a long time. Consequently, it causes severe damage to inshore fisheries. To elucidate the relationship between bromoform emission from coralline algae and isoyake, we measured the emission of bromoform from *L. yessoense*, a major inhabitant of isoyake areas in Japan. The data showed that the alga also produced bromoform and its derivatives at a rate of 0.007 ng/min/cm^2 of algal surface (0.017 ng/min/g wet algae; the apparent value was low because of the large amount of calcium carbonate skeleton in crustose coralline algae), which was the same emission rate level of *C. pilulifera*. Similarly with *C. pilulifera*, *L. yessoense* emits not only bromoform but also dibromomethane and chlorodibromomethane (approximately 6:3:1 by weight) (Fig. 4). The data supported that these compounds are produced by BPO, widely distributed in coralline algae (Yamada et al., 1985). We first reported that a major isoyake inhabitant produces bromoform and its derivatives. Interestingly, *L. yessoense* BPO was not recoverd in the supernatant solution (soluble cytosol fraction) following the disruption of algae with sea-sand and centrifugation, suggesting that BPO exists as a membrane-bound form in *L. yessoense*. Therefore, we used the cell-debris fraction as a crude enzyme preparation. BPO of *L. yessoense* required H_2O_2, KBr and oxalacetate, a suitable substrate, for bromoform production. Furthermore, the enzyme appeared to be a member of the vanadium-haloperoxidases of coralline algae (Yamada et al., 1985; Itoh et al., 1986). The bromoform-producing activity of the BPO of *L. yessoense* was estimated to be equivalent to 1.0 unit/g wet algae by the monochlorodimedone assay method.

Taniguchi et al. (1994) reported that dibromomethane is a chemical inducer of larval settlement and

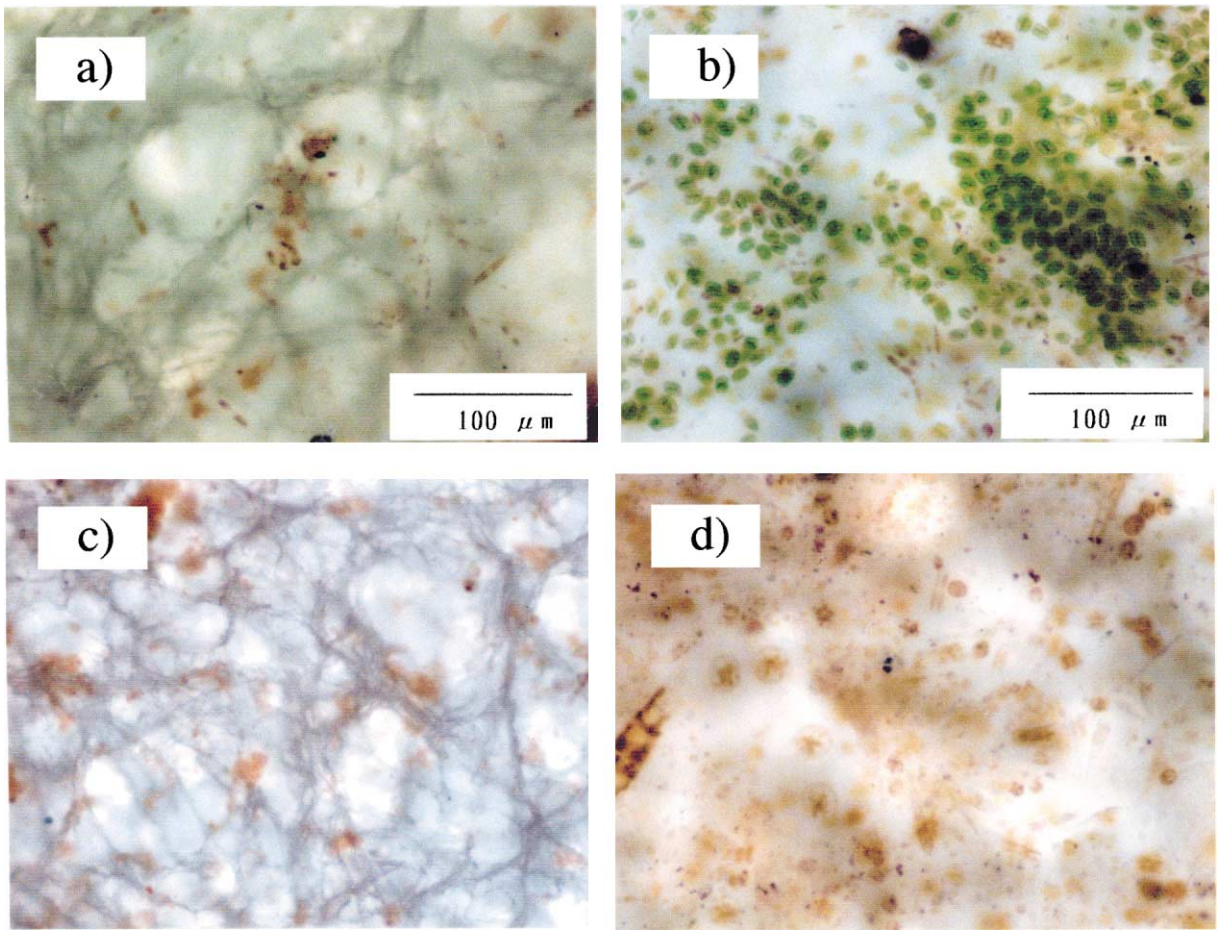

Fig. 3. Photographs by phase contrast microscopy of membranes in an air- pressurized bromoform vaporizer in the presence of $CHBr_3$ and in the absence of $CHBr_3$ after the incubation with natural seawater. The mean emission rate of bromoform was 0.26 ng/min/cm^2 membrane and seawater temperature was 19 °C from 22 May to 19 June (a). Control (b). The rate was 0.09 ng/min/cm^2 membrane and seawater temperature was 25 °C from 10 July to 7 August (c). Control (d).

metamorphosis of the sea urchin *Strongylocentrotus nudus*, and bromoform only induces settlement. Denboh et al. (1997) demonstrated that bromoform at a concentration as low as 3 ppm reduced the normal sporophyte formation of *Laminaria*, but they assumed unknown compounds to be true allelochemicals. The data presented here show that coralline algae, such as *C. pilulifera* and *L. yessoens*, suppress the growth of microalgae and other algae on their surface by releasing bromoform. By this mechanism the algae could obtain a sufficient supply of sunlight and nutrition, making it easy for them to be the dominant algae on shoreline rocks. *C. pilulifera* grows quite close together and appears to attain a high bromoform concentration as a whole. Because of bromoform's low melting point of 7.5 °C and low solubility in water, it would remain on the algal surface for some time in cold sea water. The features of bromoform appear to be suitable as an allelochemical for coralline algae. The high content of BPO (1–2%) in *C. pilulifera* (Itoh et al., 1996) suggests that the enzyme is essential for it to become the dominant algal species. Our results, together with those of Taniguchi et al. (1994) and Denboh et al. (1997), suggest a strong relationship between isoyake and bromoform produced by coralline algae. It is generally agreed that isoyake is caused by heavy grazing pressures of herbivores such as sea urchins. Coralline algae products, especially bromoform, induce larval settlement of sea urchins. We speculate that coralline algae not only induce some kinds of invertebrates but also inhibit growth of other algae; therefore, once isoyake is caused by a disturbance of the ecological balance such as temperature, nutrition and grazing by invertebrates, then the situation continues for a long time depending on the bromoform from coralline algae.

2.3. Acceleration of bromoform production by exogenous substrates

Some marine algae containing BPO are known to be accessible to substrates and are able to brominate organic compounds such as phenol red (Wever et al., 1991). We measured the acceleration of bromoform formation caused by substrates in intact *C. pilulifera*

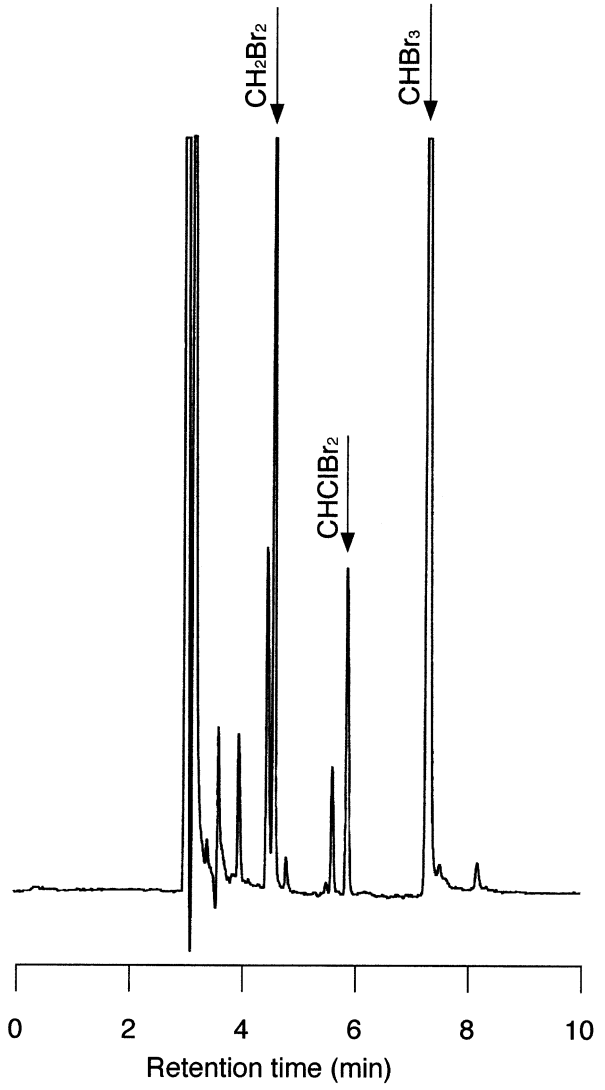

Fig. 4. Gas chromatogram (ECD) of halomethanes released by *Litophyllum yessoense*. Main peaks were identified by standard compounds, but minor peaks could not be identified.

and *L. yessoense* algae using head-space analyses. For *C. pilulifera*, the addition of exogenous substrates accelerated the emission of bromoform (Fig. 5a). The effect of adding H_2O_2 to the seawater was especially prominent, increasing the rate of emission about 10 times relative to the control. For *L. yessoense*, only H_2O_2 was effective (Fig. 5b). The results indicated that both algae are able to utilize the exogenous H_2O_2 to produce bromoform, and that the supply of H_2O_2 to the BPO reaction is the rate-determining step of bromoform formation. The effect of KBr was rather inhibitory for both algae. Therefore, the BPOs appeared to be saturated with bromide ions in vivo for both algae. Considering the high K_m value of the BPO of *C. pilulifera* toward Br^- ions (1.1×10^{-2} M) (Itoh et al., 1986) and the low concentration of Br^- ions in natural sea water (0.85 mM), the alga must concentrate Br^- ions in its body. Itoh and Shinya (1994) reported as endogenous substrates for bromoform formation by BPO,β-keto acids such as oxalacetate, pyruvate etc. Although oxalacetate addition increased the bromoform emission rate about 2.5-fold for *C. pilulifera*, it was inhibitory for *L. yessoense*. Wever et al.(1991) suggested that free Br^+OH^- released in sea water by brown algae directly reacted with dissolved organic acids in the water to produce bromoform. If this hypothesis is correct, bromoform formation must be promoted by the addition of oxalacetate. Because the oxalacetate addition was ineffective, this theory could not be adapted for *L. yessoense*.

To discover a possible natural exogenous substrate, we examined fluvic acid, which is a complex organic acid having keto and carboxylic groups made from humus soil, as a bromoform-producing substrate. As shown in Fig. 6, both molecular weight fractions of fluvic acid (see experimental) proved a good substrate for production of bromoform in *C. pilulifera*, coinciding with oxalacetate. However, the BPO in *C. pilulifera* does not liberate free Br^+OH^- through its reaction (Itoh et al., 1987c), suggesting that BPOs in the algae are located where the exogenous organic compounds can be easily accessed. A portion of the enzymes maybe localized at the calcified cell-wall. That both fulvic acid fractions were inert for *L. yessoense* clearly showed that free Br^+OH^- was not released in sea water by the alga, because free Br^+OH^- efficiently produced bromoform with fluvic acid.

2.4. Seasonal change of active oxygen-eliminating enzymes in C. pilulifera

The BPO activity in *C. pilulifera* is known to vary seasonally depending on its specific activity in vivo (Itoh et al., 1996). To elucidate its function, we compared its variation with other active oxygen-eliminating enzymes such as a catalase, peroxidase (POD) and super oxide dismutase (SOD). As shown in Table 1, we could not detect glutathion peroxidase (GPO) and ascorbate peroxidase (APO) activities in the cell-free extracts of *C.*

Table 1
The activities of active oxygen-eliminating enzymes in *Corallina pulifera*

Sample	BPO	Catalase	SOD	POD	APO	GPO
	(U/g wet algae)					
Crude extract	3.5	1.8	348	7.1	0	0
After dialysis[a]	3.1	0.8	N.T.	1.3	N.T.[b]	N.T.

[a] Dialysis was necessary to avoid the influence of Br^- -dependent catalase and peroxidase activities of BPO.
[b] N.T.: not tested.

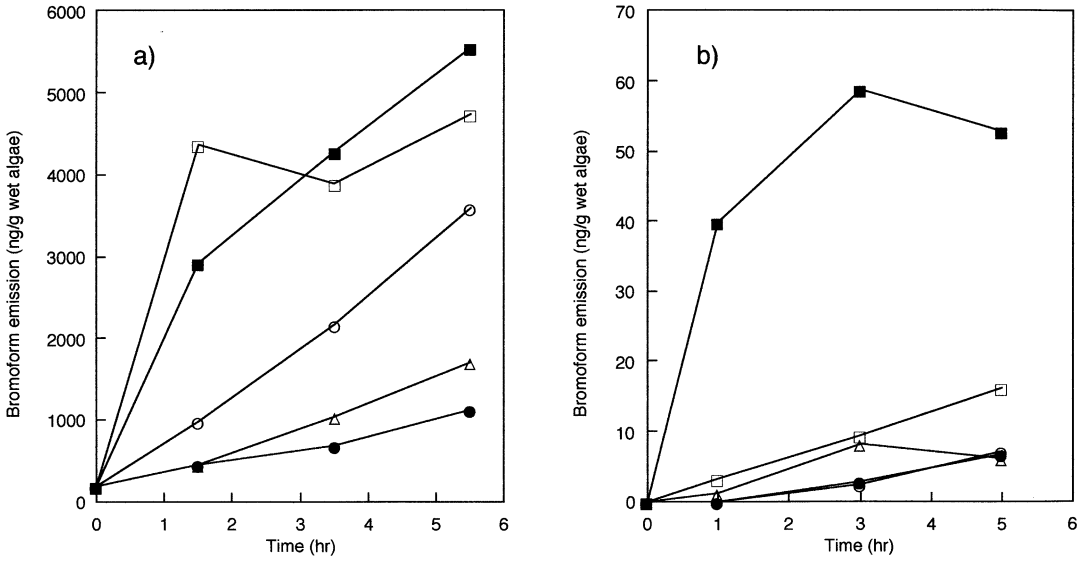

Fig. 5. The effect of addition of endogenous substrates on bromoform emission from *Corallina pilulifera* (a) and *Lithophyllum yessoense* (b): (△) control; (●) 20 mM KBr; (○) 1 mM oxalacetate; (■) 2 mM H_2O_2; (□) 1 mM oxalacetate plus 2 mM H_2O_2. Each point was the mean value of two analyses.

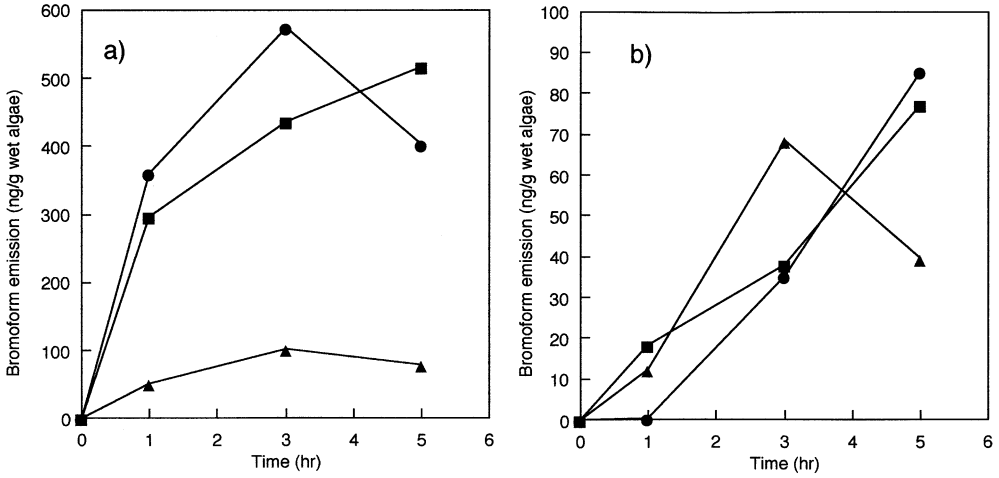

Fig. 6. The effect of addition of exogenous substrates on bromoform emission from *Corallina pilulifera* (a) and *Lithophyllum yessoense* (b): (▲) control; (■) 3 ppm of low molecular weight fraction of fulvic acid; (●) 3 ppm of high molecular weight fraction of fulvic acid. Each point was the mean value of two analyses.

pilulifera. The algae showed catalase and strong super oxide dismutase (SOD) activities and weak peroxidase activity. Therefore, the seasonal change in catalase and SOD activity was measured comparing with BPO activity throughout the year and plotted in Fig. 7. The BPO activity increased during winter and spring and peaked in late spring with the SOD activity. However, it was not synchronized with the catalase activity. The level of catalase activity was high in mid-winter and dropped in an early spring when the BPO and SOD activities were high. The results suggested that the catalase activity was repressed at low level when BPO could be used as a substitute for H_2O_2 elimination. The results suggested that BPO in *C. pilulifera* functions to eliminate H_2O_2 compensating for catalase.

2.5. Characterization of the BPO with regard to active oxygen elimination

The specific activity of BPO in *C. pilulifea* is regulated by the vanadium content of the enzyme (Itoh et al., 1996). *C. pilulifera* BPO also contains a large amount of iron whose function has been unclear. BPO oxidizes Br^- with H_2O_2 to the Br^+OH^- intermediate, and the Br^+OH^- can decompose another H_2O_2 when a suitable organic substrate is absent Eq. (1).

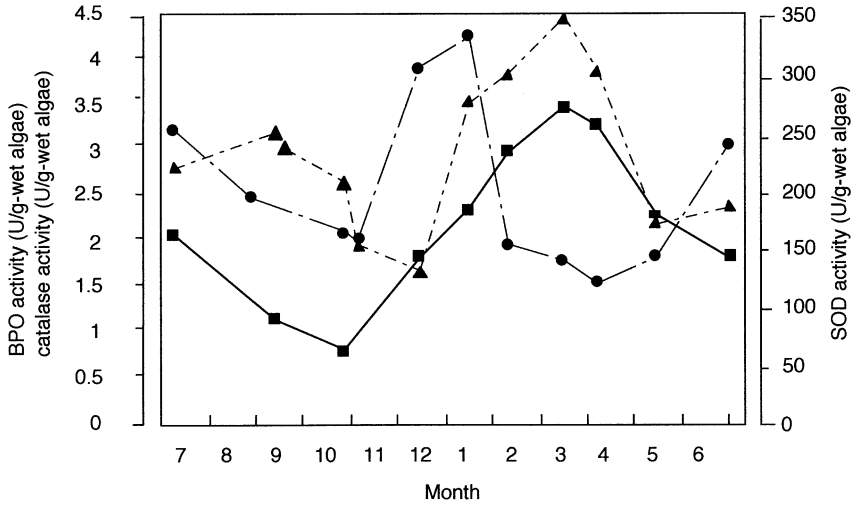

Fig. 7. Seasonal change of BPO activity (■), catalase activity (●) and SOD activity (▲) in *Corallina pilulifera* from May 1998 to April 1999 at the same spot of Himi, Toyama, Japan. Each point was the mean value of triplicate samples.

$$\begin{aligned} &\text{Enz.}+H^+X^-+H_2O_2 \rightarrow X^+OH^-(\text{or Enz}-X^+OH^-)+H_2O \\ &X^+OH^-+H_2O_2 \rightarrow H^+X^-+H_2O+O_2. \end{aligned} \quad (1)$$

This is a characteristic property of vanadium-BPO, which can catalyze an efficient Br^--dependent catalase reaction (Itoh, 1987b; Butler, 1998). The chemical reaction of Br^+OH^- with H_2O_2 is known to produce singlet oxygen. To elucidate the relationship between the enzymatic singlet oxygen formation and the vanadate and iron contents of the enzyme, we used the reconstituted enzyme after treatment of the native purified enzyme as shown in Table 2. The vanadate-treated enzyme showed high BPO activity depending on the vanadate content. However, the relationship between the activity and vanadate content of the enzyme was not linear. The results implied that there are different vanadate-binding mechanisms in the reconstituted enzyme. Although we first speculated that ferric iron co-existing with vanadate plays a role in depleting singlet oxygen, the reconstituted BPO which lost iron had a high production of singlet oxygen from KBr and H_2O_2. The emission rate of singlet oxygen coincided with the BPO activity, and has no relation with iron content. Therefore, a role for iron in eliminating the singlet oxygen produced by the enzyme was ruled out. Vanadium-BPO from *C. pilulifera* certainly followed the reaction described in Eq. (1) to decompose H_2O_2 and yield singlet oxygen.

3. Experimental

3.1. Collection of algae and crude enzyme preparation

Algal samples of *C. pilulifera* were collected at an intertidal area of Himi (N 37°, E 137°, Toyama Prefecture, Japan) on the Sea of Japan between June 1998 and May 1999, unless otherwise indicated. *Lithophyllum yessoense* samples from Taisei, Kudou-gun (N 42°, E 140°, Hokkaido, Japan) were supplied by Dr. Daisuke Fujita of The Toyama Prefectural Fisheries Experimental Station. The samples were kept in sea water and brought to our laboratory within 2 days. Apparently clean algae samples were used for the experiments. Each sample of alga (0.5 g) was disrupted with sea sand (40–80 mesh) in a chilled mortar with a pestle and extracted with 4 ml of 50 mM potassium phosphate buffer (pH 6.5). Unless otherwise indicated, this buffer was used throughout the experiments. After centrifugation ($8000\times g$, 20 min), the supernatant was used as a crude enzyme solution.

Table 2
Relationship among BPO activity, metal content and singlet oxygen forming tare of the reconstituted enzymes

Enzyme sample[a]	BPO activity (U/mg)	Vanadium content (mol/mol-enzyme)	Iron content (mol/mol-enzyme)	$^1O_2$ forming rate (μmol/min/mg)
Purified BPO	23.7	1.1	38.4	37.3
Vanadate-treated BPO	71.6	9.1	9.1	85.3
Reconstituted BPO	23.5	1.3	1.4	44.8

[a] The enzyme was purified from the stock of algae at −20 °C collected at Mikuni, Fukui 1995.

3.2. Enzyme purification

The enzyme was purified from the crude extracts of *C. pilulifera* and shown to be homogeneous on SDS–PAGE as described in the previous paper (Itoh et al., 1985).

3.3. Halomethanes analysis

Detection of halomethanes was performed by headspace analysis (Itoh and Shinya, 1994). A 0.5–2 g wet weight of *C. pilulifera or L. yessoense* sample, which had been well washed with autoclaved seawater and dried between paper towels for 2 min, was transferred into 50 ml of membrane-filtered seawater in a 50-ml vial (20 ml headspace), sealed with a silicon rubber septum and an aluminum-cap, and incubated at 20 °C, for 1–6 h. After incubation, the vial was kept at 60 °C for 15 min to insure the transfer of volatile halomethanes to the gas phase; then the gas (100 μl) was drawn and analyzed by gas chromatography (GC). A control run was done without incubation of the algal sample at 20 °C. GC analysis was performed with a Shimadzu GC-14B system equipped with a DB-624 capillary column (0.3 mm×30 m, 3 μm film, J & W Scientific, CA) under the following conditions: electron capture detector (ECD), injection and detection temp. 180 °C, column temp. 130 °C, flow rate 0.75 ml/min of N_2, split ratio 15. In vitro formation of bromoform was measured in a reaction mixture consisting of 5 mmol of buffer (pH 6.0), 0.5 mmol potassium bromide, 50 μmol of oxalacetate or fulvic acid (3 ppm), 50 μmol of hydrogen peroxide, and an appropriate amount of bromoperoxidase (ca. 1 unit) in a total volume of 50 ml using a 50-ml headspace vial in the same manner described above. The reactions were carried out for 2 h at 25 °C then treated at 60 °C. A control run was done without the enzyme or hydrogen peroxide.

3.4. Enzyme assay

The bromoperoxidase (BPO) activity was measured as described in previous papers based on the conversion of monochlorodimedone to bromochlorodimedone at 290 nm (Yamada et al., 1985). One unit of enzyme activity was defined as the amount of the enzyme that catalyzed the conversion of 1 μmol of monochlorodimedone ($\varepsilon = 19{,}900\ M^{-1}\ cm^{-1}$) in 1 min at 25 °C.

Super oxide dismutase (SOD) activity was assayed according to the methods of McCord and Fridovich (1978). The reaction mixture contained 75 μmol of the buffer (pH 7.8), 150 nmol EDTA, 15 nmol cytochrome *c*, 75 nmol xanthine, 0.04 U xanthine oxidasae and a suitable amount of enzyme solution in a total volume of 1.5 ml. The activity was monitored at 550 nm at 25 °C, and one unit of enzyme activity was defined as the amount of enzyme that inhibited 50% of the reduction of cytochrome *c*.

Catalase activity was assayed by measuring the decrease at 240 nm (the absorption maximum of hydrogen peroxide, $\varepsilon = 43.6\ M^{-1}\ cm^{-1}$) in a total volume of 1.5 ml as described previously (Itoh et al., 1986).

Glutathion peroxidase (GPO) activity was measured according to the method of Flohe and Gunzler (1984). The reaction mixture contained 75 μmol of the buffer (pH 6.0), 3 μmol EDTA, 1.5 μmol reduced glutathione, 0.3 μmol hydrogen peroxide, 0.24 μmol NADPH, 3 μmol NaN_3, 0.11 U oxidized glutathione reductase and a suitable amount of enzyme solution in a total volume of 1.5 ml. Ascorbate peroxidase (APO) activity was assayed by the decrease in absorption at 290 nm due to ascorbate ($\varepsilon = 2{,}800\ M^{-1}cm^{-1}$) oxidation (Ishikawa et al., 1995). The reaction mixture contained 75 μmol of the buffer (pH 7.0), 0.75 μmol ascorbate, 45 nmol hydrogen peroxide, and a suitable amount of enzyme solution in a total volume of 1.5 ml.

General peroxidase (POD) activity was measured with *o*-dianisidine at 25 °C. The appearance of the oxidized compound ($\varepsilon = 11{,}300\ M^{-1}\ cm^{-1}$) was measured at 460 nm in the reaction mixture consisting of 15 μmol of the buffer (pH 6.0), 0.008% (w/v) *o*-dianisidine, 0.2 μmol hydrogen peroxide, and a suitable amount of enzyme solution in a total volume of 1.5 ml (Anon, 1972).

The protein concentration was estimated by measuring the absorbance at 280 nm or by using the Bio-Rad Protein Assay kit with bovine serum albumin as a standard protein according to the manufacturer's protocol.

3.5. Reconstitution of the enzyme and metal analysis

The purified BPO was dialyzed against 50 mM citrate buffer (pH 3.7) with 1 mM EDTA to remove the prosthetic group, then incubated with 0.5 mM Na_2VO_3 in 0.1 M Tris–HCl buffer (pH 7.0) to reconstitute the enzyme, and dialyzed against Tris–HCl buffer (pH 7.0) plus 1 mM EDTA (reconstituted enzyme); or the enzyme was first incubated with 5 mM Na_2VO_3 and then dialyzed against 0.1 M Tris–HCl buffer(pH 7.0) plus 1 mM EDTA (vanadate-treated enzyme). Quantitative analysis of the vanadium and iron content of the enzyme was done by HPLC-spectrometry of chelated complexes of an azo dye with metal ions as described previously (Miura and Itoh, 1997).

3.6. Singlet oxygen analysis

Generation of singlet oxygen ($^1O_2$) in the BPO-catalyzed reaction was determined by measuring the chemiluminesecence from 2-methyl-6-(4-methoxyphenyl)-3,7-dihydroimidazo[1,2-a]pyrazin-3-one hydrochloride (MC LA) with an ALOKA Luminescence reader BLR-201

(ALOKA, Tokyo, Japan) (Nakano, 1990). The reaction mixture comprised 2 μmol sodium acetate buffer (pH 4.5), 1.0 nmol MCLA, 2 μmol H_2O_2, 2 μmol KBr and 2.8 units of BPO in a total volume of 1.0 ml. The reaction was started by addition of the enzyme. Chemiluminesecence counts per min were determined from the calibration curve, which had been made by chemical reaction of MCLA with NaOBr solution. One micromole of NaOBr produced 22,000 kcounts/min of chemiluminesence.

3.7. Bromoform vaporizer

As shown in Fig. 2, we constructed an air-pressurized bromoform vaporizer system to mimic the emission of bromoform from *C. pilulifera* in vivo. This apparatus was made of stainless steel, and could emit bromoform across a hydrophobic polytetrafluoroethylene (PTFE) membrane interface with air into seawater. The system was placed into a stainless tank (0.8 meter in depth), and clean natural sea water flowed in and out of the tank at 5 l/min for four weeks. Bromoform emission was controlled by the flow rate of air and sea water temperature. A control was done without bromoform.

3.8. Microscopic analysis

Scanning electron microscopy (SEM) observation of the surfaces of living or dead *C. pilulifera* was performed with a Hitachi S-2400 scanning electron microscope. Coralline algae is quite useful for SEM observation, because it has a solid calcium carbonate skeleton. A collected living alga sample releasing bromoform was placed into a stainless mesh cylindrical container (diameter:5 cm, height:9 cm) with a glass cap to prevent predation by benthonic invertebrates, in which the algae could freely receive fresh sea water and sunlight, and laid in a solid clean sea spot (90±30 cm depth). After two weeks incubation under natural conditions, the specimen and a control (dead algae incubated under the same conditions) were briefly washed with fresh water and dried under vacuum. The specimens were coated with gold by an ion spattering apparatus, and measured by SEM at 15 kV.

The surface of the PTFE membranes settled on the bromoform vaporizer was removed and observed using an Olympus BX-50 phase-contrast microscope (Tokyo, Japan).

3.9. Chemicals

Xanthine oxidase was obtained from Oriental Yeast, Tokyo, Japan, and ferricytochrome *c* from Wako Pure Chemical Industries, Japan. MCLA was supplied by Tokyo Kasei Co., Ltd., Japan, and fulvic acid by the Japanese Society of Humic Substances, Kobe, Japan. The fulvic acid was separated into low molecular weight (lower than Mr:1330) and high molecular weight (higher than Mr:1330) fractions by Sephadex G-25 gel filtration chromatography with water as an eluent using cyanocobalamin as a marker compound (Mr:1330), and the two fractions evaporated and dried under vacuum. All other reagents used in this study were of analytical grade.

Acknowledgements

Abstract

Grape berries (*Vitis vinifera* L., cv Ugni blanc) were harvested at 12 different weeks of development in 1996 and 1997. Ripening was induced at *veraison*, the crucial stage of berry softening, and was followed by a rapid accumulation of glucose and fructose and an increase of pH. Total RNAs, crude proteins and cell wall material were isolated from each developmental stage. A partial length cDNA (*pme*1, accession number AF159122, GenBank™) encoding a pectin methyl-esterase (PME, EC 3.1.1.11) was cloned by RT–PCR with degenerate primers. Northern blots revealed that mRNAs coding for PME accumulate from one week before the onset of ripening until complete maturity, indicating that this transcript represents an early marker of *veraison* and could be involved in berry softening. However, PME activity was detected during all developmental stages. Total activity per berry increased, whereas "specific" activity, on a fresh weight basis, decreased during development. The amount of cell wall material (per berry and per g of berry) followed the same pattern as that of PME activity (total and "specific" respectively), indicating they were tightly correlated and that PME levels varied very little in the cell walls. Nevertheless, the degree of methyl-esterification of insoluble pectins decreased throughout the development from 68% in green stages to less than 20% for the ripe berries, and this observation is consistent with the induction of PME mRNAs during ripening. Relations between transcript expression, PME activity, the DE of insoluble pectic polysaccharides and their involvement in grape berry ripening are discussed. © 2001 Elsevier Science Ltd. Keywords: Cell wall; Development; Grape berry; Pectin methyl-esterase; softening

1. Introduction

Plant cell walls consist of complex networks of polysaccharides and proteins surrounding the plasma membrane. The cell wall is involved in the mechanical resistance of the plant cell but must also allow for growth. Primary cell walls in fruit parenchyma are composed of pectic polysaccharides, cellulose and hemicellulose, and minor components such as structural proteins (Carpita and Gibeaut, 1993).

Plant cell growth involves the enlargement of these networks, of which the composition and elasticity is controlled by a complex set of cell wall modifying enzymes. Rapid softening is also frequently encountered during fruit ripening (Fischer and Bennett, 1991). The release and depolymerization of polygalacturonans play a major role in fruit softening. Pectin methyl esterase (PME, EC 3.1.1.11), a ubiquitous cell wall-bound enzyme, catalyses the hydrolysis of methyl-ester groups from galacturonosyl residues. PMEs may play important roles in determining the extent to which demethylated

polygalacturonans are accessible to degradation by polygalacturonases (Fischer and Bennett, 1991), releasing galacturonic acid (exo-PG, EC 3.2.1.67) or oligogalacturonate (endo-PG, EC 3.2.1.15), and the availability of homogalacturonan carboxylic groups for Ca^{2+} binding. Increasing the number of carboxylic groups in pectins should lead to an increase in the number of Ca^{2+} bridges between homogalacturonan chains but also to an increase in their accessibility to cell wall hydrolases (Fischer and Bennett, 1991; Seymour and Gross, 1996). These two factors may have an opposing effect on cell wall deformability.

Usually, several PME isoforms with different pH and temperature optima, pI and molecular masses are present in the same plant species (Warrilow and Jones, 1995; Micheli et al., 2000), but their respective functions and action patterns have not been elucidated. In tomato plant, multiple isoforms of PME were present in different tissues, and both tissue-specific and ubiquitously expressed isoforms of PME have been reported (Gaffé et al., 1994). A specific isoform has been described as involved in cell wall metabolism during fruit growth and development prior to ripening (Ray et al., 1988), whereas another isozyme could be specific to ripening. The expression in tomatoes of an antisense PME gene resulted in a higher degree of methyl-esterification of pectins, thereby decreasing their sensivity to PG and resulting in higher molecular mass pectins in transgenic fruit juice (Thakur et al., 1996). However, transgenic tomatoes with reduced PME activity ripened normally (Tieman et al., 1992).

Nevertheless, the exact roles of PME during the softening of fruits is still only partially understood, and several authors have described contradictory changes of PME activity during fruit-ripening (Seymour et al., 1991; Christensen et al., 1998).

The cell walls of grape berries, especially from the epidermal cells of the skin, form a barrier to the diffusion of components such as aromas and polyphenols which are important for the quality of wines. Grape primary cell walls are also the source of wine pectic polysaccharides. The structural properties of cell walls determine the mechanical resistance, the texture, and the ease of processing berries. Grape berries are non-climacteric fruits. The earliest signal of the induction of ripening is an abrupt increase in fruit deformability which occurs within 24 h (Kanellis and Roubelakis-Angelakis, 1993). Berries undergo dramatic changes (acceleration of growth, rapid softening) at the stage called *veraison* which corresponds to the onset of ripening, and occurs 5–8 weeks before maturity (Kanellis and Roubelakis-Angelakis, 1993). *Veraison* is also characterized by the end of organic acid accumulation and the onset of glucose and fructose storage. As for other fruits, softening is possibly due to enzymic mechanisms whose identity and expression regulation remain very partially understood. It can be expected that enzymes involved in cell wall metabolism should be particularly active during the softening period, typical of *veraison*.

The understanding of changes during the development and softening of grape berries may have considerable importance in enology. The primary cell walls of grape berries have a common set of structural polysaccharides with their distribution varying among cultivars. The main glycosyl residues of grape cell walls are cellulosic glucose and galacturonans (Lecas and Brillouet, 1994). The degree of methyl-esterification of grape HGs can vary from 40 to 80% (Lecas and Brillouet, 1994) according to the cultivar, the development stage and the tissue. In grapes, PME displays maximum activity at pH 7.0–7.5 (Lee et al., 1979), although earlier studies (Marteau et al., 1961) reported a maximum activity at pH 5.6.

The aim of this study was to elucidate the role of PME and the consequences of its action on cell walls during the maturation of grape berries. Molecular biology tools have been used to elucidate the possible involvement of PMEs in grape (*Vitis vinifera* L., cultivar Ugni blanc) ripening and softening. A cDNA coding for PME has been isolated and the expression patterns of the corresponding mRNA were followed during ripening, in parallel with PME activity and the degree of homogalacturonan esterification.

2. Results

2.1. Grape berry development

Veraison, previously described by viticulturists as the onset of color change, has been defined in this study as the beginning of berry softening and of the accumulation of glucose and fructose. Both events happened at week 7 (*veraison*) in the present study. The changes of berry fresh and dry weights, pH and sugar content are typical for grapes (upper panel Fig. 1). The average weight of berries increased steadily (phase I or herbaceous period, weeks 1 to 6) until *veraison*, before growth slowed (phase II or lag phase, weeks 7 and 8) and then increased again up to maturity (phase III or maturation period, weeks 9 to 12, Fig. 1A). The growth of berries followed a typical double sigmoid curve (Kanellis and Roubelakis-Angelakis, 1993) and *veraison* corresponded to the inception of the slow growth phase. Dry weight, pH, and °Brix (Fig. 1B) were stable until week 6, and increased markedly from *veraison*. The pH value remained between 2.45 and 2.55 during the first phase (herbaceous period) marked by the accumulation of organic acids. The pH increased from *veraison* to reach a maximum of 3.2–3.3 at maturity. Total soluble solids remained in the range 4.8–6°Brix during the early phase of organic acid accumulation until week 6, and

increased notably from week 7 due to the massive accumulation of sugars and water (Kanellis and Roubelakis-Angelakis, 1993).

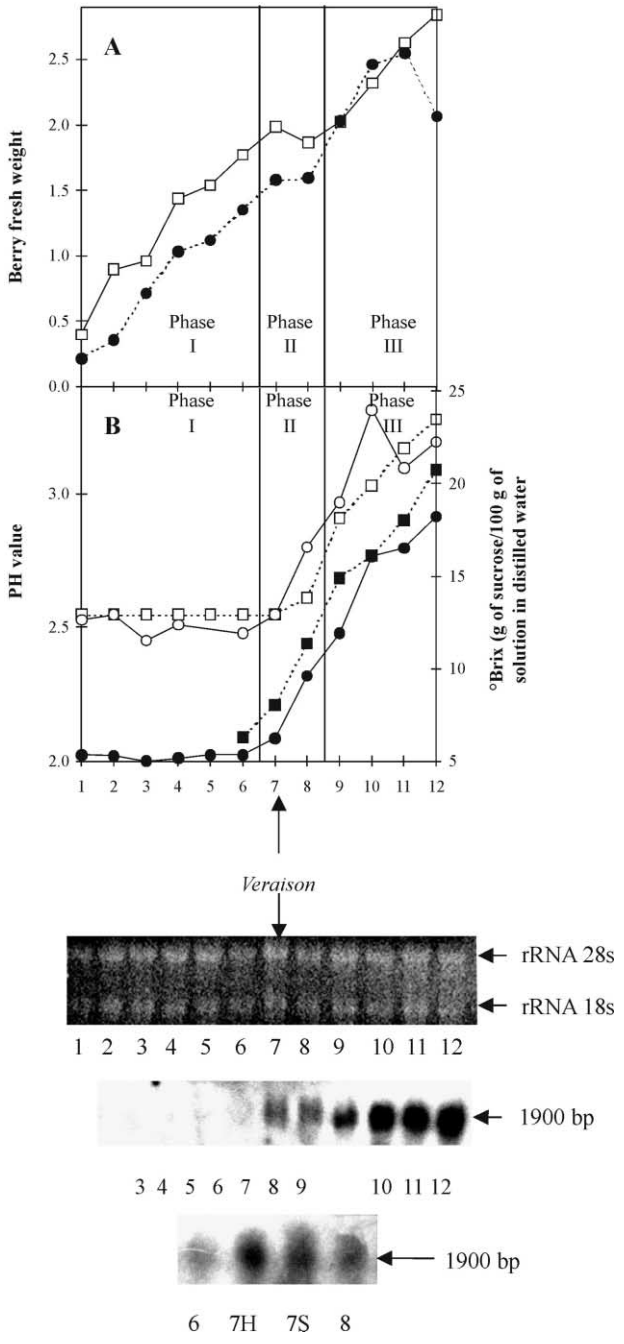

Fig. 1. Upper panel, the development of Ugni blanc berries. A, average berry fresh weight (□, 1996 and ●,1997). B, pH (□, 1996 and ○, 1997) and °Brix (■, 1996 and ●, 1997) of the resulting must. Lower panel, expression pattern of mRNA coding for *pme*1. Fifteen micrograms of total RNA were separated on 1.2% denaturing agarose-formaldehyde gel electrophoresis and transferred onto a nylon membrane. C, total RNA blots were stained with ethydium bromide as a loading control; northern blots were hybridized with the *pme*1 probe (^{32}P labelled cDNA); D, total RNA from harvest 1997, week 7 (*veraison*) corresponding to a mix of ~ 50% hard and soft berries from veraison stage; E, northern blot differentiating hard (7H) and soft (7S) berries from the *veraison* stage (week 7).

2.2. Isolation of a cDNA clone for pectin methylesterase

PCR allowed the amplification of a 290 base long fragment *pme*1 from first strand cDNA. Sequence alignment using ClustalV indicated that the corresponding sequence obtained by RT-PCR showed significant similarities with PMEs in data banks (Fig. 2). The amino acid sequence deduced for *pme*1 showed 82% identity and 90% similarity with a PME (AA 333 to 428, on a full length alignment basis) from *Prunus persica* (Glover et al., 1996).

2.3. Expression pattern of mRNAs coding for PME

Total RNA loadings were controlled by staining the ribonucleic acids with ethydium bromide (Fig. 1C). The expression of mRNAs coding for PME in grape berries at several developmental stages was followed by Northern-blot with *pme*1 clone as probe. Only one mRNA band (Fig. 1D) was detectable (between 1.9 kb in length ± 0.1 kb, according to the membrane considered). No transcripts could be detected during phase I (green stages). PME mRNAs accumulated from one week before *veraison* (week 6) to week 12 (Fig. 1D), and a similar pattern of mRNA expression was observed for the 1996 harvest (data not shown). A third Northern-blot, in which total RNAs of hard and soft berries from *veraison* stage were separated (data not shown), revealed that PME mRNAs accumulated prior to softening (Fig. 1E).

2.4. PME activity

Crude protein extracts from grape berries at all developmental stages (1996 and 1997) were analyzed for PME activity and determination were performed in triplicates. PME activity was detected at all stages of development, even during phase I, although mRNA transcripts had not been previously detected. The activity patterns were similar between the two vintages (data not shown). The values of PME activity are expressed either as total (in nkat/berry), as "specific" activity (in nkat/g of berry fresh weight), or as nkat per mg of CWM (Fig. 3).

Total PME activity per berry (Fig. 3A) increased almost linearly during the green stages to reach a maximum one week before *veraison* (ca. 39 nkat/berry). The enzymic activity decreased between weeks 6 and 8, before increasing again to reach a maximum of ca. 53 nkat/berry (week 11) at maturity. This substantial increase in PME activity as ripening progresses, is consistent with pattern previously described for non-climacteric fruits such as raspberry (Iannetta et al., 1999).

The general patterns of "specific" activity (nkat/g of berry fresh weight, Fig. 3A) were also very similar for the two years studied. PME "specific" activity reached a

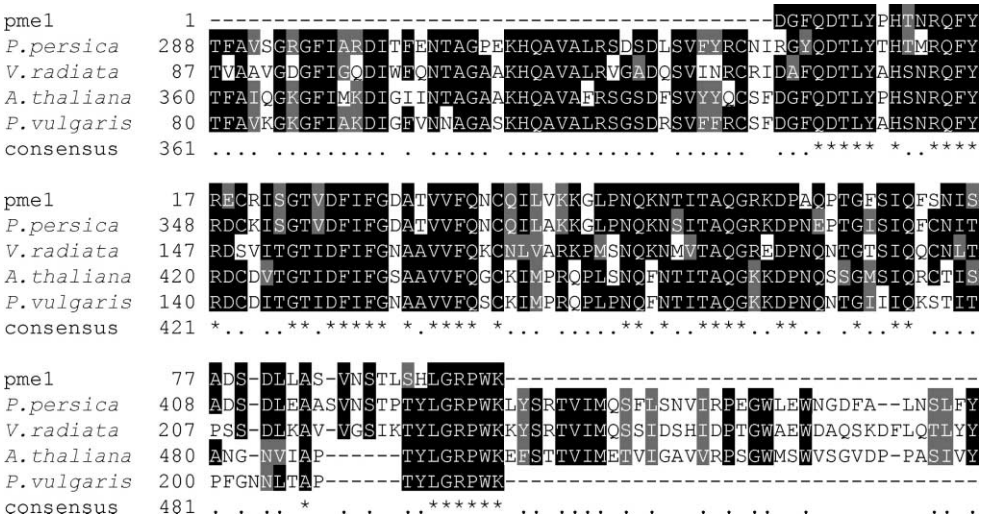

Fig. 2. Alignments of the deduced amino acid sequences of *pme*1 clone with several plant PMEs (accession numbers are X95991 for *P. persica*, X94443 for *V. radiata*, X81585 for *A. thaliana* and S25171 for *P. vulgaris*). (*) Identity, (.) similarity. Authors thank BOXSHADE for shading sequence alignments.

maximum during week 1 (ca. 46 nkat), decreased steadily until week 4 (ca. 26 nkat), and then remained steady up to week 6 (ca. 26–28 nkat). The lag phase around *veraison* was also characterized by a decrease in PME "specific" activity which remained constant during phase III (ca. 18 nkat at week 12).

When expressed on per mg of CWM, PME activity is still detectable but to a lower extent and the pattern remains to a steady state level all along the berry development (Fig. 3B).

2.5. Isolation and quantification of cell wall material

Cell walls were isolated from each developmental stage in 1997. Grape cell wall quantities (Fig. 4) have been expressed either as total (mg per berry) or on a fresh weight basis (mg per g of berry fresh weight). These curves showed similar patterns to those of total and "specific" PME activity. As PMEs are cell wall-bound enzymes, it is also interesting to express results as nkat per mg of dry cell wall. This calculation showed that on a per mg of CWM basis (Fig. 3B), PME activity remained similar throughout development (in the range of 1.2–1.5 nkat) although activity tended to increase between weeks 7 and 8.

2.6. Concentration and degree of methyl-esterification of cell wall homogalacturonans

The cell wall isolation procedure leads to the recovery of primary cell walls devoid of water-soluble pectins after endogenous hydrolases had been inactivated during the phenol extraction procedure (Huber, 1991). Uronic acid (UA) contents were determined as anhydromoles of galacturonic acid by the colorimetric *m*-hydroxydiphenyl assay (Blumenkrantz and Absoe-Hansen, 1973) (Fig. 5). Uronic acids, mainly galacturonic acids (at least 94.6% checked by methanolysis and trimethylsilylation, detection was performed by GC–EIMS, data not shown), accumulated during the green stages (phase I, week 1 to 5) and their relative cell wall content increased from 4 to 10% (Fig. 5A). Both phases II and III were characterized by a slow increase to reach 12.5% at complete maturity. Together with the accumulation of total cell wall material per berry, these data indicate that the whole period of ripening is marked by homogalacturonan biosynthesis. On a per berry basis (Fig. 5A), the accumulation of UA followed the same general pattern as the percentage in cell wall material, which increased from 0.5 (week 1) to 4 mg at maturity (week 12).

The percentage of esterification (DE) of cell wall homogalacturonans (Fig. 5B) decreased rapidly during green stages until week 3 (from 68 to ca. 40%) underwent a 3 week steady-state period until week 6, and finally decreased from *veraison* (week 7) to reach less than 20% in the last stages of ripening (maturation period).

3. Discussion

Samples of grape berries (*Vitis vinifera* L., cv Ugni blanc) were harvested during two vintages (1996 and 1997). Even in a single-cultivar vineyard, variations in timing, developmental kinetics and the extent of ripening occur between berries on a cluster, between clusters on a vine and between different vines. Therefore, sampling allowed us to discard unsynchronized berries in order to minimize variation within samples.

The development of berries, cv Ugni blanc, was characterized by physical and biochemical analysis (upper

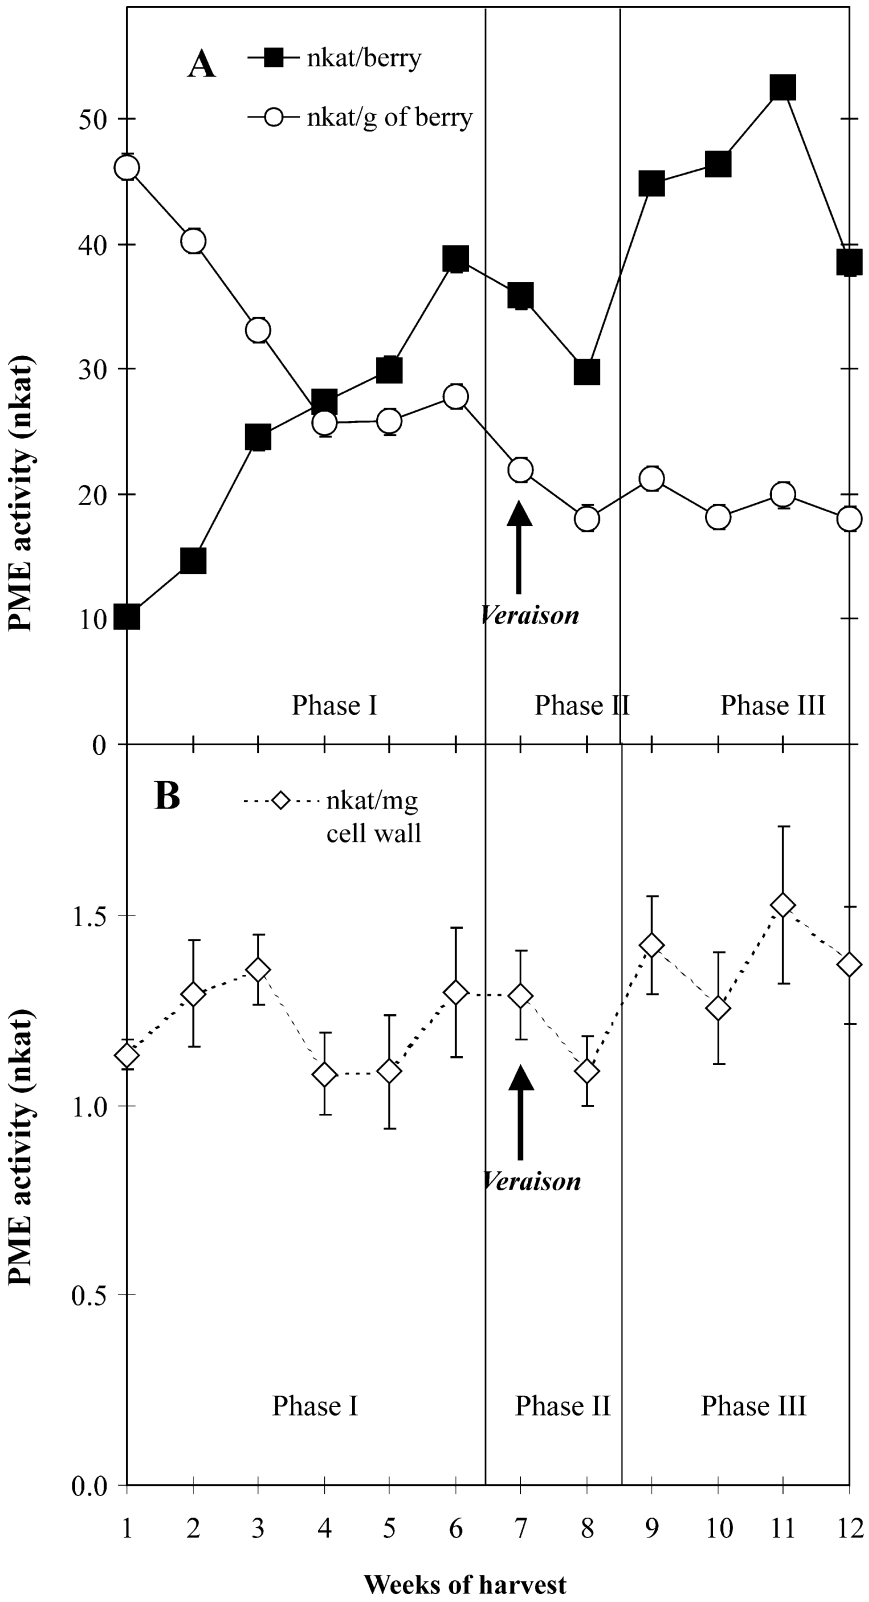

Fig. 3. PME activity during the ripening of grape berries in 1997. A, total activity in nkat per berry (■) and "specific" activity in nkat per g of berry fresh weight (○); B, activity in nkat per mg of dried cell wall material (◇). Bars represent standard error ($n = 3$).

panel, Fig. 1). The growth of grape berries is divided into 3 phases, and follows a typical double sigmoid curve (Kanellis and Roubelakis-Angelakis, 1993). Phase I (green stages) is characterized by a rapid accumulation of organic acids. Acidity reaches its highest level during phase II, a slow growth (lag) phase. *Veraison* (week 7) is

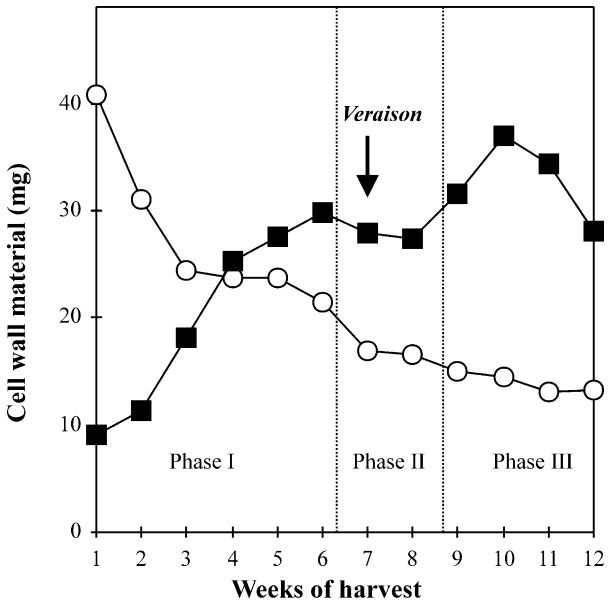

Fig. 4. Amount of cell wall material (CWM) of Ugni blanc grape berries during ripening in 1997, expressed as mg of dried cell wall per berry (■) and per g of fresh weight (○).

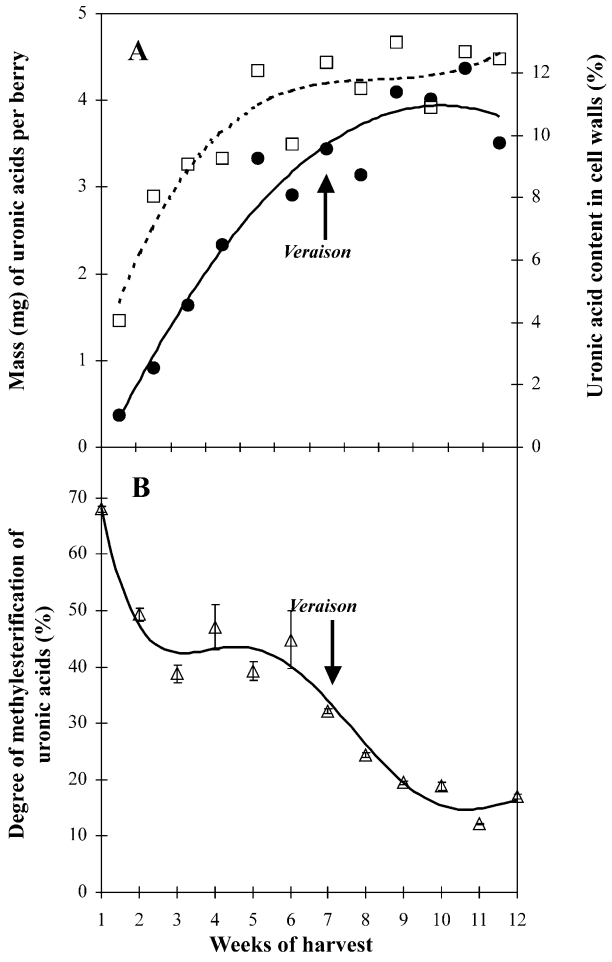

Fig. 5. Amount of cell wall uronic acids during the ripening of grape berries in 1997. A, relative content as a percentage of cell walls (□), mass (mg) of uronic acids per berry (●), data are means ($n=3$) and the variation was lower than 10% of the reported data; B, degree of methyl esterification (△), bars represent standard error ($n=3$).

characterized by several marked changes affecting berries: initial softening and an increase in deformability followed by a second acceleration of growth linked to the accumulation of glucose, fructose and water, and a decrease of organic acid content (Kanellis and Roubelakis-Angelakis, 1993). These last phenomena continue during ripening (phase III, ripening or maturation period). For both vintages 1996 and 1997, *veraison* was clearly indicated by the sudden softening of berries, associated with the increase in °Brix (corresponding to glucose and fructose accumulation) and the concomitant increase in pH (Fig. 1B).

Results presented here clearly show that major changes occuring at the beginning of ripening (i.e. softening, the onset of the second growth period, sugar accumulation, acid breakdown) are associated with the expression of the *pme*1 gene. Moreover, the *pme*1 mRNAs detected here were induced about one week before softening (week 6) and Fig. 1E revealed that the inception of mRNA accumulation occurred prior to softening. The existence of early molecular events associated with the triggering of ripening constitutes a key for the study of signal events responsible for the induction of ripening in non-climacteric (ethylene insensitive) fruits like grape berries. This rapid increase in *pme*1 transcripts is consistent with the accumulation of a large number of cDNAs in Shiraz grape (Davies and Robinson, 2000) occurring at the onset of ripening, including a putative N-terminal domain of some pectin methylesterases.

The *pme*1 deduced amino acid sequences shared significant similarity with other plant PMEs (Fig. 2). The size of the *pme*1 transcript (1.9 ± 0.1 kb) is consistent with previous data (Ray et al., 1988; Nairn et al., 1998). The clone had been isolated from grapes harvested at a post-*veraison* stage (one week later) and may be specific for this period of ripeness. Therefore, the presence of other PME isoforms exhibiting a different expression pattern during grape berry development cannot be excluded. This hypothesis is reinforced by the failure to detect mRNAs during green phase I, a period marked by a high PME "specific" activity in grapes. Therefore other PME genes, with no cross-reactivity with *pme*1, may be expressed before ripening (phase I).

Different kinetic properties of PME isoforms can reflect different physiological functions. For instance, the PE-C form of tomato PME is more effective on pectins with low DE than other isoforms (Warrilow and Jones; 1995). In the present study, the lack of *pme*1 mRNAs in green stages may be explained by similar mechanisms. Nevertheless, according to the expression pattern of mRNAs obtained, the partial length cDNA isolated in the present study can be considered as an early marker of *veraison*. In order to elucidate the presence of several

PME isoforms, lower stringency conditions and/or Southern blots will be necessary.

During phase I, the thickening, and expansion of cell walls was accompanied by a marked increase of newly synthesized homogalacturonans. The growth of berries after the onset of ripening is mainly due to the accumulation of sugars and to water influx but is also due to the synthesis of wall material (Nunan et al., 1998). During phase II and III, CWM and homogalacturonans accumulated more slowly, corresponding with slower cell enlargement and thinning of walls to accommodate fruit expansion (Fougère-Rifot et al., 1996). However, biosynthesis in phase I and II is not sufficient to offset thickening and enlargement of walls.

The total amount of uronic acids per berry increased rapidly during phase I and more slowly during phases II and III. The continuous accumulation of uronic acids throughout berry development can be explained by the bio synthesis of highly methyl-esterified homogalacturonans (Liners and VanCutsem, 1992).

Total pectins from Muscat Gordo grapes (Nunan et al., 1998) decline from 58%, two weeks before *veraison*, to reach 47% four weeks after *veraison*. The large decrease observed during the development of Ugni blanc grapes may be cultivar-specific.

Immunocytochemical studies of carrot cells revealed that pectins of different DE can be located separately inside primary walls and middle lamellae (Liners and VanCutsem, 1992). In the present study, DE values are averages calculated for total pectins which are in fact a mixture of "old" de-esterified and de novo synthesized, highly methylated pectins (Liners and VanCutsem, 1992). The average DE value decreased in two steps during berry development and was not strictly correlated with the pattern of PME activity (expressed either as total or as "specific" activity). This might suggest the presence of other PME isoforms and a precise regulation mechanism of the activity of these isoenzymes. As the activity of PME in the cell wall was constant and DE decreased throughout maturation, different isoforms of PME could be expressed at specific stages of development. However, in vitro determination of PME activity does not necessarily reflect the in vivo regulation of the enzyme. Even though PME activity was not strictly correlated with DE values of the cell wall, the observed decrease of DE indicates that PME(s) play(s) a major role in the development of grape berries, possibly by allowing the action of depolymerases such as polygalacturonase.

Further analysis of polysaccharides present in these HEPES extracts and the determination of the molecular size distribution of pectic polysaccharides (CWM and extracts) could be a key to understanding the mechanism of solubilization and depolymerization of pectins during grape berry ripening. Further work needs to be done in order to elucidate the substrate and product specificity, and conditions for optimal activity of the different PME isoenzymes that may be involved in important cell wall changes associated with grape berry development.

4. Experimental

4.1. Plant material

Grape berries (*Vitis vinifera* L., cv. Ugni blanc) were harvested (Domaine du Chapître, INRA, Villeneuve-Les-Maguelone, France) weekly from June to September during 1996 and 1997. Berries were immediately cooled to 4 °C and separated according to their diameter until *veraison* (week 7) and according to their density (determined by flotation in several sucrose solutions) after softening occurred. A randomly chosen sample (30 berries) was kept aside for further characterization as described below. Whole berries were frozen in liquid nitrogen (less than 2 h after harvest), deseeded and powdered with a ball blender (Dangoumau). The resulting ground berries were stored at −80 °C and further used for total RNA, protein and cell wall extractions.

4.2. Berry measurements

For each sample, the average diameter, fresh and dry (by lyophilisation) weight of berries were determined. The musts from squeezed berries were used to measure pH and total soluble solids (degrees Brix determined by using an ATAGO N1 hand refractometer).

4.3. Isolation of total RNA

Total RNA isolation was performed on 5 g aliquots of ground berries. Total RNA concentration and purity were estimated by measurement of absorbance at 230, 260 and 280 nm. The quality of the RNA was checked with 1% agarose gel electrophoresis (Tesnière and Vayda, 1991).

4.4. Isolation of partial cDNA clones

Total RNAs (15 μg) extracted from pre-mature berries (week 8) were used as a template for reverse-transcription (RT) reactions according to the supplier's protocol (SuperScript™ II, Gibco BRL, Life Technologies). Degenerate PCR primers obtained by sequence alignments were kindly supplied by Dr B. Fils-Lycaon (Unité de Technologie des Produits Végétaux, INRA Avignon, France). The primers used in the RT-PCR were originally discribed to amplify a PME fragment of apricot fruit (*Prunus armeniaca*). The sequences were obtained by sequence alignment with other fruit PMEs in conserved regions, corresponding to the COOH

terminal region (AA 333–428) of a peach (*Prunus persica*) sequence.

Deduced degenerate oligonucleotides were synthesized with the sequences 5′-GA(C/T)G(G/C)IT(A/T)(C/T)CA(A/G)GA(C/T)ACICTIT-3′ (upstream primer, corresponding to DGFQDTLY) and 5′-TTCCAIGGIC(G/T)ICCNAG(A/G)TA-3′ (downstream primer, corresponding to YLGRPWK of the amino acid sequences) respectively, where I is inosine, an analogue to G, and N is all 4 nucleotides. Cycles (40 repeats) of specific amplification by PCR (MiniCycler™ MJ Research) were performed as follows: 94 °C 1 min, 42 °C 1 min and 72 °C 1 min. PCR products were separated on a 1.2% agarose gel electrophoresis (Nusieve® GTG®, FMC®) and purified using a gel extraction kit (JETsorb, Genomed). The purified PCR fragments were cloned in pGEM®-T Easy vector (Promega). DNA sequences were performed with the Taq DyeDeoxy™ Terminator Cycle Sequencing Kit (Applied Biosystems, Inc) using SP6 and T7 primers, and were analysed with an ABI (model 373A, Applied Biosystems, Inc) sequencer. Analysis of the cloned sequences was performed by a similarity search using the BLASTX + BEAUTY Web site.

4.5. Northern blot analyses

For northern blot analyses, 15 μg of total RNAs were loaded onto a 1.2% denaturing agarose-formaldehyde gel electrophoresis, running for 3 h (80 mV) and transferred onto a nylon membrane (Hybond™-N, Amersham) during 20 h. cDNA probes used were obtained by *Eco* RI digestion (5 u/μg DNA, 2 h at 37 °C). ^{32}P labelled probes were obtained from 50 ng cDNA according to the Megaprime DNA labelling system (random priming, Amersham). ^{32}P dCTP and non-labelled nucleotides were discarded by NICK™ Columns (Pharmacia Biotech) purification. Membranes were pre-hybridized in 5×SSC, 5× Denhardt's solution, 0.5% SDS and 300 μg/ml of denatured salmon sperm DNA during 4 h at 65 °C. Labelled probes were added to the pre-hybridization buffer (1.10^6 cpm/ml buffer), and hybridization occurred at 65 °C for 20 h. Northern blots were washed stringently at 65 °C in 2×SSC, 0.1% SDS for 20 min (twice); 1×SSC, 0.1% SDS for 20 min and a rapid final wash in 0.1×SSC at room temperature. Autoradiography was performed with Blue XB-1 imaging film (18×24 cm, Kodak) at −80 °C. Signals on the hybridized membranes were quantified by SigmaGel (Jandel Scientific).

4.6. Extraction of total proteins

All steps were performed at 4 °C. Aliquots of ground berries (5 g each) were homogenised for 15 h in 10 ml of 0.5 M Tris-HCl pH 8.5, containing 1% Triton X-100 (w/v), 20% glycerol (v/v), 5% polyvinylpyrrolydone (w/v), 2 M NaCl and 20 mM ß-mercaptoethanol. The suspension was then centrifuged at 17,000×*g* for 30 min. The whole extraction procedure was repeated on the pellets. Supernatants (ca. 25 ml) were pooled and ammonium sulphate was slowly added up to 100% saturation, the suspension was then stirred for 2 h and left to stand for 12 h at 4 °C. The precipitated proteins were removed and redissolved in 5 ml of 0.1 M sodium phosphate pH 7.5 to give the crude extract used for the determination of PME activity.

4.7. Determination of PME activity

The PME activity in crude protein extracts was determined by following the release of methanol (Klavons and Bennett, 1986) from citrus pectin (Fluka AG, M_r ca. 25,000–50,000), all assays being performed in triplicate for the 2 harvests 1996 and 1997. Aliquots of crude protein extracts (10 μl each) were diluted 10-fold in 0.1 M sodium phosphate, pH 7.5 to which was added 1 ml 0.05% (w/v) citrus pectin in the same buffer and transferred into screw-cap tubes. The reaction rates of methyl hydrolysis were checked at several time points. Finally, the mixture was incubated 30 min at 30 °C and the reaction was stopped by boiling for 10 min. Alcohol oxidase (1 unit/ml, Sigma A-2404) was added and incubated 15 min at 25 °C. A 2 ml solution of 20 mM 2,4-pentanedione in 2 M ammonium acetate 50 mM acetic acid was added and the reaction mixture was incubated at 60 °C for 15 min (Klavons and Bennett, 1986). The absorbance was then measured at 412 nm against the same reaction mixture incubated with a boiled crude extract. The amount of methanol released allowed the determination of PME activity expressed in nkat.

4.8. Purification of grape berry cell walls

The procedure of purification was adapted from Huber (1991). All steps prior to phenol extraction were performed at 4 °C. The ground "powder" (5 g) obtained by milling whole deseeded grape berries in liquid nitrogen was thawed for 2 h in 25 ml of 40 mM HEPES pH 7.0 and centrifuged at 10,000×*g* for 30 min. Extraction was repeated twice with 25 ml HEPES. Lipids and bound proteins were extracted from insoluble pellets with 25 ml of buffered phenol in 0.5 M Tris–HCl pH 7.5 under agitation (20 °C, 60 min). Supernatants were eliminated by centrifugation (23,000×*g*, 30 min, 20 °C). This procedure was repeated once. Phenol was then removed by treatment with chloroform followed by filtration (filters Sartorius, Teflon®, 47 mm, 0,45 μm) under vacuum. Cell wall material (CWM) was freeze-dried and stored overnight in a vacuum oven at 55 °C in the presence of P_2O_5 and weighed. Finally, CWM was finely milled in liquid nitrogen with a Spex 6700 Freezer-mill for 5 min (top impact frequency), stored under vacuum at 55 °C in the presence of P_2O_5 and weighed.

4.9. Analysis of cell walls

All procedures were carried out on ca. 5 mg of dried CWM. Uronic acids were measured in triplicate by the *m*-hydroxydiphenyl method (Blumenkrantz and Absoe-Hansen, 1973) using polygalacturonic acid (sodium-salt 85–90%, Sigma) as a standard (0 to 20 μg range), with a preliminary dissolution of the CWM in concentrated sulphuric acid 98%. The degree of methyl-esterification of HGs was determined by saponification of CWM and enzymic oxidation of methanol released by alcohol oxidase, as described earlier.

Effect of *Mentha* × *piperita* essential oil and monoterpenes on cucumber root membrane potential

Massimo Maffei*, Wanda Camusso, Silvano Sacco

Department of Plant Biology, University of Turin, Viale P.A. Mattioli 25, I-10125 Torino, Italy

Received 12 February 2001; received in revised form 2 July 2001

Abstract

Peppermint (*Mentha piperita* L.) essential oil and its main components were assessed for their ability to interfere with plant plasma membrane potentials. Tests were conducted on root segments isolated from etiolated seedlings of cucumber (*Cucumis sativus* L.). Increasing the concentration of peppermint essential oil from 5 to 50 ppm caused a decrease in membrane potential (V_m) hyperpolarization of 10–3 mV, whereas concentrations from 100 up to 900 ppm caused an increasing depolarization of V_m (from 5 to 110 mV). When tested at 300 ppm, (+)-menthyl acetate, (−)-limonene and 1,8-cineole did not exert any significant effect on V_m, whereas (+)-menthofuran (73 mV), (+)-pulegone (85 mV), (+)-neomenthol (96 mV), (−)-menthol (105 mV) and (−)-menthone (111 mV) showed increased ability to depolarize V_m. A plot of log of octanol–water partition coefficient (K_{ow}) against their depolarizing effect showed a significant negative correlation, suggesting that among all monoterpenoids increased membrane depolarization depends on lower K_{ow}. However, among monoterpene ketones, alcohols and furans, increased membrane depolarization is associated with a decline in water solubility. The possible effect of monoterpenoids on membrane ion fluxes is also discussed, since changes in the bioelectric potential of cells imply changes in the flux of ions across the plasma membrane © 2001 Published by Elsevier Science Ltd.

1. Introduction

Membrane potential (V_m) results from an imbalance in the number of cations and anions across biological membranes. However, the binding of many plant natural products to membranes causes conformational changes in the ion channels and membrane-bound proteins, increasing or decreasing ion flow (Warber, 1998). Higher plants synthesize a great variety of terpenoid natural products, which can be involved in plant-plant, plant-pathogen and plant-herbivore interactions. Monoterpenoids are the major components of some essential oils: they have toxic effects on seed germination (Robinson, 1983; Rice, 1984), growth of some bacterial strains (Knobloch et al., 1989; Economou and Nahrstedt, 1991), development and growth of some insects (Lee et al., 1999), growth of pathogenic fungi (Adam et al., 1998), and interact at the cell level with cytosolic Ca^{2+}, probably through an intracellular Ca^{2+} store release (Takeuchi et al., 1994) and Ca^{2+} channel blocking (Taylor et al., 1985; Hills and Aaroson, 1991). Due to the relative hydrophobicity of most monoterpenoids, it is postulated that these compounds would accumulate in biological membranes (Griffin et al., 2000), and thus could affect ion flow.

Previous studies have demonstrated that peppermint (*Mentha piperita* L.) essential oil and its main monoterpenoid components are able to interfere with cucumber (*Cucumis sativus* L.) root respiratory functions (Mucciarelli et al., 2001). In particular, (+)-pulegone was found to be the most toxic compound for root and mitochondrial respiration. (−)-Menthone had less inhibiting action than (+)-pulegone, whereas (−)-menthol was the least inhibitory compound tested. In the same study it was noted that terpenoids had a greater inhibition on the respiration of intact cucumber root segments than on isolated root mitochondria, suggesting that inhibition was probably due to terpenoid interaction

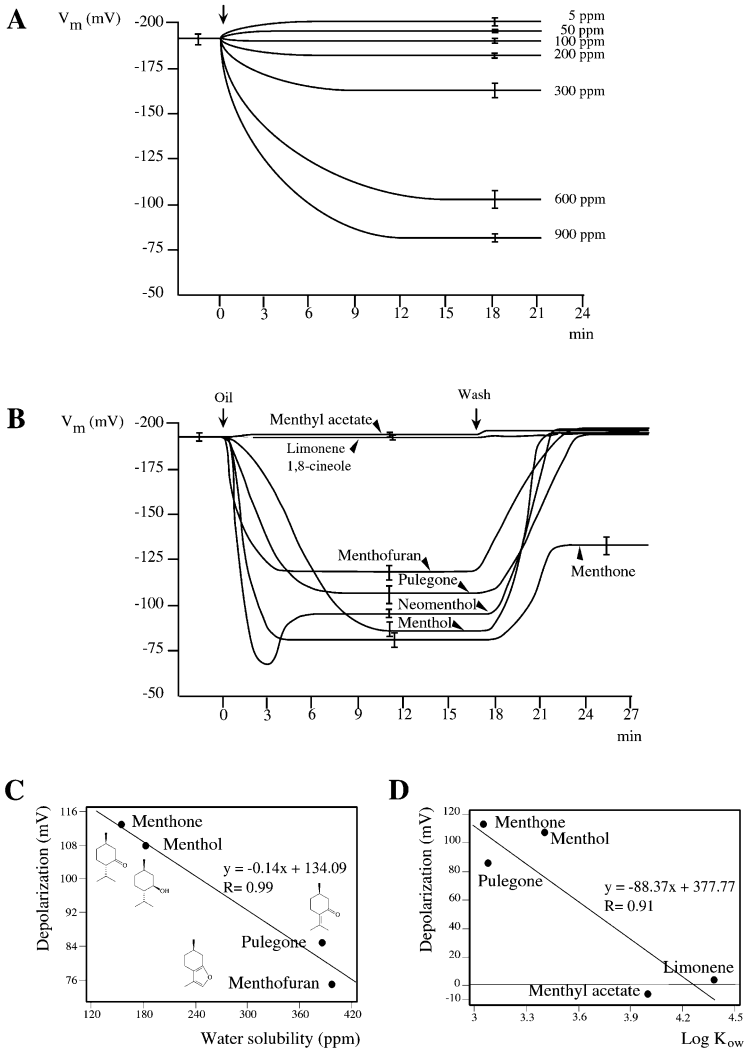

Fig. 1. A. Effect of increasing peppermint oil concentrations on transmembrane potential (V_m). Essential oil concentrations up to 50 ppm induce a slight hyperpolarization, whereas concentrations greater than 100 ppm cause a drastic membrane depolarization. Arrow indicates the starting time of essential oil perfusion. B. Effect of some essential oil components used at 300 ppm on V_m. (−)-Limonene and 1,8-cieneole do not exert any significant effect, wherease menthyl acetate caused a slight hyperpolarization. (+)-Neomenthol perfusion caused a rapid and transient depolarization of V_m which reaches a steady depolarized value after a few minutes. The depolarizing effect of all compounds, except (−)-menthone, is annulled by washing root segments with a fresh buffer solution. Arrows indicate the starting time of component perfusion (oil) and the starting time when a fresh buffer solution was perfused (Wash). C. Plot of the depolarizing value of some oxygenated monoterpenes tested against their water solubility. A negative correlation was found between depolarizing effect and water solubility of compounds. D. Plot of the depolarizing value of some monoterpene tested against log of octanol–water partition coefficient (K_{ow}) as reported by Griffin et al. (1999). Even in this case a significant negative correlation was found between depolarizing effect and log K_{ow} of compounds. For all plots, bars indicate standard deviation.

with cell walls and plasma membranes (Mucciarelli et al., 2001). A interaction of terpenoids with the plasma membrane could trigger the initiation of a series of physiological responses via intracellular transduction pathways (Kombrink and Somssich, 1995). Besides, interaction of terpenes may alter ion permeability and fluxes across the plasma membrane, possibly triggering an oxidative burst as observed in some plant cell systems after elicitor treatments (Nürnberger et al., 1994).

The aim of the present work was the evaluation of the effect of peppermint essential oil and individual oil components on transmembrane potential in root cells of *Cucumis sativus*.

2. Results and discussion

The essential oil of the peppermint plants used in this study was characterized by the presence of the oxygenated monoterpene compounds, (−)-menthol (40.53%), (−)-menthone (14.63%), (+)-menthofuran (4.32%), (+)-menthyl acetate (4.07%) (+)-pulegone (0.80%) and (+)-neomenthol (2.02%) along with substantial percentages of the monoterpene oxide 1,8-cineole (6.53%) and the olefin (−)-limonene (2.57%). Minor mono- and sesquiterpenes as reported earlier (Maffei and Sacco, 1987) made up the remainder of the oil composition.

Perfusion of cucumber root segments with increasing concentrations of peppermint essential oil caused a significant change in the V_m (Fig. 1A). Perfusion with peppermint oil at 5 and 50 ppm prompted a significant membrane hyperpolarization, whereas increased depolarization was observed with oil concentrations from 100 up to 900 ppm. Depolarizing and hyperpolarizing effects were fully reversible by washing root segments with a fresh buffered solution (data not shown). These results parallel previous studies in which there was a positive correlation between peppermint oil concentration and inhibition of cucumber root and mitochondrial respiration for concentrations ranging from 50 to 900 ppm (Mucciarelli et al., 2001).

In order to understand which of the oil components was responsible for the depolarizing effects, (+)-pulegone and some other oil components were perfused at 300 ppm on root membranes and the V_m measured (Fig. 1B). Perfusion with 300 ppm (−)-menthyl acetate, caused a slight and not significant membrane hyperpolarization, whereas 300 ppm (−)-limonene and 300 ppm 1,8-cineole did not cause any significant V_m variation. Increasing root membrane V_m depolarization was observed when (+)-menthofuran, (+)-pulegone, (+)-neomenthol, (−)-menthol and (−)-menthone were applied at 300 ppm (Fig. 1B). Washing out of all compounds with fresh buffer prompted a membrane hyperpolarization with full recovery of the original V_m for all compounds except (−)-menthone, for which root membrane V_m remained depolarized even after washing. In particular, (+)-neomenthol and (−)-menthone induced a very rapid membrane depolarization, with (+)-neomenthol showing a transient depolarization of at least 130 mV (S.E. ± 1.7), followed by a slight hyperpolarization, to end up at a net depolarized V_m. This observation suggests that monoterpenoids interact reversibly with the plasma membrane [except (−)-menthone, for which recovery of V_m was only partial], probably by affecting ion channels or acting as pore-forming molecules, as demonstrated in artificial lipid bilayers (Griffin et al., 2000). These data are also in agreement with previous data on cucumber root respiration inhibition, where washing of cucumber root and mitochondria with a fresh solution recovered initial respiratory levels (Mucciarelli et al., 2001).

Assuming that V_m depolarization caused by 600 ppm of essential oil was additive and dependent on the relative percentage of each component in the total oil (Fig. 1A), and assuming the oil composition is as stated above, it is possible to extrapolate that when tested at 300 ppm (Fig. 1B) (−)-menthol was tested 1.23 times (40.53% of 600 ppm total oil = 243 ppm menthol; 300 ppm /243 ppm = 1.23), (−)-menthone 3.41 times, (+)-menthofuran 26.09 times, (+)-pulegone 75 times, (+)-neomenthol 25 times, (−)-menthyl acetate 12.5 times, (−)-limonene 18.75 times and 1,8-cineole 7.5 times greater than the concentration expected in 600 ppm of the total essential oil. Thus, (−)-menthol appears to be the main component responsible for depolarization of V_m by the total essential oil, followed by (−)-menthone. (+)-Pulegone, used at 75 times the normal concentrations expected in a 600 ppm oil solution does not exceed (−)-menthol and/or (−)-menthone V_m depolarization.

The plot of V_m depolarization against the water solubility (WS, expressed in ppm) (Fischer, 1991; Weidenhamer et al., 1993) of some oil components (Fig. 1C) showed a significant negative correlation, with a direct correlation between V_m depolarization and lipophily of oxygenated monoterpenes. Fig. 1D shows the plot of V_m depolarization against the log of octanol–water partition coefficient (K_{ow}) for some of the monoterpenoids tested, as reported by Griffin et al. (1999). Also in this case a significant negative correlation was observed, with decreasing V_m depolarization values with increasing log K_{ow}. Recent findings have shown that monoterpenes affect biological membranes by damaging their structure and changing their lipid packing density which increases ion permeability and perturbs membrane-bound enzyme function (Griffin et al., 2000). Our results suggest that decreasing water solubility of monoterpenes increases the possibility for terpenoids to interact with and disrupt membrane integrity, thus causing a rapid and reversible membrane V_m depolarization. These data parallel previous investigations done on antimicrobial activity (Knobloch et al., 1989), toxicity in plant cell cultures (Brown et al., 1987), and inhibition of tissue (Fisher, 1986; 1991) and mitochondria respiration (Mucciarelli et al., 2001).

Changes in the bioelectric potential of cells imply changes in the flux of ions across the plasma membrane. Changes in membrane potential initiate several signal transduction pathways (Sanders and Bethke, 2000). Preliminary data on (−)-menthol-induced increase of cucumber root cytosolic free calcium ions, $(Ca^{2+})_i$, (Maffei and Camusso, 2000) suggest that (−)-menthol could play an important role in early events in the signal transduction pathway. Ca^{2+} channels are activated by membrane depolarization; by implication, signals that elicit membrane depolarization, such as the action on some monoterpenes, could trigger entry of Ca^{2+} from the external medium (Sanders and Bethke, 2000). Moreover, opening of anion channels not only results in a loss of Cl^- from the cytosol but also in membrane depolarization (see also Swandulla et al., 1986; Hawthorn et al., 1988; Hills and Aaronson, 1991; Chiyotani et al., 1994; Dierkes et al., 1997). Anion channel opening appears to be an early event in many signal transduction pathways and probably leads to the activation of voltage-gated Ca^{2+} channels (Sanders and Bethke, 2000).

A direct comparison of the present data with our previous results (Mucciarelli et al., 2001) indicates that

(+)-pulegone, which acts as a possible uncoupling agent of cucumber root and mitochondria respiration, has little effect on membrane potential, whereas (−)-menthol shows an almost 100-fold V_m depolarizing action with respect to (+)-pulegone, although (−)-menthol has less inhibitory action on root respiration. The fact that (−)-menthol is more disruptive to membrane potential, while (+)-pulegone inhibits root respiration more readily could be an explanation why plants make mixtures of monoterpenes; perhaps they can have different modes of action. For allelopathic purposes, it may be useful for a plant to have more than one kind of weapon at its disposal.

Since monoterpenes can cause such extensive membrane depolarization, they are clearly toxic to plant cells. Perhaps this is why they are often found to be sequestered in secretory structures (Gershenzon et al., 2000).

Further studies are under way to understand better the effect of monoterpenes on membrane ion equilibrium and their direct and indirect involvement in the signal transduction pathway.

3. Experimental

3.1. Plant material and seed germination

Cucumber (*Cucumis sativus* L. var. ''Piccolo di Parigi'') seeds were purchased from Franchi Sementi, Bergamo, Italy. Seeds were washed with tap water for 4 h and then placed for 48 h in the dark (20 °C isothermal) on 9 cm Petri dishes containing 2 paper filters saturated with 5 ml of 5 mM MES-Na (2-[*N*′-morpholino] ethanesulfonic acid sodium salt) buffer, pH 6.0, with the addition of 0.5 mM $CaSO_4$. Peppermint (*Mentha* × *piperita* L.) plants were grown in experimental plots of the Botanical Garden of the University of Torino, and were distilled when in full bloom.

3.2. Essential oil distillation and chemicals

Peppermint oil was steam distilled by using a modified Clevenger apparatus as reported earlier (Mucciarelli et al., 2001). Essential oil GC analyses and compound identification were performed as reported elsewhere (Maffei et al., 1999). (−)-Menthol, (−)-menthyl acetate, (+)-neomenthol, (−)-menthone, (+)-pulegone, (−)-limonene, 1,8-cineole and (+)-menthofuran (purity > 99%) were purchased from Sigma-Aldrich (Milano, Italy).

3.3. Root segment membrane potential determination

For treatments and controls, 15 seeds per each of 10 Petri dishes were incubated in the dark at 28 °C. Three days after germination, roots of seedlings were used for membrane potential determination. Membrane potentials were determined in root segments. The transmembrane potential (V_m) was determined in the root elongating zone with glass micropipettes with a tip resistance of 4–10 MΩ and filled with 1 M KCl. Micropipettes were used as micro-salt bridges to Ag/AgCl electrodes and inserted vertically in the tissue by means of a Narishige micromanipulator (Sacco and Maffei, 1997). Cucumber roots were always equilibrated for 60 min in 5 mM MES-Na (pH 6.0).

3.4. Effect of essential oil and essential oil component upon membrane potential

V_m from root segments of control seedlings germinated for three days in the dark were measured for ca. 30 min, then perfusion was carried on with the addition of increasing concentrations of total essential oil (from 5 to 900 ppm). Root segments were also perfused with 300 ppm of (+)-pulegone and other oil components. Total essential oil and oil components were dissolved in methanol ($\leqslant 0.4\%$) which was present in both treatments and controls. Water solubility values were obtained from Smyrl and Le Maguer (1980) and Weidenhamer et al. (1993), whereas values of Log octanol-water partition coefficient (K_{ow}) were obtained from Griffin et al. (1999).

3.5. Statistics

At least five replicates were performed for each experiment. The data obtained were analyzed by standard ANOVA using Systat 5.2 software for Macintosh. Significant differences are intended at $P < 0.05$.

Biosynthesis of ochratoxins by *Aspergillus ochraceus*

Jonathan P. Harris, Peter G. Mantle*

Biochemistry Department, Imperial College of Science, Technology and Medicine, London, SW7 2AY, UK

Received 19 January 2001; received in revised form 5 July 2001

Abstract

Shaken liquid fermentation of an isolate of *Aspergillus ochraceus* showed growth-associated production of ochratoxins A and B, followed by production of a related polyketide diaporthin. Later, between 150 and 250 h, mellein accumulated transitorily. In contrast, shaken solid substrate (shredded wheat) fermentation over 14 days produced mainly ochratoxins A and B (ratio ca. 5:1) in very high yield (up to 10 mg/g). In these systems experiments with ^{14}C-labelled precursors and putative intermediates revealed temporal separation of early and late stages of the ochratoxin biosynthetic pathway, but did not support an intermediary role for mellein. The pentaketide intermediate ochratoxin β was biotransformed very efficiently into both ochratoxins A and B, 14 and 19%, respectively. The already chlorinated ochratoxin α was only biotransformed significantly (4.85%) into ochratoxin A, indicating that chlorination is mainly a penultimate biosynthetic step in the biosynthesis of ochratoxin A. This was supported by poor (1.5%) conversion of radiolabelled ochratoxin B into ochratoxin A. Experiments implied that some ochratoxin B may arise by dechlorination of ochratoxin A. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

The mycotoxin ochratoxin A (OTA, **1**) (Fig. 1), first obtained from a South African *Aspergillus ochraceus* isolate (van der Merwe et al., 1965a), consists of a dihydroisocoumarin moiety (the pentaketide-derived ochratoxin α, **3**; Fig. 2) linked through the carboxyl group to phenylalanine. Corresponding des-chloro analogues are ochratoxins B (OTB, **2**) and β (**4**). Unlike ochratoxin α, ochratoxin β and mellein (**5**) have both been isolated from ochratoxinogenic *A. ochraceus* fermentations (Moore et al., 1972; Delgadillo, 1986).

^{14}C-labelled precursor feeding experiments and subsequent chemical degradation showed that phenylalanine was incorporated into OTA, whereas ochratoxin α was constructed from five acetate units with a one carbon addition at C-7 from methionine (Ferriera and Pitout, 1969; Searcy et al., 1969; Steyn et al., 1970). A crude cell-free enzyme preparation (OTA synthetase, requiring ATP and Mg^{++} ions) catalysed the linking of ochratoxin α with phenylalanine (Ferriera and Pitout, 1969). Wei et al. (1971) demonstrated incorporation of ^{36}Cl into OTA. The methylation inhibitor ethionine completely inhibited OTA production (Yamazaki et al. 1971).

The ^{13}C NMR spectrum of OTA was fully assigned by de Jesus et al. (1980); ochratoxinogenic fungal cultures fed [1-^{13}C] or [1, 2-$^{13}C_2$]acetate showed enhanced signals and ^{13}C–^{13}C coupling evidence supporting a pentaketide folding pattern similar to that in the biosynthesis of citrinin and mellein.

Huff and Hamilton (1979), recognising the lack of research in the pathway of OTA biosynthesis, proposed a scheme, although this unfortunately ignored the ubiquitous OTB. Subsequently, the ochratoxin polyketide synthase was reported to produce mellein; Abell et al., (1982) showed that there was no keto-enol tautomerism, but an unfunctionalised double-bond between C-6 and C-7 in the mellein pentaketide chain. Also, the carbonyl at C-3 may have been reduced to a hydroxyl prior to folding (Abell et al., 1983). The requisite methylation step was thought to occur after the production of mellein although the subsequent putative intermediates 7-methylmellein, 7-methoxymellein and 7-formylmellein

have not been isolated from fungal fermentation producing ochratoxins.

Chlorination of ochratoxin β by a chloroperoxidase was reasoned as occurring prior to joining the aromatic nucleus to phenylalanine via an acyl activated phosphoochratoxin α reacting with phenylalanine with its carboxy group protected by ethyl esterification. This reaction would result in ochratoxin C which could be transesterified to the OTA methyl ester, both of which OTA derivatives have been isolated from *A. ochraceus* cultures (van der Merwe et al. 1965b; Steyn and Holzapfel, 1967). Alternatively, ochratoxin C might be hydrolysed directly to OTA.

OTA, as a nephrotoxin and a carcinogen, is currently the subject of proposed EC legislation to place an upper limit of 5 μg/kg (5 ppb) in commodities for human food. It is timely, therefore, to contribute to the understanding of some fermentation dynamics of *A. ochraceus*, as one of the fungi involved in commodity spoilage, and of some later steps in the biosynthesis of ochratoxins.

2. Results and discussion

2.1. Experiments in shaken liquid fermentation

2.1.1. Culture dynamics

In potato dextrose broth, accumulation of biomass was complete within 3–4 days and was closely associated with production of ochratoxins (Fig. 3) (also noted by Steyn et al., 1970; Wei et al., 1971). There were also second and third temporal phases of secondary metabolite occurrence measured concerning the polyketides diaporthin (**6**; Fig. 4) and mellein.

Throughout the phase of ochratoxin occurrence there was a ratio of A:B of approximately 3:1. Diaporthin was also accompanied by approximately half the amount of orthosporin (de-*O*-methyl diaporthin; Harris and Mantle, 2001). The transitory appearance of mellein might plausibly be interpreted as reflecting cessation of involvement of this putative intermediate in ochratoxin biosynthesis after growth-associated production of the phenylalanine moiety declined. Alternatively, the observed temporal sequence of metabolites simply reflected progressive decline in biosynthetic complexity from ochratoxins (requiring phenylalanine, methionine, acetate and chlorine) to mellein which is solely derived from acetate.

2.1.2. Effect of ethionine

The only marked effect of the methylation inhibitor ethionine on accumulation of ochratoxins in submerged fermentation was on yield of OTA when added during early idiophase at 32 h (Table 1). This is consistent with methylation of the pentaketide occurring early in biosynthesis. The less obvious or nil effect on excreted OTB would be consistent with some of this arising by dechlorination of OTA.

2.1.3. Radioactivity experiment

Radiolabel from [1-^{14}C]acetate was incorporated into OTA when added as early as only 8 h into the fermentation; the finding demonstrated the close association of ochratoxin biosynthesis with replicatory growth (Table 2). The optimum time of addition of the polyketide precursor to achieve maximum specific radioactivity in OTA was at 22.5 h, consistent with a principle of maximum rate of isocoumarin biosynthesis preceding prominent occurrence of OTA in broth (Fig. 3). Reinterpretation of the data of Lillehoj et al.

22.5	143	37
32	143	18
50	152	15

(1978) reveals evidence of a similar temporal separation of steps in ochratoxin biosynthesis.

2.2. Experiments in shaken solid substrate fermentation

2.2.1. Culture dynamics

Ergosterol, as a measure of fungal mycelium in the substrate, increased linearly through days 4–8 of *A. ochraceus* growth in shaken shredded wheat substrate (Fig. 5). Accumulation of OTA and OTB closely followed fungal growth and was near maximum after 2 weeks; a 5:1 ratio up to day 9 diverged later in favour of OTB, possibly reflecting limitation of substrate chlorine ions for OTA formation (Stander et al., 2000). Yields of 10 mg OTA/g substrate have been achieved. If ergosterol were even as much as 1% of *A. ochraceus* mycelial biomass, OTA would become 1/10th of fungal biomass; this is probably a conservative estimate. Mellein, diaporthin and orthosporin were absent or barely detected throughout this two-week fermentation. Contentious aspects of ochratoxin biosynthesis were therefore explored in this unusual medium in which secondary metabolism in *A. ochraceus* was highly focused on the ochratoxin pathway.

2.2.2. Radioactivity experiments

The magnitude of the relative incorporations of the three radioactive biosynthetic precursors into OTA and

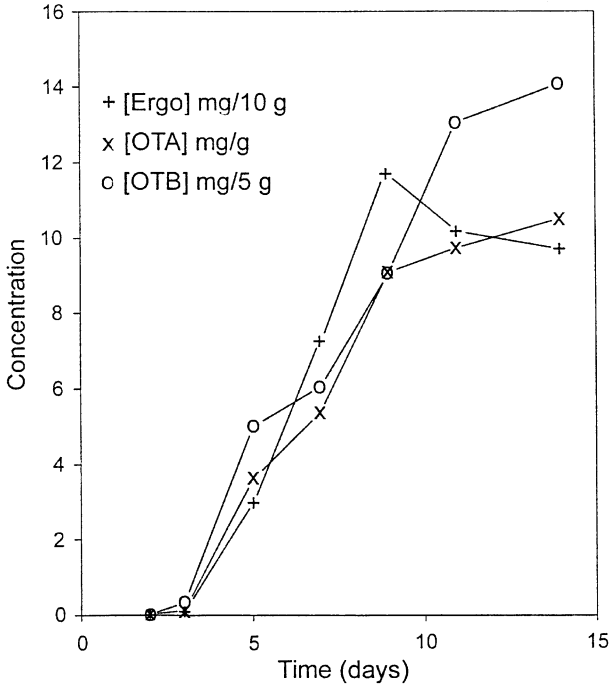

Fig. 5. Changes in ergosterol ([Ergo]), ochratoxin A ([OTA]) and ocratoxin B ([OTB]) concentraion during 2 weeks of an *Aspergillus ochraceus* solid substrate fermentation.

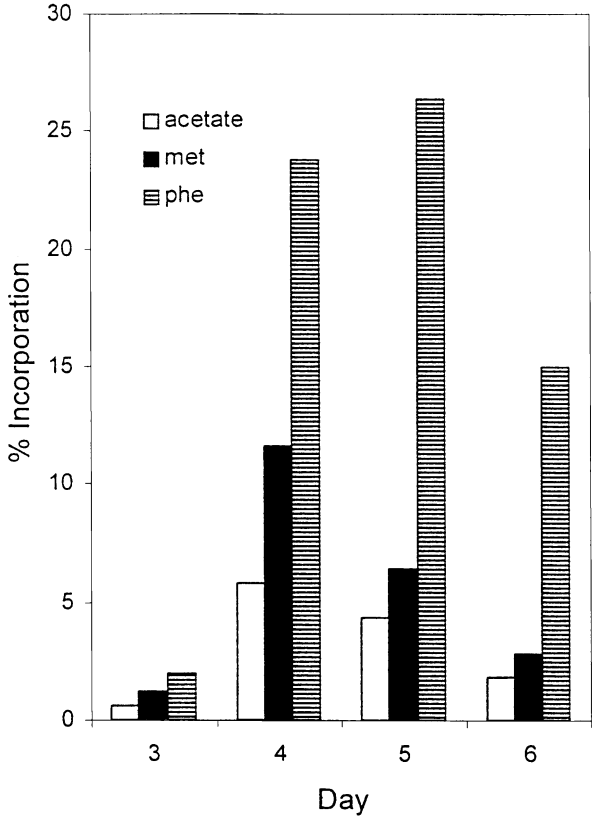

Fig. 6. The % incorporation of 5 μCi of either [1-^{14}C]acetate, [methyl-^{14}C]methionine or [U-^{14}C]phenylalanine into [^{14}C]ochratoxin A during 5 h after adding to *Aspergillus ochraceus* solid substrate fermentations on days 3, 4, 5 and 6.

OTB, when added to fermentations on days 3, 4, 5 or 6 (Figs. 6 and 7), showed that the experimental system was well suited to biosynthetic study. The data also demonstrated temporal separation of optima for isocoumarin biosynthesis (day 4 for OTA; days 4–5 for OTB) and addition of the phenylalanine moiety (day 5 for OTA; days 5–6 for OTB). Notably, 50% of the L-[U-^{14}C]phenylalanine added at 5 days was incorporated into OTA and OTB.

Relative incorporations of the putative intermediates ochratoxins α and β and mellein (Table 3) indicated a strong preferential role of α into A, but similar strong involvement of β into both A and B as subsequently isolated. ^{14}C from mellein occurred in much smaller amount in ochratoxins, which may only reflect indirect incorporation of the radiolabel from mellein catabolism. To suggest that the rather negative experimental result arose from poor uptake of added mellein seems weak when added ochratoxins α and β, both only having an additional carboxyl group, were incorporated so extensively into OTA and OTB. Mellein was only a transitory product in shaken liquid culture (Fig. 3) and therefore *A. ochraceus* is well able to degrade it; no trace of mellein was found in the fermentation fed [^{14}C]mellein. Indeed, the same putative indirect incorporation may explain the small amount of radiolabel in OTB after feeding with ochratoxin α.

Autoradiography of chromatograms of neutral and acidic components of extracts of cultures fed ochratoxin α showed some ^{14}C in neutral non-polar components, in addition to qualitative confirmation of incorporation into ochratoxins. This supports the interpretation of only indirect incorporation from ochratoxin α to OTB. Conversely, there was no autoradiographic evidence of biotransformations in the fermentation given ochratoxin β other than into OTA and OTB. In the fermentation given [^{14}C]mellein there were no particular locations of radiolabel in any fraction of extract, supporting the notion of its rather rapid and extensive catabolism.

In following the fate of dual-labeled OTA and OTB in shaken shredded wheat culture, more than 40% of the added OTA was recovered in the form as added (Table 4). However, an amount equivalent to ca.10% was present as OTB although with the ^{3}H:^{14}C ratio being slightly different. If this is a real change it might imply that the phenylalanine moiety can be transferred to OTB more readily than can the dihydroisocoumarin moiety, which would have to be dechlorinated. Very little (approx. 6.5%) of the added dual-labeled OTB was recovered as such with a similar ^{3}H:^{14}C ratio and even less was incorporated into OTA. Thus, experimental change of doubly-labelled OTA into OTB 5 h after it was added to a fermentation in early idiophase (Table 4) was the most significant interconversion observed. Generally maintained

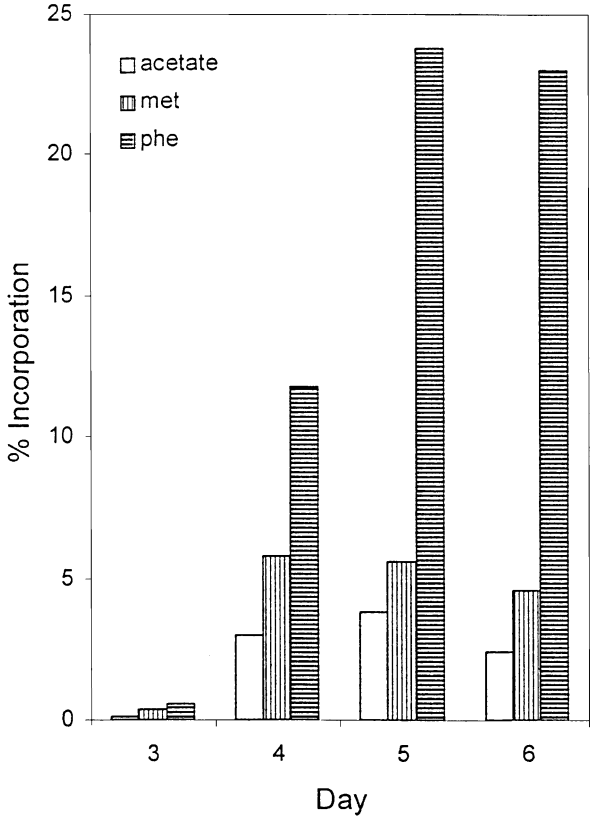

Fig. 7. The % incorporation of 5 μCi of either [1-^{14}C]acetate, [methyl-^{14}C]methionine or [U-^{14}C]phenylalanine into [^{14}C]ochratoxin B during 5 h after adding to *Aspergillus ochraceus* solid substrate fermentations on days 3, 4, 5 and 6.

Table 3
The % incorporation of 0.13 μCi [^{14}C]ochratoxin α, 0.1 μCi [^{14}C] ochratoxin β or 0.096 μCi [^{14}C]mellein into [^{14}C]ochratoxins A and B during 5 h of solid substrate fermentation at the 4 day stage

	[^{14}C]ochratoxin α	[^{14}C]ochratoxin β	[^{14}C]mellein
Ochratoxin A	4.85	14.32	0.56
Ochratoxin B	0.47	18.98	0.68

^{3}H:^{14}C ratios confirmed the validity of most of the transformations observed. Correct interpretation of the findings depends on the extent of cellular uptake of the compounds administered; conversion of OTA to OTB as a catabolic step could be extracellular, but chlorination of OTB to OTA probably requires cellular uptake. If there is not an uptake mechanism for OTB, this could impose a limit on experimentation. It is concluded from all the experiments that chlorination of both ochratoxin β and OTB can give rise to OTA. However, there was no evidence for the intermediate role of the ester ochratoxin C proposed by Huff and Hamilton (1979), presumably interpreted as having a role in protecting the phenylalanine carboxyl during the last biosynthetic steps. These results suggest that one, possibly dominant, biosynthetic pathway involves ochratoxins β→α→A, with also a branch for ochratoxins β→B. An alternative pathway might be ochratoxins β→B→A but, if ochratoxin α is not directly involved, it is difficult to explain the present demonstration that it can occur naturally. However, mellein seems not to be involved as a precursor of either pathway. The discovery of 5-methyl-, 5-formyl- and 5-carboxymellein in culture broth of *Nummulariella marginata* (Whalley and Edwards, 1985) provides a precedent for an oxidation system for a substituted methyl group, yet if such compounds are stable enough to be isolated from fermentation broth it is questioned why 7-methyl- and 7-formylmellein have not, so far, been discovered. Results of the second dual-labeling experiment complemented the first (Table 4). Over half the added OTA was recovered and only 3% was incorporated into OTB although with a slightly different radionuclide ratio. Autoradiography of culture extract chromatograms showed no ^{14}C in neutral fractions, in contrast to results from experiments with [^{14}C] ochratoxins α and β and mellein. Where [^{14}C] OTA or OTB was added, radioactivity was only obvious in the unchanged ochratoxin corresponding to what had been added. Thus, although it was shown that OTA can be converted into OTB nonspecifically, there was no convincing evidence whether or not specific biotransformation of OTB into OTA had occurred.

Since the dual-labelled experiments did not achieve the high percentage incorporations of the experiments in which ochratoxins α and β were administered, it could be argued that the inter-conversion of OTA and OTB, although shown to occur, is not as important in the biosynthetic pathway as the reactions involving ochratoxins α and β.

3. Experimental

3.1. Fungi

Two isolates of A. ochraceus were used; D2306 for its high yield of ochratoxins (Connole et al. 1981; as also used since by Tapia and Seawright, 1984, Stander et al., 2000; Stoev et al., 2000) and KBf for its production of mellein (though not producing ochratoxins; Mantle and McHugh, 1993). The fungi were maintained on potato dextrose agar (Difco).

3.2. Culture conditions

Submerged liquid culture was in potato dextrose broth (Difco), 100 ml in 500 ml Erlenmeyer flasks, inoculated with spores to give 2–4×10^{6} spores ml^{-1} and incubated on an orbital shaker (200 rpm, 10 cm eccentric throw), at 28 °C for isolate D2306 and 22 °C for isolate KBf.

Table 4
The % incorporation and ^{3}H:^{14}C ratio of ochratoxins A and B recovered after adding dual-labelled ochratoxins A and B to solid substrate fermentations

Experiment	Isotope	% Incorporation	^{3}H:^{14}C
Ochratoxin A added for 5 h on day 5			
Ochratoxin A	^{3}H	43.2	1:0.47
	^{14}C	41.5	
Ochratoxin B	^{3}H	12.1	1:0.33
	^{14}C	8.2	
Ochratoxin B added for 5 h on day 5			
Ohratoxin A	^{3}H	1.4	1:0.43
	^{14}C	1.5	
Ochratoxin B	^{3}H	6.7	1:0.37
	^{14}C	6.4	
Ochratoxin A added on day 6 and incubated overnight			
Ochratoxin A	^{3}H	58.3	1:0.48
	^{14}C	57.5	
Ochratoxin B	^{3}H	3.3	1:0.29
	^{14}C	2	

Shaken solid substrate fermentation in Erlenmeyer flasks was developed from the principle first devised for aflatoxins (Shotwell et al., 1966), then applied to OTA (Hesseltine, 1972) and scaled up to rotating barrel fermenters (Lindenfelser and Ciegler, 1975). Shredded wheat breakfast cereal (Cereal Partners UK, Welwyn Garden City), 40 g per flask, was autoclaved, moistened to an initial moisture content of approximately 35% with sterile water (16 ml) and incubated on the orbital shaker at 28 °C. Sterile water was also added at 24 and 48 h (4 and 2 ml, respectively). Water evaporation and metabolic dissimilation of substrate during the subsequent 2 weeks of shaken fermentation resulted in approximately 35 g of moist chocolate-coloured granules in each flask. Some small-scale fermentations were performed as 2 g of shredded wheat in 50 ml flasks for radiochemical experiments.

3.3. Biosynthetic preparation of dual-labeled OTA and OTB

After 4 days in standard shredded wheat culture, 2 g material was transferred to a 50 ml flask and given 5 μCi each of [methyl-^{14}C]methionine and L-[2, 3, 4, 5, 6-^{3}H]phenylalanine. Shaken incubation continued for 5 h and the culture was extracted for OTA (3.4 mg, 0.15 μCi ^{3}H:0.07 μCi ^{14}C, ratio ^{3}H:^{14}C 1: 0.47) and OTB (1.5 mg, 0.29 μCi ^{3}H:0.11 μCi ^{14}C, ratio ^{3}H:^{14}C 1: 0.38). Radioactivity from phenylalanine was incorporated about twice as efficiently as that from methionine.

3.4. Preparation of ^{14}C labeled ochratoxins α and β

OTA (1.16 mg, 0.21 μCi) and OTB (1.44 mg, 0.14 μCi), from cultures fed [methyl-^{14}C]methionine for 5 h on day 4, were each hydrolysed in 50 ml 6 M HCl by reflux for 18 h. The cooled mixture was extracted with EtOAc and ochratoxins α and β were purified by HPLC (see below) detected at 323 nm (retention time, Rt, 10 and 6 min, respectively, at 8.4 ml min^{-1}).

3.5. Biosynthetic preparation of [^{14}C]mellein

Sodium [1-^{14}C]acetate (10 μCi) was added to a 37 h liquid fermentation flask culture of isolate KBf and the fermentation continued for 1 h. [^{14}C] Mellein (2.22 mg) was obtained by extraction of culture filtrate with EtOAc followed by C18 SepPak and HPLC purification (see below). The measured radioactivity (1.67 μCi) represented 16.7% incorporation of radiolabel from [1-^{14}C]acetate.

3.6. Source of authentic compounds

OTA and OTB were isolated from solid substrates (2 g) by extraction in 100 ml EtOAc:0.01 M H_3PO_4, 9:1 (v:v), partition into aqueous $NaHCO_3$ (3%), acidified and back extracted into EtOAc. Residues were taken up in MeOH. OTA and OTB were purified by preparative HPLC (see later).

Ochratoxins α and β were synthesized by the acid hydrolysis of 1 mg OTA or OTB, respectively, followed by preparative HPLC (see later).

Mellein was obtained from 1 week potato dextrose broth culture of isolate KBf. The filtered broth, adjusted to pH 3, was extracted with EtOAc (100 ml) and the organic phase partitioned against a 3% aqueous $NaHCO_3$ solution to remove acidic metabolites. The organic extract was taken to dryness. The solutes, dissolved in MeOH, were processed by HPLC (below; detection at 239 nm, Rt 30 min). Combined eluates corresponding to mellein were mixed with an equal volume of H_2O and passed through a C18 SepPak classic cartridge pre-conditioned first with MeOH (20 ml) and then with H_2O (20 ml). Mellein was eluted in EtOH in the 2nd and 3rd 0.5 ml fraction. Diaporthin and orthosporin were available from other studies (Harris and Mantle, 2001).

All compounds were investigated by HR-MS, and linked scan EIMS (B/E and B^2/E) to interpret fragmentation. The EI mass spectra of OTA and OTB differ by the chlorine or proton substituent at C5, respectively. Molecular ions are very weak, as are those corresponding to losses of H_2O or CO_2. Therefore, use of EIMS for confirming OTA relies on the two important fragment ions, in this case m/z 255 and 239 (base peak). These represent, respectively, the isocoumarin moiety still with the amino nitrogen of phenylalanine and the isocoumarin alone. Principles of further EI fragmentation of the latter, with a carboxyl group reconstituted at C10, are illustrated by ochratoxin α. It is helpful to have a rationale for occurrence of fragment ions in EIMS at

least for diagnostic purposes and this has not been available before. From accurate mass measurements and linked-scan analysis of ochratoxins α and β, and of mellein, rationalised MS fragmentation [Scheme 1, extending the data of Delgadillo (1986)] showed considerable homology between ochratoxins α and β. Also, the composition of ion *m/z* 149 in ochratoxin β was identical to that of mellein. However, there was much less homology between the fragmentation patterns of the ochratoxins and mellein. Notably in ochratoxin β, absence of a B^2/E relationship between the fragment ion *m/z* 204 and the molecular ion implies that the loss of water was a thermal effect. In ochratoxin α two distinct ions of *m/z* 194 were recognised, arising via different fragmentations of the molecular ion, the minor route being via the base peak (*m/z* 212). There are also two forms of the corresponding fragment ion (*m/z* 160), with different elemental composition, in ochratoxin β. All major fragmentation losses of mellein occur in ochratoxins α and/or β. Composition of the prominent fragment ion *m/z* 134 in mellein is the same as that in ochratoxin β, but there its origin was not clear.

3.7. Analytical

The preparative HPLC system used a C18 column (30 × 2.5 cm), detection by fluorescence (excitation 340 nm, emission 400 nm) and UV absorbance (332 nm) in sequence, isocratic mobile phase H_2O:CH_3COOH:acetonitrile, 59.5:1:39.5 (v:v:v), at 5.6 ml min^{-1} (Rt ochratoxins A and B, 20 and 15 min, respectively). Ochratoxins A and B were purified further in MeOH:H_2O, 7:3 (v:v), Rt 21 and 16 min, respectively.

Analytical HPLC of 20 μl samples in MeOH used a C18 column (15 × 0.5 cm), a diode array detector and solvent flow at 1 ml min^{-1}: Rt ochratoxins A and B, 7.8 and 4.5 min, respectively. Neutral metabolites (mellein, diaporthin and orthosporin), monitored at 239 nm, had Rt of 4.5, 3.5 and 1.8 min, respectively.

TLC of portions of acidic and neutral extracts from radiolabelling experiments was performed on 10 × 10 cm TLC plates (SIL G, UV_{254} Camlab, Cambridge) in toluene–EtOAc–HCOOH, 5:4:1 (v:v:v). Dried plates were autoradiographed at −70 °C for 1 week. Ochratoxins were recognised by fluorescence. Mellein was visualised by spraying with 3% $FeCl_3$ in butan-1-ol whereby mellein is stained red (van der Merwe et al., 1965b).

3.7.1. Assay of ergosterol

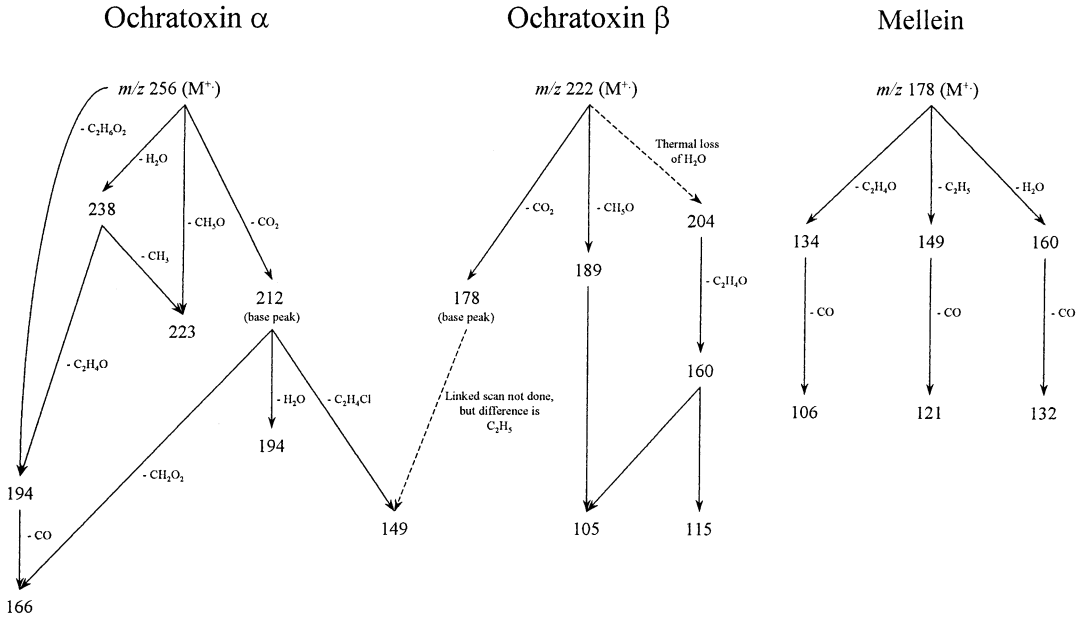
One gram sample of shredded wheat culture was refluxed in MeOH (100 ml) for 2 h. 4% KOH in 95% aqueous EtOH (20 ml) was added and neutral lipids were partitioned into pentane (3×40 ml). Solutes were dissolved in MeOH for analytical HPLC in 95% aqueous MeOH, detection at 282 nm, Rt 8 min (after Newell et al., 1988).

3.8. Treatment with ethionine

Ethionine (10 ml of a 5 mg ml^{-1} sterile solution) was added to potato dextrose broth cultures 32, 50, 56 or 72 h post-inoculation. Sterile water (10 ml) was added to a control culture. After 80 h, ochratoxins were extracted from the broth and quantified.

3.9. Relative dynamics of secondary metabolite production in submerged and solid substrate fermentations

At intervals, 10 ml samples were taken from triplicate liquid cultures. Broth was filtered through a weighed sintered 10 ml glass syringe and the retained biomass



Scheme 1. EIMS fragmentation of ochratoxins α and β and mellein deduced from mass measurements and linked scan experiments.

was lyophilised to constant weight. Acidified filtrate was extracted with EtOAc which was partitioned against bicarbonate. Ensuing acidic or neutral solutes were dissolved in MeOH for HPLC quantitation. Similarly, l g solid culture was taken at intervals and acidic and neutral metabolites analysed.

3.10. Experiments with radiolabelled precursors on isolate D2306

[1-^{14}C]acetate (5 μCi) was added to a liquid fermentation at 8, 22.5, 32 or 50 h post inoculation to determine the time of optimal incorporation into OTA, as assessed at 80 h. A portion (8–25%) of extracts was analysed by HPLC and radioactivity in eluates corresponding to specific quantified metabolites was measured by scintillation counting. 2 g aliquots of fermenting shredded wheat were transferred to groups of three 50 ml flasks from standard flask fermentations after 3, 4, 5 and 6 days. To each was added 200 μl of sterile water containing 5 μCi of either [1-^{14}C]acetate, L-[U-^{14}C]phenylalanine or L-[methyl-^{14}C]methionine. Each solution was applied to the substrate as very small drops. Incubation was continued for a further 5 h before extraction of ochratoxins to compare efficiencies of incorporation of precursors.

Similarly, three 2 g amounts of 4 day culture were given 200 μl sterile water containing 0.1 μCi of either [^{14}C]ochratoxin α, [^{14}C]ochratoxin β or [^{14}C]mellein and incubated for 5 h before extraction to measure fates of the radiolabeled probes. Similar fermentation material, though at the 5 day stage, was treated with dual-labeled OTA (231 μg) or OTB (1.02 mg) to explore their fate during 5 h. Again, dual-labeled OTA (1.28 mg in 3% $NaHCO_3$) was given to 6 day culture and incubated for longer (overnight).

Received 17 May 2001; received in revised form 10 July 2001

Abstract

Polyunsaturated highly branched isoprenoid (HBI) hydrocarbon distributions of laboratory cultures of five strains of the planktonic diatom *Rhizosolenia setigera* (Brightwell) are shown herein to be highly variable. Some strains produced both haslenes with from three to five double bonds and rhizenes. The haslenes comprised not only Δ5 alkenes but also those with C7(20) unsaturation, including hasla-7(20),9*E*,*Z*, 23-trienes and hasla-7(20),9*E*,*Z*-13, 23-tetraenes. The rhizenes contained C7(25) unsaturation and the vinyl moiety common to all algal haslenes so far characterised. The effects of temperature and salinity on HBI composition, along with isotopic content, were determined in strain CS 389/A. Increase in growth temperature from 18 to 25 °C increased the degree of unsaturation in the haslenes and *E* to *Z* isomerisation in the triene. There was also an increase in unsaturation in the rhizenes at the highest growth temperature, with hexaenes dominant over the pentaenes but in the rhizenes, *Z* to *E* isomerisation increased. Increased salinity from 15 to 35 psu increased cell growth and rhizene production but decreased haslene production. Unsaturation in haslenes was not changed by increased salinity but unsaturation in the rhizenes decreased. These may reflect growth rate differences. The carbon isotopic compositions of the haslenes and rhizenes were similar to that of the major sterol at 18 °C, but the major HBI isomers were 3–4 per mil depleted relative to phytol released by saponification from chlorophyll a. This suggests biosynthesis of HBIs from a different isotopic pool of isopentenyl biphosphate to that from which phytol is biosynthesised. At 25 °C, further isotopic differences were observed. The variables controlling HBI distributions in *R. setigera* are still not fully understood and rationalisation of the environmental controls on the sedimentary distributions of the HBIs from *R. setigera* may only be possible once such factors are established. © 2001 Elsevier Science Ltd. 1. Introduction

The only highly branched isoprenoid (HBI) hydrocarbons reported to date in the diatom *Rhizosolenia setigera* (Brightwell) are either a C_{25} pentaene (I) or C_{30} alkenes (Volkman et al., 1994, 1998; Sinninghe Damsté et al., 1999a). We have proposed the name 'haslenes' for the HBI C_{25} alkenes (Rowland et al., 2001), because they were first reported (Volkman et al., 1994) from the diatom *Haslea ostrearia* (Simonsen). We now suggest the name 'rhizenes' for the corresponding C_{30} HBIs, as they were first reported from *R. setigera* (Volkman et al., 1994).

The single haslapentaene (**I**) identified thus far in *R. setigera*, has been characterised by NMR spectroscopy and comparison with data for the same compound in *H. ostrearia* (Wraige et al., 1997; Sinninghe Damsté et al., 1999b) and the double bond positions of four rhizenes have recently been established (Belt et al., 2001). However, the factors controlling the distributions of HBIs in *R. setigera* are at present unknown. These are important since HBIs are quite commonly reported in oceanic sedimenting particles (reviewed in Belt et al., 2000a) where they may be useful indicators of specific diatom inputs. Whilst a number of benthic diatoms are known to produce haslenes (e.g. several *Haslea* spp. and

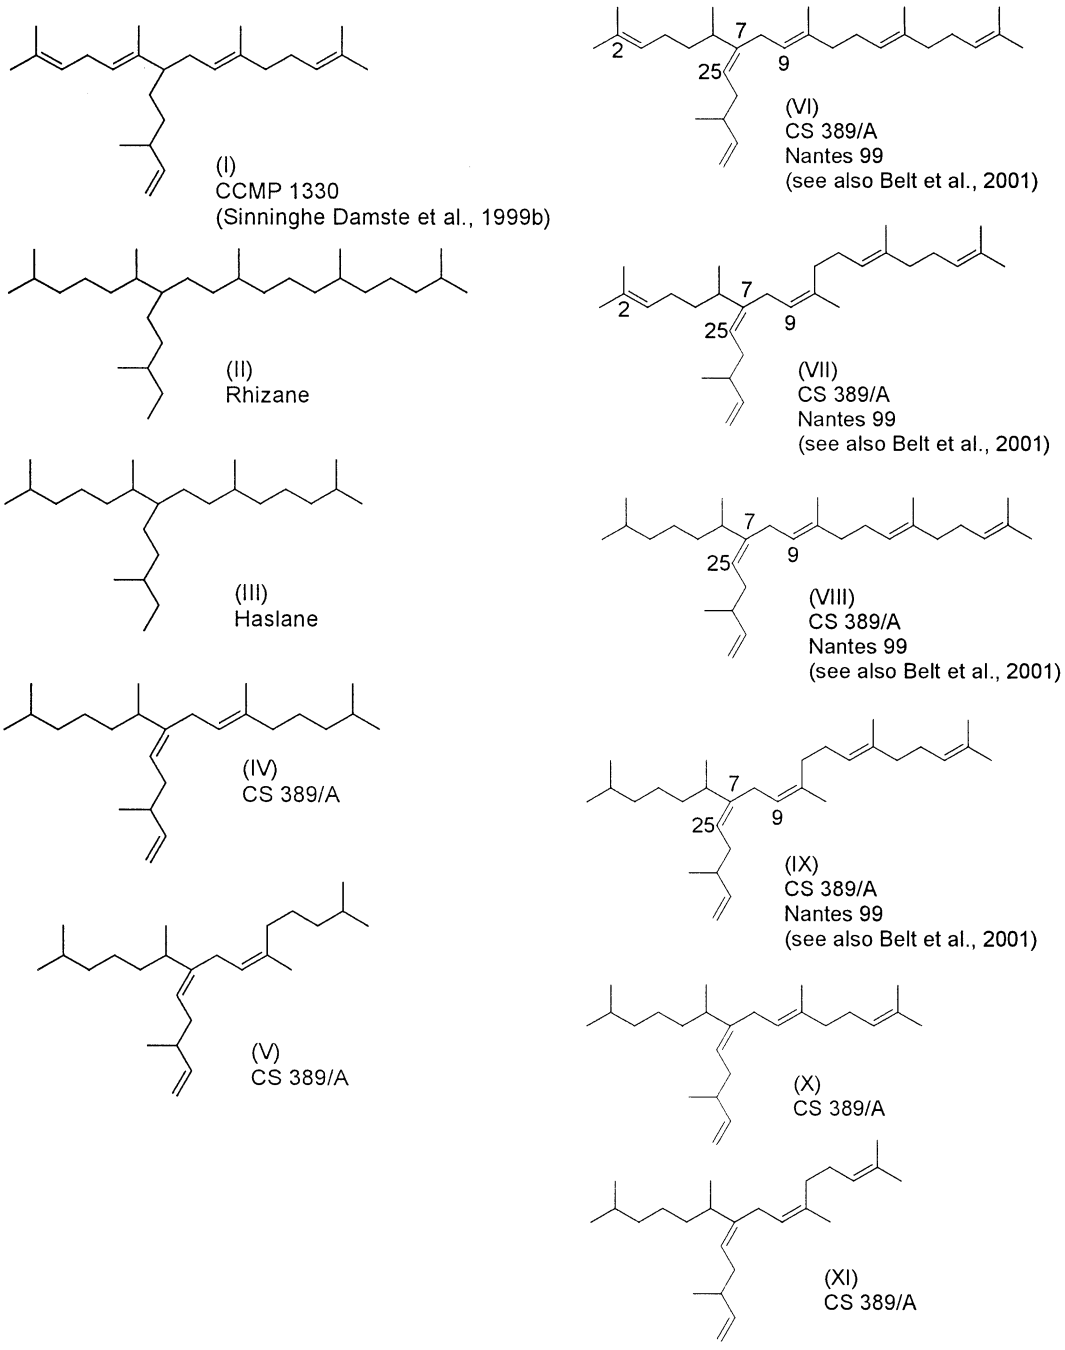
PII: S0031-9422(01)00318-1



Pleurosigma intermedium; Belt et al., 2000a), *R. setigera* is to date the only marine planktonic diatom known to produce either haslene or rhizene HBIs.

The haslenes in estuarine sediments appear to allow resolution of the contributions of the benthic species to the total diatom flux (Cooke et al., 1998) and some haslenes also appear to possess cytostatic effects against human lung cancer cells in vitro (Rowland et al., 2001). It would therefore be interesting to know whether the rhizenes are equally geochemically specific and/or bioactive. Here, we report the haslenes and rhizenes of five strains of *R. setigera* and investigate the effects of growth temperature and salinity on haslene and rhizene production in one strain. Furthermore, we have investigated the effects of these variables on the carbon isotopic composition of the haslenes and rhizenes in this strain. Such data may eventually help to allow the environmental distributions of HBIs in sediments and sedimenting particles to be understood.

2. Results and discussion

R. setigera (Brightwell) is a common diatom often found in the plankton of coastal and marine waters

(Round et al., 1990). The taxonomy of the genus is however, somewhat uncertain (Round et al., 1990; Volkman et al., 1994, and references therein) and has been revised by Sundström (1986) and also been subject to several other modifications, including the transfer of the only two freshwater *Rhizosolenia* species to a new genus *Urosolenia* (Round et al., 1990).

The HBIs of three strains of *R. setigera* have been reported previously (Volkman et al., 1994, 1998; Sinninghe Damsté et al., 1999a) and, in contrast to the production of haslenes only in the benthic diatom *H. ostrearia*, the HBIs of *R. setigera* varied from rhizenes characterised by GCMS and hydrogenation to the parent rhizane (**II**) in two Australian strains CS-62 and CS-389/1 grown at 20 and 18.5 °C and 70–80 μE m^{-2} s^{-1} white light and 28 psu salinity (Volkman et al., 1994, 1998), to haslapentaene (**I**) only, in strain CCMP1330 grown at 4, 12 and 20 °C in North Atlantic seawater (Sinninghe Damsté et al., 1999a). Since the distributions in the previous reports were rather different from one another, we decided to examine further the hydrocarbons of strain CCMP 1330 and four other strains of *R. setigera*.

2.1. *R. setigera CS strain 389/A*

2.1.1. *HBI identifications and partial structural characterisation of rhizenes*

A 10 l culture of *R. setigera* was grown from an inoculum obtained from the Huon estuary, Tasmania, Australia. The wet paste obtained after centrifugation was extracted by allowing it to stand in chloroform (24 h). This yielded 220 mg of total chloroform extractable lipids. Microscale hydrogenation (Adam's catalyst) of a small aliquot of the total lipids of a culture grown at 18 °C (35 psu salinity) produced rhizane (**II**) and haslane (**III**) as the only HBIs, identified by GCMS and GC retention indices compared to the synthetic alkanes (Robson and Rowland, 1986, 1988). A small amount of an unidentified C_{30} alkane (RI $2543_{HP\text{-}5}$) with two degrees of unsaturation (ca. 10% relative to **II**) was also present (cf Prahl et al., 1980).

The total chloroform extract was further fractionated by open column chromatography on silica and fractions containing respectively, two C_{25} trienes, three C_{30} pentaenes, and three C_{30} hexaenes (identified by GCMS) obtained by elution with successive volumes of pentane. GCMS, ^{1}H and ^{13}C NMR spectroscopy revealed that the C_{25} trienes were identical to those recently identified in *Pleurosigma intermedium* (Belt et al., 2000a) viz. hasla-7(20),9*E*/*Z*,23-trienes (**IV** and **V**). Both *E* (major) and *Z* isomers were present. These Δ7(20) haslenes are therefore different to those of *H. ostrearia* and indeed of *R. setigera* strain CCMP 1330 (Sinninghe Damsté et al., 1999a) which contained a Δ5 double bond (**I**).

The presence of inseparable mixtures of three C_{30} alkenes in each of the pentaene and hexaene fractions precluded full structural characterisations by NMR, but a number of features were nonetheless clear. Namely, the rhizenes all contained a vinyl moiety (Δ28)—present in all haslenes and rhizenes identified in diatoms thus far—a number of trisubstituted double bonds and, consistent with the presence of the haslatrienes (**IV** and **V**), Δ7(25) unsaturation (^{1}H NMR: δ 5.71, 1H, *ddd*, H-28; 4.9, 2H, *m*, H-29; ^{13}C NMR DEPT,COSY,COLOC; δ 144.6, C-28; 112, C-29;142, C-7). Full structural characterisation of four of the six alkenes (**VI**–**IX**) was possible upon isolation of two pairs of isomers from a further strain of *R. setigera,* Nantes 99 (vide infra; Belt et al., 2001).

Thus, this study has shown that *R. setigera* is able to biosynthesise simultaneously, haslenes *and* rhizenes, whereas previously only one or the other was reported, and that whilst *H. ostrearia* produces haslenes with Δ5 and Δ6(17) double bonds, *P. intermedium* and *R. setigera* apparently produce haslenes with Δ7(20) unsaturation. Interestingly, haslenes and rhizenes have been reported to co-occur in some marine sediments and the present findings raise the possibility that in such cases both may have derived from *R. setigera*.

2.1.2. *Effects of salinity and temperature on HBI distributions*

To investigate the controls on the concentrations and the apparent variability of haslene and rhizene distributions in *R. setigera,* small scale cultures of strain CS 389/A were grown at two salinities (18 °C; 15 and 35 psu) and three temperatures (10,18, 25 °C; 35 psu). Each culture was grown for three growth cycles then a single sample taken from each after the third growth cycle (i.e. four samples) before culturing and harvesting in triplicate after a fourth cycle (i.e. a further 12 samples). This multiple cycle culturing was designed to allow the algae to acclimate somewhat to each set of new culture conditions. Cell concentrations in the fourth growth cycle were monitored by a calibrated fluorescence method (days 0, 2, 4, 6, 7; Fig. 1) and by microscopy (days 0, 7: mean cell counts). Cells were harvested at day 7. Cultures were filtered and filters extracted with chloroform with ultrasonication after addition of *n*-docosane as internal standard for quantification by GCMS. Recovery of the internal standard was 137±17% ($n=12$). Extracts were also saponified, re-extracted into hexane and after silylation the non-saponifiable lipids were examined by GCMS and by GC-isotope ratio monitoring-MS (GC-irm-MS). The absolute concentrations of HBIs ranged from about 5 to 20 pg $cell^{-1}$. The cell concentrations in the day 7 samples were used to estimate these concentrations.

Cell growth was faster at 35 psu salinity than at 15 psu (Fig. 1) and at 35 psu total HBI production (mean 19.4±

0.6 pg cell^{-1}) was twice that at 15 psu (10.23±0.57 pg cell^{-1}; Fig. 2a). In contrast, haslene production was greatest at the lower salinity (Fig. 2b).

The ratio of rhizenes to haslenes was, however, much higher at 35 psu (Fig. 2c) due to the higher absolute concentrations of rhizenes. Whilst unsaturation in the *E,Z* Δ7(20) haslatrienes (**IV**, **V**) was unchanged by salinity (Fig. 3a and b)—as was also the case for the Δ6(17) triene in *H. ostrearia* (Wraige et al., 1998)—unsaturation within the rhizenes was changed and was higher at the lower salinity (Figs. 2d and 3a). Whether these variations can be attributed directly to the differences in salinity, or actually reflect the difference in growth rates, will require further investigation at further, intermediate, salinities.

At 35 psu salinity, *R. setigera* did not grow well after 4 days at 10 °C (Fig. 1) but at 18 and 25 °C growth was good to 7 days (Fig. 1). Variation of growth temperature from 10 to 18 to 25 °C produced a change in the total HBI production, which maximised at 18 °C (19.4± 0.6 pg cell^{-1}; Fig. 2e). [The mean value at 10 °C (Fig. 2e) should be treated as a maximum since the measurement was based on cell counts determined at 7 days where growth had decreased (Fig. 1).] Thus maximum HBI production in *R. setigera* occurred at 35 psu, 18 °C. This may reflect the conditions to which the strain had become best acclimated in culture previously.

Within the HBIs, maximum haslene production was observed at 25 °C, and there was a steady increase in haslene production with increasing temperature (Fig. 2f). In contrast, rhizene production maximised at 18 °C, leading to a maximum in the rhizene/haslene ratio at this temperature (Fig. 2g).

Unsaturation in the haslenes also varied with temperature; haslatrienes (**IV** and **V**) were accompanied by haslatetraenes (**X**, **XI**) at 25 °C (Fig. 4c). This variation of the degree of unsaturation in the haslenes of *R. setigera* with growth temperature in strain CS 389/A contrasts with the previous observation of the invariance in the single haslapentaene (**I**) produced by *R. setigera* strain CCMP 1330 with variation of temperature between 4 and 20 °C (Sinninghe Damste et al., 1999a). However, the degree of unsaturation in the two strains CCMP 1330 vs CS 389/A was quite different (viz. 5 vs 3 and 4 double bonds, respectively) and furthermore, haslenes in the CCMP 1330 strain had a Δ5 double bond whereas those of strain CS 389/A had 7(20) unsaturation. The variation of unsaturation with temperature in this strain is similar to, though less pronounced than, that observed in the Δ5 and Δ6(17) haslenes of *H. ostrearia* which varied from diene production at 5 °C to tetraene and pentaene production at 25 °C (Rowland et al., 2001). Isomerisation of the *E* to *Z* haslene isomers also increased with increasing temperature (Fig. 4).

Strain CS 389/A cultured herein, produced both the haslenes and rhizenes at all temperatures. In contrast, strain CS 389/1 cultured at 18.5 °C, produced only rhizenes (Volkman et al., 1994), suggesting that co-production of haslenes and rhizenes is not a general phenomenon even in *R. setigera* strains from the same

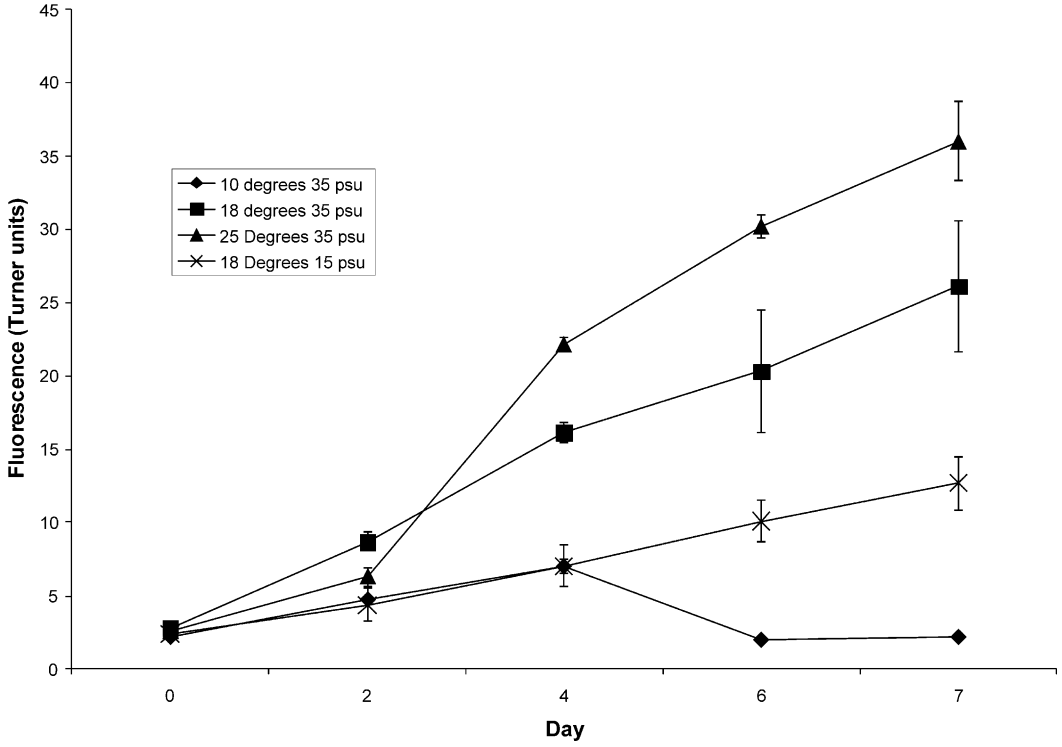


Fig. 1. Growth curves of *Rhizosolenia setigera* strain CS 389/A at 15 and 35 psu, 10, 18 and 25 °C ($n=3\pm1$ standard deviation).

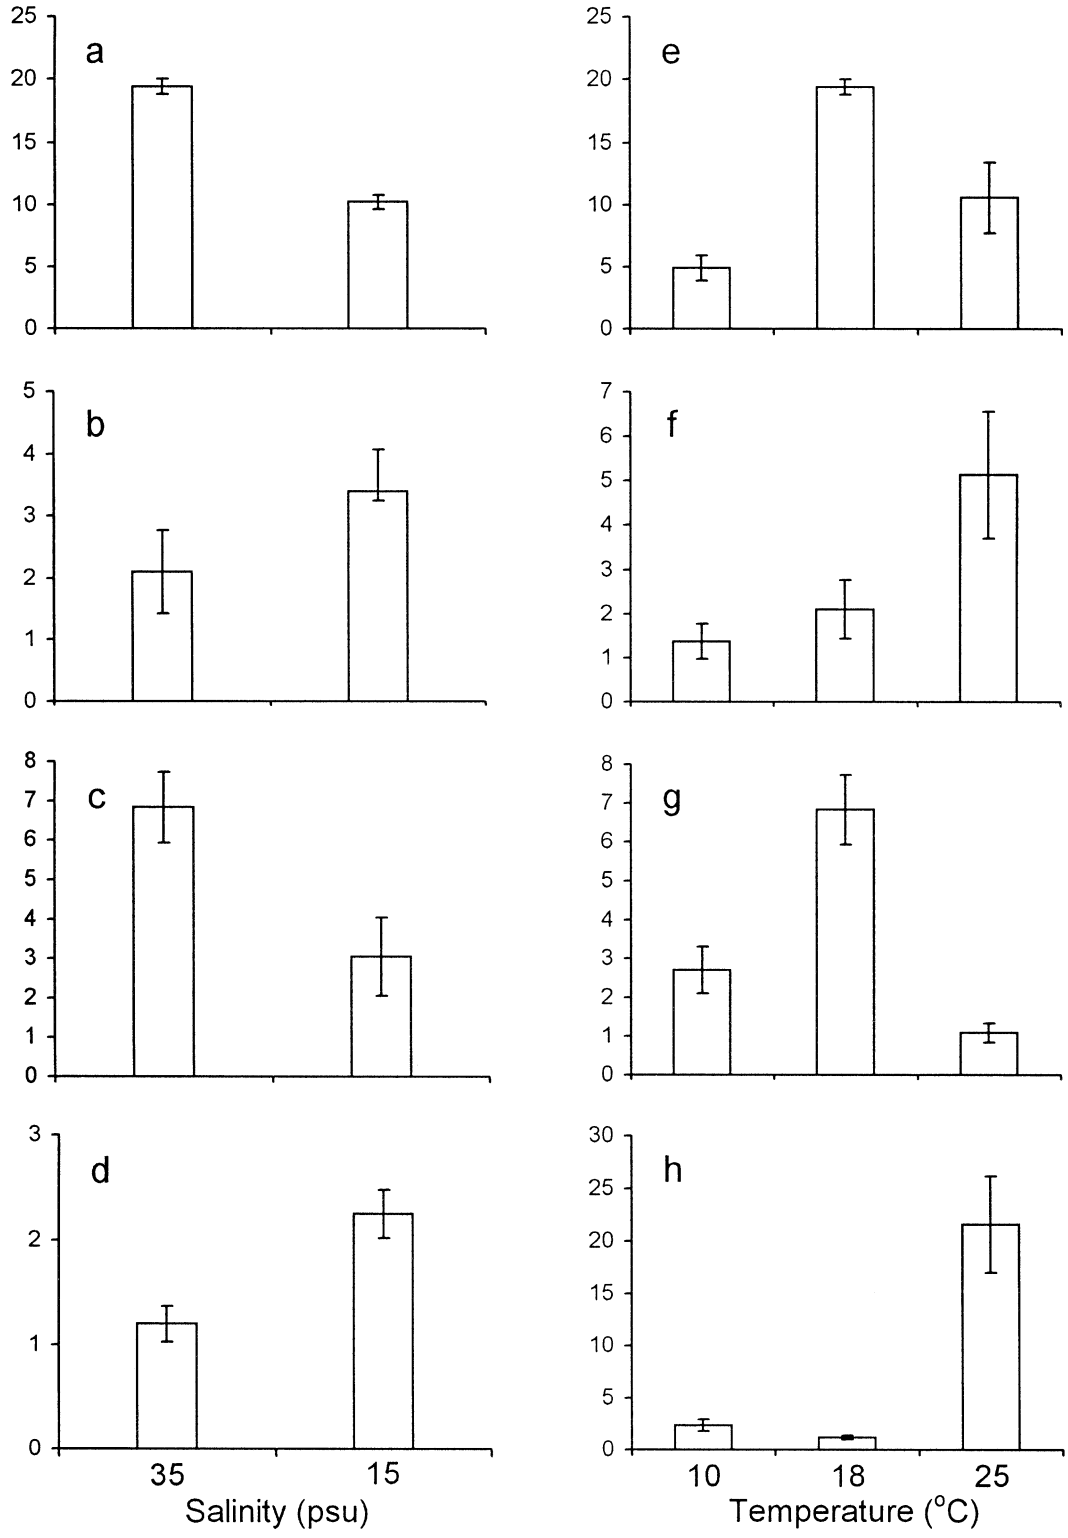

Fig. 2. Histograms illustrating variations of haslene and rhizene production (pg cell^{-1}) at different salinities and growth temperatures. Error bars indicate standard deviations of means of triplicate culturing experiments: a and e: total HBI concentrations; b and f: total haslene concentrations; c and g: rhizenes:haslenes ratio; d and h: rhizahexaenes:rhizapentaenes ratio.

general location. Nonetheless, 18 °C was the optimum temperature for rhizene production in strain CS 389/A (Fig. 2g). As with the haslene distributions, the degree of unsaturation in the rhizenes of strain CS 389/A changed reproducibly with temperature; the proportion of hexaenes to pentaenes increasing markedly with an

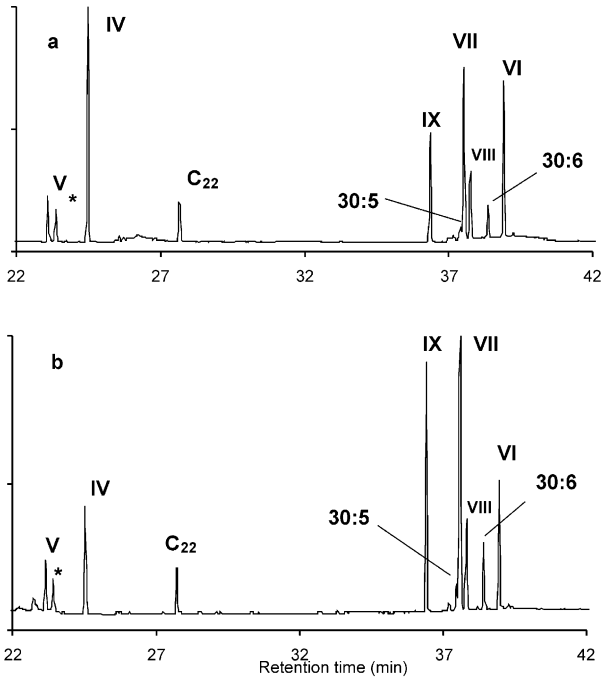

Fig. 3. GCMS total ion current chromatograms of total chloroform extracts of *Rhizosolenia setigera* strain CS 389/A at (a) 15 psu and (b) 35 psu salinity, 18 °C. Roman numerals refer to HBI structures shown in text. C_{22} = *n*-docosane internal standard. * = *n*-Henicosahexaene. 30:5, 30:6 = unknown C_{30} pentaene and hexaene, respectively.

increase in temperature from 18 to 25 °C (Figs. 2h and 4a–c). Again, this is somewhat similar to the change observed in the Δ5 and Δ6(17) haslenes of *H. ostrearia* (Rowland et al., 2001). However, opposite to the haslenes, Z to E isomerisation occurred in the rhizenes (Fig. 4).

2.1.3. Effects of temperature on the isotopic compositions of HBIs

The $^{13}C/^{12}C$ isotope ratios (in the δ notation relative to PDB standard) of phytol, haslene (**IV**), five of the six rhizenes and cholest-5, 24-dienol (Barrett et al., 1995) in *R. setigera* CS 389/A grown at 18 and 25 °C were measured by GC-irm-MS. Certified reference materials [*n*-hexadecane (*n*-C_{16}), *n*-icosane (*n*-C_{20}), *n*-tetracosane (*n*-C_{24}) and *n*-dotriacontane (*n*-C_{32})] each of known isotopic composition, were co-chromatographed with each sample during each GC-irm-MS analysis. The isotope value of the *Z*-haslatriene (**V**) could not be obtained due to insufficient GC resolution from *n*-henicosahexaene. The δ per mil value of each analyte was measured. Then, to allow for within-run instrument drift, differences between the measured and certified values of the nearest eluting *n*-alkane reference were added to the measured value of each analyte to give a range. The means and standard deviations for the ranges obtained in replicate experiments were then calculated and are shown as box and whisker diagrams in Figs. 5 and 6.

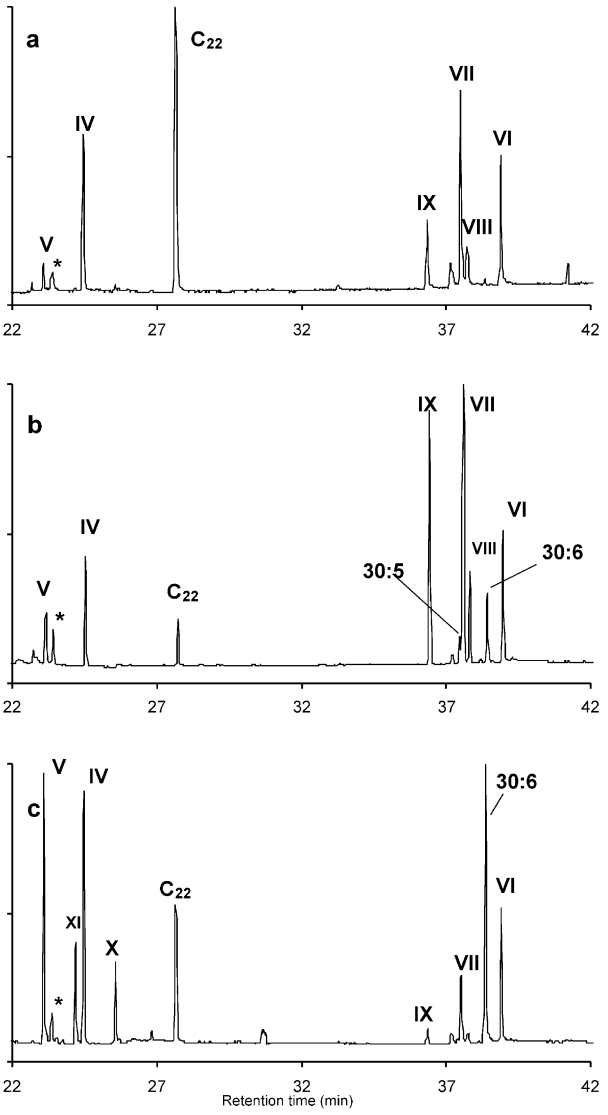

Fig. 4. GCMS total ion current chromatograms of total chloroform extracts of *Rhizosolenia setigera* strain CS 389/A at 35 psu salinity, (a) 10 (b) 18 and (c) 25 °C. Roman numerals refer to HBI structures shown in text. C_{22} = *n*-docosane internal standard. * = *n*-Henicosahexaene. 30:5, 30:6 = unknown C_{30} pentaene and hexaene, respectively.

Thus, any major differences in δ between the individual lipids which emerge are unlikely to be artefactual. The mean within-run variations from the certified values were: [($n = 10$) *n*-C_{20}, 0.4 ± 0.3 per mil; *n*-C_{24}, 0.3 ± 0.3 per mil; *n*-C_{32}, 0.4 ± 0.2 per mil].

At 18 °C, the *E*-haslatriene (**IV**) was about 3–4 per mil depleted in ^{13}C compared to phytol. This applied to both the algae cultured for three generations (Fig. 5a) and the final fourth generation samples (Fig. 5b). At 25 °C the result was the same (Fig. 5a). A previous study showed that haslapentaene (**I**) in *R. setigera* strain CCMP 1330 grown at 12 °C was 4.5 per mil depleted compared with phytol (Schouten et al., 1998). This is probably not significantly different from the 3–4 per mil determined in the present study.

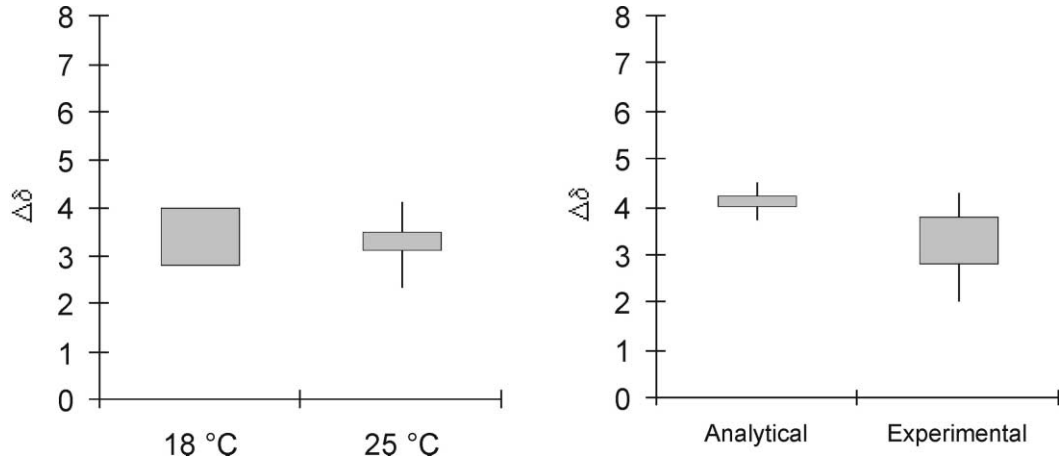

Fig. 5. Bar and whisker diagrams illustrating the influence of growth temperature on the Δδ ^{13}C isotope values of hasla −7(20), 9*E*,23-triene (**IV**) compared with phytol TMSi ether (isotopically corrected) in *Rhizosolenia setigera* CS 389/A. (a). Culture grown for three growth cycles at 18 and 25 °C. Analyses made in duplicate (18 °C) and triplicate (25 °C). (b). Culture grown for four growth cycles at 18 °C in triplicate. The results of triplicate analysis of a single sample ('Analytical') and full experimental triplicate ('Experimental') are shown. The data indicate a 3–4 per mil depletion in ^{13}C in **IV** compared with phytol.

The isotopic compositions of the haslene (Fig. 5) and cholest-5,24-dienol (desmosterol) in the present strain grown at 18 °C, were about equal (Fig. 6f), again as found previously (Schouten et al., 1998). Schouten et al. concluded from these similarities, that (**I**) was biosynthesised, like the sterol, in the cytosol of the diatom cell and not in the plastid. Our data support the contention that the haslene and the sterol in *R. setigera* CS 389/A were biosynthesised from a similar isotopic pool of isopentenyl diphosphate in the culture grown at 18 °C; perhaps in the cytosol.

At 25 °C, however, the Δδ values of the haslene (ca. 3–4 per mil; Fig. 5a) and the sterol (1–2 per mil; Fig. 6f) were somewhat different; certainly in the 4th generation samples for which the most comprehensive data set was obtained (Figs. 5a and 6f). In fact, the Δδ value of the sterol at both 18 and 25 °C, closely matched the value of the dominant alkene at each temperature (Fig. 6a, d, and f). Thus, at 18 °C, the dominant rhizenes were the *E*-pentaene (Figs. 4b and 6a; **IX**) and hexaene (Figs. 4b and 6c; **VII**) and the Δδ values of both these (and the *E*-haslatriene) and the sterol were about 3–4 per mil in the 3rd generation and in the 4th generation samples (Figs. 5a,b and 6a, c, and f). At 25 °C, the dominant alkene was an unknown hexaene (30:6 Figs. 4c and 6d), and whilst there was some spread in the data, the mean range of Δδ values of both this and the sterol were lower than those of the haslene (Fig. 5a) and the other rhizenes.

These data suggest that the biosynthesis of the dominant alkenes and sterol are coupled at both temperatures, probably from an isotopically similar pool of isopentenyl diphosphate.

Interestingly, the Δδ values of some of the individual alkenes varied quite considerably. Thus whilst the values for the C_{30} rhizapentaene (**VIII**; Fig. 6b) and rhizahexaenes (**VII**; Fig. 6c; **VI**; Fig. 6e) were similar to that of the haslenes (ca. 3–4 per mil) at both temperatures, these varied somewhat from those of the unknown hexaene 30:6 (Fig. 6d) . (Although there also appeared to be a difference in the Δδ values of the pentaene (**IX**; Fig. 5a) between 18 and 25 °C (Fig. 6a) this probably reflected the very low abundance of the pentaene at the higher temperature (0.15 ± 0.07 pg cell^{-1}; Fig. 4c), which made measurement much less accurate and prone to influences from co-eluting compounds such as bis(2-ethylhexyl)phthalate, a contaminant which was present in the procedural blank and had a similar retention index to the alkene).

Clearly, the isotope studies support our earlier conclusion that biosynthesis of the HBIs in *R. setigera* strain CS 389/A is complex. The following interpretations must therefore be viewed as speculative. Overall the isotopic measurements suggest:

1. Biosynthesis of phytol from an isotopically different pool of IPP to the haslenes, rhizenes and sterol at 18 °C, in the plastid, in agreement with a previous report for a Δ5 haslene in a different *R. setigera* strain.
2. Particularly close coupling of the biosynthesis of the major alkenes and the sterol at both temperatures, but some differences in isotopic fractionation of carbon even within the different C_{30} alkenes, especially between VI,VII and the unknown $C_{30:6}$ (Fig. 5c, d and e) at the highest growth temperature.

We propose, at both 18 and 25 °C, biosynthesis of phytol in the chloroplast from geranyl diphosphate probably via a non-mevalonate route from CO_2 as is true of phytol production in some other diatoms (Cvejic and Rohmer, 2000).

At 18 and 25 °C, we envisage biosynthesis of haslenes probably outwith the plastid, either via a mevalonate

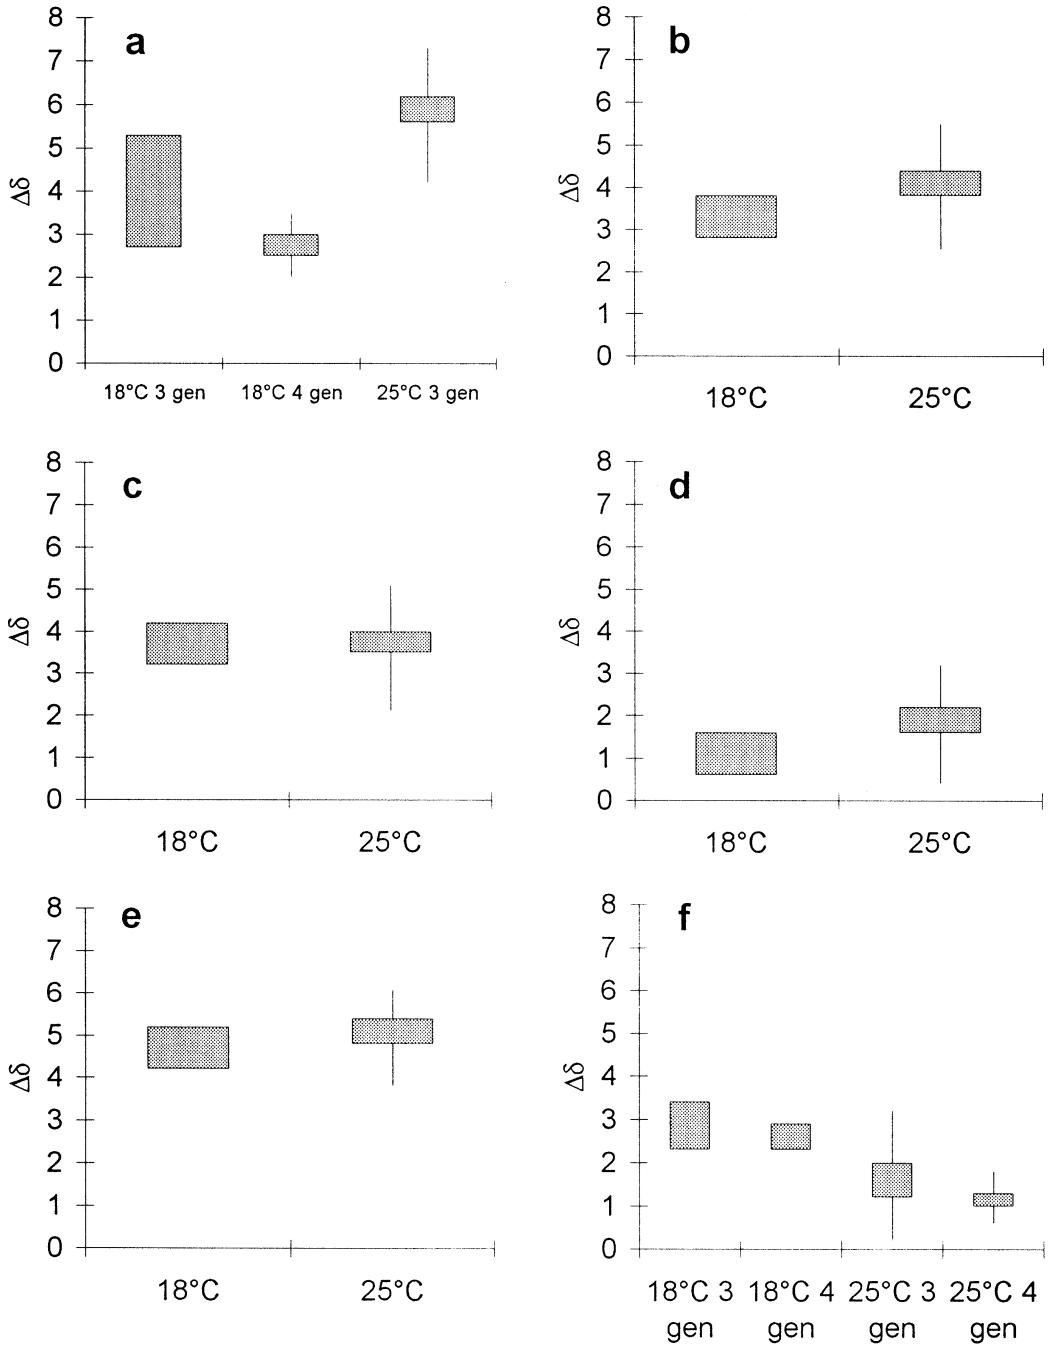

Fig. 6. Bar and whisker diagrams illustrating the influence of growth temperature on the $\Delta\delta$ ^{13}C isotope values of alkenes (**VII**–**IX**, Unknown 30:6) and cholesta-5,24,-dienol (TMSi ether, isotopically corrected) compared with phytol TMSi ether (isotopically corrected) for *Rhizosolenia setigera* CS 389/A cultures grown for three (3 gen) and four (4 gen) generations at 18 and 25 °C. (a) Rhizapentaene **IX**; (b) Rhizapentaene **VIII**; (c) Rhizahexaene **VII**; (d) unknown C_{30} hexaene 30:6; (e) Rhizahexaene **VI**; (f) cholest-5,24-dienol.

route leading to isotopic differences in the IPP compared with that used in phytol biosynthesis, or via a non-mevalonate route using an IPP pool which is isotopically distinct from that used in phytol production (cf. Cvejic and Rohmer, 2000). This might involve condensation of geranyl diphosphate (GPP) and a C_{15} isoprenyl moiety (possibly peruviyl diphosphate, PPP). The involvement of PPP rather than farnesyl diphosphate (FPP) might explain coupling to give the C-7 branched HBI structure, rather than coupling of GPP and FPP which would probably lead to a squalene-type structure.

Biosynthesis of many of the rhizenes at 18 and 25 °C (**VI**, **VII**, **VIII**, **IX**) might be from the same pool of IPP (and hence PPP) as that used for haslene biosynthesis at 18 and 25 °C, but biosynthesis of some C_{30} alkenes (e.g. unknown $C_{30:6}$)—and the sterol at 25 °C, must be from

a somewhat isotopically distinct IPP pool. Given the similarities in the isotopic values of the dominant alkenes and the sterol at both temperatures, we assume alkene synthesis from these IPP pools takes place out with the plastid, even though some terpene secondary metabolites are also believed to be produced in the chloroplast (e.g Cvejic and Rohmer, 2000, and references therein). Production in the cytoplasm is consistent with previous findings that diatoms are able to use different carbon sources in different cell compartments (Cvejic and Rohmer, 2000) and our unpublished findings which indicate that haslenes in *H. ostrearia* are not associated with the fatty acid storage lipids (which are found in the chloroplast).

Whilst more definitive studies of the biosynthetic pathways to the HBIs in *R. setigera* will also require growth of the diatom with isotopically enriched substrates, such as with $^{13}CO_2$ and also studies of the sites of ^{13}C incorporation by ^{13}C NMR, the GC-irm-MS approach used herein provided useful complementary information and did not require perturbation of algal growth with artificially high substrate concentrations or mixotrophic growth conditions. The results of our studies with isotopically enriched substrates will be published separately.

2.2. R. setigera strain CCMP 1330

When North Atlantic (off Massachusetts, USA), strain CCMP 1330 was cultured at 4–20 °C previously, it was shown to produce haslapentaene (**I**) as the only HBI, even when growth temperature was varied. (**I**) was also the only HBI produced when the same strain was cultured at 15 °C in the present study (Fig. 7a). The HBI was identified by comparison of GC and MS data with authenticated samples from *H. ostrearia* (Wraige et al., 1997) and an aliquot of the previous sample isolated from *R. setigera* (Sinninghe Damsté et al., 1999b). The *n*-alkenes reported previously were also present (Fig. 7a).

2.3. R. setigera strain CCMP 1820

The HBIs of this strain have not been reported previously but were found herein (Fig. 7b) to comprise haslapentaene (**I**) as the only HBI in a culture grown at 15 °C . Again, *n*-alkenes were also present (Fig. 7b).

2.4. R. setigera Nantes 1999 and Nantes 2000

Strains of *R. setigera* isolated from the North Atlantic (off southern Brittany, France) contained, like the Tasmanian strain CS 389/A, both haslenes and rhizenes (Fig. 7c and d) and similar to that strain, the haslenes included trienes (**IV** and **V**) with C7(20) unsaturation. The corresponding tetraene [viz. hasla-7(20),9*E*,13, 23-tetraene; **X**] and traces of the corresponding Δ2 pentaene (cf. Belt et al., 2000b) were also present in this strain grown at 15 °C. All compounds were identified by GCMS retention time and mass spectral comparison with previously authenticated compounds from *P. intermedium* (Belt et al., 2000a,b). The rhizenes present comprised two pentaenes and two hexaenes, both with C7(25) unsaturation (**VI**–**IX**) as determined by NMR for strain CS 389/A above. The relative proportions of HBIs, which were very similar in two samples, collected and cultured one year apart, are shown in Fig. 7c and d.

3. Experimental

3.1. Algal cultures

R. setigera strain CS 389/A isolated from the Huon estuary, Tasmania, Australia, was grown at 10, 18 or 25 °C, 35 psu, under white light at 80 μE m^{-2} s^{-1} in fE or fE/2-1 medium as described previously for other strains (Volkman et al., 1994, 1998). Both small scale (250 ml Erlenmeyer flasks) and larger scale samples (10 l, 18 °C) were cultured.

R. setigera strains isolated from France (Nantes 99 and Nantes 00) were isolated from Le Croisic, France and cultured in 4×60 l tanks containing underground saltwater enriched with $NaNO_3$ (8 mg ml^{-1}) and Guillard's medium (f/2, 0.2 ml l^{-1}) at 16–18°C and on the smaller scale at 15°C. Samples for hydrocarbon analysis were obtained by centrifugation. Strains CCMP 1330 and 1820 were purchased from the Guillard Collection USA and grown under the same conditions as the French strains above.

3.2. Lipid extraction and alkene isolation

Alkenes were isolated by extraction of the centrifuged algal paste with chloroform (strain CS 389/A) or hexane, aided by ultrasonication (45 min, Kerry Pulsatron HB172) followed by column chromatogaphy on silica and elution with hexane. Selected samples were saponified by heating (60 °C, 1 h) in methanolic KOH (e.g. Volkman et al., 1998) and derivatised with BSTFA/TMCS (60 °C, 30 min) prior to analyses by GC-MS and GC-irm-MS.

3.3. NMR spectroscopy

NMR spectroscopy was conducted on a JEOL EX 270 multinuclear (^1H, ^{13}C) 270 MHz spectrometer. Data were recorded on the delta scale (ppm) using the resonances of $CDCl_3$ (7.25 ppm ^1H, 77.0 ppm ^{13}C) as internal references.

3.4. Gas chromatography–mass spectrometry

Derivatised total chloroform extracts (Figs. 3 and 4), non-saponifiable lipids (Fig. 7) or alkene fractions (for

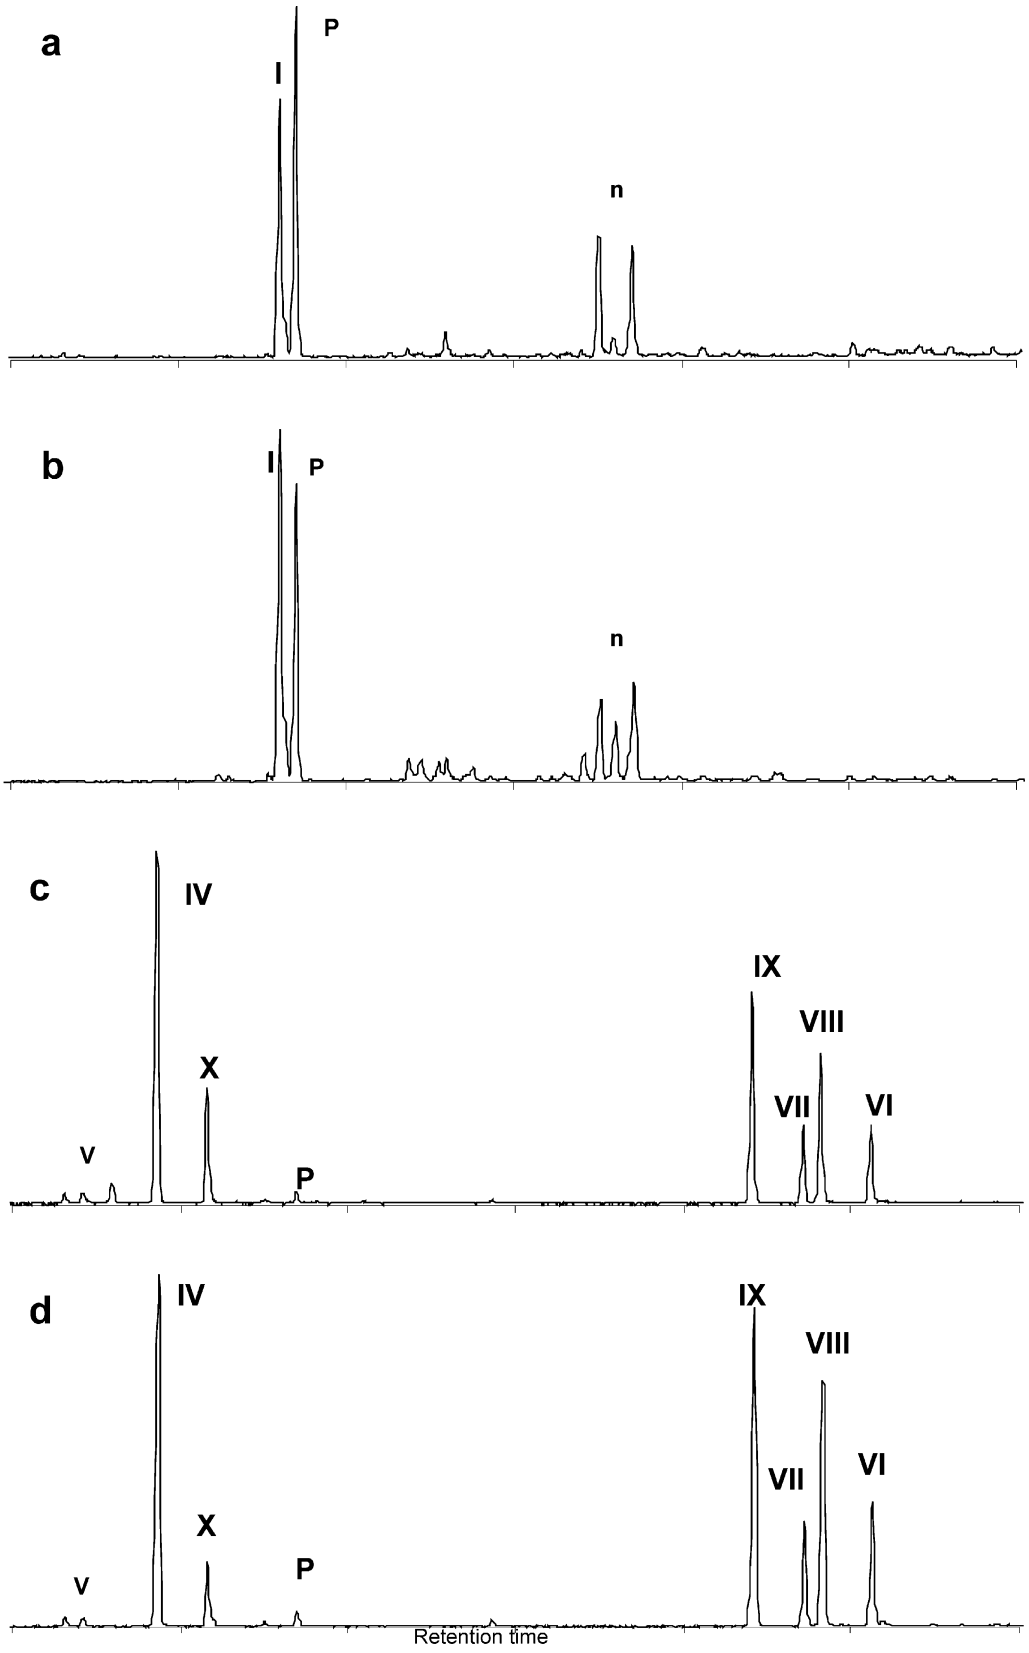

Fig. 7. GCMS total ion current chromatograms of non-saponifiable lipids (TMSi ethers) of *R. setigera* strains CCMP 1330, CCMP 1820, Nantes 99 and Nantes 00. P = phytol, TMSi ether; n = *n*-alkenes. Roman numerals refer to HBI structures shown. (a) *Rhizosolenia setigera* CCMP 1330; (b). *Rhizosolenia setigera* CCMP 1820; (c) *Rhizosolenia setigera* Nantes 1999; (d) *Rhizosolenia setigera* Nantes 2000.

NMR) from strain CS 389/A were examined by gas chromatography–mass spectrometry (GC-MS) performed using a Fisons Instruments MD800 equipped with a Carlo Erba on-column injector. The gas chromatograph was fitted with a 12 m (0.2 mm i.d.) fused silica capillary column (HP-5 Ultra stationary phase). Helium carrier gas was used. The gas chromatograph oven temperature was programmed from 40 to 300 °C at 5 °C min^{-1} and held at the final temperature for 10 min. Mass spectrometer operating conditions were; ion source temperature 250 °C and 70 eV ionisation energy. Spectra (40–650 Daltons) were collected using Fisons Masslab™ software. Alkene fractions from all other strains were examined by gas chromatography-mass spectrometry (GC-MS) performed using a Hewlett Packard 5890 series II gas chromatograph coupled to a Hewlett Packard 5970 mass selective detector fitted with a 12 m (0.2 mm i.d.) fused silica capillary column (HP-1 Ultra stationary phase). Auto-splitless injection and helium carrier gas were used. The gas chromatograph oven temperature was programmed from 40 to 300 °C at 5 °C min^{-1} and held at the final temperature for 10 min. Mass spectrometer operating conditions were; ion source temperature 250 °C and 70 eV ionisation energy. Spectra (35–500 Daltons) were collected using Hewlett Packard Chemstation™ software.

3.5. Gas chromatography–isotope ratio monitoring–mass spectrometry

GC-irm-MS was performed with a Finnigan Delta S mass spectrometer essentially as described previously (Merrit et al., 1995). GC conditions were: oven temperature 40–135 °C at 30 °C min^{-1}, 135–300 °C at 4 °C min^{-1}; 60 m DB-1, helium carrier gas. Isotopic values were determined by integration of the ion currents of m/z 44–46 produced by combustion of chromatographically separated compounds and comparison with CO_2 reference gas. Certified reference materials comprising *n*-hexadecane, *n*-icosane, *n*-tetracosane, *n*-dotriacontane and *n*-hexatriacontane of known isotopic composition were co-chromatographed with the algal lipids derivatised with BSTFA/TMCS. Determinations of the haslene were made in full procedural triplicate, including culturing conditions and in analytical triplicate (Fig. 5b). To correct for the isotopic effect of the derivatisation of phytol and cholest-5,24-dienol with BSTFA/TMCS, both free phytol (Aldrich, 97% mixture of *E* and *Z* isomers; *E*-phytol, −28.02 per mil delta notation relative to PDB standard) and a sample of phytol derivatised with each batch of BSTFA/TMCS were examined by GC-irm-MS. The difference in values was used to calculate the isotopic composition of the TMS group using a published method (Jones et al., 1991).

Acknowledgements

We thank the British Council in Australia and the Royal Society of London for travel awards (S.J.R.) and the British Council for ALLIANCE travel awards (S.T.B., J.-M.R.). We are grateful to Dr. J. Sinninghe Damsté (NIOZ, The Netherlands) for a sample of pentaene (I) isolated previously from *R. setigera* CCMP 1330 (Sinninghe Damsté et al., 1999a,b).

Herbivore-induced allene oxide synthase transcripts and jasmonic acid in *Nicotiana attenuata*

Jörg Ziegler[1], Markku Keinänen[2], Ian T. Baldwin*

Department of Molecular Ecology, Max-Planck Institute for Chemical Ecology, Carl-Zeiss-Promenade 10, D-07745 Jena, Germany

Received 9 May 2001; received in revised form 8 June 2001

Abstract

Exogenous jasmonate treatment of *Nicotiana attenuata* Torr. ex Wats. plants elicits durable resistance against herbivores and attack from its specialist herbivore, *Manduca sexta,* results in an amplification of the transient wound-induced increase in endogenous jasmonic acid levels (JA). To understand whether this ''JA burst'' is under transcriptional control, we cloned allene oxide synthase (AOS; EC 4.2.1.92), the enzyme that catalyzes the dehydration of 13(*S*)-hydroperoxy octadecatrienoic acid to an allene oxide, the first specific reaction in JA biosynthesis. An AOS cDNA coding for a 520 aa protein (58.6 kDa) with an isoelectric point of 8.74 was overexpressed in bacteria and determined to be a functional AOS. Southern blot analysis indicated the presence of more than one gene and AOS transcripts were detected in all organs, with the highest levels in stems, stem leaves and flowers. Attack by *M. sexta* larvae resulted in a sustained JA burst producing an endogenous JA amount 9-fold above control levels and 3-fold above maximum wound-induced levels, a response which could be mimicked by the addition of *Manduca* oral secretion and regurgitant to puncture wounds. *M. sexta* attack, wounding and regurgitant treatment transiently increased AOS transcript in the wounded leaf, but increases were not proportional to the JA response. Moreover, transcript accumulation lagged behind JA accumulation. Systemic wound-induced increases in AOS transcript, AOS activity or JA accumulation could not be detected. We conclude that increase in AOS transcript does not contribute to the initial increase in endogenous JA, but may contribute to sustaining the JA burst. © 2001 Elsevier Science Ltd. 1. Introduction

Research into the molecular basis of herbivore resistance (Korth and Dixon, 1997; Reymond et al., 2000; Hermsmeier et al., 2001) has revealed that a plant's wound response is involved and that the octadecanoid pathway plays a central role in resistance in three plant–insect systems (Howe et al., 1996; McConn et al., 1997; Baldwin, 1998). This is not surprising given that herbivores force their way past their host plant's protective barriers and cause wounding when they feed. It is, however, now clear that plants respond differentially to mechanical damage as compared to damage caused by herbivores (Baldwin, 1990; Korth and Dixon, 1997; Reymond et al., 2000; Schittko et al., 2001). How herbivore feeding modifies a plant's wound responses has been studied in the model plant-herbivore system: *Nicotiana attenuata–Manduca sexta*.

In *Nicotiana* species, both herbivory and mechanical wounding of leaves leads to a strong accumulation in nicotine biosynthesis that can result in amounts lethal to many herbivores (Baldwin et al., 1994a; Baldwin, 1999). After wounding, a signal is transported from the leaves to the roots where putrescine methyltransferase transcript is induced followed by nicotine synthesis (Winz and Baldwin, 2001) and the newly synthesized nicotine is translocated back to the leaves (Baldwin, 1989). Additionally, a suite of growth and defense related genes show an altered expression (Hermsmeier et al., 2001). These responses can be mimicked by the application of jasmonates to leaves or roots (Baldwin et al., 1996; Winz and Baldwin, 2001) and the wound response is strictly dependent on the plant's ability to increase endogenous

jasmonic acid (JA) levels (Baldwin et al., 1997). The strong positive relationships between the amount of wounding, the amount of JA and the strength of the responses are disrupted, however, when *M. sexta* larvae cause the damage (Baldwin et al., 1997; Schittko et al., 2001; Winz and Baldwin, 2001). After larval attack, a further elevation in the transient, wound-induced increase in JA can be accompanied by a suppression as well as an elevation of wound-induced responses (McCloud and Baldwin, 1997; Kahl et al., 2000; Schittko et al., 2000). These effects can also be elicited by placing minute amounts of oral secretion and regurgitant, consisting of a suite of fatty acid–amino acid conjugates, into puncture wounds on a leaf (McCloud and Baldwin, 1997; Schittko et al., 2000; Halitschke et al., 2001). The differential correlation between wound- and larval- induced responses and JA accumulation led us to consider the regulation of jasmonate biosynthesis in *N. attenuata*.

Allene oxide synthase (AOS) catalyzes the first step after the branch point 13(*S*)-hydroperoxy 9(*Z*)11(*E*)15(*Z*) octadecatrienoic acid (13(*S*)-HPOT) in the oxylipin pathway that leads to jasmonate biosynthesis (Hamberg and Gardner, 1992). This pathway starts with the lipoxygenase (LOX)-catalyzed insertion of molecular oxygen into position 9 or 13 of linolenic or linoleic acid, resulting in fatty acid hydroperoxides which can serve as substrates for several enzymes such as divinylether synthase, peroxygenase or hydroperoxide lyase. Only the dehydration of one specific linolenic acid hydroperoxide, 13(*S*)-HPOT, by AOS forms the intermediate allene oxide for JA biosynthesis (Fig. 1). This allene oxide is highly unstable and is either chemically hydrolyzed to α- and γ-ketol and racemic 12-oxo-phytodienoic acid (PDA) or is cyclized by allene oxide cyclase to enantiomeric PDA, which subsequently undergoes reduction and β-oxidation to yield JA.

AOS was first purified and the cDNA cloned from flax (*Linum usitatissimum* L.). It was shown to be a cytochrome P450-dependent oxidase of the CYP74A family (Chapple, 1998; Song and Brash, 1991; Song et al., 1993). The expression of the AOS gene has been strongly correlated with increased JA contents in many study systems. Tissues with high JA levels have high levels of AOS transcripts (Maucher et al., 2000). Treatments known to lead to increased JA levels, such as wounding or treatment with sorbitol or glucose, also increase AOS transcript levels (Harms et al., 1998; Laudert et al., 1998; Howe et al., 2000; Maucher et al., 2000; Sivasankar et al., 2000) or lead to high AOS promoter activity (Kubigsteltig et al., 1999). These results suggest an important regulatory role for AOS in the biosynthesis of JA and led us to examine the correlation between AOS transcript accumulation and JA accumulation in *N. attenuata*. We report herein the cloning[1], characterization and expression patterns of AOS after mechanical wounding, regurgitant treatment, and feeding by *M. sexta* larvae.

2. Results and discussion

2.1. Cloning and characterization of Nicotiana attenuata AOS

A cDNA library prepared from *N. attenuata* shoots subjected to larval feeding for 24 h was screened with the *Arabidopsis thaliana* AOS cDNA (Laudert et al., 1996). One clone of 1649 bp with strong sequence homology to other AOS cDNAs was obtained, but this clone did not encompass the whole coding region as indicated by the absence of a start codon. The missing upstream sequence was, therefore, generated by 5'RACE using mRNA isolated from leaves treated with MeJA. The full length sequence of 1761 bp contained an open reading frame of 1560 bp coding for a protein with 520 amino acids with a calculated molecular mass of 58.6 kDa and an isoelectric point of 8.74. On the protein level, the NaAOS was 79.4 and 71.3%, identical to both tomato AOS's (Sivasankar et al., 2000; Howe et al., 2000; accession numbers AJ271093, AF230371), 62.8% to the guayule AOS (Pan et al., 1995; X78166), 61.7% to the

[1] The cDNA sequence reported herein has been deposited in the GenBank database under the GenBank Accession Number AJ295274.

flax AOS (Song et al., 1993; U00428) and 60.3% to the *Arabidopsis* AOS (Laudert et al., 1996; X92510), but only 53.6% to the two AOSs of barley (Maucher et al., 2000; AJ250864, AJ251304). The heme binding consensus sequence P-V-NKQCAG of the CYP74A family of enzymes as well as the -G-KIL conserved motif, which is a CYP74-specific variation of the I helix forming the oxygen binding pocket in P450 enzymes (Brash and Song, 1995; von Wachenfeldt and Johnson, 1995) are largely preserved in the *N. attenuata* sequence (Fig. 2), but their contribution to AOS catalysis is yet unknown. It will be interesting to establish the importance of both motifs and their species-specific variations on the catalytic properties of AOS, especially considering that an allene oxide forming enzyme from corals exists that is not a member of the cytochrome P450-dependent enzymes but rather an enzyme with catalase-like properties (Koljak et al., 1997).

With the exception of guayule (*Parthenium argentatum*), where AOS represents the major protein in rubber particles and where the function is unknown (Pan et al., 1995), all AOS's implicated in JA biosynthesis have associated with chloroplasts. Arguments for this have either been the presence of an N-terminal chloroplast transit peptide on the protein (von Heijne et al., 1989; Song et al., 1993; Laudert et al., 1996; Howe et al., 2000; Sivasankar et al., 2000) or biochemical and immunocytological detection (Harms et al., 1995; Blée and Joyard, 1996; Maucher et al., 2000; Froehlich et al., 2001). The 5′ end of the NaAOS also codes for a chloroplast signal peptide as determined by the enrichment of hydroxylated amino acid residues (10% T and 18% S within the first 49 residues), the presence of an A at position 2, and the absence of charged amino acids at the N-terminal 20 amino acids (Fig. 2). Computer analysis of the first 100 amino acids using the Chlorop V1.1 program (http://www.cbs.dtu.dk/services/ChloroP/) also predicted a chloroplastidial localization with a putative cleavage site between positions 44 and 45. This indicates that the NaAOS probably also resides within the chloroplasts.

A truncated clone from the cDNA library screen that lacks 13 N-terminal residues was cloned in the expression vector pQE31 and transformed into *Escherichia coli* SG13009 host cells. Measurements of the decrease in absorbance at 235 nm revealed that bacteria harboring the vector including the insert showed a 13(*S*)-HPOT decomposing activity of 5.1 nkat/mg of protein, which was absent either in uninduced bacteria or bacteria transformed with the vector lacking the insert. GC–MS analysis of the reaction products showed the presence of two peaks with mass spectra identical to α-ketol and PDA, indicating that the recombinant *N. attenuata* protein is able to catalyze the AOS reaction.

2.2. Genomic organizsation and tissue specificity

Southern blot analysis of genomic DNA digested with endonuclease *EcoRI* or *EcoRV*, for which there are no recognition site within the *aos* reading frame, revealed in both cases a very strong, broad hybridizing band, which might be composed of two closely migrating

Fig. 2. A, N-terminal sequence of *N. attenuata* AOS; underlined: sequence obtained by 5′RACE; double underlined: putative chloroplast transit peptide cleavage site as predicted by the Chlorop V1.1 program (http://www.cbs.dtu.dk/services/ChloroP/). B, comparison of the heme binding domain and the oxygen binding I-helix of all AOS cloned thus far. N.a., *Nicotiana attenuata*; L.u., *Linum usitatissimum* (accession number: U00428); P.a., *Parthenium argentatum* (X78166), A.t., *Arabidopsis thaliana* (X92510); H.v. *Hordeum vulgare* (AJ250864 and AJ251304 for 1 and 2, respectively); L.e. *Lycopersicon esculentum* (AJ271093 and AF230371 for 1 and 2, respectively).

fragments (Fig. 3). Restriction with endonuclease *HindIII* or *XbaI*, for which one recognition site is present within the *aos* reading frame, gave a more complex banding pattern, suggesting the existence of at least two genes coding for AOS in the *N. attenuata* genome. The expression level of AOS transcript was almost undetectable in roots and rosette leaves, but was clearly visible in stem leaves and flowers (Fig. 4). Consistent with the AOS promoter activity in *Arabidopsis* (Kubigsteltig et al., 1999) and the AOS transcript level in *Lycopersicon esculentum* (Howe et al., 2000), *N. attenuata* AOS was highly expressed in stems.

2.3. AOS mRNA, activity and JA levels after M. sexta attack, wounding, regurgitant and MeJA treatment

Leaf damage could be observed within minutes after *M. sexta* larvae had been placed on the leaf and within 1 h of feeding, JA levels were significantly elevated and continued to increase up to 6 h, followed by a plateau until 12 h with amounts up to 1.8 μg/g fr., an approximate 9-fold increase above unwounded levels and a 3-fold increase above maximum wound-induced levels (Fig. 5A). As judged by the leaf damage, the larvae slowed down feeding after 12 to 14 h and JA levels strongly decreased until even uninduced levels at 18 h are attained.

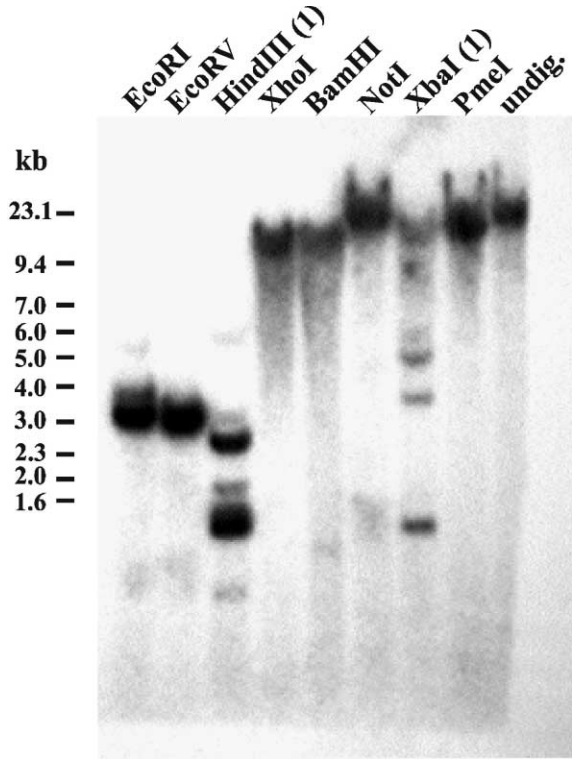

Fig. 3. Southern blot analysis of *Nicotonia attenuata* AOS. Genomic DNA was digested with the indicated restriction endonucleases. Numbers in parenthesis refer to the number of restriction endonucleases recognition within the cDNA used for hybridization. Undig., undigested genomic DNA.

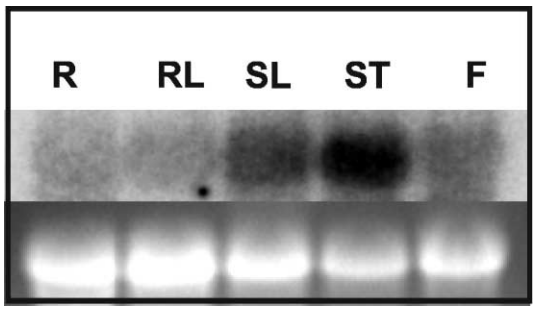

Fig. 4. Tissue specific expression of *Nicotonia attenuata* AOS. R, roots; RL, rosette leaves; SL, stem leaves; ST, stems; F, flowers. Ethidium bromide stain of 28S rRNA serves as loading control.

JA levels increased again when larvae started to feed again during the next light phase. The strong association of JA induction with feeding activity was observed in all three replicates and was found to be independent of light conditions. Concomitant with the increase in JA values, AOS transcript started to accumulate after 1 h and remained elevated for the entire time period, although at a lower level during the last 12 h (Fig. 5B). Quantification of the AOS transcript level and regression against leaf JA contents showed no significant correlation ($r^2 = 0.143$; $t_{slope} = 1.634$; $P = 0.122$). Increases in AOS transcript or JA levels in the systemic leaves were not observed.

Measurements of the metabolism of 13(*S*)-HPOT in crude extracts, which includes several enzyme activities in addition to AOS, revealed no significant change throughout the feeding experiment (data not shown). An enzyme assay with ^{14}C-labeled substrate failed to identify any AOS-specific reaction products. Instead, only substances co-migrating on reversed-phase HPLC with those observed after incubation of the substrate with recombinant hydroperoxide lyase could be detected (M. Keinänen, J. Ziegler and I.T. Baldwin, unpublished data). AOS enzyme activity could be recovered from many plant species as well as in preparations from the bacterial-expressed *N. attenuata* AOS. The same extraction method and co-incubation with plant extracts did not change the activity of recombinant AOS. Active AOS enzyme is, therefore, likely present in leaf extracts but at a very low level, that could be masked by strong hydroperoxide lyase activity. Although the constant hydroperoxide decomposing activity observed throughout the experiment may have resulted from changes in relative contributions of enzymes to this reaction, we did not observe changes in the profiles of the reaction products, which suggests that no significant changes occurred in AOS activity.

To control the onset and duration of wounding more precisely, *Nicotiana* plants were wounded with a fabric pattern wheel and either water or regurgitant was immediately applied to these wounds. A sharp JA burst starting already after 5 min that reaches a maximum at 45 min was observed, after which the JA level returned

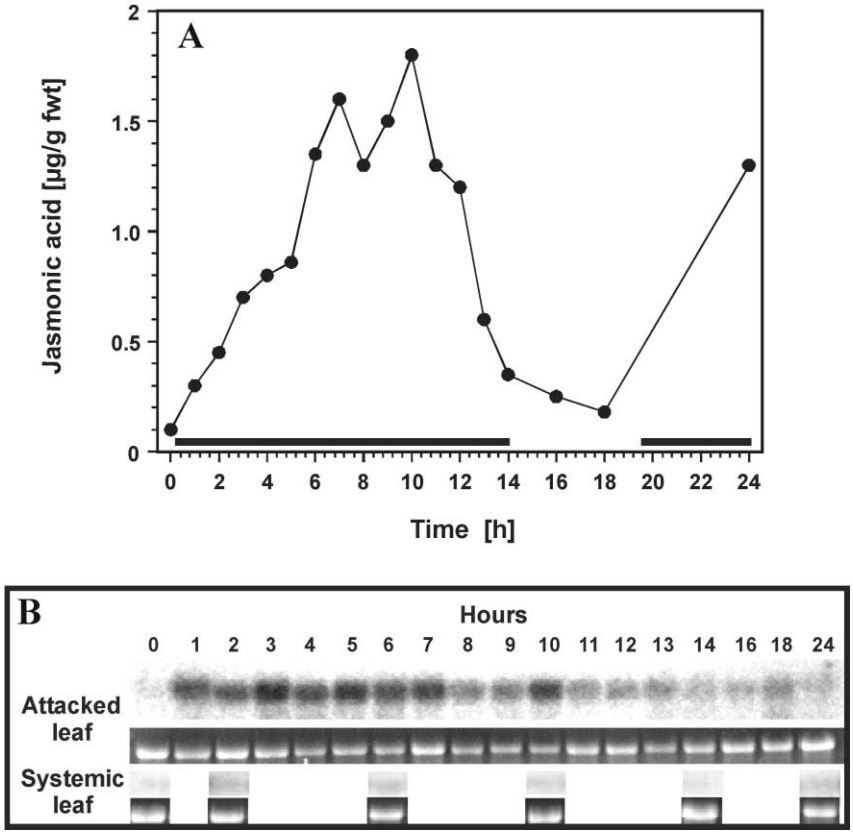

Fig. 5. Jasmonic acid levels (A) and AOS transcript accumulation (B) in attacked and adjacent, unattacked (systemic) leaves. Three first instar *Manduca sexta* larvae were placed on a mature leaf and allowed to feed for the times indicated. An individual plant was harvested at each time point and JA and northern analyses were performed on the attacked leaf tissue, while only northern analysis was performed on the unattacked leaf tissue because JA levels are known not to increase in adjacent unattacked leaves after *Manduca sexta* attack (Baldwin et al., 1997). The black bar in A denotes the time when larvae were actively feeding. Ethidium bromide stained 28S rRNA is shown as loading control.

to and remained at the basal level throughout the time course (Fig. 6A; Kahl et al., 2000; Schittko et al., 2000). Such a burst of JA also occurred during the wound response in *Macaranga tanarius* (Heil et al., 2001), but in tomato, *Arabidopsis* and *Nicotiana tabacum*, the wound-induced increase in JA persists for several hours after the initial increase or is biphasic (Laudert et al., 1996, 2000; Laudert and Weiler, 1998; Reymond et al., 2000). Although one can not exclude species specific variations, the differences in the JA response might be explained by the different types of mechanical wounding, since long lasting JA accumulations were induced by wounding larger leaf areas with a hemostat, whereas the JA bursts were induced by punching small wholes into the leaves, either with a needle or with a fabric pattern wheel.

The application of oral secretion and regurgitant from larvae reared on *N. attenuata* leaves to the puncture wounds amplified the wound-induced JA response approximately 2-fold (Fig. 6A; Kahl et al., 2000; Schittko et al., 2000). Elevated levels of AOS transcript were observed in *N. attenuata* for 3 to 4 h after wounding and were clearly preceded by the rapid increase in JA (Fig. 6B). This differs from flax, tomato and *Arabidopsis*, where AOS transcript remains elevated for more than 10 h (Harms et al., 1998; Howe et al., 2000; Sivasankar et al., 2000) or has been shown to be biphasic with a depression at 2 h (Laudert et al., 1996; Laudert and Weiler, 1998, but see Reymond et al., 2000) and where the induction of AOS gene expression accompanied or preceded JA accumulation.

Interestingly, while regurgitant treatment doubled the JA response, significant differences in neither the magnitude nor the kinetics of AOS transcript accumulation in the two treatments were detected (t_{13}s < 0.5; Ps > 0.62; Fig. 6B). In addition, the changes in AOS transcript accumulation after caterpillar attack (Fig. 5B) are not dramatically different from those resulting from mechanical wounds (Fig. 6B), despite the 9-fold differences in the amount of JA (Figs. 5A and 6A). Comparison of transcript accumulations between blots should, however, be interpreted with caution.

A second wounding event between 1–4 h after the first elicited a new burst of JA accumulation that was comparable in magnitude and timing to the first JA burst (Fig. 7A). Even an additional wounding event after 1 h, at a time when the JA content had started to decrease, led to second increase in JA, albeit slightly attenuated. This suggests a rapidly-regulated mechanism of JA generation

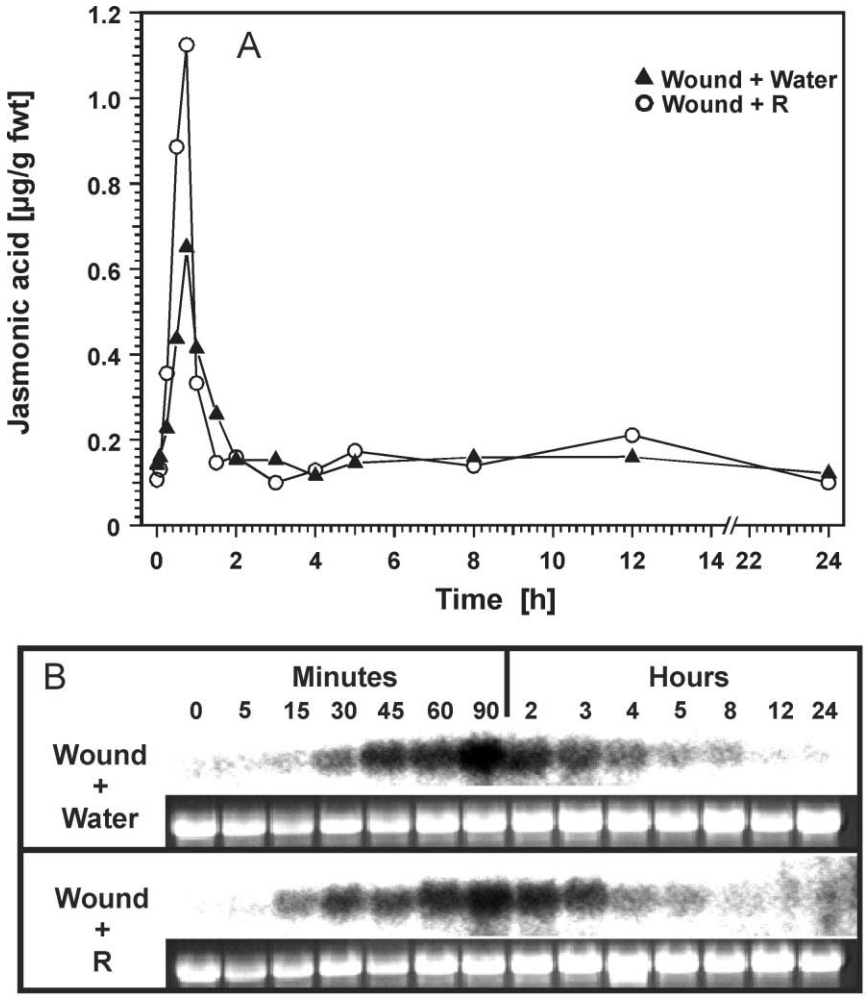

Fig. 6. Jasmonic acid levels (A) and AOS transcript accumulation (B) after wounding and water treatment or treatment with oral secretion and regurgitant (R) from *Manduca sexta* larvae. Leaves were wounded once at time zero using a fabric pattern wheel. Treated leaves from separate plants were harvested at the times indicated. Regurgitant was collected from 4th to 5th instar *Manduca sexta* larvae, diluted 1:5 with water and applied immediately after leaves were wounded. Ethidium bromide visualized 28S rRNA serves as loading control.

and degradation. If transcriptionally regulated de novo synthesis and degradation of AOS were responsible for these rapid changes, comparably rapid changes in transcripts should also occur. But the accumulation of AOS transcript after two wounding events (Fig. 7B) was not substantially different from those observed after a single wounding event (Fig. 6B). The higher basal AOS transcript level in this experiment was occasionally observed and was depending on the age and the growth of the plants.

There was only a tendency for a sustained increase the longer the second wound event was delayed (Fig 7B). The data on the kinetics and correlation of JA accumulation, AOS transcript and enzyme activity after a single wounding event raises the question whether the induction of JA in *N. attenuata* is caused by transcriptional activation of AOS. Although one cannot exclude that in *N. attenuata* other biosynthetic enzymes show an induction pattern on the transcriptional level concomitant with the JA levels, comparison with other systems suggest that neither transcripts of AOS (Fig. 5B; Laudert et al., 1996; Harms et al., 1998; Laudert and Weiler, 1998; Howe et al., 2000; Sivasankar et al., 2000), LOX (Bell et al., 1993; Heitz et al., 1997), 12-oxo-phytodienoic acid reductase (Costa et al., 2000) and allene oxide cyclase (Ziegler et al., 2000) nor their respective protein or enzyme activities change as rapidly as observed in wound-induced JA levels. Thus, other mechanisms other than transcriptional activation of JA biosynthetic genes are likely to account for wound-induced JA accumulation.

One possible explanation is post-translational activation. Although there is no report on post-translational activation of JA biosynthetic enzymes, the observation that tobacco plants compromised in the expression of a wound-inducible protein kinase (Seo et al., 1995) failed to accumulate JA after wounding as well as that the incubation of barley leaves with ursolic acid, a selective inhibitor of cyclic AMP-dependent protein kinases (Wasternack at al., 1994; Wang and Polya, 1996) failed to accumulate JA after sorbitol stress, indicates that

protein phosphorylation/dephosphorylation might play a role in the regulation of JA accumulation. In animal systems, for example, phosphorylation activates a phospholipase A2, which leads to the release of arachidonic acid needed for the biosynthesis of prostaglandins and leukotrienes. Whether a similar scenario also occurs in plant cells remains to be established, although free linolenic acid content after wounding (Conconi et al., 1996) and sorbitol stress increases simultaneously with the JA level. This suggests that substrate availability may have a role in the regulation of JA biosynthesis.

Although there are at least two lipoxygenase isoforms in *Arabidopsis*, co-suppression of only one specific chloroplast lipoxygenase gene resulted in the inability to induce JA biosynthesis (Bell et al., 1995). In contrast to this, antisense mediated depletion of one of two 13(*S*)-HPOT specific, wound-inducible lipoxygenase genes in potato did not affect JA levels, but reduced downstream events such as the induction of proteinase inhibitors (Royo et al., 1999). Thus, apart from enzymatic properties

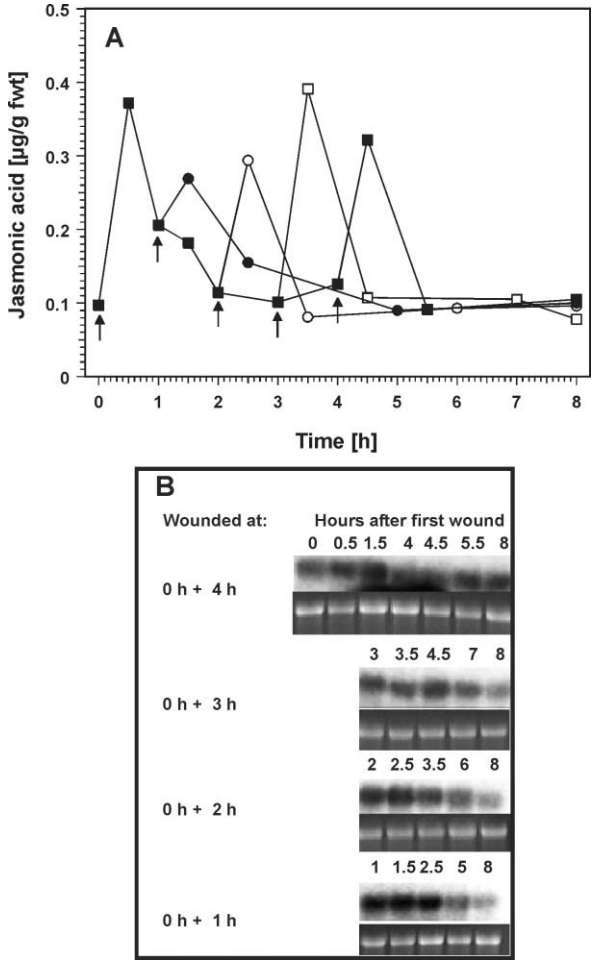

Fig. 7. Jasmonic acid levels (A) and AOS expression (B) after repetitive mechanical wounding. Leaves were wounded with a fabric pattern wheel at time zero (closed squares) and a second time (→) at either 4 h (■), 3 h (□), 2 h (○) or 1 h (●) after the initial wounding event. Leaves from an individual plant were harvested at each sampling time.

and the induction pattern, other factors must be decisive for the control of JA biosynthesis. One of these factors might be the compartmentation of biosynthetic enzymes. This is supported by the recently reported spatial distribution of enzymes for JA biosynthesis and competing reactions, which suggests that substrate flow through the different pathways might regulate JA accumulation (Froehlich et al., 2001). Laudert and Weiler (1998) recently suggested that the transport of precursors might regulate JA biosynthesis, reasoning that the decrease in JA biosynthesis by salicylic acid treatment might be due to the inhibition of the export of the JA precursor PDA out of the chloroplast. While these are plausible models, the available data on the rate-limiting steps of stress-induced JA accumulation are still too preliminary to favor support any one distinct particular mechanism.

AOS expression was strongly and transiently induced in leaves after MeJA treatment (Fig. 8) and, with a delay of 8 h, was accompanied by a steady increase in hydroperoxide metabolizing activity. But again, this activity could only be ascribed to hydroperoxide lyase activity (M. Keinänen, J. Ziegler and I.T. Baldwin, unpublished results). MeJA-induced AOS transcript level is also observed in flax (Harms et al., 1998), *Arabidopsis* (Laudert and Weiler, 1998), barley (Maucher et al., 2000) and tomato (Sivasankar et al., 2000). This can be interpreted as feedback activation of AOS leading to an increased capacity of the octadecanoid pathway (Laudert and Weiler, 1998). Recent experiments in barley have demonstrated that exogenous application of MeJA or JA does not lead to de novo biosynthesis of JA (Kramell et al., 2000), although the level of AOS transcript (Maucher et al., 2000) and enzyme activity (Ziegler, unpublished) are induced. The biological significance and the role of the induction of AOS gene transcription by exogenous MeJA remains unclear.

3. Materials and methods

3.1. Plant growth and treatments

Seeds from an inbred line (DI92) of *N. attenuata* originating from a natural population in Utah (Baldwin, 1998) were germinated in peat soil soaked with 1:50 dilution of liquid smoke (House of Herbs, Passaic, NY, USA) to synchronize germination (Baldwin et al., 1994b). After two weeks, seedlings were transferred to individual pots. After growth for an additional 10–14 days, plants had reached the rosette stage with 6–8 leaves and were ca. 2–3 days before bolting. The experiments were then conducted. Plants were grown in a 32 °C/16 h light, 26 °C/8 h dark regime with a constant air humidity of 65%. The same conditions were used during the experiments. In a phyllotactically consecutive leaf sequence, the leaf one leaf position older than the source/sink

transition leaf was assigned as the treated, local leaf, and the leaf one position younger was assigned as the systemic, untreated leaf.

Manduca sexta larvae were hatched from eggs (Carolina Biological Supply, Burlington, NC, USA) as described (Hermsmeier et al., 2001). Regurgitant was collected from the oral cavity of 4th and 5th instar larvae fed *N. attenuata* foliage according to (Schittko et al., 2001). Leaves were wounded by rolling a fabric pattern wheel six times parallel to the midvein over the upper leaf surface. In treatments with regurgitant, 20 μl of the diluted regurgitant were applied to the fresh puncture wounds of the leaf. In feeding experiments, three first instar *M. sexta* larvae were placed on a leaf and were allowed to feed for the times indicated in Fig. 5. MeJA was applied to the upper surface of the treated leaf in a lanolin paste. Each individual leaf was harvested as follows: one incision was made along the midvein taking care to leave one section without the midvein and two parallel incisions were made in the middle of the leaf lamina across the midvein, resulting in six leaf sections, which were weighed, flash frozen in liquid nitrogen and stored at −80 °C until used. The basal and apical parts without the midrib were used for the analysis of JA, the corresponding parts with the midrib were used for the extraction of RNA, and the central two parts were used for the extraction of enzymes.

3.2. Analysis of JA

JA was extracted and quantified with [1,2-^{13}C] JA as an internal standard by GC–MS as described in Baldwin et al. (1997).

3.3. Preparation of protein extracts

Leaf tissue was ground under liquid nitrogen and the resulting powder was extracted with 50 mM Na-phosphate buffer pH 7 containing 2% (w/v) PVPP and 0.1% (v/v) Triton X-100. The homogenate was centrifuged at 12,000 *g* for 10 min and the supernatant was used as the enzyme extract.

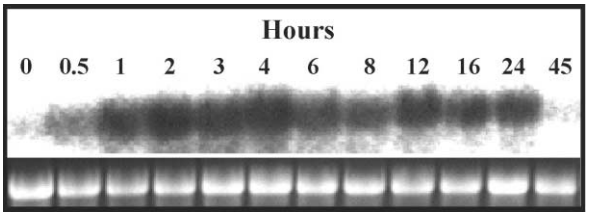

Fig. 8. AOS expression after treatment with methyl jasmonate. Fifty micrograms MeJA was applied to the upper surface of the leaf in 20 μl of lanolin paste. Ethidium bromide stain of 28S rRNA serves as loading control.

3.4. Enzyme assays

The substrate, 13(*S*)-HPOT, was prepared by incubation of linolenic acid with soybean lipoxygenase as described (Hamberg and Gotthammar, 1973). Hydroperoxide decomposing activity was measured in 50 mM sodium phosphate pH 7 in a total volume of 1 ml. The enzyme assay was started by the addition of 13(*S*)-HPOT to a final concentration of 100 μM and the reaction was followed photometrically by the decrease in the absorbance at 235 nm. To differentiate between the various hydroperoxide decomposing activities, the enzyme assay was performed with 1-[^{14}C]-13(*S*)-HPOT, the products extracted with ether and separated and quantified by RP–HPLC as described (Ziegler et al., 1997). For product identification by GC–MS, unlabelled 13(*S*)-HPOT was used as the substrate and the methylated and trimethylsilylated products were subjected to GC–MS analysis (HP 5890 Series II, Hewlett-Packard, St Louis, MO, USA) on a DB-5MS column (30 m length, 0.25 mm. i.d., 0.25 μm film thickness; J&W Scientific, Folsom, CA, USA) with a helium flow rate of 1 ml/min, and detected by MS (HP 5971) in SIM mode.

3.5. Isolation of AOS cDNA and overexpression in Escherichia coli

A cDNA library in λ-ZAPII (Stratagene) prepared from *N. attenuata* shoots after 24 h of feeding by *M. sexta* larvae was used. 5×10^5 phages of this cDNA library were screened with the 5′-*EcoRI*/*XhoI* (700 bp) fragment of the *Arabidopsis thaliana* AOS cDNA (Laudert et al., 1996). Prehybridization was performed at 55 °C in 5×SSC, 5×Denhardt's reagent, 0.5% SDS, 125 μg ml^{-1} salmon sperm DNA for 3 h, followed by hybridization at 55 °C overnight with the ^{32}P-labelled *Arabidopsis thaliana* AOS fragment in the prehybridization solution. Filters were washed 3 times for 15 min at 55 °C in 2×SSC and 0.1% SDS. Putative positive phages were checked for the presence of an AOS insert by PCR with the following primers: upstream 5′-TTC AC(CT) GG(AT) ACT TA(CT) ATG CC-3′, downstream: 5′-GTT GC(AGC) AAC GGT TG(AG) TA(GCT) CC-3′. The temperature program was 4 min at 94 °C followed by 25 cycles 1 min at 94 °C, 2 min 50 °C, 2 min at 72 °C and a final extension time for 10 min at 72 °C. A PCR fragment of 850 bp was identified as AOS by dideoxy cycle sequencing and was used for further screening under same conditions as described above, but the hybridization and washing temperatures were raised to 65 °C. The positive plaques were converted into phagemids by in vivo excision. 5′RACE was performed using the 5′RACE Kit (Gibco, Gaithersburg, MD) according to the instructions of the manufacturer. Purified mRNA (Oligotex-mRNA purification Kit, Qiagen, Hilden, Germany) from leaves treated for 4 h with MeJA was

used as a template. The gene specific primers were 5′-GTC GCA AAA CGG TTG GTA CCC-3′ for the reverse transcription and 5′-GAA ACG TCG AAG AGG GTG GG-3′ for the PCR amplification at an annealing temperature of 60 °C. The PCR fragment was cloned into the TOPO-TA cloning vector (Invitrogen San Diego, CA, USA) and sequenced.

For overexpression, the AOS cDNA was cut from the plasmid with SmaI and XhoI and cloned into the *SmaI*/*SalI* sites of the His-tag vector pQE31 (Qiagen, Hilden, Germany). *E. coli* SG13009 served as the host strain. Expression was induced by the addition of 1 mM IPTG for 4 h and the bacteria were extracted by sonication in 50 mM sodium phosphate pH 7, 300 mM NaCl, 7% glycerol, 0.1% Triton X-100 and 10 mM imidazole. After centrifugation at 12,000 *g* for 20 min the supernatant was used for tests of activity.

3.6. Northern and Southern blots

The extraction and blotting of RNA and genomic DNA was performed using standard methods (Maniatis et al., 1989). For Southern blot analysis 10 μg of genomic DNA was digested with the restriction endonucleases indicated and resolved in a 0.8 % agarose gel. For both, Northern and Southern, blots prehybridization was performed at 65 °C in 5×SSC, 5×Denhardt's reagent, 0.5% SDS, 125 μg/ml salmon sperm DNA for 3 h, followed by hybridization at 65 °C overnight with the ^{32}P-labelled 850 bp *N. attenuata* AOS fragment. Membranes were washed 3 times for 15 min at 65 °C in 2×SSC and 0.1% SDS. Autoradiograhy of the membranes on X-ray films was performed at −80 °C in the presence of intensifying screen. After scanning, the blots were quantified using the ImageQuaNT™ program (Molecular Dynamics, Krefeld, Germany).

Acknowledgements

We are grateful to Professors Elmar Weiler and Dietmar Laudert (Ruhr-University Bochum, Germany) for providing the *Arabidopsis thaliana* AOS cDNA clone. We thank Natalia Sandoval for preparing the *N. attenuata* cDNA library and Domenica Schnabelrauch for the nucleotide sequence analysis. Funded by the Max Planck Gesellschaft.

Received 19 February 2001; received in revised form 5 June 2001

Abstract

Two species of grasshoppers (*Melanoplus bivittatus* and *M. sanguinipes*) tolerated high levels of miserotoxin (3-nitro-1-propyl-β-D-glucopyranoside) in their diet. Miserotoxin is a causative agent in cattle poisoning when timber milkvetch (*Astragalus miser*) is consumed. Toxic effects were averted by grasshoppers in part by excretion of the intact glycoside. When the aglycone was administered, detoxification was achieved by two routes: by oxidation of the aglycone to 3-nitropropionic acid which was then conjugated with glycine, and by glucosylation of the aglycone to miserotoxin, in each case followed by excretion. 1. Introduction

Miserotoxin (3-nitro-1-propyl-β-D-glucopyranoside), a causative agent in cattle poisoning on rangelands in the western USA, was originally isolated from *Astragalus miser* var. *oblongifolius* (Leguminosae) (Stermitz et al., 1969). The glycoside was subsequently isolated from *A. miser* var. *serotinus* (timber milkvetch), which occurs in the Southern Interior of British Columbia, Canada (Majak and Bose, 1974). Other glycosides of 3-nitropropanol (NPOH) were also identified in timber milkvetch (Long et al., 1992). Miserotoxin is rapidly hydrolyzed by microbial enzymes of the rumen, and the aglycone is absorbed and converted to 3-nitropropionic acid (Muir et al., 1984), a potent inhibitor of mitochondrial enzymes essential to respiration (Alston et al., 1977). 3-Nitropropionic acid (NPA) is also implicated as a causative agent of neuronal degeneration in mammals (Alexi et al., 1998).

Previously we reported on the lack of NPA toxicity to melanopline grasshoppers (*Melanoplus bivittatus* and *M. sanguinipes*; Orthoptera: Acrididae), and their metabolic ability to detoxify NPA by way of conjugation with amino acids. The NPA was excreted in the frass (dry fecal pellets) as amides of glycine, L-serine and L-glutamate (Majak et al., 1998). Karakin, a glucose triester of NPA, was also detoxified after hydrolysis in vivo and conjugation of the NPA to the same amino acids (Majak et al., 1998). In feeding trials with the same species of grasshoppers using freeze-dried timber milkvetch, none of the grasshoppers died, nor did they show any sign of altered behavior or disability after subsisting on *A. miser* for 96 h at room temperature (D.L. Johnson, unpublished data). The objectives of this study were to further explore the resistance of grasshoppers to miserotoxin, and to determine the metabolic fate of the aglycone.

2. Results and discussion

2.1. Experiment 1

The concentration of miserotoxin in the timber milkvetch was found to be 4.5–5.2% on a dry-matter basis.

The individual consumption rate of the milkvetch was approximately 40 mg/day, per grasshopper, which is a typical rate of feeding on finely ground dried plant material at room temperature. The rate of intake of miserotoxin was equivalent to approximately 2 mg of the glycoside per grasshopper per day. There was no mortality in treated or untreated groups, and there was no other signs of toxicity.

2.2. Experiment 2

Typically, more than 90% of the food that was treated with the purified glycoside and provided in feeding trays was consumed by the two-striped grasshoppers during the assessment period. The average intake of miserotoxin was estimated at approximately 4.5–4.8 mg per grasshopper per day. There was no mortality or other sign of toxicity. The frass was extracted and miserotoxin was detected on silica gel TLC.

2.3. Experiment 3

No grasshoppers died in the treated groups (a total of one grasshopper in the control groups died), and no other changes in behavior that would indicate possible toxicity were observed. The average amount of the glycoside provided was 11.5 mg per grasshopper, per day, but because of losses (estimated at ca. 20%) in tumble-treatment of the lettuce, and quantities remaining on unconsumed food, the amount of glycoside was estimated to be 6–7 mg per grasshopper. By far, the major component in the frass giving a colour test specific for aliphatic nitro compounds (Majak and Bose, 1974) was miserotoxin, as evidenced by co-chromatography with an authentic standard. The identity of the glycoside as a nitro alkyl excretion product (3.5% of the frass on a dry-matter basis) was confirmed by ^{1}H and ^{13}C NMR spectroscopy. Only a small portion ($<10\%$) of the administered miserotoxin was recovered from the frass, which suggested other pathways of elimination or reductive detoxification (although this feeding experiment was not intended to provide quantitative analysis of fate of all products). Some anaerobic bacteria can reduce the nitro alkyl moiety to the amino group (Anderson et al., 1993), and sequestration of the intact glycoside could also be possible (Duffey, 1980). However, extraction of the grasshopper cadavers and TLC screening did not reveal endogenous accumulation of ninhydrin-positive or nitro alkyl-positive products.

There was no evidence of the aglycone on TLC, suggesting the absence of β-glucosidase activity in *M. bivittatus*, and a possible avoidance of toxicity, through the elimination of the intact glycoside. The low level of β-glucosidase activity agrees with earlier tests that indicated the absence of cyanide formation when homogenates of *M. bivittatus* were incubated with amygdalin (W. Majak, unpublished data). However, a second, minor spot was observed on the TLC that was also visualized with the reagent for nitro compounds. Its R_f was consistent with that of an amino acid conjugate of NPA. This result suggested partial hydrolysis of the glycoside by the insect, or possibly by microflora of the gut, and then oxidation of the aglycone to NPA before conjugation.

2.4. Experiment 4

The average intake of the aglycone was approximately 0.5 mg per grasshopper per day. There was no mortality or other sign of toxicity, and no behaviour indicating disorientation or loss of appetite. When the frass was extracted and fractionated, an amino acid conjugate of NPA was isolated, which was identified by NMR as the glycyl amide of NPA. Clearly, it was demonstrated that *M. bivittatus* had the capacity to oxidize the aglycone, and to detoxify the NPA through conjugation with glycine. There was no evidence of excess NPOH in the frass.

However, the more common method of NPOH detoxification by *M. bivittatus* appeared to be through glucosylation to form the β-D-glucoside, which, in effect, is miserotoxin. Based on colour intensity on TLC, the ratio of the glycoside to the amino acid conjugate appeared to be approximately 2:1. On a molar basis, the yield of the glycoside (25 mg) accounted for approximately 10% of the administered aglycone. This type of glucosylation reaction has long been recognized in higher plants. When simple phenols, such as phloroglucinol or phenol itself, are administered to higher plants, they are detoxified by conversion to the corresponding glucosides (Towers, 1964). Thus, there are now three methods for the metabolic detoxification of the miserotoxin aglycone: (1) conjugation after oxidation; (2) glucosylation and (3) reduction of the nitro group to the much less toxic amino group which is effected by rumen bacteria (Anderson et al., 1993).

3. Experimental

3.1. General experimental procedures

NMR spectra were measured with a Bruker AM-400 spectrometer at 400 MHZ (^{1}H) and 100 MHZ (^{13}C) of samples dissolved in D_2O or MeOH-d4. The TLC solvent system on silica gel was chloroform–methanol (3:1) with 0.2% HCOOH and the R_f's were 0.32 for miserotoxin and 0.30 for the glycyl conjugate. The ^{1}H and ^{13}C NMR spectra of these compounds were as reported (Majak et al., 1998; Benn and Majak, 1989).

3.2. Biological materials

The grasshoppers used were the first captive generation produced from eggs laid by field-collected adult grasshoppers. [The grasshoppers we used were not from

the widely used non-diapause *Melanoplus sanguinipes* laboratory strain (Pickford and Randell, 1969), which have been shown to have enhanced detoxicative enzyme activity: Isman et al., 1996]. Grasshoppers used in toxicity assessments and feeding trials were confined in cages constructed of screen, glass and wood and supplied with adequate air flow and lighting (photoperiod 15 h light, 9 h dark; measured temp. 27–29 °C day, 22–24 °C night). Methods of rearing and handling of grasshoppers, and of assessment of grasshopper feeding, were similar to those described by Johnson and Pavlikova (1986) and Lactin and Johnson (1995). *A. miser* var. *serotinus* specimens were field collected in the Southern Interior of British Columbia. Specimens were freeze dried and ground prior to grasshopper feeding.

3.3. Experiments

3.3.1. Experiment 1: consumption and gross toxicity

Groups of 12 grasshoppers (repeated separately for *M. bivittatus* and *M. sanguinipes*, two complete replications for each species) were each confined with 1 g of freeze-dried *A. miser* var. *serotinus*, which they consumed within 48 h. Feeding behavior and frequency was observed in order to confirm that all individuals were consuming the plant material. At the end of 48 h, a second gram of freeze-dried *A. miser* var. *serotinus* was added to each cage and again it was consumed within 48 h. The concentration of miserotoxin in the timber milkvetch was determined by HPLC (Quinton et al., 1989). The experiment was subsequently repeated in four complete replications to confirm results regarding gross toxicity.

3.3.2. Experiment 2: intake and toxicity of the purified glycoside

A total of 40 fifth-instar *M. bivittatus* were confined in cages with wheat bran that was treated with (or without) purified miserotoxin, which was dissolved in water. (Treatment identifiers were coded, and unknown to handlers and observers during the assessments.) The grasshoppers were confined with measured quantities of the wheat bran provided in feeding trays each day for 8 days. The administered miserotoxin was isolated from timber milkvetch by conventional procedures (Majak and Bose, 1974; Majak et al., 1992), but continuous ethyl acetate extraction was used before column chromatography. To detect the glycoside in the frass, 1 g of it was extracted with hot ethanol and the concentrate was fractionated on silica gel column chromatography (25×2 cm) and centrifugally accelerated radial TLC (Chromatotron) as described previously (Majak et al., 1998).

3.3.3. Experiment 3: assessment of intake, excretion and fate of the glycoside

In the third experiment, the purified glycoside was applied to a mixture of lettuce leaves (streaking with pipette), and to wheat bran (stirred and mixed by tumbling until evenly absorbed). A total of 80 two-striped grasshopers (*M. bivittatus*) were confined with the treated feed in cages for 4 days. The grasshoppers were kept alive for an additional 7 days after that time, to observe any possible delayed mortality. The collected frass was extracted and fractionated by conventional procedures (Majak et al., 1998). Individual fractions were screened by TLC.

3.3.4. Experiment 4: intake of the aglycone and fate of NPOH

In a fourth experiment, the aglycone was fed to grasshoppers to determine the metabolic fate of NPOH. A total of 50 two-striped grasshoppers (*M. bivittatus*) were confined in feeding cages and fed aglycone for 6 days. 3-Nitropropanol was synthesized from 3-bromopropanol by Gary Yost, University of Utah. Frass from the grasshoppers (0.93 g) was extracted as described above.

Received 6 February 2001; received in revised form 3 May 2001

Abstract

A basic heme-peroxidase (WP1) was purified to homogeneity from wheat (*Triticum aestivum*) kernels. The protein was not glycosylated and exhibited a molecular mass of 36 kDa and a pI of 8.0. The N-terminal amino acid sequence revealed a very high similarity with a wheat flour peroxidase allergen associated with baker's asthma. WPI showed indole-3-acetic acid oxidase activity in the presence of Mn^{2+} and phenolic cofactors. Antifungal assays performed in vitro towards phytopathogenic fungi indicated that WP1 was active in inhibiting germ tube elongation. This first report on antifungal properties of a heme-peroxidase gives experimental support to the idea that peroxidases play a defensive role against invading pathogens. © 2001 Elsevier Science Ltd. 1. Introduction

Plant peroxidases (EC 1.11.1.7) are heme-proteins that use H_2O_2 to oxidise a large variety of hydrogen donors such as phenolic substances, amines, ascorbic acid, indole and certain inorganic ions (Van Huystee, 1987). These proteins are widespread in the plant kingdom and peroxidase isoenzymes are known to occur in a variety of plant tissues. The pattern of expression of each isoform varies in the different tissues of healthy plants and is developmentally regulated and influenced by environmental factors (Lagrimini and Rothstein, 1987); however, the role of each isoform is not fully understood. Various experiments suggest the involvement of plant peroxidases not only in biosynthetic processes related to wall development such as lignification (Lagrimini et al., 1987), suberification (Roberts and Kolattukudy, 1989) and polymerisation of hydroxyproline-rich glycoproteins (Bradley et al., 1992), but also in the regulation of cell wall elongation (Greppin et al., 1986), wound healing (Espelie and Kolattukudy, 1985; Lagrimini and Rothstein, 1987) and resistance against infection by pathogens (Flott et al., 1989; Graham and Graham, 1991; Reimers et al., 1992; Young et al., 1995; Chittoor et al., 1997). Such a wide spectrum of functions is consistent with the presence of several isoforms suggesting that different peroxidase isoenzymes might be involved in distinct processes. Moreover, peroxidases can be considered useful markers for environmental stresses since their activity is affected by low temperature, air pollution, ozone, heavy metals, wounding, salts, pathogen attack and UV radiation (Penel et al., 1992).

A better understanding of the physiological roles of peroxidases can be obtained through the isolation and structural-functional characterisation of new proteins and the identification of their targets. The major cationic peroxidases from horseradish and turnip have been intensively studied and their amino acid sequences have been determined (Welinder, 1979; Mazza and Welinder, 1980). Isolation and characterization of peroxidase isoenzymes have been reported also from several dicots such as potato, tomato, tobacco (Roberts and Kolattukudy, 1989; Roberts et al., 1988; Lagrimini et al., 1987a), and to a lesser extent from monocots. Less information is available on wheat peroxidases, probably because the isolation of a single protein is complicated by the presence of several different isoforms encoded by the hexaploid genome (Liu et al., 1990). The characterisation of

PII: S0031-9422(01)00226-6

three full length and one truncated wheat peroxidase genes has been reported, as well as the tissue-specific pattern of expression (Baga et al., 1995). These genes were found to be closely related to wheat peroxidases previously characterised from different cultivars suggesting that they represent variants of the same genes (Hertig et al., 1991; Rebmann et al., 1991). Recently, the purification and partial characterisation of a wheat peroxidase associated with baker's asthma and highly homologous with the previously characterised barley peroxidase BP1 (Rasmussen et al., 1991) has been reported (Sanchez-Monge et al., 1997).

In this paper we report the isolation and purification from wheat seeds of a cationic peroxidase (coded WP1) that also displays indole-3-acetic acid (IAA) oxidase activity in the presence of Mn^{2+} and phenolic cofactors. Antifungal experiments in vitro using different pathogenic and non-pathogenic fungi show that WP1 exhibits a weak inhibitory activity exerted on germ tube elongation, whereas it has no effect on spore germination.

2. Results and discussion

2.1. Protein purification and characterisation

Salt-soluble proteins extracted from wheat kernels and fractionated by precipitation with ammonium sulfate were subjected to cation exchange chromatography on a CM-Sepharose column (Fig. 1). The three pooled fractions with peroxidase activity (peaks I, II and III) exhibited a large number of isoenzymatic forms by isoelectric focusing. The full characterization of peak I, containing anionic isoperoxidases, is currently in progress; peak III has not been studied at the moment due to the very low amount of protein despite its high peroxidase activity. Peak II, which showed the lowest number of isoforms, was further purified by two different procedures to obtain either the heme-depleted peroxidase (apoWP1) or the enzymatically active hemeprotein (holoWP1). The complete purification of the holoenzyme was achieved submitting peak II to IE-chromatography on a Resource S column (Fig. 2A); the active peak II-2, showing only one peroxidase band on IEF, was finally loaded on an UltroPac TSK CM-3SW column and purified to homogeneity by IE-HPLC (Fig. 2B). Peak II-1, characterised by the presence of two isoforms, is still under investigation. The purification of apoenzyme was achieved in homogeneous form submitting the peak II to RP-HPLC (Fig. 3). The purified holoWP1 was homogeneous upon analysis by

SDS–PAGE, showing a molecular weight of 36 kDa. Isoelectric focusing on purified holoWP1 stained by both Coomassie Blue and peroxidase activity confirmed the homogeneity of the sample and showed an isoelectric point of 8.0 (data not shown). Since it has been reported that several plant peroxidases are glycoproteins, holoWP1 was digested with endo-β-*N*-acetyl glucosaminidase F from *Flavobacterium meningosepticum* (Endo F) to determine the presence of sugar components. The digestion was also carried out on a standard glycoprotein (chicken ovalbumin) in order to evaluate the efficiency of the treatment. SDS-PAGE analysis of digested and untreated holoWP1 showed a single protein band with the same electrophoretic mobility indicating that WP1 was not a glycoprotein. On the contrary, a shift in the electrophoretic mobility of digested ovalbumin with respect to the control protein was detected indicating that the Endo-F treatment used for both proteins was efficient (data not shown). Moreover, analysis of both holoWP1 and ovalbumin was also performed after non denaturing-PAGE using the periodic acid-Schiff procedure that allows the detection of about 0.2 μg protein-associated carbohydrate (Doerner and White, 1990). The electrophoresis was carried out using both chicken ovalbumin (20 μg) which approximately contains 4% mannose residues by weight (0.8 μg carbohydrate) and holoWP1 (40 μg). The analysis confirmed the absence of oligosaccharide chains linked to the peroxidase whereas a detectable band was evidenced only for ovalbumin (data not shown).

The Reinheitszahl (RZ) value (A_{403}/A_{280}) for WP1 was 2.8–3, in good agreement with the values reported for other heme-peroxidases (Van Huystee, 1987). The cationic isoperoxidase we isolated displays low specific activity for guaiacol (3.0 U/mg), whereas it shows high affinity for indole-3-acetic acid (1680 U/mg). It is well known that the main natural auxin (indole-3-acetic acid) is oxidised by peroxidases and that this degradation may regulate the auxin levels in plant tissues (Gaspar et al., 1991). Moreover, it is widely reported that phenolic substances could play an important role in the regulation of IAA oxidation although the ability of some peroxidases to catalyze the oxidation of IAA in the absence of these cofactors has been reported (Gazaryan et al., 1999). The ability of wheat leaf peroxidases to catalyze the IAA oxidation in the presence of Mn^{2+} and phenolic cofactors is known from many years (Machackova et al., 1975) and our results are in agreement with these findings. However, holoWP1 ability of catalysing the aerobic oxidation of IAA in the absence of such substances was also verified. In such conditions, the enzyme was unable to degrade IAA, suggesting that it cannot be considered as a functional auxin oxidase involved in the IAA catabolism.

2.2. Sequence analysis and homology studies

The N-terminal sequence of reduced and pyridylethylated apoWP1 was determined using an automated apparatus. The sequence of the first 24 amino acid residues of WP1 aligned with the corresponding regions of a wheat peroxidase associated with baker's asthma (wheat allergen) (Sanchez-Monge et al., 1997), the two cloned peroxidases from wheat POX1 (Hertig et al., 1991) and pPOX381 (Rebmann et al., 1991), the two cloned peroxidases from barley BP1 (Johansson et al., 1992) and BP2 (Theilade and Rasmussen, 1992), and two mature proteins from horseradish (Welinder, 1979) and turnip (Mazza and Welinder, 1980) is shown in Fig. 4. Unlike other plant peroxidases the N-terminal of WP1 was accessible to the Edman degradation according to what reported also for the barley peroxidases BP1 and BP2. WP1 is less than 40% identical to the wheat peroxidase POX1 and POX381, whereas it exhibits a higher degree of identity toward the two peroxidases isolated from barley, a species closely related to wheat. A low degree of identity is observed between WP1 and two well-known peroxidases (HRP C and TP 7) from the dicot species horseradish and turnip. WP1 is highly

Fig. 4. Sequence comparison of the N-terminal region of wheat WP1 aligned with the corresponding regions of peroxidases from 36 kDa allergen, HRPC, POX1, pPOX381, BP1, BP2 and TP 7. Amino acids are shown in the one-letter code. N-terminal Z indicates pyroglutamate. The sequences are aligned to maximise homology. Residues common to six out of eight sequences are in bold face. The conserved region of IAA oxidases is boxed.

identical (23 N-terminal invariant residues out of 24) to a 36 kDa allergen purified from wheat by Sanchez-Monge et al. (1997); anyhow, it is worth noting that, unlike the wheat allergen, WP1 was found to be not glycosylated. This allergen has been indicated as a peroxidase on the basis of its enzymatic activity and sequence homology with the barley peroxidase BP1. These results may indicate that variations in the molecular structures of peroxidases are more role-specific rather than species-specific. During evolution peroxidase isoforms may have conserved large portions of their structure when they participate in similar biological functions, or have diverged to carry out different functional roles.

Very recently the presence of a binding site for IAA distinct from that involved in the binding and cleavage of hydrogen peroxide has been reported for plant peroxidase (Savitsky et al., 1999). In particular, five structurally similar fragments (helices A, B, D-D′ and C) were identified between some plant peroxidases and several auxin-binding proteins and one of this is located at the N-terminus of peroxidases (helix A) (Savitsky et al., 1999). The relevant IAA oxidase activity described in the present paper for holoWP1 prompted us to look for structural elements related to this feature. The presence at the N-terminus of a region similar to helix A (Savitsky et al., 1999) is noted in Fig. 4, confirming this close structure/function relationship of IAA oxidases.

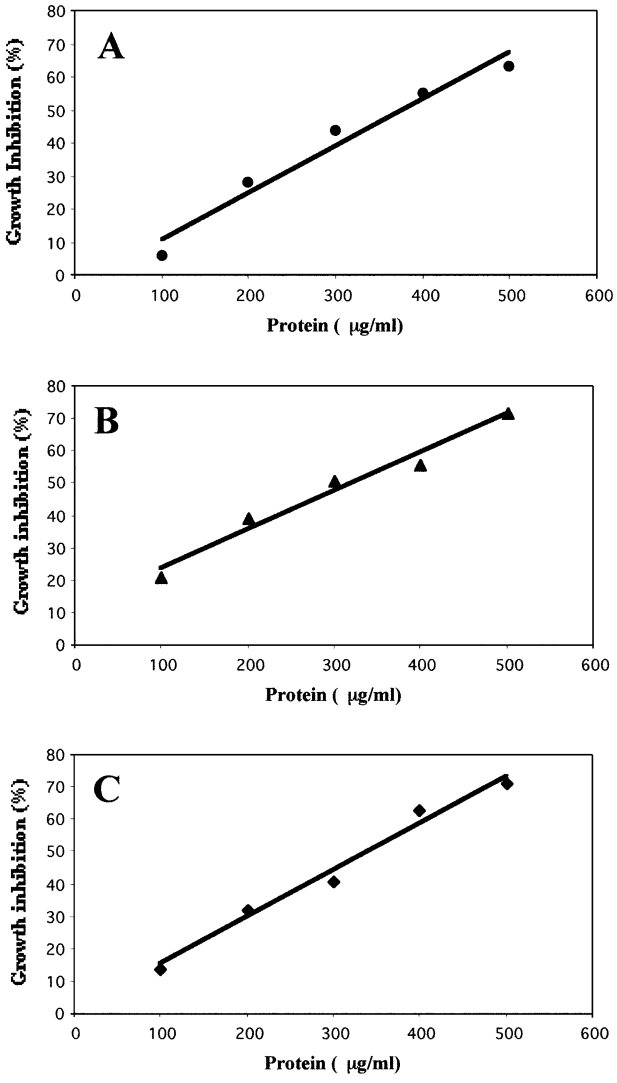

Fig. 5. Antifungal activity of holoWP1 towards *Botrytis cinerea* (A), *Trichoderma viride* (B) and *Fusarium culmorum* (C). Relative hyphal growth is expressed as percentage of hyphal growth of control cultures and data are means of two independent experiments.

2.3. Antifungal activity

In order to investigate the biological role of the heme-peroxidase WP1, the antifungal activity was tested utilizing the wide host range pathogen *Botrytis cinerea*, the wheat pathogen *Fusarium culmorum* and the non pathogenic *Trichoderma viride*. The concentration of holoWP1 required for 50% growth inhibition (IC_{50} value) of the tested fungi was determined from the dose–response curves (% growth inhibition versus protein concentration) shown in Fig. 5. HoloWP1 inhibited germ tube elongation of all the tested fungi showing IC_{50} values of 315, 336 and 377 μg/ml for *F. culmorum, T. viride* and *B. cinerea*, respectively. IC_{50} values of wheat PR-4 proteins wheatwin1 and wheatwin2 on *B. cinerea* and *F. culmorum*, assessed by the same assay, were 20–25 fold lower (Caruso et al., 1996), showing that the peroxidase was less effective than PR-4 proteins in inhibiting fungal hyphal growth. Anyway, WP1 antifungal activity, although less strong, is significant and correlated to its tridimensional structure. In fact, control experiments with heat-inactivated holoWP1 confirmed that the

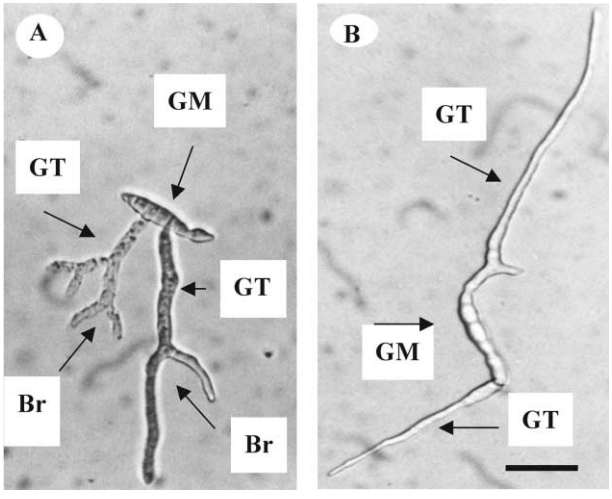

Fig. 6. *F. culmorum* growth in the presence (A) and in the absence (B) of holoWP1 (300 μg/ml). Br = branching; GM = germinating macroconidium; GT = germinating tube. Bar = 30 μm.

observed inhibition pattern was not due to a general effect on cell growth found for some basic proteins, but depends on a specific action of the native protein. To confirm the importance of the native tridimensional structure of the holoWP1, antifungal activity was also tested on the heme-depleted apoWP1 showing that the growth of the tested fungi was not affected. In any case, the antifungal activity was directed only to the inhibition of hyphal growth since the spore germination was not influenced at all in the tested concentration range.

Hyphal growth inhibition was also accompanied by a diffuse hyphal branching for all the fungi tested. *F. culmorum* growth in the presence and in the absence of WP1 is shown in Fig. 6. No accumulation of exudates was observed around hyphae, thus suggesting that the biological effect of WP1 is not directed on the modification of fungal cell wall or membranes.

3. Conclusions

The functional significance of the antifungal activity of holoWP1 is not fully understood, but the existence of a protein with antifungal activity in wheat seeds might represent a selective advantage towards a wide range of potential pathogens activity even if the toxic effect is less effective than that reported for other proteins. Anyhow, its expression together with other antifungal proteins, such as those belonging to the PR group, could indicate a protective role during seed germination and may be considered as part of the defence mechanisms that the plant activates against pathogens. This is the first report describing a weak but direct antifungal activity of a peroxidase from wheat seeds. This unique feature has never been observed before suggesting that this peroxidase could play a role in defence against invading hosts.

4. Experimental

4.1. General experimental procedures

CM-Sepharose fast flow, Resource S and isoelectric focusing reagents were from Pharmacia Biotech (Uppsala, Sweden); a μ-Bondapak C_{18} reverse-phase column (0.39×30 cm) was from Waters-Millipore (Milford, MA, USA); an UltroPac TSK CM-3SW ion-exchange column (7.5×150 mm) was from LKB-Pharmacia Biotech (Uppsala, Sweden). SDS-PAGE reagents, including low molecular weight markers, were from Bio-Rad (Italy). Bovine serum albumin, chicken ovalbumin, trifluoroacetic acid, IAA, dithiothreitol and 4-vinylpyridine were from Sigma Chemical Co. (St. Louis, MO, USA); guaiacol (*o*-methoxyphenol), 2,4-dichlorophenol (DCP) and hydrogen peroxide were from BDH (UK). All the reagents were of the highest purity commercially available.

4.2. Plant and fungal materials

Triticum aestivum, pure variety San Pastore, was kindly supplied from Istituto Sperimentale per la Cerealicoltura (S. Angelo Lodigiano, Italy). The following fungal isolates were used: *Fusarium culmorum* (isolate ISPAVE 485), *Botrytis cinerea* (isolate Bc 91/3) and *Trichoderma viride* (isolate Tv56). Sporulating cultures were obtained by growing the isolates on potato dextrose agar (PDA) (Oxoid, Hampshire, UK) at 24 °C for 14 days.

4.3. Enzyme purification

Finely ground flour from wheat seeds was extracted overnight with 0.15 M NaCl (4 ml/g) under stirring at 4 °C. The suspension was centrifuged at 18,000 *g* for 20 min at 4 °C and the clear supernatant was fractionated by ammonium sulfate; the 10–80% precipitate was collected by centrifugation at 18,000 *g* for 20 min at 4 °C and extensively dialysed against 20 mM ammonium acetate buffer (pH 7.8) at 4 °C (buffer A). The clear dialysed sample was fractionated on a CM-Sepharose fast flow column (1.6×10 cm) equilibrated with buffer A; the bound proteins were eluted with a linear gradient from 20 to 100% of 300 mM ammonium acetate buffer (pH 7.8) (buffer B) at a flow rate of 1.5 ml/min; the eluate was monitored measuring the absorbance at 280 nm and the enzymatically active fractions were pooled, concentrated by ultrafiltration and equilibrated in 20 mM ammonium acetate buffer (pH 7.4) (buffer C). Peroxidase activity was distributed into three fractions, coded peaks I, II and III in order of elution. Peak II was further purified by two different procedures to obtain either the heme-depleted peroxidase (apoenzyme) or the enzymatically active hemeprotein (holoenzyme).

4.3.1. Apoenzyme purification (apoWP1)

Peak II was resolved on a reverse phase μ-Bondapak C_{18} column using an HPLC System GOLD® (Beckman, USA) equipped with a 126 Solvent Module and a 166 UV/Vis detector interfaced with a personal computer. Eluant A was aqueous 0.07% trifluoroacetic acid and eluant B was 0.05% trifluoroacetic acid in acetonitrile. Elution was accomplished at a flow rate of 1 ml/min according to the following program: isocratic elution for 5 min at 25% B, followed by linear gradient from 25 to 34% B in 20 min, and from 34 to 44% B in 45 min. Eluate was monitored measuring the absorbance at 220 nm. Fractions were manually collected and freeze-dried.

4.3.2. Holoenzyme purification (holoWP1)

Peak II was loaded onto a Resource S column equilibrated in 20 mM ammonium acetate buffer (pH 7.4) (buffer C); the column was washed with 2 ml of buffer C

and the bound proteins were eluted with a liner gradient of NaCl (0–30 mM in 7.5 min and 30–70 mM in 30 min) in buffer C at 1.0 ml/min, the absorbance being monitored at 280 nm. The fractions containing peroxidase activity (Peaks II-1 and II-2) were concentrated by ultrafiltration and equilibrated in buffer C. Peak II-2 was further purified by IE-HPLC on a TSK-3SW high performance column equilibrated in buffer C; elution was accomplished at a flow rate of 0.6 ml/min monitoring the absorbance at 220 nm and using the following program: linear gradient from 0 to 100% of 100 mM NaCl in buffer C in 140 min, then isocratic elution for 15 min with buffer C. The eluate was monitored by measuring the absorbance at 220 nm; the enzymatically active fractions were pooled and freeze-dried on a speed-vac concentrator.

4.4. Enzyme and protein assay

The protein concentration was determined by the Bio-Rad assay, following the manufacturer's instructions and using bovine serum albumin as a standard. Peroxidase activity was measured at 30 °C in a reaction mixture (3 ml final volume) containing 13 mM H_2O_2 and 124 μM guaiacol in 50 mM Tris, pH 7.0; the reaction was started by adding the enzyme and the absorbance increase at 470 nm due to the formation of tetraguaiacol (ε 26.6 mM^{-1} cm^{-1}) was measured. One unit of enzymatic activity is defined as the amount of enzyme required for the production of 1 μmol of tetraguaiacol per minute in the above assay conditions. The oxidation of IAA was followed at 30 °C by measuring the absorbance at 247 nm; the reaction mixture (1 ml final volume) contained 1 mM $MnCl_2$, 0.23 mM IAA, 1 mM DCP in 20 mM KH_2PO_4, pH 4.7. One enzyme unit (EU) is arbitrarily defined as the amount of enzyme which produces a 0.01 absorbance change at 247 nm per min. The aerobic oxidation of IAA in the absence of phenolic compounds was performed using an O_2 micro electrode fitted with a glass tube (Hansatech instruments LTD, England). The reaction was followed at 30 °C using 2 mM IAA and 0.05, 0.1, 0.2 μM peroxidase in 50 mM sodium acetate buffer, pH 4.5 and KH_2PO_4, pH 6.0.

4.5. Electrophoresis and isoelectric focusing

SDS-PAGE was carried out in 15% polyacrylamide gel with a mini-Protean apparatus (Bio-Rad) using the discontinuous system described by Laemmli (1970); both Coomassie Blue and silver staining procedures were used following the instruction of the manufacturer. Periodic acid-Schiff staining (PAS) was performed according to Doerner and White (1990) following non-denaturing PAGE. IEF was performed in the pH range 3.5–10 using both an LKB apparatus (Pharmacia) and a mini-IEF apparatus from Bio-Rad. Proteins in the IEF gels were fixed with 20% TCA; the gels were then washed with a mixture containing 30% methanol and 10% acetic acid and stained and destained as reported for SDS–PAGE. IEF gels were also stained for peroxidase activity; the gels were soaked for 10 min in 50 mM Tris buffer (pH 7.0), and then incubated with 0.46 % (v/v) guaiacol and 13 mM H_2O_2 in the same buffer at room temperature until red bands appeared. The gels were then fixed in water/methanol/acetic acid (6.5:2.5:1, v/v).

4.6. Endo-F digestion

HoloWP1 (10 μg) and ovalbumin (10 μg) were digested with endoglycosidase F (Endo-F) (Boehringer, Mannheim) from *Flavobacterium meningosepticum* according to Elder and Alexander (1982). The proteins were incubated with 0.2 enzyme units at 37 °C for 18 h in acetate buffer 20 mM, pH 5.4, containing Triton X-100 0.2% (v/v), 0.1 mM β-mercaptoethanol and 20 mM EDTA. Both treated and untreated proteins were then analysed by SDS–PAGE.

4.7. Sequence analysis

Purified apoWP1 (apoenzyme) from RP-HPLC was reduced and pyridylethylated before sequence analysis. Protein (5 nmol) was treated with 1.5 μmol of dithiothreitol in 0.1 ml 0.25 M Tris buffer (pH 8.0), 2 mM EDTA, 6 M guanidine–HCl, for 2 h at 37 °C under nitrogen atmosphere. Alkylation was performed with 4-vinylpyridine (45 μmol) for 2 h at room temperature in the dark under nitrogen atmosphere. The reaction was stopped by freezing and excess reagents were removed by RP-HPLC on a μ-Bondapak C_{18} column. Eluents A and B and the elution program were those described above. The S-pyridylethylated apoWP1 was manually collected, freeze-dried then dissolved in aqueous 0.1% trifluoroacetic acid and subjected to automated sequence analysis using a pulsed liquid-phase automatic sequencer (Perkin Elmer-Applied Biosystems model 477A) equipped on-line with a phenylthiohydantoin amino acid derivative analyser (Perkin Elmer-Applied Biosystems model 120A). The sample was loaded onto a trifluoroacetic acid-treated glass-fiber filter, coated with polybrene and washed according to manufacturer's instructions. The sequence reagents were from Perkin Elmer-Applied Biosystems.

4.8. Antifungal activity

The antifungal activity of WP1 was tested in vitro against the following fungal isolates: *Botrytis cinerea* (isolate BC91/3), *Fusarium culmorum* (isolate ISPAVE485) and *Trichoderma viride* (isolate Tv56). Sporulating cultures were obtained by growing the isolates on Potato Dextrose Agar (PDA) (Oxoid-Unipath)

at 24 °C for 14 days. Conidia were collected by scraping a sterile inoculating loop across the surface of the plate in presence of 2× potato dextrose broth (PDB) (Sigma - Aldrich), counted with a hemocytometer and diluted to give a concentration of 106 conidia/ml. Antifungal activity assay was performed as previously reported (Chilosi et al., 2000) at WP1 concentrations from 100 to 500 μg/ml. In the controls, sterile distilled water or hot-denaturated holoWP1 replaced the native protein. The mixtures were placed on microscope slides and incubated for approximately 16 h at 21 °C in the dark in a moist environment; after incubation, germ tube elongation was evaluated by observing microscopically 100 germinating spores for each of three replicates. Hyphal growth inhibition was expressed as IC50 (protein concentration required for 50% growth inhibition) determined by regression from the dose–response curves.

Received 16 January 2001; received in revised form 8 May 2001

Abstract

Reinvestigation of the fermentation broth and mycelium of the coprophilous fungus *Guanomyces polythrix*, grown in static conditions, led to the isolation of several phytotoxic compounds, including two new naphthopyranone derivatives, namely (2*S*, 3*R*)-5-hydroxy-6,8-dimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one and (2*S*, 3*R*)-5-hydroxy-6,8,10-trimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one. The structures of the new compounds were established by spectral and chiroptical methods. In addition, the structure of 8-hydroxy-6-methyl-9-oxo-9*H*-xanthene-1-carboxylic acid methyl ester was unambiguously determined by X-ray analysis. The isolates caused significant inhibition of radicle growth of two weed seedlings (*Amaranthus hypochondriacus* and *Echinochloa crusgalli*) and interacted with both spinach and bovine brain calmodulins. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Guanomyces polythrix*; *Amaranthus hypochondriacus*; *Echinochloa crusgalli*; Calmodulin; Affinity chromatography; (2*S*, 3*R*)-5-Hydroxy-6,8-dimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one; (2*S*, 3*R*)-5-Hydroxy-6,8,10-trimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one; 8-Hydroxy-6-methyl-9-oxo-9*H*-xanthene-1-carboxylic acid methyl ester; Ergosta-4,6,8(14),22-tetraen-3-one; 4-Hydroxybenzoic acid

1. Introduction

As part of our systematic search for new herbicidal lead structures from natural sources, we have recently reported the isolation and structure elucidation of several phytotoxins from the mycelium and culture broth of the coprophilous fungus *Guanomyces polythrix* grown in agitation conditions. Fourteen compounds (**1**–**14**) were isolated, of which the phytotoxic compounds included the five new dihydronaphtopyrones derivatives (**1**–**5**), rubrofusarin B (**11**), emodin (**12**), citrinin (**13**) and 4-hydroxy-benzoic acid methyl ester (**14**). The isolates caused noted inhibition of radicle growth of two weed seedlings [*Amaranthus hypochondriacus* L. and *Echinochloa crusgalli* (L.) Beauv.] and behaved as plant calmodulin (CaM) interactors (Macías et al., 2000). For this reason, we have undertaken the further chemical investigation of *G. polythrix* grown in static conditions. Herein, we report the isolation and structure elucidation of two additional novel naphthopyranone derivatives (**6** and **7**) along with several known compounds. In addition, the phytotoxic properties of the isolates and the potential role of CaM as molecular target of the phytotoxic action are described.

2. Results and discussion

2.1. Bioactivity-guided isolation

G. polythrix was grown in liquid-substrate fermentation on PDB (potato dextrose broth). The mycelium and fermentation broth were extracted with CH_2Cl_2. The combined extract exhibited significant phytotoxic activity on seedlings of *A. hypochondriacus* and *E. crusgalli* (Table 1). Bioassay-guided fractionation of the active

extract led to the isolation of two new naphtophyranone derivatives identified as (2*S*, 3*R*)-5-hydroxy-6,8-dimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one (**6**), and (2*S*, 3*R*)-5-hydroxy-6,8,10-trimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one (**7**). In addition, compounds **1-5**, rubrofusarin B (**11**), emodin (**12**), citrinin (**13**), *p*-hydoxybenzoic acid methyl ester (**14**), *p*-hydroxybenzoic acid (**8**) 8-hydroxy-6-methyl-9-oxo-9*H*-xanthene-1-carboxylic acid methyl ester (**9**) and ergosta-4,6,8(14),22-tetraen-3-one (**10**) were obtained. Compounds **8**–**10** are new to this species. Compounds **1**–**5** were identified by comparison with authentic samples (Macías et al., 2000) and compounds **8** and **10** were identified from their IR and ^{1}H NMR spectroscopic data, which were identical to those previously described in the literature (Porter et al., 1975; Seitz and Paukstelis, 1977).

2.2. Structure elucidation of compounds **6** and **7**

The molecular formulae of compounds **6** and **7** were established as $C_{17}H_{18}O_5$ and $C_{18}H_{20}O_6$, respectively, by HREIMS and were identical to those of compounds **1** and **2**, respectively, suggesting that each set of compounds were isomers. The uni and bidimensional NMR (Table 2) spectra of compounds **6** and **7** were almost identical to those of **1** and **2**, respectively (Macías et al., 2000) indicating that the new natural products have the same 2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one skeleton and that the position of the hydroxy and

methoxyl groups along the dihydronaphtopyrone core was the same. The most obvious differences between the NMR spectra of **6** and **7** and those of **1** and **2** were: (i) the chemical shifts and coupling constants of the methines attributable to H-2/C-2 [δ_H/δ_C 4.59 (*dq*, $J=6.5$, 3.5 Hz)/75.26 in **6** and 4.66 (*dq*, $J=3.5$, 10 Hz)/75.73 in **7** vs 4.20 (*dq*, $J=6.5$, 10 Hz)/78.0 in **1** and 4.28 (*dq*, $J=6.5$, 10 Hz)/78.3 in **2**]; and (ii) the chemical shift values of the methyl groups at C-2 and C-3 [δ_H/δ_C 1.40/16.38 (C-11), 1.22/9.6 (C-12) in **6** and 1.45/16.4 (C-11), 1.24/9.6 (C-12) in **7** vs 1.50/19.8 (C-11), 1.26/10.4 (C-12) in **1** and 1.57/19.8 (C-11), 1.28/10.8 (C-12) in **2**]. The small $J_{2\text{-}3}$ value (3 Hz) clearly indicated that the methyl groups at C-2 and C-3 in **6** and **7** were *cis* rather than *trans* as in **1** and **2**. The CD spectra of **6** and **7** showed a negative Cotton effect around 314 nm, supporting the depicted 2*S* absolute configuration (Gaffield, 1970; Macías et al., 2000). Automatically the configuration at C-3 was established as *R* due to the *cis* relationship of the methyl groups. Altogether, these observations revealed that compounds **6** and **7** were the corresponding epimers at C-3 of compounds **1** and **2,** respectively. Consequently compounds **6** and **7** were identified as (2*S*, 3*R*)-5-hydroxy-6,8-dimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one, and (2*S*, 3*R*)-5-hydroxy-6,8,10-trimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one.

2.3. X-ray crystallographic analysis of compound 9

The structure of compound **9** was unequivocally established as 8-hydroxy-6-methyl-9-oxo-9H-xanthene-1-carboxylic acid methyl ester by X-ray crystallography. The ORTEP-like view as obtained by the single-crystal X-ray analysis is shown in Fig. 1. Except for the ester group, the compound is planar (root-mean-square-deviation 0.048 Å). The mean plane defined by the atoms of the methyl ester is almost perpendicular (77.9°) to the plane of the tricyclic moiety. The hydroxyl group at C-8 is intramolecularly hydrogen bonded [O1-H1... O2 1.83(3) Å]. In the crystal, molecules of **9** stack into columns along the ***c*** axes in an anti-parallel fashion with an adjacent molecule, while the main molecule axis makes an angle of 65.8° in the opposite direction. Both types of stacking are almost perfect, as judging the

angles among the mean planes of 0.0 and 3.6°, and mean planes separations of 3.44 and 3.32 Å, respectively. It is important to point out that this compound was previously isolated from the fungus *Monilinia fructicola* (Hideaki and Takeshi, 1996). In that occasion only UV, MS and ^{1}H NMR spectroscopic data were described.

2.4. Phytogrowth-inhibitory activity of the phytochemicals

Natural products **6–10** were evaluated for their ability to inhibit the seed germination and seedling growth of *A. hypochondriacus* and *E. crusgalli*. Table 1 summarizes the phytotoxic effect of the isolates compounds at three different concentrations. The results in Table 1 are expressed as IC_{50} values (50% inhibitory concentration). As in the case of compounds **1–5** and **11–14** (Macías et al., 2000), the phytotoxins **6–10** were more potent as radical growth inhibitors than as germination inhibitors. Compound **9** was the most active against *E. crusgalli* (IC_{50} was 9.8×10^{-6} M), being more potent than the positive control 2,4-dichlorophenoxyacetic acid (2,4-D, $IC_{50}=8.8\times10^{-4}$ M). However, *A. hypochondriacus* was more sensitive to compounds **7–10**.

2.5. Interaction of phytotoxic compounds with spinach and bovine brain calmodulins

Calmodulin (CaM) is an intracellular receptor for Ca^{2+} in eukaryotes which modulates enzymatic response to calcium. This protein plays a leading role in plant signal

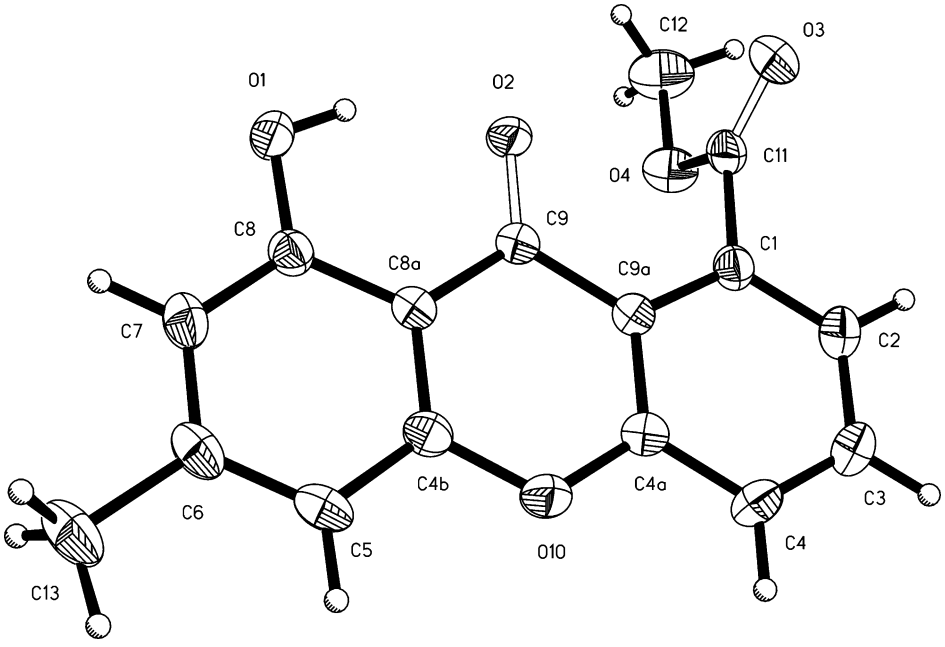

Fig. 1. ORTEP-like view of the molecular structure of 8-hydroxy-6-methyl-9-oxo-9*H*-xanthene-1-carboxylic acid methyl ester (**9**). Thermal ellipsoids at 30% probability level.

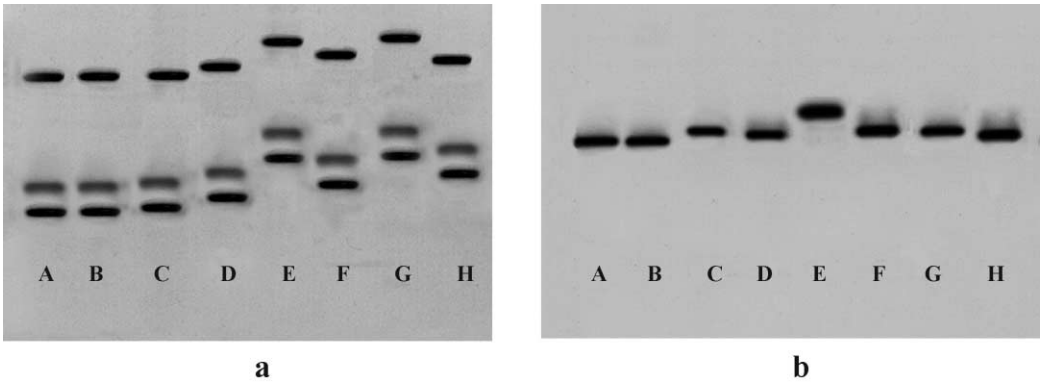

Fig. 2. SDS-PAGE of spinach (a) and bovine (b) calmodulins after treatment with compounds **6–10**. Electrophoresis of 2 μg samples of calmodulins in the presence of 1 mM $CaCl_2$. Pretreatments of the calmodulin samples: 1.5 h at 30 °C in the presence of $CaCl_2$ (A) control; B, DMSO; C, 0.033 μg/ml quercetin in DMSO; (D) **6**; (E) **7**; (F) **9**; (G) **10**; (H) **8**. In all cases were applied 0.033 μg/ml of compounds (**6–10**) in DMSO.

transduction during germination and plant growth modulating the activity of several important plant enzymes (Snedden and Fromm, 1998). Thus, continuing with our search of potential herbicides agents that could interact with CaM, the phytotoxic compounds were further evaluated for their ability to bind spinach and bovine brain Ca^{2+}–CaM complex. The interaction of any compound with Ca^{2+}–CaM complex alters its conformation and changes its electrophoretic mobility as detected in a SDS-PAGE electrophoresis (Leung et al., 1984, 1985). Fig. 2 shows that spinach CaM treated with Ca^{2+} (1 mM) and the isolates (0.033 μg/ml) had a lower electrophoretic mobility than untreated calmodulin. The strongest effect was observed with compound **7**. The mobility shift of bovine brain CaM (Fig. 2) in the presence of compounds **6**–**10** was similar to that of spinach CaM. Once more compound **7** exerted the strongest effect.

According to the results shown in Fig. 2 and those previously reported for compounds **1**–**5** and **11**–**14** (Macías et al., 2000), the interaction of compounds **1**–**14** with both spinach and bovine-brain CaMs could be irreversible (covalent), although the denaturing conditions in the SDS-PAGE electrophoresis would release any phytotoxin bound non-covalently. Thus, to obtain more information about the nature (covalent vs noncovalent) of the interaction of compounds **1**–**14** with CaM, an affinity-based chromatographic procedure employing a bovine brain CaM-agarose column was used (Bonza et al., 1998). After application of the phytotoxic compounds, the CaM-agarose column was eluted under non-denaturing (buffers I and II) and denaturing conditions (buffers III, NaCl and urea). In all cases, the eluents were analyzed spectrophotometrically to detect quantitatively the amount of bound compound (Table 3). According to the results summarized in Table 3, the interaction of compounds **1--7** and **10**–**12** with bovine brain CaM is irreversible (covalent). These phytotoxins remained attached to the CaM-agarose complex after extensive washing in non-denaturing and denaturing conditions. Compounds **8**, **9**, **14** and quercetin, however, were initially absorbed by the CaM–agarose conjugate, subsequently partially eluted with EGTA [ethylene glycol-bis(β-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid] containing buffer II and then totally removed on addition of urea 6M. The last set of results indicated that the interaction of **8**, **9**, **14** and quercetin with bovine brain CaM requires calcium and that the nature of the binding is non covalent. Finally, compound **13** showed a different elution profile and almost half of the phytotoxin remains attached to the CaM-agarose matrix after eluting in different conditions.

The aromatic compounds from *G. polythrix* interact directly with bovine brain and spinach CaM suggesting that these compounds may exert their phytotoxic action by inhibiting CaM-dependent process, although they could also interfere with other cellular metabolic phenomena. Affinity chromatography on CaM–agarose beads indicated that in most cases the interaction is covalent. Apparently the phytotoxins interact with the protein at different binding sites. Further work with calmodulin dependent enzymes will provide new insight about the interaction sites.

3. Experimental

3.1. General

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. IR spectra were obtained

using KBr disks on a Perkin-Elmer FT 1605 spectrophotometer. UV spectra were obtained on a Lambda II UV spectrometer in MeOH solution. Optical rotations were taken on a Perkin-Elmer 241 polarimeter. CD spectra were performed on a JASCO 720 spectropolarimeter at 25 °C in MeOH solution. NMR spectra including COSY spectra, NOESY, HMBC and HMQC experiments were recorded on a Bruker DMX500, in $CDCl_3$, either at 500 (^1H) or 125 (^{13}C) MHz, using tetramethylsilane (TMS) as an internal standard. EI mass spectra were performed using a JEOL SX 102 mass spectrometer. X-ray analysis of compound **9** was accomplished on a Siemens P4/PC diffractometer equipped with graphite-monochromated radiation. Open column chromatography: silica gel 60 (70–230 mesh, Merck). Analytical and preparative TLC were performed on precoated silica gel 60 F254 plates (Merck).

3.2. Fungal material

The fungus *G. polythrix* was isolated from bat guano in Tepozotlán, Morelos, México. Voucher specimens (24486) have been deposited in the National Herbarium (MEXU), Instituto de Biología, Universidad Nacional Autónoma de México, México D.F and in the mycological collection of the Department of Plant Pathology (GAM 5803) University of Georgia, Athens, GA, USA.

Ten 2-l Erlenmeyer flasks, each containing 1000 ml of potato dextrose broth (PDB, Difco), were individually inoculated with one 1-cm^2 agar plug taken from a stock culture of *G. polythrix* maintained at 4 °C on potato dextrose agar (Difco). Flask cultures were incubated in static conditions at 28 °C for 30 days.

3.3. Extraction and isolation

After incubation, the flask contents were combined and filtered. The culture filtrate (10 l) was extracted exhaustively with CH_2Cl_2 (3×10 l). The combined organic phase was filtered over anhydrous Na_2SO_4 and concentrated in vacuo to give a green solid (615.6 mg). In addition, the mycelium was extracted with CH_2Cl_2 (3×2 l). The combined mycelial extract was evaporated to yield 1.9 g of a green solid. The extracts (culture and mycelial) were combined (2.5 g) and subjected to column chromatography on silica gel (50 g) eluting with a gradient of hexane–CH_2Cl_2 (5:5→0:10) and CH_2Cl_2–MeOH (9.9:0.1→0:10). Four hundered and fifty Fractions (30 ml each) were collected and pooled on the basis of their TLC profiles to yield 12 major fractions (FI–FXII). Bioactivity in the phytogrowth bioautographic bioassay (BPIB) showed five active pools: FIV (38.1 mg), FV (95.7 mg), FVI (105.4 mg), FVII (49.8 mg) and FVIII (77.6 mg). Active fraction FIV, eluted with hexane–CH_2Cl_2 (2:8), was resolved by preparative TLC (CH_2Cl_2) to yield **9** (5.2 mg). Phytotoxic fraction FV, eluted with hexane–CH_2Cl_2 (1:9), was applied to a on silica gel (10 g) column which was eluted with a gradient of hexane–CH_2Cl_2 (5:5→0:10) and CH_2Cl_2–MeOH (9.9:0.1→5:5). Ten secondary fractions were obtained (FV-1–FV-10). According to the BPIB, the phytotoxic activity was concentrated in secondary FV-5, eluted with CH_2Cl_2. Extensive TLC (CH_2Cl_2) of fraction FV-5 yielded **6** (5.2 mg) and **7** (4.6 mg), **1** (9.8 mg), **2** (5.1 mg), **3** (4.1 mg) and **4** (3.2 mg). Primary fraction FVI, eluted with CH_2Cl_2, was further resolved on another silica gel (15 g) column using the same elution system as for fraction FV to yield eight secondary fractions (FVI-1–FVI-8). The phytotoxic activity was found in secondary fraction FVI-6, eluted with CH_2Cl_2–MeOH (99:1). Further purification of this fraction by successive preparative TLC (CH_2Cl_2) yielded **10** (13.5 mg), **5** (3.5 mg), **11** (3.8 mg) and **14** (4.0 mg). From active fraction FVII, eluted with CH_2Cl_2–CH_3OH (99:1), spontaneously crystallized **12** (5.2 mg). Finally, fraction FVIII, eluted with CH_2Cl_2–CH_3OH (97:3), was resolved by preparative TLC [CH_2Cl_2–CH_3OH (97:3)] to render compounds **8** (5.3 mg) and **13** (15.2 mg).

3.4. Spectral data of compounds

Compound **6** [(2*S*, 3*R*)-5-hydroxy-6,8-dimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho[2,3-b]-pyran-4-one]. Yellow crystalline needles, mp 165–166 °C; $[\alpha]_D + 128°$ (MeOH; *c* 1); UV (MeOH) λ_{max} nm (log ε) 409.5 (3.85), 320 (3.97), 277.5 (4.54), 252 (4.19), 235 (4.43), 214 (4.26), 209 (4.27); CD (MeOH) $\Delta\varepsilon$ (nm) -1.5×10^4 (314); IR ν_{max} (KBr) cm^{-1}: 3500, 1638, 1610; EIMS *m*/*z* 302 [M^+ (100)], 246 (90), 218 (12), 203 (6), 190 (19); HRMS *m*/*z* 302.330 (calcd for $C_{17}H_{18}O_5$, 302.322); ^1H and ^{13}C NMR (Table 2).

Compound **7** [(2*S*, 3*R*)-5-hydroxy-6,8,10-trimethoxy-2,3-dimethyl-2,3-dihydro-4*H*-naphtho-[2,3-b]-pyran-4-one]. Yellow solid, mp 154–156 °C; $[\alpha]_D + 150°$ (MeOH; *c* 1); UV (MeOH) λ_{max} nm (log ε) 411 (3.34), 320 (3.46), 277.5 (4.07), 252 (3.71), 235 (3.96), 214 (4.28), 209 (4.29); CD (MeOH) $\Delta\varepsilon$ (nm) -1.6×10^4 (314); IR ν_{max} (KBr) cm^{-1}; 3500, 1638, 1610; EIMS *m*/*z* 332 [M^+ (98)], 317 (90), 261 (100), 233 (66), 218 (14); HRMS *m*/*z* 332.351 (calc. for $C_{18}H_{20}O_6$, 332.348). ^1H and ^{13}C NMR (Table 3).

Compound **9** [8-hydroxy-6-methyl-9-oxo-9*H*-xanthene-1-carboxylic acid methyl ester]. Pale yellow needles, mp 197–198 °C; UV (MeOH) λ_{max} nm 233, 256, 289, 300, and 360; IR ν_{max} (KBr) cm^{-1} 3148, 1732 and 1650; EIMS *m*/*z* (rel. int.): 284 [M^+ (48)], 252 (100), 223 (14), 139 (8), 127 (8), 77 (9); ^{13}C NMR NMR ($CHCl_3$, 125 MHz) δ 180.44 (C-9), 169.66 ($CH_3O\underline{O}\underline{C}$-8), 161.45 (C-1), 156.02 (C-8), 155.69 (C-4a), 149.39 (C-3), 134.75, 133.61 (C-10a), 122.50 (C-7), 119.40 (C-5), 117.57 (C-8), 111.73 (C-2), 107.38 (C-4), 106.99 (C-9a), 133.61 (C-10a), 53.09 ($\underline{CH_3}OOC$-8), 22.62 (CH_3-3).

3.5. X-ray crystallographic analysis of compound **9**

Suitable crystal of **9** was obtained from EtOAc by slow evaporation. The crystal belongs to the monoclinic system, space group C2/c with $a=21.014(1)$ Å, $b=10.4145(3)$ Å, $c=13.5140(4)$ Å, $\beta=114.57(5)$ °, $Z=8$, $V=2689.75(17)$ Å^3, $D_c=1.404$ g cm^{-3}, and $\mu(CuK_\alpha)=0.882$ mm^{-1}. Of the 3733 reflections collected, only 1809 were used for structural analysis. The structure was solved by direct methods (SIR92) (Altomare et al., 1994) and refined by the full matrix-least squares methods using SHELXTL97 (Sheldrick, 1997) based on F^2 to a final $R=0.046$ and $Rw=0.134$ with $w^{-1}=[\sigma^2(Fo^2)+(0.0779P)^2+1.1731P]$ where $P=(Fo^2+2Fc^2)/3$. The hydrogen atoms attached to carbon atoms were included at idealized positions following a riding model, the hydrogen atom of the hydroxyl group was identified by difference Fourier methods and its positional parameters refined.

Crystallographic data for the structure reported in this paper have been deposited at the Cambridge Crystallographic Data Center. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

3.6. Bioassays

3.6.1. Phytogrowth-inhibitory bioassays

The phytogrowth inhibitory activity of the extract and pure compounds was evaluated on seeds of *Amaranthus hypochondriacus* L. and *Echinochloa crusgalli* (L.) Beauv by using a Petri dish bioassay (Mata et al., 1998). In addition, a direct bioautographic bioassay system was employed to guide secondary fractionation and speed up the isolation of active compounds. The direct bioautographic assay was carried out as previously described. The results were analyzed by ANOVA ($P<0.05$), and IC_{50} values were calculated by Probit analysis based on percent of radicle growth or germination inhibition. The extract was evaluated at 10, 100 and 1000 μg ml^{-1}. The pure compounds were tested at 1, 10 and 100 μg ml^{-1}. 2,4-D was used as the positive control. The bioassays were performed at 28 °C.

3.6.2. SDS-PAGE of compounds **1–5** with spinach and bovine brain calmodulins

The interaction of the isolated compounds with both spinach and brain calmodulins (Sigma) was performed using SDS gel electrophoresis (SDS-PAGE). SDS-PAGE was done according to previously described procedures using 15% polyacrylamide gels (Leung, et al., 1984, 1985; Liao et al., 1996). The interaction of the phytotoxins with both calmodulins was determined by observing the difference in electrophoretic mobility in the presence of Ca^{2+}. In each case the electrophoresis run was done in triplicate. Quercetin was used as the positive control (Nishino et al., 1984).

3.6.3. CaM affinity chromatography

The non-reversible effect of the compounds was determined by affinity chomatography employing a bovine brain calmodulin-agarose (SIGMA) column (Bonza et al., 1998). One milligram of each compound was dissolved in 1 ml of DMSO and 10 μl of this mixture was loaded to 200 μl bed volume of calmodulin–agarose previously equilibrated with buffer I (20 mM Tris–HCl, pH 7.0, 1 mM $CaCl_2$). The column was eluted consecutively with five volumes of buffer I, five volumes of buffer II (20 mM Tris–HCl, pH 7.0, 1 mM EGTA), five volumes of buffer III (20 mM Tris–HCl, pH 8.0, 1 mM $CaCl_2$), five volumes of NaCl 1 M and five volumes of urea (6M). In each case aliquots of 200 μl were collected, concentrated in vacuo and analyzed spectrophotometrically to determine the retention of each compound. 3,4′-Dihydroxy-5,5′-dimethoxybibenzyl, obtained from *Scaphyglottis livida* (Estrada et al., 1999), was used as a negative control since this compound was not retained in the column after eluting with buffer I.

Received 2 January 2001; received in revised form 19 April 2001

Abstract

Exogenous hydroxyl radical treatments increased the levels of β-*N*-oxalyl-L-α, β-diaminopropionic acid (ODAP) in grass pea seedlings. Lipid peroxidation initiated by hydroxyl radicals can be alleviated when grass pea seedlings were pretreated with exogenous ODAP, suggesting that ODAP might act as an hydroxyl radical scavenger in vivo. Competing with salicylate for hydroxyl radicals in the hydroxyl radical generating/detecting system, ODAP's in vitro hydroxyl radicals scavenging activity was assessed to confirm this result, and the role of ODAP as an effective hydroxyl radical scavenger is discussed. © 2001 Elsevier Science Ltd. Keywords: *Lathyrus sativus*; Leguminosae; Legume; Grass pea; β-*N*-Oxalyl-L-α, β-diaminopropionic acid; Hydroxyl radicals

1. Introduction

Grass pea (*Lathyrus sativus* L.), a grain legume rich in protein, is cultivated as a drought tolerant food crop requiring minimal care in semi-arid areas of Africa, Asia and Europe. It is very popular since it can give acceptable yields in dry seasons, under conditions when lentils or chickpeas fail (Praveen et al., 1994). In spite of its extreme drought tolerance, grass pea has no morphological characteristics indicative of this tolerance. Under drought conditions, the production of active oxygen species increases significantly (Smirnoff and Colombé, 1988), and many plants react to osmotic stress by increasing the concentration of proline or other amino acids to scavenge active oxygen species, including hydroxyl radical (•OH) (Smirnoff and Cumbes, 1989). It has been reported that grass pea contains a nonprotein amino acid, called β-*N*-oxalyl-L-α, β-diaminopropionic acid (ODAP), that causes animal lathyrism (Malathi et al., 1970). Our previous studies have shown that ODAP accumulated gradually in grass pea when it is subjected to polyethylene glycol stress (Xing et al., 2000). So it is important and of interest to assess whether ODAP might play a role in drought stress (Lambein et al., 1990). In the present investigation, we tested the ability of ODAP to scavenge hydroxyl radicals (•OH), one of the most reactive and toxic active oxygen species.

2. Results and discussion

2.1. The effects of •OH on the contents of ODAP and malondialdehyde in grass pea seedlings

Among the active oxygen species, •OH may be responsible for most of the oxidative damage during drought stress (Shen et al., 1997). It is highly reactive and, therefore, potentially damaging to cells, in particular by initiating lipid peroxidation (Smirnoff and Cumbes, 1989). In the present paper, the effects of •OH stress on the levels of ODAP and malondialdehyde (MDA) in grass pea seedlings were examined. •OH radical species were generated by Fenton reaction ($Fe^{2+} + H_2O_2 \rightarrow {}^{\bullet}OH + Fe^{3+} + OH^-$) and the "•OH concentration" in this paper was represented by the concentrations of the reagents, i.e. Fe^{2+} and H_2O_2 in the generation system. As shown in Fig. 1, the levels of ODAP and MDA increased with increases of •OH radical forming capacity. At lower concentrations

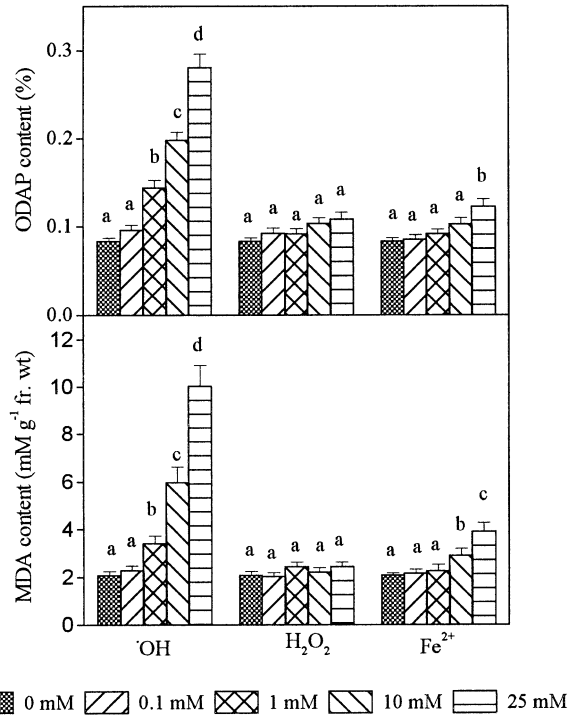

Fig. 1. The effect of ·OH, H_2O_2 and Fe^{2+} on the contents of ODAP and MDA in grass pea seedlings. Values denoted by the same letter do not significantly differ at $P<0.05$.

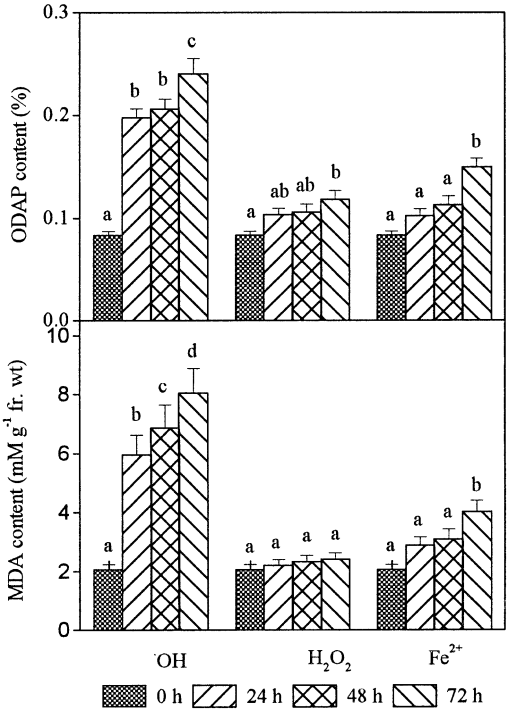

Fig. 2. Time courses of the effect of ·OH (10 mM), H_2O_2 (10 mM) and Fe^{2+} (10 mM) on the contents of ODAP and MDA in grass pea seedlings. The illustrations and significance of the letters are the same as in Fig. 1.

(0.1 mM), ODAP and MDA changed little in grass pea foliage. But at 1, 10 and 25 mM Fe^{2+} + H_2O_2 concentrations, the contents of ODAP were about 173, 237 and 336% of the control and the contents of MDA were about 164, 287 and 484% of the control, respectively. When grass pea foliage was stressed in 10 mM Fe^{2+} + H_2O_2 for 24, 48 and 72 h, the contents of ODAP and MDA increased rapidly and the former amounted to 237, 247 and 288% of the control, the later 287, 331 and 388% of the control, respectively (Fig. 2). These results indicate that with increasing levels of ·OH stress or over time at the same concentration (10 mM) of stress, an increase in lipid peroxidation appeared, along with ODAP accumulation in grass pea seedlings.

In order to make sure that the increase of ODAP and MDA resulted from the effect of ·OH, but not that of Fe^{2+} and H_2O_2, the main reagents in the Fenton reaction mixture, grass pea leaves were treated with Fe^{2+} and H_2O_2 individually. No significant changes in the levels of ODAP and MDA were observed by the presence of H_2O_2 alone at different concentrations up to 25 mM or with different treatment times (Figs. 1 and 2). This result indicated that H_2O_2 could not induce enhancement of ODAP levels or stimulate the increase of MDA. ODAP content amounted to 123 and 146% of the control when Fe^{2+} increased to 10 and 25 mM, respectively, but the levels had not been affected by the lower concentrations of Fe^{2+} (Fig. 1). When grass pea seedlings were treated with 10 mM Fe^{2+} for 24, 48 and 72 h, ODAP content increased gradually to 123, 135 and 179% of control (Fig. 2). Compared with ·OH, however, ODAP and MDA induced by Fe^{2+} were much less. Taken together, the results of the individual treatments of H_2O_2 and Fe^{2+} suggest that it is the ·OH generated by the Fenton reaction that causes the enhancement of ODAP and MDA levels in grass pea seedlings exposed to $Fe^{2+} + H_2O_2$. Statistical analysis revealed that lipidoxidation and accumulation of ODAP induced by Fe^{2+} only occurred under higher concentrations (above 10 mM indicated by MDA and 25 mM indicated by ODAP) or long-term treatment (72 h) when exposed to Fe^{2+} stress. Although iron is an essential mineral nutrient required for normal growth and development of plants at low concentrations, excess iron leads to oxidative stress. It has been reported that genes coded for both iron uptake and oxidative stress response are regulated by the same transcription factor in *E.coli* and yeast (Kampfenkel et al., 1995).

2.2. The effect of pretreatment with ODAP and DMSO on lipid peroxidation initiated by ·OH or Fe^{2+} in grass pea seedlings

The above results showed that ODAP could accumulate under oxidative stress. It has been proposed that the oxidation of membrane lipids, which may occur in plant cells exposed to adverse conditions, is a reliable indication of oxidative stress (Moran et al., 1994). In order to

determine whether the accumulated ODAP plays a role in moderating oxidative stress, grass pea seedlings pretreated with ODAP or DMSO were exposed to Fe^{2+} + H_2O_2 or Fe^{2+} stress and then MDA, the product of lipid oxidation, was measured. As shown in Fig. 3, both ODAP and DMSO pretreatments inhibited the formation of MDA initiated by •OH or Fe^{2+}, which indicated that ODAP could act as an effective scavenger of •OH in vivo. It is noteworthy that pretreatment with ODAP could significantly suppress the increase of MDA induced by higher concentrations of Fe^{2+} in grass pea seedlings. Minotti and Aust (1987) have indicated that oxidative stress induced by Fe^{2+} at high concentration is mainly due to the formation of •OH in superoxide-driven Fenton reaction catalyzed by iron. Therefore, the alleviation of Fe^{2+} stress after ODAP pretreatment might be owed to the ability of ODAP to scavenge •OH.

2.3. In vitro •OH scavenging activity of ODAP

The •OH scavenging activity of ODAP in vitro was assessed by allowing it to compete with salicylate for •OH in the •OH generating/detecting system (Smirnoff and Cumbes, 1989). A reduction in hydroxylation indicates an effective competition for •OH. Our results showed that the •OH scavenging activity of ODAP and DMSO increased as their concentrations increased (Fig. 4), this suggested that ODAP was able to scavenge •OH, which was in accordance with the result obtained in vivo that ODAP could inhibit the formation of MDA.

In conclusion, the results presented in this paper prove that ODAP could protect cells against internally generated •OH or supplement endogenous radical scavenging mechanisms. Since oxidative stress is a major damaging factor in plants exposed to drought stress, the accumulation of ODAP in grass pea under drought stress may share the same mechanism with that under •OH stress. Further experiments are needed to determine the extent to which ODAP could play this role in vivo in grass pea and to explore the mechanisms of the ODAP accumulation response to oxidative stress.

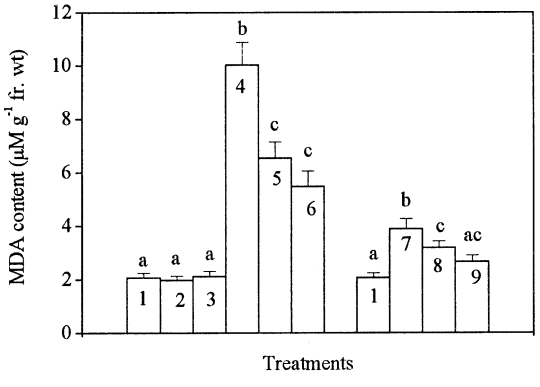

Fig. 3. The effect of pretreatment with ODAP or DMSO on the content of MDA in grass pea seedlings exposed to •OH or Fe^{2+} stress. The set of bars on the left refer to •OH stress and the set on the right refer to Fe^{2+} stress. 1—control, 2—ODAP(30 mM), 3—DMSO(30 mM), 4—•OH (25 mM), 5—ODAP + •OH, 6—DMSO + •OH, 7—Fe^{2+}(25 mM), 8—ODAP + Fe^{2+}, 9—DMSO + Fe^{2+}. The illustrations and significance of the letters are the same as in Fig. 1.

3. Experimental

3.1. Plant materials and growth conditions

Grass pea seeds were surface-sterilized with 0.2% (w/v) $HgCl_2$ for 10 min and rinsed with running water, then were soaked in water and germinated in the dark at 4 °C for 3–4 days. The seeds were grown in a Hoagland nutrient solution in a growth cabinet (PGV36, Canada) at 23/10 °C with a photoperiod of 16/8 h light/dark. Foliage excised from 15-day-old seedlings were used for all investigations.

3.2. Treatments of hydroxyl radicals and antioxidants

•OH was generated by Fenton reaction (Fe^{2+} + $H_2O_2 \rightarrow$ •OH + Fe^{3+} + OH^-). The final concentrations of each Fenton reagent were 0.1, 1, 10 and 25 mM. Foliage excised from seedlings was floated in the system used to produce •OH for 24 h with the photoperiod as described above. •OH takes effect in plant cells since it can be formed intracellularly after uptake of Fe^{2+} and H_2O_2. Another group was treated with 10 mM Fenton reagents for 24, 48 and 72 h, respectively. The •OH generating solution was refreshed every 12 h. To examine the effect of ODAP on lipid peroxidation initiated by •OH, the foliage was pretreated with 30 mM ODAP or 30 mM dimethylsulfoxide (DMSO), a specific scavenger of •OH, for 12 h in darkness and then exposed to Fe^{2+} + H_2O_2 treatment for 24 h. Foliage treated with distilled water was used as controls.

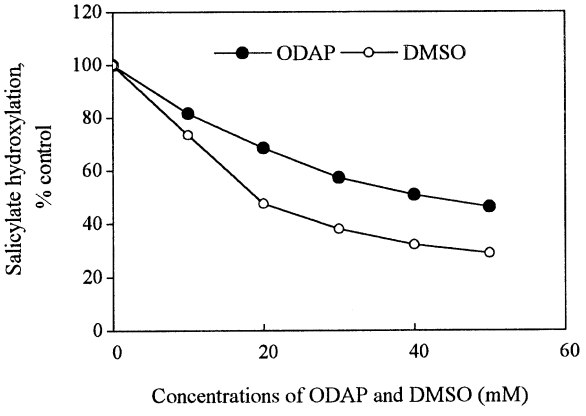

Fig. 4. The effect of ODAP or DMSO on salicylate hydroxylation initiated by •OH generated by ferrous and hydrogen peroxide.

3.3. Assessment of ODAP on •OH scavenging activity in vitro

•OH was generated by the Fenton reaction and detected by its ability to hydroxylate salicylic acid as described by Smirnoff and Cumbes (1989). The reaction mixture, total volume of 3 ml, contained 150 mM potassium phosphate buffer (pH 7.4), 0.26 mM ascorbic acid, 0.15 mM $FeSO_4$, 0.6 mM H_2O_2, 2 mM Na salicylate and varying concentrations of ODAP. The •OH scavenging activity of ODAP was assessed according to its ability to compete with salicylate for •OH. To ascertain the effect of ODAP, the specific •OH scavenger DMSO was also added to the •OH generating / detecting system and served as the reference.

3.4. Determination of ODAP content and lipid peroxidation

ODAP contents were measured as described by Wang et al. (2000): about 20 mg of dried foliage was accurately weighed and added to 2 ml of ethanol–water (3:7, v/v), shaken briefly and sonicated for 30 min (with ice added and water temperature kept at about 8 °C), then agitated with a magnetic stirrer for 2 h, centrifuged for 15 min at 15,000 *g* and filtered. A known amount of sample extract was dried under vacuum. The residue was dissolved in 100 μl $NaHCO_3$ solution (0.5 M), then 100 μl of the derivatizing reagent (100 mg of 1-fluoro-2,4-dinitrobenzene in 10 ml of acetonitrile) was added and the solution was thoroughly mixed. The derivatization was completed in 30 min at 60 °C. After cooling to room temperature, the reaction mixture was added to 0.8 ml KH_2PO_4 solution (0.01 M), vortexed for several seconds and 20 μl of the product was taken for HPLC analysis. The HPLC system consisted of a Waters Model 600E pump, a Cartridge C_{18} (5 μm) column 3.9×150 mm, a column heater and a Model 2487 dual wavelength absorbance detector set at 360 nm (all from Waters). Millenium 32 software, from Waters, was used to control system operation and collect and analyse data. The mobile phase A consisted of 0.03 M K_2HPO_4 and 1% dimethyl formamide in water (v/v) and was adjusted to pH 5.6 with glacial acetic acid, whereas the mobile phase B was acetonitrile. The mobile phase solutions were filtered through a 0.45 μm membrane filter and degassed before use. The column was thermostated at 26 °C and operated at a flow rate of 1.0 ml/min.

Determination of lipid peroxidation involved measuring the amount of MDA, a product of lipid peroxidation, in the grass pea foliage (0.5g fr. wt) by the thiobarbituric acid reaction (Stewart and Bewley, 1980). The crude extract was mixed with the same volume of a 0.5% (w/v) thiobarbituric acid solution containing 20% (w/v) tricloroacetic acid. The mixture was heated at 95 °C for 30 min and the reaction was stopped by quickly placing in an ice-bath. The cooled mixture was centrifuged at 10,000 *g* for 10 min, and the absorbance of the supernatant at 532 and 600 nm was read. After subtracting the non-specific absorbance at 600 nm, the MDA concentration was determined by its extinction coefficient of 155 mM^{-1} cm^{-1}.

3.5. Statistical analysis

The results presented here were the mean of five replicates. Means were compared by one way analysis of variance and Duncan's multiple range test at the 5% level of significance.

Acknowledgements

We wish to thank Dr. Wang Fei for his kind help for the determination of ODAP. The work was supported with the NKBRSF project of china (G200018603) and Science Foundation of Gansu Province (YS01-A25-004).

Abstract

Ethyl acetate extracts of the air-dried fruits of *Ferula kuhistanica* afforded three daucane esters: kuhistanicaol H, I and J, together with nine other known compounds. Their structures were established on the basis of spectroscopic evidence. Isolated compounds in this paper and previously reported compounds from the roots and stems of *F. kuhistanica* were tested for antibacterial activity. Some of them were selectively toxic against Gram-positive bacteria, including methicillin-sensitive and methicillin-resistant *Staphylococcus aureus* (MSSA and MRSA). © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Ferula kuhistanica*; Umbelliferae; Sesquiterpenes; Daucane esters; Kuhistanicaol H, I, J; Antibacterial activity; MSSA; MRSA

1. Introduction

The exclusively Old World genus *Ferula* belongs to the family Umbelliferae, and has about 130 species distributed throughout the Mediterranean to Central Asia. The chemical constituents of this genus have been studied by many groups. Several species of this genus have been used in folk medicine as tranquilizers and for the treatment of digestive disorders, rheumatism, headache, arthritis, dizziness, toothache, etc. (Gonzalez and Barrera, 1995). *Ferula kuhistanica* has been used in Uzbekistan folk medicine to treat skin diseases and wounds. In previous studies, we investigated the constituents of the roots and stems of *F. kuhistanica* (Chen et al., 2000a,b). We report here the structural elucidation of three new daucane-type sesquiterpene, kuhisutanicaols H-J (**1**–**3**) and nine known compounds from the fruits of *F. kuhistanica*. To confirm the evidence of this folk medicine for the treatment of skin diseases and wounds, we tested the antibacterial activities of some isolated compounds from the roots, stems, and fruits of *F. kuhistanica* against several bacterial species, including methicillin-resistant *Staphylococcus aureus* (MRSA).

2. Results and discussion

Ethyl acetate extracts of the air-dried fruits of *F. kuhistanica* were separated by repeated column chromatography to give three new compounds; kuhistanicaol H (**1**), I (**2**) and J (**3**), together with nine known compounds; jaeschkeanadiol *p*-hydroxybenzoate (ferutinin) (**4**), jaeschkeanadiol vanillate (**5**) (Miski et al., 1983), lancerotriol 9α-(*p*-hydroxybenzoate) (**6**) (Fraga et al., 1985), lancerotriol 9β-(*p*-hydroxybenzoate) (El-Sayed, 1990), lancerodiol *p*-hydroxybenzoate, 4β,8β-dihydroxy-6α-vanilloxdauc-9-ene, isolancerotriol 6-vanillate (Miski and Jakupovic, 1990), ferutriol 5α-(*p*-hydroxybenzoate) (Ahmed, 1990), isolancerotriol 2-*epi*-5-*p*-hydroxybenzoate (Ahmed, 1991).

Kuhistanicaol H (**1**) showed absorption bands for hydroxy (3285 cm^{-1}), ester (1698 cm^{-1}), and benzene

(1609 cm^{-1}) groups in the IR spectrum. The UV spectrum of **1** showed the presence of an aromatic ring (258 nm). The ^1H NMR spectrum exhibited the presence of an angular methyl [δ_H 1.15 (3H, *s*)], an isopropyl group [δ_H 0.74, 0.90 (each 3H, *d*, $J=6.8$ Hz), 2.10 (1H, *m*)] and a *p*-hydroxy benzoic acid [δ_H 6.73 (2H, *d*, $J=8.7$ Hz), 7.81 (2H, *d*, $J=8.7$ Hz)] (Table 1). The ^{13}C NMR spectrum of **1** revealed the presence of an ester carbonyl (δ_C 168.4), a benzene ring (δ_C 116.1×2, 123.0, 133.0×2, 163.5), three oxygenated methines (δ_C 62.4, 74.4, and 75.2), two oxygenated quaternary carbons (δ_C 58.8, 87.6), one quaternary carbon, four methyls, three methylenes and two methines (Table 2). These facts were consistent with a molecular formula of $C_{22}H_{30}O_6$, which was supported by HR–FAB–MS data (*m/z* 413.1937 $[M+Na]^+$).

Except for the presence of an oxygenated carbon signal at δ_C 62.4 in **1**, the ^{13}C NMR spectrum of compound **1** was very similar to that of jaeskeanin (Razdan et al., 1989). The ^1H–^1H COSY spectrum of **1** showed proton correlations of δ_H 2.48 (5-H) with δ_H 5.37 (6-H); δ_H 2.89 (9-H) with δ_H 1.45 (10-Hα) and δ_H 1.99 (10-Hβ); δ_H 7.81 (2′-H) with δ_H 6.73 (3′-H). In the HMBC spectrum of **1**, the correlations of δ_H 3.94 (7-H) with δ_C 51.0

6′	133.0	124.4	133.0
7′	168.4	165.7	168.1
OCH_3	–	56.2	

Compounds **1** and **3** were measured in CD_3OD; compound **2** was measured in $CDCl_3$.

(C-5), δ_C 74.4 (C-6) and δ_C 58.8 (C-8); δ_H 0.74 (12-H_3) with δ_C 87.6 (C-4); δ_H 1.37 (14-H_3) with δ_C 62.4 (C-7), δ_C 58.8 (C-8) and δ_C 75.2 (C-9); δ_H 1.15 (15-H_3) with δ_C 45.6 (C-1), δ_C 40.0 (C-2), δ_C 51.0 (C-5) and δ_C 41.7 (C-10) were observed. Based on these findings, compound **1** was deduced to be a daucane-type sesquiterpene (Gonzalez and Barrera, 1995). In addition, the correlations of 5-H with 13-H_3 and 7-H in the NOESY spectrum showed that the configuration of the isopropyl group is α while that of 7-OH is β. Furthermore, the correlations of 6-H with 15-H_3 and 14-H_3, and correlations of 9-H with 14-H_3 and 15-H_3 showed that the configuration of the ester moiety and epoxide is α. Therefore, the structure of **1** was determined to be as shown in Fig. 1.

The ^{13}C NMR spectrum of kuhistanicaol I (**2**) was very similar to that of kuhistanicaol D (Chen et al., 2000b), except that **2** had a ketone group (δ_C 210.5). The negative HR–FAB–MS of **2** gave a molecular formula of $C_{23}H_{30}O_7$. In the ^1H–^1H COSY spectrum of **2**, correlations of δ_H 5.47 (6-H) with δ_H 3.44 (5-H), δ_H 2.34 (7-Hα) and δ_H 2.62 (7-Hβ); δ_H 5.36 (9-H) with δ_H 2.87 (10-H) were observed. The carbon chemical shift of C-1 (δ_C 60.5) of **2** showed a significant downfield shift compared with those for other daucane-type sesquiterpenoids (δ_C 40–45) (Chen et al., 2000b), and the signal due to 3-H_2 of **2** appeared to be of the AB type. Consequently, the ketone group could be placed at C-2. Correlations of 6-H with 5H and 11-H, and 15-H_3 with 10-H were observed in the NOESY spectrum. Therefore, the configuration of the isopropyl group and 10-OH is α, while that of the ester moiety is β. Thus, the structure of **2** was determined to be as shown. Many Daucane-type sesquiterpene esters were isolated from the natural source and these compounds have the ester at C-6. The configuration of this ester is almost α position but compound **2** has rare β position.

The ^{13}C NMR spectral data of kuhistanicaol J (**3**) were very similar to those of 4β, 8β, 9α-trihydroxy-6α-*p*-hydroxybenzoyloxydaucane (Ahmed, 1990), except for a methine carbon with a hydroxy group at δ_C 76.4 instead of a ketone at δ_C 215.0 in **3**, as well as the downfield shift of C-8 (δ_C 78.3) and C-10 (δ_C 51.6). In addition, the ^1H NMR spectrum of 10-H_2 of **3** appeared to be of the AB type. In the ^1H–^1H COSY spectrum of **3**, correlations of δ_H 5.47 (6-H) with δ_H 2.40 (H-5), δ_H 2.15 (7-Hα) and δ_H 2.36 (7-Hβ) were observed. Thus, the ketone could be placed at C-9. This assignment was in agreement with the NOESY spectrum, in which 15-H_3 was correlated with 6-H. Also, 5-H was correlated with 7-Hα, and 7-Hα was correlated with 14-H_3. Therefore, the configuration of the isopropyl group and the ester moiety is α, and that of 8-OH is β. Hence, the structure of **3** was determined to be as shown in Fig. 1.

To confirm the evidence for this folk medicine, three compounds (**4**–**6**) isolated from the fruits and former reported six compounds (Fig. 2); kuhistanol D (**7**), kuhistanol A (**8**), kuhistanicaol A (**9**), 3-farnesyl-*p*-hydroxybenzoic acid (**10**), 5α-*p*-hydroxybenzoyloxydauc-2-ene-1-one (**11**), kuhistanol E (**12**) (Chen et al., 2000a,b, 2001) from the roots and stems of *F. kuhistanica* were tested for antibacterial activity by the disc-diffusion test for methicillin-sensitive *S. aureus* (MSSA) and methicillin-resistant *S. aureus* (MRSA). Compounds **4**, **5**, **7**, and **8** showed significant activity by the disc-diffusion test. These compounds were measured for minimum inhibitory concentration (MIC) values against eight species of Gram-positive and Gram-negative bacteria: *S. aureus* (MSSA, MRSA), *Staphylococcus epidermidis*, *Enterococcus faecalis*, *Bacillus subtilis*, *Salmonella typhimurium, Proteus mirabilis*, and *Escherichia coli* (Table 3). Compared with other natural compounds, compounds **4** and **5** showed significant activity against the Gram-positive bacteria; *S. aureus* (MSSA, MRSA), *S. epidermidis, E. faecalis*, and *B. subtilis* (Sato et al., 1997) similar to those of standard antibiotics (ampisillin and chloramphenicol).

To study the relationship between bioactivity and structure, compound **4** was hydrolyzed under acidic conditions to give compound **13** and *p*-hydroxybenzoic acid. The MIC values of both compounds were measured. Compound **13** showed an MIC value of 125 μg/ml, while *p*-hydroxybenzoic acid was inactive (Table 3). These results showed that the bioactivity of compound **4** depends on both the sesquiterpene unit and the *p*-hydroxybenzoic acid substituent.

F. kuhistanica has been used in Uzbekistan folk medicine to treat skin diseases and wounds. Our findings

regarding the antibacterial activity of isolated compounds from *F. kuhistanica* confirmed the value of this plant in the folk medicine of Uzbekistan.

3. Experimental

3.1. General

^{1}H NMR 400 MHz, ^{13}C NMR 100 MHz with TMS as an int. standard; MS: JEOL JMS SX102A instrument; CC: silica gel, Sephadex LH-20 (Pharmacia); HPLC: silica gel (Si60, Hibar RT 250-25, Merck).

3.2. Plant material

The fruits of *F. kuhistanica* were collected in July 1998 from Uzbekistan. Herbarium specimens were deposited in the herbarium of the Institute of Botany and Botanical Garten, Academy of Sciences, Uzbekistan. The plant material was identified by Professor Ozodbek Ashurmetov.

3.3. Extraction and isolation

The fruits of *F. kuhistanica* (600 g) were crushed and extracted with hexane. The residue was extracted with OEtAc. The OEtAc extracts were concd in vacuo to give a residue (60 g), which was subjected to CC on a silica gel column eluted with solvents of increasing polarity (Hex–OEtAc) to give 16 frs. Fr. 9 (5.4 g) was subjected to CC on silica gel with $CHCl_3$–MeOH to give 4 frs. (9.1–9.4). Fr. 9.1 (179.6 mg) was separated by HPLC (silica, hexane–OEtAc = 1:1) to give **2** (2.5 mg), **3** (4.3 mg), ferutriol 5α-(*p*-hydroxybenzoate) (5.3 mg) and isolancerotriol (5.9 mg). Fr 9.2 (485.5 mg) was separated by HPLC (silica, hexane–OEtAc = 1:1) to give lancerotriol 9α-(*p*-hydroxybenzoate) (74.1 mg) and isolancerotriol 2-*epi*-5-*p*-hydroxybenzoate (9.1 mg). Fr. 9.3 (512.1 mg) was subjected to CC on silica gel and separated by HPLC (silica, hexane–OEtAc = 1:1) to give 4β, 8β-dihydroxy-6α-vanilloxdauc-9-ene (12.5 mg). Fr. 9.4 (3.0 g) and fr. 11 (2.5 g) were subjected to CC on Sephadex LH-20 with MeOH and CC on silica gel with $CHCl_3$–MeOH, and then separated by HPLC (silica, hexane–OEtAc = 1:2) and preparative TLC (Hex–OEtAc = 1:2) to give **5** (2.5 mg). Fr. 3 (3.3 g) was subjected to CC on silica gel with hexane–OEtAc to give **4** (2.3 mg) and fr. 3.2. Fr. 3.2 (353.9 mg) was subjected to CC on silica gel and separated by HPLC (silica, hexane–OEtAc = 1:1, $CHCl_3$–MeOH = 95:5) to give **1** (4.8 mg), lancerotriol 9β-(*p*-hydroxybenzoate) (5.3 mg) and lancerodiol *p*-hydroxybenzoate (73.1 mg).

3.4. Kuhistanicaol H (*1*)

$[\alpha]_D^{25}$ +115.6°(MeOH *c* 0.30); IRν_{max}^{KBr} cm^{-1}: 3285, 1698, 1609, 1594, 1271, 1165, 1096, 1041; UVλ_{max}^{MeOH} nm (log ε): 258 (4.3); ^{1}H NMR δ_H(CD_3OD): Table 1; ^{13}C NMR (CD_3OD): Table 2; HR–FAB–MS *m/z* 413.1937 $[M+Na]^+$, $C_{22}H_{30}O_6Na$, requires 413.1940.

3.5. Kuhistanicaol I (*2*)

$[\alpha]_D^{25}$ +44.3°(MeOH *c* 0.50); IRν_{max}^{KBr} cm^{-1}: 3529, 1706, 1601, 1513, 1281, 1100; UVλ_{max}^{MeOH} nm (log ε): 261 (4.2); ^{1}H NMR δ_H($CDCl_3$): Table 1; ^{13}C NMR ($CDCl_3$): Table 2; HR–FAB–MS *m/z* 417.1878 $[M-H]^-$, $C_{23}H_{29}O_7$, requires 417.1913.

3.6. Kuhistanicaol J (*3*)

$[\alpha]_D^{25}$ +41.6°(MeOH *c* 0.30); IRν_{max}^{KBr} cm^{-1}: 3734, 1703, 1609, 1508, 1278; UVλ_{max}^{MeOH} nm (log ε): 258 (4.0); ^{1}H NMR δ_H (CD_3OD): Table 1; ^{13}C NMR (CD_3OD): Table 2; HR–FAB–MS *m/z* 389.1937 $[M-H]^-$, $C_{22}H_{29}O_6$, requires 389.1964.

3.7. Antibacterial activity

3.7.1. Preparation of bacterial cells

MRSA, methicillin-sensitive *S. aureus* (MSSA) strains (Sato et al., 2000) and other bacterial strains listed in Table 3 were from laboratory stock cultures. After culturing all strains on Muller–Hinton agar (Difco, Detroit, MI, USA), the cells were resuspended in Muller–Hinton broth (Difco) to give 10^8 colony-forming units/ml; the resuspended cells were then incubated.

3.7.2. Determination of antibacterial activity

During the extraction and purification procedure, disc-diffusion tests were performed with Whatman AA discs (13.0 mm) containing various concentrations of extract and DMSO as a control. The discs were placed on Mueller–Hinton agar inoculated with 10^5 colony-forming units/ml of MSSA and MRSA. The zone of inhibition was determined after incubation at 37 °C for 24 h. The disc containing DMSO showed no zone of inhibition. To estimate the antibacterial activity of the purified isolates, the minimum inhibitory concentration (MIC) was determined using Muller–Hinton agar according to the method described by the Japanese Society for Antimicrobial Chemotherapy (1981). Cell suspensions (1×10^6 colony-forming units/ml) of the examined bacteria were inoculated onto agar plates using a replicating device. Plates were read after 24 h of incubation at 37°. Ampicillin and chloramphenicol were performed by similar method.

Received 23 April 2001; received in revised form 18 June 2001

Abstract

Bioassay-guided fractionation of the leaves from *Andira inermis* was undertaken as part of a screening program to verify the traditional use of herbal remedies against malaria. Among the isolated phenolic compounds three novel 2-arylbenzofuran-3-carbaldehydes, andinermal A–C, were obtained together with a new flavanonol glycoside, taxifolin-3-*O*-(3″-*O*-*trans*-cinnamoyl)-α-L-rhamnopyranoside. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Andira inermis*; Fabaceae; Antiplasmodial activity; *Plasmodium falciparum*; 2-Arylbenzofuran-3-carbaldehydes; Andinermal A–C; Flavonoids; Isoflavones

1. Introduction

During a screening program on antimalarial compounds from plant sources we investigated *Andira inermis* (W. Wright) H.B.K., Fabaceae, a tall tree characterised by a thick trunk and redpurple flowers, native from southern Mexico to northern South America. From the phytochemical point of view *A. inermis* is known to contain several isoflavones and related compounds as well as β-sitosterol and stigmasterol (Cocker et al., 1962; Lock de Ugaz et al., 1991). Recently, we demonstrated that the crude lipophilic extracts of stems and leaves showed moderate in vitro activity against *Plasmodium falciparum*; further investigation of the stems led to the isolation of active isoflavones (Kraft et al., 2000). In the present study we report the isolation and structural elucidation of three novel 2-arylbenzofuran-3-carbaldehydes as well as a new flavanonol glycoside from the active fractions of the leaves. In vitro antiplasmodial effects of the compounds were assessed.

2. Results and discussion

Bioassay-guided fractionation of the extracts from the leaves of *A. inermis* led to the isolation of the isoflavones afformosin (**1**; Caballero and Smith, 1986), calycosin (**2**; Kobayashi et al., 1985), formononetin, and prunetin (**3**, **4**; Kraft et al., 2000). Furthermore **5** and **6** turned out to be the flavanonol 3-*O*-α-L-rhamnosides astilbin (Tschesche et al., 1979) and engelitin (Reisch et al., 1984), respectively. Whereas **2**, **3**, and **4** had already been reported as constituents of the stems (Kraft et al., 2000), **1**, **5** and **6** could be isolated for the first time from *A. inermis*. Additionally four novel compounds could be obtained which turned out to be three 2-arylbenzofuran-3-carbaldehydes (**7**–**9**) and a *trans*-cinnamic acid ester of the taxifolin glycoside astilbin (**10**). Their structural elucidation was carried out by EIMS, FAB–MS, and HR–EIMS, ^{1}H NMR, ^{13}C NMR, HMBC, and COSY as well as NOE experiments.

The EIMS of **7** exhibited an ion peak at m/z 344 $[M]^+$, its molecular formula was determined as $C_{18}H_{16}O_7$ by HR–EIMS. The signals of the ^{13}C NMR (Table 1) indicated the presence of three methoxy groups, one carbonyl group and fourteen additional carbon atoms. They were similar to published data of 2-arylbenzofuran-3-carbaldehydes (ebenfuran II and ebenfuran III) from *Onobrychis ebenoides* Bioss & Spuner, Fabaceae (Halabalaki et al., 2000). The signal for a carbonyl group at 192 ppm could be correlated to the signal at 9.81 ppm (1H, *s*) in the ^1H NMR spectrum (Table 1), thus hinting to a carbaldehyde. Additionally the ^1H NMR spectrum revealed a signal at 10.15 ppm (1H, *s*) corresponding to a chelated hydroxy group. Furthermore the ^1H NMR displayed characteristic signals of a pair of *meta*-coupled protons at 6.36 ppm (1H, *d*, $J = 1.9$ Hz, H-5) and 6.72 ppm (1H, *d*, $J = 1.9$ Hz, H-7), as well as of *ortho*-coupled protons at 6.99 ppm (1H, *d*, $J = 8.6$ Hz, H-5′) and 7.22 ppm (1H, *d*, $J = 8.6$ Hz, H-6′). In the HMBC the chelated hydroxy proton, the carbaldehyde, and both *meta*-coupled protons showed correlation to a carbon at 108 ppm corresponding to C-3a of 2-arylbenzofuran-3-carbaldehydes (Fig. 1; Table 1). The positions of the three methoxy groups (3.82, 3.85, and 3.97 ppm) were established by NOESY and HMBC experiments. Between the methoxy singlett at 3.85 ppm and the signals for H-5 and H-7 NOESY crosspeaks could be observed, as well as between the singlett at 3.92 ppm and the doublett of H-5′. The position of the third

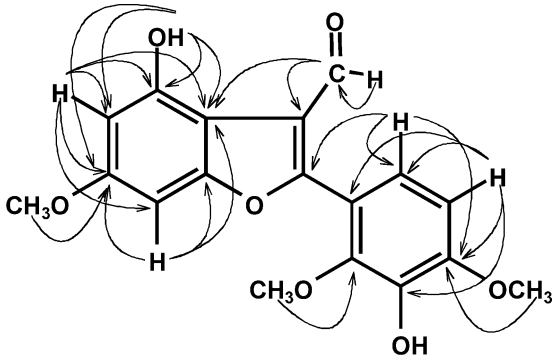

Fig. 1. HMBC correlations of compound **7**.

methoxy group could be deduced from the HMBC spectrum (Fig. 1; Table 1). Thus, **7** is 2-(2′, 4′-dimethoxy-3′-hydroxyphenyl) - 4 - hydroxy - 6 - methoxy-benzofuran-3-carbaldehyde. Compounds **8** and **9** showed again the characteristic signals at 9.78 and 9.82 ppm for the carbaldehyde moiety and at 10.24 and 10.16 ppm for the C-4 hydroxy group, respectively, in their ^{1}H NMR spectra.

The molecular formula of **8** was determined as $C_{18}H_{14}O_8$. The ^{1}H NMR spectrum indicated the presence of a methylendioxy group (6.03 ppm, 2H, *s*) and one isolated aromatic proton at 6.76 ppm. The shift of this proton, which is quite similar to that of H-7 in **7** and **9**, is a hint to a 5,6- instead of a 6,7-methylendioxy moiety. The shift and coupling patterns of the aromatic protons and methoxy groups were nearly identical with those of **7**, thus suggesting the same substitution pattern in ring B.

The EIMS of **9** showed a molecular ion peak at *m*/*z* 330, its molecular formula was calculated as $C_{17}H_{14}O_7$. Whereas the proton signals from ring A of **9** were identical with the ^{1}H NMR spectral data of **7**, the *ortho*-coupled signals in ring B are significantly highfield shifted compared to those of **7**. The position of the methoxy group at C-6 was established by NOE experiments. Irradiation of the methoxy singlett at 3.85 ppm led to the enhancement of the H-5 (6.36 ppm) and H-7 (6.72 ppm) signals; whereas the position of the second methoxy group (3.74 ppm) at C-2′ could be deduced from the shifts of the aromatic protons and the lack of NOE from H-5′ to the methoxy signal. Additionally, the fragmentation pattern in the EIMS of **9** differs from those of **7** and **8**. Dehydration of the molecule yielded the ion peak at *m*/*z* 312 $[M–H_2O]^+$, thus suggesting an *ortho*-position of the two hydroxy groups at C-3′ and C-4′. In the EIMS of **7** and **8** no dehydration could be observed. In conclusion, due to the NOE results and the observed fractionation pattern in the EIMS methylation of the hydroxy groups at C-3′ and C-4′ could be excluded. Compounds **7**–**9** represent novel 2-arylbenzofuran-3-carbaldehydes, for which we propose the names andinermal A (**7**), andinermal B (**8**), and andinermal C (**9**). Whereas isoflavones are common in the Fabaceae, the occurrence of 2-arylbenzofuran-3-carbaldehydes seems to be very rare throughout the

plant kingdom (Ferreira et al., 1975; Halabalaki et al., 2000); 2-aryl-benzofurans typically co-occur with structurally related isoflavonoids (Harborne, 1994). From the biosynthetical point of view, it is not yet clear if the benzofuran-3-carbaldehyde moiety is related to isoflavones via pterocarpanes (Ferreira et al., 1975) or if it is built directly from flavonoid precursors. The substitution pattern of ring A in this case might hint to the second possibility.

The FAB–MS spectrum of compound **10** (negative mode) showed a characteristic ion peak at *m/z* 579 $[M-H]^-$ suggesting a molecular formula of $C_{30}H_{28}O_{12}$. The ^1H NMR spectrum (Table 2) showed characteristic signals for a flavanonol moiety with a *trans*-configuration of the two protons at C-2 and C-3 ($J = 10.7$ Hz), which could be identified as taxifolin. Furthermore, signals for a α-L-rhamnosyl moiety and a *trans*-cinnamoyl moiety could be observed. The attachment of the rhamnopyranoside at C-3 was deduced from the HMBC spectrum (Table 2). The double doublet signal (5.12 ppm, $J = 3$, 9.7 Hz) of the 3″-proton of the sugar moiety was shifted lowfield and hinted to an ester bonding with *trans*-cinnamic acid. Thus **10** could be established as 3″-*O*-*trans*-cinnamoyl-astilbin, a novel flavanonol glycoside.

In the in vitro antiplasmodial assay against *Plasmodium falciparum* the lipophilic crude extract of the leaves from *A. inermis* showed moderate activity (IC_{50} values: 56 μg/ml [poW], 58.6 μg/ml [Dd2]; Kraft et al., 2000); by fractionation we found an enhanced activity for fraction 6 (IC_{50} value: 16.3 μg/ml [Dd2]), from which we isolated formononetin (**3**) and andinermal B (**8**). As **3** showed no inhibitory effects at all (Kraft et al., 2000) we suggest **8** as one active principle, which unfortunately could not be tested due to the lack of sufficient amount and additional plant material. Whereas the crude hydrophilic extract and three fractions yielded after liquid-liquid-partition (petrol, EtOAc, and H_2O) proved to be inactive, the $CHCl_3$-fraction exhibited an IC_{50} value of 20.3 μg/ml against Dd2. Antiplasmodial activities of isolated compounds from this fraction are shown in Table 3. Andinermal A (**7**) exhibited the strongest antiplasmodial activity with IC_{50} values of 2.3 μg/ml against poW and 3.9 μg/ml against Dd2; andirnermal C was slightly less active (5.9 μg/ml [poW], 6.3 μg/ml [Dd2]). Whereas the 3-*O*-rhamnosides **5** and **6** proved to be inactive, 3″-*O*-*trans*-cinnamoyl-astilbin (**10**) showed a 50% growth inhibition at 10.4 μg/ml (poW) and 4.2 μg/ml (Dd2). Taxifolin, not yet isolated from active fractions, but mentioned for A. *inermis* (Lock de Ugaz et al., 1991), was tested as a control and was slightly less active against poW (15.8 μg/ml) as well as inactive against Dd2 (38.4 μg/ml). Obviously the *trans*-cinnamoyl residue could enhance the antiplasmodial activity of the unsubstituted rhamnoside **5**. The group of the isoflavones did not show homogenous

activity against *P. falciparum* at all and it is not clear which substitution patterns are necessary for the activity, nevertheless isoflavones could be detected in all active fractions and some of them, e.g. calycosin (**2**), proved to be active (Kraft et al., 2000). Additionally the 2-arylbenzofuran-3-carbaldehydes are responsible for the activity and it might be interesting, to find out the contribution of the carbaldehyde moiety to this activity.

3. Experimental

3.1. General

For fractionation silica gel 60 (70-230 mesh) was utilised. Preparative high performance liquid chromatography (HPLC) was performed on a Knauer Eurochrom 2000 equipped with a Nucleosil P 300 C-18 (10 μm) column or a Eurospher 100-C 18 (10 μm). EIMS were recorded on a Finnigan MAT CH7A (70 eV); FAB–MS and HR–EIMS on a Finnigan MAT 711 (80 eV). ^{1}H NMR, ^{13}C NMR, COSY, and NOE spectra were obtained on a Bruker AVANCE DPX 400 MHz or a Bruker DRX 500 MHz spectrometer (TMS as int. standard; acetone-d_6 as solvent).

3.2. Plant material

Leaves of *A. inermis* were collected in the area of Panama City (at the road El Llano-Carti), Republic of Panama, during March 1997. Voucher specimens (FLORPAN 2758) were identified by Professor M.D. Correa A. and deposited at the Herbarium of the University of Panama.

3.3. Extraction and isolation

Ground leaves (200 g) were extracted three times with 1.5 l of petrol–EtOAc (1:1, v/v) for 24 h at room temperature to gain a lipophilic extract. The solvents were evaporated under reduced pressure and the plant material was treated again three times with 1 l MeOH–H_2O (8:2, v/v). The MeOH was evaporated and the remaining aqueous phase was successively extracted with petrol, $CHCl_3$, and EtOAc.

The oily residue of the lipophilic extract (5 g) was subjected to column chromatography on silica gel 60 (75 g) and eluted with cyclohexane, cyclohexane–EtOAc mixtures, and MeOH to yield eight fractions. Due to the results of the bioassay, fraction 6 (30 mg, eluted with cyclohexane–EtOAc 7:3 [v/v]) was further purified by preparative HPLC (RP-18) at a 1.5 ml/min flow rate of MeOH–H_2O 4:6 (v/v) and yielded **3** (6.5 mg) and **8** (< 1 mg).

The dried $CHCl_3$ fraction (2 g) of the hydrophilic extract was chromatographed over a silica gel column (20 g) using $CHCl_3$–MeOH mixtures as eluent. The six obtained fractions were tested for their antiplasmodial activity, and fractions 2–4 were further investigated. Fractions 2 and 3 (eluted with $CHCl_3$–MeOH 9:1and 8:2 [v/v], respectively) were separated by preparative HPLC (RP-18) at a flow rate of 5.5 ml/min using a gradient H_2O–MeOH 60:40 to 0:100 (v/v) in 60 min. From 2 we gained compounds **1** (1.5 mg), **2** (1.5 mg), **3** (8 mg), **4** (1.5 mg), **7** (7 mg), and **9** (1 mg); fraction 3 afforded **10** (22 mg). Fraction 4 (eluted with $CHCl_3$–MeOH 7:3 [v/v]) was purified with H_2O–MeOH 55:45 (v/v) to afford **5** (6.7 mg) and **6** (9.2 mg).

3.4. Andinermal A (7; 2-[2′, 4′-dimethoxy-3′-hydroxyphenyl]-4-hydroxy-6-methoxy-benzofuran-3-carbaldehyde)

^{1}H NMR and ^{13}C NMR (400 MHz; acetone-d_6) see Table 1. HMBC (500 MHz; acetone-d_6) correlations: see Fig. 1; Table 1. HR-EIMS *m*/*z*: 344.089480 (calc. for $C_{18}H_{16}O_7$, 344.08961).

3.5. Andinermal B (8; 2-[2′, 4′-dimethoxy-3′-hydroxyphenyl]-4-hydroxy-5,6-methylendioxy-benzofuran-3-carbaldehyde)

^{1}H NMR (400 MHz; acetone-d_6) see Table 1. EIMS *m*/*z*: $[M]^+$ 358 (96), $[M–OCH_3]^+$ 327 (100), $[M–OCH_3/-CH_3]^+$ 312 (19). HR–EIMS *m*/*z*: 358.0690 (calc. for $C_{18}H_{14}O_8$, 358.06887).

3.6. Andinermal C (9; 2-[3′, 4′-dihydroxy-2′-methoxyphenyl]-4-hydroxy-6-methoxy-benzofuran-3-carbaldehyde)

^{1}H NMR (400 MHz; acetone-d_6) see Table 1. EIMS *m*/*z*: $[M]^+$ 330 (100), $[M–CH_3]^+$ 315 (9), $[M–H_2O]^+$ 312 (10), $[M\text{-}OCH_3]^+$ 299 (57), $[M–CH_3OH]^+$ 298 (24). HR–EIMS *m*/*z*: 330.07531 (calc. for $C_{17}H_{14}O_7$ 330.073953).

3.7. 3′-O-trans-Cinnamoyl-astilbin (10)

$[\alpha]_D^{20}+1.29$ (acetone; *c* 0.22). ^{1}H NMR (400 MHz; acetone-d_6), ^{13}C NMR (500 MHz, CD_3OD) and HMBC (500 MHz; CD_3OD) correlations see Table 2. (–) FAB *m*/*z*: $[M\text{-}H]^-$ 579.

3.8. In vitro bioassay

The bioassay was performed as described earlier (Kraft et al., 2000). The chloroquine-sensitive strain poW (IC_{50} for chloroquine ×2 H_3PO_4 = 0.011 μM) and the chloroquine-resistant clone Dd2 (IC_{50} for chloroquine ×2 H_3PO_4 = 0.12 μM) of *Plasmodium falciparum*

were maintained in continuous culture according to Trager and Jensen (1976). The antiplasmodial assay was carried out according to the method described by Desjardins et al. (1979) and activities were determined by a ^{3}H-hypoxanthine-incorporation assay.

Acknowledgements

The authors are indebted to Mrs. U. Ostwald and Dr. G. Holzmann (Institut für Organische Chemie der FU Berlin) for recording the FAB and HR–EIMS spectra, to Dr. J. Klein (AnalytiCon Discovery) for performing the NOE spectra, to Mr. C. Guerra, for his support in collecting the plant material, and to Professor M.D. Correa A., Herbarium of the University of Panama, Republic of Panama, for her identification of the species.

Synthesis and antifeedant properties of *N*-benzoylphenylisoserinates of *Lactarius* sesquiterpenoid alcohols

Piotr Kopczacki[a], Maria Gumułka[a], Marek Masnyk[a], Halina Grabarczyk[b], Gerard Nowak[b], Włodzimierz M. Daniewski[a,*]

Received 5 February 2001; received in revised form 18 June 2001

Abstract

The esterification of various sesquiterpenoid alcohols of *Lactarius* origin with *N*-benzoyl-[2*R*,3*S*]-phenylisoserine (side chain of Taxol®) produced compounds whose antifeedant properties against storage pests *Tribolium confusum, Trogoderma granarium* and *Sitophylus granarius* were measured. The introduction of the taxol side chain in these molecules, in comparison to original compounds, moderately enhanced their antifeedant activities, as well as changed their selectivity of activity towards the test insects.

Keywords: *N*-Benzoylphenylisoserinates; *Lactarius* sesquiterpenes; Paclitaxel; Antifeedant activity; Storage pests; *Tribolium confusum*; *Trogoderma granarium*; *Sitophilus granarius*; *Rhizopertha dominica*

1. Introduction

In our recent paper (Daniewski et al., 1998) we have identified a group of compounds responsible for the resistance of *Taxus baccata* to the attack of insects. It appeared that the taxanes 10-deacetylbaccatin III (**1**) and its 7α isomer (**2**), contained in the needles of *T. baccata* and possessing a very strong antifeedant activity, protect them from the attack of insects (Fig. 1).

This fact prompted us to investigate the antifeedant activity against the storage pests, of paclitaxel (**3**), the very important anticancer compound isolated from *Taxus brevifolia*. The antifeedant activity tests of paclitaxel (**3**) revealed its very potent activity, and perhaps, its role in the bark of *T. brevifolia* in defence against insects. In our previous papers (Daniewski et al., 1993, 1995) we studied the antifeedant properties of sesquiterpenoid alcohols from *Lactarius* species. The sesquiterpenes, as in the case of 10-deacetylbaccatin III (**1**) or paclitaxel (**3**), are responsible for chemical defence of the mushrooms against several predators. Since paclitaxel (**3**) is the 10-acetyl-13-*N*-benzoylphenylisoserine ester of 10-deacetylbaccatin III, we decided to attach the paclitaxel side chain to a series of sesquiterpenoid alcohols to produce *N*-benzoylphenylisoserine esters and to investigate their biological properties.

2. Results and discussion

There are many methods of attachment of *N*-benzoylphenylisoserine to the baccatin core to produce Taxol® (Farina, 1995); among them, a very simple one, involves the synthesis of the oxazoline derivative (**5**) of *RS* (natural) phenylisoserine (**4**) (Scheme 1):

Originally the synthesis of oxazoline (**5**) required as starting material the phenylisoserine with unnatural configuration at asymmetric center 2. In order to simplify the procedure and to use the phenylisoserine with natural configuration, which is commercially available, we decided to use trimethyl *ortho*-benzoate for the cyclisation, as recently described (Kamata et al., 1998). The hydrolysis of the ester **5** to the free acid **6** as well as its esterification with properly protected baccatin III was described by Kingston et al. (1994) in the semisynthesis of paclitaxel (**3**). The same esterification procedure was applied for the acid **6** and sesquiterpenoid alcohols and it is exemplified by the following scheme where lactarorufin A (**31**) was used as sesquiterpenoid alcohol (Scheme 2).

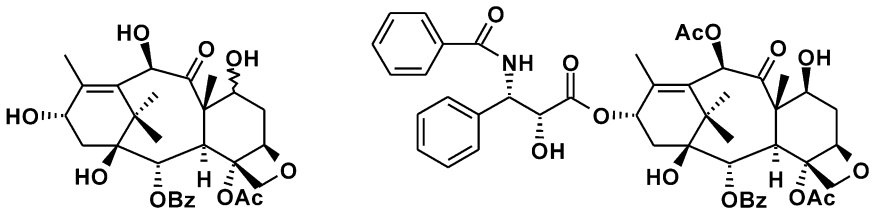

Fig. 1. **1**, R = β-OH (10-deacetylbaccatin III); **2**, R = α-OH (7-*epi*-10-deacetylbaccatin III).

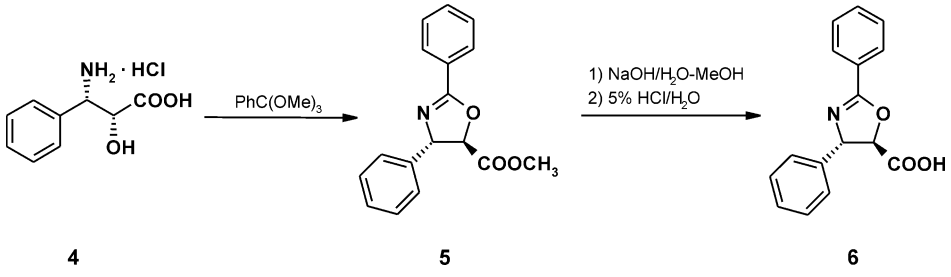
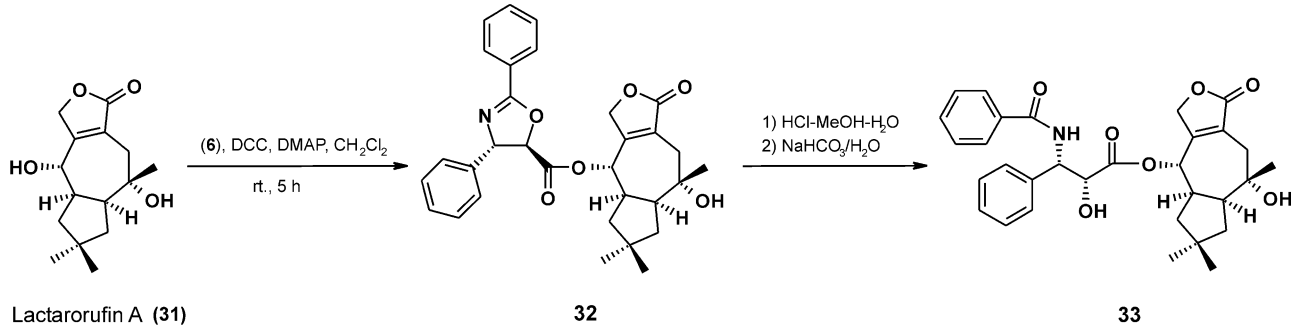
The esterification reaction went smoothly to give the cyclic ester **32**. The hydrolysis of the cyclic ester to form the *N*-benzoylphenylisoserinate (**33**) required different conditions from those used for the synthesis of paclitaxel. To avoid elimination of the side chain low temperature and methanol as solvent had to be used.

Using the above general method described in the experimental part a series of *N*-benzoylphenylisoserinates of various *Lactarius* sesquiterpenoid alcohols was prepared. (Scheme 2). The series included esters of marasmane, isolactarane and lactarane sesquiterpenes. The structures of all the compounds were substantiated by their ^{1}H NMR and ^{13}C NMR spectra which are included in the experimental part. The marasmane esters (**8**, **9**) possess very characteristic signals which allow their identification. The geminal cyclopropane protons at C-4 give rise to a pair of doublets with $J = 4$–5 Hz. The geminal methyl groups at C-11 appear as singlets at ca. δ 0.90–1.1, while the C-12 methyl resonates at lower field (ca. δ 1.15–1.5). Similarly isolactarane esters (**11, 12, 14, 15**) exhibited ^{1}H NMR spectra showing three methyl group singlets, one of them (C-12) resonating at lower field. The cyclopropane protons at C-5, as in the case of marasmane sesquiterpenes produced a pair of doublets (gem. coupling $J = 5.5$ Hz). An important and characteristic ^{1}H NMR spectral feature of isolactarane esters is involving the ABq system with $J = 10$ Hz, typical of saturated γ-lactone ring, In case of ^{1}H NMR spectra of lactarane esters, signals of methyl groups appear as in the previously discussed groups. Depending on heterocyclic rings (furans or lactones), characteristic signals are exhibited. The C-13 or C-5 methylene protons of lactones form an ABq system with a large coupling constant (15–20 Hz). The value of H-8, H-9



Scheme 1.



Scheme 2.

coupling constants are indicative of the *cis* or *trans* stereochemistry. As general feature the signals of protons on carbons bearing the ester groups, in the ^{1}H NMR spectra, are down field shifted in comparison with those of free alcohols (Fig. 2).

The ^{13}C NMR spectra of all the phenylisoserinates confirmed their structures and are included in the experimental part.

3. Antifeedant properties

As it was already mentioned in the introduction, we wanted to check the antifeedant properties of the synthesised compounds in order to find the influence of introduction of paclitaxel side chain into their molecules. First we checked paclitaxel (**3**) (Item 1, R = c, R' = Ac) that has a very potent antifeedant activity to the storage pests mentioned in Table 1. Therefore one can assume that its role in *Taxus brevifolia* is to protect the plant against insects. 10-Deacetyl baccatin III (**1**) (Item 1, R = H, R' = H), which is a good antifeedant, demonstrated lower activity than paclitaxel, especially against *Trogoderma granarium* and *Sitophylus granarius*. The bonding of paclitaxel side chain to the molecule of isovellerol (Item 2) decreased its activity. Introduction of paclitaxel side chain into the molecule of isolactarorufin (**10**) (Item 3, R = H) (which is an attractant) enhanced its antifeedant properties. Change of stereochemistry at C-8 (Item 4) did not influence activity. Similarly esterification of furanol (Item 5) did not have important effect on antifeedant activity. In case of furandiol (**19**) (Item 6), the esterification gave a compound **21** with twice as high activity. Introduction of the paclitaxel side chain into "artifact" (Item 7) as well as into lactarorufin A (Item 8) influenced only the selectivities of antifeedant activity. Esterification of 8-*epi*-lactarorufin A (**34**) (Item 9), which is inactive, caused some activity. Introduction of the side chain into 5-deoxy-lactarolid B (Item 10) did not increase its activity but changed its selectivity towards storage pests. Our procedure was verified with azadirachtin (Item 11) test.

4. Experimental

4.1. General

All melting points were measured on a Koffler hot plate and are uncorrected. ^{1}H and ^{13}C NMR spectra were run at 500 and 125 MHz respectively (Bruker 500 MHz spectrometer) in $CDCl_3$ as otherwise noted, using TMS as internal standard. Column chromatography (CC) was carried out using silica gel, and the TLC were conducted on silica gel or RP-18.

The phenylisoserinates were prepared from sesquiterpenoid alcohols isolated from mushrooms (*Lactarius rufus, Lactarius vellereus,* voucher numbers 33550, and 32260 respectively, specimen deposited at the Department of Systematics and Geography of Plants of the University of Warsaw) or synthesized by transformation of natural products. The references on the procedures of isolation or preparation of all the sesquiterpenes (**7**, **10**, **13**, **16**, **19**, **22**, **25**, **28**, **31**, **34**, **37**, **40**) can be found in the recent review (Daniewski and Vidari, 1999).

4.2. Preparation of oxazoline methyl ester (*5*)

Phenylisoserine (*R*,*S*) (2.87 g, 0.013 mol) was suspensed in dry toluene (50 ml) in round bottom flask (200 ml) equipped with magnetic stirrer and a still head. The reaction was heated to boiling and 15 ml of toluene was distilled off. Subsequently trimethylorthobenzoate (5 ml, 0.029 mol) was added and the volatile components were removed slowly by distillation during 8 h. Residual solids were filtered off and the filtrate evaporated in rotavap. The resulting oil was purified by chromatography over silica-gel in hexane–ethyl acetate gradient solvent system. Proper fractions were collected and gave pure ester **5** (1.5 g, 41% theoretical yield). $[\alpha]_D = +14.2^\circ$ (EtOH, *c* 1.0); ^{1}H NMR (200 MHz): δ_H 3.90 (3H *s*), 4.96 (1H, *d*, J = 6.5 Hz,), 5.50 (1H, *d*, J = 6.5 Hz,), 7.30–7.62 (8H, *m*), 8.10–8.20 (2H,*m*); ^{13}C NMR ($CDCl_3$, 50 MHz): δ_C 52.68, 74.59, 83.07, 126.39, 126.72, 127.97, 128.15, 128.22, 128.39, 128.64, 128.79, 131.86, 141.04, 163.89, 170.55.

The unidentified residual solids, by treatment with another portion of trimethyl ortho benzoate in presence of *p*-toluenesulphonic acid in toluene, can be converted into the desired ester **5**. In this way overall yield can be improved up to 66%.

4.3. (4S,5R) 2,4-Diphenyl-4,5-dihydro-oxazol-5-carboxylic acid (*6*)

Compound **5** (1.52 g, 0.0054 mol) dissolved in methanol (8 ml) was treated with sodium hydroxide (0.33 g, 0.00835 mol) dissolved in methanol (20 ml) and water (0.5 ml) at room temperature. The reaction was followed by TLC and when no starting material was detected (5 h), hydrochloric acid (6 ml, 5%) was added to the reaction mixture to obtain the pH value equal 6. Precipitated solid was filtered, washed with water and dried to give 1.23 g of the desired product with 86% yield. mp. = 207–211 °C, $[\alpha]_D = -9.97^\circ$ (0.05 *N* NaOH aq., c 1.01),^{1}H NMR (200 MHz, DMSO-d_6,): δ_H 5.00 (1H, *d*, J = 6.4 Hz,), 5.41 (1H *d*, J = 6.4 Hz,), 7.20–7.70 (8H,*m*), 7.90–8.10 (2H,*m*); ^{13}C NMR (DMSO-d_6, 50 MHz) δ_C 73.78, 82.42, 126 53, 126.64, 127.79, 128.18, 128.71, 128.80, 132.09, 141.54, 162.86, 171.45.

4.4. General method for the synthesis of esters of (4S,5R)-2,4-diphenyl-4,5-dihydro-oxazol-5-carboxylic acid and sesquiterpenoid alcohols of Lactarius origin

A sesquiterpenoid alcohol (1 mmol), the acid (**6**) (1.1 mmol), DMAP (18.3 mg, 0.15 mmol) and DCC (247.2 mg, 1.2 mmol) were dissolved in methylene chloride (25 ml) in a round bottom flask. The reaction was carried out at room temperature and was monitored by TLC. When the reaction was completed (3–12 h) the content of the flask was fitered, the solution evaporated in vacuo and the residue purified by chromatography to give the desired esters.

4.5. General method for the hydrolysis of esters of (4S,5R)-2,4-diphenyl-4,5-dihydro-oxazol-5-carboxylic acid and sesquiterpenoid alcohols of Lactarius origin into (2S,3R)-phenyl-isoserinates

A sesquiterpenoid alcohol (4*S*,5*R*)-2,4-diphenyl-oxazol-5-carboxylate (0.2 mmol) dissolved in methanol (25 ml) was chilled to 0 °C and treated with 0.5 N aq. HCl solution (2.5 ml). The reaction must be carried out at 0 °C. After completion of the reaction the solution was neutralised with saturated aq. sodium hydrogen carbonate solution (pH = 7) and left for 15 min. Subsequently the solution was diluted with water (75 ml) and extracted with chloroform (3×40 ml). The chloroform extract was dried over magnesium sulphate, filtered and evaporated to dryness leaving a residue, which was purified by chromatography in proper solvent system and gave the desired *N*-benzoylphenylisoserinate.

4.6. Antifeedant activity test

The test is described in detail in Błoszyk et al. (1995). Insects (adults and larvae) used for the test were reared under laboratory conditions at temp. of 26 °C and 75% humidity. All compounds investigated were dissolved in EtOH at concentration of 10 mg ml^{-1}. Air dry wheat wafer discs were used as test food. The discs (1 cm in diameter) were saturated with EtOH solutions of pure compounds to produce 0.5% (by weight) contamination of the wafer in every test. Feeding of insects was recorded under three conditions: (1) on pure food (control); (2) on food with possibility of choice (choice test); on food with the compounds tested (no choice test). The wafer discs were weighed after saturation and drying in

air for 30 min before the experiments and again after 7 days of feeding by beetles or larvae. On the basis of eaten food, the index of activity of the compounds tested was calculated in the following way: three values of the food eaten were obtained in the control KK, in the no-choice test EE, and in the choice test K, E.

Thus, the relative coefficient of antifeedancy:

$$R = \frac{K - E}{K + E} \times 100$$

The total coefficient of antifeedancy is equal to $T = A + R$, and the maximum value of the coefficient can reach 200 for a perfect antifeedant.

Dedicated to Professor Yoshinori Asakawa on the occasion of his 60th birthday

Abstract

The sesquiterpene constituents of the essential oils of the Taiwanese liverworts *Lepidozia fauriana* and *L. vitrea* were investigated. 11,12-Dihydrochiloscyphone and 7,10-anhydro-11,12-dihydrochiloscypholone were isolated from *L. fauriana* and spectroscopically characterised together with their hydrogenation products. From the same species three amorphane derivatives amorpha-4,9-dien-14-al, amorpha-4,9-dien-2-ol and 7,14-anhydroamorpha-4,9-diene, and from *L. vitrea* two oxygenated elemanes, namely 7-acetoxy-elema-1,3-dien-8-ol and elema-1,3-dien-7-ol, were isolated and identified. Structure elucidation was carried out by NMR spectroscopy and chemical correlations in conjunction with enantioselective gas chromatography were utilized to establish absolute configurations. © 2001 Elsevier Science Ltd. Keywords: *Lepidozia fauriana*; *L. vitrea*; Hepaticae; Essential oil; Structure elucidation; Amorphane; Chiloscyphane; Elemane; Sesquiterpene

1. Introduction

Liverworts are a rich source of terpenoid compounds with a variety of biological activities (Asakawa, 1995). In the present work the leafy liverworts *Lepidozia fauriana* and *L. vitrea* (Lepidoziaceae) of Taiwanese origin were investigated. In the Japanese liverwort *L. vitrea* vitrenal, isobicyclogermacrenal (Matsuo et al., 1980, 1984), eudesm-3-ene-6β,7α-diol and eudesm-4(15)-ene-6β,7α-diol (Toyota et al., 1996) and in Taiwanese *L. vitrea* and *L. fauriana* lepidozenolide, 5α-hydroperoxylepidozenolide and 6β-acetoxyvitranoxide have been identified (Shu et al., 1994). These relatively polar compounds were not detected in the hydrodistillation products of our samples, but other compounds bearing these sesquiterpene backbones and some of those reported for this liverwort family were identified. Essential oil samples were analysed by GC–MS. Individual components, including a number of new oxygenated sesquiterpenes, were isolated by preparative GC and investigated by NMR (^{1}H, ^{13}C, ^{1}H–^{1}H COSY, HMQC, HMBC, TOCSY, NOESY). The absolute configuration of the new compounds was derived by dehydration of the related alcohols, polarimetric measurements, total hydrogenation and enantioselective gas chromatography using cyclodextrin stationary phases.

2. Results and discussion

The following sesquiterpenoids in the order of their elution from a capillary column with polydimethylsiloxane (CPSil-5) were identified as constituents of the essential oil of *L. fauriana* (YYF-9904-42 and YY-9803-11; relative concentrations of major compounds are given in parentheses, all other compounds are below 3% relative abundance, only identified compounds are given): δ-elemene, α-ylangene, α-copaene, β-elemene, (+)-7,10-anhydro-11,12-dihydrochiloscypholone (**3,** 10%), (−)-bicyclogermacrene (18%), (+)-11,12-dihydrochiloscyphone (**2,** 3%), 4-eudesm-7α-ol (**11,** 4%) (Barrero et al., 1997), (+)-dihydrochiloscypholone (**1**) (Nagashima et al., 1996) (19%), (−)-lepidozenal (**14**) (Matsuo et al., 1984). In the essential oil of plant sample YY-9904-30 isoledene, β-longipinene, isosativene, β-caryophyllene,

β-cedrene, thujopsene, aromadendrene, β-barbatene, **3**, *allo*-aromadendrene, α-amorphene (8%), (−)-bicyclogermacrene (23%), β-bazzanene, δ-cuprenene, **2**, maaliol, globulol, viridiflorol, cedrol, **11**, (−)-isospathulenol (**16**) (Maurer and Hauser, 1983), (+)-amorpha-4,9-dien-2-ol (**7**), (+)-amorpha-4,9-dien-14-al (**6**, 5%), **1**, (+)-7,14-anhydroamorpha-4,9-diene (**8**), and **14** (4%) were found.

In the essential oil of *L. vitrea* the following sesquiterpenoids were identified: δ-elemene, α-ylangene, β-bourbonene, β-elemene, α-barbatene, γ-maaliene, isobazzanene, β-barbatene (13%), δ-selinene, ledene (4%), cuparene, α-cuprenene, δ-cadinene, (+)-elema-1,3-dien-7-ol (**10**) (13%), germacrene B, maaliol, spathulenol, rosifoliol, (−)-eudesm-4-en-7α-ol (**11**) (10%), guai-5-en-11-ol, eudesm-4(15)-en-7-ol (**13**, 8%) (Toyota et al., 1999), (+)-eudesm-3-en-7-ol (**12**, 7%) (Toyota et al., 1999), **14,** vetivazulene (**15**) (Hayashi et al., 1969; Bellesia et al., 1976), and (+)-7-acetoxy-elema-1,3-diene-8-ol (**9**). All previously known compounds were identified by mass spectrometry in conjunction with their gas chromatographic retention indices by comparison with a spectral library established under identical experimental conditions (Joulain and König, 1998).

The mass spectrum of the new tricyclic sesquiterpene enolether 7,10-anhydro-11,12-dihydrochiloscypholone (**3**) exhibits a molecular ion signal at *m/z* 220 and an elemental composition of $C_{15}H_{24}O$. The proton NMR spectrum shows one singlet and one doublet for methyl groups (δ 0.56, 0.74) and two downfield shifted methyl singlets (δ 1.67, 1.85) indicating that these methyl groups are attached to a double bond. As the ^{13}C NMR reveals, three downfield shifted quaternary carbons (δ 152.9, 95.1, 89.1), only one double bond and another quaternary carbon bearing an oxygen function fits to this pattern. The chemical shifts of these carbons clearly indicate the presence of an enolether structure which results in a tricyclic system for the molecule. In the ^{13}C NMR four primary carbon atoms (δ 10.9, 16.5, 17.9, 19.2), five secondary carbons (δ 22.5, 25.9, 27.1, 29.9, 34.5), two tertiary (δ 32.1, 47.2) and four quaternary carbons (δ 50.7, 89.1, 95.1, 152.9) are found. The connectivity of the different groups for the chiloscyphanes **1**, **2**, **3**, **4** and **5** was established through $^1H^1$-H-COSY and HMBC experiments. The NOE-couplings of **3** and **4** are shown in Fig. 1.

To verify the structure of **3,** compound **1** was isolated and characterised by NMR. During acidic treatment (Amberlyst) of **1** compound **3** was generated which itself was converted to **2** during this process. As a result of the dehydration in 10-position the 1(10)-ene- (**2**) and 9-ene- (**2a**, not shown) double bond isomers are expected. From the ^1H NMR and TOCSY experiment conducted with **2**, it was evident that **2** was formed in a 10:1 ratio over **2a** and that the two isomers coeluted on the GC column. Hydrogenation with H_2-Pd/C of the isolated compounds **1**, **2** and **3** yielded **4** as a common product. Further reduction of **4** to the alcohol **5** was achieved with $LiAlH_4$.

Because of the lability of **1,** it can not be excluded that **2** and **3** may be generated by the sample preparation method and not be originally present in the plant.

The mass spectrum of the new sesquiterpene aldehyde amorpha-4,9-diene-14-al (**6**) exhibits a molecular ion signal at *m/z* 218 and an elemental composition of $C_{15}H_{22}O$. The proton NMR spectrum shows two doublets for methyl groups (δ 0.76, 0.82) and one methyl singlet with a downfield shift (δ 1.54) indicating that this methyl group is attached to a double bond. The one-proton-signal at δ 9.37 clearly indicates an aldehydic proton. The HSQC spectrum reveals the presence of three primary (δ 21.3, 21.8, 24.1), three secondary (δ 24.6, 27.0, 28.4) and seven methine carbons (δ 29.4, 34.8, 36.3, 44.2, 119.4, 153.5, 193.5). From the HMBC spectrum the presence of two quaternary carbons is derived (δ 137.0, 142.4). This information together with the data of the two dimensional measurements results in an amorphane skeleton.

The identification of **7** and **8** was facilitated by the analogies to **6**: The methyl doublets and the downfield

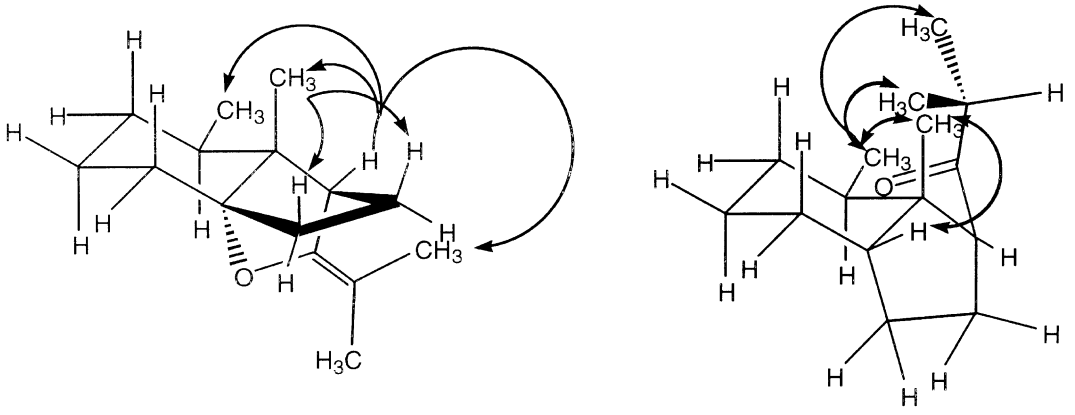

Fig. 1. Important observed NOE contacts of the chiloscyphanes **3** and **4**.

shifted singlet of a methyl attached to a double bond were present in both compounds (**7**: δ 0.87, 0.91, 1.57; **8**: δ 0.89, 0.93, 1.61). For **7** an additional methyl singlet instead of the aldehyde signal in **6** appears at δ 2.01 while in **8** the aldehyde group of **6** is reduced to an ether giving signals at δ 3.81 and 3.99, each with the integral of one proton. It is remarkable that for the ring junction protons H-1 and H-6 in all three compounds broad singlets (**6**: δ 2.60, 2.71; **7**: δ 2.30, 2.62; **8**: δ 2.48, 2.68) are observed. Complete NMR investigation of **7** together with the observed spectral analogies confirmed structure **7**. For **8** the ^{1}H-^{1}H-COSY yielded the fragment depicted in Fig. 3 which was correlated with the amorphane structure due to the obvious spectral homologies to compounds **6** and **7**. Fig. 2 gives an interpretation of the NOESY data for compounds **6** and **7**.

The absolute configuration of the amorphane derivatives was determined by correlation with (+)-α-amorphene (Bülow and König, 2000). Partial hydrogenation of **6**, **7** and **8** with H_2-Pd/C in hexane/benzene 70:30 among other products yielded differing amounts of α-amorphene which was identified by enantioselective GC on heptakis(6-*O*-tert-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin to be the (+)-enantiomer (König et al., 1999). The hydrogenation was repeated with **8** to check its reproducibility: under the same conditions again (+)-α-amorphene was obtained together with some side products which were also obtained in the hydrogenation reaction of an α-amorphene standard.

For the oxygenated elemadienes **9** and **10** complete NMR investigations were carried out (NOESY interpretation illustrated in Fig. 4). The relative configuration at chiral center C-7 carrying the acetoxy group was not assigned beyond doubt due to lack of coupling correlations with neighbouring protons in the NOESY spectrum. The assumed configuration is the more likely one, as the methyl group H-12 shows close spatial relationship to H-6a, which itself must be in the equatorial position giving NOE-contacts with H-5 and O*H*. Dehydration of **10** yielded (5*R*,10*R*)-elema-1,3,6-triene (δ-elemene) as a single enantiomer, (5*R*,10*R*)-elema-1,3,7-triene (Ohloff et al., 1959), and (−)-γ-elemene which revealed the opposite absolute configuration of the chiral centers C-5 and C-10 when compared with the product obtained from the dehydration reaction of the reference compound (−)-elemol (Toyooka et al., 1997).

As a philogenetic peculiarity of liverworts both groups of newly identified amorphane and elemane ses-

quiterpenes display opposite configuration as compared to higher plants. Again enantioselective GC proved as a sensitive technique in stereochemical analysis as long as reference compounds with known absolute configuration are available (König et al., 1999).

3. Experimental

3.1. General experimental procedures

3.1.1. Gas chromatography

Orion Micromat 412 double column instrument with 25 m fused silica capillaries with polysiloxane CPSil-5 and polysiloxane CPSil-19 (Chrompack); Carlo Erba Fractovap 2150 or 4160 gas chromatographs with 25 m fused silica capillaries with octakis(2,6-di-*O*-methyl-3-*O*-pentyl)-γ-cyclodextrin, heptakis(2,6-di-*O*-methyl-3-*O*-pentyl)-β-cyclodextrin or heptakis(6-*O*-tert-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin in OV 1701 (50%, w/w), split injection; split ratio approx. 1:30; FID; carrier gas 0.5 bar H_2; injector and detector temperatures 200 and 250 °C, respectively.

3.1.2. Preparative GC

Modified Varian 1400 and 2800 instruments, equipped with a stainless steel column (1.85 m× 4.3 mm) with 10% polydimethylsiloxane SE-30 on Chromosorb W-HP or with 2.5% octakis(2,6-di-*O*-methyl-3-*O*-pentyl)-γ-cyclodextrin in OV-1701 (50 %, w/w) on Chromosorb G-HP or with 6 % heptakis(6-*O*-tert-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin in SE-52 (50 %, w/w) on Chromosorb W-HP; FID; helium as carrier gas at a flow rate of 240 ml/min; injector and detector temperatures were 200 and 250 °C, respectively.

3.1.3. GC-MS

GC-MS measurements (EI, 70 eV) were carried out with a Hewlett Packard HP 5890 gas chromatograph coupled to a VG Analytical 70-250S mass spectrometer. Ion source temperature: 200° C.

3.1.4. NMR-spectroscopy

NMR measurements were carried out with a Bruker WM 400 or a Bruker WM 500 instrument using TMS as internal standard.

3.1.5. Polarimetry

Measurements were performed with a Polarimeter 341 (Perkin Elmer) at 589 nm at 20 °C. Due to the very small amounts of isolated compounds only the sense of optical rotation is given to avoid inaccuracies.

All microreactions were carried out with approx. 50 μg of sample; in cases where NMR investigation followed the transformation up to 0.5 mg of sample was used.

Dehydration of **1** was carried out by addition of phosphoryl chloride to a solution of the compound in benzene at 0 °C. After 0.5 h of stirring water was added and the workup was performed with aq. $NaHCO_3$ solution and benzene extraction. For (−)-elemol and **10,** the same conditions were applied with pyridine as the solvent.

Hydrogenation of **1**, **2, 3** and **8** was executed by bubbling hydrogen gas through the sample dissolved in hexane with an addition of palladium-charcoal for 1 min and additional stirring of the reaction mixture under slight positive hydrogen pressure for 3 h. Partial reduction of **6**, **7** and **8** was performed with H_2-Pd/C (1 min bubbling H_2 through the solution) in hexane/benzene 70:30 and additional stirring under hydrogen atmosphere for 30 min. Further hydrogenation of **4** was achieved by addition of an ether solution of $LiAlH_4$ to the cooled sample of **4** in ether. The reaction was quenched with water after 40 min and extracted twice with ether, and the ether phase dried over $MgSO_4$. After removal of the solvent the sample was taken up in benzene.

Rearrangement reaction of (+)-**1** was performed at room temperature in benzene with an addition of Amberlyst®. Samples were taken after 30 and 105 min respectively, and analysed by GC-MS.

3.2. Plant material and essential oils

L. fauriana was collected at Yuanyang Lake, alt. 1700 m, Hsinchu Hsien, Taiwan, in March 1998 (voucher no. YY-9803-11), and twice in April 1999 (voucher nos. YY-9904-30, YYF-9904-42). The essential oils of the liverworts were obtained by hydrodistillation (2 h) of ca. 70 g of air dried liverworts using *ca.* 1 ml of *n*-hexane as collection solvent. *L. vitrea* (voucher no. SP-9709-60) was collected in Sheipa National Park, Hsinchu Hsien, at 2000 m alt. in September 1997. 35 g of the plant material was ground and hydrodistilled yielding ca. 0.6 ml of a purple oil. Specimens of all collections are deposited at Tamkang University, Tamsui, Taiwan.

3.3. Isolation of single constituents of essential oils

The isolation was carried out using preparative GC: The oil of *L. fauriana* YYF-9904-42 was fractionated using SE-30 at 120 °C with a heating rate of 2 °C/min and yielded **1**, **2**, **3** and **11** as pure fractions. A prefractionation of oil from sample YY-9904-30 was conducted with SE-30 (120 °C; 2 °C/min) and **6**, **7**, **8** and **14** were obtained with impurities, that were removed by further gas chromatographic fractionation on octakis(2,6-di-*O*-methyl-3-*O*-pentyl)-γ-cyclodextrin. Prefractionation of *L. vitrea* oil SP-9709-60 (SE-30; 120 °C; 2 °C/min) yielded **11** and further purification using octakis(2,6-di-*O*-methyl-3-*O*-pentyl)-γ-cyclodextrin (170 °C/ 20 min; 175 °C/10 min) gave **10**. Compounds **12** and **13** were obtained using heptakis(6-*O*-tert-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin (140 °C isothermal) and **9** and **15** could be separated from each other using heptakis(6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin (160 °C isothermal) and octakis(2,6-di-*O*-methyl-3-*O*-pentyl)-γ-cyclodextrin, consecutively (Fig. 5).

3.4. Dihydrochiloscypholone (*1*)

(+)-(1*S*,3a*R*,7*S*,7a*S*)-2,3,3a,4,5,6,7,7a-Octahydro-3a-hydroxyl-7,7a-dimethyl-1-(2-methylpropanonyl)-1*H*-indene, colourless oil; RI_{CPSil5}: 1718; sense of optical rotation (benzene): +; ^{1}H NMR (500.1 MHz, C_6D_6): δ 0.57 (3H, *d*, H-15, *J* = 6.6 Hz), 0.63 (3H, *s*, H-14), 0.80 (3H, *d*, H-12, *J* = 7.9 Hz), 0.94 (3H, *d*, H-13, J = 7.6 Hz), 1.04–1.13 (1H, *m*, H-3a), 1.32–1.49 (3H, *m*, H-1a, H-2a, H-3b), 1.56–1.72 (3H, *m*, H-8a,b, H-9a), 1.85-1.89 (1H, *m*, H-9b), 1.91 (1H, *dd*, H-1b, *J* = 5.1, 12.9 Hz), 2.25–2.33 (2H, *m*, H-2b, H-11), 2.37–2.41 (1H, *m*, H-4), 2.60–2.63 (1H, *m*, H-6), 5.62 (1H, *d*, O*H*, *J* = 3.5 Hz); ^{13}C NMR (125.8 MHz, C_6D_6): δ 17.41 (*q*, C-12), 17.88 (*q*, C-15), 18.64 (*q*, C-13), 20.39 (*q*, C-14), 21.19 (*t*, C-2), 27.61 (*t*, C-8), 29.82 (*d*, C-4), 29.84 (*t*, C-3), 30.50 (*t*, C-1), 38.63 (*t*, C-9), 43.02 (*d*, C-11), 53.82 (*s*, C-5), 57.48 (*d*, C-6), 81.17 (*s*, C-10), 221.20 (*s*, C-7); MS (EI, 70 eV), *m*/*z* (rel. int.): 238 $[M]^+$(3), 149 (100), 139 (29), 122 (16), 107 (18), 93 (24), 81 (15), 79 (11), 71 (15), 69 (15), 55 (24), 43 (71), 41 (36).

3.5. 11,12-Dihydrochiloscyphone (*2*)

Chemical study of the essential oil of *Cyperus rotundus*

Mesmin Mekem Sonwa, Wilfried A. König*

Institut für Organische Chemie, Universität Hamburg, D-20146 Hamburg Germany

Received 4 April 2001; received in revised form 25 June 2001

Abstract

Minor constituents of the essential oil of *Cyperus rotundus* have been investigated. The three new sesquiterpene hydrocarbons (−)-isorotundene, (−)-cypera-2,4(15)-diene, (−)-norrotundene and the ketone (+)-cyperadione were isolated and their structures elucidated. The absolute configuration of (−)-rotundene was derived by chemical correlation and enantioselective gas chromatography. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Cyperus rotundus*; Cyperaceae; Sesquiterpenes; Norsesquiterpene; (−)-Isorotundene; (−)-Cypera-2,4(15)-diene; (−)-Norrotundene; (+)-Cyperadione

1. Introduction

Cyperus rotundus is a cosmopolitan sedge belonging to the family of the Cyperaceae. It is encountered in tropical, subtropical and temperate regions. *C. rotundus* is a traditional medicinal plant appearing among Indian, Chinese and Japanese natural drugs used against spasms and stomach disorders (Dassanayake and Fosberg, 1985). The essential oil as well as solvent extracts of the rhizomes of *C. rotundus* have been subject to numerous studies (Ohira et al., 1998 and cited literature) resulting in the isolation of many terpenoids. Here we describe the isolation and structure elucidation of new patchoulane and rotundane sesquiterpenes from the essential oil of this plant.

2. Results and discussion

The analysis of the essential oil of *Cyperus rotundus* by GC and GC–MS allowed the identification of cyprotene (**1**), cypera-2,4-diene (**2**), α-copaene (**3**), cyperene (**4**), α-selinene (**5**), rotundene (**6**), valencene (**7**), ylanga-2,4-diene (**8**), γ-gurjunene (**9**), *trans*-calamenene (**10**), δ-cadinene (**11**), γ-calacorene (**12**), *epi*-α-selinene (**13**), α-muurolene (**14**), γ-muurolene (**15**), cadalene (**16**), nootkatene (**17**) by comparison with a spectral library established under identical experimental conditions (Joulain and König, 1998), cyperotundone (**18**) (Hikino et al., 1966), mustakone (**19**) (Nyasse et al., 1988), cyperol (**20**) (Hikino et al., 1967), isocyperol (**21**) (Hikino et al., 1967) and α-cyperone (**22**) (Howe and McQuillin, 1955; Haaksma et al., 1992) (Fig. 1). However, several minor compounds could not be identified by their mass spectra and had to be isolated for further investigations. Consequently, the essential oil was first separated by silica chromatography into a hydrocarbon fraction and a more polar oxygenated fraction. The hydrocarbon fraction was further separated by column chromatography, TLC over silver nitrate precoated silica and preparative GC. This resulted in the isolation and characterization of isorotundene (**23**), cypera-2,4(15)-diene (**24**) and norrotundene (**25**). From the oxygenated fraction cyperadione (**26**), a patchoulane type sesquiterpene, was isolated.

2.1. (−)-Isorotundene (*23*)

The unknown compound **23** was assigned the molecular formula $C_{15}H_{24}$ ($[M]^+$ at $m/z = 204$). The ^{13}C NMR spectrum showed 15 carbon signals, two of which were olefinic (δ 107.9 and 151.08). Through the DEPT technique two methyl groups, seven methylene groups, four methine and two quaternary carbon atoms were identified. The compound has four unsaturations and only one double bond, therefore the presence of three rings

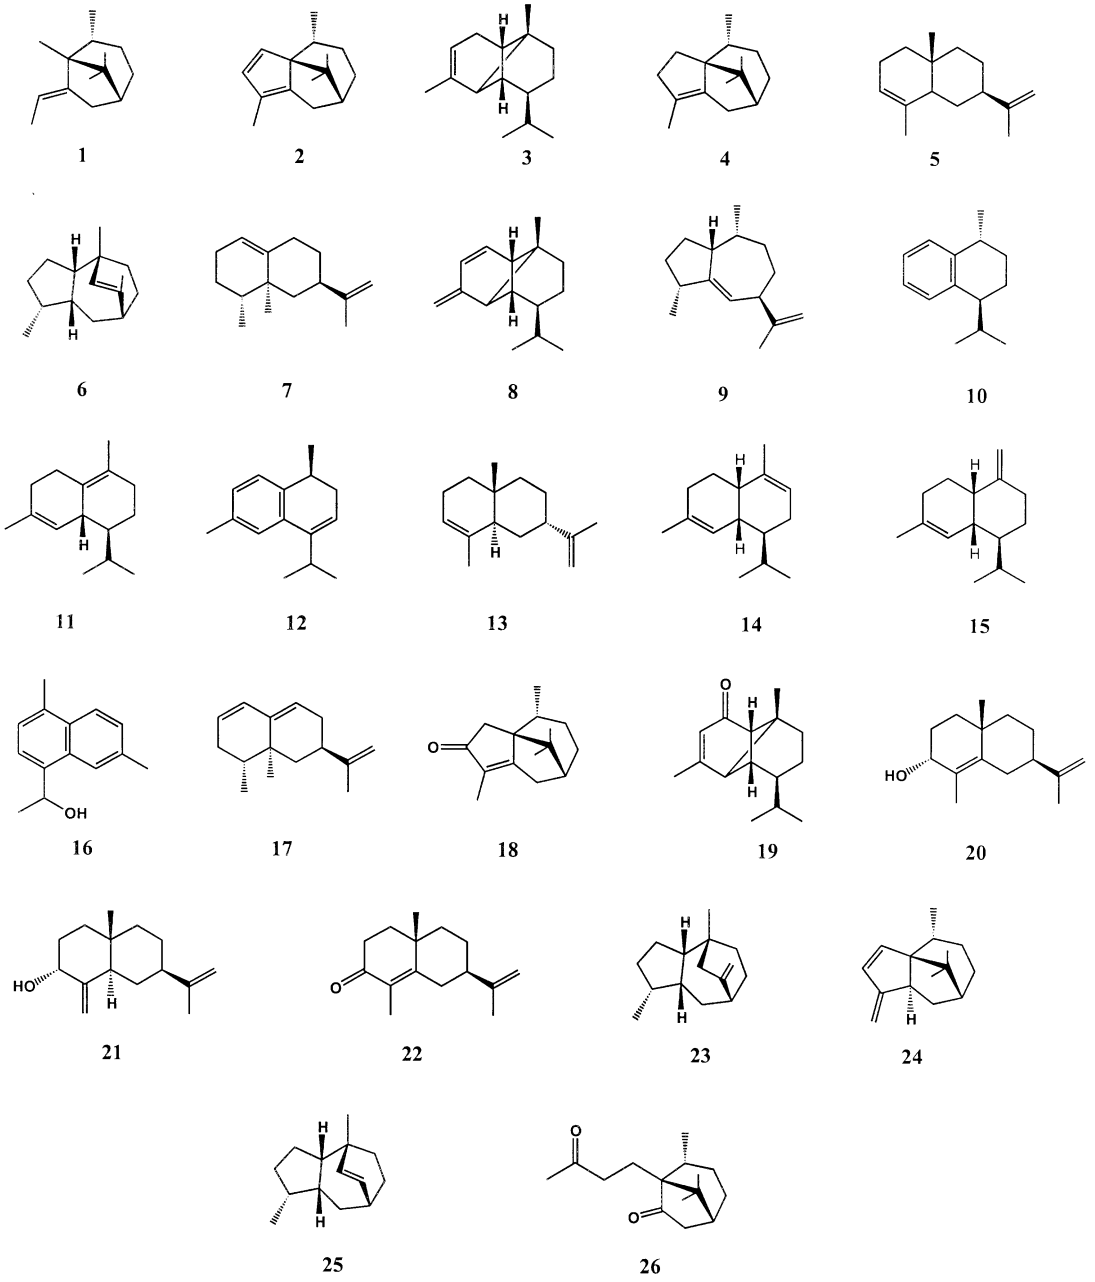

Fig. 1. Sesquiterpenes from the essential oil of *Cyperus rotundus*.

was concluded. The ^{1}H NMR and ^{13}C NMR signal assignments, achieved by ^{1}H–^{1}H-COSY and HMQC, correlations, afforded three substructures. The methine proton CH-5 (δ 1.99) couples with the methine proton CH-4 (δ 1.90) which is vicinal to methyl group CH_3-15 (δ 0.86). The latter methine proton also couples with the methylene group CH_2-3 (δ 1.22 and 1.68) itself coupled to another methylene group CH_2-2 (δ 1.46 and 1.52) which further couples with the methine proton CH-1 (δ 1.81) giving the partial structure–CH–CH(CH_3)–CH_2–CH_2–CH–. The methine proton δ 1.99 also couples with a methylene group CH_2-6 (δ 1.00 and 1.70) itself coupled to the methine proton CH-7 (δ 2.52). The proton H-7 also couples with the methylene group CH_2-8 (δ 1.05 and 1.71) which again couples with CH_2-9 (δ 1.44 and 1.72) to give the second substructure–CH–CH_2–CH–CH_2–CH_2–. The methylene group CH_2-11 (δ 2.14 and δ 2.27) and the olefinic proton at δ 5.85 couple with each other and give the third substructure–CH_2–C=CH_2. The proton-carbon long-range coupling correlations derived from the HMBC spectrum allowed to identify the skeleton of the compound. Long-range coupling correlations were found between the protons H-11, H-13 and carbon C-7 as well as between the methine proton H-7 and the carbons C-11, C-12 and C-13, indicating a bond connecting C-7 and C-12. The

proton H-11 also correlated with the carbons C-1, C-9, C-10 and C-14 while the methyl group H-14 correlates with the carbons C-1, C-9, C-10 and C-11. From these observations it was deduced that C-10 is connected to C-11, C-14 to C-10, and C-10 to C-1. Long-range correlations were observed between the protons H-6, H-5, H-4 and carbon C-1 as well as between H-1 and the carbons C-2, C-4, C-5, C-6 and C-10 indicating a bond between C-1 and C-5. The combination of all these informations led to a rotundane skeleton with an exocyclic double bond. The relative configuration at the chiral centres C-1, C-4, C-5, C-7 and C-10 was concluded from the NOESY diagram. The correlations observed between protons H-1, H-4 and H-5 indicate that these protons are on the same side of the molecule. Furthermore, the protons H-1 and H-5 show spatial interactions with the proton H-11a, which is only possible if H-1 and H-5 are located at the same side as the C-11-C-12 bridge. Therefore, compound **23**, which was named isorotundene, has the relative configuration as shown in Fig. 2.

To verify the rotundane skeleton a partial synthesis of **23** by oxymercuration-demercuration (Brown and Geoghegam, 1970) of rotundene (**6**) to isorotundenol (**27**) and subsequent dehydration (Greenwood et al., 1968) to isorotundene (**23**) and rotundene (**6**) was performed (Fig. 3). The synthesized and the isolated compounds **23** have identical spectroscopic data. Although rotundene (**6**) has been known for a long time its stereochemistry was not known as yet. The relative configuration of rotundene could not be derived from its NOESY diagram because of the overlapping of all the important signals. However, the fact that isorotundene (**23**) could be obtained from rotundene as shown in Fig. 3, proves that rotundene and isorotundene have the same relative configuration.

The identity of the relative configuration of rotundene (**6**) and isorotundene (**23**) still leaves the question about the absolute configuration open. In order to determine the absolute configuration of the two compounds, a chemical transformation of rotundene was performed in order to correlate it with (+)-γ-gurjunene (**9**). Rotundene (**6**) was submitted to ozonolysis followed by reduction with dimethyl sulfide under nitrogen (McMurry and Bosch, 1987). The desired aldehyde was not stable and was oxydised directly the to ketoacid **28** which could be isolated. The acid **28** was then decarboxylated (Fristad et al., 1983) to give ketone **29**. Subsequently **29** was allowed to react with methylenetriphenylphosphine in dimethyl sulfoxide (Greenwald et al., 1963) to yield the hydrocarbon **30** which was hydrogenated (Harmon et al., 1969) to give compound **31** (Fig. 4). Compound **31** was finally compared by enantioselective gas chromatography with the fully hydrogenated products of (+)-γ-gurjunene (**5**) and proved to have the same retention time with the major hydrogenation product (Fig. 5). The co-injection was made in a column which separates (+)- and (−)-γ-gurjunene (Fig. 6). Unfortunately, the small quantity of (−)-γ-gurjunene (which we isolated from the liverwort *Marchantia polymorpha*) was insufficient for hydrogenation and comparison with **31**. However, it is very probable that the used column also would have separated the hydrogenation products of the two enantiomers. Therefore, it is very likely that rotundene has the absolute configuration as shown for **23**.

2.2. (−)-Cypera-2,4(15)-diene (24)

The isolation of cypera-2,4(15)-diene (**24**) was achieved by a combination of column chromatography and preparative GC. The compound was assigned the molecular formula $C_{15}H_{22}$ ($[M]^+$ at $m/z = 202$). The ^{13}C NMR spectrum combined with the DEPT technique revealed three methyl groups, four methylene groups, one being olefinic (δ 102.84), five methine groups, two of which are olefinic (δ 133.26 and 139.17) and three quaternary carbon atoms, one of which is olefinic (δ 148.94).

The proton NMRspectrum displayed some signals common to patchoulane sesquiterpenes, namely the two

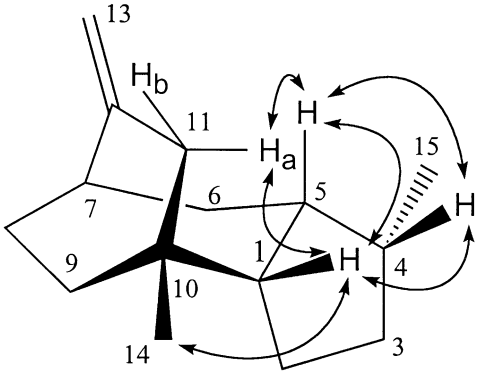

Fig. 2. Relative configuration of isorotundene with relevant NOEs.

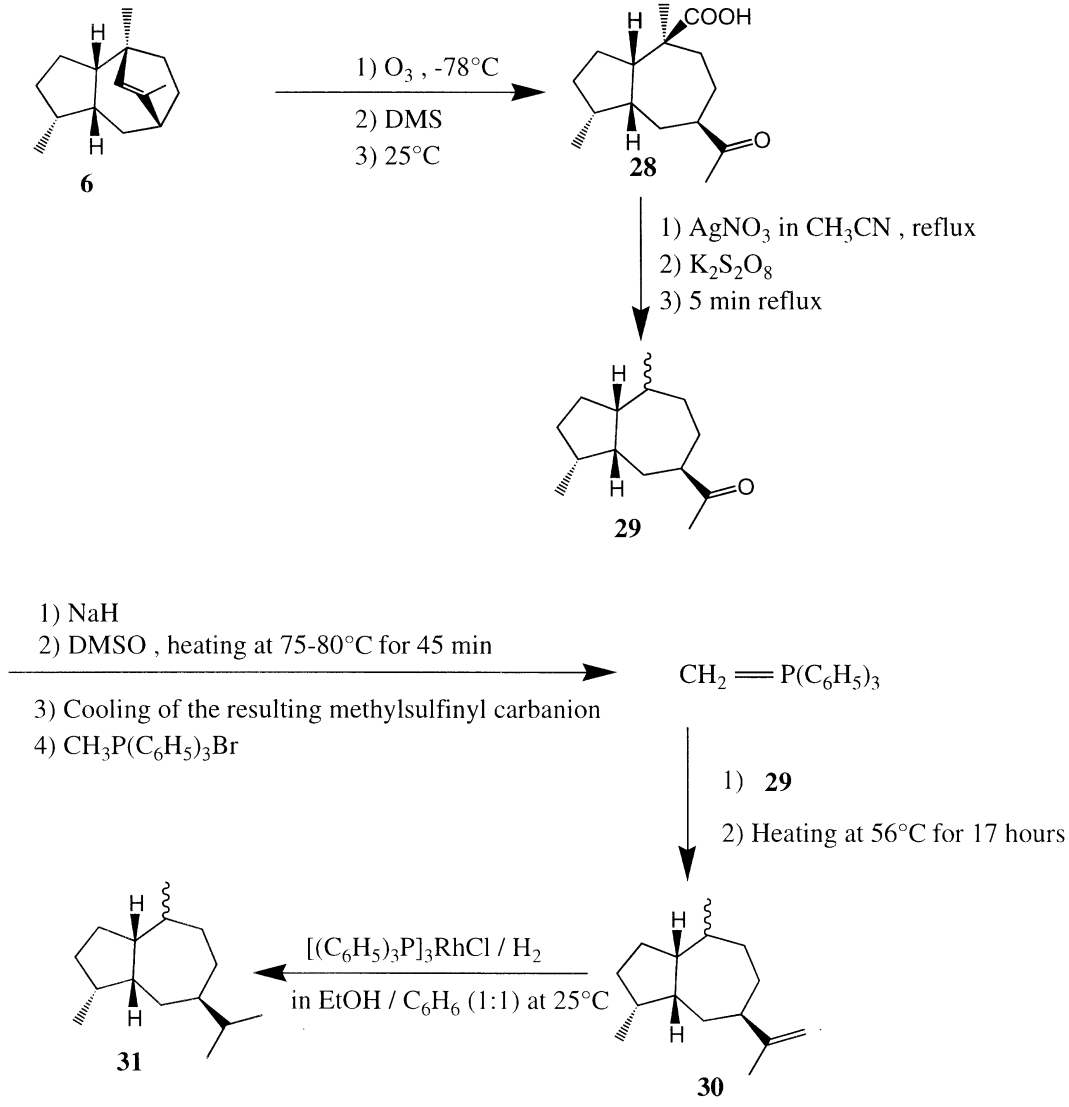

Fig. 4. Chemical conversion of the rotundane to a guaiane skeleton.

geminal methyl groups H-12 and H-13 (δ 0.99 and 1.01) which are coupled to each other (W-coupling), the methyl group at δ 0.77, appearing as a doublet and coupling with the methine proton H-10 (δ 2.12). The vinylic proton H-2 (δ 6.17) couples with another vinylic proton H-3 (δ 5.69), itself coupled to the olefinic methylene group H-15 (δ 4.98) and also to the methine proton H-5 (δ 3.03) giving the substructure –CH=CH–C(CH)=CH_2. Moreover, the coupling constant between H-2 and H-3 ($J = 5.60$ Hz) indicates that they belong to a five-membered ring. The methine proton H-5 also couples with the methylene group CH_2-6 (δ 1.68 and 2.10) which further couples with the methine proton H-7 (δ 1.85) itself coupled to the methylene group CH_2-8 (δ 1.51 and 1.86) which again couples with the methylene group CH_2-9 (δ 1.03 and 1.29) itself coupled to the methine proton CH-10 (δ 2.12). From these informations the substructure CH–CH_2–CH–CH_2–CH_2–CH– is derived.

All these informations from the ^{13}C NMR and DEPT as well as the ^1H–^1H-COSY led us to propose structure **24** for the compound. Its relative configuration resulted from the NOESY diagram which shows NOE correlations between H-5, H-9 and H-14 at one side and between H-13 and H-10 at the other. The observed correlations indicate that the methine proton H-10 is on the same side with the bridge C-1–C-7, while H-5, H-9 and H-14 are located at the opposite side of the molecule (Fig. 7). **24** was before found as a minor product during the reduction of cyperotundone (**18**) to the corresponding alcohol and subsequent dehydration to **2** (Fig. 8) (Mekem Sonwa et al., 1997).

2.3. (−)-Norrotundene (25)

The isolation of **25** was performed by the combination of many separation methods including CC at low temperature (−20° C), CC over silver nitrate precoated

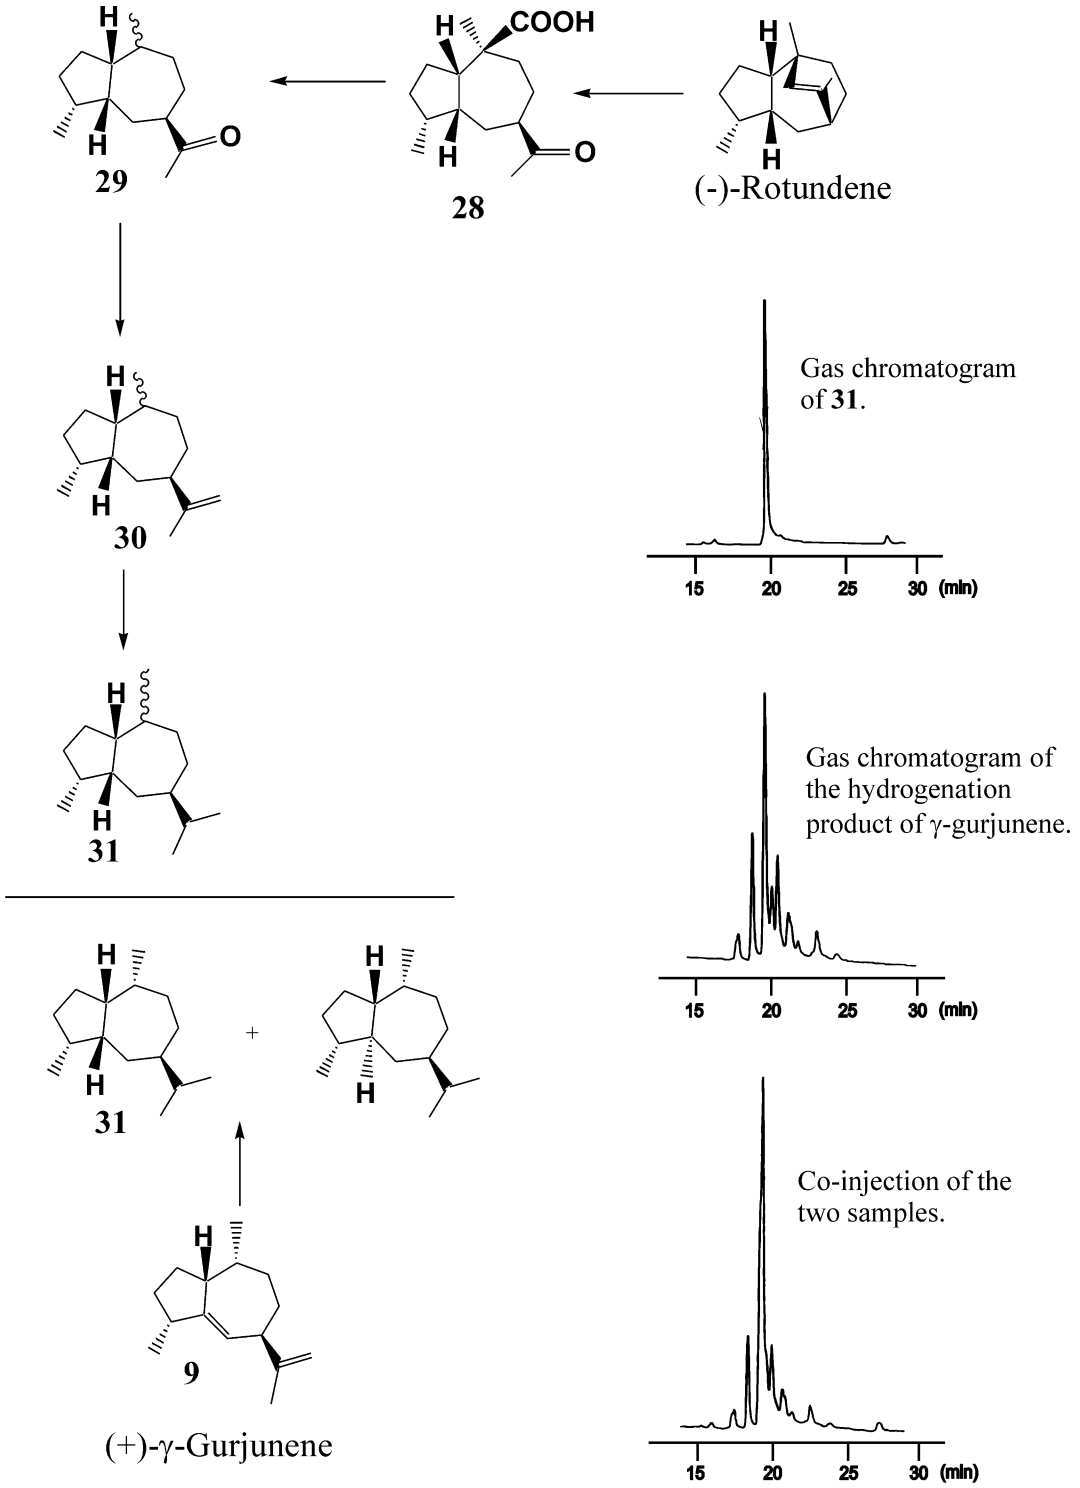

Fig. 5. Chemical transformation of rotundene and GC comparison with the hydrogenation product of (+)-γ-gurjunene.

silica, preparative TLC and GC. The compound has the molecular formula $C_{14}H_{22}$ in agreement with its mass spectrum ($[M]^+$ at m/z =190). The ^{13}C NMR and DEPT spectra revealed 14 carbon atoms, two methyl groups, five methylene groups, six methine groups from which two are olefinic (δ 129.15 and 139.10) and one quaternary carbon atom. Therefore the compound should consist of three rings since it has a total of four unsaturations, one being a double bond. The constitution of **25** was derived from interpretation of the ^1H NMR spectrum and the phase-sensitive ^1H–^1H-COSY spectrum together with the HMQC and the HMBC diagrams.The methine proton CH-1 (δ 2.20) couples with the methylene group CH_2-2 (δ 1.61 and 1.54) which

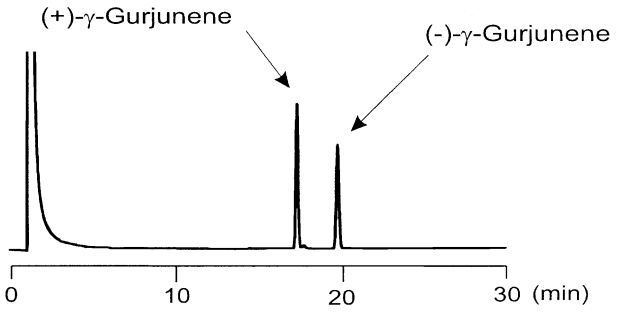

Fig. 6. Separation of (−)- and (+)-γ-gurjunene by capillary gas chromatography on a 25 m capillary column with heptakis(6-*O*-*t*.butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin (50% in OV 1701, w/w) at 100 °C.

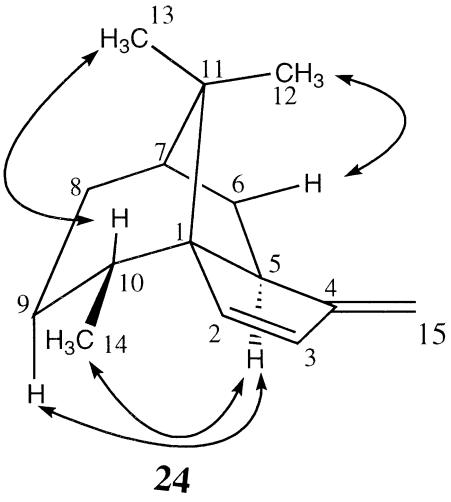

Fig. 7. Stereostructure of cypera-2,4(15)-diene (**24**) and important NOEs.

further couples with another methylene group CH_2-3 (δ 1.42 and 1.87) which couples again with the methine proton H-4 (δ 2.10) itself coupled to the methyl group CH_3-14 (δ 0.90) and the methine proton CH-5 (δ 1.80) which further couples with the methine proton H-1 (δ 2.20) and gives rise to a five-ring partial structure *a*: C_1H–CH_2–CH_2–$CH(CH_3)$–CH–C_1H–.

The methine proton H-5 also couples with methylene group CH_2-6 (δ 0.95 and 1.66) which further couples with the methine proton H-7 (δ 2.56), itself coupled to the methylene group H-8 (δ 1.12 and 1.91) which couples again with the methylene group H-9 (δ 1.52 and 1.83) to give the substructure *b*: CH–CH_2–CH–CH_2–CH_2–. Moreover, the vinylic protons H-11 and H-12 (δ 6.02) are coupled to the methine proton H-7, indicating a partial structure *c*: –CH=CH–CH–. Observing that the substructures *a* and *b* have C-5 in common and that *b* and *c* have C-7 in common, the three partial structures can be connected to give a new substructure A (Fig. 9). It may be assumed that the only tertiary methyl group of the molecule CH_3-13 is linked to the only quaternary carbon and thus yielding substructure B: CH_3–C. This assumption is confirmed by the HMBC diagram which shows long-range correlations between the protons H-13 and C-1, C-10 and C-11. Proton H-1 shows long-range connectivities to C-2, C-5, C-10 and C-11. The protons of methylene group CH_2-9 show connectivities to C-1, C-8, C-10 and C-11, while the olefinic proton H-11 is long-range coupled to C-1, C-7, C-9, C-10, C-12 and C-13. All these observations imply the two carbon-carbon connections between C-10–C-1 and C-10–C-11, leading to a rotundane skeleton for **25** (Fig. 9).

The relative stereochemistry at the chiral centres of the molecule could not be derived from the NOESY spectrum. The signals of the two methine protons H-1 and H-4 overlap and hence it is not possible to know which one of them is responsible for the NOE with the proton H-5. However, using the phase-sensitive COSY technique as well as the gradient selected HMQC method, it was possible to calculate the scalar coupling constant between H-4 and H-5 ($J = 5.85$ Hz). This value of the coupling constant corresponds (Karplus curve) to an angle of $\Phi = 35°$ between the two protons, which means that they are on the same side of the molecule. Accordingly, both of them have spatial interactions with H-1. It remains to investigate the stereochemistry at C-7 and C-10. To solve this problem the NOESY diagram was of no help because the protons H-1 and H-5 are too far from the vinylic protons H-11 and H-12. The solution came from the ^{1}H–^{1}H-COSY diagram where a long-range coupling correlation is found between proton H-1 and one of the H-9 protons. This is a case of ^4J coupling through a σ-bond which requires a particular geometry (W arrangement of the two protons) for the molecule, and this is only possible if the H-1 proton and the C-11–C12 bridge are on the same side of the molecule. Moreover, the axial–axial coupling between H-5 and H-6a is only possible for this stereochemistry of the molecule (Fig. 10). Norrotundene is probably biogenetically related to rotundene and should have the same absolute configuration.

2.4. Cyperadione (*26*)

Cyperadione (**26**) was isolated from the oxygenated fraction of *C. rotundus* oil by preparative GC. The compound has the molecular formula $C_{15}H_{24}O_2$ ($[M]^+$ at $m/z = 236$). The ^{13}C NMR- and the DEPTspectrum indicate that it has four methyl groups, two methine protons and four quaternary carbon atoms, two of which being carbonyl carbons (δ 208.50 and 220.25). From the ^{1}H NMR and the ^{1}H ^{1}H-COSY spectra, three substructures were assigned which helped to derive the full structure of the product. The methyl group CH_3-14 (δ 0.78) couples with the methine proton CH-10 (δ 2.10) which also couples with the methylene group CH_2-9 (δ 1.10 and 1.68) itself coupled to the methylene group CH_2-8 (δ 1.45 and 2.01) which further couples with the

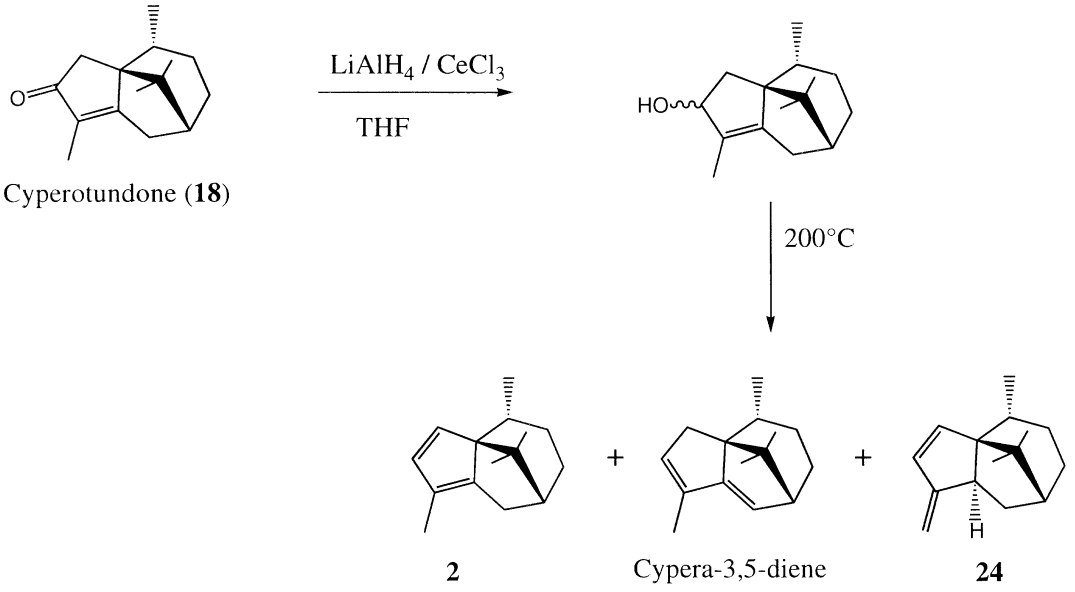

Fig. 8. Formation of cypera-2,4(15)-diene (**24**) form cyperotundone (**18**).

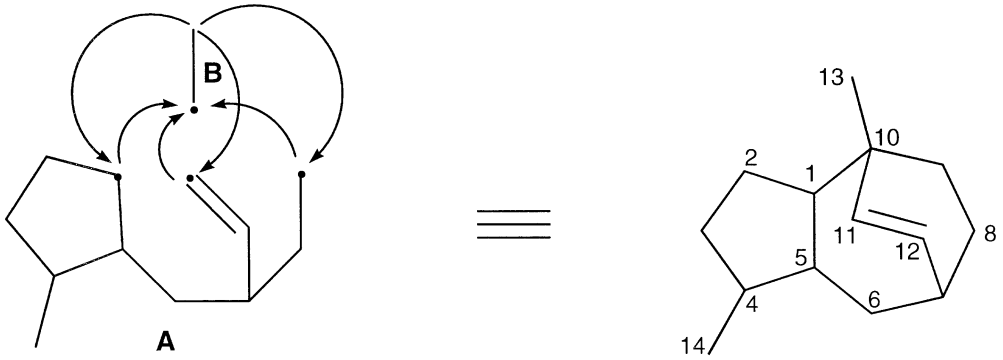

Fig. 9. Important proton-carbon long-range correlations in the HMBC spectrum of norrotundene (**25**).

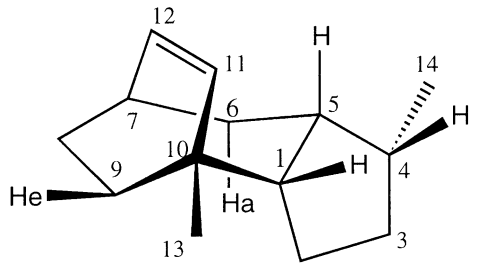

Fig. 10. Relative configuration of norrotundene (**25**). Note the W-arrangement between H-1 and H-9e, and the axial-axial disposition between H-5 and H-6a. These two geometrical patterns which are supported by the observed coupling correlations are only possible for the given stereostructure of the molecule.

methine proton CH-7 (δ 1.90) itself coupled to the methylene group CH_2-6 (δ 1.96 and 2.48). It should be pointed out that the signals of this methylene group appearing at lower field and showing no other coupling correlation to a proton may be adjacent to a carbonyl group. This is confirmed by the HMBC diagram where correlations are observed between the protons H-6 and carbonyl carbon C-7. From all this information substructure CH_3–CH–CH_2–CH_2–CH–CH_2–CO can be derived. The two methyl groups at δ 0.98 and 1.28 appearing as singlets are coupled to each other (W coupling), what indicates that they are linked to the same quaternary carbon atom giving the substructure CH_3–C–CH_3. The deshielded methyl group CH_3-15 at δ 2.18 is probably adjacent to a carbonyl function (this is also confirmed by the HMBC spectrum) and shows a long-range coupling correlation to the methylene group CH_2-3 (δ 2.35 and 2.44) which further couples with the methylene group CH_2-2 (δ 1.50 and 2.11) to give the partial structure CH_3–CO–CH_2–CH_2–. Additional structural informations were drawn from the HMBC diagram. The methylene protons H-2 are long-range correlated to carbons C-1, C-3, C-4, C-5, C-10 and C-11 while the methine proton H-10 shows connectivities to C-1, C-2, C-5, C-9, C-11 and C-14. From these observations the

three carbon–carbon connections C-1–C-2, C-1–C-10 and C-1–C-5 were deduced. Moreover, the methyl protons H-12 and H-13 are long-range correlated to C-1, C-7 and C-11, establishing the two connections C-11–C-1 and C-11–C-7. All these considerations led to structure **26** (Fig. 11), with a skeleton related to the patchoulane skeleton of cyperene (**4**). To confirm structure **26** we performed an ozonolysis of cyperene (**4**) (Fig. 12). The reaction product displayed the same spectral data as the isolated compound.

2.5. Biogenesis of patchoulane and rotundane type sesquiterpenes

Patchoulane and rotundane sesquiterpenes are characteristic for the genus *Cyperus*. Cyperene (**4**) is always the major hydrocarbon component in *Cyperus* species. Rotundene (**6**) also is always present as a major sesquiterpene hydrocarbon component. These two compounds appear to be of some chemotaxonomic importance. We have previously reported the isolation of cyprotene (**1**), a norsesquiterpene biogenetically related to cyperene from the essential oil of *Cyperus alopecuroides*. Here, we described a new norsesquiterpene, norrotundene (**25**), which most likely has a biogenetic relationship to rotundene. Besides **1** compound **25** was also identified in *C. papyrus*. It, therefore, seems to be a peculiarity of *Cyperus* species to produce norsesquiterpenes.

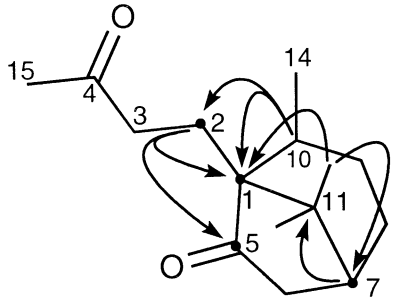

Fig. 11. Long-range correlations from the HMBC spectrum of cyperadione (**26**).

The biosynthesis of cyperene and rotundene may involve two successive cyclisation steps of farnesyl diphosphate FDP leading via a cyclodecadienyl to a cationic azulane type intermediate. At this stage two pathways *a* and *b* may take place: Path *a* proceeds by a 1,2- proton shift followed by a deprotonation leading to α-guaiene from which cyperene is formed by subsequent protonation, cyclisation and deprotonation. Path *b* proceeds by ring formation followed by a deprotonation yielding rotundene or isorotundene (Fig. 13).

3. Experimental

3.1. GC-MS

Electron impact (70 eV) GC–MS measurements were carried out on a Hewlett-Packard HP 5890 gas chromatograph equipped with a 25 m polydimethylsiloxane (Chrompack CP Sil 5 CB) capillary column and coupled to a VG Analytical VG 70-250S mass spectrometer. Helium was used as carrier gas.

3.2. NMR spectroscopy

NMR spectra were recorded using a Bruker DRX 500 (^{1}H: 500 MHz, ^{13}C: 125 MHz) and a Bruker DRX 400 (^{1}H: 400 MHz, ^{13}C: 100 MHz). Tetramethylsilane (TMS) was used as reference signal ($\delta = 0.00$).

3.3. Capillary GC

Orion Micromat 412 double column instrument with 25 m fused silica capillaries with CPSil 5 and CPSil 19 (Chrompack); Carlo Erba Fractovap 2150, 4160 instruments with 25 m fused silica capillaries with heptakis(2,6-di-*O*-methyl-3-*O*-pentyl)-β- (2,6-Me-3-Pe-β-CD) and - γ - cyclodextrin, respectively, and heptakis(6 - *O* - t.butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin (6T-2,3-Me-β-CD), all in polysiloxane OV1701 (50 wt%); split injection, flame ionization detection; carrier gas 0.5 bar hydrogen.

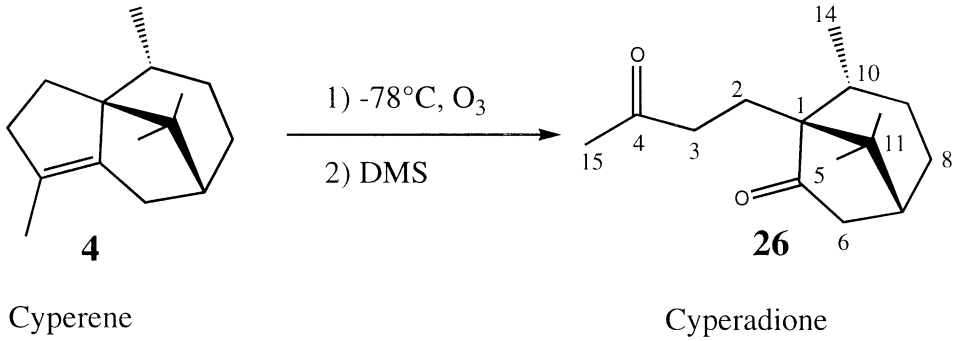

Fig. 12. Preparation of cyperadione by ozonolysis of cyperene.

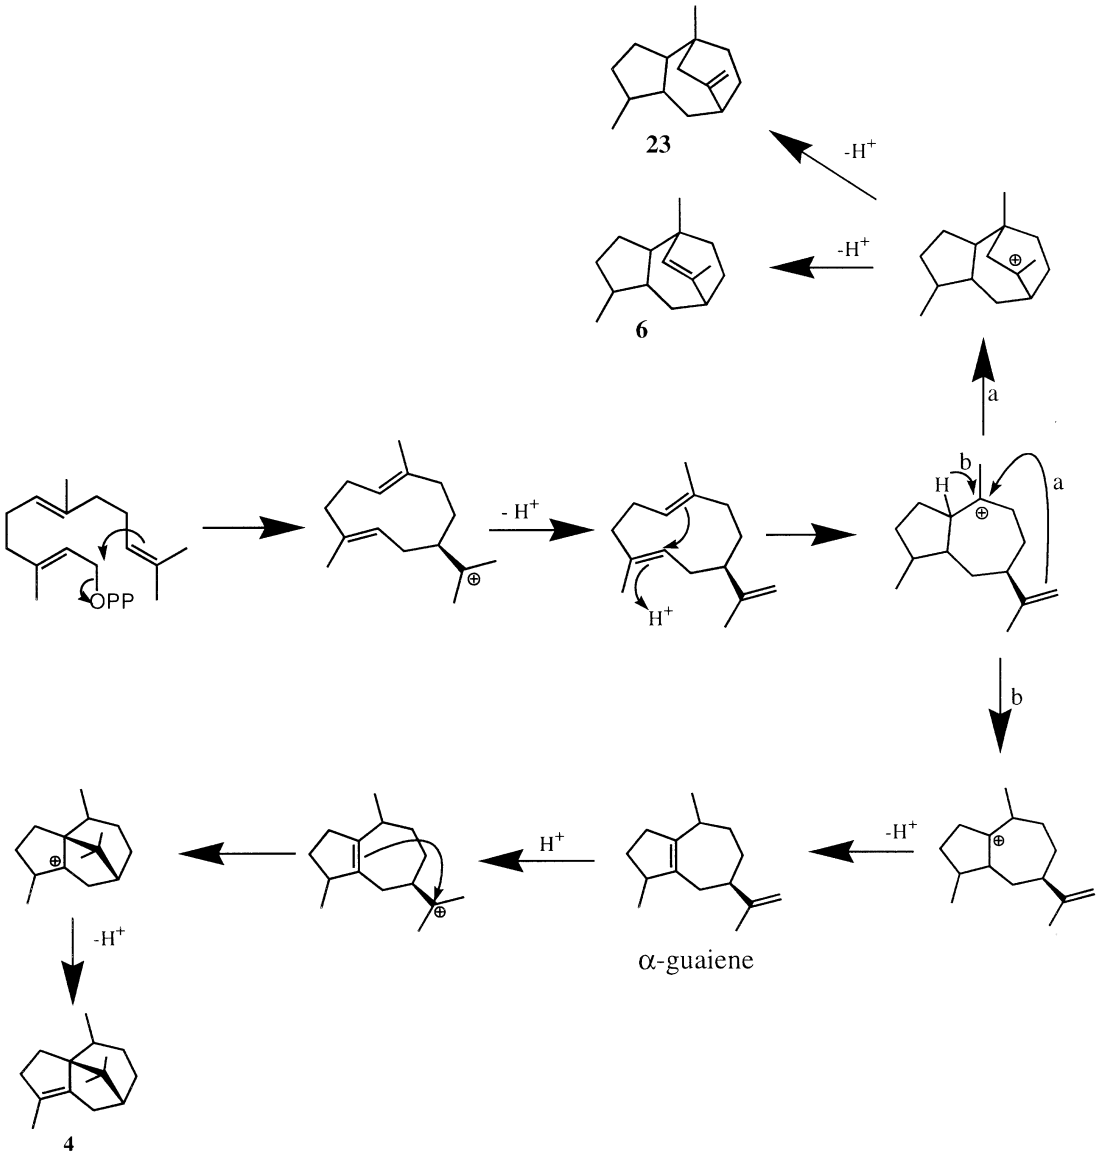

Fig. 13. Proposed biogenetic pathway for cyperene, rotundene and isorotundene.

3.4. Column chromatography at low temperature

Prefractionations of essential oils were performed on a silica gel column equipped with a condenser and connected to a Kryoflex KF 40 cooling system from Messgeräte-Werk Lauda at −20 °C. Ethanol was used as cooling liquid.

3.5. Thin layer chromatography

Thin layer chromatography was effected using glass and aluminum plates of silica 60 F_{254} (Merck). Silver nitrate coated plates were prepared by immersing the plates into an ethanol–water (4:1) solution of silver nitrate (5 mg $AgNO_3$ in 50 ml of solvent). After 30 min the plates were removed from the solution and dried in an oven. An ethanolic solution of sulfuric acid (10%) was used as a spray reagent.

3.6. Essential oil

The essential oil of *C. rotundus* was a gift of K.-D. Protzen, Paul Kaders GmbH, Hamburg.

3.7. Isolation of compound **23**

A preliminary separation of the essential oil was performed by column chromatography at low temperature (−20 °C). This resulted in a fractionation of the oil into a hydrocarbon and an oygenated fraction. One gram of the hydrocarbon fraction was then separated by TLC using petroleum ether as eluting solvent. The aim of this

separation was to eliminate the major hydrocarbon (cyperene) from the sample before any other operation. Three bands were obtained, the first two containing mainly cyperene and α-copaene. Only the third fraction ($R_f = 0.45$) was interesting because it contained the unknown products. This fraction was further separated by preparative GC (column 6T-2,3-Me-β-CD, temperature programme: from 110 to 180 °C, heating rate 2°/min). Fraction 5 of the chromatogram contained (+)-ylanga-2,4(15)-diene (**8**). Fraction 8 was analysed by GC–MS and three major products were present: α-selinene (**5**), valencene (**7**), and an unknown product. This sample was further separated by preparative TLC on silver nitrate precoated plates, using petroleum ether as eluting solvent. Two bands were obtained, the second of which ($R_f = 0.35$) was taken up in petroleum ether and purified by preparative GC. Spectroscopic analysis resulted in the structure of isorotundene **23**.

3.8. (−)- Isorotundene (*23*)

^{1}H NMR (500 MHz, C_6D_6): see Table 1. ^{13}C NMR (100 MHz, C_6D_6): δ 16.10 (*q*, C-15), 25.20 (*t*, C-2), 27.53 (*t*, C-8), 29.28 (*t*, C-9), 31.48 (*t*, C-3), 32.28 (*q*, C-14), 33.15 (*t*, C-6), 34.38 (*s*, C-10), 38.25 (*d*, C-4), 38.64 (*d*, C-7), 41.52 (*d*, C-5), 44.36 (*t*, C-11), 56.19 (*t*, C-1), 107.98 (*t*, C-13), 151.08 (*s*, C-12). 3.9. Preparation of isorotudene (*23*) from rotundene (*6*)

3.9.1. Hydration of rotundene by oxymercuration-demercuration

In a 50 ml flask, fitted with a magnetic stirrer, 48 mg of mercuric acetate were placed. To this, 3 ml of water were added followed by 3 ml of THF. After addition of 30 mg (0.148 mmol) of rotundene the reaction mixture was stirred for 15 min at room temp. to complete the oxymercuration. 3 ml of 3.0 M sodium hydroxyde were added followed by 3 ml of a solution of 0.50 M sodium borohydride in 3.0 M sodium hydroxide. Reduction of the mercurial complex is almost instantaneous. The mercury is allowed to precipitate. Sodium chloride was added to saturate the water layer. The upper layer of THF was removed and purified by preparative GC, yielding 26 mg (80%) of isorotundenol (**27**).

3.9.2. Isorotundenol $C_{15}H_{25}OH$ (*27*)

^{1}H NMR (500 MHz, C_6D_6): δ 0.75 (3H, *d*, $J = 6.61$ Hz), 0.76 (3H, *s*), 1.02 (3H, *s*), 1.08-1.54 (12H, *m*), 1.57–1.65 (2H, *m*), 1.75 (1H, *m*), 2.15 (1H, *m*). MS (EI, 70 eV), *m*/*z* (rel. int.) : 222 (5), 204 (19), 189 (27), 175 (7), 161 (14), 147 (12), 133 (13), 121 (33), 108 (100), 93 (57), 81 (39), 67 (24), 55 27), 41 (35).

3.9.3. Dehydration of isorotundenol

Phosphoryl chloride (0.5 ml) was added to a pyridine solution (1 ml) of isorotundenol (10 mg). The mixture was stirred for 10 h and pyridine was then removed by distillation at low pressure. The remaining residue was taken up in hexane and separation by prep. GC yielded 3 mg of isorotundene and 3 mg of rotundene.

3.10. Ozonolysis of rotundene

A solution of rotundene (50 mg) in dichloromethane (20 ml) was treated at −78° C with a stream of ozone until a persistant blue colour was observed. The solution was then purged with nitrogen for 5 min. After addition of dimethylsulfide (3 ml) the solution was washed with ice-cold sodium bicarbonate solution (25 ml), water and brine. The organic layer was dried ($NaSO_4$) and the solvent was evaporated. Purification of the residue by prep. GC gave the keto-acid **28** (45 mg).

^{1}H NMR (400 MHz, $CDCl_3$): δ 1.10 (3H, *d*, $J = 6.61$ Hz), 1.30 (1H, *m*), 1.35 (3H, *s*), 1.65–1.92 (9H, *m*), 2.11 (1H, *m*), 2.20 (1H, *m*), 2.29 (3H, *s*), 2.58–2.85 (2H,*m*). ^{13}C NMR (100 MHz, $CDCl_3$): 16.73, 25.10, 25.66, 27.47, 28.30, 30.07, 31.09, 31.60, 39.64, 41.70, 48.56, 48.64, 50.55, 184.59, 212.01. MS (EI, 70 eV) *m*/*z* (rel. int): 252 (13) $[M]^+$, 234 (7), 206 (15), 191 (11), 163 (36), 149 (7), 133 (10), 121 (18), 107 (25), 95 (68), 81 (43), 67 (22), 55 (28), 43 (100).

3.11. Decarboxylation of keto-acid **28**

The keto-acid (40 mg, 0.16 mol) and silver nitrate (1 mg) were dissolved in acetonitrile (6 ml) and water (2 ml) and heated to reflux. To this solution potassium peroxosulfate ($K_2S_2O_8$) (0.32 mg) in water (5 ml) was slowly added. Refluxing was continued for another 5 min before the reaction mixture was cooled and extracted with a saturated sodium bicarbonate solution (10 ml, three times), dried ($MgSO_4$) and purified by prep. GC to give 14 mg of ketone **28**.

^{1}H NMR (500 MHz, $CDCl_3$): 0.96 (3H, *dd*, $J=6.62$ Hz), 1.06 (3H, *s*), 1.40 (1H, *m*), 1.60–1.84 (7 H, *m*), 1.97–2.1 (2H, *m*), 2.13–2.24 (3H, *m*), 2.27 (3H,*s*), 2.44 (1 H, *m*), 2.69 (1H, *dd*, $J_1=13.87$ Hz, $J_2=6.94$ Hz). ^{13}C NMR (100 MHz, $CDCl_3$): 15.10 (*q*), 21.52 (*q*), 26.09 (*t*), 26.80 (*t*), 27.85 (*q*), 30.26 (*t*), 33.25 (*t*), 37.46 (*t*), 37.99 (*d*), 38.04 (*d*), 46.82 (*d*), 56.70 (*d*), 61.65 (*d*), 207.93 (*s*). MS, (EI, 70 eV), *m*/*z* (rel. int): 208 (5) $[M]^+$, 190 (7), 175 (6), 161 (5), 150(8), 135 (9), 123 (27), 109 (23), 95 (100), 81 (31), 67 (25), 55 (29), 43 (52).

3.12. Reduction of ketone **29**

In a three-necked flask sodium hydride (0.45 mmol) was washed with several portions of pentane to remove the mineral oil. The flask was then equipped with rubber stopper, a reflux condenser and a magnetic stirrer. The system was alternately evacuated and filled with nitrogen; 3 ml of dimethyl sulfoxide was introduced via a syringe and the mixture was heated at 75–80° C for 45 min. The resulting solution of methylsulfinyl carbanion was cooled in an ice-water bath, and 108 mg of methyltriphenylphosphonium bromide in 100 ml of warm dimethyl sulfoxide were added. The resulting dark red solution of the ylide was stirred at room temperature for 10 min before 7 mg of the ketone **29** in two ml of dimethyl sulfoxide were added. The reaction mixture was then heated at 56°C for 16 h after which the solution was allowed to cool and 10 ml of water were added. The two phases were extracted three times with *n*-pentane (40 ml). The *n*-pentane fractions were combined and washed with 10 ml of a (1/1) water/dimethyl sulfoxide solution and then with 30 ml of 50% saturated sodium chloride solution. The pentane layer was then dried over anhydrous sodium sulfate and purification by preparative GC gave 2 mg of the alkene **30**.

MS (EI, 70 eV), *m*/*z* (rel. int): 206 (12) $[M]^+$, 191 (18), 177 (6), 163 (51), 149 (25), 122 (39), 107 (56), 95 (60), 81 (100), 67 (57), 55 (66), 41 (79).

3.13. Hydrocarbon 31

a. **30** (1 mg) was dissolved in a mixture of ethanol (1 ml) and benzene (1 ml). The catalyst $[(Ph)_3P]_3RhCl$ (1 mg) was added and the solution turned orange. A gentle stream of hydrogen was then passed through the solution under normal pressure for 15 min. The solvent was removed under reduced pressure and petroleum ether was added, since most of the catalyst remains undissolved. Filtration through a column of alumina afforded the pure alkane **31**. MS (EI, 70 eV), $[M]^+$ $m/z=208$.

b. The hydrogenation of (+)-γ-gurjunene (**9**) followed the same procedure as that of the alkene **30** except the catalyst was replaced by nickel on charcoal.

3.14. Isolation of cypera-2,4(15)-diene and norrotundene

For the above described chemical transformation, a relatively large amount of rotundene had to be isolated from the essential oil of *C. rotundus*. For the isolation 5 g of the hydrocarbon fraction of the oil were separated by column chromatography over silver nitrate precoated silica using a petroleum ether–chloroform gradient for elution. The eluent from the column was monitored by capillary GC and 16 fractions were collected. Fractions 1–6 obtained by elution with petroleum ether contained only known hydrocarbons. Fractions 7–10 were obtained by elution with petroleum ether–chloroform (7/3) and contained the rotundene. It could be proved by GC–MS of fraction eighth that the sample also contained an unknown minor component. The separation of this fraction was performed by prep. GC (column: 2,6-Me-3Pe-β-CD; temp. programme: 100–140 °C, heating rate 2 °C/min). The chromatogram displayed five peaks the fifth containing the pure unknown product which was characterized as cypera-2,4(15)-diene (**24**). Fractions 11–15 were eluted with petroleum ether–chloroform (1/1). GC–MS revealed the presence of an unknown product of molecular weight 190 among many known sesquiterpene hydrocarbons. In order to isolate the unknown compound, the joined fractions 14 and 15 were first separated by prep. TLC over silver nitrate precoated plates, using petroleum ether–chloroform (7/3) as eluting solvent. Three bands were obtained and the third one, which contained the norsesquiterpene as major product was separated by preparative GC (column: SE 30, temp. 125 °C). Spectroscopic data permitted the characterization of the compound as norrotundene (**25**).

3.14.1. (−)-Cypera-2,4(15)-diene (**24**)

^{1}H NMR (400 MHz, C6D6): see Table 2. ^{13}C NMR (400 MHz, C6D6) : 17.32 (*q*), 19.61 (*q*), 26.36 (*q*), 26.64 (*q*), 27.70 (*t*), 28.48 (*s*), 30.16 (*t*), 32.58 (*t*), 44.96 (*d*), 47.66 (*d*), 61.93 (*s*), 102.84 (*t*), 133.26 (*d*), 139.17 (*d*), 148.94 (*s*). 3.15. Isolation of cyperadione (*26*)

The fraction of oxygenated sesquiterpenes was submitted to prep. TLC using petroleum ether–ethyl acetate (8/2) as eluting solvent. The second band (R_f=0.35) was then taken up in diethyl ether and submitted to further separation by prep. GC (column: 6T-2,3-Me-β-CD, 120–180 °C, 2 °C/min).

3.16. Ozonolosis of cyperene (*4*)

Three mg of cyperene in dichloromethane (20 ml) were treated at −78 °C with a stream of ozone until a persistant blue colour was observed. The solution was then purged with nitrogen for 5 mins. 1 ml of dimethylsulfide was then added, and washed with 10 ml of an ice-cold sodium bicarbonate solution, water and brine. The organic layer was dried over $MgSO_4$ and the solvent evaporated. The residue was then purified by prep. GC to give 3 mg of cyperadione (**26**).

Received 19 March 2001; received in revised form 5 June 2001

Abstract

From the aerial part of *Acanthus ebracteatus*, a megastigmane glycoside (ebracteatoside A), three aliphatic alcohol glycosides (ebracteatosides B–D), as well as 7-chloro-(2*R*)-2-*O*-β-D-glucopyranosyl-4-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one (7-Cl-DIBOA-Glc) were isolated together with 22 known compounds. Structural elucidations were based on analyses of spectroscopic data.

Keywords: *Acanthus ebracteatus*; Acanthaceae; Megastigmane glycoside; Aliphatic alcohol glycoside; Benzoxazinoid glucoside; Ebracteatosides A–D

1. Introduction

As part of our ongoing study on Thai medicinal plants in the genus *Acanthus* (Kanchanapoom et al., 2001a,b), we investigated the constituents of *Acanthus ebracteatus* Vahl (Acanthaceae, Thai name: Ngueak-Pla-Mo, Nam-Mo) collected from Pattani province. *A. ebracteatus* is a spiny herb distributed in the mangroves of southern Thailand. In Thai traditional medicine, the plant is widely used as a purgative and an anti-inflammatory, as well as the leaves dispensed with pepper (*Piper nigrum* L.) as tonic pills for longevity. In the preliminary studies, anti-mutagenicities of the organic extracts have been reported (Rojanapo et al., 1990). The present study deals with the isolation and structural elucidation of one new megastigmane glycoside (**3**), three new aliphatic alcohol glycosides (**5**–**7**) and one new benzoxazinoid glucoside (**10**), along with 22 known compounds from the aerial part of this plant. Also, the usage in Thai traditional medicines is discussed.

2. Results and discussion

The methanolic extract of the aerial part of *A. ebracteatus* was suspended in H_2O and defatted with Et_2O. The aqueous layer was subjected to a column of highly porous copolymer resin of styrene and divinylbenzene, using H_2O, 30% MeOH, 60% MeOH, MeOH and Me_2CO, successively. The fractions eluted with 30% and 60% MeOH were repeatedly subjected to silica gel column chromatography, as well as other RP-18 or prep. HPLC to afford 27 compounds. Twenty two were identified as known compounds; plucheoside B (**1**), alangionoside C (**2**) (Otsuka et al., 1995), premnaionoside (**4**) (Sudo et al., 2000), (2*R*)-2-*O*-β-D-glucopyranosyl-2*H*-1,4-benzoxazin-3(4*H*)-one (HBOA-Glc, **8**) (Tietze et al., 1991), (2*R*)-2-*O*-β-D-glucopyranosyl-4-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one (DIBOA-Glc, **9**) (Hartenstein and Sicker, 1994), phenethyl alcohol 8-*O*-β-D-glucopyranosyl-(1→2)-*O*-β-D-glucopyranoside (**11**) (Ono et al., 1999), benzyl alcohol 7-*O*-β-D-glucopyranosyl-(1→2)-*O*-β-D-glucopyranoside (zizybeoside I, **12**) (Okamura et al., 1981), adenosine (**13**) (Otsuka et al., 1989), verbascoside (**14**), isoverbascoside (**15**), leucosceptoside A (**16**) (Miyase et al., 1982), martynoside (**17**) (Sasaki et al., 1978), β-hydroxyacteoside (**18**) (Kitakawa et al., 1984), vecenin-2 (**19**), schaftoside (**20**) (Markham and Chari, 1982), luteolin-7-*O*-β-D-glucuronide (**21**), apigenin-7-*O*-β-D-glucuronide (**22**) (Hase et al., 1995), (+)-lyoniresinol 3α-*O*-β-D-glucopyranoside (**23**), (−)-lyoniresinol 3α-*O*-β-D-glucopyranoside (**24**) (Achenbach et al., 1992), (8*R*, 7′*S*, 8′*R*)-5,5′-dimethoxylariciresinol 4′-*O*-β-D-glucopyranoside (**25**) (Ida et al., 1994), magnolenin C (**26**) (Rao and Wu, 1978), and (+)-syringaresinol-4-*O*-β-D-apiofuranosyl-(1→2)-*O*-β-D-glucopyranoside (**27**) (Kinjo et al., 1991)

by comparison of physical data with literature values and from spectroscopic evidence.

The molecular formula of compound **3** was determined as $C_{24}H_{40}O_{12}$ by HR-FAB mass spectrometry. The ^1H NMR spectrum revealed the presence of three singlet methyls, one methyl doublet, two olefinic protons, and two anomeric protons of sugar moieties. The ^{13}C NMR spectrum indicated the presence of the β-D-apiofuranosyl-(1→2)-*O*-β-D-glucopyranose unit, compared to compound **4**. The stereochemistry of an apiose could assign as D-form by the coupling of H-5″ at δ 3.61, which showed the magnetically equivalent (Snyder and Serianni, 1987). The remaining 13 carbon signals were suggested to present a megastigmane skeleton. The aglycone moiety of compound **3** was expected to be the same as that of plucheoside B (**1**) and alangionoside C (**2**). On enzymatic hydrolysis of **1**, **2** and **3** gave the same compound **1a**, identified by spectral analyses and comparing the HPLC retention time (R_f 3.38). Comparison of the ^{13}C NMR spectrum of **3** with those of **1a** showed

a significant downfield shift of C-9 (+7.9 ppm) together with the upfield shifts of C-8 (−2.1 ppm) and C-10 (−2.8 ppm), indicating that the sugar moiety is located at C-9. The absolute configuration at C-9 of **3** was assigned to be *R* from the chemical shifts at C-9 and C-10 (77.4 and 21.0, respectively) (Pabst et al., 1992; Takeda et al., 1997). Also, the absolute configurations at C-9 of **1** and **2**, which could not be determined from the previous reports (Uchiyama et al., 1989; Otsuka et al., 1995), were concluded to be *R*. Consequently, the structure of compound **3** was elucidated as shown, named ebracteatoside A.

The molecular formula of compound **5** was determined as $C_{25}H_{44}O_{15}$ by HR-FAB mass spectrometry. The ^{13}C NMR spectrum showed the presence of three sugar moities, which were identified to be a terminal β-D-glucopyranose, a terminal β-D-xylopyranose connected to a core β-D-glucopyranose unit, in addition to eight carbon signals for the aglycone. Acid hydrolysis gave D-xylose and D-glucose which were identified by TLC and comparison of the optical rotation with authentic samples. DEPT experiments indicated the presence of one methyl (δ 14.5), five methylenes (δ 23.6, 25.5, 32.9, 35.7 and 116.9) as well as two methines (δ 82.3 and 140.5) in the aglycone moiety. The chemical shifts of **5** were almost the same as those of (3*R*)-1-octen-3-ol-3-*O*-β-D-xylopyranosyl-(1→6)-*O*-β-D-glucopyranoside (**5a**), previously isolated from *Mentha spicata* (Yamamura et al., 1998), except for the additional signals of a β-D-glucopyranosyl unit. The downfield shift of C-2′ (+8.5 ppm) together with the upfield shift of C-1′ (-1.7) and C-3′ (−0.7 ppm) of the substituted sugar established the attachment of an additional unit to C-2′. Also, the HMBC correlations confirmed the positions of the sugar moieties as shown in Fig 1. Moreover, the EI–MS of its trimethylsilyl ethers exhibited the fragment ion characteristic of the 1,6-linked biose unit at *m*/*z* 481, due to TMSi-hexose-(6→1)-TMSi-pentose (Kasai et al., 1977), indicating the position of β-D-xylopyranose to C-6′. Therefore, the structure of compound **5** was assigned as (3*R*)-1-octen-3-ol-3-*O*-β-D-xylopyranosyl-(1‴→6′)-*O*-[β-D-glucopyranosyl-(1″→2′)]-*O*-β-D-glucopyranoside, named ebracteatoside B.

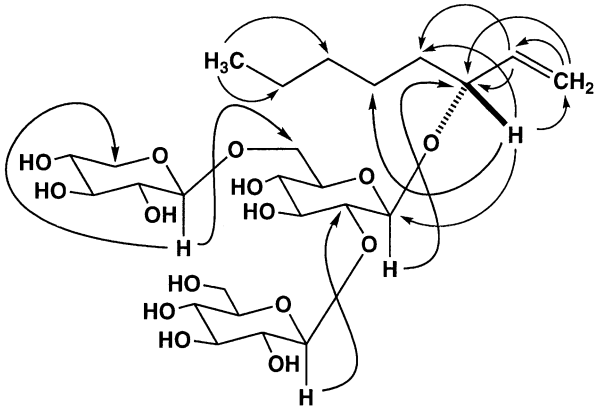

Fig. 1. The HMBC correlations of compound **5**.

Compound **6** had the molecular formula $C_{20}H_{36}O_{12}$, determined from HR-FAB mass spectrometry. The ^{13}C NMR spectrum revealed the presence of two β-D-glucopyranosyl units, one of which was attached at C-2′ due to the downfield shift (δ 83.6) of this carbon signal, in addition to eight signals for the aglycone moiety. Acid hydrolysis afforded D-glucose, identical by TLC and comparison of the optical rotation with authentic sample. The chemical shifts of the aglycone carbons were similar to those of **5**. However, the absence of the methyl signal at δ 14.5 together with the presence of one more methylene carbon at δ 62.9 were observed in **6**, indicating that the terminal methyl was substituted by a hydroxyl group. The absolute configuration at C-6 was suggested to be in the *R*-form by comparing the ^{13}C NMR spectral data with those of **5**. From these results, the structure of compound **6** was identified as (6*R*)-7-octene-1,6-diol 6-*O*-β-D-glucopyranosyl-(1→2)-*O*-β-D-glucopyranoside, named ebracteatoside C.

Compound **7** had the molecular formula $C_{19}H_{34}O_{11}$, deduced from HR-FAB mass spectrometry. The chemical shifts were very similar to those of **6**, except for the difference signals of the terminal sugar which was identified as a β-D-xylopyranose. The terminal sugar was assigned to attach at C-6′ (δ 69.5) of β-D-glucopyranose, due to the downfield shift of this signal. Consequently, the structure of compound **7** was elucidated to be (6*R*)-7-octene-1,6-diol 6-*O*-β-D-xylopyranosyl-(1→6)-*O*-β-D-glucopyranoside, named ebracteatoside D.

Compound **10** showed the characteristic pattern due to have a chlorine atom from negative FAB–MS. The molecular formula was determined by HR–FAB mass spectrometry as $C_{14}H_{16}ClNO_9$. The ^1H and ^{13}C NMR spectral data were similar to those of DIBOA-Glc (**9**). However, the ^1H NMR spectrum revealed the presence of an ABX system at δ 7.16 (1H, $J=8.5$, 2.2 Hz), δ 7.24 (1H, $J=8.5$ Hz) and δ 7.30 (1H, $J=2.2$ Hz), indicating that the chlorine atom was attached to an aromatic ring. The position of the chlorine atom was assigned to C-7 by comparing the calculation of the chemical shifts effect from the Cl atom and the observed chemical shifts from ^{13}C NMR spectrum. The chemical shift differences of the aromatic ring between **9** and **10** as to the *ipso* (C-7), *ortho* (C-6), *ortho* (C-8), *meta* (C-5), *meta* (C-9) and *para* (C-10) were +4.6, −1.0, +0.5, +1.3, +0.9 and −0.5, respectively, which agreed with those for the chlorine substituted at C-7 of the aromatic ring (Silverstein et al., 1981). The configuration at C-2 was suggested to be *R* since the optical rotation measured has a positive value as **9**. Therefore, the structure of compound **10** was identified as 7-chloro-(2*R*)-2-*O*-β-D-glucopyranosyl-4-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one (7-Cl-DIBOA-Glc).

The biological activities of the isolated compounds have not been investigated. The presence of benzoxazinoids (**8**–

9) and phenylpropanoids (**14**–**15**) as the major constituents are in agreement with Thai traditional usage as an anti-inflammatory preparation (Otsuka et al., 1988; Cometa et al., 1993). Furthermore, the toxicological and pharmacological properties of benzoxazinoids have been reported as the chemical resistance factors against insects, fungi, bacteria and viruses in many crop plants of the family Gramineae (Niemeyer, 1988; Sicker et al., 2000), as well as having mutagenic activities (Hashimoto and Shudo, 1996). Also, the aglycone of **9** (DIBOA) was shown to be mutagenic in a test with *Salmonella typhimurium* TA 100 and TA 98 (Hashimoto and Shudo, 1996). The results on the mutagenicities of benzoxazinoids contrasted with the reported as anti-mutagenicities of the organic extracts of this plants by Rojanapo and co-workers (1990), which could be explained by the structural requirements for biological activities of benzoxazinoids. The 2-hydroxyl group of benzoxazinoids has been considered to be important for biological activities more than glucoside forms (Niemeyer, 1988). From these reports, the usage of this species for internal treatments in Thai traditional medicine should be considered.

3. Experimental

3.1. General

NMR spectra were recorded in methanol-d_4 or DMSO-d_6 using a JEOL JNM A-400 spectrometer (400 MHz for ^{1}H NMR and 100 MHz for ^{13}C NMR) with tetramethylsilane (TMS) as internal standard. MS were recorded on a Jeol JMS-SX 102 spectrometer. Optical rotations were measured with a Union PM-1 digital polarimeter. Preparative HPLC was carried out on columns of ODS (150×20 mm i.d., YMC) and polyamine II (250×20 mm i.d., YMC) with a Tosoh refraction index (RI-8) detector. Analytical HPLC was carried out on a column of ODS (100×4.6 mm i.d., YMC). For CC, silica gel G 60 (Merck), YMC-gel ODS (50 μm, YMC), and highly porous copolymer resin of styrene and divinylbenzene (Mitsubishi Chem. Ind. Co. Ltd) were used. The solvent systems were: (I) EtOAc–EtOH–H_2O (4:1:0.1), (II) EtOAc–EtOH–H_2O (7:3:0.3), (III) EtOAc–EtOH–H_2O (6:4:1), (IV) 10% MeCN, (V) 80% MeCN, (VI) 75% MeCN, (VII) EtOAc–MeOH-H_2O (4:1:0.1), (VIII) EtOAc–MeOH–H_2O (7:3:0.3), (IX) EtOAc–EtOH–H_2O (6:4:1), (X) 15% MeCN, (XI) 20% MeCN, (XII) 25% MeCN and (XIII) 40% MeOH. The spray reagent used for TLC was 10% H_2SO_4 in 50% EtOH.

3.2. Plant material

A. ebracteatus Vahl was collected in May 1997 from Pattani Province, Southern Thailand. The identification of the plant was confirmed by Professor Vichiara Jirawongse, Department of Pharmaceutical Botany and Pharmacognosy, Faculty of Pharmaceutical Sciences, Khon Kaen University. A voucher sample (KKU-0002) is kept in the Herbarium of the Faculty of Pharmaceutical Sciences, Khon Kaen University, Thailand.

3.3. Extraction and isolation

The dried aerial part (2.8 kg) of *A. ebracteatus* was extracted with hot MeOH. After removal of the solvent by evaporation, the residue (513.0 g) was defatted with Et_2O. The aqueous layer was subjected to a column of highly porous copolymer resin of styrene and divinylbenzene and eluted with H_2O, 30% MeOH, 60% MeOH, MeOH and Me_2CO, successively. The fraction eluted with 30% MeOH (21.0 g) was subjected to a column of silica gel (systems I, II and III, respectively) affording six fractions. Fraction 2 (4.0 g) was separated on RP-18 (system IV) to provide compound **8** (2.2 g). Fraction 3 (5.6 g) was purified by using RP-18 (system IV) and HPLC-polyamine II (system V) to give compounds **1** (30 mg), **3** (30 mg), **4** (36 mg), **9** (3.8 g) and **11** (42 mg). Fraction 4 (2.1 g) was subjected to RP-18 (system IV), then followed by HPLC-polyamine II (system VI) to afford compounds **6** (78 mg), **7** (5 mg) **12** (18 mg) and **13** (22 mg). Fraction 6 (2.5 g) was further purified by using RP-18 (system V) to provide compound **19** (190 mg).

The fraction eluted with 60% MeOH (48.0 g) was subjected to a column of silica gel (systems VII, VIII and IX, respectively) to give seven fractions. Fraction 2 (10.0 g) was subjected to a column of RP-18 (system X), the followed by HPLC-ODS (system XI or XII) to afford compounds **14** (3.0 g), **15** (325 mg), **16** (38 mg) and **17** (30 mg). Fraction 4 (3.7 g) was purified by using RP-18 (system X) and HPLC-ODS (system XIII) to give compounds **2** (11 mg), **18** (20 mg), **23** (112 mg) and **24** (50 mg). Fraction 5 (3.9 g) was separated on RP-18 (system X) to give nine fractions. Fractions 5-5 and 5-6 were purified by HPLC-ODS (system XIII) to provide compounds **10** (12 mg), **25** (33 mg) and **26** (36 mg). Fractions 5-8 and 5-9 were similarly purified by HPLC-ODS (system XII) to afford compounds **5** (142 mg) and **27** (34 mg). Fraction 6 (2.5 g) was subjected to RP-18 (system X) to provide six fractions. Compound **20** (75 mg) was crystallized from fraction 6-3. Finally, fraction 7 (9.9 g) was purified by RP-18 (system X), then followed by HPLC-ODS (system X) to give compounds **21** (98 mg) and **22** (66 mg).

3.4. Ebracteatoside A (*3*)

Amorphous powder, $[\alpha]_D^{17}$ −52.2° (MeOH, *c* 2.0); ^{1}H NMR (methanol-d_4): δ 1.77 (1H, *dd*, J = 12.7, 12.5 Hz, H-2ax), δ 1.43 (1H, *ddd*, J = 12.2, 3.4, 1.2 Hz, H-2eq), δ 3.74 (1H, *dt*, J = 12.0, 3.9 Hz, H-3), δ 6.07 (1H, *d*, J = 16.1 Hz, H-7), δ 5.56 (1H, *dd*, J = 16.1, 7.0 Hz, H-8),

δ 4.42 (1H, *qd*, *J*=6.6, 1.0 Hz, H-9), δ 3.82 (1H, *brd*, *J*=3.4 Hz, H-4), δ 1.30 (3H, *d*, *J*=6.4 Hz, H-10), δ 1.07 (3H, *s*, H-11), δ 1.03 (3H, *s*, H-12), δ 1.83 (3H, *s*, H-13), δ 4.44 (1H, *d*, *J*=7.8 Hz, H-1′ Glc), δ 3.51 (1H, *dd*, *J*=9.3, 7.8 Hz, H-2′ Glc), δ 3.46 (1H, *dd*, *J*=9.0, 9.0 Hz, H-3′ Glc), δ 3.33 (1H, *dd*, *J*=9.5, 8.5 Hz, H-4′ Glc), δ 3.18 (1H, *ddd*, *J*=9.5, 4.6, 2.2 Hz, H-5′ Glc), δ 3.78 (1H, *dd*, *J*=11.7, 2.4 Hz, H-6′ Glc), δ 3.66 (1H, *dd*, *J*=11.9, 4.9 Hz, H-6′ Glc), δ 5.38 (1H, *d*, *J*=1.7 Hz, H-1″ Api), δ 3.94 (1H, *d*, *J*=1.7 Hz, H-2″ Api), δ 4.06 (1H, *d*, *J*=9.5 Hz, H-4″ Api), δ 3.71 (1H, *d*, *J*=9.5 Hz, H-4″ Api), δ 3.61 (2H, *s*, H-5″ Api); ^{13}C NMR (methanol-d_4): Table 1; negative HR–FAB–MS, *m*/*z* 519.2449 ($C_{24}H_{39}O_{12}$ requires 519.2441)

3.5. Enzymatic hydrolysis of plucheoside B (*1*), alangionoside C (*2*), and ebracteatoside A (*3*)

Each sample of plucheoside B (**1**) (17 mg), alangionoside C (**2**) (9 mg) and ebracteatoside A (**3**) (15 mg) was dissolved in 0.5 ml of MeOH. A solution of crude hesperidinase (100 mg in 20 ml of H_2O) was added in each experiment. After stirring at 37 °C for 5 days, the mixtures were extracted with EtOAc, and concentrated to dryness, affording **1a** (7, 2 and 4 mg, respectively). The structure was identified by spectral analyses and comparing the HPLC retention time (R_f 3.38, solvent system: 50% MeOH)

3.8. Trimethylsilylation of ebracteatoside B (**5**)

Ebracteatoside B (ca. 2 mg) was heated with trimethylsilylimidazole (three drops) in a stoppered microtube at 90 °C for 1 h. After dilution with H_2O, the reaction mixture was extracted with *n*-hexane. The *n*-hexane layer was concentrated to dryness by blowing N_2 gas at room temperature. The residue was subjected to determination of EI–MS.

3.9. Ebracteatoside C (**6**)

Amorphous powder, $[\alpha]_D^{22}$ −19.8° (MeOH, *c* 2.62); ^{1}H NMR (methanol-d_4): δ 3.54 (2H, *t*, *J* = 6.1 Hz, H-1), δ 1.35–1.44 (4H, *m*, H-2, 4), δ 1.54 (2H, *m*, H-3), δ 1.72 (1H, *m*, H-5), δ 1.56 (1H, *m*, H-5), δ 4.15 (1H, *dd*, *J* = 12.9, 6.6 Hz, H-6), δ 5.89 (1H, *ddd*, *J* = 17.8, 10.0, 7.6 Hz, H-7), δ 5.22 (1H, *brd*, *J* = 17.3 Hz, H-8), δ 5.12 (1H, *brd*, *J* = 10.5 Hz, H-8), δ 4.44 (1H, *d*, *J* = 7.6 Hz, H-1′ Glc), δ 4.63 (1H, *d*, *J* = 7.8 Hz, H-1″ Glc); ^{13}C NMR (methanol-d_4): Table 2; negative HR–FAB–MS, *m*/*z* 467.2093 ($C_{20}H_{35}O_{12}$ requires 467.2128)

3.10. Acid hydrolysis of ebracteatoside B (**5**) and ebractestoside C (**6**)

Ebracteatoside B (50 mg) was dissolved in 5% HCl and heated at 90 °C for 2 h. After cooling, the reaction mixture was extracted with Et_2O. The aqueous layer was neutralized with $NaHCO_3$, concentrated to dryness. The residue was then applied to a silica gel column (system VII), affording D-xylose (6 mg, R_f 0.29, $[\alpha]_D^{24}$ +20.0°) and D-glucose (8 mg, R_f 0.16. $[\alpha]_D^{24}$ +49.5°), comparing with authentic samples. By the same method, ebracteatoside C (30 mg) provided D-glucose (5 mg, $[\alpha]_D^{24}$ +47.4°).

3.11. Ebracteatoside D (**7**)

Amorphous powder, $[\alpha]_D^{22}$ −57.7° (MeOH, *c* 0.35); ^{1}H NMR (methanol-d_4): δ 3.53 (2H, *t*, *J* = 6.6 Hz, H-1), δ 1.35–1.44 (4H, *m*, H-2, 4), δ 1.55 (2H, *m*, H-3), δ 1.68 (1H, *m*, H-5), δ 1.56 (1H, *m*, H-5), δ 4.14 (1H, *dd*, *J* = 12.9, 6.6 Hz, H-6), δ 5.87 (1H, *ddd*, *J* = 17.3, 10.5, 6.8 Hz, H-7), δ 5.22 (1H, *brd*, *J* = 17.3 Hz, H-8), δ 5.10 (1H, *brd*, *J* = 10.3 Hz, H-8), δ 4.31 (1H, *d*, *J* = 8.0 Hz, H-1′ Glc), δ 4.33 (1H, *d*, *J* = 7.3 Hz, H-1″ Xyl); ^{13}C NMR (methanol-d_4): Table 2; negative HR–FAB–MS, *m*/*z* 437.2015 ($C_{19}H_{33}O_{11}$ requires 437.2022).

3.12. 7-Chloro-(2R)-2-O-β-D-glucopyranosyl-4-hydroxy-2H-1,4-benzoxazin-3(4H)-one(7-Cl-DIBOA-Glc, **10**)

Amorphous powder, $[\alpha]_D^{22}$ +18.6° (DMSO, *c* 0.86); ^{1}H NMR (DMSO-d_6): δ 5.94 (1H, *s*, H-2), δ 7.24 (1H, *d*, *J* = 8.5 Hz, H-5),δ 7.16 (1H, *dd*, *J* = 8.5, 2.2 Hz, H-6), δ 7.30 (1H, *d*, *J* = 2.2 Hz, H-8), δ 4.56 (1H, *d*, *J* = 7.8 Hz, H-1 Glc), δ 2.91 (1H, *dd*, *J* = 8.6, 8.0 Hz, H-2 Glc), δ 3.13 (1H, *dd*, *J* = 9.3, 9.0 Hz, H-3 Glc), δ 2.99 (1H, *dd*, *J* = 9.5, 9.3 Hz, H-4 Glc), δ 3.17 (1H, *m*, H-5 Glc), δ 3.40 (1H, *dd*, *J* = 12.0, 5.9 Hz, H-6 Glc), δ 3.70 (1H, *brd*, *J* = 12.0 Hz, H-6 Glc), δ 11.10; ^{13}C NMR (DMSO-d_6): Table 3; negative HR–FAB–MS, *m*/*z*: 376.0403 ($C_{14}H_{15}O_9NCl$ requires 376.0435).

Abstract

Zea mays was incubated with the natural phytotoxin benzoxazolin-2(3*H*)-one (BOA) to investigate the detoxification process. A hitherto unknown detoxification product, 1-(2-hydroxyphenylamino)-1-deoxy-β-gentiobioside 1,2-carbamate (**3**), was isolated and identified. A reinvestigation of known BOA detoxification products by NMR methods led to the finding that the structure of benzoxazolin-2(3*H*)-one-*N*-β-glucoside (**1**) first reported from *Avena sativa* has to be revised. In fact, the correct structure is that of the isomeric 1-(2-hydroxyphenylamino)-1-deoxy-β-glucoside 1,2-carbamate **2**, which is structurally related to **3**. It was now shown with a synthetic mixture of **1** and **2** that **1** underwent spontaneous isomerization to form **2** in solution. Thus, *N*-glucosylation of BOA in the plant led finally to the carbamate **2**. In contrast to BOA-6-*O*-glucosylation, BOA-induced *N*-glucosylation appears first after 6–8 h of incubation. As soon as *N*-glucosylation is possible, BOA-6-*O*-glucoside is not further accumulated, whereas the amount of glucoside carbamate increases continuously during the next 40 h. Synthesis of gentiobioside carbamate seems to be a late event in BOA detoxification. All detoxification products are released into the environment via root exudation. © 2001 Elsevier Science Ltd. 1. Introduction

Plants show different, species dependent sensitivities when treated with phytotoxic allelochemicals. This well known phenomenon was observed, for instance, after application of benzoxazinones, such as DIBOA and its degradation product benzoxazolin-2(3*H*)-one (BOA) (Barnes and Putnam, 1987; Barnes et al., 1986; Sicker et al., 2000; Sicker and Schulz, 2001). One reason for the species dependent differences should be more or less developed strategies and capacities of BOA detoxification as it was recently found for diverse plant species belonging to European grain field or hoed vegetable communities (Schulz and Wieland, 1999). Species well equipped for BOA metabolization detoxify the compound via *N*-glucosylation (Wieland et al., 1998) and, to a lower degree, BOA is hydroxylated in position 6 and immediately glucosylated resulting in BOA-6-*O*-glucoside (Wieland et al., 1999). Since the Poaceae tested produced more BOA-*N*-glucoside they exhibited a more efficient BOA detoxification than dicots investigated. Most of these species contained BOA-6-*O*-glucoside as the major detoxification product. Among the monocots, corn has the best detoxification capacity as *N*-glucosylation was performed mainly whereas *O*-glucosylation was a minor detoxification product. In BOA-incubated corn roots an additional, hitherto not identified product was detected. The structure of the new disaccharidic carbamate will be presented together with the results of a reinvestigation of the detoxification pathway based on BOA-*N*-β-D-glucoside.

2. Results and discussion

2.1. Isomerization of BOA-N-β-glucoside 1 reported as a plant detoxification product of BOA

Surprisingly, on repeating our own BOA-*N*-glycosidation described we have obtained not a single compound

PII: S0031-9422(01)00299-0

as in the first run but a ca. 1:3 mixture of two very similar compounds. This finding prompted a reinvestigation of both the natural detoxification products and the synthetic material described earlier (Wieland et al., 1998). The spectrometrical analyses show clearly that 3-β-glucopyranosyl-benzoxazolin-2(3*H*)-one **1** (BOA-*N*-β-D-glucoside) dissolved in methanol is not a stable compound, but the molecule is subjected to ring transformation yielding the constitutional isomer 1-(2-hydroxyphenylamino)-1-deoxy-β-glucopyranoside 1,2-carbamate (**2**) (Fig. 1), which represents a yet unknown natural product.

Therefore, the structure of our detoxification product assigned initially as BOA-*N*-β-glucoside (**1**) (Wieland et al., 1998) has to be revised and the compound reported there has to be described as the carbamate **2**, correctly. The structures of glucoside **1** and its isomeric carbamate **2** were determined by ^{1}H NMR, $^{1}H,^{1}H$ COSY, heteronuclear direct $^{1}H,^{13}C$ (HMQC), and long-range $^{1}H,^{13}C$ (HMBC) 2D NMR shift correlation. First spectra of the real BOA-*N*-β-glucoside (**1**) only could be obtained from an approximately 1:3 mixture together with the rearranged product **2**. The signals of **1** appeared slightly broadened but with typical coupling pattern and expected COSY cross peaks. The doublet of the anomeric proton at δ 5.45 showed a coupling constant of 8.9 Hz, indicating β-configuration. Due to the shielding effect of the aryl ring of the heterocycle, the double doublets of H-4′ (δ 3.05) and H-2′ (δ 2.92) appeared at unusual high field. Similar high field shift already has been observed by Hennig et al. (1998) for such protons (H-2 and H-4) in the D-ring of the antibiotic moenomycin A. 2D NMR spectra of the carbamate **2** were recorded after complete transformation under the same conditions. The β-glucopyranosyl configuration of the sugar unit was identified by chemical shifts, coupling constants (around 9 Hz, showing that all protons are axial) and COSY-correlation peaks. Protons H-4′ and H-2′ of this compound appeared now at unusual low field positions (δ 3.52 and 4.06, respectively). Characteristic HMBC correlations were observed between H-1′ (δ 5.30) and C-2′ (δ 70.0), C-3′ (δ 77.8), C-5′ (δ 80.2) (glucopyranosyl moiety), C=O (δ 154.5) (carbamate moiety), and C-1 (δ 129.5) [*N*-(hydroxyphenylamino) moiety] as well. In positive mode HR–ESI–MS experiments, both the pure carbamate **2** and the 1:3 mixture of **1** and **2** gave rise to the same spectrum with a $[M+H]^{+}$ peak at m/z 298.0919 which confirmed the conclusion that **1** and **2** are isomers with the elemental composition $C_{13}H_{15}NO_7$.

Hitherto, only two representatives of this class of carbohydrate carbamates are known which result from synthetic approaches, exclusively. Thus, the *N*-unsubstituted 1-deoxy-β-glucopyranoside 1,2-carbamate was prepared from D-glucopyranosylamine and phosgene in alkaline solution (Steyermark, 1962) as well as from *N*-(β-D-glucopyranosyl)triphenyl-phosphine imide and carbon dioxide in DMF (Kovacs et al., 1985). The *N*-isobutylamino derivative has been obtained by the cyclization of 1-(2-chloroethyl)-3-isobutyl-3-β-D-glucopyranosyl-1-nitrosourea (Tsujihara et al., 1981). In no case a biological activity has been reported for the compounds mentioned. In conclusion, the rearrangement observed is not described yet. An assumption for the driving force of the isomerization may be derived from the circumstance that the alcoholic 2-OH group of the glucoside **1** is more nucleophilic than the phenolic OH-group of the carbamate **2**.

The isomerization is found to be favored in alkaline solution. At pH 8, 90% of BOA-*N*-glucoside present in the 1:3 mixture is rearranged to carbamate, at pH 7

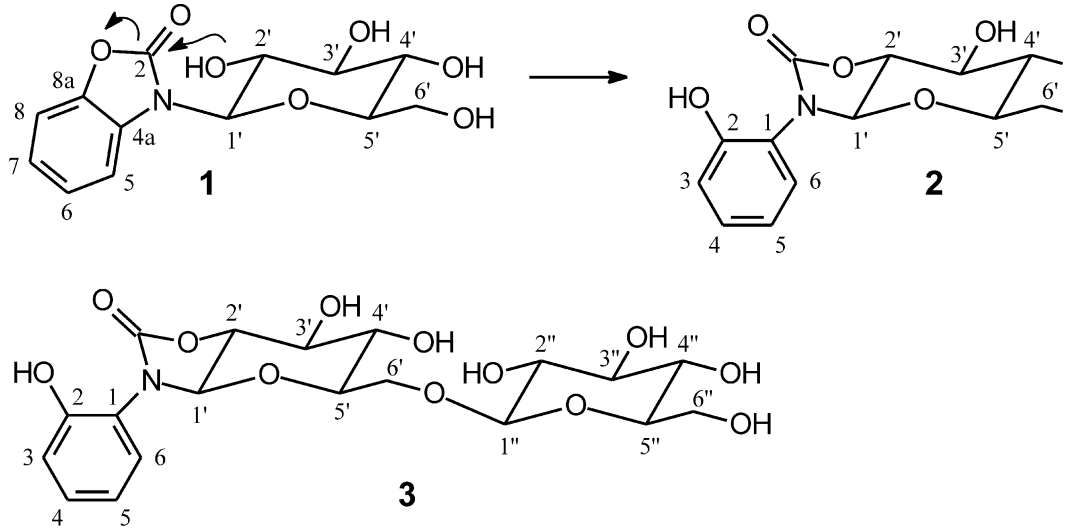

Fig. 1. Rearrangement of BOA-*N*-β-glucoside (**1**) to carbamate **2**; structure of 1-(2-hydroxyphenylamino)-1-deoxy-β-gentiobiose-1,2-carbamate (**3**).

60%, and at pH 6 only 40% when treated at 30°C for 65 min. Boiling accelerated the reaction also at pH 6.

2.2. Detection of **2** and 1-(2-hydroxyphenylamino)-1-deoxy-β-gentiobioside 1,2-carbamate **3** in extracts and exudates of corn roots

Re-investigation of a methanolic solution of synthetic BOA-*N*-glucoside that had been stored for several months at −20 °C revealed an additional, slightly more hydrophilic compound in addition to BOA-*N*-glucoside. The more hydrophilic peak was identical to the major detoxification product **2** first assumed to present BOA-*N*-glucoside and now identified as 1-(2-hydroxyphenylamino)-1-deoxy-β-glucopyranoside 1,2-carbamate **2**. Therefore, it must be concluded that in all extracts of plant species found to be able to detoxify BOA via *N*-glucosylation the glucoside carbamate should be the final product (Wieland et al., 1998; Schulz and Wieland, 1999).

In root extracts obtained from corn plants that have been incubated for 48 h, an additional compound (**3**) appeared. This compound was collected and treated with β-D-glucosidase. HPLC analysis of the enzyme assay revealed unequivocally that the treatment resulted in glucoside carbamate **2** as the only UV active product. Therefore, the additional product was assumed to present compound **2** conjugated with an additional β-D-glucose moiety. Spectroscopical analysis led to the assignation of 1-(2-hydroxyphenylamino)-1-deoxy-β-D-gentiobioside 1,2-carbamate for the structure of **3**. Thus, the ^{1}H and ^{13}C NMR spectra of carbamate **3** clearly exhibit signals of the aglycon moiety and two carbohydrate units. The chemical shift values and proton coupling pattern of the hydroxyphenylamino moiety resemble those of the corresponding unit in compound **2**. The coupling constants of H-1′ (δ 5.28, $J = 9.4$ Hz) and H-1″ (δ 4.30, $J = 7.8$ Hz) proved β-configuration at both anomeric centres. 2D Homo- and heterocorrelation experiments were used to assign all proton and carbon signals unambiguously. An HMBC cross signal between H-1′ and C-1 (δ 130.3) indicated attachment of the disaccharide to the aglycon through the nitrogen atom. The interglycosidic linkage between both glucose units was detected by means of a ^{1}H–^{13}C long-range heteronuclear correlation signal between H-1″ and C-6′ (δ 70.1), indicating the disaccharide to be gentiobiose. A positive mode HR–ESI–MS revealed an elemental composition of $C_{19}H_{25}NO_{12}$ for the neutral carbamate **3** and confirmed the findings of NMR.

With the purpose to get more insight in the course of BOA detoxification, corn seedlings were incubated, roots harvested and extracted after increasing incubation times (Fig. 2).

HPLC analyses revealed that during the first 6–8 h only BOA-6-*O*-glucoside was produced. Glucoside carbamate first appeared after 8 h. Thus, BOA-6-*O*-glucoside is not further accumulated as soon as *N*-glucosylation is possible. As gentiobioside carbamate was detectable for the first time after 18 h, this step is obviously a late event in BOA detoxification.

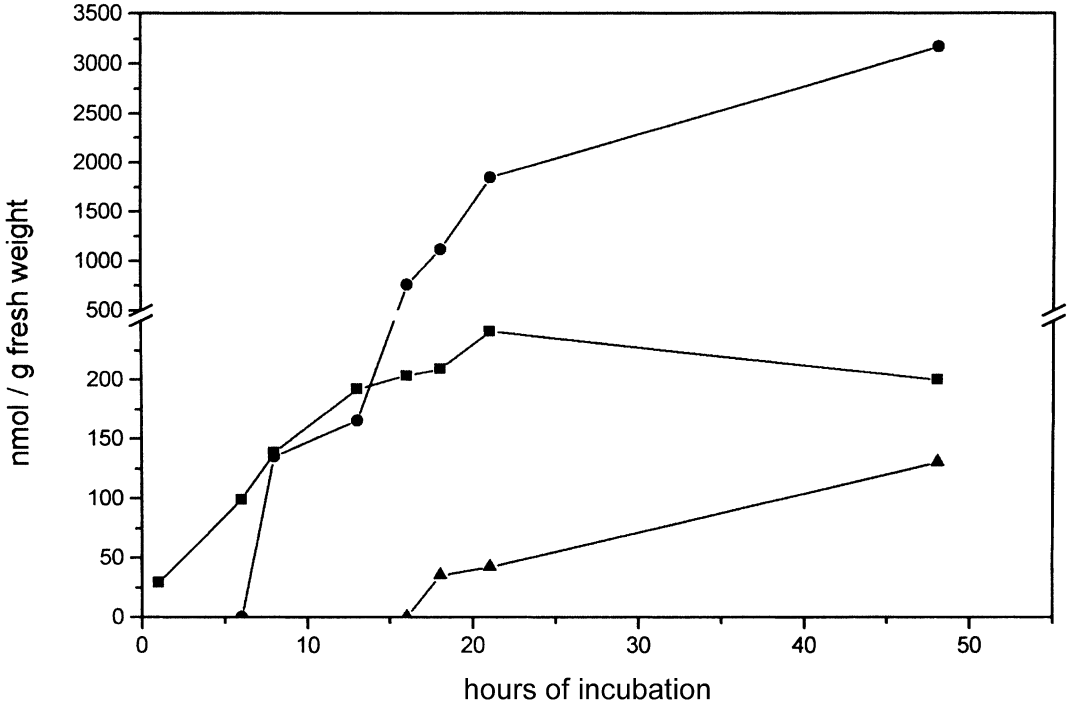

Fig. 2. Accumulation of BOA-6-*O*-glucoside (squares), gentiobioside carbamate (triangles) and glucoside carbamate (circles) in corn roots (average values from three experiments).

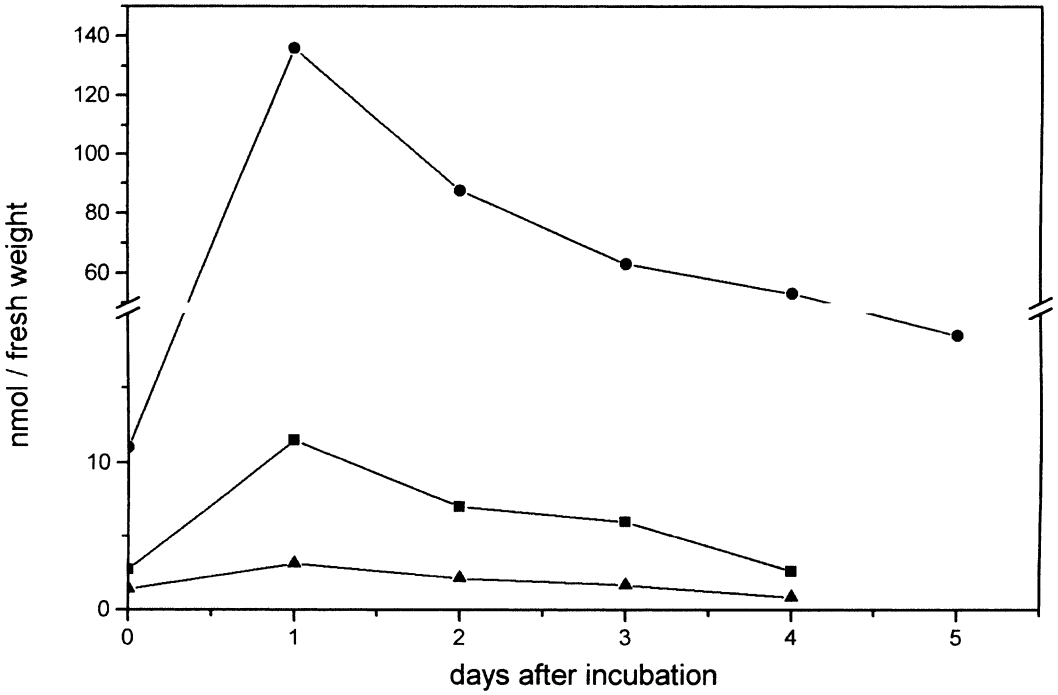

Fig. 3. Decrease of glucoside carbamate **2** (circles), of 1-(2-hydroxyphenylamino)-1-deoxy-β-gentiobioside1,2-carbamate (**3**) (triangles) and BOA-6-*O*-β-glucoside (squares) in roots of BOA incubated corn seedlings (average values of three experiments).

Since BOA metabolites were detected occasionally in the incubation medium (Wieland et al., 1999) a stable accumulation of those products in treated species was questionable. However, occurrence of the metabolites could be due to wounding as cut roots were used for incubations. Subsequent experiments gave rise of the assumption, that the compounds are released into the environment by root exudation. When corn seedlings transferred to pots after BOA incubation were checked for metabolites over a period of 4–5 days, none of the compounds was preserved at a stable level. During the first 24 h after incubation, the concentration of the metabolites still increased, reaching a maximum within the plant one day after incubation. The next days all metabolites decreased continuously: glucoside carbamate **2** was released most rapidly (5th day: 15–20% left), followed by gentiobioside carbamate **3** (4th day: 25% left) and less rapidly, the small amount of BOA-*O*-glucoside was diminished to 35% (Fig. 3).

Decrease of BOA metabolites is not restricted only to corn roots, but could be observed with BOA-incubated *Coriandrum sativum* and *Galinsoga ciliata* as well. Seedlings of the two species lost their main detoxification product BOA-6-*O*-β-D-glucoside within 5 days up to 40% (*C. sativum*) or almost completely (*G. ciliata*), (Fig. 4). It is not yet clear whether the compounds are exuded or not.

Recovery of 1-(2-hydroxyphenylamino)-1-deoxy-β-glucopyranoside 1,2-carbamate (**2**) and traces of 1-(2-hydroxyphenylamino)-1-deoxy-β-gentiobioside 1,2-carbamate (**3**) probably exuded by corn roots succeeded after concentration of the tap water where plants were placed after BOA incubation. The occurrence of 1-(2-hydroxyphenylamino)-1-deoxy-β-glucopyranoside 1,2-carbamate (**2**) in the concentrate reflected the increase and decrease of the compound in the roots (Figs. 3 and 5).

The gentiobioside carbamate **3** was detected only in traces. It is the question what happen to the exuded compounds under natural conditions. Rather likely, microbial activities might cleave one glucose moiety from compound **3** very easily resulting in glucoside carbamate **2**, the same may be true for BOA-*O*-glucoside which was not detectable in the concentrate. The further fate of the glucoside carbamate and BOA-6-OH is still unknown, but metabolization by soil microorganisms seems feasible.

3. Experimental

*3.1. Isolation of 1-(2-hydroxyphenylamino)-1-deoxy-β-gentiobioside 1,2-carbamate (**3**)*

Incubations of *Zea mays, C. sativum* and *G. ciliata* seedlings with BOA were performed as described in Schulz and Wieland (1999). For kinetics of BOA detoxification products, corn roots were incubated for 1, 2, 3, 4, 5, 6, 8, 13, 16, 18, 21, and 48 h. Corn roots were homogenized in presence of quartz sand and 30% methanol. The extract was filtered through miracloth and centrifuged for 20 min at 20 000 *g*. The supernatant was evaporated to dryness and dissolved in 2 ml 15%

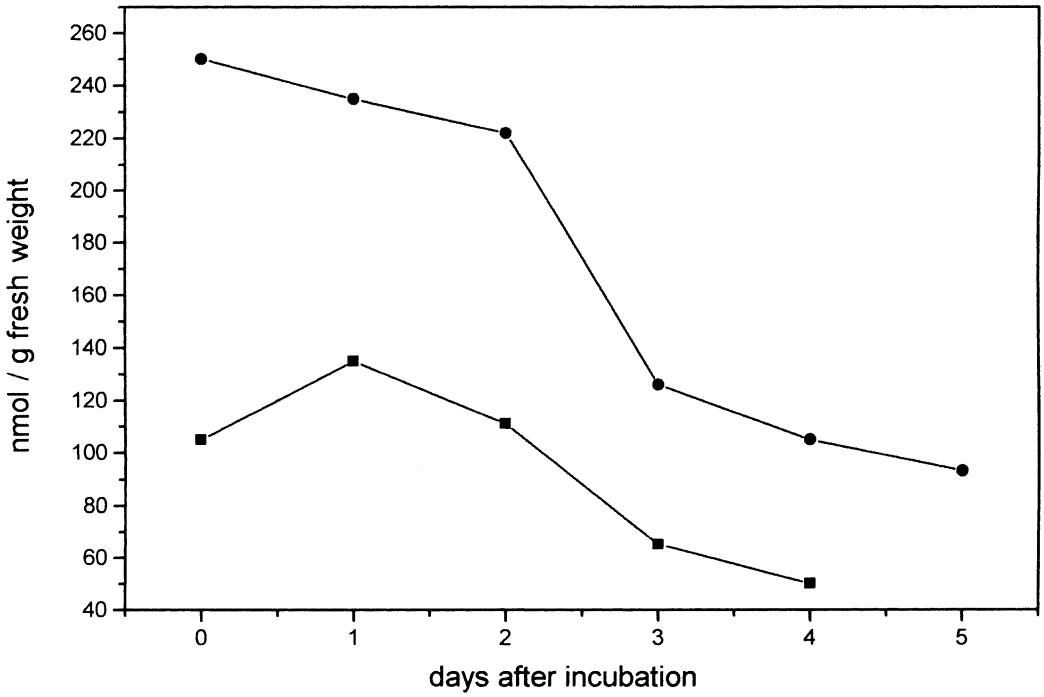

Fig. 4. Decrease of BOA-6-*O*-β-glucoside in seedlings of *Coriandrum sativum* (circles) and *Galinsoga ciliata* (squares) (average values from two experiments).

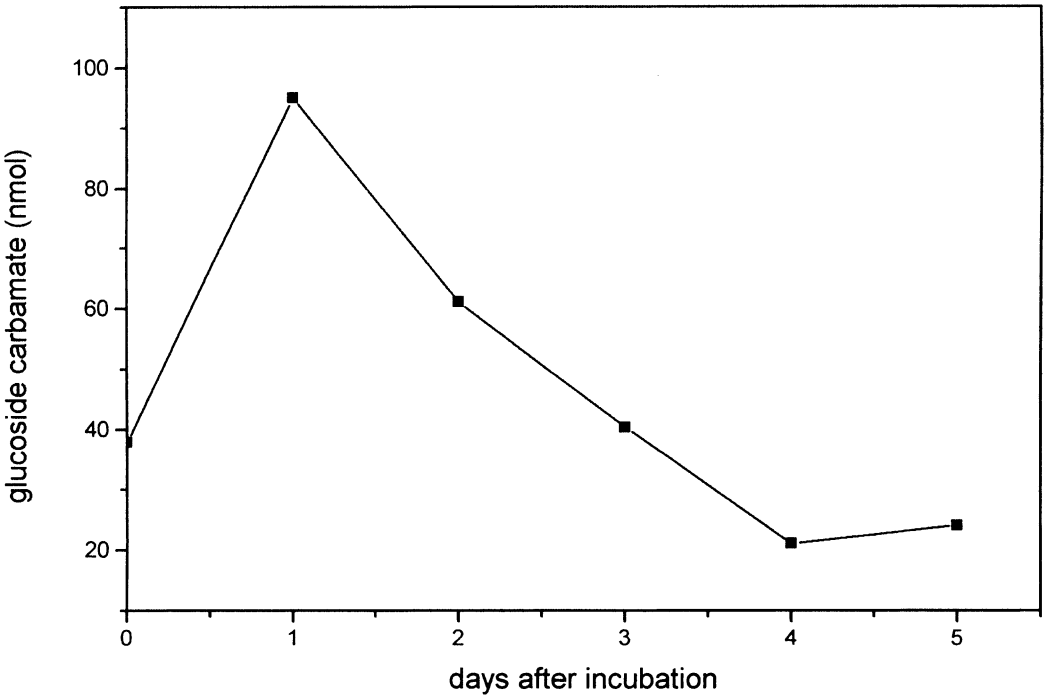

Fig. 5. Appearance of glucoside carbamate **2** in tap water (1 l per 10 g seedlings) with corn seedlings previously incubated with BOA (average values from **3** experiments).

methanol. After centrifugation at 10 000 *g* for 4 min the solution was analyzed by HPLC using the same equipment and gradient as described by Wieland et al. (1998). Quantification of detoxification products was performed using external standards (Wieland et al., 1998). The compound of interest eluting with a retention time of 16–17 min was collected, the fractions combined and evaporated in a speed vacuum centrifuge at 4 °C and

500 *g* overnight. The residues were dissolved in 500 μl 15% methanol, 10 μl of the solution was assayed with β-D-glucosidase from almonds at pH 5.5 for 10 min at 30 °C. The assay mixture was boiled for 10 min and centrifuged at 10 000 *g* for 5 min to pellet coagulated protein. The remaining part of the concentrate was purified via HPLC using first the following gradient: 20% B to 80% B in 7 min; 100% B in 1 min, the detection wavelength was 280 nm. The gradient mentioned above was used as a second step of purification. The compound was manually collected, evaporated to dryness and used for NMR studies.

3.2. BOA metabolite exudation studies

Seedlings of corn, *C. sativum* and *G. ciliata* were incubated with 500 μM BOA for 48 h and placed subsequently in soil filled pots (corn: five pots with 30 seedlings each, *G. ciliata* and *C. sativa*: 100 seedlings per pot). 30 seedlings of corn and 100 of the two other species were directly extracted and analyzed for detoxification products. Over a period of 4–5 days seedlings from one pot each day and each species were removed, cleaned from soil and either totally (*G. ciliata, C. sativa*) or only the roots were extracted. The extracts were analyzed for BOA metabolites.

For exudate collecting, aeroponically grown corn seedlings (100) were incubated with 500 μM BOA for 48 h and transferred to basins filled with aerated tap water (1 l) after washing. The tap water was collected every day and replaced over a period of 5 days. The five collected water samples were evaporated to dryness, the residues dissolved in 2 ml 15% methanol each and used for HPLC analysis after clearing by centrifugation at 10 000 *g* for 4 min.

For identification of the traces of the new compound in stored extracts, a 1:3 synthetic mixture of **1** and **2** obtained according to Wieland et al. (1998) was used for analytical comparisons.

3.3. Structural determinations

NMR analyses of the BOA-*N*-β-glucoside (1) and of carbamate 2 were carried out on a Bruker DRX 600 spectrometer [600.13 MHz (^{1}H) and 150.92 MHz (^{13}C)] and of carbamate 3 on a Bruker DRX 500 spectrometer [500.13 MHz (^{1}H) and 125.76 MHz (^{13}C)] in MeOD_4. ^{1}H NMR, ^{1}H–^{1}H COSY, HMBC, and HMQC experiments were recorded in a 5 mm TBI probe head (600 MHz) and in a 2.5 mm inverse detection microprobe head (500 MHz), respectively. Broadband decoupled ^{13}C spectra were run using a 2.5 mm broadband microprobe head (500 MHz). Tetramethylsilane (TMS) was used as an internal reference. Chemical shifts are given in δ values. High resolution mass spectra were recorded on a Bruker Daltonics 7T APEX II FT-ICR masspectrometer with electron spray ionsation (positive mode).

3.3.1. 3-β-Glucopyranosyl-benzoxazolin-2(3H)-one (*1*)

^{1}H NMR spectral data (600.13 MHz, CD_3OD): δ 7.33 (1H, *d*), 7.23 (1H, *dd*), 6.93 (1H, *d*), 6.66 (1H, *dd*), 5.45 (1H, *d*, $J_{H\text{-}1'\text{-}H\text{-}2'} = 8.9$ Hz, H-1′), 3.90 (1H, *dd*, Ha-6′), 3.62 (1H, *dd*, Hb-6′), 3.45 (1H, H-3′), 3.44 (1H, *m*, H-5′), 3.05 (1H, *dd*, H-4′), 2.92 (1H, *dd*, H-2′). ^{13}C NMR spectral data (150.92 MHz, CD_3OD): δ 132.1 (C-H), 123.1 (C-H), 120.4 (C-H), 116.2 (C-H), 86.2 (C-1′), 79.5 (C-5′), 77.3 (C-3′), 71.3 (C-2′), 70.7 (C-4′), 62.1 (C-6′) (signals detected from HMQC).

3.3.2. 1-(2-Hydroxyphenylamino)-1-deoxy-β-glucoside 1,2-carbamate (*2*)

^{1}H NMR spectral data (600.13 MHz, CD_3OD): *N*-(hydroxyphenylamino) moiety: δ 7.37 (1H, *dd*, $J_{H\text{-}6\text{-}H\text{-}5} = 7.8$ Hz, $J_{H\text{-}6\text{-}H\text{-}4} = 1.0$ Hz, H-6), 7.28 (1H, *dd*, $J_{H\text{-}3\text{-}H\text{-}4} = 7.8$ Hz, $J_{H\text{-}3\text{-}H\text{-}5} = 1.0$ Hz, H-3), 7.23 (1H, *ddd*, $J_{H\text{-}5\text{-}H\text{-}4} = 7.3$ Hz, $J_{H\text{-}5\text{-}H\text{-}6} = 7.8$ Hz, $J_{H\text{-}5\text{-}H\text{-}3} = 1.0$ Hz, H-5), 7.19 (1H, *ddd*, $J_{H\text{-}4\text{-}H\text{-}5} = 7.3$ Hz, $J_{H\text{-}4\text{-}H\text{-}3} = 7.8$ Hz, $J_{H\text{-}4\text{-}H\text{-}6} = 1.0$ Hz, H-4), glucose moiety: δ 5.30 (1H, *d*, $J_{H\text{-}1'\text{-}H\text{-}2'} = 9.4$ Hz, H-1′), 4.06 (1H, *dd*, $J_{H\text{-}2'\text{-}H\text{-}1'} = 9.4$ Hz, $J_{H\text{-}2'\text{-}H\text{-}3'} = 8.9$ Hz, H-2′), 3.93 (1H, *dd*, $J_{Ha\text{-}6'\text{-}Hb\text{-}6'} = 12.2$ Hz, $J_{Ha\text{-}6'\text{-}H\text{-}5'} = 2.1$ Hz, Ha-6′), 3.75 (1H, *dd*, $J_{Hb\text{-}6'\text{-}H\text{-}5'} = 5.7$ Hz, Hb-6′), 3.56 (1H, *dd*, $J_{H\text{-}3'\text{-}H\text{-}2'} = 8.9$ Hz, $J_{H\text{-}3'\text{-}H\text{-}4'} = 8.9$ Hz, H-3′), 3.55 (1H, *m*, H-5′), 3.52 (1H, *dd*, $J_{H\text{-}4'\text{-}H\text{-}3'} = 8.9$ Hz, $J_{H\text{-}4'\text{-}H\text{-}5'} = 9.4$ Hz, H-4′). ^{13}C NMR spectral data (150.92 MHz, CD_3OD): *N*-(hydroxyphenylamino) moiety: δ 143.2 (C-2), 129.5 (C-1), 124.1 (C-5), 123.1 (C-4), 111.5 (C-6), 109.8 (C-3), carbamate moiety: δ 154.5 (C=O, detected by HMBC), glucopyranosyl moiety: δ 84.7 (C-1′), 80.2 (C-5′), 77.8 (C-3′), 70.2 (C-4′), 70.0 (C-2′), 61.7 (C-6′). HR–ESI–MS *m/z*: 298.0919 (calc. for $C_{13}H_{16}NO_7^+$ $[M+H]^+$ 298.0921).

3.3.3. 1-(2-Hydroxyphenylamino)-1-deoxy-β-gentiobioside 1,2-carbamate (*3*)

^{1}H NMR spectral data (500.13 MHz, CD_3OD): *N*-(hydroxyphenylamino) moiety: δ 7.35 (1H, *dd*, $J_{H\text{-}6\text{-}H\text{-}5} = 7.6$ Hz, $J_{H\text{-}6\text{-}H\text{-}4} = 1.3$ Hz, H-6), 7.26 (1H, *dd*, $J_{H\text{-}3\text{-}H\text{-}4} = 7.6$ Hz, $J_{H\text{-}3\text{-}H\text{-}5} = 1.3$ Hz, H-3), 7.21 (1H, *ddd*, $J_{H\text{-}5\text{-}H\text{-}4} = 8.1$ Hz, $J_{H\text{-}5\text{-}H\text{-}6} = 7.6$ Hz, $J_{H\text{-}5\text{-}H\text{-}3} = 1.3$ Hz, H-5), 7.17 (1H, *ddd*, $J_{H\text{-}4\text{-}H\text{-}5} = 8.1$ Hz, $J_{H\text{-}4\text{-}H\text{-}3} = 7.6$ Hz, $J_{H\text{-}4\text{-}H\text{-}6} = 1.3$ Hz, H-4), gentiobiose moiety: δ 5.28 (1H, *d*, $J_{H\text{-}1'\text{-}H\text{-}2'} = 9.4$ Hz, H-1′), 4.30 (1H, *d*, $J_{H\text{-}1''\text{-}H\text{-}2''} = 7.8$ Hz, H-1″), 4.23 (1H, *dd*, $J_{Ha\text{-}6'\text{-}Hb\text{-}6'} = 11.3$ Hz, $J_{Ha\text{-}6'\text{-}H\text{-}5'} = 1.8$ Hz, Ha-6′), 4.03 (1H, H-2′), 3.82 (1H, *dd*, $J_{Ha\text{-}6''\text{-}Hb\text{-}6''} = 12.0$ Hz, $J_{Ha\text{-}6''\text{-}H\text{-}5H} = 2.1$ Hz, Ha-6″), 3.80 (1H, *dd*, $J_{Hb\text{-}6'\text{-}Ha\text{-}6'} = 11.3$ Hz, $J_{Hb\text{-}6'\text{-}H\text{-}5'} = 5.3$ Hz, Hb-6′), 3.74 (H-5″), 3.61 (1H, *dd*, $J_{Hb\text{-}6''\text{-}Ha\text{-}6} = 12.0$ Hz, $J_{Hb\text{-}6''\text{-}H\text{-}5''} = 5.4$ Hz, Hb-6″), 3.55 (H-4′), 3.54 (H-3′), 3.31 (H-3″), 3.25 (H-4″), 3.22 (H-5′), 3.19 (H-2″), ^{13}C NMR spectral data (125.76 MHz, CD_3OD): *N*-(hydroxyphenylamino) moiety: δ 144.1 (C-2), 130.3 (C-1), 125.2 (C-5), 124.1 (C-4), 112.5 (C-6), 110.9 (C-3), carbamate moiety: δ 155.3 (C=O, detected from HMBC), gentiobiose moiety: δ 104.7 (C-1), 85.5 (C-1′), 79.9 (C-5″), 78.4 (C-3′), 78.0 (C-

5′ and C-3″), 75.1 (C-2″), 71.5 (C-4″), 71.2 (C-4′), 71.0 (C-2′), 70.1 (C-6′), 62.7 (C-6″). HR–ESI–MS *m/z*: 460.1449 (calcd for $C_{19}H_{26}NO_{12}^{+}$ $[M+H]^{+}$ 460.1452).

Black Pepper, *Piper nigrum*. Medicinal and Aromatic Plants—Industrial Profiles
P.A. Ravindran (Ed.) Vol. 13; Harwood Academic Publishers, The Netherlands, 2000. ISBN 90-5702-453-5, $125, £86

In his Introduction to this scholarly and well-written book, P.A. Ravindran describes black pepper as the 'King of Spices' and this theme is carried through the entire work. The history of the pepper industry from Biblical times to the present is well researched, and gives an insight into the true importance of this spice. Kerela State in India was the original source of black pepper, but nowadays it is grown extensively (95% of Indian production) in this State as well as Indonesia, the second most ancient pepper growing country, Brazil, Malaysia, Sri Lanka, Malagasy Republic, several South East Asian countries, South Pacific Islands, Latin America and a number of African countries. Although India is the largest producer in terms of tonnage per annum (average 191,000 tonnes), Thailand has the highest productivity in terms of kg per ha (3595). The International Trade Centre in Geneva has estimated the current trade in spices to be 400,000–450,000 metric tonnes valued at US$1.5–2.0 billion per annum: pepper contributes 34% of the total trade in spices.

Bearing in mind the value of the plant, substantial efforts have been made to investigate and improve its crop management. Chapter 2 describes the historical recordings of the plant since Linnaeus in 1753 and the current status of over 100 cultivars. Detailed botanical descriptions of the plant parts are also given wherein the pepper fruit is described as a drupe, but more often referred to as a berry. The breeding program instigated in India over many years has produced a number of useful hybrids which are assessed for their oleoresin content, volatile (essential) oil yield and composition. Piperine is an alkaloid that contributes towards the pungency of the pepper and varies from 2 to 7.4% among the cultivars with the volatile levels being within the range 0.4–7.0%. Biotechnology has also played an important part in the improvement of the crop with in vitro culture methods for cloning from explants such as shoot tips, nodal segments and apical meristems from both juvenile and mature plants being used. *Agrobacterium tumefaciens*-mediated gene transfer has been employed to transform pepper with disease resistance to *Phytophthora* foot rot. RFLP/PCR studies and RAPD profiles have been used to establish genetic similarities and differences between different species of pepper.

In Chapter 3, details are given of the phytochemistry of the spice. Several studies into the analyses of pepper volatile oil are cited, indicating a range of concentrations for the major constituents. In summary, 15 monoterpenes have been identified with α- and β-pinenes, sabinene and limonene as the major compounds along with some 43 oxygenated compounds of monoterpenoid nature. β-Caryophyllene is the major sesquiterpene hydrocarbon found in the pepper oil, with another 24 having been identified together with around 20 oxygenated sesquiterpenes. A number of miscellaneous compounds may also be present including eugenol, myristicin and safrole. Attempts have been made to correlate phytochemical analyses with sensory evaluation.

Agronomical and nutritional aspects of pepper production are covered in detail in the next two Chapters, the latter giving specific attention to production in Indonesia. Following logically from this, there are chapters on disease conditions caused by fungi, bacteria, virus, mycoplasma, nematodes and insects. Biological control through antagonistic micro-organisms has shown some promising results. A number of shorter chapters deals with various aspects of industrial processing. Further chapters deal in some detail with the world pepper economy giving numerous graphical presentations of trends within the market.

One of the most interesting chapters in the book was that dedicated to pharmacological, toxicological and clinical applications of *Piper nigrum*. Pepper is described as a drug which increases digestive power, improves appetite, cures cold, cough, dyspnoea, diseases of the throat, intermittent fever, colic, dysentery, worms and piles. As with many spices, it also possesses a broad spectrum antimicrobial activity. Analgesic, antipyretic and anti-inflammatory actions are also described, with piperine having been shown to be one of the active

compounds in such cases. Neither pepper nor piperine produces any hepatotoxicity. In contrast, a protective impact upon key liver enzymes has been noted. In terms of mutagenic and carcinogenic properties, pepper gave favourable results, based on the Ames test. The antioxidant capacity of pepper phenolic amides was shown to be superior to the synthetic moieties BHT and BHA.

The book rounds off with considerations of end uses of pepper, listing a large number of traditional and modern uses of the spice. The chapters on the future of pepper usage considers the main obstacles to further cultivation of the plant and how best these may be overcome.

Overall, this is an exhaustive treatise on an economically important spice that is well written, enthusiastic for the subject and comprehensively covers every aspect of usage of black pepper. The book is an important addition to the literature on plant science. It will be of particular interest to students and researchers in botany, ethnobotany, biotechnology, phytochemistry, pharmacology/pharmacognosy, tropical agriculture and food technology/processing.

Cell and Developmental Biology of Arabinogalactan-Proteins

E.A. Nothnagel, A. Bacic and A.E. Clarke (Eds.); Kluwer Academic/Plenum, New York, 2000, 301 pp., ISBN 0-306-46469-1, $139, £96

The book *Cell and Developmental Biology of Arabinogalactan-Proteins* edited by Nothnagel, Bacic and Clarke contains reviews of different aspects related to Arabinogalactan-Proteins (AGPs), from the definition of this group of proteins itself to the applications that they have or they may have. Data regarding the possible function of AGPs in relation to plant development are especially considered. The articles are essentially reviews but in some cases they contain also original results and they are presented in 23 chapters divided into six sections and a final section containing 16 short papers and abstracts. The six sections are devoted to specific subjects: Structure and Biosynthesis of AGPs, Localization and Action of AGPs at the Subcellular and Cellular Levels, AGPs in Somatic Embryogenesis, AGPs in Reproductive Development, AGPs in Vegetative Development and Medically and Industrially Important AGPs and Related Macromolecules. The importance and the evolving state of the subject deserves for sure a book although the reader is left with the feeling that basic questions still remain to be answered. It is remarkable, for instance, that the first chapter devotes16 lines to AGP function including a comment regarding the proposal that AGPs may be ''the garbage bin of plant metabolism''. I am sure that the authors and editors of the book would not share this opinion.

The book is based on the Proceedings of the Twentieth Symposium in Plant Physiology (Riverside, January 1999) and it is one of the rare books that may be found entirely devoted to AGPs with a special emphasis in plant development. Arabinogalactan-proteins have been a subject of interest both due to the use of arabic gum for a number of industrial applications and since it was shown that they may be useful markers for plant development. The applications of AGPs have led to the analysis of the fractions and to the finding of the complex glycoprotein nature of this family of proteins. The molecular analysis has been possible only when recombinant DNA approaches were used as it is the general case for glycoproteins in plants where these fractions are very difficult to define and characterize. The recent cloning of cDNAs corresponding to the protein component of AGPs has allowed the first analysis of their polypeptide backbone. In the book some of these results are summarized but, as references stop in 1998, the reader will find only a partial view for such a recently initiated subject.

In general terms the analysis of the protein components of the plant cell wall and the genes coding for these proteins provides interesting tools to study plant development mechanisms but the picture is still far from satisfactory. For this reason it is useful to have in a single book the various aspects related to a group of still intriguing and important protein components of the wall. The book will be useful for readers interested in the structure of the plant cell wall and its relation to plant development, in the methods to analyse complex mixtures of plant glycoproteins and in the

compounds in such cases. Neither pepper nor piperine produces any hepatotoxicity. In contrast, a protective impact upon key liver enzymes has been noted. Announcement

PSE Symposium: Dietary Phytochemicals and Human Health

Salamanca, Spain,
18–20 April 2002

The meeting aims to review the present knowledge on the implications on health of natural, non-nutrient phytochemicals. Important topics are the structure–activity relationships, bioavailability and mechanisms of uptake and transport, biomarkers of exposure and effects, and the effects of dietary phytochemicals and their metabolites on gene expression, apoptosis and cell proliferation. Furthermore the impact of recent developments in genomics and proteomics technology on phytochemical research will be dealt with. The date of the meeting invites one to consider new research proposals with respect to the coming European FrameWork 6 programme.

Major topics of the symposium:

Bioavailability of phytochemicals
Epidemiology and effects
Biomakers of exposure and effect
Genomics and proteomics in phytochemical research

Registration fees

Before 15 March 2002:

- PSE members, students unemployed and retired people: 240 euro
- Rest of participants: 350 euro

After 5 March 2002:

- PSE members, students unemployed and retired people: 300 euro
- Rest of participants: 410 euro
- Accompanying people: 100 euro

Preparation of antibody against agatharesinol, a norlignan, using a hapten-carrier conjugate

Takeshi Nagasaki[a], Seiichi Yasuda[b], Takanori Imai[a,*]

Received in revised form 3 July 2001

Abstract

In order to immunolabel heartwood extractives in Japanese cedar (Sugi, *Cryptomeria japonica*), we attempted to prepare antibodies against agatharesinol, a major norlignan of these heartwood extractives. Agatharesinol by itself is not antigenic due to its low-M_r, and thus was covalently bound to bovine serum albumin in order to synthesize an antigenic hapten-carrier conjugate (artificial antigen). The number of agatharesinol molecules per artificial antigen molecule was estimated as 27–28 by quantifying Lys in an acid hydrolysate of the artificial antigen by HPLC. Reaction between the artificial antigen and serum obtained from a rabbit immunized with the artificial antigen was competitively inhibited by agatharesinol, indicating the successful production of anti-agatharesinol antibodies. Inhibition by sequirin C, another major norlignan in Sugi, was weaker than that by agatharesinol. Furthermore, an EtOAc soluble fraction, which contains mainly norlignans, inhibited the reaction more strongly than any of the other fractions of Sugi heartwood extractives. Thus, the antiserum we have produced reacts most strongly with agatharesinol and recognizes norlignans almost selectively among Sugi heartwood extractives. © 2001 Elsevier Science Ltd. 1. Introduction

When heartwood is treated with various kinds of organic solvents, low-M_r substances called "heartwood extractives" are extracted. The formation of heartwood extractives has been studied from both biochemical (Hillis and Inoue, 1966) and cytological (Wardrop and Cronshaw, 1962; Nobuchi and Harada, 1985) perspectives.

In cytological studies, reagents that react with chemically unsaturated structures, such as potassium permanganate or osmium tetraoxide, are used to examine the heartwood extractives (Wardrop and Cronshaw, 1962; Nobuchi and Harada, 1985). Nobuchi and Harada, (1985) reported that in the inner white zone of Sugi, cytoplasmic matrices in ray parenchyma cells and accumulations over the inner surfaces of tracheid cell walls adjacent to parenchyma cells were strongly stained with the dye-reagent. This observation suggests that the stained substances, which were believed to be heartwood extractives, were biosynthesized in parenchyma cells and then transferred to tracheids, where they accumulated. However, to determine the precise chemical structure of such stained substances is impossible, and no irrefutable proof exists that these substances were heartwood extractives. Consequently, questions concerning the biosynthesis, transfer, accumulation and distribution of heartwood extractives are still open to investigation.

In immunological studies, a particular compound can be surveyed and characterized according to the selectivity of an antigen–antibody reaction. By applying immunolabeling to microscopic sections of plant tissues, various kinds of plant polymers such as proteins (Moukha et al., 1993; Nakashima et al., 1997), polysaccharides (Moore et al., 1986; Awano et al., 1998) and lignin (Joseleau and Ruel, 1997; Ruel et al., 1999) have been localized in situ, and their formation examined.

Substances with a M_r of less than 1000 are not ordinarily antigenic, which include most heartwood extractives. However, antibodies can be raised to low-M_r substances using antigenic hapten-carrier conjugates (artificial antigens) in which low-M_r substances (haptens) are covalently bound to proteins or synthetic

PII: S0031-9422(01)00323-5

polypeptides (hapten-carriers). This strategy has been applied to various kinds of low-M_r substances such as plant hormones (Atzorn and Weiler, 1983; Moctezuma and Feldman, 1999), flavonol glucoside (Lamoureux et al., 1986), steroids (Africa and Haber, 1971) and cinnamyl alcohols (Lewis and Davin, 1992). Therefore, immunolabeling may be an effective method by which to study the formation of heartwood extractives in situ.

Japanese cedar (*Cryptomeria japonica* D. Don, Sugi) is one of the species in which heartwood extractives have been well studied. Its major extractives are classified as norlignans, with agatharesinol being one of the most abundant norlignans (Ogiyama et al., 1983). Although agatharesinol is not present in normal sapwood, it can be detected in sapwood wounded mechanically (Ohashi et al., 1990) or damaged by insects (Takahashi et al., 1983), indicating that the biosynthesis of agatharesinol can be induced artificially in sapwood. Thus, agatharesinol is the most suitable substance with which to dynamically investigate the formation of heartwood extractives in Sugi.

In the present study, we attempted to immunolabel heartwood extractives from Japanese cedar by preparing antibodies against agatharesinol. Agatharesinol was covalently bound to bovine serum albumin (BSA) in order to produce an artificial antigen. The number of haptens in the artificial antigen (epitope density) was determined. A rabbit was then immunized with the artificial antigen, and production of anti-agatharesinol antibodies and recognition selectivity of the serum examined.

2. Results and discussion

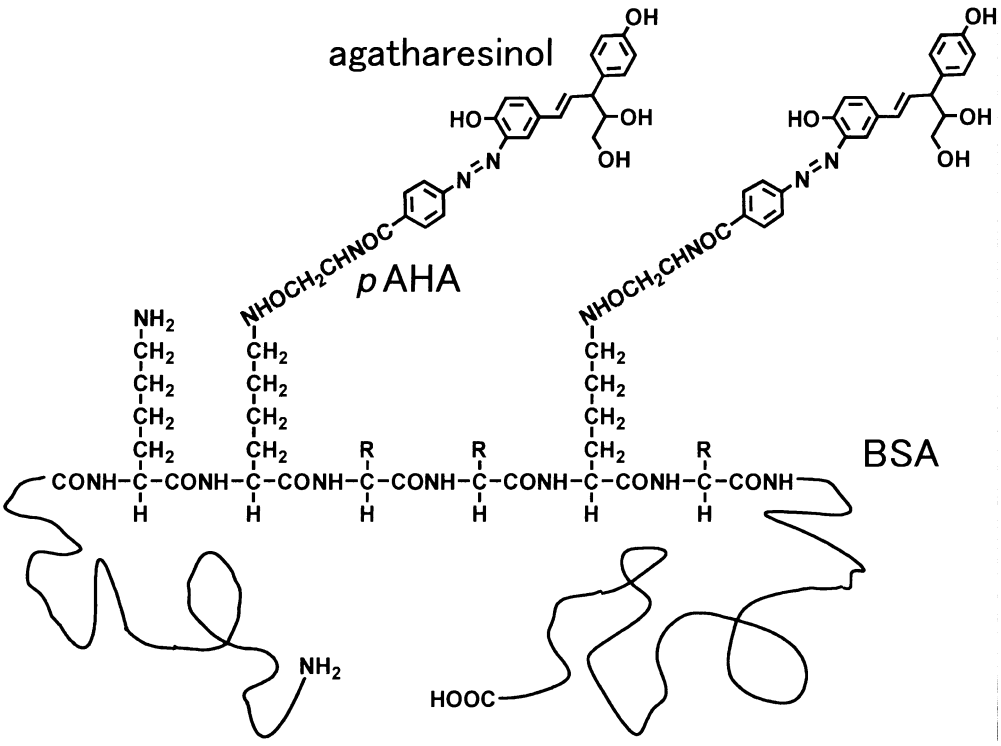
2.1. Determination of the epitope density of the agatharesinol artificial antigen

Epitope density affects an antibody titer to the hapten (Erlanger, 1980). Fig. 1 shows the supposed structure of our artificial antigen. To synthesize this artificial antigen, *p*-aminohippuric acid (*p*AHA) was bound to BSA in order to provide an aromatic amino group, and then agatharesinol was diazocoupled. Agatharesinol is assumed to be bound to the ε-amino group of the Lys residue in BSA via the interposing *p*AHA. Therefore, epitope density can be estimated by determining the number of free ε-amino groups of Lys residues that remain unsubstituted by *p*AHA coupled with agatharesinol. To distinguish the substituted Lys residues from the unsubstituted ones, the artificial antigen was reacted with 2,4-dinitrofluorobenzene (DNFB). Because DNFB easily reacts with amino groups, the unsubstituted Lys residues are converted to dinitrophenyl Lys (DNP-Lys) residues by dinitrophenylation. The artificial antigen and the dinitrophenylated artificial antigen (DNP-artificial antigen) were then hydrolized with 6N HCl. *p*AHA coupled with agatharesinol is bound to BSA via an amide linkage, and the linkage is easily hydrolyzed by the acid treatment. Therefore, during acid hydrolysis of the artificial antigen, Lys is generated from both the substituted and unsubstituted Lys residues. On the other hand, because DNP-Lys is never converted to Lys by treatment with acid, the hydrolysis of the DNP-artificial antigen gives Lys only from the substituted Lys residues. The proportion of the amount of Lys generated from the DNP-artificial antigen to that from the artificial antigen indicates the degree of substitution of Lys residues with haptens. Lys in the hydrolysates was quantified by HPLC employing Phe in the hydrolysates as an internal standard because Phe is stable during acid hydrolysis and dinitrophenylation. Using this procedure, the degree of substitution was determined to be 46.1%. The number of Lys residues per BSA, as indicated in the Entrez datebase, is 59. Thus, 27–28 Lys residues per artificial antigen molecule are assumed to be substituted with the hapten.

2.2. Confirmation of production of anti-agatharesinol antibody

To confirm the production of antibodies against the artificial antigen, dot-blot immunoassays and enzyme-linked immunosorbent assays (ELISAs) were used. In the dot-blot immunoassay, varying amounts of the artificial antigen and serum concentrations were tested, with coloration decreasing as both the amount of artificial antigen and serum concentration decreased. Thus, coloration depends on both the amount of the artificial antigen and the concentration of the serum (Fig. 2). Coloration was not observed when the dots were incubated with preimmune serum, nor was any coloration seen in dots that had not absorbed the artificial antigen (Fig. 2). These results indicate that anti-artificial antigen antibodies had been produced. In ELISA, coloration increased with an increase in both the amount of artificial antigen and serum concentration. This assay also demonstrated production of anti-artificial antigen antibodies (Fig. 3).

Production of antibodies against agatharesinol was examined by dot-blot immunoassay and ELISA. In dot-blot immunoassay using the artificial antigen, *p*AHA-substituted BSA and BSA, coloration was observed only for the artificial antigen, but was very faint for both BSA and *p*AHA-substituted BSA (Fig. 4). This indicates that antibodies which recognize the agatharesinol moiety in the artificial antigen have been produced. In an ELISA using a competitive inhibition reaction in which antiserum preincubated with agatharesinol was used, coloration decreased with an increase in the concentration of agatharesinol (Fig. 5). This decrease was proportional to the concentration of agatharesinol ranging from 10^{-3} to 10^{-5} M when the assay was carried out using serum diluted 20,000 fold. The inhibition of col-



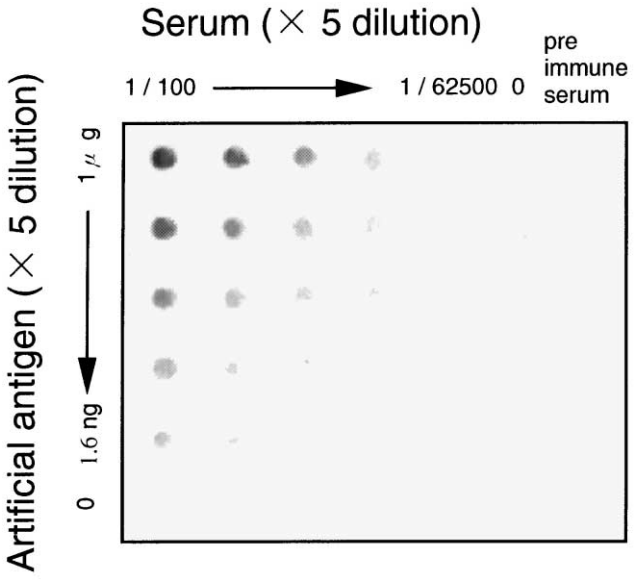


Fig. 2. Dot blot immunoassay using various amounts of artificial antigen and various concentrations of serum. Preimmune serum is serum obtained from the rabbit before injection of the artificial antigen.

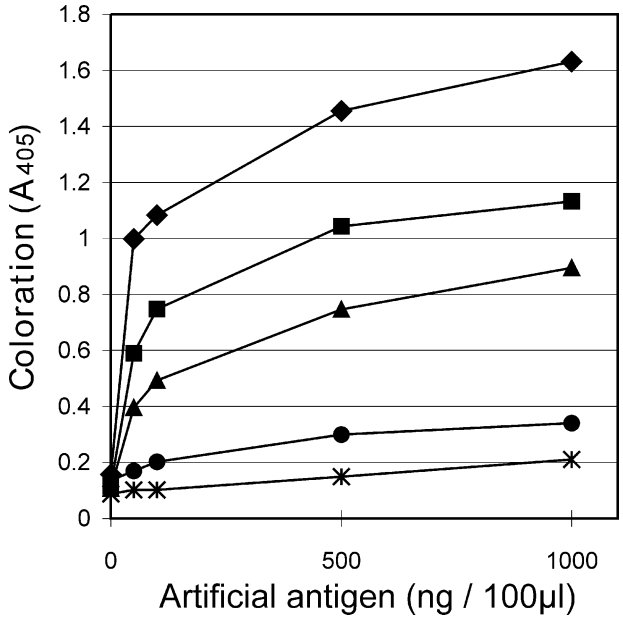

Fig. 3. Checkerboard titration of the artificial antigen against the following dilutions of antiserum: 1/1000 (◆), 1/5000 (■), 1/10,000 (▲), 1/50,000 (●), 1/100,000 (∗).

oration was due to the fact that some antibodies had already reacted with agatharesinol during the pre-incubation, resulting in a decrease in anti-agatharesinol antibodies available for the following reaction between the artificial antigen and the antiserum. Therefore, the competitive inhibition-ELISA definitively demonstrated that anti-agatharesinol antibodies had been produced.

2.3. Recognition selectivity of the antiserum

In the antiserum, antibodies against hapten-carrier (*p*AHA-substituted BSA) moiety of the artificial antigen were also supposed to present, and they must reduce the sensitivity in competitive inhibition-ELISA for determining

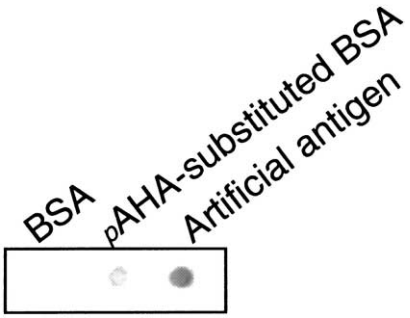

Fig. 4. Dot-blot immunoassay using BSA, *p*AHA-substituted BSA and artificial antigen.

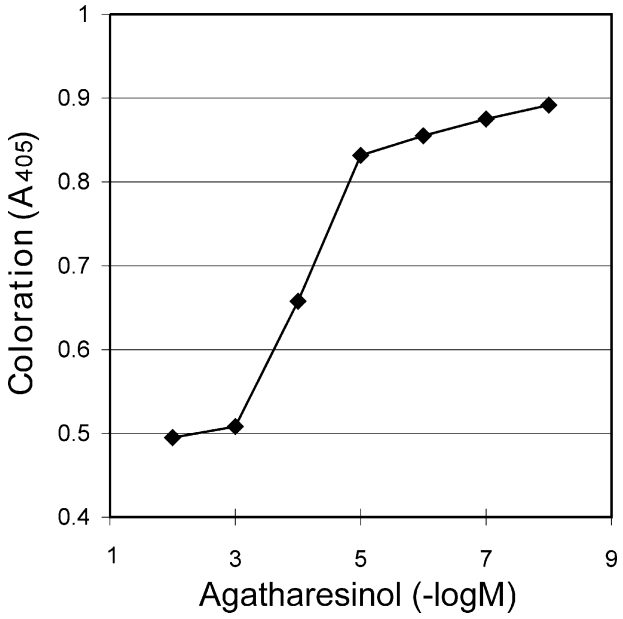

Fig. 5. Inhibition of reaction between artificial antigen and antiserum by agatharesinol.

the recognition selectivity of the antiserum. Then, to remove these antibodies, the antiserum was submitted to the affinity purification using gel to which *p*AHA-substituted BSA had been covalently bound. Reactivities of our antiserum with other Sugi heartwood norlignans (sequirin C, sugiresinol, hydroxysugiresinol and hinokiresinol) were compared with that of agatharesinol by competitive inhibition-ELISA to examine the recognition selectivity (Table 1, their structural formulae shown in Fig. 6). The reactivity of our antiserum with the norlignans showed a similar tendency before and after purification. The inhibition ability of sugiresinol, an isomer of agatharesinol of which dihydroxypentene structure so-called side chain is cyclized, was lower than that of agatharesinol, that is, our antiserum is less reactive with sugiresinol than with agatharesinol. Our antiserum was also reactive with hinokiresinol, an analogue of agatharesinol of which dihydroxyethane structure in the side chain is substituted with an ethene structure, while the

Table 1

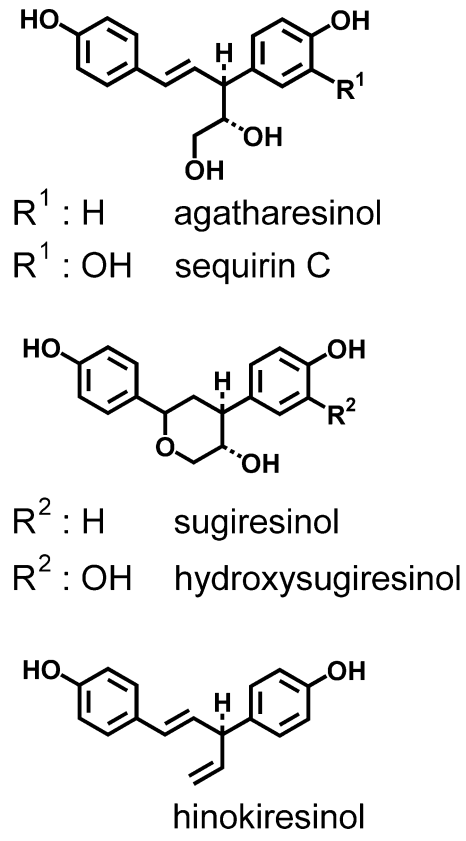

Fig. 6. Structural formulae of Sugi heartwood norlignans.

propene structure remains. These results indicate that the propene structural unit in the side chain participates in the reaction between the antiserum and norlignan. The inhibition ability of sequirin C, a derivatives of agatharesinol of which aromatic ring is mono-hydroxylated, was lower than that of agatharesinol, indicating

that *p*-hydroxy substitution pattern on the aromatic ring also participates in the antigen-antibody reaction. The difference in the reactivities among norlignans could lead to proposal of the chemical structure required as antigenic determinant, that is, 1,3-bis-(*p*-hydroxy phenyl) propene structural unit. Thus, the antiserum is able to recognize a slight difference in chemical structure and differentiate between the norlignans.

Phenylpropanoids classified other than norlignan such as cinnamyl alcohol (coniferyl alcohol), cinnamic acid (*p*-coumaric acid), lignan (hinokinin) and guaiacylglycerol-*β*-guaiacyl ether (model compound for lignin *β*-O-4 structural unit) were also used as competitors to examine the cross reactivity (Table 1). Their inhibition abilities were lower than those of the norlignans both before and after the purification, indicating that the antiserum is less reactive with phenylpropanoids other than norlignan. The partially purified antiserum, especially, was much less reactive with coniferyl alcohol, *p*-coumaric acid and guaiacylglycerol-*β*-guaiacyl ether (approximately 30% of that of agatharesinol). Thus, the recognition selectivity of the antiserum was improved by the affinity purification, and the purified antiserum is able to differentiate norlignans among other phenylpropanoids with the highest reactivity to one of the norlignans, namely, agatharesinol.

Competitive inhibition-ELISAs using MeOH extract (whole extracts before successive fractionation) of Sugi heartwood, and its *n*-hexane, C_6H_6 and EtOAc soluble fractions as competitors, were performed to examine the reactivity of the antiserum among Sugi heartwood extractives (Table 2). The MeOH extract and the EtOAc extract strongly inhibited the antigen–antibody reaction, but inhibition by the *n*-hexane extract and the C_6H_6 extract was much smaller. The EtOAc extract had the strongest inhibition ability. These results indicate that the antiserum reacts preferentially with the EtOAc extractives in Sugi heartwood. The EtOAc extract contains mainly norlignans which consist exclusively of agatharesinol and sequirin-C, while the amount other norlignans present, such as sugiresinol and hydroxysugiresinol, is markedly less (Ogiyama et al., 1983). As previously mentioned, the reactivity of the antiserum with sequirin C was lower than that with agatharesinol. Thus, our antiserum reacts strongest with agatharesinol and recognizes norlignans almost selectively among Sugi heartwood extractives.

Table 2
Inhibition of reaction between artificial antigen and antiserum by Sugi heartwood extracts[a]

[b] MeOH extract of Sugi heartwood.
[c] MeOH extract successively fractionated by *n*-hexane, C_6H_6 and EtOAc.
[d] Inhibition by the EtOAc extract was defined to be 100%.

3. Experimental

3.1. Isolation of heartwood extractives from Sugi

Sugi wood meal (ca. 2 kg) was extracted with MeOH at room temp. for 5 days. The MeOH extract was successively fractionated with *n*-hexane, C_6H_6 and EtOAc. The EtOAc soluble part was further fractionated by silica gel column chromatography (Me_2CO–*n*-hexane (4 : 3)). Agatharesinol (ca. 2 g) and sequirin-C (ca. 5.7 g) were isolated and then identified by ^1H, and ^{13}C NMR spectroscopic analyses.

3.2. Preparation of the agatharesinol artificial antigen

The artificial antigen was prepared according to the method of Weiler (1980). The procedure consisted of the following steps.

3.2.1. Binding of pAHA to BSA

BSA (200 mg), *p*AHA (200 mg) and 1-ethyl-3-(3-dimethylamino propyl)-carbodiimide (EDC) (200 mg) were dissolved in water (120 ml). The soln. was adjusted to pH 6.4 and stirred in the dark at room temp. for 20 h, during which time more EDC (100 mg) was added. The reaction soln. was then dialyzed against water and lyophilized to produce *p*AHA-substituted BSA.

3.2.2. Diazotization of pAHA-substituted BSA

Substituted BSA (120 mg) was dissolved in water (20 ml) and the pH adjusted to 1.5 with 1 M HCl. The soln. was cooled on an ice bath, and $NaNO_2$ (240 mg) in water (2 ml) and ammonium sulfamate (120 mg) in water (2 ml) added successively.

3.2.3. Coupling of the diazotized pAHA-substituted BSA to agatharesinol

The soln. of diazotized *p*AHA-substituted BSA was added dropwise to a soln. of agatharesinol (10 mg) in MeOH (0.5 ml) and borate buffer (0.1 M, pH 9.0) (10 ml). The soln. was allowed to stand in an ice bath for 30 min and the reaction soln. then dialyzed against water and lyophilized to produce the artificial antigen.

3.3. Determination of epitope density

Epitope density was determined by measuring the number of free amino groups of Lys residues in the

artificial antigen. The procedure for the determination consisted of the following steps.

3.3.1. Dinitrophenylation

The artificial antigen (1 mg) was dissolved in 5% (w/v) aqueous sodium hydrogencarbonate containing 6 M guanidine (500 μl), and the soln. stirred in the dark at room temp. for 1 h. Next, 10% (v/v) DNFB in EtOH (1 ml) was added and the mixture stirred in the dark at room temp. for 2 h. The reaction mixture was centrifuged and the ppt. washed successively in water, EtOH and Et_2O, and dried at room temp. over calcium chloride under reduced pressure.

3.3.2. Acid hydrolysis

The artificial antigen (1 mg) or the dinitrophenylated artificial antigen (1 mg) were hydrolyzed with 6 N HCl at 110 °C in sealed glass tubes for 20 h. The reaction solns. were then evaporated to dryness under reduced pressure.

3.3.3. HPLC analysis

The hydrolysates obtained above were analyzed by HPLC according to the method of Kuwano et al., (1987). The hydrolysate was dissolved in EtOH–water–TEA (triethylamine) (2:2:1) (20 μl), then the solvent was removed under reduced pressure. The residue was dissolved in EtOH–water–TEA–PITC (phenylisothiocyanate) (7:1:1:1) (50 μl), and the soln. was allowed to stand at room temp. for 20 min. The reaction solns. were then evaporated to dryness under reduced pressure. The phenylthiocarbamyl (PTC) amino acids were separated by HPLC using a Wakopack WS-PTC column (ϕ 4×200 mm), and (A) CH_3CN–0.1 M CH_3COONH_4 (5:95) and (B) CH_3CN–0.1 M CH_3COONH_4 (60:40) as the mobile phase at a flow rate of 1.0 ml/min. The gradient elution program was as follows; 0% B to 70% B for 15 min on a linear gradient and 70% B for next 5 min. The separated PTC-amino acids were detected at 254 nm.

3.4. Immunization

A New Zealand White, 11-week-old rabbit was immunized. The initial injection was carried out with a mixture of the artificial antigen (1 mg) dissolved in phosphate buffered saline (PBS) (0.5 ml) and Freund's complete adjuvant (0.5 ml). Injection was repeated 4 times at 10-day intervals in the same way using Freund's incomplete adjuvant instead of the complete adjuvant. One week after the last injection, blood was collected and allowed to stand at room temp. for 1 h, then centrifuged to separate out the serum.

3.5. Purification of the antiserum

The antiserum was submitted to partial affinity purification to remove antibodies against *p*AHA-substituted BSA (hapten-carrier) moiety of the artificial antigen. The procedure consisted of the following steps.

3.5.1. Preparation of affinity gel

*p*AHA-substituted BSA (40 mg) dissolved in water (1 ml) were mixed with Affi-Gel 102 (Bio-rad) (1 ml), followed by addition of EDC (5 mg). The soln. was adjusted to pH 4.9 and gently stirred by inversion in the dark at room temp. for 3 h, during which time more EDC (5 mg) was added. The reaction soln. was then centrifuged to give the affinity gel (ca. 1 ml).

3.5.2. Affinity purification

The antiserum was diluted with the equal volume of Tris buffered saline (TBS; 25 mM Tris–HCl (pH 7.6), 150 mM NaCl). The antiserum solution (6 ml) was mixed with the affinity gel (ca. 1 ml) and gently stirred by inversion at 4 °C for 20 h. The reaction soln. was then centrifuged to give the purified antiserum.

3.6. Dot-blot immunoassay

All procedures described below were performed at room temp. A sheet of Hybond-P membrane (Amersham) was soaked in MeOH for 10 min and PBS for 15 min, successively. The sheet was then placed in a dot-blot manifold and artificial antigen (1 μg, 200 ng, 40 ng, 8 ng, 1.6 ng) in PBS (10 μl) or PBS alone (10 μl, as a control) was added to the wells. The solns. were aspirated, the wells washed with PBS (100 μl) and then the wells were blocked with PBS-milk (3% (w/v) skim milk in PBS) (300 μl). After the wells were washed three times with PBS-T (PBS containing 0.5% (v/v) Tween 20), rabbit sera (1/100, 1/500, 1/2500, 1/12500, 1/62500) diluted in PBS (100 μl), preimmune serum (1/100) diluted in PBS (100 μl), or PBS alone (100 μl, as a control) was added to the wells. After 1 h, the wells were washed thoroughly with PBS-T, then goat: anti-rabbit IgG-alkaline phosphatase conjugate (Bio-Rad) (1/3000) diluted in PBS-milk (100 μl) was added to the wells. After 1 h, the wells were washed thoroughly with PBS-T.

The membrane was then removed from the manifold and washed again with PBS. Coloration was performed using an alkaline phosphatase conjugate substrate kit (Bio-Rad) containing 5-bromo-4-chloro-3-indolylphosphate toluidinium as the substrate and nitroblue tetrazolium as the enhancer, according to the manufacturer's instructions.

In other dot-blot immunoassays, the artificial antigen, *p*AHA-substituted BSA and BSA (each 1 μg) in PBS were absorbed onto a membrane, and this membrane assayed using the serum diluted (1/2000) in PBS (100 μl) according to the procedure described above.

3.7. ELISA

ELISA was carried out according to the method of Hassan et al. (1988) with slight modifications. All

procedures described below were performed at room temp. Artificial antigen (1 μg, 500 ng, 100 ng, 50 ng) in PBS (100 μl) or PBS alone (100 μl, as a control) was added to the wells of a 96-well microtitration plate (Iwaki), and the plate allowed to stand for 2 h. All solns. were then removed and the wells were washed three times with PBS (400 μl). Wells were blocked with PBS-OA (5% (w/v) ovalbumin and 5% (w/v) sucrose in PBS) (400 μl), washed three times with PBS and rabbit sera (1/1000, 1/5000, 1/10,000, 1/50,000, 1/100,000) diluted in PBS (100 μl) added to the wells. After 2 h, the wells were washed thoroughly with PBS, then goat: anti-rabbit IgG-alkaline phosphatase conjugate (1/3000) diluted in PBS (100 μl) was added to the wells. After 1 h, the wells were washed thoroughly with PBS. Coloration was performed using an alkaline phosphatase substrate kit (Bio-Rad) containing *p*-nitrophenylphosphate as the substrate, according to the manufacturer's instructions.

3.8. Competitive inhibition-ELISA

The amount of artificial antigen for plate coating and the concentration of the rabbit serum to be used in the competitive inhibition-ELISA were determined using the checkerboard titration described above (Fig. 3) (Hassan et al., 1988). The inhibition reaction was performed using 300 ng/100 μl of the artificial antigen soln. for the coating and rabbit serum diluted 1/20,000.

When using agatharesinol as the competitor, rabbit antiserum was preincubated with agatharesinol in MeOH (10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}, 10^{-7}, 10^{-8} M) at room temp. for 2 h, and ELISA using the preincubated antisera was performed according to the procedure described above.

When comparing the reactivity of the serum to agatharesinol and those to other phenylpropanoids (sequirin C, sugiresinol, hydroxysugiresinol, hinokiresinol, coniferyl alcohol, *p*-coumaric acid, hinokinin and guaiacylglycerol-β-guaiacyl ether), the optimal concentration of competitors (10^{-4} M) was chosen from the results of an agatharesinol inhibition ELISA (Fig. 5), since a linear relationship was observed between coloration and competitor concentration. The reactivities of the purified antiserum with the phenylpropanoids were also examined using 2000 ng/100 μl of the artificial antigen soln. for the coating, purified antiserum diluted 1/5000 and 10^{-3} M of the competitor concentration.

When using Sugi heartwood extracts as the competitors, the rabbit antiserum was first incubated with an equal concentration (5 ng/μl) of extract dissolved in MeOH at room temp. for 2 h, and the preincubated antisera then used for the ELISA.

Characterization of native and yeast-expressed tomato fruit fructokinase enzymes

Marina Petreikov, Nir Dai, David Granot, Arthur A. Schaffer*

Department of Vegetable Crops, Agricultural Research Organization, Volcani Center, Bet Dagan, 50250, Israel

Received 8 April 2001; received in revised form 16 July 2001

Abstract

Three fructokinase isozymes (FKI, FKII, FKIII) were separated from both immature and ripe tomato fruit pericarp. All three isozymes were specific for fructose with undetectable activity towards glucose or mannose. The three isozymes could be distinguished from one another with respect to response to fructose, Mg and nucleotide donor concentrations and this allowed the comparison of the fruit enzymes with the gene products of the two known cloned tomato fructokinase genes, *LeFRK1* and *LeFRK2*. FKI was characterized by both substrate (fructose), as well as Mg, inhibition; FKII was inhibited by neither fructose nor Mg; and FKIII was inhibited by fructose but not by Mg. ATP was the preferred nucleotide donor for all three FKs and FKI showed inhibition by CTP and GTP above 1 mM. All three FKs showed competitive inhibition by ADP. During the maturation of the tomato fruit total FK activity decreased dramatically. There were decreases in activity of all three FKs, nevertheless, all were still observed in the ripe fruit. The two tomato *LeFRK* genes were expressed in yeast and the gene products were characterized with respect to the distinguishing characteristics of fructose, Mg and nucleotide inhibition. Our results indicate that FKI is the gene product of *LeFRK2* and FKII is probably the gene product of *LeFRK1*. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

The developing tomato fruit sink metabolizes translocated suc via either invertase or suc synthase. The path of sucrose catabolism is developmentally regulated: the sucrose synthase pathway is associated with the young fruit which transiently accumulates starch, while the invertase pathway is associated with the later stages of fruit development (Ruan and Patrick, 1995; Ho, 1996; Schaffer and Petreikov, 1997a). In addition to changes in the biochemical pathway, the transition between the two developmental stages is accompanied by changes in the translocation pathway, from a symplastic to an apoplastic one, as well (Ruan and Patrick, 1995; Ho, 1996).

Irrespective of the initial enzyme in the pathway, free fru accounts for one half of the imported suc and its phosphorylation is requisite for its further metabolism. Fru phosphorylation may be carried out either by hexokinases (EC 2.7.1.1), which can phosphorylate both glucose and fructose, or by specific fructokinases (EC 2.7.1.4). The irreversible fructokinase reaction is likely to play an important role in determining carbon flux in sink tissue (Viola, 1996). The activity pattern of fructokinase in developing tomato fruit, but not hexokinase, parallels the transient starch content in the fruit (Schaffer and Petreikov, 1997a).

Fructokinases have been characterized from a number of plant tissues (see recent review by Pego and Smeekens, 2000). It is not uncommon to find two or three isoforms upon separation by ion-exchange chromatography (i.e. potato tuber, Gardner et al., 1992; Renz and Stitt 1993) which may also show tissue and developmental specifity (Renz et al., 1993). Some fructokinases show substrate inhibition by fructose (i.e. tomato, Schaffer and Petreikov, 1997b; potato, Gardner et al. 1992; Renz and Stitt, 1993) which may be physiologically significant in the case of tomato fruit which contains high fructose levels (Schaffer and Petreikov, 1997b). Fructokinases can also be characterized by their nucleotide specificity; Huber and Akazawa (1985) reported a fructokinase utilizing UTP while most other

PII: S0031-9422(01)00331-4

reported fructokinases show relative specificity to ATP. FKs can also be distinguished by the characteristic of inhibition by excess Mg ions. The fructokinase from pollen grains (Nakamura et al., 1991) and from soybean nodules (Copeland and Morell, 1985) was inhibited by Mg concentrations above 1–2 mM while that of pea seeds was not (Turner et al., 1977). A fructokinase from tomato fruit similarly showed the phenomenon of Mg inhibition (Schaffer and Petreikov, 1997b).

Tomato fruit fructokinases have recently attracted increasing attention due to their possible role in transient starch accumulation (Schaffer and Petreikov, 1997a; Kanayama et al., 1997, 1998), in addition to possible physiological roles in hexose accumulation and sugar sensing (Pego and Smeekens, 2000). Martinez-Barajas and Randall (1996) separated two isoforms of fructokinase from tomato fruit, which showed similar sensitivity to inhibition by fructose and similar nucleotide specificity. However, Kanayama et al. (1997) cloned two fructokinase genes from tomato with different expression patterns, as well as different kinetic characteristics of the expressed protein. One of the genes (*LeFRK2*) which is expressed primarily in the early stages of fruit development yields a gene product which, when expressed in yeast shows inhibition by fructose (Kanayama et al., 1998). The other gene (*LeFRK1*) is expressed throughout fruit development (Kanayama et al 1997) and its yeast-expressed gene product is not inhibited by fructose (Kanayama et al., 1998). The *LeFRK2* gene was hypothesized to be responsible for the fructokinase activity associated with transient starch accumulation (Kanayama et al., 1998) while the *LeFRK1* gene was suggested to play a housekeeping role in carbohydrate metabolism throughout the plant, supplying fru6P for glycolysis.

In light of these recent data we reinvestigated fructokinase activity in developing tomato fruit. We report here three FK isoforms, which can be distinguished one from the other on the basis of fru and Mg inhibition and nucleotide specificity. Furthermore, we attempt to relate the two known *LeFRK* gene products to the FK isoforms present in the tomato fruit.

2. Results

2.1. Fructokinase isoenzymes during fruit development

2.1.1. Separation on HPLC-ion exchange

Hexose phosphorylation activity from young tomato fruit were separated by HPLC-ion exchange chromatography (Fig. 1). We observed three peaks of activity with fructose as substrate, as well as two additional peaks of activity with glucose (termed HKI and HKII). The three fructose phosphorylating peaks (termed FKI, FKII and FKIII, according to the order of elution) were observed using two assay methods. One assay contained low fru (1.0 mM) and low Mg (0.5 mM), with which the FKI enzyme showed maximal activity. The second assay contained high fru (10 mM) and high Mg (3 mM), which gave maximal activities for FKII. The FKIII enzyme, which eluted only under high ionic concentration, showed approximately equal activities with both assays.

2.1.2. Activity during development

The total FK activity in crude extracts of immature (15 DAA) and ripe fruit pericarp is presented in Table 1. Recovery experiments indicated that differences in extractable activity between the different stage fruit were not artifactually due to inhibitory substances in the mature fruit. Similar recovery of a known amount of purified FKI (from the MonoQ fractions, as described further on) was obtained from both fruit developmental stages (not shown). Activity with both assay systems is higher in the young fruit and sharply declines in the more mature fruit. At both stages of fruit development activity is higher with the low fru/low Mg assay system, indicating that even in the mature fruit the major activity is inhibited by excess fructose and Mg.

A comparison of the chromatograms of the pericarp fructokinase enzymes from immature (15 DAA) and ripe fruit stages (Fig. 2) indicates that the three peaks of fructose phosphorylation activity were observed in both stages. The enzyme first eluted (FKI), assayed under low substrate conditions, remained the dominant peak of activity even in the ripe fruit. The FKII enzyme was present in the ripe fruit but generally was the least active of the three FKs.

2.2. Characterization of the three tomato fruit FK enzymes and comparison with the two yeast-expressed LeFRK (LeFRK-Y) gene products

In order to determine the relationships between the native FK enzymes and the products of the two *LeFRK* genes, enzyme extracts from mutant yeast lacking endogenous hexose kinase activity and expressing each of the two described *LeFRK* genes were separated on

Table 1
Fructokinase activity in immature and mature tomato fruit pericarp

Maturity stage	Fructokinase activity (nmol g^{-1} fw min^{-1})	
	Assay 1[a]	Assay 2[b]
Immature	184 + 25	85 + 8
Mature	63 + 8	27 + 1

[a] Assay 1 contained low fru (1.0 mM) and low Mg (0.5 mM).
[b] Assay 2 contained high fru (10 mM) and high Mg (3 mM). Data are averages + S.E. of 4 (immature) and 7 (mature) separate extractions from individual fruit.

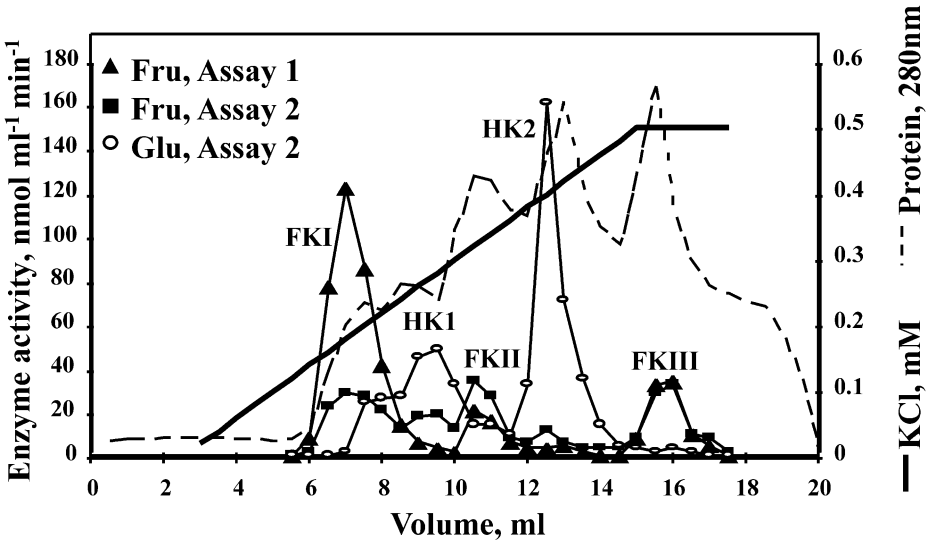

Fig. 1. HPLC-ion exchange (MonoP) separation of hexose kinase activity in immature tomato fruit pericarp. Assay 1 contained low fru (1.0 mM) and low Mg (0.5 mM). Assay 2 contained high fru or glu (10 mM) and high Mg (3 mM).

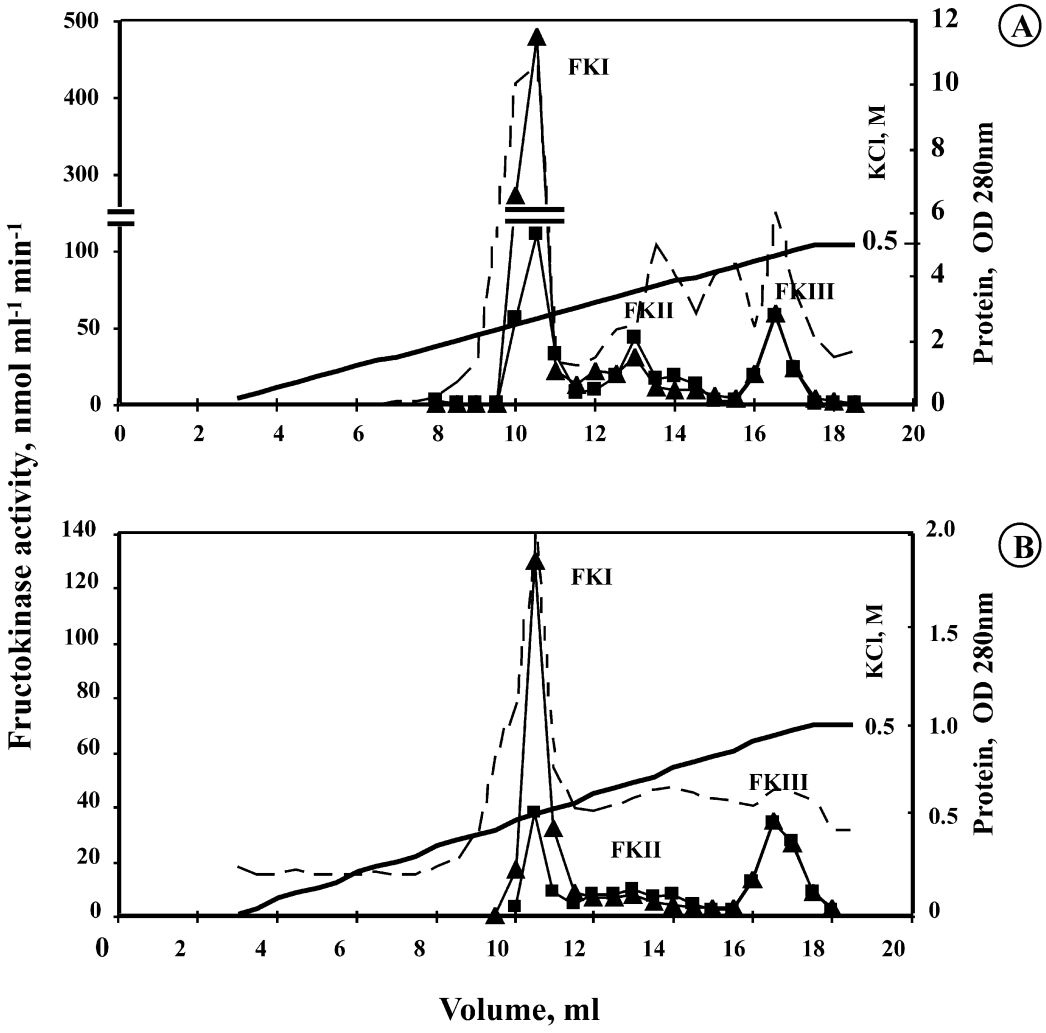

Fig. 2. HPLC-ion exchange (MonoQ) separation of fructokinase activity in immature (A) and mature (B) tomato fruit pericarp. Assays are as in Fig. 1. Note the different scales in the two chromatograms.

MonoQ ion chromatography under the same conditions as the tomato extract (not shown). The partially purified native FK enzymes and the yeast-expressed enzymes were partially characterized and compared as described below.

2.2.1. Hexose specificity and inhibition by fru

All three native fruit enzymes were specific for fru, with no discernible activity with glu or mannose (not shown). Of the three enzymes FKII had the lowest affinity for the substrate (Fig. 3a). Both yeast-expressed enzymes were also specific for fru, with no discernible activity with glucose or mannose. The *LeFRK1*-Y enzyme has an affinity pattern for fru analogous to FKII (Fig. 3b). Both FKI and FKIII from tomato fruit show the characteristic of substrate inhibition by high levels of fructose, while FKII shows Michaelis-Menten kinetics with fru concentrations up to 10mM (Fig. 3a). The yeast-expressed *LeFRK1*-Y similarly shows Michaelis-Menten kinetics with fru concentrations up to 10mM, while *LeFRK2*-Y shows the characteristic of substrate inhibition by high levels of fructose (Fig. 3b).

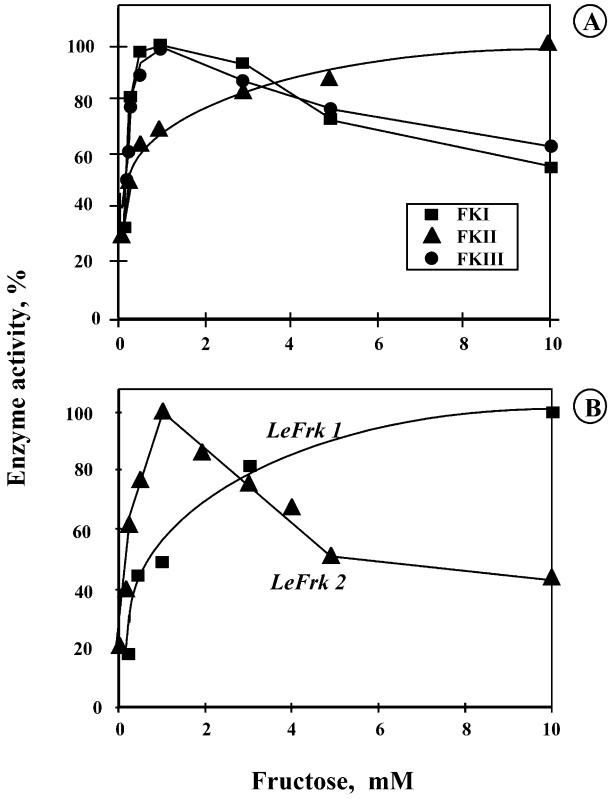

Fig. 3. Effect of fru concentration on the activity of the three fructokinase isoforms from (A) immature fruit pericarp and from (B) yeast-expressed *LeFRK* genes. Data are expressed as percentage of maximal activity for each enzyme in order to emphasize the similar and distinct patterns of activity. Maximal activities were, nmol g^{-1} fw min^{-1}: FK1, 710; FKII, 38; FKIII, 71; *LeFRK1-Y,* 148; *LeFRK2-Y,* 238.

2.2.2. Inhibition by Mg

Of the fruit enzymes only FKI shows the characteristic of inhibition by Mg concentrations above 1 mM (Fig. 4a). FKII shows no inhibition by Mg while FKIII shows little, if any, inhibition. Of the yeast-expressed enzymes only *LeFRK2*-Y is inhibited by Mg concentrations above 1 mM, while *LeFRK1*-Y is not (Fig. 4b).

2.2.3. Nucleotide specificity

The three fruit enzymes responded differently to the four nucleotide substrates (Fig. 5 a–c). FKI had highest activity with ATP and GTP at concentrations up to 0.5 mM. However, above 0.5 mM this enzyme showed inhibition by GTP and CTP. FKII and FKIII showed preferred activity with ATP with no indication of inhibition by high NTP concentrations. All three enzymes also showed product inhibition by ADP (not shown).

The two yeast-expressed enzymes also responded differently to the four nucleotide substrates (Fig. 6a and b). *LeFRK2*-Y responded in a similar fashion as the tomato fruit FKI, with highest activity with ATP and GTP at concentrations up to 0.5 mM, together with inhibition by GTP and CTP at concentrations above 0.5 mM. *LeFRK1*-Y showed preferred activity with ATP alone. Both enzymes also showed product inhibition by ADP.

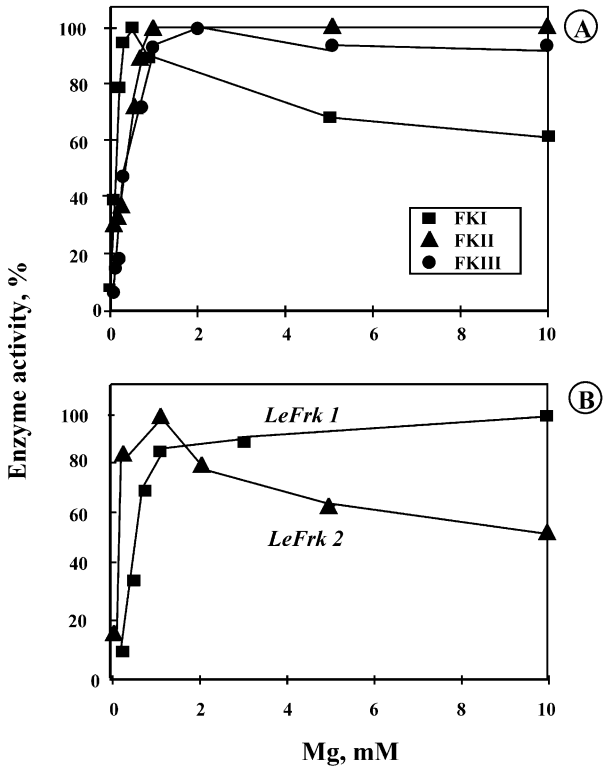

Fig. 4. Effect of Mg concentration on the activity of the three fructokinase isoforms from (A) immature fruit pericarp and from (B) yeast-expressed *LeFRK* genes. Data are expressed as percentage of maximal activity for each enzyme. Maximal activities were, in nmol ml^{-1} min^{-1}: FK1, 840; FKII, 52; FKIII, 161; *LeFRK1-Y,* 150; *LeFRK2-Y,* 226.

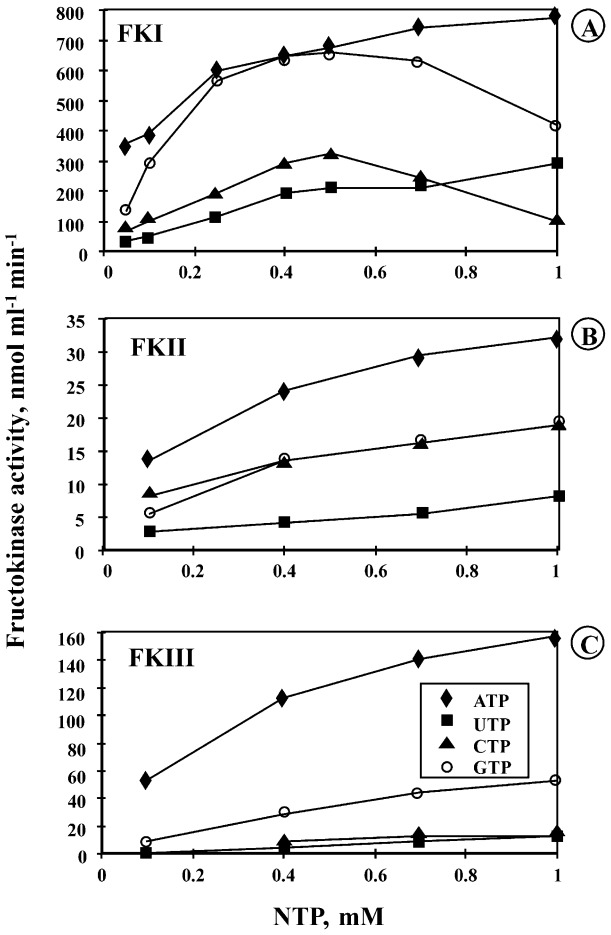

Fig. 5. Effect of nucleotide concentrations on the activity of the three fructokinase isoforms from immature tomato fruit pericarp. (A), FKI; (B), FKII; (C) FKIII.

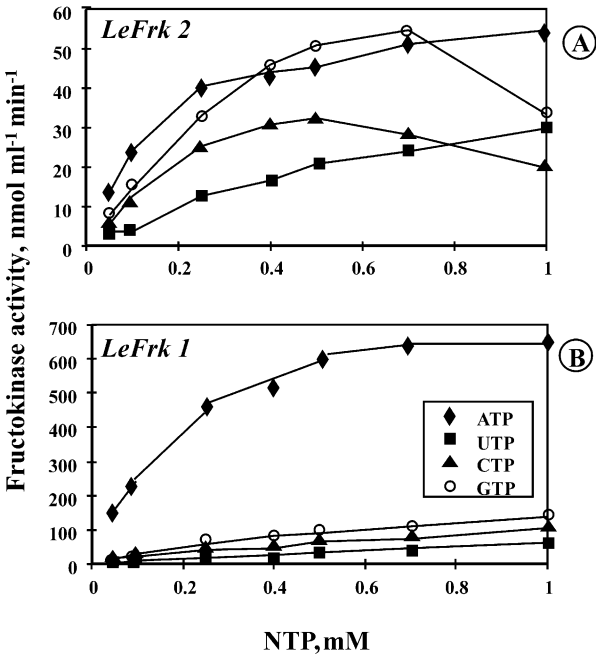

Fig. 6. Effect of nucleotide concentrations on the activity of the two yeast expressed fructokinase enzymes. (A), *LeFRKI*; (B), *LeFRKII*.

2.2.4. Coelution of yeast-expressed and tomato fruit fructokinase

Each of the *LeFkr-Y* gene products were chromatographed individually, and also together with the enzyme extract from tomato pericarp, in order to determine whether they coelute with any of the tomato enzymes. *LeFRK2*-Y coeluted with the tomato FKI under the same conditions used for the separation of the fruit enzymes. The *LeFRK1*-Y protein eluted slightly after FKII, coeluting with the second hexokinase enzyme, HK2 (not shown).

3. Discussion

We report here three distinct forms of fructokinase in tomato fruit, which can be distinguished one from the other on the basis of their responses to fructose, Mg and NTP concentrations. The first enzyme which eluted from ion-exchange chromatography, FKI, was inhibited by both high fru and high Mg. It also showed a characteristic and unique response to NTP concentration, with inhibition at high concentrations of GTP and CTP. The second eluted enzyme, FKII, had lowest affinity for fru and was inhibited by neither fru nor Mg, while the third enzyme, FKIII, was inhibited by fru but not by Mg.

These distinguishing characterisitics allowed us to compare the gene products for the two known *LeFRK* genes and to attempt to assign gene–product relationships between the genes and the native enzymes. The *LeFRK2* gene encodes for the FK1 protein, based on the similarities in fru inhibition, Mg inhibition and, especially, the unique response to NTPs, together with the coelution of the two proteins. To further prove this identity we have recently shown that antisense *FRK2* tomato fruit show a complete knockout of the FKI protein specifically, while the other two peaks of activity are unmodified (unpublished).

The gene product of *LeFRK1* appears likely to be the FKII protein, based on their similar low affinity for fructose and the absence of inhibition by either fru or Mg. Although the *LeFRK1*-Y protein product eluted slightly after the native FKII protein, this may be due to different post-translational modifications in plants and yeast, as previously suggested (Dai et al., 1997; Veramendi et al., 1999). The FKIII protein may be either be a distinct gene product or a post-translationally modified product of either of the two known genes. However, considering the distinguishing characterisitics of fru and Mg inhibition, together with the large difference in ionic strength required to elute the protein, it is reasonable to suggest that it is, in fact, a product of a third gene. Pego and Smeekens (2000) reported a third FK

gene in Arabidopsis and we have found an additional FK gene in tomato which is exclusively expressed in anthers, and is presently under study (unpublished).

Multiple fructokinases have been reported in other plant tissues. In potato tuber three enzymes were separated by ion-exchange chromatography (Gardner et al., 1992; Renz and Stitt, 1993) but in one study all three forms were inhibited by high fructose concentrations (Renz and Stitt, 1993) while in the other report only the first two eluted proteins were inhibited (Gardner et al., 1992). Similarly, Martinez-Barajas and Randall (1996) reported two tomato fruit isoforms and considering their relatively similar kinetic characterisitics they are possibly due to minor modifications of the *LeFRK2* gene product (Martinez-Barajas et al., 1997). Regretfully, much of the enzyme data for FKs available in the literature cannot be directly compared, due to the different techniques used in separation and enzyme characterization. Pego and Smeekens (2000) recently attempted to clarify the confusion regarding the different fructokinases in plants and suggested that the reported fructokinase isoforms may be attributed to only two different enzymes. Considering that so few genes for fructokinases have so far been characterized, the classification of the fructokinases will undoubtedly become clearer with additional gene cloning, which will allow for classification based on homologies between a large population of sequences from numerous plant species.

Fructokinase activity in tomato fruit has been associated with the transient accumulation of starch (Schaffer and Petreikov, 1997a). Kanayama et al. (1997, 1998) showed that the temporal and spatial expression of the *LeFRK2* gene in tomato fruit coincides with, although is not limited to, this transient starch accumulation and suggested that the *LeFRK2* gene product was particularly important for starch synthesis. We therefore hypothesized that since the FKI protein is the *LeFRK2* gene product, its activity would most likely be absent or relatively low, in comparison to the other FK enzymes in the mature fruit. The results of the present study show that the *LeFRK2* gene product remains the major native FK in the ripe fruit. It does not undergo any particular loss of activity, compared to the other fructokinases and its suggested specific role in transient starch synthesis is not certain.

The distinguishing characteristics of the three enzymes (inhibition by fru and Mg and response to nucleotides) may be of physiological significance, perhaps related to distinct localization and compartmentation of the isoforms. The trait of fructose inhibition has been proposed as a possible classifying characterisitc of fructokinase enzymes (Pego and Smeekens, 2000) and its physiological significance may be related to a parallel fructose inhibition of the sucrose synthase enzyme at physiological levels of fructose found in tomato fruit (Schaffer and Petreikov, 1997b) leading to a 'double brake' mechanism which may control sucrose metabolism flux (Kanayama et al., 1997, 1998; Schaffer and Petreikov, 1997b; Pego and Smeekens, 2000). Based on the similar characteristic of the yeast-expressed enzyme, the trait of Mg inhibition appears to be inherent to the enzyme and not artifactual, although we do not posit physiological significance. Similarly the unique trait of CTP and GTP inhibition of the FKI enzyme is also characteristic of the protein and not artifactual since the heterologous yeast-expressed protein has the identical trait.

This study paves the way for the analysis of the physiological significance of the individual tomato fruit fructokinases using plants with genetically modified activities of the individual fructokinases. These studies are in progress.

4. Experimental

4.1. Plant materials and yeast strains

Plants of tomato (*Lycopersicon esculentum* Mill (cv. 7844 and F144) were grown under standard conditions in a greenhouse in Bet Dagan, Israel. Flowers were allowed to self-pollinate. Chemicals and enzymes were purchased from Sigma or Boehringer Mannheim. Yeast strains and transformation methods were as described previously (Kanayama et al., 1998).

4.2. Enzyme extractions and assays

Fructokinase (EC 2.7.1.4) and hexokinase (EC 2.7.1.1) activities were extracted from pericarp tissue (4.5 g) of immature green (approximately 15 days after flowering) or red tomato fruit as described in Schaffer and Petreikov (1997a) with the addition of 1 mM PMSF to the extraction buffer. The 25–80% ammonium sulfate precipitate was collected, resuspended in extraction buffer, desalted on Sephadex G-25 and filtered through a 0.2 μm polysulfone membrane (Whatman International Ltd., Maidstone, England). The protein separation was performed on a Shimadzu HPLC system. For the separation of the fructokinase enzymes in young and mature fruit, as well as the yeast-expressed enzymes, the protein extract was applied (flow rate 0.5 ml/min) to a Mono-Q column HR 5/5 (Pharmacia Biotech AB, Uppsala, Sweden) prequilibrated with buffer containing 20 mM HEPES (pH 7.0) and 2.5 mM DTT. Unbound protein was eluted with the same buffer, followed by a 0–0.5 M KCl salt gradient. Protein was monitored at 280 nm. Fractions of 0.5 ml were collected and both fructose and glucose phosphorylating activities were measured. The fractions containing peak activities of the individual isoenzymes were bulked for further characterization.

The yeast-expressed enzymes were extracted as described previously (Kanayama et al., 1998). Enzyme extracts were separated on Mono-Q ion-exchange chromatography under identical conditions as for the fruit pericarp enzyme extracts. For the results presented in Fig. 1 a Mono-P column was used under identical elution and buffer conditions as described for the Mono-Q column.

Two different assays were used for measuring fructokinase activity. Assay 1 was conducted with low fructose and magnesium concentrations and the reaction mixture (1 ml) contained 30 mM HEPES (pH 7.6), 9 mM KCl, 0.5 mM $MgCl_2$, 1 mM ATP, 1 mM NAD, 1 unit PGI (type III), 1 unit NAD-dependent G-6-P DH (from *Leuconostoc*) and the reaction was initiated with 1 mM fructose. Assay 2 for fructokinase activity was conducted with high fructose (10 mM) and magnesium (3 mM) concentrations. For determining hexokinase activity glucose (10 mM) served as substrate, magnesium levels were 3 mM $MgCl_2$ and PGI was excluded from the reaction mixture. All the enzymatic reactions were carried out at 37 °C and $A_{340\ nm}$ was monitored continuously, as previously described (Petreikov and Schaffer, 1997a). Optimum conditions for each isoenzyme were used in enzyme assays for characterization of the three FK isoforms. For FKI assay 1 (low fru and Mg), while for FKII and FKIII, assay 2 (high fru and M) were used. ADP inhibition studies were carried out using the same enzyme extract with ADP concentrations ranging up to 5.0 mM.

Received 4 April 2001; received in revised form 20 June 2001

Abstract

To understand the regulation of phenylalanine ammonia-lyase (PAL) activity in the corn smut fungus, *Ustilago maydis*, we examined the effects of different media, metabolic effectors (including aromatic amino acids), and environmental factors on induction and repression of PAL activity. PAL was detected only in cell extracts and not in the culture medium. *U. maydis* PAL is constitutively produced at a low level in all media tested but its regulation can be influenced by aromatic amino acids. L-Tryptophan (0.3 mM) induces PAL activity 3- to 5-fold but tryptophan analogs and tryptophan-related metabolites do not. The enzyme is most readily induced during the early stationary phase of growth and the induced activity remains relatively constant during stationary stage. No induction or inhibition of PAL activity was observed as a function of culture temperature, pH or light. PAL induction was repressed by glucose but not by its reaction product, *t*-cinnamic acid. Induction did not require de novo protein synthesis, suggesting that some form of post-translational protein modification or a metabolic effect may be involved. This study shows that the regulation of *U. maydis* PAL is very different from the patterns known for plants and other fungi. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Phenylalanine ammonia-lyase (PAL; EC 4.3.1.5) catalyzes the nonoxidative deamination of L-phenylalanine to form *trans*-cinnamic acid and a free ammonium ion. The enzyme occurs in plants (Camm and Towers, 1973), fungi (Vance et al., 1975), and actinomycetes (Emes and Vining,1970), but not in animals. The properties and genetic control of PAL in both plants and fungi are important factors in our general understanding of the metabolic processes that yield phenylpropanoid secondary metabolites and energy. Substrate inducibility of PAL activity is observed in some fungi, but not in plants, which raises the question of how the mechanisms underlying the regulation of PAL differ among fungi, and between plants and fungi.

In plants, PAL is the entrypoint enzyme into phenylpropanoid metabolism and it regulates the biosynthesis of a wide range of secondary compounds, including lignin, flavonoids, furanocoumarin and isoflavonoid phytoalexins, and wound protectant hydroxycinnamic acid esters (Jones, 1984). Plant PAL activity can be induced by pathogen attack, and by environmental stresses such as wounding and light (Hahlbrock and Scheel, 1989). In gherkin and mustard, PAL induction is reported to result from the activation of a constitutive pool of inactive enzyme (Attridge et al., 1974), but in other plant species, PAL induction is the result of de novo synthesis of the enzyme (Hahlbrock and Schröder, 1975), or of a decrease in the rate of degradation of the enzyme (Zucker, 1971). Plant PAL activity appears to be regulated largely at the level of transcription (Lawton and Lamb, 1987) but it can also be modulated by the protein components of a system that inactivates the enzyme (Ritenour and Saltveit, 1996).

While PAL has been extensively studied in plants, relatively little is known about the fungal enzyme.

Studies on fungal PAL induction and regulation have been limited to *Rhodosporidium toruloides* (formerly *Rhodotorula glutinis*) (Gilbert and Tully, 1982; Kane and Fiske, 1984) and *Neurospora crassa* (Sikora and Marzluf, 1982) although phenylalanine catabolism has been observed in many microbial species. In *R. toruloides*, the enzyme is induced by L-phenylanine or L-tyrosine, while growth with glucose or ammonium salts represses enzyme synthesis. This regulation has been shown to occur at the level of transcription (Kane and Fiske, 1984; Gilbert et al., 1983)]. *R. toruloides* PAL is also inducible in response to signals of nitrogen deprivation or carbon limitation (Marusich et al., 1981). In *N. crassa*, PAL synthesis requires specific induction by L-phenylalanine and nitrogen derepression (Gilbert et al., 1983). This pattern of responses suggests that deamination by PAL could be the initial step in phenylalanine catabolism in these fungi, but this has not been systematically examined.

The corn smut fungus, *U. maydis*, is a pathogenic basidiomycete that can cause significant economic losses in corn production (Agrios, 1988). The infection of corn by this fungus is characterized by distinct galls (plant tumors) on stems, leaves, ears, and tassels. The disease symptoms also include stunting, and chlorosis, and accumulation of anthocyanins in stems and leaves, especially in the areas with developing tumors. In a previous study, we purified and characterized the PAL protein from *U. maydis* (Kim et al., 1996). Compared to yeast and plant PALs, *U. maydis* PAL has some unique protein properties such as high substrate specificity for L-phenylalanine, high pI value (pH 6.3), and marked thermal stability (Kim et al., 1996), but these traits provide little insight into the physiological role of the enzyme. In order to gain a better understanding of the function of PAL in pathogenic *Ustilago* species, we have investigated the nature of induction of PAL activity in the corn pathogen, *U. maydis*. Our results reveal a pattern of regulation of *Ustilago* PAL that is very different from the patterns known for plants and other fungi.

2. Results

2.1. Induction experiments

In order to determine whether PAL activity is detectable in *U. maydis* cells grown in standard microbial culture media, we tested seven different nutrient sources. Minimal medium containing 2% (w/v) ammonium nitrate, beef extract, casamino acid, potato dextrose broth, peptone or yeast extract were employed. PAL activity was present in cells grown with each of the nutrient sources tested, although the level varied. In all cases, PAL activity was detected only in cell extracts and not in the growth medium. Based on these results, regulation of PAL was investigated in two media: a nutrient-rich (complete) medium and a minimal medium. Depending on inoculum density, the PAL specific activity levels measured at the early stationary phase of cell growth ranged from 4 to 16 pkatal/mg protein in minimal medium, and from 14 to 22 pkatal/mg protein in complete medium.

Since aromatic amino acids have been shown to function as inducers of PAL in some fungi (Kalghatgi and Subba Rao, 1976; Gilbert and Tully, 1982; Sikora and Marzluf, 1982), L-phenylalanine, L-tyrosine, and L-tryptophan were tested for their ability to induce PAL in *U. maydis* strain 518. The PAL activity levels obtained from fungal cells grown in minimal medium (pH 7.0) supplemented with these amino acids (1 mM each) are presented in Fig. 1. The highest PAL activity was obtained in cells grown in L-tryptophan-supplemented medium, whereas L-tyrosine or L-phenylalanine supplementation had very little effect. Interestingly, PAL induction by L-tryptophan was strongly reduced by co-supplementation with L-phenylalanine.

U. maydis was able to grow slowly on either tryptophan or phenylalanine (2% w/v) as a sole carbon and nitrogen source. In this case, culture growth was better in the tryptophan medium, but PAL activity was higher in the phenylalanine medium. In absolute terms, however, these culture conditions did not result in any marked enhancement of PAL specific activity as compared to the results shown in Fig. 1.

To determine whether PAL induction by tryptophan is concentration-dependent, different amounts (0.03, 0.1, 0.3, 1.0, and 3.0 mM) of L-tryptophan were used to supplement minimal medium cultures. The increase in PAL activity responded linearly to the increase in L-tryptophan

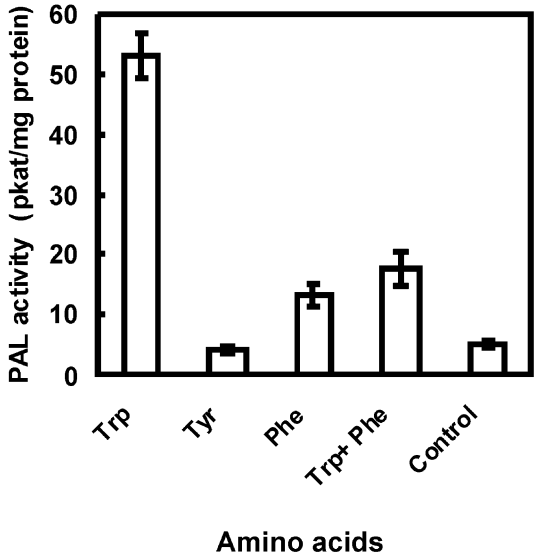

Fig. 1. Effect of aromatic amino acids on induction of PAL activity in *Ustilago maydis*. Each amino acid (1 mM) was added to minimal medium and the fugal cells were grown for 36 h, harvested and assayed for PAL activity. Trp, L-tryptophan; Tyr, L-tyrosine; Phe, L-phenlalanine; control, H_2O.

concentration up to 0.3 mM amino acid, and then declined (data not shown). Based on these results, 0.3 mM L-tryptophan was used for the subsequent studies of PAL regulation.

2.2. PAL induction period

In order to define the time-point of highest PAL inducibility during the culture cycle, *U. maydis* cultures were supplemented with 0.3 mM L-tryptophan at various time points in the growth cycle, incubated for two hours, harvested and assayed for PAL activity. Enhancement of PAL activity by these additions of exogenous L-tryptophan was only observed in cultures that had entered stationary phase (Fig. 2). This pattern was also observed when tryptophan was provided to the cells at the beginning of the culture growth, and cultures were subsequently harvested at various time points in the growth cycle and assayed for PAL activity (data not shown). In this case, the elevated PAL levels were stable for at least twelve hours during the stationary phase of culture growth (data not shown).

2.3. PAL inducibility by tryptophan isomers, precursors, and metabolites

An array of tryptophan optical isomers, precursors, and metabolites was tested for their ability to induce PAL. Both isomeric forms of tryptophan tested were able to induce increased PAL activity, and to a similar degree (Table 1). On the other hand, PAL activity failed to increase in response to any of the tryptophan precursors and metabolites tested, although indole-3-pyruvic acid gave a slight positive response. Therefore, PAL induction appears to be tryptophan-specific. Indole-3-acetic acid (IAA), which has been reported to occur naturally in *U. maydis* cultures (Navarre, 1990), reduced PAL activity almost 50% below control levels, while indole (0.3 mM) itself was too inhibitory to fungal cell growth to test for PAL induction.

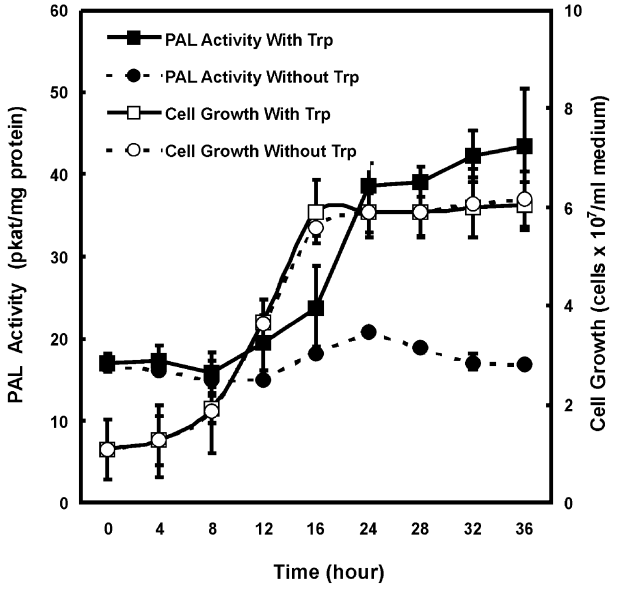

Fig. 2. Effect of L-tryptophan (Trp) addition on cell growth and extractable PAL activity in *Ustilago maydis*. L-Trypophan (0.3 mM) was added at different times in the cell cycle. Cells were harvested 2 h later and assayed for PAL activity.

2.4. Tryptophan effect on PAL induction in other U. maydis strains and Ustilago species

The observation that PAL induction was tryptophan-specific prompted us to investigate whether PAL induction by L-tryptophan is a general phenomenon in *Ustilago* species. For this purpose, several *U. maydis* strains and other smut species were tested (Table 2). PAL

Table 1
Effect of tryptophan analogs and tryptophan-related metabolites on PAL induction in *Ustilago maydis*[a]

Compounds	Relative PAL activity (%)[b]
No supplement	100
Anthranilic acid	110±10
Indole-3-acetamide	82±9
Indole-3-acetic acid	55±6
Indole-3-acetonitrile	107±11
Indole-3-butyric acid	114±12
Indole-3-carbinol	116±9
Indole-3-carboxylic acid	101±10
DL-Indole-3-lactic acid	88±7
Indole-3-pyruvic acid	135±5
Kynurenic acid	76±9
Tryptamine	98±10
Tryptophol	86±8
D-Tryptophan	318±14
L-Tryptophan	340±12

[a] Cells were grown in minimal medium for 16 h before addition of the exogenous compounds (0.3 mM each), harvested after 2 h further incubation, and used for PAL assay.

[b] Relative PAL activity is presented as the percentage of the value of PAL activity in the control which has no supplement. Control PAL activity was12 pkatal/mg protein.

Sporisorium reilianum	Wild type field isolate	Bakkeren et al. (1992)

induction (4- to 7-fold) by L-tryptophan was observed in all six *U. maydis* strains tested (data not shown). However, among other *Ustilago* species, only *U. nigra* displayed PAL induction by L-tryptophan (Fig. 3). All the *Ustilago* species tested did possess PAL, and its expression was detectable even without L-tryptophan supplementation. These results show that although PAL is widespread within the *Ustilago* genus, its induction by L-tryptophan is confined to certain species.

2.5. Effect of carbon and nitrogen sources on PAL activity induction

Various carbon and nitrogen sources were tested for their effect on PAL activity. Different levels of PAL activity and cell growth were obtained from the cells grown with the carbon sources tested (Fig. 4). Among these carbon sources, lactose and galactose resulted in the highest PAL activity, even though they proved to be the poorest sources for cell growth. In general, *U. maydis* cultures displayed higher PAL activity when they were grown on carbon sources that supported poorer growth, and lower activity when grown on more readily metabolized sugars such as glucose, mannose and sucrose.

To understand how carbon sources influence PAL activity under tryptophan-induction conditions, glucose was selected as a representative carbon source and its effect on PAL induction in *U. maydis* was investigated. Glucose supplementation repressed PAL production both in the presence and absence of L-tryptophan, and in both the nutrient-rich (complete) and minimal (glutamine only) media (Fig. 5). The repressive effect of glucose was observed under tryptophan-induced conditions

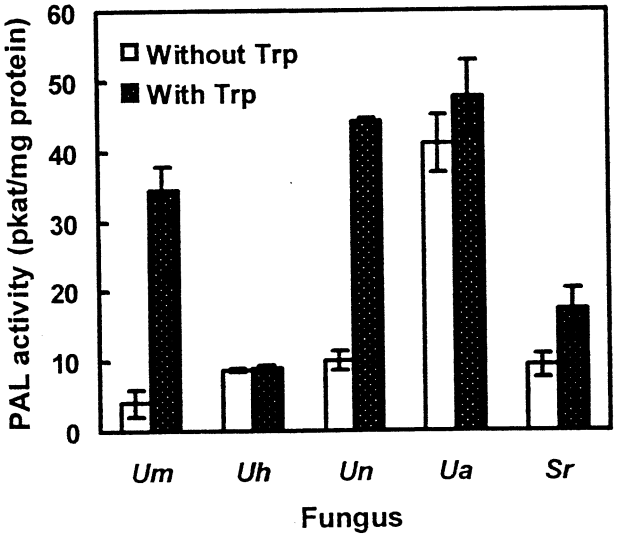

Fig. 3. Effect of L-trytophan (Trp) supplement on PAL activity in different *Ustilago* and related species. The fungal cells were grown in minimal media for 36 h with or without 0.3 mM L-trytophan, harvested, and assayed for activity. *Um, U. maydis; Uh, U. hordei; Un, U. nigra; Ua, U. aegliopsidis; Sr, Sporisorium reilianum.*

if the glucose was present from the beginning of the culture cycle, but not if the extra glucose was added later (16 h) in the culture cycle (data not shown). These results indicate that glucose repression can modulate *Ustilago* PAL expression, but that the repressive effect is limited to the early growth stage.

The effects of nitrogen source on *U. maydis* cell growth and PAL activity level are shown in Fig. 6. Provision of nitrogen in the form of inorganic salts, or asparagine, reduced PAL activity far below the levels obtained when L-tryptophan or L-phenylalanine was provided as the sole nitrogen source for cultures. Varying the ratio of ammonium nitrogen to nitrate nitrogen from 1:10 to 10:1 in the non-amino acid media did influence the level of PAL in the cultures after 24 h growth (data not shown), but the pattern of change did not suggest a strong preference for one form of inorganic nitrogen.

2.6. Effect of inhibitors on PAL activity in vivo

It had previously been determined that purified *U. maydis* PAL could be partially inhibited by the reaction product, *t*-cinnamic acid (Kim, 1997). When *t*-cinnamate (0.3 mM) was added to the L-tryptophan-supplemented culture medium, it substantially inhibited culture growth (60% of control), but had only a modest effect on the levels of PAL induced by 0.3 mM L-tryptophan supplementation (80% of control). Inhibition of PAL activity by addition of the potent and specific PAL inhibitor, 2-aminoindane-2-phosphonate (Zon and Amrhein, 1992) (0.1 mM), had no effect on fungal growth during the subsequent 24 h (data not shown).

2.7. Influence of physical environment

In order to examine the effect of environmental factors on PAL regulation, *U. maydis* cultures were grown in complete medium under various light, pH, and temperature regimes. No PAL induction or inhibition was observed when the cultures were incubated in light or dark, or at different medium pH values (pH 4, 5, 6, 7, 8), and/or at different temperatures (18, 24, 30°) (data not shown).

2.8. De novo synthesis versus activation in PAL induction

Induction of PAL activity in most plants and some fungi results from de novo synthesis of the enzyme. The origins of induced PAL activity in *U. maydis* were investigated by the use of inhibitors of translation and transcription, and with radiotracers and immunoprecipitation. In both the L-tryptophan-induced and-uninduced conditions, PAL activity was reduced slightly (to 70–80% of control) when *U. maydis* cells were incubated in the presence of

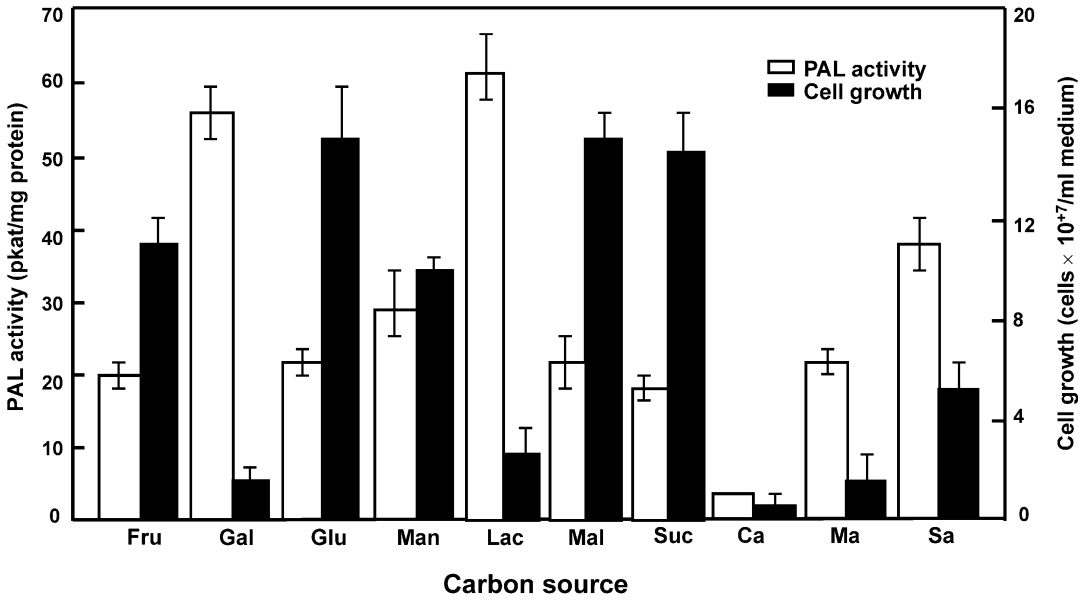

Fig. 4. Effect of various carbon sources on *Ustilago maydis* cell growth and PAL activity. Fru, fructose; Gal, galatose; Glu, glucose; Man, Mannose; Lac, lactose; Mal, maltose; Suc, sucrose; CA, citric acid; MA, malic acid; SA, succinic acid. Cells were grown for 36 h in minimal medium composed of 20 mM NH_4NO_3 and basal salt solution with each carbon source (2%) and harvested for PAL assay and cell count.

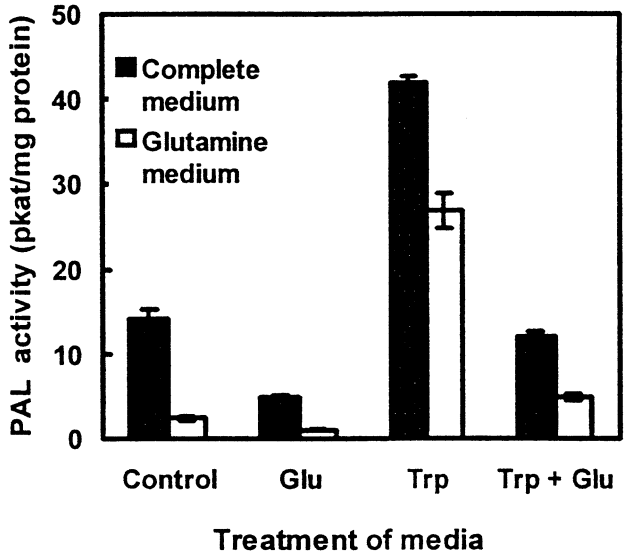

Fig. 5. Effect of glucose addition on *Ustilago maydis* PAL induction by L-trytophan. For the effect of glucose (Glu) addition, complete medium and glutamine (20 mM)-only medium were each supplemented with 2% glucose or 0.3 mM L-trytophan (Trp), or both. The fungal cells were grown in these media for 36 h and harvested for PAL assay.

actinomycin-D, a transcriptional inhibitor, or cycloheximide, an inhibitor of translation (Table 3). This implies that gene transcription and protein synthesis are needed to maintain PAL levels during the log phase of culture growth. However, radiolabeling of newly synthesized proteins showed that there was no difference in PAL protein labeling between the cells grown in L-tryptophan-induced and-uninduced conditions (Table 4). Taken together, these observations suggest that the induction of PAL activity by L-tryptophan supplementation is not primarily the result of de novo synthesis of PAL, but may instead reflect activation of PAL enzyme produced during the log phase of culture growth. The fact that the greatest enhancement of PAL activity by exogenous L-tryptophan is obtained in the stationary phase of culture growth (Fig. 2), when most protein synthesis has ceased, is consistent with this interpretation.

3. Discussion

3.1. PAL induction by L-tryptophan

The influence of aromatic amino acids on fungal PAL regulation has been studied in only a few species. In the red yeast (Marusich et al., 1981), *R. toruloides*, L-phenylalanine and L-tyrosine acted as PAL inducers, while in *N. crassa* (Sikora and Marzluf, 1982), L-phenylalanine and in *R. solani* (Kalghatgi and Subba Rao, 1976) L-phenylalanine, L-tyrosine, and L-tryptophan all served as PAL inducers. In all of these cases, the best PAL inducer was its substrate, L-phenylalanine. In contrast, the most effective inducer of PAL activity in *U. maydis* was L-tryptophan (Fig. 1), although L-phenylalanine had some effect. The response to tryptophan is also quite sensitive, since the level of L-tryptophan (0.3 mM) giving the highest PAL induction in *U. maydis* is substantially lower than the level of L-phenylalanine supplementation (6 mM) required for PAL induction in *R. toruloides* (Marusich et al., 1981; Wick and Willis, 1982).

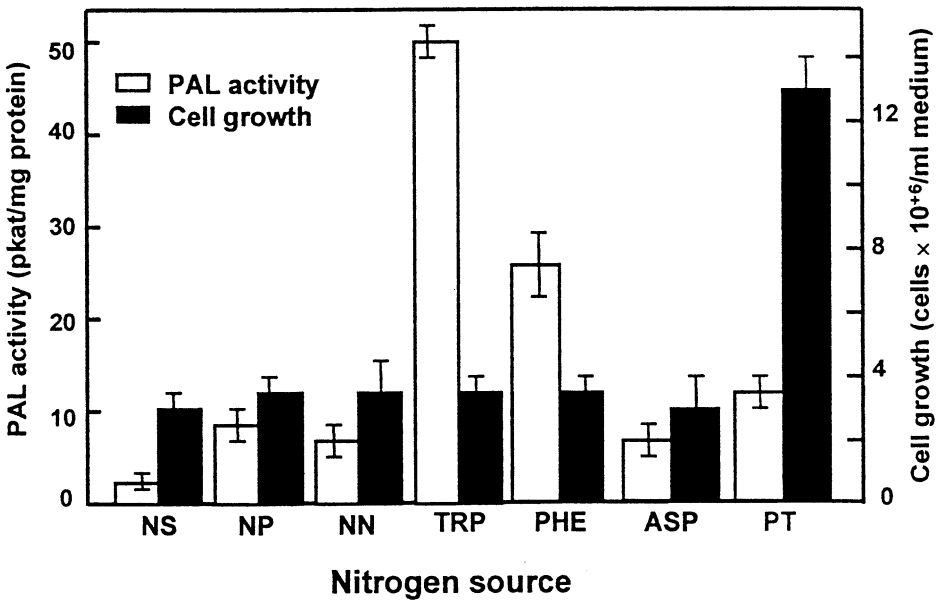

Fig. 6. Effect of nitrogen source on *U. maydis* cell growth and PAL acitivity. Each nitrogen source (3 mM) was added to minimal medium and the fungal cells were for 36 h and harvested for PAL assay and cell count. NS, $(NH_4)_2SO_4$; NP, $NH_4H_2PO_4$; NN, NH_4NO_3; TRP, L-tryptophan; PHE, L-phenylalanine; ASP, L-asparagine, and PT, peptone.

Table 3
Effect of actinomycin D and cycloheximide on *Ustilago maydis* PAL activity

Treatment[a]	PAL activity (pkatal/mg protein)			
	Induced[b]		Uninduced	
	12 h	16 h	12 h	16 h
No addition	19.6±1.8	32.8±2.2	13.3±1.6	20.5±2.1
Actinomycin D	13.9±1.9	23.3±0.8	9.2±1.2	15.1±0.6
Cycloheximide	16.2±1.7	26.4±1.3	11.3±1.0	16.8±1.2

[a] Actinomycin D (100 μg ml^{-1}) and cycloheximide (10 μg ml^{-1}) were added at mid (12 h) or late (16 h) log phase in the cell growth cycle, and cells were harvested 4 h later and used for the PAL assay.

[b] Induced: L-tryptophan (0.3 mM) was added to minimal medium at the time of inoculation; uninduced: no L-tryptophan supplement was added.

Table 4
PAL protein synthesis in L-tryptophan-induced and-uninduced conditions[a]

Cell harvest time	Newly synthesized PAL (dpm) [b]	
	Induced	Uninduced
16 h	382±36	388±47
20 h	461±56	473±62

[a] Induced: L-tryptophan (0.3 mM) was supplemented to minimal medium at the time of inoculation; uninduced: no L-tryptophan supplement was added.

[b] Proteins of *Ustilago maydis* were radiolabeled in vivo with L-^{3}H-amino acid mixture. The labeled PAL proteins were immunoprecipitated with anti-PAL antibodies and counted. The reported dpm values were obtained by subtracting the values of control proteins immunoprecipitated with pre-immune-serum.

However, induction of PAL in *Ustilago* cultures by L-tryptophan does not appear to be a typical microbial catabolic system directed at nutrient scavenging. First, a significant basal level of PAL is always detectable in the cultures, unlike in the three fungal species mentioned above, in which PAL activity is detectable only when the fungi are grown in media supplemented with aromatic amino acids which induce PAL. Second, in contrast to other fungi like *R. toruloides* and *N. crassa*, the inducer does not appear to have a logical metabolic connection with the reaction catalyzed by the induced enzyme. L-Phenylalanine, the obvious induction candidate, is much less effective in this role than L-tryptophan. Finally, the L-tryptophan effect on PAL induction is not operative in all the *Ustilago* species tested.

Since PAL induction in *U. maydis* results only from tryptophan supplementation and not from tryptophan precursors or metabolites, it is worth asking whether the endogenous level of tryptophan in the host plants is sufficient for *U. maydis* PAL induction. There are no data for corn, but the level of free tryptophan in tobacco leaves and carrot cell cultures has been reported as 16.7 μM (Widholm, 1974) and 81 μM (Widholm, 1972), respectively. In this study, *U. maydis* PAL was measurably induced by 30 μM tryptophan supplementation, suggesting that the enzyme might be inducible by either the endogenous level of free tryptophan, or enhanced levels of tryptophan resulting from proteolytic degradation of host proteins during biotrophic growth of the fungus in corn tissues.

3.2. Regulatory features of PAL

The production of many inducible enzymes by microorganisms is subject to catabolic repression when the organisms are grown in the presence of a potential carbon and energy source. In addition to carbon catabolic enzymes, many proteins, including those involved in bioluminescence, photosynthesis, sporulation, antibiotic biosynthesis, pigment biosynthesis, and extracellular macromolecular degradation, have been shown to be subject to catabolic repression (Saier, 1991). Glucose repression was observed with *U. maydis* in the present study. Both basal PAL levels and the induction of PAL by L-tryptophan were reduced by glucose addition to the medium (Fig. 5). A similar phenomenon was reported in *R. toruloides*, where PAL induction by L-phenylalanine was repressed by glucose (Gilbert and Tully,1982). We found that glucose repression of *U. maydis* PAL induction took place only at the early growth stage, but there are no corresponding data for *R. toruloides*. It thus remains unclear whether glucose repression of PAL at the early growth stage is a common feature in PAL-producing fungi.

The induction of PAL in *U. maydis* by tryptophan is not primarily the result of de novo synthesis of the protein, as shown by immunoprecipitation (Table 3) and Western blot assay results (data not shown). Alternative mechanisms could be some form of post-translational protein modification such as phosphorylation of the enzyme (Bolwell, 1992; Allwood et al., 1999), or a metabolic (non-covalent) influence on the *Ustilago* PAL activity. The behavior of the *Ustilago* enzyme is thus very different from that seen in *Rhodosporidium* (Wick and Willis, 1982; Gilbert et al., 1985) and *Neurospora* (Sikora and Marzluf, 1982), where induction of elevated PAL activity by phenylalanine is controlled primarily at the transcriptional level.

Some aspects of the results obtained in this study are reminiscent of classic microbial secondary metabolism. For example, the tryptophan inducibility of PAL is invoked only during the stationary phase of culture growth, and the induction appears to require tryptophan itself, rather than tryptophan metabolites or precursors. The pattern of highest inducibility and longer stability of *U. maydis* PAL during the stationary phase of growth differs from that seen with *R. toruloides*, where PAL was highly induced by L-phenylalanine during mid- to late-log phase of growth and showed variation in stability during the stationary phase of growth (Gilbert et al., 1983; Marusich et al., 1981)

It is noteworthy that IAA is also most actively produced at the stationary phase in the culture cycle of *U. maydis* (Navarre, 1990). Considering that tryptophan is the major precursor for IAA production in this fungus, the induction and suppression of PAL by tryptophan and IAA, respectively, suggests that a metabolic control mechanism links phenylalanine metabolism to tryptophan metabolism during the late growing period of *U. maydis*. It has been clearly established in both prokaryotes and eukaryotes that the synthesis of these two aromatic amino acids, phenylalanine and tryptophan, is derived from chorismate through the shikimate pathway (Braus, 1991; Hrazdina and Jensen, 1992). Logically, the synthesis and catabolism of each amino acid will be regulated to reflect their demands and their levels. From this perspective, it is conceivable that *U. maydis* PAL regulation is indirectly under the influence of tryptophan levels through metabolic feedback mechanisms that control synthesis and catabolism of all the aromatic amino acids. The suppressive effect of L-phenylalanine on tryptophan's ability to induce *U. maydis* PAL (Fig. 1) may reflect such an interaction. Studies on the effect of tryptophan on the synthesis of the PAL substrate, phenylalanine, could provide further insight into potential metabolic connections between tryptophan metabolism and PAL regulation.

t-Cinnamic acid, the product of the PAL reaction, is moderately inhibitory to *U. maydis* cell growth. Toxicity of *t*-cinnamic acid was also observed in *R. toruloides* cultures (Kane and Fiske, 1984; Marusich, Jensen and Zamir, 1981). In some plant systems like bean (Bolwell et al., 1988) and alfalfa (Orr. Edwards and Dixon, 1993) cell suspension cultures, addition of exogenous *t*-cinnamic acid was shown to suppress PAL induction. This has led to the suggestion that feedback inhibition by *t*-cinnamic acid could help control diversion of L-phenylalanine from primary metabolism to secondary metabolism and thereby avoid the accumulation of *t*-cinnamic acid to levels that might become toxic to cells. However such a mechanism does not appear to operate in *U. maydis*.

In conclusion, the work described in this paper has provided new information concerning fungal PAL regulation. When compared to higher plants and the fungal saprophytes, *R. toruloides* and *N. crassa*, regulation of PAL in *U. maydis* presents several novel features. However, it remains to be established whether or how this novelty is related to the biotrophic life-style of this organism. We are currently exploring that question by isolation and manipulation of the gene encoding PAL in *U. maydis*.

4. Experimental

4.1. Fungal strains and cultures

The Ustilago strains used in this study are listed in Table 1. Cultures were grown on potato dextrose agar (PDA, Difco) and on complete or minimal medium (2% glucose, 20 mM NH_4NO_3, and salt solution, pH 7.0) (Kim et al., 1996). A sporidial suspension (1 ml) (about

10^7 cells) was inoculated into 50 ml complete or minimal medium in 250 ml Erlenmeyer flasks and grown for 24–48 h at 30° with shaking (250 rpm). Alternatively, 100 μl sporidial suspension was inoculated into 5 ml complete or minimal medium in 15 ml culture tubes and grown for 16–36 h. Unless otherwise indicated, *U. maydis* strain 518 and minimal medium were used for the experiments on PAL regulation. Fungal cell growth was measured by counting the number of sporidia using a haemocytometer, with five replicates. Measurements for cell growth are illustrated in the figures with columns (mean value) and vertical bars (±S.D.). The experiments were repeated three times with essentially identical results. S.D. values calculated from the means of these independent experiments were less than 10%.

4.2. Chemicals

L-^{3}H-amino acid mixture was purchased from ICN Biomedical Pharmaceuticals, Inc. L-[U-^{14}C]-phenylalanine (474 mCi/mmol) was purchased from Amersham International. 2-Aminoindan-2-phosphonic acid (AIP) (Zon and Amrhein, 1992) was provided by J. Zon (Technical University Wroclaw, Poland). Diethyl pyrocarbonate (DEPC), cycloheximide, actinomycin D, Protein A-Sepharose beads, bovine serum albumin, L-phenylalanine, L-tyrosine, L- or D-tryptophan, t-cinnamic acid, indole, and indolic derivatives were obtained from Sigma (St. Louis, Mo.). Westran membrane was purchased from Schleicher & Schuell; Zeta-Probe membrane from Bio-Rad, and microbial media from Difco. All other chemicals (analytical reagent grade) were obtained from Sigma or Aldrich.

4.3. Enzyme extraction and assay

Cultures were harvested in a 1.5 ml microfuge tube and the fungal cells were washed two times with sterile distilled water. The cell pellet was homogenized for 20 s at 4 °C with alumina and a mini-pestle (Mandel Scientific Co.). The homogenate was suspended in 200 μl ice-cold 0.5 M sodium phosphate buffer, pH 8.0, vortexed for 5 min with frequent cooling in ice and then centrifuged at 14,000 g for 15 min at 4 °C. The supernatant was desalted through a PD-10 column (Pharmacia) and used for PAL assays and other experimental analyses. PAL activity (three replicates per protein extract) was measured by a radiometric method as described by Campbell and Ellis (1992) using L-[U-^{14}C]-phenylalanine as substrate. Protein was determined by a dye-binding method (Bradford, 1976) with bovine serum albumin as a standard. Unless otherwise described, all experiments were repeated at least twice with three or five replicates. Values presented in Tables are the mean and SD of all activity measurements for three cultures, while in figures, the PAL activity column indicates the mean and the vertical bar indicates S.D. S.D. values calculated from the means of these independent experiments were less than 10%.

4.4. Immunoprecipitation of radio-labeled PAL protein

U. maydis cells were grown in minimal medium (50 ml) for 12 or 16 h with or without L-tryptophan (0.3 mM). After addition of 50 μCi ^{3}H-labeled amino acid mixture, the cultures were further incubated for 4 h. Following harvest by centrifugation at 6000 g for 10 min at 4 °C, the cells were washed three times with sterile distilled water and frozen in liquid nitrogen. Protein crude extracts were prepared by grinding the cells with alumina as described above. Radiolabeled PAL proteins were immunoprecipitated with U. maydis PAL antiserum (or preimmune serum) and protein A-Sepharose 4B beads, using a protocol described in 'Antibodies: A Laboratory Manual' (Harlow and Lane, 1988). After heating in SDS sample buffer at 85 °C for 10 min, immunoprecipitated proteins were separated from the beads by centrifugation and the radioactivity in the supernatant was measured using a Beckman LS-5000TA scintillation counter.

Received 9 March 2001; received in revised form 19 June 2001

Abstract

A strongly cationic isoperoxidase named PC3 was purified to homogeneity from scented-geranium (*Pelargonium graveolens*) callus by using DEAE-Sephacel chromatography, CM–cellulose chromatography and Sephacryl S-200 gel filtration, respectively. The enzyme was a glycoprotein with M_r of ca. 58 kDa estimated by SDS–PAGE and Sephadex G-150 gel filtration. The pI value of the enzyme was 9.1. Kinetic studies revealed that PC3 had a very low K_m value for scopoletin of 0.01 mM and could use ascorbate as a substrate. Interestingly, PC3 could not oxidize ferulic acid as a substrate. Chemical modification of the enzyme showed that PC3 was rapidly inactivated by His, Cys, Trp and Lys-specific reagents. The second order rate constants and reaction orders with respect to these inactivations were determined. Notably, ca. 4–7-fold activity boosting of PC3 occurred by adenine and imidazole when anilino substrates, such as *o*-dianisidine and *o*-phenylenediamine were oxidized, whereas this activity boosting did not occur when several phenolic substrates were used. © 2001 Published by Elsevier Science Ltd.

1. Introduction

Multiple forms of plant peroxidases (EC 1.11.1.7) are widely distributed in all higher plants (van Huystee and Cairns, 1982). Peroxidases have been implicated in a wide range of cellular reactions such as phenolic compound oxidation, indole-3-acetic acid oxidation, lignification and polysaccharide cross-linking. Obviously they play a key role in plant growth and development (van Huystee, 1987). Moreover, they are known to be related with the defense mechanisms toward pathogens and various stresses including metal ion (Antje et al., 1996), salt (Bakardjieva et al., 1996) and air pollution damage (Castillo et al., 1987).

According to the classification by Welinder (Dunford, 1999; Hiraga et al., 2001), classical secretory plant peroxidases such as horseradish peroxidase (HRP), peanut peroxidase and barley peroxidase belonged to the class III peroxidase superfamily. They have two conserved calcium ions, an N-terminal signal peptide, four conserved disulfide bridges and 0–25% carbohydrate content. All the enzymes in class III have an imidazole side chain of His as their proximal ligands, and conserved Arg and His residues on the distal side of the heme. However, distinct differences in physicochemical and catalytic properties have been reported among peroxidase isozymes even within one plant family (Lee and Kim, 1994). Therefore, more detailed catalytic and molecular studies of individual isoperoxidases are desirable. There are at least eight distinguishable isoperoxidases in Korean radish, and six of them were purified to near homogeneity (Yoo and Kim, 1988; Lee and Kim, 1990, 1993, 1998a,b; Lee et al., 1994; Kim and Kim, 1996). The physicochemical, catalytic and immunological properties of Korean radish peroxidases (KRP) were studied in detail (Yoo and Kim, 1988; Lee and Kim, 1990, 1993, 1998a,b; Lee et al., 1994; Kim and Kim, 1996), indicating that different isoperoxidases might have different specificities toward physiological substrates in vivo. Studies on the gene structure, overexpression and promoter function of individual isoperoxidase have been intensively studied in various plants such as tobacco (Dowd et al., 2000), Arabidopsis (Tognolli et al., 2000), rice (Hiraga et al., 2000), sweet potato (Kim et al., 2000) as well as Korean

radish (Park and Kim, 1996a, b; Lee and Kim, 1998; Lee et al., 1999).

Pelargonium graveolense, referred to as scented-geranium, is an important ornamental plant worldwide, and has been studied extensively with respect to its conventional horticultural traits (Raj et al., 1997). However, only few reports have so far focused on the isolation and characterization of catalytic and kinetic properties of enzymes from this plant.

In the present investigation, a strongly cationic isoperoxidase PC3 was purified to homogeneity from scented-geranium callus and some of its physicochemical, kinetic and catalytic properties examined in detail.

2. Results and discussion

2.1. Enzyme purification

Scented-geranium (*P. graveolense*) callus was induced as previously reported (Lee and Lee, 2000). The crude extracts of geranium callus contained three cationic isoperoxidases, PC1, PC2 and PC3, and three anionic isoperoxidases, PA1, PA2 and PA3, when subjected to starch gel electrophoresis at pH 7. In this nomenclature system, the suffix numbers denote which isoperoxidase migrates the greater distance to either anode (letter "A") or cathode (letter "C"). The lower the number the less the migration. Among the cationic isoforms, a strongly cationic isoperoxidase, PC3, was purified 56-fold to an electrophoretically homogeneous form by chromatographic sepn methods of DEAE–Sephacel chromatography, CM–cellulose chromatography and Sephacryl S-200 gel filtration (Tables 1 and 2).

2.2. Physicochemical properties

The M_r of PC3 was determined to be ca. 58 K by SDS–PAGE (Fig. 1) and Sephadex G-150 gel filtration, showing that PC3 is a monomeric protein. These results suggest that the M_r for PC3 falls within the range of other isoperoxidases such as KRP (Lee and Kim, 1994), HRP (Shannon et al., 1966), JRP (Morita et al., 1971) and peanut peroxidase (van Huystee, 1987). The isoelectric point of PC3 was determined to be 9.1, and the enzyme was shown to contain carbohydrate (Grossman and Neville, 1971). The enzymes in class II secreted fungal peroxidase and class III classical secretory plant peroxidase are glycosylated (Dunford, 1999). Potential *N*-glycosylation sites and carbohydrate contents have been determined for KRP (Kim and Kim, 1996), HRP (Shannon et al., 1966) and peanut peroxidase (Shaw et al., 2000; Lege et al., 2001) by deglycosylation, *N*-glycan profiling or NMR spectroscopy.

2.3. Kinetic studies

Substrate utilities of isoperoxidase PC3 have been investigated in terms of optimal pH and K_m values in order to infer the physiological functions of the enzyme. Geranium isoperoxidase PC3 had a pH optimum around 6.0 when guaiacol and H_2O_2 were used as the substrates. The optimum pHs with respect to various substrates such as *o*-dianisidine, *o*-phenylenediamine, caffeic acid, esculetin, scopoletin, chlorogenic acid, and ascorbic acid were also determined to be in the range of 4.0–6.0 (Table 3). These ranges were similar to those of six isoperoxidases from Korean radish (Lee and Kim, 1994).

Geranium PC3 had K_m values of 7.3 mM for guaiacol and 3.0 mM for H_2O_2. The K_m values of six Korean radish isoperoxidases against guaiacol ranged within 5.6–19.4 mM, and the K_m values against H_2O_2 ranged within 0.19–2.5 mM (Lee and Kim, 1994). PC3 showed high affinities for scopoletin among various substrates tested with the K_m value of 0.01 mM, and showed sigmoidal saturation mode for scopoletin oxidation in spite of its monomeric structure. Similar sigmoidal saturation curve for scopoletin oxidation was also shown in C_1 and A_3 from Korean radish (Lee and Kim, 1990; Park et al., 1994). The K_m values of five Korean radish isoperoxidases toward scopoletin ranged between 0.18 and 5.6 mM, and only A_{3n} could not use scopoletin as a substrate (Lee and Kim, 1998a). Interestingly, geranium PC3 could not utilize ferulic acid, the intermediate of lignin biosynthesis in the cell, as a substrate. Furthermore, ascorbate was peroxidized by PC3 with the low K_m value of 0.03 mM, indicating that PC3 has good ascorbate peroxidase activity as well. However, six isoperoxidases from Korean radish could not utilize

Table 1
Purification of isoperoxidase PC3 from scented-geranium callus

ascorbate as the substrate (Lee and Kim, 1994). Ascorbate peroxidase from Japanese radish utilized mainly ascorbate as the substrate with the K_m value of 0.77 mM, while it did not utilize guaiacol at all (Ohya et al., 1997). In contrast, ascorbate peroxidase from soybean utilized both guaiacol and ascorbate very much (Dalton et al., 1987) like our geranium PC3.

2.4. Chemical modification

In order to find out which amino acid residues might be involved in the catalysis of substrates at or near the active site of geranium PC3, chemical modification of the enzyme was performed using various modifying reagents (Table 4). PC3 was rapidly inactivated by the His specific reagent DEP, when the time dependent inactivation of the enzyme in the presence of DEP was examined. The time course for the inactivation was dependent on the reagent concentration, and the slopes of the inactivation plots obtained at different concentrations of DEP were linearly related to the DP concentration (data not shown).

From this plot, the second-order rate constant for inactivation was determined to be 2.0×10^3 M^{-1} min^{-1}. A double-logarithmic plot of the reciprocal of the half-time of inactivation against reagent concentration yielded a reaction order of 1.04 with respect to DEP, indicating that there might be one essential His residue per active site. The inactivation by DEP was completely protected in the presence of substrate guaiacol (data not shown), suggesting that the His residue modified by DEP might be located at or near the guaiacol binding site. In the case of KRP, DEP did not significantly inactivate the enzyme (Yoo and Kim, 1988), although highly conserved His-containing sequences were expected to be in the region of active site (Park and Kim, 1996a). Geranium PC3 was also rapidly inactivated by the Trp specific reagent NBS and the Lys specific reagent PLP with second order rate constants of $1.7\times$

Table 4
Summary of second-order rate constants and reaction orders for isoperoxidase PC3 inactivation by various chemical modification reagents

Modification reagents	Second-order rate constants (M^{-1} min^{-1})	Reaction orders
PHMB	1.0×10^5	0.95
Iodoacetamide	9.3×10^2	1.01
DTNB	1.2×10^3	1.08
NBS	1.7×10^4	0.92
DEP	2.0×10^3	1.04
PLP	2.1×10^3	1.02

PHMB, *p*-hydroxymercuribenzoic acid; DTNB, 5,5′-dithiobis-2-nitrobenzoic acid; NBS, *N*-bromosuccinimide; DEP, diethylpyrocarbonate; PLP, pyridoxal-5-phosphate.

10^4 and 2.1×10^3 M^{-1} min^{-1}, respectively. Reaction orders with respect to NBS and PLP were 0.92 and 1.02, respectively, again indicating that one essential Trp and one essential Lys residue were present. Notably, the thiol specific reagents PHMB, iodoacetamide and DTNB inactivated the enzyme rapidly with second order rate constants of 1×10^5, 9.3×10^2 and 1.2×10^3 M^{-1} min^{-1}, respectively. PC3 inactivation by PHMB was much stronger than by DTNB and iodoacetamide. Class III secretory plant peroxidases are reported to have four conserved disulfide bridges and thus there seemed to be no free Cys residue (Dunford, 1999). However, isoperoxidase A_1 from Korean radish (Lee and Kim, 1993) and ascorbate peroxidase from Japanese radish (Ohya et al., 1997) were reported to be inactivated by PHMB and DTNB, implying that free Cys participate in the active center or maintenance of the conformation of the enzyme. Moreover, *Arabidopsis thaliana* peroxidase N (Mirza et al., 2000) also has a free Cys residue at the substrate-binding site, unlike other class III secretory plant peroxidases.

2.5. Activity boosting by various nitrogenous compounds

Effects of various nitrogenous compounds on the peroxidative activity of geranium PC3 were examined (Table 5). Oxidation of the anilino substrate *o*-dianisidine was stimulated by adenine and imidazole at pH 8 as much as 4- and 7-fold, respectively. Stimulations by adenine and imidazole did not occur at lower pH values. Moreover, activity boostings by adenine and imidazole also occurred in the *o*-phenylenediamine oxidation by PC3. However, the oxidation of phenolic substrates such as guaiacol, chlorogenic acid, caffeic acid, scopoletin and esculetin was not stimulated by any of the nitrogenous compounds such as adenine, imidazole, cytosine, guanine, histidine, nicotinate, tryptophan and uracil (Table 5).

In particular, ammonium salt, which has been reported to be an excellent stimulator of dianisidine oxidation in HRP (Kuo and Fridovich, 1988), had no effect on the PC3. A similar boosting effect of imidazole on dianisidine oxidation was found in KRP (Lee et al., 2000), whereas a boosting effect did not occur in myeloperoxidase, chloroperoxidase, *Escherichia coli* hydroperoxidase and methemoglobin peroxidase (Kuo and Fridovich, 1988). More detailed kinetics of these boosting reactions and active site structure determination will be needed in order to understand the mechanism of adenine and imidazole action on anilino substrate oxidation.

3. Experimental

3.1. Experimental plant and callus induction

The plant material used in this investigation, *P. graveolens* or scented-geranium, was purchased from a local market near Asan, Korea. Scented-geranium callus induction was performed as previously reported (Lee and Lee, 2000).

3.2. Peroxidase activity assays with various substrates

Peroxidase activity was assayed by a modified procedure of Lee and Kim (1994). Briefly, the assay mixture contained 15 mM substrate, 5 mM H_2O_2, 40 mM Na–Pi buffer (pH 6.5) and 50 ul of enzyme solution in a total volume of 1 ml. The reaction was initiated by the addition of H_2O_2. Substrates for the enzyme included guaiacol, *o*-dianisidine, *o*-phenylenediamine, caffeic acid, esculetin, scopoletin, chlorogenic acid, ascorbic acid, ferulic acid and H_2O_2. Kinetic data were obtained from triple replications of activity assays.

3.3. Gel electrophoresis

Starch gel electrophoresis was performed as described (Lee and Kim, 1994). Isoperoxidase bands were visualized by placing the gel in a solution of 100 mg of 3-amino-9-ethyl carbazole in 10 ml of DMF, 184 ml of 50

Table 5
Effect of various nitrogenous compounds on the peroxidative activity of isoperoxidase PC3 from scented-geranium callus[a]

Effector	Adenine	Ammonium ion	Cytosine	Guanine	Histidine	Imidazole	Nicotinate	Tryptophan	Uracil
Amino substrate

Scopoletin	1.5	1.1	0.85	1.07	1.2	1.2	0.97	0.9	0.8

[a] The values presented here have been shown relative to the peroxidative activity without booster which was given a value of 1. All experiments were repeated four times.

mM NaOAc buffer (pH 5.0), 10 ml of 100 mM $CaCl_2$ and 0.2 ml of 30% H_2O_2. SDS–PAGE was carried out as described by Laemmli (1970).

3.4. Enzyme purification

Scented-geranium callus was homogenized with 50 mM Na–Pi buffer (pH 6.5) containing sea sand. The homogenate was centrifuged at 12,000 ***g*** for 20 min and the supernatant was saturated with $(NH_4)_2SO_4$ up to 90% and centrifuged at 13,000 ***g*** for 30 min. The precipitate was then dialyzed twice against 5 mM Na–Pi buffer (pH 6) and used as the enzyme extract. The enzyme preparation was loaded on a DEAE–Sephacel ion exchange column (3.5×12 cm) pre-equilibrated with 5 mM Na–Pi buffer (pH 6). Initial elution of the DEAE–Sephacel column with 5 mM Na–Pi buffer (pH 6) yielded largely a mixt. of all cationic isoperoxidases. The eluant was applied on a CM–cellulose ion exchange column (2.5×4 cm) pre-equilibrated with 10 mM Na–Pi buffer (pH 6). Isoperoxidase PC3 was eluted with 50 mM Na–Pi buffer (pH 6) following the elution of PC1 and PC2 with 30 mM Na–Pi buffer (pH 6). Sephacryl S-200 gel filtration chromatography with CM–cellulose fractions which contain PC3 activity was also performed. This procedure removed minor contaminating proteins and provided a single polypeptide band as evidenced by SDS–PAGE analysis.

3.5. Molecular weight and glycosylation determination

M_r of isoperoxidase PC3 was estimated by gel filtration chromatography on Sephadex G-150 column (1.5×78 cm). The subunit M_r of the enzyme was determined by SDS-PAGE. Glycosylation was determined by the procedure described by Grossman and Neville (1971).

3.6. Chemical modification

The purified PC3, kept at a final concentration of 40 nM, was incubated with several modifying reagents such as *p*-hydroxymercuribenzoic acid (PHMB) in 50 mM NaOAc buffer (pH 4.5), *N*-bromosuccinimide (NBS) in 50 mM NaOAc buffer (pH 4.0), iodoacetamide in 50 mM Na–Pi buffer (pH 6.5), 5,5′-dithiobis-2-nitrobenzoic acid (DTNB) and diethylpyrocarbonate (DEP) in 50 mM Na–Pi buffer (pH 7.2) and pyridoxal-5-phosphate (PLP) in 50 mM Na–Pi buffer (pH 7.0) at 30 °C. The chemical modification reagents were added at different final concentrations (0.1–10 mM), and the residual enzyme activity was measured at predetermined time intervals. The second order rate constants and reaction orders with respect to the inactivation with these modifying reagents were also determined as described by Lee and Kim (1993).

3.7. Effects of nitrogenous compounds on the peroxidation of various substrates

The stimulatory effects of nitrogenous compounds on the peroxidation of several substrates were examined as described (Lee et al., 2000). The reaction mixtures contained 0.18 mM nitrogenous compounds, 0.36 mM H_2O_2, and 50 ul of 5 nM enzyme in a total volume of 1 ml. The buffer systems were 50 mM NaOAc buffer, 50 mM Na–Pi buffer and 50 mM Tris–HCl buffer depending upon the pH ranges studied. The nitrogenous compounds tested included adenine, guanine, cytosine, ammonium ion, histidine, imidazole, nicotinic acid, tryptophan and uracil.

Received 13 November 2000; received in revised form 8 June 2001

Abstract

A program combining ethnopharmacology and bioinformatic approaches has successfully been applied on anti-inflammatory activity. (i) An ethnobotanical study allowed the identification of several plants associated with putative anti-inflammatory properties as potential leads. (ii) On the other hand, it is well known that phospholipase A_2 is a target implicated in the pro-inflammatory process. Thus, (iii) some selected plant extracts were experimentally tested on phospholipase A_2. Finally, (iv) these experimental results combined with bioinformatic tools, such as database exploitation and molecular modeling, allowed to suggest that one compound, betulin and its oxidative form betulinic acid, might be responsible of the anti-PLA_2 activity. This suggestion was confirmed experimentally. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Ethnopharmacology; Bioinformatic; Anti-inflammatory; Phospholipase A_2

1. Introduction

A research program aiming at the discovery of 'new leads' (Bernard et al., 1999a), combining ethnopharmacology studies with bioinformatic ones, was initiated to find new molecules implicated in the modulation of inflammation processes. The first step of this program was to define the biomolecular target (enzyme, receptor...). The criteria for the selection of this target were (i) implication of the target in the inflammatory process, (ii) the feasibility of an assay (availability of enzyme sources, completion of the enzymatic tests...) and (iii) the quantity of experimental data available for the bioinformatic treatment. Since the phospholipase A_2 (PLA_2) plays a crucial role in modulating both the cyclooxygenase and the 5-lipoxygenase pathways which are simultaneous pathways of the inflammation process, PLA_2 was found to be the best target.

PLA_2 corresponds to a class of enzymes which catalyze the hydrolysis of membrane glycerophospholipids at the sn-2 position to release fatty acids and lysophospholipids. When the fatty acid is the arachidonic acid, a complementary metabolism leads to pro-inflammatory mediators such as prostaglandins, leukotrienes, thromboxanes and platelet activating factors (PAF) (Irvine, 1982). Thus, modulating pro-inflammatory lipid mediator production by inhibiting PLA_2 activity remains a potential strategy for the development of new drugs for the treatment of inflammatory diseases (Mayer and Marshall, 1993; Posadas et al., 2000; Seno et al., 2001). Nevertheless, the evidence now exists that more than one form of PLA_2 might be found (Mayer and Marshall, 1993; Friess et al., 2001). The first one which corresponds to the low molecular weight (14 kDa) is a Ca^{2+}-dependent extracellular PLA_2. It is found in mammalian pancreases, several snake venoms, human platelets, human placentas, and rheumatoid synovial fluids (Dennis et al., 1991). The second form is represented by a high molecular weight (85 kDa) cytosolic PLA_2 (Clark et al., 1990). The latter, a less known form, will not be used in this bioinformatic study, even if some authors suggested that both the 14 kDa and 85 kDa PLA_2 may be potential targets for the modulation of inflammatory diseases (Mayer and Marshall, 1993).

Since several PLA_2 inhibitors are known, we used them in a recent study, to propose a pharmacophore of

the human non-pancreatic PLA_2 (Bernard et al., 2001). In this study, we confirmed that an anionic group, such as a carboxylate group, is highly desirable in ligands interacting with this enzyme. We also demonstrated that this anionic group is necessary in both human and bovine pancreatic PLA_2 inhibitors (Pintore et al., 2001). In addition, the analysis of the different crystallized PLA_2/ligand complexes available in the Protein Brookhaven Data Bank (PDB) (http://www.rcsb.org/pdb/) revealed the importance of the phosphate or carboxylate groups in PLA_2 ligands. Indeed, such groups are found to be in interaction with the calcium ion present in the PLA_2 structures.

Among all the PLA_2, one subtype was selected and used as reference in this study: the bovine pancreatic phospholipase A_2 (bp-PLA_2). Indeed, this enzyme presents the double advantage to be crystallized (the three dimensional structure is available and can be used in a bioinformatic study) and to be commercially available to realize enzymatic tests. In addition, the homology between the different phospholipasesA_2 is relatively high and the catalytic site of the different PLA_2 remains similar. Thus, even if some ligands are specific of some PLA_2, the same lead structure can be used for every PLA_2; only pharmaco-modulations will give the specificity. For example, the indole substructure has been used to design PLA_2 inhibitors in both human non-pancreatic PLA_2 and cytosolic PLA_2 (Draheim et al., 1995; Dillard et al., 1996; Lehr, 1997).

We describe the combination between experimental data and bioinformatic data to rationalize a phytochemical lead discovery. The use of our database (Bernard et al., 1999a) containing ethnopharmacological experimental information will allow it to identify the chemical compound responsible for the PLA_2 inhibition, from a plant extract where anti-PLA_2 activity was detected.

2. Results and discussion

2.1. Plants selection and extracts screening on PLA_2 activity

An ethnobotanical study realized in South America (Santarem, Brasilia) allowed the identification of 56 plants used as anti-inflammatory remedies, often used to cure snake and dog bites or rheumatic pains. Six plants from other regions were also selected with the same ethnobotanical properties. Starting from this plant material, 68 extracts were obtained as described in the experimental section and tested for PLA_2 inhibition. The results are listed in Table 1. In this table, the lower the activity value, the better is the inhibitory potency of the corresponding extract. Positive values seem to indicate an activation of the PLA_2 activity. In Table 1, seven plants were found to inhibit more than 50% of the PLA_2 activity. These

(b) Representation of betulinic acid inserted into the binding site, described by the lipophilic volume contour. The close define a large lipophilic domains. The carboxylate group, located in the bottom of the cavity, interacts with the calcium atom, not visible in this view.

plants are *Genipa americana* (100% of inhibition), *Scoparia dulcis* (100%), *Leopoldinia imperialis* (70-80%), *Caraipa minor* (70%), *Morus alba* (70%), *Zizyphus joazeiro* (70%) and *Entada africana* (60%).

There is no qualitative and quantitative correlation between the anti-PLA_2 activity of the plant extracts and

the anti-inflammatory ethnopharmacological properties. Two reasons can explain this observation. First, the traditional uses can include some non-appropriate applications. Second, several other biological targets might be responsible for the anti-inflammatory properties of these plants.

2.2. Chemical identification of the anti-PLA_2 activity compound from the selected plant extracts

Different ethnobotanical databases, such as our database (Bernard et al., 1999a), the NAPRALERT database (available from STN International, c/o Chemical Abstracts Service, PO Box 3012, Columbus, OH 43210, USA) and the combined chemical library database (available from CRC Press UK, Pocock House, 235 Southwark Bridge Road, London, SE1 6LY, UK), were used to analyze the known chemical composition of each selected plant. The bibliographic chemical analysis revealed a variable number of chemicals according to each plant; no chemical components are described for *Leopoldinia* whereas more than 60 chemicals are described for *Morus alba*. Interestingly, although all phytochemicals have not yet been identified, the chemical comparison of these selected plants indicates that only one compound, betulinic acid, was present in four plants among the seven: *Scoparia dulcis*, *Caraipa minor*, *Morus alba* and *Zizyphus joazeiro*. Three 'inactive' plants were also described to possess betulinic acid: *Bowdichia*, *Cassia* and *Vismia*, but in bark and not in leave or seeds. These observations suggest that betulinic acid might be responsible of the activity. Moreover, two arguments could be in agreement with this suggestion. First, triterpens have already been described as anti-inflammatory compounds (Recio et al., 1995). Betulinic acid has also been described for numerous biological activities, such as antitumor, antiviral, antimalarial, antiplasmodial activities (Combined chemical library

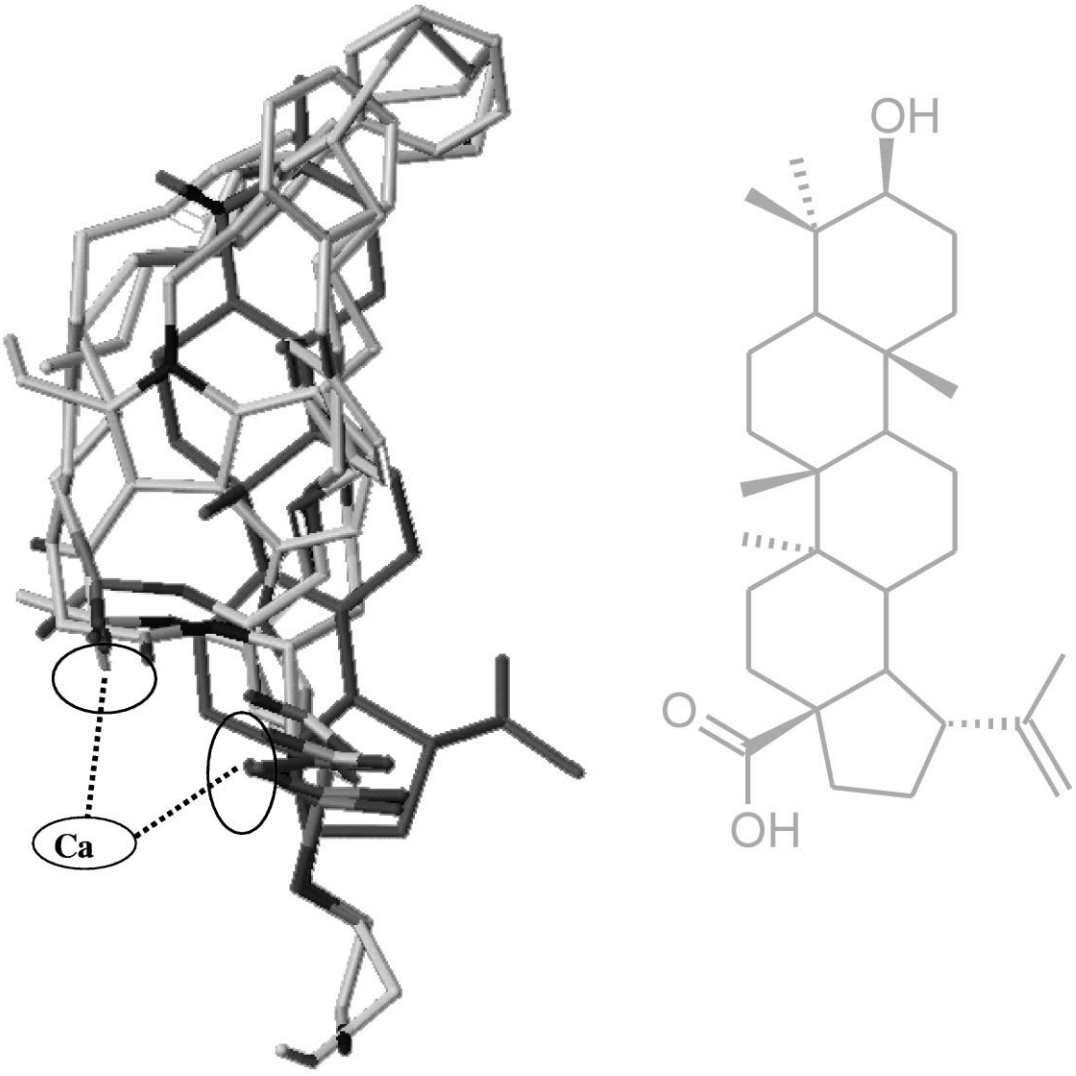

Fig. 2. Protein-based alignment of betulinic acid, in magenta, compared to the other ligands extracted from the crystallographic data. The interactions with the calcium atom are visualized.

database). Second, as mentioned in the experimental section, this compound possesses a carboxylate group as defined by our pharmacophore model of PLA_2.

In order to verify if betulinic acid corresponded to a candidate implicated in the PLA_2 inhibition, this compound was docked into the PLA_2 crystal structure. The docking, presented in Fig. 1, confirms that betulinic acid can be inserted into the PLA_2 binding site with correct energy values. Indeed, the binding energy of betulinic acid into the enzyme binding site is about −90 kcal/mol. This binding energy is in the same order as the binding energies found for the ligand-enzyme complexes extracted from the crystallographic databank PDB and minimized in the same conditions than betulinic acid-PLA_2 complex. For example, the binding energies for the GEL-PLA2 complex and the GLE-PLA2 complex are -85 kcal/mol (backbone rms = 0.17 Å) and −70 kcal/mol (backbone rms = 0.23 Å), respectively. Moreover, Fig. 2 presents the proteine-based alignment of the betulinic acid compared to the four other ligands, described in the experimental section and extracted from their crystal structure PLA_2 complexes. This figure is in agreement with the fact that betulinic acid, well fits to the others ligand structures and occupies the same volume. For indication, betulinic acid represents a cylinder, of about 13 Å long with a diameter of 5 Å, which occupies the place of the natural substrates, the phospholipids.

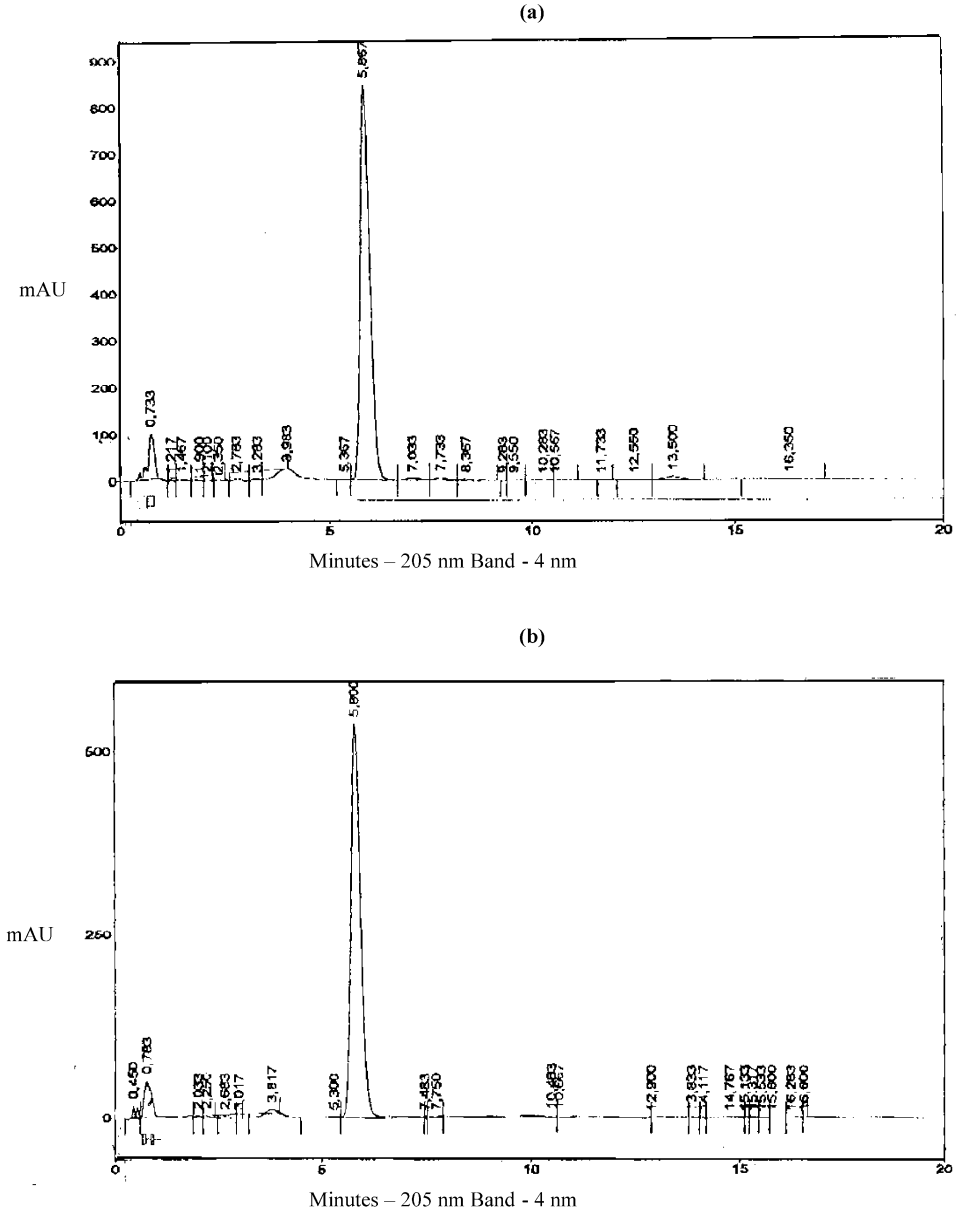

Fig. 3. Comparison of the HPLC profiles of (a) betulin and (b) *Betula alba* triterpenic extract.

Following the bibliographical chemical analysis, three plant extracts, active on anti-PLA_2 activity, were found without betulinic acid. These results suggest that either the presence of betulinic acid was not confirm in these plants, or another chemical is responsible for the biological activity. Nevertheless, among the other described chemicals, no compound was able to be correctly docked into the enzyme binding site. The anti-PLA_2 activity of these plants still remains not elucidated.

2.3. Experimental confirmation that betulinic acid is implicated in the anti-PLA_2 activity

In order to experimentally confirm that betulinic acid is implicated in the anti-PLA_2 activity, we realized an extract of *Betula alba* L. (Betulaceae), which is known to be among the plants richer in betulin and betulinic acid (Bruneton, 1993). The extract, realized as described in the experimental section, was developed to obtain a

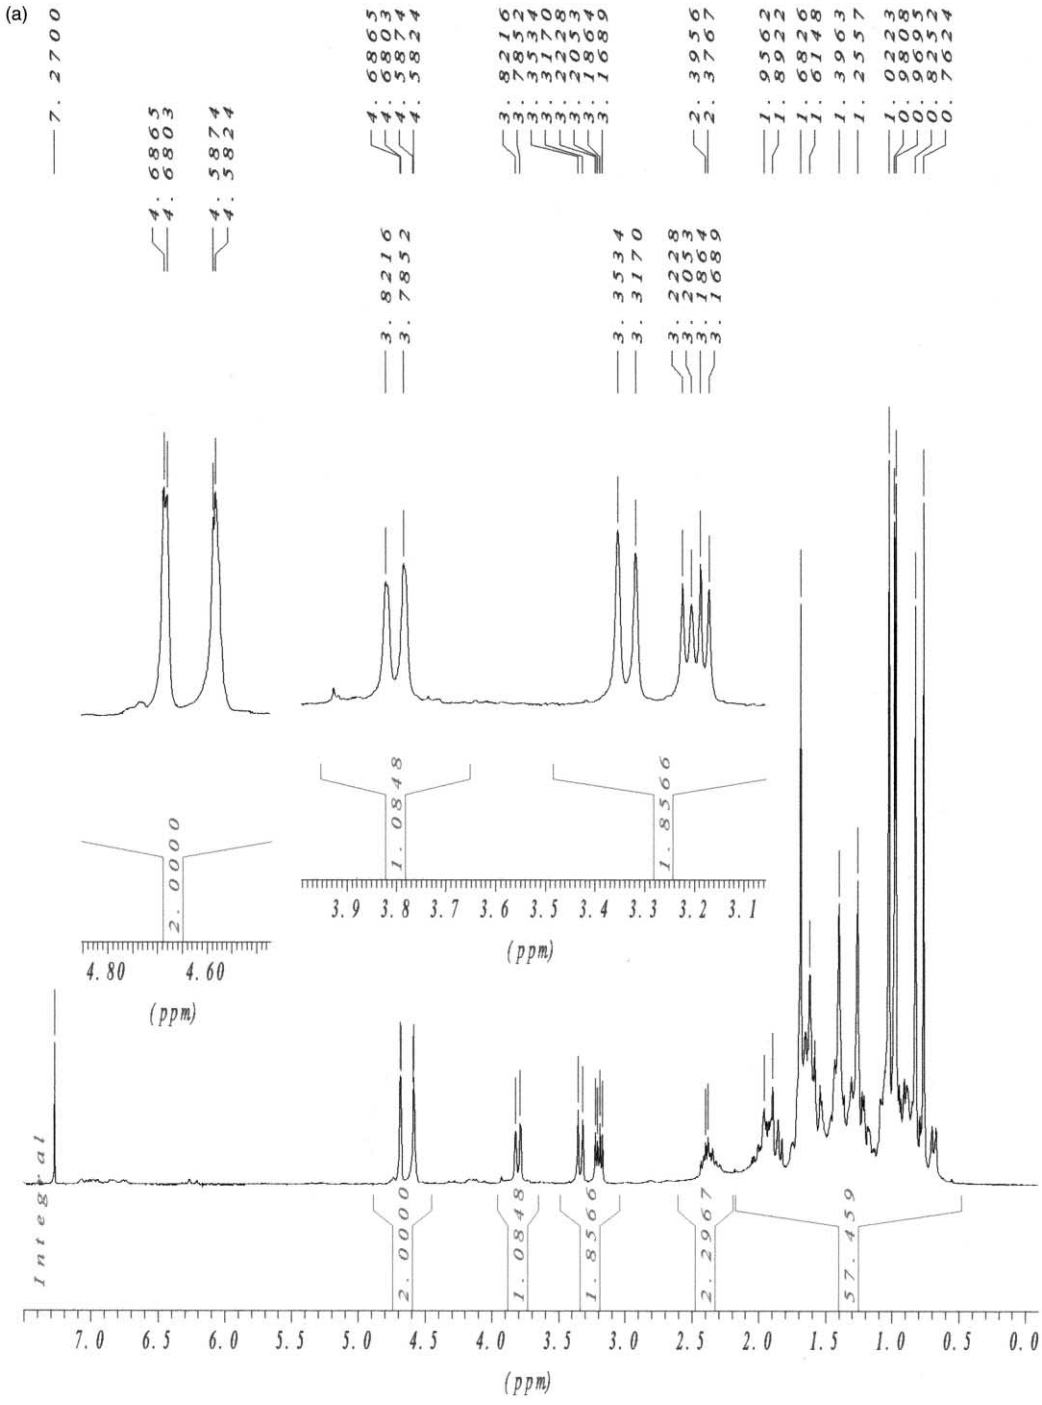

Fig. 4. NMR spectra of *Betula alba* triterpenic extract: (a) [^{1}H] NMR and (b) [^{13}C] NMR.

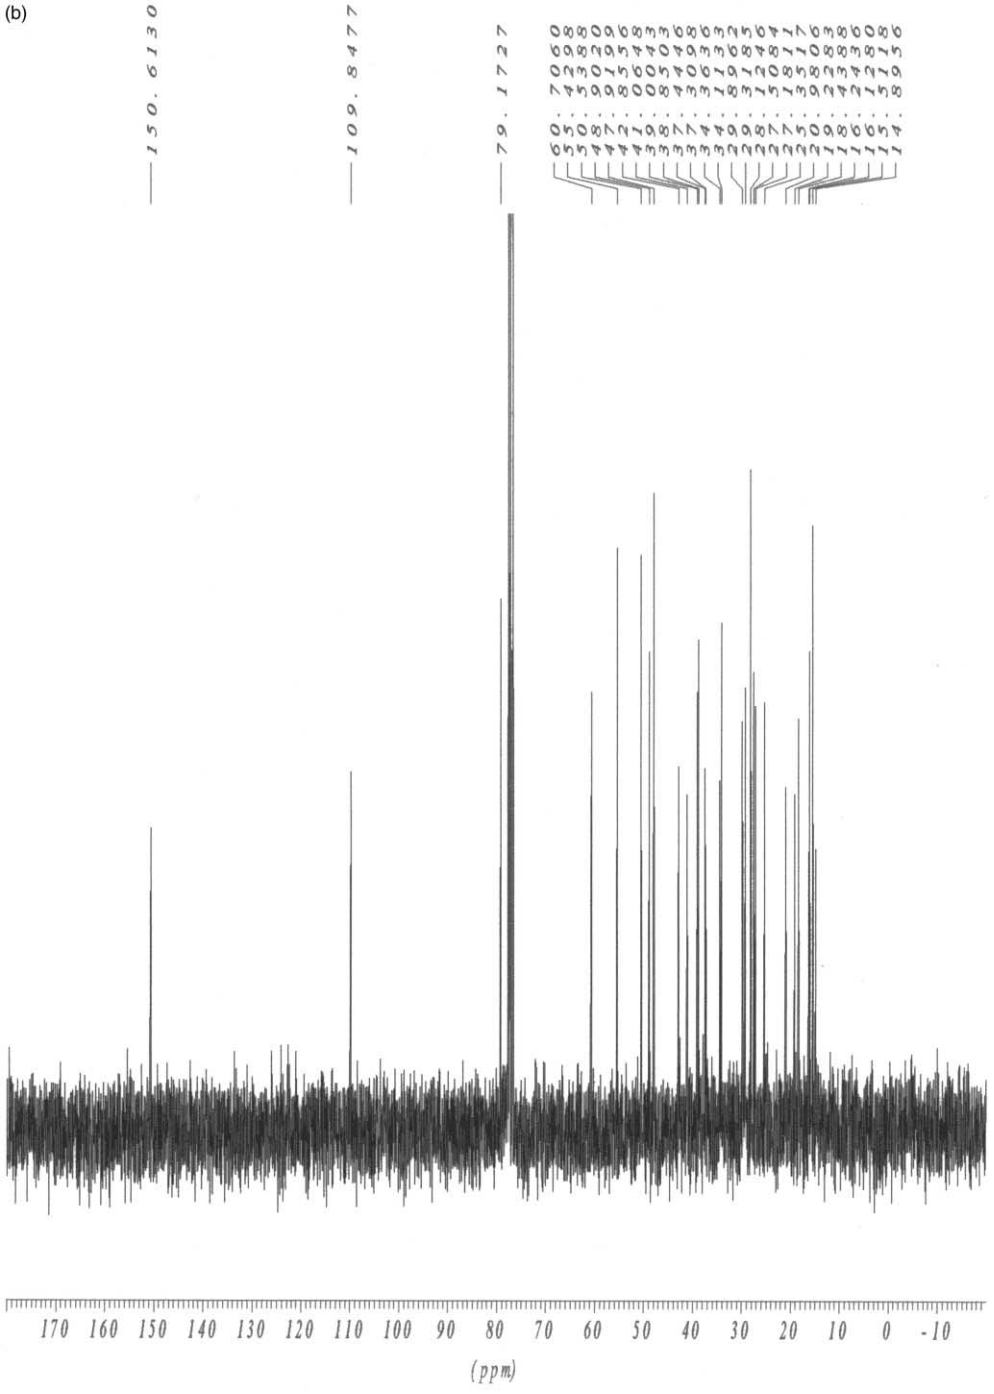

Fig. 4 (*continued*).

larger quantity of triterpens. Interestingly, the characterization by mean of HPLC and NMR analyses revealed that this extract contains essentially betulin, the reduced form of betulinic acid. Then, this extract, betulin and betulinic acid were tested on the PLA_2. The biological results are presented in Table 2. This table confirms that *Betula alba* extract, betulin and betulinic acid have an anti-PLA_2 activity. Moreover, betulinic acid is found to be the better inhibitor of PLA_2. This result is in agreement with our pharmacophore model which describes the importance of a carboxylate group for the inhibition of the PLA_2.

2.4. Conclusion

This study allowed to validate the approach which consists in the combination of the ethnopharmacological domain with the bioinformatic one. Indeed, the experimental data in one hand, combined with the database exploitation and molecular modeling in another hand,

Table 2
PLA_2 inhibitory activity of betulinic acid, betulin and *Betula alba* extract. These standards were dissolved to a concentration of 0.5% (w/v) in 96% (v/v) ethanol. The values indicate the percent of inhibition at a given concentration

Final volume and corresponding concentration added in the anti-PLA_2 assay	Inhibition of PLA_2 (%)		
	Betulinic acid	Betulin	*Betula alba* extract
200 µl (~2.5 µM)	30	15	10
400 µl (~5 µM)	40	30	30

allowed to identify one compound implicated in the anti-PLA_2 activity.

This approach will be more and more efficient and precise with the growing number of phytochemical data.

3. Experimental

3.1. Plant materials

All plants and their ethnobotanical information were obtained from the Greentech company via its network, which has a permit (permission No: 1/41/94/0084-0, Health Ministry: 101656-2) for collecting and exporting plant materials from Brazil. A collection of voucher specimens is available within the Greentech company.

3.2. Plant extracts

All plant extracts were realized in the same conditions: each plant extract, listed in Table 1, was prepared with 10% of dried plant organs mixed during 20 min in a solution of propylene glycol/deionized water 50 °C. Then, the final plant extracts were obtained after filtration.

3.3. Extraction purification and characterization methods

Triterpens were extracted from *Betula alba* as described hereafter (patent in record). The dried bark of *Betula alba* (3 kg) was crushed and mixed at room temperature (12 h) with toluene (1/1). After impregnation, the bark was mixed with toluene (1:5) at 111 °C during 8 h. The solution was filtrate and after evaporation, a second extraction in the same condition was realized. The obtained dry extract was now mixed at 40 °C with an ethanol solution 99° (1:10). The triterpenic extract was finally obtained by filtration and concentration under vacuum to give a residue (90 g) which was subjected to chemical analyses.

Twenty microlitres of a solution 1.5 mg/ml of the triterpenic extract was submitted to isocratic HPLC analysis, acetonitrile/water: 78/22. A column purospher RP 18 and 5 µm 125×4 mm was used. The detection at 205 nm reveals a major peak at 5.80 mn (Fig. 3). Since betulin possesses the same HPLC profile is these conditions, the peak was identified as being betulin.

To confirm this hypothesis, a NMR study of the triterpenic extract was realized. [^{1}H] and [^{13}C] NMR spectra were performed as following. Each reference substance (10 mg), betulin and betulinic acid, purchased by Sigma-Aldrich was dissolved in 0.7 ml of $CDCl_3$. Spectra were recorded on a DPX Avance 300 Bruker using standard parameters. Spectra analyses of the *Betula alba* extract are shown in Fig. 4: (a) [^{1}H] NMR in $CDCl_3$ of the *Betula alba* extract shows typical peaks of betulin at $\delta = 4.68$ and 4.58 ppm (*d*, 1H, $J = 1.7$ Hz, $=CH_2$), 3.80 and 3.33 ppm (*d* 1H, $J = 10.9$ Hz, CH_2OH), 3.19 ppm (*dd*, 1H $J = 5.3$, 10.9 Hz, C*H*OH) and no signals after 7.00 ppm, sign of the lack of acidic proton, as in case of betulinic acid. (b) This is confirmed with the [^{13}C] NMR in $CDCl_3$. Indeed, no acid carbon were detected but an alcoholic carbon is recorded at 60.7 ppm. Thus, the [^{1}H] NMR and the [^{13}C] NMR, in agreement with the chromatographic data, clearly demonstrate the presence of pure betulin in this *Betula alba* extract.

3.4. Compounds

Betulin and betulinic acid were purchased from Sigma-Aldrich. These molecules were used as reference compounds. The standards were dissolved to a concentration of 0.5% (w/v) in 96% (v/v) ethanol.

3.5. Enzymatic tests on PLA_2

Bovine pancreatic PLA_2 and lecithin were purchased from Sigma Chemical Co. PLA_2 activity was determined by titrimetric method according to the Sigma procedure. Briefly, a mixture, which contains 10 ml of a lecithin solution 2% prepared according to the Sigma procedure, is maintained at pH = 8 by addition of a solution 10 mM NaOH until pH stabilization (pH variation does not exceed 0.01 pH unit/mn). 200 µl of a bp-PLA_2 solution 2,5 units/ml, with or without 400 µl of a solution containing either plant extract or inhibitor compound, is added to the mixture. The inhibitory effect is recorded by measuring the quantity of NaOH added to the total mixture to maintain the pH = 8.

The percent inhibition of PLA_2 activity is calculated as follows:

$$\% \text{ Inhibition} = [(A - B)/A] \times 100$$

where A = [NaOH] added in the sample without plant extract or inhibitor and B = [NaOH] added in the sample with plant extract or inhibitor.

3.6. Bioinformatic section

3.6.1. Enzyme

Since the inhibitory activities used in the experimental section were measured on the bovine pancreatic PLA_2, crystal structure of bovine pancreatic PLA_2 were used in the modeling section.

Many bovine pancreatic PLA_2 have been crystallized and are available in the PDB. Nevertheless, only bp-PLA_2-ligand complexes were selected because they include a 'pocket', near the site active, able to receive more easily the inhibitor ligands. Thus, only four structures were selected: PDB code: 1BP2 (Dijkstra et al., 1981), 1FDK (Sekar et al., 1997), 1MKV (Sekar et al., 1998) and 3BP2 (Dijkstra et al., 1984). The four ligands associated to bovine structures are respectively, (i) 2-methyl-2,4-pentanediol (MPD) (PDB code: 1BP2), (ii) 1-decyl-3-trifluoro ethyl-*sn*-glycero-2-phosphomethanol (GLE) (PDB code: 1FDK), (iii) L-1-*o*-octyl-2-heptylphosphonyl-*sn*-glycero-3-phosphoethanolamine (GEL) (PDB code: 1MKV) and (iv) pyruvoil group (PVL) (PDB code: 3BP2). Amidst the bp-PLA_2 complexed structures, the 1MKV complex was chosen because the GEL is the biggest ligand of the series. Thus, the opening of the binding site is maximal with this ligand. Furthermore, it binds the Ca^{2+} ion of the active site as a bidentante ligand, with a mechanism similar to the other ligands-PLA_2 complexes (Schevitz et al., 1995). Moreover, it has been demonstrated that this binding region is a pharmacophore element of different types of PLA_2 (Bernard et al., 2001; Pintore et al., 2001).

To make the selected structure suitable for further modeling, water molecules were removed and hydrogen atoms were added to the original PDB structures using the BIOPOLYMER module of Sybyl/Tripos (Sybyl is available from Tripos Associates, 1699 South Hanley Road, St Louis, MO 63144). Then the geometry of the protein was optimized using the Tripos Force Field with a gradient convergence of 0.01 kcal/mol and with the Kollman charges, implemented in the Sybyl package, as electrostatic component.

3.6.2. Ligands

The ligands were modeled using Sybyl 6.5 on a Silicon Graphics O_2 R10000 station. The starting conformations were optimized by molecular mechanics algorithm using the Tripos Force Field. The lowest energy conformations were found by means of the SYBYL/SEARCH option and then used as initial conformations for docking. The charges were calculated by the MOPAC AM1 semi-empirical method.

3.6.3. Ligand-enzyme docking

In our previous papers (Bernard et al., 2001; Pintore et al., 2001), we had identified the importance of an acidic region on the pharmacophore of the PLA_2 inhibitors. Indeed, this pharmacophoric element interacts with the calcium atom inserted in the enzyme structure. Therefore, the priority, for the identification of new natural inhibitors of PLA_2, was the presence of this carboxylate group. Then, the FIT ATOMS option of Sybyl allowed to place the carboxyl group of the selected ligands into the enzyme, prepared as mentioned above, at the position corresponding to the GEL phosphoryl group. Since GEL bounds the calcium atom by means of two oxygen atoms, the two GEL oxygen atoms were successively used as the anchor point. The molecule was then rotated around the three coordinate axis as previously described (Bernard et al., 1999b) with a step of 30°. For each orientation a complete conformational search was made using the SYBYL/SYSTEMATIC SEARCH option. All rotatable bonds were relaxed and the rotation step was also fixed at 30°. The total energy of the enzyme-ligand complex was calculated for each conformation generated. The geometry of the lowest energy conformations found for the enzyme-ligand complexes was then refined by further spatial rotations and conformational search with a step of 5° in the interval of ±30° around the torsion values obtained. These refined enzyme-ligand complexes were optimized using the Tripos Force Field with a gradient convergence of 0.01 kcal/mol. An approximation of the binding energy E_{int} resulting from the ligands binding into the enzyme active site is calculated as follow:

$$E_{int} = E_{complex} - (E_{enzyme} + E_{inhibitor})$$

where $E_{complex}$, E_{enzyme} and $E_{inhibitor}$ are the energies of the minimized complex, the enzyme of the complex and the inhibitor extracted from the complex, respectively.

Received 16 July 2001; received in revised form 3 August 2001

Abstract

The biosynthesis of 5-(3-buten-1-ynyl)-2,2′-bithiophene was studied in root cultures of *Tagetes patula*. Organ cultures were grown with [U-$^{13}C_6$]glucose or [1-^{13}C]glucose. The bithiopene and amino acids from cell protein were isolated and analysed by quantitative NMR spectroscopy. Retrobiosynthetic analysis establish acetyl-CoA or a closely related compound (e.g. malonyl-CoA) as building blocks and their orientations in the bithiophene. The data confirm a previously suggested biosynthetic route via long-chain fatty acids and polyacetylenes. However, a polyketide-like biosynthesis via a carbocyclic intermediate cannot be excluded. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

A naturally occurring thiophene derivative, α-terthiophene, was isolated in 1947 from *Tagetes erecta* (Zehmeister and Sease, 1947). In the meantime, more than 150 thiophene-type natural products comprising one, two, or three thiophene rings and side chains with a variable number of double or triple bonds (Bohlmann and Zdero, 1985; Kagan, 1991) have been characterized from Asteraceae and fungi (Sörensen, 1977; Bohlmann, 1988).

In *Tagetes* species, bi- or trithiophenes with 12 carbon atoms are predominant (Bohlmann et al., 1973). Oleic acid has been proposed to serve as precursor in thiophene biosynthesis via acetylene intermediates; cysteine has been proposed to serve as sulphur source (Bohlmann et al., 1973; Jente et al., 1981, 1988; Bohlmann, 1988; Menelaou et al., 1991; Arroo et al., 1995). Labelling experiments were hampered by low isotope incorporation rates ($<1\%$).

Isotope incorporation studies are commonly interpreted as if metabolism proceeded in a linear and unidirectional fashion. Based on this implicit assumption, the diversion of isotope from a given precursor to a given target compound is accepted as evidence for direct metabolic relatedness between the respective molecular species. In reality, however, metabolism is a complex network, and metabolic flux can occur from any node in the network to virtually any other node. As a consequence, isotope incorporation studies have repeatedly resulted in remarkable errors of interpretation, especially in the case of low incorporation rates.

Recently, relatively fail-safe alternatives using general ^{13}C labelled precursors, such as glucose or acetate, have been developed for the quantitative assessment of carbon flux in bacteria and suspension cultures of plant cells (for review, see Eisenreich and Bacher, 2000). Briefly, the isotopomer composition of metabolites in biosynthetic sinks (e.g., amino acids) can be used to reconstruct the isotopomer pattern of central metabolic intermediates (e.g., acetyl-CoA, phosphoenolpyruvate, pyruvate, hydroxyethyl-TPP) on a retrobiosynthetic basis. These labelling patterns can then be used to predict labelling patterns of secondary metabolites via hypothetical biosynthetic pathways. Predictions can be verified or falsified by comparison with the observed labelling patterns of secondary metabolites. Moreover,

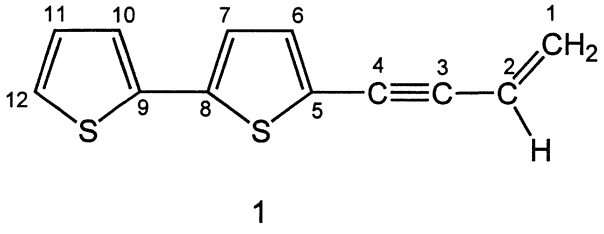
the labelling patterns reveal quantitative aspects of carbon flux and transport in the metabolic network of the organism under investigation.

This paper describes the incorporation of [U-$^{13}C_6$]- and [1-^{13}C]glucose by root cultures of *Tagetes patula*. Retrobiosynthetic analysis of amino acids is used to quantitatively establish the flux of carbon from glucose into 5-(3-buten-1-ynyl)-2,2′-bithiophene (BBT, **1**, Fig. 1).

2. Results and discussion

2.1. NMR signal assignments

Since retrobiosynthetic NMR studies are dependent on correct NMR signal assignments, the reported ^{13}C NMR signal assignments of [5-(3-buten-1-ynyl)-2,2′-bithiophene (BBT, **1**, Fig. 1) (Menelaou et al., 1991) were confirmed by INADEQUATE spectroscopy of multiply ^{13}C-labeled samples (from the incorporation experiment with totally ^{13}C-labeled glucose) (Table 1).



1

Fig. 1. Structure of 5-(3-buten-1-ynuyl)-2,2′-bithiophene (BBT, **1**).

2.2. Incorporation experiments

Root cultures of *Tagetes patula* described in this study produced [5-(3-buten-1-ynyl)-2,2′-bithiophene (BBT, **1**, Fig. 1) at 8.5 mg per g of dry cell mass.

Preliminary incorporation experiments using isotope labelled acetate samples as precursors revealed incorporation rates into BBT well below 1% (data not shown) in accordance with published data (Menelaou et al., 1991). The low enrichments might reflect poor uptake rates of the proffered potential precursors, or poor utilization of exogenous acetate for cell metabolism in root cells of *Tagetes*.

In order to quantitatively establish the carbon flux from a general carbon source into thiophenes, we decided to use ^{13}C-labelled glucose as precursor. The organ culture could be grown in medium containing glucose instead of sucrose without loss of viability or thiophene production. The root cells were, therefore, grown in medium containing a mixture of [U-$^{13}C_6$]glucose or [1-^{13}C]glucose and natural abundance glucose at ratios of 1:10 or 1:2, respectively (w/w). After 13 days, the cells were harvested. BBT was isolated and analysed by quantitative NMR spectroscopy as described in the Experimental Section.

All ^{13}C NMR signals of BBT from the experiment with [U-$^{13}C_6$]glucose are shown in Fig. 2. Quaternary atoms show low intensities due to their relaxation behaviour. The average ^{13}C abundance of all carbon atoms determined as described under Experimental was 12.1±0.9% ^{13}C (Table 1). With the exception of C-1 and C-12, carbon signals showed relatively intense satellites indicative of ^{13}C–^{13}C coupling via one bond (coupling constants, 50–110 Hz, Table 1). The relative

[a] ^{13}C abundance.

[b] Relative fractions of ^{13}C-coupled satellites in the overall signal intensity of a given atom.

fractions of satellite signals in the global ^{13}C NMR signal intensities of all atoms except for C-1 and C-12 was 75.0±1.9%. The signals of C-1 and C-12 showed satellites of much lower relative intensities (10.0 resp. 11.1%) reflecting ^{13}C–^{13}C coupling caused by statistical recombination of ^{13}C labelled precursor units.

BBT isotopomers derived from the analysis of carbon–carbon coupling constants (Table 1) as well as from a two-dimensional INADEQUATE experiments (Table 1, Fig. 3) are summarized in Fig. 4A. The figure represents a superposition of five $^{13}C_2$-isotopomers. The numbers in Fig. 4A indicate the relative fractions of each respective isotopomer. No isotopomers with more than two adjacent ^{13}C atoms were detected at significant abundance. It follows that the $^{13}C_6$-labelled glucose precursor had been converted into $^{13}C_2$-fragments prior to incorporation into the thiophene.

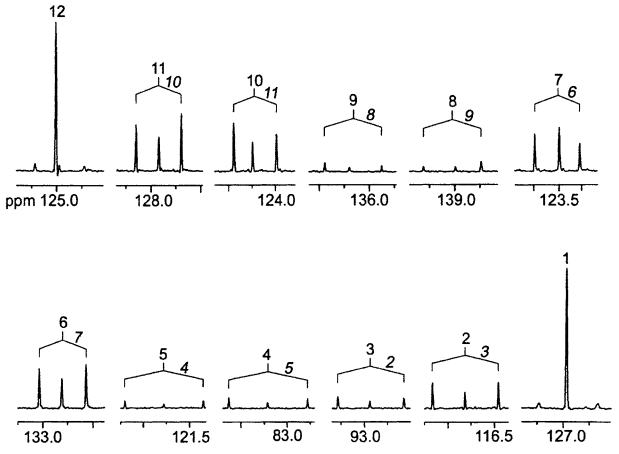

Fig. 2. ^{13}C NMR signals of BBT from the experiment with [U-$^{13}C_6$]glucose. ^{13}C-coupling patterns are indicated. Numbers in italics indicate carbon atoms ^{13}C-coupled to the respective index atoms.

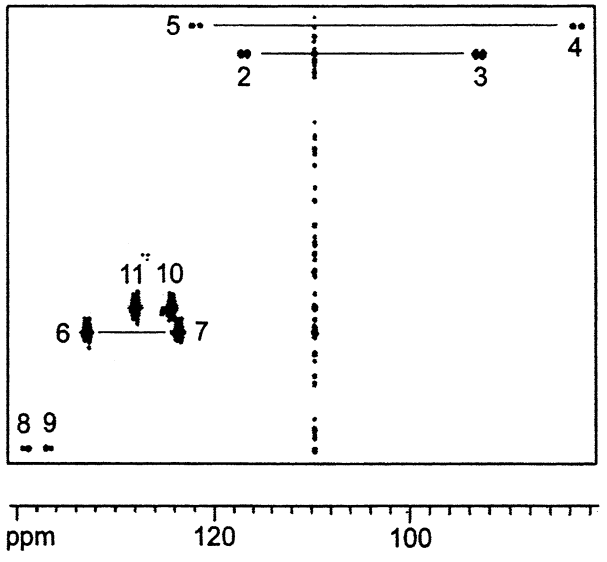

Fig. 3. Two-dimensional INADEQUATE spectrum of BBT from the experiment with [U-$^{13}C_6$]glucose.

The experimentally determined isotope distribution of BBT from the experiment with [1-^{13}C]glucose as precursor is summarized in Table 1 and Fig. 4B. From [1-^{13}C]glucose, six carbon atoms of BBT acquired ^{13}C enrichment with an average ^{13}C abundance of 9.6±1.2% ^{13}C, whereas six positions had ^{13}C abundances of 1.3±0.3% ^{13}C, i.e. in the natural abundance range (Table 1, Fig. 4B).

2.3. Analysis of labelling patterns by the retrobiosynthetic approach

Biosynthetic hypotheses can be subjected to a rigorous test via prediction of BBT labelling patterns from labelling patterns of putative biosynthetic precursors. These can be derived in turn from experimentally determined labelling patterns of amino acids by retrobiosynthetic analysis which has been reviewed recently (Eisenreich and Bacher, 2000).

The labelling patterns of phenylalanine (**2**), leucine (**4**), and valine (**6**) obtained by hydrolysis of cell mass from the experiment with [U-$^{13}C_6$]glucose are shown in Fig. 5. The side chain of phenylalanine reflects the labelling pattern of phosphoenol pyruvate (**3**) from which it is biosynthetically obtained via the shikimate pathway of aromatic amino acid biosynthesis. As a result, phosphoenol pyruvate (**3**) acquired contiguous ^{13}C-labelling from [U-$^{13}C_6$]glucose via glycolytic degradation. Notably, the presence of a significant fraction of [2,3-$^{13}C_2$]phosphoenol pyruvate signalled its biosynthetic origin (approximately 25% of phosphoenol pyruvate biosynthesized during the feeding period) via a

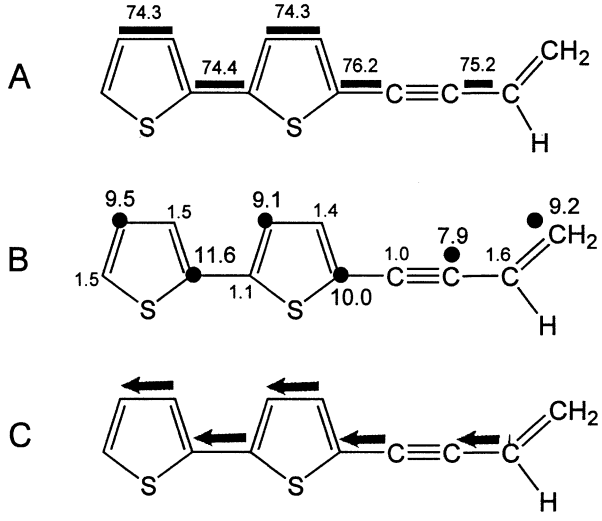

Fig. 4. (A) ^{13}C-labelling patterns of BBT from the experiment with [U-$^{13}C_6$]glucose. Bold lines indicate $^{13}C_2$-labelled isotopomers and numbers indicate their relative abundance (see Experimental). (B) ^{13}C-labelling patterns of BBT from the experiment with [1-^{13}C]glucose. Filled circles indicate significantly ^{13}C-enriched atoms. Numbers indicate ^{13}C abundance in%. (C) Orientation of the acetate precursor units is symbolised by bold arrows directed from C-1 to C-2.

triose phosphate processed in the reductive branch of the pentose phosphate cycle.

The labelling pattern of plastidic acetyl-CoA (**5**), and that of hydroxyethyl-TPP (''activated acetaldehyde'', **7**) can be extracted from the labelling patterns of leucine (**4**) and valine (**6**) on basis of the unique leucine and valine biosynthetic pathways which are assumed to proceed in the plastidic compartment of the plant cell. As a result, significant fractions of [U-$^{13}C_2$]acetyl-CoA and [U-$^{13}C_2$]hydroxyethyl-TPP were detected (Fig. 5). There is no evidence for the formation of singly ^{13}C-labelled isotopomers of acetyl-CoA or hydroxyethyl-TPP from [U-$^{13}C_6$]glucose. Obviously, the doubly ^{13}C-labeled isotopomers in **5** and **7** were generated from a plastidic triose phosphate pool via decarboxylation of pyruvate. In keeping with this hypothesis, the ''bond labelling'' between C-1 and C-2 of acetyl-CoA (**5**) and hydroxyethyl-TPP (**7**) closely resembles the ^{13}C-connectivity between C-2 and C-3 of phosphoenolpyruvate (**3**, Fig. 5).

The observed labelling pattern in BBT implies biosynthetic precursors with only two contiguous ^{13}C atoms (Fig. 4A). The labelling pattern of the two-carbon building block can be reconstructed accurately from the labelling pattern of BBT as shown by the standard deviations (Fig. 6A). The reconstructed labelling pattern of acetyl-CoA from leucine closely matches the labelling pattern of the two-carbon building block in the thiophene derivative indicating its biosynthetic origin via plastidic acetyl-CoA. This result clearly suggests a polyketide origin of BBT (**1**) either anabolically from acetate units or catabolically from a preformed fatty acid such as oleic acid by partial degradation.

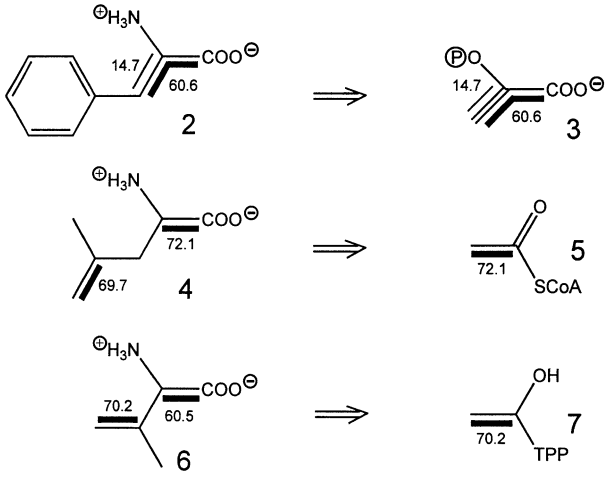

Fig. 5. Incorporation experiment with [U-$^{13}C_6$]glucose. Reconstruction of the labelling patterns of phosphoenol pyruvate (**3**), acetyl-CoA (**5**), and hydroxyethyl-TPP (**7**) from the labelling patterns of phenylalanine (**2**), leucine (**4**), and valine (**6**), respectively. Bold lines indicate multiple ^{13}C-labelled isotopomers and numbers indicate their relative abundance. The isotopomer composition of the aromatic ring of phenylalanine could not be determined due to signal overlapping.

The same retrodictive/predictive approach can be applied for the experiment with [1-^{13}C]glucose. The labelling patterns of phenylalanine, leucine, valine, and their precursors phosphoenol pyruvate, acetyl-CoA, and hydroxyethyl-TPP (obtained by retrobiosynthetic analysis) are shown in Fig. 7. Briefly, [1-^{13}C]glucose is converted into [3-^{13}C]phosphoenol pyruvate, [2-^{13}C]acetyl-CoA, and [2-^{13}C]hydroxyethyl-TPP by the mechanisms described above. Similar labelling patterns were observed in incorporation experiments using [1-^{13}C]glucose in various plants and plant cell cultures (Eichinger et al., 1999; Eisenreich et al., 1999; Goese et al., 1999; Werner et al., 1999; Wang et al., 2001).

The reconstructed labelling patterns of the two-carbon building block from BBT and acetyl-CoA (Fig. 6B) were identical within the experimental limits of quantitative NMR spectroscopy confirming the biosynthetic origin of BBT from acetyl-CoA or a closely related compound (i.e. malonyl-CoA). In addition to the information obtained from the experiment with [U-$^{13}C_6$]glucose, the orientation of the C_2 building blocks can now be determined (Fig. 4C).

The low incorporation rates of isotope-labelled acetate into BBT (see above) show that only a minor fraction of plastidic acetyl-CoA can be assembled from exogenous acetate in root cultures of *Tagetes* under the conditions of cultivation. On the other hand, high enrichment values were found with ^{13}C-labelled glucose as a precursor. Obviously, exogenous glucose is channelled efficiently into plastidic acetyl-CoA.

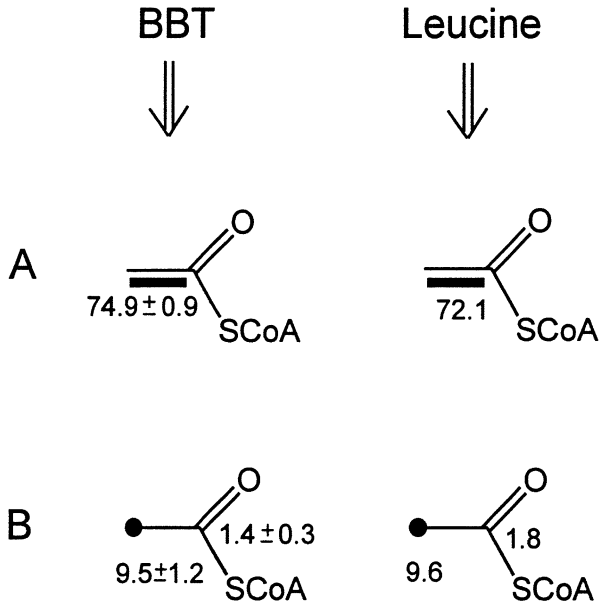

Fig. 6. Comparison of the labelling patterns of acetyl-CoA reconstructed from leucine (cf. Fig. 5) with the labelling patterns of the C_2 building blocks in the bithiophene BBT, (A) in the experiment with [U-$^{13}C_6$]glucose and (B) in the experiment with [1-^{13}C]glucose. For more details, see Fig. 4.

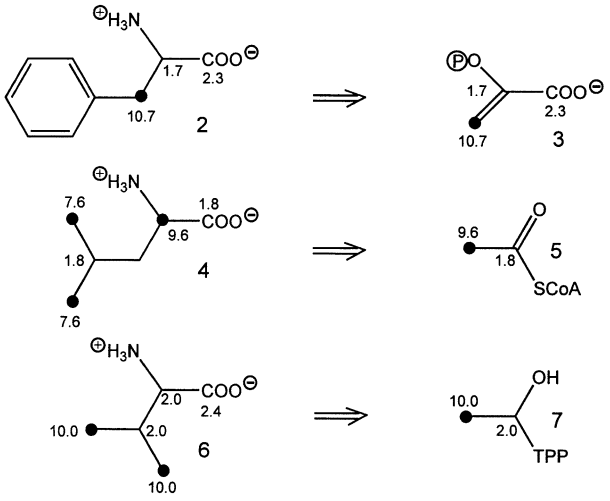

Fig. 7. Incorporation experiment with [1-^{13}C]glucose. Reconstruction of the labelling patterns of phosphoenol pyruvate (**3**), acetyl-CoA (**5**), and hydroxyethyl-TPP (**7**) from the labelling patterns of phenylalanine (**2**), leucine (**4**), and valine (**6**), respectively. Filled circles indicate significantly ^{13}C-enriched atoms. Numbers indicate ^{13}C abundance in%. The labelling pattern of the aromatic ring of phenylalanine could not be determined due to signal overlapping.

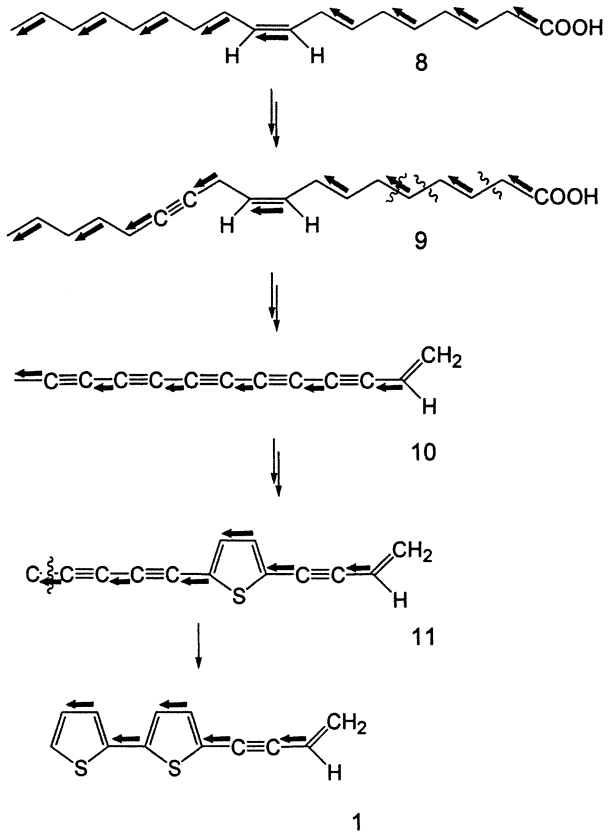

Fig. 8. Orientation of acetate units in BBT (**1**) biosynthesized from oleic acid (**8**) via crepenynic acid (**9**), **10** and **11** (see also text). The orientation of the acetate precursor units is symbolised by bold arrows directed from C-1 to C-2 (cf. Fig 4C).

Mainly based on the co-existence of thiophenes, oleic acid and polyacetylenes in Asteraceae, biosynthesis of **1** has been proposed to proceed via crepenynic acid (**9**), **10** and **11** (Fig. 8) (Sörensen et al., 1954; Gunstone et al., 1967; Bohlmann et al., 1976; Jacobs et al., 1995). Plant enzymes catalysing triple bond formation in C_{18} fatty acids were characterized recently (Lee et al., 1998). The reaction of long-chain polyines and H_2S leading to thiophenes is a well-known reaction in vitro (Bohlmann and Zdero, 1985).

The labelling patterns found in our study are well in line with that earlier proposal (Fig. 8). However, it must be emphasised that our data do not exclude a biosynthetic route in which a thiophene precursor could be obtained by ring opening of a cyclic polyketide intermediate.

3. Experimental

3.1. Materials

[U-$^{13}C_6$]Glucose (99% ^{13}C) and [1-^{13}C]glucose (99% ^{13}C) were obtained from Omicron (South Bend, IN). [1,2-$^{13}C_2$]Acetate (sodium salt) was from Isotec (Miamisburg, OH).

3.2. Plant cell cultures

Commercially available seeds of *Tagetes patula* (L.) cv. Carmen were sterilized with 70% (v/v) EtOH and 10% (v/v) household bleach (HYPO), rinsed twice with sterile water, and placed on hormone-free Nitsch medium (Nitsch and Nitsch, 1969). After one week in darkness, the approximately 1 cm-long roots of the seedlings were cut and transferred into 10 ml of MS medium, pH 6, (Murashige and Skoog, 1962) containing 100 mg of myo-inositol, 100 mg of NZ-amine, and 30 g of sucrose per liter (medium A). After 10 days, 10 ml of medium A were added to the growing cultures. After three weeks, the root cultures were transferred into 300 ml shake flasks containing 100 ml of medium A and incubated for 14 days.

3.3. Labelling experiments

Roots of *T. patula* (35 g of wet cells) grown on MS medium were transferred into a 300 ml Erlenmeyer flasks with 100 ml of autoclaved medium A containing 27 g of unlabelled glucose and 3 g of [U-$^{13}C_6$]glucose or 20 g of unlabelled glucose and 10 g of [1-^{13}C]glucose per litre as sole carbon source. The cultures were grown for 8 days in darkness at 23 °C under shaking (100 rpm). A sterile solution of 100 mM methyljasmonate (50 μl) was added, and the cultures were incubated for 5 days. The root cell material was harvested by suction and washed

with a small amount of water. The yield was 63 g (wet weight).

3.4. Isolation of BBT

The plant material was extracted three times with 200 ml of 70% (v/v) methanol. The extract was filtered. The solution was extracted twice with 600 ml of a hexane/*tert*-butylmethylether mixture (1:1, v/v). The organic phase was concentrated to dryness under reduced pressure. The residue was dissolved in 3 ml of hexane. Aliquots of 600 μl were spotted onto TLC plates (Polygram, SIL/UV 254, Macherey-Nagel). The plates were developed with a mixture of hexane, dioxane and butanol (75:25:1, v/v). The plates were dried and illuminated at 360 nm. The R_f value was 0.79 for BBT (dark blue fluorescent). Zones containing BBT were scraped off and were eluted with freshly distilled diethylether. The solution was concentrated to dryness under reduced pressure. Crude BBT was dissolved in 300 μl of hexane and placed on a column of silica gel 60 (0.032–0.063 mm, Merck, 6×0.5 cm) which had been equilibrated with hexane. The column was subsequently developed with 4 ml of hexane, 4 ml of hexane containing 1% (v/v) diethylether, 4 ml of hexane containing 3% diethylether, 4 ml of hexane containing 5% diethylether, and finally with 4 ml of hexane containing 10% diethylether. Fractions of 1 ml were collected and concentrated to dryness under reduced pressure. BBT eluted with hexane containing 1% (v/v) diethylether. All steps were carried out under dim light.

3.5. Isolation of amino acids

Amino acids were isolated from residual cell mass as described elsewhere (Eisenreich et al., 1991).

3.6. Gas chromatography

The purity of BBT was >95% as estimated by GC analysis (Perkin Elmer 8500; fused silica coated with PERMABOND OV-1 DF, Macherey-Nagel, 25 m×0.25 mm; temperature gradient, 120–300 °C, 5 °C min^{-1}; flow, 1.5 ml min^{-1}; retention times, BBT, 12.41 min).

3.7. NMR spectroscopy

^1H and ^{13}C NMR spectra were recorded at 500.13 and 125.6 MHz, respectively, using a DRX 500 spectrometer from Bruker Instruments, Karlsruhe, Germany. Two-dimensional INADEQUATE experiments were performed according to standard Bruker software (XWINNMR 1.3). BBT was measured in deuterated chloroform as solvent. Tyrosine was measured in D_2O (pH 13), and leucine and valine were measured in D_2O (pH 1). Signals were referenced to solvent peaks or external trimethylsilylpropane sulfonate.

3.8. Determination of ^{13}C enrichment

Determination of ^{13}C enrichment has been described earlier. Briefly, ^{13}C NMR spectra of the isotope labeled compound under study and of natural abundance material were recorded under the same experimental conditions. Integrals were determined for every ^{13}C NMR signal, and the signal integral for each respective carbon atom in the labeled compound was referenced to that of the natural abundance material, thus affording relative ^{13}C abundances for each position in the labeled molecular species.

In certain cases, these relative abundances can be converted to approximate absolute enrichment by assigning a value of 1.1% to the carbon atom with the lowest ^{13}C enrichment and referencing all other carbons to that position. In other cases, absolute ^{13}C enrichment can be obtained for certain atoms from ^{13}C coupling satellites in ^1H NMR spectra provided that any hydrogen atom of the compound under study is a singlet or a doublet where the coupling satellites can be determined to relatively high accuracy.

In NMR spectra of multiple-labeled samples displaying ^{13}C–^{13}C coupling, each satellite in the ^1H-decoupled spectra is integrated separately. The integral of each respective satellite pair is then referenced to the global signal intensity of a given carbon atom.

Calystegines in *Calystegia sepium* derive from the tropane alkaloid pathway

Yvonne Scholl, Dirk Höke, Birgit Dräger*

Institut für Pharmazeutische Biologie, Martin-Luther-Universität Halle-Wittenberg, Hoher Weg 8, 06120 Halle/Saale, Germany

Received 5 July 2001; received in revised form 2 August 2001

Abstract

Calystegines were measured in roots and aerial parts of *Calystegia sepium*. The accumulation appears developmentally regulated. Calystegine accumulation in hairy root cultures follows growth and reaches maximal values of 1,5 mg/g dry mass. ^{15}N-Labelled tropinone was fed to root cultures and the incorporation of label into calystegines and further metabolites of the tropane alkaloid pathway was measured after 2, 4 and 6 days. Pseudotropine was completely labelled after 2 days, and calystegine A_3 was labelled faster than the calystegines of the B-group. 2,7-Dihydroxynortropane also incorporated ^{15}N from tropinone and is suggested to be a by-product of the tropane alkaloid pathway leading to calystegines. © 2001 Elsevier Science Ltd. Keywords: *Calystegia sepium*; Convolvulaceae; Root culture; Calystegine; Tropane alkaloid; Biosynthesis; ^{15}N-Tropinone

1. Introduction

Calystegines, hydroxylated nortropane derivatives, were first identified in transformed root cultures of *Calystegia sepium* (Convolvulaceae) (Goldmann et al., 1990). Due to their resemblance to monosaccharides calystegines show specific glycosidase inhibitory activity and have a high therapeutic potential like other alkaloidal glycosidase inhibitors (Asano et al., 2000). Initially, 105 different plant species from 26 families were screened, and calystegines were shown to be restricted to roots of *Calystegia sepium*, *Convolvulus arvensis* and *Atropa belladonna* (Solanaceae), they were not found in aerial parts (Tepfer et al., 1988). Later, Schimming et al. (1998) described a wide-spread distribution of calystegines in the family of Convolvulaceae. Their occurrence varies in both, quantity and composition, in different plants and plant organs. Calystegines were shown in aerial parts of many Convolvulaceae as well as in roots.

Convolvulaceae are closely related to Solanaceae for which tropane alkaloids are typical metabolites, and Convolvulaceae also contain tropane alkaloids or metabolites of their biosynthesis, e.g. cuscohygrin was reported for several Convolvulaceae (Evans and Somanbandhu, 1973). Tropine esters as well as pseudotropine esters were isolated from Convolvulaceae (Jenett-Siems et al., 1998). Tropine and pseudotropine derivatives in *Convolvulus arvensis* have been suspected to be responsible for animal intoxication (Todd et al., 1995).

It is proposed that calystegines are biosynthesised by the tropane alkaloid pathway which has been elucidated in a number of Solanaceae (Fig. 1). The tropane ring in tropinone is formed starting from putrescine. Tropinone is reduced by two different enzymes, which catalyse the formation of either tropine or pseudotropine (Dräger et al., 1988; Portsteffen et al., 1992; Hashimoto et al., 1993; Dräger and Schaal, 1994). Tropine is incorporated into the medicinally important tropane alkaloid hyoscyamine (racemic mixture: atropine), while pseudotropine was postulated to be the first specific precursor for calystegines in Solanaceae (Dräger et al., 1994). Tropinone reductases were characterised from roots of several Solanaceae, but they have not been reported for Convolvulaceae so far. Thus, the hypothesis of calystegine biosynthesis by a specific branch of the tropane alkaloid pathway is supported by the co-occurrence with tropane alkaloids and by the structural similarity, but evidence by labelled precursor feeding is scarce. Application of ^{14}C-putrescine, an early metabolite

PII: S0031-9422(01)00362-4

in the tropane pathway, resulted in labelled calystegines in *Calystegia sepium* root cultures (Goldmann et al., 1990). After feeding of ^{15}N-tropinone to root cultures of *Atropa belladonna* (Solanaceae), labelled calystegine A_3 could be isolated (Dräger et al., 1994).

Recently, dihydroxy nortropane alkaloids were isolated from root cultures of *Calystegia sepium* (Asano et al., 2001). These compounds carry hydroxyl functions in positions 2 and 7, 2 and 3, or 3 and 7 on the nortropane skeleton. Their origin from tropinone and pseudotropine is difficult to explain for those structures that do not carry a hydroxyl group in position 3. We were interested whether these compounds as well as the calystegines in *Calystegia sepium* could be put into one biosynthetic line starting from tropinone.

We show here a detailed kinetic analysis of ^{15}N-tropinone incorporation into pseudotropine and into the major calystegines in root cultures of *Calystegia sepium*. For clarification of calystegine accumulation in the plant, aerial parts and roots of the intact *Calystegia sepium* plants were analysed at different developmental stages.

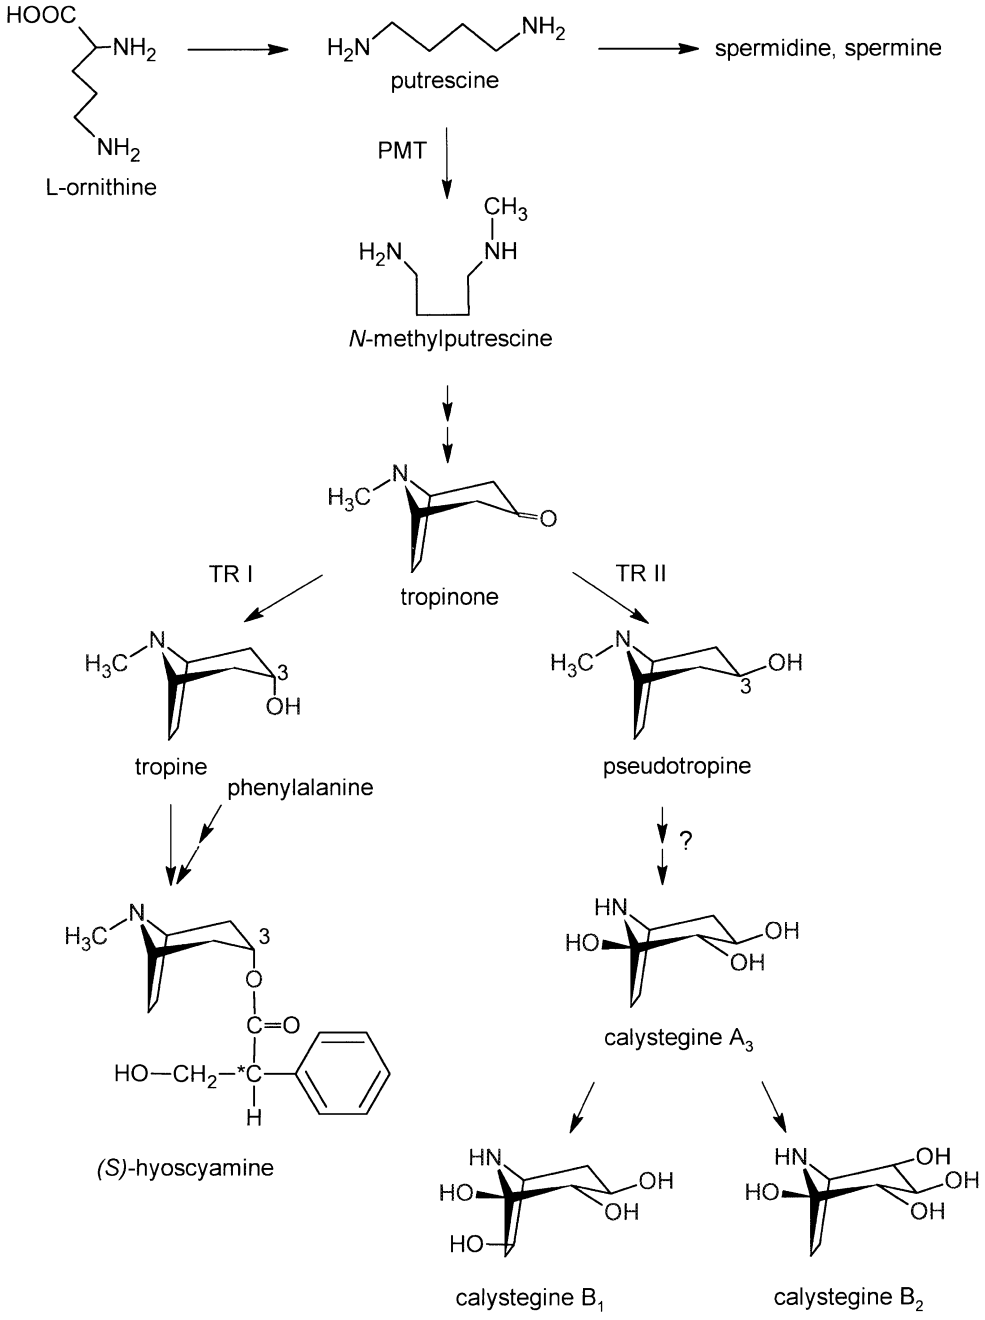

Fig. 1. Tropane alkaloid metabolism. Dotted arrows may indicate more than one biosynthetic step; PMT = putrescine methyltransferase; TR I = tropine forming tropinone reductase; TR II = pseudotropine forming tropinone reductase.

2. Results and discussion

2.1. Distribution of calystegines in Calystegia sepium plants

Seedlings 4–5 days after germination show highest concentrations in total calystegines (5.7 mg/g dry mass, Fig. 2). After 1 week in the climate chamber plants had grown up to 10 cm (ca. 40 mg total dry mass) and were separated in roots and aerial parts. The total calystegine concentration in roots was in the same range as in seedlings, while calystegines in aerial parts were less concentrated. The level of calystegines in roots decreased during further plant growth. In 3 week-old plants young leaves were the tissues with highest calystegine levels (2.3 mg/g dry mass). A similar accumulation pattern was shown for several species of Solanaceae before, where young aerial parts of the plants accumulated maximal calystegine concentrations, e.g. ca. 7 mg/g dry mass in young leaves of *Atropa belladonna* (Dräger, 1995). In *Calystegia sepium*, only low amounts of calystegines (ca. 500 μg/g dry mass) were measured in flowers.

Calystegines A_3 and B_2 were the major compounds, and the ratio of calystegines B_2 to A_3 was rather constant (1:2–3) in all tissues, except for flowers which contain similar concentrations of calystegines A_3, B_1 and B_2. In most samples calystegines A_5 and B_1 could be detected in comparison with authentic compounds by GC–MS, but they were not quantified. Further calystegines cannot be excluded, but dihydroxynortropanes were not found in aerial parts of plants. The non-uniform distribution of calystegines, especially the low concentration (less than 100 μg/g dry mass) in fully developed leaves, may be a reason why calystegines were not detected in the above-ground organs of *Calystegia sepium* in earlier investigations (Tepfer et al., 1988).

2.2. Accumulation of calystegines in Calystegia sepium root culture

Calystegine accumulation (Fig. 3) paralleled growth of the hairy root culture and was maximal (total 1.5 mg/g dry mass) in the late culture stage. Root cultures of *Atropa belladonna* showed a similar accumulation pattern and concentration (total 2 mg/g dry mass) for calystegines (Rothe et al., 2001). In addition to the calystegine mixture in intact *C. sepium* plants, calystegine B_1 appeared in root cultures in the same concentration range as calystegines A_3 and B_2. Further calystegines, e.g. calystegine A_5 and 2,7-dihydroxynortropane were identified in roots older than 16 days, but they appeared too dilute (< 10 μg/g dry mass) to be quantified reliably. Calystegine production (μg accumulation per flask and day) was calculated to be best at day 18, thus 16-day-old cultures were chosen for feeding labelled precursors.

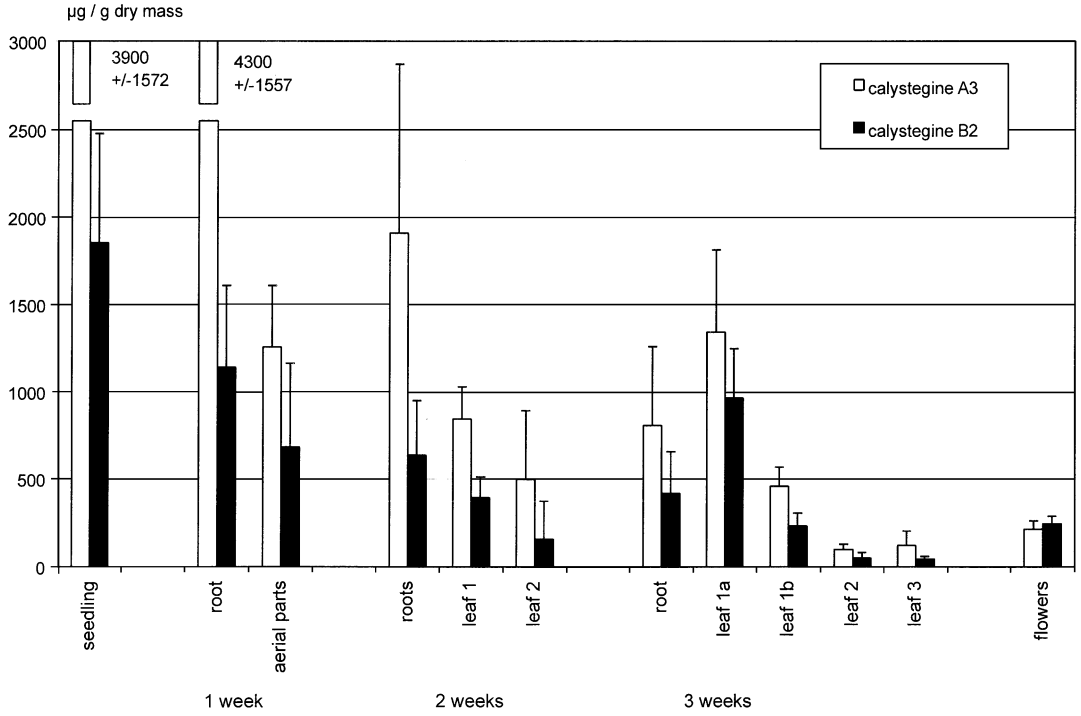

Fig. 2. Accumulation of calystegines in plants of *Calystegia sepium* (bars represent standard deviation). Leaf 1 and leaf 1b = 1-week-old leaves; leaf 1a = developing leaves including the shoot top within 1-week-old leaves; leaf 2 = 2-week-old leaves; leaf 3 = 3-week-old leaves.

2.3. Feeding of ^{15}N-tropinone

^{15}N-Tropinone was applied in a final concentration of 1 mM to *Calystegia sepium* root cultures for 2, 4 and 6 days. Pseudotropine, the calystegines A_3, B_1 and B_2 and 2,7-dihydroxynortropane were identified by their typical fragmentation pattern in GC–MS (Table 1). For the calystegines a molecular ion could not be detected in the GC–MS-spectrum. A continuous increase in the ratio of labelled to non-labelled nitrogen-containing fragments was observed for all calystegines during the period of 6 days.

The incorporation of label by ^{15}N into one representative fragment of each of the calystegines A_3, B_1 ad B_2 and into the molecular ion of 2,7-dihydroxynortropane and pseudotropine was followed quantitatively at 3 points of time (Fig. 4). The N-containing major fragment of calystegine A_3 (156) was almost completely replaced by the m/z +1-fragment (157) after 6 days (Fig. 4A). For calystegine B_1 the increase in fragment m/z 244 + 1 in relation to fragment m/z 244 is illustrated (Fig. 4B). The major fragment of calystegine B_2 [m/z 217, putative $(CH)_3$-$(O\text{-}TMS)_2^+$ (Dräger, 1995)] does

Table 1
MS-fragmentation of pseudotropine and nortropane alkaloids as TMSi-derivates

Compound	Retention time in min	Characteristic ions (abundance %)[b]					
Pseudotropine	5.60	83 (100)[a]	96 (55)	124 (13)	184 (15)	198 (10)	213 (8)[d]
2,7-Dihydroxy- nortropane	10.36	80 (68)	81 (71)	156 (18)	171 (36)	272 (2)	**287** (10)[d]
Calystegine A_3	14.91	101 (1)[b]	116 (1)[b]	**156** (100)	244 (8)	285 (3)	
Calystegine B_1	18.40	101 (2)[b]	129 (16)[b]	**244** (46)	373 (8)		
Calystegine B_2	20.04	**156** (7)[c]	217 (100)[b]	244 (7)	373 (2)		

[a] Values in brackets indicate relative abundance.
[b] No nitrogen contained; all fragments except those labelled with [b] increased +1 in mass after ^{15}N-tropinone feeding.
[c] Fragments in which the incorporation of label is followed quantitatively (Fig. 5) are printed in bold.
[d] Molecular ion.

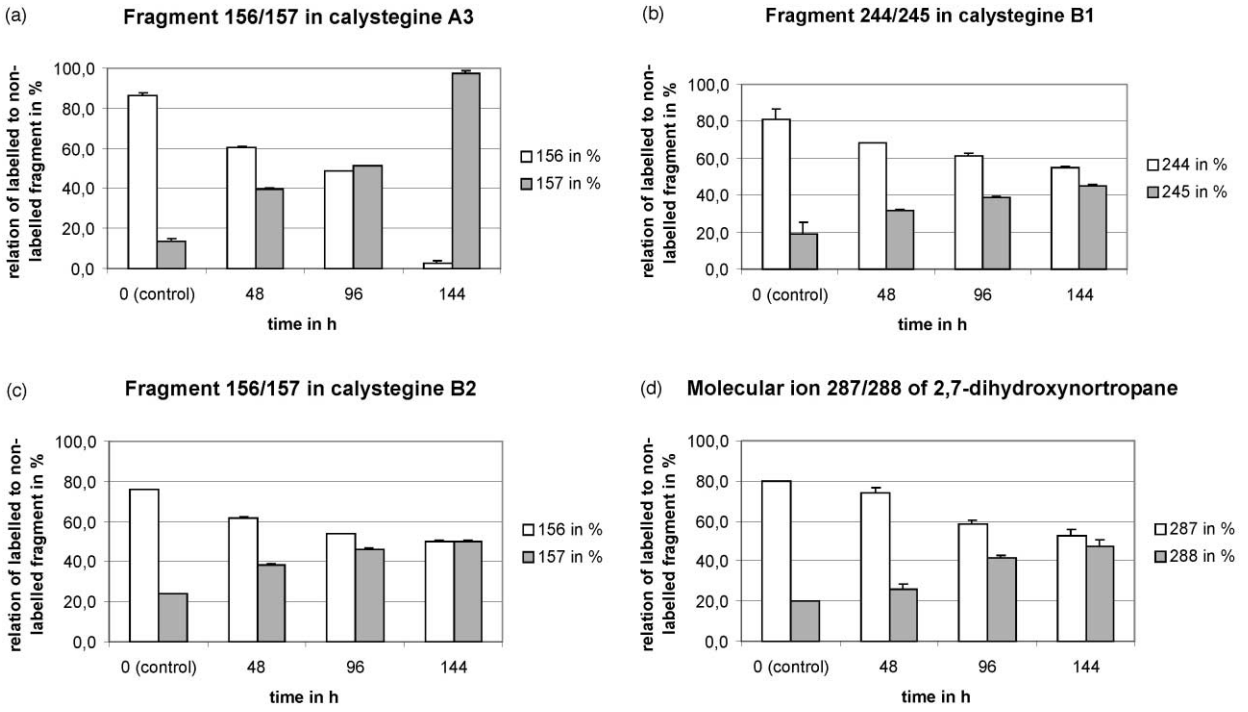

Fig. 4. Incorporation of ^{15}N into fragments of calystegines A_3, B_1, B_2 and 2,7-dihydroxynortropane. Data are average of 3 determinations. Standard deviation is given in bars.

not contain nitrogen, thus the fragment m/z 156/157 was monitored. Although the relative abundance of the fragment is low, an increase of the m/z 156 + 1-fragment can be seen here as well (Fig. 4C).

Incorporation of ^{15}N-tropinone into 2,7-dihydroxynortropane is evident by the increase of +1 in the molecular ion (Fig. 4D). The other fragments increased in the m/z +1 proportion in a similar manner. A possible fragmentation route for the silylated 2,7-dihydroxynortropane is suggested in Fig. 5. The label in 2,7-dihydroxynortropane indicates the origin of the compound in the tropane pathway, however, the direct lineage from tropinone is improbable because of the lack of an hydroxyl group in position 3.

Regarding the velocity of incorporation of ^{15}N, pseudotropine was labelled first and appeared as almost 100% m + 1 in the molecular ion after 2 days (data not shown). The ratio of labelled fragments in the calystegine A_3 rises faster than in the calystegine B pool. This may be taken as a hint that calystegines of the A-group are synthesised first and followed by tetra-hydroxylated nortropanes. For 2,7-dihydroxynortropane an ^{15}N-incorporation velocity similar to that of calystegines B_1 and B_2 was measured. 2,7-Dihydroxynortropane rather is a by-product of the biosynthetic pathway. The positions of the two hydroxyl groups and the relatively low labelling impair the idea that the dihydroxylated compound might be a metabolite on the way to the tri- and tetrahydroxylated calystegines.

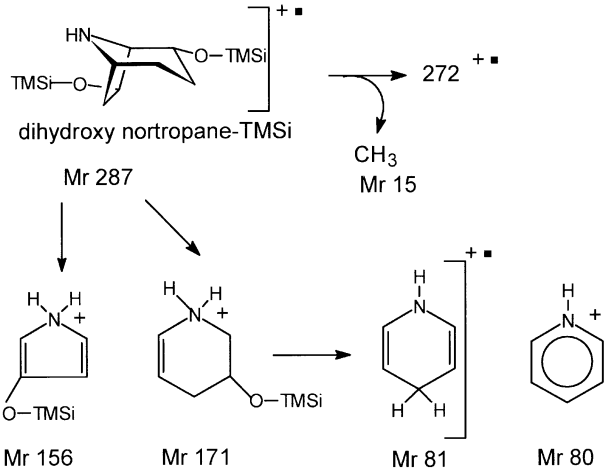

Fig. 5. Suggested fragmentation of 2,7-dihydroxynortropane after silylation in GC–MS analysis.

The incorporation of ^{15}N-tropinone into the calystegines that is shown here is consistent with the biosynthetic Scheme first proposed by Dräger et al. (1994).

3. Conclusions

Calystegines are accumulated in the whole plant of *Calystegia sepium* in a development-related pattern. Calystegines are products of the tropane alkaloid

pathway. 2,7-Dihydroxynortropane also appears as metabolite of that pathway, the loss of the hydroxyl group at C3 requires further investigations. The biological role of calystegines may relate to their interaction with carbohydrate accepting enzymes and remains to be elucidated.

4. Experimental

4.1. Plant material

Seeds and flowers of *Calystegia sepium* were collected from wild grown plants at the bank of the river Saale in Halle/ Germany. The seeds were shaken in conc. H_2SO_4 for 1 h, thereafter in 6% NaOCl for 15 min followed by 15 min in 10% H_2O_2. The surface-sterilised seeds were carefully slit with a scalpel to enable fast soaking and a simultaneous germination. They were laid out on petri dishes containing water agar (1,5% agar in distilled water) and kept dark. After 4 days, 3–4 cm long roots were formed and the cotyledons were unfolded. Twelve hours incubation under artificial light promoted the greening of the cotyledons. The seedlings were planted into pots containing sterilised soil (compost soil mixed with sand) and cultivated in climate chambers (HERAEUS HB 1014; 14 h light, 10 h darkness; 23 °C in light, 18 °C in darkness; 80% humidity). Plants were harvested after 1, 2 and 3 weeks after transfer into the climate chamber. The plant material was separated into roots and aerial parts. Leaves of 2-week-old plants and 3-week-old plants were further separated according to their age. In 3-week-old plants, the youngest leaves were separated into leaves (1b) and developing leaves including the shoot top (1a). Side stems (runners) were separated accordingly. Fresh mass and dry mass after lyophilisation were determined of all samples.

4.2. Root cultures

Hairy root cultures (transformed by *Agrobacterium rhizogenes* 15834) of *Calystegia sepium* were obtained from the Institute of Pharmaceutical Biology, TU Braunschweig, Germany, in 1996 and continuously cultivated in Gamborg's B5 medium with 3% sucrose in 300 ml flasks containing 70 ml medium on a gyratory shaker at 100 rpm. Approx. 50 mg fresh mass were subcultured into fresh medium every 3 weeks. For analysis roots were separated from the medium, blotted dry on filter paper, weighed and lyophilised. Dry mass was determined of all growth stages.

4.3. ^{15}N-Tropinone feeding

Sixteen-day-old cultures were fed with a sterile aq. soln. of ^{15}N-tropinone (98 at.% ^{15}N, measured by MS), 50 mM, buffered with HCl to pH 7.0, and with non-labelled tropinone, 50 mM sterile buffered aq. soln. as control. Final concentrations were always 1 mM in the culture medium. Roots were harvested after 48, 96 and 144 h, weighed and lyophilised.

4.4. Extract preparation

Fresh or freeze-dried tissues (typically 1–3 g fresh mass) were homogenized twice with an Ultra Thurrax in 20 ml 50% MeOH and centrifuged at 4500 *g*. The combined supernatants were reduced under vacuum to 1.5–2.0 ml aq. soln. in a rotary vaporizer.

For leaf tissue analysis this extract (0.5 or 1 ml) was directly lyophilised and the residue was derivatised by silylation with 30 μl pyridine, 40 μl HMDS and 10 μl TMCS. Dissolution was completed if necessary by an ultrasonic bath (1 min). Gentle heating, ca. 70 °C for 30 min ensured complete derivatisation. Fifty microliters of a stock soln. of azobenzene (1 mg/ml in *n*-hexane) were added as internal standard. 370 μl *n*-hexane filled up the volume to 500 μl.

For root tissues the crude extract was purified by strong acidic cation exchange resin I LAB (Merck, Darmstadt, Germany) as described (Keiner and Dräger, 2000).

An aliquot of the purified extract was lyophilised and derivatised as described above.

Plant tissues were extracted and analysed as 8 individual samples from at least 4 different plants, results are given as average. Calystegines in root cultures were determined in 8 different flasks and are expressed as average.

Concentrations of metabolites are expressed on dry mass basis. Typical relations of fresh mass to dry mass for above ground organs are 8–12% dry mass and for roots 12.5–14.3% dry mass. Roots cultures had 8–12% dry mass depending on their growth stage.

4.5. GC

Instrumentation: gas chromatograph HP 6890; simultaneous detection by FID and PND, column HP5 (30 m×0.25 mm i.d., 0.25 μm film thickness), split injection 20:1, carrier gas helium (1 ml min^{-1} constant flow), injection temp. 250 °C, detector temp. 310 °C, temp. programme 160 °C, 5°/min up to 240 °C.

4.6. GC–MS

Instrumentation: Gas chromatograph HP 5890, detector HP 5972, column DB5 (30 m x 0.32 mm i.d., 0.25 μm film thickness), splitless injection, carrier gas helium (1 ml min^{-1} constant flow), injection temp. 250 °C, detector temp. 250 °C, EIMS 70eV, temp. programme 100 °C, 2 min hold, 5°/min up to 240 °C.

Acknowledgements

We thank Henry D. Boswell and David J. Robins, Glasgow University, for synthesis of ^{15}N-tropinone and Richard J. Robins, Nantes, France, for providing it. Isolated 2,7-dihdyroxynortropane was a generous gift from Naoki Asano, Kanazawa, Japan. We thank Ines Böttcher in our laboratory for establishment and initial characterisation of the *C. sepium* root culture. Y. Scholl is grateful for a grant from the Landesgraduiertenförderung Sachsen-Anhalt.

Received 8 June 2001; received in revised form 24 July 2001

Abstract

Biotransformation of sesquiterpene 4β-hydroxyeudesmane-1,6-dione by the filamentous fungi *Gliocladium roseum* and *Exserohilum halodes* was achieved. With *Exserohilum halodes*, only one metabolite was obtained, as a result of the regio- and stereoselective reduction of the keto group at C-1, which is difficult to achieve by chemical means. Five metabolites were produced with *Gliocladium roseum*, three of which, the 7α-hydroxylated, the 7α,11- and the 1α,8α-dihydroxylated derivatives, have not previously been reported. The hydroxylation at C-11 is the main action of this microorganism. These 11-hydroxylated compounds can be chemically transformed into 6β,12-eudesmanolides. © 2001 Published by Elsevier Science Ltd.

Keywords: Biotransformation; Sesquiterpene; Eudesmane; Hydroxylation; *Gliocladium roseum*; *Exserohilum halodes*

1. Introduction

Gliocladium roseum (CECT 2733), the anamorphic form of *Nectria ochroleuca* (IMI 40022), is a filamentous fungus that had been used previously to hydroxylate the sesquiterpene patchoulol (Becher et al., 1978) as well as to biotransform a derivative of the diterpene varodiol in order to produce an *ent*-ambrox® derivative (García-Granados et al., 1999). *Exserohilum halodes* (CECT 2716) is a synonym of *Exserohilum rostratum*, the anamorphic form of *Setosphaeria rostrata* (IMI 76563).

Eudesmane sesquiterpenes are common in nature (Fischer et al., 1979; Fraga, 2000) and they possess significant biological properties (Rodríguez et al., 1976; Picman, 1986; Robles et al., 1995; Marles et al., 1995; Fraga, 1997; Schmidt, 1999). Several biotransformations of eudesmane compounds have been accomplished in the last decade (Amate et al., 1991; Atta-ur-Rahman et al., 1994; Shimizu et al., 1994; García et al., 1995; El-Sharkawy et al., 1996; Miyazawa et al., 1997; García-Granados et al., 1998, 2000a,b).

In previous papers (García-Granados et al., 1991, 1993) we reported the incubations of several 4β-hydroxyeudesmane compounds by the filamentous fungi *Curvularia lunata* (ATCC 12017) and *Rhizopus nigricans* (ATCC 10404). The action of these microorganisms was directed mainly to the isopropyl moiety, *Curvularia lunata* to C-12 and *Rhizopus nigricans* to C-11. In both cases, the best results were obtained on the 1,6-diketo derivative. Consequently, we have chosen this substrate to carry out several biotransformations with the microorganisms *Exserohilum halodes* and *Gliocladium roseum*.

2. Results and discussion

4β-Hydroxyeudesmane-1,6-dione **(1)** was obtained from a natural compound **(2)** isolated from *Sideritis varoi* subsp. *cuatrecasasii* (García-Granados et al., 1985), a synonym of *Sideritis leucantha* Cav. subsp. *meridionalis* (Font Quer) O. Socorro (Socorro, 2001). Deacetylation of **2** gave the trihydroxyl derivative **3**, which was oxidized to give the 1,6-diketo derivative **1**.

The incubation of **1** with *Exserohilum halodes* for 13 days produced only a limited quantity (15%) of meta-

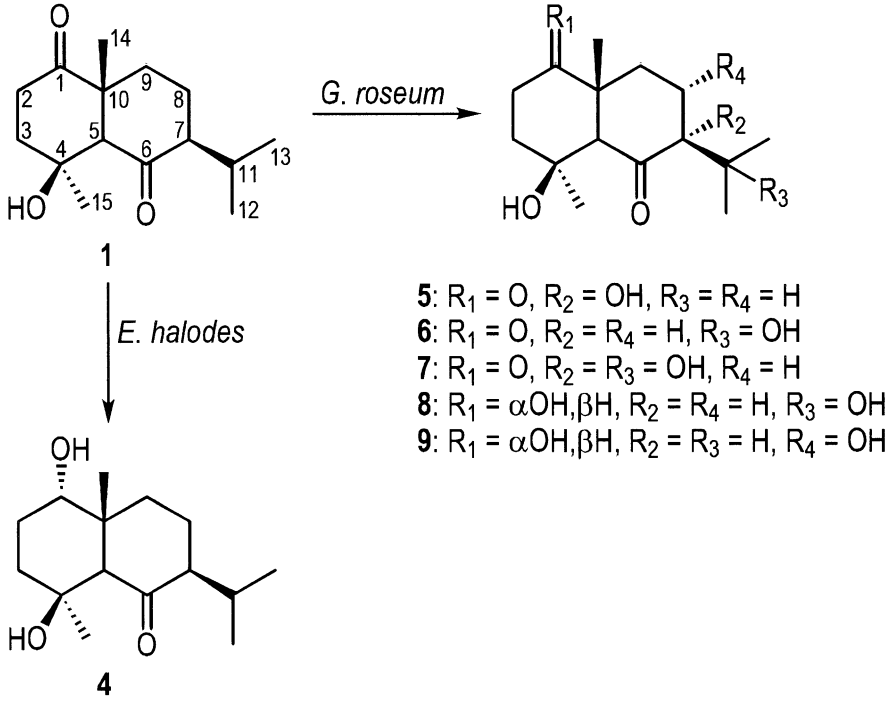

Fig. 1. Bioconversion of sesquiterpene 4β-hydroxyeudesmane-1,6-dione by *Gliocladium roseum* and *Exserohilum halodes*.

bolite **4**. This metabolite (**4**) was the result of the regio- and stereoselective reduction of the keto group at C-1 of substrate **1** from the β face giving a (1*S*)-hydroxyl derivative, which, due to the steric hindrance, is difficult to achieve by chemical means. The *S* configuration at C-1 could easily be deduced from the signal in the ^{1}H NMR spectrum (δ 3.52, 1H, *dd*, $J_{1,2\beta} = J_{1,2\alpha} = 3.0$ Hz), with coupling constants corresponding to an equatorial proton. This metabolite previously appeared in the incubation of substrate **1** with the microorganism *Curvularia lunata* (García-Granados et al., 1991).

Substrate **1** was more efficiently biotransformed by *Gliocladium roseum*. Incubation of this compound for 5 days yielded the metabolites **5** (2%), **6** (27%), **7** (3%), **8** (58%) and **9** (5%).

Metabolite **5** had a molecular formula of $C_{15}H_{24}O_4$, which indicated the presence of an additional hydroxyl group in the molecule. The ^{13}C NMR spectrum revealed β-effects on C-8 and C-11 and γ-effects on C-5, C-9, C-12 and C-13, positioning the new hydroxyl group at C-7. Consequently, metabolite **5** was 4β,7α-dihydroxyeudesmane-1,6-dione.

Metabolite **6** had the same molecular formula as the above metabolite (**5**), and its spectral data suggested a new hydroxyl group at C-11. This metabolite (**6**) was previously obtained in the incubation of substrate **1** with *Rhizopus nigricans* (García-Granados et al., 1993).

The molecular formula ($C_{15}H_{24}O_5$) of the third metabolite (**7**) was in agreement with the presence of two new hydroxyl groups. These functional groups were positioned at C-7 and C-11, by comparison of the spectral data of this metabolite (**7**) with those of metabolites **5** and **6**. Hence, metabolite **7** was 4β,7α,11-trihydroxyeudesmane-1,6-dione.

The main metabolite isolated (**8**) showed spectral data that, by comparison with those of metabolites **4** and **6**, indicated that *Gliocladium roseum*, besides the introduction of a hydroxyl group at C-11, also had reduced the carbonyl group at C-1 of the molecule, producing an *S*-alcohol. This metabolite (**8**) also resulted from the incubation of substrate **1** with *Rhizopus nigricans* (García-Granados et al., 1993).

The last metabolite isolated (**9**) had the same molecular formula ($C_{15}H_{26}O_4$) as metabolite **8**. Its ^{1}H NMR spectrum revealed two signals of geminal protons to hydroxyl groups at δ 3.55 (1H, *dd*, $J_{1,2\beta} = J_{1,2\alpha} = 2.9$ Hz), characteristic of a 1α-hydroxyl group, and at δ 4.04 (1H, *ddd*, $J_{8,9\alpha} = 10.8$, $J_{8,7} = 10.1$, $J_{8,9\beta} = 5.0$ Hz) due to an axial proton. The position of the new function was determined by the β-effects found on the adjacent carbons (C-7 and C-9). Therefore, metabolite **9** was 1α,4β,8α-trihydroxyeudesman-6-one.

3. Conclusions

Several conclusions can be drawn from the above biotransformation results. On the one hand, bioconversion of substrate (**1**) by *Exserohilum halodes* is more limited, reducing only the carbonyl group at C-1, producing an *S*-alcohol, as is usual in enzymatic reductions (Sih and Rosazza, 1976). On the other hand, *Gliocladium*

roseum achieved the complete bioconversion of substrate (**1**), producing mainly 11-hydroxyl derivatives (88%). These 11-hydroxylated compounds can be chemically transformed into 12-hydroxyl derivatives, precursors of 6β,12-eudesmanolides (García-Granados et al., 1993). The main action achieved on the substrate (**1**) by *Gliocladium roseum* is similar to the carried out by *Rhizopus nigricans* (García-Granados et al., 1993), although the first one, also produced 7α- and 8α-hydroxylated derivatives. All the microorganisms tested on the substrate (**1**) have reduced only the carbonyl group at C-1, while the one situated at C-6 remained unaltered (García-Granados et al., 1991, 1993).

In summary *Exserohilum halodes* produced only one known compound of difficult access by chemical means while *Gliocladium roseum* originated five compounds, three of which, have not previously been reported.

4. Experimental

Measurements of NMR spectra (300.13 MHz ^{1}H and 75.47 MHz ^{13}C) were made in $CDCl_3$ (which also provided the lock signal) in a Bruker AM-300 spectrometer. The assignments of ^{13}C chemical shifts (Table 1) were made with the aid of distortionless enhancement by polarization transfer (DEPT) using a flip angle of 135°. IR spectra were recorded on a Nicolet 20SX FT–IR spectrometer. High-resolution mass spectra were made by LSIMS (FAB) ionization mode in a MICROMASS AUTOSPEC-Q spectrometer (EBE geometry). Melting points (uncorr.) were determined using a Kofler (Reichter) apparatus. Optical rotations were measured on a Perkin-Elmer 241 polarimeter at 25°. Silica gel Scharlau 60 (40–60 μm) was used for flash chromatography. CH_2Cl_2 or $CHCl_3$ containing increasing amounts of Me_2CO were used as eluents. Analytical plates (silica gel, Merck 60 G) were rendered visible by spraying with H_2SO_4–AcOH, followed by heating to 120°. The identity of compound **2** was confirmed by direct comparison with an authentic sample (IR, MS, NMR, etc.).

4.1. Isolation of 6β-acetoxy-1β,4β-dihydroxyeudesmane (*2*)

6β-Acetoxy-1β,4β-dihydroxyeudesmane was isolated from *Sideritis varoi* subsp. *cuatrecasasii* (García-Granados et al., 1985), a synonym of *Sideritis leucantha* Cav. subsp. *meridionalis* (Font Quer) O. Socorro (Socorro, 2001).

4.2. Deacetylation of *2*

6β-Acetoxy-1β,4β-dihydroxyeudesmane (**2**, 1.20 g) was dissolved in MeOH/H_2O (70%) (70 ml) containing KOH (5%) (3.5 g) and refluxed for 1 h. The reaction mixture was extracted with CH_2Cl_2, dried over Na_2SO_4 and evaporated to dryness. Chromatography on a silica gel column yielded 1β,4β,6β-trihydroxyeudesmane (**3**, 952 mg, 92%) (García-Granados et al., 1991).

4.3. Oxidation of *3*

Jones' reagent was added dropwise to a stirred solution of 1β,4β,6β-trihydroxyeudesmane (**3**, 905 mg) in acetone at room temp. until an orange-brown colour persisted (30 min), following the oxidation by TLC. Methanol was then added and the reaction mixture was diluted with water and extracted with CH_2Cl_2. The organic layer was dried over anhydrous Na_2SO_4 and evaporated to dryness. Chromatography on a silica gel column yielded 4β-hydroxyeudesmane-1,6-dione (**1**, 815 mg, 91%) (García-Granados et al., 1991). Syrup; $[\alpha]_D = +67°$ ($CHCl_3$, *c* 1); IR ν_{max} ($CHCl_3$): 3527, 1712 and 1705 cm^{-1}, ^{1}H NMR ($CDCl_3$): δ 0.87 and 0.91 (3H each, *d*, $J = 6.6$ Hz, 3H-12 and 3H-13), 1.24 and 1.25 (3H each, *s*, 3H-14 and 3H-15), 2.58 (1H, *s*, H-5) and 3.07 (1H, *ddd*, $J_{2\beta,2\alpha} = J_{2\beta,3\alpha} = 14.2$, $J_{2\beta,3\beta} = 6.0$ Hz, H-2β).

4.4. Organism, media and culture conditions

Gliocladium roseum CECT 2733 and *Exserohilum halodes* CECT 2716 were obtained from the Colección Española de Cultivos Tipo, Departamento de Microbiología, Facultad de Ciencias, Universidad de Valencia, Spain, and was kept in YEPGA medium containing yeast extract (1%), peptone (1%), glucose (2%) and agar (2%) in H_2O at pH 5. In all transformation experiments a medium of peptone (0.1%), yeast extract (0.1%), beef extract (0.1%) and glucose (0.5%) in H_2O at pH 5.7 was used. Erlenmeyer flasks (250 ml) containing 80 ml of medium were inoculated with a dense suspension of the corresponding microorganism. The cultures were incubated by shaking (150 rpm) at 28° for 6 days, after which, substrate 1 (5–10%) in EtOH was added.

4.5. Biotransformation of substrate *1* with Exserohilum halodes

Substrate **1** (124 mg) was dissolved in EtOH (2 ml), distributed between 2 Erlenmeyer flask cultures and incubated for 13 days, after which the cultures were filtered and pooled; the cells were washed thoroughly with water and the liquid was satd. with NaCl and extracted twice with CH_2Cl_2. Both extracts were pooled, dried with anhydrous Na_2SO_4, and evaporated at 40° in vacuum to give a mixture of compounds (102 mg). This mixture was chromatographed on a silica gel column to obtain 83 mg of starting material **1** and 19 mg (15%) of 1α,4β-dihydroxyeudesman-1-one (**4**) (García-Granados

et al., 1991). Syrup; $[\alpha]_D = +21$ ($CHCl_3$, *c* 1); IR ν_{max} ($CHCl_3$): 3444 and 1690 cm^{-1}; ^1H NMR ($CDCl_3$): δ 0.85 and 0.88 (3H each, *d*, $J = 6.6$ Hz, 3H-12 and 3H-13), 0.98 (3H, *s*, 3H-14), 1.18 (3H, *s*, 3H-15), 2.64 (1H, *s*, H-5) and 3.52 (1H, *dd*, $J_{1,2\beta} = J_{1,2\alpha} = 3.0$ Hz, H-1).

4.6. Biotransformation of substrate *1* with Gliocladium roseum

670 mg of substrate **1** were dissolved in EtOH (9 ml), distributed between 9 Erlenmeyer flask cultures and incubated for 5 days, after which the cultures were processed as indicated above for the biotransformation of substrate **1** with *Exserohilum halodes*. The resulting mixture (667 mg) was chromatographed on a silica gel column to obtain 11 mg (2%) of 4β,7α-dihydroxyeudesmane-1,6-dione (**5**); syrup; $[\alpha]_D = +91^\circ$ ($CHCl_3$, *c* 1); IR ν_{max} ($CHCl_3$): 3514 and 1701 cm^{-1}; ^1H NMR ($CDCl_3$): δ 0.92 and 0.94 (3H each, *d*, $J = 6.8$ Hz, 3H-12 and 3H-13), 1.24 and 1.25 (3H each, s, 3H-14 and 3H-15), 3.08 (1H, *ddd*, $J_{2\beta,2\alpha} = J_{2\beta,3\alpha} = 14,3$, $J_{2\beta,3\beta} = 6.1$ Hz, H-2β) and 3.54 (1H, *s*, H-5); HRLSIMS, m/z: $[M+Na]^+$ 291.1565, ($C_{15}H_{24}O_4Na$, 291.1572, PPM +2.4); 190 mg (27%) of 4β,11-dihydroxyeudesmane-1,6-dione (**6**) (García-Granados et al., 1993); syrup; $[\alpha]_D = +61^\circ$ ($CHCl_3$, *c* 1); IR ν_{max} ($CHCl_3$): 3527 and 1700 cm^{-1}; ^1H NMR ($CDCl_3$): δ 1.18 and 1.21 (3H each, *s*, 3H-12 and 3H-13), 1.23 and 1.24 (3H each, *s*, 3H-14 and 3H-15), 2.39 (1H, *dd*, $J_{7,8\beta} = 12.2$, $J_{7,8\alpha} = 7.3$ Hz, H-7), 2.55 (1H, *s*, H-5) and 3.03 (1H, *ddd*, $J_{2\beta,2\alpha} = J_{2\beta,3\alpha} = 14.2$, $J_{2\beta,3\beta} = 6.0$ Hz, H-2β); 20 mg (3%) of 4β,7α,11-trihydroxyeudesmane-1,6-dione (**7**); syrup; $[\alpha]_D = +89^\circ$ ($CHCl_3$, *c* 1); IR ν_{max} ($CHCl_3$): 3498 and 1700 cm^{-1}; ^1H NMR ($CDCl_3$): δ 1.22 and 1.26 (3H each, *s*, 3H-14 and 3H-15), 1.30 and 1.44 (3H each, *s*, 3H-12 and 3H-13), 1.70 (1H, *ddd*, $J_{3\alpha,3\beta} = J_{3\alpha,2\beta} = 14.3$, $J_{3\alpha,2\alpha} = 4.5$ Hz, H-3α), 2.04 (1H, *ddd*, $J_{3\beta,3\alpha} = 14.3$, $J_{3\beta,2\beta} = 5.9$, $J_{3\beta,2\alpha} = 2.8$ Hz, H-3β), 2.15 (1H, *ddd*, $J_{2\alpha,2\beta} = 14.3$, $J_{2\alpha,3\alpha} = 4.5$, $J_{2\alpha,3\beta} = 2.8$ Hz, H-2α), 3.07 (1H, *ddd*, $J_{2\beta,2\alpha} = J_{2\beta,3\alpha} = 14.3$, $J_{2\beta,3\beta} = 5.9$ Hz, H-2β) and 3.45 (1H, *s*, H-5); HRLSIMS, m/z: $[M+Na]^+$ 307.1527, ($C_{15}H_{24}O_5Na$, 307.1521, PPM-1.9); 414 mg (58%) of 1α,4β,11-trihydroxyeudesman-6-one (**8**) (García-Granados et al., 1993); syrup; $[\alpha]_D = +50^\circ$ ($CHCl_3$, *c* 1); IR ν_{max} ($CHCl_3$): 3443 and 1684 cm^{-1}; ^1H NMR ($CDCl_3$): δ 1.00 (3H, *s*, 3H-14), 1.19 (3H, *s*, 3H-15), 1.18 and 1.23 (3H each, *s*, 3H-12 and 3H-13), 2.41 (1H, *ddd*, $J_{7,8\beta} = 12.7$, $J_{7,8\alpha} = 6.3$, $J_{7,5} = 1.1$ Hz, H-7), 2.64 (1H, *bs*, H-5) and 3.51 (1H, *dd*, $J_{1,2\beta} = J_{1,2\alpha} = 2.8$ Hz, H-1); and 32 mg (5%) of 1α,4β,8α-trihydroxyeudesman-6-one (**9**); syrup; $[\alpha]_D = +100^\circ$ ($CHCl_3$, *c* 1); IR ν_{max} ($CHCl_3$): 3412 and 1690 cm^{-1}; ^1H NMR ($CDCl_3$): δ 0.96 (3H, *s*, 3H-14), 1.06 and 1.10 (3H each, *d*, $J = 7.1$ Hz, 3H-12 and 3H-13), 1.22 (3H, *s*, 3H-15), 2.62 (1H, *s*, H-5), 3.55 (1H, *dd*, $J_{1,2\beta} = J_{1,2\alpha} = 2.9$ Hz, H-1β), and 4.04 (1H, *ddd*, $J_{8,9\alpha} = 10.8$, $J_{8,7} = 10.1$, $J_{8,9\beta} = 5.0$ Hz, H-8); HRLSIMS, *m/z*: $[M+Na]^+$ 293.1727, ($C_{15}H_{26}O_4Na$, 293.1729, PPM +0.7).

Received 23 April 2001; received in revised form 24 July 2001

Abstract

Indole is presumably a product of indole-3-glycerol phosphate catabolism in *Isatis tinctoria*. It is oxidized into indoxyl and stored in young leaves as indigo precursor. Further oxidation and dimerization of indoxyl produces indigoid pigments. In this work, we describe an HPLC method dedicated to the identification and quantification of indigoid pigments (indigo, indirubin, isoindigo and isoindirubin) and indigo precursors produced in *I. tinctoria* (Woad). This work, carried out with two cultivars of *I. tinctoria*, has confirmed that the quantity of indigo precursors is dependent on the species and the harvest period. In addition we have shown for the first time that young leaves of *I. tinctoria*, harvested in June contained a new indigo precursor in addition to isatan B (indoxyl-5-ketogluconate) and indican (indoxyl-β-D-glucoside). We suggest the name "isatan C" for this new indigo precursor in *I. tinctoria*. Its chemical characteristics point to an dioxindole ester with PM of 395. We have shown that isatan C reacts with isatan B increasing the red pigment production. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Woad; *Isatis tinctoria*; Brassicaceae; Indigo; Indirubin; Isoindirubin; Isatan; Indican

1. Introduction

The blue dye indigo (indigotin) is one of the oldest natural dyestuffs known to human beings (Ensley et al., 1983). Indigo has, for centuries, been obtained from a variety of plant sources such as *Indigofera* (tropical species, Africa, Asia, East Indies, South America), *Polygonum tinctorium* (Far East, China, Korea) and *Isatis tinctoria* (Woad) (Europe). Indigo is an artefact of secondary metabolism. *Indigofera tinctoria* and *P. tinctoriuni* contain indican (indoxyl-β-D-glucoside) which serves as a starting material for indigo production, whereas *I. tinctoria* (Woad) contains isatan B (indoxyl-β-ketogluconate), as a major indigo precursor and indican as minor a indigo precursor (Epstein et al., 1967; Maier et al., 1990). In old leaves, precursors are broken down by hydrolases when the leaves are damaged and exposed to the air. The liberated indoxyl is spontaneously oxidized by oxygen yielding indigo. Isatin is generated from indoxyl in an oxygen-rich environment as a side reaction. The condensation of indoxyl with isatin produces indirubin which is a by-product of biosynthetic indigo production. It is well known that plants contain, in addition to *trans*-indigo (indigotin, blue) and *trans*-indirubin (isoindigotin, red), certain impurities such as *cis*-indigo (blue), *cis*-indirubin (isoindirubin, red), indigo brown (isoindigo), indigo gluten, indigo yellow and traces of flavonoids that makes natural indigo a more pleasing tinge than synthetic indigo (Perkin and Bloxam, 1907; Perkin, 1907).

In the present work, a qualitative and quantitative HPLC method is described for the identification and the separation of indigoid pigments and precursors present in *I. tinctoria* leaves. We show for the first time, that *I. tinctoria* produces three indigo precursors, isatan B as a major precursor, indican as a minor precursor and an other precursor that we named "isatan C". Eventually, this work describes the possible effect of isatan C on the red pigments production.

2. Results and discussion

2.1. Extraction and identification of compounds from Isatis tinctoria

An extract of *I. tinctoria* (IT BM) harvested on 27th June 2000 is displayed in Fig. 1.

Extraction and HPLC analyses were performed as described in Experimental. The major compounds produced in *I. tinctoria* were identified by their UV and mass spectra:

Compound **1**: *Indican*. HPLC t_R 7.6 min, UV λ_{max} 218, 280. MS: *m/z* 296 (MH^+). HPLC t_R, mass spectrum and UV spectrum were identical to those of commercially available indican (Sigma).

Compound **2**: *Isatan B*. HPLC t_R 9.2 min, UV λ_{max} 218, 280. MS: *m/z* 310 (MH^+). No standard was available for isatan B. Consequently, it was necessary to produce pure isatan B and characterize it using NMR. ^1H NMR (D_2O) δ (ppm) 3.42 (*s*, 2H, H-1), 3.71 (*d*, 1H, H-4 or H-7), 3.73 (*d*, 1H, H-4 or H-7), 4.85 (*d*, 1H, H-4 or H-7), 6.98 (d, 1H, H-4 or H-7), 7.00 (*d*, 1H, H), 7.12 (*t*, 1H, H-4 or H-7), 7.31 (*d*, 1H, H-5 or H-6), 7.58 (d, 1H, H-5 or H-6).

Compound **3**: *Isatin*. HPLC t_R 11.9 min, UV λ_{max} 210, 244, 305. MS: *m/z* 148 (MH^+). HPLC t_R, mass spectrum and UV spectrum were identical to those of commercially available isatin (Sigma).

Compound **5**: *Indoxyl*. HPLC t_R 18.3 min, UV λ_{max} 240 nm. MS: *m/z* 134 (MH^+). HPLC t_R, mass spectrum and UV spectrum were identical to those of product generated by the hydrolysis of commercial 3-acetoxindole (indoxyl acetate) by the lipase of *Rhizomucor miehei*.

Compounds **6**, **7** and **8**: HPLC t_R 19.3, 21.6 and 22.2 min respectively. UV spectra of these three compounds correspond to flavonoid spectra.

Compound **4**: HPLC t_R 14.9 min. The mass spectrum indicated 396, assigned as MH^+, 398, assigned as MH_3^+ and 378, assigned as $MH^+–H_2O$. High resolution–mass spectrometry indicated 777 assigned as $[2(M–H_2O)+Na]^+$. A possible molecular formula is $C_{20}H_{13}O_8N_1$ (M, 395). The UV spectrum (UV λ_{max} 218, 280, Fig. 3) was similar to isatan B, indican and indoxyl acetate spectra. The amount of material isolated has not permitted the acquisition of a ^1H NMR spectrum. Alkaline media, in presence of oxygen, induce the synthesis of indigoid pigments out of isatan B and indoxylacetate, whereas indican remains unhydrolysed. This instability in alkaline media is consistent with the ester bound of isatan B, indoxyl acetate and compound **4**. On the basis of these results, we conclude that compound **4** is a new indigo precursor present in young leaves of *I. tinctoria*. Indeed, compound **4** is probably composed of dioxindole moiety (UV λ_{max} 218, 280) which binds an organic acid through ester bound. This new indigo precursor was named isatan C.

Acetone extract of young leaves of *I. tinctoria* (harvested June 27 2000), plated on TLC were developed by fuming ammonia vapour (pH > 13). One band developed a red/brown colour at R_f 0.7, one band developed a blue color at R_f 0.6 and one band developed a brown colour at R_f 0.2. These three compounds are three indigo precursors of woad, indican (R_f 0.2), isatan B (R_f 0.6) and isatan C (R_f 0.7).

Compounds **9**, **10**, **11**, **12** and **13**: the indigoid pigments produced in *I. tinctoria* were separated into five

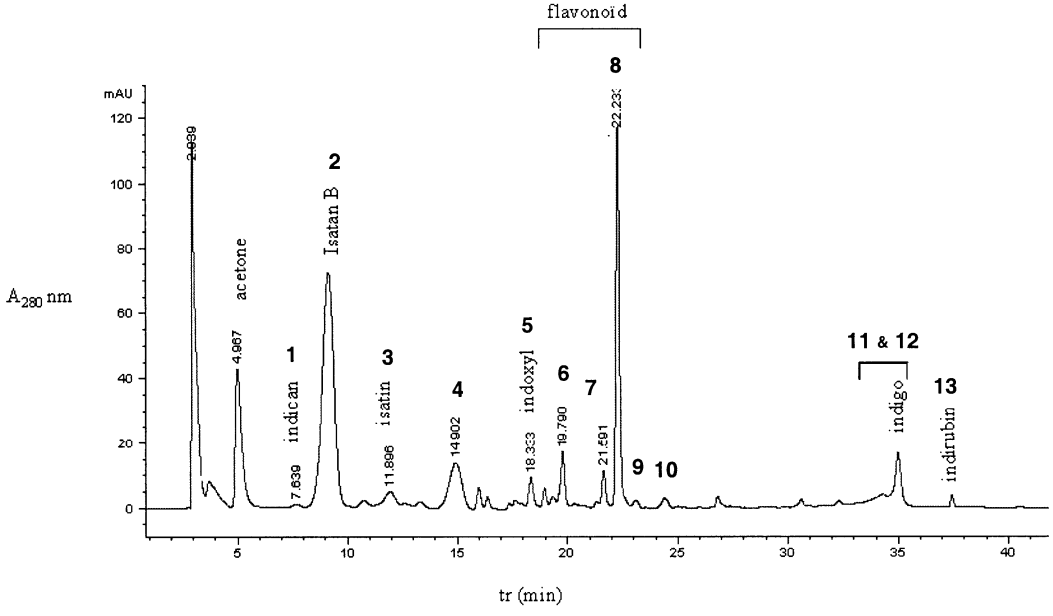

Fig. 1. HPLC analysis of an extract of *Isatis tinctoria* leaves harvested on 27 June 2000. Chromatograms were recorded at 280 nm. HPLC analysis was performed as described in Experimental.

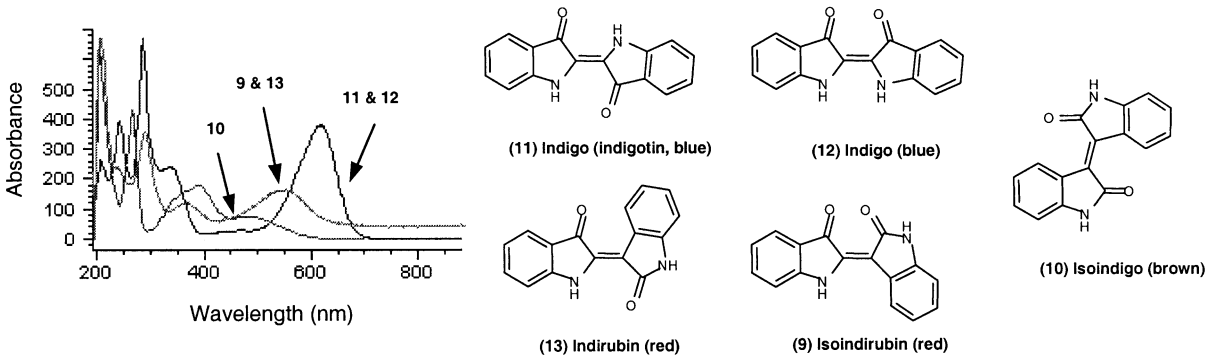

Fig. 2. UV/visible spectrocopy of pigments **9**, **10**, **11**, **12** and **13** formed in *Isatis tinctoria*. The pigments were seperated by HPLC, and UV/visible spectra were recorded. The spectrum of pigment **9** is typical of isoindirubin, pigment **10** corresponds to isoindigo, **11** and **12** are two isomers of indigo and **13** corresponds to indirubin.

compounds, of which two were blue (**11** and **12**, HPLC t_R: 34–36 min), two were red/purple (**9**, HPLC t_R: 23 min, **13**, HPLC t_R: 37.5 mm) and one was brown (10, HPLC t_R: 24.5 min). Pigments **11** and **13** were much more predominant. The UV/visible spectra of compounds **11** and **13** (UV 603 and 552 nm λ_{max} respectively) match the literature for *trans*-indigo (indigotin) and *trans*-indirubin (isoindigotin), respectively (Fearon and Boggust, 1950; Friedmann et al., 1950). The UV/visible spectra of compounds **9**, **10** and **12** (Fig 2, UV λ_{max} 552 nm, 500 nm and 603 nm respectively) correspond to *cis*-indirubin (isoindirubin), isoindigo (indigo brown) and *cis*-indigo, respectively. Mass spectrum yielded an apparent MH^+ ion at *m*/*z* 263 for compounds 9, 10, 11, 12 and 13, indicating a molecular mass of 262. Fragmentation of the *m*/*z* 263 ion in each case yielded *m*/*z* 235 (−CO) and 219 (−CO−NH_2). The same ions were seen when standard indigo (Sigma) was fragmented in the same way. We noted that *cis*-indirubin and *cis*-indigo had exactly the same UV/visible spectrum and mass spectrum (MS: *m*/*z* 263, MH^+) as *trans*-indirubin and *trans*-indigo, respectively. Isoindirubin (*cis*) is an isomer of indirubin (*trans*), as *cis*-indigo is an isomer of *trans*-indigo (indigotin) (Fig. 2).

2.2. Quantification of indigo precursors from Isatis tinctoria

The amount of indigo precursors present in old leaves and young leaves of two cultivars of *I. tinctoria* (IT BM and IT MC) was estimated at A_{280} (Fig. 4). The concentrations were evaluated with leaves harvested on 9, 15 and 30 May 2000 and 27 June 2000. The two cultivars of *I. tinctoria* contain similar but not identical concentrations of indigo precursors. We may notice that indigo precursors' quantity present in the young leaves, increased during time. Moreover, the amount of precursors present in IT MC young leaves is higher than the amount present in IT BM young leaves. Finally, young leaves contain higher concentrations of indigo precursors than older ones. This study confirms that the quantity of indigo precursors is dependent of the cultivars and of the period of harvest. It is important to notice that isatan B was observed in *I. tinctoria* leaves, from the harvest of April, whereas indican and compound **4** (isatan C) were observed and consequently quantified only from the harvest of the end of June.

2.3. Transformation of indigo precursors in alkaline media

The conversion of indigo precursors into indigo was followed by HPLC. Products were detected using a UV detector at 280, 550 (red pigments) and 603 nm (blue pigments) (Fig. 5, Table 1, Scheme 1). HPLC analysis was performed as described in Experimental.

Pure isatan B treated with an alkaline medium (NaOH solution 0.05 M, in water/CH_3CN 90/10, v/v. pH 13), produces indoxyl since the ester bond spontaneously brakes down. Indoxyl is then oxidized by air yielding indigo (**11**) (HPLC t_R: 32 min, blue).

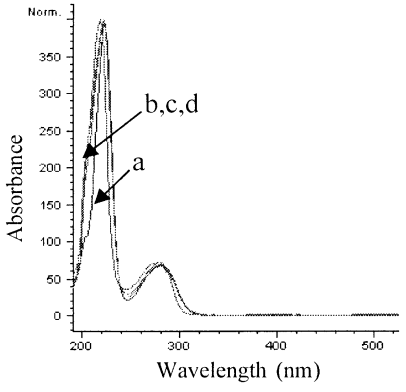

Fig. 3. Spectral characterization of compound **4**. UV spectrum online from HPLC: (a) indican, (b) indoxyl acetate, (c) isatan B, (d) compound **4**.

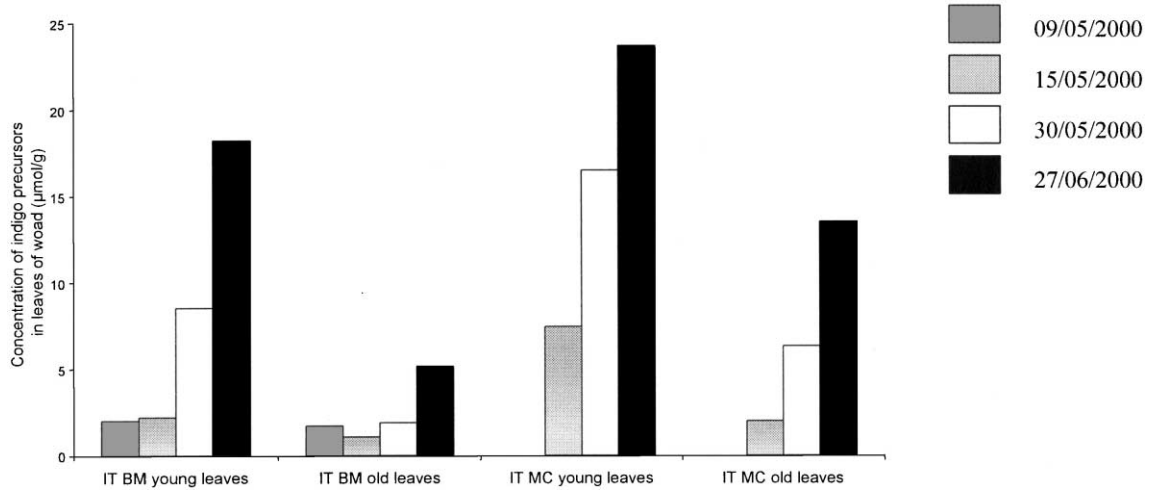

Fig. 4. Concentration of indigo precursors present in old leaves and young leaves of two cultivars of *Isatis tinctoria*. We consider young leaves as those located on the apex and old leaves those located underneath. Young leaves may be easily differentiated from old ones since they are light green and smaller than old leaves which are dark green. The concentrations were measured on leaves harvested on 9, 15 and 30 May 2000 and, finally, on 27 June 2000. Extraction and quantification were performed as described in Experimental.

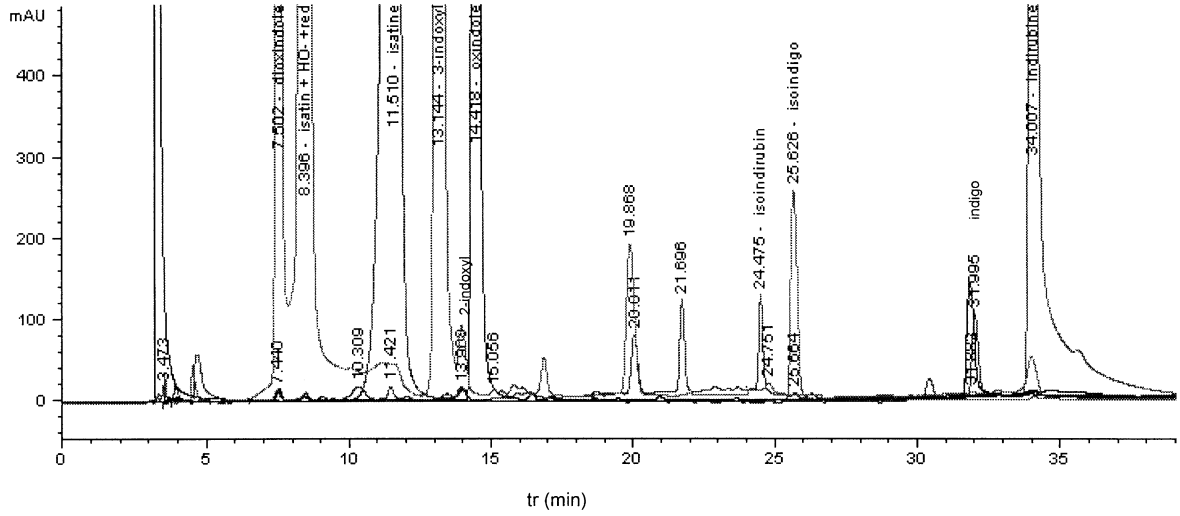

Fig. 5. HPLC analysis of the transformation of indigo precursors. Chromatograms were recorded at 280 nm. HPLC analysis was performed as described in Experimental.

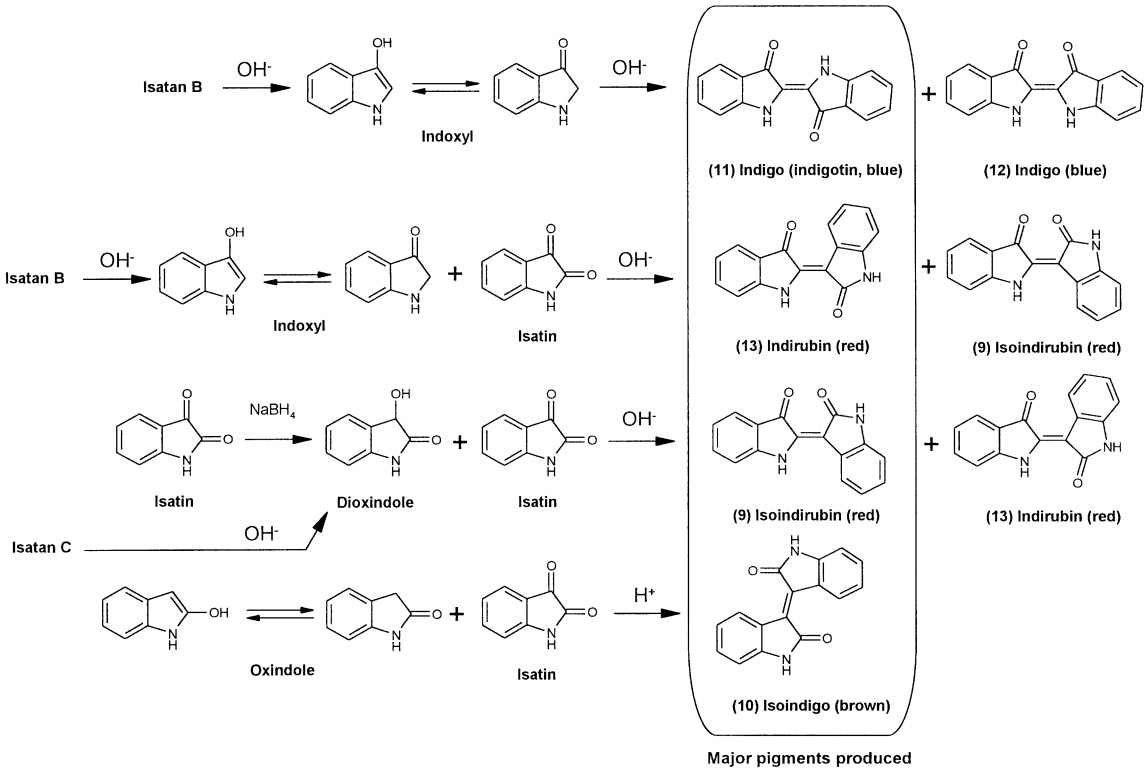
Table 1
Alkaline formation of indigoid pigments

	Indigo (**11**) A_{603}, area units	Indirubin (**13**) A_{552}, area units	Isoindirubin (**9**) A_{552},area units
Isatan B	8000	5	–
Isatan C	300	200	5000
Isatan B and Isatan C	5000	200	100
Isatan B and Isatin	6800	3000	–
Isatan C and Isatin	870	1000	50

Indigo precursors were incubated with NaOH solution 0.05 M, in water/CH_3CN 90/10, v/v, pH 13. After 30 min, mixtures were analysed by HPLC. HPLC analysis was performed as described in Experimental. Dye production was analysed by recording A_{603} for blue pigments and A_{552} for red pigments.



Scheme 1. Chemical pigments formation.

Isatan B added to isatin solution in 0.05 M NaOH, produces indoxyl which is oxidized yielding indigo. In addition, indoxyl reacts with isatin yielding indirubin (**13**) (HPLC t_R: 34 min, red). We noticed that indigo appeared to be the major pigment produced. When higher concentrations of isatin were used, pigment production decreased. Under these conditions, isatin appeared to be an inhibitor of the pigments production.

Isatan C in alkaline solution (0.05 M NaOH) produces dioxindole since the ester bond brakes down. Dioxindole is then oxidized by air yielding three pigments, indigo (**11**) and indirubin (**13**) (HPLC t_R: 34 min) as minor pigments, and another major red pigment, isoindirubin (**9**) (HPLC t_R: 24.5 min). The same result is obtained with a solution of isatin reduced by $NaBH_4$ in alkaline medium. Indeed, the product generated by $NaBH_4$ reduction of isatin is dioxindole (HPLC t_R: 7.5 min) as confirmed by HPLC t_R and UV spectra. Dioxindole may react with isatin in alkaline medium yielding isoindirubin and indirubin.

The reaction of isatan B and isatan C in alkaline medium produces indoxyl and dioxindole, which may be oxidized by air yielding indigo (**11**), indirubin (**13**) and isoindirubin (**9**).

A solution of oxindole and isatin in an alkaline medium do not produce any pigment. The condensation of oxindole with isatin may only be achieved in acidic media. In these conditions, the solution produces isoindigo, a brown pigment (**10**) (HPLC t_R: 25.6 min, λ_{max} 500 nm).

These results confirm that isatan C hydrolysis produces dioxindole that may react with isatin yielding isoindirubin (**9**) and indirubin (**13**). Isatan C is an indigo precursor and more specifically a precursor of red pigments present in *I. tinctoria*, and its chemical nature was established as dioxindole ester.

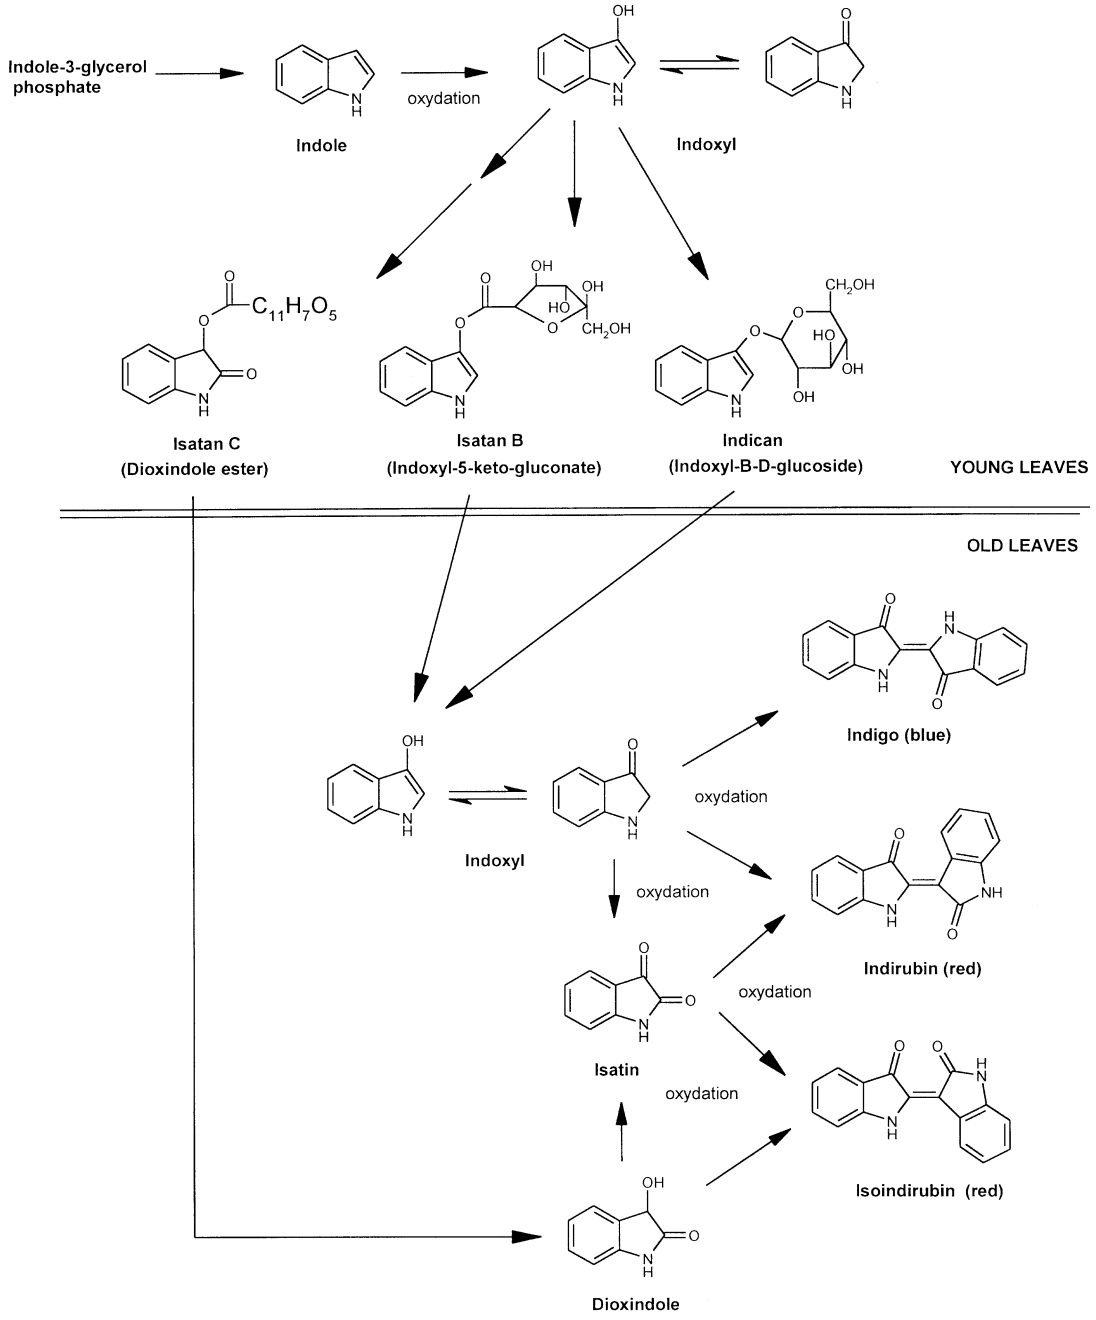
2.4. Discussion

The metabolism of indigo precursors is still under study. It is likely that indole is a product of indole-3-glycerol phosphate (Xia and Zenk, 1992) but not of tryptophan catabolism in vegetables. The indole ring could be oxidised by cytochrome P450 enzyme producing indoxyl and dioxindole. P450s are monooxygenases that catalyze the oxidation of a remarkably broad range of endogenous and exogenous chemicals. In plants they play important roles in biosynthetic pathways, including those of sterols, isoprenoids, alkaloids, oxygenated fatty acids, and phenylpropanoids (Bolwell et al., 1994; Durst and O'Keefe, 1995; Schuler, 1996). Indeed there is not yet evidence for the existence in plants of naphtalene dioxygenase or xylene mono-oxygenase (Ensley et al., 1983; Mermod et al., 1986), enzymes which are known to oxidize indole to indoxyl in some bacteria. In young leaves plants protect indoxyl, a highly unstable intermediate, from spontaneous oxidation to indigo by glycosylation to yield indican or by addition of 5-ketogluconate to yield isatan B. Further oxydation transforms

indoxyl to dioxindole. As indoxyl, plants may protect dioxindole by addition of an organic acid to yield isatan C. In the case of indican, this pathway has been located in vacuoles in which indican is synthesized from UDP-glucose and indoxyl (Minami et al., 2000; Marcinek et al., 2000). These indigo precursors are broken down by hydrolases when the leaves are old or damaged. Indoxyl liberated from isatan B and indican in old leaves is oxidized spontaneously by air yielding indigo. Isatin is generated from indoxyl and/or dioxindole in an oxygen-rich environment as a side reaction. Dioxindole is liberated from isatan C. The condensation of indoxyl with isatin produces indirubin, whereas the condensation of dioxindole with isatine yields isoindirubin and indirubin, which are by-products of the biosynthesis of indigo (Scheme 2).

3. Conclusion

In this work, an HPLC method is described to identify and quantify the pigments (indigo, indirubin and isoindirubin) and the indigo precursors produced in *I. tinctoria*. Our work with two cultivars of *I. tinctoria* has



Scheme 2. Pigment formation in *Isatis tinctoria*.

confirmed that the quantity of indigo precursors is dependent of the cultivars and harvest period. We have shown for the first time that young leaves of *I. tinctoria*, harvested from June, produced a new indigo precursor in addition to isatan B and indican. The name "isatan C" is proposed to describe this new indigo precursor in woad. Its chemical nature was tentatively established as dioxindole ester with PM of 395 and possible molecular formula $C_{20}H_{13}O_8N$. However its structure is not completely specified due to low amounts of the precursor and to higher instability. Finally, we have shown that isatan C increases the pigments production and especially isoindirubin. These results confirm that *I. tinctoria* harvested in June produced isatan C as indigo precursor which favours the production of red pigments, indirubin and isoindirubin.

4. Experimental

4.1. Biological and chemical material

Indigo, indican, isatin, oxindole and 3-acetoxy-indole (indoxyl acetate), were obtained from Sigma Chemical Co. (USA). Isatan B and isatan C were obtained from an extract of woad. The extraction procedure is described below.

4.2. Chemical pigment synthesis

Indirubin was prepared by reaction of isatin with 3-acetoxy-indole in alkaline media. Under argon, isatin (1 mmol) and sodium carbonate (2.4 mmol) were added to a solution of indoxyl acetate (1 mmol) in methanol (5 ml) (Hoessel et al., 1999; Russel and Kaup, 1969). The mixture was stirred for 1 h at room temperature and filtered off after 24 h hold. The residue was washed with methanol and cold water until neutral reaction of the filtrate. The product (dark violet crystals) was dried over potassium hydroxide in the dessicator. Indirubin was identified by ^{1}H NMR, UV spectrum and mass analysis (coupled to HPLC). Indirubin: yield 85%, UV λ_{max} 552 nm, M: m/z 263 (MH^+).

Isoindirubin was prepared by reaction of isatin with $NaBH_4$ in alkaline media. Isatin (1 mmol) and $NaBH_4$ (0.5 mmol) were stirred at 25 °C in methanol (3 ml). After 1 h, isatine (1 mmol) and 1 ml of NaOH 0.1 M were added. The mixture was stirred at room temperature and was filtered after 12 h hold, The residue was washed with methanol and cold water. Products (two dark violet crystals) were dried over potassium hydroxide in a dessicator. Pigments were identified according to the UV spectrum and mass analysis (coupled to HPLC). Indirubin: yields 85%, UV λ_{max} 552 nm, MS: m/z 263 (MH^+); Isoindirubin: yield 10%, UV λ_{max} 552 nm, MS: m/z 263 (MH^+).

Isoindigo was prepared by reaction of isatin with oxindole in acid media and identified by ^{1}H NMR, UV spectrum and mass analysis (coupled to HPLC) (Hoessel et al., 1999; Russel and Kaup, 1969). Oxindole (1 mmol) and isatin (1 mmol) were stirred at 95 °C in a mixture of glacial acetic acid (3 ml) and concentrated hydrochloric acid (50 μl). After 3 h, the precipitate (dark brown crystals) was filtered off and washed with methanol and diethyl ether. Yield: 90%, UV λ_{max} 550, MS: m/z 263 (MH^+).

4.3. Plant material

Two cultivars of *I. tinctoria* (IT BM and IT MC) were grown in a field of CRITT Horticole (St Savin, France). The date of seeding was 23 March 2000. In this paper, we consider young leaves as those located on the apex and old leaves those located underneath. Young leaves may be easily differentiated from old ones since they are light green and smaller than old leaves which are dark green. Leaves were harvested from June to September. The leaves were weekly for indigo quantification. Four overall harvests were carried out monthly.

4.4. Extraction

Reactions were conducted in screw-cap glass vials. In standard procedure, fresh leaves were ground in a mortar and suspended in acetone/acetic acid 1% v/v (10 ml/g of fresh leaves) and stirred at 24 °C for 4 h. After filtration, acetone was evaporated under reduced pressure. The residue was dissolved in a small volume of methanol and analyzed by TLC and HPLC or HPLC–MS.

Pigment concentrations and yields of indigo precursors produced from *I. tinctoria* were quantified by HPLC analysis with reference to a standard curve of products dissolved in methanol.

4.5. TLC analysis

TLC was used for qualitative analysis on silica gel 60 F plates (Merck). Elution was carried out with the mixture: ethyl acetate/acetone (1/1, v/v). Conversion of the indoxyl glycosides (indigo precursors) into indigo and indirubin on TLC plates were achieved by fuming with NH_3 vapor from a concentrated solution (pH >13).

4.6. Separation and identification of Indigo precursors and pigments from Isatis tinctoria by HPLC

Separation and identification of indigo precursors and pigments was conducted using an HPLC system from Hewlett Packard (processor, pump, UV detector and injector model 1100). Analyses were carried out with an Ultrasep C18 (250×4 mm, 6 μ) reverse phase column from ICS (France), at 50 °C with a flow rate of 0.85 ml/

min using a gradient made of solvent A (CH_3OH/TFA 0.2%) and solvent B (H_2O/TFA 0.2%). Programme: 0–10 min: 85% B/ 15% A to 75% B/ 25% A; 10–30 min: 75 to 30% B; 30–40 min: hold at 30% B; 40–45 min: 30 to 85% B. Products were detected and quantified using a diode array detector at 280 nm. During the chromatographic analysis, UV/visible spectra of each individual peak were acquired online using a diode array detector. Further characterisation of purified peaks was achieved by HPLC–MS analyses, with comparisons to the A_{280} traces (online) obtained with rapid-scanning UV analysis.

4.7. Hydrolysis of indigo precursors

To identify products (indoxyl, dioxindole, isatin, indigo, indirubin, isoindirubin) formed from indigo precursors, pure indigo precursors or extracts of *I. tinctoria* leaves were incubated with (i) a NaOH solution (0.05 M) in H_2O/CH_3CN, 90/10, v/v, pH 13, or (ii) with Lipozyme® (lipase from *R. miehei*) in an appropriate medium (*tert*-amyl alcohol/water, 95/5, v/v). Aliquots (200 μl) were taken at different time and methanol (200 μl) was added. The mixture was analysed by HPLC and TLC.

4.8. Purification of indigo precursors and study of isatan C transformation

The purification of indigo precursors and the transformation of isatan C in alkaline media were followed by preparative HPLC. We used an Ultrasep C18 (250×8 mm, 6 μ) reverse phase column from ICS (France), at 50 °C with a flow rate of 2.3 ml/min and with a gradient composed of solvent A (CH_3CN/TFA 0.2%) and solvent B (H_2O/TFA 0.2%). Programme: 0–10 min: 85% B/ 15% A to 75% B/ 25% A; 10–30 min: 75 to 30% B; 30–40 min: hold at 30% B; 40–45 min: 30 to 85% B. Products were detected using a UV detector at 280, 550 and 603 nm.

4.9. Structural analysis

^{1}H NMR were recorded on a Jeol-JNM LA400 (400 MHz) spectrometer (Laboratoire Commun d'Analyse, Université de La Rochelle), with an internal reference of tetramethylsilane. HPLC–MS analysis was carried out in the Centre Régional de Mesure Physiques de L'Ouest (CRMPO), Université de Rennes, France. HPLC–MS analyses were recorded using an HPLC coupled to an API III+ (Sciex, Thornhillm, L3T 1P2, ON. Canada). We have used the same column and gradient system as described above.

Isolation, structure determination, and phytotoxicity of unusual dioxopiperazines from the phytopathogenic fungus *Phoma lingam*

M. Soledade C. Pedras*, Corinne J. Biesenthal

Department of Chemistry, University of Saskatchewan, 110 Science Place, Saskatoon SK S7N 5C9, Canada

Received 24 May 2001; received in revised form 16 July 2001

Abstract

The isolation, chemical structure elucidation, and bioactivity of polanrazines B–F, five new dioxopiperazines produced by isolates of the blackleg fungus [*Phoma lingam,* perfect stage *Leptosphaeria maculans* (Desm.) Ces. et de Not.] originating from Poland, are reported. Polanrazines C and E showed moderate but selective toxicity, causing necrotic and chlorotic lesions (1–3 mm diameter) on brown mustard leaves. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Blackleg disease; Crucifer; Dioxopiperazines; *Leptosphaeria maculans*; *Phoma lingam*

1. Introduction

Blackleg of cruciferous plants is a devastating fungal disease caused by the phytopathogen *Leptosphaeria maculans* (Desm.) Ces. et de Not., asexual stage *Phoma lingam* (Tode ex Fr.) Desm. Virulent isolates of the fungus have caused enormous yield losses in rapeseed (*Brassica napus* L. and *B. rapa* L.) and canola (*B. napus* L. and *B. rapa* L.) in Canada and worldwide (Gugel and Petrie, 1992). To develop appropriate control practices that prevent blackleg disease outbreaks and a rapid breakdown of plant resistance, it is essential to characterize and differentiate the various fungal isolate types. Initially, two different groups of *P. lingam* (originally called "strains") were characterized in Canada on the basis of virulence, host range, and cultural tests: a highly virulent type (V) causing leaf spots and severe stem cankers on rapeseed and cabbage (*B. oleracea* L.) and a weakly virulent type (W) causing only superficial leaf and stem lesions on rapeseed and cabbage (McGee and Petrie, 1978). Subsequently, due to the broad variability of fungal isolates causing blackleg, additional subgroups within each of the V and W groups were proposed (Williams and Fitt, 1999; Howlett et al., 2001). Thus far, isolates belonging to the V group, also known as A group or aggressive, appear to be responsible for the largest yield losses in Canada, UK, France, Germany, and Australia, whereas in Poland the W isolates appear to cause significant crop damage as well (Williams and Fitt, 1999). Current evidence indicates that isolates of the blackleg fungus occurring in Canada and previously characterized as W isolates, also known as avirulent, B group, or nonaggressive, are likely *P. wasabiae* Yokogi, and not *P. lingam* (Pedras et al., 1995, 1996; Taylor et al., 1995; Pedras, 1998; Reddy et al., 1998); however, since no formal reclassification has occurred yet, these isolates will be hereon referred to as W group. Moreover, we have also reported on isolates Laird 2 and Mayfair 2, thus far two unique W Canadian isolates classified as *P. lingam*, whose metabolite profile is rather different from those of either V or W isolates (Pedras et al., 1998, 1999).

Recent studies of isolates of the species *P. lingam* collected in different countries suggested that there are at least three distinct groups which may constitute three different *Phoma* species (Pedras and Biesenthal, 2000). Chemical analysis of the secondary metabolites of such isolates indicated that isolates of *P. lingam* originating from Poland were clearly different from Canadian, French, German, or Australian isolates (Pedras and Biesenthal, 1998, 2000). To characterize and clarify the relationship among diverse blackleg isolates, we have analyzed fungal isolates from Poland and here wish to report their secondary metabolites, compounds **1**–**7**.

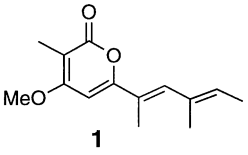
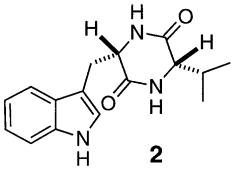
Dioxopiperazines **3**–**7** represent new metabolites which we named polanrazines B, C, D, E and F. Discussion of the implications of our findings and suggestions for isolate grouping are also provided.

2. Results and discussion

Initially, eight Polish isolates (IBCN 19–26) of *P. lingam* were grown in liquid cultures, the culture broths extracted with EtOAc, and the extracts analyzed by TLC, HPLC, and ^{1}H NMR spectroscopic analyses. Both the HPLC chromatograms and ^{1}H NMR spectra of each extract were similar and suggested the presence of aromatic compounds not available in our library containing *P. lingam* metabolites isolated to date (Pedras, 1998). Furthermore, bioassay of those extracts (as reported in the Experimental) on leaves of canola, brown mustard (*B. juncea*), and white mustard (*Sinapis alba*) suggested that these extracts were more phytotoxic to brown mustard than to canola or white mustard. Subsequently, Polish isolate IBCN 19 was selected to grow on a larger scale for metabolite isolation and chemical structure determination. The EtOAc extract of the culture broth was fractionated by FCC followed by multiple fractionation by prep. TLC, as described in the experimental, to yield phomapyrone A (**1**) and compounds **2**–**7**. The structures of phomapyrone A (**1**) (Pedras et al., 1994) and L-valyl-L-tryptophan anhydride (**2**) (Pedras et al., 1998) were readily established by comparison of their chromatographic and spectroscopic data with that of authentic samples available in our compound library (Pedras and Biesenthal, 2000). Phomapyrone (**1**) was previously isolated from W Canadian isolates (Pedras et al. 1994), isolates Mayfair 2 and Laird 2 (Pedras et al., 1998, 1999) whereas **2** was only isolated from isolates Mayfair 2 and Laird 2 (Pedras et al., 1998, 1999).



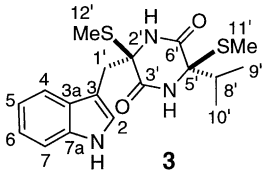
1



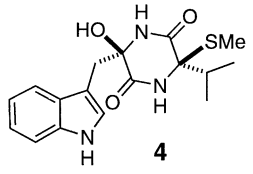
2

The remaining constituents appeared to be structurally related to dioxopiperazine **2**, as their ^{1}H and ^{13}C NMR spectra showed the expected signals of a 2,5-dioxopiperazine ring containing 3-methyleneindolyl and isopropyl substituents (Table 1). Compared to L-valyl-L-tryptophan anhydride (**2**), the least polar of the dioxopiperazines (**3**) showed two methyl singlets instead of the methine protons at C2′ and C5′. That these methyl groups were likely attached to sulfur atoms was suggested by their chemical shifts, and confirmed by HRMS (for $C_{18}H_{23}N_3O_2S_2$). Because no trivial name was assigned to L-valyl-L-tryptophan anhydride (**2**) we propose that it be named polanrazine A and that compound **3** be named polanrazine B. Similarly, the structures of **4**–**7** were assigned from analysis of NMR (Table 1) and HRMS data. The regiochemistry of the substituents at C2′ and C5′ was assigned based on HMBC correlations of the methyl protons to C5′, in compounds **4** and **6**, or to C2′, in compound **5**. Compound **6** was readily distinguished from **4** based on the chemical shifts of the methyl group (δ_H 3.18, δ_C 51.5 in **6** vs. δ_H 0.81, δ_C 9.7 in **4**). The unusually low proton and carbon chemical shifts of the SMe group of **4** might be due to a shielding effect of the indole ring (Lambert et al., 1998). The relative configurations were established by NOE experiments between the methylene protons at C1′ and methyne proton at C8′. The absolute configuration of compounds **3**–**7** was not established; however in previous work we established by total synthesis that the stereogenic centers of **2** (2′ and 5′) had *S,S* configuration, and are now suggesting a similar assignment for the corresponding stereogenic centers of **3**–**7**. Similar to trivial names of **2** and **3,** we propose that **4**–**7** be named polanrazines C–E.

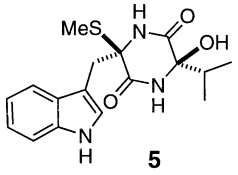
Dioxopiperazines are common secondary metabolites produced by a variety of microorganisms of both marine and terrestrial origin; in fact V isolates of *P. lingam* produce a variety of epithiodioxopiperazines including the phytotoxins sirodesmins (Pedras, 1998). On the other hand, dioxopiperazines such as polanrazines C-E having OH/OR groups at the α-carbon of the amino acid residues appear to be rather unusual (e.g. Nozawa et al., 1989; King et al., 1992).



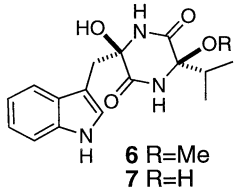
3



4



5



6 R=Me
7 R=H

The phytotoxicity assays of polanrazines A–E (**2**–**7**) on plants resistant and susceptible to *P. lingam* indicated that both **4** and **6** had moderate but selective toxicity, causing necrotic and chlorotic lesions (1–3 mm diameter) on brown mustard leaves (5×10^{-4} M), whereas no damage was observed on canola or white mustard leaves. Lower concentration of these metabolites (**2**–**7**) caused no macroscopic effects. Furthermore,

preliminary inoculations of canola and brown mustard with spores of isolate IBCN 19 have shown that brown mustard is more susceptible to Polish isolates than canola, whereas the W isolates from Canada cause low to no disease symptoms on either species (Gugel and Petrie, 1992).

The present studies indicate that blackleg W isolates originating from Poland produce metabolites similar to those obtained from Canadian isolates Laird 2 and Mayfair 2 (Pedras et al., 1998, 1999). It may be that Mayfair 2 and Laird 2 isolates have not originated in Canada but got to North America through seed brought in from European countries (Pedras and Biesenthal, 2000). Further studies to establish the secondary metabolite profiles of blackleg fungal isolates will be of great assistance in the chemotaxonomic classification of the "complex species" presently known as *P. lingam*/*L. maculans*. Polanrazines A–E will be useful chemotaxonomic markers for grouping new isolates in the appropriate "W group" as they do not appear to be produced by other blackleg isolate types. Nonetheless, this statement does not imply that the virulence of the Polish fungal isolates is related with the production of polanrazines A–E, such a conclusion will require additional investigations. Moreover, the metabolite profile obtained for Polish isolates suggest that this group is distinct from the W Canadian group (*P. wasabiae*). Because brown mustard, a crop traditionally resistant to blackleg disease, was shown to be more susceptible to these "W Polish" isolates, there is a possibility that such isolates will cause new blackleg epidemics. Thus, to prevent additional disease outbreaks, systematic screening of blackleg isolates must be carried out in areas where brown mustard is widely grown.

3. Experimental

3.1. General

All chemicals were purchased from Sigma-Aldrich Canada Ltd., Oakville, ON. All solvents were HPLC grade and used as such, except for CH_2Cl_2 and $CHCl_3$ which were redistilled. Preparative (prep.) TLC: (Merck, Kieselgel 60 F_{254}), 20 × 20 cm × 0.25 mm; analytical TLC (Merck, Kieselgel 60 F_{254}, aluminum sheets) 5 × 2 cm × 0.2 mm; compounds were visualized by exposure to UV light and by dipping the plates in a 5% aq (w/v) phosphomolybdic acid solution containing a trace of ceric sulfate and 4% (v/v) H_2SO_4, followed by heating at 200 °C. Flash column chromatography (FCC): silica gel Merck, grade 60, mesh size 230–400, 60 Å.

High pressure liquid chromatography (HPLC) analysis was carried out with a high performance liquid chromatograph equipped with quaternary pump, automatic injector, and diode-array detector (wavelength

range 190–600 nm), degasser, and a Hypersil ODS column (5 μm particle size silica, 4.6 i.d. × 200 mm), equipped with a low-dispersion column-inlet filter. Two different elution methods were employed; method A: linear gradient from 75% H_2O–25% CH_3CN to 100% CH_3CN, at a flow rate 1.0 ml/min over 35 min; method B: isocratic elution 80% H_2O–20% CH_3CN for 10 min, followed by gradient elutions, 80% H_2O–20% CH_3CN to 60% H_2O–40% CH_3CN for 10 min, and 60% H_2O–40% CH_3CN to 25% H_2O–75% CH_3CN for 10 min, at a flow rate 1.0 ml/min.

NMR spectra were recorded on a Bruker AMX 300 or 500 spectrometer; for ^1H (300 or 500 MHz), δ values were referenced to CD_3OD (CD_2HOD at 3.31 ppm), CD_2Cl_2 ($CDHCl_2$ at 5.32 ppm), or CD_3CN (CHD_2CN at 1.94 ppm), and for ^{13}C (75.5 or 125.8 MHz) referenced to CD_3OD (49.15 ppm), CD_2Cl_2 (54.00 ppm), or CD_3CN (118.69 ppm). The list of coupling constants (J, reported to the nearest 0.5 Hz) corresponds to the order of the multiplicity assignment.

Mass spectra (MS) [high resolution (HR), electron impact (EI), or fast atom bombardment (FAB)] were obtained on a VG 70 SE mass spectrometer, employing a solids probe. Specific rotations, $[\alpha]_D$ were determined at ambient temperature on a Perkin-Elmer 141 polarimeter using a 1 ml, 10 cm path length cell; the units are 10^{-1} deg cm^2 g^{-1} and the concentrations are reported in g/100 ml. Infrared spectra were recorded on a Bio-Rad FTS-40 spectrometer. Spectra were measured by the diffuse reflectance method on samples dispersed in KBr; only diagnostic peaks are reported.

3.2. Fungal cultures and bioassays

The eight Polish isolates of *P. lingam*, IBCN 19-26, were obtained from the IBCN blackleg collection at Agriculture and Agri-Food Canada, Saskatoon. Liquid cultures of these isolates were grown as previously reported (Pedras and Biesenthal, 2000). For isolation of metabolites, isolate IBCN 19 was grown in 250 ml Erlenmeyer flasks containing 100 ml minimal medium (total 4 l) inoculated with fungal spores at 2×10^9 per flask were incubated on a shaker at 150 rpm, at 24±2 °C for 6 days, and worked up as described below.

Plants were grown in a growth chamber for 3 weeks, with 16 h light (fluorescent and incandescent, 450–530 μmol s^{-1} m^{-2})/8 h dark, at 24±2 °C. Three different species of known resistance to V isolates of *Phoma lingam* were employed in the bioassays: *Brassica napus*, cv. Westar (susceptible) and *B. juncea*, cv. Cutlass (resistant), *Sinapis alba*, cv. Ochre (resistant). EtOAc extracts (2 mg/ml) or pure compounds (5×10^{-4}, 1×10^{-4}, 2×10^{-5}M) where dissolved in MeOH–H_20 (1:1). Leaves were punctured with a needle (6 punctures per leaf) and 10 μl droplets (6 droplets per leaf) were applied on punctured sites. Control leaves were treated similarly employing a 1:1 MeOH–H_20 solution. Plants were incubated in a growth chamber as reported above (16 h light/8 h dark, at 24±2 °C); leaves were observed over a 1-week period and the diameter of each lesion was measured after 7 days.

3.3. Isolation of compounds 3–7

The broth and mycelium were separated by gravity filtration, the broth (3 l) was concentrated (400 ml) and extracted with EtOAc (220 mg). Flash column chromatography (FCC) (eluted with CH_2Cl_2–MeOH, 95:5, 250 ml; 90:10, 250 ml of the EtOAc extract yielded the following fractions: F1 containing compounds **1** and **3**, F2 containing compounds **2**–**4**, F3–F4 containing compounds **2** and **5**, F6–F9 containing compounds **6** and **7**. Prep. TLC separation (CH_2Cl_2–MeOH, 97:3, double elution) of F1 (20 mg) yielded phomapyrone A (**1**, 4 mg) and polanrazine B (**3**), which was combined with a prep. TLC fraction eluted from F2 and further separated to yield chromatographically homogeneous material (**3**, 3.5 mg). Prep. TLC separation (CH_2Cl_2–MeOH, 96:4, double elution) of F2 (30 mg) yielded polanrazine B (**3**) which was combined with a prep. TLC band obtained from F1, and a mixture (20 mg) containing polanrazines C and D (**4**, **5**). Separation of this mixture using multiple prep. TLC (CH_2Cl_2–MeOH, 96:4, multiple development) yielded chromatographically homogeneous materials **4** (6.5 mg) and **5** (2.5 mg). Finally prep. TLC separation (CH_2Cl_2–MeOH, 96:4, double elution) of F6-9 (6 mg) yielded polanrazine E (**6**, 1 mg) and F (**7**, 1.5 mg).

3.4. Polanrazine B (3)

HPLC $t_R = 22.4$ min (solvent system B); $[\alpha]_D -60°$ (c 0.2 $CHCl_3$); HR–EI–MS m/z (% relative abundance) measured: 377.1230 (377.1232 calc. for $C_{18}H_{23}N_3O_2S_2$); FTIR υ_{max}: 3388, 3190, 2926,1665, 1452, 1413, 1075 cm^{-1}; λ_{max} (log ε) 218 (4.5) nm.

3.5. Polanrazine C (4)

HPLC $t_R = 10.6$ min (solvent system B); $[\alpha]_D$ 16° (c 0.18 MeOH); HR–EI–MS m/z (% relative abundance) measured: 347.1306 (347.1304 calcd. for $C_{17}H_{21}N_3O_3S_1$); FTIR ν_{max}: 3335 3220, 2956, 2926, 1673, 1435, 1075 cm^{-1}; λ_{max} (log ε) 219 (4.3) nm.

3.6. Polanrazine D (5)

HPLC $t_R = 11.3$ min (solvent system B); $[\alpha]_D -8.2$ ° (c 0.18 MeOH); HREIMS m/z (% relative abundance) measured: 347.1306 (347.1303 calc. for $C_{17}H_{21}N_3O_3S_1$. FTIR ν_{max}: 3444, 3347, 2968, 2926, 1677, 1625, 1465, 1427, 1058 cm^{-1}; λ_{max}(log ε) 219 nm (4.0).

3.7. Polanrazine E (6)

HPLC $t_R = 9.6$ min (solvent system B); $[\alpha]_D - 6$ ° (*c* 0.07 MeOH); HREIMS *m/z* (% relative abundance) measured: 331.1531 (331.1532 calc. for $C_{17}H_{21}N_3O_4$). FTIR v_{max}: 3342, 3223, 2962, 2927, 2857, 1682, 1429, 1094 cm_{-1}; λ_{max} (log ε) 222 (4.3), 282 (3.7) nm.

3.8. Polanrazine F (7)

HPLC $t_R = 7.0$ min (solvent system B); $[\alpha]_D - 10$ ° (*c* 0.26 MeOH); HR–EI–MS *m/z* (% relative abundance) measured: 317.1377 (317.1376 calcd. for $C_{16}H_{19}N_3O_4$); FTIR v_{max}: 3319, 2970, 2931, 1680, 1426, 1086, 1043 cm_{-1}; λ_{max} (log ε) 219 (4.2), 281 (3.5) nm.

Received 21 May 2001; received in revised form 23 July 2001

Abstract

In *Pssu-ipt*-transformed tobacco, apical dominance was released by defoliation of the upper nodes, while the apex remained intact. After defoliation, the concentration of cytokinins (CKs) increased whereas IAA remained constant, evoking an increase in the CK/IAA ratio in the buds. Moreover, defoliation resulted in a tremendous increase in the concentrations of aromatic amines (AAs): tyramine (TYR), phenethylamine (PEA) and an as yet unidentified compound. Although the total aliphatic monoamine and polyamine (PA) concentration remained constant, putrescine (PUT) and spermidine (SPD) concentrations in the axillary buds decreased, whereas the concentration of spermine (SPM) increased. Similar changes in PAs and AAs could be observed in the buds of untransformed SR1 plants after decapitation, whereas defoliation without removal of the apex had no effect. This is the first report on the possible involvement of PAs and AAs in apical dominance. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

By its correlative control the shoot apex exerts a central coordinating influence on plant development (eg. axillary bud growth, the orientation of laterals, the growth of rhizomes and stolons, and leaf abscission) (Phillips, 1975; Cline, 1991, 1997; Tamas, 1995; Beveridge, 2000). Tamas (1995) discussed the up-to-date knowledge of the hormonal regulation of apical dominance and this for shoot apex dominance as well as for reproductive dominance. Most important conclusions concerning the expression of the dominance exerted by the shoot apex were (Tamas, 1995).

(1) The apex produces IAA and may be substituted for by applied IAA (references in Hillman, 1984; Tamas, 1995). The expression of dominance by the shoot apex requires basipetal IAA transport in the subapical part of the stem, as evidenced by the release of axillary buds from inhibition by application of TIBA in lanolin below the shoot apex (Tucker, 1978). The weak apical dominance in tomato line "Craigella" may be explained by a lack of IAA transport from the shoot apex (Brenner et al., 1987).

(2) Exogenous cytokinin application to axillary buds stimulates bud outgrowth. Axillary bud growth potential is generally well correlated with the level of naturally occurring cytokinins in the bud. This may be under the control of the shoot apex (auxin gradient). Repressed lateral buds do not synthesize cytokinins. Axillary bud growth might be triggered either by a redirection of the cytokinin supply from the roots, necessary to initiate axillary bud growth, or by a decline in auxin supply from the apex, enabling the axillary buds to start cytokinin synthesis or by the conversion of an inactive precursor to an active cytokinin (references in Tamas, 1995).

(3) Exogenously applied gibberellins do not release axillary buds from apical dominance, but are able to cause rapid elongation in released buds.

(4) The inhibition of axillary bud growth is closely related to the abscisic acid content of the buds. In *Phaseolus vulgaris*, bud outgrowth is preceded by several hours by a decline in ABA level (Gocal et al., 1991). In nonbranching mutants of tomato (Blind, Cls) the ABA content of the axillary buds is much higher than in the

branching parental line *Craigella* (Tucker, 1978). The ABA accumulated in inhibited buds is either and most probably transported from the leaves or synthesized within the buds. ABA is probably not the correlative signal released by a dominant shoot apex, but its level is regulated by basipetal transport of IAA. This way ABA acts in the suppressed bud as a second factor under control of a dominant shoot apex. In *Phaseolus*, decapitation lowers the ABA level in axillary buds, but this is prevented by the application of IAA to the cut stump (Knox and Wareing, 1984). The function of ABA might be the inhibition of the cell cycle (Nougarede et al., 1990).

(5) In spite of some reports on the involvement of ethylene in apical dominance, recent evidence shows a general lack of correlation between axillary bud growth inhibition and ethylene levels in bud tissue (references in Tamas, 1995).

Although much information is available on hormonal effects on apical dominance, the basic mechanism of apical dominance remains unresolved. IAA seems to be the best candidate as correlative signal. Cytokinin might

Table 1
Growth of axillary buds and leaves of intact *ipt*-plants, and of plants defoliated at the upper 6 nodes (1–6) or at the lower ones (7–12). The more + the more swelling was seen. Negative sign means no effect. 0 = no axillary shoot outgrowth. Lengths are given in mm. Remnants are the remnants of the winged petioles. Apical leaves and apical buds are the leaves and buds above the upper defoliated node (+1: just above, +3 more to the apex). Axillary shoots: lengths in mm of the shoots that developed from the buds. Axillary shoots + leaf: total length of axillary shoot + longest leaf (in mm)

be the key factor in promoting axillary bud growth (Tamas, 1995).

In a previous study with *ipt* (isopentenyl transferase)-transformed tobacco plants we analysed the polyamine and sterol composition in leaves of different physiological age (Geuns et al., 1997). In these plants the chimeric *Pssu-ipt* gene consisted of gene 4 (*ipt*) from *Agrobacterium tumefaciens* coupled to the light-inducible ssu-promotor (*Pssu*) from the gene encoding for the small subunit of Rubisco of *Pisum sativum* L. The *ipt* gene encodes an isopentenyl transferase that catalyses the conversion of 5′-AMP and isopentenyl pyrophosphate into isopentenyl-adenosine-5′-monophosphate, the first and rate-limiting step in the biosynthesis of CKs. Transformed *ipt*-plants are generally known to have a low apical dominance, but our untreated *ipt*-transformed tobacco plants did not show release from apical dominance at the age used. After cutting the leaves, we observed an enhanced outgrowth of the axillary buds. Polyamines are essential in plant growth and differentiation and are involved in cell elongation and division (Galston and Kaur-Sawhney, 1995). Therefore, we studied polyamines, amines and hormones during the development of axillary buds of *ipt* transformed plants after cutting off the leaves.

2. Results and discussion

In preliminary experiments it was shown that removal of all the leaves of *ipt*-transformed tobacco plants provoked the swelling of all the axillary buds after 3 days (upper, middle and lower ones). However, 6 days after defoliation, only the upper buds continued swelling and growing and the lower buds became repressed again. Removal of only one leaf at the top (leaf 1, see Fig. 5), in the middle (leaf 8) or at the bottom (leaf 15) did not influence the swelling of the axillary buds (results not shown). Removal of all the leaves of control SR1 plants had no influence on the outgrowth of the axillary buds (results not shown).

In intact *ipt*-plants all the axillary buds remained small and repressed for the whole duration of the experiment (Table 1, intact). Removal of the upper 6 leaves provoked swelling of the upper axillary buds (1–6) as well as of the lower ones (7–12) after 3 days (Table 1, 3 days). The upper buds continued swelling and developed side shoots and even the leaves of the side shoots expanded (Table 1, days 15 and 21). After 6 days the lower axillary buds arrested swelling and obviously became repressed again. The remnants of the winged petioles of the upper leaves were also enlarged and continued expanding till day 15. It has to be emphasised that in all these experiments the apex remained attached to the plants. The apex leaves started growing out and also their axillary buds were swelling. After 21 days the apex leaves became very large and the axillary buds of the apex leaves just above the first defoliated node developed shoots (Table 1, Fig. 5). This enhanced growth of the apex leaves and the remnants of the winged petioles may be explained by an enhanced availability of nutrients as the sink by the upper leaves was removed. Removal of the lower 6 leaves provoked a minor swelling of the lower axillary buds after 3 days, whereas the upper buds were not influenced. After 6 days the lower buds did not continue swelling and obviously became repressed again. The remnants of the winged petioles did not grow out. The apex leaves grew out but at 21 days their length was only a fraction of the length of the apex leaves grown on plants with the upper leaves removed, and their axillary buds did not swell (Table 1). Defoliation of untransformed SR1 plants did not influence swelling or outgrowth of axillary buds (results not shown). To the best of our knowledge this is the first report that in *ipt*-plants removal of the upper leaves evokes the release from apical dominance at an early stage of development.

From the above observations it was obvious that removal of the upper leaves provoked the most pronounced physiological effects on release of apical dominance. Therefore, we studied the influence of the removal of the upper 5 leaves on the swelling and polyamine content of the upper 5, the middle 5 and the lower 5 axillary buds. For each treatment the buds of 11 plants were combined giving sufficient material for biochemical analyses. The upper and middle buds doubled their fresh and dry weights between days 1 and 2 after defoliation, the lower buds doubling in size between days 2 and 3 (results not shown).

In the axillary buds the following AAs and PAs were identified by co-chromatography and LC–MS data obtained with authentic standards: PUT, SPD, SPM, TYR and PEA (results not given). A compound eluting in the HPLC chromatograms before PEA could not be positively identified, but it was certainly not identical to diaminopropane. For convenience, it was given the same calibration value as that of PEA and therefore expressed as μmolU or nmolU.

In untreated *ipt*-plants the concentrations of the PAs and AAs did not change significantly during the duration of the experiment (results not shown).

After defoliation of the upper 5 nodes, the PUT concentration decreased in upper buds 1 day after defoliation (Fig. 1A), and was partly restored from day 2 on. The PUT concentration at day 1 was lower due to a decrease of the PUT amount per bud and not due to a sudden increase in weight. The PUT concentration started to increase between days 1 and 2. This means that its rate of biosynthesis was much higher than the growth rate as the buds doubled in weight between days 1 and 2 and its concentration still increased. Consequently the absolute amounts of PUT per bud significantly increased (Fig. 1A). The SPD concentration gradually

decreased between days 0 and 3 (Fig. 1B). At day 1 the SPD concentration was lower due to less SPD per bud. As the concentration of SPD remained more or less constant between days 1 and 2 it can be deduced that its rate of biosynthesis paralleled the growth rate as both the weight of the buds and their SPD content doubled (Fig. 1B). The SPM concentration increased at day 1 and decreased when the growth of the buds proceeded (Fig. 1C). The rate of SPM biosynthesis was higher than the growth rate as its concentration increased between 0 and 1 days, paralleled growth rate between days 1 and 2 and levelled off between days 2 and 3. Possibly the increase in SPM is partly due to a rapid conversion of PUT and SPD into SPM as the absolute amounts of PUT and SPD significantly decreased at day 1 and that of SPM significantly increased.

In middle buds the changes of PUT, SPD and SPM showed the same trend as in upper buds, however, they were less pronounced whereas in the lower buds hardly any changes were observed (results not shown).

In the upper buds of defoliated plants the concentration of TYR, PEA and the unknown increased very significantly already 1 day after defoliation and continued increasing until day 3 after defoliation (Fig. 2 A–C). The amount of TYR per bud increased from 0.43 nmol/bud to 19.3 at day 3, i.e. ca. 45 ×, that of PEA from 0.1 nmol/bud to 0.91 (9×) and of the unknown from 0.13 to 1.68 nmolU/bud (ca. 13×).

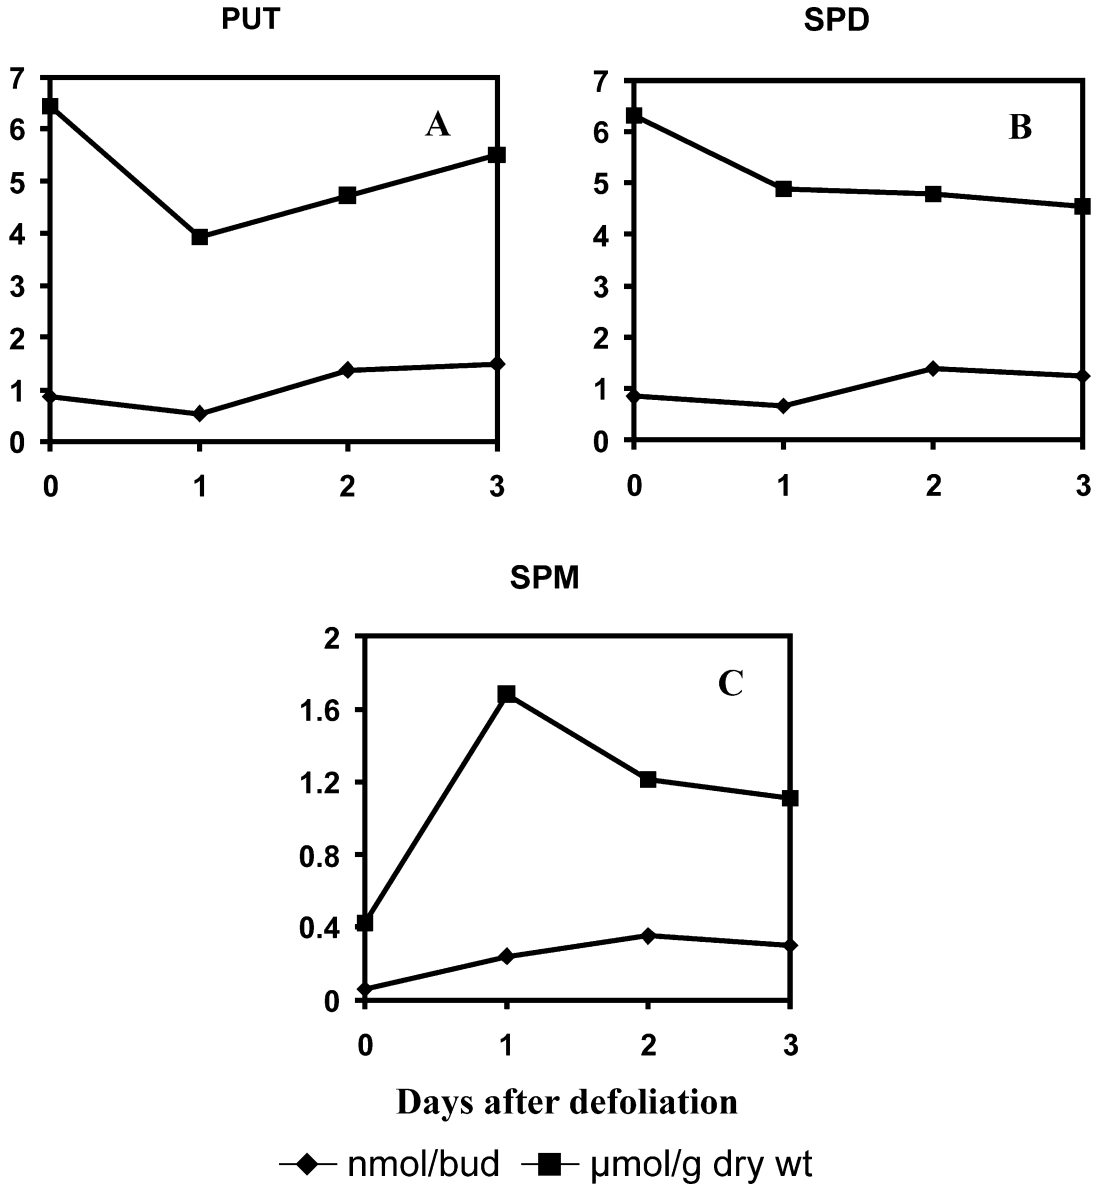

Fig. 1. Put (A), Spd (B) and Spm (C) in upper axillary buds after defoliation of the upper 5 nodes of *ipt*-plants. The concentration is in µmol/g dry wt, the amounts in nmol/bud; s.e. between 5 and 10%, not given in the figure as error bars have the same size as the data labels.

In the middle and lower buds the same trend of changes of amines occurred as in upper buds, but much more attenuated and with a tendency to decrease at day 3, as these buds became repressed again (results not shown).

In untransformed SR1 tobacco plants, no effects of defoliation on axillary bud growth were observed. Release of apical dominance was only induced by decapitation. In order to investigate whether the same phenomena could be observed by decapitation of SR1 plants as by defoliation of *ipt*-plants, SR1 plants were decapitated above the first leaf having a length of ca. 20 mm.

The fresh and dry weights of the upper axillary buds of intact SR1 plants did not change significantly. The fresh and dry weights of upper axillary buds from decapitated plants gradually increased with time starting from 6 h after decapitation. As expected application of 1% IAA to the cut surfaces nearly abolished the weight increases of the buds (results not shown). The effects of decapitation decreased from the first to the fifth nodes, the upper 3 buds showing the most pronounced effects that furthermore occurred earlier than in lower buds. However, to reduce the information only the mean values of buds 1–3 are discussed.

In intact SR1 plants the concentration of PUT, SPD, TYR and PEA did not change significantly, nor the amounts per bud. SPM was present only in trace amounts (results not shown).

In decapitated SR1 plants the PUT and SPD concentration remained constant in upper buds, because growth increase was compensated for by higher PUT

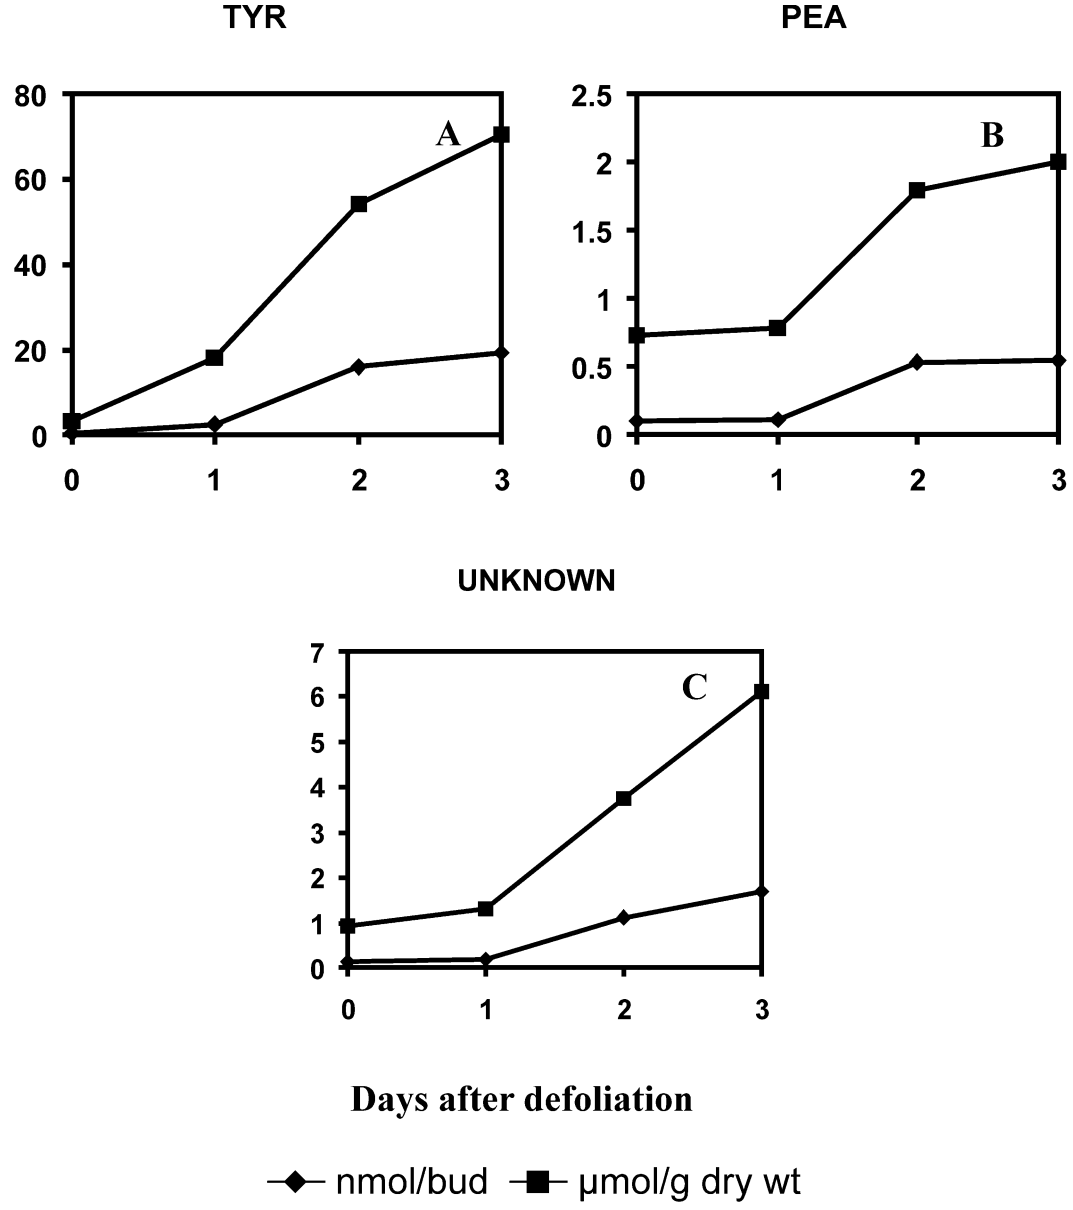

Fig. 2. Tyr (A), Pea (B) and unknown (C) in upper axillary buds after defoliation of the upper 5 nodes of *ipt*-plants. The concentration is in µmol/g dry wt, the amounts in nmol/bud; s.e. between 5 and 10%, not given in the figure as error bars have the same size as the data labels.

and SPD amounts per bud (results not shown). The concentration of TYR started to increase from 6 h on to reach a concentration of 28 μmol/g dry wt (Fig. 3A), due to a huge accumulation per bud (change from 0.12 to 46.7 nmol/bud (389 ×) at day 3). The PEA concentration started increasing after 12 h (Fig. 3B), the accumulation in the bud at 6 h already changing from 0.04 to 30.9 nmol/bud (772 ×) at day 3. The fifth bud showed only a small increase in weight and a small increase in AA concentration (results not shown).

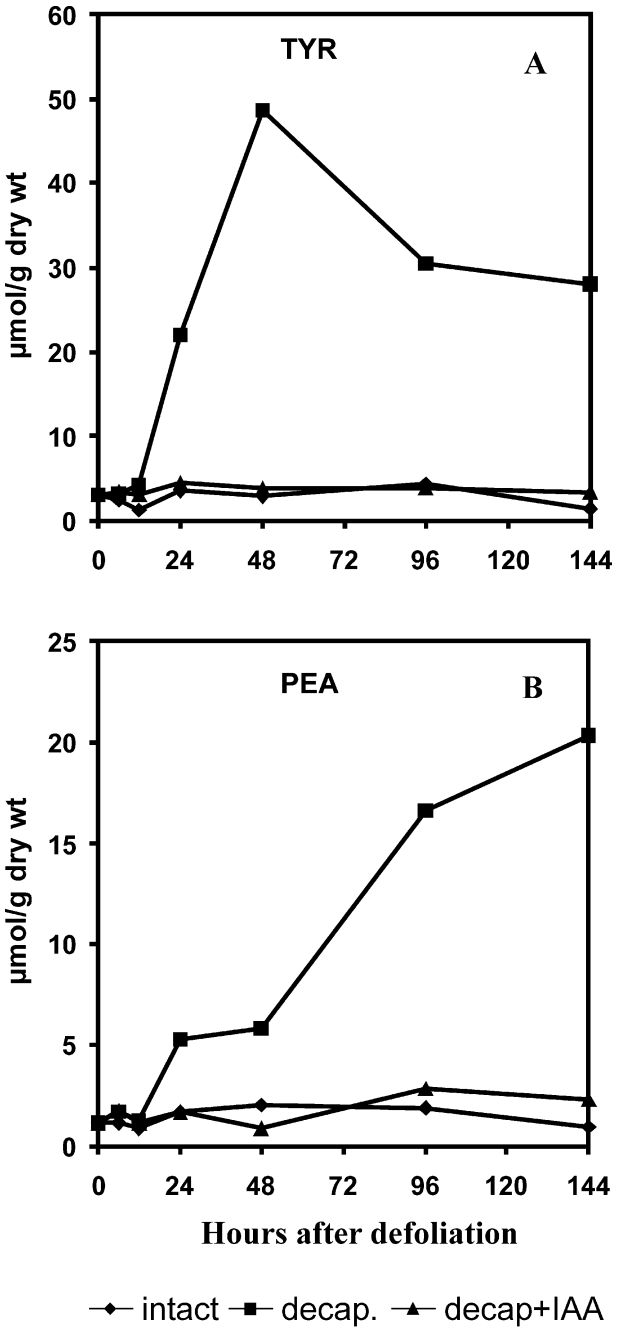

Fig. 3. Tyr (A) and Pea (B) concentration in μg/g dry wt in upper axillary buds of decapitated SR1 plants and in decapitated plants that received 1% IAA in lanolin; s.e. between 5 and 10%, not given in the figure as error bars have the same size as the data labels.

Application of IAA to the stumps of decapitated SR1 plants completely prevented the increases in concentration and in accumulation of PAs (results not shown) and AAs (Fig. 3A and B) as well as release from apical dominance.

As far as we know no studies have been published on the changes of AAs in the axillary buds in relation with apical dominance. The huge increases in AA concentration during release from apical dominance as well as the inhibition of both AAs and growth when IAA is applied to decapitated SR1 plants, suggest that AAs may have a fundamental function in the release from apical dominance or in the subsequent development and growth of the axillary shoots. From our results it is not clear whether these compounds mediate the action of plant hormones or whether they are part of their signal response pathways. Further research should be done to unravel their exact function.

High PA concentrations have often been correlated with cell division and rapidly growing tissues (Serafini-Fracassini, 1991) but the function of AAs is far from being understood. One of the first indications for a physiological function of TYR and PEA in tobacco was reported by Perdrizet and Prevost (1981). PEA was the main amine of green vegetative tissue, but TYR was the main amine in the stem and it accumulated in the flowers. Béranger-Novat et al. (1994) showed that dormancy break of spindle tree embryos by GA3 was accompanied with an increase in aliphatic amines and ADC activity, whereas TYR decreased. Aziz et al. (1998) found that the effects of salt stress on proline accumulation were correlated with the changing levels of PAs and TYR in leaf discs of tomato. Low concentrations of applied TYR stimulated the proline accumulation. In leaf explants of *Medicago sativa* the early cellular events were correlated with the endogenous contents of PAs and AAs. Proembryogenic cell mass formation was positively correlated with free TYR and negatively correlated with free PEA contents (Cvikrová et al., 1999). Martin-Tanguy (1997) found a relationship of PAs and AAs in relation with flowering in tobacco. SPD as well as TYR availability (in conjugated forms) could be limiting factor(s) in sexual development in tobacco.

Christou and Barton (1989) found that various substituted phenethylamines were extremely toxic towards wild-type callus tissue cultures of tobacco, soybean, corn and sunflower. In calli from plants transformed with genes encoding enzymes of CK biosynthesis, the toxicity was inversely correlated with the CK content. Exogenous applied CKs reduced the toxicity. Tobacco crown gall cultures with a high CK content were resistent. Phenethylethanol and PEA were weakly inhibitory. Structures with an additional aromatic hydoxyl (TYR, octapamine) showed a severe toxicity. A second hydroxyl

group on the aromatic ring (dopamine) enhanced toxicity and even calli containing the *ipt*-gene became inhibited. Epinephrine with two aromatic hydroxyls and a methyl group on the amine, was lethal to all types of tissues tested, including crown gall. It is a very interesting point that PEA, TYR and an unknown very strongly accumulated in axillary buds together with the CKs (see below). It is not known whether these AAs have any antagonistic activity with CKs in the axillary buds of defoliated *ipt*-plants or decapitated SR1-plants. Further research should be done to unravel these problems.

As the effects of defoliation of upper nodes of transgene *ipt*-lines were most pronounced in upper axillary buds, cytokinins (CKs) and IAA levels in these organs were determined. IAA, iPMP, iPA, iP, iPG, ZRP, DHZP, ZR, DHZR, Z, DHZ, Z-N9-G, DHZ-N9-G were the compounds analysed in three independent series of sampling.

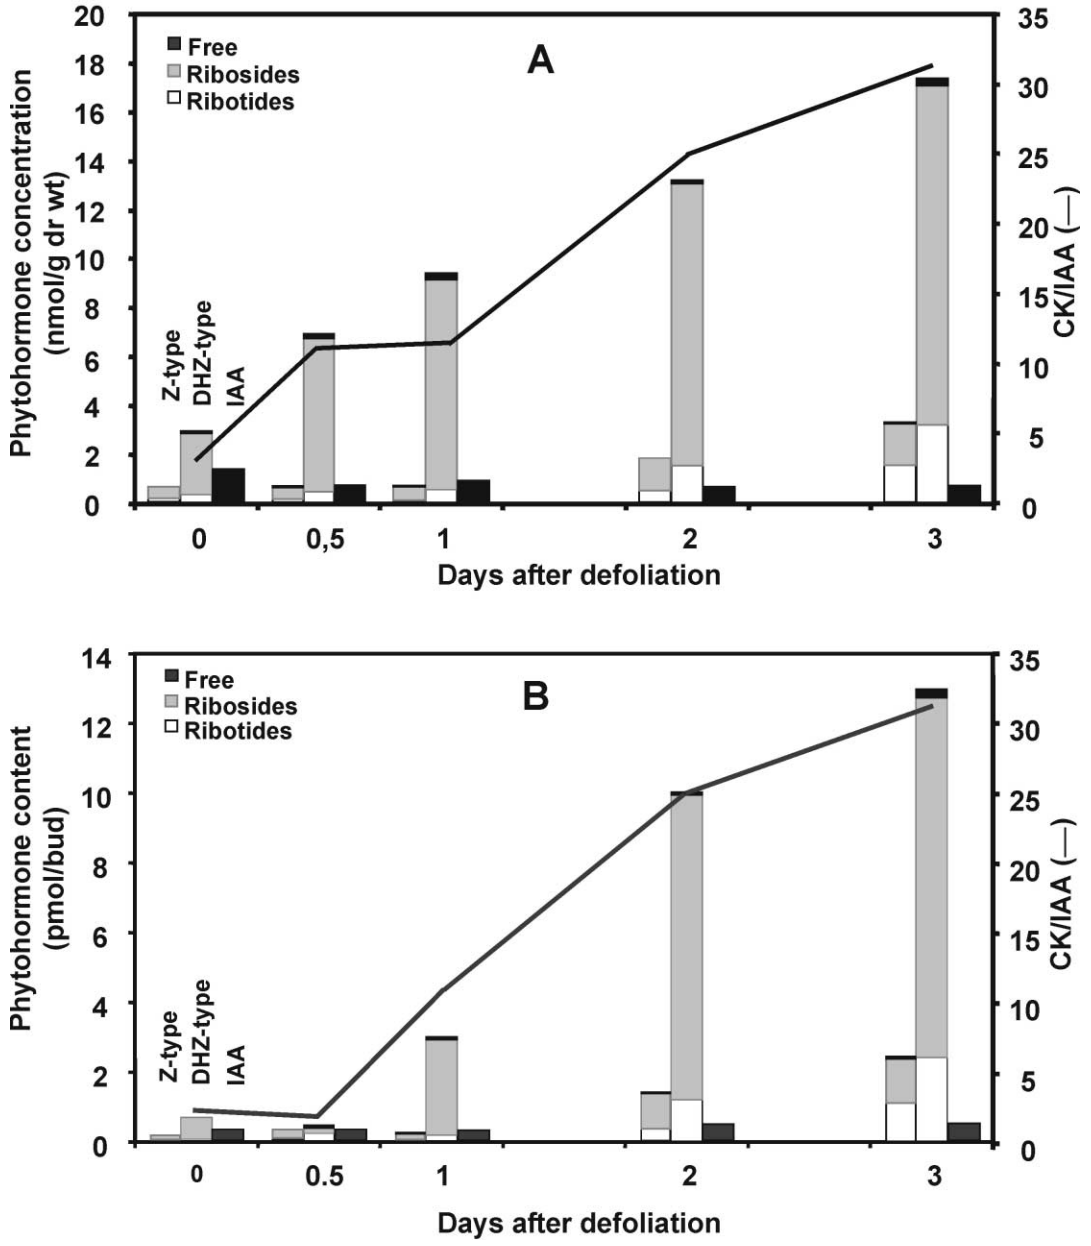

Fig. 4. CKs and IAA in upper axillary buds of *ipt*-plants after defoliation of the upper 5 nodes. A: CKs (in nmol/g dry wt) in function of time after defoliation. DHZ: dihydrozeatin (black zone, DHZ-type bars); DHZR: dihydrozeatin riboside (grey zone, DHZ-type bars); DHZRP: dihydrozeatin-5′-phosphate (white zone, DHZ-type bars); Z: zeatin (black zone, Z-type bars); ZR: zeatin riboside (grey zone, Z-type bars); ZRP: zeatin riboside-5′-phosphate (White zone, Z-type bars); IAA: indolyl-3-acetic acid; CK/IAA: ratio of CKs over IAA concentration (curve). B: CKs in pmol/bud. Although between different experiments the CK changes followed the same trend, the absolute amounts found differed among the individual experiments. Therefore, a typical analysis is given.

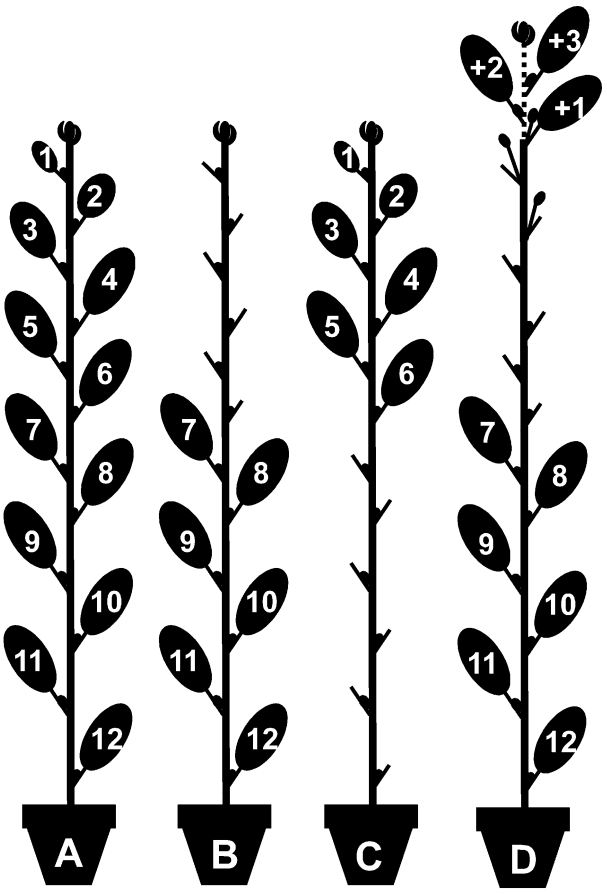

Fig. 5. A. Numbering of leaves and axillary buds of SR1 and *ipt*-plants. B. Defoliation of the six top leaves. C. Defoliation of the six lower leaves. D shows a defoliated plant (upper nodes) after a 3 weeks growth period. The apex leaves and axillary buds have been growing and are numbered +1–+3 (see Table 1).

An initial increase in the total amount of CKs, caused by the dihydrozeatin derivates, was observed 12 h after defoliation (Fig. 4). As the bud dry weights remained constant, an increased CK concentration occurred. A 3-fold increase in the levels of cytokinins occurred at day 2 in comparison to day 1. Although this increase coincided with a doubling in fresh and dry weights, still an enhanced concentration was observed meaning that their rate of accumulation in the bud surpassed the growth rate of the buds. This phenomenon was due to a dramatic increase in the dihydrozeatin type CKs and to a lesser extent the zeatin type CKs. For both types of CKs, mainly the ribosides accumulated after defoliation. Also their ribotide precursors showed a strong increase in concentrations. The initially relative low ZRP level was probably caused by its high turn-over rate into ZR, DHZP and Z. The free bases zeatin and dihydrozeatin demonstrated a steady state level during the first day and a slight increase from day 2 on. The concentration of zeatin, probably the physiologically active component (Dewitte et al., 1999; Laureys et al., 1998) seems to be strictly regulated as no huge accumulation was observed. The glucosides and iP-components were present only in small amounts and their concentrations were not significantly influenced by defoliation (results not shown).

Analysis of upper axillary buds of intact control SR1 plants revealed only trace amounts of the CKs found in buds of untreated *ipt*-plants (results not shown). From these analyses it may be concluded that the upper axillary buds of untreated *ipt*-plants contained CKs in amounts far above those in control SR1 tobacco, proving that the *ipt*-gene was active before defoliation.

Buds showed no significant difference in levels of IAA (Fig. 4B) during the experiment, resulting in a slight decrease of its concentration (Fig. 4A). This seems to point out that IAA in the buds acts independently from the physiological changes. As after defoliation, the total amount of CKs increased whereas the IAA levels remained constant, the CK/ IAA balance in the upper axillary buds shifted in favor of release from apical dominance. After passing a certain threshold, not being reached by WT or intact *ipt*-plants, buds started to grow. In pea, decapitation and partial defoliation led to slightly decreased levels of ABA, unchanged levels of GAs, lowered levels of IAA (2-fold) and significantly enhanced levels of Z and ZR (up to 5-fold) in the internodes. The release of apical dominance corresponded well with the (Z + ZR)/IAA ratio (Kotov and Kotova, 2000). Emery et al. (1998) found that in lupin, a plant not adhering to classical apical dominance, the best relationship between the level of growth factors in apical buds and branching pattern was the ratio CK/IAA, implying that a high CK/IAA at a given bud would promote growth.

In the buds, mainly DZR and ZR were found to accumulate after triggering. As shown by Werbrouck et al. (1995), these compounds are the dominant CK derivates being transported through the xylem out of the roots towards the upper organs. Therefore, defoliation might shift the xylem transpiration stream from the leaves to the buds causing an increase in CK levels. However, as buds were released from apical dominance only after defoliation of five but not of a single leaf, a relocation of CK transport alone does not seem to explain the complete process. In *Ipomoea nil*, Cline et al. (1997) decapitated the shoots and defoliated the upper nodes. IAA applied to the cut surfaces of the stems and to all the petioles but one prevented the release of the axillary buds, except the bud of the petiole stump without IAA. Cambridge and Morrid (1996) showed a transfer of IAA from the leaf by the phloem to the polar auxin transport pathway in pea. These results support the idea that the IAA supply from the leaf is important in the maintenance of apical dominance. After decapitation in bean (Bangerth, 1994) and in pea (Li et al., 1995), strong increases in CK levels in the xylem were observed. Feeding NAA to the top of the plant could

reduce these amounts. Defoliating the 5 upper nodes of *ipt* transformed plants might therefore cause a drop in the basipetal IAA transport, resulting in an increased release of mainly DZR and ZR from the roots into the xylem. According to Lomax et al. (1995), the velocity of basipetal IAA transport varied from 5 to 20 mm/h depending on the species and the place of measurement across the stem. Plants used in our experiment were treated at a height of about 25 cm. This implies that the reduced IAA signal would reach the roots after at least 12 h. Therefore, the initial increase in CK amount and concentration after 12 h might be due to a relocation of the CK transport from the leaf to the bud. The strong increase in CK levels and dry weight between days 1 and 2 however, could be the result of a response of the roots after a decline in IAA transported out of the leaves. The removal of only one leaf causes probably a minor reduction in IAA transport that is not sufficient to induce enhanced CK levels in the xylem. Swelling of the lower buds, which took place at the same time as for the upper buds is then also caused by these elevated CK concentrations in the xylem. However, because the upper buds act as a stronger sink, they will become dominant over the lower ones. Why lower buds stop swelling after defoliation of their nodes is however unclear. Differences in age of leaves and/ or buds in comparison to the upper organs, causing a differential response, might explain the reason lower buds being prevented to grow out.

Faiss et al. (1997) proposed the concept that CKs have paracrine, i.e. locally restricted, functions in tobacco. Also Rupp et al. (1999) suggested that cytokinins present in *ipt*-transformed *Arabidopsis* shoot meristems are synthesised locally. These data however do not really conflict ours. The already high cytokinin concentrations in the axillary buds of the transgene lines before the onset of our experiment are probably derived from local production. The fact that we worked with a light sensitive *Pssu* promoter supports the idea that these cytokinins are not root derived. As the *ipt*-gene is already active, defoliation probably causes non *ipt*-related CKs to be transported out of other plant organs, plausibly the root, into the buds. Thereby, a certain threshold in the CK/IAA balance is passed, which causes buds to form axillary shoots. The model we propose therefore supports the idea that CK's playing a role in apical dominance of *ipt*-tranformed plants, are locally as well as root derived.

2.1. General conclusion

From our results it may be deduced that defoliation of upper nodes of *ipt*-plants leads to an enhanced CK concentration in the axillary buds, the basal level of CK being already high in *ipt*-transformed plants. As a result the CK/IAA ratio quickly exceeds a threshold value releasing the axillary buds from apical dominance. It might be possible that by a reduced IAA gradient more CKs are transported upwards from the roots to the buds. This releases both upper and lower buds from apical dominance, the lower buds becoming repressed again by the developing upper buds. Axillary bud release is accompanied by a change in PA composition (decrease of PUT and SPD, increase in SPM), their total concentration remaining constant. The release of apical dominance is also accompanied by a tremendous increase in the concentrations of TYR, PEA and a yet unknown compound. This might indicate that these compounds have a fundamental function in the subsequent growth and development of axillary buds into shoots. This study seems to be the first report on a possible function of PAs and AAs in apical dominance. However, additional studies are required to determine the exact function of these amines in relation with hormone effects.

3. Experimental

3.1. Plant material and treatment

Seeds of *Pssu-ipt*-transformed tobacco (*Nicotiana tabacum* L. cv. Petit Havana SR1) were of the same progeny and were grown as described (Geuns et al., 1997). Plants with a shoot length of ca. 30 cm and having at least 15 leaves were selected and used in the study. These plants are further named *ipt* plants. Numbering of leaves was from upper (=1) to lower leaves (see Fig 5A for numbering).

At day 0, the treatment consisted in removing different numbers of leaves (Fig. 5B and C). Care was taken not to remove or damage the axillary buds. In all cases the apex remained attached to the stems. The defoliated plants were visually inspected after 3, 6, 10, 15 and 21 days.

For the experiments using *ipt* plants, the buds of ca. 30 cm high plants were collected at different time intervals after defoliation. The upper axillary buds (1–5), the middle (6–10) and the lower ones (11–15) of the different plants were combined to obtain sufficient material for analyses. After registration of the fresh weight, the buds were frozen in liquid nitrogen and freeze dried.

Non-transformed tobacco seedlings (SR1) with a shoot length of ca. 30 cm were selected. The apex consisted of the apical meristem and the smallest leaves. The uppermost leaf of ca. 20 mm length was named the first leaf. Control SR1-plants were decapitated above the first leaf. Thirty plants were taken per treatment and all the axillary buds of the first till the fifth nodes were collected separately. One series of decapitated plants was treated with 1% IAA in lanolin to inverse the release from apical dominance.

3.2. Polyamine analysis

PAs and AAs were analysed after dansylation as described in Geuns et al. (1997).

3.3. Hormone analyses

For cytokinin and IAA determinations, buds of tobacco plants grown in a greenhouse were harvested. Samples were immediately frozen in liquid nitrogen, lyophylized and stored at −70 °C until extraction. Frozen plant samples were ground in liquid nitrogen, transferred into Bieleski solution (Bieleski, 1964) and extracted overnight at −20 °C. For respectively IAA and each cytokinin compound determined, 250 pmol of [phenyl-$^{13}C_6$]-IAA (Cambridge Isotope Laboratories Inc., Andover, MA, USA) and 10 pmol of the corresponding deuterated cytokinin standard ([$^2H_5$] DHZ, [$^2H_5$]DHZR, [$^2H_5$]DHZ-N9-G, [$^2H_5$]DHZMP, [$^2H_6$]iP, [$^2H_6$]iPA, [$^2H_6$]iPG, [$^2H_6$]iPMP from APEX Int., Honiton, Devon, UK) were added to the sample before centrifugation (24,000 *g*, 15′, 4 °C). The pellet was resuspended for 1 h at 4 °C in 80% MeOH and centrifuged once more. The supernatants of both fractions were pooled and dried. After dissolving in water, cytokinins were purified by a combination of solid phase and immunoaffinity chromatography as previously described by Redig et al. (1996). IAA is concentrated on a consecutive C18 cartridge (Prinsen et al., 1995) underneath the immunoaffinity column and methylated prior to analysis (Prinsen et al., 1995, 1997). Hormones were quantified by microLC-(ES+)MS/MS in MRM mode (Prinsen et al., 1998). The chromatograms obtained were processed by means of Masslynx software (Micromass). Concentrations were calculated following the principles of isotope dilution and expressed in nmol per gram dry wt.

Deep blue anthocyanins from blue *Dianella* berries

Stephen J. Bloor

Industrial Research Ltd, PO Box 31-310, Lower Hutt, New Zealand

Received 17 May 2001; accepted 3 August 2001

Abstract

Three anthocyanins, all acylated delphinidin 3,7,3′,5′-tetraglucosides, and a naphthalene glycoside, 2-acetyl-1,5-dihydroxy-3 methyl-8-*O*(xylosyl-(1→6)-glucosyl) naphthalene, have been isolated from the berries of two *Dianella* species, *D. nigra* and *D. tasmanica*. The anthocyanins show exceptional blueness at in vivo pH values due to effective intramolecular copigmentation involving *p*-coumaroyl-glucose units (GC) at the 7, 3′ and 5′ of the delphinidin anthocyanidin. Evidence is presented to show that the effectiveness of the copigmentation can be ranked; 3′,5′ GC > 7 GC > 3 GC. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: Liliaceae; *Dianella nigra*; *Dianella tasmanica*; Acylated anthocyanin; Blue berries; Delphinidin

1. Introduction

Anthocyanins with acylated sugar residues have been the subject of much study both for their contribution to natural flower colour and their potential as colourants for food or cosmetics. Many of the anthocyanins responsible for blue flower colour belong to this class. Typically, the most effective blue anthocyanins are those with two aromatic acyl groups attached to sugar groups which are directly attached to the anthocyanidin chromophore, e.g. ternatins (Saito et al., 1985; Terahara et al.,1996), the blue pigments of *Ceanothus* (Bloor, 1997), and cinerarin (Goto et al., 1984). Recently, evidence has also been presented to show that placement of such groups at the 3, 7 and 3′ positions is especially advantageous in terms of colour stability (Figueiredo et al., 1999).

A search for anthocyanin pigments with even greater blueness and stability has led to a study of the pigments present in the blue berries of two *Dianella* species. For the first time, delphinidin anthocyanins substituted with glucose at the 3, 7, 3′ and 5′ positions are reported. The four delphinidin tetraglucosides, **1**–**4**, described in this work bear *p*-coumaroyl groups on two, three, all four, or none of the sugars respectively.

Dianella species (Blue flax lily, blueberry lily) are rhizomatorous herbs characterised by blue or blue-violet berries. The major New Zealand species is *Dianella nigra* Colenso featuring small, intensely blue, round berries. Of the more numerous Australian species, *Dianella tasmanica* Hook. f. is remarkable for its larger and more elongated blue-violet fruits. Previous chemical studies of the genus have focused on the naphthoquinone compounds (in roots of *D. nigra* and *D. revoluta* R. Br.) which are also found in other members of the Liliaceae (Cooke and Sparrow, 1965; Briggs et al., 1975). Some of these quinones have been shown to be associated with the toxic effects of various Liliaceae species when ingested by livestock (Colegate et al., 1986).

2. Results and discussion

Preliminary analysis by HPLC of the berry juice and extract from *D. nigra* and *D. tasmanica* showed the presence of three anthocyanins (**1**–**3**). Both species contained **2** as the major pigment but *D. nigra* had **3** as a minor pigment while in *D. tasmanica* the minor pigment was **1**.

The three anthocyanins were purified from acidic water and alcoholic extracts of the berries using RP CC, cyanopropyl CC, and Sephadex LH20 CC. From ^{1}H NMR data, the predominant anthocyanin **2** comprised a delphinidin anthocyanin unit, four β-glucose sugars and three *trans*-*p*-coumaroyl groups. This was supported by the clear ESMS molecular ion at m/z 1389. Two of the glucoses and two of the *p*-coumaroyl groups were identical in the NMR spectra and were characterised by broad signals in the ^{1}H NMR spectrum. Long range H–C

4 deacyl **1**

coupling identified the anomeric protons of the sugars at C-3 and C-7 of the delphinidin unit and connections evident from a TOCSY experiment showed the 6 position of the C-3 sugar was not acylated while the 6 position of the 7 sugar was shifted downfield by acylation. An HMBC correlation showed that the one of the *p*-coumaroyl groups was attached at this latter site. The remaining set of equivalent glucose 6-*O*-*p*-coumaroyl moieties could be assigned to the 3′ and 5′ positions of the delphinidin. A long range coupling between the anomeric protons of these latter groups and a carbon signal at 148 ppm confirmed this. The diagnostic singlet signal for H-2′ and H-6′ of the delphinidin (broad at 7.9 ppm in spectra run at 25 °C but sharper at 45 °C) was further evidence for the symmetrical 3′,5′ disubstitution. Thus, **2** is delphinidin 3-glucoside-7,3′,5′-tri(6-*O*-*p*-coumaroyl-β-glucoside).

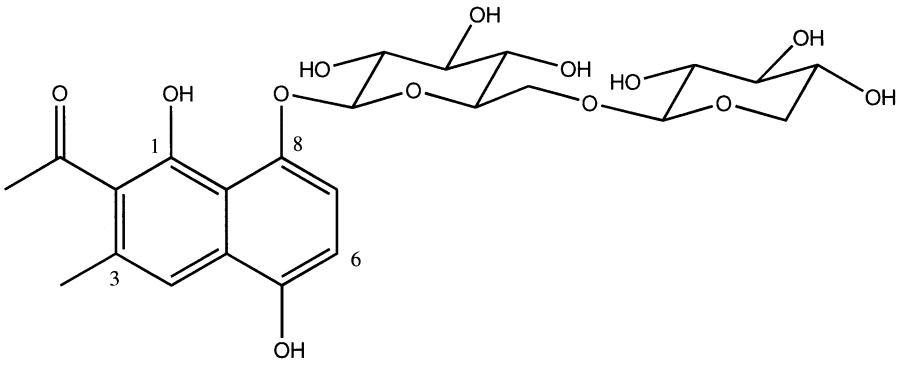
The *D. nigra* minor anthocyanin, **3**, eluted later on HPLC suggesting the possibility of extra acylation. An ESMS ion at 1535 and additional peaks in the NMR spectra indicated **3** had yet another *p*-coumaric acid group. Assignment of this acyl group to the last logical site, the C-6 position of the 3-sugar was confirmed by the downfield ^{1}H NMR shift of this signal relative to that seen in **2**. Most of the other signals were very similar to those for **2** showing **3** was delphinidin 3,7,3′,5′-tetra (6-*O*-*p*-coumaroyl-β-glucoside).

The third anthocyanin, **1**, was lacking one of the *p*-coumaroyl groups of **2**. The remaining two *p*-coumaroyl groups had identical NMR data showing these were the substituents on the 3′ and 5′ glucoses. The remaining NMR data were consistent with delphinidin 3,7-diglucoside-3′, 5′-di(6-*O*-*p*-coumaroyl-β-glucoside).

Alkaline hydrolysis of the major anthocyanin **2** yielded delphinidin 3,7,3′,5′-tetraglucoside (**4**). Partial alkaline hydrolysis gave **1** as well as a number of other products that, from their on-line spectra, were clearly the other various possible mono- and di-acylated anthocyanins.

This is the first time that an anthocyanin has been described with glycosylation at these four sites. As glycosylation of anthocyanins is known to occur almost always at the 3 position, often at either the 5- or 7-positions (but not both), sometimes at the 3′, or 3′ and 5′, and never at the 4′ position then these *Dianella* compounds could be said to be maximally glycosylated. The substitution of the sugars by aromatic acyl groups is known to be a major factor in the in vivo stabilisation of these pigments. Formation of folded conformations whereby the acyl groups are stacked above and below the plane of the anthocyanidin protect the molecule from hydration. Pigments **1**–**3** demonstrate this effect and offer an opportunity to assess the relative stacking capability of the variously situated acyl groups.

Recently Yoshida et al. (2000) have demonstrated, using ^{1}H NMR spectral data, that in acidic methanol conditions a caffeoyl residue on the 5 sugar makes little contribution to stacking while that on the 3′ sugar has a significant stacking ability. Work with other pigments show that *p*-coumaroyl groups attached to sugars at the 7 and 3′ (e.g. *Ceanothus*) or 3′ and 5′ positions (e.g. ternatins) are especially well sited to doubly stack to the delphinidin pyrilium chromophore. Using similar arguments the stacking ability of the various *p*-coumaroyl groups in **1**–**3** can be assessed. Firstly, the ^{1}H NMR chemical shifts of the delphinidin H-4 and those of the *p*-coumaroyl groups are shifted upfield by the shielding effect of ring currents due to stacking. The relative upfield shift as the number of *p*-coumaroyl groups increases from 2 to 4 (8.33 in **1**, 8.18 in **2** and 8.08 in **3**) suggests that all four *p*-coumaroyl groups have some



5

contribution. The chemical shifts of the *p*-coumaroyl protons in **2** are very similar to those found for the *p*-coumaroyl groups on the 7 and 3′ sugars in the *Ceanothus* anthocyanins, which are known to be involved in stacking. The relative upfield shifts are most pronounced for the 3′ and 5′ *p*-coumaroyl groups followed by the 7 and then the 3. This data suggests the 3′ and 5′ *p*-coumaroyl groups stack more tightly with the anthocyanidin than the 7 group, which in turn is more tightly stacked than the *p*-coumaroyl group on the 3 sugar. This observation is similar to that seen in the ternatins. In those members of the ternatin series of pigments, which have linear chains of *p*-coumaroyl-glucose groups attached at the 3′ and 5′ positions, the inner *p*-coumaroyl groups appear to stack more tightly than the more distant groups.

The coupling constants between H-5 and H-6 of the glucose units can also be used to assess the degree of folding. In **2** and **3** the 7 sugar has a large J_{5-6b} indicating a high ratio of the folded rotamer. In compound **3** the 3 sugar has a more normal rotamer distribution. The analogous data for the 3′ and 5′ sugars is not accessible since the signals for these groups in the ^{1}H NMR spectrum of **1**–**3** are too broad. This agrees with the chemical shift data above in that the *p*-coumaroyl group at position 3 is the least tightly stacked of the four groups. Further confirmation of this ranking of copigmentation ability is seen in the visible spectra of **1**–**3**. The bathochromic shift of the visible maximum relative to the parent glycoside has been shown to be a convenient guide to the degree of copigmentation. In this case the visible spectral maxima for **2** and **3** are the same, whereas the maximum for **1** is lower, supporting a more effective copigmentation role for the 7 *p*-coumaroyl group than the 3 *p*-coumaroyl group.

The juice expressed from the *Dianella nigra* berries is deeply blue. Microscopic examination shows this colour is due to a combination of soluble blue pigment and appreciable quantity of deep blue particles. Analysis of the supernatant and a methanolic solution of the pellet from centrifugation of the juice showed the water-soluble pigment was mainly **2** while the pigment in the particles was almost pure **3**. The tetra-acylated anthocyanin **3** is almost insoluble in water and the intensely blue particles are most probably made up of self-associated aggregates of this pigment. Pigment **2** is intensely blue in mildly acidic buffer solutions above pH 4. The pH of the berry juice is 5.4.

The extracts from the berries also contained a yellow, non-anthocyanic pigment, **5** (ESMS 526 amu). This compound was clearly a diglycoside and comparison of NMR data with known constituents of *Dianella* species indicated 5 had not been previously reported but was closely related to dianellin, a naphthalene rhamnoglucoside (Briggs et al., 1975). The sugar groups of **5** were identified as xylose and glucose from their NMR data. The xylose is linked to the 6 position of the glucose based on NOE data and the shift of the glucose C-6. Compound **5** also features an acetyl group at C-2 and a methyl group at C-3 attached to the napthalene nucleus, that are characteristic of most of the *Dianella* compounds. An H-bonded hydroxy group at 9.6 ppm was assigned to the C-1 position adjacent to the acetyl group and a NOE between the glucose anomeric proton and this hydroxy proton placed the disaccharide chain at C-8. The other hydroxyl group could be assigned to C-5 based on the observed coupling pattern of the aromatic protons. Thus **5** is 2-acetyl-1,5-dihydroxy-3-methyl-8-*O* (xylosyl(1→6)glucosyl) naphthalene.

Despite their attractive appearance the berries of *Dianella* appear to have attracted limited attention as a food or colourant. This may be due to the presence of quinones or quinone precursors such as **5**. Upon acid hydrolysis **5** yields stypandrone, a known toxin (Colegate et al., 1986).

3. Experimental

3.1. General procedures

NMR experiments were run at 500 MHz or at 300 MHz (75 MHz for ^{13}C). Anthocyanin samples **1**–**3** were

dissolved in 2% CF_3COOD in CD_3OD. Compound **5** was run in DMSO-d_6. MS were obtained using a VG Quattro (Electrospray) or VG ZAB (FAB) instrument. RP HPLC analyses were performed as described previously (Bloor, 1997) using a Waters 600 solvent delivery system with a Merck Lichrospher (5 μm, 119×4 mm) 100 RP-18 endcapped column (column temperature 24 °C) and a Waters 996 PDA detector.

3.2. Isolation of pigments

Berries were collected in summer from cultivated plants at the Gracefield Science Centre, Lower Hutt, N.Z. (*D. nigra*) and Commonwealth Park, Canberra, ACT, Australia (*D. tasmanica*). Fresh or frozen berries were extracted by crushing with 0.2% TFA in H_2O. After standing for 1 h the mixture was centrifuged. The aqueous supernatant was lyophilised. The remaining berry residue was further extracted by grinding with 0.2% TFA in MeOH and again centrifuged. H_2O was added to the MeOH extract and the MeOH was evaporated and the extract lyophilised. The solid aqueous extract was subjected to RP CC eluted with a 0.1% TFA in H_2O to MeOH gradient. Pigment fractions were further purified using Sephadex LH20 CC or Lobar CN LPCC (both using 1:1 MeOH: H_2O with 0.1% TFA) to yield pigments **1**, **2** and **5**. Compound **3** was purified from the solid MeOH extract using a Lobar CN column (3:1 MeOH:H_2O with 0.1% TFA).

3.3. Hydrolysis of pigments

Alkaline hydrolysis was performed on **2** by adding 1 N NaOH to a methanolic solution of **2** at 0 °C under nitrogen. Complete hydrolysis was achieved in 30 mins., (for partial hydrolysis the reaction was stopped after 10 mins) and the reaction was halted by the addition of 2N HCl. Compound **4** was purified from the hydrolysis mixture by RP CC (3:97 MeOH:H_2O with 0.1% TFA).

3.3.1. Delphinidin 3,7-Di-O-β-glucopyranoside-3′, 5′-di-O- (6-O-p-coumaroyl-β-glucopyranoside) (*1*)

Received 19 March 2001; received in revised form 5 July 2001

Abstract

Chloroperoxidase from *Caldariomyces fumago* was able to chlorinate 17 of 20 aromatic hydrocarbons assayed in the presence of hydrogen peroxide and chloride ions. Reaction rates varied from 0.6 min^{-1} for naphthalene to 758 min^{-1} for 9-methylanthracene. Mono-, di- and tri-chlorinated compounds were obtained from the chloroperoxidase-mediated reaction on aromatic compounds. Dichloroacenaphthene, trichloroacenaphthene, 9,10-dichloroanthracene, chloropyrene, dichloropyrene, dichlorobiphenylene and trichlorobiphenylene were identified by mass spectral analyses as products from acenaphthene, anthracene, pyrene and biophenylene respectively. Polycyclic aromatic hydrocarbons with 5 and 6 aromatic rings were also substrates for the chloroperoxidase reaction. The importance of the microbial chlorination of aromatic pollutants and its potential environmental impact are discussed.

1. Introduction

Organochlorine industrial compounds, chlorinated pesticides and polychlorinated biphenyls (PCBs) are considered among the most important pollutant xenobiotics. Their toxic effects have been extensively studied (Evangelista de Duffard and Duffard, 1996; Giesy and Kannan 1998; Tilson and Kodavanti, 1998). Because of their potential public health risk, some organochlorine compounds, such as PCBs, have been banned in western countries, but many are still manufactured and used as pesticides, plasticizers, paint and printing-ink components, adhesives, flame retardants, hydraulic and heat transfer fluids, refrigerants, solvents, additives for cutting oils, and textile auxiliaries. Thus, contamination with organochlorine compounds still occurs and this is of great public concern due to potential toxicity to humans and wildlife. Microbiological studies have been almost entirely focused on the degradation of these toxic compounds (Robinson, 1998; Wiegel and Wu, 2000; Chaudhry and Chapalamadugu, 1991).

In spite of the microbial capacity to produce halogenated compounds (Neidleman, 1975; de Jong and Field, 1997), information is scarce on the microbial production of toxic organochlorine compounds. In addition to de novo synthesis of chlorinated compounds, microorganisms transform some non-halogenated xenobiotics into organochlorine compounds with a possible increase in their toxicity. In this work, we show the capacity of chloroperoxidase from the fungus *Caldariomyces fumago* to chlorinate aromatic hydrocarbons, including polycyclic aromatic hydrocarbons (PAHs). PAHs are widely dispersed in the environment, and they are considered to be a potential health risk because of their possible carcinogenic and mutagenic activities. Chloroperoxidase (CPO) is a 42,000 Da extracellular heme glycoenzyme containing ferriprotoporphyrin IX as the prosthetic group (Sundaramoorthy et al., 1995). CPO exhibits a broad spectrum of chemical reactivities, it is a peroxide-dependent chlorinating enzyme and it also catalyzes peroxidase-, catalase- and cytochrome P450-type reactions of dehydrogenation, H_2O_2 decomposition and oxygen insertion, respectively (Yi et al., 1999). CPO is only one of a variety of halogenase enzymes that can be found in nature, other enzymes such as vanadium and non-heme halogenases (van Pee et al., 2000; Vollenbroek et al., 1995) are also potentially able to chlorinate organic pollutants.

2. Results and discussion

Chloroperoxidase was able to utilize 17 of the 20 aromatic hydrocarbons assayed as substrate (Table 1). Only biphenyl, and the oxygen-containing dibenzofuran and anthrone, were not substrates for CPO under our reaction conditions. The specific activity values were from 0.6 min^{-1} for naphthalene to 758 min^{-1} for 9-methylanthracene. Interestingly, recalcitrant and carcinogenic 5- and 6-aromatic rings PAHs were substrates for chloroperoxidase in the presence of hydrogen peroxide and chloride ions. Chloroperoxidase is able to perform a broad range of reactions, like the enantioselective epoxidation of alkenes (Zaks and Dodds, 1995), oxidation of phenolic pollutants (Aitken et al., 1994; Carmichael et al., 1983), oxygenation of sulfides (Colonna et al., 1990), oxidation of organophosphorus pesticides (Hernandez et al., 1998), and the PAH–DNA adduct formation (Marquez-Rocha et al., 1997), to give only a few examples. In addition, CPO is able to oxidize very complex molecules, such as asphaltenes (Fedorak et al., 1993) and complex mixtures such as petroleum distillates (Ayala et al., 1998). Thus this halogenating enzyme is the most versatile enzymatic hemoprotein. Other halogenases are also able to perform halogenations, mainly chlorination, on a variety of substrates (Neidleman, 1975; Vollenbroek et al., 1995).

Table 1
Specific activity of chloroperoxidase from *Caldariomyces fumago* against aromatic compounds

Aromatic compound	Specific activity (min^{-1})
9-Methylanthracene	758 (±27)
Azulene	676 (±34)
Anthracene	134 (±14)
2-Methylanthracene	107 (±8)
7,12-Dimethylbenzanthracene	87 (±8)
Benzo[a]pyrene	84 (±6)
7-Methylbenzo[a]pyrene	81 (±7)
Acenaphthene	65 (±8)
Pyrene	53 (±6)
Benzo[ghi]perylene	45 (±7)
Perylene	25 (±10)
Biphenylene	10 (±0.5)
Phenanthrene	7 (±0.1)
Fluoranthene	3 (±0.2)
Fluorene	1.9 (±0.13)
Triphenylene	0.8 (±0.09)
Naphthalene	0.6 (±0.01)
Biphenyl	NR[a]
Dibenzofuran	NR[a]
Anthrone	NR[a]

[a] NR, no reaction detected.

The chemical nature of the reaction products was determined by gas chromatography–mass spectrometry (GC–MS). The mass spectra of the products from the enzymatic reaction with acenaphthene, anthracene, biphenylene, fluorene, phenanthrene, pyrene, and triphenylene are shown in Table 2. Monochlorinated, dichlorinated and trichlorinated compounds were found (Fig. 1), and they showed major ions at $m/z = [M^+]$-35, $m/z = [M^+]$-70, and $m/z = [M^+]$-105, respectively. No oxygen incorporation was detected in any of the products from the CPO-mediated reactions. In addition, no reaction could be detected with any PAH tested under peroxidase activity conditions (pH 5.0 and in the absence of chlorine ions). Significant information is available on the toxicity of chlorinated aromatic compounds, such as polychlorophenols (International

Table 2
Mass spectral data of the products from the chloroperoxidase-mediated reaction on aromatic compounds

Substrate	Product	Mass spectral ions (m/z)[a,b]
Acenaphthene	Dichloroacenaphthene	224 (39), 222 (64) [M^+], 187 (100), 152 (95), 93 (17), 75 (24).
	Trichloroacenaphthene	258 (57), 256 (81) (M^+], 221 (66), 186 (100), 150 (50), 110 (27), 98 (18), 75 (23).
Anthracene	9,10-Dichloroanthracene	248 (68), 246 (100) [M^+], 176 (43), 87 (10).
Biphenylene	Dichlorobiphenylene	222 (64), 220 (100) [M^+], 185 (17), 150 (45), 75 (11).
	Trichlorobiphenylene	258 (30), 256 (93), 254 (100) [M^+], 219 (13), 184 (49), 149 (14), 74 (10).

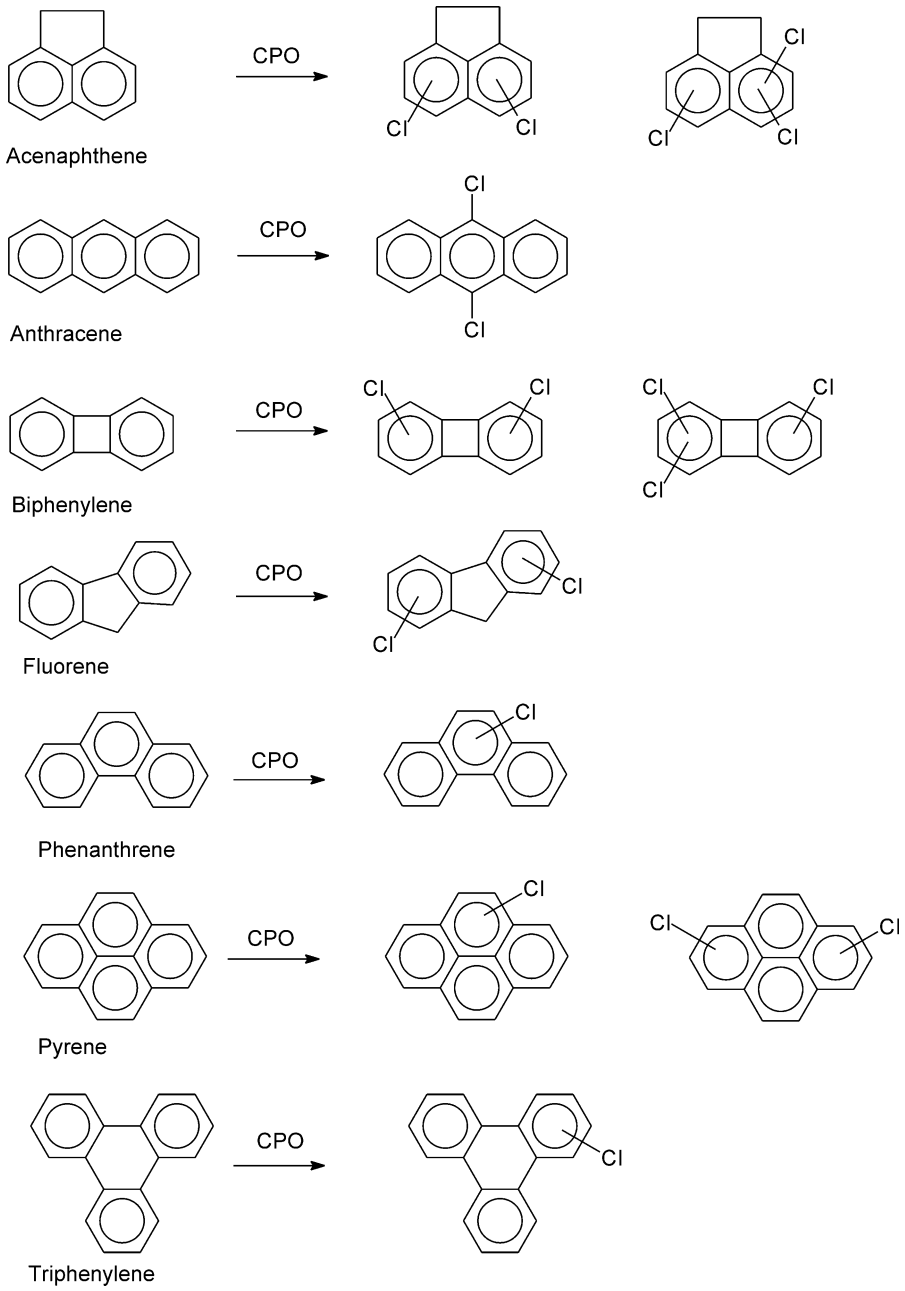

Fig 1. Chlorinated products from the enzymatic halogenation of aromatic compounds by chloroperoxidase in the presence of hydrogen peroxide and chloride ions.

Agency for Research on Cancer, 1999) and PCBs (Robinson, 1998; Wiegel and Wu, 2000), and to a less extent, on the toxicity of chlorinated derivatives of polycyclic aromatic hydrocarbons. Chlorinated PAHs have been tested for mutagenic activity by the Ames test on *Salmonella typhimurium* (Colmsjo et al., 1984; Johnsen et al., 1989). Chlorinated fluorene, flouranthene and benzo(a)pyrene acted as strong mutagens both in the presence and in the absence of metabolic activation, while only benzo(a)pyrene showed mutagenic activity as parent hydrocarbon. Mono- and di-chloropyrene isomers showed from 40 to 4000 times higher mutagenic activity than 1-nitropyrene and pyrenoquinones, respectively. On the other hand, a mixture of chlorinated chrysene isomers was considerably more potent than the parent hydrocarbon in terms of embryolethality and cytochrome P450 induction (7-ethoxyresorufin-*O*-deethylase and aryl hydrocarbon hydroxylase) (Gustafsson et al., 1994). The chlorinated chrysene caused anomalies, including edema and beak defects, similar to those reported after treatment of chick embryos with coplanar PCBs. These effects of the chlorinated mixture were mainly accounted for by 6-chlorochrysene and 6,12-dichlorochrysene. Chloronaphthalene was 5000-times

more potent than naphthalene for the inhibition of mitochondrial respiration in molar basis (Beach and Harmon, 1992). Monochloronaphthalene represent a risk for human health (Tsunenar et al., 1982) and for aquatic organisms (Ward et al., 1981).

3. Conclusions

Chloroperoxidase from the imperfect fungus *Caldariomyces fumago* is the most versatile enzyme in the hemoprotein family (Yi et al., 1999). CPO performs halogenase, peroxidase, catalase and cytochrome P450-like reactions. However, under our reaction conditions and with PAHs as substrates, CPO only acts as halogenase and no oxygenated products could be detected. In contrast, peroxidase activity on aromatic compounds produces mainly quinones, such as in the case of lignin peroxidase (Hammel et al., 1986; Vazquez-Duhalt et al., 1994) and manganese peroxidase (Bogan et al., 1996).

Caldariomyces fumago has been isolated from damp sites and also has been reported as a marine fungus (Dawson and Sono, 1987; Colonna et al., 1999). Chloroperoxidase, as other halogenases, is an extracellular enzyme that can react with a variety of substrates in the microbial environment. This enzyme is able to catalyze PAH-DNA adduct formation in vitro (Marquez-Rocha et al., 1997), suggesting the production of genotoxic aromatic intermediates. The present work shows that the transformation of aromatic pollutants into chlorinated derivatives by microbial enzymes may occur in polluted sites. This biocatalytic process should be considered because the toxicity and environmental impact of aromatic compounds may be increased.

4. Experimental

4.1. Chemicals

Purified CPO [EC 1.11.1.10] from *C. fumago* 89362 (Commonwealth Mycological Institute, Kew, Surrey, UK) was produced in a fructose medium and purified according to Pickard et al. (1991); all preparations used in this study had an $Rz = 1.36$, which corresponds to 95% purity. Hydrogen peroxide and buffer salts were obtained from J.T. Baker (Phillisburg, NJ). Polycyclic aromatic hydrocarbons were purchased from Aldrich Chemical (Milwaukee, WI). HPLC-grade acetonitrile and methylene chloride were purchased from Fisher Scientific (Springfield, NJ).

4.2. Reaction rate measurements

Reactions were carried out in a 1-ml reaction mixture containing 20 μM substrate and 15% acetonitrile in a 60 mM acetate buffer, pH 3.0, with 20 mM KCl at room temperature. From 0.4 pmol to 0.2 nmol of the purified enzyme were used in the mixtures. Reactions were started by addition of 1 mM H_2O_2 and monitored by HPLC. Reaction rates were measured from the differences in peak area after 10 min and referred to the purified protein concentration for specific activity calculations. Reported values are the mean of three replicates. Specific reaction rates are given as mol of substrate converted per mol of enzyme per minute or simply in min^{-1}. Reactions for 5 and 6 aromatic rings PAHs 7,12-dimethylbenzanthracene, benzo[a]pyrene, 7-methylbenzo[a]pyrene, benzo[ghi]perylene and perylene were also monitored by fluorescence spectrum, with an excitation at 300 nm, in a Luminescence spectrometer, Perkin-Elmer, Model LS 50, during 2 min at 25 °C. The CPO activity was measured as the disappearance of the respective maximum emission peak for each PAH over a two minute reaction.

4.3. Analytical methods

Substrate concentration was measured in a Perkin-Elmer (series 200) HPLC system, using a C_{18} Hypersyl 5 μm Hewlett-Packard column eluted with an acetonitrile–water (70:30 v/v) solvent mixture. Substrate and product detection was carried out using a diode array detector coupled to the HPLC system. Product identification was performed in a Hewlett-Packard GC (model 6890)-MS (model 5972) equipped with a SPB-20 column (30 m×0.25 mm, Supelco). The temperature program started at 100 °C for 2 min; the temperature was raised to 290 °C at a rate of 8 °C/min and kept at 290 °C for 10 min.

Received 9 March 2001; received in revised form 17 July 2001

Abstract

Volatile compounds produced by intact plants and ground leaf tissue from endophyte-infected (E+) and endophyte-free (E−) tall fescue (*Festuca arundinacea* Schreb.) were collected by a purge-and-trap procedure and analyzed by gas chromatography/mass spectrometry The volatile compound profile from ground leaf tissue was similar between E+ and E− clonal plants; however, the sheaths of E+ clonal plants produced higher levels of 1-octen-3-ol, a characteristic volatile compound derived from lipid peroxidation in fungi, which was absent in E− clonal plants. Intact plants produced fewer volatiles than macerated leaves. At 25 °C, (*Z*)-3-hexen-1-ol acetate was the most abundant compound, accounting for 77 and 89% of the total volatile emission from E+ and E− plants, respectively. Higher temperature (32 °C) significantly reduced the production of (*Z*)-3-hexen-1-ol acetate. Nonanal was the most abundant compound at 32 °C accounting for 52 and 45% of the total volatile emission from E+ and E− plants. Treatment of E+ and E− plants with jasmonic acid (JA) dramatically altered the volatile compound profile. The levels of (*E*)-β-ocimene increased more than 200-fold and accounted for at least 43% of the total volatile emission. Although the presence of endophyte resulted in some qualitative and quantitative differences in the production of volatile compounds, they are unlikely to account for the differences in insect resistance between E+ and E− plants. Nevertheless, the production of a unique spectrum of volatiles after JA treatment may represent a significant plant-based defense response in tall fescue that is independent of endophyte. © 2001 Elsevier Science Ltd. 1. Introduction

Tall fescue *Festuca arundinacea* Schreb., one of the most widespread agricultural grass species, is often asymptotically infected by the fungal endophyte *Neotyphodium coenophialum*, which resides in the intercellular spaces of the leaf sheath. The benefit of the symbiotic endophyte–grass association has been widely demonstrated both in the laboratory and in field trials (Bacon et al., 1997). It is well documented that endophyte-infected (E+) turfgrasses often exhibit superior resistance to insects and diseases, and may even be more tolerant of drought and other abiotic environmental stresses, compared to their endophyte-free (E−) counterparts (Clay, 1988, 1992; Clay and Cheplick, 1989; Breen, 1994; Siegel and Bush, 1996; Bush et al., 1997; Leuchtmann and Clay, 1997). The enhanced resistance of E+ grasses towards insects and diseases is generally considered to result from the production of defense compounds by the endophyte–grass interaction. The most thoroughly described compounds to date are alkaloids including the ergot alkaloids, lolitrems, peramine, and lolines, which are toxic agents to grazing animals and/or insect feeding deterrents (Siegel and Bush, 1996). However, there are other defense mechanisms that may well operate in endophyte–grass associations. It is known that volatile compounds emanating from plants play an important role in plant–insect interactions, and may allow insect pests to find suitable plant hosts on which to feed, or may be used by insect predators in search of prey (Berney and Chapman, 1994). Knowledge of volatiles in E+ grasses may, therefore, be useful in understanding the chemical basis for the benefits of endophyte–grass associations. Recently, volatiles of E− tall fescue cultivars have been studied in relation to animal feed palatability (Tava et al., 1991; 1995; Mayland et

al., 1997). Little is known, however, about the volatile profile of E+ grasses. The present study examined the spectrum of volatile compounds from E+ and E− tall fescues to determine whether the presence of *Neotyphodium* endophyte affects the production of volatile compounds.

2. Results and discussion

2.1. Macerated tissue

Macerated tissue may provide information concerning the production of volatiles from tissue either damaged mechanically or by herbivory. The majority of the identified volatiles from macerated tissue are lipid degradation products classified as hydrocarbons, aldehydes, ketones, alcohols, esters, and furans. Most of these compounds have previously been reported to occur in the essential oil and/or fresh tissues of tall fescue (Tava et al., 1991; 1995; Mayland et al., 1997). There are more individual volatiles present in the E+ and E− FD4N clones (Table 1) than in selections 161, 230, 246 and 259 (Table 2). In addition to lipid peroxidation products, there are, however, several carotenoid breakdown products, such as β-cyclocitral, β-homocyclocitral, β-ionone, detected in selections 161, 230, 246 and 259.

Among the listed compounds in Table 1 are a variety of 6-carbon aldehydes [(*Z*)-3-hexenal, (*E*)-2-hexenal] and alcohols [hexanol, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexen-1-ol acetate], which are commonly described as "green leaf volatiles" (GLVs). These are the major components of E+ and E− FD4N plants, representing 60–80% of the total volatile emission. In E+ FD4N plants, GLVs represent 62% of total volatiles in the sheaths and 80% in the blades. The blades of E+ FD4N plants produced much higher levels of (*Z*)-3-hexen-1-ol acetate than the sheaths. There are, however, no significant differences in GLVs between the sheaths and blades in E− FD4N plants. The blades of E− FD4N produced much higher levels of (*E*,*Z*)-2,6-nonadienal and 2-nonenal than the sheaths, whereas the levels of these compounds were similar in sheaths and blades of E+ clones. The results indicate that volatile production depends upon the tissue type, and the presence of endophyte. E+ FD4N plants produced lower levels of 1,3-heptadienal, 2,4-heptadienal, nonanal, (*E*,*Z*)-2,6-nonadienal, 2-nonenal, and 5-ethyl-2(5H) furanone, than E− FD4N plants. 1-octen-3-ol, a major component which accounted for 16.3% of total volatiles in the sheaths of E+ FD4N tall fescue, was not found in the sheaths and blades of E− FD4N plants, and was also absent in the blades of E+ FD4N plants, where only a few endophytes are present. The endophyte may be responsible for the emission of this compound from E+ plants.

Nonetheless, 1-octen-3-ol was present in all four E+ and E− natural plant selections (Table 2), although it was at much lower levels than in the FD4N E+ clone. Previous studies have also shown that 1-octen-3-ol was detectable in E− tall fescues (Tava et al., 1995; Mayland et al., 1997). It is not clear how endophytes affect the production of 1-octen-3-ol in E+ plants. It has been demonstrated that 1-octen-3-ol is a major volatile in mushroom (*Agaricus campestris*) (Tressl et al., 1982), in other filamentous fungi including *Laetisaria arvalis* and *Pleurotus pulmonarius* (Brodowsky and Oliw, 1993), and also bracket fungi (*Fomitopsis pinicola* and *Fomes fomentarius*) (Faldt et al., 1999). If endophytes can indeed enhance the production of 1-octen-3-ol in E+ plants, the lower levels of this compound found in E+ cultivars 230 and 246, as compared to the E+ FD4N plant sheaths, may reflect either lower levels of endophyte infection or the influences of plant genotype.

In the genetically related E+ and E− selections, nonanal was the most abundant component, representing 35–56% of total volatiles (Table 2), whereas it was less than 3% of total volatiles in the clonal FD4N plants. GLVs, which were major volatiles in FD4N plants, were 19–39% of total volatiles in E+ and E− selections. It has been documented that nonanal is primarily produced from auto-oxidation of oleic acid (Hwang et al., 1994) and GLVs are formed by enzymatic oxidative degradation of unsaturated fatty acids, particularly of linoleic and linolenic acid (Hatanaka, 1983). The higher ratio of nonanal to GLVs in the selections 161, 259, 246 and 230 suggest that these plants may have higher ratios of oleic acid to linoleic or linolenic acid.

The four genetically related E+ and E− selections exhibited a similar volatile profile, and they only differed in a few trace components. Nevertheless, quantitative differences in both relative amounts of individual components within a selection and total amount of volatile emission collected from each selection were observed. Among the four genetically related E+ and E− selections, 230 produced the highest levels of total volatiles.

(*Z*)-3-hexen-1-ol acetate was the only volatile produced at lower levels in E+ plants (both FD4N clones and the genetically related plant selections) compared to E− plants. E− selections 161 and 259 produced (*Z*)-3-hexen-1-ol acetate at the levels of 183 and 205 ng/g/3 h, respectively. In E+ plants 230 and 246, the level of this compound was 44 and 30 ng/g/3 h, respectively. The sheaths of the E− FD4N plant produced (*Z*)-3-hexen-1-ol acetate at 166 ng/g/3 h, while it was only 14 ng/g/3 h in the sheaths of the E+ FD4N plant. Further investigations are warranted to determine if endophytes can inhibit the synthesis of (*Z*)-3-hexen-1-ol acetate in E+ tall fescues.

Volatiles are known to mediate insect-plant interactions and may be attractants or repellents (Berney and Chapman, 1994). 1-Octen-3-ol has been reported as a strong attractant to the moth *Epinotia tedella* (Faldt et al., 1999), tabanid flies (French and Kline, 1989), tsetse flies (Vale et al., 1988), and mosquitoes (Van Essen et al., 1994). 1-Octen-3-ol, (*E*)-2-hexenal and 1-octen-3-one, are known to enhance the aggregation of red legged earth mites (*Halotydeus destructor*) at low concentrations

and reduce the aggregation at higher concentration (Jiang et al., 1997). (*Z*)-3-hexen-1-ol acetate, which is present at lower levels in E+ plants than in E− plants, has been found to be attractive to adult Colorado potato beetles (*Leptinotasa decemlineata*) (Lwande et al., 1988) and cabbage root flies (Wallbank and Wheatley, 1979).

2.2. Intact plants

Intact E+ and E− plants produced a smaller number of volatile compounds than macerated leaf tissue (Table 3). Most notably was a decline in GLVs, particularly the 6-carbon aldehydes and alcohols. The predominant volatiles were 7–10 carbon aldehydes, (*Z*)-3-hexen-1-ol acetate and several monoterpenes. A dramatic change in the volatile profile of intact E+ and E− plants occurred with a change in temperature. At 25 °C, (*Z*)-3-hexen-1-ol acetate was the most abundant compound, accounting for 77 and 89% of the total volatile emission from E+ and E− plants, respectively. Higher temperature (32 °C) significantly reduced the production of (*Z*)-3-hexen-1-ol acetate. Nonanal was the most abundant compound at 32 °C accounting for 52 and 45% of the total volatile emission from E+ and E− plants. The monoterpenes accounted for a higher percentage of the total volatile emission profile at the higher temperature, although there were no differences in the amounts of monoterpenes or nonanal at 32 °C compared to 25 °C (data not shown). Since insects often respond to a mixture of volatile compounds rather than one compound in itself, this change in composition may affect plant–insect interactions. In fruit tissue, volatile esters are synthesized by an alcohol acyltransferase from 4 to 6 carbon alcohols and acetyl CoA (Perez et al., 1993). If a similar enzyme exists in tall fescue leaves, it may be much less active at 32 °C than at 25 °C.

Jasmonic acid (JA) is a hormone produced from linolenic acid especially after membrane lipids in the leaf are damaged by herbivory. JA treatment of E+ and E− plants significantly affected the volatile compound emission profile (Table 4). JA induced the synthesis of the monoterpene (*E*)-β-ocimene more than 200-fold in FD4N E+ and E− clonal plants, and accounted for more than 43% of the total volatile emissions. Another compound, whose spectrum matched closely with both (*Z*)-β-ocimene and (*E*)-α-ocimene, but which we could not conclusively identify, accounted for 31% of the total volatile emission. There were also significant increases in other monoterpenes such as (*E*,*Z*)-allo-ocimene, limonene, myrcene and linalool. Methyl salicylate, indole and nonanal also increased after JA treatment. Similar results were found for the four genetically related tall fescue selections (data not shown). β-Ocimene is produced in cotton and other plants in response to herbivore damage (Pare and Tumlinson, 1997). β-Ocimene is a powerful attractant of predatory mites (Takabayashi et al., 1994; Gols et al., 1999), aphid parasitoids (Du Yongjun et al., 1998) and the generalist parasitoid *Cotesia marginiventris* (Rose et al., 1998). In gerbera daisy leaves (*Gerbera jamesonii*), JA treatment induced the production of a complex odor blend comprised largely of terpenoids, including (*E*)-β-ocimene, which attracted the predatory mite, *Phytoseuilus persimilis* (Gols et al., 1999). The induction of β-ocimene by JA may, therefore, be a component of the defense response of tall fescue to phytophagous insect attack.

Although there were some qualitative and quantitative differences in the production of volatile compounds between plant genotypes and the presence of endophyte, they are unlikely to account for the differences in insect resistance between E+ and E− plants. Nevertheless, the production of volatiles after JA treatment may represent a significant plant-based defense response of tall fescue that is independent of the presence of endophyte.

3. Materials and methods

3.1. Plant materials

Five tall fescue selections (FD4N E+ and E− clonal plants, two naturally occurring E− plants designated as selections 161 and 259, and two naturally occurring E+ plants designated as selections 230 and 246) were used in this study. FD4N E− clones were generated from FD4N E+ plants by fungicidal treatment. Selections 161, 230, 246 and 259 are genetically related having the same pollen parent. The presence of *Neotyphodium coenophialum* endophyte was tested by rose bengal staining (Saha et al., 1988). All grasses were maintained in 15-cm containers at 25 °C day and 20 °C night temperatures in the greenhouse.

3.2. Method of collecting volatiles from the macerated plants

To analyze volatiles in macerated tissues, 10 g of sample was quickly homogenized in liquid nitrogen with a mortar and pestle, and tissue homogenates were poured into a purge-and-trap apparatus fitted with a Tenax-Carbo trap tube and purged with ultra-pure nitrogen gas. Ten μl of 100 ppm toulene-d_8 in methylene chloride (Baker Chemicals) was added as an internal standard. Trapping was undertaken at 50 °C for 60 min with nitrogen gas at a flow rate of 40 ml/min.

3.3. Method of collecting volatiles from intact plants

Intact plant volatiles were collected by dynamic headspace analysis based upon a modification of the methods previously described (Robertson et al., 1993). Greenhouse-grown plants were placed in a growth chamber at 25 °C, with a 12 h photoperiod, for 1 day before trapping volatile compounds. Generally, the plant being examined was removed from its container and the roots washed free of soil mix with tap water followed by distilled water. The plant was placed in a 400-ml beaker with 200 ml of distilled water, and then placed into a 3-l glass chamber equipped with air inlet, flowmeter and Tenax-Carbo trap tube. Air, filtered through traps containing molecular sieve 5 Å and activated charcoal, was purged at a rate of 35 ml/min and then drawn over the plant for 3 h by a small diaphragm vacuum pump at a rate 150 ml/min. The apparatus was

set up in a growth chamber at 25 °C with a light level of 250 μmol/m^2/s. Volatile compounds were trapped approximately 6 h after the beginning of the photoperiod.

3.4. JA treatment

From a stock solution of JA (200 μmol/ml), 50 μl was diluted into 5 ml of water and then sprayed onto the whole plant. After 24 h, the volatiles were collected as described above.

3.5. Experimental design

For each experiment there were three samples per plant or treatment. Data were analyzed by an analysis of variance and means separated by LSD test, $P \leqslant 0.05$. Each experiment was repeated once with similar results.

3.6. Gas chromatography-mass spectrometry (GC-MS)

The Tenax-Carbo trap tube was purged with nitrogen for 30 min at a rate of 25 ml/min to remove moisture. Volatiles trapped on the adsorbent tube were directly and thermally desorbed into the GC injector by using the Short Path Thermal Desorption System II (SIS, Ringoes, NJ) at 250 °C for 5 min. A Varian 3400 GC was fitted with DB-I capillary column (30 m, I.D. = 0.25 mm, film thickness = 0.15 μm, J&W Scientific, Folsom, CA). Injector temperature was 250 °C. The initial oven temperature was −20 °C, and it was raised to 40 °C at a rate of 5 °C/min, then to 150 °C at a rate of 3 °C/min and finally up to 280 °C at a rate of 15 °C/min. Split ratio was 5:1. A Finnigan magnetic sector mass detector (MAT 8230) was connected to the GC with an interface tube at 280 °C. The electron ionization voltage was 70 eV and the mass range scanned was 35–350. Peak identification was based on co-chromatography and mass spectral comparisons with authentic standards, or when not available, tentative identifications were determined using a NIST or Wiley mass spectral library.

Received 20 June 2001; received in revised form 10 August 2001

Abstract

A new acetylated flavone glycoside, acacetin 7-*O*-[6‴″-*O*-acetylglucosyl(1‴″→2″)]rhamnosyl(1‴→6″)glucoside, has been isolated from the leaves of *Calamintha glandulosa* together with the known compound acacetin 7-*O*-rhamnosyl(1‴→6″)glucoside. The occurrence of these flavonoids in the closely related genera *Satureja, Micromeria, Acinos* and *Clinopodium* indicates that their distribution may be of taxonomic significance. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Calamintha glandulosa*; *Micromeria*; Lamiaceae; Acacetin 7-*O*-[6‴″-*O*-acetylglucosyl(1‴″→2″)]rhamnosyl(1‴→6″)glucoside; Acacetin 7-*O*-rhamnosyl(1‴→6″)glucoside (linarin); Chemosystematics

1. Introduction

Calamintha Miller, *Micromeria* Benth., *Satureja* L., *Clinopodium* L. and *Acinos* Miller are five closely related genera of aromatic plants belonging to the family Lamiaceae, subfamily Nepetoideae and tribe Saturejeae. Many species grow in open habitats in the Mediterranean area, and some are endemic to local regions of the Balkan Peninsula. The boundaries among the genera are poorly defined, and their taxonomic treatment has changed many times. For example, Briquet (1896) treated them as only one genus, *Satureja sensu lato*, whereas Bentham (1848) and Boissier (1879) recognised *Micromeria, Satureja* and *Calamintha* (*Acinos* and *Clinopodium* being included in *Calamintha*). They are treated as five separate genera in Flora Europaea (Ball and Getliffe, 1972; Chater and Guinea, 1972) and by Silic (1979). In contrast, Stace (1991) again merged *Acinos* and *Calamintha* with *Clinopodium* in his treatment for the Flora of the British Isles. These different conclusions suggest that more characters are needed to define the generic boundaries in this group of plants.

Chemical characters can often provide additional information to complement data from morphological and other studies. For this reason a number of species representing each genus was surveyed for flavonoids. During this investigation, which was carried out using both HPLC coupled to diode array detection and liquid chromatography–mass spectrometry (LC–MS), a new acetylated acacetin glycoside (**1**) was detected in the leaf extracts of several species. The compound always co-occurred with another acacetin glycoside (**2**). This communication describes the isolation of **1** and **2** from *Calamintha glandulosa* (Req.) Benth. [Syn. *C. nepeta* (L.) Savi ssp. *glandulosa* (Req.) P.W. Ball], the identification of the compounds by means of spectroscopic techniques, and their distribution among the five genera.

2. Results and discussion

2.1. Identification of flavone glycosides *1* and *2*

Compounds **1** and **2** were obtained from a methanolic extract of *C. glandulosa* leaves by preparative PC and

1

semi-preparative HPLC. Their UV spectra were identical ($\lambda_{max} = 268$ and 333 nm) and typical of those of flavone 7-*O*-glycosides (Markham, 1982). First-order APCI–MS (positive mode) of **1** and **2** gave $[M+H]^+$ ions at *m*/*z* 797 and 593, respectively, with both showing a protonated aglycone $[A+H]^+$ at *m*/*z* 285. These data suggested that **1** and **2** were glycosylated derivatives of the same flavonoid aglycone.

The ^{1}H NMR spectrum of **1** contained resonances characteristic for an $ArOCH_3$ group (δ 3.87), three anomeric sugar protons (δ 5.22, 4.57 and 4.52) and an acetyl group (δ 1.95), as well as those for aromatic and other glycosidic protons. Analysis of the aromatic proton resonances, their corresponding ^{13}C NMR chemical shifts (HSQC) and their long range ^{1}H–^{13}C connectivities (HMBC) indicated that the aglycone was a derivative of apigenin (5,7,4′-trihydroxyflavone) (Markham et al., 1982; Markham and Geiger, 1994). The downfield shift of the H-3′,5′ protons at δ 7.15 compared to apigenin (δ 6.98) indicated that the 4′-hydroxyl group of **1** was substituted. The nature of this substitution was determined by 1D ROESY experiments using the XSROESY pulse sequence (Gradwell et al., 1997). A strong ROE connectivity detected between H-3′,5′ and the methoxyl group at δ 3.87 confirmed that the aglycone was apigenin 4′-methyl ether (acacetin). This was consistent with the prominent ion observed at *m*/*z* 285 in APCI-MS of **1**, corresponding to $[A+H]^+$.

ROE connectivities were also detected between the anomeric proton at δ 5.22 and both H-6 and H-8 of the aglycone, indicating that the site of glycosylation was at C-7. Assignment of the ^{1}H and ^{13}C NMR resonances of the primary sugar was achieved using DQF–COSY and HSQC data acquired in DMSO-d_6 (Table 1). Use of this solvent allowed the exchangeable sugar hydroxyl resonances to be retained in the ^{1}H NMR spectrum. These were assigned from $^3J(^1H, ^1H)$ connectivities observed in DQF–COSY spectra with the corresponding non-exchangeable sugar protons (Veitch et al., 1998). The $^3J_{H\text{-}1'',H\text{-}2''}$ coupling constant of 7.1 Hz and the ROE connectivities detected between H-1″ and both H-3″ and H-5″ confirmed that the primary sugar was β-glucopyranose. The DQF–COSY data indicated that free

hydroxyl groups were absent from both C-2″ and C-6″ of the primary Glc residue. A weak ROE connectivity detected between the 6″-CH_2 proton of the primary Glc residue at δ 3.88 and the anomeric proton at δ 4.57 indicated that a second sugar residue was attached at C-6″. Assignment of the ^{1}H and ^{13}C NMR resonances of this residue (DQF–COSY, HSQC and HMBC data) identified it as α-rhamnopyranose (Table 1). Further analysis of the DQF–COSY data indicated that resonances corresponding to 2‴-OH, 3‴-OH and 4‴-OH were present in the ^{1}H NMR spectrum. This confirmed that no additional groups were linked to the Rha residue.

A ROE connectivity detected between H-1″ of the primary Glc residue and the remaining anomeric proton at δ 4.52 confirmed that a third sugar residue was linked

at the 2″ position. This was also evident from the characteristic downfield shift of the C-2″ resonance to δ_C 82.8. The (1‴→2″)-linked sugar was identified as β-glucopyranose by complete assignment of its ^1H and ^{13}C NMR resonances, and the $^3J_{H\text{-}1''',H\text{-}2'''}$ coupling constant of 7.9 Hz (Table 1). The ^1H and ^{13}C resonances of the 6‴-CH_2 group of this Glc residue were also downfield shifted. DQF–COSY data indicated that only resonances for 2‴-OH, 3‴-OH and 4‴-OH were present in the ^1H NMR spectrum. This confirmed that 6‴-CH_2 was the site of substitution of the acetyl group of **1** (δ_H 1.95; δ_C 20.4, 170.1). Further evidence was provided by the series of ions noted in the first order APCI–MS (positive mode) of **1** at *m*/*z* 651, 447 and 285, which corresponded to successive losses of Rha (146 amu), acetylGlc (204 amu) and Glc (162 amu) from the pseudomolecular ion at *m*/*z* 797. High resolution MS of **1** gave a molecular formula of $C_{36}H_{44}O_{20}$. Compound **1** was therefore identified as acacetin 7-*O*-[6‴-*O*-acetylglucosyl (1‴→2″)]rhamnosyl(1‴→6″)glucoside, a new acylated flavone triglycoside.

The ^1H NMR spectrum of **2** was similar to that of **1** but lacked the resonances of the acetylglucosyl residue. Comparison of the NMR data with spectra obtained for an authentic sample confirmed **2** to be the known compound, acacetin 7-*O*-rhamnosyl(1‴→6″)glucoside (acacetin 7-*O*-rutinoside or linarin).

2.2. Occurrence of compounds 1 and 2 in Acinos, Calamintha, Clinopodium, Micromeria and Satureja species

The distribution and relative amounts of leaf flavonoids **1** and **2** in species of the above five genera are summarised in Table 2. *Calamintha glandulosa* and all the species of *Micromeria* investigated contained both compounds. They were the most abundant flavonoids in *C. glandulosa* and *M. dalmatica*, and among the major flavonoids in *M. thymifolia* and *M. albanica*. However, in *M. juliana* and *M. cristata*, **1** and **2** were only minor compounds. All four *Satureja* species, *Acinos arvensis* and *A. hungaricus* contained **2**, but lacked **1**. The compounds were not detected in either *A. majoranifolius* or *Clinopodium vulgare*.

Several acacetin glycosides have been reported previously from *Calamintha nepeta* (Souleles and Shammas, 1985) including **2**, which has also been isolated from *Micromeria* spp. (Tomás-Barberán et al., 1991). In addition, the flavanone glycoside corresponding to **2**, isosakuranetin 7-*O*-rutinoside (neoponcirin), has been reported from five species of *Micromeria* (*M. graeca*, *M. fruticulosa*, *M. juliana*, *M. montana*, *M. thymifolia*) and from *Calamintha nepeta* (Bellino et al., 1980).

Bentham (1848), Boissier (1879) and Stace (1991) considered *Calamintha* to be so closely related to *Acinos* and *Clinopodium* that they combined the three genera into one. However, the distribution of the unusual acetylated acacetin glycoside **1** suggests that the genus *Calamintha*, or at least *C. glandulosa*, is more closely related to the genus *Micromeria* than to *Acinos* or *Clinopodium*. The quantitative differences in the content of acacetin glycosides among species of *Micromeria* are also of systematic interest. *Micromeria albanica, M. thymifolia* and *M. dalmatica*, which have higher relative levels of **1** and **2,** are placed in section *Pseudomelissa* Benth., whereas *M. juliana* and *M. cristata*, with lower relative levels of these compounds, are placed in section *Eumicromeria*. These flavonoid glycoside characters correlate well with results obtained from other studies, in which the two sections were distinguished by differences in the flavone aglycone profiles of their leaf surfaces (Tomás-Barberán et al., 1991) and micromorphological features (Husain et al., 1990).

Table 2
Distribution of acacetin 7-*O*-[6‴-*O*-acetylglucosyl(1‴→2″)]rhamnosyl (1‴→6″)glucoside (**1**) and acacetin 7-*O*-rhamnosyl(1‴→6″)glucoside (**2**) in *Calamintha* and related taxa and relative amounts present in the plants

3. Materials and methods

3.1. General

^1H NMR (500 and 400 MHz) and ^{13}C NMR (125 and 100 MHz) spectra were recorded in DMSO-d_6, with the residual solvent resonances used as internal references at δ 2.50 and 39.5, respectively. High-resolution ESIMS (negative mode) were obtained on a Bruker Apex II instrument (calibrant masses 307, 514, 611 and 784). Positive ion first-order APCI–MS were obtained with a quadrupole ion-trap instrument (Finnigan LCQ) using

a vaporiser temperature of 550 °C, sheath and auxiliary nitrogen gas pressures of 80 and 20 psi, a needle current of 5 μA, and a heated capillary temp. of 150 °C. Samples were introduced by direct infusion, or via an HPLC fitted with a Merck (Darmstadt, Germany) LiChrospher 100RP-18 (250×4.0 mm i.d.; 5 μm particle size) column using a 20 min linear gradient of 25–100% MeOH in 1% aq. HOAc at 1 ml/min. The system for analytical and semipreparative HPLC consisted of a Waters LC600 pump and a 996 photodiode array detector. For analytical HPLC, the same column and gradient were used as for LC–MS described above, but the eluting solvents were 2% aq. HOAc and MeOH, HOAc, H_2O (18:1:1). An identical LiChrospher column but with 10 mm i.d. was used used for semipreparative HPLC, and the eluting solvents consisted of H_2O (A) and MeOH (B). Elution was with a linear gradient, starting with 50% B and changing to 60% B over 15 min, followed by isocratic elution with 100% B for 5 min. The column temperature was 30 °C for both analytical and semi-preparative HPLC.

3.2. Plant material

The origin and accession numbers of *Calamintha glandulosa* and species from other genera studied are given in Table 3. The samples were identified and authenticated by the first author. Voucher specimens have been deposited at the Herbarium of the Botanical Institute and Garden, Faculty of Biology, University of Belgrade.

3.3. Extraction and isolation

Air dried leaves (0.5 g) of the 13 accessions of *Acinos*, *Calamintha*, *Clinopodium*, *Micromeria*, and *Satureja* were crushed and boiled for ca. 2 min in 10 ml of 80% aq. MeOH (H_2O:MeOH, 20:80), and then extracted at room temperature for 24 h. After filtration and solvent removal by rotary evapn, each of the extracts was dissolved in 1 ml of 80% aq. MeOH. The crude extracts were analysed by HPLC with diode array detection and then separated into several fractions by means of preparative paper chromatography to remove rosmarinic acid from the flavonoids. These fractions were analysed by both HPLC and LC–MS. Compounds **1** and **2** were found in the fractions with an R_f-value of 0.50 in solvent BAW (*n*-BuOH, HOAc, H_2O, 4:1:5, v/v, upper layer). To isolate the flavonoids, an extract of *Calamintha glandulosa* was prepared by the same method described above, but with 20 g of dried leaves and 250 ml of 80% aq. MeOH. A preliminary purification was carried out with preparative paper chromatography using BAW and 15% aq. HOAc as solvents and the fractions containing **1** and **2** were further separated by semi-preparative HPLC to obtain pure samples of each flavonoid for spectroscopic analysis. An authentic sample of acacetin 7-*O*-rhamnosyl(1‴→6″)glucoside (acacetin 7-*O*-rutinoside or linarin) (**2**) was obtained from Apin Chemicals Ltd.

3.4. Acacetin 7-O-[6‴-O-acetyl-β-glucopyranosyl (1‴→2″)]α-rhamnopyranosyl(1‴→6″)β-glucopyranoside (*1*)

Abstract

Although extracts from *Hamamelis* bark have long been used in therapy of skin diseases and in cosmetic formulas there are only few pharmacological investigations verifying the activity of distinct *Hamamelis* bark constituents. Therefore two major classes of constituents, namely polymeric proanthocyanidins and polysaccharides were isolated from *Hamamelis* bark and tested concerning their influence on proliferation and differentiation of cultured human keratinocytes. While the polysaccharide fraction, consisting mainly of arabans and arabinogalactans, did not effect human keratinozytes, the proanthocyanidins strongly increased the proliferation of the cells, while the differentiation was not influenced significantly. Within a preliminary cumulative in vivo study on SLS-irritated skin, proanthocyanidins (ProcyanoPlus) were proven to reduce transepidermal water loss and erythema formation. Furthermore, a clinical scoring indicated that procyanidins can influence irritative processes significantly. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

Extracts and destillates from *Hamamelis* bark and leaves are widely used as part of skin care products and in dermatological treatment of sun burn, irritated skin, atopic eczema (Korting et al., 1995) and to promote wound healing via anti-inflammatory effects (Korting et al., 1993). Several reports from traditional medicine indicate the efficacy of *Hamamelis* preparations in dermatology (Laux and Oschmann, 1993; Swoboda and Meurer, 1991). On the other side the clinical effects of this herbal drug in dermatology are proven only by very preliminary studies (Erdelmeier et al., 1996) while no information is available on pharmacological in vitro activities of *Hamamelis* ingredients on relevant skin cells to get a positive in vivo–in vitro correlation. However, the compounds responsible for the dermatological activity, are not identified clearly yet. It is assumed that the tannin fraction, consisting of hydrolysable and condensed tannins, which acounts up to 12% for *Hamamelis* bark (Hoffmann-Bohm et al., 1993) may contribute to the efficacy. Nevertheless, this was not proven unambigiously up to now.

During aqueous extraction of the plant material the presence of higher amounts of polysaccharides gets obvious. As some high-molecular carbohydrates are known to influence skin physiology in some cases quite extensively (Kitamura et al., 1997; Yagi et al., 1997; Chithra et al., 1998; Strickland et al., 1999; Eskelinin and Santalahti, 1992) the polysaccharide fraction of *Hamamelis* also may contribute to the dermatological activity.

The aim of the present study was first to investigate the structural features of the *Hamamelis* bark polysaccharides and secondly to evaluate the dermatological potential of these polysaccharides and of high-molecular proanthocyanidin fraction on in vivo and in vitro skin proliferation and skin differentiation in keratinozyte in vitro culture.

A widely used pharmacological test system for such investigations are in vitro submerged cell cultures of human keratinocytes as a dynamic proliferating and differentiating system. This in vitro system represents the complex differentiation process of epidermal skin, leading to the anuclear cells filled with fibrous keratin and getting plasticized by hydration (Ponec and Kempenaar, 1995; Gibbs et al., 1997; van der Sandt et al., 1999). Beside toxic effects, different reaction patterns of keratinocytes towards exogenous test compounds can be detected using this system: compounds inducing cell differentiation can be separated from substances promoting the differentiation by increased formation of keratins K1 and K10. Therefore submerged keratinocytes allow detailed statements of potential mode of action of the test compounds.

2. Results

2.1. Isolation, fractionation and characterization of Hamamelis polysaccharides

Raw polysaccharides (RPS) with a carbohydrate content >99% and residual protein impurities of 0.4% were isolated from *Hamamelis* bark in a yield of 0.4%. A 1% solution of RPS showed kinematic viscosity of 1080 mPa s^{-1}, indicating that the mucilage consists of polymers with a low degree of polymerisation.

Fractionation of RPS by IEC resulted in one neutral and three acidic polymer fractions (Table 1). Each fraction was further separated by GPC on Sephacryl S-300 to yield, finally, 10 subfractions which were characterized concerning average molecular weight, uronic acid content, monosaccharide composition and linkage types of the respective monomers.

Neutral fractions H I.2 and H I.3 with quite low molecular weights between 4 and 13 kDa consisted mainly of arabinose. Linkage analysis of these fractions and GC–MS identification of the partially methylated alditol acetates indicated the presence of highly branched arabans with 1,3- and 1,3,5-linked arabinose residues (Table 2). This linkage pattern can be correlated to

an araban with 1,3-backbone and side chains of 1,2-arabinose units, attached to the backbone via O-5 (Fig. 1).

The high molecular fraction H I.1 consisted mainly of arabinose and galactose in the ratio of about 3 to 2. The respective linkage pattern showed the existence of a typical neutral type II arabinogalactan with a 1,3-galactose backbone and branched arabinose side chains attached via O-6. The proportion of 1,2- and 1,4,6-linked glucose was determined to origin from starch.

All neutral fractions were contaminated with minor amounts of a glucan with 1,4- and 1,4,6-linked glucose. These carbohydrates may derive from α-linked starch, as the respective β-linked glucans would not be soluble by the aqueous extraction.

Acidic fractions consisted of a variety of heterogenous acidic arabinorhamnogalacturonans: the main chain of these polymers is build up by 1,3-linked galacturonic acid units; inserted 1,2-linked rhamnose units bear more or less branched arabinose-galactose side chains which are attched to the backbone via three-fold linked rhamnose units. These acidic polymers are the main compounds of fractions H II.2, H III.1, H III. 2, and H IV.1 and 2.

Fractions H II.1 and H III.3 additionally were composed by mannoglucans, typical reserve polysaccharides with β-1,4-mannose-glucose blocks, similar to that found in several *Digitalis* species (Hensel et al., 1998).

2.2. Influence of Hamamelis polysaccharides on keratinocytes

Raw polysaccharides (RPS) from *Hamamelis* bark were tested in concentrations of 0.1, 1, 10 and 50 μg/mL. After about three days of incubation it was obvious by mircroscopic observation that cells treated with 10 and 50 μg RPS showed nearly the same proliferation and differentiation behaviour as the untreated control groups.

Evaluation of proliferation rates by BrdU-incorporation indicated no significant influence of RPS after 10 days of incubation (Fig. 2A). The keratin K1 and K10

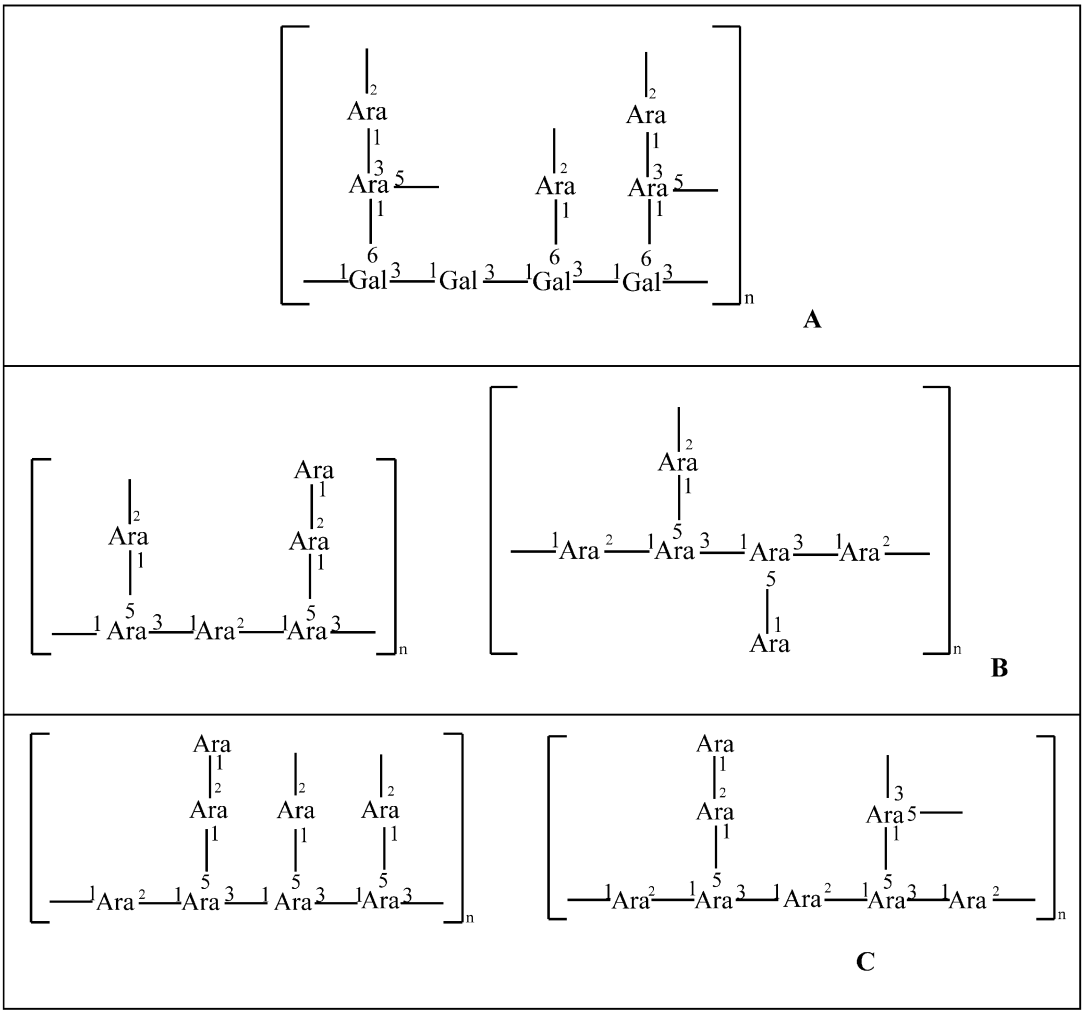

Fig. 1. Proposed structures of polysaccharides from *Hamamelis virginiana*: general structure of type II arabinogalactan H I.1 (A), neutral araban H I.2 (B), neutral araban H I.3 (C). The degree of substitution and length of side chains may vary among the polymers by heterodispersity.

formation also was not influenced significantly by RPS (Fig. 2B).

Mitochondrial activity of RPS-treated keratinocytes was significant lower for the cells treated with 10 and 50 μg polysaccharides compared to the untreated control. This phenomenon may be attributed to an adhesive polymer layer on the outer cell surface with an inhibited energy flux into the cells.

LDH values were on control levels for all groups, indicating RPS to be non-toxic.

Summarizing *Hamamelis* polysaccharides have no influence on proliferation, differentiation and metabolic activity of human keratinocytes.

2.3. Influence of polymeric proanthocyanidins on human keratinocytes

Two fractions, B and C, of polymeric proanthocyanidins have been isolated from *Hamamelis* bark and characterized according to methods described in a recent study (Dauer et al., 1998; Dauer, 2000). These fractions with a high purity (>95% calculated as catechin) were characterized as proanthocyanidins consisting of 3-*O*-galloylated catechin- and 3-*O*-galloylated epicatechin units with 4⇒8-interflavan linkage. Galloylation occurred only at the *O*-3 position while all other positions were not esterified. The respective polymers showed average molecular weights of about 1500 Da (fraction B) and 3400 Da (fraction C) determined by GPC and thiolytic degradation.

Toxic effects of both tannin fractions against human keratinocytes were not observed in the dose range from 1 to 100 μg/ml as evaluated by the respective lactatdehydrogenase titers, which were on control level (<5 U/ml) over the complete time of incubation.

Treatment of keratinocytes with both fractions B and C for 9 days resulted in the formation of typical cell monolayers which differed from the untreated control groups by the degree of confluence: while the procyanidin-treated groups formed complete monolayers, the control groups showed only about 40 to 50% confluence at the same time.

As expected from these observations, a signficant increase of cell proliferation was found for the procyanidin-treated groups, as determined by bromo-deoxyuridine (BrdU)-incorporation into the keratinocyte DNA and subsequent quantification by anti-BrdU-antibodies (Fig. 3). After 9 days of incubation fraction B enhanced the cell proliferation rates in doses of 1 and 10 μg/ml significantly, while fraction C had no effects at 1 μg level, but exceeded significant proliferation rates at 10 μg/ml. All further studies were performed with fraction C because of the limited availability of fraction B.

When monitoring the cell proliferation rates during incubation procyanidin fraction C significant differences to the control groups occured after 6 days of incubation: a time-dependent increase of cell growth compared to the control group was observed. Differences were significant after an incubation period of 6 days (Fig. 4). This indicates that the procyanidins do not act when added to the incubation medium as an punctuell stimulus, but have to be applied continously over longer time periods to stimulate growth processes.

Mitochondrial activity of the keratinocytes was determined by MTT-test by feeding fraction C in doses

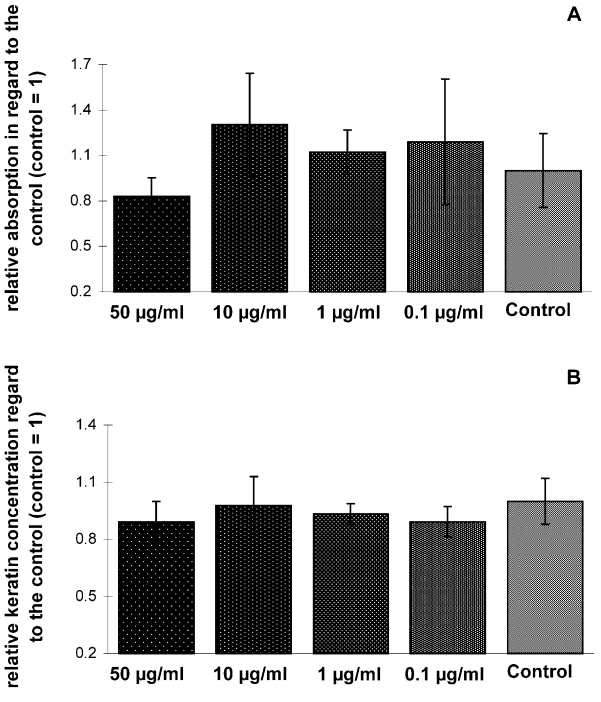

Fig. 2. Effects of raw polysaccharides from *Hamamelis virginiana* on cell proliferation (A) and differentiation (B) of normal human keratinocytes in different concentrations after 9 days of incubation. Results, determined by BrdU-incorporation in cell DNA and keratin K1/K10 determination (ELISA) are the mean±SD ($n=5$) and are not significant to the untreated control groups.

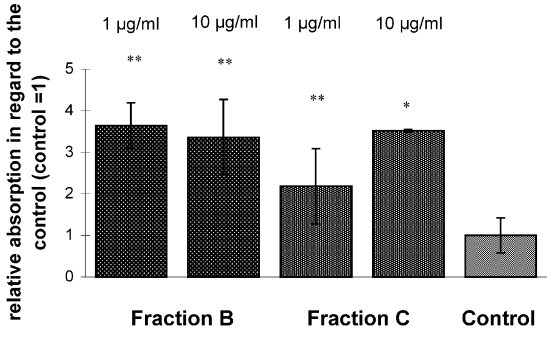

Fig. 3. Effects of oligomeric procyanidin fractions B and C (ProcyanoPlus) from *Hamamelis virginiana* on cell proliferation of normal human keratinocytes in concentrations of 1 and 10 μg/ml after 9 days of incubation. Results, determined by BrdU-incorporation in cell DNA, are the mean±SD ($n=10$) with $*P>0.1$ and $**P>0.05$ in comparison to the untreated control groups.

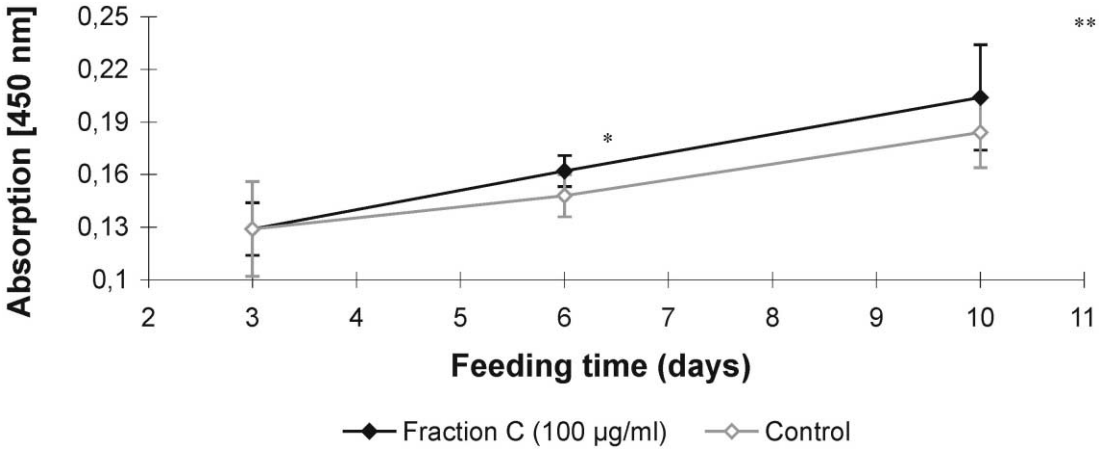

Fig. 4. Effect of oligomeric procyanidin fraction C (ProcyanoPlus) on cell proliferation of normal human keratinozytes over a 10 days incubation period as dertermined by BrdU-incorporation test (*$P > 0.1$ and **$P > 0.05$ in comparison to the untreated control groups).

of 1 and 10 µg/ml (Fig. 5). Significant increase of mitochondrial activity were observed with both concentrations and indicated an induction of metabolic activity by contact of the cells with fraction C.

In addition to these parameters, typical differentiation-specific keratins K1 and K10 (Muzarelli et al., 1999; Lane et al., 1985) were surveyed in the cells treated with fractions B and C with high-dose calcium as positive control. At doses of 1 and 10 µg/ml no significant increase of keratin formation was observed in procyanidin-treated groups (Fig. 6). This clearly indicates that the condensed tannins only induce keratinocyte proliferation, but do not act on the differentiation towards cornified cells.

2.4. Influence of procyanidins on irritated skin

For preliminary in vivo evaluation of *Hamamelis* procyanidins on irritated skin a semi-solid formulation containing 1% of *Hamamelis* procyanidin (ProcyanoPlus) was tested on its efficacy in preventing an sodium lauryl sulfate (SLS) induced irritant contact dermatitis in a standardized repeated short-time occlusive irritation test (ROIT) (Fartasch et al., 1999; Schnetz et al., 2000).

Over a three day period, defined skin areas of healthy volunteers were irritated using 0.5% SLS and with procyanidins in aqueous Eucerin®. To evaluate the influence of the pure cream formulation aqueous "placebo" Eucerin® without procyanidins was used additionally. One test site (positive control) received the irritant alone, two further test sites served as control (remained untreated or water).

The results of the TEWL correlated well with the results of the clinical score and the colorimetry. In all cases an irritation with SLS—with or without test product—had led to an increase of the TEWL values in comparison to the untreated area. This shows clearly that a local barrier disruption had occurred. By the pretreatment with ProcyanoPlus in aqueous eucerine and by pretreatment with eucerine alone the intensity of

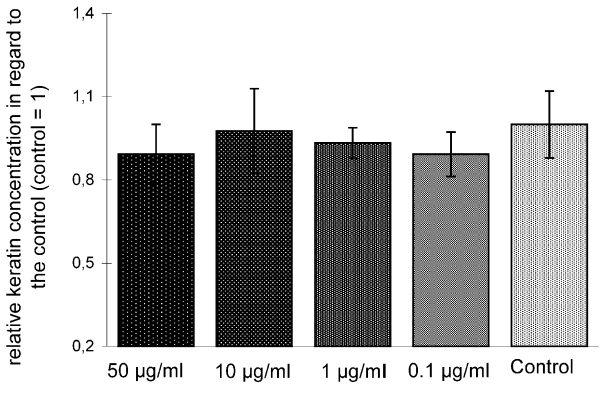

Fig. 5. Effects of oligomeric procyanidin fractions B and C (ProcyanoPlus) from *Hamamelis virginiana* on cell differentiation of normal human keratinocytes in concentrations of 1 and 10 µg/ml after 9 days of incubation. Results, determined by quantification of keratin K1, K10 concentrations (ELISA), are not significant to the untreated control groups.

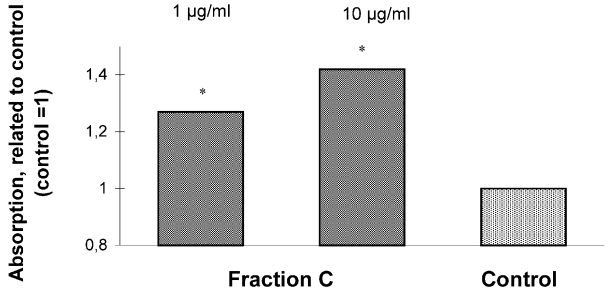

Fig. 6. Effects of oligomeric procyanidin fraction C (ProcyanoPlus) from *Hamamelis virginiana* on mitochondrial activity of natural human keratinocytes in concentrations at 1 and 10 µg/ml level after 9 days of incubation. Results, determined by MTT-test, are the mean ± SD ($n = 10$) with *$P > 0.1$ in comparison to the untreated control groups.

the reaction was diminished (Fig. 7). This effect was clearly more pronounced when ProcyanoPlus was applied. Treatment of the SLS-irritated skin areas with "placebo" aqueous Eucerin® reduced TEWL-increase for 45%, in comparison to SLS induced TEWL enhancement. Treatment with the procyanidin-containing formulation decreased TEWL significantly by 53%.

2.4.1. Clinical score

Treatment with 0.5% SLS caused an increase in the clinical scoring as a measure of dermal inflammation (Fig. 8). The clinical signs of an inflammation were clearly reduced by treatment with either aqueous Eucerine of ProcyanoPlus. But the effect of ProcyanoPlus was significantly better compared to pure eucerine.

Similar results were obtained by colorimetry measurements (Fig. 9), assessing skin color as a sign for erythema formation: irritation with SLS leads to strongly increased values, which are reduced when the irritated skin areas are treated with procyanidins.

3. Discussion

Information on pharmacological effects of high molecular compounds from *Hamamelis* bark is limited to only few reports due to the complexicity of the chemical structures of these compounds. Erdelmeier et al. (1996) reported on antiviral and antiphlogistic activities of high molecular weight proanthocyanidins from *Hamamelis* bark.

Up to now, no information is available about effects of *Hamamelis* plant metabolites on normal human keratinocytes. Furthermore, to our knowledge this is the first time that structural data about polysaccharides

occurring in the bark of *Hamamelis virginiana* L. are provided.

This study focused on the effects of polymeric proanthocyanidins and polysaccharides isolated from the bark of *Hamamelis virginiana* on normal human keratinocytes.

Additionally, polysaccharides were included in this study, due to the fact that carbohydrates—also polysaccharides—are getting more and more into the focus of skin research because of antiphlogistic and proliferation enhancing effects as well as for stimulation of skin immune response (Berthod et al., 1994; Kitamura et al., 1997; Muzarelli et al., 1999).

For this reason, water-soluble polysaccharides were isolated in good yields from *Hamamelis* bark, fractionated and structurally characterized. Molecular weights, monomer composition and linkage types were determined. Principally, three different types of polysaccharides were identified: low molecular 1,3-linked arabans were the major polymers of the neutral fraction. While arabans are commonly 1,5-linked polymers the *Hamamelis* arabans represent quite unusual structures. Minor amounts of type II arabinogalactans, commonly occuring as cell structural components, were found additionally to the arabans in the neutral fraction of the mucilage. The heterogeneous acidic fractions consisted almost exclusively of rhamnogalacturonans with a high portion of neutral pentoses, mainly arabinose.

Testing of these polysaccharides on a dynamic keratinocyte cell system with the specific properties of forming differentiated, cornified cells after adequate stimuli did not indicate any positive carbohydate-mediated activity. Thus, polysaccharides cannot significantly contribute to the skin activity of *Hamamelis* bark.

In contrast, two different polymeric procyanidin fractions exhibited strong and dose-dependent induction of cell proliferation and mitochondrial activity of keratinocytes. Interestingly, these compounds did not influence the state of differentiation of keratinocytes. These results indicate, that *Hamamelis* proanthocyanidins only stimulate cell growth extensively, but do not influence the formation of cross-linked cornified envelopes (Thatcher and Rice, 1985). Thus, polymeric proanthocyanidins act as good proliferation stimulants for skin cells, leading probably to enhanced cell growth. As the effects were observed at low doses, likely to be reached under in vivo conditions in the skin epidermis the results may be of relevance for the respective in vivo situation. Similar inductors of cell proliferation, without induction to keratinized, differentiated cells are part of classical skin care products, as for example *Aloe vera* gel. From our point of view, it is promising that the tannins tested are not toxic towards the cells. The adstringent properties of the tannins do not have any negative influence on the cells within the dose-range tested.

In a preliminary clinical pilot study the procyanidins were tested within a cumulative irritation model on skin of healthy volunteers. All test parameters, including clinical scoring, transepidermal water loss and measurement of the skin colour, indicated clearly that the procyanidins positively influenced SLS induced irritation and skin barrier disruption.

Summarizing, high-molecular proanthocyanidins from the bark of *Hamamelis virginiana* L. can be assessed to be at least partly responsible for the medicinal use of this plant in dermatology and cosmetics. If and to what extent the hydrolysable and low-molecular condensed tannins, which are also present in the material contribute to the skin activity has to be evaluated in further studies.

Summarizing also, the results of this study demonstrate that polymeric proanthocyanidins from *Hamamelis virginiana* can be assessed to be at least partly responsible for the medicinal use of tannin-containing *Hamamelis*-preparations in dermatology and cosmetics by influencing keratinocyte proliferation.

4. Experimental

4.1. General

Heat-sterilization was performed either at 121 °C/1 h in an autoclave or at 175 °C/2 h in an oven. Statistical analysis was done using an unpaired student *t*-test.

Hamamelis polysaccharides were extracted from a batch of *Hamamelis viriginiana* bark, obtained in 1998 from Abtswinder Naturheilmittel, Abtswind, Germany. A voucher specimen is retained in the documentation center of the Institute of Pharmaceutical Biology, University of Erlangen.

Proanthocyanidins (patent pending) were obtained under the trade name ProcyanoPlus by DermoPlus-Hensel (Schlossbergstrasse 53, CH-8820 Wädenswil, Switzerland).

4.2. Isolation and fractionation of polysaccharides and procyanidins

Polysaccharide isolation: 200 g of powdered material were pre-extracted for 20 h in a Soxhlet system with acetone and subsequently for 30 h with methanol. The eluates were discarded. The residue was dried at 40 °C (154 g) and after addition of 30 g polyvinylpyrrolidone extracted three times with 770 ml of water. The combined extracts were concentrated to a 150 ml volume and slowly added into 600 ml 2-propanol. The precipitated raw polysaccharides (RPS) were centrifuged at 3600 *g*, dialysed and lyophilized to yield a nearly white powder (0.51% related to the dried starting material).

Fractionation of RPS was performed by IEC on DEAE-Sephacel (Pharmacia, Freiburg). Conditions: gel in the phosphate form, column dimension 20×2 cm, flow rate 80 ml/h, fraction size 5 ml, mobile phases: water, then step gradient with sodium phosphate buffers pH 6.0 with ion strength 0.1 mol/l, 0.25 mol/l, 0.5 mol/l. Carbohydrate-containing fractions were pooled, dialysed and lyophilized.

All fractions obtained from IEC were further fractionated by GPC on Sephacryl HR S-300 (Pharmacia, Freiburg). Conditions: column dimensions 1.9×77 cm, flow rate 25 ml/h, fraction size 2 ml, mobile phase: water. Carbohydrate-containing fractions were pooled, dialysed and lyophilized.

Isolation of proanthocyanidins (Dauer et al., 1998): the powdered *Hamamelis* bark (400 g) was percolated using acetone–water mixture in the ratio 7:3. The acetone was removed from the extract in vacuo and the aqueous residue was first extracted extensively with petroleum ether (rejected) and following with ethyl acetate (5×300 ml, rejected). The aqueous phase was freeze-dried to yield 47 g solid, brownish product. Of this 6.0 g were chromatographed on a Sephadex LH-20 column (Amersham-Pharmacia, Upsala) with ethanol (fraction A, yield 46%), methanol (fraction B, yield 26%) and acetone–water mixture (fraction C, yield 11%).

4.3. Polysaccharide analysis

Total carbohydrates were assayed with the phenol–sulphuric test (Dubois et al., 1956) and by resorcinol-test (Monsigny et al., 1988). Determination of uronic acids was performed using m-hydroxydiphenyl and galacturonic acid as reference material (Blumenkrantz and Asboe-Hansen, 1973). Carbohydrate-containing solutions were concentrated under reduced pressure at temperatures below 40 °C. Cellulose membranes with cut-off of 3500 Da were used for dialysis. The molecular weight distribution of polysaccharides was determined by GPC using standard dextrans (Sigma, Steinheim, Germany). Polysaccharides were hydrolysed with trifluoracetic acid 2 mol at 121 °C for 60 min. Alditol acetates of neutral sugars were prepared according to Blakeney et al. (1983). GLC was performed on a Hewlett-Packard HP 6890 system with mass selective detector at 220 °C with helium as carrier gas (pressure 1.3 bar) on a HP-225 fused silica capillary column (30 m×0.25 mm i.d., film thickness 0.25 μm).

Reduction of acidic polysaccharides to the carboxyl-reduced polymers was accomplished in the presence of carbodiimide and $NaBD_4$ as described by Taylor and Conrad (1972). Methylation analysis was performed according to the Hakamori method, modified by Harris et al. (1984).

4.4. Submerged keratinocyte culture

Keratinocytes were obtained either from commercial available cultures (Cell Systems, St Katharinen) or isolated from human skin, obtained by operative resection. Therefore the skin was decontaminated using a solution of fungizone (0.2%), gentamycin (5.9 μg/ml), sodium hydrogen carbonate (7.5%) in DMEM medium (Gibco, Karlsruhe). Tissue was dissected mechanically and after incubation of the tissue in dispase solution, dermis and epidermis were separated. The epidermis was trypsinated for 15 min at 34 °C with trypsin 0.05% and sodium edetate 0.53 mM. Reaction was stopped by the addition of TNS (Cell Systems, St Katharinen). Keratinocytes were centrifuged at 463 *g* for 5 min, resuspended in PBS, centrifuged again and resuspended in KGM-2 incubation medium in 96-well-tissue plates. Incubation was perfomed at 34 °C in a humidified 5% carbon dioxide atmosphere.

Secondary cultures were obtained at 60 to 70% confluence after trypsinisation. All cultures were free from contaminants of fibroblasts or melanocytes and were confluent after about 9 to 14 days of culture.

Feeding of the test substances to the keratinocytes was done after dissolving the compounds in KGM–2/DMSO mixtures. Positive controls were obtained from high-calcium media (Ca^{2+}, 1.5 mM), negative controls incubated in medium with no supplements.

4.5. Characterization of keratinocyte physiology

Growth rates were determined after trypsinisation using trypan-blue, mitochondrial activity by the MTT-test according to Mosmann (1983).

Lactat dehydrogenase (Amador et al., 1963) was quantified from the incubation supernatant using LDH-assay kit (Sigma, Steinheim).

Cell proliferation was determined by BrdU-kit (Boehringer, Mannheim) according to Porstmann et al., 1985.

For quantification of keratins K1 and K10 the cells were washed with PBS and keratins solubilized by adding 150 μl urea 8 M, β-mercaptoethanol 0.2 M and Tris 1.5 mM. Fifty microlitres of the solubilisate was transferred to a 96-well microtiter plate with 100 μl sodium carbonate buffer 0.05 M. The mixture was incubated for 18 h at 4 °C. After removal of excess of the keratin antigen and 1 h incubation with block medium (milk powder 7% in PBS with Tween 20, 0.05%) 100 μl of a monoclonal mouse-anti-human-keratin-antibody (Dako, Hamburg, diluted 1:400 in block medium) was added. The mixture was incubated at 37 °C for 60 min. After washing three times with 150 μl PBS containing Tween 20 0.05%, 150 μl POD-conjugated goat-anti mouse-IgG-antibody (Sigma, Steinheim, 1:2000 in block medium) was added and the mixture incubated at 37 °C for 60 min. After 3 washing steps, 100 μl of substrate solution (phenylendiamine 0.4 mg/ml in sodium

phosphate buffer 0.2 M, pH 5.0 and 11 μl hydrogen peroxide 30%) was added, the mixture reacted 10 min at room temperature and the reaction stopped by addition of 100 μl sulfuric acid 2.5 M. The absorbance was determined in an ELISA-reader at 492 nm. Calibration was performed using standard keratins.

4.6. Clinical testing

4.6.1. Test protocol (ROIT)

Fifty microliters of the irritant (aqueous SLS, 0.5%, purity of SLS >99%, Merck, Darmstadt, Germany) was applied twice daily under patch occlusion for 30 min, with an interval of 3–3.5 h. This schedule was followed for 3 consecutive days. Application was performed by means of a flat aluminum chamber (Large Finn Chambers®, inner diameter: 12 mm) with filter paper discs, fixed on Scanpor® tape. The middle part of both volar forearms was used as the test site with a total of 2 patches on each arm. One test site received the irritant alone, two other test sites were pretreated with the test products (ProcyanoPlus and aqueous Eucerine, 0.05 ml/2 cm^2 skin) 10 min before the irritant was applied. Two further test sites served as control sites (remained untreated or water). The procedure was repeated every day during the experiment. The placing of the products was changed from person to person according to a system of rotation (randomization).

4.6.2. Evaluation

All measurements were carried out in air-conditioned rooms (room temperature 20–22 °C, relative humidity between 30–45%, room temperature and humidity data being recorded during the measurements, applying the guidelines of the Standardization Group of the European Society of Contact Dermatitis (Pinnagoda et al., 1990; Fullerton et al., 1996). All measurements were performed after a rest of 30 min for equilibration. Measurements were performed in the morning of day 1 and in the afternoon of day 3.

4.6.3. Transepidermal water loss (TEWL) measurements

The quantitative measurements of TEWL were carried out using the Tewameter TM 210 (Courage and Khazaka, Cologne, Germany). The TEWL was calculated automatically and expressed in g/m^2 h. The Tewameter probe was used in a holding device to avoid heating of the probe. The probe was rested on the skin and TEWL was continuously recorded for a period of 3 min. Mean values were obtained from two successive recordings for every test site.

4.6.4. Skin temperature

Skin temperature was measured prior to TEWL measurements using a Digimed H11S device (ttw, Waldkirch, Germany) and had to range between 28–32 °C (Mathias et al., 1981).

4.6.5. Clinical examination

Visual scoring was performed according to the following scale: 0, no reaction; 0.5, slight scaling or very weak erythema; smooth surface; 1, weak erythema, possibly slight infiltration, slight roughness, slight scaling, mild edema, fine fissures; 2, erythema, more roughness, scaling and edema, fissures; 3, pronounced erythema, extensive scaling, pronounced edema, possibly vesicles, bullae, pustules and/ or pronounced crusting.

4.6.6. Colorimetry

For colorimetry, the measuring head of a Chroma-Meter CR 300 (Minolta, Ahrensburg, Germany) was applied to the skin avoiding pressure. Measurements were conducted in triplicate. For the measurements the L^* a^* b^* system was chosen, for this coordinates most closely reflects the color of human skin (Ale et al., 1996); a^* represents the green ($-a^*$)–red ($+a^*$) axis, therefore we used this coordinate for evaluation.

4.6.7. Volunteers

Seven healthy caucasian subjects (2 male, 5 female; age 22 to 38 years, mean age 29.8 years) with no history of atopic eczema or other skin diseases. Written informed consent was obtained from all of them. The study was approved by the ethical committee.

Abstract

Seven quassinoids including a new 12-*epi*-11-dehydroklaineanone were isolated from the leaves of *Eurycoma longifolia* (Simaroubaceae) as plant growth inhibitors or related compounds. The strongest activity was found in 14,15β-dihydroxyklaineanone.

Keywords: *Eurycoma longifolia*; Simaroubaceae; Plant-growth inhibitor; Quassinoid

1. Introduction

Eurycoma longifolia (Simaroubaceae) is one of the most well known folk medicines for intermittent fever (malaria) in Southeast Asia (Chan et al., 1986). This plant has been reported to contain various bioactive quassinoids and squalene- or tirucallane-type tritertpenoids (Morita et al., 1993a,b; Itokawa et al., 1992). In our continuing investigation on plant growth regulators from Thai plants, we found plant growth inhibitory potentials in this plant. This report deals with the isolation and identification of the active principles and their plant growth inhibitory activities against cucumber seedlings, i.e. compounds **1**–**7**.

2. Results and discussion

Bioassay guided purification gave two major active fractions, A and B. Seven compounds were isolated by further chromatography including preparative HPLC of these two fractions. The spectral data of **1** and **2** were identical with those of C_{19}-quassinoids (Fig. 1), longilactone and 6-dehydrolongilactone, respectively (Morita et al., 1993a,b). Compounds **3**, **5**, **6** and **7** were identified as klaineanone-type C_{20}-quassinoids, 11-dehydroklaineanone, 15β-hydroxyklaineanone, 14,15β-dihydroxyklaineanone, and 15-β-*O*-acetyl-14-hydroxyklaineanone (Fig. 1), respectively, by comparison of the spectral data with those of known compounds previously reported (Itokawa et al., 1992; Morita et al., 1993b; Polonsky and Baskevitch, 1995). This is the first finding that compound **6** occurs in *E. longifolia*, while its occurrence in *Perriera orientalis* has been previously reported (Polonsky and Baskevitch, 1995).

A new compound (**4**) was obtained as a glassy resin ($[\alpha]_D^{25}$ −11.2° ($c=0.1$, MeOH); UV λ_{max} (MeOH) nm (log ε): 238 (4.2); IR ν_{max} (KBr) cm^{-1}: 3400, 1720, 1660). The HR–EIMS spectrum of **4** exhibited a molecular ion peak at m/z 362.1727 ($C_{20}H_{26}O_6$ calc. for 362.1729). The ^1H NMR spectrum (Table 1) resembled that of **3** except for signals corresponding to H-9, H-12, H-13, H-14, H-15β and H-15α. The resonances corresponding to H-9, H-13 and H-15α were shifted upfield to 3.08, 2.07 and 2.93 ppm in **4** from 3.74, 2.25 and 3.67 in **3**, respectively. Also the signals of H-12, H-14 and H-15β appearing at 3.72, 1.93 and 2.64 ppm in **3** were shifted downfield to 4.02, 2.07 and 2.75 ppm in **4**, respectively.

Furthermore, the coupling constant of H-12 of **4** ($J=10.9$ Hz) was larger than that ($J=2.9$ Hz) of **3**, suggesting that **4** is an epimer of **3** at C-12. In support of

H-14	1.93 (*m*)	–	2.07 (*m*)	–	−0.14	
H-15 β	2.64 (*dd*)	6.7, 19.3	2.75 (*dd*)	6.3, 19.0	−0.11	
H-15 α	3.67 (*dd*)	12.4, 19.4	2.93 (*dd*)	12.6, 19.0	0.74	
H-18	1.98 (*s*)	–	1.98 (*s*)	–	0.00	
H-19	1.26 (*s*)	–	1.28 (*s*)	–	−0.02	
H-20	1.13 (*s*)	–	1.13 (*s*)	–	0.00	
H-21	1.11 (*d*)	7.06	1.12 (*d*)	6.3	−0.01	[a]

[a] NOEs to H-12 were observed.

this, NOEs were observed between Hα-9 and H-12, H-12 and H-13, and H-12 and H-21. Hence, the structure of **4** was determined to be the epimer of **3** at C-12 named 12-*epi*-11-dehydroklaineanone (Fig. 1).

The plant-growth inhibitory activities of **1**–**7** against cucumber seedlings were tested as described in the previous report (Jiwajinda et al., 2000). Of the compounds tested, the activities of **5** and **6** were significantly higher than the others. In particular, the activity of **6** against root growth is remarkable (Table 2). Interestingly, while **3** showed slight activity to inhibit growth of cucumber (IC_{50} = 55.6 μM on shoot growth and 77.3 μM on root growth, compound **4** was inactive at a concentration less than 200 μM. It is notable that **7** showed an effective inhibitory activity (IC_{50} = 17.6 μM) towards root growth but was inactive against shoot growth. Compounds **1**–**7** showed no inhibitory activity against rice seedlings (IC_{50} > 200 μM). Based on these results, the following conclusions may be provisionaly presented for plant growth inhibition of quassinoids. (1) C-20 quassinoids with a hydroxyl group at C-15 may possess more significant plant growth inhibitory activity than C-19 quassinoids. (2) The absolute configuration of the C-12 hydroxyl group may be one important factor for activity. (3) Masking of the hydroxyl group at C-15 with an acyl group may be a factor to give selectivity in plant growth inhibition.

So far, quassinoids have been reported to exhibit a wide range of bioactivities to animals on both in vitro

Table 2
Inhibitory activities of quassinoids (**1**–**7**) against the growth of cucumber and rice seedling[a]

Compound	Cucumber seedling		Rice seedling	
	IC_{50} (μM) root growth	IC_{50} (μM) shoot growth	IC_{50} (μM) root growth	IC_{50} (μM) shoot growth
1	65.6±10	95.0±1.0	>200	>200
2	25.7±0.5	48.6±0.5	>200	>200
3	55.6±1.0	77.3±1.0	>200	>200
4	>200	>200	>200	>200
5	10.5±0.5	23.7±0.5	>200	>200
6	2.5±0.5	22.7±0.5	>200	>200
7	17.6±0.5	>200	>200	>200

[a] IC_{50}s were graphically determined by the plot between log (concentration) and % inhibition in the length of roots or shoots to that of the controls (without test compound). Inhibitions (%) were calculated by {[average length in the control—average length with test compound]/average length in the control}×100.

and in vivo (Morita et al., 1993b; Itokawa et al., 1992; Okano et al., 1990). Thus, plant growth inhibitory activity may be useful as a preliminary screening method for finding valuable quassinoids with medicinal activities. Further investigation on other bioactivities to the animal cells of these isolated quassinoids is now in process.

3. Experimental

3.1. General

Melting point were determined by a micro melting point apparatus (Yanaco Seisakusho Co., Ltd., Japan) and were uncorrected. Optical rotation dispersion measurements employed a Jasco J-5 polarimeter. Infrared and UV absorption spectra were recorded on Shimadzu model 435 and Shimadzu UV-200 spectrophotometers, respectively. Proton NMR spectra were obtained on a Jeol JX 400 NMR spectrometer, 400 MHz, in $CDCl_3$ and TMS as an internal standard. High resolution mass spectra were recorded on a Jeol-DX 300 Mass spectrometer. High performance liquid chromatography was carried out on a Hitachi 665-A HPLC.

3.2. Plant materials

Leaves of *Eurycoma longifolia* were collected at Surajthani, Thailand. A voucher specimen (Specimen No. BK 4316 collecter PUT No.2724) is kept in Bangkok Herbarium, Department of Agriculture, Ministry of Agriculture and Co-operation, Bangkok, Thailand.

3.3. Bioassay

The assays were tested in triplicate. The control experiments were conducted in distilled water (without test compound). The maximum concentration of test compound in the assay was 200 μM.

Cucumber seedling test: the seeds of *Curcumis sativas* were sterilized by soaking in sodium hypochlorite solution (1% active chloride content) for 15 min, and washed under running tap water for 2 h. Ten sterile seeds were sown on filter paper containing a definite concentration of test compound in a petri dish (9 cm id.). Distilled water (3 ml) was added to the Petri dish and incubation was carried out at 30 °C under continuous light for 5 days. The elongation of roots and shoots were measured compared to those of the controls.

Rice seedling test: seeds of rice *Oryza sativa*, cv. Nipponbare were sterilized as well as cucumber seeds. Sterile seeds were dipped in distilled water and incubated at 30 °C for 3–5 days until the seeds were germinated (about 2 mm hypocotyl), with changes of the water twice a day. Seven germinated seeds were transferred to a glass tube (3 cm id.×2 cm height) containing a definite concentration of test compound in distilled water (1 ml) and incubated at 30 °C under continuous light for 7 days. The elongation of second leaf sheath and dry weight of root were measured compared to those of the controls.

3.4. Extraction and isolation

Separation of the active principles was guided by a bioassay using cucumber seedlings. The ethanol extract (9 g) from the dried leaves (500 g) of *Eurycoma longifolia* was partitioned between EtOAc (300×2 ml) and H_2O (500 ml). The active EtOAc part (2.5 g) was applied to silica gel column (25×500 mm) eluted stepwise with 20% increasingly EtOAc in hexane, 100% EtOAC and then MeOH. Two active fractions, A (100% EtOAc eluate, 90 mg) and B (100% MeOH eluate, 146 mg), were derived. Both fractions were further purified on silica gel and ODS gel, and finally by preparative HPLC on μ-Bondasphere C_{18} (19×150 mm) eluted with 35% MeOH in water (7 ml/min) to give compound **1** (5.6 mg, t_R 12.5 min), **4** (3.0 mg, t_R 13.5 min) and **6** (6.2 mg, t_R 19.5 min) from fraction A. Also, **2** (8.0 mg, t_R 22 min), **3** (6.9 mg,

t_R 26.2 min), **5** (23 mg, t_R 28.5 min), and **7** (18.0 mg, t_R 20.5 min) were obtained from fraction B.

Compound **4**: 12-*epi*-11-dehydroklaineanone, a colorless glassy resin, $[\alpha]_D^{25}$ −11.2 ° ($c = 0.1$, MeOH); EI–MS at 70 ev, m/z (% rel. int.) 362 [M^+] (36), 344 (10), 333 (18), 315 (12), 283 (11), 239 (14), 213 (15), 187 (20), 159 (31), 135 (32), 119 (28), 109 (34), 95 (82), 77 (44), 67 (62), 55 (68), 41 (100); HR–EIMS (probe): 70 ev). [M^+] m/z 362.1727 ($C_{20}H_{26}O_6$, requires 362.1729); UV λ_{max} (MeOH) nm (log ε): 238 (4.2); IR ν_{max} (KBr) cm^{-1}: 3400, 1720, 1660; ^1H NMR (see Table 1).

Acknowledgements

We wish to thank Dr. Vichai Korpraditsakul of Kasetsart University, Thailand, for supplying the plant materials and Mr. Winai Somprasong of Bangkok Herbarium, Department of Agriculture, Ministry of Agriculture and Co-operation, Bangkok, Thailand, for helpful identified plant specimen. S.J. gives grateful thanks for a research fellowship from the Japan Society for the Promotion of Science (JSPS).

Acetyl and butyrylcholinesterase-inhibiting triterpenoid alkaloids from *Buxus papillosa*

Atta-ur-Rahman[1], Shehnaz Parveen, Asaad Khalid, Afgan Farooq, M. Iqbal Choudhary*

H.E.J. Research Institute of Chemistry, International Center for Chemical Sciences, University of Karachi, Karachi-75270, Pakistan

Received 19 March 2001; received in revised form 20 June 2001

Abstract

Three triterpenoid alkaloids, buxakashmiramine [(20*S*)-20-dimethylamino-4′,6′-dimethoxy-5′-hydroxybenzoylamino-3β-methyl-buxan-31-ol] (**1**), buxakarachiamine [(20*S*)-20-dimethylamino-2′-hydroxy-3β-methyl-3′-methyl-butanoylamino-9,10-*seco*-buxa-9(11), 10(19)-dien-31-ol] (**2**) and buxahejramine [(20*S*)-20-dimethylamino-2′-hydroxy-3β-methyl-3′-methyl-pentanoylamino-9,10-*seco*-buxa-9(11), 10(19)-dien-31-ol] (**3**) were isolated from the leaves of *Buxus papillosa*. Four known bases, cycloprotobuxine-C (**4**), cyclovirobuxeine-A (**5**), cyclomicrophylline-A (**6**) and sempervіraminol (**7**) were isolated for the first time from this species. Their structures were established through extensive spectroscopic studies. Most of these compounds exhibited anticholinesterase activity.

Keywords: *Buxus papillosa*; Buxaceae; Triterpenoid alkaloids; Buxakashmiramine; Buxakarachiamine; Buxahejramine; Anticholinesterase activity

1. Introduction

Buxus papillosa C.K. Schneider (Buxaceae) is widely distributed in the North West frontier province of Pakistan. *Buxus* species find extensive use in the treatment of various ailments, such as rheumatism, skin disorders and venereal diseases in the indigenous system of medicine (Cordell, 1981). *B. papillosa* is the most extensively investigated species of the genus *Buxus* and has so far afforded more than 50 triterpenoidal and steroidal alkaloids (Atta-ur-Rahman, 1990; Naz, 1995). As a consequence of continuing phytochemical investigations on this plant, we report on the isolation and characterization of three new bases buxakashmiramine (**1**), buxakarachiamine (**2**) and buxahejramine (**3**), along with four known triterpenoidal bases cycloprotobuxine-C (**4**), cyclovirobuxeine-A (**5**), cyclomicrophylline-A (**6**) and sempervіraminol (**7**). The structure elucidation studies were carried out through extensive spectroscopic studies.

2. Results and discussion

The ethanolic extract of the air-dried leaves of *B. papillosa* was evaporated to a gum and dissolved in water. After defatting with hexane, the aqueous layer was extracted with $CHCl_3$ at different pH values. The fraction obtained at pH 9.0 afforded compounds **1–3**.

Buxakashmiramine (**1**), $C_{36}H_{56}N_2O_5$, showed UV absorptions at 211 and 260 nm, attributable to a substituted secondary benzamidic chromophore (Silverstein et al., 1981). The IR spectrum displayed bands at 3352 (OH), 2854 (CH), and 1578 (C=C) cm^{-1}. The HREI MS displayed the M^+ at m/z 596.4238 corresponding to the molecular formula $C_{36}H_{56}N_2O_5$ (calc. 596.4188) indicating 10 degrees of unsaturation in the molecule. Cleavage of the substituted benzoyl moiety yielded a peak at m/z 181. The base peak at m/z 72 represented the trimethyliminium ion cleaved from the C-17 of main skeleton (Budzikiewicz, 1972). The overall mass fragmentation pattern of alkaloid **1** was very similar to *Buxus* alkaloids bearing an *N,N*-dimethyl amino group at C-20 and a benzamide group at C-3 (Atta-ur-Rahman, 1990).

Three 3H singlets at δ 0.78, 0.92, and 0.93 in the ^1H NMR spectrum of **1** were assigned to the tertiary C-30, C-18 and C-32 methyl group protons. A doublet at δ 0.98 ($J_{21,\ 20} = 6.5$ Hz) was due to the C-21 secondary methyl protons, while the vicinal C-20 methine proton appeared as a multiplet at δ 2.04. A set of AB doublets at δ 3.18 and 3.35 ($J_{31\alpha,\ 31\beta} = 12.5$ Hz) was due to the C-31 hydroxymethylene protons. The C-19 methylene protons of the cyclopropane ring also appeared as AB

7

doublets at δ 0.37 and 0.56 ($J_{19\alpha,\ 19\beta}$ = 4.1 Hz). A 3H singlet at δ 2.90 and a broad 6H singlet at δ 2.31 were due to the N_a-methyl at C-3 and the N_b-dimethyl protons at C-20, respectively. The C-3H appeared as a double doublet at δ 4.69 ($J_{3,\ 2\alpha}$ = 3.7 Hz, $J_{3,2\beta}$ = 10.8 Hz). The axial disposition (α-orientation) of C-3H is consistent with the *trans* diaxial coupling of 10.8 Hz observed between C-3αH and the C-2βH. The α-stereochemistry of the C-31 hydroxymethylene protons is based on X-ray diffraction studies done by Guilhem (1975) and the ^{13}C NMR studies by Sangare et al. (1975) in which it was shown that of the two methyl substituents at C-4, it is the α (C-31) methyl which undergoes preferential oxidation. As the *Buxus* alkaloids are biogenetically related to cycloartenol, the configuration at six of its asymmetric centres is predicted as 5α, 8β, 9β, 10β, 13β and 14α. Similarly the assignment of α-configuration to the 20-methyl amino group is again on the basis of biogenetic precedents, where it is known that all reported 20-amino steroids possess the α-configuration at that centre (Brown and Kupchan, 1962). An interesting 6H singlet at δ 3.87 was assigned with the help of various NMR techniques such as HMBC and HMQC to the two methoxy groups substituted at C-4′ and C-6′ of the benzoyl ring, while a downfield 2H singlet at δ 6.56 was due to the two aromatic protons at C-3′ and C-7′ of the benzoyl group.

The broad-band decoupled ^{13}C NMR spectra of **1** indicated the presence of 9 methyl, 10 methylene, 7 methine, and 10 quaternary carbons. The C-19 methylene appeared at δ 29.8, while the C-3 methine appeared at δ 56.7. The two methoxy carbons resonated at δ 56.6. Five downfield signals at δ 173.4, 127.7, 104.3 and 136.4 were assigned to the amidic carbonyl, C-4′/C-6′ bearing the methoxy groups, C-5′ bearing the hydroxyl, the aromatic C-3′/C-7′ and the C-2′, respectively. One-bond ^{1}H/^{13}C chemical shift correlations were determined by the HMQC (Atta-ur-Rahman and Choudhary, 1996). Complete assignments of ^{1}H and ^{13}C NMR spectra, multiplicities and one-bond ^{1}H/^{13}C connectivities are shown in Table 1.

The dimethoxy benzoyl fragment, has very rarely been observed in *Buxus* alkaloids. It was established by the long-range ^{1}H/^{13}C correlations as determined by the HMBC spectrum (Fig. 1). The C-4′/C-6′ methoxy protons at δ 3.87 were found to be correlated with the C-4′/C-6′ (δ 147.4) and the C-5′ (δ 127.7) in the HMBC spectrum. The aromatic protons resonating at δ 6.56 (H-3′/H-7′) showed long-range heteronuclear correlation with the C-1′ carbonyl (δ 173.8) and with C-2′ (δ 136.4) and C-4′ (δ 147.4) of the benzoyl ring. The N_a-CH_3 protons (δ 2.90) and H-3α (δ 4.69) also showed long-range interactions with the C-1′ carbonyl. The COSY-45° couplings observed between H-3α (δ 4.69)/H_2-2 (δ 2.08, 1.72), H_2-2/H_2-1 (δ 1.37, 1.78), H-5 (δ 2.10)/H_2-6 (δ 1.75), H_2-6/H_2-7 (δ 1.39), H_2-7/H-8 (δ 1.49), H_2-11 (δ 1.72)/H_2-12 (δ 1.38), H_2-15 (δ 1.60, 1.65)/H_2-16 (δ 1.17), H-31α (δ 3.18)/H-31β (δ 3.35) and H-19α (δ 0.37)/H-19β (δ 0.56) helped in unraveling the spin systems involved and in assigning structure **1** to this new alkaloid.

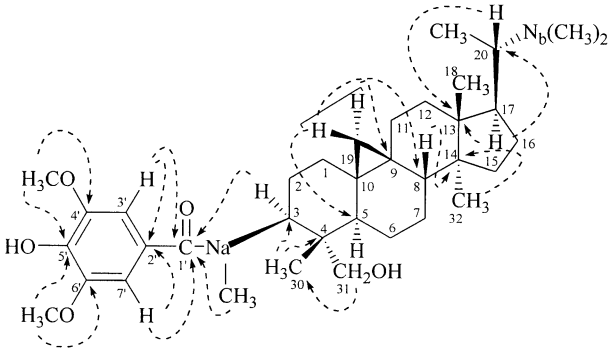

Fig. 1. Important HMBC interactions observed for compound **1**.

Compound **2** (*m*/*z* 514.4149, $C_{32}H_{54}N_2O_3$) which was isolated as white amorphous powder, showed UV absorption maxima at 238 and 245 nm characteristic of a 9(10→19) *abeo*-diene system (Atta-ur-Rahman et al., 1991). The IR spectrum displayed bands at 3358 (OH), 2855 (CH), 1645 (amide carbonyl) and 1602 (C=C) cm^{-1}. The HREI MS of alkaloid **2** displayed the M^+ at *m*/*z* 514.4149, $C_{32}H_{54}N_2O_3$ (calc. 514.4134) indicating seven double bond equivalents in the molecule. The M^+ was further confirmed by FD MS. A peak at *m*/*z* 499 arose due to the loss of a methyl group from the M^+. The base peak at *m*/*z* 72 was due to the trimethyliminium cation.

The ^1H NMR spectrum ($CDCl_3$, 400 MHz) of alkaloid **2** featured three singlets for the three tertiary methyl groups at δ 0.65, 0.71 and 0.77 assigned to C-30, C-18 and C-32, respectively, while a doublet at δ 1.31 ($J_{20,\ 21} = 5.8$ Hz) was due to the C-21 secondary methyl protons. Two other 3H doublets, resonating at δ 0.82 ($J_{5',\ 3'} = 6.7$ Hz) and 1.05 ($J_{4',\ 3'} = 6.8$ Hz), were assigned to the C-5′ and C-4′ methyl protons of the isobutanol group attached to the C-3 amidic carbonyl, respectively.

A 6H singlet at δ 2.64 was assigned to the *N,N*-dimethyl protons at C-20, while a 3H singlet at δ 2.89 was due to the N_a-methyl protons at C-3. A set of AB doublets resonating at δ 3.10 and 3.30 ($J_{31\alpha,31\beta}=12.8$ Hz) was due to the C-31α and C-31β methylenic protons geminal to the hydroxyl group. A broad singlet at δ 5.50 was assigned to the vinylic H-11, while a singlet at δ 5.99 was due to the isolated vinylic H-19. The C–3H appeared as a double doublet at δ 4.54 ($J_{3\alpha,2\alpha}=3.0$ Hz, $J_{3\alpha,2\beta}=12.7$ Hz). The *trans* diaxial coupling of 12.7 Hz established its stereochemistry to be axial (α-orientation). A doublet resonating at δ 4.29 ($J_{2',3'}=3.3$ Hz) was ascribed to the C-2′ methine proton geminal to the hydroxyl group in the C-3 amidic side chain. The vicinal C-3′ H appeared as a multiplet at δ 1.88. The configuration at C-2′ was determined by Horeau's method for secondary alcohols (Horeau, 1962) and was determined to be *S*.

The COSY-45° spectrum displayed cross-peaks between H-3α (δ 4.54)/H_2-2 (δ 1.63, 2.06), H-31α (δ 3.10) /H-31β (δ 3.30) and H-17 (δ 1.51)/H_2-16 (δ 1.32, 1.50). The H-2′ (δ 4.29) geminal to a hydroxyl group was found to be coupled with the vicinal H-3′ (δ 1.88) which was further coupled with the two methyls (H_3-4′ and H_3-5′) resonating at δ 1.05 and 0.82, respectively. The HMBC spectrum served to confirm the disposition of the different groups in the C-3 side chain (Fig. 2). In the HMBC spectrum, H_3-4′ and H_3-5′ showed correlations with the C-3′ (δ 31.0) and C-2′ (δ 72.8), while the H-1′ was correlated with C-3′ (δ 31.0), C-4′ (δ 19.8), and C-5′ (δ 15.3), and with the carbonyl carbon (δ 177.0). The N_a–CH_3 protons were found to be correlated with the carbonyl carbon and with C-3 (δ 57.6). Complete ^{1}H and ^{13}C NMR assignments, multiplicties along with one-bond ^{1}H/^{13}C connectivities are presented in Table 1.

Alkaloid **3** (*m*/*z* 528.4293, $C_{33}H_{56}N_2O_3$, calc. 528.4291) was also isolated as white amorphous powder. It closely resembled alkaloid **2** in its spectral behavior, as the only difference between them is the presence of an additional CH_2 in the side chain of **3**. This was manifested in the ^{1}H NMR spectra in the appearance in **3** of a doublet at δ 0.76 ($J_{6',3'}=6.5$ Hz) and of a triplet at δ 0.95 ($J_{5',4'}=7.0$ Hz), both integrating for three protons each. In the COSY-45° spectrum the H_3-6′ doublet at δ 0.76 was found to be coupled with H-3′ (multiplet at δ 1.60), which was further coupled with H-2′ at δ 4.45. The 3H triplet of H_3-5′ (δ 0.95) showed cross-peaks with the two 1H multiplets of H_2-4′ at δ 1.45 and 1.55, thus establishing the C-3 amidic side chain of alkaloid **3**. It was apparent from these data that **3** differed in its structure from alkaloid **2** only in the nature of the C-3 side chain, there being a 1-hydroxy-2-methyl butyl moiety in **3**, instead of 1-hydroxy-2-methyl propyl group as in alkaloid **2**. The ^{13}C NMR spectra (BB, DEPT, $CDCl_3$, 500 MHz) of **3** were in good accord with the established structure, displaying nine CH_3, nine CH_2, nine CH and six quaternary carbon centers. The complete ^{13}C NMR data are presented in the experimental section.

In addition to these new natural products, four known triterpenoid alkaloids cycloprotobuxine-C (**4**) (Kuchkova et al., 1976), cyclovirobuxeine-A (**5**) (Khoung-Huu et al., 1966), cylomicrophylline-A (**6**) (Nakano and Terao, 1965), and sempervirаminol (**7**) (Atta-ur-Rahman et al., 1999) were also isolated for the first time from this species of the genus *Buxus*. The isolates were characterized by comparison of their UV, IR, ^{1}HNMR, and MS spectral data with those reported in the literature.

These alkaloids were tested for acetylcholinesterase and butyrylcholinesterase inhibitory activity because buxaminol-E, a steroidal alkaloid from *B. sempervirens* was reported as a good inhibitor of the enzyme (Kvaltinova et al., 1991). Inhibition of acetylcholinesterase is considered as a promising approach for the treatment of Alzheimer's disease (AD) and for possible therapeutic applications in the treatment of Parkinson's disease, ageing, and myasthenia gravis (Quinn, 1987; Nochi et al., 1995). Meanwhile, BChE has been considered to be directly associated with the side effects of the AChE inhibitors and the existing drugs of Alzheimer's disease (Tong et al., 1996). More recent studies have shown that BChE is found in significantly higher quantities in AD plaques than in the plaques of age related non-demented brains. Other recent studies have also reported that the unfavorable side effects profile of AChE inhibitors are

not associated with their poor selectivity towards AChE (Yu et al., 1999). Thus, new cholinesterase inhibitors, in addition to their potential clinical importance if followed by proper pharmacological-investigations, would help in defining the role of BChE in brain development, health and ageing and would in the meantime reveal the value of BChE inhibition as a novel strategy for the treatment of AD. The concentration of alkaloids that inhibited the enzyme activity by 50% (IC_{50}) are presented in Table 2. Eserine ((−)-physostigmine) was used as a positive control.

3. Experimental

3.1. General experimental procedure

Optical rotations were measured on a Jasco DIP-360 digital polarimeter. UV and IR spectra were recorded in MeOH on Shimadzu UV-240 and in $CHCl_3$ on Shimadzu IR-2240 spectrophotometers, respectively. ^{1}HNMR spectra were recorded in $CDCl_3$ at 400 MHz and 500 MHz on Bruker AM-400 and AMX-500 NMR spectrometers, respectively. ^{13}CNMR were recorded at 100 and 125 MHz on the same instruments. HREI MS were recorded on a Jeol-JMS HX 110 mass spectrometer. Column chromatography was carried out using silica gel (70–230 mesh, ASTM, Merck) and preparative TLC was done with silica GF-254 plates (20×20 cm, 0.25 mm thick).

3.2. Materials and methods

The leaves of *Buxus papillosa* C.K. Schneider (100 kg) were collected from the Northern regions of Pakistan in December 1994. The plant was identified by Dr. Tahir Ali, Plant Taxonomist and a specimen voucher (KUH 66486) was deposited in the herbarium of the Department of Botany, University of Karachi. The EtOH extract of the leaves was concentrated to a gum (3.5 kg). Water (5 l) was added and the mixture was defatted with hexane (20 l). The defatted aqueous extract was extracted with $CHCl_3$ (20 l) at different pH values (3.0, 7.0, 9.0). The $CHCl_3$ fraction obtained at pH 9.0 (88.5 g) was subjected to column chromatography using silica gel (70–230 mesh, ASTM, Merck, 2 kg) and eluted with increasing polarities of pet. ether–$CHCl_3$ and $CHCl_3$–MeOH mixtures. The fraction obtained on elution with $CHCl_3$–MeOH (95:5) was repeatedly washed with acetone and then with MeOH to yield **1** as a white powdery mass (30 mg, 8.5×10^{-4}% yield).

Elution of the column with $CHCl_3$–MeOH (96:4) afforded a fraction (4.0 g) which showed several alkaloidal spots on TLC. This was loaded onto a silica gel column (120 g) using pet. ether:acetone:diethylamine (95:4:1) as eluant. A fraction thus obtained (50 mg) was subjected to prep. TLC using the same solvent system to afford **2** (R_f=0.14, 15 mg, 4.3×10^{-4}% yield) and **3** (R_f=0.12, 12 mg, 3.4×10^{-4}% yield) as white amorphous solids.

HREI MS *m*/*z* (rel. int. %): 528.4239 ($C_{33}H_{56}N_2O_3$, 15), 513.4026 ($C_{32}H_{53}N_2O_3$, 3), 72.0800 ($C_4H_{10}N$, 100).

3.2.4. AChE and BChE inhibition assay

Electric eel acetylcholineesterase, horse serum butyrylcholinesterase, acetylthiocholine iodide, butyrylthiocholine chloride, 5-5′-thiobis-2-nitrobenzoic acid (DTNB) and eserine were purchased from Sigma (St. Louis, MO). Buffers and other chemicals were of analytical grade. Acetylcholinesterase inhibition was determined spectrophotometrically using acetylthiocholine as substrate by modifying the method of Ellman et al. (1961). The reaction was carried in 100 mM sodium phosphate buffer (pH 8.0) at 25 °C. In a typical assay

140 μl buffer, 20 μl enzyme preparation and 20 μl test compound solution were mixed and incubated for 30 min. 10 μl of DTNB was added and the reaction was then started by adding 10 μl of acetylthiocholine. The butyrylthiocholine chloride was used as a substrate to assay BChE with all the other reagents and conditions being same. The hydrolysis of acetylthiocholine/butyrylthiocholine was determined by monitoring the formation of yellow 5-thio-2-nitrobenzoate anion (as a result of the reaction of 5,5′-dithiobis-2-nitrobenzoic acid with thiocholine released by the enzymatic hydrolysis of acetylthiocholine/butyrylthiocholine) at a wavelength of 412 nm on microtitre plate spectrophotometer (Molecular Devise, USA).

ent-Daucane and acorane sesquiterpenes from ×*Cupressocyparis leylandii* foliage

Laurence G. Cool*

University of California Forest Products Laboratory, 1301 S. 46th St., Richmond, CA 94804, USA

Received 24 April 2001; received in revised form 10 July 2001

Abstract

One new *ent*-daucadiene and enantiomers of four previously reported daucadienes or acoradienes were identified in foliage of the hybrid cypress species ×*Cupressocyparis leylandii*. The major compound is (+)-dauca-5,8-diene; minor congeners are (−)-dauca-4,8-diene, (−)-dauca-8,11-diene, (−)-acora-3,7(14)-diene and 1*S*-dauca-4(11),8-diene. None of these compounds is observed in foliage of either of the parent species, *Cupressus macrocarpa* and *Chamaecyparis nootkatensis*. However, we have subsequently found them in some specimens of *Cupressus macnabiana*. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Cupressocyparis leylandii*; *Cupressus macnabiana*; Cupressaceae; Foliage; Sesquiterpenes; Enantiomers; Daucane; Acorane

1. Introduction

×*Cupressocyparis leylandii* (Jacks. et Dall.) Dall. is an intergeneric artificial hybrid of *Cupressus macrocarpa* Hartw. ex Gord. and *Chamaecyparis nootkatensis* (D. Don) Spach. (Dallimore and Jackson, 1948). It is a rapid-growing and rather popular horticultural plant.

Gas chromatographic–mass spectral (GC–MS) analysis of the foliage volatiles showed that the sesquiterpenes were unlike those of any other member of the Cupressaceae thus far studied. Moreover, the major hydrocarbon and several of the minor ones do not appear in published spectral libraries, nor were they in our extensive collection of terpenoid GC–MS data. A recent paper (Mardarowicz et al., 1999) on the foliar essential oil of *C. leylandii* was unhelpful, since most of the sesquiterpenes were unidentified. The structure of these sesquiterpene hydrocarbons is the subject of this report.

2. Results and discussion

The major sesquiterpene from ×*Cupressocyparis leylandii* foliage oil was purified and identified as (+)-dauca-5,8-diene **1**. The NMR data of the *C. leylandii* material was identical to that given by Hashidoko et al. (1992) for (−)-dauca-5,8-diene from glandular trichomes of *Rosa rugosa* leaves, but the optical rotation was +100° vs. −121° for the *R. rugosa*-derived material. Enantioselective capillary GC of the hydrocarbons from both sources resolved the enantiomers very well (Table 1) and showed that dauca-5,8-diene from each source was of high (>95%) optical purity. The only other report of **1** is as a minor constituent in *Daucus carota* seed oil (Mazzoni et al., 1999), where its co-occurrence with other 1*R* dauc-8-enes implies it is the same (−) enantiomer as in *R. rugosa*.

Mass spectral data given by Hashidoko et al. (1992) for congeners of dauca-5,8-diene matched two other unknowns in *C. leylandii*, and GC–MS analysis of the sesquiterpenes from both sources under identical conditions confirmed the presence of dauca-8,11-diene (isodaucene) **2** and acora-3,7(14)-diene **3**. Sufficient **2** was obtained from *C. leylandii* for ^{1}H NMR confirmation of its identity. Both compounds have been reported by Castro et al. (1984) from *Calea prunifolia* foliage, with the same absolute stereochemistry [i.e., (+)] as in *R. rugosa*. (+)-Isodaucene apparently occurs in *Vernonia galpinii* foliage (Bohlmann and Zdero, 1982; structure revised by Cassidy and Ghisalberti, 1993) and *Daucus carota* seed oil (Mazzoni et al., 1999).

Table 1
GC retention indices of *Cupressocyparis leylandii* sesquiterpenes and enantiomers on permethylated β-cyclodextrin column

Compound and source	Kovats Retention Index
(+)-daucene ex *Daucus carota* seed oil	1399
(–)-daucene ex *Cupressocyparis leylandii* foliage	1408
(+)-acora-3,7(14)-diene ex *Rosa rugosa* foliage	1484
(–)-acora-3,7(14)-diene ex *C. leylandii* foliage	1486
(+)-dauca-5,8-diene ex *C. leylandii* foliage	1499
(–)-dauca-5,8-diene ex *R. rugosa* foliage	1506
(–)-dauca-8,11-diene ex *C. leylandii* foliage	1538
(+)-dauca-8,11-diene ex *R. rugosa* foliage	1539
(+)-dauca-4(11),8-diene ex *C. leylandii* foliage	1557

A minor *C. leylandii* component was dauca-4,8-diene (daucene) **4**, identified by GC–MS comparison with carrot seed oil.

Since **1** is enantiomeric to dauca-5,8-diene from *R. rugosa*, it was expected that the biosynthetically-related compounds **2**–**4** would also occur as the (heretofore unreported) antipodes in *C. leylandii*. Enantioselective GC proved that this is indeed the case. The Kovats indices for the relevant enantiomers are given in Table 1.

A late-eluting unknown sesquiterpene had a distinctive mass spectrum with a base peak of 136. Its structure was determined by 1D and 2D NMR spectroscopy to be dauca-4(11),8-diene **5**. Proton-carbon assignments were by HMQC; three-bond ^1H–^1H connectivites were determined by DQCOSY and HMQC–TOCSY experiments. The HMBC spectrum verified key heteronuclear three-bond linkages: H-15 to C-2,-5 and -10; and H-14 to C-7. A *trans* ring fusion is indicated by the δ 19.0 value for C-15, compared to $\delta \sim 25$ expected for a *cis*-fused daucadiene (Seto et al., 1985; Marcos et al., 1995). There was insufficient material for accurate measurement of the optical rotation, but the sign appears to be (+).

Dauca-4(11),8-diene was recently reported from the liverwort *Bazzania trilobata* (Warmers and König, 1999) but the MS and NMR spectral data of the liverwort-derived material do not agree with that from *C. leylandii*. There are problems with some of the NMR assignments in the *B. trilobata* study that make the identity of this component questionable. In the following discussion, the C_6D_6 (rather than $CDCl_3$) data of Warmers and König (1999) are used, and the δ-ranges for ^1H multiplets have been abbreviated to their approximate midpoints.

The data presented by Warmers and König (1999) for C-3 (^{13}C: δ 41.2; ^1H: δ∼1.36, ∼1.48) are not consistent with an allylic methylene in this position; values closer to ^{13}C: δ∼30 and ^1H: δ∼2.3 would be expected (Bohlmann et al., 1983). More significantly, the data assigned to C-10 are ^{13}C: δ 31.0 (^1H: δ∼2.02 and ∼2.23), while other dauc-8-enes typically have a ^{13}C signal at $\delta \sim 42$ (^1H: δ∼2) for C-10 (Bohlmann and Zdero, 1982; Bohlmann et al., 1983; Hashidoko et al. 1992; Ghisalberti, 1994; Mazzoni et al., 1999). In fact, there is no methylene group in the *B. trilobata* sesquiterpene that is a candidate for this allylic C-10 methylene.

An alternative identification of this *B. trilobata* sesquiterpene as *trans*-dauca-4(11),7-diene is proposed. This appears to be consistent with the 1D NMR spectroscopic data (including NOEs) of Warmers and König (1999) if the ring carbon signals are assigned as follows (C_6D_6 solvent data; changed assignments in bold type): δ 44.7 (C-1), 41.2 (**C-2/10**), 31.0 (**C-3**), 139.0 (C-4), 52.4 (C-5), 30.2 (**C-6**), 124.1 (**C-7**), 136.1 (C-8), 30.0 (**C-9**), 40.2 (**C-10/2**). Examination of the ^{13}C NMR spectral data of Marcos et al. (1995) on several analogs of dauc-7- and dauc-8-enes shows that these reassignments are in good accord with the proposed structure. It is particularly significant that all *trans*-dauc-8-enes have a C-6 signal around $\delta \sim 24$, while the two *trans*-dauc-7-ene analogs have $\delta \sim 30$, very close to the value for the *B. trilobata* sesquiterpene.

To substantiate the assumed 1*S* absolute stereochemistry of **5** from *C. leylandii*, the hydrocarbon was hydrogenated over Pd/C using the conditions of Warmers and König (1999) and the products compared with the hydrogenation products of authentic (−)-isodaucene **2**. Two monounsaturated and two saturated compounds were produced from each starting material, and the mixtures were qualitatively identical by GC–MS and enantioselective GC.

GC–MS examination of the foliar terpenes of a number of specimens of the *C. leylandii* parent species *C. macrocarpa* and *C. nootkatensis* showed no trace of **1**–**5**. This implies that although the relevant cyclase gene must be carried by one of the parents, it is apparently silent. Why this is so and how the biosynthetic pathway is activated in the hybrid are intriguing questions that remain to be answered.

Sesquiterpenes **1**–**5** are also absent from 17 other *Cupressus* species we have examined, but our recent work on the California endemic *C. macnabiana* A. Murr.—a tree supposedly rather distantly related to *C. macrocarpa* within the genus—has revealed the same compounds, in similar proportions, in some individuals (K. Jiang et al., unpublished data).

3. Experimental

3.1. Plant material

Foliage of ×*Cupressocyparis leylandii* was collected from several horticultural specimens in Pismo Beach, CA (December 1997). *Rosa rugosa* leaves were collected from a horticultural specimen in Berkeley, CA in March 2000.

3.2. Sesquiterpene isolation and purification

Hydrodistillation (from satd NaCl with $NaHCO_3$) of the LN_2-ground *C. leylandii* foliage (ca. 2 kg); LC of the oil (silica gel; hexane–EtOAc eluents); prep. GC and FTIR of purified **1** were as described before (Kim et al., 1994). Before LC most of the monoterpenes were removed by evaporation under N_2 flow at ca. 100 °C. The hydrocarbon fraction from LC was then separated by repeated complexation LC on 20% $AgNO_3/SiO_2$ using hexane–EtOAc or hexane–benzene gradients. Final purification of **1**–**4** was by prep. GC on a Carbowax 20M column, 160 °C; **5** required an additional purification step on an SE-30 column (185 °C).

Fresh *R. rugosa* leaves were extracted whole with *n*-pentane. The extract was passed through silica gel to isolate a hydrocarbon fraction for GC–MS and enantioselective GC analysis.

Enantioselective GC was by splitless (0.7 min) injection of the relevant compound or fraction, with *n*-hexadecane as internal retention time standard, on a 10% permethyl-β-cyclodextrin/90% OV-1701 WCOT capillary column, 0.25 mm i.d. × 30 m. Injector 180 °C, column temperature program: 60 °C (0.7 min), 30 °C min^{-1} to 90 °C, 1 °C min^{-1} to 135 °C. Kovats indices were determined by r.t. comparison with *n*-alkanes analysed with the same temperature program.

3.2.1. (+)-Dauca-5,8-diene (*1*)

Oil; $[\alpha]_D^{22}$ +100 °C (*n*-hexane; *c* 1.6). IR ν_{max}^{KBr} cm^{-1}: 2956, 2874, 1463, 1449, 1414, 1383, 1374, 1366, 1136, 1057, 929, 766, 715.

3.2.2. (+?)-Dauca-4(11),8-diene, (3aS,8aS)-3-isopropylidene-6,8a-dimethyl-1,2,3,3a,4,5,8,8a-octahydroazulene (*5*)

Oil; $[\alpha]_D^{22} > +40$ °C (*n*-hexane; $c < 0.1$); EIHRMS: $[M]^+$ *m/z* 204.18769 (calcd for $C_{15}H_{24}$, 204.18780); GC–MS 70 eV, *m/z* (rel.int.): 204 $[M]^+$ (22), 189 $[M–Me]^+$ (2), 161 (18), 148 (3), 136 (100), 133 (10), 121 (60), 119 (10), 107 (17), 105 (15), 93 (19), 91 (18), 79 (12), 77 (11), 55 (10), 41 (22); ^1H NMR (499.9 MHz, C_6D_6, δ from TMS): 0.98 (3H, *s*, H-15), 1.42 (1H, *ddd*, *J* = 11.6, 11.3, 9.0 Hz, H-2b), 1.53 (1H, *ddd*, *J* = 11.6, 7.5, ~1 Hz, H-2a), 1.58 (1H, *dddd*, *J* = 13.7, 12.1, 11.7, 2.6 Hz, H-6a), 1.77 (3H, *br s*, H-12), 1.85 (3H, *br q*, *J* = 1.7 Hz, H-13), 1.88 (3H, *br s*, H-14), 2.11 (1H, *ddd*, *J* = 14.7, 5.2, 2.6 Hz, H-7a), 2.15 (1H, *br d*, *J* ~ 15 Hz, H-10a), 2.20 (1H, *dd*, *J* = 15.1, 8.1 Hz, H-10b), 2.18–2.25 (1H, *br m*, H-7b), 2.25–2.32 (1H, *br m*, H-5), 2.28–2.35 (1H, *br m*, H-3a), 2.33–2.36 (1H, *m*, H-6b), 2.39–2.47 (1H, *br m*, H-3b), 5.59 (1H, *br m*, H-9). ^{13}C NMR (125.7 MHz, C_6D_6, δ from TMS): 19.0 (*q*, C-15), 20.4 (*q*, C-13), 23.2 (*q*, C-12), 25.1 (*t*, C-6), 27.1 (*q*, C-14), 29.6 (*t*, C-3), 34.4 (*t*, C-7), 40.3 (*t*, C-2), 41.4 (*t*, C-10), 42.5 (*s*, C-1), 57.5 (*d*, C-5), 121.9 (*s*, C-11), 122.7 (*d*, C-9), 138.0 (*s*, C-4/8), 138.1 (s, C-8/4); multiplicities by DEPT and HMQC.

Acknowledgements

Thanks to Dr. Clayton Heathcock for helpful discussions of NMR spectroscopic data and for reviewing the manuscript, and to Dr. Robert P. Adams and M. Joseph Casanova for sending samples of carrot seed oil and components. Special thanks to Dr. Donald J. Bowler for invaluable help with the 2D NMR experiments. *Deo gratias*.

Synthesis and bioactivity of natural and C-3 fluorinated biosynthetic precursors of 28-homobrassinolide

Lydia R. Galagovsky*, Eduardo G. Gros, Javier A. Ramírez

Departamento de Química Orgánica, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Pabellón 2, Ciudad Universitaria, 1428 Buenos Aires, Argentina

Received 24 April 2001; received in revised form 3 August 2001

Abstract

In this paper we describe the synthesis of two new fluorinated brassinosteroids: (22*R*,23*R*)-22,23-dihydroxy-3α-fluorostigmastan-6-one and (22*R*,23*R*)-22,23-dihydroxy-3β-fluorostigmastan-6-one. Their bioactivities were evaluated in the rice lamina inclination test and compared with that of 28-homocastasterone, 28-homotyphasterol and 28-homoteasterone, possible biosynthetic precursors of 28-homobrassinolide. Results confirmed expected similarities between the biosynthesis of 24-ethylbrassinosteroids (named as the 28-homo series) and that described for 24-methylbrassinosteroids, and also indicated that these precursors might exhibit per se activities. © 2001 Published by Elsevier Science Ltd.

1. Introduction

Brassinosteroids have attracted considerable interest since 1979, when the isolation and structure determination of brassinolide (**1**) (see Fig. 1) was reported (Grove et al., 1979). Some brassinosteroids, including **1** and castasterone (**2**), display powerful plant growth-regulating activity at doses as low as 1 ng per individual plant (Grove et al., 1979; Cutler et al., 1991). Brassinosteroids are able to increase yield and stress resistance of a number of important crops (Sakurai et al., 1999; Khripach et al., 1999). Numerous studies of the chemistry and biology of brassinosteroids, as well as of their potential commercial applications, have been reported (Arteca, 1995). Some structural variations of active brassinosteroids involving the presence of a 24-ethyl group have also been reported. This 28-homo family of brassinosteroids is basically formed by 28-homobrassinolide (**3**), 28-homocastasterone (**4**), 28-homotyphasterol (**5**) and 28-homoteasterone (**6**) (see Fig. 1) which possess substantial bioactivity (Takatsuto and Ikekawa, 1984; Schmidt et al., 1993; Abe et al., 1995) and have been widely employed in field trials (Cutler et al., 1991) because of their greater synthetic accessibility compared to **1**.

Many studies have been devoted in establishing the biosynthetic pathway to natural brassinosteroids. The most important features of this pathway were deduced from biochemical studies using cultured cells administered labelled compounds (Fujioka and Sakurai, 1997; Sakurai and Fujioka, 1997), but the discovery of brassinosteroid-deficient mutants provided new experimental methodologies. Genetic, molecular and biochemical studies on these mutants confirmed the proposed pathways, and also gave the molecular basis for this biosynthesis (Sakurai et al., 1999). Fig. 2 shows the last steps of the well established early C6-oxidation pathway (Fujioka et al., 1995). 3-Dehydroteasterone (**7**) (see Fig. 2) was found to be an intermediate in the reversible conversion between teasterone and typhasterol (Suzuki et al., 1995). This is a rather unusual equilibrium because it involves the transformation from a more stable equatorial 3β-alcohol into the axial less stable 3α-alcohol in typhasterol (Khripach et al., 1999). The bioactivity displayed in several bioassays by the biosynthetic intermediates shown in Fig. 2 was found to increase according to the position on the biosynthetic pathway (Fujioka et al., 1995). These results were explained by assuming that the precursors are transformed into the more active compounds in plant tissues during the bioassay; the closer the intermediate in the pathway to brassinolide, the greater is the exhibited activity (Suzuki et al., 1995).

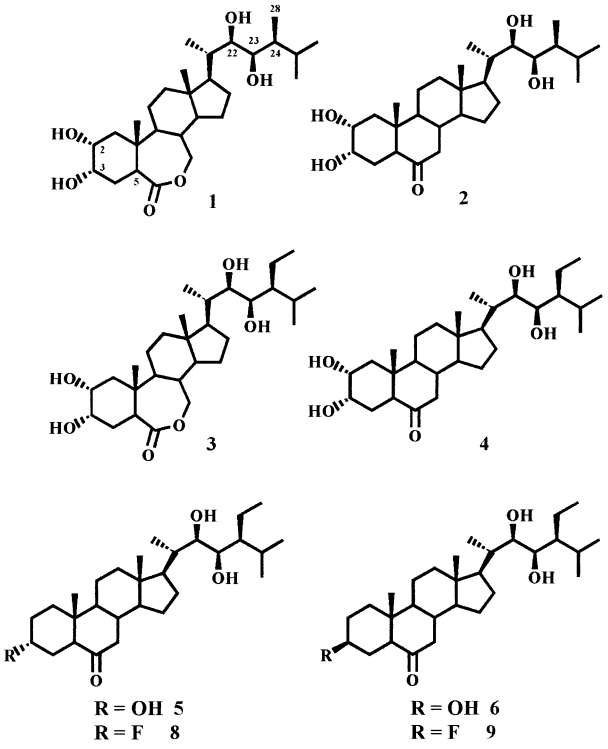

Fig. 1. Structures of various brassinosteroids.

28-Homobrassinosteroids may be biosynthesized from the corresponding plant steroid (sitosterol) through similar pathways to those of brassinolide, although no evidence for this has yet been reported (Sakurai, 1999). The presence of a C-3 fluorine in the A ring replacing the C-3 hydroxy group may alter its ability to go through the biosynthetic pathway, particularly in the case of a C-3β fluorine.

Our aim was to perform studies on the biosynthesis of 28-homobrassinosteroids. Thus, we have synthesized known compounds **3**–**6**, and two new analogs (22*R*,23*R*)-22,23-dihydroxy-3α-fluorostigmastan-6-one (**8**) and (22*R*, 23*R*)-22,23-dihydroxy-3β-fluorostigmastan-6-one (**9**), in which a fluorine atom replaces the 3-hydroxy group of the related natural compounds 28-homotyphasterol (**5**) and 28-homoteasterone (**6**), respectively (see Fig. 1).

Bioactivities were tested by the rice lamina inclination assay (Takeno and Pharis, 1982), using *Oriza sativa* L. cv Chui, a local rice cultivar.

2. Results and discussion

Syntheses of compounds **3**–**6** were performed as reported (Takatsuto and Ikekawa, 1984; Voigt et al., 1996; Teme Centurión et al., 1998).

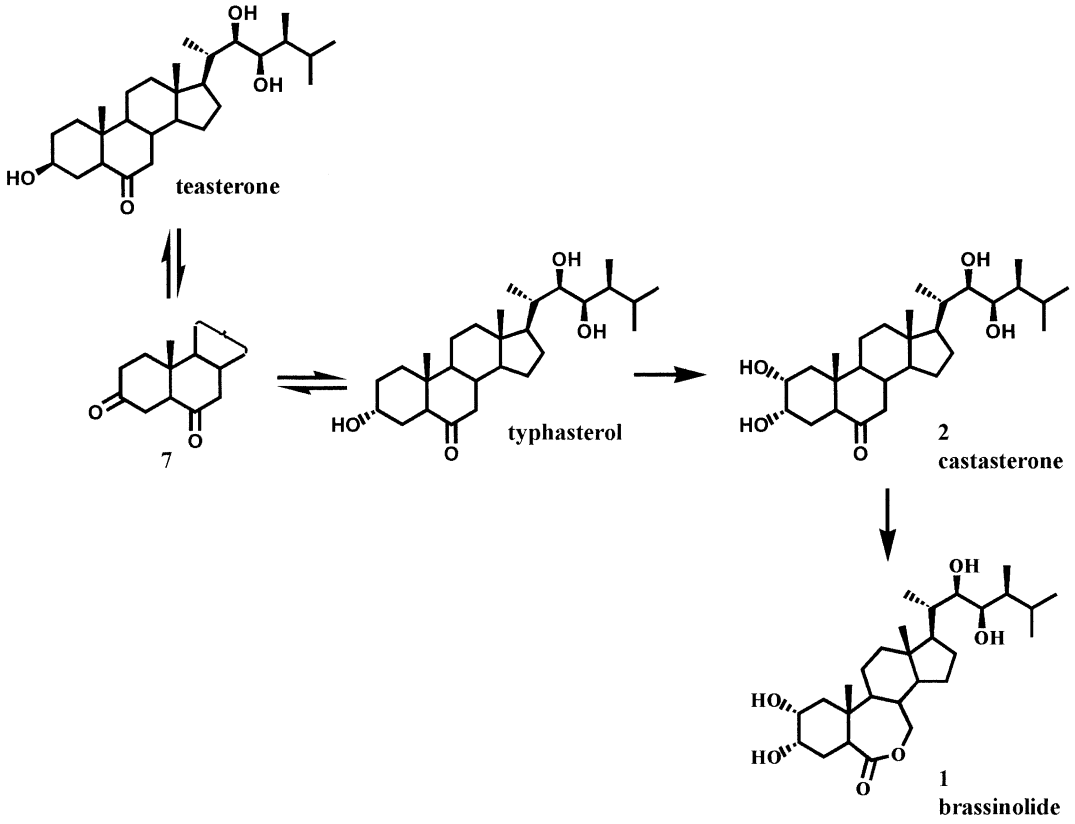

Fig. 2. Brassinosteroid biosynthesis: the early C6-oxidation pathway.

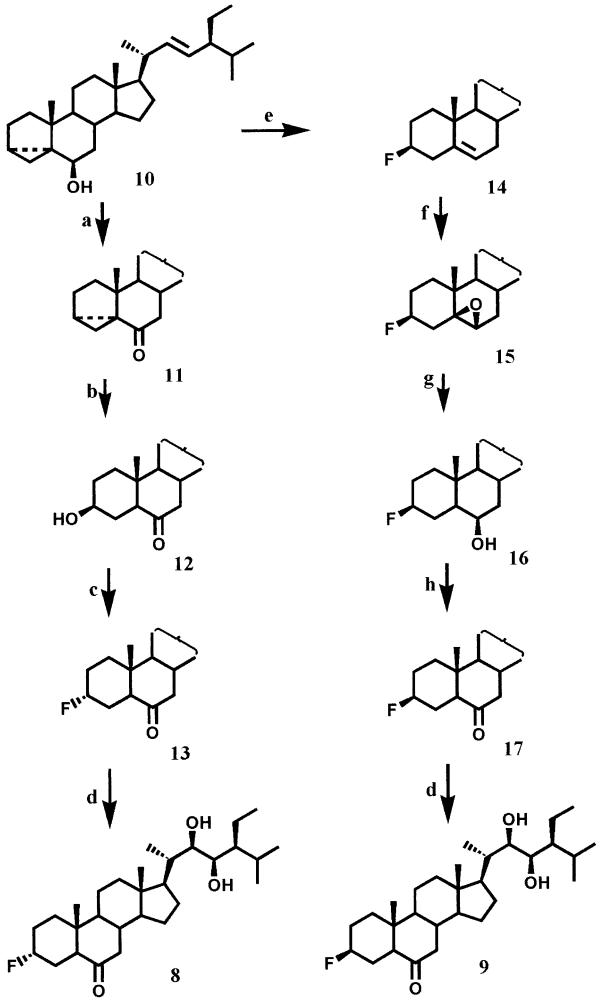
Reasons for replacing the hydroxyl groups of biological molecules by fluorine have been reviewed (Welch, 1987). Due to its high electronegativity, a fluorine atom should exert a similar polar effect as oxygen does and could act as an hydrogen bond acceptor as well. Furthermore, the van der Waals' radius of fluorine does not introduce any disturbance on the molecular geometry. Thus, compounds **8** and **9** might mimic 28-homotyphasterol (**5**) and 28-homoteasterone (**6**), respectively. However, the strong C–F bond usually prevents chemical reactions of the carbon attached to fluorine. Thus compound **9** would not be expected to produce downstream metabolites in the biosynthetic pathway considering that it cannot be dehydrogenated to a 28-homo analog of **7** (see Fig. 2). Selection of C-3 fluorinated analogs was also made on the basis of recent reports concerning interesting changes in bioactivity due to the introduction of fluorine in brassinosteroids analogs (Back et al., 1999; Ramírez et al., 2000).



Scheme 1. Synthetic strategy to obtain fluorinated analogs **8** and **9**. Reagents and conditions: *a*: Jones reagent, acetone, 0 °C, 15 min. *b*: $HClO_4$, dioxane, H_2O, reflux, 1 h. *c*: DAST, CH_2Cl_2, −78 °C, 10 min. *d*: K_2OsO_4, $K_3Fe(CN)_6$, $(DHQD)_2Phal$, K_2CO_3, *t*-BuOH, H_2O, $CH_3SO_3NH_2$, r.t., 9 days. *e*: HF 48% aq, toluene, r.t., 1 h. *f*: $KMnO_4$, $Fe(NO_3)_3$, *t*-BuOH, H_2O, CH_2Cl_2, r.t., 2h. *g*: $NaBH_3CN$, $BF_3.Et_2O$, THF, reflux, 1 h. *h*: PCC, $HPy^+CF^3COO^-$, CH_2Cl_2, r.t., 15 min.

Synthesis of the fluorinated brassinosteroid analogs **8** and **9** is summarized in Scheme 1. Compound **11** was obtained in three steps following the described procedure by Wada and Marumo (1981). Hydrolytic cleavage of this 3α,5-cyclo-6-keto steroid with perchloric acid yielded compound **12**, which was subsequently fluorinated with diethylaminosulfurtrifluoride (DAST) (Rozen et al., 1979) to give compound **13**. The substitution of the 3β-hydroxy group, by a fluoride, proceeded with inversion of configuration according to the multiplicity pattern of the resulting 3β-H geminal to the fluoro group is evidencec assessed by ^1H NMR special analysis (see Table 1).

Osmium-catalyzed asymmetric dihydroxylation (Sharpless et al., 1992) (CAD) of the Δ^{22} double bond of **13** using $K_3Fe(CN)_6$ as cooxidant and hydroquinidine-1,4-phthalazinediyl diether [$(DHQD)_2$-PHAL] as chiral ligand gave, after purification, 38% yield of compound **8** (9% total yield from stigmasterol). CAD yields the diasteromeric 22S,23S isomer in a minor proportion (ratio 3:1), and more than 30% of the starting material, that could be recycled.

(22*E*)-3β-Fluorostigmasta-5,22-diene (**14**) was obtained as described (Ponce et al., 2000). Stereo and regioselective epoxidation of **14** with $KMnO_4/Fe(NO_3)_3$/*t*-BuOH gave compound **15** and reductive opening of the resulting 5β,6β epoxide with sodium cyanoborohydride gave compound **16**. Activation of the epoxide by complexion with boron trifluoride etherate as a Lewis acid (Hutchins et al., 1981) was required to ensure the attack of the hydride at the more substituted position. Subsequent oxidation of **16** with PCC to **17** followed by CAD gave compound **9** in 8% yield (from stigmasterol). Configurations at C-22 and C-23 were established by comparison with chemical shifts and coupling constants of closely related known compounds (Ando et al., 1993). The correct stereochemistry at C-5 in both compounds **8** and **9** was determined on the basis of coupling constants between the 5α-H and both 4α- and 4β-H in their ^1H NMR spectra.

All the proposed structures were verified by MS and NMR spectroscopic analyses. The presence of a fluorine in the A ring introduces additional complexity in both the ^1H and ^{13}C NMR spectra due to long-range coupling; these effects are a valuable source for structural information. Considering that an assignment of 3-fluoro steroids has not been previously reported, a complete analysis with DEPT-135, COSY-45, and HETCOR experiments was performed on these new analogs.

Table 1 details the NMR spectral description of the main positions of the 3-fluoro analogs **8** and **9**. Dose dependent bioactivities of compounds **3**, **4**, **5**, **6**, **8** and **9** were evaluated using the highly sensitive modified rice lamina inclination test (Table 2). Data are presented as

Table 2
Rice lamina inclination test[a]

	Compounds					
Dose (ng/plant)	**3**	**4**	**5**	**6**	**8**	**9**
5	35±3[b]	30±2	24±4	10±2	10±1	11±1
50	90±4	84±5	72±8	25±6	34±8	23±4
500	101±4	97±4	77±8	60±6	86±6	38±8

[a] Values are angles (degrees) between the lamina and sheath, representing the means of 15–25 replicates.
[b] ± Standard error. Average angle of control: 11±2.

mean values with standard errors. Results showed, as expected, decreasing values when the upstream biosynthetic precursor was tested (see Fig. 1). Compounds **3** and **4** showed highest bioactivity at all doses tested. Biosynthetic precursors **5** and **6** were 20–40% less active than **3** and **4**, respectively, at the highest dose tested. This characteristic diminished for compound **5** and was maintained for compound **6**, at lower doses. Compounds **6**, **8** and **9** gave no significant response at 5 ng/plant.

Fluorinated compounds exhibited different behavior. Compound **8** showed a similar response to that of its naturally related compound **5**, at the highest dose, but was 50% less active at 50 ng/plant.

Compound **9** showed similarly low response at 50 ng/plant, but was 40% less active relative to its natural analog **6** at, the highest dose.

Visual inspection of the plant seedlings treated with the natural precursors **5** and **6** showed that in spite of the lower average response (Table 2) a significant number of seedlings exhibited a large response, typical for that of the most active compounds. This fact suggested that the statistical distribution of responses could be analyzed.

Fig. 3a–c shows the histogram for the pairs of compounds **3**–**4**, **5**–**8** and **6**–**9** at the highest tested dose, respectively. Top values of the bars of each histogram have been linked for clearer observation of the distribution profiles.

Fig. 3a shows the distribution displayed—which proved to be normal—for the more active compounds **3** and **4**. Highest frequency of angle values falls into the 91–120° interval. Fig. 3b shows the comparative profile of the distribution obtained for the natural compound **5** and its fluorinated analog **8**. Profiles elicit clear bimodal distributions. The most frequent angle values for compound **5** fall into the 61–90 and 121–150 ranges, and for the fluorinated analog **8**, the most frequent angles fall into the 31–60 and 91–120 ranges. This bimodal distribution may be interpreted as a partially overlapped two-phase response.

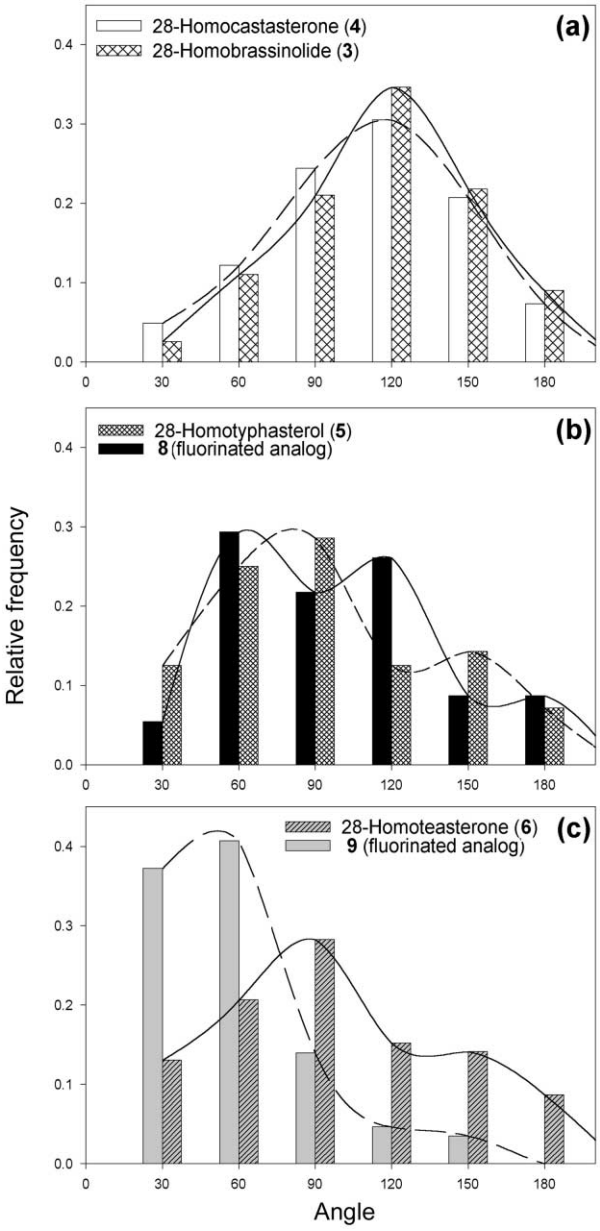

Fig. 3. Number of seedlings (relative to total number) vs. angle in the rice lamina inclination test.

Responses shown in Fig. 3c indicate a clear bimodal profile for the natural compound **6** with the most frequent angle values in the 61–90 and 121–150 ranges. On the other hand, fluorinated analog **9** shows a skewed distribution profile with the most frequent angle values in the 31–60 range. The presence of a fluorine atom in position 3β of compound **9** could have blocked its further biosynthetic transformation into a 3-keto intermediate, so that the bioactivity elicited could be assumed as a per se response and not due to downstream metabolites. This type of per se activity has been recently reported for non fluorinated analogs (Sung et al., 2000). On the other hand, the presence of a α-fluorine at C-3 in compound **8** seems not to interfere with further biotransformations. Considering these facts, it seems reasonable to assume that compounds **5**, **6** and **8** show a bimodal distribution due to an intrinsic bioactivity, partially overlapped with that due to further biosynthetic metabolites.

3. Conclusions

Along with the synthesis of known compounds **3**–**6**, two new C-3 fluorinated analogs of the natural 28-homobrassinosteroids, named (22*R*,23*R*)-22,23-dihydroxy-3α-fluorostigmastan-6-one (**8**) and (22*R*,23*R*)-22,23-dihydroxy-3β-fluorostigmastan-6-one (**9**) were prepared. Evaluation of the relative bioactivities of compounds **3**–**6** seems to indicate a similar biosynthetic pattern between the C-24 ethyl and the more abundant C-24 methyl brassinosteroids. Responses showed that the closer the intermediate in the biosynthetic pathway to 28-homobrassinolide, the more active it is.

Considering that compound **9** is not able to undergo further biosynthetic transformation during the bioassay, then the exhibited bioactivity indicates a per se activity which has an average value 60% lower than that of the most active compound. On the other hand, compounds **5**, **6** and **8**, elicite a larger average bioactivity due to intrinsic activity coupled with those of greater activity coming from more downstream biosynthetic metabolites produced during the bioassay.

Finally, the rice lamina inclination test, the most commonly used bioassay for evaluating the bioactivity of brassinosteroids, can mask information when the mean and the standard error is reported for compounds which do not show a normal response distribution.

4. Experimental

Melting points (mp) were determined on a Fisher Johns apparatus and are uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Brüker AM-500 at 500 MHz and at 125.1 MHz, respectively, chemical shifts (δ) are given in ppm downfield from TMS as the internal standard. ^{19}F-NMR spectra were recorded on a Bruker AM-500 at 470.4 MHz., chemical shifts (δ) are given in ppm upfield from CFCl3 as the internal standard. Coupling constant (J) values are in Hz. High-resolution mass spectra (EI and FAB) were obtained for all new compounds on a ZAB BEqQ instrument (VG-Micromass). FAB were obtained using NBA-Li as matrix. Low resolution mass spectra were recorded on a Shimadzu QP-5000 at 70 eV. Unless otherwise indicated, all solvents and reagents used were of commercial grade. Reactions were monitored by TLC on precoated plates with silica gel F254 0.2 mm (Merck). Column

chromatography was carried out on silica gel 60, 0.04–0.063 mm (Merck).

4.1. Rice lamina inclination test

Rice seedlings (*Oryza sativa*, cv Chui) were washed with ethanol (1 min) and water and were then left in water at 30 °C for two days (with a 16 h photoperiod). Germinated seeds were cultivated on agar under the same growing conditions for four days. Intact seedlings (4–5 cm long) were inoculated with 0.5 μl of the test compound solution (in ethanol) just under the 2nd leaf joint. After 48 h in the dark (at 30 °C), the magnitude of the induced angle between the leaf and the sheath was measured by using Bersoft Image Measurement™ (http://bersoft.com/bimagem/index.html).

4.2. Synthesis

4.2.1. (22E)-3α-Fluorostigmast-22-en-6-one (**13**)

A solution of (22*E*)-3β-hydroxystigmast-22-en-6-one (Wada and Marumo, 1981) (**12**) (430 mg, 1.00 mmol) in 18 ml of CH_2Cl_2 was slowly added to a solution of DAST (0.49 g, 3.04 mmol) in 3 ml of CH_2Cl_2 cooled to −78 °C. After 10 min the mixture was warmed to room temperature and poured into water, washed with $NaHCO_3$ and treated in the usual manner. Purification of the crude product by column chromatography (hexane/EtOAc 98:2) yielded 57% of **13**. Mp 156–157 °C. ^{1}H NMR: 0.68 (H-18, 3H, s), 0.73 (H-19, 3H, *s*), 0.79 (H-27, 3H, *d*, $J=6.5$ Hz), 0.81 (H-29, 3H, *t*, $J=7.4$ Hz), 0.85 (H-26, 3H, *d*, $J=6.3$ Hz), 1.02 (H-21, 3H, *d*, $J=6.7$ Hz), 2.31 (H-7α, 1H, *dd*, $J=13.0$ Hz, 4.5 Hz), 2.63 (H-5α, 1H, *dd*, $J=12.8$ Hz, 3.0 Hz), 5.02 (23-H, 1H, *dd*, $J=15.1$ Hz, 8.6 Hz), 4.90 (H-3β, 1H, double *m*, $J_{H,F}=48.3$ Hz), 5.15 (22-H, 1H, *dd*, $J=15.1$ Hz, 8.6 Hz). ^{13}C NMR: 12.2 (*q*, C-18), 12.2 (*q*, C-29), 12.3 (*q*, C-19), 18.9 (*q*, C-26), 21.1 (*t*, C-11), 21.1 (*q*, C-27), 21.2 (*q*, C-21), 24.0 (*t*, C-15), 25.4 (*t*, C-28), 25.9 (*dt*, C-4, $J_{C,F}=21.4$ Hz), 26.3 (*dt*, C-2, $J_{C,F}=21.7$ Hz), 28.7 (*t*, C-16), 31.7 (*d*, C-25), 31.9 (*t*, C-1), 38.0 (*d*, C-8), 39.4 (*t*, C-12), 40.4 (*d*, C-20), 41.2 (*s*, C-10), 42.9 (*s*, C-13), 46.8 (*t*, C-7), 51.2 (*d*, C-24), 51.9 (*d*, C-5), 53.8 (*d*, C-9), 55.9 (*d*, C-17), 56.9 (*d*, C-14), 88.5 (*dd*, C-3, $J_{C,F}=167.1$ Hz), 129.6 (*d*, C-23), 138.0 (*d*, C-22), 211.8 (*s*, C-6). ^{19}F NMR: −184.0 (m). MS (EI) *m*/*z* (rel. int.): 430 (M+, 8.1), 415 (1.0), 387 (6.3), 289 (13.3), 149 (40.9), 55 (100). HRMS (EI): calc. for $C_{29}H_{47}OF$: 430.3611, found: 430.3608.

4.2.2. (22R,23R)-22,23-Dihydroxy-3α-fluorostigmastan-6-one (**8**)

A mixture of **13** (180 mg, 0.42 mmol), *t*-butanol/water (1:1) (40 ml), $(DHQD)_2$–PHAL (390 mg, 0.21 mmol), methansulfonamide (190 mg, 0.84 mmol), potassium ferricyanide (1.9 g, 2.51 mmol), potassium carbonate (828 mg, 42 mmol), and potassium osmate dihydrate (15 mg, 0.04 mmol) was stirred at room temperature for 9 days. An excess of $NaHSO_3$ was added until no evolution of bubbles was observed. Layers were separated and the aqueous phase was thoroughly extracted with CH_2Cl_2/MeOH (95:5). Combined organic layers were washed with 0.25 M H_2SO_4 and 2% NaOH. Purification by column chromatography (CH_2Cl_2/acetonitrile gradient) separated (22*R*,23*R*)-22,23-dihydroxy-3α-fluorostigmastan-6-one from its 22S, 23*S* diasteromer, with 38% yield. Mp 201–202 °C. ^{1}H NMR: 0.68 (H-18, 3H, *s*), 0.73 (H-19, 3H, *s*), 0.91 (H-21, 3H, *d*, $J=6.8$ Hz), 0.92–0.99 (H-26, H-27 and H-29, 9H, m), 2.31 (H-7α, 1H, *dd*, $J=12.9$ Hz, 4.4 Hz), 2.63 (H-5α, 1H, *dd*, $J=12.9$ Hz, 3.0 Hz), 3.58 (H-22, 1H, *dd*, $J=8.4$ Hz, 1.3 Hz), 3.71 (H-23, 1H, *dd*, $J=8.4$ Hz, 1.3 Hz), 4.90 (H-3β, 1H, *double m*, $J_{H,F}=48.3$ Hz). ^{13}C NMR: 12.0 (*q*, C-21), 12.2 (*q*, C-18), 12.3 (*q*, C-19), 13.8 (*q*, C-29), 19.1 (*t*, C-28), 19.6 (*q*, C-26), 21.1 (*t*, C-11), 21.3 (*q*, C-27), 24.0 (*t*, C-15), 25.9 (*dt*, C-4, $J_{C,F}=21.5$ Hz), 26.3 (*dt*, C-2, $J_{C,F}=21.6$ Hz), 28.7 (*t*, C-16), 29.2 (*d*, C-25), 31.9 (*t*, C-1), 37.2 (*d*, C-20), 38.0 (*d*, C-8), 39.4 (*t*, C-12), 41.2 (*s*, C-10), 42.9 (*s*, C-13), 46.7 (*d*, C-24), 46.8 (*t*, C-7), 51.9 (*d*, C-5), 53.8 (*d*, C-9), 55.9 (*d*, C-17), 56.9 (*d*, C-14), 72.6 (*d*, C-23), 74.5 (*d*, C-22), 88.5 (*dd*, C-3, $J_{C,F}=167.2$ Hz), 211.8 (*s*, C-6). ^{19}F NMR: −184.0 (*m*). MS (FAB) *m*/*z* (rel. int.): 471.3 (87) $[M+Li]^+$, 294.0 (19). HRMS (FAB): calc. for $C_{29}H_{47}OFLi$ $(M+Li)^+$: 471.3826, found: 471.3811.

4.2.3. (22E)-5β,6β-Epoxy-3β-fluorostigmast-22-ene (**15**)

A mixture of potassium permanganate (1.1 g, 6.96 mmol) and ferric nitrate nonahydrate (0.55 g, 1.36 mmol) was ground to a fine powder and water (0.4 ml) was added. To a stirred suspension of this mixture in CH_2Cl_2 (20 ml), (22*E*)-3β-fluorostigmasta-5,22-diene (**14**) (Ponce et al., 2000) (0.9 g, 2.17 mmol) and *t*-butanol (2 ml) were added. After 2 h at room temperature the reaction was completed and the product was separated from the inorganic residue by adding Et_2O (20 ml), stirring for 5 min and filtering through Celite. After evaporation of the solvent, the crude product was purified by column chromatography (hexane/EtOAc 97:3) yielding **15** (72%). Mp 130 °C. ^{1}H NMR: 0.66 (H-18, 3H, *s*), 0.79 (H-27, 3H, *d*, $J=6.5$ Hz), 0.81 (H-29, 3H, *t*, $J=7.4$ Hz), 0.85 (H-26, 3H, *d*, $J=6.3$ Hz), 1.01 (H-19, 3H, *s*), 1.02 (H-21, 3H, *d*, $J=6.7$ Hz), 3.03 (H-6α, 1H, *d*, $J=2.1$ Hz), 4.57 (H-3α, 1H, *double m*, $J_{H,F}=49.5$ Hz), 5.02 (H-23, 1H, *dd*, $J=15.1$ Hz, 8.6 Hz), 5.15 (H-22, 1H, *dd*, $J=15.1$ Hz, 8.6 Hz). ^{13}C NMR: 11.9 (*q*, C-18), 12.2 (*q*, C-29), 17.0 (*q*, C-19), 18.8 (*q*, C-26), 21.1 (*t*, C-11), 21.1 (*q*, C-21), 21.1 (*q*, C-27), 24.2 (*t*, C-15), 25.4 (*t*, C-28), 27.8 (*dt*, C-2, $J_{C,F}=21.0$ Hz), 28.8 (*t*, C-16), 29.6 (*d*, C-8), 31.6 (*d*, C-25), 32.4 (*t*, C-7), 34.7 (*dt*, C-4, $J_{C,F}=21.1$ Hz), 35.4 (*s*, C-10), 38.7 (*dt*, C-1, $J_{C,F}=10.1$

Hz), 39.6 (*t*, C-12), 40.3 (*d*, C-20), 41.9 (*s*, C-13), 50.6 (*d*, C-9), 51.2 (*d*, C-24), 56.0 (*d*, C-17), 56.3 (*d*, C-14), 62.0 (*d*, C-5, $J_{C,F}=15.0$ Hz, 63.1 (*d*, C-6), 90.0 (*dd*, C-3, $J_{C,F}=170.1$ Hz), 129.7 (*d*, C-23), 138.0 (*d*, C-22). ^{19}F NMR: −171.3 (m). MS (EI) *m/z* (rel. int.): 430 (M+, 7.6), 413 (4.3), 387 (4.0), 369 (12.3), 289 (15.1), 43 (100). HRMS (EI): calc. $C_{29}H_{47}OF$: 430.3611, found: 430.3611.

4.2.4. (22E)-3β-Fluoro-6β-hydroxystigmast-22-ene (16)

A solution of the epoxide **15** (170 mg, 0.39 mmol), $NaBH_3CN$ (85 mg, 1.35 mmol), and a small quantity of bromocresol green indicator in 10 ml of dry THF was stirred, while BF_3–OEt_2 in a few ml of THF was added dropwise until a color change to yellow was noted, and stirring was continued under N_2 atmosphere at reflux for 1 h. Upon completion, the reaction was diluted with NaCl (satd. soln.) and extracted with ether. After the solution was dried (Na_2SO_4), the solvent was removed under reduced pressure. The residue was purified by column chromatography (hexane/EtOAc 95:5) to yield **16** in 80%. Mp 136 °C. ^1H NMR: 0.71 (H-18, 3H, *s*), 0.79 (H-27, 3H, *d*, $J=6.5$ Hz), 0.81 (H-29, 3H, *t*, $J=7.4$ Hz), 0.85 (H-26, 3H, *d*, $J=6.3$ Hz), 1.01 (H-19, 3H, *s*), 1.02 (H-21, 3H, *d*, $J=6.7$ Hz), 3.80 (H-6α, 1H, *d*, $J=2.5$ Hz), 4.52 (H-3α, 1H, *double* m, $J_{H,F}=49.3$ Hz), 5.02 (H-23, 1H, *dd*, $J=15.1$ Hz, 8.6 Hz), 5.15 (H-22, 1H, *dd*, $J=15.1$ Hz, 8.6 Hz). ^{13}C NMR: 12.1 (*q*, C-29), 12.3 (*q*, C-18), 15.7 (*q*, C-19), 18.9 (*q*, C-26), 21.0 (*q*, C-27), 21.2 (*t*, C-11), 21.2 (*q*, C-21), 24.3 (*t*, C-15), 25.4 (*t*, C-28), 28.9 (*t*, C-16), 31.7 (*d*, C-25), 31.8 (*d*, C-8), 28.5 (*dt*, C-2, $J_{C,F}=19.0$ Hz), 35.4 (*s*, C-10), 32.4 (*dt*, C-4, $J_{C,F}=18.0$ Hz), 37.8 (*dt*, C-1, $J_{C,F}=12.0$ Hz), 39.6 (*t*, C-7), 39.8 (*t*, C-12), 40.4 (*d*, C-20), 42.6 (*s*, C-13), 46.7 (*dt*, C-5, $J_{C,F}=9.5$ Hz), 51.2 (*d*, C-24), 54.1 (*d*, C-9), 56.0 (*d*, C-17), 56.8 (*d*, C-14), 71.8 (*d*, C-6), 93.1 (*dd*, C-3, $J_{C,F}=172.5$ Hz), 129.6 (*d*, C-23), 138.0 (*d*, C-22). ^{19}F NMR: −169.5 (m). MS (EI) *m/z* (rel. int.): 432 (M^+, 29.7), 417 (2.8), 371 (21.3), 275 (30.0), 55 (100). HRMS (EI): calc. for $C_{29}H_{49}OF$: 432.3767, found: 432.3761.

4.2.5. (22E)-3β-Fluorostigmast-22-en-6-one (17)

A solution of compound **16** (210 mg, 0.49 mmol) in CH_2Cl_2 (25 ml) was treated with pyridinium chlorochromate (109 mg, 0.51 mmol) and pyridinium trifluoroacetate (30 mg, 0.155 mmol). The mixture was stirred for 15 min at room temperature and then filtered through Celite, and the solution evaporated under reduced pressure. After chromatographic purification of the crude product (hexane/EtOAc 97:3), compound **17** was isolated in 92% yield. Mp 146–147 °C. ^1H NMR: 0.71 (H-18, 3H, *s*), 0.78 (H-19, 3H, *s*), 0.79 (H-27, 3H, *d*, $J=6.5$ Hz), 0.81 (H-29, 3H, *t*, $J=7.4$ Hz), 0.85 (H-26, 3H, *d*, $J=6.3$ Hz), 1.02 (H-21, 3H, *d*, $J=6.5$ Hz), 2.17 (H-5α, 1H, *d*, $J=12.6$, Hz), 2.33 (H-7α, 1H, *dd*, $J=13.2$, 4.4 Hz), 4.46 (H-3α, 1H, double *m*, $J_{H,F}=48.5$ Hz), 5.02 (H-23, 1H, *dd*, $J=15.1$ Hz, 8.6 Hz), 5.15 (H-22, 1H, *dd*, $J=15.1$ Hz, 8.6 Hz). ^{13}C NMR: 12.1 (*q*, C-29), 12.2 (*q*, C-18), 13.1 (*q*, C-19), 18.8 (*q*, C-26), 21.1 (*t*, C-11), 21.1 (*q*, C-27), 21.2 (*q*, C-21), 24.0 (*t*, C-15), 25.4 (*t*, C-28), 27.2 (*dt*, C-4, $J_{C,F}=19.7$ Hz), 28.0 (*t*, C-2, $J_{C,F}=17.9$ Hz), 28.7 (*t*, C-16), 31.7 (*d*, C-25), 36.0 (*t*, C-1, $J_{C,F}=10.8$ Hz), 37.8 (*t*, C-8), 39.4 (*t*, C-12), 40.4 (*d*, C-20), 40.9 (*s*, C-10), 42.9 (*s*, C-13), 46.6 (*t*, C-7), 51.2 (*d*, C-24), 55.9 (*d*, C-17), 56.0 (*dd*, C-5, $J_{C,F}=10.8$ Hz), 56.8 (*d*, C-9), 56.8 (*d*, C-14), 92.3 (*dd*, C-3, $J_{C,F}=174.1$ Hz), 129.7 (*d*, C-23), 138.1 (*d*, C-22), 209.7 (*s*, C-6). ^{19}F NMR: −172.6 (m). MS (EI) *m/z* (rel. int.):430 (M^+, 3.2), 415 (0.6), 387 (2.4), 318 (4.5), 289 (5.5), 44 (100). HRMS (EI): calc. for $C_{29}H_{47}OF$: 430.3611, found: 430.3605.

4.2.6. (22R,23R)-22,23-Dihydroxy-3β-fluorostigmastan-6-one (9)

Compound **17** (180 mg, 0.42 mmol) was treated similarly to compound **13**. After chromatographic purification of the crude product (hexane/EtOAc 85:15), compound **9** was isolated in 31% yield. Mp 198 °C. ^1H NMR: 0.68 (H-18, 3H, *s*), 0.78 (H-19, 3H, *s*), 0.91 (H-21, 3H, *d*, $J=6.8$ Hz), 0.92–0.99 (H-26, H-27 and H-29, 9H, *m*), 2.17 (H-5α, 1H, *d*, $J=12.6$ Hz), 2.33 (H-7α, 1H, *dd*, $J=13.2$, 4.4 Hz), 3.58 (H-22, 1H, *dd*, $J=8.4$ Hz, 1.3 Hz), 3.71 (H-23, 1H, *dd*, $J=8.4$ Hz, 1.3 Hz), 4.45 (H-3α, 1H, double m, $J_{H,F}=48.9$ Hz). ^{13}C NMR: 12.0 (*q*, C-21), 12.2 (*q*, C-18), 13.1 (*q*, C-19), 13.8 (*q*, C-29), 19.1 (*t*, C-28), 19.6 (*q*, C-26), 21.1 (*t*, C-11), 21.3 (*q*, C-27), 24.0 (*t*, C-15), 27.2 (*dt*, C-4, $J_{C,F}=19.7$ Hz), 28.0 (*dt*, C-2, $J_{C,F}=18.0$ Hz), 28.7 (*t*, C-16), 29.3 (*d*, C-25), 36.1 (*t*, C-1, $J_{C,F}=10.5$ Hz), 37.2 (*d*, C-20), 37.8 (*d*, C-8), 39.4 (*t*, C-12), 40.8 (*s*, C-10), 42.9 (*s*, C-13), 46.7 (*t*, C-7), 46.7 (*d*, C-24), 55.8 (*d*, C-17), 56.1 (*dd*, C-5, $J_{C,F}=10.9$ Hz), 56.8 (*d*, C-9), 56.9 (*d*, C-14), 72.5 (*d*, C-23), 74.4 (*d*, C-22), 92.2 (*dd*, C-3, $J_{C,F}=174.0$ Hz), 209.6 (*s*, C-6). ^{19}F NMR: −172.6 (m). MS (FAB) *m/z* (rel. int.): 471.3 (100) M+Li, 397.3 (29), 294.0 (20). HRMS (FAB): calc. for $C_{29}H_{47}OFLi$ $(M+Li)^+$: 471.3826, found: 471.3816.

Cysteine sulfoxide derivatives in *Petiveria alliacea*

Roman Kubec, Rabi A. Musah*

Department of Chemistry, State University of New York at Albany, Albany, NY, 12222, USA

Received 9 March 2001; received in revised form 19 June 2001

Abstract

Two diastereomers of *S*-benzyl-L-cysteine sulfoxide have been isolated from fresh roots of *Petiveria alliacea*. Their structures and absolute configurations have been determined by NMR, MALDI-HRMS, IR and CD spectroscopy and confirmed by comparison with authentic compounds. Both the R_S and S_S diastereomers of the sulfoxide are present in all parts of the plant (root, stem, and leaves) with the latter diastereomer being predominant. Their total content greatly varied in different parts of the plant between 0.07 and 2.97 mg g^{-1} fr. wt, being by far the highest in the root. *S*-Benzylcysteine has also been detected in trace amounts (<10 μg g^{-1} fr. wt) in all parts of the plant. This represents the first report of the presence of *S*-benzylcysteine derivatives in nature. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Petiveria alliacea*; Phytolaccaceae, *S*-Benzylcysteine sulfoxide; Petiveriin; *S*-Benzylcysteine; Flavor precursor

1. Introduction

Petiveria alliacea L. (family Phytolaccaceae) is a perennial shrub indigenous to the Amazon Rainforest and widely distributed in other areas including tropical America, the Caribbean, Africa, Sri Lanka, and the southeastern Unites States. It is known by many names among which "anamu", "apacin", "guiné", "pipi", "tipi", and "garlic guinea henweed" are noteworthy. It has commonly been used in folk medicine and various preparations made from this plant are considered to have antiinflammatory, antimicrobial, antispasmodic, diuretic, and stimulant effects, among others.

The presence in *P. alliacea* of several volatile compounds, most of them containing a benzyl or phenyl moiety has been reported. Whereas Szczepanski et al. (1972) identified benzyl-2-hydroxyethyl trisulfide, Adegosan (1974) found *cis*-3,5-diphenyl-1,2,4-trithiolan (trithiolaniacin), benzaldehyde, benzoic acid, elemental sulfur, and *trans*-stilbene. Sousa et al. (1990) isolated dibenzyl trisulfide and Ayedoun et al. (1998) observed benzaldehyde, benzyl alcohol, *cis*- and *trans*-stilbenes, benzyl benzoate, dibenzyl disulfide, and dibenzyl trisulfide in the root oil.

The present paper describes our investigations on isolation and identification of non-volatile precursors of the above mentioned compounds.

2. Results and discussion

Two abundant constituents of an amino acid fraction from the roots of *Petiveria alliacea* were isolated by ion-exchange chromatography and prep. HPLC as white crystalline solids. Their NMR, IR, and UV spectra as well as their chromatographic behavior were very similar. The ^1H and ^{13}C NMR spectra revealed that both compounds are α-amino acids containing an unsubstituted benzyl moiety and two pairs of heterosteric methylene protons. The IR spectra contained a very strong absorption band near 1020 cm^{-1}, indicating the presence of a sulfoxide group. The MALDI-HRMS data showed m/z $[M]^+$ of 227.0616 and 227.0626, respectively, corresponding to a molecular formula of $C_{10}H_{13}NO_3S$ for both compounds (req. 227.0616). In accordance with the above data, the two amino acids were identified as diastereomers of *S*-benzylcysteine sulfoxide.

There are two chiral centers in *S*-benzylcysteine sulfoxide (the sulfur and α-carbon atoms) and thus four stereoisomers exist. All of them were synthesized and their absolute configurations were determined by NMR and CD spectrometry. The CD spectra of corresponding

diastereomers were almost mirror images, consisting of a single maximum around 224 nm (Fig. 1). Unfortunately, when strongly perturbing groups are present around the sulfur atom (e.g. alkylthio, allyl, benzyl), CD spectrometry cannot be used to directly determine the absolute configuration of sulfoxides (Axelrod et al., 1968; Ottenheijm et al., 1981). However, the diastereomers of all *S*-substituted cysteine sulfoxides display ^{1}H NMR spectra with a characteristic ABX pattern for the S(O)CH_2CH(NH_2) methylene protons. The isomers with both the amino group and the oxygen atom on the same side of the molecule show two distinct doublets of doublets at $\sim\delta$ 3.25 ($J_{AX} = \sim 7$–8.5 Hz) and δ 3.50 ($J_{BX} = \sim 5.5$–7 Hz), respectively. On the other hand, the methylene protons of derivatives with the opposite configuration typically resonate in the much narrower region of $\sim\delta$ 3.30–3.45 with the coupling constants of $J_{AX} = \sim 3.5$–4 Hz and $J_{BX} = \sim 8.5$–10.5 Hz. The coupling constants J_{AB} are similar for both diastereomers ($\sim$13.5–14 Hz) (Kuttan et al., 1974; Broek et al., 1987; Kubota et al., 1998). Employing this rule, the absolute configuration of all synthesized derivatives was unambiguously determined. Furthermore, the specific rotation values of the corresponding antipodes were nearly opposite, confirming the correct structural assignment. Along with NMR, CD spectrometry and polarimetry were also employed to determine the absolute configuration of the compounds isolated from the root of *P. alliacea*. The CD spectrum of the first eluting isomer showed a positive sign of the Cotton effect ($\Delta\varepsilon_{max}$ +12.7 at 222 nm) and a specific rotation of $[\alpha]_D^{22}$ +31°. The second isomer gave a CD spectrum with a negative sign of the Cotton effect ($\Delta\varepsilon_{max}$−14.6 at 224 nm) and a specific rotation of $[\alpha]_D^{22}$ −55°. On the basis of the above data and together with their other spectroscopic and chromatographic characteristics, the absolute configuration of the isolated amino acids were determined as (R_CR_S)-*S*-benzyl-L-cysteine sulfoxide (**1a**) and (R_CS_S)-*S*-benzyl-L-cysteine sulfoxide (**1b**), respectively. In close analogy to alliin (*S*-allylcysteine sulfoxide) and other related *S*-alk(en)ylcysteine sulfoxides, the new amino acids have trivially been named petiveriin A (the dextrorotary R_CR_S isomer, **1a**) and petiveriin B (the levorotary R_CS_S isomer, **1b**).

Aliphatic *S*-substituted cysteine sulfoxides have been isolated from various plants, fungi, and algae. They occur almost exclusively in the R_CS_S configuration (e.g. in *Allium* and *Brassica* species). So far, there are only two known *S*-substituted cysteine derivatives in which both diastereomeric forms have been found to occur in nature. (R_CR_S)-*S*-(*trans*-1-Propenyl)cysteine sulfoxide is widely distributed in onion and other alliaceous species, whereas its (R_CS_S) diastereomer was identified in *Santalum album* L. (in the form of a γ-glutamyl dipeptide; Kuttan et al., 1974). Similarly, (R_CS_S)-*S*-(methylthiomethyl) cysteine sulfoxide was found in *Marasmius* species (Gmelin et al., 1976; Broek et al., 1987) and the corresponding (R_CR_S) diastereomer has recently been isolated from *Scorodocarpus borneensis* Becc. (Kubota et al., 1998). However, the presence in a plant of both diastereomers has not been reported thus far. Using pure synthetic diastereomers, we have observed that the cysteine sulfoxides are not interconvertible under the conditions

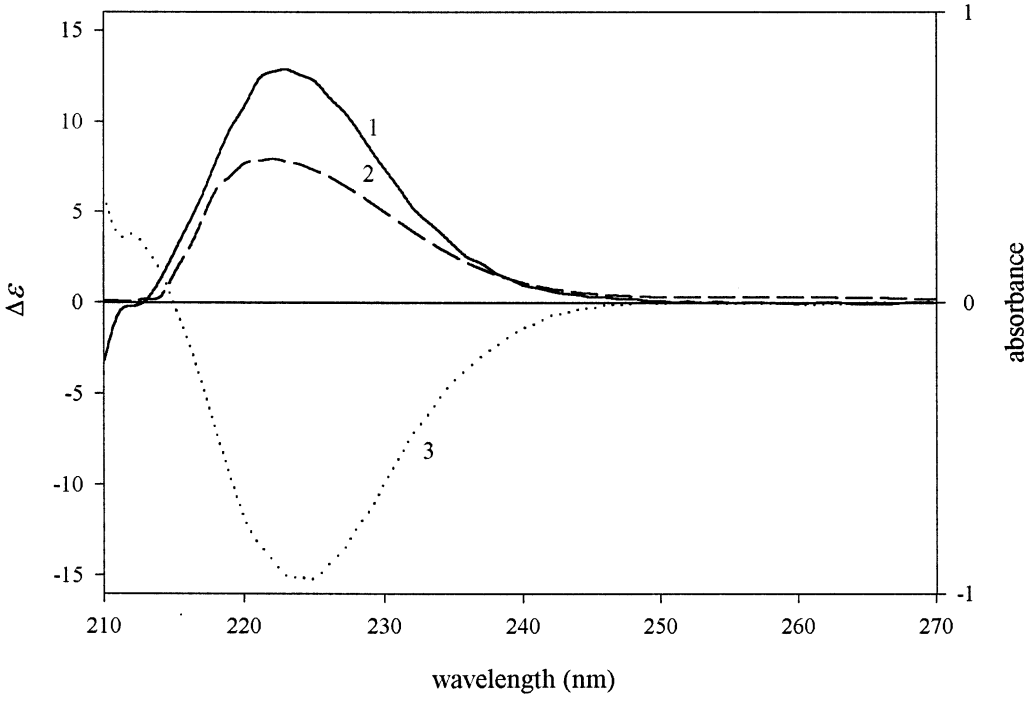

Fig. 1. The CD and UV spectra of petiveriin A (1 and 2, respectively) and the CD spectrum of petiveriin B (3).

used during extraction and isolation of the compounds (e.g. refluxing in MeOH for 20 min). Thus, they are not artifacts arising during isolation and they are naturally present in the tissue. To our knowledge, **1a** and **1b** are the first naturally occurring *S*-benzyl cysteine derivatives to be observed and the first naturally occurring aromatic *S*-substituted cysteines to be reported. In view of the presence of these aromatic cysteine derivatives, it appears likely that some aliphatic cysteine sulfoxide derivatives analogous to those observed in garlic, onion and other alliaceous plants may also be present in the *P. alliacea*.

S-Benzyl-L-cysteine, a presumable biochemical precursor of petiveriin, has also been detected in all parts of the plant. However, due to its very low content (<10 μg g^{-1} fr. wt) it could not be isolated in sufficient quantity to confirm its structure by spectroscopic methods. Identification was made by comparing its chromatographic behavior (TLC and HPLC) with that observed for *S*-benzyl-L-cysteine obtained from laboratory synthesis (Fig. 2).

The total content of both *S*-benzylcysteine sulfoxide diastereomers has been determined in different parts of the plant (root, stem, and leaves) by HPLC. As shown in Table 1, the content ranges between 0.07 and 2.97 mg g^{-1} fr. wt, being the highest in the root. Interestingly, it was observed that not only the total content but also the relative amounts of petiveriin A and B vary significantly from 40:60 in the root to 22:78 in the leaves and 12:88 in the stem. However, the content of *S*-substituted cysteine derivatives depends on many factors including soil composition, climate, harvest date etc. (Fenwick and Hanley, 1985; Block, 1992). Thus, it can be assumed that the content of petiveriin is dependent on such factors and may vary considerably in plants growing in different areas.

Further research on *P. alliacea* is still being conducted in our laboratory. Our preliminary data indicate that both petiveriin A and B serve as non-volatile precursors of the phenyl/benzyl-containing volatile compounds

Table 1
The total content and relative ratios of *S*-benzylcysteine sulfoxides in different parts of *P. alliacea*

Tissue analyzed	mg g^{-1} fr. wt	**1a:1b**
Root	2.97±0.16	40:60
Stem	0.29±0.03	12:88
Leaves	0.07±0.01	22:78

previously found in this plant. We propose that these amino acids are enzymatically cleaved to give *S*-benzyl phenylmethanethiosulfinate in a fashion similar to that observed in the formation of allicin (diallyl thiosulfinate) and other thiosulfinates in *Allium* species (Stoll and Seebeck, 1949; Block, 1992). Our results also indicate that the vast majority of the volatiles that have so far been identified in extracts of *P. alliacea* are not present in a fresh tissue. They are, in fact, only degradation products generated during isolation procedures from labile *S*-benzyl phenylmethanethiosulfinate (Kice et al., 1960; Furukawa et al., 1973; White and Dellinger, 1985; Block, 1992).

3. Experimental

3.1. General experimental procedures

^{1}H and ^{13}C NMR spectra were recorded on a Varian Gemini 300 HC spectrometer, and IR spectra were recorded using a Perkin Elmer RX I FTIR spectrometer. UV spectra were measured on a Shimadzu UV-1601PC spectrophotometer and CD spectra on an Aviv 62DS circular dichroism spectrometer. Specific rotation values were determined by means of a Perkin-Elmer 243B polarimeter. HPLC separations were performed on a Dynamax SD-200 binary pump system, employing a Varian PDA 330 detector, a C-18 reverse phase column (Rainin Microsorb-MV 100 Å, 250×4.6 mm, 5 μm), using 10 mM KH_2PO_4 buffer (solv. A, pH 7.0) with MeCN (solv. B) as the mobile phase, with a flow rate of 1 ml min^{-1}. The gradient was as follows: A/B 100/0 (0 min), 95/5 (in 20 min), 60/40 (in 30 min) held for 15 min. Alternatively, a preparative C-18 reverse phase column (Rainin Dynamax-100 Å, 250×21.4 mm, 8 μm) was used. TLC was performed on precoated Aldrich plastic plates (silica gel polyester) with *n*-BuOH–H_2O–HOAc (4:1:1 v/v/v) or *n*-PrOH–H_2O (7:3 v/v/v) as the mobile phase. Ninhydrin (0.2% soln. in ethanol) was used for detection. Melting points (uncorr.) were determined using a Köfler hot stage.

3.2. Plant material

Whole fresh plants of *Petiveria alliacea* were obtained from Native Habitat Landscaping, FL, USA. They were

collected in Vero Beach, Indian River County, FL, USA in October 2000, immediately shipped, and stored in the freezer at −30 °C until analysis. A voucher specimen is deposited in the herbarium PIHG at the Florida Department of Agriculture and Consumer Services, Division of Plant Industry, Gainesville, FL, USA under the number 7801.

3.3. Extraction and purification

Fresh roots (69.0 g) were carefully cleaned and homogenized in MeOH using a blender, and extracted with boiling MeOH (2×600 ml). The extracts were combined, concentrated to ca. 400 ml by vacuum evaporation (40 °C), and adjusted to 500 ml by addition of 3% HCl. The precipitate that appeared on acidification was filtered off and the filtrate was passed through a cation-exchange column (19×2.1 cm; Amberlite 200, H^+ form, 20–50 mesh). After washing the column with 3% HCl (300 ml) and H_2O (300 ml), the amino acid fraction was eluted with 500 ml of 1 M NH_4OH. The yellow eluent obtained was concentrated to ca. 20 ml and subjected to prep. HPLC. The fractions eluting at 18.1 and 18.9 min were collected, evaporated, and the residues re-crystallized from boiling H_2O to yield 24 and 29 mg of white crystalline **1a** and **1b**, respectively.

3.4. Quantitative determination

Extracts were prepared from each part of the plant (leaves, stem, and root) as described above. These were analyzed by HPLC without derivatization. *S*-(4-Chlorobenzyl)cysteine, added to the samples before extraction, was used as an internal standard. At least three analyses of each extract were done. Calibration curves were computed using solutions prepared from the synthetic diastereomers of *S*-benzyl-L-cysteine sulfoxide (**1a** and **1b**).

3.5. Reference compounds

S-Benzylcysteine, *S*-(4-chlorobenzyl)cysteine (internal standard) and *S*-benzylcysteine sulfoxide were synthesized as described by Stoll and Seebeck (1949). Pure diastereomers of *S*-benzylcysteine sulfoxide were obtained by repeated fractional re-crystallization (H_2O–Me_2CO–HOAc 70:30:1 v/v/v) and by prep. HPLC.

Book reviews

Sage: The Genus *Salvia*

S.E. Kintzios (Ed.); Harwood Academic Publishers, Amsterdam, 2000, 296 pp., ISBN 90-5823-005-8, £73

This multi-author book is volume 14 of the series *Medicinal and Aromatic Plants—Industrial Profiles*. This is a very timely and interesting wide ranging review of the genus *Salvia*. The genus has been attracting a lot of renewed interest with several companies and academic groups trying to show therapeutic effects to support claims for benefits in, for example, treating CNS disorders.

The volume is divided into sections covering the botany, chemical constituents, cultivation and breeding, pharmacology, biotechnology, commercial aspects and bibliographic information sources. There are 20 chapters with nearly half concerned primarily with aspects of the chemistry, folklore and therapeutic activity.

Chapter 1 starts with a list of the approximately 400 species. Although, for some reason, authorities are used sporadically in the list, nonetheless it contains interesting information on folk uses of certain species and in particular cosmetic uses. The chapters in general have a lot of detail for the specialist, e.g. Li on the chemistry of salvianolic acids and Korousou et al. on the botany of Greek sage species.

The review of the pharmacology by Baricevic and Bartol is particularly good, covering a wide range of activities and modes of action and is very well referenced and written in a manner suitable for both the specialist and non-specialist. Research on the anti-hypertensive properties of Dan-Shen and the active chemical is described in some detail.

The section on biotechnology includes a chapter by Isabelle Hippolyte on cell culture as a way of producing rosmarinic acid which can be obtained in 36% dry weight yields.

All in all, this is a good reference book on Sage knowledge to date and will be a good introduction to new workers on the genus or people interested in herbal medicines in general who want to understand the modes of action and biology of the plants.

Ginkgo biloba

T.A. van Beek (Ed.), Vol. 12 in the series Medicinal and Aromatic Plants—Industrial Profiles; Harwood Academic Publishers, Amsterdam, The Netherlands, 2000, 548 pp., ISBN 90-5702-488-8, £79 or $126

Several books have already appeared on this fascinating tree of Chinese origin which has become over the last 10 years one of the most widely used herbal medicines. The interest in Ginkgo and in its constituents is still growing after several studies and clinical trials demonstrated its potential in the treatment of Alzheimer's disease. The publication of the present book is timely as it covers really all aspects of *Ginkgo biloba* and the phytopharmaceuticals derived from its leaves. The book is divided into 28 different chapters, all of them are written by scientists actively involved in one way or another in the study of Ginkgo. The first five chapters deal with botanical and ecological aspects as well as with the large-scale cultivation of the tree and plant cell biotechnology. Chapters 6–12, and chapter 14 are of prime importance as they are devoted to the constituents of Ginkgo, their isolation and their analysis. Very useful information on all analytical problems

involving the four main classes of Ginkgo constituents, namely the ginkgolides and other terpenoids, the flavonoids, the alkyl phenols and the polyprenols, is provided. Of special historical interest is Chapter 8 by K. Nakanishi who established the structures of the ginkgolides in 1966. At this time, no biological activity was known for these important compounds. Chapters 15–22 deal with the pharmacology of Ginkgo constituents and extracts, with the mode of action as well as with adverse effects. Very important for all phytopharmaceuticals are clinical trials. Fortunately, they are not missing in the present book where accounts of randomised clinical trials are reported.

The Editor of this book has done an outstanding work by selecting the appropriate topics and contributors in order to provide a full coverage of a plant which is becoming a major phytopharmaceutical worldwide. The three aspects of any herbal remedy, namely safety, efficacy and quality, are particularly well, and also critically, treated. This masterly work is a must for all people interested in medicinal plants. It will be useful for every teacher in the field of pharmacognosy, for pharmacists who sell drugs of plant origin, for medical doctors who have to answer questions of their patients, for scientists involved in plant analysis, for biologists and agronomists and finally for researchers in industry who are involved in the development of phytopharmaceuticals.

The book is well presented with some illustrations and with numerous and accurate literature references. It can be warmly recommended and should find its place in all scientific libraries in academia as well as in industry. The affordable price will also convince many individuals to purchase it.

3β-Brassinosteroid dehydrogenase activity in *Arabidopsis* and tomato

Ute Stündl[1], Bernd Schneider*

Max-Planck-Institut für Chemische Ökologie, Carl-Zeiss-Promenade 10, D-07745 Jena, Germany

Received 14 May 2001; received in revised form 6 August 2001

Abstract

Enzymatic conversion of 24-epiteasterone to 3-dehydro-24-epiteasterone, representing a reversible step in the biosynthesis of 24*R*-methyl brassinosteroids, was monitored in vitro in *Arabidopsis thaliana* and *Lycopersicon esculentum* using fluorescent tagging and HPLC analysis. In both species 24-epiteasterone was metabolized by the cytosolic fraction of induced root-callus suspension cultures in a NAD dependent manner. This 3β-dehydrogenation was only slightly inhibited by 12-fold excess of other 3β-hydroxy intermediates of the early (cathasterone) and late C-6 oxidation pathway (6-deoxo-cathasterone, 6-deoxo-teasterone), indicating a rather specific protein. 3-Dehydro-6-deoxoteasterone and 3α-hydroxy intermediates of brassinosteroid biosynthesis did not reduce conversion of 24-epiteasterone to 3-dehydro-24-epiteasterone. In contrast to light-grown cultures the reaction was clearly inhibited in the dark. © 2001 Elsevier Science Ltd. All rights reserved.

Keywords: *Arabidopsis thaliana*; *Lycopersicon esculentum*; Biosynthesis; Brassinosteroids; 3-Dehydro-24-epiteasterone; 24-Epiteasterone; 3β-Steroid dehydrogenase

1. Introduction

Brassinosteroids represent the only known steroidal group of plant growth regulators. Their biosynthetic pathways and biological activity have been elaborated during the last decades. However, only by means of recent molecular characterization of brassinosteroid-deficient mutants these compounds have gained acceptance as a new class of plant hormones. Several mutants are known, which are blocked in biosynthetic steps in the phytosterol part of the pathway or in steps of the brassinosteroid-specific part of the biosynthetic sequence downstream campesterol (Altmann, 1999). Molecular characterization of these mutants indicated sequence homologies of highly conserved domains with known enzymes. These experiments provided evidence for involvement of cytochrome P450s (Szekeres et al., 1996; Choe et al., 1998; Bishop et al., 1999), steroid reductase (Fujioka et al., 1997; Li et al., 1997), desaturase (Choe et al., 1999b), and multifunctional enzymes (Choe et al., 1999a) in brassinosteroid biosynthesis, for example, although functional expression of cloned proteins was achieved in only a few cases. There are, however, also a number of biosynthetic steps for which mutants are not yet available. In the brassinosteroid specific downstream part of the pathway, this is true for inversion of configuration at C-3, 2α-hydroxylation, and conversion of castasterone to brassinolide by Baeyer-Villiger oxidation.

Inversion of stereochemistry at C-3 from 3β- to 3α-hydroxyl represents a biosynthetic feature common for many steroids, e.g. ecdysteroids (Milner and Rees, 1985), cardenolides (Kawaguchi et al., 1993), and pregnanes (Finsterbusch et al., 1999). It has been reported that inversion of 3β-hydroxy function to 3α-hydroxy of brassinosteroids may also operate in the opposite direction and, therefore, has to be considered reversible. Moreover, the equilibrium between 3α- and 3β-epimers is strongly influenced by regio- and stereoselective 3β-glycosidation (Kolbe et al., 1998). Involvement of 3-dehydro intermediates in the epimerization of plant (Suzuki et al., 1994; Hai et al. 1996) and mammalian steroids (Huang and Luu-The, 2000; Chetyrkin et al., 2001) has been demonstrated several times. This finding raises the question of whether this reversible inversion process is catalyzed by one protein, an ''epimerase'', or by a set of up to four enzymes, which probably catalyze

PII: S0031-9422(01)00387-9

individual oxidative and reductive reactions. Three of four possible reactions were demonstrated with enzyme preparations from cultured tomato cells (Winter et al., 1999). When 3-dehydro-24-epiteasterone was incubated with a microsomal fraction, 24-epiteasterone was formed in a NADPH dependent reaction. Formation of 24-epityphasterol from the same substrate was achieved by means of a cytosolic fraction preferring NADH as a cofactor. The same cytosolic fraction was able to convert 24-epityphasterol to 3-dehydro-24-epiteasterone in the presence of NAD. These results suggest that at least two enzymes are involved in inversion of C-3 stereochemistry in *Lycopersicon esculentum*. However, the conversion of 24-epiteasterone to 3-dehydro-24-epiteasterone could not be demonstrated in these experiments. Here we report the latter conversion in *Arabidopsis* and tomato, and characterization of the enzyme in some detail.

2. Results and discussion

2.1. Optimization of assay conditions

Cytosolic and microsomal fractions of *A. thaliana* root-callus suspension cultures were prepared and incubated with 24-epiteasterone (**1**) to demonstrate conversion to 3-dehydro-24-epiteasterone (**2**) (Fig. 1). In preliminary experiments, assay conditions were similar to those previously used successfully with preparations from tomato cell suspensions (10 mM Na-K-phosphate buffer, pH 7.0; 250 mM sucrose; 400 mM sodium ascorbate; 1 mM NAD; 3 h, 30 °C) (Winter et al., 1999) to convert 24-epityphasterol (**3**) to **2**. Incubation of the cytosolic fraction with the substrate 24-epiteasterone (**1**) resulted in the dehydrogenated product, 3-dehydro-24-epiteasterone (**2**), while experiments using the microsomal fraction failed to give any product. Both substrate **1** and product **2**, after derivatization with dansylaminophenylboronic acid, were analyzed by reversed-phase HPLC and fluorescence detection. Under the chromatographic conditions used, **1** was detectable at 20.3 min in the HPLC trace, and 3-dehydro-24-epiteasterone (**2**) appeared at 17.4 min.

To identify optimal assay conditions for conversion of 24-epiteasterone, different buffer systems were tested within the pH range of 6.0 to 9.0. Maximum formation of 3-dehydro-24-epiteasterone (**2**) was measured in 20 mM phosphate buffer at pH 7.5 with NAD as a cofactor, 15% glycerol, and 1 mM EDTA for 19 h at 30 °C (Fig. 2). For optimum product formation, the root-callus cultures have been induced with 1 μM 24-epiteasterone. Preparations from non-induced *Arabidopsis* cultures exhibited neglectable activity only.

These general conditions, therefore, were used in all further experiments. In comparison with phosphate buffer, for example, the pH optimum in 20 mM Tris–HCl buffer was shifted to 8.0 and the reaction was significantly inhibited. Only the cytosolic fraction was able to convert 24-epiteasterone (**1**) to 3-dehydro-24-epiteasterone (**2**). No product formation was observed after incubation using the optimized conditions with the microsomal fraction.

The results presented here and earlier (Winter et al., 1999) reveal that at least two enzymes are involved in the reversible inversion of configuration of 3-hydroxy function in brassinosteroid biosynthesis. Both 3β- and 3α-dehydrogenase activities of *Arabidopsis* are localized in the cytosol, respectively. Stereospecific reduction of 3-dehydro-24-epiteasterone as a substrate was found separately in cytosolic (reduction to 3α-OH) and microsomal fractions (reduction to 3β-OH) (Winter et al., 1999). Together with regio- and substrate-specific glycosidations (Kolbe et al., 1998), this reversible part of brassinosteroid biosynthesis suggests the possibility of back conversion and temporarily removes intermediates from the main stream of biosynthesis. This mechanism might be considered an important instrument regulating endogenous levels of brassinosteroids in specific stages of plant development.

Interestingly, a cytosolic fraction of cultured cells of the liverwort *Marchantia polymorpha* (Park et al., 1999) has been used to convert teasterone to typhasterol without the presence of any cofactor. This is in contrast to the 3β-dehydrogenase from *Arabidopsis* described here, whose activity was clearly enhanced by application of an electron acceptor and preferred NAD over NADP.

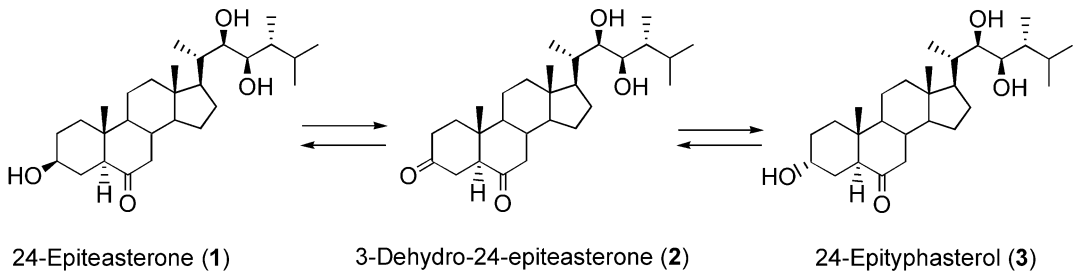

Fig. 1. Reversible conversion of 24-epiteasterone (**1**) to 24-epityphasterol (**2**) via 3-dehydro-24-epiteasterone (**2**) in *Arabidodpsis thaliana* and *Lycopersicon esculentum*.

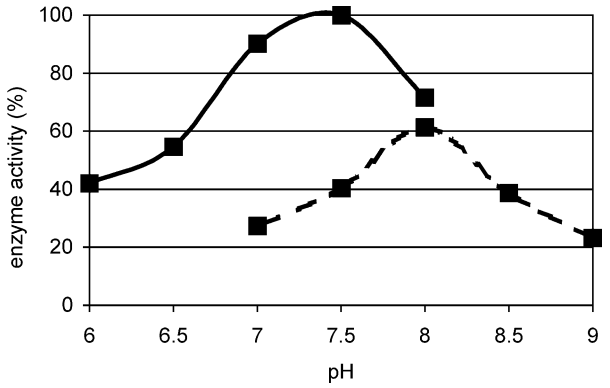

Fig. 2. pH Optimum of 3β-brassinosteroid dehydrogenase activity from *Arabidopsis thaliana* in 20 mM phosphate buffer (solid line) and 20 mM Tris–HCl buffer (dotted line) (NAD, 15% glycerol, 1 mM EDTA, 19 h, 30 °C).

2.2. 3β-Dehydrogenase activity in light- and dark-grown Arabidopsis suspension cultures

The detection of parallel early and late C-6 oxidation route of brassinosteroid biosynthesis in *Catharanthus roseus* (Choi et al., 1997) and *Arabidopsis thaliana* (Noguchi et al., 2000) raises the question of the function of these pathways. It has been suggested that brassinosteroid biosynthesis is regulated by light (Li et al., 1996) and that the early C-6 oxidation predominates in dark-grown *Arabidopsis* seedlings and the late C-6 oxidation pathway occurs mainly in light-grown plants (Fujioka et al., 1997; Choe et al., 1998). Although the biosynthesis of 24*R*-configured brassinosteroids has not been studied in detail, it is expected to proceed in a manner analogous to the established biosynthetic sequence of 24*S*-configured brassinosteroids to brassinolide. In our experiments, the 24*R* configured substrate, 24-epiteasterone, was used. Reversible steps in the biosynthesis as, for example, C-3 epimerization, which occur within both the 24*S* and 24*R* series, are considered possible mechanisms to regulate the level of endogenous plant growth regulators. Therefore we studied the activity of dehydrogenase activity in the cytosolic fractions of light-and dark-grown *A. thaliana* root-callus suspension cultures. The results shown in Table 1. indicate that in contrast to light-grown cultures the reaction is clearly inhibited in dark-grown cells.

Table 1
3β-Dehydrogenase activity in the cytosolic fraction of *Arabidopsis thaliana* root-callus suspension cultures derived from light-and dark-grown seedlings. Average enzyme activities of experiments carried out in triplicate are shown

Culture conditions	Assay conditions	Enzyme activity	
		μmol min^{-1}	%
Light-grown	1 mM NAD	1.200	100.0
Light-grown	–	0.085	7.1
Dark-grown	1 mM NAD	0.563	46.9
Dark-grown	–	0.035	2.9

This finding disagrees to some extent with the hypothesis mentioned above, which emphasizes that the early C-6 pathway operates in the dark and the late C-6 pathway is predominant in the light (Fujioka et al., 1997; Choe et al., 1998). However, since only an individual non-rate-limiting reaction has been studied here, conclusions about the total pathway with respect to regulation by light are not possible.

2.3. Substrate specificity of 3β-dehydrogenase

24*R*- and 24*S*-methyl brassinosteroids, co-occurring in *Arabidopsis* (Schmidt et al., 1997) and many other plants, probably are derived from the two epimeric precursors campesterol and 22,23-dihydrobrassicasterol. Further branching into the early and late C-6-oxidation pathway takes place from campestanol, during which routes 6-oxo- and 6-deoxobrassinosteroids are formed. Several compounds of either type have been found (Fujioka et al., 1998; Noguchi et al., 1999) and determined quantitatively (Nomura et al., 2001). These different brassinosteroids might be specifically involved in various growth and developmental processes, which are controlled by that class of plant hormones.

It has been suggested that brassinosteroid biosynthetic enzymes might have dual functions in parallel early and late C-6 oxidation pathways, e.g. 22α-hydroxylation of campestanol and 6-oxocampestanol is catalyzed by CYP90B (Bishop et al., 1999). Dual or even multiple functions of brassinosteroid biosynthetic enzymes might be true also for other steps which neccessarily have to be passed through in each of established or hypothetical subpathways. Inversion of configuration, including 3β-dehydrogenation, occurs both in the early and late C-6 oxidation pathways and is also suggested for further parallel routes to brassinosteroids possessing different side chain alkylation pattern or stereochemistry, as, for example 24*R*- or 24*S*-methyl substituents. Hitherto it has not been clear whether the enzymes involved in epimerization are specific to a special substrate or are able to accept intermediates of parallel pathways. To characterize the substrate specificity of the enzyme under investigation, we tested the inhibitory effect of the hypothetical 3β-intermediates cathasterone (early C-6 oxidation pathway to brassinolide), 6-deoxocathasterone, and 6-deoxoteasterone (late C-6 oxidation pathway to brassinolide). These three substances showed a slight inhibitory effect on dehydrogenation rate of 24-epiteasterone when used in 12-fold concentration in comparison with the substrate (Table 2). Teasterone (early C-6 oxidation pathway) was also tested but unfortunately interfered with 24-epiteasterone in HPLC and GC–MS analyses. 3α-Epimeric compounds, 6-deoxotyphasterol and 6-deoxocastasterone, and a 3-

Table 2
Effect of brassinosteroid biosynthetic intermediates on the conversion of 24-epiteasterone (**1**) to 3-dehydro-24-epiteasterone (**2**) by the cytosolic fraction of *Arabidopsis thaliana* root-callus suspension cultures. The experiment without intermediates was used as control. Average enzyme activities of experiments carried out in triplicate are shown

Compound	Substituent at C-3	Enzyme activity	
		μmol min^{-1}	%
Control		1.200	100.0
Cathasterone	3β-OH	1.134	94.5

[a] Control experiment without substrate.

keto intermediate, 3-dehydro-6-deoxoteasterone, were also used in these experiments because 3α-dehydrogenase acitivity and reductive conversion of 3-dehydro intermediates have been observed earlier in a cytosolic fraction of tomato (Winter et al., 1999). However, no significant inhibition of 3α-dehydrogenation of 24-epiteasterone could be observed by these competing substrates.

In conclusion, the protein studied here seems to be rather specific for 3β-dehydrogenation of 24-epiteasterone. Other 3β-configured substrates compete only slightly with the substrate.

2.4. Conversion of 24-epiteasterone in tomato

It has been reported that intermediates of the early C-6 oxidation pathway in tomato have been depleted (Bishop et al., 1999). This depletion might be connected to reduced activity of one or more enzymes in that branch of the pathway. With respect to the finding that 3β-dehydrogenase activity from *Arabidopsis* seems to be rather specific for dehydrogenation of 24-epiteasterone, representing a member of the hypothetical early C-6 oxidation route to 24*R* brassinosteroids, non-detection of this activity in tomato (Winter et al., 1999) seems to confirm Bishop's hypothesis. Therefore, it is useful to know if there is generally any 24-epiteasterone 3β-dehydrogenase activity in tomato or if gene activity has been lost due to utilization of long-term subcultured tomato cell suspension cultures in previous experiments (Winter et al., 1999). Thus, root-callus suspension cultures of two different tomato varieties have been freshly established for each feeding experiment and their 24-epiteasterone metabolizing activity has been tested in an analogous manner as described for *Arabidopsis* cultures. Whereas tomato root-callus suspension cultures of the variety 'Harzfeuer', induced with 1 μM 24-epiteasterone, showed 3β-dehydrogenase activity of 0.97 μmol min^{-1} (Table 3) comparable to those of *Arabidopsis* (1.20 μmol min^{-1}, Table 1), we could not detect any 24-epiteasterone metabolizing activity in cultures of the variety Tamina. Only neglectable activity was found in non-induced cultures of 'Harzfeuer'.

As summarized in Table 3, the cytosolic fraction of tomato variety 'Harzfeuer' converted 24-epiteasterone (**1**) to 3-dehydro-24-epiteasterone (**2**) in a NAD-dependent manner. NADP was also active as an electron acceptor. These findings suggest that there may be some species specificity in *Lycopersicon* with respect to 3β-dehydrogenase activity. Consequently, in 'Tamina', which is not able to form 3-dehydro-24-epiteasterone (**2**) from 24-epiteasterone (**1**), an alternative pathway to produce active brassinosteroids may operate.

3. Experimental

3.1. Plant material and culture conditions.

Arabidopsis thaliana cv. *C24* and *Lycopersicon esculentum* cv. Harzfeuer and cv. Tamina were used. Sterile seeds were germinated on auxin- and cytokinin-free B5 medium (Gamborg et al., 1968) containing sucrose (20 g l^{-1}) at 23 °C on a rotary shaker at 85 rpm for two weeks under permanent illumination (15 μmol m^{-2} s^{-1}). The roots were separated from the seedlings, minced under sterile conditions, and placed into 100 ml of RM 28 medium (Ecker, 1990) in 250 ml conical flasks. The cultures were maintained for three weeks under the same conditions as the seedlings, with weekly replacement of the nutrient medium. The *Arabidopsis* cultures used for probing enzyme activity in the dark were kept in complete darkness by wrapping with alumina foil. During the three-week culture period, root-callus suspension cultures developed, which were used for further investigations. Cultures have been freshly established from seeds of *A. thaliana* and *L. esculentum*, respectively, for every experiment.

3.2. Enzyme preparation and assay conditions

Twelve hours before extraction the root-callus suspension cultures of *Arabidopsis* and tomato were induced by application of 100 nmol 24-epiteasterone (1 μM final concentration). Preparations from non-induced cells were used as controls. Freshly harvested callus tissue (about 5 g fr. wt.) was frozen with liquid N_2. After mechanical disruption with mortar and pestle, the homogenate was dissolved in 20 mM phosphate buffer (pH 7.5, 15% glycerol, 1.0 mM EDTA, 0.1 mM DTE) and centrifuged twice at 5000 *g* for 10 min and at 25,000 *g* for 30 min. Separation of the cytosolic and microsomal fraction was performed twice by ultracentrifugation at 100,000 *g* for 1 h. For enzymatic studies the 25,000 *g* and 100,000 *g* pellets were washed with buffer before use. All experiments have been carried out in triplicate.

If not otherwise mentioned in the text, assays were carried out in a total volume of 1.0 ml containing 2.5 μM brassinosteroid, 1 mM electron acceptor, and 250 μg protein in phosphate buffer. After incubating the assay mixtures for 19 h at 30 °C, we extracted the brassinosteroids with $CHCl_3$. The organic phase was separated by centrifugation, removed from the upper phase, and evaporated with a SpeedVac. 50% aliquots of the samples were analyzed by HPLC with fluorescence detection. Protein quantification was performed according to Bradford (1976). The enzyme activity was measured as the relative peak area of substrate and product.

3.3. HPLC and derivatization

Aliquots from enzyme assays were treated with 100 μl of dansylaminophenylboronic acid (1 mg in 1 ml MeCN–pyridine 99:1) for 20 min at 75 °C to convert brassinosteroids to boronates. Chromatographic analysis of dansyl derivatives was carried out on LiChrospher 100 RP18; 5 μm; 2504 mm; 0.8 ml min^{-1}. An excitation wavelength of 230 nm and emission wavelength of 520 nm were used in all cases. Separations were carried out using MeCN–H_2O (17:3, v:v) under isocratic conditions.

Acknowledgements

We thank Takao Yokota (Utsunomiya, Japan) for kind gifts of cathasterone, 6-deoxocathasterone, 6-deoxoteasterone, teasterone, 6-deoxotyphasterol, 6-deoxocastasterone, and 3-dehydro-6-deoxoteasterone, and Thomas Altmann (Golm, Germany) for a gift of *Arabidopsis* seeds and his advice in establishing root-callus cultures. Emily Wheeler (Jena, Germany) is gratefully acknowledged for linguistic support in the preparation of this manuscript. Partial purification and characterization of a soybean β-glucosidase with high specific activity towards isoflavone conjugates

Ming-Ching Hsieh[1], Terrence L. Graham*

Department of Plant Pathology, The Ohio State University, Columbus, OH 43210, USA

Received 4 May 2001; received in revised form 6 August 2001

Abstract

A β-glucosidase with high specific activity towards isoflavone conjugates was purified from soybean [*Glycine max*] roots by high salt extraction from a low speed centrifugal pellet and subsequent anion and cation exchange chromatography. Purification required stabilization throughout fractionation in 10% glycerol. The enzyme is most likely a dimer (approximate M_r 165 kDa) with potential subunits of M_r 80 and/or 75 kDa. The pH and temperature optima are pH 6 and 30 °C, respectively. The enzyme was highly heat-stable. Of the various potential effectors examined, silver and mercury ions were the most inhibitory. The IC_{50} of silver ions was increased from 140 μM to 14 mM in the presence of 250 μM β-mercaptoethanol. Glucono-δ-lactone was not strongly inhibitory (IC_{50} 24 mM). The activity was highly active against isoflavone conjugates, with a specificity constant 160–1000 fold higher for isoflavone conjugates over the generic chromogenic substrate, *p*-nitrophenyl β-glucoside. The enzyme was inactive against the flavonol glycosides tested. The partially purified enzyme had similar K_m and k_{cat} towards 7-*O*-glucosyl- and 7-*O*-glucosyl-6″-malonyl-isoflavones, suggesting that it may be able to cleave the esterified glucosyl conjugate. We hypothesize that the enzyme is involved in the release of daidzein and genistein, both of which play central roles in soybean defense. © 2001 Elsevier Science Ltd. All rights reserved.

1. Introduction

β-Glucosidases (β-D-glucoside glucohydrolase, EC 3.2.1.21) comprise a heterogeneous group of enzymes that are able to cleave the β-glucosidic linkages of di- and/or oligo-saccharides, or other glucose conjugates. β-Glucosidases are widely distributed in the living world and play pivotal roles in many biological processes, such as degradation of cellulosic biomass, hydrolysis of glycolipids, cyanogenesis, and modification of secondary metabolites (Esen, 1993). In plants, β-glucosidase activity is involved in processes such as the compartmentalization and activity of phytohormones (Kleczkowski and Schell, 1995), defense mechanisms against microbes, insects, or parasitic plants (Bell, 1981; Poulton, 1990; Phillips and Streit, 1996), floral development and pigmentation (Harborne and Mabry, 1982; Koes et al., 1994), and they are also thought to have roles in lignification and cell wall decomposition (Hösel et al., 1978; Leah et al., 1995). Several β-glucosidases of plant origin are highly substrate-specific, such as those having selective specificity toward sapinin (Inoue and Ebizuka, 1996), hydrojuglone (Duroux et al., 1998), cinnamyl alcohols (Dharmawardhana et al., 1995), cyanogenic glycosides (Conn, 1993), flavones (Maier et al., 1993) and isoflavones (Hösel and Barz, 1975). Despite the availability of crystal structures for several plant β-glucosidases, the aglycone-binding site is still poorly understood. In a recent study, the active site of the maize β-glucosidase for the substrate DIMBOA-glucoside and its interaction with the cyanogenic glucoside dhurrin was examined (Czjzek et al., 2000).

Isoflavone conjugates are sometimes constitutively present in large quantities in legumes (see e.g. Graham,

1991b). These isoflavone conjugates, including isoflavone 7-*O*-glucosides and isoflavone 7-*O*-glucoside-6″-*O*-malonates, may serve as pools for the release of free aglycones, which in turn may play important roles in plant-microbe interactions and defensive mechanisms against pathogen infection (Graham et al., 1990; Kessmann et al., 1990; Mackenbrock and Barz, 1991; Dakora and Phillips, 1996). Released isoflavones, for instance, can be either incorporated into the biosynthetic pathway of phytoalexins (Ebel, 1986; Barz and Welle, 1992; Kleczkowski and Schell, 1995) or act as preformed toxins, termed phytoanticipins (Johnson et al., 1976; Kramer et al., 1984; Weidenborner et al., 1990; Rivera-Vargas et al., 1993). Free isoflavones may also function as chemoattractants for both pathogens (Morris and Ward, 1992) and symbionts (Phillips et al., 1992) or as regulators of gene expression in Rhizobium spp. (Hungria and Stacey, 1997). More recently, the isoflavone genistein has been hypothesized to play a regulatory role in the activation of a soybean Type II NADH oxidase thought to participate in the establishment of competency for response to pathogen elicitors (see Graham and Graham, 1996a,b and reviews Graham and Graham, 1999, 2000).

In plants, the accumulation of isoflavone conjugates may be mediated by several enzymes (Fig. 1). The hydrolytic enzymes, isoflavone 7-*O*-glucoside-6″-*O*-malonate malonylesterase and isoflavone 7-*O*-glucoside β-glucosidase, from chickpea have been purified and characterized (Hösel and Barz, 1975; Hinderer et. al., 1986). Although non-specific β-glucosidase activities hydrolyzing isoflavone glucosides in the process of miso preparation and a lactase phlorizin hydrolase have been reported in soybean (Matsuura and Obata, 1993; Matsuura et al., 1995; Day et al., 2000), we know of no reports of characterization of β-glucosidases in soybean with preferential activity towards isoflavone conjugates. Because of the critical roles daidzein and genistein may play in soybean defense, we undertook the characterization of some of the enzymes involved in the turnover of their conjugates. In this report, a soybean isoflavone conjugate-hydrolyzing β-glucosidase (ICHG) was partially purified and characterized. The enzyme has high specific activity towards genistein/daidzein 7-*O*-glucoside (genistin and daidzin) and genistein/daidzein 7-*O*-glucosyl 6″-*O*-malonate (MGD and MGG), with very low K_m and high k_{cat} values. The specificity constant (k_{cat}/K_m) is 160–1000 fold higher for the isoflavone

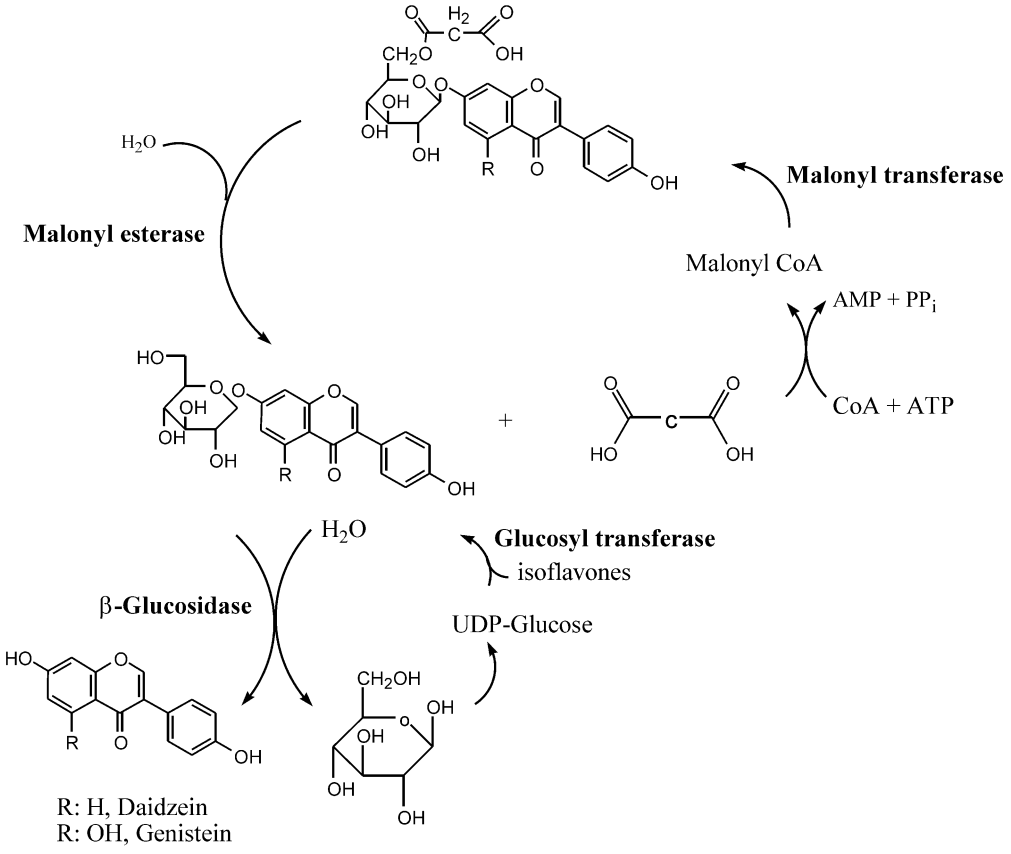

Fig. 1. Enzymatic regulation of the isoflavone conjugate pools. The scheme is based on the four purified enzymes from chickpea where malonylesterase and β-glucosidase hydrolyze isoflavone 7-*O*-glucoside-6″-*O*-malonates and isoflavone 7-*O*-glucosides, respectively, and glucosyltransferase and malonyltransferase transfer glucose and malonate sequentially to the isoflavone moiety.

conjugates over the chromogenic substrate *p*-nitrophenyl β-glucoside. Isoflavone conjugate hydrolysis in soybean may differ from that of chickpeas in that we found no evidence for an esterase active on MGG or MGD. Although we cannot preclude the existence of such an esterase, the partially purified glucosidase characterized in this report was able to hydrolyze both the glucosyl and malonyl glucosyl isoflavones directly with similar kinetics.

2. Results and discussion

2.1. Purification of the isoflavone conjugate-hydrolyzing β-glucosidase

Many studies were performed with various soybean organs to develop the optimal purification protocol. For example, vacuum infiltration of soybean cotyledons with 0.2 M phosphate buffer, pH. 6, containing 200–500 uM NaCl and subsequent isolation of the intercellular washing fluids by centrifugation led to a preparation highly enriched for the glucosidase, suggesting a possible apoplastic localization. These intercellular washing fluids contain no cytoplasmic marker enzymes (T.L. Graham, unpublished). However, due to the relatively low level of the ICHG in cotyledons and the difficulty in preparing large amounts of the intercellular fluids, we chose to work with roots. Roots contained the highest specific activity of ICHG in the soybean seedling. For example, a crude preparation from roots was about 800-fold more enriched for the enzyme than a crude preparation from cotyledons (data not shown). In roots, activity was found to be associated with the low speed centrifugal pellet.

Enzyme activity was solubilized from the pellet with 0.2 M phosphate buffer, pH 6, containing 0.5 M NaCl and fractionated by 40–60% ammonium sulfate saturation. Due to empirical results regarding the instability of the enzyme, a desalting column (Sephadex G-25) was chosen over dialysis for salt removal, and 10% glycerol was always present in the buffer from this step onward. When the desalted protein solution was passed through a DEAE-Sephadex A-50 column at pH 6.0, nearly all of the enzyme activity was in the unbound fractions (Fig. 2A). The active fractions were pooled and 5 mM final concentration of sodium ascorbate was introduced to maximize stability. The protein sample was then loaded onto a CM-Sephadex C-50 column and eluted with a linear gradient of buffer F in buffer E. The activity peak was eluted at 0.56 M NaCl (Fig. 2B). SDS polyacrylamide gel electrophoresis (PAGE) of various fractions under reducing conditions is shown in Fig. 3. Although the banding patterns for the fractions from the DEAE and CM-Sephadex columns are qualitatively similar, the analysis of the gel with ImageQuant software (Molecular Dynamics) determined that the pixel volume of the 80 kD band was three to four fold enriched in comparison to the other minor bands. This is consistent with the separation from a majority of other proteins for this fraction as shown in Fig. 2B. At this point, the ICHG was purified approximately 20-fold with a 20% recovery rate (Table 1). The most active fractions were pooled and lyophilized until almost only glycerol was left. Aliquots of this glycerol solution of ICHG were stored at −20 °C for further study. Under these conditions, the enzyme aliquots did not freeze solid and activity was stable for at least six months.

2.2. Properties of the isoflavone conjugate-hydrolyzing β-glucosidase

The molecular mass of ICHG upon SDS PAGE under non-reducing conditions was judged to be approximately 165 kDa (data not shown), while under reducing conditions a major band of mass 80 kDa and a less intensely staining band of 75 kDa were seen (Fig. 3). Though both of these bands were reproducibly associated with activity throughout purification, it is not clear whether the two bands represent different polypeptides or different post-translational modifications of a single polypeptide. Thus, while it is likely that the enzyme is a dimer, with monomers linked through a disulfide bond, its precise subunit composition will require further clarification. The ICHG tolerates very high concentrations of β-mercaptoethanol, with 50% inhibition of enzyme activity (IC_{50}) at 1.1 M, suggesting that the monomer form may also be catalytically active. Many β-glucosidases contain either identical or non-identical subunits. The number of subunits varies from 2 to 10 (or more) depending on the enzyme. For instance, a 60 kDa coniferin-hydrolyzing β-glucosidase from lodgepole pine has two non-identical subunits with M_r of 28 and 24 kDa (Dharmawardhana et al., 1995). The furostanol glycoside 26-*O*-β-glucosidase from *Costus speciosus* is a 110 kDa protein with two subunits with M_r of 54 and 58 kDa (Inoue and Ebizuka, 1996). Furthermore, the isoflavone hydrolyzing β-glucosidase from chickpea has apparent M_r of 125–135 kDa with two identical subunits of 68 kDa (Hösel and Barz, 1975).

The ICHG showed a pH optimum at approximately pH 6 at 30 °C. The optimum temperature was 30 °C. Both are typical for β-glucosidases (Esen, 1993). The enzyme is highly heat stable and remains substantially active (87%) after 45 min at 50 °C.

Several chemicals reported to be effectors of β-glucosidases were examined. Of all the chemicals tested for the inhibition of enzyme activity, only silver and mercury ions were inhibitory at the 1 mM level (Table 2), suggesting that sulfhydryl groups may play an essential role in enzyme activity. However, other sulfhydryl

Table 1
The purification scheme for the isoflavone conjugate-hydrolyzing β-glucosidase from soybean roots

Purification step	Total activity[a] (mU)	Total protein (mg)	Specific activity (mU/mg protein)	Yield (%)	Purity (fold)
Root cell wall wash	8780	124	70	100	1
Ammonium sulfate (40–60%)	10,540	50	220	120	3
DEAE-Sephadex	2960	12	240	34	3.4
CM-Sephadex	1740	1.3	1340	20	20

[a] The enzyme activity was measured by an HPLC method using a natural isoflavone conjugate mixture as substrate. The activity was calculated from the concentration of the released daidzein.

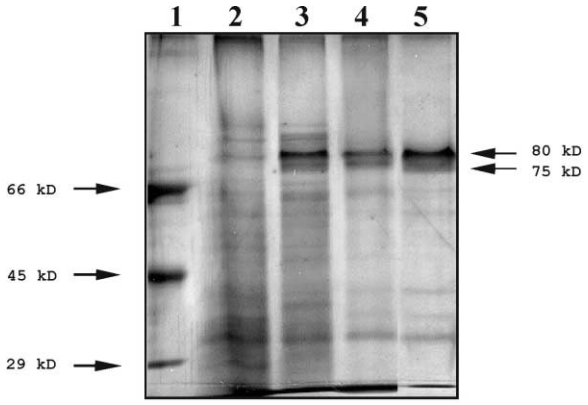

Fig. 3. SDS-PAGE analysis. Protein samples from each step of purification were subjected to SDS-PAGE (7.5% acrylamide) under reducing conditions. lane 1, protein markers; lane 2, crude root pellet extract; lane 3, 40–60% ammonium sulfate fraction; lane 4, activity peak from DEAE-Sephadex; lane 5, activity peak from CM-Sephadex.

group modifiers such as iodoacetate and *p*-chloromercuribenzoate (PCMB) had little or no effect (Table 2), possibly due either to the different accessibility of the protein SH groups to these compounds (Esen, 1992) or to their different redox potentials (Jocelyn, 1972). Consistent with the presence of critical sulfhydryl groups, inhibition by silver ions was prevented in the presence of β-mercaptoethanol. In the presence of 250 mM β-mercaptoethanol, the IC_{50} for Ag^{+} inhibition increased 100 fold from 140 μM (without β-mercaptoethanol) to 14 mM (data not shown). The importance of SH groups in ICHG is consistent with the fact that cysteine residues are involved in stability and enzyme activity of β-glucosidases (Rotrekl et al., 1999; Hakulinen et al., 2000), although most β-glucosidases in Family 1 (Henrissat, 1991) require two essential carboxylates for their catalytic activity, contributing to the general acid/base and nucleophilic catalysis (Zechel and Withers, 2000). The transition state analogue inhibitor, glucono-δ-lactone, was not very effective. The IC_{50} with this inhibitor was 24 mM (data not shown), while the counterpart in chickpea was more sensitive to this inhibitor, with an IC_{50} of 1 mM (Hösel and Barz, 1975).
